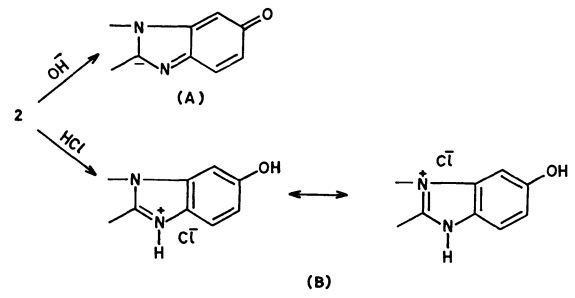
The structure of compounds **2** has been determined on the basis of IR, UV spectra, and elemental analysis. The IR spectra of these compounds showed bands at 3340, 1210 (phenolic OH), 1625 (C=N), 1315 (C–N), and 1450 cm^{-1} (aromatic ring). Electronic absorption spectra of **2** have been studied which have a bearing on their finer structure, particularly with regards to the position of phenolic hydroxyl group which could be either on 9th or 8th carbon atom.

Compounds **2** show the characteristic bathochromic shifting of the absorption maximum in the longer wavelengths in both acid and alkaline medium.

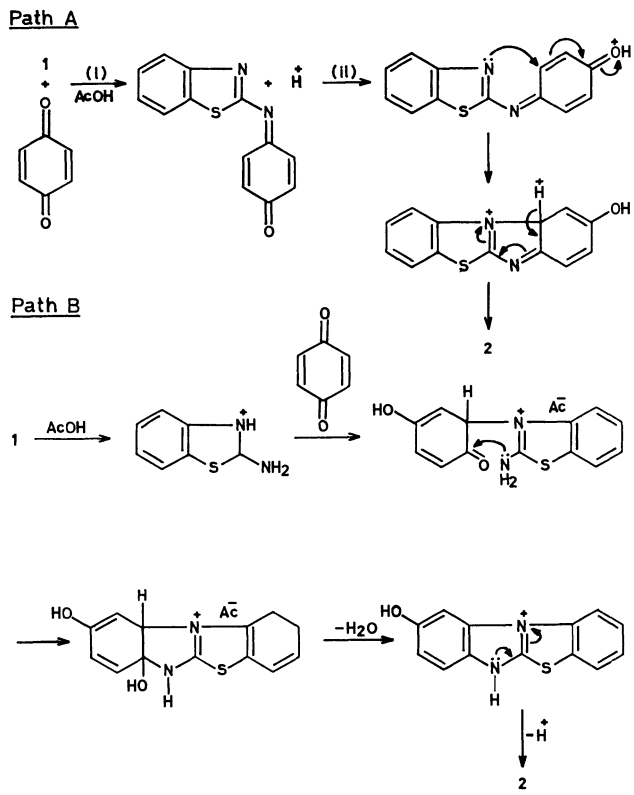


In alkaline medium this red shift of about 100 nm is more pronounced and is ascribed to the quinonoid structure (A) as one of the contributing form to the total structure. In acid medium (about 40 nm) it should be due to the salt formation (B).

The quaternary compounds **3** show a further red shifting of absorption maxima in the visible region (λ_{max}>500 nm) (Table 2). This may be attributed to salt formation and contribution of the dipolar betaine structure in ethanol.

The formation of **2** can be explained by the following mechanisms.

Whichever of the two mechanisms cited here may be taking place, the position of phenolic hydroxyl group remains ascertained as meta to the bridgehead nitrogen atom and para to second imidazole nitrogen, through either of these routes.



Thanks are due to the U.G.C., New Delhi for the award of a Junior Research Fellowship to R.P.S. and to the Director, C.D.R.I., Lucknow for the IR spectra and elemental analysis.

Atropisomerism in Metal Chelates. The Crystal Structure and Absolute Configuration of $(-)_{589}$-3-(2,4-Dinitro-1-naphthyl)-2,4-pentanedionato[tris(2-aminoethyl)amine]cobalt(III) Dibromide

Yoshiharu NAKANO*,† and Shoichi SATO

The Institute for Solid State Phisics, The University of Tokyo, Roppongi 7-22-1, Minato-ku, Tokyo 106

(Received June 8, 1981)

The crystal structure and the absolute configuration of $(-)_{589}$-3-(2,4-dinitro-1-naphthyl)-2,4-pentanedionato-[tris(2-aminoethyl)amine]cobalt(III) dibromide were determined by X-ray diffraction. The complex crystallizes as the orthorhombic space group $P2_12_12_1$, with $a=13.738(2)$, $b=15.446(1)$, $c=12.243(1)$ Å, and $Z=4$. The structure was solved by the Patterson-Fourier method and refined to a final R_1 value of 0.038 for the 3347 observed reflections with $|F_o|>3\sigma(|F_o|)$. The acetylacetonate (acac) ring adopts a more deformed boat conformation than that in 3-(6-methyl-2,4-dinitrophenyl)-2,4-pentanedionato analogue. The three chelate rings of tris(2-aminoethyl)amine (tren) have envelope conformations and adopt λ, λ, and δ conformations. The absolute configuration of the title compound can be designated as *R*.

One of the present authors (Y. N.) has synthesized and resolved a series of optically active complexes whose optical activity arises from the restricted rotation of an aromatic ring system. The crystal structure of a member of the series has been determined by X-ray diffraction (Complex II in Fig. 1).[1] In this complex, the $[CoN_4O_2]$ chromophore possesses approximately the C_{2v} symmetry, while the two apical five membered chelate rings formed by tren have enantiomeric conformations. Although the 6-methyl-2,4-dinitrophenyl group is, as expected, almost perpendicular to the acac ring, the acac ring bends slightly toward the 2-nitro group.

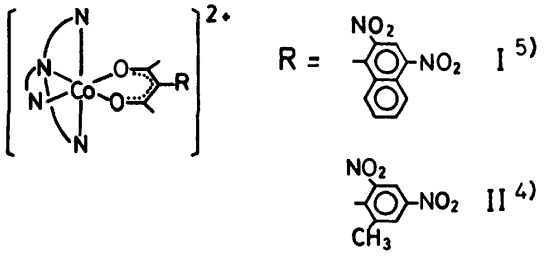

Fig. 1. Skeletal stucture of 3-aryl-2,4-pentanedionato-[tris(2-aminoethyl)amine]cobalt(III) cation.

Since the title complex has the same chromophore as Complex II, except for its π-electronic system of the aromatic ring, almost all the transitions in the CD spectrum of Complex II should also appear in that of Complex I. In fact, the CD spectrum of the title complex showed the same sign and reasonable rotational strength compared to that of $(-)_{589}$-complex II in the first absorption region. Accordingly, the following structural features, observed in Complex II, were also expected for Complex I: (1) The relative configuration of the 2-nitro group with respect to the tren chain, (2) the bent structure of the acac ring, and (3) the disposition of the aromatic system relative to the acac ring.

The authors' interest lies in clarifying the structural details, such as those described above and other structural factors which may contribute to the rotatory strength.

Experimental

The present complex[2] consists of orange-red plates. The crystal data and data collection detailes are summarized in Table 1. The intensities were corrected for Lorentz and polarization effects and for absorption. The structure was solved by the heavy-atom method. All the parameters for non-hydrogen atoms were refined by a block-diagonal least-squares method with anisotropic thermal parameters. The weights for the refinement were $w=1/[\sigma^2(|F_o|)+(0.015|F_o|)^2]$. The refinement converged to $R_1=0.038$ and $R_2=0.042$. The final positional parameters shift of C(2) was 1.5σ, those of the other non-hydrogen atoms were less than their σ. The final difference Fourier maps showed no peaks greater than 0.6 e/Å^3.

Table 1. The crystal data[a] and data collection

$C_{21}H_2Br_2CoN_6O_6$	
Orthorhombic	$P2_12_12_1$
$a=13.738(2)$ Å, $b=15.446(1)$ Å, $c=12.243(1)$ Å, $V=2598.1(4)$ Å^3	
$D_x=1.74$, $D_m=1.73$ g cm^{-3}; $Z=4$, $\mu=40.0$ cm

a) $U_{eq}=(U_{11}+U_{22}+U_{33})/3$.

The positional parameters of all the atoms with their standard deviations, are listed in Table 2. The thermal parameters[3] and observed and calculated structure factors[3] are kept in the office of the Chemical Society of Japan. The atomic-scattering factors were taken from Ref. 4. The calculations were performed on a FACOM 230-48 computer of this Institute with a local version of UNICS.[5]

The absolute configuration was determined by anomalous-scattering techniques. Some Friedel pairs were examined on equi-inclination Weissenberg photographs taken with Cu $K\alpha$ radiation. Observed and calculated intensities are compared, for which $|F_c(hkl)|$ and $|F_c(h\bar{k}\bar{l})|$ differd by more than 35%.[3] The concordance of the intensities indicated that the absolute configuration of this complex is R, according to the Cahn-Ingold-Prelog notation.[6] When the enantiomeric structure was refined under identical conditions, it converged to $R_1=0.056$ and $R_2=0.058$. An application of the residual-index-ratio-test[7] showed that this structure could be rejected at the 0.005 significance level in favor of the R configuration.

Description of Structure and Discussion

Figures 2 and 3 show the projection of the crystal structure along the c and b axes respectively. The complex cations are linked through N–H···Br hydrogen bonds to form zigzag chains along the a axis. The

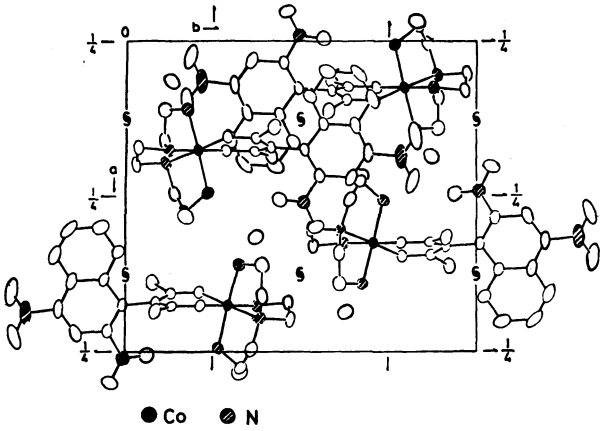

Fig. 2. A projection of the unit cell along the c axis.

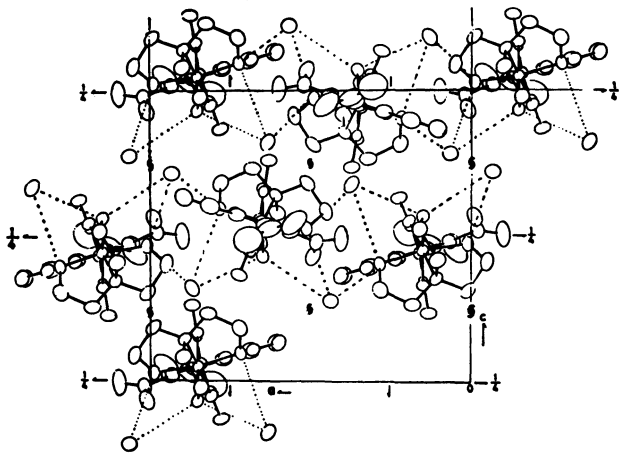

Fig. 3. A projection of the unit cell along the b axis. Broken lines indicate hydrogen bonds.

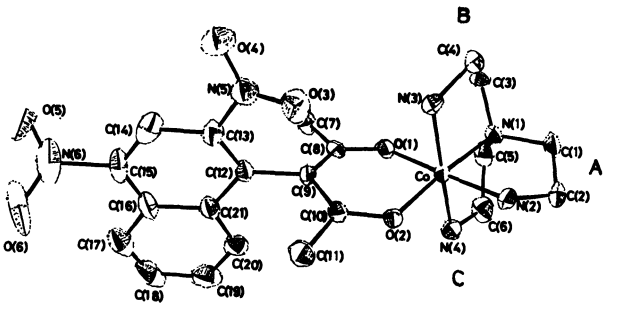

Fig. 4. A perspective drawing of the complex cation and the numbering scheme of the atoms. The three chelate rings are denoted by A, B, and C.

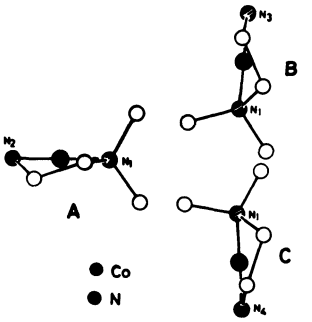

Fig. 5. Conformation of the tren chain.

interatomic distances and bond angles of the hydrogen bonds[3] and the short intermolecular distances[3] are listed in the supplementary materials.

A perspective drawing of the complex ion is shown in Fig. 4. In contrast to the case of Complex II, neither disorder in the chelate-A ring nor a large libration of the aromatic ring was observed. The chelate rings of tren (labeled A, B, and C, as are shown in Fig. 5) adopt the envelop conformation. The B and C rings are almost enantiomeric, and their conformations are λ and δ respectively, whereas A ring takes a λ conformation. The conformation of the rings favors the formation of hydrogen bonds between the primary amino groups and bromide ions (see Fig. 3).[3] Bond distances and angles in the cation are listed in Table 3.[3] The Co–N(1) and Co–N(2) bonds in the chelate ring A are significantly shorter than the other two, Co–N(3) and Co–N(4) (see Table 3). The Co–N(3) and Co–N(4) bonds are not colinear, the N(3)–Co–N(4) angle being 171.4(2)°. Such a deformation is attributable to the strain due to fused chelate-ring formation. Similar distortions are observed in Complex II and other related chelate complexes.[8,9]

Figure 6 shows a projection of the complex cation along the line through the two oxygen atoms of the acac ring. The ring assumes a boat conformation similar to that in Complex II.[1] This seems to be due to electrostatic interaction between the amino and 2-nitro groups as will be described below. The deformation of the acac ring in this complex is larger than that in Complex II. The mean plane of O(1), O(2), C(8), and C(10) makes dihedral angles of 15.3° with respect to the coordination plane of the acac ring and 7.9° with respect to the plane of C(8), C(9), and C(10). The bonds around the atoms

TABLE 3. BOND LENGTHS AND ANGLES; WITH THEIR STANDARD DEVIATIONS

	Bond lengths(l/Å)

C(12)–C(13)–N(5)	122.6(5)	O(3)–N(5)–O(4)	123.2(5)

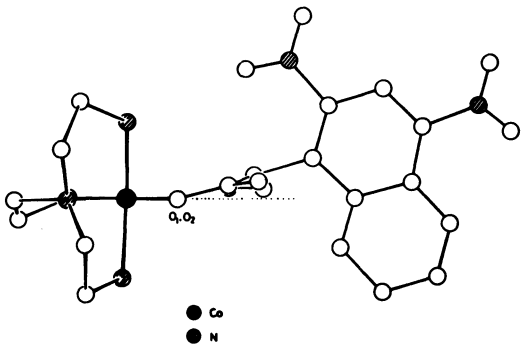

Fig. 6. A projection of the complex cation along the line of two oxygen atoms, O(1) and O(2).

of C(8) and C(10) have the sp^2 character. Thus, the two sets of groups, O(1), C(7), C(8), and C(9), and O(2), C(9), C(10), and C(11), are almost planar. The maximum shifts of the atoms from the least-squares planes of the two groups are 0.01 and 0.02 Å respectively. The former plane makes dihedral angles of 4.2° with respect to the plane of O(1), O(2), C(8), and C(10), and the latter, 8.0°. Consequently, the C(7) and C(11) atoms shift from the plane of O(1), O(2), C(8), and C(10) to the opposite side of the C(9) atom.

The two coordination bonds of the acac ring differ significantly from each other. Such a difference was also observed in Complex II. The bond distance, Co–O(2), is shorter than Co–O(1) by 0.020 Å. Mitsui observed a similar shortening in an analogous glycine chelate.[8] The pivot bond, C(9)–C(12), tilts by 5.1(4)° from the plane of C(8), C(9), and C(10). The aromatic system tilts slightly around the pivot bond, so that the 2-nitro group approaches the O(2) atom. The direction of the tilt is opposite to that found in Complex II. The angle between the O(1)–Co–O(2) plane and the mean plane of the aromatic system is 85.4°. In this complex, the distances between the amino nitrogen atom, N(3), and the oxygen atom of the 2-nitro, is 3.367(6) Å, while that between O(3) and H(N3A) is 2.77(5) Å. The bond angle of N(3)–H(N3A)–O(3) is 130(4°). These values suggest that the formation of a strong hydrogen bond between N(3) and O(3) is not favored. Electrostatic interaction between the amino and 2-nitro groups may force the acac ring to adopt a boat conformation.

In an aqueous solution, all the polar groups and the bromide ions will be solvated; interactions between the 2-nitro group and the amino group will diminish, and the hydrogen bonds between the bromide ions and the amino groups will be broken. These changes will lead to random conformations of the tren instead of rigid dissymmetric conformations. Therefore, the disposition and configuration of the aromatic system relative to the tren chain seems to contribute most to the rotational strength in the present complex.

In the resolution chromatography of the complexes, I and II, *R* isomers are eluted faster than *S* isomers. The *R* isomers associate with the $(+)_{589}$-tartratoantimonate(III) ion more strongly than the *S* isomers, and they can be dissociated more easily from the sulfonate groups of SP-Sephadex resin.[10] Furthermore, the pair of elution bands in Complex I are more separated than those in Complex II; the pair of the elution bands are completely separated in Complex I, but the tail of the *R*-isomer band overlaps the S isomer in Complex II. These facts suggest that the π-electronic system may play a role in discriminating the enantiomers. The associative complex of the *S* isomer with tartratoantimonate(III) ion are probably less stable than that of the *R* isomer because of the steric hindrance of the benzo moiety in the associative complex. A crystallographic study of the tartratoantimonate salt of the title complex would shed light on the problem.

Part of the cost of this research was met by a Grant-in-Aid for Scientific Research (No. 364206) from the Ministry of Education, Science and Culture, to which the authors' thanks are due.

(Received June 29, 1981)

A series of TiO_2 catalysts loaded with transition metals were prepared by photodeposition. The activity order for these catalysts in the title reaction was as follows: $Pt/TiO_2 > Rh/TiO_2 > Pd/TiO_2 > Ru/TiO_2 > Ir/TiO_2 > TiO_2$. Upon heat treatment the activities of all the metal/TiO_2 catalysts were enhanced, but the above sequence was unaltered.

The recent and on-going concern with photocatalytic production of hydrogen from water or organic materials is related to solar energy conversion and storage. Among the catalysts used in this type of reactions are metal-loaded oxides[1,2] such as Pt/TiO_2 and $Rh/SrTiO_3$ as well as binary oxides[3,4] such as $NiO–SrTiO_3$ and $RuO_2–TiO_2$. In our laboratory we prepared a series of polycrystalline metal/TiO_2 powders (metal=Ru, Rh, Pd, Ir, Pt), and compared their photocatalytic activities, relative to TiO_2, for dehydrogenation of 2-propanol. A few related experiments were also made to gain a better understanding of this reaction. This paper reports the results of these experiments.

Experimental

Materials. Anatase was purchased from Kanto Chemical Co., Inc.: the absence of rutile was confirmed by X-ray powder diffraction, and the BET surface area was determined to be 11.5 m^2/g. Metal salts (H_2PtCl_6, $RhCl_3$, $IrCl_4$, $PdCl_2$, $RuCl_3$) used for catalyst preparation were also commercially obtained. 2-Propanol (Wako Pure Chemical Ind., Guaranteed grade) was used without further purification. All aqueous solutions or suspensions of these chemicals were prepared using distilled water.

Apparatus. Figure 1 illustrates the photochemical reaction vessel used for both catalyst preparation and kinetic studies. The reaction vessel consists of two parts separable at joint J. There are two interchangeable inner parts of an identical shape and size, one made of pyrex glass and the other of quartz. Unless otherwise stated, the experiments in this report were conducted using the quartz unit. An irradiation lamp can be placed inside the innermost wall A. Water from a thermostatically controlled bath can flow through the thin space between A and B, cutting off the thermall energy from the irradiation lamp. The outer part is a three side-necked flask, one sideneck connected to a cooler, a second used for sampling, and the other (not indicated in the figure) for bubbling of N_2 or Ar to purge air before reaction. During reaction the third sideneck was sealed with a pinchcock. The outermost space D between walls B and C is the reaction region. The whole reaction vessel is immersed in a thermostatted water bath. The reaction temperatures recorded are those of this bath.

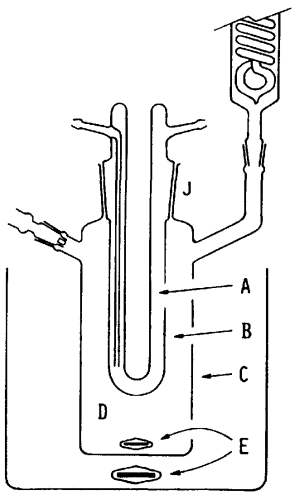

Fig. 1. Reaction vessel.
A—D: See text, E: Teflon-coated magnetic bars.

Catalyst Preparation. Three metal/TiO_2 catalysts (metal=Ru, Pd, Pt) were prepared by photodeposition of the metal on TiO_2 according to a method similar to that of Kraeutler and Bard.[5] As a typical example, anatase powders (3 g) were homogenized in water (50 ml) for 1 h in a Mitamura Riken ultrasonic cleaner (70 W). To the resulting slurry was added an aqueous solution of an appropriate concentration of H_2PtCl_6, a $CH_3COOH–CH_3COONa$ buffer (pH=4, *ca.* 10 ml), and water to adjust the whole volume to *ca.* 250 ml. The whole mixture was transferred to space D of the reaction vessel, and N_2 was bubbled for 20 min to eliminate dissolved air. To commence the photocatalytic deposition of the metal, a 30-W low-pressure Hg lamp was switched on, and irradiation was carried out at 40 or 55 °C under continued stirring and N_2 bubbling until metal deposition was complete (1 h for Pd; 2.5 h for Ru and Pt). After irradiation, the mixture was filtered off through a Gelman Membrane Filter DM-450 (pore size 0.45 μm), washed with water until the washings were neutral. The precipitate collected was dried first at 45 °C overnight between filter papers in an electric oven and then under reduced pressure for several days at room temperature, and finally stored in a vial under a nitrogen atmosphere.

The above procedure was not applicable to the preparation of Rh/TiO_2 and Ir/TiO_2 because of the difficulty to achieve complete reduction of $RhCl_3$ and $IrCl_4$ to the metallic state. The following modifications were thus made: methanol was used instead of the $CH_3COOH–CH_3COONa$ buffer, and the irradiation source was replaced by a more intense 100-W high-pressure Hg lamp.

Air treatment of the metal/TiO_2 catalysts was conducted by heating for 2 h at 380 °C under a stream of air in an electric furnace. Before heat treatment, all the metal/TiO_2 catalysts were off-white. Upon heat treatment, Ru/TiO_2 acquired a slightly blueish tint, while there was no significant variation in appearance for the other metal/TiO_2 catalysts.

Kinetic Procedure. The photocatalytic dehydrogenation of 2-propanol was conducted as follows. To space D of the reaction vessel were introduced a metal/TiO_2 catalyst (0.1 g)

and a water–2-propanol mixture (1 : 1 by vol., 200 ml). Argon was bubbled through the suspension for 30 min, then the photocatalyzed dehydrogenation was started by irradiating at 40 °C with the 100-W high-pressure Hg lamp. Small portions of the reaction solution were withdrawn at intervals and analyzed for product acetone by a gas chromatograph using a 2 m × 3 mm i.d. column of 30% PEG 20 M on 30—60 mesh chromosorb WAW at 60 °C. The gas evolved was led through the cooler-attached sideneck into water or aqueous $Ba(OH)_2$ solution, and collected in a gas burette.

Results and Discussion

Stoichiometry and Reaction Profile. The gas evolved under irradiation in the presence of metal/TiO_2 catalysts did not make the aqueous $Ba(OH)_2$ solution turbid, and consisted almost exclusively of hydrogen, judged from mass spectral data. It has been confirmed with Pt/TiO_2 that acetone and H_2 are produced in nearly equal amounts by photocatalytic dehydrogenation of 2-propanol (Inset a, Fig. 2). A small amount of 2,3-dimethyl-2,3-butanediol (pinacol) was detected as the only by-product (Inset b). Pinacol formation was completely suppressed upon replacing the quartz inner part of the reaction vessel by the pyrex glass one. Thus it is very likely that pinacol is produced by the reaction of 2-propanol with ultraviolet-excited acetone. No reaction occurred at all with the mercury lamp switched off. The rates of acetone formation in duplicate experiments conducted under identical conditions were reproducible within 5%.

At the beginning of the reaction, as seen from Fig. 2, the amount of acetone produced increased almost

Table 1. Activities of TiO_2 and metal/TiO_2 catalysts for photocatalytic dehydrogenation of 2-propanol to acetone

Catalyst	V [a] / μmol min^{-1}	R_1^{rel} [b]	R_2^{rel} [c]
	Before heat treatment		
TiO_2	1.6(V_0)	1	—
Ru/TiO_2	7.6	4.7	0.076
Rh/TiO_2	38.4	24	0.37
Pd/TiO_2	13.1	8.2	0.12
Ir/TiO_2	4.0	2.5	0.021
Pt/TiO_2	194	121	1
	After heat treatment		
Ru/TiO_2	12.6	7.8	0.12
Rh/TiO_2	51.1	32	0.48
Pd/TiO_2	15.1	9.4	0.14
Ir/TiO_2	6.9	4.3	0.035
Pt/TiO_2	200	124	1

a) Obtained using 0.1 g of each catalyst. b) $R_1^{rel} \equiv V/V_0$, the activity relative to TiO_2. c) $R_2^{rel} \equiv \{V(\text{metal})/M(\text{metal})\}/\{V(\text{Pt})/M(\text{Pt})\}$, where M is the molecular weight. Thus, R_2^{rel} represents the activity relative to Pt/TiO_2, referred to unit molar quantity of the loaded metal.

linearly with time, and then gradually leveled off. With the metal/TiO_2 catalysts containing 1 wt% metal, the extent of the initial linear region ranged from *ca.* 1 h (Pd, 0.05% conversion) to 2.5 h (Pt, 1.2% conversion). The photocatalytic dehydrogenation rates of a series of Pt/TiO_2 catalysts were estimated from the initial slope, and are plotted in Fig. 3 (curve A) as a function of Pt content. It is seen that as the Pt loading increases, the rate increases almost linearly and then approaches a constant value. The rate per mg Pt (curve B) remains almost constant in the low Pt loading region, and then decreases with increasing Pt loading.

Catalytic Activity. The activities of these metal-loaded catalysts diminished somewhat during storage in a vial; rather rapidly in the first few days (*e.g.*, by

20—30%), and then quite slowly (*e.g.*, by a further 20—30% after storage for a few months). The activity data of Table 1 were obtained with those metal/TiO_2 catalysts that had been loaded with 1% metal and stored for about a week. The values of V for the catalyst samples before heat treatment indicate that the activities fall in the sequence

$$Pt/TiO_2 > Rh/TiO_2 > Pd/TiO_2 > Ru/TiO_2 > Ir/TiO_2 > TiO_2. \quad (1)$$

In accord with this sequence, Kawai and Sakata[1] have shown recently that Pt/TiO_2 is twice as active as Pd/TiO_2 in photocatalyzed dehydrogenation of methanol. A comparison of the V values between the heat-treated and untreated catalysts shows that the heat treatment somewhat enhanced the activity for all the metal/TiO_2 catalysts, but did not alter sequence (1). The cause of the activity enhancement due to heat treatment is not clear at present: It could be (i) the rearrangement of surface metal atoms, (ii) the burning-off of undetected surface impurities, or (iii) the partial oxidation of the loaded metal.

In connection with item (i), it is interesting to refer to Johnson and Keith's paper[6] dealing with the state of platinum in Pt/Al_2O_3 catalysts. They have found that air or O_2 treatment of the catalysts at high temperatures (427—650 °C) followed by reduction leads to a high dispersion of the platinum. In relation to item (iii), it is to be noted that the metal in metal/semiconductor catalysts acts as the pool of electrons photogenerated under irradiation. Partial oxidation of the platinum possibly increases the capacity of the pool, thereby also increases the concentration of positive holes in the TiO_2 phase.

Additional Remarks. A fundamental question about any photocatalytic phenomenon is whether it is really catalytic. To answer this question, let us estimate "the turnovers accomplished."[7] This quantity represents the total number of molecules reacted per surface site. The rough numerical calculations were made based on the acetone formation over the initial 2h-period of reaction; a surface area for TiO_2 of 11.5 m^2/g was used and a catalytic site concentration of $5 \times 10^{14}/cm^2$ was assumed. The turnovers accomplished thus estimated are listed in Table 2. The quite large values for Pt/TiO_2 and Rh/TiO_2 indicate clearly that the dehydrogenation of 2-propanol was really photocatalytic on these two catalysts. The reaction on Ru/TiO_2 and Pd/TiO_2 is also likely to be photocatalytic.

Lehn *et al.*[2] compared a variety of metal/$SrTiO_3$ catalysts for water splitting under illumination. Since these catalysts and the reaction resemble ours, it seems worthwhile to compare the activities. The activity sequence they observed was

$$Rh/SrTiO_3 > Ru/SrTiO_3 > Re/SrTiO_3 > Ir/SrTiO_3 = Pt/SrTiO_3 > Pd/SrTiO_3 > Os/SrTiO_3 > Co/SrTiO_3 > SrTiO_3. \quad (2)$$

As far as the loaded metals are concerned, sequence (1) does not conform to sequence (2). This discord might stimulate further studies in this area.

TABLE 2. THE TURNOVERS ACCOMPLISHED FOR EACH CATALYST

Catalyst	Turnovers accomplished / molecules site^{-1}	
	Before heat treatment	After heat treatment
TiO_2	2	—
Ru/TiO_2	9	16
Rh/TiO_2	46	57
Pd/TiO_2	11	11
Ir/TiO_2	5	5
Pt/TiO_2	247	266

We thank Dr. Y. Takagi for valuable discussions, Mr. A. Ikuo and M. Watanabe for their technical assistance, and Mrs. N. Tejima for her BET measurement of the TiO_2 catalyst. This work was supported by a grant from the Science and Technology Agency towards the Solar Energy Reseach Project.

ESR Studies of Cobalt(II) in $[TMPD^+]_2[Ni(mnt)_2]$ and $[TMPD^+]_2[Pt(mnt)_2]$ ($TMPD^+$: *N,N,N′,N′*-Tetramethyl-*p*-phenylenediamine Cation, mnt: 1,2-Dicyano-1,2-ethylenedithiolato)

Tomoyoshi SETOI,† Motomich INOUE,†† and Daiyu NAKAMURA*
Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464
(Received July 27, 1981)

The Co(II) and triplet exciton ESR spectra of Co(II)-doped $[TMPD^+]_2[Ni(mnt)_2]$ and $[TMPD^+]_2[Pt(mnt)_2]$ were observed at different temperatures. The triplet exciton signals of the solid solutions yielded practically the same ESR parameters as those of the pure Ni(II) and Pt(II) complexes. The Co(II) spectra showed a well-resolved hyperfine structure, each component line of which became broad with increasing temperature. This can be interpreted in terms of exciton transfer from $TMPD^+$ lattices to the metal ions.

The compound $[TMPD^+]_2[Ni(mnt)_2]$ consisting of planar organic radical cations and also planar metal-chelate anions has recently attracted considerable attention because of its novel crystal structure[1] schematically shown in Fig. 1. In this structure, $TMPD^+$ radicals form alternating chains whereas $[Ni(mnt)_2]^{2-}$ ions are stacked equidistantly to construct regular chains. The intradimer spin interaction of $TMPD^+$ radicals ($2J_1=-0.23$ eV) is strong enough, as compared with the interdimer one in a $TMPD^+$ chain ($|J_2/J_1|\approx 0.1$), to generate triplet excitons which migrate throughout in the chain.[1,2]

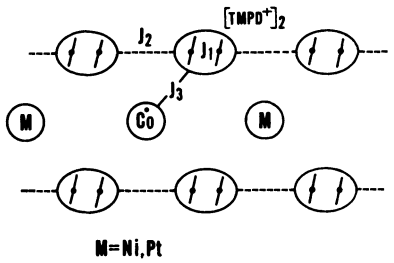

Fig. 1. Structure of $[TMPD^+]_2[M(mnt)_2]$ (M=Ni or Pt) depicted schematically.

Previously, we studied the ESR of the solid solution $[TMPD^+]_2[Cu_xNi_{1-x}(mnt)_2]$ and found the existence of magnetic interaction between Cu(II) ions and $TMPD^+$ dimers. This can be interpreted in terms of the partial migration of triplet excitons onto neighboring metal chelate chains.[2,3] It is known that Co(II) ions usually have an electron-spin relaxation time shorter than that of Cu(II) ions. Therefore, we can expect to obtain further information about the exciton-metal interaction by use of Co(II) ions as a probe to detect it. The present ESR investigation has been undertaken on Co(II) ions and triplet excitons in Co(II)-doped $[TMPD^+]_2[Ni(mnt)_2]$ and $[TMPD^+]_2[Pt(mnt)_2]$, both pure complexes of which are known to be isostructural to each other from our previous ESR study.[3]

Experimental

A boiling ethanol solution of $(Et_4N)_2[Co(mnt)_2]$ and $(Et_4N)_2[Ni(mnt)_2]$ mixed in an appropriate ratio was added all together to a boiling ethanol solution of $[TMPD^+]ClO_4$.[2] On cooling, the resulting solution separated black needle crystals having the crystal form identical with that of the pure Ni(II) complex. The crystals were identified as $[TMPD^+]_2[Co_xNi_{1-x}(mnt)_2]$. The solid solution of $[TMPD^+]_2[Co_xPt_{1-x}(mnt)_2]$ was synthesized in a similar manner from $(Et_4N)_2[Pt(mnt)_2]$, $(Et_4N)_2[Co(mnt)_2]$, and $[TMPD^+]ClO_4$.[2,3] Black needle crystals were obtained. All preparative experiments were carried out under a dry-nitrogen atmosphere.

The ESR spectra of the crystalline powders prepared were recorded by means of a JEOL ES-SCXA X-band spectrometer in a temperature range of 80—300 K. Mn^{2+}/MgO was employed as a marker. The sample temperature was controlled by use of a cold-gas flow system. Two copper *vs.* constantan thermocouples were mounted near either side of the sample tube along the stream of cold nitrogen gas for the determination of sample temperatures. The observed temperature was estimated to be accurate within ±2 K.

Results

Figure 2 shows the ESR spectra of $[TMPD^+]_2[Co_xNi_{1-x}(mnt)_2]$ ($x\approx 0.02$) recorded at different tem-

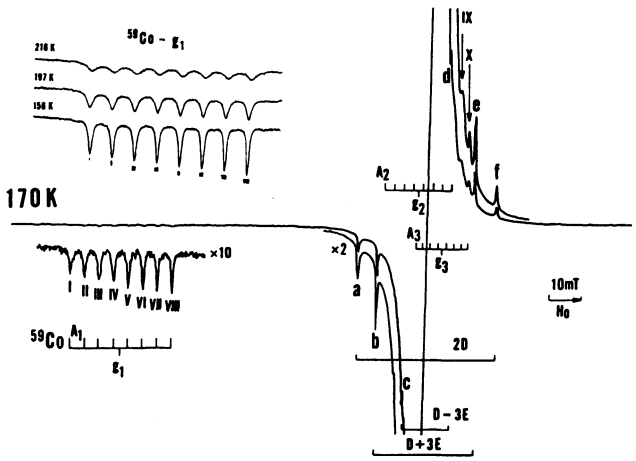

Fig. 2. ESR spectrum of $[TMPD^+]_2[Co_xNi_{1-x}(mnt)_2]$ ($x\approx 0.02$) recorded at 170 K. The hyperfine peaks I—VIII due to ^{59}Co are shown for the temperatures 156, 197, and 216 K. g_2 and A_2 determined for the Bu_4N^+ salt are shown for reference.

peratures. In the temperature range 160—200 K, signals assignable to Co(II) (indicated by Roman numerals) were observed well separately from triplet exciton signals (indicated by the alphabet) arising from $TMPD^+$ dimers. With decreasing temperature, the $TMPD^+$ signals became weak whereas the Co(II) signals increased their intensity in conformity with the Curie law. Below 160 K, only the latter signals were observed. The ESR spectra of $[TMPD^+]_2[Co_xPt_{1-x}(mnt)_2]$ are given in Fig. 3. These spectra closely resemble those of the Co(II)-doped Ni(II) analogue.

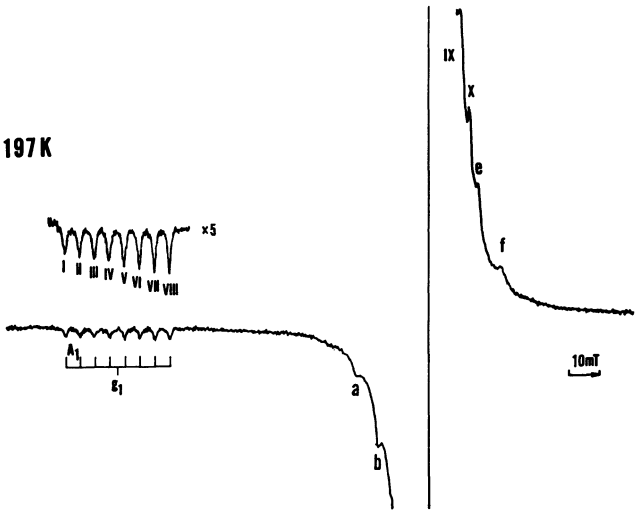

Fig. 3. ESR spectrum of $[TMPD^+]_2[Co_xPt_{1-x}(mnt)_2]$ ($x\approx0.01$) recorded at 197 K.

The triplet exciton signals are interpreted in terms of a fine structure represented by

$$\mathcal{H}_{fs} = D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2). \quad (1)$$

The zero splitting parameters (D and E) obtained from the spectra of the Ni(II) and Pt(II) solid solutions agree well with those of the pure Ni(II) and Pt(II) complexes, respectively, as given in Table 1. The well resolved hyperfine structure due to ^{59}Co nuclei yields the g_1 value and the corresponding hyperfine coupling constant A_1 as indicated in Table 2. The peaks IX and X can be assigned to the component lines of the g_3 signal by comparing them to the ESR spectrum of Co(II) ions diluted in $(Bu_4N)_2[Ni(mnt)_2]$.[4] The separation between the two peaks is nearly equal to the A_3 value of Co(II) in the butylammonium salt. If the equal separation is assumed for the eight component lines, the g_3 value can be evaluated as given in Table 2 in agreement with the value of Co(II) in the butylammonium salt. In each spectrum of the Ni(II) and Pt(II) solid solutions, an extra strong signal attributable to $TMPD^+$ monomers unavoidably involved as an impurity appeared at $g=2.006$, where the g_2 signals of Co(II) should be observed. Therefore, we could not determine the g_2 and A_2 values of the present compounds. The values of g_2 and A_2 in Fig. 2 show the data reported for Co(II) diluted in $(Bu_4N)_2[Ni(mnt)_2]$.[4] These g_2 and A_2 values are thought not to be much different from the respective inherent values of the $TMPD^+$ complex. All of the ESR parameters thus determined were independent of the concentration of Co(II) ions.

Table 1. TRIPLET EXCITON ESR PARAMETERS D AND E AND THE EXCHANGE INTEGRAL J_1 OF $[TMPD^+]_2[Co_xNi_{1-x}(mnt)_2]$ ($x\approx0.02$) AND $[TMPD^+]_2[Co_xPt_{1-x}(mnt)_2]$ ($x\approx0.01$)

Compound	D/mT	E/mT	$-2J_1$/eV
$[TMPD^+]_2[Co_xNi_{1-x}(mnt)_2]$	21.6	2.8	0.19
$[TMPD^+]_2[Co_xPt_{1-x}(mnt)_2]$	23.0	2.9	0.23
$[TMPD^+]_2[Ni(mnt)_2]$[a]	21.6	2.9	0.23
$[TMPD^+]_2[Pt(mnt)_2]$[b]	22.9	2.9	0.21

a) Refs. 1 and 2. b) Ref. 3.

With increasing temperature above 160 K, the signals of $TMPD^+$ in the Ni(II) solid solution become gradually strong. The intensity I of the triplet exciton ESR signal should increase in proportion to the triplet density ρ and also to reciprocal temperature. Accordingly, one can obtain the following equation when $2|J_1| \geqq kT$.

$$I \propto \rho/T = 3[\exp(2J_1/kT)]/T. \quad (2)$$

From the temperature dependence of the exciton signal intensity, the exchange integral J_1 of $TMPD^+$ dimers was determined as $2J_1 = -0.19$ eV. Above 200 K, the $TMPD^+$ signals gradually broaden owing to the migration of triplet excitons within $TMPD^+$ chains. It is interesting to note that the Co(II) signals also gradually broaden above 200 K. This indicates that the triplet excitons have some magnetic interaction with the Co(II) ions.

Since the peaks I—VIII are separated well from each other, we can determine the temperature dependence of the half-height width. When the line broadening is assumed to be caused by a thermal activation process with an activation energy ΔE, the linewidth W can be expressed as[2,5]

$$W = W_0 + W_1 \exp(-\Delta E/kT). \quad (3)$$

Here, W_0 denotes the linewidth at the low temperature limit, and can be regarded, in the present problem, as that observed at 78 K. Figure 4 shows the semilogarithmic plot of $(W-W_0)$ against T^{-1} for the Ni(II) solid solution. The experimental results deviate from

Table 2. Co(II) ESR SIGNAL PARAMETERS OF $[TMPD^+]_2[Co_xNi_{1-x}(mnt)_2]$ ($x\approx0.02$) AND $[TMPD^+]_2[Co_xPt_{1-x}(mnt)_2]$ ($x\approx0.01$)

Compound	g_1	g_2	g_3	A_1/mT	A_2/mT	A_3/mT

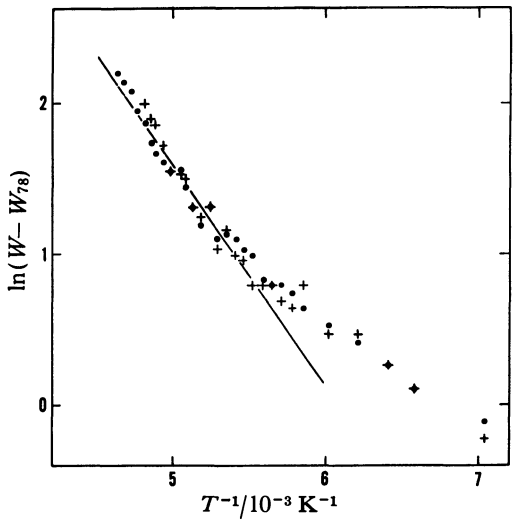

Fig. 4. Temperature dependence of the half-height width of the ^{59}Co hyperfine peaks I (+) and VIII (●) observed for the Co(II)-doped $[TMPD^+]_2[Ni(mnt)_2]$. The straight line shows the best fit of Eq. 3 to the peak VIII above 185 K. W_{78} in the ordinate denotes the linewidth at 78 K.

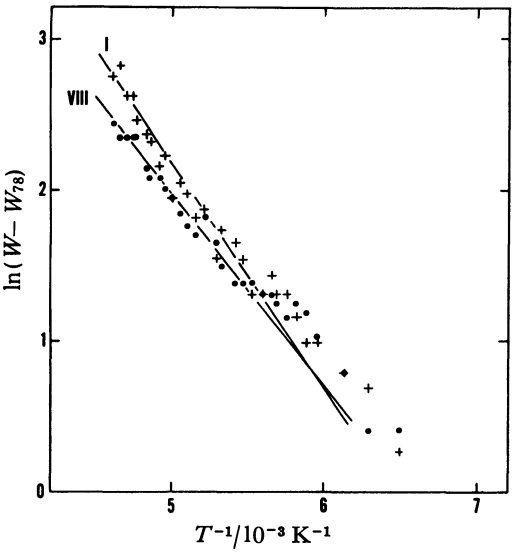

Fig. 5. Temperature dependence of the half-height width of the ^{59}Co hyperfine peaks I (+) and VIII (●) observed for Co(II) in $[TMPD^+]_2[Pt(mnt)_2]$. The straight lines show the best fits of Eq. 3 to the peaks I and VIII. The slopes of the lines give different activation energies, but the difference is smaller than the experimental errors.

Eq. 3 in the low temperature region. However, the linear relation is satisfied above 200 K yielding $\Delta E = 0.15 \pm 0.04$ eV.

The Co(II)-doped platinum salt yielded the ESR parameters very similar to those of the Ni(II) solid solution as given in Tables 1 and 2. The temperature dependence of the Co(II) linewidth in the Pt(II) complex (shown in Fig. 5) gave the ΔE value equal to that of the Ni(II) solid solution.

Discussion

Since the $TMPD^+$ signal parameters D, E, and J_1 of the present solid solutions agree with the corresponding values of the pure Ni(II) or Pt(II) salt, it is thought that the crystal lattices remain almost unchanged even in the solid solutions. Therefore, the ESR results can be discussed on the basis of the structure of the respective pure salts. The Co(II) signals of the solid solutions yield similar ESR parameters to those of Co(II) in $(Bu_4N)_2[Ni(mnt)_2]$. This indicates that magnetic interaction operating between organic radicals and metal chelates is weak enough to permit one its quantitative evaluation with ESR experiments. It is interesting to note that Co(II) ions diluted in $(Et_4N)_2[Ni(mnt)_2]$ yielded Co(II) ESR signals showing no line broadening in the temperature range in which the line broadening was observed for the $TMPD^+$ salt. Therefore, the line broadening of the Co(II) signals observed is ascribable to the triplet excitons.

When magnetic interaction between Co(II) ions and triplet excitons is a main cause for the Co(II) electron spin relaxation, the linewidth W of Co(II) ESR signals can be written as[2,6]

$$W = W_0 + W'\rho = W_0 + 3W' \exp(2J_1/kT). \quad (4)$$

On comparing the functional form of this equation with that of Eq. 3, ΔE is apparently equal to $2|J_1|$. The magnetic interaction of triplet excitons is accompanied by their migration over a barrier into adjacent sites. If this effect is taken into account, the ΔE value should be greater than $2|J_1|$. In the present solid solutions, however, the value of ΔE determined from the data at higher temperatures is certainly smaller than $2|J_1|$. This clearly indicates that the relaxation mechanism of Co(II) ESR given by Eq. 4 is inadequate for the interpretation of the present results. It is known that an electron spin on an isolated Co(II) ion can easily relax through *IS*- and/or *LS*-coupling.[7] In our previous experiments,[2,3] Cu(II) ESR signals in both Et_4N^+ and $TMPD^+$ salts showed a remarkable saturation effect, whereas no such effect was detectable for the Co(II) signals even at the highest power level ($\approx$100 mW) of our microwave oscillator. Accordingly, we have to take into account another relaxation mechanism for the Co(II) ESR of the present compounds such as modulation of *IS*- and/or *LS*-coupling through field fluctuation induced by the motion of $TMPD^+$ triplet excitons.

Figures 2 and 3 obviously show that the Co(II) signals I—VIII carefully taken at a given temperature for finely powdered samples have different linewidths from each other, whereas the component lines of Co(II) in the Et_4N^+ salt showed practically the same half-height width. The electronic state of the Co(II) ions can be fluctuated by exciton transfer from the $TMPD^+$ lattices to the metal ions. This transfer is accompanied by the so-called partial oxidation of the Co(II) ions in solids. This is considered to take place without difficulty, since the ligand mnt forms stable metal complexes with high oxidation states of the central metals.[8] The fluctuated electronic state of Co atoms induces the fluctuation of the g and A values. Owing to this effect,

the ESR Hamiltonian for the peaks I—VIII is given by the time dependent g and A:

$$\mathcal{H} = g_1(t)\mu_B HS_1 + A_1(t)I_1S_1. \quad (5)$$

The fluctuation in the present complexes is slow enough as compared with the ESR frequency, because the hyperfine lines are well separated. Under this condition, the linewidth W is[7]

$$W \approx \frac{1}{T_2}$$
$$= \frac{1}{2\hbar}\int_{-\infty}^{\infty} \overline{[H_{\alpha\alpha}(t+\tau) - H_{\beta\beta}(t+\tau)][H_{\alpha\alpha}(t) - H_{\beta\beta}(t)]}\,d\tau, \quad (6)$$

where $H_{\alpha\alpha}$ and $H_{\beta\beta}$ are the matrix elements of the above Hamiltonian. The values $g_1(t)$ and $A_1(t)$ can be reasonably assumed to be fluctuated with the same time constant τ_c, because the fluctuation comes from the same origin. Under this assumption along with $\omega\tau_c \gg 1$, we obtain

$$\frac{1}{T_2} = \frac{\tau_c}{\hbar^2}(g_1\mu_B H + A_1 M_I)^2, \quad (7)$$

where g_1 and A_1 are time independent. The ratio of the linewidths of the peaks $M_I = 7/2$ and $-7/2$ is evaluated as $(225+4.6\times 7/2)^2/(225-4.6\times 7/2)^2 = 1.3$, which agrees well with the observed ratio 1.5 of the half-height widths of the peaks I and VIII. Thus, the difference of linewidth among the peaks I—VIII at an arbitrary temperature can be interpreted in terms of a random modulation of the *IS* coupling by the motion of triplet excitons.

Since the linewidth of each Co(II) peak broadens with increasing temperature, τ_c in Eq. 7 should be temperature dependent. If we assume that the aforementioned triplet-exciton transfer is thermally activated with an energy ε, the correlation time τ_c may be written as,

$$\tau_c \propto \frac{1}{|J_3|}\exp(-\varepsilon/kT), \quad (8)$$

where J_3 denotes the exchange integral between $[TMPD^+]_2$ and Co(II) ions. In this mechanism, the linewidth can be given by the same functional form as Eq. 3. Accordingly, the triplet excitons in the present solid solutions transfer onto the metal lattices with the activation energy of $\Delta E \approx 0.15$ eV and result in the relaxation of the Co(II) electron spin through its *IS*-coupling. The relaxation is correlated only in the indirect process to the triplet excitons activated thermally with $2|J_1|$. The activation energy does not depend on the kind of the host crystals. The interaction between the metal chelates is so weak that an exciton transferred to a Co(II) chelate undergoes no further transfer to the adjacent metal chelates.

Static and Dynamic Properties of Quinoxalines in the Phosphorescent Triplet State from Optically Detected Magnetic Resonance

Kazuhiko SUGA and Minoru KINOSHITA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received August 27, 1981)

The static and dynamic properties of the phosphorescent triplet states of quinoxaline and 2,3-disubstituted derivatives in hexane have been studied at 1.4 K using the methods of optically detected magnetic resonance. In addition, the absorption and phosphorescence excitation spectra have also been measured to attain the information about the low lying excited states. A systematic comparison has been made for the purpose of examining the effect of substitution. A significant enhancement of the pumping rates for the y spin sublevel observed in the chlorine-substituted derivatives is concluded to be due to the additional indirect process of intersystem crossing which occurs from S_1 of n,π^* to T_1 passing through the intermediate triplet state of π,π^*. A detailed discussion on the observed phosphorescence spectra originating from the three sublevels has achieved a satisfactory success in understanding the mechanisms responsible for the radiative decay processes. It is concluded that the mechanisms due to vibronic coupling with closely lying n,π^* triplet states are of little importance in the systems studied here.

Quinoxaline is one of the most widely studied aza-aromatics from a variety of viewpoints. In particular, the properties of the lowest excited triplet state have attracted considerable attention[1-13] since the method of optically detected magnetic resonance (ODMR) was successfully applied to organic compounds.

Optical and magnetic resonance studies[5-13] have revealed that the interaction between the lowest π,π^* triplet state and low lying n,π^* states plays an important role in the decay and populating processes. However, with a few exceptions[12,13] the studies reported so far have little information on the detailed mechanisms, which give rise to the radiative decay from the individual spin sublevels.

Commonly, in order to obtain much information about the radiative activity of the spin sublevels at the vibronic bands, it is desirable to measure the phosphorescence spectra coming from the sublevels separately. Microwave-induced delayed phosphorescence (MIDP) method provides a useful procedure to obtain a sublevel emission spectrum. A set of three sublevel emission spectra makes it possible to discuss in detail the radiative properties even for the vibronic bands of small intensity.

In addition to quinoxaline, three 2,3-disubstituted quinoxalines are studied here in order to obtain closer insight into static and dynamic properties of the phosphorescent states by a systematical comparison. Besides the sublevel emission spectra, the kinetic rate constants are measured by means of the conventional MIDP method. The results are discussed in terms of the possible mechanisms of radiative transitions. The mechanisms operative in the intersystem crossing process are also discussed. The transition energies of the excited states are determined from the absorption and phosphorescence excitation spectra to provide supplementary information.

Experimental

Quinoxaline, 2,3-dimethylquinoxaline, 2-chloro-3-methylquinoxaline, and 2,3-dichloroquinoxaline were purified by recrystallization and vacuum sublimation. Hexane of spectroscopic grade obtained from Tokyo Kasei Co., Ltd. was used as received. The equipment and procedure for the optical and magnetic resonance experiments are essentially the same as described in previous papers.[14] The molecular structures and axis system for the compounds studied are shown in Fig. 1.

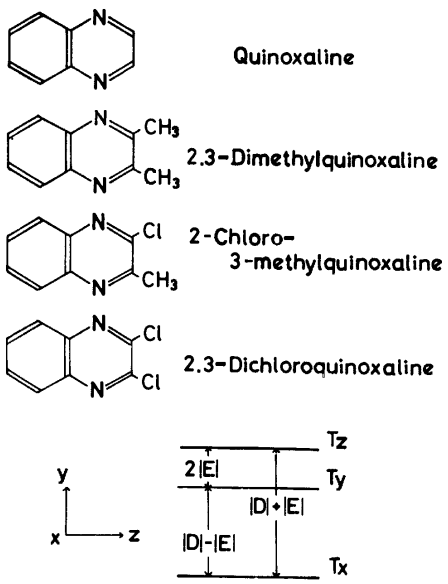

Fig. 1. Molecular structure and choice of axis system.

Absorption Spectra

The absorption spectra of quinoxaline and the three derivatives were measured in hexane at room temperature. The spectra are shown in Fig. 2.

Quinoxaline. As concerns quinoxaline, the analysis was based on the theoretical prediction about the transition energies and the moments for the transitions to the π,π^* excited singlet states reported in the literature.[15,16]

The first $^1A_1(\pi,\pi^*)$ band is observed with onset at 31490 cm^{-1}, and shows a slow decline, extending to $\cong$40000 cm^{-1}, which could be attributed to the presence of the second allowed π,π^* transition of B_2 symmetry. Accordingly, the peak found at 32780 cm^{-1} may be assigned as $^1B_2(\pi,\pi^*)$ band, predicted to lie at $\cong$32750 cm^{-1}.[15]

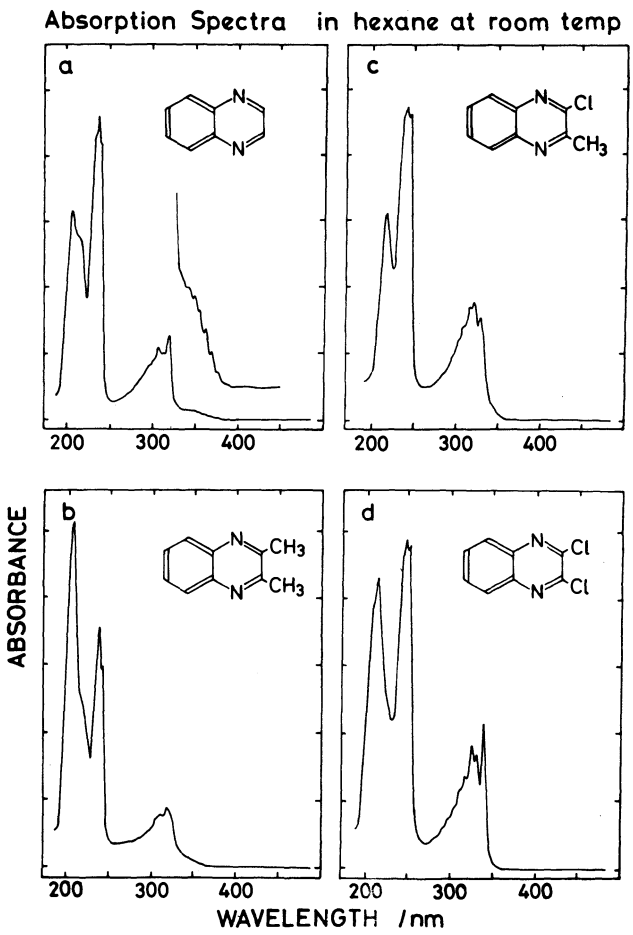

Fig. 2. The absorption spectra of quinoxalines in hexane at room temperature.
(a) Quinoxaline, (b) 2,3-dimethylquinoxaline, (c) 2-chloro-3-methylquinoxaline, and (d) 2,3-dichloroquinoxaline.

The second distinct structure is seen at 42720 cm^{-1} and, with reason, associated with the $^1A_1(\pi,\pi^*)$, which has been calculated to lie at 42670 cm^{-1}.[16] A more diffuse maximum is noted at ≅46930 cm^{-1} and followed by intense band with maximum at ≅49250 cm^{-1}. The former is likely attributed to the transition to the $^1B_2(\pi,\pi^*)$ state suggested to lie at ≅47200 cm^{-1} [15] and the latter to the $^1A_1(\pi,\pi^*)$ predicted at 49500 cm^{-1} [15] from the results of calculations.

In addition, the spectrum of quinoxaline contains a $^1B_1(n,\pi^*)$ transition at about 26300 cm^{-1}, which is in good agreement with the calculated value of 26382 cm^{-1}.[16] The electronic origin of this transition has been reported previously to lie at 25825 cm^{-1} in a naphthalene host crystal by Clarke *et al.*,[17] and at 27071 cm^{-1} in vapor phase by Glass *et al.*[18]

Substituted Quinoxalines. It is seen from Fig. 2 that the absorption spectra of the substituted quinoxalines are similar to that of quinoxaline. This apparent similarity permits the analysis to be made easily by comparison. The effect of substitution shifts the π,π^* excited singlet states to the red by a considerable amount.

It is to be noted that in the case of chloro-substituted quinoxalines, the absorption bands corresponding to the band at 46930 cm^{-1} of quinoxaline reduce the intensity significantly. In fact, the band in the spectrum of 2-chloro-3-methylquinoxaline is buried in the subsequent intense band, and the band in 2,3-dichloroquinoxaline is recognized only as a weak shoulder.

Phosphorescence Excitation Spectra

The phosphorescence excitation spectra of the four compounds were observed in hexane at 4.2 K. The spectra are shown in Fig. 3. It is seen from Figs. 2 and 3 that the lowest excited singlet states of all the three substituted quinoxalines are also of n,π^* character in hexane.

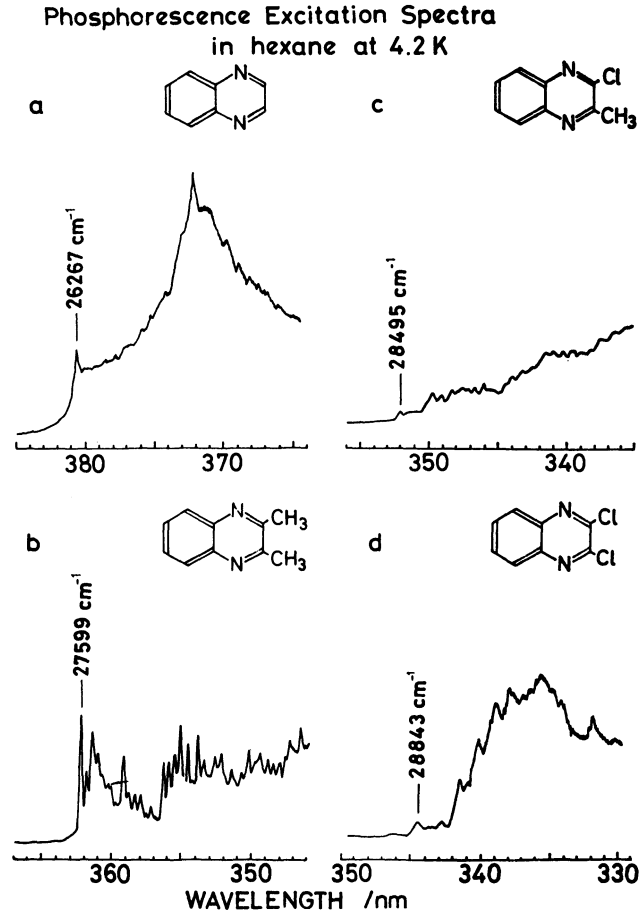

Fig. 3. The phosphorescence excitation spectra of quinoxalines in hexane at 4.2 K.
(a) Quinoxaline, (b) 2,3-dimethylquinoxaline, (c) 2-chloro-3-methylquinoxaline, and (d) 2,3-dichloroquinoxaline.

The phosphorescence excitation spectra of the neat crystals of quinoxaline and 2,3-dimethylquinoxaline were also measured as shown in Fig. 4. The first absorption bands in these excitation spectra correspond to the $^3B_2(\pi,\pi^*)\leftarrow S_0$ transitions. The absorption bands found at 24032 cm^{-1} in the spectrum of quinoxaline and at 25182 cm^{-1} in that of 2,3-dimethylquinoxaline are assigned to the $^3B_1(n,\pi^*)\leftarrow S_0$ transitions.

The energy separations between the $^1B_1$ and $^3B_1(n,\pi^*)$ states are very similar in these two compounds, and about 2350 cm^{-1}. By assuming that these states of all the compounds studied here are separated by the

amount of 2350 cm^{-1}, the locations of $^3B_1(n,\pi^*)$ states are estimated. All the data for the locations of the excited states obtained from the absorption, phosphorescence excitation, and phosphorescence spectra are listed in Table 1.

ODMR Results

The zero-field (zf) transitions among the spin sublevels were measured to determine the zf splitting parameters D and E by means of the steady state phosphorescence microwave double resonance (PMDR) technique and/or the MIDP technique. The zf splitting parameters D and E are defined in a similar manner used commonly for naphthalene (Fig. 1). The total decay rates, k_i, steady state populations, N_i^0, and relative populating rates, P_i, for the spin sublevels (i=x, y, z) were also obtained by the MIDP method. The results for all the compounds are summarized in Table 2 for the sake of comparison.

Quinoxaline. Only two strong zf ODMR signals were observed by monitoring the phosphorescence emission in hexane. The signal at 1.157 GHz is assigned to the $T_z \leftrightarrow T_y$ transition, which has been observed at 1.187 GHz in a durene host[9] and at 1.132 GHz in a naphthalene-d_8 host.[9,13] The signal at 3.557 GHz is referable to the $T_z \leftrightarrow T_x$ transition, which has been found at 3.641 GHz in durene[9] and at 3.480 GHz in naphthalene-d_8.[9] The total decay rates obtained here are similar to those in durene[9] and naphthalene-d_8[9,13] reported by other authors.

2,3-Dimethylquinoxaline. The zf transitions are observed at 1.239 GHz for the $T_z \leftrightarrow T_y$ transition and at 3.731 GHz for $T_z \leftrightarrow T_x$. The total decay rates for all the three sublevels of 2,3-dimethylquinoxaline are

smaller by a factor of about 0.6 than those of quinoxaline.

2,3-Dichloroquinoxaline. The observed zf transitions at 2.510 and 3.586 GHz can be assigned to the $T_y \leftrightarrow T_x$ and $T_z \leftrightarrow T_x$ transition, respectively, which have been reported to be at 2.467 and 3.515 GHz in a durene host crystal.[19,20] The total decay rates of the sublevels determined here are somewhat smaller than those obtained in other crystal systems.[19-22] It is to be noted that the relative populating rate of the y sublevel is as large as that of the z sublevel.

2-Chloro-3-methylquinoxaline. As in the case of 2,3-dichloroquinoxaline, the zf ODMR signals found at 2.483 and 3.616 GHz are attributed to the $T_y \leftrightarrow T_x$ and $T_z \leftrightarrow T_x$ transition, respectively. The total decay rate for the y sublevel is smaller to a certain extent than that of 2,3-dichloroquinoxaline, while with respect to the z and x sublevels, there is little difference between these compounds. The pattern of populating process is also characterized by high selectivity for both the z and y sublevels, as in the case of 2,3-dichloroquinoxaline.

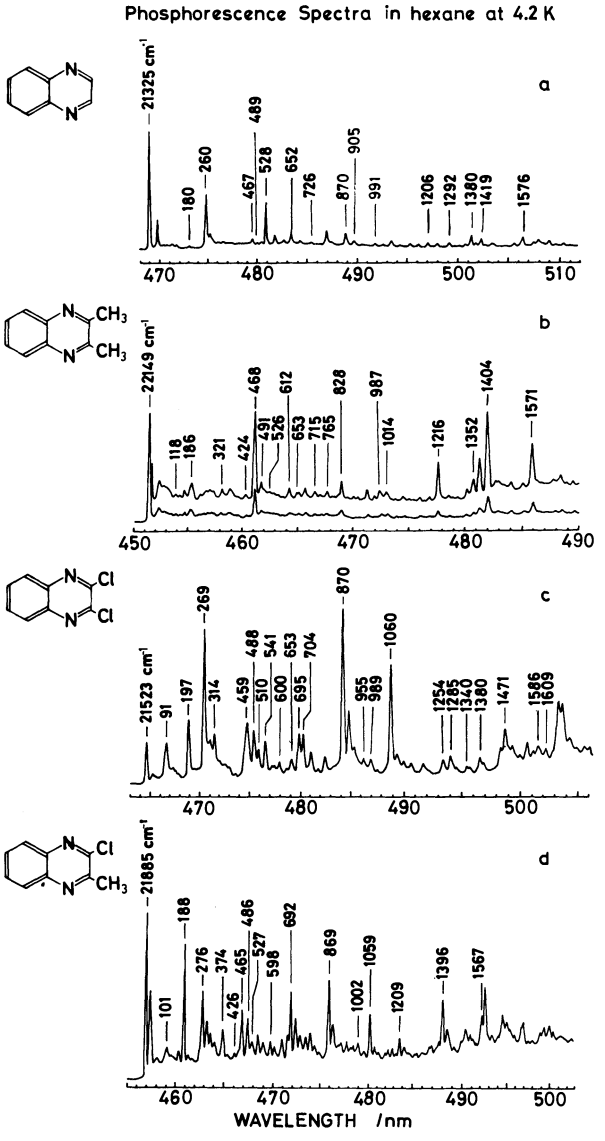

Fig. 5. The phosphorescence spectra in hexane at 4.2 K. (a) Quinoxaline, (b) 2,3-dimethylquinoxaline, (c) 2,3-dichloroquinoxaline, and (d) 2-chloro-3-methylquinoxaline.

Phosphorescence Spectra

The phosphorescence spectra of quinoxaline and the three derivatives in hexane are characterized by well resolved feature (FWHM=0.3 nm). The spectra obtained at 4.2 K are presented in Fig. 5. Assignments of the vibronic bands in the spectra were made in reference to the vibrational assignments of the IR and Raman spectra reported in the literature.[23-25]

Quinoxaline. The spectrum obtained in hexane differs from those observed in the naphthalene-d_8[13] and durene[7,10,12] host crystals. The vibronic bands at 180, 260, and 904 cm^{-1} from the origin appear with considerable intensity in hexane. However, the corresponding bands are far from being observable in the other host crystal systems.[7,10,12,13]

2,3-Dimethylquinoxaline. There is noticeable difference between quinoxaline and 2,3-dimethylquinoxaline. The intensity of the vibronic band at 0−467 cm^{-1} exceeds those of the vibronic bands such as 0−525 cm^{-1} involving totally symmetric vibrations, in contrast with quinoxaline.

2,3-Dichloroquinoxaline. There is some difference between the spectra obtained in hexane and in durene.[19,22] The vibronic bands observed at 197, 459, 510, and 695 cm^{-1} from the origin appear with considerable intensity in hexane, whereas in the durene host, these bands appear as nothing more than weak traces. The vibronic bands found at 0−197 and 0−695 cm^{-1} are due to the b_1 vibrations, corresponding probably to the frequencies of 180 and 725 cm^{-1} of quinoxaline. The band at 0−459 cm^{-1} is attributed to the vibronic band involving a_2 vibration corresponding to that of 647 cm^{-1} of quinoxaline. The remaining band at 0−510 cm^{-1} is assigned to the vibronic band due to totally symmetric vibration.

2-Chloro-3-methylquinoxaline. The frequencies of the vibrations appearing in the spectrum of 2-chloro-3-methylquinoxaline are in excellent correspondence to those in that of 2,3-dichloroquinoxaline. This enables one to readily analyze the vibrational structure by comparing the spectra of these compounds. It is to be noted that the origin band appears intensely in the spectrum of 2-chloro-3-methylquinoxaline, whereas in 2,3-dichloroquinoxaline, the intensity of the 0,0 band is quite small.

Sublevel Emission Spectra

The sublevel emission spectra of all the four molecules measured by means of the MIDP method are shown in Fig. 6. The relative radiative decay rates for the 0,0 and some vibronic bands of interest were also determined. The results are shown in Table 3, where experimental errors are estimated to be about ±20% for the k_x^r and k_y^r values larger than 0.02 and about +100—−50% for those less than 0.02. It is to be noted that the sublevel spectra in Fig. 6 show only the qualitative feature of the spin selectivity of each sublevel; in other

words, the spectra are not compatible with the data in Table 3, because some of the spectra were taken with different slit widths.

Brief comments on some of the specific experimental findings are described in the following.

Quinoxaline. It is clearly seen in Fig. 6(a) that the intensity of the vibronic bands such as 0—260, 0—904, 0—1380, and 0—1618 cm^{-1} relative to the 0,0 band is significantly larger in the y and x sublevel spectra than z. On the other hand, no spin state selectivity is noted with regard to the intensity of the bands such as 0—467, 0—527, 0—651, and 0—1576 cm^{-1}. The vibronic bands involving b_2 vibrations have a certain intensity in the y and x sublevel spectra.

2,3-Dimethylquinoxaline. The emission spectra of the spin sublevels resemble each other. It is found that the vibronic bands due to the b_1 vibrations such as 185, 424, and 490 cm^{-1} appear more intensely in all the three sublevel spectra in comparison with those of quinoxaline.

2,3-Dichloroquinoxaline. The vibronic bands involving a_2 or b_1 vibrations appear more strongly in all the three sublevel spectra than those of quinoxaline. On the other hand, the vibronic bands due to the b_2 vibrations have a considerable intensity only in the y sublevel spectrum. By examining carefully the change in the intensity, it is found that as concerns the y sublevel spectrum, the bands such as 0—269 cm^{-1} are affected by chlorine substitution to a more extent than the bands such as 0—459 cm^{-1}, although these vibrations are classified into the same species of a_2. With respect to the vibronic bands due to b_1 vibrations, a similar situation is found by comparing, for example, the bands at 0—197 and 0—488 cm^{-1}. This can be seen more clearly in Table 3(c).

2-Chloro-3-methylquinoxaline. Although both the a_2 and b_1 species in C_{2v} point group are reduced to the a″ species in C_s, the distinction between these species remains with regard to the radiative decay process, with an exception that the y sublevel emits strongly at the 0,0 band. This indicates clearly that the radiative decay process of 2-chloro-3-methylquinoxaline is governed by the mechanisms similar to those of 2,3-dichloroquinoxaline.

Assignments of Some Vibrations

Most of the vibronic bands in the phosphorescence spectra are assigned on the basis of the vibrational data reported previously[23-25] and confirmed by the experimental findings in the sublevel spectra. Several vibronic bands, however, are assigned anew. The bands such as 0—197 and 0—695 cm^{-1} of 2,3-dichloroquinoxaline are assigned only in view of the observed sublevel spectra. Here, the reasons for the assignments of the bands of importance are commented briefly.

Although no data of the vibrational assignments from IR and Raman spectra are available concerning the vibrations of 197 and 695 cm^{-1} of 2,3-dichloroquinoxaline, the vibronic bands due to these vibrations can be assigned to those of b_1 symmetry for the following reasons. First, the 0—197 cm^{-1} band appears with more intensity than the 0,0 band in the phosphorescence spectrum. Therefore, it is reasonable to leave the possibility of a_1 or b_2 species out of consideration. In fact, there are no vibrational modes of a_1 or b_2 species with such low frequency. Second, the behavior of this

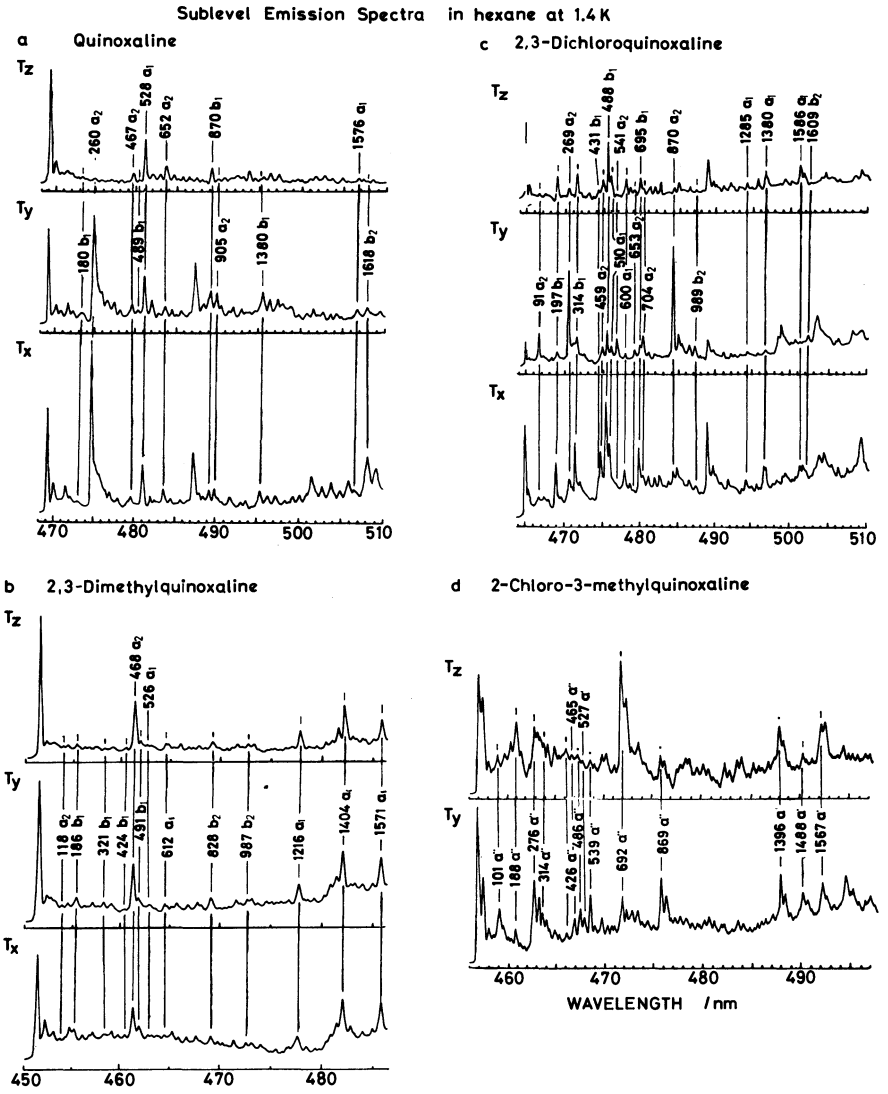

Fig. 6. The sublevel emission spectra in hexane at 1.4 K. (a) Quinoxaline, (b) 2,3-dimethylquinoxaline, (c) 2,3-dichloroquinoxaline, and (d) 2-chloro-3-methylquinoxaline.

band in the sublevel spectra is different from that of the vibronic band due to a_2 vibration such as 0—269 cm^{-1}, but rather similar to that of the band due to b_1 such as 0—488 cm^{-1}. The 0—695 cm^{-1} band can also be assigned to the band due to b_1 vibration in view of intensity behavior in the sublevel spectra. In fact, the corresponding band, 0—692 cm^{-1}, of 2-chloro-3-methylquinoxaline appears with much intensity in the z sublevel spectrum as well as the 0—188 cm^{-1} band corresponding to the 0—197 cm^{-1} band of 2,3-dichloroquinoxaline, but in contrast to the 0—276 cm^{-1} band corresponding to the 0—269 cm^{-1} band of 2,3-dichloroquinoxaline.

Electronic States

Some comments on the assignment of the low lying electronic states may be added, although the absorption and excitation spectra have been discussed briefly above. The absorption spectra of quinoxaline and 2,3-dichloroquinoxaline in hexane have been reported previously by another author.[26] The band at 42720 cm^{-1} of quinoxaline and the corresponding band at 40150 cm^{-1} of 2,3-dichloroquinoxaline have been assigned to the $^1B_2 \leftarrow S_0$ transition in the earlier works.[18,26] In the present study, however, these bands are assigned to the $^1A_1 \leftarrow S_0$ transition. This assignment is in good agreement with the theoretical predictions.[15,16]

It is again emphasized that the lowest excited singlet state is the $^1B_1(n,\pi^*)$ state for all the compounds studied here. Yamauchi and Azumi[22] have suggested that in a durene host the $^1B_1(n,\pi^*)$ state of 2,3-dichloroquinoxaline lies at 29520 cm^{-1}, higher by 1210 cm^{-1} than the $^1A_1(\pi,\pi^*)$ state, even though the transition monent for the transition to the $^1B_1$ state is considered to be much smaller than that to the $^1A_1$. On the other hand, the phosphorescence excitation spectrum of 2,3-dichloroquinoxaline in hexane obtained here shows that the $^1B_1(n,\pi^*)$ state lies lower than the $^1A_1$ state and is the lowest excited singlet state without question.

All the results for 2,3-dimethylquinoxaline and 2-chloro-3-methylquinoxaline are determined anew. The

locations of the $^3B_1$ states of quinoxaline and 2,3-dimethylquinoxaline are also determined from the present observation of the excitation spectra of the neat crystals.

The values of D are all very similar. They differ from each other only within 4%. The same holds true for the values of E. The methyl group and chlorine atom seem to have a little influence on the lowest excited triplet state with regard to the stationary properties of the wave function. Thus, it is reasonably assumed that (1) all the molecules studied here have essentially the same type of orbital wave function as that of the parent molecule, quinoxaline, and (2) there occurs no significant rotation of spin axes by going from the molecules with C_{2v} symmetry to the molecule with C_s. This latter point is strongly corroborated by the dynamic measurements. In fact, 2-chloro-3-methylquinoxaline shows the decay pattern similar to that of 2,3-dichloroquinoxaline.

Total Decay Rates

As for the z sublevel of aza-aromatics, the low lying n,π^* states are known to be of importance in the interactions relevant in causing both the radiative and radiationless decays.[1-5] Therefore, the decrease in k_z on substitution is presumably due to the reduction of the interaction with n,π^* states, resulting from the increased energy separations.

Quinoxaline and 2,3-dimethylquinoxaline show the relation of $k_z > k_y$. The decay process from the y sublevel is expected to be determined mainly by the interactions with n,π^* states.

On the other hand, in the case of chloro-substituted quinoxalines, the relation of $k_z < k_y$ indicates that there exists an additional mechanism for the decay from the y sublevel. The π electrons are likely to delocalize onto the chlorine atom(s) in some degree, so that one center integrals at the chlorine atom are expected to mean something to the spin orbit coupling matrix elements. Hence, the y sublevel can mix significantly with the $^1\sigma,\pi^*$ state *via* a one-center spin orbit coupling matrix element, in addition to the mixing with the ^{1}n,π^* state *via* a two-center spin orbit coupling matrix element. Accordingly, the large activity of the y sublevel in the decay process observed in 2-chloro-3-methylquinoxaline is also ascribed to the influence of chlorine substitution on the spin orbit interaction as stated before for 2,3-dichloroquinoxaline.[19,22]

Intersystem Crossing

It is seen from Table 2 that in the case of quinoxaline and 2,3-dimethylquinoxaline, the z sublevel is populated in much preference to the other sublevels *via* intersystem crossing from S_1. Considering that the lowest excited singlet states of these compounds are n,π^* states of B_1 symmetry, the high selectivity for the z sublevel with respect to the intersystem crossing process must be, as stated before,[8,9] a consequence of the efficient spin orbit coupling between the $^1B_1$(n,π^*) and $^3B_2$(π,π^*) states, by way of which only the z sublevel is coupled directly.

The situation is quite different for the chlorosubstituted quinoxalines. The populating pattern of these compounds is characterized by highly selective intersystem crossing to both of the z and y sublevels. Seeing that the $^1B_1$(n,π^*) is the lowest excited singlet state, as observed above, the direct spin orbit coupling with S_1 accounts for P_z. The value of P_y is quite large for the chlorosubstituted derivatives as compared with that for quinoxaline and 2,3-dimethylquinoxaline. For a similar enhancement in the system of 2,3-dichloroquinoxaline in durene, Tinti and El-Sayed have suggested two possible mechanisms which differ depending on the assignment of the nature of the lowest excited singlet state.[19] On the basis of the present n,π^* assignment, these mechanisms can be discriminated unambiguously. The $^3A_1$(π,π^*) state is expected to lie lower in energy than the $^1B_1$(n,π^*) state in the case of 2,3-dichloroquinoxaline, because chlorine substitution shifts π,π^* states to the red and n,π^* states to the blue, as mentioned above. Further, considering the n orbitals to be mixed with other σ orbitals of the aromatic frame (delocalization) to a certain extent, $^3A_1$(π,π^*) state could couple with $^1B_1$(n,π^*) state appreciably. If this is the case, it is necessary to take into account an indirect process, which goes from S_1 through the intermediate triplet state, $^3A_1$(π,π^*), and then to T_1. This process can populate only the y sublevel. Thus, the large value of P_y observed in 2,3-dichloroquinoxaline is surely ascribed to this additional intersystem crossing mechanism. The same holds true for 2-chloro-3-methylquinoxaline.

Mechanisms of Radiative Decay

As described above, all the molecules studied here are considered to have essentially the same type of orbital wave function. In the following discussion, therefore, it is assumed that all the molecules can well be characterized by C_{2v} point group symmetry for the purpose of avoiding unnecessary complications. Including up to the second order perturbations, the possible mechanisms, which are group-theoretically predicted, are divided into the following classes.[27]

(I) Spin orbit coupling.

(II) Vibronic coupling in the singlet manifold with spin orbit coupling.

(III) Spin orbit coupling with vibronic coupling in the triplet manifold.

(IV) Spin vibronic coupling.

Among a number of the mechanisms group-theoretically allowed, the mechanisms of little importance are excluded in view of the following criteria:

(1) Spin orbit, spin vibronic, and vibronic coupling operators are considered as the sum of one-electron operators in good approximation;

(2) As concerns mechanisms of types (II) and (III), the perturbing singlet configurations, which have allowed transitions to the ground state, are limited to π,π^*;

(3) With respect to mechanisms of type (IV), the contribution of the mechanisms involing $^3\pi,\pi^*$ and $^1\pi,\pi^*$ states is neglected because of the vanishingly small magnitude of the matrix elements between these states.

TABLE 4. ALL THE POSSIBLE MECHANISMS FOR THE RADIATIVE DECAY PROCESS

	IV.4	$T_y \leftarrow sv \rightarrow {}^1B_1(\sigma,\pi^*)$
	II.9	$T_x \leftarrow so \rightarrow {}^1A_1(\pi,\pi^*) \leftarrow v \rightarrow {}^1B_2(\pi,\pi^*)$
	III.9	$T_x \leftarrow v \rightarrow {}^3A_1(\pi,\pi^*) \leftarrow so \rightarrow {}^1B_2(\pi,\pi^*)$

a) The first column shows the coupled vibrational species.
b) The interaction is indicated by the following notations: so, spin orbit coupling; v, vibronic coupling; sv, spin vibronic coupling.

Accordingly, the mechanisms, which are listed in Table 4, remain to be taken into consideration.

In the case of chloro-substituted quinoxalines, the π electron orbitals of the aromatic frame are mixed in some degree with the out-of-plane atomic orbital on the chlorine atom. This is responsible for the large red-shift of the π,π^* excited singlet states. This also causes the matrix elements of the spin orbit coupling to contain integrals over the chlorine atomic orbitals. Since σ orbitals are easily mixed with the in-plane orbitals of the chlorine atom, the matrix elements between π,π^* and σ,π^* states become large through one-center integrals on the chlorine atom. In view of the localized character of n orbitals, the integrals over the chlorine atomic orbitals make relatively small contribution to the matrix elements between π,π^* and n,π^* states. These points are to be kept in mind in the following discussion.

The 0,0 Band and Vibronic Bands Involving a_1 Vibrations. As seen in Table 3(a), the z sublevel has the largest radiative activity at the 0,0 band in the phosphorescence spectrum of quinoxaline. As suggested by other authors,[5-8,10-13] there is no doubt to conclude that the main mechanism, which accounts for the activity of the z sublevel at the 0,0 band, is mechanism (I.1). This is a consequence of not only the efficient spin orbit coupling from the one-center terms on the N atom, but also rather small energy separation between the ${}^3B_2(\pi,\pi^*)$ and ${}^1B_1(n,\pi^*)$ states.

In the case of substituted quinoxalines, the spin orbit interaction between the ${}^3B_2(\pi,\pi^*)$ and ${}^1B_1(n,\pi^*)$ states is expected to be reduced in response to the increase in the energy separation, ΔE_{ST}. If the magnitude of the spin orbit matrix element is assumed to be affected by no means on substitution, the mixing coefficient, $(<|H_{SO}|>/\Delta E_{ST})^2$, is predicted to decrease by factors of 0.81, 0.56, and 0.46 for 2,3-dimethyl-, 2-chloro-3-methyl-, and 2,3-dichloroquinoxaline, respectively. Although the radiative and radiationless parts in the total decay rates can not be strictly separated for the lack of quantum yield data for phosphorescence and triplet formation, the degree of reductions of the total decay rates k_z appears to be in good correlation with the values estimated above, presumably indicating that the mixing with the ${}^1B_1(n,\pi^*)$ state is also the main source of the radiative activity of substituted quinoxalines.

In the x sublevel spectrum, the 0,0 band can gain radiative character through the interaction with ${}^1A_1(n,\pi^*)$ state; mechanism (I.5). In view of the ratio k_x^x/k_z^x, the radiative decay rate constants of the x sublevel for the 0,0 band are found to increase to some degree on chlorine substitution. This increase is mainly a consequence of the decrease in the energy difference between ${}^3B_2(\pi,\pi^*)$ and ${}^1A_1(\pi,\pi^*)$, and the increase in the probability of the transition between the ${}^1A_1(\pi,\pi^*)$ and the ground state (see Fig. 2).

On the other hand, the influence of chlorine substitution significantly enhances the radiative activity of the y sublevel at the 0,0 band. Therefore, in the case of chloro-substituted quinoxalines, the major source, which gives rise to the radiative activity at the 0,0 band, is concluded to be mechanism (I.4), of which the matrix element contains one-center integrals over the chlorine atomic orbitals. The same explanation has been suggested by other authors for 2,3-dichloroquinoxaline.[22] The large intensity of the 0,0 band in the y sublevel spectrum of 2-chloro-3-methylquinoxaline is attributable to the reduction in molecular symmetry to C_s, where A_2 symmetry is reduced to A''. Unlike the chloro-substituted quinoxalines, mechanism (I.4) is expected to make a minor contribution, and mechanism (I.3) is likely to be the main one in the case of 2,3-dimethylquinoxaline, as stated for quinoxaline.[13] In fact, the rather small energy denominator and the large contribution of the N atomic orbital to the matrix element are in favor of mechanism (I.3).

The Vibronic Bands Involving a_2 Vibrations. For the vibronic bands due to a_2 vibrations, mechanisms (II.1), (II.2), (III.1), and (III.2) may contribute to the z sublevel emission. In the case of naphthalene, the bands of this type, which are exclusively due to the interaction involving σ,π^* states; mechanisms (II.2) and (III.2), have a negligible intensity in the spectrum.[28] Thus, it is reasonable to leave mechanisms (II.2) and (III.2) out of consideration.

If mechanism (III.1) plays an important role, the

intensity of these bands in the z sublevel spectrum in comparison to that of the 0,0 bands is expected to decrease significantly in response to the increase in the energy difference between the $^3B_2(\pi,\pi^*)$ and $^3B_1(n,\pi^*)$ states. If mechanism (II.1) is the case, in contrast, these bands will increase intensity to a certain extent.

It is easily seen that the bands due to a_2 vibrations appear in the z sublevel spectra of substituted quinoxalines with somewhat more intensity than those of quinoxaline. In an instant, this leads to the conclusion that mechanism (II.1) is the main source in producing the radiative activity of the z sublevel at the bands involving a_2 vibrations. The fact that the vibronic bands due to a_2 vibrations appear also in the $^1B_1(n,\pi^*)\leftarrow S_0$ absorption spectrum of quinoxaline in a naphthalene host crystal[17] strongly supports the validity of the inference described above.

With respect to the y sublevel, mechanisms (II.3), (II.4), (III.3), and (III.4) may make a contribution. An argument similar to that made concerning the z sublevel emission may explain the increase in intensity on chlorine substitution. The increase in intensity clearly indicates that mechanism (III.3) can not be of importance.

By examining the experimental results in detail, it is noticed that the vibronic bands such as 0−269, 0−541, and 0−870 cm^{-1} are enhanced by chlorine substitution more largely than the bands such as 0−459 and 0−653 cm^{-1}. This can also be seen from the relative radiative decay rate constants (see Table 4(c)). This difference in the enhancement can be understood in the following way. The former bands can be associated with mechanisms (II.4) and/or (III.4), in which the spin orbit matrix elements between σ,π^* and π,π^* states are affected strongly by the large one-center terms on the chlorine atom(s), whereas the latter bands can be due to mechanism (II.3), in which the contribution from the chlorine atom(s) is rather small.

The Vibronic Bands Involving b_1 Vibrations. The fact that naphthalene has no activity at the bands due to b_1 vibrations[28] evidently allows one to limit the possibility to mechanisms (II.5) and (III.5) with respect to the z sublevel. Since the bands of this type appear strongly in the chloro-substituted quinoxalines as compared with quinoxaline, there is no doubt to conclude that the z sublevel gains activity at these bands by mechanism (II.5). The increase in intensity can be ascribed to the decrease in the energy difference between the $^1B_1(n,\pi^*)$ and $^1A_1(\pi,\pi^*)$ states. In addition, the manifest evidence for the strong vibronic interaction between the $^1B_1$ and $^1A_1$ states has been found in the $^1B_1(n,\pi^*)\leftarrow S_0$ absorption spectrum reported previously.[17]

The detailed examination of the y sublevel emission reveals that the vibronic bands such as 0−197 cm^{-1} behave in different way from the bands such as 0−488 cm^{-1} with regard to the effect of chlorine substitution. Accordingly, by an argument similar to that made for the a_2 vibrations, it is possible to conclude that mechanisms (II.8) and/or (III.8) as well as (II.7) make a contribution toward producing the radiative activity at the bands due to b_1 vibrations.

The x sublevel emission is ascribed to either mechanisms (IV.1) or (IV.2). The experimental finding that the chlorine substitution affects the intensity to a great extent assuredly indicates that the x sublevel gains the radiative activity through mechanism (IV.2) in preference to (IV.1).

The Vibronic Bands Involving b_2 Vibrations. The vibronic bands due to b_2 vibrations are observable in the y and x sublevel emission. With regard to the y sublevel, mechanisms (IV.3) and (IV.4) may contribute. Of the two mechanisms, the former seems to be more favorable in view of the energy denominators. The intensity of the bands due to b_2 vibrations in the y sublevel emission is by no means affected by chlorine substitution. This seems to take a side with mechanism (IV.3).

Mechanisms (II.9) and (III.9) are predicted group-theoretically to contribute to the x sublevel emission. It is worthy to note that the configuration of the perturbing $^1B_2$ state is probably $\pi(b_1),\pi^*(a_2)$. Accordingly, the experimental finding that the bands due to b_2 vibrations appear in the spectrum of 2,3-dichloroquinoxaline with less intensity than in that of quinoxaline can be attributed to the decrease in the transition moment for the transition to the $^1B_2$ state, which is readily seen from the absorption spectra.

ESR Studies on the Free Radical Intermediates in the Photoreduction of Duroquinone in Alcohol Solutions

Shoji NODA,* Kiyoshi SANEHIRA, Takahisa DOBA, and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received September 9, 1981)

ESR measurements during photolysis of duroquinone (DQ) solutions in ethanol and 2-propanol have revealed the generation of both durosemiquinone anion (DQ^-) and durosemiquinone radicals (DQH·). Correspondingly, alkoxyl radicals have been detected from the photolyzed solutions by the spin trapping-ESR technique, though the quantum yield of their formation is very low (10^{-3} for the ethanol solution). Main conclusions deduced from the present work are (1) that DQ^- is generated through the one-electron reduction of DQ by α-hydroxyalkyl radical and through the photodissociation of ($DQ-DQH_2$) complex, and (2) that DQH· is generated through the hydrogen abstraction of $^3DQ^*$ either from solvent alcohols or from photoproduct durohydroquinone (DQH_2). The one-electron reduction in alcohol solution previously reported for *p*-benzoquinone is a minor pathway of chemical quenching of $^3DQ^*$. The quantum yield of the DQH_2 formation in an early period of photolysis of a dilute DQ in methanol, ethanol, and 2-propanol has been observed to be 0.12, 0.23, and 0.36 respectively. These values are discussed in terms of the mechanism of the quinone photoreduction.

Despite extensive studies[1-9] on the photochemistry of duroquinone (DQ) in alcohol solutions, there still remains a controvery about the initial photochemical reaction, the chemical quenching of triplet excited duroquinone ($^3DQ^*$). This reaction can be explained either as a hydrogen abstraction (reaction (1))[1-8] giving a durosemiquinone radical (DQH·), or as a one-electron transfer (reaction (2))[9] giving a durosemiquinone anion (DQ^-):

$$^3DQ^* + RR'CHOH \longrightarrow DQH\cdot + RR'\dot{C}OH, \quad (1)$$

$$^3DQ^* + RR'CHOH \longrightarrow DQ^- + RR'CH\dot{O} + H^+. \quad (2)$$

DQ^- should also be generated through the reduction of DQ by α-hydroxyalkyl radical:[10]

$$DQ + RR'\dot{C}OH \longrightarrow DQ^- + RR'C{=}O + H^+. \quad (3)$$

The formation of DQ^- is thus expected by either mechanism of the chemical quenching. However, no definite detection of DQ^- by electron spin resonance (ESR) technique has been reported for the photolysis of DQ in alcohol solutions. The ESR detection of DQH· has been reported by several research groups,[11-13] but an efficient chemical quenching of $^3DQ^*$ by durohydroquinone (DQH_2), a main photoproduct,

$$^3DQ^* + DQH_2 \longrightarrow 2\,DQH\cdot \quad (4)$$

may be a dominant source of the detected DQH·. The ESR observations do not seem to have been well explained in the mechanism of photoreduction of DQ in alcohols.

We have demonstrated in the previous ESR study during the photolysis of *p*-benzoquinone in ethanol that the yields of semiquinone radical and semiquinone anion depend on the flow rate of the solution and *p*-benzoquinone concentration.[14] We have also detected ethoxyl and 1-hydroxyethyl radicals by the spin trapping-ESR technique.[14] In contrast, no α-hydroxyalkyl radical has been detected by this technique from the photoreduction of DQ in several alcohols.[15] The spin trapping-ESR detection of α-hydroxyalkyl radicals will depend on the efficiency of the reduction of quinones with the radicals, such as reaction (3).

In order to give further insight into the generation and behavior of semiquinone intermediates, the steady-state ESR measurements during photolysis combined with the spin trapping-ESR measurements are extended in the present investigation to DQ in ethanol and 2-propanol.

Experimental

Chemicals. DQ and DQH_2 from Tokyo Chemical Industry Co. were purified by repeated sublimation. Methanol, ethanol, and 2-propanol of 99.5% purity from Wako Pure Chemical Ind. were used without further purification. Occasionally the effects of purifying the alcohols were examined, but no significant difference was observed in the results. α-Phenyl-*N*-butylnitrone (PBN) was synthesized as described previously[14] and was used as a spin trap.

ESR Measurements during Photolysis. The transient semiquinone intermediates were observed by ESR measurements with a Varian E-109 spectrometer during continuous photolysis of the DQ solution in ethanol or 2-propanol flowing through a quartz flat cell in the resonant cavity, as described in detail elsewhere.[16] The photolysis was carried out with light from a supper-high pressure mercury lamp (Philips, SP-500) or from a mercury-xenon lamp (Conrad-Hanovia 941B0010). Occasionally degassed solutions in a quartz ESR tube were photolyzed in the resonant cavity.

Spin Trapping-ESR Measurements. The DQ solutions in ethanol or 2-propanol containing a small amount of PBN were degassed, sealed in a rectangular quartz optical cell (optical path of 1.0 cm) connected with a Pyrex tube (0.2 cm i.d.) for ESR measurements, and photolyzed with light of 436 nm from a high pressure mercury lamp (Toshiba, SHL-100UV) through filters (Toshiba VY-42 and VV-42).

Optical Absorption Measurements. The decay of DQ and the formation of DQH_2 were followed by observing their absorption spectra with a recording spectrophotometer (Shimadzu, MPS-5000) before and after an intermittent photolysis of the DQ solutions in methanol, ethanol, and 2-propanol sealed in a rectangular quartz optical cell (optical path of 1.0 cm) under a pressure of 10^{-3} Pa. The photolysis was carried out with the light of a sharp resonance line at 254 nm from a low pressure mercury lamp (Toshiba, GL-15) through a glass filter (Toshiba, UVD33S) and an aqueous solution of $NiSO_4 \cdot H_2O$ (500 g dm^{-3}) of 1 cm path length. The intensity of the incident light was calibrated by actinometry with potassium trioxalatoferrate(III).

Results

ESR Detection of Semiquinone Intermediates. ESR spectra observed during photolysis show only semiquinone intermediate(s) as shown in Figs. 1A and B. Dilute DQ solutions ($\leq 10^{-4}$ mol dm^{-3}) in ethanol and 2-propanol flowing in the cell gave only the spectrum of $DQ^{\cdot}$ with thirteen hyperfine lines equally separated with a splitting constant of 0.19 mT (Fig. 1A). Its intensity increased with increasing resident time of the solutions in the resonant cavity up to 1s (with decreasing flow rate of the solutions). This increase is probably due to the accumulation of $DQ^{\cdot}$ during the photolysis of the solution within the effective volume of the cell, and give a rough estimate of the lifetime of $DQ^{\cdot}$ of 1s. The estimated value is of the same order of magnitude as that expected by combining an observed steady-state concentration ($\approx 5\times 10^{-8}$ mol dm^{-3}) and a reported second order rate constant for bimolecular decay of $DQ^{\cdot}$, 3.5×10^{6} mol^{-1} dm^{3} s^{-1}.[2] When the DQ concentration is high, a weak spectrum due to DQH· ($7\times 7\times 2$ line spectrum with hyperfine splittings of 0.48, 0.07, and 0.03 mT)[17] was superimposed on the intense spectrum of $DQ^{\cdot}$. Both spectra decreased in intensity with increase of the resident time.

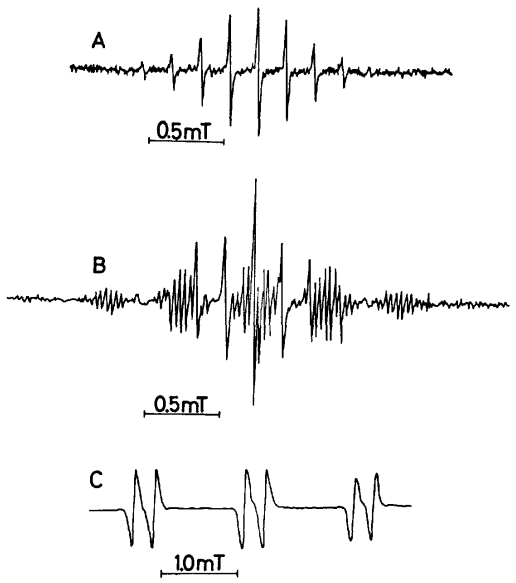

Fig. 1. A: ESR spectrum of a continuously photoirradiated flowing solution of DQ in ethanol. [DQ]$=5\times 10^{-5}$ mol dm^{-3} and resident time was one second. B: ESR spectrum of a continuously photoirradiated sealed solution of DQ in ethanol. [DQ]$=50$ mmol dm^{-3}. C: ESR spectrum of spin-adduct radical. [DQ]$=1$ mmol dm^{-3}, [PBN]$=0.1$ mol dm^{-3}.

The concentration ratio of DQH·to $DQ^{\cdot}$ depends on the flow rate of the solutions and the DQ concentration. This varying ratio indicates neither that the acid-base equilibrium between DQH· and $DQ^{\cdot}$ is reached rapidly compared with their lifetime nor that the ratio is determined by the branching ratio of the chemicalquenching pro cesses, (1) and (2). There will

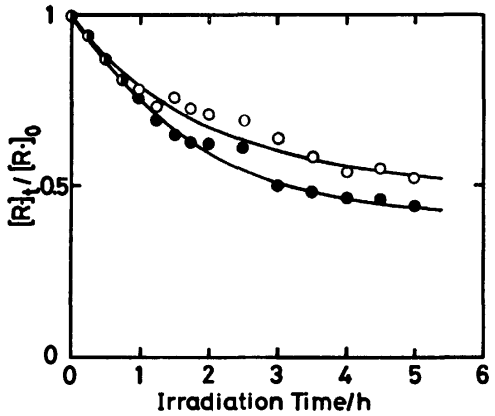

Fig. 2. The variation of $DQ^{\cdot}$ and DQH· yields with irradiation time.
$[DQ]_0=20$ mmol dm^{-3}, ○: $DQ^{\cdot}$, ●: DQH·.

exist reaction pathway(s) of generating semiquinone intermediates other than reactions (2) and (3).

When the solution of high DQ concentration (50 mmol dm^{-3}) sealed in a quartz sample tube was continuously photolyzed, DQH· was observed with comparatively intense spectral intensity, as shown in Fig. 1B. The ratio of steady-state concentration of DQH· to that of $DQ^{\cdot}$ was initially about 2. As the photolysis was prolonged, both the DQH· and the $DQ^{\cdot}$ gradually decrease in their spectral intensity, and the concentration ratio also decreased as shown in Fig. 2. The former observation is due to the decrease in the DQ concentration. The quenching of ^{3}DQ* by diduroquinone, one of photoproducts in the solution of a high DQ concentration, may also contribute to it.[4,5] The latter observation is not compatible with the rapid acid-base equilibrium. It is interpreted by the quenching of ^{3}DQ* by DQH_2, which competes with the quenching by solvent alcohols, and by the more efficient ionic dissociation of directly photoexcited CT complex (DQ–DQH_2) in the later period of photolysis.

The influence of DQH_2 was examined by photolyzing a flowing 2-propanol solution of a fixed DQ concentration with DQH_2 added to it with various concentrations. The $DQ^{\cdot}$ formation was enhanced in the presence of

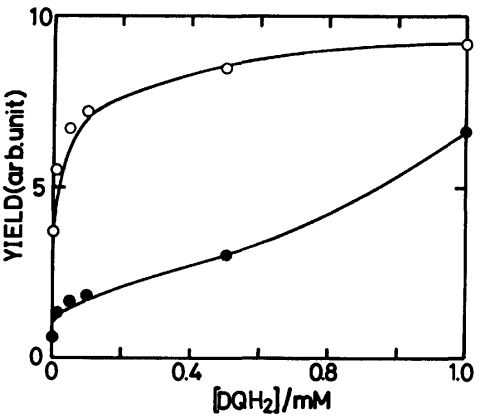

Fig. 3. Effects of DQH_2 on the yields of $DQ^{\cdot}$ and DQH· in ethanol solution of DQ.
[DQ]$=1$ mmol dm^{-3}, ○: $DQ^{\cdot}$, ●: DQH·.

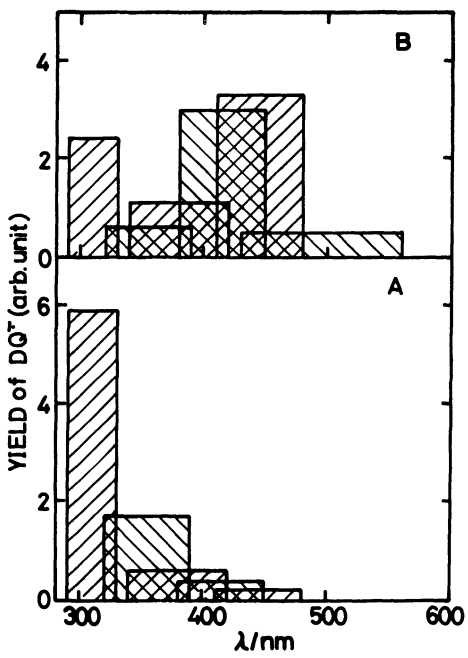

Fig. 4. Wavelength dependence of $DQ^{\cdot}$ yield in a flowing solutions (A) of 1 mmol dm^{-3} DQ and (B) of 1 mmol dm^{-3} DQ+1 mmol dm^{-3} DQH_2.

DQH_2 at low concentration, whereas the DQH· yield increased steadily with DQH_2 concentration throughout its concentration range studied, as shown in Fig. 3. DQH· is generated by the quenching of $^3DQ^*$ by DQH_2 in its presence.

In order to see the origin of $DQ^{\cdot}$, its yield was examined for the solutions of 1 mmol dm^{-3} DQ with and without 1 mmol dm^{-3} DQH_2 in ethanol and in 2-propanol by photolyzing the light successively cut off with a long-wave pass filter whose 50% transmission wavelength was 310, 350, 390, 420, 450, 480, or 580 nm. The dependence of the yield on the wavelength without DQH_2 agreed qualitatively with the absorption spectrum of DQ, but the dependence of the yield with DQH_2 showed an additional peak of the action spectrum at 400—450 nm, as shown in Fig. 4, for the ethanol solutions. Correspondingly, the ethanol solution of equimolar DQ and DQH_2 showed a weak, broad absorption band extending from 380 to 600 nm with λ_{max} of 410 nm, which is attributed to a (DQ–DQH_2) complex. $DQ^{\cdot}$ is generated by the direct excitation of DQ followed by the reactions (1) and (3) or the reaction (2), or by the photodissociation of the complex into ions,

$$(DQ\text{–}DQH_2) \xrightarrow{h\nu} DQ^{\cdot} + DQH_2^{+} \qquad (5)$$

depending on the wavelength of light and on the concentration of the coexisting DQH_2. The solutions containing 50 mmol dm^{-3} DQ and 50 mmol dm^{-3} DQH_2 gave no $DQ^{\cdot}$ spectrum at all for any wavelength of light between 254 and 600 nm. This will be discussed later.

Spin Trapping of Free Radicals from Alcohols. Although α-hydroxyalkyl radicals have been detected together with benzophenone ketyl radicals from the photoreduction of benzophenone in alcohols by ESR,[16] no ESR spectrum of free radicals generated from solvent alcohols has been observed from the photoreduction of quinones in alcohol solutions. This may be due to the efficient oxidation of α-hydroxyalkyl radicals by quinones (such as reaction (3)). Alkoxyl radicals, if generated, will be rapidly transformed into the α-hydroxyalkyl radicals by the hydrogen abstraction reactions. The alkoxyl radicals, if any, will be difficult to detect, because their spectra are broadened with their short T_1.[18] The spin trapping-ESR technique is useful to detect the transient free radicals generated from alcohols. The technique was first utilized successfully for the photoreduction of quinones in alcohols by McLauchlan and Sealy.[15] The present authors have studied in detail by the same technique the free radicals from solvent ethanol for the photoreduction of *p*-benzoquinone, and observed the formation of both α-hydroxyethyl and ethoxyl radicals.[14] The study has been extended here to the photoreduction of DQ in ethanol and in 2-propanol. PBN has been used as a spin trap, because it reacts efficiently with both α-hydroxyalkyl and alkoxyl radicals.[14]

In the photoreduction of DQ, the observed ESR spectrum is exclusively due to the spin adduct of ethoxyl or isopropoxyl radical, as reported previously.[15] Figure 1C shows the spectrum of the ethoxyl radical adduct with hyperfine constants of 1.46 mT for a nitrogen nucleus and 0.26 mT for a proton, which is the same as that reported previously.[14,15,19] The quantum yield of the spin adduct was determined to be 10^{-3} or less for the ethanol solution, by examining the intensity of the ESR spectrum as a function of the PBN concentration. These quantum yields are much lower than the quantum yield for the conversion of DQ into DQH_2 described later. The quantum yield was still lower for the 2-propanol solution. The dependence of the spin adduct yield on the wavelength was examined by cutting off the photolyzing light in the same way as for the $DQ^{\cdot}$ yield, and it was found to agree qualitatively with the absorption spectrum of DQ. The above observations lead to the conclusion that the alkoxyl radicals are generated by the reaction of photoexcited duroquinone, $^3DQ^*$, with solvent alcohols, *i.e.*, *via* reaction (2), though it is a minor pathway for the chemical quenching of $^3DQ^*$.

Yield of DQH_2. In order to compare with the kinetic behavior of the transient intermediates, the conversion of DQ into a major final product DQH_2 was examined by photolyzing dilute solutions of DQ in methanol, ethanol, and 2-propanol with light of 254 nm. The decay of DQ and the formation of DQH_2 were monitored with the intensity of their optical absorption using the reported molar absorptivities.[5] Isosbestic points observed at 233, 279, and 320 nm for the spectral curves during the photolysis indicate that the simple conversion of DQ into DQH_2 is the major consequence of the photolysis. The conversion proceeded linearly with the number of absorbed photons in the very early period of the photolysis, and then the conversion rate gradually decreased as demonstrated previously by Nafisi-Movaghar and Wilkinson for DQ in 2-propanol.[5] The initial quantum yield of the DQH_2 formation was

determined from the conversion curves to be 0.12, 0.23, and 0.36 for the methanol, ethanol, and 2-propanol solutions of 8×10^{-5} mol dm^{-3} DQ. This quantum yield determination will be discussed further in the following section.

Discussion

The present investigation was motivated by the following two questions: what is the role of semiquinone anions which we detected by ESR from the photoreduction of quinones in alcohols, and why have the semiquinone anions (especially $DQ^{\cdot}$) been unobserved in most of the previous photolysis-ESR studies?

The present results clearly show that $DQ^{\cdot}$ is generated in alcohol solutions either directly from the photoexcited DQ through its chemical quenching with solvent alcohols (reaction (2)) or indirectly from α-hydroxyalkyl radicals through a one-electron transfer (reaction (3)). The former is, however, a minor pathway for the $DQ^{\cdot}$ formation, because the quantum yield of alkoxyl radicals, the counterproduct of the reaction (2), is much lower than the quantum yield for the disappearance of DQ. Therefore, the $DQ^{\cdot}$ formation observed significantly in the present ESR study is attributed to the latter reaction pathway. Scheer and Grätzel[9] have reported that in a more polar solvent, *i.e.*, water–ethanol mixed solvent, the chemical quenching of $^3DQ^*$ leads almost exclusively to the formation of $DQ^{\cdot}$, as the solvation of ions favors the ionic dissociation of encounter exciplexes.

In aqueous solution, the acid-base equilibrium

$$DHQ\cdot \rightleftharpoons DQ^{\cdot} + H^+ \qquad (6)$$

is reached very quickly. The $DQ^{\cdot}$ observed in the flash photolysis-optical absorption study has been attributed to the dissociation of DQH·.[2] However, the forward reaction (6) is not significant in alcohols as a reaction pathway for the $DQ^{\cdot}$ formation. From the acid-base equilibrium of phenol and its analogues in water and in methanol, the relationship of pK_a (methanol)$=pK_a$ (water)$+4.4$ has been found experimentally and rationalized theoretically.[20] Provided that this relationship holds for DQH·, the pK_a of DQH· in methanol is estimated to be 9.4 from the reported pK_a of 5 in water.[21,22] The pK_a value will be somewhat larger in ethanol and in 2-propanol. Provided further that the reverse reaction (6) is diffusion-controled ($k_{-6}=10^{10}$ mol^{-1} dm^3 s^{-1}), 4×10^{-10} mol dm^{-3} of K_a leads to the rate of the forward reaction, k_6, being as low as 4 s^{-1}. The dissociation of DQH· is too slow to account for the present ESR observation of $DQ^{\cdot}$ in the alcohol solutions. The delayed formation of $DQ^{\cdot}$ in ethanol observed in the previous flash photolysis study cannot be due to the reaction (6) but due to the reaction (3), as pointed out by Amoyal and Bensasson.[8]

An additional path opens for the $DQ^{\cdot}$ formation, when DQH_2 either accumulates in the photolyzed DQ solution or is intentionally added and the absorption band of the (DQ–DQH_2) complex is excited. As the pK_a of DQH_2 in water is 11.3,[23] the pK_a in methanol will be 15.7. This gives rough estimates of pH, 9.3 and 8.4 for 1 and 50 mmol dm^{-3} DQH_2 present in the

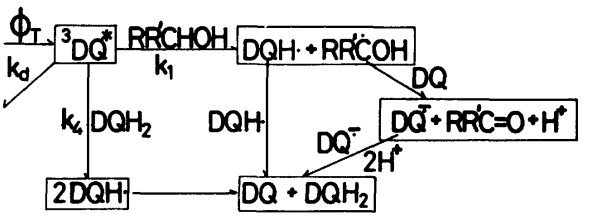

Fig. 5. A photoreduction scheme of DQ in alcohol.

alcohol solution. Comparison of these values with the pK_a of DQH·, the equilibrium (6) favors very much to the left at the higher concentration of DQH_2, so that $DQ^{\cdot}$ will be readily transformed into DQH·. This is consistent, though qualitatively, with the ESR observation during the photolysis of ethanol solutions of DQ and DQH_2 sealed in ESR sample tubes.

The reaction mechanism of major significance for the formation of the final product, DQH_2, has been proposed as shown in Fig. 5 based on the flash photolysis and product analysis results.[5] The quenching of $^3DQ^*$ by DQH_2 results in the DQH· formation but gives effectively no net chemical change. The steady-state treatment gives the following relationship:

$$\frac{I_T}{[DQH_2]} = \frac{k_4[DQH_2]}{2k_1\phi_T[RR'CHOH]} + \frac{k_d+k_1[RR'CHOH]}{k_1\phi_T[RR'CHOH]}, \qquad (7)$$

where I_T is the number of photons absorbed in the unit volume of the solution, ϕ_T is the quantum yield of $^3DQ^*$ generation, and k_d is the rate constant of deexcitation of $^3DQ^*$ to the ground state.[5] Actually, the present results of the DQH_2 formation follow the expected linear relationship between $I_T/[DQH_2]$ and $[DQH_2]$, as shown in Fig. 6. The quantum yield of the DQH_2 formation in the absence of DQH_2 is determined, from the inverse of the intercept, to be 0.12, 0.23, and 0.36 in methanol, ethanol, and 2-propanol, respectively. The result for

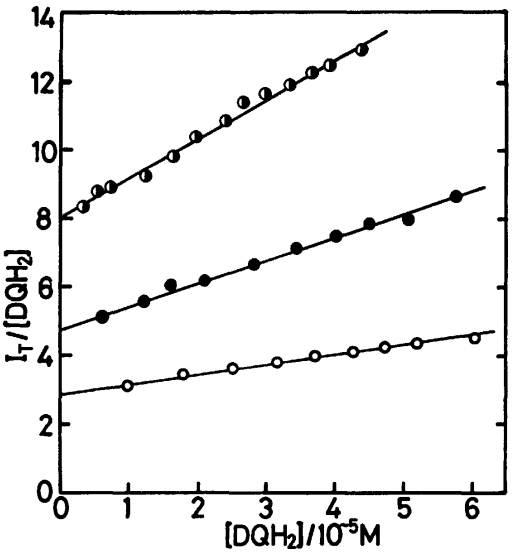

Fig. 6. A kinetic plots of DQH_2 formation (see text in detail).
○: 2-Propanol, ●: ethanol, ◑: methanol.

the 2-propanol solution agrees with the previous result obtained in the same way.[5] Combining these values with the pseudo-first order decay rate of $^3DQ^*$, $k_d+k_1[RR'CHOH]$, determined by the laser-flash photolysis experiment, 6.6×10^4 s^{-1} in ethanol[8] and 1×10^5 s^{-1} in 2-propanol,[3] k_d and k_1 can be determined separately, as $\phi_T=1.0$.[5,6,8] The results are $k_d=5.2\times10^4$ and 6×10^4 s^{-1}, and $k_1=8.1\times10^2$ and 3×10^3 mol^{-1} dm^3 s^{-1} for ethanol and 2-propanol. The chemical quenching of $^3DQ^*$ is three times as efficient in 2-propanol as in ethanol, whereas the physical quenching is independent of the alcohols.

According to the reaction scheme, $DQ^{\cdot}$ and DQH· should be generated with an identical yield during the photoreduction of DQ into DQH_2 in alcohols, if the efficient chemical quenching of $^3DQ^*$ by DQH_2 is not predominant. Actually, $DQ^{\cdot}$ could be detected by the present steady-state ESR measurements, when photolyzed solutions were refreshed by flowing. The comparatively weak ESR spectrum due to DQH· (or its absence) is attributed to the lifetime of DQH· much shorter than that of $DQ^{\cdot}$: The steady-state concentration of DQH· in the fresh DQ solutions is too low for its ESR detection. The rate constant for the disproportionation of DQH· has been reported to be 3.7×10^8 mol^{-1} dm^3 s^{-1} which is larger by two order of magnitude than that of $DQ^{\cdot}$.[2] The previous ESR studies of DQ in alcohols have shown the spectrum to be due exclusively to DQH·. The $DQ^{\cdot}$ spectrum has not been observed even in the absence of a hydrogen donor. This seems to have been caused by the inevitable contamination with DQH_2 of the solution photolyzed for a long time. A small amount of oxygen in a solution resulting from an insufficient degassing should reduce the $DQ^{\cdot}$ yield because of an efficient electron transfer from $DQ^{\cdot}$ to O_2.[21] The ESR observations on DQH· cannot necessarily be a proof for the hydrogen abstraction of $^3DQ^*$ from alcohols (reaction (1)) before excluding a possible occurrence of reaction (4).

In conclusion, the present investigation has shown the correct location of the semiquinone intermediates observed by ESR in the reaction scheme of the DQ photoreduction in alcohol solutions. In addition, the present ESR study has indicated three reaction pathways for the $DQ^{\cdot}$ formation: The photoinduced one-electron transfer from alcohol to DQ, though the quantum yield for it is very small, the one-electron transfer from α-hydroxyalkyl radical to DQ, and the ionic dissociation of a photoexcited CT-complex (DQ–DQH_2), which becomes important at high DQH_2 concentrations with irradiation by an incandescent light.

Liquid Crystal Formation in Binary Systems. V.[1] Liquid Crystals Induced in *N*-[4-(Dimethylamino)benzylidene]-4-ethoxyaniline-*N*-(4-Nitrobenzylidene)-4-nitroaniline and Related Mixtures

Kotaro Araya and Yoshio Matsunaga*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received September 10, 1981)

The induction of liquid crystals was demonstrated with binary mixtures comprising *N*-(4-nitrobenzylidene)-4-nitroaniline and *N*-[4-(dimethylamino)benzylidene]-4-alkoxyaniline or *N*-(4-alkoxybenzylidene)-4-(dimethylamino)aniline. Both nematic and smectic phases were observed with the ethoxy derivatives, but only a smectic A phase with the propoxy derivatives. The mesophases appear in the region centered around 30 mol% of the dinitro compound. Similarly, liquid crystals could be induced in several mixtures of *N*-[4-(dialkylamino)benzylidene]-4-(dialkylamino)aniline with *N*-(4-nitrobenzylidene)-4-alkoxyaniline or *N*-(4-alkoxybenzylidene)-4-nitroaniline. The bis(dialkylamino) and dinitro derivatives of azoxybenzene were also shown to be efficient as one of the component compounds in producing binary liquid crystals.

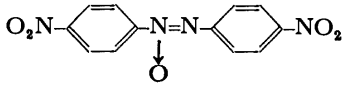
As we reported earlier, nematic and smectic liquid crystals can be induced by mixing a nonmesogenic electron donor and a nonmesogenic electron acceptor of the type 4-X-C_6H_4-Z-C_6H_4-Y-4.[2,3] Donor molecules having a dimethylamino group on one end and acceptor molecules having a nitro group on one end were employed in those works. The donor and acceptor molecules each had a short alkoxyl group of the same kind on the other end. The central double bond linkages were chosen from -CH=CH-, -CH=N-, and -N=N- groups. Although the component compounds themselves form no mesophase, they may be considered potentially mesogenic, because the molecules are elongated and lath-liked in shape. The induction or the enhancement of the thermal stability of liquid crystals in the above-mentioned mixtures is maximized when the mole ratio is near 1 : 1. The orientational cohesive force arising from the interaction of the electron donor-acceptor type may be responsible for the ordered arrangement of the molecules in liquid crystals. In ordinary crystals, this sort of intermolecular interaction is known to result in the parallel alignment of the planar component molecules.

As the molecules of *N*-benzylideneanilines are generally nonplanar, the intermolecular interaction in the induced liquid crystals may be more or less localized between the benzene ring with a dimethylamino group in the donor molecule and that with a nitro group in the acceptor molecule. If so, each benzene ring in the dinitro derivative may be able to interact with a molecule of the dimethylamino derivative. Similarly, a molecule of the bis(dimethylamino) derivative may associate with two molecules of the mononitro derivative. In this paper, we wish to report that liquid crystalline phases are really induced with such combinations.

Experimental

Materials. The *N*-benzylideneanilines were prepared

by a condensation reaction between a *p*-Y derivative of benzaldehyde and a *p*-X derivative of aniline, and were purified by repeated recrystallizations from a suitable solvent. Hereafter, they are represented by the terminal groups in parentheses, (X, Y). 4,4'-Dinitroazoxybenzene (DNAO)



was obtained by the oxidation of *p*-nitroaniline with ammonium peroxodisulfate, as described by Witt and Kopetschni.[4] The crude product was treated with fuming nitric acid and then recrystallized from benzene.[5] 4,4'-Bis-(dimethylamino)azoxybenzene (BDMAAO) was synthesized by the catalytic reduction of *p*-nitroso-*N*,*N*'-dimethylaniline with hydrazine hydrate, following the method reported by Busch and Schulz.[6] 4,4'-Bis(diethylamino)azoxybenzene (BDEAAO) was analogously prepared. The procedure of preparing binary mixtures was given in our previous paper.[2]

Measurements. The calorimetric and spectroscopic measurements were carried out as described in Part II of this series.[2]

Results and Discussion

N-(4-Nitrobenzylidene)-4-nitroaniline (NO_2, NO_2) as an Electron Acceptor. The following four donor Schiff bases were found to form liquid crystals when mixed with this acceptor: (NMe_2, EtO), (EtO, NMe_2), (NMe_2, PrO), and (PrO, NMe_2). As the acceptor has a melting point of 200 °C, which is higher by 53 to 85 °C than those of the donors, and the observation of liquid crystals is limited to the composition range from 15 to 40 mol% of (NO_2, NO_2), we studied the phase diagrams only up to 50 mol%.

In the (NMe_2, EtO)-(NO_2, NO_2) system, the nematic and smectic liquid crystals appear from the supercooled isotropic melt (see Fig. 1a). The former phase exists as a single phase only below 20 mol%. When the temperature drops, two transitions associated with liquid crystals were detected at the composition of 25 mol%. The first transition is found at 127 °C and is ascribed to the appearance of a metastable smectic phase accompanied by the isotropic melt; the second one, at 120 °C, is ascribed to the transformation into a metastable nematic phase in equilibrium with the smectic phase. The latter temperature is that of the intersection between the isotropic liquid-smectic liquid crystal (I-S) transition curve and the isotropic liquid-

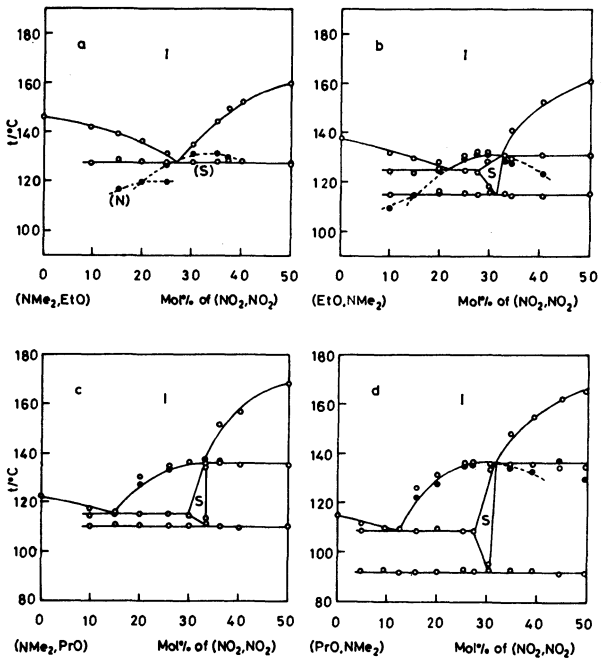


Fig. 1. Phase diagrams of the systems of (NO_2, NO_2) with (a) (NMe_2, EtO), (b) (EtO, NMe_2), (c) (NMe_2. PrO), and (d) (PrO, NMe_2). The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

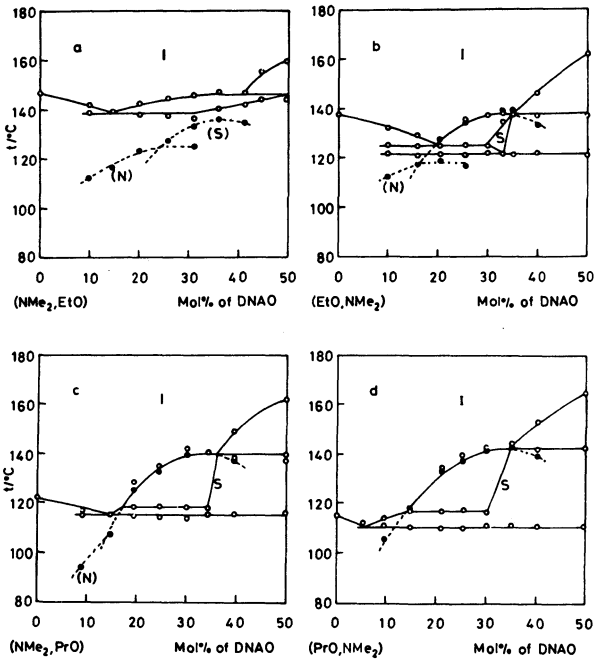

Fig. 2. Phase diagrams of the systems of DNAO with (a) (NMe_2, EtO), (b) (EtO, NMe_2), (c) (NMe_2, PrO), and (d) (PrO, NMe_2). As to the open and shaded circles, see the caption of Fig. 1.

nematic liquid crystal (I-N) transition curve. The maximum of the I-S transition occurs at 131.5 °C and 33 mol%.

The phase diagram of the (EtO, NMe_2)–(NO_2, NO_2) system shown in Fig. 1b is more complicated than that described above. Enhancement of the smectic phase is so pronounced that the I-S transition curve encounters the freezing point curve of the donor compound at 125 °C and 22 mol% and also another freezing point curve at 131 °C and 32.5 mol% of (NO_2, NO_2). The horizontal line at 125 °C terminates at 27.5 mol%, indicating that the isotropic melt and a smectic liquid crystal are in equilibrium with each other in the temperature range specified by the I-S transition curve and this line. This smectic phase is stable above 115 °C with the coexisting solid. The region of existence of this mesophase as a single phase is represented by a triangle in the diagram and lies in the composition range between 27.5 and 32.5 mol%. The intersection between the I-S and I-N transition curves is at 115 °C and 14.7 mol%. Below this composition, the metastable nematic liquid crystal may be observed without any coexisting phase.

Figure 1c presents the diagram of the (NMe_2, PrO)–(NO_2, NO_2) system. The area bounded by the following points represents the condition for the stable existence of the induced liquid crystal as a single phase: 115 °C and 30 mol%, 136 °C and 33.3 mol%, and 110 °C and 33.3 mol% of (NO_2, NO_2). The mesophase appearing at 33 mol% was identified as a smectic A phase by the miscibility test with *N*-(4-phenylbenzylidene)-4-(ethoxycarbonyl)aniline, which exhibits a smectic A phase stable between 121.6 and 131 °C.[7]

The diagram of the (PrO, NMe_2)–(NO_2, NO_2) system shown in Fig. 1d is also of the same type. The corners of the region for a stable smectic phase existing without any other phase are located at 108.5 °C and 27.5 mol%, 136.5 °C and 31.8 mol%, and 92 °C and 30.5 mol% of (NO_2, NO_2).

4,4'-Dinitroazoxybenzene (DNAO) as an Electron Acceptor. This compound has a melting point of 192 °C. All the four donors employed for the systems shown in Fig. 1 can produce mesophases by mixing with DNAO. Their phase diagrams are given in Fig. 2. Again, the induction of the smectic liquid crystal in the combination with (NMe_2, EtO) is not sufficient to make the phase enantiotropic (see Fig. 2a). The maximum temperature of the induced smectic phase is 136 °C. The I-S and I-N transition curves meet each other at 125 °C and 24 mol%. The presence of a horizontal line extending from this intersection to 31 mol% is indicative of the coexistence of the smectic phase and the isotropic melt above this line and that of the smectic phase and the nematic phase below this line.

The diagram for the (EtO, NMe_2)–DNAO system bears some similarity to that for the (EtO, NMe_2)–(NO_2, NO_2) system (compare Figs. 1b and 2b). The I-S transition curve intersects the freezing point curve of the donor compound at 125 °C and 20 mol% of DNAO and the other freezing point curve at 138 °C and 35 mol%. The triangle for the stable single smectic phase is specified by the latter intersection and the following two: 125 °C and 30 mol% and 121.5 °C and 32 mol%. The intersection between the I-S and I-N transition curves occurs at 118 °C and 16 mol%.

The (NMe_2, PrO)–DNAO and (PrO, NMe_2)–DNAO systems yield diagrams greatly different from the preceding cases. The S-I transition curve encounters

Table 1. The maximum temperature of the smectic liquid crystal-isotropic liquid transition/°C

Acceptor	Donor			
	(NMe_2, EtO)	(EtO, NMe_2)	(NMe_2, PrO)	(PrO, NMe_2)
(NO_2, NO_2)	131.5	131	136	136.5
DNAO	136	139	140	143

the freezing point curve twice on the acceptor-rich side. The points of intersection are found at 118 °C and 17 mol% and at 140 °C and 36 mol% in the former system. As is evident from the presence of a horizontal line at 118 °C, the induced smectic phase and the isotropic melt are involved in the composition range from 17 to 34 mol%.

Similarly, the diagram of the (PrO, NMe_2)–DNAO system has two intersections between the S-I transition curve and the freezing point curve. They are located at 117 °C and 15 mol% and at 143 °C and 35 mol%. At the latter composition, the solid is wholly transformed into the mesophase at 110.5 °C and then into the isotropic melt at 143 °C. The horizontal line separating the solid and the smectic liquid crystal, both of which coexist with the isotropic melt, appears at 117 °C and below 30 mol%.

The maximum temperatures of the S-I transition in the eight systems described above are summarized in Table 1. For a given electron donor, DNAO gives consistently higher transition temperatures, but only by several degrees, than (NO_2, NO_2) does. It is not clear whether the differences are attributable to the effect of the central double bond linkage on the induction of mesophase or on the latent transition temperature of the acceptor compound. Nevertheless, it may be added that the same sequence has been found for the N-I transition temperatures.[8] As to the donor compounds, the smectic phases induced by the propoxy derivatives are more thermally stabilized than those induced by the ethoxy derivatives. This effect of terminal substituents is in agreement with our observation made in an earlier work.[2]

The donor and acceptor compounds employed in the present work are yellow, while their combinations are reddish brown or dark red, suggesting the formation of solid molecular complexes of the electron donor-acceptor type. The phase diagrams suggest that the solid complex is formed at the composition of 50 mol% or higher of the dinitro compound. The electronic spectrum of (NMe_2, PrO)–(NO_2, NO_2) at 50 mol% is shown in Fig. 3, along with those of the solid component compounds. New absorption bands undoubtedly appear and are located at about 18 and 22×10^3 cm^{-1}. They may be assigned to the charge-transfer transitions from (NMe_2, PrO) to (NO_2, NO_2). The spectrum of (NMe_2, PrO)–DNAO at 50 mol% is very much like the aforementioned, but the first band is shifted further to the low-energy side, by $(1.5—2)\times10^3$ cm^{-1}. This shift may imply that the electron affinity of DNAO is larger by about this extent than that of (NO_2, NO_2). This postulate is not unreasonable if one compares the electronegativities of the atoms in the central linkages. As the color of the mesophases is similar to that of the corresponding solid complex, it is very likely that the unusually pronounced nonlinear behavior of smectic liquid crystals is caused by the complexation between the donor and acceptor molecules in appropriate mole ratios.

N-[*4-(Dimethylamino)benzylidene*]-*4-(dimethylamino) aniline* (*NMe_2, NMe_2*) *as an Electron Donor.* Smectic phase is produced when (NO_2, PrO) is combined with this donor compound. As is shown in Fig. 4a, the induced mesophase is entirely metastable. The maximum of the I-S transition curve is located at 121 °C near 30 mol% of (NMe_2, NMe_2).

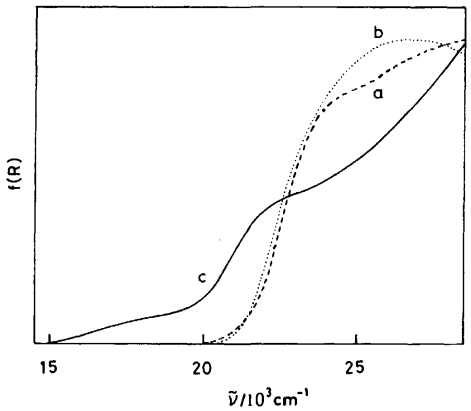

Fig. 3. Diffuse reflection spectra of (a) (NMe_2, PrO), (b) (NO_2, NO_2), and (c) the binary system at 50 mol%.

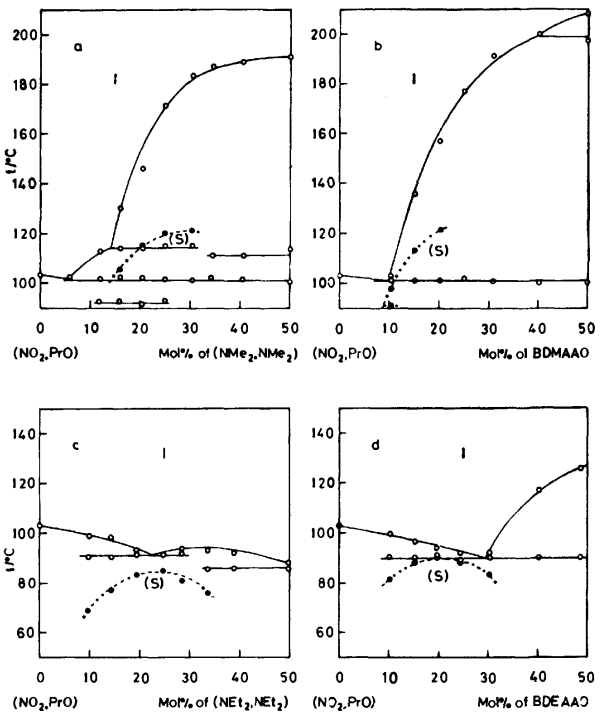

Fig. 4. Phase diagrams of the (a) (NMe_2, NMe_2)–(NO_2, PrO), (b) BDMAAO–(NO_2, PrO), (c) (NEt_2, NEt_2)–(NO_2, PrO), and (d) BDEAAO–(NO_2, PrO) systems. As to the open and shaded circles, see the caption of Fig. 1.

Metastable nematic liquid crystals appear when the donor compound is mixed with (NO_2, EtO) and also with (PrO, NO_2). In the former combination, the mesophase is observable in the composition range from 10 to 20 mol% of (NMe_2, NMe_2) and at temperatures between 105 and 113 °C. The mesophase relatively rich in the donor compound can persist only within a few degrees below the transition curve. The nematic liquid crystal in the latter system can be found below 25 mol%. The curve extends from the I-N transition point of (PrO, NO_2) and reaches 112 °C by the said composition.

4,4'-Bis(dimethylamino)azoxybenzene (BDMAAO) as an Electron Donor. According to our survey, made by the contact method,[9] the induction of mesophase occurs only in the system with (NO_2, PrO). The metastable smectic phase is observed in the range from 10 to 20 mol% of BDMAAO (see Fig. 4b). The transition temperature at the former composition is 98 °C, while that at the latter is 122 °C. The coexistence of smectic and nematic liquid crystals is found at 10 mol% and below 91 °C.

In contrast to the mesophases obtained with the dinitro compounds shown in Figs. 1 and 2, the liquid crystals induced with the bis(dimethylamino) compounds are not very stable. The melting point of (NMe_2, NMe_2) is as high as 234.5 °C and that of BDMAAO is even higher: *i.e.*, 244 °C. Because of the large differences in melting point between the donor and acceptor compounds, the major part of the induced mesophases is far below the freezing point curve on the donor-rich side. In such a situation, it is hard to suspend the solidification down to the I-S transition temperature. Consequently, we tried the bis(diethylamino) compounds, the melting points of which are expected to be appreciably lower, as electron donors.

N-[4-(Diethylamino)benzylidene]-4-(diethylamino)aniline (NEt_2, NEt_2) as an Electron Donor. This compound melts at 118 °C. Nevertheless, liquid crystal can be produced only when the compound is mixed with (NO_2, PrO) and exists as a metastable phase (see Fig. 4c). The smectic phase is induced in the range from 10 mol% of (NEt_2, NEt_2) to the composition of the solid complex. The maximum of the I-S transition curve lies at 85 °C and about 25 mol%. This temperature is markedly lower than that found in the (NMe_2, NMe_2)–(NO_2, PrO) system.

4,4'-Bis(diethylamino)azoxybenzene(BDEAAO) as an Electron Donor. The melting point of this compound is 158 °C, which is lower by 86 °C than that of BDMAAO. Smectic liquid crystals could be observed in the mixtures not only with (NO_2, PrO) but also with (PrO, NO_2). The diagram of the former system is presented in Fig. 4d. The mesophase is seen in the range from 10 to 30 mol% of BDEAAO. The maximum transition temperature is almost in coincidence with the eutectic temperature and is found at about 20 mol%. The smectic phase induced by mixing with (PrO, NO_2) is less stable; the maximum lies at 71 °C and about 20 mol%.

Thus, the lowering of the melting point by the replacement of dimethylamino groups with diethylamino groups is appreciable; however, the observation of induced mesophases is not made much easier. It seems highly likely that the latent I-S transition temperature is also lowered by this replacement, as we suggested in our earlier work on the *N*-benzylidene-4-aminoazobenzenes.[1] The latter effect may be, at least partly, lifted if the *N*-benzylideneanilines carrying a dimethylamino group on one end and a diethylamino group on the other end are employed. Indeed, (NEt_2, NMe_2) is known to melt at 140—141 °C.[10] This temperature is only 22 °C higher than the melting point of (NEt_2, NEt_2).

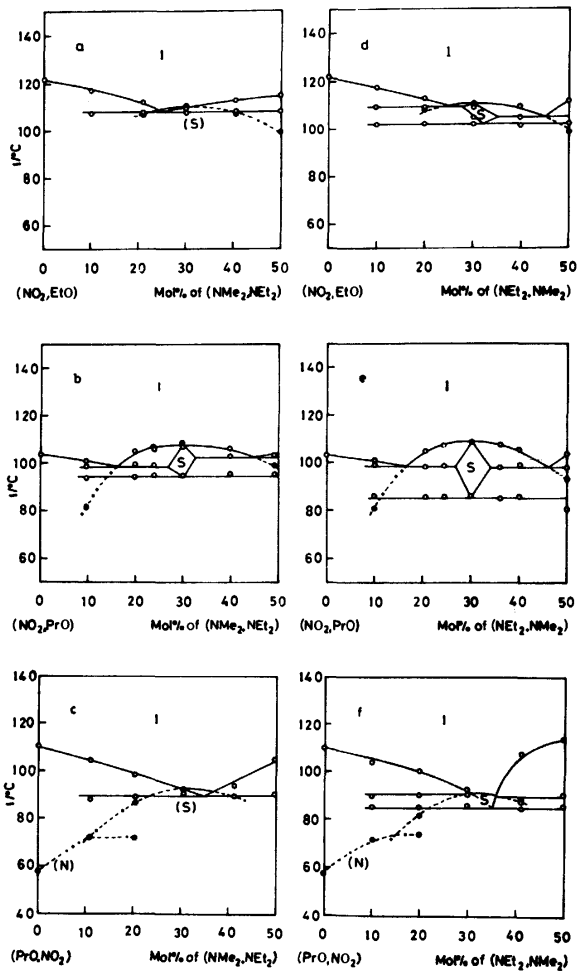

Fig. 5. Phase diagrams of the (a) (NMe_2, NEt_2)–(NO_2, EtO), (b) (NMe_2, NEt_2)–(NO_2, PrO), (c) (NMe_2, NEt_2)–(PrO, NO_2), (d) (NEt_2, NMe_2)–(NO_2, EtO), (e) (NEt_2, NMe_2)–(NO_2, PrO), and (f) (NEt_2, NMe_2)–(PrO, NO_2) systems. As to the open and shaded circles, see the caption of Fig. 1.

N-[4-(Dimethylamino)benzylidene]-4-(diethylamino)aniline (NMe_2, NEt_2) as an Electron Donor. The acceptors, (NO_2, EtO), (NO_2, PrO), and (PrO, NO_2) were found to produce smectic liquid crystals when combined with this donor, the melting point of which is 136 °C. Their phase diagrams are given in Figs. 5a, b, and c. In all the cases, the induced mesophase has an area where it can exist as a single stable phase. The system with (NO_2, EtO) produces a mesophase observable in the range from 20 to 50 mol% of (NMe_2,

NEt_2). The maximum of the transition curve lies at 111 °C and about 30 mol%.

The smectic phase is most stabilized in the system with (NO_2, PrO). The I-S transition curve is met by the freezing point curve of (NO_2, PrO) at 98 °C and 16 mol% and by that on the (NMe_2, NEt_2)-rich side at 102 °C and 44.5 mol%. The maximum of the transition curve is found at 107 °C. The composition is not distinguishable from that of the eutectic point, 94 °C and 30 mol%.

The mesophase induced in mixtures with (PrO, NO_2) is metastable except for the small area above the eutectic point. The enantiotropic I-S transition is seen only between 31 and 36.5 mol%. The maximum is located at 92 °C. Below 72 °C and 11 mol%, the nematic phase can exist as a single phase.

N-[4-(Diethylamino)benzylidene]-4-(dimethylamino)aniline (NEt$_2$, NMe$_2$) as an Electron Donor. Smectic liquid crystals are induced in the systems with (NO_2, EtO), (NO_2, PrO), and (PrO, NO_2) and are generally more stable than those induced with the isomeric donor compound, (NMe_2, NEt_2) (see Figs, 5d, e, and f).

The diagrams in Figs. 5d and e are similar to that given in Fig. 5b. With (NO_2, EtO), the I-S transition curve intersects the freezing point curve of (NO_2, EtO) at 109.5 °C and 25 mol% and that on the donor-rich side at 105 °C and 45 mol%. The maximum temperature of 111.5 °C is found around 30 mol%. The smectic phase and the isotropic melt coexist in most of the area below the I-S transition curve. The lower temperature limit as a single stable mesophase is 102 °C located at 32 mol%.

The enantiotropic I-S transition curve in the system with (NO_2, PrO) covers the composition range from 16.5 to 46 mol% of (NEt_2, NMe_2), passing through a maximum at 109 °C and about 30 mol%. The area in which the induced smectic phase appears as the sole stable phase covers the temperature range from 85 to 109 °C and the composition range from 27 to 34 mol%.

When mixed with (PrO, NO_2), the mesophase is stable in the area specified by the intersections between the I-S transition curve with the freezing point curves at 91 °C and 31 mol% and at 90 °C and 36 mol% and by the eutectic point at 85 °C and 35 mol%. The metastable I-S transition curve encounters the metastable I-N transition curve at 74 °C and 15 mol%.

The upper temperature limits of the smectic phases induced with the six donor compounds are compared in Table 2. As to the donors, the temperature changes in this order:

Table 2. The maximum temperature of the smectic liquid crystal-isotropic liquid transition/°C

Donor	Acceptor		
	(NO_2, EtO)	(NO_2, PrO)	(PrO, NO_2)
(NMe_2, NMe_2)	—	121	—
BDMAAO	—	122	—
(NMe_2, NEt_2)	111	107	92
(NEt_2, NMe_2)	111.5	109	92
(NEt_2, NEt_2)	—	84	—
BDEAAO	—	90	71

$$\text{BDMAAO} \simeq (NMe_2, NMe_2) > (NEt_2, NMe_2) \simeq (NMe_2, NEt_2) > \text{BDEAAO} > (NEt_2, NEt_2).$$

As the melting point follows the same order except for the last two, it is not possible to compare the stabilization of the induced phases based on this order.

The color developed with these bis(dialkylamino) compounds is not so deep as that developed with the dinitro compounds. For example, the 1:2 (NMe_2, NMe_2)–(NO_2, PrO) complex is brown. Comparison of the diffuse reflectance spectrum of the complex with those of the components reveals the occurrence of a weak absorption around 19×10^3 cm^{-1}. This energy value is only a little bit lower than that found in the combination of (NMe_2, EtO) and (NO_2, EtO) reported earlier.[2] The shift arises from the rather small improvement of the donor strength by the replacement of an electron-donating alkoxyl group with another electron-donating dialkylamino group. In contrast, the shift found in Fig. 3 is large. The increase in the acceptor strength is due to the replacement of an alkoxyl group with an electron-withdrawing nitro group. The thermal stabilization of smectic liquid crystals induced by the dinitro compounds is more extensive than that induced by the mononitro compounds. This observation may be also attributed to the rather large difference in the acceptor strength.

The composition at the maximum of the I-S transition curve varies with the combination of electron donor and acceptor but, without exception, occurs near 30 mol% of the dinitro or bis(dialkylamino) compound. The exact composition is supposed to depend not only on the extent of the formation of 2 : 1 or 1 : 2 molecular complexes in the mesophases but also on the difference in the latent I-S transition temperature between the component compounds. The above-mentioned compositions suggest that the temperatures of the dinitro and bis(dialkylamino) compounds are considerably lower than those of the other component compounds employed in this work.

The authors wish to express their sincere thanks to Mr. Nobuhiko Miyajima for the preparation of 4,4'-bis(dimethylamino)azoxybenzene. The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 543001).

Electron Spin Resonance of X-Irradiated Single Crystals of Dicyclohexyldiazene 1,2-Dioxide

Yoshihisa FUJII, Michio KASHIWAGI,†,†† Hideki NAKADA,†,††† and Yukio KURITA*
Department of Materials Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240
†*Basic Research Laboratory, Toray Industries, Inc., Tebiro, Kamakura 248*
(Received September 11, 1981)

ESR studies of X-irradiated single crystals of dicyclohexyldiazene 1,2-dioxide, $(C_6H_{11}NO)_2$, revealed the generation of the stably trapped radicals $C_6H_{11}N(O)N'H''(O')C_6H_{11}$. The principal elements of the g value were found to be 2.0030, 2.0060, and 2.0086. The principal elements of the hyperfine coupling constants were found to be 3.88, 1.53, and 1.38 mT for N, and 1.53, 1.41, and 1.14 mT for H''. The direction cosines of these principal elements, when compared with those of the bonds in the parent molecule, indicate that the radical is formed by addition of a hydrogen atom to the N=N' double bond without causing a large change in the molecular framework. The spin densities for this radical were calculated to be 0.041 and 0.47 in the 2s and 2p orbitals of the atom N, respectively.

C-Nitroso compounds in solution produce nitroxide radicals by photochemical or thermal decomposition. It is well established that the radical formation takes place through the nitroso monomer:[1]

$$(RNO)_2 \underset{\text{or } \Delta}{\overset{h\nu}{\rightleftharpoons}} 2RNO \xrightarrow[\text{or } \Delta]{h\nu} R\cdot + NO\cdot$$

$$+ RNO \longrightarrow R_2NO\cdot + NO\cdot$$

However, little is known about the decomposition of *C*-nitroso compounds in the solid state, where they exist as dimers.

Nitrosocyclohexane has industrial significance as a precursor of cyclohexanone oxime, which is used to give poly(ε-caprolactam). X-Ray analysis revealed that nitrosocyclohexane exists as a dimeric form, dicyclohexyldiazene 1,2-dioxide (**1**), in the crystalline state.[2] This paper will report the ESR study of X-irradiated single crystals of **1**.

Experimental and Results

Compound **1**, $(C_6H_{11}NO)_2$, mp 117—118 °C, was prepared according to the method of Okamura *et al.*[3] Single crystals were grown by the slow evaporation of a saturated methanol solution in a refrigerator at 5 °C. The crystals obtained were thin plates (8 mm × 3 mm × 1 mm, Fig. 1) with well developed planes: {100}, {010}, and {001}.

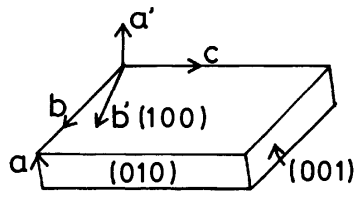

Fig. 1. The crystal form of **1** and the crystallographic axes abc and the rectangular coordinate axes a'b'c employed for analysis of the ESR spectra.

The crystal structure has been determined by Tanimura *et al.* using X-ray methods.[2] The crystal is triclinic and the space group is $P\bar{1}$ with the unit cell of dimensions: $a_0=1.0133$, $b_0=0.6758$, $c_0=0.5583$ nm, $\alpha=121°42'$, $\beta=96°50'$, $\gamma=78°06'$. The unit cell contains one molecule, which has a center of symmetry at the midpoint of the N=N' bond.

A rectangular coordinate system a'b'c was chosen for the ESR measurements. The c axis is the same as the crystal c axis. The b' axis is selected in the bc plane, perpendicular to the c axis, and the a' axis is perpendicular to the bc plane. The crystal axes were determined by comparing interfacial angles calculated from the lattice constants with those measured with an optical goniometer. The results are shown in Fig. 1.

Single crystals were irradiated with X-rays of 180 keV to a dose of about 1 Mrad (10^4 J/kg) at 77 K. The ESR spectra were measured using a Varian Model V4501 X-band spectrometer.

The ESR spectra measured at 77 K immediately after X-ray irradiation at 77 K were impossible to analyze, since they consisted of a broad, almost featureless

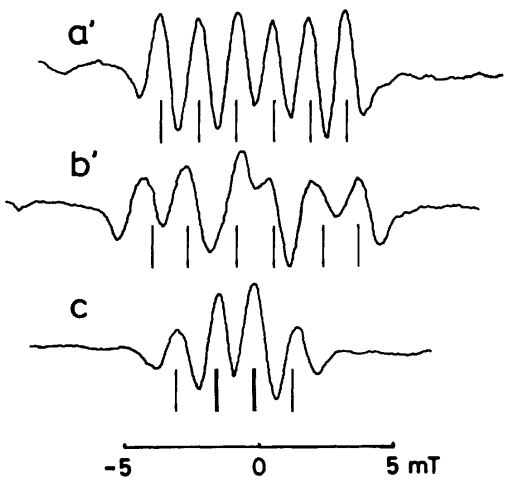

Fig. 2. Second derivative ESR spectra of a single crystal of **1**, which was measured at room temperature after X-Rays irradiation at 77 K. The magnetic filed was applied parallel to the a', b', or c axis, and measured relative to the reference DPPH signal ($g=2.0036$).

Table 1. The principal values of g, A^N, and A^H and their direction cosines with regard to the a'b'c system

g, A^N, and A^H	Principal values	Direction cosines with regard to the a'b'c system		
g_1	2.0030	0.670	−0.743	0.018
g_2	2.0060	0.709	0.631	−0.314
g_3	2.0086	0.222	0.223	0.949
A_1^N/mT	3.88	0.643	−0.765	0.023
A_2^N/mT	1.53	0.659	0.569	0.492
A_3^N/mT	1.38	0.389	0.301	−0.871
A_1^H/mT	1.53	0.539	0.309	0.784
A_2^H/mT	1.41	0.639	−0.756	−0.141
A_3^H/mT	1.14	0.549	0.577	−0.605

absorption. However, the spectra measured at room temperature became simple after storage at room temperature. Some typical spectra are shown in Fig. 2. Each spectrum, consisting of six lines with equal intensity, can be interpreted in terms of one anisotropic nitrogen hyperfine coupling constant A^N and one nearly isotropic proton hyperfine coupling constant A^H. Each component line is broad, having about 0.7 mT of maximum slope width.

The observed angular dependencies of A^N, A^H, and g values are plotted in Fig. 3. Principal elements of A^N-, A^H-, and g-tensors are determined using the least-squares method and are given in Table 1. The solid lines in Fig. 3 are the theoretical angular variations calculated from the principal elements in Table 1.

Discussion

The observed coupling constants clearly show that the free radical contains a nitrogen atom having a large fraction of unpaired electrons and β-type hydrogen atom with nearly isotropic coupling constant. Table 1 shows that the nitrogen coupling tensor has almost cylindrical symmetry about the A_1^N direction. This symmetry is to be expected for the unpaired electron in a nitrogen orbital aligned in this direction when the contribution from unpaired electrons on other orbitals is negligible. The analysis of coupling tensors of this type has been fully discussed in a previous paper.[4] The results are summarized as follows.

The molecular orbital containing the unpaired electron can be written as

$$\phi = C_s\phi_{2s}{}^N + C_p\phi_{2p}{}^N + C_h\phi_{1s}{}^H\ C_x\phi^X,$$

where $\phi_{2s}{}^N$, $\phi_{2p}{}^N$, and $\phi_{1s}{}^H$ are the 2s, 2p atomic orbitals of the nitrogen atom and the 1s atomic orbital of the hydrogen atom, respectively, and ϕ^X is a normalized orbital of a group of atoms that makes negligible contribution to the hyperfine structure. Coefficients are obtained from the relations:

$$C_s{}^2 = a^N/A_{2s}{}^N,$$
$$C_p{}^2 = (A_1{}^N - a^N)/(2B_{2p}{}^N),$$
$$C_h{}^2 = a^H/A_{1s}{}^H,$$
$$C_x{}^2 = 1 - C_s{}^2 - C_p{}^2 - C_h{}^2,$$

where

$$a^N = (A_1{}^N + A_2{}^N + A_3{}^N)/3,$$
$$a^H = (A_1{}^H + A_2{}^H + A_3{}^H)/3.$$

The 2p orbital is parallel to the direction of $A_1{}^N$(maximum) and g_1(minimum).

With the observed values in Table 1 and $A_{2s}{}^N$=55.0 mT, $B_{2p}{}^N$=1.71 mT, and $A_{1s}{}^H$=50.8 mT,[5] one finds $C_s{}^2$=0.041, $C_p{}^2$=0.47, $C_h{}^2$=0.027, and $C_x{}^2$=0.462; the total spin density on the nitrogen atom is 0.51. The directions of g_1 and $A_1{}^N$ are calculated to be 1.6° apart; they are parallel within the experimental error.

The spin densities and g values of this radical are compared in Table 2 with those of nitroxide and iminoxyl radicals, which are typical π- and σ-radicals, respectively. The comparison suggests that this radical

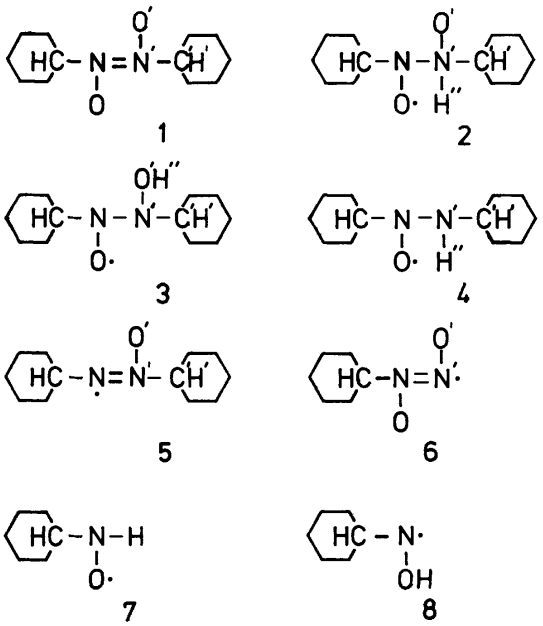
Table 2. Spin densities and g factors of radicals containing N–O group

	Nitroxyl radical[a,b]	The radical in this work	Iminoxyl radical[c]
C_s^2	0.027	0.041	0.050
C_p^2	0.50	0.47	0.36
g_1	2.0027	2.0030	2.0025
g_2	2.0061	2.0060	2.0064
g_3	2.0089	2.0086	2.0118

a) Ref. 7. b) The isotropic proton coupling constant of dimethyl nitroxide radical was 1.23 mT: J. Q. Adams, S. W. Nicksic, and J. R. Thomas, *J. Chem. Phys.*, **45**, 654 (1966). c) Ref. 4.

has an electronic structure similar to that of nitroxide radical except for the high spin density on the 2s atomic orbital of the nitrogen atom.

Stable radicals trapped in irradiated organic crystals at room temperature include the following types: (1) The primary free radicals formed by dissociation of the undamaged molecules; (2) the secondary free radicals formed by addition of the primary radicals of small size to the undamaged molecule or to diamagnetic molecular fragments that are produced by the dissociation of the undamaged molecules. There are seven possible radicals (**2**—**8**) of this type that can be produced from **1** and have a coupling nitrogen atom with the spin density of about one half. All the radicals except **2** will be readily excluded from the canditates for the observed radical since these radicals cannot be reconciled with the observed coupling constants.



Radical **7** has an anisotropic coupling proton of the NH group. The anisotropy of the coupling constant, $A_{max}^{H}-A_{min}^{H}$, for an α proton of an >N̈–H π radical is proportional to the spin density on the nitrogen 2p orbital (ρ_π^N) with a proportional constant of 3.2 mT.[6] With the spin density of 0.47, the anisotropy in **7** is estimated to be 1.5 mT; this is different from the observed anisotropy of 0.39 mT. It is shown in the same way that the proton coupling of the OH group of **8** has an anisotropy different from the observed one. Thus **7** and **8** are excluded.

Radicals **5** and **6** probably give rise to two discernible couplings due to N and N′ atoms, because spin densities on these atoms do not seem to differ too much. Because only one nitrogen coupling was observed, **5** and **6** can be excluded.

Radicals **2**, **3**, and **4** can be formed from the parent molecule as a result of hydrogen addition or hydrogen addition after oxygen abstraction. Therefore, it can be assumed that all atoms in these radicals except O′ and H″ occupy the same positions in the lattice as those in the parent molecule. The isotropic coupling constant of H, a^H(CH), can be expressed by McConnell's $\cos^2\theta$ rule:

$$a^H(CH) = Q_N^{CH}\rho_\pi^N \cos^2\theta,$$

where θ is a dihedral angle between the C–H bond in the parent molecule and the unpaired electron orbital (parallel to A_1^N and g_1) in the observed radical, and $\rho_\pi^N=(C_{2p}^N)^2$. The orientation of the parent molecule in the crystal, determined by X-ray analysis, is given in Table 3. Using the value of 76—77° for θ calculated from Tables 1 and 3, 0.47 for ρ_π^N from Table 2, and 5.0 mT for Q_N^{CH}, one obtains 0.2 mT for a^H(CH). Because this value is much smaller than the observed isotropic proton coupling of 1.36 mT, the observed one is not attributable to the hydrogen atom of the CH group.

Table 3. Orientation of the parent molecule with regard to the a′b′c system

Bond and normal	Direction cosines with regard to the a′b′c system		
	a′	b′	c
C–H	−0.445	−0.151	−0.882
N–C	0.551	0.379	−0.743
N–O	0.164	0.256	0.952
N–N′	−0.720	−0.655	−0.228
n_1[a]	0.478	−0.874	−0.091
n_2[b]	0.646	−0.758	0.093

a) n_1: The normal to the plane HCN of **1**. b) n_2: The normal to the plane CNO of **1**.

The ESR of *t*-butyl cyclohexylamino nitroxide analogous to **4**, has been studied in solution; its isotropic couplings were 1.86 mT for N(NO), 0.09 mT for N(NH), H(CH), and H(NH).[8] The isotropic coupling constant of H(NH) of **4** is probably close to 0.09 mT; this value cannot account for the observed value of 1.36 mT. In nitroxide radicals, the unpaired electron is mainly localized on the >N–O moiety; hence the proton coupling constant of H(OH) in **3** will be too small to explain the observed constant. Thus there remains only **2** as a candidate. The following discussion will show that **2** is consistent with the ESR data of the trapped radical.

In the parent molecule **1**, six atoms CNOC′N′O′ are almost planar and oxygen atoms are placed *trans*

with regard to the N=N′ bond. Radical **2** is produced by the rupture of this π bond with the addition of H″ at N′. For the time being, we shall assumed that CNON′ in **2** occupies the same position in the lattice as in the parent molecule. Then, the unpaired electron occupies a molecular orbital composed of the p_π orbitals of N and O, which are perpendicular to the CNO plane. This can explain the result that the normal to the CNO plane was calculated from the direction cosines in Tables 1 and 3 to make an angle of 4° with the directions of g_1 and A_1^N, therefore with the direction of the p_π orbital. On addition of H″ to N′, the hybridization of the nitrogen orbitals changes from sp^2 to sp^3. Then O′ is moved and N′–H″ uses one of the sp^3 hybrid orbitals, making a dihedral angle of 30° with the p_π orbital of the unpaired electron. Though nitroxide radicals with –N(O·)NH(O)– moiety have not been reported, a radical $HN^{\cdot}$–NH_3^+ somewhat analogous to **2** was reported by Shrivastava and Anderson[9] and extensively discussed by Gordy.[6] The resultant parameters are $a^N(NH_3)=0.4$ mT, $a^H(NH_3)=1.50$ mT, $\rho_\pi^N=0.97$, $Q_N^{NH}=3.09$ mT, where Q_N^{NH} is the coefficient in

$$a^H(NH_3) = Q_N^{NH}\rho_\pi \cos^2\theta.$$

Applying this relation to **2** with $\rho_\pi^N=0.47$ and $\theta=30°$, we obtain 1.09 mT for the coupling constant of H″, which agrees well with the observed one of 1.36 mT.

The hydrogen atom H″ added at N′ will occupy two positions in the lattice; one lies above the NN′C′ plane, the other below the plane. The anisotropic coupling tensor of each hydrogen atom is calculated and compared with the observed coupling tensor of A^H. The position of H″ was not determined with assurance because of the relatively large angular error in the observed coupling tensor.

The coupling of β-nitrogen is supposed to be proportional to the spin density on the α-nitrogen. The coupling constant of 0.4 mT for $\rho_\pi^N=0.97$ in HN–NH_3^+ predicts that of **2** to be about 0.2 mT from $\rho_\pi^N=0.47$. This is within the observed line width of 0.7 mT.

If the nitroxide moiety of **2** is perfectly planar, it will have the spin density on the nitrogen 2s orbital approximately equal to that of ordinary nitroxide radicals. However, Table 2 shows that the former (0.041) is appreciably larger than the latter (0.027). The difference suggests a change of nitroxide moiety from planar configuration. Experimental and theoretical studies have shown that the methyl radical is planar and the radicals CF_3, CHF_2, and CH_2F are pyramidal.[10,11] Pauling has shown by a simple quantum-mechanical argument that the electronegativity difference of the atom is the major factor in determining the configuration of these radicals.[11] For a radical $\dot{M}X_3$, as X is more electronegative than M, the unpaired electron orbital will contain more charactor of M and the radical will have a pyramidal structure. This explains the configuration change in nitroxide radicals: If one replaces an alkyl group in the dialkyl nitroxide radical with a nitrogen function, the spin density on the nitrogen 2s orbital of the nitroxide moiety will increase.

We therefore conclude that the radical stably trapped in the solid state is **2**.

Selective Reduction of Nitrogen Monoxide with Hydrogen on Pt/Al_2O_3 Containing a Metal Oxide

Yukio Kosaki,* Akira Miyamoto, and Yuichi Murakami
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received September 18, 1981)

By using a three-way catalyst containing a metal oxide, NO can be selectively converted to N_2 and N_2O without the formation of NH_3 even at the "rich" side of the air/fuel ratio. In order to elucidate the mechanism of this action of the added metal oxide, the NO–H_2 reaction on $Pt–V_2O_5/Al_2O_3$ catalyst was investigated using the pulse reaction technique. In the NO–H_2 reaction on Pt/Al_2O_3 catalyst, a significant amount of NH_3 was formed in the "rich" region of the reactants ($H_2/NO>1$), although NO was completely removed. In the NO–H_2 reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst, on the other hand, no NH_3 was formed even in the "rich" region of the reactants; in addition, NO was completely removed. During the NO–H_2 reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst, the V_2O_5 in the catalyst was found to be reduced from V^{5+} to V^{4+}. The reaction of NO with NH_3 and the reaction of NH_3 or H_2 with $Pt–V_2O_5$ mixed catalysts for various states of mixing were also investigated. From these results, the NO–H_2 reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst has been shown to be composed of the following three main steps: Step I, the formation of NH_3 by the reduction of NO with H_2 on Pt; Step II, the NO–NH_3 reaction on Pt to form N_2 or N_2O; and Step III, the reduction of V_2O_5 in the catalyst by H_2 which is accelerated by the "hydrogen spillover." In the NO–H_2 reaction on Pt/Al_2O_3 catalyst, NO is first reduced to NH_3 in Step I and the NO–NH_3 reaction in Step II follows. In the "rich" region, the formation of NH_3 takes place more readily than the subsequent NO–NH_3 reaction. In the NO–H_2 reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst, the formation of excess NH_3 is suppressed by the removal of hydrogen from Pt in Step III, and the NH_3 thus produced reacts with NO to form N_2 or N_2O selectively in Step II. The rates of Steps I, II, and III were also discussed in terms of the structure of the catalysts and composition of the reactants.

The three-way catalyst system is used for the simultaneous removal of nitrogen monoxide, carbon monoxide, and hydrocarbons in the automotive exhaust emissions.[1–5] This is done in a single bed of catalyst by controlling the air/fuel ratio within a region near the stoichiometric point, which is called the "window." The width of the "window" is usually very narrow; therefore, in order to control the air/fuel ratio within the "window," a feedback control system of the air/fuel ratio has been developed using an oxygen sensor.[3,6–14] The three-way catalyst coupled with this feedback control system, however, cannot fully control the fluctuation of the air/fuel ratio within the "window," and this brings about the incomplete removal of NO, CO, and hydrocarbons, and also the formation of NH_3. The development of a three-way catalyst with a broad "window" is therefore highly desirable. Although the supported Rh or Rh–Pt catalyst has a "window" with a broader width than the supported Pt or Pd catalyst,[15–19] a large demand for Rh cannot be met by supply because of the limited reserve of the resources.[4,20]

The three-way catalyst containing a metal oxide such as V_2O_5,[21] Re_2O_7,[22,23] MoO_3,[24] or CeO_2[25,26] has been shown to deal effectively with the fluctuation of the air/fuel ratio; thereby, the width of the "window" has been markedly broadened. The role of the added metal oxide has been considered as "oxygen storage."[27–29] However, further details of the mechanism of the action of the metal oxide added to the three-way catalyst have not been clarified. This may be due to the complexity of the system: (i) The automative exhaust gas contains many components, including NO, CO, H_2, hydrocarbons, SO_2, and water, which lead to very complex networks of elementary reactions on the catalyst, and (ii) the three-way catalyst containing the metal oxide has not been well characterized.

As a first step to the investigation of the mechanisms of the reactions involved in the automotive exhaust emissions control using a three-way catalyst containing a metal oxide, the purposes of this study were (i) to investigate whether the action of the added metal oxide for the selective reduction of NO can also be observed in the NO–H_2 reaction on $Pt–V_2O_5/Al_2O_3$ catalyst—a system which is much simpler than the real three-way catalyst system, and (ii) to reveal the action of the metal oxide in the NO–H_2 reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst. The NO–H_2 reaction was investigated, since this reaction is one of the most important reactions in the "rich" region for the removal of NO,[30,31] and is mainly responsible for the formation of NH_3.[32] It should be noted that the rate of the reaction in the "rich" region is considered to be much slower than that in the "lean" region.[28] V_2O_5 was chosen as the metal oxide because (i) the structure of V_2O_5 on Al_2O_3 support has been well characterized[33] and (ii) it is one of the metal oxides which have been known to be excellent additives to the three-way catalyst.[21] A pulse reaction technique was employed in this study because this technique is useful for investigating the kinetic behavior of the reduction or oxidation process involved in the redox cycles of a catalyst.[34–36]

Experimental

Catalysts. Pt/Al_2O_3 catalyst (Pt loading was 0.5 wt%) was purchased from Nippon Engelhard Ltd. $Pt–V_2O_5/Al_2O_3$ catalyst was prepared by impregnating the Pt/Al_2O_3 particles (0.3—0.6 mm) with an oxalic acid solution of ammonium metavanadate, followed by drying and subsequent heating in a stream of O_2 at 773 K for 3 h. Unless otherwise specified, the content of V_2O_5 in the $Pt–V_2O_5/Al_2O_3$ catalyst was 9 wt%, although $Pt–V_2O_5/Al_2O_3$ with 36 wt% V_2O_5 loading was also

used. A V_2O_5 was prepared by the thermal decomposition of ammonium metavanadate in an O_2 stream at 773 K for 3 h. A Pt/Al_2O_3–metal oxide(M) catalyst (the ratio of Pt/Al_2O_3 to the metal oxide was 1/1 in weight)was prepared by mixing powders of Pt/Al_2O_3 and the metal oxide in a mortar for 20 min without water. A Pt/Al_2O_3–V_2O_5(P) catalyst was obtained by mixing Pt/Al_2O_3 particles (0.3—0.6 mm) with an equal weight of V_2O_5 particles (0.3—0.6 mm) with a spatula, followed by shaking in a pulse reactor.

Reagents. Commercial NO (more than 99.5% purity), H_2 (99.99% purity), and NH_3 (99.9% purity) were used without further purification. He or Ar as a carrier gas was purified with a titanium metal sponge heated at 1023 K and a Molecular Sieve at room temperature.

Apparatus and Procedures. Experiments were conducted using a pulse reaction apparatus, the reactor consisting of a Pyrex glass tube (4 mm i.d.). Unless otherwise specified, experiments were carried out under the following conditions: The carrier gas flow rate was 87 cm³-STP/min; the reaction temperature was 573 K; the total amount of a single pulse was 5 cm³-STP; the concentration of NO in pulse was 2.3% which corresponded to the amount of NO 5.1 μmol; the concentration of H_2 was varied over the range 1.15—4.6%, which corresponded to the amounts of H_2 2.25—10.2 μmol; catalyst weights were 5—218 mg. Before introducing the reactant pulse, all catalysts containing a metal oxide were treated with an O_2 stream at 773 K for 30 min. Columns used for gas-chromatographic analysis were tetraethylenepentamine on Difron for NH_3, silica gel for N_2O, and Molecular Sieve type 13X for H_2, N_2, and NO; they were connected in an intermediate cell system.[37] Ar (in the case of He carrier) or N_2 (in the case of Ar carrier) was used as an internal standard.

Converions of NO (X_{NO}) and H_2 (X_{H_2}), yields of NH_3 (Y_{NH_3}), N_2 (Y_{N_2}), and N_2O (Y_{N_2O}), and selectivities to NH_3 (S_{NH_3}), N_2 (S_{N_2}), and N_2O (S_{N_2O}) were calculated from outlet amounts of NO (Q_{NO}), H_2(Q_{H_2}), NH_3 (Q_{NH_3}), N_2 (Q_{N_2}), and N_2O (Q_{N_2O}) as follows:

$$X_{NO} = 1 - Q_{NO}/Q^\circ_{NO}, \quad (1)$$

$$X_{H_2} = 1 - Q_{H_2}/Q^\circ_{H_2}, \quad (2)$$

$$Y_{NH_3} = Q_{NH_3}/Q^\circ_{NO}, \quad (3)$$

$$Y_{N_2} = 2Q_{N_2}/Q^\circ_{NO}, \quad (4)$$

$$Y_{N_2O} = 2Q_{N_2O}/Q^\circ_{NO}, \quad (5)$$

$$S_{NH_3} = Y_{NH_3}/(Y_{NH_3} + Y_{N_2} + Y_{N_2O}), \quad (6)$$

$$S_{N_2} = Y_N/(Y_{NH_3} + Y_{N_2} + Y_{N_2O}), \quad (7)$$

$$S_{N_2O} = Y_{N_2O}/(Y_{NH_3} + Y_{N_2} + Y_{N_2O}), \quad (8)$$

where Q°_{NO} and $Q^\circ_{N_2}$ are the amounts of NO and H_2 injected into the reactor.

The oxidation state of V_2O_5 in the catalysts before and after the pulse reaction was studied by ESR spectroscopy, using a JEOL ME 1X spectrometer.

Results

Effect of the H_2/NO Ratio on the NO–H_2 Reaction on Pt/Al_2O_3 and Pt–V_2O_5 Mixed Catalysts. Figures 1 and 2 show results of the NO–H_2 reaction on the Pt/Al_2O_3, Pt–V_2O_5/Al_2O_3, Pt–Al_2O_3/V_2O_5(M), and Pt/Al_2O_3–V_2O_5(P) catalysts at various inlet H_2/NO ratios. As is evident from Figs. 1 and 2, the catalytic properties of these catalysts changed significantly depending on the kind of catalysts and composition of the reactants. As shown in Fig. 1, X_{NO} varied with the

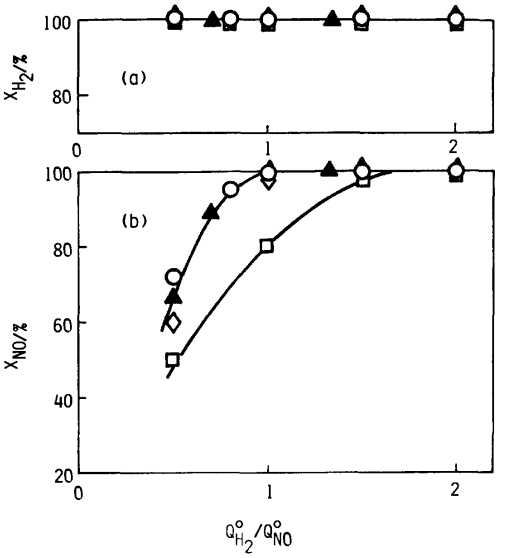

Fig. 1. Effect of the H_2/NO ratio on the conversions of NO (X_{NO}) and H_2 (X_{H_2}) in the NO–H_2 reaction on the Pt/Al_2O_3 and Pt–V_2O_5 mixed catalysts.
Catalyst weight: Pt/Al_2O_3=100 mg, Pt–V_2O_5/Al_2O_3 =109 mg, Pt/Al_2O_3–V_2O_5 (M)=200 mg, Pt/Al_2O_3–V_2O_5 (P)=200 mg (Pt weight in catalysts=500 μg). ▲: Pt/Al_2O_3, ○: Pt–V_2O_5/Al_2O_3, □: Pt/Al_2O_3–V_2O_5 (M), ◇: Pt/Al_2O_3–V_2O_5 (P).

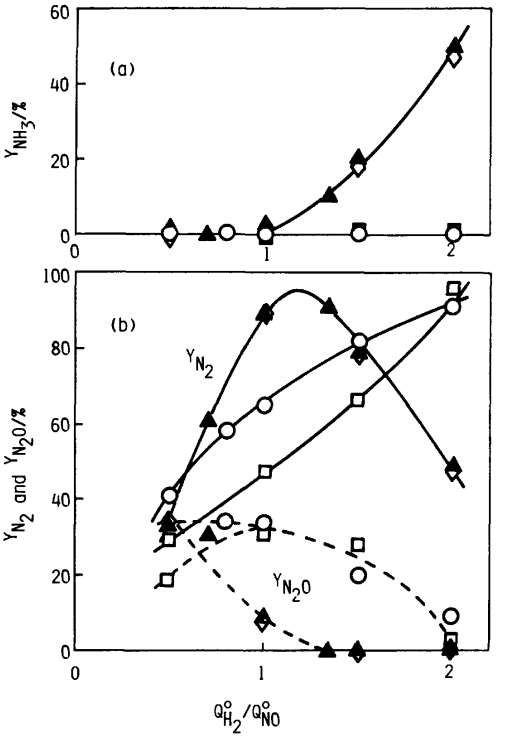

Fig. 2. Effect of the H_2/NO ratio on the yields of NH_3 (Y_{NH_3}), N_2 (Y_{N_2}), and N_2O (Y_{N_2O}) in the NO–H_2 reaction on the Pt/Al_2O_3 and Pt–V_2O_5 mixed catalysts.
Catalyst weight: Pt/Al_2O_3=100 mg, Pt–V_2O_5/Al_2O_3= 109 mg, Pt/Al_2O_3–V_2O_5(M)=200 mg, Pt/Al_2O_3–V_2O_5-(P)=200 mg (Pt weight in catalysts=500 μg). ▲: Pt/Al_2O_3, ○, Pt–V_2O_5/Al_2O_3, □: Pt/Al_2O_3–V_2O_5(M), ◇: Pt/Al_2O_3–V_2O_5(P), —: Y_{N_2}, ···: Y_{N_2O}.

$Q^\circ_{H_2}/Q^\circ_{NO}$ and the kind of catalysts, while the X_{H_2} was 100% for all of the catalysts indicated. X_{NO} for the Pt/Al_2O_3 catalyst was 100% when $Q^\circ_{H_2}/Q^\circ_{NO}$ was more than unity; that is, when $Q^\circ_{H_2}$ was greater than the stoichiometry ($Q^\circ_{H_2}/Q^\circ_{NO}=1$, that is, $H_2+NO=H_2O+1/2N_2$). As $Q^\circ_{H_2}$ decreased from the stoichiometry, X_{NO} for the Pt/Al_2O_3 catalyst decreased. X_{NO} for the $Pt-V_2O_5/Al_2O_3$ or $Pt/Al_2O_3-V_2O_5$(P) catalyst was almost equal to X_{NO} for the Pt/Al_2O_3 catalyst at any $Q^\circ_{H_2}/Q^\circ_{NO}$, while X_{NO} for the $Pt/Al_2O_3-V_2O_5$(M) catalyst was slightly lower than that for the Pt/Al_2O_3, $Pt/Al_2O_3-V_2O_5$(P), or $Pt-V_2O_5/Al_2O_3$ catalyst especially in the "lean" region, *i.e.* $Q^\circ_{H_2}/Q^\circ_{NO}<1$. As shown in Fig. 2, in the "rich" region, *i.e.* $Q^\circ_{H_2}/Q^\circ_{NO}>1$, a considerable amount of NH_3 was produced in the NO–H_2 reaction on the Pt/Al_2O_3 catalyst, and Y_{NH_3} increased markedly with increasing $Q^\circ_{H_2}/Q^\circ_{NO}$. In the NO–$H_2$ reaction on the $Pt-V_2O_5/Al_2O_3$ and $Pt/Al_2O_3-V_2O_5$(M) catalysts, no NH_3 was produced independent of the value of $Q^\circ_{H_2}/Q^\circ_{NO}$, while NO was almost selectively reduced to N_2 or N_2O as shown in Fig. 2(b). It should be emphasized that no NH_3 was produced even in the "rich" region, *i.e.* $Q^\circ_{H_2}/Q^\circ_{NO}>1$. Y_{NH_3}, Y_{N_2}, and Y_{N_2O} for the $Pt/Al_2O_3-V_2O_5$(P) catalyst were almost the same as those for the Pt/Al_2O_3 catalyst. The V_2O_5 alone was not active for the NO–H_2 reaction under the experimental conditions of the present study.

ESR spectra of all the $Pt-V_2O_5$ mixed catalysts were measured before and after the reaction at $Q^\circ_{H_2}/Q^\circ_{NO}=1.5$ or 2.0. For the $Pt-V_2O_5/Al_2O_3$ and $Pt/Al_2O_3-V_2O_5$(M) catalysts, the ESR intensity of V^{4+} ions in the used catalyst increased markedly compared with that in the fresh catalyst. For the $Pt/Al_2O_3-V_2O_5$(P), on the other hand, the ESR intensity of V^{4+} ions in the used catalyst was the same as that in the fresh catalyst. The fresh $Pt-V_2O_5$ mixed catalysts were all yellow in color. The color of the used $Pt-V_2O_5/Al_2O_3$ and $Pt/Al_2O_3-V_2O_5$(M) catalyst changed to black, but the color of the used $Pt/Al_2O_3-V_2O_5$(P) catalyst remained yellow. These data indicate that the V_2O_5 in the $Pt-V_2O_5/Al_2O_3$ and $Pt/Al_2O_3-V_2O_5$(M) catalysts was reduced during the NO–H_2 reaction in the "rich" region, *i.e.* at $Q^\circ_{H_2}/Q^\circ_{NO}=1.5$ or 2.0, while the V_2O_5 in the $Pt/Al_2O_3-V_2O_5$(P) catalyst was not reduced.

Effect of the Catalyst Weight on the NO–H_2 Reaction. The NO–H_2 reaction in the "rich" region ($Q^\circ_{H_2}/Q^\circ_{NO}=1.5$) on the Pt/Al_2O_3, $Pt-V_2O_5/Al_2O_3$, and $Pt/Al_2O_3-V_2O_5$(M) catalysts was investigated using various amounts of the catalysts. The results are shown in Figs. 3 and 4. Here, the weight of Pt in the catalyst gave the measure of the catalyst weight, since V_2O_5 was not active for the NO–H_2 reaction. Figure 3(a) shows the results of the Pt/Al_2O_3 catalyst. The maximum yield of NH_3 was attained when the Pt weight in the catalysts was *ca.* 25 μg, then Y_{NH_3} decreased gradually up to 50 μg, and it remained unchanged even with further increase of the Pt weight in catalyst. X_{NO} and X_{H_2} increased monotonically with increasing Pt weight in the catalyst, and attained 100% when the Pt weight was 50 μg. Figure 3(b) shows the results of the Pt–

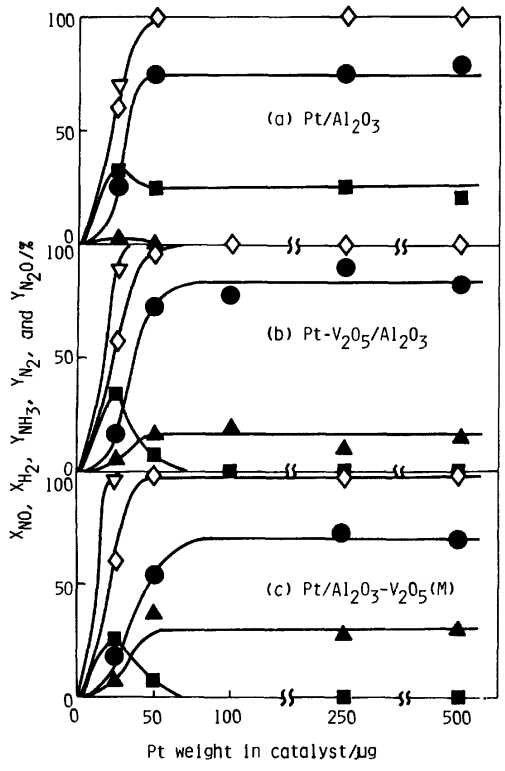

Fig. 3. Relationship between the Pt weight in the Pt/Al_2O_3 and $Pt-V_2O_5$ mixed catalysts and the activities and yields in the NO–H_2 reaction in the "rich" region ($Q^\circ_{H_2}/Q^\circ_{NO}=1.5$).

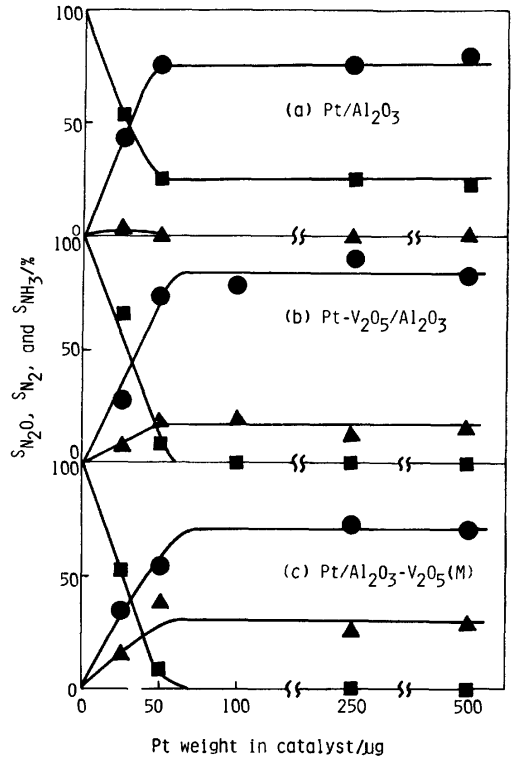

Fig. 4. Relationship between the Pt weight in the Pt/Al_2O_3 and $Pt-V_2O_5$ mixed catalysts and the selectivities in the NO–H_2 reaction in the "rich" region ($Q^\circ_{H_2}/Q^\circ_{NO}=1.5$).
■: S_{NH_3}, ●: S_{N_2}, ▲: S_{N_2O}.

V_2O_5/Al_2O_3 catalyst. Y_{NH_3} attained its maximum, which was almost the same Y_{NH_3} value as that for the Pt/Al_2O_3 catalyst when the Pt weight in the catalyst was *ca.* 25 μg, then decreased significantly with increasing Pt weight in the catalyst, and finally reached 0% when the Pt weight in the catalyst was 75 μg. The relationship between X_{NO} and the Pt weight was the same as that for the Pt/Al_2O_3 catalyst. However, X_{H_2} for the $Pt–V_2O_5/Al_2O_3$ catalyst was higher than that for the Pt/Al_2O_3 catalyst at the same Pt weight: For example, when the Pt weight in the catalyst was 25 μg, X_{H_2} for the $Pt–V_2O_5/Al_2O_3$ catalyst was about 90%, while X_{H_2} for the Pt/Al_2O_3 catalyst was about 70%. Figure 3(c) shows the results of the $Pt/Al_2O_3–V_2O_5$(M) catalyst. X_{NO}, X_{H_2}, Y_{NH_3}, Y_{N_2}, and Y_{N_2O} for the $Pt/Al_2O_3–V_2O_5$(M) were respectively in accord with those for the $Pt–V_2O_5/Al_2O_3$ catalyst. Figure 4 shows the results of S_{NH_3}, S_{N_2}, and S_{N_2O} at various catalyst weights. It is interesting to note that S_{NH_3} increased markedly with decreasing Pt weight in the catalyst in the region of low Pt weight (50 μg) and it was extrapolated to almost 100% when the Pt weight decreased to 0 μg. A similar relationship was also observed for the reaction in the "lean" region, while S_{NH_3} became 0 when the Pt weight in the catalyst was 50 μg.

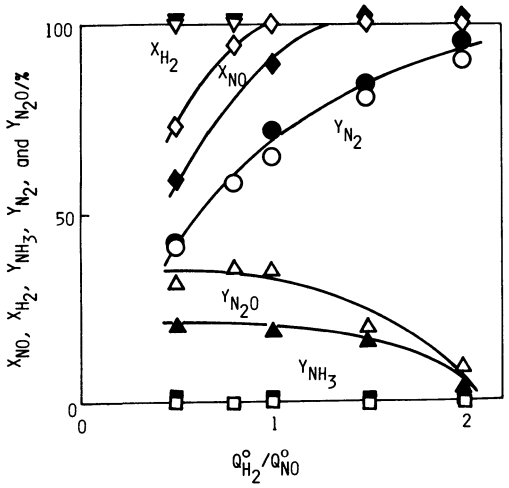

Fig. 5. Effect of the loading of V_2O_5 in the $NO–H_2$ reaction on various $Pt–V_2O_5/Al_2O_3$ catalysts.
Catalyst weight: $Pt–V_2O_5/Al_2O_3$ (9 wt% V_2O_5) = 109 mg, $Pt–V_2O_5/Al_2O_3$ (36 wt% V_2O_5) = 136 mg (Pt weight in catalysts = 500 μg). ◇, ◆: X_{NO}, ▽, ▼: X_{H_2}, □, ■: Y_{NH_3}, ○, ●: Y_{N_2}, △, ▲: Y_{N_2O}. Open symbols: $Pt–V_2O_5/Al_2O_3$ (9 wt% V_2O_5); closed symbols: $Pt–V_2O_5/Al_2O_3$ (36 wt% V_2O_5).

Effect of V_2O_5 Loading on the $NO–H_2$ Reaction on the $Pt–V_2O_5/Al_2O_3$ Catalyst. Figure 5 shows the results of the $NO–H_2$ reaction on the $Pt–V_2O_5/Al_2O_3$ catalysts with two different loadings of V_2O_5, 9 and 36 wt%. X_{H_2} was 100% irrespective of the V_2O_5 loading. X_{NO} for the $Pt–V_2O_5/Al_2O_3$ (36 wt% V_2O_5) was slightly lower than that for the $Pt–V_2O_5/Al_2O_3$ (9 wt% V_2O_5) when $Q^\circ_{H_2}/Q^\circ_{NO}$ was less than 1.5. NH_3 was not produced with either of the catalysts. Y_{N_2} was not significantly changed with the V_2O_5 loading, while Y_{N_2O} for the

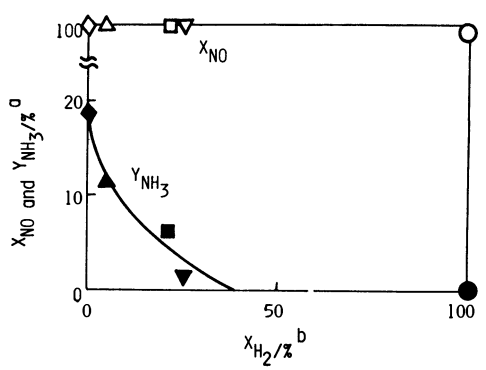

Fig. 6. Relationship between the conversion of NO (X_{NO}) and the yield of NH_3 (Y_{NH_3}) in the $NO–H_2$ reaction on various Pt–metal oxide(M) catalysts and the conversion of H_2 (X_{H_2}) in the reaction of H_2 with catalysts.
a: The $NO–H_2$ reaction, $Q^\circ_{H_2}/Q^\circ_{NO} = 1.5$, b: the reaction of H_2 with catalysts, concentration of H_2 in pulse = 3.7%. Catalyst weight; Pt/Al_2O_3 = 100 mg, Pt/Al_2O_3–metal oxide(M) = 200 mg (Pt weight in catalysts = 500 μg). ◇, ◆: Pt/Al_2O_3, △, ▲: $Pt/Al_2O_3–SnO_2$(M), □, ■: $Pt/Al_2O_3–WO_3$(M), ▽, ▼: $Pt/Al_2O_3–MoO_3$(M), ○, ●: $Pt/Al_2O_3–V_2O_5$(M). Open symbols: X_{NO}, closed symbols: Y_{NH_3}.

$Pt–V_2O_5/Al_2O_3$ (36 wt% V_2O_5) was slightly lower than that for the $Pt–V_2O_5/Al_2O_3$ (9 wt% V_2O_5).

The $NO–H_2$ Reaction on Various Pt/Al_2O_3–Metal Oxide(M) Catalysts. Figure 6 shows the results of the $NO–H_2$ reaction on various Pt/Al_2O_3–metal oxide(M) catalysts at $Q^\circ_{H_2}/Q^\circ_{NO} = 1.5$; under this condition, X_{NO} was 100% for all of the catalysts and the metal oxide itself was inactive for either the $NO–H_2$ reaction or the reaction of H_2 (or NH_3) with the catalyst. Here, the results are represented as a relationship between Y_{NH_3} in the $NO–H_2$ reaction and X_{H_2} for the reaction of H_2 with the catalyst. As shown, Y_{NH_3} for the $NO–H_2$ reaction decreased monotonically with increasing X_{H_2} for the reaction of H_2 with the catalyst and it was 0% for the $Pt/Al_2O_3–V_2O_5$(M) catalyst.

The $NO–NH_3$ Reaction, and the Reaction of H_2 or NH_3 with the Catalysts. Table 1 shows the results of the $NO–NH_3$ reaction and those of the reaction of H_2 or NH_3 with the catalysts. These experiments were

a) Pt weight in catalyst = 500 μg. b) The inlet NO/NH_3 ratio = 1/1 (the inlet concentration of NO in pulse = 2.5%). c) The reaction of H_2 with the catalyst; the inlet concentration of H_2 in pulse = 3.7%. d) The reaction of NH_3 with the catalyst; the inlet concentration of NH_3 in pulse = 2.5%.

Table 2. Conversion of H_2 in the reaction of H_2 with various Pt-V_2O_5 mixed catalysts at 573 K

Catalyst	Pt weight	V_2O_5 weight	X_{H_2} a)
	μg	mg	%
Pt-V_2O_5/Al_2O_3(9 wt%V_2O_5)	25	0.5	12
Pt-V_2O_5/Al_2O_3(36 wt%V_2O_5)	25	1.8	14
Pt/Al_2O_3-V_2O_5(M)	25	5.0	19

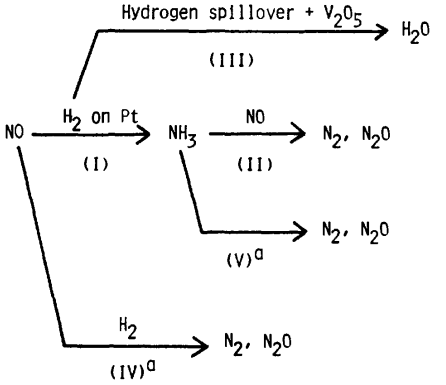
a) The concentration of H_2 in pulse=10% (22 μmol).

made because these reactions are considered to be important steps in the NO-H_2 reaction. As shown in Table 1, X_{NO} in the NO-NH_3 reaction was almost constant for the Pt/Al_2O_3, Pt-V_2O_5/Al_2O_3, Pt/Al_2O_3-V_2O_5(M), and Pt/Al_2O_3-V_2O_5(P) catalysts, while X_{NO} for the V_2O_5 was considerably lower than those for the former catalysts. This indicates that the activity of the Pt/Al_2O_3 catalyst for the NO-NH_3 reaction is not markedly increased by the addition of V_2O_5. X_{H_2} in the reaction of H_2 with the catalyst was 100% for both the Pt-V_2O_5/Al_2O_3 and Pt/Al_2O_3-V_2O_5(M) catalysts, while it was 0% with the Pt/Al_2O_3, Pt/Al_2O_3-V_2O_5(P), or V_2O_5 catalyst. Table 2 also shows the results of X_{H_2} in the reaction of H_2 with the catalyst; the catalyst weight was considerably decreased in order to decrease the value of X_{H_2}. As shown, X_{H_2} was almost constant for the Pt-V_2O_5/Al_2O_3 (9 wt% V_2O_5), Pt-V_2O_5/Al_2O_3 (36 wt% V_2O_5), and Pt/Al_2O_3-V_2O_5(M) catalysts. These data indicate that the V_2O_5 in the Pt-V_2O_5/Al_2O_3 and Pt/Al_2O_3-V_2O_5(M) catalysts was reduced by H_2, while the V_2O_5 in the Pt/Al_2O_3-V_2O_5(P) or V_2O_5 catalyst was not reduced. The data of X_{NH_3} for the reaction of NH_3 with the catalyst (Table 1) indicate that this reaction occurred with the Pt-V_2O_5/Al_2O_3 catalyst, but NH_3 was not decomposed very much on the Pt/Al_2O_3, Pt/Al_2O_3-V_2O_5(M), Pt/Al_2O_3-V_2O_5(P), or V_2O_5 catalyst.

Discussion

Selective Reduction of NO with H_2 on the Pt-V_2O_5/Al_2O_3 Catalyst. A large amount of NH_3 is formed in the NO-H_2 reaction on Pt/Al_2O_3 catalyst.[32] The production of a large amount of NH_3 has also been confirmed in the NO-H_2-O_2 reaction on Pt/Al_2O_3 catalyst in the "rich" region.[31] These results are undesirable from the viewpoint of the selective reduction of NO to N_2 or N_2O. As shown in Fig. 2, for the NO-H_2 reaction on the Pt/Al_2O_3 catalyst, also, a significant amount of NH_3 was produced in the "rich" region of the reactant ($Q^\circ_{H_2}/Q^\circ_{NO}>1$), and the yield of NH_3 increased significantly with increasing $Q^\circ_{H_2}/Q^\circ_{NO}$. This is in accordance with the behavior in the NO-H_2 reaction[32] and in the NO-H_2-O_2 reaction[31] on Pt-Al_2O_3 catalyst. It is interesting that no NH_3 was produced in the NO-H_2 reaction on the Pt-V_2O_5/Al_2O_3 catalyst even in the "rich" region of the reactants; in addition, the conversion of NO was 100%. This behavior of the NO-H_2 reaction on the Pt-V_2O_5/Al_2O_3 catalyst is similar to that of the reaction of the synthetic exhaust gas on a three-way catalyst containing a metal oxide.[28] This indicates that the action of the added metal oxide for the selective reduction of NO to N_2 or N_2O can also be observed in the NO-H_2 reaction on Pt/Al_2O_3 catalyst containing V_2O_5—a system which is much simpler than the real three-way catalyst system.

Reaction Scheme. Although the scheme of the NO-H_2 reaction on the Pt/Al_2O_3 or Pt-V_2O_5/Al_2O_3 has not been well established, the previous data of the NO-H_2 reaction and NO-NH_3 reaction on Pt/Al_2O_3 and metal oxide catalysts lead to the reaction steps shown in Scheme I. Here, Step I is a process where NH_3



Scheme 1. Mechanism of the NO-H_2 reaction on the Pt/Al_2O_3 and Pt-V_2O_5/Al_2O_3 catalysts. a: Step IV or V does not play an important role in the NO-H_2 reaction under the conditions of this study.

is produced by the NO-H_2 reaction on Pt.[32] Step II is a process where N_2 or N_2O is formed by the NO-NH_3 reaction on Pt/Al_2O_3[38,39] and V_2O_5.[40,41] Step III is a process where V_2O_5 is reduced by the reaction with hydrogen spilled over from Pt.[42-44] Step IV is a process where NO is directly reduced to N_2 or N_2O without the formation of NH_3 as an intermediate, and it is observed in the NO-H_2 reaction on some metal oxides.[41,45-47] Step V is a process where NH_3 is decomposed to N_2 on Pt or is oxidized by V_2O_5 to N_2 or N_2O and the latter is observed on Pt-V_2O_5/$BaSO_4$[48] and metal oxides.[49] Scheme 1 merely indicates some possible steps for the NO-H_2 reaction on the Pt/Al_2O_3, and Pt-V_2O_5/Al_2O_3 catalysts; therefore, it is necessary to investigate which of these Steps I—V play the main role in the NO-H_2 reaction on the Pt/Al_2O_3 and Pt-V_2O_5/Al_2O_3 catalysts.

First, the scheme of the NO-H_2 reaction on the Pt/Al_2O_3 catalyst is discussed: Step III cannot play an important role on the Pt/Al_2O_3 catalyst because of the absence of the metal oxide. Step V is also negligible, since the decomposition of NH_3 did not occur on the Pt/Al_2O_3 (Table 1). According to Scheme 1, the primary products of the NO-H_2 reaction are determined by the relative rate of Step I to that of Step IV. From the results of S_{NH_3}, S_{N_2}, and S_{N_2O} shown in Fig. 4(a), Step IV is not considered to play a significant role in the NO-H_2 reaction on the Pt/Al_2O_3 catalyst. This is because S_{NH_3} is extrapolated to almost 100% when the Pt weight is decreased to 0. In other words, NH_3 formed by Step I is the main primary product of the NO-H_2 reaction on the Pt/Al_2O_3 catalyst. The formation of NH_3 for the reaction even in the "lean"

region supports the validity of this conclusion. As the catalyst weight increases, Y_{NO} and S_{N_2} increase, while S_{NH_3} decreases [Fig. 4(a)]. According to Scheme 1, this is ascribable to the formation of N_2 by the reaction of the unreacted NO with the formed NH_3, that is, Step II. It is therefore considered that Steps I and II proceed successively in the NO–H_2 reaction on the Pt/Al_2O_3 catalyst. This agrees with the previous inference that NH_3 is an important intermediate for the reduction of NO in the synthetic exhaust emissions[50] or for the NO–H_2–O_2 reaction[31] on the Pt/Al_2O_3 catalyst.

Next, the scheme of the NO–H_2 reaction on the Pt–V_2O_5/Al_2O_3 catalyst is discussed. As mentioned above, the V_2O_5 in the Pt–V_2O_5/Al_2O_3 and Pt/Al_2O_3–V_2O_5(M) catalysts was reduced from V^{5+} to V^{4+} during the NO–H_2 reaction in the "rich" region; and these catalysts were effective for the selective reduction of NO to N_2 or N_2O in the "rich" region. On the other hand, the V_2O_5 in the Pt/Al_2O_3–V_2O_5(P) was not reduced during the NO–H_2 reaction; and this catalyst was not effective for the selective reduction of NO. From these results coupled with the data of the reaction of H_2 with the catalyst (Table 1), Step III is considered to proceed readily in the NO–H_2 reaction on the Pt–V_2O_5/Al_2O_3 and Pt/Al_2O_3–V_2O_5(M) catalysts. Similar to the case of the Pt/Al_2O_3 catalyst, S_{NH_3} for the Pt–V_2O_5/Al_2O_3 and Pt/Al_2O_3–V_2O_5(M) catalysts is extrapolated to almost 100% when the catalyst weight decreases to 0. This indicates that Step IV does not play an important role in the NO–H_2 reaction on the Pt–V_2O_5/Al_2O_3 or Pt/Al_2O_3–V_2O_5(M) catalyst; in other words, NH_3 is the main primary product of the NO–H_2 reaction. From the data of the reaction of NH_3 with the catalyst (Table 1), Step V can take place for the Pt–V_2O_5/Al_2O_3, but it proceeds on neither the Pt/Al_2O_3–V_2O_5(M) nor Pt/Al_2O_3–V_2O_5(P) catalyst. However, Step V also does not play an important role in the selective reduction of NO to N_2 or N_2O.[51]

Rates of Steps I and III. As mentioned above, the NO–H_2 reaction on the Pt–V_2O_5/Al_2O_3 catalyst is composed of Steps I, II, and III, and the consumption of hydrogen by Step III proceeding competitively with Step I at the upper part of the catalyst bed is the main factor for the selective reduction of NO in the "rich" region. According to Scheme 1, if the rate of Step III is much slower than that of Step 1, an excess amount of NH_3 is formed in Step I. Even if a part of the excess NH_3 is converted to N_2 or N_2O in Step II, a considerable amount of NH_3 is exhausted from the catalyst bed. According to Scheme 1, also, if the rate of Step III is much faster than that of Step I, the amount of NH_3 produced in Step I is not enough to convert NO completely to N_2 or N_2O in Step II; therefore, the unreacted NO is emitted from the outlet of the catalyst bed. If the rate of formation of NH_3 in Step I is successfully controlled by Step III, the NH_3 produced in Step I reacts with the unreacted NO to form N_2 or N_2O selectively (Step II). Therefore, it is important to investigate the rates of Steps I and III in terms of the composition of the reactants and structures of the catalysts. Although we have not conducted experiments to determine the rates of Steps I and III, $Q_{H_2}(I)$ and $Q_{H_2}(III)$ defined by Eqs. 9 and 10 would be useful as measures of the rates of Steps I and III.

$$Q_{H_2}(I) = Q^\circ_{NO}(5/2\ Y_{NH_3} + Y_{N_2} + 1/2\ Y_{N_2O}), \quad (9)$$

$$Q_{H_2}(III) = Q^\circ_{H_2} \cdot X_{H_2} - Q_{H_2}(I). \quad (10)$$

Each coefficient of Y_{NH_3}, Y_{N_2}, or Y_{N_2O} in Eq. 9 is determined by the stoichiometry of the formation of each product. As is evident from Eqs. 9 and 10, $Q_{H_2}(I)$ and $Q_{H_2}(III)$ are respectively the amounts of H_2 consumed by Steps I and III during the NO–H_2 reaction. Under the experimental conditions shown in Figs. 1, 2, and 5, X_{H_2} is 100%; therefore, Eq. 10 leads to Eq. 11 under the stated conditions.

$$Q_{H_2}(III) = Q^\circ_{H_2} - Q^\circ_{H_2}(I). \quad (11)$$

$Q_{H_2}(I)$ and $Q_{H_2}(III)$ are calculated from the data of the NO–H_2 reaction shown in Figs. 1, 2, and 5. As shown in Figs. 7 and 8, $Q_{H_2}(I)$ for the Pt/Al_2O_3 is almost equal to $Q^\circ_{H_2}$ at any $Q^\circ_{H_2}/Q^\circ_{NO}$, while $Q_{H_2}(III)$ for the Pt/Al_2O_3 is very small, which means that almost all of the H_2 in the reactants are consumed by Step I. This is reasonable since Step III occurs only very slightly on the Pt/Al_2O_3 catalyst. As for the results of the Pt–V_2O_5/Al_2O_3 catalysts, $Q_{H_2}(I)$ is almost equal to $Q^\circ_{H_2}$ in the "lean" region of the reactants ($Q^\circ_{H_2}/Q^\circ_{NO}<1$). Correspondingly, the value of $Q_{H_2}(III)$ is very small in this region. In other words, in the "lean" region of the reactants, little H_2 is consumed in Step III but most of the H_2 is consumed in Step I. In the "rich" region of the reactants ($Q^\circ_{H_2}/Q^\circ_{NO}>1$), $Q_{H_2}(I)$ for the Pt–V_2O_5/Al_2O_3 catalyst is almost independent of $Q^\circ_{H_2}/Q^\circ_{NO}$, while $Q_{H_2}(III)$ increases markedly with increasing $Q^\circ_{H_2}/Q^\circ_{NO}$. This means that excess H_2 in the "rich" region is almost selectively removed by Step III, and hence the formation of excess NH_3 in Step I is suppressed. Such changes of $Q_{H_2}(I)$ and $Q_{H_2}(III)$ with $Q^\circ_{H_2}/Q^\circ_{NO}$ for the Pt–V_2O_5/

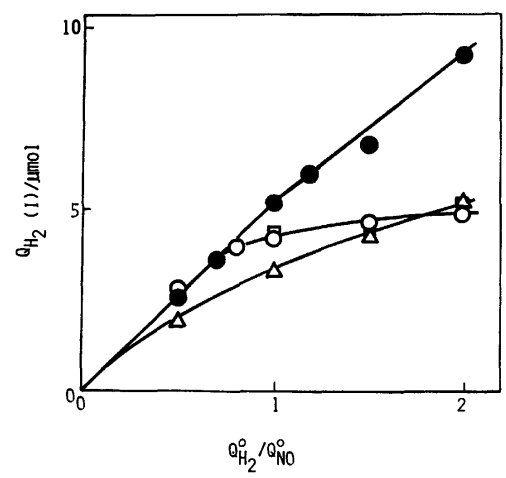


Fig. 7. Consumption of H_2 in Step I in the NO–H_2 reaction on the Pt/Al_2O_3 and various Pt–V_2O_5 mixed catalysts.
Catalyst weight: Pt/Al_2O_3=100 mg, Pt–V_2O_5/Al_2O_3 (9 wt% V_2O_5)=109 mg, Pt–V_2O_5/Al_2O_3 (36 wt% V_2O_5)=136 mg, Pt/Al_2O_3–V_2O_5(M)=200 mg (Pt weight in catalysts=500 μg). ●: Pt/Al_2O_3, ○: Pt–V_2O_5/Al_2O_3 (9 wt% V_2O_5), □: Pt–V_2O_5/Al_2O_3 (36 wt% V_2O_5), △: Pt/Al_2O_3–V_2O_5(M).

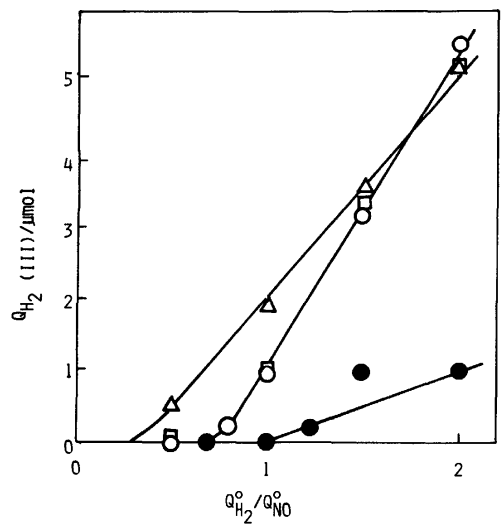

Fig. 8. Consumption of H_2 in Step III in the NO–H_2 reaction on the Pt/Al_2O_3 and various Pt–V_2O_5 mixed catalysts.
Catalyst weight: Pt/Al_2O_3=100 mg, Pt–V_2O_5/Al_2O_3 (9 wt% V_2O_5)=109 mg, Pt–V_2O_5/Al_2O_3 (36 wt% V_2O_5)=136 mg, Pt/Al_2O_3–V_2O_5(M)=200 mg (Pt weight in catalysts=500 μg). ●: Pt/Al_2O_3, ○: Pt–V_2O_5/Al_2O_3 (9 wt% V_2O_5), □: Pt–V_2O_5/Al_2O_3 (36 wt% V_2O_5), △: Pt/Al_2O_3–V_2O_5(M).

Al_2O_3 catalyst are desirable from the viewpoint of the selective reduction of NO. The reason for this is that, in the "lean" region, a reducing agent (H_2) is effectively used for the reduction of NO, whereas, in the "rich" region, an excess amount of reducing agent is removed by Step III and the formation of excess NH_3 is suppressed. In this manner, selective reduction of NO to N_2 or N_2O is warranted for a broad composition of the reactants. As shown in Fig. 7, Q_{H_2}(I) for the Pt–V_2O_5/Al_2O_3 is almost independent of $Q^{\circ}_{H_2}/Q^{\circ}_{NO}$ in the "rich" region of the reactants. This is in accordance with the behavior of the reduction of NO in the NO–H_2–O_2 reaction on Pt/Al_2O_3 catalyst.[31] According to the computer simulation of the NO–H_2–O_2 reaction on the Pt/Al_2O_3 catalyst,[31] the rate of the reduction of NO with H_2 is only slightly decreased even if the amount of adsorbed hydrogens on Pt surface is decreased by the addition of O_2 to the system.

(Received October 2, 1981)

Electric birefringence (EB) and electric linear dichroism (ED) of a sonicated DNA ($M_w = 1.24 \times 10^5$) sample were studied in solutions containing various additives at 7 °C. Signals of EB at 535 nm and of ED at 260 nm were measured in the electric field range 0—*ca.* 19 kV/cm. Both signals obeyed the Kerr law at low field strengths ($E <$ *ca.* 5 kV/cm) and showed a saturating trend at high fields. The mean relaxation time, $\langle\tau\rangle_{EB}$, obtained from the decay of EB, was field-strength dependent, indicating the effect of the polydispersity of sDNA. The field strength dependence of steady-state EB signals was nearly identical with that of ED signals. These results were analyzed with the "classical" orientation functions derived for mono- and polydisperse systems. The optical anisotropy factor ($g_3 - g_1$) of sDNA was *ca.* -2.0×10^{-2}, while the average angle between the orientation axis of sDNA and the transition moment of the base pair was *ca.* 70° at 260 nm. The electric moment of sDNA was influenced by ionic strength, counterions, and other additives. The weight-average length l_w of sDNA decreased in this order: 0.2 mM NaCl**>9-aminoacridinium chloride ($P/D = 10$)>1.0 mM NaCl>0.33 mM $MgCl_2$> 20 vol% glycerol. Values of l_w/base pair were 2.8—2.7 Å in the glycerol and 3.6—3.4 Å in the 1.0 mM NaCl.

Electric dipole moments of DNA in solutions have been investigated by various methods, *e.g.*, electric birefringence (EB),[1-16] electric dichroism (ED),[3-5,17-27] and dielectric relaxation.[28-33] Both EB and ED are powerful techniques for studying the optical, electric, and hydrodynamic properties of DNA in aqueous solutions. With reversing-pulse electric birefringence, Greve and Heij[7] and Yamaoka and Matsuda[15] recently demonstrated that DNA fragments have no permanent dipole moment. Hogan *et al.*[21] found that an apparent dipole moment of DNA is inversely proportional to the square-root of ionic strength. There have been numerous observations that the electro-optical property of DNA is very sensitive to its molecular weight and to external conditions such as ionic strength and small molecular weight additives in solutions.[5,11,13-16,19,21,23] Stellwagen[16] recently studied the electro-optical and hydrodynamic properties of restriction enzyme fragments of DNA whose lengths vary widely, exposing a number of interesting points to be clarified. The decay process of birefringence, for example, could not be explained by a monodisperse system when the DNA fragments are larger than 217 base pairs (bp). The previous studies[1-33] are unanimous in pointing out that native DNA in solution can be oriented by an external electric field, but they also indicate that the nature of the electric moments responsible for field orientation remains to be clarified. Sustained efforts are needed for resolving this problem. For this purpose, the intrinsic effects of the polydispersity of DNA length and the flexibility of DNA chain, and the external effects of the various ionic additives must be considered on a systematic basis.

The present study is the first of a series of work on the electro-optical properties of DNA and related biopolymers. In this paper, the electric field strength dependence of steady-state signals of EB and ED was examined with a sonicated rodlike DNA (sDNA) sample under various ionic conditions. The decay curve of the EB signal was also measured an a function of field strength. This is a result that cannot be explained if the sample is monodisperse. Hence, tan analytical method for the polydisperse system was utilized to compare the observed EB and ED data with theoretical orientation functions. The length of sDNA in solutions with various additives was not constant, but was influenced by external factors. The applicability of the "classical" mixed orientation function $\Phi(\beta, \gamma)$[34] was tested for the sDNA system.

** 1 mM = 10^{-3} mol dm^{-3}.

Experimental

Materials. A calf thymus DNA sample was purchased from Worthington Biochemical Corp (USA). The sonication procedure for sDNA was described elsewhere.[26] The protein content was determined to be less than 0.01 mg/1 mg DNA by the microbiuret method. The weight-average molecular weight was determined to be *ca.* 1.24×10^5 by ultracentrifugation.[26] (The ratio of the weight-average to the number-average molecular weight for sonicated DNA samples is known to be in the range between 1.02 and 1.11.[35]) The cationic dye, 9-aminoacridinium chloride (AA), was described in previous papers.[36-38] Other chemicals used were of reagent grade.

Preparation of Sample Solutions. The stock sDNA solution (*ca.* 1 mg cm^{-3}) containing *ca.* 1 mM NaCl was prepared in an ice bath. The solutions were unbuffered to avoid any effect of buffer cations.[37] Each stock DNA solution was diluted ten-fold and dialyzed against NaCl or $MgCl_2$ solutions of desired ionic strength at 4 °C for *ca.* 48 h. The concentration of AA was determined by using a molar absorption coefficient, ε, of 1.03×10^4 M^{-1} cm^{-1} at 401 nm.[37] The sDNA–AA solution was prepared by adding the dye solution to the sDNA solution at a molar mixing ratio of DNA-phosphate residue-to-dye (P/D) of 10, the final concentration of AA being 10 μM. The concentration of sDNA solution was determined photometrically with a molar absorption coefficient of 6400 M^{-1} cm^{-1} at 258.5 nm.[39] The sDNA in a 20 vol% glycerol–0.8 mM NaCl solution was prepared in an ice bath by adding glycerol to the aqueous sDNA solution. The hyperchromicity of the denatured sDNA solution containing either 1.0 mM NaCl or 0.2 mM NaCl was higher than 30%.[39,40] Absorption spectra were measured at 7 °C on a

Hitachi EPS-3T double-beam recording spectrophotometer equipped with a thermostated cell holder.

Measurements of Electric Birefringence and Electric Linear Dichroism. An EB apparatus constructed in our laboratory was used.[41] The voltage and the duration of a single square-wave electric pulse field were continuously varied between 0.248 and 3.24 kV and between *ca.* 40 and 150 μs, respectively. The instrumental response time for a transient birefringence signal was usually faster than 0.5 μs; this was checked with nitrobenzene.[42] The linear response between the transmitted light intensity and the output voltage generated across a load resistor was verified by testing the Malus law.[42] In order to determine the sign of the birefringence and to increase the sensitivity of the signal, a quarter-wave plate was placed before the analyzer. The phase retardation was measured at 535 nm and at 7 °C with the procedure described previously.[4,5,42] An electric linear dichroism apparatus was also built in our laboratory and has been described in detail.[24,38] Both the parallel dichroism ($\Delta A_{\parallel}/A$) and the perpendicular dichroism ($\Delta A_{\perp}/A$)[24,25,38] were measured at 7 °C and at 260 nm. The voltage and the duration of a single square-wave electric pulse field were varied between 0.455 and 3.91 kV and between 50 and 200 μs. The linear response between the photocurrent and the incident light intensity was checked with a metal mesh of a known absorbance (= 1.20),[24] the deviation being always kept less than 1%. For both EB and ED, optical path lengths of the "Kerr" cell were 2 cm (electrode gap 0.33 cm) and 1 cm (electrode gap 0.207 cm).[38] Two electric pulses were usually applied to each fresh solution, but the sample solution was discarded after a single high-field pulse to avoid denaturation of sDNA.

Method of Data Analysis

Analysis of Steady-state. For a monodisperse system, the steady-state birefringence (Δn) of a rodlike polymer of axial symmetry (the 3-axis) may be given as[34]

$$\Delta n = \frac{\lambda}{d}\cdot\frac{\delta}{2\pi} = \frac{2\pi C_v}{n}(g_3-g_1)\Phi, \tag{1}$$

where λ is the wavelength of light *in vacuo*, d is the path length, δ is the phase retardation of solution, n is the refractive index of the solution, C_v is the volume fraction of solute, (g_3-g_1) is the optical anisotropy factor, and Φ is the orientation function. Correspondingly, the steady-state reduced dichroism ($\Delta A/A$) is given as[4,38,43]

$$\frac{\Delta A}{A} = \frac{A_{\parallel}-A_{\perp}}{A} = \frac{\Delta A_{\parallel}}{A} - \frac{\Delta A_{\perp}}{A} = \frac{3}{2}(3\cos^2\theta - 1)\Phi, \tag{2}$$

where $\Delta A_{\parallel}/A$ and $\Delta A_{\perp}/A$ are the specific parallel and perpendicular dichroisms, respectively. A is the isotropic absorbance of the solution in the absence of an electric field. θ is the angle between the transition moment of a chromophoric group and the orientation axis of sDNA.

For a polydisperse system, the molecular weight (or the length for rodlike molecules) distribution of a polymer sample must be considered. For this purpose, the Schulz-Zimm function was assumed;[44,45] then, the number-average length distribution density function $f_n(l)$ is given as[38]

$$f_n(l) = \frac{(ym_0)^k}{\Gamma(k)} l^{k-1}e^{-ym_0 l}, \tag{3}$$

where y and k are related to the number-average and the weight-average molecular weights (M_n and M_w) as $M_n = k/y$ and $M_w = (k+1)/y$. The conformation of sDNA is a rigid double-stranded helix and is approximated by a cylindrical model. The molecular weight M of an sDNA molecule may be equated to $m_0 l$, where l is the contour length and m_0 is the molecular weight per unit length. The ratio M_w/M_n may be equated to the ratio of weight-average length to number-average length, *i.e.*, l_w/l_n. According to the analytical method devised for the polydisperse system,[27] Eqs. 1 and 2 may be expressed in terms of the sum of the contributions from component species of heterogeneous lengths, for which the length distribution density function is defined by Eq. 3:[38]

$$\Delta n = \frac{2\pi(g_3-g_1)\bar{C}_v}{n}\cdot\frac{\int_{L_1}^{L_2} l f_n(l)\Phi dl}{\int_{L_1}^{L_2} l f_n(l) dl} \equiv \frac{2\pi(g_3-g_1)\bar{C}_v}{n}\langle\Phi\rangle_w, \tag{4}$$

and similarly,

$$\frac{\Delta A}{A} \equiv \frac{3}{2}(3\cos^2\theta - 1)\langle\Phi\rangle_w, \tag{5}$$

where $\bar{C}_v$ is the total volume of all solute molecules with various chain lengths divided by the volume of solution and $\langle\Phi\rangle_w$ is the weight-average orientation function. Both L_1 and L_2 are the lower and upper limits of l.

The field strength dependence of the steady-state EB or ED for many DNA systems[5,13,14,16,18,19,21,25,27] has been described by the "classical" orientation function, $\Phi(\beta,\gamma)$, where $\beta = \mu E/kT$ and $\gamma = \Delta\alpha E^2/2kT$ (≥ 0).[34] Notations are the same as those in Refs. 34 and 38.

Analysis of Decay Process. The electric birefringence-average relaxation time $\langle\tau\rangle_{EB}$ and initial slope $\langle S\rangle_{EB}$ of the decay process of EB for the polydisperse system are given as[27,46,47]

$$\langle\tau\rangle_{EB} = \int_0^{\infty}\frac{\Delta n(t)}{\Delta n(0)}dt = \frac{\int_{L_1}^{L_2}\tau(l) l f_n(l)\Phi dl}{\int_{L_1}^{L_2} l f_n(l)\Phi dl}, \tag{6}$$

$$\langle S\rangle_{EB} = -\int_{L_1}^{L_2}\tau(l)^{-1} l f_n(l)\Phi dl \Big/ \int_{L_1}^{L_2} l f_n(l)\Phi dl, \tag{7}$$

where $\Delta n(t)$ is the birefringence at time t after removal of an electric field, $\Delta n(0)$ is the birefringence of the steady-state. $\tau(l)$ is the relaxation time for a cylindrical molecule of length l and may be calculated from the Broersma equation:[48]

$$\tau(l) = \frac{\pi\eta_0 l^3}{18kT}\left[\ln\frac{l}{b} - 1.57 + 7\left(\frac{1}{\ln(l/b)} - 0.28\right)^2\right]^{-1}, \tag{8}$$

where η_0 is the viscosity of the solvent and b is the radius of the cylinder.

At infinitely high field strength, Φ approaches unity.[34,43] Then, Eqs. 6 and 7 become the weight-average relaxation time,

$$\langle\tau\rangle_w = \int_{L_1}^{L_2}\tau(l) l f_n(l) dl \Big/ \int_{L_1}^{L_2} l f_n(l) dl, \tag{9}$$

and the weight-average initial slope,

$$\langle S\rangle_w = -\left\langle\frac{1}{\tau}\right\rangle_w = -\int_{L_1}^{L_2}\tau(l)^{-1} l f_n(l) dl \Big/ \int_{L_1}^{L_2} l f_n(l) dl, \tag{10}$$

respectively. These quantities are independent of the electric parameters, β and γ, since the orientation function is not involved. Once $\langle\tau\rangle_w$ and $\langle S\rangle_w$ are obtained from the experimental data, the ratio l_w/l_n and the length l_w can be evaluated;[27] with these values, the most likely Schulz-Zimm function may be determined.

Results and Discussion

Electric Field Strength Dependence of the Steady-state Birefringence and Linear Dichroism. Figure 1 shows the field strength dependence of the birefringence ($\Delta n/C$) of sDNA in solutions with various additives. Values of $\Delta n/C$ tend to saturate at high field strengths. The sign of Δn is negative in all cases. No positive or peculiar signal of Δn could be observed at low fields, contrary to the report by Colson *et al.*[6] At a given field strength, *e.g.*, 10 kV/cm, values of $-\Delta n/C$ of sDNA decrease with solvent compositions in this order: 0.2 mM NaCl>AA(P/D=10)–1.0 mM NaCl>1.0 mM NaCl>0.33 mM $MgCl_2$>20 vol% glycerol–0.8 mM NaCl. This result does not necessarily indicate a difference in the degree of orientation of sDNA in solutions with various additives. The birefringence at an electric field strength and at a wavelength is given by the product of the orientation factor and the optical factor (*cf.* Eq. 1). Hence, the different values of Δn arise from the differences in these factors. In order to obtain values of (g_3-g_1), μ, and $\Delta\alpha$ of sDNA, the experimental points will be compared with the theoretical orientation functions (see Discussion, together with Fig. 5).

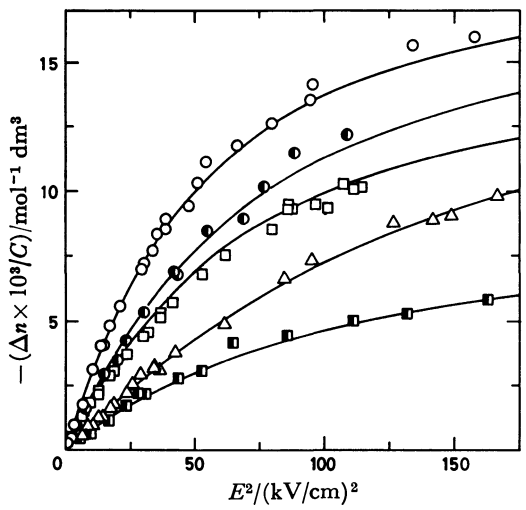

Fig. 1. The field strength dependence of the birefringence ($\Delta n/C$) of sDNA at 535 nm and at 7 °C in solutions with various additives. The residue concentration of sDNA (C) and the concentration of additives are: C=0.165 mM and [NaCl]=0.2 mM (○); C=0.10 mM, [AA]=0.01 mM, and [NaCl]=1.0 mM (◐); C=0.171 mM and [NaCl]=1.0 mM (□); C=0.22 mM and [$MgCl_2$]=0.33 mM (△); C=0.10 mM, [NaCl]=0.8 mM, and 20 vol% glycerol (◧). Symbols indicate experimentally determined points, while solid curves are the theoretical ones calculated by using the orientation function $\langle\Phi(\beta,\gamma)\rangle_w$ for the polydisperse system.

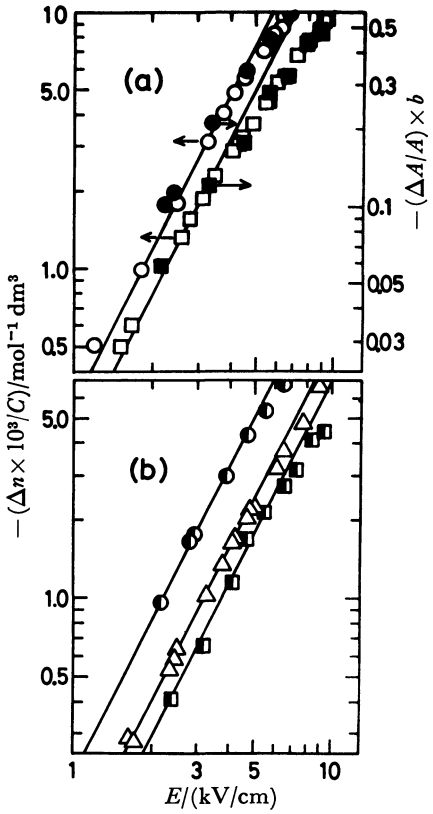

Fig. 2. The double-logarithmic plots of the field-strength dependence of both $\Delta n/C$ and $\Delta A/A$ of sDNA in the low field strength region. The slope of the straight lines is 2. The right ordinate refers to values of $\Delta A/A$ of sDNA at 260 nm and at 7 °C in 0.2 mM NaCl (●), for which b=1.1, and in 1.0 mM NaCl (■) for which b=1.0. Other symbols and conditions are the same as in Fig. 1.

Figure 2 shows the double logarithmic plots of $\Delta n/C$ against E. In the low field strength region, the experimental points follow a straight line with a slope of 2; thus, the Kerr law holds for sDNA in various solvents (E<5 kV/cm). The field strength dependence of reduced dichroism ($\Delta A/A$) of sDNA in 0.2 and 1.0 mM NaCl solutions is also shown in Fig. 2(a) (closed symbols). The sign of $\Delta A/A$ is negative for both cases. In the same low field strength region (E<5 kV/cm), the Kerr law holds for sDNA. This quadratic field strength dependence of EB and ED has been predicted by the electro-optical theories for molecules with cylindrical symmetry.[34,43,49] Hence, the dependence of EB and ED on the first power of electric field in the low field region, as was observed by Sokerov and Weill for the aqueous sDNA solution,[12] must be considered rather anomalous. From our result in Fig. 2, it is now verified that the Kerr law holds for the low molecular weight, rodlike sDNA in diverse cases. The fact that the straight lines of $\Delta n/C$ and $\Delta A/A$ in Fig. 2(a) are superimposed upon each other is reasonable, considering that the orientation function Φ in Eqs. 1 and 2 must be the same for a given sDNA solution provided that the backbone conformation of the sDNA molecule is rigid.

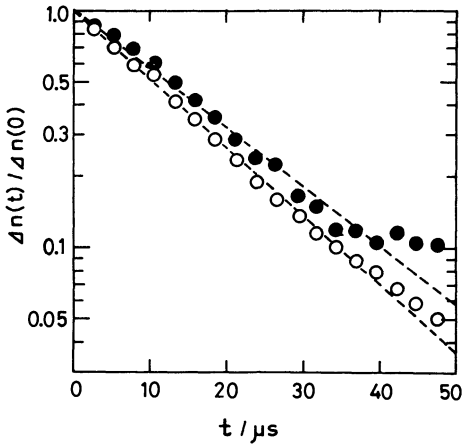

Fig. 3. The semi-logarithmic plots of the field-free decay curves of EB for sDNA in a 20 vol% glycerol–0.8 mM NaCl solution at a low field strength (E=6.45 kV/cm) (●) and at a high field strength (E=10.5 kV/cm) (○). Dashed lines (------) are straight lines.

Electric Field Strength Dependence of the Relaxation Time of sDNA. As a precautionary example, two normalized decay curves of birefringence, $(\Delta n(t)/\Delta n(0))$, are shown in Fig. 3 for sDNA in a 20 vol% glycerol–0.8 mM NaCl solution. The field-free decay curve (open circles) of EB after removal of a high electric field yields a nearly straight line (dashed line) on a semilogarithmic plot, whereas the curve displayed by a solution subjected to a low electric field (filled circles) deviates slightly from the straight line, being larger than the former. This example clearly indicates that a single decay curve of EB at a relatively high electric field may often result in an ambiguity over whether or not a polymer system is monodisperse. In order to determine whether the polymer system is polydisperse, the electric field strength dependence of relaxation times must be examined. The field-free relaxation time of sDNA from a low electric field should be larger than that of sDNA from a high electric field, if the sample is polydisperse.

Figure 4 shows the electric field dependence of birefringence-average relaxation time $\langle\tau\rangle_{EB}$. The persistence length of DNA is generally 1.5×10^3 Å in 5 mM NaCl[50] or 1.3×10^3 Å in 30 mM NaCl.[51] These values are much larger than the contour length of an sDNA molecule of 1.24×10^5 daltons. Therefore, the present sDNA sample is probably a rigid rod with little

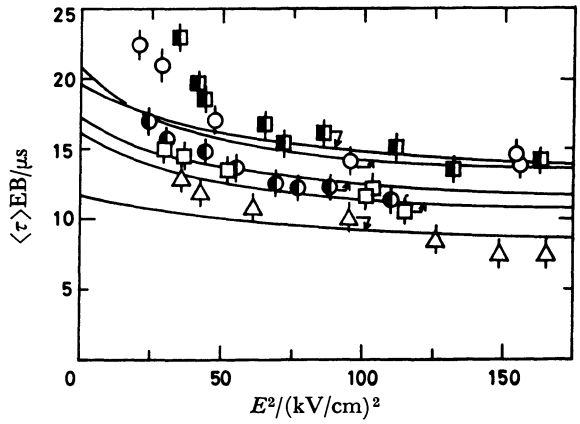

Fig. 4. The dependence of birefringence-average relaxation times, $\langle\tau\rangle_{EB}$, of sDNA solutions obtained from the field-free decay curves on the applied electric field strength. Symbols and conditions are the same as in Fig. 1. Solid lines are theoretical curves calculated by the use of Eq. 6 with the parameters (l_w/l_n, l_w, $\beta_w^2/2\gamma_w$). These values for each curve are: l_w/l_n=1.16, l_w=742 Å, and $\beta_w^2/2\gamma_w$=2 (—○—); l_w/l_n=1.16, l_w=674 Å, and $\beta_w^2/2\gamma_w$=2 (—□—); l_w/l_n=1.16, l_w=533 Å, and $\beta_w^2/2\gamma_w$=4 (—■—); l_w/l_n=1.16, l_w=682 Å, and $\beta_w^2/2\gamma_w$=4 (—◐—); l_w/l_n=1.16, l_w=596 Å, and $\beta_w^2/2\gamma_w$=2 (—△—).

flexibility at low ionic strengths. The results in Fig. 4 may be best explained by the effect of the length polydispersity of sDNA. An analytical method for treating the decay process of the polydisperse rigid rodlike system was recently developed.[27] According to this method, the values of l_w/l_n and l_w for a given sDNA sample can be determined from the weight-average relaxation time $\langle\tau\rangle_w$ and the weight-average initial slope $\langle S\rangle_w$ at infinitely high field, provided that an appropriate length distribution is assumed. The best values of l_w/l_n and l_w can be determined by comparing experimental values of $\langle\tau\rangle_w$ and $\langle S\rangle_w$ with the theoretical values of $\langle\tau\rangle_w$ and $\langle S\rangle_w$ which were calculated from Eqs. 9 and 10. In this work, the Schulz-Zimm function (Eq. 3) was used for the length distribution density function, together with two values of 10 Å[52] and 13 Å[16,21] for the radius b of the cylinder assumed for sDNA. Two sets of parameters (l_w/l_n, l_w) thus determined are given in Table 1. The theoretical relaxation times calculated from Eq. 6 with the experi-

a) I is the ionic strength. b) Values obtained from the relaxation time $\langle\tau\rangle_{EB}$ which is extrapolated to infinitely high field strength. c) b is the radius of the cylinder for sDNA in Å (1 Å=0.1 nm). d) Values of l_w were evaluated from Eqs. 9 and 10 with experimental values of $\langle\tau\rangle_w$ and $-\langle S\rangle_w^{-1}$(=4.68μs) by using a constant value of l_w/l_n. e) bp is the number of base pairs, which is 188 for sDNA.

mentally obtained parameters (l_w/l_n, l_w, and $\beta_w^2/2\gamma_w$) for each sDNA solution are also shown by solid curves in Fig. 4. The "classical" mixed orientation function $\langle\Phi(\beta, \gamma)\rangle_w$ was utilized for the calculation of the theoretical relaxation times (the reason is given later). Except for the low field strength region, the experimental points are in fairly good agreement with the theoretical curve in each case.

The weight-average length (l_w) of sDNA given in Table 1 decreases with the increase of the ionic strength or the valence of counterion. The value of $\langle\tau\rangle_{EB}$ or $\langle\tau_w\rangle$ for the sDNA in the 20 vol% glycerol–0.8 mM NaCl solution is almost equal to that for the sDNA in the 0.2 mM NaCl solution. However, the values of l_w are very different. This is because the solvent viscosity of the former solution is about 2.2 times larger than that of the latter. The weight-average length per base pair (l_w/bp) is also given in Table 1; it decreases in the order: 0.2 mM NaCl>AA ($P/D=10$)–1.0 mM NaCl> 1.0 mM NaCl>0.33 mM $MgCl_2$>20 vol% glycerol–0.8 mM NaCl. The value of l_w/bp in 1.0 mM NaCl is 3.4—3.6 Å, which is close to that for B-form DNA, whereas it is 2.7—2.8 Å in 20 vol% glycerol–0.8 mM NaCl, which is close to that of A-form DNA. The latter value appears to support the proposals by Nelson and Johnson[53] and Ivanov *et al.*[54,55] that the A-form DNA exists in water–alcohol solutions.

The decay curve of ED was not analyzed in the present work, because the time constant for the signal detector of our ED apparatus was *ca.* 2.7 μs (with a load resister of 12 kΩ) for good signal-to-noise ratios. The good transient signals of EB could be measured with the instrumental decay time less than 0.5 μs (at a load resister of 2 kΩ) for the same sDNA solutions under the identical experimental conditions; therefore, the analysis of decay curves was possible in this case. Since the field strength dependence of the steady-state EB and ED is superimposable upon each other (*vide post*), the mean relaxation times of EB and ED may be the same for a given sDNA solution.

Electro-optical Properties of sDNA. Figure 5 shows the field strength dependence of the steady-state EB and ED signals of sDNA in 0.2 mM (circles) and 1.0 mM (squares) NaCl solutions. In order to obtain both the electric dipole moments responsible for field orientation and the intrinsic birefringence and dichroism (Δn_s and $(\Delta A/A)_s$), the experimental data may be compared with the theoretical orientation function. The orientation function $\Phi(\kappa)$ proposed by Kikuchi and Yoshioka,[49]

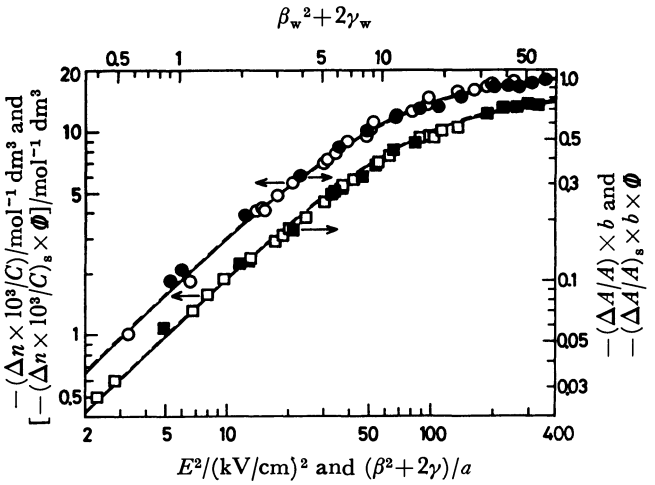

Fig. 5. Comparison of experimental values of birefringence and reduced dichroism for sDNA in 0.2 mM NaCl (○ for EB and ● for ED) and 1.0 mM NaCl (□ for EB and ■ for ED) solutions with the theoretical orientation functions, Φ, for the monodisperse and polydisperse systems. Two sets of the double-logarithmic plots are shown: $\Delta n/C$ against E^2 (○, □); $(\Delta n/C)_s\,\Phi(\beta, \gamma)$ against $(\beta^2+2\gamma)/a$ (——); $(\Delta n/C)_s\,\langle\Phi(\beta, \gamma)\rangle_w$ against $(\beta_w^2+2\gamma_w)$ (----); $\Delta A/A$ against E^2 (●, ■); $(\Delta A/A)_s\,\Phi(\beta, \gamma)$ against $(\beta^2+2\gamma)/a$ ¦(——); $(\Delta A/A)_s\,\langle\Phi(\beta, \gamma)\rangle_w$ against $\beta_w^2+2\gamma_w$ (----). The intrinsic values of $(\Delta n/C)_s$ and $(\Delta A/A)_s$ are given in Table 2. The factor a is 0.192, while the factor b is 1.0 for (■) and 1.1 for (●). Symbols and experimental conditions are the same as in Fig. 2 (a).

in which ion-atmosphere polarization is considered, seems to be the most reasonable one for the polyelectrolyte with axial symmetry. The applicability of $\Phi(\kappa)$ has been already tested for sodium poly(*p*-styrenesulfonate) (NaPSS) and NaPSS–AA systems.[38] It was, however, found that the fitting of $\Phi(\kappa)$ to the experimental data is good only in the low field strength range. In view of this fact, the function $\Phi(\beta, \gamma)$ has been employed for many DNA systems.[5,13,14,16,18,19,21,25,27] It will be also used in this work, although it was originally derived for nonionized polymers.

The experimental points in Fig. 5 (open symbols for EB and closed symbols for ED) fit not only the theoretical curves for monodisperse system, $\Phi(\beta, \gamma)$.[34] but also those for polydisperse system, $\langle\Phi(\beta, \gamma)\rangle_w$, fairly well over a wide range of field strength, provided that values of the interaction terms, β and γ, or, β_w and γ_w, are

a) The number-average distribution density function $f_n(l)$ with the parameters ($l_w/l_n=1.16$, l_w in Table 1) was used. b) 1 D$=3.336\times10^{-30}$ C m, and 1 $\mathrm{cm^3}=1.113\times10^{-16}$ F $\mathrm{m^2}$. c) C stands for the residue concentration of sDNA. d) Values in parentheses are the angles θ in degrees.

adjusted. This is because the curve of $\Phi(\beta, \gamma)$ for the monodisperse system differs only slightly from that of $\langle\Phi(\beta, \gamma)\rangle_w$, if $l_w/l_n<1.3$. Hence, it is difficult to determine uniquely the exact electric property of sDNA in solutions from the field strength dependence of Δn (or $\Delta A/A$). Nevertheless, $\langle\Phi(\beta, \gamma)\rangle_w$ should be employed because, as noted in the preceding section, it was verified that the sDNA sample is a polydisperse system. The best values of β_w ($=\mu_o l_w E/kT$) and γ_w ($=\Delta\alpha_o l_w E^2/2kT$), where $\mu_w=\mu_o l_w$ and $\Delta\alpha_w=\Delta\alpha_o l_w$, were read by the curve fitting method[25,34,38,42] and are given in Table 2. It has been shown by reversing-pulse electric birefringence that sDNA has no appreciable permanent dipole moment, but has only a pseudo-permanent dipole moment.[15] It is clear that this moment depends strongly on the ionic strength and the species of counterions and decreases in the order (*cf.* Table 2): 0.2 mM NaCl>1.0 mM NaCl>AA ($P/D=10$)-1.0 mM NaCl>20 vol% glycerol-0.8 mM NaCl>0.33 mM $MgCl_2$. In conclusion, the electric dipole moment of sDNA may be accounted for by the counterion-induced dipole moment which originates from the interaction between the counterions of sDNA and the applied external field.

From values of Δn_s at infinitely high field strength, together with the partial specific volume of 0.55 cm^3/g in 1 mM NaCl (Emonds-Alt *et al.*),[13] the optical anisotropy factor (g_3-g_1) was estimated to be $-(2.7-1.1)\times10^{-2}$ for sDNA at 535 nm. This result is in good agreement with the values of $-(2.0-0.5)\times10^{-2}$ at 550 nm (Houssier *et al.*)[5,13] and $-(2.8-2.3)\times10^{-2}$ at 633 nm (Stellwagen).[16] These values are much larger than $-(7.1-6.4)\times10^{-4}$ for high molecular weight DNA at 633 nm (Marion *et al.*).[14]

The apparent angle θ between the plane of base pair and the orientation axis of sDNA helix was estimated from Eq. 5 and is given in Table 2. It is in good agreement with the θ value of $73°\pm3°$ at 265 nm obtained for digested fragment DNA by Hogan *et al.*[22] It is very close to the value for A-form DNA or the revised B-form DNA,[56] but differs from that for the original B-form DNA. The apparent tilt angle remains unchanged by a 5-fold increase in NaCl concentration, while the weight-average length per base pair, l_w/bp, decreases about 10% (*cf.* Table 1). In 1.0 mM NaCl, however, the value of l_w/bp is 3.6 Å, which is close to that of B-form DNA (l_w/bp=3.4 Å). The value of $(\Delta A/A)_s$ should represent the true tilt angle of *ca.* 70° between the plane of the bases and the orientation axis of the sDNA helix, only if no out-of-plane transition (such as the n-π^* transition) is involved in the 260 nm band of the bases. In order to determine the exact conformation of rigid rodlike DNA in solutions with various additives, we should study the wavelength dependence of reduced dichroism spectra of DNA over the entire UV region.

Conclusion

The field strength dependence of both the steady-state EB and the field-free relaxation time of sDNA in solutions with various additives can be described over a wide range of field strength by the "classical" mixed-dipole orientation function $\langle\Phi(\beta, \gamma)\rangle_w$ for the polydisperse system. Similarly, the dependence of steady-state ED of sDNA is fitted by this orientation function with the same electric and distribution parameters (β_w, γ_w, l_w/l_n, and l_w). The weight-average length and the electric dipole moment for sDNA are strongly influenced by the ionic strength, the species of counterions, and additives, while the optical properties such as the apparent tilt angle (*ca.* 70°) and the optical anisotropy factor (*ca.* −0.02) are constant. The value of l_w/bp for sDNA in 20 vol% glycerol is close to 2.5 Å for A-form DNA, but that of l_w/bp for sDNA in 1 mM NaCl is close to 3.4 Å for B-form DNA.

We are deeply indebted to Mr. K. Fukudome for the use of his original computer program for calculating the polydispersity parameters, for participating in many discussions, and for determining the protein content of a DNA sample. We also thank Mr. K. Takarada for measuring the ED data.

(Received October 13, 1981)

Conformations of (*Z*)-stilbene, (*E*)-stilbene, and various methyl-substituted (*E*)-stilbenes were discussed from the standpoint of photoelectron spectroscopy. Photoelectron spectral data of (*Z*)-stilbene and (*E*)-stilbene were found to be perfectly consistent with the results by the gas electron diffraction method concerning the twist angles of the phenyl groups. The twist angles of the phenyl groups in various methyl-substituted (*E*)-stilbenes were estimated using the photoelectron spectral data by the new method presented recently. These estimated values correspond well to those obtained from the standpoint of the electronic absorption spectra.

Steric hindrance and molecular conformation are important subjects in organic chemistry. We have been studying the steric hindrance effect on photoelectron spectra[1] and the application of photoelectron spectroscopy to conformational analysis[2] of various types of organic compounds. In this paper we investigate the conformations of some stilbenes from the standpoint of photoelectron spectroscopy.

Conformations of stilbenes have long been and are still attracting great interests from the structural chemical and reaction mechanistic standpoints.[3] Although (*Z*)-stilbene (ZS) has mostly and reasonably been regarded or concluded to be nonplanar or twisted because of the steric hindrance effect between the two phenyl groups, (*E*)-stilbene (ES) has often been presumed on the basis of the x-ray crystallographic analysis,[4] or concluded to be essentially planar even in the fluid phases (see, however, Ref. 5, for example). However, according to the recent gas electron diffraction study,[6] ES is not planar but its two phenyl groups are twisted by 32.2° from the olefinic group plane, and this value is rather close to that of ZS, 43.2°.[7]

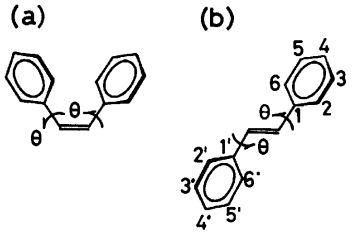

Fig. 1. Twisted conformations of (*Z*)-stilbene (a) and (*E*)-stilbene (b).

In this work, at first we examine if the photoelectron spectral data of ZS and ES are consistent with the gas electron diffraction results[6,7] concerning the twist angles of the phenyl groups, θ, and then we carry out the conformational analysis of various methyl-substituted ES's. In the conformational analysis we use the new technique developed in our recent paper.[2c] Concerning the photoelectron spectra of stilbenes, formerly we[1e] and Maier and Turner[8] studied both ZS and ES regarding ES as (nearly) planar in the vapors. Dewar and Goodman[9] reported the ionization energy values of ES by a low-resolution instrument, and Kricka *et al.*[10] those of ZS without interpretation. Afterwards Hudson *et al.*[11] treated the photoelectron spectra of ES and diphenylpolyenes regarding these as planar, and McAlduff and Chan[12] those of ES, (*E*)-4-methylstilbene (E4MS), and other 4-substituted ES's, concluding that these are planar.

Previously one of us (H.S.) developed a method for conformational analysis using electronic absorption spectra on the HMO level and discussed the conformations of various stilbenes in detail.[5,13] In this paper the conformational analysis by photoelectron spectroscopy is compared with that by this electronic absorption spectroscopic method.

Experimental

Materials. (*E*)-2,2′-Dimethylstilbene (E22′ DMS) (mp 81.0—82.0 °C, from hexane), (*E*)-3,3′-dimethylstilbene (E33′-DMS) (mp 58.0—58.5 °C, from ethanol), and (*E*)-2,2′,5,5′-tetramethylstilbene (E22′55′TMS) (mp 161.0—162.0 °C, from hexane) were prepared according to the procedure of Mukaiyama *et al.*[14] (Melting points are uncorrected.) Found for E22′55′TMS: C, 91.31; H, 8.70%; M+, 236. Calcd for $C_{18}H_{20}$: C, 91.47; H, 8.53%; M, 236. Preparations of (*E*)-4-methylstilbene (E4MS), (*E*)-4,4′-dimethylstilbene (E44′DMS), and (*E*)-2,2′,4,4′,6,6′-hexamethylstilbene (E22′44′66′HMS) were reported previously,[13c] and ZS was a commercial product of Aldrich Chemical Co.

Measurements. The HeI photoelectron spectra of the methyl-substituted ES's were measured using the photoelectron spectrometer described formerly.[1c] The sample inlet and target chamber systems were heated and kept at 131 °C for E4MS and E44′DMS, at 115 °C for E22′DMS, at 111 °C for E33′DMS and E22′55′TMS, and at 134 °C for E22′44′-66′HMS.

The electronic absorption spectra of ZS, E22′DMS, E33′-DMS, and E22′55′TMS in heptane were newly measured on a Hitachi EPS-3T spectrometer.

Computational

The CNDO/S calculations of ZS and ES were carried out with a FACOM 230-75 computer at the Institute of Physical and Chemical Research. All the necessary atomic integrals and parameters were taken from or estimated according to Ref. 15.

The geometrical structural parameters of ES and ZS necessary for the CNDO/S calculations were taken from or properly assumed based on Refs. 6 and 7. Their values are as follows:

The C=C–C bond angles, the C=C and the C–C bond lengths are 129.5°, 1.334 Å, and 1.489 Å for ZS, and 127.0°, 1.332 Å, and 1.483 Å for ES, respectively. The C=C–H bond angles, the C=C and the C–H bond lengths were taken to be 129.4°, 1.398 Å, and 1.095 Å, respectively, commonly both for ZS and ES.

Results and Discussion

(Z)- and (E)-Stilbene. The photoelectron spectra of ZS and ES were formerly studied by us[1e] in detail and also by Maier and Turner.[8] According to these former researches the first and the fifth bands of each compound are the so-called conjugation π bands and correspond to the ionizations from the π molecular orbitals delocalized over the entire molecular carbon frameworks, and the energy difference between these two molecular orbitals is quite sensitive to the change in θ. We use, therefore, the differences between the first and the fifth vertical ionization energies, $\Delta E_{IV}^{1,5}$, of these compounds to estimate θ from the photoelectron spectra.

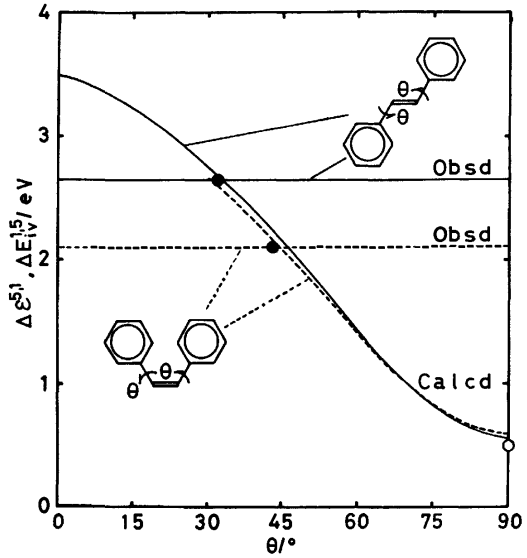

Fig. 2. Twist angle, θ, dependences of calculated energy differences between fifth and first highest occupied π molecular orbitals, $\Delta\varepsilon^{5,1}$, for (*Z*)- and (*E*)-stilbene with observed differences between first and fifth vertical ionization energies, $\Delta E_{IV}^{1,5}$.
The solid circles denote the gas electron diffraction results combined with the observed $\Delta E_{IV}^{1,5}$ values and the open one the estimated $\Delta E_{IV}^{1,5}$ for $\theta=90°$.

In Fig. 2 are shown the energy differences between the fifth and the first highest occupied π molecular orbitals, $\Delta\varepsilon^{5,1}$, for ZS and ES calculated by the CNDO/S method against θ. In the calculations the twist angles θ of the two phenyl groups of ZS or ES were assumed to be the same as each other. The $\Delta E_{IV}^{1,5}$ values at the twist angles of 90° for ZS and ES are commonly estimated to be 0.49 eV by using the first and the second ionization energies of ethylbenzene, 8.78 and 9.27 eV,[2c] and the first ones of (*Z*)- and (*E*)-1,2-dimethylethylene, 9.12 eV.[16] The calculated $\Delta\varepsilon^{5,1}$ *vs.* θ curve for ZS or ES passes the point very close to this estimated value at 90°. This fact suggests that the calculated $\Delta\varepsilon^{5,1}$ *vs.* θ curves in Fig. 2 simulate well the real $\Delta E_{IV}^{1,5}$ *vs.* θ curves for ZS and ES in the large θ region.

At first as a test case we treat ZS which is apparently a heavily sterically hindered compound. If we compare the observed difference between the first and the fifth vertical ionization energies, 2.10 eV, with the $\Delta\varepsilon^{5,1}$ *vs.* θ curve for ZS, we get 45° as the estimation for the θ value of ZS. This estimated value is very close to that observed by the gas electron diffraction method, 43.2°.[7] This satisfactory result and the point that ZS is structurally closely related with ES may guarantee the applicability of the same procedure to ES to estimate θ.

By applying the above procedure to ES we get 33° as θ. This estimated value is again very close to the one determined by the gas electron diffraction method, 32.2°.[6] From this result we can say that the photoelectron spectra of ZS and ES are perfectly consistent with the gas electron diffraction results concerning the twist angles, and that the phenyl groups of ES are considerably twisted in the gas phase from the photoelectron spectral point of view also.

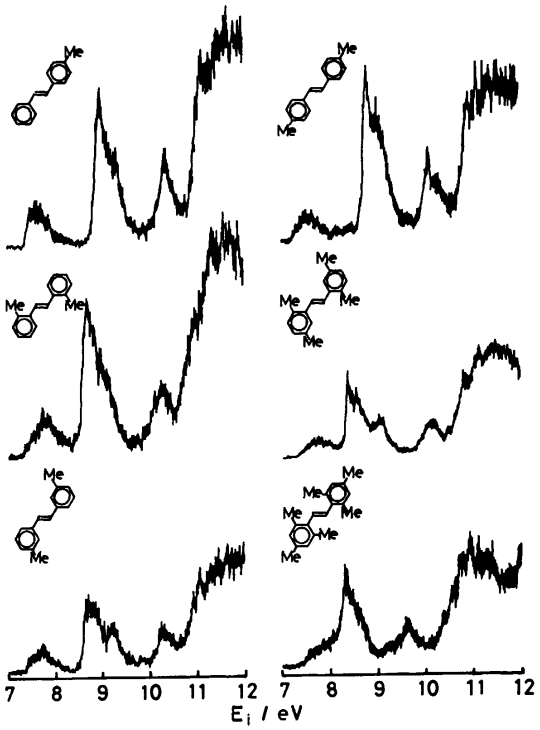

Fig. 3. Photoelectron spectra of methyl-substituted (*E*)-stilbenes.

Methyl-substituted (E)-Stilbenes. Now let us move to the conformational analysis of various methyl-substituted ES's. The photoelectron spectra of various methyl-substituted ES's are shown in Fig. 3. The vertical ionization energies obtained from these spectra are summarized in Table 1.

Judging from the vertical ionization energy values the first five bands of the methyl-substituted ES's are safely correlated with those of ES,[1e] respectively, that is, the first and the fifth bands correspond to the ioniza-

TABLE 1. VERTICAL IONIZATION ENERGIES, E_{iv}, OF STILBENES

Compound	E_{iv}/eV

a) Ref. 1e.

tions from the π molecular orbitals delocalized over the entire molecular carbon frameworks. The second and the third bands of each compound correspond to the ionizations from the π molecular orbitals formed by the combinations between the two benzene ring e_{1g}(A) type orbitals, and the fourth band to the ionization from the π molecular orbital formed mainly by the out-of-phase type of combination between the two benzene ring e_{1g}(S) type orbitals slightly mixed with the olefinic anti-bonding π orbital. Here the e_{1g}(S) orbital denotes one of the degenerate $e_{1g}\pi$ orbitals of benzene ring and is symmetric against the mirror plane passing the 1- and the 4-position and perpendicular to the benzene ring plane, and the e_{1g}(A) orbital denotes the other e_{1g} orbital orthogonal to the e_{1g}(S) orbital mentioned above.

Now we estimate the θ values of these methyl-substituted ES's using the energy differences between the first and the fifth π bands. We have already seen the fact that the $\Delta\varepsilon^{5,1}$ *vs.* θ curves for ZS and ES pass the points very close to the experimentally estimated point for $\theta=90°$, and the fact that the comparison of the $\Delta\varepsilon^{5,1}$ *vs.* θ curves for ZS and ES with the observed energy differences between the first and the fifth vertical ionization energies give very good estimates for θ in these compounds. Judging from these facts we can safely say that the calculated $\Delta\varepsilon^{5,1}$ *vs.* θ curves simulate very well the real $\Delta E_{iv}^{1,5}$ *vs.* θ curves in the case of ZS and ES. Therefore, we use the calculated $\Delta\varepsilon^{5,1}$ *vs.* θ curve for ES as the starting point for the estimation of θ of the methyl-substituted ES's.

In order to estimate the θ values of the methyl-substituted ES's we use the essentially same procedure as developed in our recent paper,[2c)] that is, we correct the $\Delta\varepsilon^{5,1}$ *vs.* θ curve of ES for the methyl-substituent effect by the first order perturbation theory regarding the methyl substitutions as perturbations, and get the estimated $\Delta E_{iv}^{1,5}$ *vs.* θ curves for the methyl-substituted ES's. In the perturbation theoretic calculations we use the parameters evaluated in the preceding paper.[2c)] By comparing the estimated $\Delta E_{iv}^{1,5}$ *vs.* θ curves for the methyl-substituted ES's with the observed $\Delta E_{iv}^{1,5}$ values we can estimate the twist angles. As an example, the estimated $\Delta E_{iv}^{1,5}$ *vs.* θ curve for E44′DMS is shown in Fig. 4. By comparing the observed $\Delta E_{iv}^{1,5}$ value of this compound with the curve in Fig. 4, we get 36° as

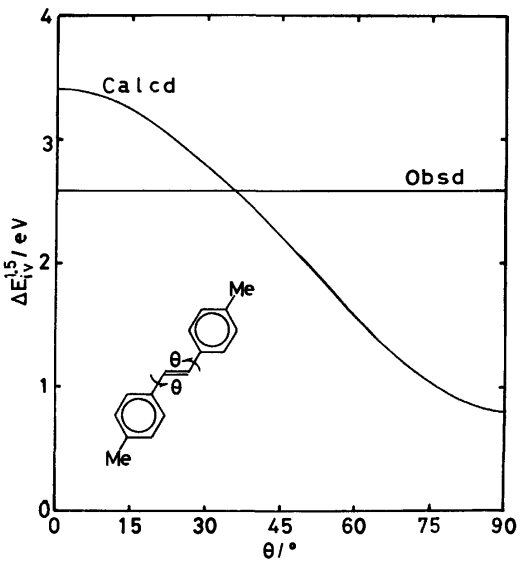

Fig. 4. Estimated θ dependence of $\Delta E_{iv}^{5,2}$ for (*E*)-4,4′-dimethylstilbene with observed $\Delta E_{iv}^{1,5}$.

θ. The θ values estimated for the various methyl-substituted ES's in this manner are summarized in Table 2 with those by other methods. In the case of E22′DMS the estimated θ values for the three main types of conformers, the (*E*)-2,2′-, (*E*)-6,6′-, and (*E*)-2,6′-dimethyl conformers, were the same. This was also the case for E33′DMS. In the case of E22′55′-TMS the estimated θ values for the (*E*)-2,2′,5,5′-, (*E*)-3,3′,6,6′-, and (*E*)-2,3′,5,6′-tetramethyl conformers were 41, 40, and 40°, respectively.

The estimated θ value of E4MS, 32°, that of E33′DMS, 37°, and that of E44′DMS, 36°, are very close to that of and the observed one of ES, 33° and 32.2°, as seen in Table 2. This is reasonable because the methyl groups can not cause any steric hindrance in these molecules.

In the case of E22′DMS and E22′55′TMS the estimated θ values are 40 and 40—41°, respectively, and these are slightly larger than that for ES. This suggests the presence of slight steric hindrance by the 2- and 2′-methyl groups. In the case of E22′44′66′HMS, the estimated value is considerably larger than that of E22′DMS or E22′55′TMS, and this is reasonable

a) The values in the parentheses are the assumed ones. b) The estimated error range for θ is around ±5° in the case of E22'44'66'HMS and ±4° in the case of the other methyl-substituted ES's. c) The HMO level method, Ref. 8. d) The electronic absorption spectral method on the HMO level, this work except for E22'44'66'HMS. e) See the text. f) The electron diffraction method, Refs. 6 and 7 for ES and ZS, respectively. g) The x-ray diffraction method, Ref. 4d. h) The NDDO method, Ref. 17. i) The molecular mechanics method, Ref. 18. j) Ref. 13c.

because the 2-, 2'-, 6-, and 6'-methyl groups are expected to cause greater steric hindrance than the pair of the 2- and 2'-methyl groups only.

As discussed above the estimated θ values show very reasonable tendency, and this fact supports the validity of the method used here.

Comparison with the Electronic Absorption Spectroscopic and Other Approaches. Formerly one of us (H.S.) developed a method on the HMO level to estimate the twist angles using the energies of the longest-wavelength electronic absorption spectral band maxima and discussed the conformations of various stilbenes in detail.[5,13)] We now compare the conformation analytical results obtained by photoelectron spectroscopy with those by electronic absorption spectroscopy.

For this purpose the electronic absorption spectra of ZS, E22'DMS, E33'DMS, and E22'55'TMS were newly measured in heptane and are shown in Fig. 5.

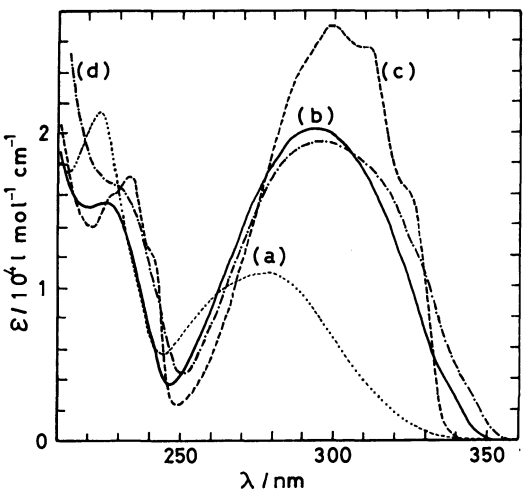

Fig. 5. Electronie absorption spectra of (*Z*)-stilbene (a), (*E*)-2,2'-dimethylstilbene (b), (*E*)-3,3'-dimethylstilbene (c), and (*E*)-2,2',5,5'-tetramethylstilbene (d) in heptane.

The wavelengths and the molar absorption coefficients at the absorption maxima of the longest-wavelength intense bands of these compounds are as follows:
ZS, 278.7 nm, 1.031×10^4 l/mol cm; E22'DMS, 293.6 nm, 2.022×10^4 l/mol cm; E33'DMS, 299.5 nm, 2.699×10^4 l/mol cm; E22'55'TMS, 295.4 nm, 1.945×10^4 l/mol cm.
The spectra of the other stilbenes treated in this study were reported formerly.[5,13c)]

The twist angles of the stilbenes estimated by using the energies of the first conjugation bands according to the method described formerly in detail[5,13c)] are summarized in Table 2. The electronic bathochromic effects of the methyl substituents located on the benzene nuclei were taken into account by adequately choosing the reference compounds for correlation between the calculated transition energies and the observed ones as described in Ref. 13c. The θ values of the entry I in Table 2 were estimated on the assumption that ES, E4MS, E33'DMS, and E44'DMS are completely planar, and those of the entry II on the assumption that the θ values for these compounds are commonly 32.2°, adopting the gas electron diffraction result for ES.[6)]

The θ values estimated from the photoelectron spectral data of these stilbenes are consistent in the tendency with those of the entry I in Table 2 and are almost quantitatively consistent with those of the entry II. These facts support the validities of the both methods which are independent of each other and suggest that the relative conformational situations are similar to each other between the gas and the solution phases.

In Table 2 are also given the θ values calculated by other authors for the sake of comparison. The recent NDDO result[17)] seems to be fair as for the θ value of ES. The empirical molecular mechanics type calculation[18)] underestimated the θ value for ES though the method is for free molecules.

Electronic Absorption Spectral Band Features. Finally let us examine the band features of the electronic

absorption spectra of some stilbenes from the conformational standpoints briefly. Formerly it has been pointed out and discussed in detail[13c,19] that the longest-wavelength absorption band of an apparently sterically hindered stilbene such as E22'44'66'HMS is considerably weaker in intensity than that of a sterically (almost) unhindered one such as ES, E4MS, or E44'DMS, and that the former is almost structureless while the latter shows well-resolved fine structures.

Keeping this point in mind let us see the electronic spectra of E22'DMS and E22'55'TMS shown in Fig. 5. The first bands of these spectra are almost structureless, almost equal to each other in intensity, and considerably weaker in intesity than that of E33'DMS shown in Fig. 5 which is reasonably regarded to be sterically unhindered. These facts mean clearly that the θ values of E22'DMS and E22'55'TMS are almost equal to each other and larger than that of E33'DMS. And this is consistent with the tendency of the θ values for these compounds estimated in this paper.

The longest-wavelength electronic absorption band of E33'DMS is quite similar in intensity and in fine structures to those of ES,[5] E4MS,[13c] and E44'DMS.[13c] These facts mean that E33'DMS is unhindered and support the validity of the mutual closeness of the θ values for these compounds estimated from the photoelectron spectra in this study. However, the fine structures of the longest-wavelength band of E33'DMS are slightly blurred compared to that of ES, E4MS, or E44'DMS, and this point may reflect the fact that the three main conformers, which may be designated as (*E*)-3,3'-, (*E*)-5,5'-, and (*E*)-3,5'-dimethylstilbene and are almost energetically equivalent to one another, are contributing to the ground state of E33'DMS in the fluid phases.

The Insertion Reaction of NH Singlet Radicals into the C-H Bonds of Cyclopropane and Isobutane in the Liquid Phase

Jun-ich HAMADA, Shigeru TSUNASHIMA,* and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 21, 1981)

Hydrogen azide was photolyzed in liquid cyclopropane at the temperature of Dry Ice–methanol. The main products observed were nitrogen, cyclopropylamine, and ammonia. The relative yields of the products depended slightly on the concentration of hydrogen azide. The results were then compared with those obtained with paraffin and olefin. The isobutane solution of hydrogen azide was photolyzed at 0 °C. The products observed were the same as those obtained at the temperature of Dry Ice–methanol. The relative yields of the products and the concentration dependence, however, were different.

In spite of many investigations of the reactions of $O(^1D)$ and $CH_2(^1A_1)$, only a few investigations have been reported of the reactions of the NH singlet ($a^1\Delta$), which is isoelectronic with O and CH_2.[1] Recently, we have photolyzed hydrogen azide in liquid ethane, propane, isobutane, ethylene, and propene at the temperature of Dry Ice–methanol.[2-4] In the case of paraffin, the main basic products were ammonia and amines, *i.e.*, ethylamine from ethane, propyl- and isopropylamine from propane, and isobutyl- and *t*-butylamine from isobutane. The amine formations were explained by the insertion reaction of the NH singlet into the C–H bonds of paraffin. In the case of olefin, aziridines were found to be formed; they were explained by the addition reaction of the NH singlet to the double bond of olefin. When hydrogen azide was photolyzed in liquid carboxylic acid, the formation of amino acids was observed.[5,6] Recently, Kajimoto and Fueno studied the photolysis of a mixture of hydrogen azide and ethane in the gas phase at room temperature.[7] They showed that the reactions of the NH singlet with ethane give insertion, abstraction, and deactivation products with branching ratios of 60%, 10%, and 30% respectively. These studies have shown that the main reaction of the NH singlet is the insertion reaction into the C–H bond.

In the case of the paraffin solution at the temperature of Dry Ice–methanol, the relative yield of amine decreased, and that of ammonia increased, with an increase in the concentration of hydrogen azide.[2,3] In the case of olefin, however, no concentration dependence was observed.[4] The difference was tentatively explained by a "solvent effect" on Reaction 1:

$$NH(a^1\Delta) + HN_3 \rightarrow NH_2 + N_3. \quad (1)$$

In order to get further information about the reactions of the NH singlet, hydrogen azide was photolyzed in the liquid cyclopropane at the temperature of Dry Ice–methanol, since cyclopropane is known as a hydrocarbon which shows a property intermediate between paraffin and olefin. The isobutane solution of hydrogen azide was also photolyzed at 0 °C in order to study the effects of the temperature on the reactions.

Experimental

The experimental methods were essentially the same as those described in the previous papers.[2-4] Hydrogen azide was prepared *in vacuo* by heating a mixture containing sodium azide and an excess amount of stearic acid, and was used after having been dried with phosphorus pentaoxide and degassed at −120 °C. Research-grade ethane, cyclopropane, and isobutane (Takachiho Shoji Co.) were purified by repeated trap-to-trap distillation. The mixture of hydrogen azide and hydrocarbon was prepared in a quartz tube with an o.d. of 8 mm and irradiated with a medium-pressure mercury lamp (Wako Denki Co.) through a filter (Toshiba UV 27) at the temperature of Dry Ice–methanol or 0 °C. The amount of the solution was about 1 cm^3.

After the irradiation, non-condensable products at −196 °C were analyzed with a combination of a Toepler pump, a gas burette, and a CuO furnace at 300 °C. The solvent was evacuated at about −80 °C. Less volatile products, including unreacted hydrogen azide, were passed through a trap packed with NaOH-coated glass wool. The products thus obtained were analyzed with GLC, using columns packed with Amipack 124 (Gasukuro Kogyo Co.) and with Porapak Q. For the identification of the products, a mass spectrometer and an NMR spectrometer were used. D_2O was used as a solvent for the NMR analysis.

Results

Cyclopropane–Hydrogen Azide Solution. When hydrogen azide was photolyzed in liquid cyclopropane at the temperature of Dry Ice–methanol, the formation of a white precipitant was observed, much as in the cases of paraffin and olefin.[2-4] The non-condensable products at −196 °C were nitrogen and hydrogen. No methane formation was observed. The H_2/N_2 ratio was 0.015 ± 0.004, independent of the changes in the concentration of hydrogen azide. Among the less volatile products, ammonia and cyclopropylamine were found. Allylamine, which is expected to be formed by the isomerization of the vibrationally excited cyclopropylamine, was not found. The yields of ammonia and cyclopropylamine relative to nitrogen are plotted in Fig. 1 as a function of the concentration of hydrogen azide. For comparison, previous results obtained with propane and propene are also included in Fig. 1.[3,4] The concentration dependence obtained with cyclopropane shows behavior intermediate between that obtained with propane and with propene. The sum of the relative yields of the products, $(c\text{-}C_3H_5NH_2 + 3H_2 + 4NH_3)/N_2$, was 0.95 ± 0.06 for the concentration range examined.

Cyclopropane–Ethane–Hydrogen Azide Solution. When ethane was added to a cyclopropane solution of hydrogen

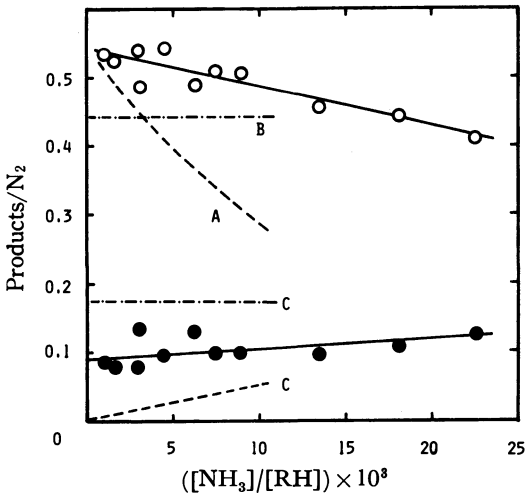

Fig. 1. Yields of cyclopropylamine (○) and ammonia (●) relative to nitrogen as a function of the concentration of hydrogen azide. (------) and (-·-·-) show the results obtained in the propane and propene solutions (from Refs. 3 and 4). A: (propyl- and isopropylamine)/N_2, B: (methylaziridine+allylamine)/N_2, C: NH_3/N_2.

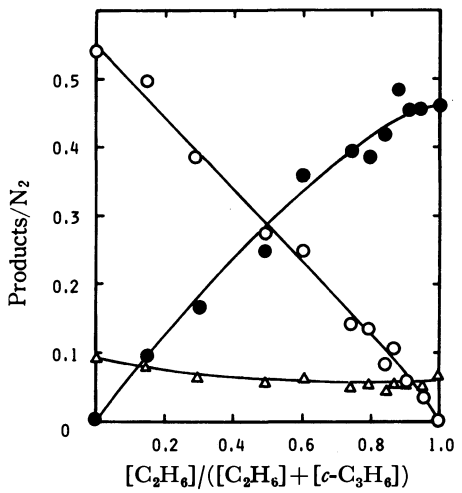

Fig. 2. Effects of ethane on the photolysis of cyclopropane solution of hydrogen azide as a function of the mole fraction of ethane. The $[HN_3]/([C_2H_6]+[c\text{-}C_3H_6])$ ratio is 2.07×10^{-3}. ○: $c\text{-}C_3H_5NH_2/N_2$, ●: $C_2H_5NH_2$, △: NH_3/N_2.

azide, the relative yield of cyclopropylamine decreased, while the yield of ethylamine increased. The results obtained at the constant concentration of hydrogen azide, $[HN_3]/([C_2H_6]+[c\text{-}C_3H_6])=2.07\times10^{-3}$, are plotted in Fig. 2 as a function of the mole fraction of ethane, X.

Isobutane–Hydrogen Azide Solution at 0 °C. In order to investigate the effects of the reaction temperature, hydrogen azide was photolyzed in liquid isobutane at 0 °C. The products obtained at 0 °C were essentially the same as those obtained at the temperature of Dry Ice–methanol. Figure 3 shows the concentration dependence of the relative yields of ammonia and amines (the sum of isobutyl- and *t*-butylamine). The results

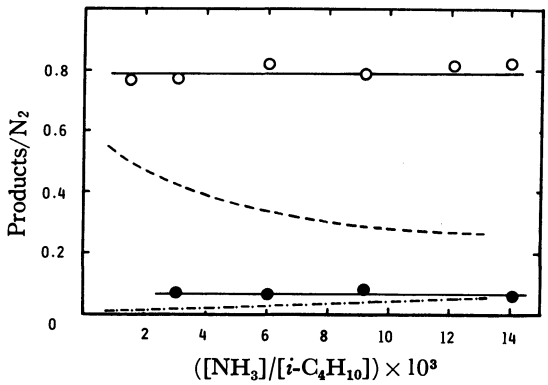

Fig. 3. Yields of isobutyl- and *t*-butylamines (○) and ammonia (●) relative to nitrogen as a function of the concentration of hydrogen azide at 0 °C. The results obtained at the temperature of Dry Ice–methanol are also shown for the amines (------) and ammonia (-·-·-) (from Ref. 3).

obtained at the temperature of Dry Ice–methanol are also included for comparison.[3] The relative yields of the products were independent of the changes in the concentration of hydrogen azide at 0 °C: $(i\text{-}C_4H_9NH_2+t\text{-}C_4H_9NH_2)/N_2=0.79\pm0.03$, $NH_3/N_2=0.06\pm0.01$, $H_2/N_2=0.03\pm0.01$, and $i\text{-}C_4H_9NH_2/t\text{-}C_4H_9NH_2=4.3\pm0.03$. The $i\text{-}C_4H_9NH_2/t\text{-}C_4H_9NH_2$ ratio obtained at 0 °C is almost equal to that obtained at the temperature of Dry Ice–methanol. The sum of the relative yields, $(i\text{-}C_4H_9NH_2+t\text{-}C_4H_9NH_2+3H_2+4NH_3)/N_2$, was close to unity, and thus different from that obtained at a lower temperature.

Discussion

Cyclopropane–Hydrogen Azide Solution. As has been discussed in previous papers,[2-4] the following general reaction mechanism can also be considered in the case of cyclopropane:

$$HN_3 + h\nu \rightarrow {}^1NH + N_2, \quad (2)$$
$$\rightarrow H + N_3, \quad (3)$$
$${}^1NH + HN_3 \rightarrow NH_2 + N_3 \quad k_a, \quad (4)$$
$${}^1NH + RH \rightarrow RNH_2 \quad k_i, \quad (5)$$
$$\rightarrow {}^3NH + RH \quad k_d, \quad (6)$$
$${}^3NH + HN_3 \rightarrow NH_2 + N_3, \quad (7)$$
$$NH_2 + HN_3 \rightarrow NH_3 + N_3, \quad (8)$$
$$H + HN_3 \rightarrow H_2 + N_3, \quad (9)$$
$$2NH_2 \rightarrow N_2H_4, \quad (10)$$
$$2N_3 \rightarrow 3N_2, \quad (11)$$

where ^1NH and ^3NH represent the NH radicals in the first excited singlet state ($a^1\Delta$) and the ground triplet state ($X^3\Sigma^-$) respectively. RH and RNH_2 are cyclopropane and cyclopropylamine respectively.

Since the $(RNH_2+3H_2+4NH_3)/N_2$ ratio was close to unity, Reaction 10 can be neglected in the case of cyclopropane, much as in the case of propene. In the case of propane, however, Reaction 10 was important to explain the facts that (1) the $(RNH_2+3H_2+4NH_3)/$

N_2 ratio was less than unity and (2) the NH_3/N_2 ratio approached zero when the concentration of hydrogen azide approached zero (*cf.* Fig. 1).

In the above reaction mechanism, the hydrogen-atom abstraction by the NH triplet is neglected;

$$^3NH + RH \rightarrow NH_2 + R, \quad (12)$$

because the reaction is about 36 kJ mol^{-1} endothermic. Reaction 13 may also be unimportant at a low temperature because of its large activation energy.[8] If Reactions

$$NH_2 + RH \rightarrow NH_3 + R \quad (13)$$

12 and 13 were important in the present system, the cyclopropyl radical, R, would abstract a hydrogen atom from hydrogen azide:

$$R + HN_3 \rightarrow RH + N_3. \quad (14)$$

As it is, it is difficult to distinguish these reactions from Reactions 7 and 8.

Kajimoto and Fueno have proposed that a part of the reaction of the NH singlet with ethane in the gas phase at room temperature is a hydrogen-atom abstraction.[7] A similar reaction is expected to occur in the present system because the reaction is about 115 kJ mol^{-1} exothermic:

$$^1NH + RH \rightarrow NH_2 + R. \quad (15)$$

If NH_2 and R abstracted a hydrogen atom from hydrogen azide, Reaction 15 would be indistinguishable from Reaction 6. In the liquid phase, however, NH_2 and R recombine because of the cage effect:

$$NH_2 + R \rightarrow RNH_2. \quad (16)$$

In this case, Reaction 15 is indistinguishable from Reaction 5. If Reaction 16 competed with Reactions 8 and 14, the NH_3/N_2 ratio would increase and the RNH_2/N_2 ratio would decrease with an increase in the concentration of hydrogen azide. This is consistent with the results obtained in the paraffin and cyclopropane solutions at the temperature of Dry Ice–methanol. This assumption, however, cannot explain the concentration dependence of the products obtained in the cases of the olefin solutions at the temperature of Dry Ice–methanol and isobutane solution at 0 °C.

Since Reaction 5 is about 460 kJ mol^{-1} exothermic, a vibrationally excited cyclopropylamine is formed; this will be isomerized to allylamine unless stabilized by a collision. In the cases of CH_2 reactions with cyclopropane, the isomerization of the initially formed vibrationally excited methylcyclopropane has been observed in the gas phase at room temperature.[9] Since no allylamine formation could be observed, the stabilization of the vibrationally excited cyclopropylamine must be efficient under the present experimental conditions.

Assuming the above reaction mechanism, Reactions 2—11, the rate constant ratios, k_a/k_i and $k_i/(k_i+k_d)$, can be estimated to be 6.4 ± 1.1 and 0.83 ± 0.01 respectively by the method described in the previous papers.[3,4] Here, the a, i, and d subscripts denote the abstraction reaction of hydrogen atom from hydrogen azide, the insertion reaction, and the deactivation of the singlet NH respectively. McDonald *et al.* have estimated the values of k_a and k_i+k_d in the gas phase at room temperature.[10] Their $k_a/(k_i+k_d)$ ratio was 2.6, about a half of the present results.

The k_a/k_i ratio was 49 in the case of propane.[3] In the case of propene, no concentration dependence was observed;[4] this means that the k_a/k_i ratio was less than unity. Thus, the difference in the concentration dependence of the yields of amine and ammonia may be explained by the difference in the k_a/k_i ratio.

Relative Rate of the Insertion. Using the results shown in Fig. 2, the relative rate can be estimated for the insertion of the NH singlet into ethane (k_{ei}) and cyclopropane (k_{ci}):

$$^1NH + C_2H_6 \rightarrow C_2H_5NH_2 \quad k_{ei}, \quad (17)$$

$$^1NH + c\text{-}C_3H_6 \rightarrow c\text{-}C_3H_5NH_2 \quad k_{ci}. \quad (18)$$

Assuming Reactions 17 and 18, the following relation can be obtained:

$$C_2H_5NH_2/(C_2H_5NH_2 + c\text{-}C_3H_5NH_2) = X/(f(1-X) + X), \quad (19)$$

where X is the mole fraction of ethane and where f is the k_{ci}/k_{ei} ratio. The left-hand-side of Eq. 19 is plotted against the weighted mole fraction, assuming various values for f. When f is assumed to be $1.0_5\pm0.1$, a good linearity is obtained, as is shown in Fig. 4; the insertion rate of the NH singlet into the C–H bond of cyclopropane is almost equal to that of ethane. Incidentally, Cvetanović and his co-workers estimated the relative rate of the reactions of $O(^1D)$ with cyclopropane and ethane to be 1.0_5 in the gas phase.[11]

As Fig. 2 shows, the relative yields of ethylamine were almost constant for the mole fractions of ethane larger than 0.85. This behavior may be explained by Reactions 2—11 under the assumption that the value of k_a depends on the mole fraction of ethane. The following relation is obtained for the yields of ethylamine:

$$C_2H_5NH_2/(C_2H_5NH_2 + c\text{-}C_3H_5NH_2 + H_2 + NH_3 + 2N_2H_4) = C_eX/(C_eA\,k_a/k_i + X + (1-X)fC_e/C_c, \quad (20)$$

where C_e and C_c are the fractions of the insertion of the NH singlet into ethane and cyclopropane respectively. A is the mole fraction of hydrogen azide; $2.0_7\times10^{-3}$. The left-hand-side of Eq. 20 is plotted in Fig. 5 as a function of the mole fraction of ethane. The amount of

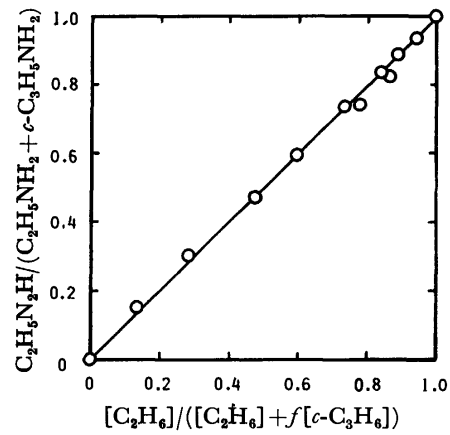

Fig. 4. Plots of $C_2H_5NH_2/(C_2H_5NH_2+c\text{-}C_3H_5NH_2)$ as a function of the weighted mole fraction of ethane, $f=1.05$. See the text for detail.

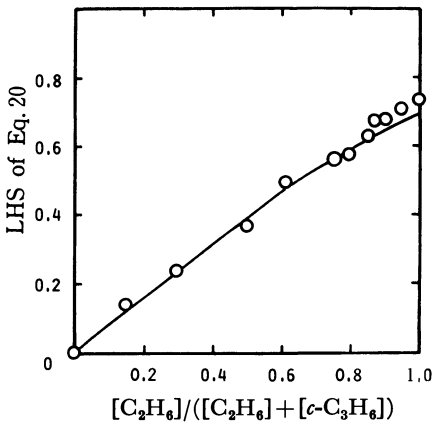

Fig. 5. Plots of the left-hand-side of Eq. 20 (○) as a function of the mole fraction of ethane. The solid curve shows the calculated ones. See the text for detail.

$$N_2H_4 = (1/5)(N_2 - C_2H_5NH_2 - c\text{-}C_3H_5NH_2 - 3H_2 - 4NH_3). \quad (21)$$

N_2H_4 was estimated using Eq. 21, as was done in a previous paper.[3] The right-hand-side of Eq. 20 is estimated by assuming Eq. 22 for the values of k_a/k_i at various mole fractions of ethane:

$$k_a/k_i = (k_a/k_i)_e^{x}(k_a/k_i)_c^{(1-x)}, \quad (22)$$

where the e and c subscripts mean the values obtained in a pure ethane solution and in a pure cyclopropane solution respectively. The results are shown in Fig. 5 as a solid curve. As Fig. 5 shows, the agreement is satisfactory.

Effects of Reaction Temperature. As Fig. 3 shows, the relative yields of the products were independent of the changes in the concentration of hydrogen azide in the case of isobutane at 0 °C. These observations may be explained by assuming a small value of k_a/k_i (less than unity) under the assumed reaction mechanism. As was shown in a previous paper,[3] the k_a/k_i ratio was 40 in liquid isobutane at the temperature of Dry Ice–methanol. If the decrease in the k_a/k_i ratio can be explained by the temperature dependence on k_i, the insertion reaction should have an activation energy larger than 21 kJ mol^{-1}. The effect of the reaction temperature was also observed in the k_d/k_i ratio, which is equal to $NH_3/(i\text{-}C_4H_9NH_2+t\text{-}C_4H_9NH_2)$ at 0 °C under the assumed reaction mechanism; *i.e.*, k_d/k_i= 0.08 at 0 °C and 0.33 at the temperature of Dry Ice–methanol.[3] From these values, the activation energy of k_i can be estimated to be about 8 kJ mol^{-1} larger than that of k_d.

In the case of O(^{1}D), no temperature effect has been observed for the insertion reaction.[12] For the reactions of the NH singlet, the temperature effect on the rate has not been studied. If the rate is independent of the changes in the reaction temperature, much as in the case of O(^{1}D), it is necessary to assume that k_a will decrease with an increase in the reaction temperature. As has been discussed above, we had to assume various values of k_a for different solutions and different temperatures. This might be due to the status of hydrogen azide in the hydrocarbon solutions. If hydrogen azide molecules were determined in isobutane to be in the form of a "cluster" at low temperatures, a large k_a value can be expected; hydrogen azide molecules are always present near the NH singlet formed by photolysis in a solution. At higher temperatures, this "cluster" may be decomposed by the motion of the solvent molecule, and a small k_a value can be expected. The size of the "cluster" may also depend on the solvent. If such a "cluster" was formed, the photolysis would take place inhomogeneously in the solution, and the recombination of NH_2 would become important. Such a "cluster," if formed, will play a significant role in the ethane, propane, and isobutane solutions at the temperature of Dry Ice–methanol.

As has been discussed above, the reactions of the NH singlet in liquid hydrocarbons are complicated. Further studies are necessary to elucidate the complete reaction mechanism.

The authors are much obliged to Professor Takeshi Nakai of this Institute for the NMR analysis.

Multi-ionic Potential and Membrane Permeability Matrix. I. NaCl-CsCl Bi-ionic System with a Cation Exchange Membrane

Kozue KAIBARA* and Hideo KIMIZUKA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received October 23, 1981)

This paper is concerned with analysis of membrane transport processes on the basis of nonequilibrium thermodynamics. Inter-ionic correlations between permeating ions are quantitatively estimated by applying the membrane permeability matrix theory to the system in which the NaCl and CsCl solution phases are divided by a highly selective cation exchange membrane. The membrane permeability matrix of the system may be expressed by four ionic correlation terms concerning with Na^+ and Cs^+. The electroconductive and diffusional membrane permeabilities are expressed as a function of the matrix elements having the dimension of permeating speed of ions. The conductive and diffusional permeabilities as well as the matrix elements are estimated from membrane potential, conductance, and ionic flux data. The external electrolyte concentration dependence of these permeability parameters is discussed. The conductive and diffusional permeabilities considerably differ from each other and their ratio changes with the external electrolyte concentration, whereas the permeability ratio of Na^+ to Cs^+ is constant. Electroconductive and diffusional characteristics of membrane transport processes are consistently analyzed in terms of the membrane permeability matrix theory.

The membrane permeability matrix theory was presented as an application of the nonequilibrium thermodynamics to the analysis of transport phenomena of ions across membrane.[1] The fundamental idea of the theory is an estimation of permeability coefficients to offer a consistent explanation for membrane properties such as membrane potential, conductance, and ionic flux. In this context, the membrane permeability matrix was introduced as a fundamental parameter characterizing membrane properties. Each matrix element possesses the dimension of permeating speed of ions across membrane and represents a partial correlation between movements of migrating ions. The membrane permeability matrix can be regarded as a modified set of coefficients in the linear phenomenological equations describing membrane transport processes.

The commonly used membrane permeability theories formulated on the basis of the Nernst-Planck equation provide only one permeability coefficient for an ion (see, for example, Refs. 2—5), but any consistent explanation for membrane phenomena cannot be presented by these theories, since membrane permeabilities estimated from diffusional and electroconductive data are remarkably different as described later. In the preceding paper,[6] an experimental verification of the permeability matrix theory was presented by using a cation exchange membrane-aqueous calcium chloride solution system and it was pointed out that the theory is advantageous for a better understanding of ionic memberane transport.

In the present paper, a bi-ionic system in which NaCl and CsCl aqueous solutions are divided by a cation exchange membrane is studied by measurement of membrane potential, membrane conductance, and ionic flux. The membrane permeability matrix is estimated from observed data and discussed in relation to membrane transport processes.

Experimental

A "CK-1, 1.0 t" cation exchange membrane (Asahi Chemical Industry Co., Ltd.) was employed throughout the experiment with aqueous NaCl and CsCl solutions prepared from conductivity water and extra pure salts. The "CK-1, 1.0 t" membrane is composed of a styrene–divinylbenzene copolymer with ion exchange group of sulfonic acid type and its basic physicochemical properties are as follows: exchange capacity, 2.8 mequiv. (g dry-resin)$^{-1}$; water content, 38%; thickness, 1.09 mm. This membrane exhibits an ideal permselectivity to monovalent cations in single electrolyte systems (concentration cells), since apparent transport numbers to Na^+ and Cs^+ estimated from potential data are almost unity. The tracers used in the flux measurements, ^{22}Na and ^{137}Cs in chloride form, were obtained from the Japan Radioisotope Association.

Membrane potentials and conductances were measured by the ordinary method and ionic fluxes were estimated by measuring ^{22}Na and ^{137}Cs radioactivities transferred across membrane from one side of the solution chamber to the

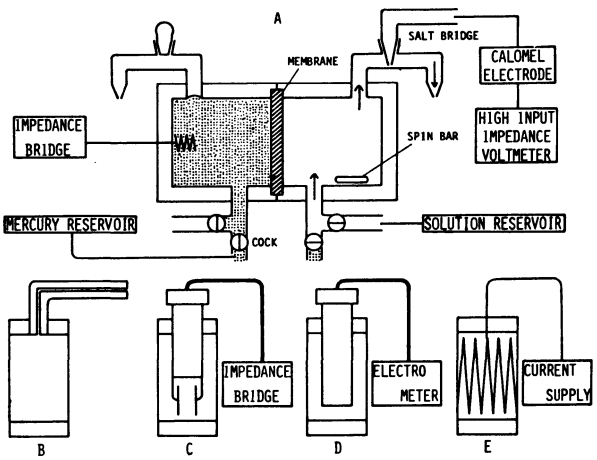

Fig. 1. Schematic representation of experimental assemblies. A shows the basic arrangement for the electrochemical measurements: potential measurements are performed by perfusing the chambers with electrolyte solutions (right-side diagram); conductance measurements are performed by means of filling the chamber with mercury as a conductivity electrode (left-side diagram). Accessary attachements B, C, and D (ion sensitive electrode) are employed to measure the volume flow, conductivity of solution, and ionic activity of solution, respectively. Attachement E is used when electric currents are applied externally.

other.[6-8] The schematic representation of experimental assemblies is given in Fig. 1. A high input impedance integrating voltmeter (Takeda Riken TR6856) and an impedance bridge circuit (Yokogawa-Hewlett-Packard 4255A and 4440B) were used to measure electrochemical properties. The detections of γ-activities of ^{22}Na and ^{137}Cs were performed by a γ-ray scintillation counter (Aloka Nd-151D). All experiments were carried out at a regulated room temperature, 20.0 ± 1.0 °C.

Results and Discussion

Experimental data are summarized in Figs. 2 and 3; measurements were carried out on the systems in which the NaCl or CsCl concentration of phase II was kept constant at 10^{-1}, 10^{-2}, or 10^{-3} mol dm^{-3}, while the CsCl or NaCl concentration of phase I was varied from 10^{-1} to 10^{-3} mol dm^{-3}. As illustrated in Fig. 2A, the membrane potential changed by about 58 mV for the tenfold alteration in electrolyte activity of phase I, whether NaCl or CsCl concentration was varied. Fig. 2A also shows that the system composed of NaCl and CsCl solutions of the same concentration generates a membrane potential of 8.7 mV where the NaCl side is positive. Membrane conductance *vs.* external salt concentration curves are given in Fig. 2B. Ionic fluxes estimated by means of the radiotracer method are plotted against the geometrical mean of NaCl and CsCl activities of external solutions in Fig. 3. These experimental results indicate that the Cl^- flux is negligibly small as compared with cationic fluxes. Thus, the ionic fluxes in the present system can be expressed by only those of Na^+ and Cs^+ as a reasonable approximation. The membrane permeability matrix for the present system can be estimated from the above electrochemical and ionic flux data on the basis of the previous theory.[1]

The membrane transport process in the present system can be characterized by the following modified phenomenological equation:

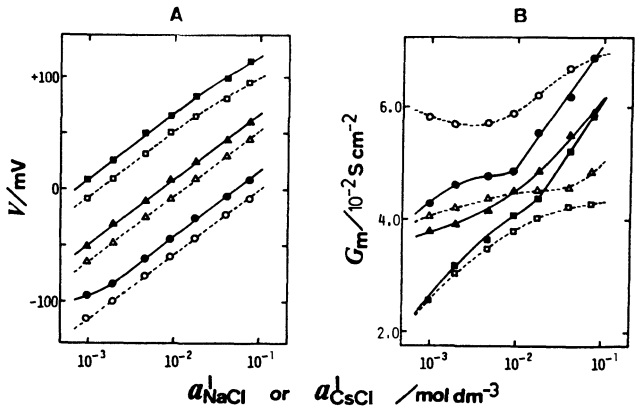

Fig. 2. Electrochemical data. Membrane potentials (A) and membrane conductances (B).

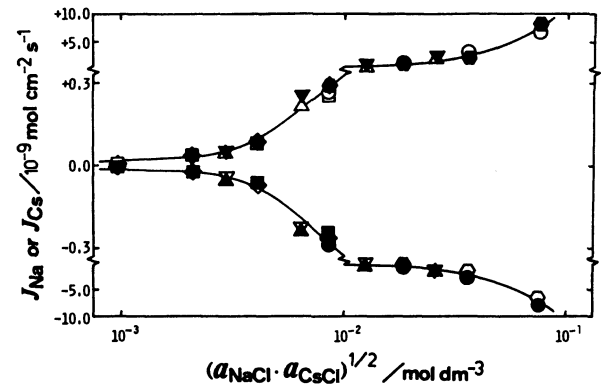

Fig. 3. Cationic flux data as a function of the geometrical mean of external NaCl and CsCl activities.
The closed and open symbols indicate J_{Na} and J_{Cs}, respectively. CsCl(I)-NaCl(II) systems, NaCl(II): (●, ○); 10^{-1} mol dm^{-3}, (▲, △); 10^{-2} mol dm^{-3}, (■, □); 10^{-3} mol dm^{-3}. NaCl(I)-CsCl(II) systems, CsCl(II): (●, ○); 10^{-1} mol dm^{-3}, (▼, ▽); 10^{-2} mol dm^{-3}, (◆, ◇); 10^{-3} mol dm^{-3}.

$$\begin{bmatrix} J_{Na} \\ J_{Cs} \end{bmatrix} = -\begin{bmatrix} P_{Na,Na} & P_{Na,Cs} \\ P_{Cs,Na} & P_{Cs,Cs} \end{bmatrix} \times \begin{bmatrix} a^{II}_{Na}\exp(FV/2RT) - a^{I}_{Na}\exp(-FV/2RT) \\ a^{II}_{Cs}\exp(FV/2RT) - a^{I}_{Cs}\exp(-FV/2RT) \end{bmatrix}, \quad (1)$$

where J is the ionic flux, a is the activity, and V is the membrane potential; F, R, and T have the usual physical meanings; the subscripts Na and Cs refer to Na^+ and Cs^+; the superscripts I and II denote the solution phases I and II divided by the membrane, respectively. The 2×2 membrane permeability matrix in the right hand side of Eq. 1 is a principal parameter to describe membrane phenomena for the present system. Each matrix element represents the partial contribution to the ionic transport caused by the inter-ionic correlation denoted by the subscript. The participation of volume flow in the mebrane transport process was neglected in the present study, since the assumption of zero volume flow was experimentally verified for the studied electrolyte concentration range with the CK-1, 1.0t membrane in a previous paper.[9] At low electrolyte concentrations less than 10^{-1} mol dm^{-3}, the estimated changes in phenomenological coefficients were so small as to be within the experimental error, whether the volume flow was taken into account or not. This may be due to the low water content and high fixed charge density of the CK-1, 1.0t cation exchange membrane.[6]

From Eq. 1, the total membrane current, I, is expressed as:

$$I = -F\{P_{Na}[a^{II}_{Na}\exp(FV/2RT) - a^{I}_{Na}\exp(-FV/2RT)] + P_{Cs}[a^{II}_{Cs}\exp(FV/2RT) - a^{I}_{Cs}\exp(-FV/2RT)]\}, \quad (2)$$

where P_{Na} and P_{Cs} are the electroconductive membrane permeabilities to Na^+ and Cs^+ defined as a function of the permeability matrix elements, respectively:

$$P_{Na} = P_{Na,Na} + P_{Cs,Na},\ P_{Cs} = P_{Na,Cs} + P_{Cs,Cs}. \quad (3)$$

On the other hand, Eq. 1 is reduced to the next form when the membrane current is absent:

$$\begin{bmatrix} J_{Na} \\ J_{Cs} \end{bmatrix} I=0 = - \begin{bmatrix} P^0_{Na} & 0 \\ 0 & P^0_{Cs} \end{bmatrix} \times \begin{bmatrix} a^{II}_{Na} \exp(FV_0/2RT) & -a^{I}_{Na} \exp(-FV_0/2RT) \\ a^{II}_{Cs} \exp(FV_0/2RT) & -a^{I}_{Cs} \exp(-FV_0/2RT) \end{bmatrix}, \quad (4)$$

where V_0 is the membrane potential at zero membrane current. P^0_{Na} and P^0_{Cs} are the diffusional membrane permeabilities which are defined as a function of the matrix elements and differ from the electroconductive permeabilities defined by Eq. 3:

$$P^0_{Na} = |P|/P_{Cs}, \quad P^0_{Cs} = |P|/P_{Na} \; ; \; |P| = \begin{vmatrix} P_{Na,Na} & P_{Na,Cs} \\ P_{Cs,Na} & P_{Cs,Cs} \end{vmatrix}. \quad (5)$$

As pointed out in the preceding paper,[1,6] the conductive and diffusional membrane permeabilities are transport parameters which represent electronductive and diffusional characteristics of membrane systems. From Eqs. 3 and 5, relationships between these permeabilities are obtained as:

$$P^0_{Na}/P_{Na} = P^0_{Cs}/P_{Cs} = 1-(P_{Cs,Na}/P_{Na}) - (P_{Na,Cs}/P_{Cs}). \quad (6)$$

The conductive permeability can be discriminated from the diffusional permeability only on the basis of nonequilibrium thermodynamical theory and it should be noted that both the permeabilities are identical when the ionic correlation between Na^+ and Cs^+ is absent. The diffusional membrane permeability can be estimated according to Eq. 4 by using the ionic flux and potential data. The conductive permeability can be calculated from the electrochemical data using the following relations:[4,7]

$$P_{Na}a^{II}_{Na} + P_{Cs}a^{II}_{Cs} = (RT/F^2)G_m \exp(-FV_0/2RT),$$
$$P_{Na}a^{I}_{Na} + P_{Cs}a^{I}_{Cs} = (RT/F^2)G_m \exp(FV_0/2RT), \quad (7)$$

where G_m is the membrane conductance.

Four elements of the membrane permeability matrix, $P_{Na,Na}$, $P_{Na,Cs}$, $P_{Cs,Na}$, and $P_{Cs,Cs}$, characterizing the present system were estimated from Eqs. 3 and 6 with the following relation between the cross matrix elements:[1]

$$\frac{P_{Na,Cs}}{P_{Cs,Na}} = \frac{(a^{I}_{Na}a^{II}_{Na})^{1/2} \sinh[F(V-V_{Na})/2RT]/[F(V-V_{Na})/2RT]}{(a^{I}_{Cs}a^{II}_{Cs})^{1/2} \sinh[F(V-V_{Cs})/2RT]/[F(V-V_{Cs})/2RT]}, \quad (8)$$

where V_{Na} and V_{Cs} are the Nernst equilibrium membrane potentials for Na^+ and Cs^+, respectively, which are defined as:

$$V_{Na} = -(RT/F)\ln(a^{II}_{Na}/a^{I}_{Na}),$$
$$V_{Cs} = -(RT/F)\ln(a^{II}_{Cs}/a^{I}_{Cs}). \quad (9)$$

In the present study, Eq. 8 must be modified under the limited experimental conditions; the relation, $-V_{Na} = V_{Cs} = \infty$, would be satisfied in the CsCl(I)–NaCl(II) system where $a^{I}_{Na} = a^{II}_{Cs} = o$, and the relation, $V_{Na} = -V_{Cs} = \infty$, in the NaCl(I)–CsCl(II) system where $a^{II}_{Na} = a^{I}_{Cs} = o$. In these limiting cases, the following relations can be obtained from Eq. 8:

$$P_{Na,Cs}/P_{Cs,Na} = \begin{cases} a^{II}_{Na}/a^{I}_{Cs} \text{ for the CsCl(I)-NaCl(II) system} \\ a^{I}_{Na}/a^{II}_{Cs} \text{ for the NaCl(I)-CsCl(II) system.} \end{cases} \quad (10)$$

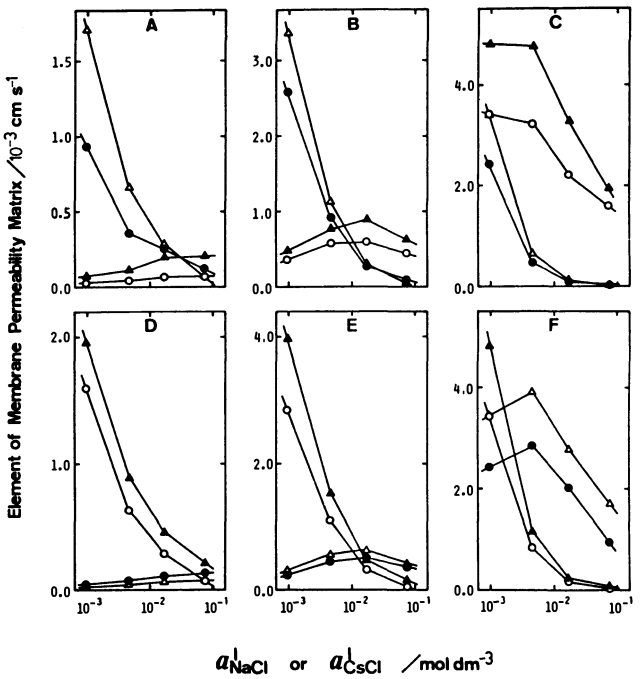

Fig. 4. Membrane permeability matrix elements as a function of mean electrolyte activity of phase I.
CsCl(I)–NaCl(II) systems, NaCl(II): A; 10^{-1} mol dm^{-3}, B; 10^{-2} mol dm^{-3}, C; 10^{-3} mol dm^{-3}. NaCl(I)–CsCl(II) systems, CsCl(II): D; 10^{-1} mol dm^{-3}, E; 10^{-2} mol dm^{-3}, F; 10^{-3} mol dm^{-3}. ●; $P_{Na,Na}$, ○; $P_{Ca,Na}$, ▲; $P_{Cs,Cs}$, △; $P_{Na,Cs}$.

Calculated transport parameters are summarized in Figs. 4 and 5. The membrane permeability matrix elements estimated for the six studied systems are plotted, in Fig. 4, against the mean electrolyte activity of phase I. From this figure, effects of inter-ionic correlations on the membrane ionic transport processes can be quantitatively evaluated. In Fig. 5, the conduc-

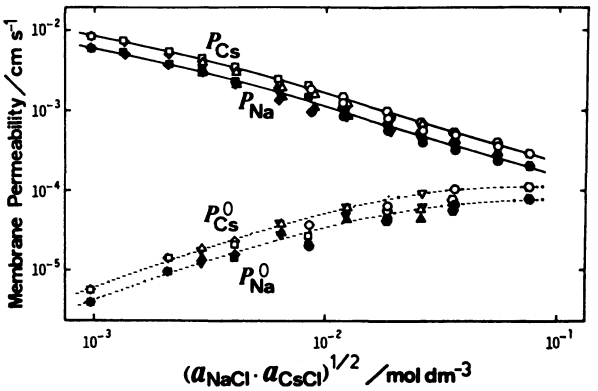

Fig. 5. Conductive and diffusional membrane permeabilities as a function of the geometrical mean of external NaCl and CsCl activities.
Solid and broken lines refer to the conductive and diffusional permeabilities; the closed and open symbols indicate the permeabilities to Na^+ and Cs^+, respectively. CsCl(I)–NaCl(II) systems, NaCl(II): (●, ○); 10^{-1} mol dm^{-3}, (▲, △); 10^{-2} mol dm^{-3}, (■, □); 10^{-3} mol dm^{-3}. NaCl(I)–CsCl(II) systems, CsCl(II): (⬢, ⬡); 10^{-1} mol dm^{-3}, (▼, ▽); 10^{-2} mol dm^{-3}, (◆, ◇); 10^{-3} mol dm^{-3}.

tive and diffusional membrane permeabilities are plotted as a function of the geometrical mean of NaCl and CsCl activities of phases I and II. As can be seen in this figure, the two types of the permeabilities are considerably different from each other and exhibit an opposite dependence upon the external electrolyte activity. The disagreement between the electroconductive and diffusional characteristics in the membrane transport processes indicates the failure of the Nernst-Einstein equation which relates the diffusion coefficient to the mobility. The deviation from the Nernst-Einstein equation has hitherto been interpreted as a contribution of electroosmotic effects (see, for example, Refs. 10 and 11). However, this effect seems to be minor especially in a highly permselective membrane system such as the CK-1, 1.0t membrane as suggested in the preceding papers.[6,9] These results showed that only a quite small electroosmotic effect is operative for the membrane having both a low water content and a homogeneous highly-charged polymer structure. In addition, the discrepancy between the diffusional and conductive permeabilities was also observed for a liquid ion exchange membrane system where no charged pores exist and accordingly where the electroosmotic permeation mechanism of solvent is not conceivable.[12,13] Moreover, the transport processes can be affected by the inter-ionic correlations even in a simple aqueous electrolyte system.[14–18] Thus, it is quite reasonable that the interaction between permeating ions should be taken into consideration as an origin for the failure of th Nernst-Einstein equation. Only when the cross terms of the permeability matrix are zero, the conductive and diffusional membrane permeabilities to ions coincide with each other; namely, the conductive and diffusional characteristics of the membrane system are consistently explained based on the classical Nernst-Einstein relation.

In Fig. 6, ratios of the diffusional to conductive membrane permeabilities, P^0_{Na}/P_{Na} and P^0_{Cs}/P_{Cs}, are plotted together with the permeability ratios,

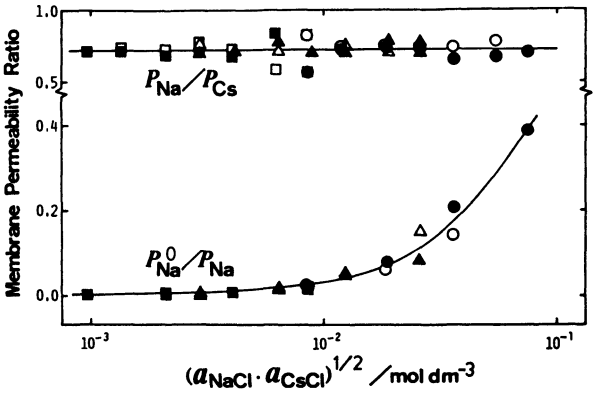

Fig. 6. Membrane permeability ratios as a function of the geometrical mean of external NaCl and CsCl activities.
Upper and lower traces indicate the values of P_{Na}/P_{Cs} and P^0_{Na}/P_{Na} $(=P^0_{Cs}/P_{Cs})$, respectively. CsCl(I)-NaCl(II) systems, NaCl(II): ●; 10^{-1} mol dm^{-3}, ▲; 10^{-2} mol dm^{-3}, ■; 10^{-3} mol dm^{-3}. NaCl(I)-CsCl(II) systems, CsCl(II): ○; 10^{-1} mol dm^{-3}, △; 10^{-2} mol dm^{-3}, □; 10^{-3} mol dm^{-3}.

$P_{Na}/P_{Cs}(=P^0_{Na}/P^0_{Cs})$. In the present system, the membrane potentials are determined by Na^+ and Cs^+ excluding Cl^-, so the following equations may be termed as the cationic pseudo-equilibrium potential:

$$V_{Na-Cs} = \begin{cases} -(RT/F)\ln(P_{Na}a^{II}_{Na}/P_{Cs}a^{I}_{Cs}) \\ \text{for the CsCl(I)-NaCl(II) system} \\ -(RT/F)\ln(P_{Cs}a^{II}_{Cs}/P_{Na}a^{I}_{Na}) \\ \text{for the NaCl(I)-CsCl(II) system.} \end{cases} \quad (11)$$

This equation suggests that the membrane potential possesses the Nernstian slope against the logarithmic activity of phase I, in the case of a constant permeability ratio, P_{Na}/P_{Cs}. As illustrated in Figs. 2A and 6, the potential data show the characteristics described above and the average value of P_{Na}/P_{Cs} is 0.72. This fact also verifies the approximation that the system is characterized by Na^+ and Cs^+ excluding the effect of Cl^-.

The significance of constant permeability ratio in the ionic membrane transport phenomena was studied from experimental and theoretical points of views.[5,7,19–21] According to the preceding paper, the following relations are satisfied:[4,6]

$$(P_{Na})^{-1} = \exp(-FV/2RT)\times \int (RTU_{Na})^{-1}\exp[(F\phi/RT) + \zeta_{Na}]dx$$
$$(P^0_{Na})^{-1} = \exp(-FV/2RT)\times \int (D_{Na})^{-1}\exp[(F\phi/RT) + \zeta_{Na}]dx, \quad (12)$$

where U_{Na} and D_{Na} are the ionic mobility and diffusion coefficient of Na^+ within the membrane phase, ϕ is the electrical potential, and ζ_{Na} is the partition factor of Na^+ between the membrane and solution phases. The integration is carried out with respect to the membrane phase. An identical relation is also satisfied for Cs^+. Since the ionic mobilities, diffusion coefficients, and partition factors of Na^+ and Cs^+ are considered to be constant, the next relation is obtained from Eq. 12:

$$\begin{aligned} P_{Na}/P_{Cs} &= (U_{Na}/U_{Cs})\exp(\zeta_{Na} - \zeta_{Cs}) \\ &= (U_{Na}/U_{Cs})K_{Na-Cs} \\ &= (D_{Na}/D_{Cs})K_{Na-Cs} \\ &= P^0_{Na}/P^0_{Cs}, \end{aligned} \quad (13)$$

where K_{Na-Cs} is the equilibrium constant for the exchange reaction between Na^+ and Cs^+ in the membrane system. This equation suggests that the ratio of diffusion coefficients as well as that of ionic mobilities takes a constant value, since the observed permeability ratios are constant. The diffusional to conductive membrane permeability ratios are indications of the interaction between Na^+ and Cs^+. The values of $P^0_{Na}/P_{Na}(=P^0_{Cs}/P_{Cs})$ increase with increasing electrolyte activity as shown in Fig. 6.

To examine the dependence of the inter-ionic correlation on the external electrolyte activity, $P_{Na\cdot Na}/P_{Na}$ and $P_{Cs\cdot Cs}/P_{Cs}$ are plotted against the external NaCl/CsCl activity ratio in Fig. 7. The Na^+ contributions to the conductive permeabilities, $P_{Na\cdot Na}/P_{Na}$ and $P_{Na\cdot Cs}/P_{Cs}$, increase as the relative activity of Na^+ to Cs^+ increases. For usual cation exchange membranes such as CK-1, 1.0t, the NaCl/CsCl concentration ratio in the membrane phase is approximately the same as that

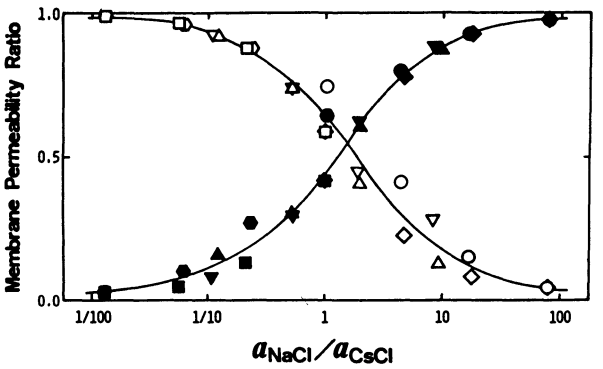

Fig. 7. $P_{Na.Na}/P_{Na}$ and $P_{Cs.Cs}/P_{Cs}$ *vs.* NaCl/CsCl activity ratio of external solutions I and II relations.
The closed and open symbols refer to the ratios for Na^+ and Cs^+. CsCl(I)–NaCl(II) systems, NaCl(II): (●, ○); 10^{-1} mol dm^{-3}, (▲, △); 10^{-2} mol dm^{-3}, (■, □); 10^{-3} mol dm^{-3}. NaCl(I)–CsCl(II) systems, CsCl(II): (●, ○); 10^{-1} mol dm^{-3}, (▼, ▽); 10^{-2} mol dm^{-3}, (◆, ◇); 10^{-3} mol dm^{-3}.

in the solution phase when the membrane is equilibrated with the electrolyte solution (unpublished data). The degree of participation of cations in the membrane transport processes would be parallel to their concentrations within the membrane phase. In the present system, the cross elements of the permeability matrix, $P_{Na.Cs}$ and $P_{Cs.Na}$, are positive quantities, so Eq. 6 leads to:

$$0 \leq 1 - (P_{Cs.Na}/P_{Na}) - (P_{Na.Cs}/P_{Cs}) \leq 1. \quad (14)$$

which is equivalent to the next relation:

$$1 \leq P_{Na.Na}/P_{Na} + P_{Cs.Cs}/P_{Cs} \leq 2. \quad (15)$$

As a limiting case, the equal signs in the right hand side of these inequalities are satisfied when the ionic interactions between Na^+ and Cs^+ are absent, *i.e.*, $P_{Na.Cs}=P_{Cs.Na}=0$. In this case, the system is characterized by:

$$P_{Na} = P^0_{Na} = P_{Na.Na}P_{Cs} = P^0_{Cs} = P_{Cs.Cs}. \quad (16)$$

Such a situation is equivalent to that of an electrolyte solution at infinite dilution where no inter-ionic interactions exist. On the other hand, the equal signs in the left hand sides are realized in the case of the situation expressed as:

$$P_{Na.Na}/P_{Na} = P_{Na.Cs}/P_{Cs}, \quad P_{Cs.Na}/P_{Na} = P_{Cs.Cs}/P_{Cs}. \quad (17)$$

But, the situation of this limiting case where $P^0_{Na}=P^0_{Cs}=0$ is physically meaningless, although P^0_{Na}/P_{Na} is very small and close to zero for lower concentrations.

These results suggest that the transport of cations takes place through the inter-ionic exchange of Na^+ and Cs^+. The participation of the rate of inter-exchange of ions in the bi-ionic systems was discussed on the basis oft he Nernst-Planck approach.[22] However, it may be pointed out that only with the aid of the membrane permeability matrix the conductive and diffusional permeabilities can be related directly to the electrical mobility and diffusion coefficient, respectively, therefore, the movement of ions in the membrane system should be interpreted on the basis of nonequilibrium thermodynamics.

The Nature of Oxygen Species Responsible for Propene Oxidation over V-Mo and V-Sn Oxides

Takehiko ONO* and Yutaka KUBOKAWA
Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591
(Received September 7, 1981)

The rate of oxidation of C_3H_6 has been investigated over V–Mo oxides using $^{18}O_2$(99%) tracer. The extent of participation of lattice oxygen in the oxidation increases with increasing MoO_3 content, showing a maximum at V–Mo (33 mol% of MoO_3) oxide. The rate of oxidation of C_3H_6 varies parallel to the extent of participation of lattice oxygen. A marked dependence of the rate of oxidation upon oxygen pressure observed with V–Mo(33) oxide is attributed to its high reducibility. Similar experiments have been carried out with V–Sn (94 mol% of SnO_2) oxide. The rate of reduction of the oxide with C_3H_6 is about ten times smaller than that of the corresponding catalytic oxidation of C_3H_6, suggesting the participation of adsorbed oxygen in the oxidation. The results of ^{18}O tracer experiments show participation of lattice oxygen in the oxidation. A mechanism which explains such conflicting results has been proposed.

We have recently investigated the rate of oxidation over V–Sn oxides of various compositions.[1] The rate shows two maxima at V–Sn (50 mol% of SnO_2) and V–Sn (94 mol%). It has been concluded that the rate maximum with V–Sn(50) arises from the formation of amorphous material from which lattice oxygen is easily released, participating in the oxidation. However, with V–Sn(94) oxide it is still unclear what oxygen species is responsible for the C_3H_6 oxidation.

There have been a number of work made on the oxidation reaction over V–Mo oxide catalysts.[2–9] It is well known that the rate of oxidation passes through a maximum at 10—30 mol% of MoO_3 and that such maximum activities are often observed under the conditions of high oxygen concentration.[2–6] On the other hand, several workers have observed no maximum activity at these compositions.[7–9] Whether or not the rate maximum is observed appears to be associated with the concentration of oxygen in the reaction mixture. Furthermore, Takita *et al.*[6] have attributed the rate maximum to formation of adsorbed oxygen species which is facilitated by the presence of V^{4+} ions. These appear to remain problems unsolved.

^{18}O Tracer studies appear to be appropriate for the purpose of solving both problems. In the present work, therefore, these studies together with comparison of the rate of oxidation of C_3H_6 in the presence and absence of oxygen have been carried out.

Experimental

Materials. *V–Mo-450 Catalyst*: The solution containing desired quantities of hexaammonium heptamolybdate and ammonium metavanadate was evaporated with constant stirring, and the dried product was calcined in air at 450 °C.

V–Mo-680 Catalyst: A mechanical mixture of V_2O_5 and MoO_3 powders in a desired ratio was melted at 680 °C for 0.5 h, and the melt was ground to powder after cooling. The method of preparation of V–Sn (94) was described previously.[1] $^{18}O_2$ (99.1%) was obtained from B. O. C. Limited (U. K.).

Apparatus and Procedure. The catalytic oxidation and the reduction of the oxides were carried out in a closed circulation system (290 cm^3). The reaction products such as acryladehyde, CO_2, and CO were analyzed by gas chromatography.

X-Ray diffraction patterns of the catalysts were obtained on a Rigaku Denki D-3F X-ray diffractometer using Cu $K\alpha$ radiation with a Ni filter. IR spectra of the catalysts were recorded on a Hitachi G2 spectrometer. The samples were prepared by the KBr pellet technique. The ^{18}O% in the reaction products were determined with a Hitachi RMU-6E mass spectrometer using the following ionization voltage; 80 V for CO and CO_2, 16.5 V for H_2O, and 15 V for CH_2=CHCHO. The BET surface area, the IR spectra, and the results of X-ray diffraction analysis are shown in Table 1.

Results and Discussion

C_3H_6 Oxidation over V–Mo Oxides and Their Reduction with C_3H_6. The rates of reduction of V–Mo oxides with C_3H_6 were determined at 320 °C in the range where the plot of the amount reacted *vs.* time is linear (0.5—3 min). The amount of oxygen removed under these conditions corresponded to one or two oxide layers, the distribution of the reaction products being 50% for CO, 35—30% for CO_2, 15—20% for CH_2=CHCHO,

below 2—3% for CH_3CHO and CH_3COCH_3. Figure 1 shows the rate of reduction thus obtained as a function of MoO_3. With V–Mo-450 as well as V–Mo-680, the rate of reduction passes through a maximum at V–Mo-(33) as reported by several workers.[2-6] The product distribution is the same throughout all the catalysts, suggesting that the reduction of vanadium ions is the main reaction. It should be noted that the preparation temperature affects the reducibility of the oxides markedly, *i.e.*, V_2O_5-450 is almost 10 times more reactive than V_2O_5-680, although the V–Mo oxides exhibit no such a marked difference in their reducibility according to their preparation temperature.

Figure 2 shows the dependence of the rate of the catalytic oxidation of C_3H_6 over V–Mo oxides upon oxygen pressure. In the oxidation at high pressure of oxygen (<40 Torr), the rate of oxidation is higher for V–Mo(33)-450 than for other V–Mo-450 oxides, although the situation is not clear in the low pressure region (>6 Torr). Such a behavior reflects the high dependence of the rate of oxidation for V–Mo(33)-450 upon oxygen pressure, *i.e.*, the order of the reaction in oxygen is about 0.4 for V–Mo(33)-450, while 0.3 for other V–Mo oxides. A similar situation is observed with V–Mo-680; The order of the reaction is 0.2 for V–Mo-(33)-680, but zero for other V–Mo-680 oxides. As is shown in Table 2, the product distribution for catalytic oxidation of C_3H_6 is essentially the same as that for the reduction of oxides with C_3H_6, *i.e.*, the oxidation of C_3H_6 in the absence of gaseous oxygen.

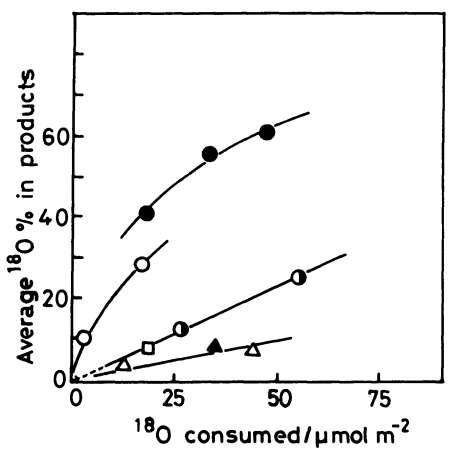

Fig. 3. Average ^{18}O%[a] in the products *vs.* amounts of oxygen consumed[b] in the oxidation.

C_3H_6 Oxidation over V–Mo Oxides Using $^{18}O_2$ Tracer. Table 2 and Fig. 3 show the results of the oxidation experiments using $^{18}O_2$ tracer. The product selectivities towards CO_2, CO, and CH_2=CHCHO are nearly the same as those of the reduction experiments (Fig. 1). No change in the ^{18}O content of the oxygen occurred during the reaction, i.e., no formation of $^{16}O^{18}O$ took place. This suggests that the heterophase exchange[11] of oxygen with the catalyst did not take place. According to the work of Blanchared *et al.*,[12] the exchange of oxygen through CO_2 appears to be negligible under the present experimental conditions.

The ^{18}O content in the products ranges from 5 to 10% at the initial stage of the reaction (Table 2 and Fig. 3), in spite of the use of 99% of $^{18}O_2$ as the reactant. This suggests that lattice oxygen participates in the oxidation. Since the anion vacancies formed by the reduction with C_3H_6 are refilled by gaseous oxygen, the ^{18}O content in the lattice oxygen increases with progress of the oxidation. If only the surface layer of the oxides participates in the oxidation, the increase of the ^{18}O content in the products with progress of the oxidation will be very rapid. On the other hand, if many sublayers participate in the oxidation, the reverse situation will result owing to the dilution of the incorporated ^{18}O with lattice oxygen. Accordingly, the feature of the increase of ^{18}O% in the products provides information to what extent the lattice oxygen participates in the reaction. Furthermore, if only the surface layer of the oxide participates in the oxidation, the surface anion vacancies formed by the reduction are refilled directly by gaseous oxygen without diffusion of the oxide ions in the lattice. On the other hand, when the extent of participation of lattice oxygen is high, most of the surface anion vacancies are refilled by diffusion of oxide ions. This suggests that whether or not the diffusion of the oxide ions is easy appears to be important for determining the extent of participation of lattice oxygen in the oxidation. As has been done by Keulks *et al.*,[13] assuming uniform distribution of the incorporated ^{18}O among the sublayers of the oxides and the number of oxygen atoms in unit area of the surface, the extent of participation of lattice oxygen in the reaction has been calculated (Table 2).

As regards V–Mo-680, the extent of participation of lattice oxygen increases with increasing MoO_3 content, showing a maximum at V–Mo(33), and then it decreases. As shown in Table 1, V–Mo(33) and V–Mo(50) consist of V_2O_5 as well as $Mo_6V_9O_{40}$, and $Mo_6V_9O_{40}$ alone, respectively. It is well known that addition of MoO_3 to V_2O_5 leads to formation of V^{4+},[2] which increases the concentration of anion vacancy in V_2O_5, *i.e.*, makes the diffusion of the oxide ions in the lattice easy. Thus, a marked increase in the participation of lattice oxygen observed with V–Mo(33)-680 is explicable, since the extent of participation of lattice oxygen is associated with the rate of diffusion of the oxide ions as described above. The decrease in the participation of lattice oxygen observed with V–Mo(50) seems to be attributed to formation of $Mo_6V_9O_{40}$ where the diffusion of oxide ions will be more difficult than with V_2O_5.

A similar situation is observed with V–Mo-450. The extent of participation of lattice oxygen is higher for V–Mo(33)-450 than for V–Mo(50)-450. Furthermore, a marked difference between the extent of lattice oxygen participation for V_2O_5-680 and -450 appears to be attributed to a higher concentration of V^{4+} for V_2O_5-450.

It is seen from Table 2 that for both V–Mo-680 and -450 oxides the extent of participation of lattice oxygen runs parallel with the rate of catalytic oxidation of C_3H_6, *i.e.*, for both series of V–Mo oxides the order V_2O_5<V–Mo(50)<V–Mo(33) holds. Such feature is in agreement with that observed with Bi–Mo oxides by Keulks *et al.*[13]

As will be shown later, the participation of lattice oxygen in the oxidation does not always exclude the possibility that adsorbed oxygen participates in the oxidation. Comparison of the rates of C_3H_6 oxidation in the presence and absence of gaseous oxygen is expected to provide information on such possibility (Fig. 2). Since the rates of catalytic oxidation of C_3H_6 over V–Mo oxides vary with the pressure of oxygen, it is difficult to compare both rates of oxidation quantita-

tively. However, as is seen in Fig. 2, there appears to be no marked difference between both rates of oxidation, suggesting that no adsorbed oxygen plays a significant role in the oxidation over V–Mo oxides.

As has been proposed by a number of workers[15] with Bi–Mo oxides, the reduction of the oxides with C_3H_6 and its oxidation by gaseous oxygen occur in different regions on the surface, A and B, respectively. The surface anion vacancies formed in the region A are refilled by diffusion of the oxide ions in the bulk, which results in formation of the surface anion vacancies in the region B. These vacancies bring about the oxygen uptake. Under such situation, the following equation holds:

$$k_A N_A P_{C_3H_6} \theta_A = k_B N_B P_{O_2}^{1/2} (1 - \theta_B),$$

where θ and 1-θ refer to the surface oxide ions and anion vacancies, respectively.

Similar situation will be expected for V–Mo oxides. Since the rate of oxidation for V–Mo oxides is not independent of oxygen pressure (Fig. 2), the values of θ_A and θ_B are less than unity, in contrast with the case of Bi–Mo oxides where $\theta_A = \theta_B = 1$ holds. There appears to be no marked difference between the values of θ_A and θ_B, since the diffusion of the oxide ions will be rapid as compared to the surface reduction. Accordingly, the above equation is transformed as follows:

$$k_1 P_{C_3H_6} \theta = k_2 P_{O_2}^{1/2} (1 - \theta),$$

where k_1 is rate constant for reduction step and k_2 for reoxidation step. The following rate equation results:

$$r = k_1 k_2 P_{C_3H_6} P_{O_2}^{1/2} / (k_1 P_{C_3H_6} + k_2 P_{O_2}^{1/2}).$$

This equation has been found to be applicable to the results shown in Fig. 2 with the values of k_1 and k_2 in

Table 3. Values of k_1 and k_2 at 320 °C

	V–Mo-450			V–Mo-680		
MoO_3 (mol%)	(0)	(33)	(50)	(0)	(33)	(50)
k_1[a]	0.01	0.03	0.01	0.0002	0.003	0.001
k_2[b]	0.04	0.025	0.03	0.04	0.10	0.10

a) $cm^4\ Torr^{-1}\ min^{-1}\ m^{-2}$. b) $cm^3\ Torr^{-1/2}\ min^{-1}\ m^{-2}$.

Table 3. It is seen that with V–Mo-680 as well as V–Mo-450 k_1 is higher for V–Mo(33) than for V–Mo(50) and V_2O_5, while no marked difference in the value of k_2 is observed for all catalysts. Such a high value of k_1 for V–Mo(33) is expected from the order of increasing reducibility of V–Mo oxides, V_2O_5<V–Mo(50)<V–Mo(33) (Fig. 1). Furthermore, it is to be noted that a marked dependence of the rate of oxidation upon oxygen pressure observed with V–Mo(33) is explicable in terms of the concept that the value of k_2/k_1 for V–Mo-(33) is smaller than the corresponding value for other catalysts.

The above considerations suggest that the rate maximum for V–Mo(33) oxide results from the weakening of V=O bond[2] and is not attributable to the fact that formation of adsorbed oxygen is facilitated by the presence of V^{4+} ions. In fact, the shifts of the V=O absorption band occur for V–Mo(33)-680 (1028→1015 cm^{-1}) and V–Mo(33)-450(1020→1012 cm^{-1}). The change in the lattice constant of V_2O_5 (d_{001}: 4.38→4.30 Å) has been observed with V–Mo(33)-680 alone. No change in the lattice constant with V–Mo(33)-450 may be attributed to the fact that dissolution of Mo ions into V_2O_5 is confined to the surface region alone.

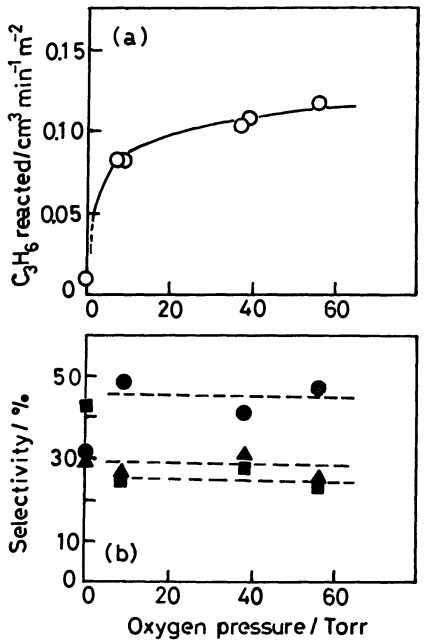

Fig. 4. C_3H_6 oxidation over V–Sn(94) oxide at various oxygen pressures.
(a) Rate. (b) Selectivity. ●: CH_2=CHCHO ▲: CO, ■: CO_2. Temp 320 °C, $P_{C_3H_6}$=23 Torr.

C_3H_6 Oxidation over V–Sn Oxides. Figure 4 shows the rate of C_3H_6 oxidation over V–Sn(94) oxide as a function of oxygen pressure. The rate of oxidation increases slightly with increasing oxygen pressure, the order of the reaction being about 0.1 in oxygen. The rate of reduction of V–Sn(94) oxide with C_3H_6, *i.e.*, the rate of oxidation of C_3H_6 in the absence of oxygen shown in Fig. 4 is 10—12 times smaller than the corresponding catalytic oxidation at 8—60 Torr of oxygen, in contrast with the results for V–Mo oxides where a slight difference is observed between both rates of oxidation. Such a marked difference in the rate of oxidation of C_3H_6 in the presence and absence of oxygen suggests that some active oxygen species may be formed in the presence of gaseous oxygen over V–Sn(94) oxide. Such an active oxygen species may be referred to adsorbed oxygen. As regards adsorbed oxygen, the following case should be mentioned. Some fraction of surface lattice oxygen is more reactive than the remainder; the redox cycle taking place in the presence of oxygen will be limited to such a small fraction. In the absence of oxygen the reaction will occur on the whole surface, including inactive regions. In this case, the enhancement of the rate of oxidation by the presence of oxygen similar to that observed for adsorbed oxygen is expected. Here, such a special type of lattice oxygen is included in the adsorbed oxygen, since it is very difficult to distinguish between both types of oxygen species. The rate of oxidation of C_3H_6 over V–Sn(94) oxide was

Table 4. ^{18}O contents in the products of C_3H_6 oxidation over V–Sn(94) oxide
Experimental conditions are the same as Table 2.

Catalyst[a]	Reaction time / min	Yield[b] of each product and its ^{18}O content (%)[c]				Total yield[e] / μmol-oxygen atoms	Average[f] ^{18}O/%

		(59)	(62)	(—)	(61)		

a)—f) See Table 2.

found to be independent of C_3H_6 in the range 8—60 Torr. Accordingly, the following rate expression holds $r=kp^0_{C_3H_6}P^{0.1}_{O_2}$. Such a low order of the reaction in oxygen as well as in C_3H_6 is different from the feature of the reaction order observed with V_2O_5 and V–Mo oxides.

C_3H_6 Oxidation over V–Sn(94) Oxide Using $^{18}O_2$ Tracer. Table 4 and Fig. 3 show the results of C_3H_6 oxidation using $^{18}O_2$ tracer for V–Sn(94) oxide. The ^{18}O content in the reaction products ranges from 40 to 60%, being much higher than those for V–Mo oxides. There is little or no difference in the ^{18}O content among CO, CO_2, and CH_2=CHCHO. The increase in the ^{18}O content with progress of the reaction is similar to that with V–Mo oxides.

If only adsorbed oxygen participated in the reaction, no incorporation of lattice oxygen in the oxidation would take place, *i.e.*, the ^{18}O content in the products would reach 100%. Such feature has been found by Morooka *et al.*[14] who investigated the oxidation of C_3H_6 over Cu_2O. The observed ^{18}O content in the products for V–Sn(94) oxide (Table 4) suggests that in addition to adsorbed oxygen, lattice oxygen participates in the oxidation. From the data at the reaction time of one minute it is concluded that the rate of incorporation of lattice oxygen (^{16}O) into the oxidation products is about 15 μmol/min m^2, being much larger than the corresponding rate of the oxidation in the absence of oxygen, *i.e.*, the reduction of the oxide with C_3H_6 which is only 2—3 μmol/min m^2 (Fig. 4). Such a marked enhancement of the rate of incorporation of lattice oxygen by the presence of gaseous oxygen suggests that the oxidation by lattice oxygen and by adsorbed oxygen do not proceed independently, *i.e.*, both oxidations are combined with each other in some way. If adsorbed oxygen attacks propene to form a reaction intermediate, which is easily oxidized by lattice oxygen, it would be possible to explain such an enhancement of the rate of incorporation of lattice oxygen by the presence of oxygen. At present, the nature of the reaction intermediate is unclear. A possible adsorbed oxygen appears to be oxygen anion radicals. Kazanskii *et al.*[16] have proposed that the O^- anion radicals can initiate an effective catalytic oxidation of CO over V_2O_5 supported on silica gel. Further study is necessary to clarify the true nature of adsorbed oxygen as well as the reaction intermediate.

The authors wish to thank Messrs. Hazime Nakazawa and Tadashi Terasaki for carrying out part of the experiments.

Kinetic Studies of Spin Trapping Reactions. III. Rate Constants for Spin Trapping of the Cyclohexyl Radical

Takahisa DOBA† and Hiroshi YOSHIDA*
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received October 19, 1981)

In order to give a quantitative basis for the spin trapping technique, the spin trapping rate constants for the reactions between commonly-used spin traps and cyclohexyl radicals have been determined. The cyclohexyl radicals were generated by γ-irradiating cyclohexane solutions of the spin traps. The rate constants for nitrosobenzene, nitrosodurene, pentamethylnitrosobenzene, 2,4,6-tri-*t*-butylnitrosobenzene, and α-phenyl-*N*-*t*-butylnitrone at 299 K are 9×10^7, 1.4×10^7, 1.6×10^7, 2.4×10^4, and 8×10^3 mol^{-1} dm^3 s^{-1}, respectively. The results are qualitatively in accordance with previous data for *t*-butyl, 1-methyl-5-hexenyl, and 5-hexenyl radicals.

The spin trapping technique, that is, the transformation of short-lived free radicals into stable, persistent radicals by a reaction with a spin trap, such as a nitroso compound, and the subsequent observation of these persistent radicals by means of conventional electron spin resonance (ESR) measurements, has proved to be useful for the detection and indentification of free radical intermediates in liquid and gas-phase reaction systems. Before the method is utilized in mechanistic and kinetic studies of free radical reactions, its quantitative aspects should be further explored. The yields of the free radical intermediates, for example, cannot be derived by this technique without a knowledge of the rate constant for the spin trapping reaction between the spin trap used and the free radical in question. There has been relatively few rate date available for spin trapping reactions.

We have reported the first systematic study on the spin trapping rate constants for reactions between several spin traps (mostly nitroso compounds) and the *t*-butyl radical.[1] It was found that the rate constant varies over a wide range, from 10^4 to 10^8 mol^{-1} dm^3 s^{-1}, depending on the spin trap. Later, Ingold *et al.* have reported investigations on the spin trapping rate constant with 5-hexenyl[2] and 1-methyl-2-hexenyl radicals,[3] and have shown a general trend in the reactivity of several spin traps toward primary, secondary, and tertiary alkyl radicals.

In the present investigation, we have determined the spin trapping rate constants for reactions of commonly-used spin traps and another secondary alkyl radical, the cyclohexyl radical. We recently found that γ-radiolysis of cyclohexane containing a spin trap gave ESR spectra which were exclusively due to a cyclohexyl radical spin adduct.[4,5] This radiation-chemical technique has been used to generate authentic cyclohexyl radical spin adducts in the present investigation.

Experimental

Spectro-grade cyclohexane was used without further purification. Pentamethylnitrosobenzene (PMNB)[6] and α-phenyl-*N*-*t*-butylnitrone (PBN, *N*-*t*-butyl-α-toluenimine *N*-oxide)[7] were synthesized as has been described previously. Nitrosobenzene (NB) and 2-methyl-2-nitrosopropane (BNO) were purchased commercially and used as received. Nitrosodurene (ND) and 2,4,6-tri-*t*-butylnitrosobenzene (BNB) were kindly donated by Dr. R. Konaka of Shionogi Pharm. Co. Ltd. and Dr. S. Moriuchi of Mitsui Petrochemical Ind. Ltd.

Sample solutions of spin traps in cyclohexane were degassed by freeze-pump-thaw cycles nder a vacuumu of 10^{-5} Torr** and sealed in quartz ESR tubes. They were irradiated with ^{60}Co γ-rays at a dose rate of about 0.5 krad/min at 289—1 K, and subjected to ESR measurement with a Varian E-109 X-band spectrometer at the ambient temperature. Decay of the spin adducts during storage was avoided by freezing the irradiated samples at 77 K.

If the concentration of the spin traps was too low to be determined by weighing, it was determined from the intensity of their optical absorption. The optical absorption data which were used are summarized in Table 1.

Results and Discussion

When the sample solution contains one kind of spin trap, it generally shows an ESR spectrum which is due exclusively to a cyclohexyl radical spin adduct, as reported previously for PMNB.[4] An exception is BNO, which gave an ESR spectrum with 3×9 hyperfine lines. This spectrum cannot be due to the cyclohexyl radical spin adduct, but is probably due to the spin adduct of a secondarily generated free radical. Although BNO is one of the most commonly used spin adducts, it was omitted from the present investigation.

When two kinds of spin traps are present, the two corresponding spin adducts of the cyclohexyl radical are observed by ESR. This is shown in Fig. 1 for a pair of spin traps, PBN and BNB. The ESR signal is comprised of a triple doublet spectrum with a nitrogen hyperfine coupling, a_N, of 1.35 mT and a proton hyperfine coupling, a_H, of 0.25 mT and a triple quartet spectrum with a_N of 1.10 mT and a_H of 0.20 mT. The former spectrum is due to a nitroxide-type cyclohexyl radical-PBN spin adduct (*N*-*t*-butyl-α-cyclohexylbenzylaminoxyl), whereas the latter is due to an anilino-type cyclohexyl radical-BNB spin adduct (*O*-cyclohexyl-*N*-(2,4,6-tri-*t*-butylphenyl)hydroxylaminyl). This assignment is based on reported hyperfine coupling data.[8,9]

Assuming the absence of decay of the spin adducts once these have been generated, the relative yields of the spin adducts should be determined by a competition between the spin trapping reactions of the coexisting

spin traps (denoted as 1 and 2). This means that the relationship

$$\frac{d[A_1]/dt}{d[A_2]/dt} = \frac{k^T_1[T_1]}{k^T_2[T_2]} \qquad (1)$$

should hold between the concentrations of spin traps and spin adducts, T_i and A_i. k^T_i is the spin trapping rate constant of the i-th spin trap, and t is the time of the γ-irradiation. The rate constant ratio k^T_1/k^T_2 has been determined for several pairs of spin traps at 289 K by irradiating the sample solutions to a low dose so that $[A_i]$ increased linearly with the irradiation time.[4] Pairs of spin traps were chosen for which overlapping spectra of spin adducts can be separated from each other. A typical example of the observed results, that of the PMNB-BNB pair, is shown in Fig. 2.

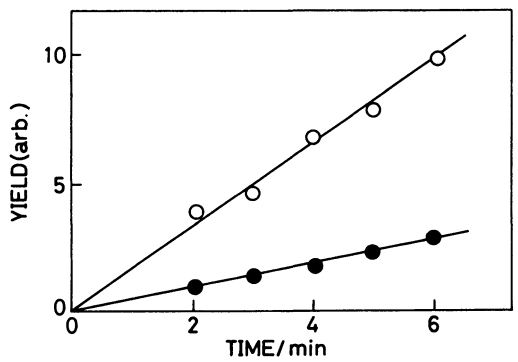

Fig. 2. Yields of (○) cyclohexyl radical-PMNB and (●) cyclohexyl radical-BNB spin adducts as a function of γ-irradiation time observed from cyclohexane containing 1.9×10^{-4} mol/dm^3 PMNB and 5×10^{-2} mol/dm^3 BNB.

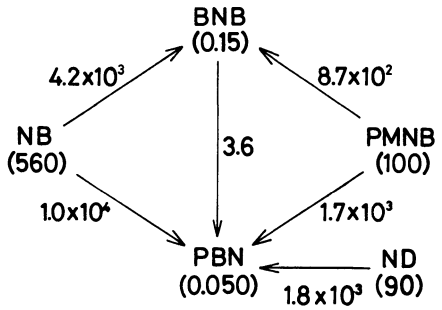
The rate constant ratio was determined according to the following scheme, where arrows connect the pairs of the spin traps examined, pointing from the more reactive to the less reactive trap. The observed ratio is given above each arrow. It is the average of two to five individual competitive measurements at various trap concentrations. The numbers in parentheses show the relative spin trapping rate constants determined with respect to PMNB by averaging all possible paths with a weight factor inversely proportional to the number of arrows along the path. For example, the rate constant for NB is $100\times[(4.2\times10^3\ 8.7\times10^2+1.0\times10^4/1.7\times10^3)/2+(1.0\times10^4/3.6\times8.4\times10^2+3.6\times4.2\times10^3/1.7\times10^3)/3]\times(6/10)=560$. The values thus determined show the validity of the scheme by their internal consistency. These values seem to be correct with an uncertainty of 20%.



The absolute value of the spin trapping rate constant can generally be determined from competition experiments using a reference reaction with a known rate constant. We previously determined the spin trapping rate constant for the reaction of PMNB and the cyclohexyl radical to be 1.6×10^7 mol^{-1} dm^3 s^{-1} at 299 K. This was done by using

$$\dot{C}_6H_{11} + (C_4H_9)_3SnH \longrightarrow C_6H_{12} + (C_4H_9)_3\dot{S}n, \qquad (2)$$

as a reference reaction.[10] The temperature was 10 K higher than that in the present experiment. The activation energy of k^T has been reported to be so small (1—3 kcal/mol)[2] that the experimental k^T_1/k^T_2 ratio

TABLE 2. SUMMARY OF RATE CONSTANTS FOR THE SPIN TRAPPING OF ALKYL RADICALS

Spin trap	$k^T/10^5$ mo^{-1} dm^3 s^{-1}

is expected to be almost temperature-independent in a small temperature range, such as that from 289 to 299 K. A difference of 1 kcal/mol in activation energy leads to a difference of 12% in the ratio. Actually, no temperature-dependence could be found experimentally for the PBN-ND pair. The spin trapping rate constant for each spin trap was calculated from the rate constant ratio determined in the present study and the absolute rate constant for PMNB reported previously.[4]

The results of the present study are shown in Table 2 together with the rate constants for spin trapping primary (5-hexenyl), secondary (1-methyl-5-hexenyl), and tertiary (*t*-butyl) radicals as reported by Ingold *et al.*[2,3] and by ourselves.[1] Alkyl radicals are efficiently spin-trapped by all of the aromatic nitroso compounds examined except BNB. The rate constants for the spin trapping reactions of the different nitroso compounds decrease in the order $k^T_{NB}>k^T_{ND}\approx k^T_{PMNB}\gg k^T_{BNB}$. This shows that substituting ortho hydrogens in the aromatic ring for bulky groups has a significant effect on the spin trapping reactions. It also supports the previous suggestion[2] that the spin trapping reaction of BNB is slow because formation of the adduct requires a fairly exact configuration of the reactions, even though the potential energy barrier to be surmounted is small. The type of trapping reaction BNB undergoes depends on the free radical trapped. For primary alkyl radicals, the result is a nitroxide-type spin adduct which many other spin traps also give. But for tertiary alkyl radicals the results is an anilino-type spin adduct. Secondary alkyl radicals are on the borderline between these two types of the trapping reactions. For the 1-methyl-5-hexenyl radical, both the anilino- and nitroxide-type spin adducts are found,[3] whereas for the cyclohexyl radical only the anilino-type spin adduct is observed.[4,9] Although the nitrone is not an efficient spin trap for alkyl radicals, including the cyclohexyl radical, it is efficient in trapping phenyl[11] and alkoxyl radicals.[12–14] It should be stressed that the spin trapping rate constants of commonly-used spin traps differ over a wide range of four orders of magnitude.

Although the overall picture for primary, secondary, and tertiary alkyl radicals has revealed that $k^T_{prim}>k^T_{sec}>k^T_{tert}$,[3] the spin trapping rate constants determined for the cyclohexyl radical in this paper are generally smaller than those for *t*-butyl radical as previously determined by ourselves.[1] This unexpected result may stem from an experimental artifact caused by an improper choice of reference reactions. Nevertheless, the results summarized in this paper gives a clue to the quantitative application of the spin trapping technique to mechanistic and kinetic studies of free radical reactions.

The authers wish to thank Dr. R. Konaka of Shionogi Pharm. Co. Ltd. and Dr. S. Moriuchi of Mitsui Petrochemical Ind. Ltd. for their kindness in donating spin traps, and Dr. K. U. Ingold of the National Research Council, Canada, for the suggestion, which enabled us to improve the data shown in Table 1.

Solvent Effects on the Fluorescence Quantum Yields and Lifetimes of 1- and 2-Acetyl- or Benzoylanthracenes

Takashi TAMAKI
Research Institute for Polymers and Textiles, Yatabe-Higashi 1-1-4, Tsukuba, Ibaraki 305

(Received October 22, 1981)

The fluorescence quantum yields and lifetimes of 1- and 2-acetyl- or benzoylanthracenes were measured in various degassed solvents at room temperature. The natural fluorescence lifetime was evaluated to be 30—40 ns, depending a little on the compounds, but little on the solvent. This strongly supports the recent finding that the lowest excited singlet state of the acylanthracenes is of a $\pi\pi^*$ character. On the basis of triplet-yield measurements, it was also confirmed that the low fluorescence yield in nonpolar solvents is due to an efficient intersystem crossing to an upper triplet state.

It is well established that an intersystem crossing (ISC) is the dominant nonradiative decay pathway for the lowest excited singlet state (S_1) of aromatic hydrocarbons. In the case of anthracene, the lowest triplet state (T_1) lies much lower in energy than S_1, so that the direct ISC to T_1 is incapable of competing with rapid fluorescence. Instead, the ISC to an upper triplet state (T_x) lying slightly below S_1 is favored.[1] On the other hand, it has been widely accepted for 9-methyl-, phenyl-, or haloanthracene that the ISC occurs dominantly from a thermally activated level of S_1 into T_x lying above S_1.[2] This temperature-dependent ISC well explains the considerable fluorescence variation with the temperature.[3—6]

The fluorescence of 1- or 2-acetylanthracenes is significantly dependent on the solvent. As a general trend, the fluorescence yield increases, with a concomitant red-shift of the peak maximum, as the solvent polarity increases.[7,8] The possible mechanisms for this solvent variation in the fluorescence yield are as follows; (I) a change in the thermal barrier of the temperature-dependent ISC due to the displacement of the S_1 level, and (II) an inversion of the excited electronic configuration from $n\pi^*$ to $\pi\pi^*$, as in the case of 3-pyrenecarbaldehyde.[9] Recently, Hirayama has pointed out that the S_1 of acylanthracenes has a $\pi\pi^*$ electronic configuration.[10] His conclusion was supported for 9-acylanthracenes by the external-pressure effect on the fluorescence.[11] If this is so also for 1- or 2-acylanthracenes, the (II) mechanism can be excluded.

This paper will describe the results of the fluorescence-quantum-yield, lifetime, and triplet-yield measurements for 1- and 2-acetyl- or benzoylanthracenes in various degassed solvents at room temperature, these findings are consistent with the (I) mechanism.

Experimental

1-Acetyl- (**1A**), 1-benzoylanthracene (**1B**), and their 2-isomers (**2A** and **2B** respectively) were the same as those used before.[8] The cyclohexane (Cy), dipropyl ether (DPE), tetrahydrofuran (THF), 1,2-dichloroethane (DCE), acetone (AC), acetonitrile (ACN), *t*-butyl alcohol (*t*-BuOH), 2-propanol (*i*-PrOH), ethanol (EtOH), and methanol (MeOH) were GR- or Spectro-grade reagents. For all optical measurements except for that of phosphorescence, the sample solutions were degassed by the freeze-thaw method ($<5\times10^{-5}$ Torr; 1 Torr$\approx$133.32 Pa).

The corrected fluorescence spectra were measured by using a Hitachi MPF 4 spectrofluorometer, and the observed spectra on the wavelength scale were transformed into those on the wave-number scale. The fluorescence spectra of the samples were independent of the excitation wavelength. The fluorescence intensities calculated from the trapezoid rule were corrected for the refractive index of the solvent and for the sample absorbance at the exciting wavelength (385 nm for **1A** and **1B** and 360 nm for **2A** and **2B**). The fluorescence quantum yields were based on that of 9,10-diphenylanthracene in EtOH (0.76[12]).

The fluorescence lifetime measurements were done using an Ortec SP-3 nanosecond fluorometer. A nanosecond flash lamp filled with 0.5 atm of air was operated at 5 kV at a frequency of 100 kHz, the half-bandwidth of the light pulse being 6 ns. A band-pass filter (Corning 3-73) was inserted between the flash lamp and the sample cell in order to excite the sample by nitrogen-line outputs at 300—400 nm effectively. The monitoring wavelengths were selected by means of a monochrometor; 430 nm for aprotic solutions and 500 nm for alcoholic solutions.

The analogous technique developed by Grinvald and Steinberg[13] was applied to the deconvolution of the fluorescence time evolution $\{f(t)\}$, which has this form:

$$f(t) = \int_0^t g(t-s)i(s)\mathrm{d}s,$$

where $g(t)$ is the response of the detection system to the excitation flash and where $i(t)$ is the required fluorescence decay function. $g(t)$ was experimentally determined after Wahl *et al.*[14] by using 2,5-bis[5-*t*-butylbenzoxazol-2-yl]thiophene (BBOT) as a fluorophore. $i(t)$ was assumed to be mono- and biexponential; thus:

$$i(t) = \sum_j^{1,2} C_j \exp(-\lambda_j t),$$

where C_j and λ_j are unknown parameters. The convolution product of $i(t)$ with $g(t)$ was iteratively calculated by Marquardt's least-squares method[15] to fit the decay curves observed. The calculation was terminated whenever

$\Delta C_j/C_j \leq 0.001$ and $\Delta\lambda_j/\lambda_j \leq 0.001$ for all j,

where ΔC_j and $\Delta\lambda_j$ are the increments in the parameters at the last iteration. In order to judge whether or not the curve smoothing is good, the autocorrelation function and the residuals between observed and calculated curves were calculated.[13] If theobserved decay data scatter randomly about the calculated curve, the autocorrelation function fluctuates near the zero line with a high frequency and a low amplitude.[13] A typical example of the computer-simulated decay curve is shown in Fig. 1.

The triplet-triplet absorption measurements were done using a Ushio UFP-105 microsecond flash apparatus. The sample concentrations were prepared to be $1—2\times10^{-4}$ mol

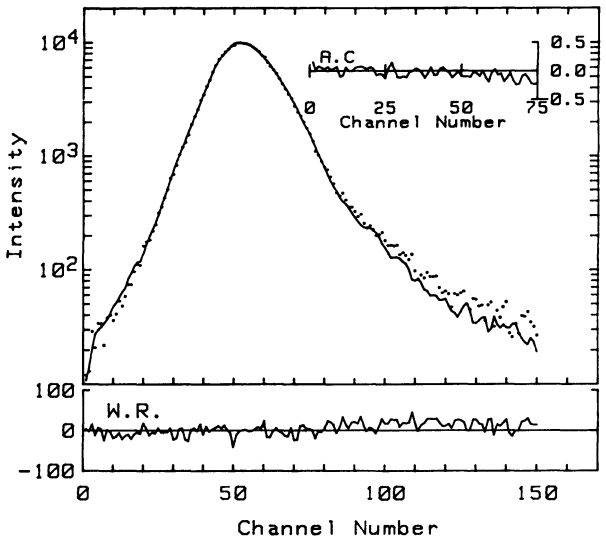

Fig. 1. Observed and simulated fluorescence decay curves of 2-acetylanthracene in cyclohexane.

dm^{-3}, so that the samples absorbed almost all the incident light selected by a Corning 3-73 filter. The relative triplet yields were determined from the initial absorbances of the maximum band lying at 485 nm for **1A**, at 437 nm for **2A**, at 422 nm for **1B**, and at 450 nm for **2B**, since the absorption spectra were little dependent on the solvent. The phosphorescence measurements were done in rigid methylcyclohexane glasses at 77 K.

Results

The absorption and fluorescence spectra of **1A** and **2A** in Cy are shown in Figs. 2a and 2b respectively. The general forms of the absorption and fluorescence spectra are little dependent on the substituent (acetyl and benzoyl) groups, but on the C-position of an anthryl ring, at which the substitution occurs. The fluorescence spectra of all the compounds examined are remarkably dependent on the solvent, while the absorption spectra undergo no corresponding change.[8] As the solvent polarity increases, the fluorescence spectra become more structureless and the peak maxima move to lower energies. Concomitantly, significant variations in the fluorescence quantum yield (ϕ_f) and the actual lifetime (τ_f) are observed. These values for **1A** and **2A** in several aprotic and alcoholic solvents, together with the energy of the fluorescence maxima ($\tilde{\nu}_f$), are listed in Table 1. In aprotic solvents, ϕ_f increases with an increase in the solvent polarity, but such a simple relation breaks in alcohols. From *t*-BuOH through MeOH, the ϕ_f value for **1A** increases, remains practically the same for **2A**, and considerably decreases for **1B** and **2B**. The observed solvent dependence of τ_f is similar to that of ϕ_f. Table 1 also shows the values of the radiative and nonradiative rate constants (k_f and k_{nr} respectively) evaluated from the observed ϕ_f and τ_f values for **1A** and **2A**.

It should be noted that the best fit to the fluorescence decay curves observed for **1B** and **2B** in alcohols was obtained by taking the biexponential function as $i(t)$; this is in contrast with the other cases, for which the observed decay curves were satisfactorily simulated with the monoexponential. The C_j and λ_j values for **2B**, together with the observed $\tilde{\nu}_f$ and ϕ_f values, are

listed in Table 2. Since the apparent lifetime of **1B** was very short, the C_j and λ_j values obtained were less reproducible.

The relative triplet yields (ϕ_T) in several solvents are listed in Table 3. An inverse relationship is observed between ϕ_T and ϕ_f as the solvent polarity increases in going from Cy through *t*-BuOH. It appears likely that the ϕ_T values in MeOH are too low to cover all of the nonradiative decay probability. This is of particular interest in the case of **1B** and **2B**, since the ϕ_f values of these compounds are also very low in the same solvent. On the other hand, the triplet lifetime was observed to be 0.2—0.4 ms, slightly dependent on the compound, but less sensitive to the solvent. The phosphorescence was detected except for **2A** (λ_{max}=684, 680, and 675 nm for **1A**, **1B**, and **2B** respectively).

Discussion

Red Shift of the Fluorescence Peak Maxima. The solvent dependence of $\tilde{\nu}_f$, as listed in Table 1, can be interpreted in terms of the nonspecific and specific solvent-solute interactions. In aprotic solvents, $\tilde{\nu}_f$ is well correlated with the macroscopic solvent polarity, which is itself associated with the dielectric constant and the refractive index.[8] This may suggest that the higher the solvent polarity, the greater the contribution of the charge-transfer (CT) resonance form in the excited state, in which positive and negative charges are localized in the anthryl and acyl moieties respectively. In reality, the excited-state dipole moments in polar solvents were measured to be 7D for **1A** and **1B** and 10D for **2A** and **2B**.[8] On the other hand, the red shift of $\tilde{\nu}_f$ in alcohols is extraordinarily larger than that to be expected from the solvent polarity. For example, $\tilde{\nu}_f$ in MeOH is lower in energy by *ca.* 2000 cm^{-1} than that in ACN, though these two solvents have quite similar polarities. The excess of the red shift in MeOH agrees with the stabilization energy due to the specific formation of hydrogen-bonded complex(es) in a hexane–MeOH mixture solution.[16]

Electronic Configuration of S_1 and ISC to the Upper Triplet State. As is shown in Table 1, k_f is little dependent on the solvent, whereas k_{nr} undergoes significant variation with the solvent. The k_f values observed in all solvents used are in an order of 2—3 $\times 10^7$ s^{-1},[17] suggesting that the electronic configuration of the compounds concerned in the S_1 state is of the $\pi\pi^*$ type, even in a very nonpolar solvent (Cy) where ϕ_f is quite low. The result is consistent with a recent conclusion.[10] The $\pi\pi^*$ nature of the fluorescence can be further confirmed by a comparison of the observed k_f value with that alternatively calculated from the observed absorption and fluorescence spectra. Unfortunately, the two $\pi\pi^*$ transition bands ascribed to ^1L_a and ^1L_b are largely overlapping in the long-wavelength absorption spectra of the compounds concerned,[8] and no mirror-symmetry relation is seen between the absorption and fluorescence spectra, as is shown in Fig. 2. Therefore, the calculation of k_f was done using the long-end absorption band obtained from the mirror-symmetry reflection of the fluorescence spectrum according to this equation:

$$\varepsilon(\tilde{\nu})/\tilde{\nu} = F(2\tilde{\nu}_0 - \tilde{\nu})/(2\tilde{\nu}_0 - \tilde{\nu})^3, \quad (1)$$

where $\varepsilon(\tilde{\nu})$ and $F(2\tilde{\nu}_0-\tilde{\nu})$ are the molar absorptivity and the fluorescence intensity as a function of the wave number respectively, and where $\tilde{\nu}_0$ is the mirror-symmetry frequency.[18] The transition band thus assumed for **1A** and **2A** is shown in Fig. 2. In such cases, k_f can be calculated from the following equation:[18]

$$k_f = 2.88 \times 10^9 n^2 \int \varepsilon(\tilde{\nu})(2\tilde{\nu}_0 - \tilde{\nu})^3 / \tilde{\nu} d\tilde{\nu}, \quad (2)$$

where n is the refractive index of the solvent. The value of k_f was obtained as 4×10^7 s^{-1} for **1A** and as 3×10^7 s^{-1} for **2A**. These values are rather close to those experimentally determined from ϕ_f and τ_f, in spite of the rough estimation of $\varepsilon(\tilde{\nu})$.

Clearly, the solvent variation in both ϕ_f and τ_f in aprotic solvents is predominantly due to the solvent variation in k_{nr}. From the inverse relation between ϕ_f and ϕ_T, it appears probable that the ISC plays an important role in the nonradiative deactivation. Furthermore, it is shown that k_{nr} decreases with a decrease in the $\tilde{\nu}_f$ value. The plot of log k_{nr} *vs.* $\tilde{\nu}_f$ for **2A** is shown in Fig. 3. A linear relation is observed between

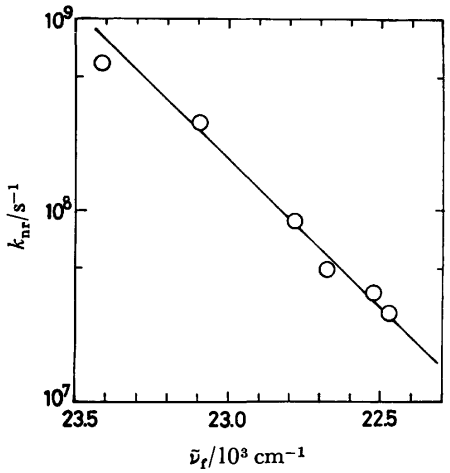

Fig. 3. Plots of log k_{nr} *vs.* $\tilde{\nu}_f$ for 2-acetylanthracene.

them. This striking relation may most reasonably be explained in terms of the (I) mechanism describing the validity of the thermally activated ISC, as in the cases of 9-haloanthracene derivatives, for which a direct correlation has been shown between the activation energy of the ISC and the solvent shift of S_1.[6] The situation is common to all the compounds examined, but it appears likely that not only the thermally activated ISC, but also the temperature-independent ISC, is operative for **1A**, **1B**, and **2B**, since these compounds exhibit the phosphorescence at 77 K, where the former ISC is inhibited. On the other hand, the temperature-independent ISC may be less important for **2A**, which emits no phosphorescence.

It was suggested for acylanthracenes that the triplet states of both $\pi\pi^*$ (T_2) and $n\pi^*$ ($T_{n\pi^*}$) are lying near S_1 and that, on the basis of the photoreduction and oxetane formation reaction, the reactive $T_{n\pi^*}$ lies above the nonreactive T_2 for the photostable derivatives.[10] The compounds concerned in this study are just like this. Combining these results with our data, the relative energy levels of relevant excited states in such noninteracting solvents as Cy may be deduced as follows; $T_{n\pi^*}>T_2>S_1$ for **2A** and $T_{n\pi^*}>S_1\geqslant T_2$ for **1A**, **1B**, and **2B**. Thus, the temperature-independent ISC to T_2 occurs only in the latter cases, but the temperature-dependent ISC to $T_{n\pi^*}$ occurs commonly in both cases.

Nonradiative Decay Pathways in Alcohols. It is clear that the fluorescence of the acylanthracenes in alcohols is perturbed by the hydrogen-bond interaction with the solvent. The very low ϕ_T values in such powerful hydrogen-donating solvents as MeOH may be due to the fact that a solvent-induced internal conversion pathway replaces ISC as the major nonradiative decay pathway.[19] However, the anomaly of the fluorescence decay kinetics observed for **1B** and **2B** cannot be explained by this mechanism alone. An explanation is, however, given by the following reaction scheme:

$$B \xrightarrow{h\nu} B^{*1} \underset{k_{-r}}{\overset{k_r}{\rightleftharpoons}} X \xrightarrow{k_d} B$$

$$B^{*1} \xrightarrow{k_f} B + h\nu' \quad B \text{ or } {}^3B^*$$

$$B^{*1} \xrightarrow{k_{nr}} {}^3B^*$$

where the k's are the rate constants, where B, $^1B^*$, and $^3B^*$ are the aromatic carbonyl compounds in the ground, excited singlet, and triplet states respectively, and where it is assumed that $^1B^*$ is reversibly converted into a nonfluorescent X. The identification of X remains ambiguous at this stage of our investigation. In this respect, it was suggested that the nonradiative decay due to intramolecular charge sepearation is responsible for the observed decrease in ϕ_f.[8] The decrease in the delocalization interaction between the anthryl and benzoyl moieties may be associated with a noncoplanar geometry between the anthryl and phenyl rings. If so, the torsional isomer appears a likely possible model for X.

The reaction scheme leads to the following equations;

$$C_1 = (\lambda_2 - Z)(C_1 + C_2)/(\lambda_2 - \lambda_1), \quad (3)$$

$$C_2 = (Z - \lambda_1)(C_1 + C_2)/(\lambda_2 - \lambda_1), \quad (4)$$

Table 4. Rate parameters for 2-benzoylanthracene

Solvents	$k_f/10^7\ s^{-1}$	$(k_f+k_{nr}+k_r)/10^7\ s^{-1}$	$(k_{-r}+k_d)/10^7\ s^{-1}$
t-BuOH	3.0	4.8	4.8
i-PrOH	3.2	6.2	5.4
EtOH	3.3	12	12
MeOH	2.1	24	6.6

$$Z = k_f + k_{nr} + k_r, \quad (5)$$

$$\lambda_1 + \lambda_2 = k_f + k_{nr} + k_r + k_{-r} + k_d, \quad (6)$$

$$\lambda_1\lambda_2 = (k_f + k_{nr})(k_{-r} + k_d) + k_r k_d. \quad (7)$$

In the photostationary state, ϕ_f is given in the form:

$$\phi_f = k_f\,(k_{-r} + k_d)/\lambda_1\lambda_2. \quad (8)$$

By using the values of C_j, λ_j, and ϕ_f observed experimentally, the values of $k_f+k_{nr}+k_r$, $k_{-r}+k_d$, and k_f can be evaluated from Eqs. 3 or 4, 6, and 8 respectively. The results for **2B** are listed in Table 4. It is noteworthy that the k_f values thus obtained are of a similar magnitude with those observed in polar aprotic solvents ($k_f \simeq 3\times10^7\ s^{-1}$). This result may support the validity of the reaction scheme postulated. It is observed that either k_{nr} or k_r, or both, increases in going from *t*-BuOH to MeOH, while the sum of k_{-r} and k_d is less variant. It appears likely that the nonradiative decay due to the solvent-induced geometry change as well as to the solvent-induced internal conversion is important for **1B** and **2B** in polar protic solvents.

The Photoassociation of 1- and 2-Acetylanthracenes with Methanol

Takashi TAMAKI
Research Institute for Polymers and Textiles, Yatabe-Higashi 1-1-4, Tsukuba, Ibaraki 305

(Received October 22, 1981)

The effect of small amounts of methanol ($\lesssim$0.34 mol dm^{-3}) upon the absorption and fluorescence spectra of 1- and 2-acetylanthracenes in hexane was investigated. While the formation of a 1 : 1 hydrogen-bonded complex in the ground state was revealed by the isosbestic points of the absorption spectra, the change in the fluorescence spectra was indicative of the photogeneration of a highly associated complex which includes at least two alcohol molecules. On the assumption that the excited 1 : 1 complex further associates with an alcohol molecule, the computer simulation by the least-squares method provided a good fit of the observed concentration dependence of methanol upon the fluorescence quantum yield. The photokinetic parameters and the thermodynamic quantities were evaluated from the simulated parameter values.

The fluorescence spectra of aromatic compounds are, in general, sensitive to solvent polarity, because the electrostatic solvent-solute interaction (dipole-dipole and dipole-induced dipole interactions) perturbs the excited singlet states of the compounds. On the other hand, the fluorescence spectra of some aromatic compounds, such as heterocycles, ketones, and amines, in nonpolar solvents are significantly affected by the addition of small amounts of a protic solvent, which are insufficient to alter the dielectric properties of the solvents.[1-4] This specific perturbation of the fluorescence is due to the formation of a hydrogen-bonded (H-bonded) complex. Recently, the photodynamics of the complex formation has been investigated by using nanosecond fluorescence spectroscopy.[5-7] In their study of time-resolved emission measurements for aminophthalimides in alcohol solvents at low temperatures, Ware and his co-workers found that the spectral shift due to the complex formation occurs in a subnanosecond, preceding the spectral shift associated with the nonspecific dipolar relaxation.[5] DeToma and Brand studied the interaction of 2-anilinonaphthalene in cyclohexane with alcohol at the ambient temperature and presented direct kinetic evidence that this system results in stoichiometric complex formation at a low alcohol concentration, followed by the reorientation of the solvent cage when the concentration of alcohol is high.[6] For the *m*-aminoacetophenone-alcohol-viscous nonpolar solvent system, Itoh and his co-workers reported the formation of an exciplex including two alcohol molecules.[7]

In a previous study of the time-dependent spectral shifts of 1- and 2-acylanthracenes in alcohols at low temperatures,[8] it was suggested that the perturbation of alcohol on the fluorescence of these compounds is caused by a combination of the specific H-bond interaction and a nonspecific dipole reorientation of the solvent, as in the case of aminophthalimide. This paper will describe the photokinetics of the complex formation for 1- (**1A**) and 2-acetylanthracenes (**2A**) with methanol in hexane.

Experimental

The acetylanthracenes (**1A** and **2A**) were the same as those used before.[8] The hexane and methanol were Spectro- and GR-grade reagents respectively and were used without further purification.

The absorption measurements were done using a Cary 17D spectrophotometer equipped with a thermostated cell holder. The concentration of the samples used was 3×10^{-5} mol dm^{-3}. Methanol was added to the sample solutions by up to 0.34 mol dm^{-3}, at which point the dielectric property of the hexane–methanol mixture solution corresponds approximately to that of dipropyl ether (ε=3.4). For the Scott plots,[9] the absorption changes in the presence of methanol were monitored by using 10-cm cylindrical cells at 440 nm for **1A** and at 424 nm for **2A**, where the absorption of uncomplexed ketones is negligible. The absorption spectra of the complex between the aromatic ketones and methanol were determined by means of the following equation:

$$\varepsilon_C(\lambda) = \varepsilon_A(\lambda)\{d(\lambda) - \alpha d_0(\lambda)\}/(1-\alpha)d_0(\lambda),$$

where $\varepsilon_A(\lambda)$ and $\varepsilon_c(\lambda)$ are the molar absorptivities of the ketones and the complex at λ nm respectively, where $d(\lambda)$ and $d_0(\lambda)$ are the absorbances in a unit of the light path at λ nm in the presence and in the absence of methanol respectively, and where α is the mole fraction of the uncomplexed ketones to the total ketones, which can be evaluated from the equilibrium constant.

The corrected fluorescence spectra were measured using a Hitachi MPF 4 spectrofluorometer. The concentrations of the samples and of methanol were the same as those used for the absorption measurements. A 1-cm square cell was placed on a thermostated cell holder connected with a Haake FK constant-temperature circulator. The excitation was done at 350 nm for **1A** and at 368 nm for **2A**, at these points the absorption spectra show their isosbestic points, so that the relative fluorescence intensities correspond directly to the relative fluorescence quantum yields. The steady-state fluorescence data were manipulated by the aid of an HP 9845B desk-top computer. Firstly, the fluorescence spectra on the wavelength scale were transformed into those on the wave-number scale, and the relative fluorescence intensities were calculated from the trapezoid rule. Secondly, the data on the fluorescence quantum yields were analyzed by the use of a software file (09845-15140) programing the nonlinear regression analysis. The initial values of the free parameters were set as 10, and the calculation was iterated until the value of each parameter converged into (1$\pm$0.1) times the preceding value.

The nanosecond fluorescence measurements and the deconvolution analysis were done in ways similar to those described elsewhere.[10] Since the fluorescence lifteime of **1A** in hexane is too short ($<$1 ns) to be detected by our apparatus, no experimental result for this compound is presented.

Results

The absorption spectra of **2A** in hexane in the presence and in the absence of methanol (M) are shown in Fig. 1. The apparent isosbestic points in the spectra are indicative of the formation of the complex. The Scott plots for **1A** and **2A** are shown in Fig. 2. The linearity of the plots is gratifying. The equilibrium constant (K_g) was evaluated to be 6.8 mol^{-1} dm^3 for **1A** and 2.7 mol^{-1} dm^3 for **2A** at 20 °C, only slightly dependent on the temperature. The absorption spectrum of the complex for **2A** is also shown in Fig. 1. The general form of this spectrum is close to that in pure methanol, which is also shown for the sake of comparison. The two vibrational bands lying at 376 and 388 nm in hexane are deformed, and the long wavelength edge extends to the red region. The red shift of the peak maximum amounts to *ca.* 100 cm^{-1} for **2A**. On the other hand, the spectral shift for **1A** is very small, and the peak maxima of the perturbed and unperturbed spectra are practically the same.

1A and **2A** emit a weak and structured fluorescence in hexane. The addition of small amounts of M induces a significant change in these fluorescence spectra. A typical example is shown in Fig. 3. The fluorescence spectra in the presence of M become intensive and move to the red area with an increase in the concentration of M ([M]). The [M] dependence of the total fluorescence quatum yield (Φ), divided by the fluorescence quantum yield (ϕ_A°) in the absence of M at several temperatures, is shown in Fig. 4.

Discussion

Reaction Scheme for the Specific Interaction of Acetylanthracenes with Methanol. The red shift of the fluorescence peak maxima for **1A** and **2A** in the presence of small amounts of M is much larger than that to be expected from the nonspecific solvent-solute interaction. As is shown in Fig. 3, the amounts of the red shift span about 30 nm under our conditions, whereas the relevent increase in the solvent polarity causes the fluorescence spectra of **1A** and **2A** to shift toward the red region by only several nm. Therefore, it appears probable that

the observed change in the fluorescence spectra is mainly due to the specific interaction between the aromatic ketones and M. The effect of added M on the fluorescence spectra is not only the red shift of the peak maxima, but also the broadening of the bandwidth, indicating the appearance of the emission band which can be ascribed to the H-bonded complex. Furthermore, the fluorescence spectra for **2A** show that an isoemissive point near 410 nm does not come out until [M] reaches *ca.* 0.05 mol dm^{-3}. This suggests that a highly associated complex, that is, one in which at least two alcohol molecules are intimately associated with the aromatic ketone, is photogenerated at a relatively high [M].

Consequently, the following reaction scheme can be postulated for the specific interaction of **1A** and **2A** with M:

$$A \underset{-M}{\overset{+M,\,K_g}{\rightleftharpoons}} C, \tag{1}$$

$$A \xrightarrow{h\nu} A^*, \tag{2}$$

$$C \xrightarrow{h\nu} C^*, \tag{3}$$

$$A^* \underset{-M,\,k_4}{\overset{+M,\,k_8}{\rightleftharpoons}} C^* \underset{-M,\,k_5}{\overset{+M,\,k_7}{\rightleftharpoons}} E^* \qquad (k_1,\ k_2,\ k_3,\ k_6,\ k_9,\ k_{10}) \tag{4}$$

$$A + h\nu'\ A \quad C + h\nu''\ C \quad C + M + h\nu'''\ C + M,$$

where A is the uncomplexed ketones, where C and E are the complexes including one and two alcohol molecules respectively, where the superscript asterisk represents the excited singlet state, and where the k's are the rate constants of the respective processes.

There is a possibility that the more highly associated complexes other than E are successively photogenerated at a high [M]. However, such a situation, requiring more sophisticated kinetic treatments, is not considered in this work. In fact, the fluorescence data observed are well consistent with the reaction kinetics to be described below.

Kinetic Treatments for Steady-state Fluorescence. In the photostationary state, the fluorescence quantum yields (ϕ) of A, C, and E relative to $\phi_A^\circ = k_1/(k_1+k_2)$ are given by the following equations:

$$\phi_A/\phi_A^\circ = \frac{\{1+P_3(1+P_1[M])+P_6[M]\}}{(\text{Denominator})}, \tag{5}$$

$$\phi_C/\phi_A^\circ = \frac{P_4[M]\{P_1+P_2(1+P_1[M])\}}{(\text{Denominator})}, \tag{6}$$

$$\phi_E/\phi_A^\circ = P_5[M](\phi_C/\phi_A^\circ), \tag{7}$$

where the ϕ's are defined as $\phi_A = k_1[A^*]/\{\varepsilon_A(\lambda)[A]+\varepsilon_C(\lambda)[C]\}$ *etc.*, (Denominator)$=(1+P_1[M])\{(1+P_2[M])\times(1+P_6[M])+P_3\}$, and

$$P_1 = K_g\varepsilon_C(\lambda)/\varepsilon_A(\lambda),$$
$$P_2 = k_3/(k_1+k_2),$$
$$P_3 = k_4/(k_5+k_6),$$
$$P_4 = k_5(k_1+k_2)/k_1(k_5+k_6),$$
$$P_5 = k_7k_9/k_5(k_8+k_9+k_{10}),$$
$$P_6 = k_7(k_9+k_{10})/(k_5+k_6)(k_8+k_9+k_{10}).$$

If these three fluorescence quantum yields could be separately determined, it would be possible to ascertain whether or not the parameter values evaluated from these experimental runs were consistent with each other. Previously, we tried to divide the perturbed fluorescence spectra into the component spectra arising from the uncomplexed ketone and the complex by subtracting the unperturbed spectra from the perturbed spectra, those which were normalized on the short wavelength side where the contribution of the complex is negligible.[8] This technique is, however, not practical in quantitative kinetic treatments, for the low fluorescence intensity at the normalized wavelength makes the errors in the subtraction procedure considerable. Moreover, it can not be applied to the **1A**–M system, for the fluorescence intensities, even on the short-wavelength side, show a monotonous increase with an increase in [M], presumably because of the large overlapping of the component spectra. Therefore, we directly analyzed the data observed for Φ/ϕ_A°, which should conform to this equation:

$$\Phi/\phi_A^\circ = 1 + [M]\{P_4(1+P_5[M]) - (1+P_6[M])\}\times \{P_1+P_2(1+P_1[M])\}/(\text{Denominator}). \tag{8}$$

Since P_1 can be independently determined from the absorption measurements, the fitting of the plots by the nonlinear regression analysis was done by holding P_1 fixed and by treating the others (P_2—P_6) as free parameters. The results for the computer simulation are shown in Fig. 4, while the values of the parameters obtained are listed in Table 1. Although the apparent dependencies of [M] on Φ/ϕ_A° are different from temper-

a) Sum of squared residuals.

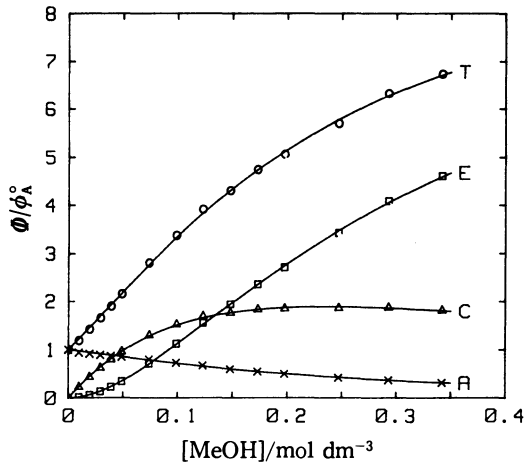

Fig. 5. Simulated concentration dependence of methanol upon the relative fluorescence yield of three emissive components for 2-acetylanthracene: A) an uncomplexed ketone, C) a 1 : 1 complex, E) a 1 : 2 complex, T) A+C+E.

ature to temperature, the simulated curves satisfactorily smooth the observed plots with the order of 10^{-2} of the sum of the squared residuals for all the experimental runs. This strongly supports the validity of the reaction scheme postulated. Particularly, the sigmoid and upward dependencies of [M] revealed at relatively high temperatures are characteristic of the formation of a highly associated complex; the formation of C alone results in no such dependencies.

The functions $\{\phi_A([M])/\phi_A^\circ$, *etc.*$\}$ predicted from Eqs. 5—7 for **2A** at 20 °C are shown in Fig. 5. It can be seen that, as [M] increases, ϕ_A decreases; ϕ_C, which increases at first, decreases slightly, and ϕ_E increases at the expense of ϕ_C. On the assumption that the only emissive species at very low [M] values are A and C, and that the peak maxima and the forms of these two fluorescence spectra do not change at higher [M] values, the perturbed fluorescence spectra can be divided into their three component spectra by using the predicted fluorescence quantum yields. The fluorescence spectra of E thus obtained were found to be invariant in general form and peak maximum at [M]$\leqslant$0.25 mol dm^{-3}. An example of such a spectral division for **2A** at [M]=0.12 mol dm^{-3} at 20 °C is shown in Fig. 6. The fluorescence spectra of the H-bonded complexes (C and E) become structureless and move to the red with an increase in the number of the associated alcohol molecule. The energies of the fluorescence peak maxima of A, C, and E for **1A** and **2A** at 20 °C, together with the amounts of the red shift relative to A, are listed in Table 2.

Photokinetics for Pulse Excitation at Low [M]. At low [M] values, where the perturbed fluorescence spectra consist of A and C, the contribution of E being negligible, the observed time evolution of the fluorescence is the convolution of a lamp decay profile, with the true fluorescence decay function given in this form:

$$F(t) = C_1 \exp(-\lambda_1 t) + C_2 \exp(-\lambda_2 t) \quad (9)$$

where:

$$\lambda_1\lambda_2 = (k_1 + k_2)(k_4 + k_5 + k_6) + k_3(k_5 + k_6)[M]. \quad (11)$$

The related photokinetics for the time evolution of the

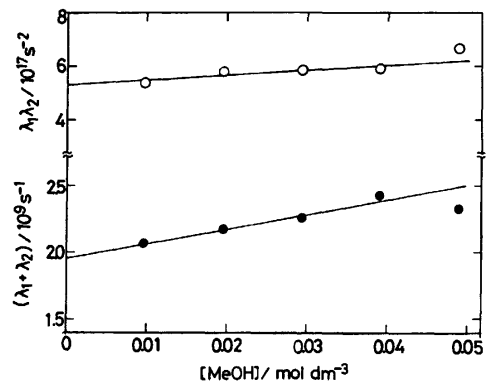

Fig. 8. Plots of $\lambda_1+\lambda_2$ and $\lambda_1\lambda_2$ *vs.* [methanol] for 2-acetylanthracene.

fluorescence at high [M] values remains unresolved in this paper, since the luminescent system involving ternary components makes the kinetic analysis extremely complex.

Figure 7 shows the actual time evolution of the fluorescence monitored at 430 nm for **2A** in the presence of M ($\leqslant$0.05 mol dm^{-3}) at 20 °C, together with the decay curves calculated by the method of convolution, assuming Eq. 9. The observed decay curves are well simulated by the biexponential decay function. The plots for $\lambda_1+\lambda_2$ and $\lambda_1\lambda_2$ *vs.* [M] are shown in Fig. 8. From the slopes of these two linear plots, the values of k_3 and k_5+k_6 are obtained as 1.1×10^{10} mol^{-1} dm^3 s^{-1} and 1.8×10^8 s^{-1} respectively. The intercepts of these plots at [M]=0 give $k_1+k_2+k_4+k_5+k_6=1.9\times10^9$ s^{-1} and $(k_1+k_2)(k_4+k_5+k_6)=5.4\times10^{17}$ s^{-1}, yielding $k_1+k_2=1.6\times10^9$ s^{-1} and $k_4+k_5+k_6=3.4\times10^8$ s^{-1}; the value of k_1+k_2 is within the limits of experimental error, proximate to the reciprocal of the fluorescence lifetime independently measured for **2A** in the absence of M at 20 °C ($1/\tau_A^\circ=1/(k_1+k_2)=1.4\times10^9$ s^{-1}). The values of the other rate constants (k_3—k_6) are in line with those evaluated from the steady-state measurements, as will be described below.

Evaluation of Photokinetic Parameters. By analogy with ϕ_A° and τ_A°, the intrinsic fluorescence efficiencies (ϕ°) and lifetimes (τ°) for C and E are written as follows; $\phi_C^\circ=k_5/(k_5+k_6)$, $\tau_C^\circ=1/(k_5+k_6)$, $\phi_E^\circ=k_9/(k_9+k_{10})$, and $\tau_E^\circ=1/(k_9+k_{10})$. One can derive the following equations;

$$\phi_C^\circ/\phi_A^\circ = (k_5/k_1)(\tau_C^\circ/\tau_A^\circ) = P_4, \quad (12)$$

$$\phi_E^\circ/\phi_A^\circ = (k_9/k_1)(\tau_E^\circ/\tau_A^\circ) = P_4P_5/P_6. \quad (13)$$

The parameter values on the right-hand side of these equations (P_4 and P_4P_5/P_6) were evaluated to be in the order of 10 (Table 1), indicating that ϕ_C° and ϕ_E° are an order of magnitude greater than ϕ_A°. The low ϕ_A° values for **1A** and **2A** are mainly due to an intersystem crossing to an upper triplet state lying near the singler state.[10] The fluorescence intensity of acylanthracenes involving **1A** and **2A** is sensitive to external variables, which induce the displacement of the excited singlet level, such as the solvent polarity,[10] the temperature,[8] and the pressure.[11] It generally increases with a decrease in the excited singlet level, which is interpreted as a result of the inhibition of the intersystem crossing due to the increase in the energy separating the singlet and triplet levels.[12] From the fact that the fluorescence spectra of C and E are sufficiently red-shifted (Fig. 6 and Table 2), the fluorescence enhancement due to the H-bond interaction may be explained by a related mechanism. This would require a decrease in the nonradiative rate constant (k_6, $k_{10}\ll k_2$). On the other hand, the alternative possibility that the increase in the radiative rate constant plays a role can be excluded for the following reasons: (1) $\tau_C^\circ/\tau_A^\circ$ for **2A** at 20 °C was obtained from the pulse-excitation measurements to be 8.9, a value which agrees well with that of P_4 (Table 1). This immediately leads to $k_5/k_1\simeq1$; *i.e.*, the radiative rate constants of A and C are almost the same. (2) This consequence is also suggested by the close simmilarity between the oscillator strengths calculated from the long-wavelength absorption bands of these emissive species (Fig. 1). With these points in mind, it appears likely that k_5 and, presumably, k_9 are approximately equal to k_1, though no specific information about k_9 was obtained.

The values of ϕ_C° and ϕ_E° were evaluated from the observed ϕ_A° values, and, on the assumption of $k_1\simeq k_5\simeq k_9$, the values of τ_C° and τ_E° were obtained from the observed τ_A° values. The results for **2A** are listed in Table 3. The values of k's except k_7 and k_8, to which there is no satisfactory route, were determined as follows; the radiative rate constants (k_1, k_5, and k_9) from the corresponding ϕ° and τ° values, the nonradiative rate constants (k_2, k_6, and k_{10}) from the corresponding $1-\phi^\circ$ and τ° values, k_3 from P_2 and τ_A°, and k_4 from P_3 and τ_C°. The results for **2A** are also listed in Table 3. The values of k_3, k_4, and k_5+k_6 at 20 °C are comparable with the

respective values determined independently from the pulse-excitation measurements at the same temperature.

The thermodynamic quantities associated with the complex formation in the excited state were determined by using the following equations:

$$\log P_2P_4/(1 + P_3) \simeq \log k_3\tau_C^\circ/(1 + k_4\tau_C^\circ), \quad (14)$$

$$\log P_5 \simeq \log k_7\tau_E^\circ/(1 + k_8\tau_E^\circ), \quad (15)$$

where $k_1 \simeq k_5 \simeq k_9$ is assumed. The experimental curves of the left-hand sides in Eqs. 14 and 15 against T^{-1} (T: absolute temperature) are plotted in Figs. 9b and 10 respectively. The slopes of these curves are negative and/or positive with respect to T. In the case of Fig. 9b, the negative temperature dependence is realized when $k_4\tau_C^\circ$ $(=P_3)>1$. Eventually, Eq. 14 can be reduced to this equation; $\log P_2P_4/P_3 \simeq \log k_3/k_4$, suggesting that the limiting temperature coefficient is consistent with the slope of the plots for $\log P_2P_4/P_3$, which can be ascribed to the enthalpy change (ΔH_C°) for the photoassociation of C. From the linear relationship obtained for $\log P_2P_4/P_3$ *vs.* T^{-1} (Fig. 9c), the value of ΔH_C° was found to be -9 kcal mol^{-1} for **1A** as well as for **2A**. The ΔH_C° values estimated from the extrapolation of the slopes shown in Fig. 9b agreed with this value within ± 2 kcal mol^{-1}. The entropy change (ΔS_C°) was calculated as -26 cal deg^{-1} mol^{-1} for **1A** and as -24 cal deg^{-1} mol^{-1} for **2A**, suggesting a rather rigid and tight complex. On the other hand, it appears likely that $k_4\tau_C^\circ$ $(=P_3)<1$ holds for the positive slope of the plots for $\log P_2P_4/(1+P_3)$, though there are few data on this side. At this time, Eq. 14 can be rewritten as $\log P_2P_4 \simeq \log k_3\tau_C^\circ$, suggesting that a thermally activated process (k_3) is responsible for the positive temperature dependence. The plots of $\log P_2P_4$ *vs.* T^{-1} are shown in Fig. 9a. The temperature coefficient for **2A** was found to be about 8 kcal mol^{-1}, ascribable to the activation energy for k_3 (ΔE_3), since τ_C° is little dependent on T (Table 3). The value of ΔE_3 obtained is larger than that to be expected from a diffusion-controlled reaction in hexane (*ca.* 2 kcal mol^{-1} [13]). The curve for **1A** is practically temperature-independent; this may be due to the fact that the negative temperature dependence of τ_C° cancels out the positive temperature dependence of k_3, but the details remain uncertain.

In substantially similar ways, the results shown in Fig. 10 can be analyzed to give the enthalpy change (ΔH_E°) and the activation energy (ΔE_7) associated with the formation of E. The plots of $\log P_5$ *vs.* T^{-1} for **2A** give the curve with $\Delta H_E^\circ \simeq -10$ kcal mol^{-1} at low temperatures and with $\Delta E_7 \simeq 5$ kcal mol^{-1} at high temperatures (the evaluation of these values is only approximate, because there are few data on either side). From the curve for **1A**, which has a positive slope over the temperature range employed, the value of ΔE_7 was evaluated to be 7 kcal mol^{-1} on the assumption that τ_E° is temperature-independent.

Conclusively, the fluorescence change observed can be explained as stoichiometric complex formation in the ground and excited states. It is striking that the steady-state fluorescence data are well simulated by the highly-associated-complex model. In the study of the time-resolved fluorescence measurements for *m*-aminoacetophenone–alcohol–viscous nonpolar solvent systems, Itoh and his co-workers observed the time-dependent fluorescence shift associated with the formation of E.[7] In contrast with their observations, no time-dependent spectral shift could be detected in the present cases using our detecting system. However, this is not necessarily in contradiction with our model, because it appears likely that, under the present experimental conditions, the relaxation by the H-bond interaction is so rapid that the time-resolved fluorescence observed is distorted by the convolution of the light pulse, which has a definite duration (half bandwidth $\simeq 6$ ns), with the decay of the sample.

On the other hand, time-resolved fluorescence measurements in viscous alcohol at low temperatures are informative from the viewpoint of complex formation. It was shown that the fluorescence spectrum of **2A** in propylene glycol undergoes time-dependent changes even at -125 °C, where the solvent relaxation time is much slower than the fluorescence decay time. This

spectral change may be ascribed to the specific solvent-solute interaction, since a general solvent relaxation would induce a more drastic change in the fluorescence spectrum of this compound.[8] Moreover, the fluorescence spectra monitored at zero- and several-ten-ns delay times at −125 °C (*cf.* Fig. 4 in Ref. 8) are quite similar to those of C and E respectively (Fig. 4). These results may support the conclusion reached in this study.

It appears probable that the complex formation is facilitated in the excited state, since the photoexcitation leads to preferential electron migration from the anthryl ring to the carbonyl group, resulting in an increase in the carbonyl basicity.[8] Therefore, the formation of the highly associated complex is electronically reasonable, but the conformation of this complex remains uncertain at this stage of the investigation.

The Decomposition of Water on the CO- or H_2-reduced Indium Oxide

Kiyoshi Otsuka,* Takao Yasui, and Akira Morikawa
Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received October 28, 1981)

The reduction of In_2O_3 by H_2 or CO and the reoxidation of the reduced oxide by water, accompanying the formation of hydrogen, have been investigated at $\geq$673 K. The reduction of In_2O_3 and the decomposition of water have been expressed by the forward reaction and the backward reaction respectively of this equation: $In_2O_3(s)+xH_2(g)\rightleftarrows In_2O_{3-x}(s)+xH_2(g)$, where $In_2O_{3-x}(s)$ is a mixture of indium metal and In_2O_3. Surface oxygen atoms of fresh In_2O_3 are easily removed by H_2- or CO-reduction at 673 K, but they can not be reformed by oxidation with water. This explains the observation that the quantity of hydrogen produced in the oxidation step was somewhat deficient compared to that consumed by the reduction. The maximum rate of the decomposition of water is observed when the oxide has been reduced up to a 50% reduction-level. However, an excessive reduction (greater than 85%) results in a sharp decrease in the rate of the decomposition of water, probably because of the isolation of metallic indium from the host In_2O_3.

Recently we have proposed a simple two-step water-decomposition process which uses a reduction-oxidation cycle of In_2O_3.[1] In Step 1, the oxide is reduced by various reductants at a high temperature. In Step 2, the reduced oxide is reoxidized by water at a low temperature, producing hydrogen. Since Steps 1 and 2 are carried out separately, pure hydrogen can be obtained in Step 2. Various reducing agents, such as diluted hydrogen, carbon monoxide or light hydrocarbons in waste gas from chemical plants, may be used as reductants in Step 1.

It has also been reported[2] that the reduction of In_2O_3 by hydrogen and the subsequent decomposition of water over the reduced oxide proceed smoothly at 673 K. However. more fundamental studies of the reduction-oxidation cycles are needed in order to develop the two-step hydrogen-production process. This report will present the results of kinetic studies of the reduction of In_2O_3 by hydrogen and carbon monoxide and of the oxidation of the reduced oxide by water. The conditions required for the hydrogen-production and the nature of the reduced In_2O_3 are also discussed.

Experimental

Materials. The In_2O_3 used was a reagent-grade powder (purity$>$99.9%) obtained from the Wako Pure Chemical Co. The surface area of the fresh In_2O_3, as measured by means of the nitrogen adsorption (BET method), was 13.9 $m^2 g^{-1}$. The hydrogen and carbon monoxide used as reducing gases were purified by passing them through a silica-gel adsorbent cooled at 77 or 195 K. The water was purified three times by trap-to-trap distillation in a vacuum apparatus. The dissolved gases in the water were removed by repeated freeze-degassing-thaw procedures.

Procedure. The apparatus employed was a conventional mercury-free static gas-circulation system with a volume of $\approx$320 ml. Before each run of the experiment, the sample oxide (0.10—0.50 g) in a U-shaped quartz reactor was degassed at 773 K for 2 h. The reduction of the sample was initiated by adding H_2 and CO to the system at 473—773 K. During the reduction, the H_2O and CO_2 produced were removed from the gaseous phase by condensing them into a trap which had been placed in the gas-circulation line and cooled by means of liquid nitrogen. Kinetic curves of the reduction were obtained by measuring the pressure drop of the reducing gas or the change in the gas-chromatographic peak. After In_2O_3 had been reduced to a certain extent, the gases in the reaction system were pumped out; the reoxidation of the reduced oxide was then started by adding and circulating a mixture of water vapor (2.1×10^3 Pa) and nitrogen (1.33×10^4 Pa, added to ensure the gas-circulation). The quantity of hydrogen produced was measured by means o gas chromatography.

Results

Reduction of In_2O_3. The reductions of In_2O_3 by H_2 and CO occur at temperatures greater than 573 and 473 K respectively under 6.7×10^3 Pa of the reducing gases. Figure 1-a indicates the temperature effect on the kinetics of the consumption of hydrogen during the reduction of In_2O_3. Although the initial pressure of hydrogen was kept constant ($6.74\pm0.08\times10^3$ Pa), the final pressure of hydrogen depended on the reaction temperature (3.02×10^3 Pa at 623 K to 0.76×10^3 Pa at 773 K). The marked decrease in the hydrogen pressure

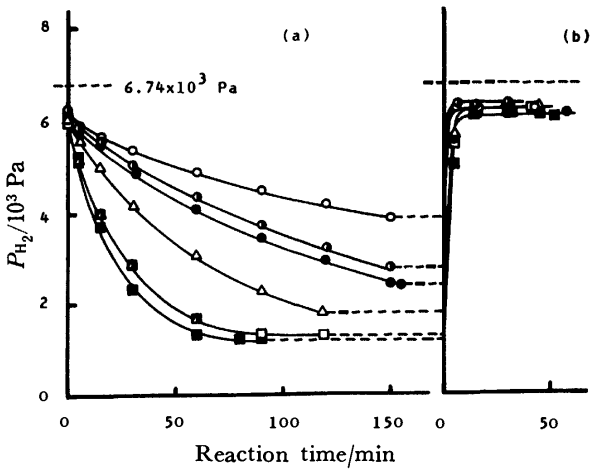

Fig. 1. (a) Kinetic curves of hydrogen-consumption during the reduction of In_2O_3 at 623—773 K. Temperature of reduction: ○: 623 K, ◑: 648 K, ●: 673 K, △: 698 K, □: 723 K, ▲: 748 K, ■: 773 K. The weight of In_2O_3 was 0.50 g. (b) Subsequent reoxidation of the reduced oxide with water accompanying hydrogen-production at 673 K. The symbols in (b) correspond to the samples of the same symbols in (a).

explained the rapid decrease in the reduction rate, especially for the high-temperature runs. For every kinetic curve, a very rapid consumption of hydrogen ($\approx$200 μmol g^{-1}) was observed at the very first contact with the oxide. After the hydrogen and water had been outgassed from the system, the addition of fresh water vapor to the reduced oxide at 673 K caused a rapid formation of hydrogen, as is shown in Fig. 1-b. The decomposition of water finished within 15 min. The amount of hydrogen produced for every kinetic curve was 200 ± 50 μmol g^{-1} less than that of the hydrogen consumed in the preceding reduction. The apparent activation energy of the reduction, as obtained from the initial rates at a 5% degree of reduction, was 72.4 kJ mol^{-1}. The degree of reduction was determined on the basis of the percentage of oxygen atoms removed from the original In_2O_3. Figure 2 shows the effect of pressure of hydrogen on the rate of reduction at 673 K as observed at different degrees of reduction. The rate increases linearly with the pressure of hydrogen, irrespective of the degree of reduction.

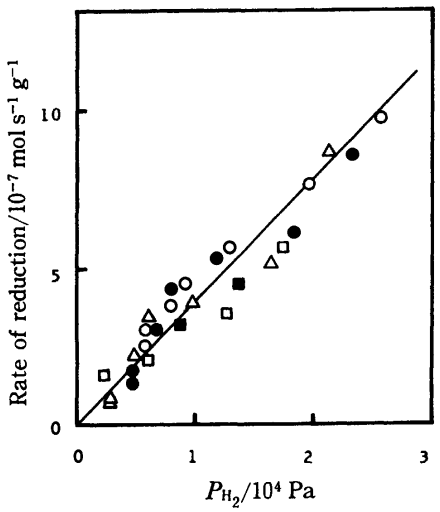

Fig. 2. The effect of pressure of hydrogen on the rate of reduction of In_2O_3 at 673 K.
Degree of reduction of In_2O_3: ○: 2%, ●: 5%, △: 10%, □: 20%, ■: 30%.

The initial rate of reduction of In_2O_3 by carbon monixide is one order of magnitude greater than that by hydrogen at the temperatures of 473—773 K under a pressure of 6.7×10^3 Pa. This fact shows that carbon monoxide is a stronger reducing agent for In_2O_3 than is hydrogen. The deficiency of $\approx$200 μmol g^{-1} in the amount of produced hydrogen compared to that of the consumed carbon monoxide in the preceding reduction was also observed in this case. The apparent activation energy of the reduction by carbon monoxide at a 2% degree of reduction was obtained as 59.4 kJ mol^{-1}.

Decomposition of Water. The decomposition of water on the H_2- or CO-reduced indium oxide occurs at temperatures higher than $\simeq$423 K. Figure 3 shows the kinetic curves of the formation of hydrogen at different temperatures for the sample with a 14% degree of reduction. The reaction at >673 K was to rapid to

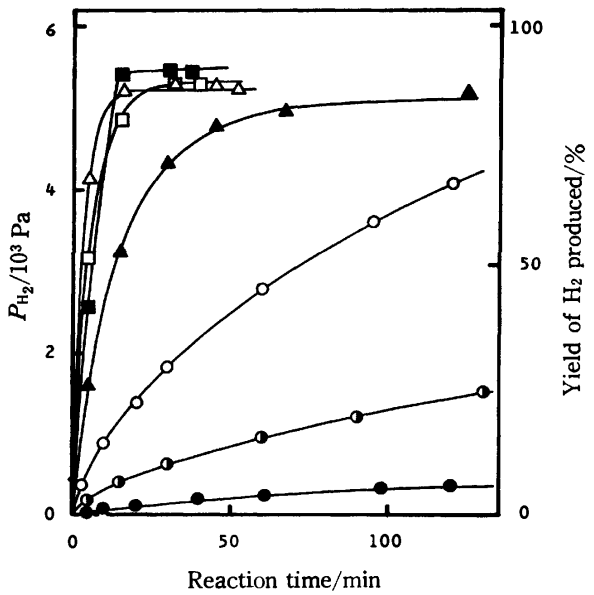

Fig. 3. Kinetic curves of the formation of hydrogen at different temperatures.
□: 873 K, ■: 773 K, △: 673 K, ▲: 573 K, ○: 523 K, ◑: 473 K, ●: 423 K. The weight of In_2O_3 used was 0.50 g.

be measured accurately. The vertical axis of the right-hand side indicates the yield of hydrogen production on the basis of the quantity of oxygen atoms transferred from water to the reduced oxide compared to that removed from In_2O_3 during the preceding reduction. The decomposition of water was completed within 15 min when the temperature was higher than 673 K. The yield of hydrogen production never reached 100%, not even at 873 K. The Arrhenius plot of the initial rate of hydrogen production, as evaluated from the slopes of the kinetic curves (423—573 K) in Fig. 3, gave the apparent activation energy of 50.1 kJ mol^{-1}.

All the results described above have been obtained for the oxide with a degree of reduction of less than 30%.

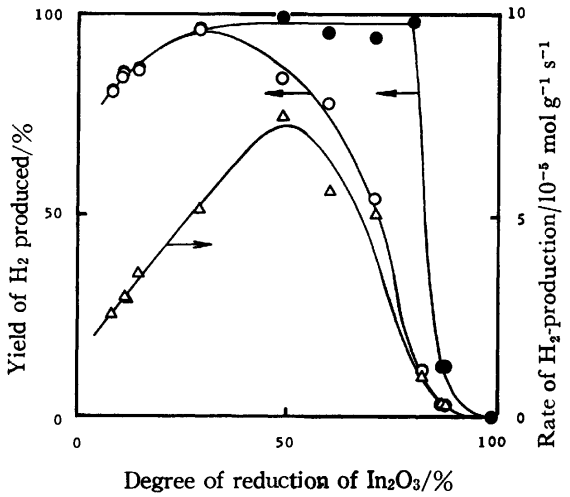

Fig. 4. The yield and rate of H_2-production as functions of the degree of reduction of In_2O_3.
○: Yield at 20 min, ●: yield at 100 min, △: initial rate of H_2-production.

Figure 4 shows the yield of water decomposition as a function of the degree of reduction. The pre-reduction of In_2O_3 had been carried out by the use of hydrogen at 673 K, and the subsequent oxidation by water was conducted at the same temperature. The triangles in Fig. 4 indicate the initial rate of water-decomposition: The quantity of hydrogen produced in 5 min divided by the time. The open and closed circles are the yields of the production of hydrogen at 20 and 100 min respectively. The results in the figure show that the maximum in the rate of hydrogen-production lies at a ≈50% degree of reduction. Although the rate of reaction decreases as the degree of reduction increases above the 50% level, the reaction is complete within 100 min when the reduction-level is lower than 85% (closed circles).

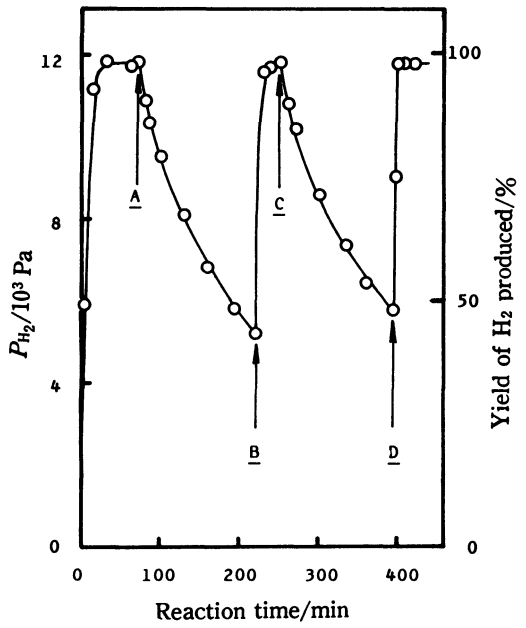

Fig. 5. Reproducible oxidation and reduction of indium oxide at 673 K.
The weight of In_2O_3 used was 0.50 g.

Figure 5 shows the progress of the oxidation-reduction cycles at 673 K: the sample oxide had been reduced by hydrogen to the degree of 29.2% before the experiments. The condensation of water vapor in the circulating gas at 77 K (Point A) caused the backward reaction; *i.e.*, the reduction of the oxide was initiated. The evaporation of the condensed water at Point B caused the decomposition of water to be resumed. The subsequent reduction and oxidation were recommenced at C and D respectively. The results shown in Fig. 5 show that smooth and repeating reduction-oxidation cycles can be operated at 673 K.

The ratio of the pressure of the water vapor to that of hydrogen under apparent equilibrium conditions has been measured using two initial systems: a partially reduced In_2O_3–water system and an In_2O_3–hydrogen system. The ratio obtained after 200 min standing at 673 K was in the range of 0.011 ± 0.003.

Discussion

The Reduced State of the Oxide. The lower valent oxides of indium than In_2O_3 suggested their existence are InO and In_2O. InO is very unstable and has been detected spectroscopically under indium-arc burning in air.[3] There is no clear evidence for the existence of InO under mild conditions. The formation of In_2O by the reduction of In_2O_3 with hydrogen was reported by Klemm and Vogel.[4] The existence of crystalline In_2O was suggested by several workers.[5,6] However, Brewer[7] concluded in his review that the supposedly crystalline In_2O is a stoichiometric mixture of indium and In_2O_3 or is a metastable homogeneous phase. Broch and Christensen[8] attempted to prepare crystalline In_2O; they came to the conclusion, after a detailed X-ray analysis of the products, that no proof for the existence of crystalline In_2O could be given. Wit *et al.*[9] commented, with regard to the existence of crystalline In_2O, that an indium suboxide like In_2O exists only as a parasitic phase, in combination with the contacting indium metal and In_2O_3, and is highly nonstoichiometric. Thus, there is still controversy with regard to the existence of crystalline In_2O. Our X-ray spectroscopic studies of the partially reduced In_2O_3 could establish only the existence of In_2O_3 and indium metal.

Therefore, let us tentatively write the following equation for the reduction of In_2O_3:

$$In_2O_3(s) + xH_2(g) \longrightarrow In_2O_{3-x}(s) + xH_2O(g), \quad (1)$$

where $In_2O_{3-x}(s)$ might be a crystalline In_2O or mixture of indium metal and In_2O_3. The ratio (0.011 ± 0.003) of the equilibrium pressure of water vapor to that of hydrogen over the oxide at 673 K observed in this work is very close to the value (0.0091) from the table[10] for the following equilibrium:

$$In_2O_3(s) + 3\,H_2(g) \rightleftarrows 2\,In(l) + 3\,H_2O(g). \quad (2)$$

This fact supports the idea that the $In_2O_{3-x}(s)$ in Eq. 1 is a mixture of indium metal and In_2O_3 under the experimental conditions applied in this work. When the sample was reduced excessively (>≈85%-degree of reduction), the formation of indium metal particles was observed at the bottom of the reactor.

The Presence of Highly Reducible Surface Oxygen Atoms. In the case of the reduction of fresh In_2O_3, a very rapid initial consumption of hydrogen was always observed, irrespective of the pressures and temperatures for the reduction. The quantity of the initial hydrogen-consumption and the BET surface area of the sample have been measured after each reduction-oxidation cycle. The results showed that the quantity of the initial rapid consumption of hydrogen decreased from 200 ± 20 (fresh sample) to 20 (second reduction) and 16 μmol g^{-1} (third reduction). The surface areas of the sample before each reduction were 13.9 (fresh sample), 5.3 (after the first oxidation), and 3.6 $m^2\,g^{-1}$ (after the second oxidation). The decrease in the quantity of the initial rapid consumption of hydrogen is too large to be explained by the decrease in the surface area of the sample. Let us assume that there are highly reactive surface oxygen atoms on fresh In_2O_3 and that, by

the use of hydrogen, they are rapidly removed as water from the surface at the very first stage of the reduction; the oxygen atoms, however, can not be recovered after the oxidation with water. This assumption explains the remarkable decrease in the quantity of the initial rapid consumption of hydrogen observed in the second and third reduction experiments compared to that for the fresh sample. The quantity of hydrogen produced on the first water-decomposition was deficient by the quantity of 200 ± 50 μmol g^{-1} compared to that consumed in the first reduction of fresh In_2O_3 (Figs. 1 and 3). The deficiency corresponds approximately to the quantity of hydrogen which had been consumed by fresh In_2O_3 at the very first stage of the reduction. Thus, the deficiency in the yield of hydrogen for the first cycle can be ascribed to the surface oxygen atoms, which are not regenerated by oxidation with water. Further studies are, however, needed to clarify the state and the nature of the active surface oxygen atoms (or might be molecules) described above.

Information from Kinetic Studies. In general, the rate of the reduction of crystalline metallic oxides to their lower oxidized states or metals is a function of three quantities: the rate of nucleation, the rate of the propagation of the interface between the reduced states and the oxide, and the size and shape of the particles. The energetics (*i.e.*, the activation energy) of the reduction process are primarily dependent upon the second of these quantities. However, the results in this work can shed little light on these factors. The rate of the reduction of In_2O_3 did not decrease, but increased for the second reduction compared to the first reduction, despite the fact that the surface area of the sample had decreased from 13.9 to 5.3 m^2 g^{-1}. The fact that the reduction rate increases in proportion to the pressure of hydrogen, irrespective of the degree of reduction (Fig. 2), indicates that the change in the surface area of the sample does not influence the rate of reduction. These observations can not yet be explained satisfactorily.

The kinetic curves of the oxidation of reduced-In_2O_3 by water did not obey a simple rate law, such as logarithmic, linear, parabolic, or cubic. Therefore, no simple oxidation mechanism can be applied for the oxidation of the reduced-In_2O_3.

Conditions Required for the Hydrogen Production. The findings on the temperature effect on the rates of reduction of In_2O_3 (Fig. 1) and of hydrogen-production (Fig. 3) show that both the reactions proceed rapidly at $\geq$673 K. This has been confirmed by the smooth and repeated cycles of the reactions at 673 K (Fig. 5). The results of Fig. 4 show that the reduction level around 50% is suitable for the hydrogen-production as far as the rate of reaction is concerned. The lower yield of hydrogen-production at a reduction level lower than 30% can be ascribed to the non-recovery of the surface oxygen atoms, as has been described earlier. The ratio of the quantity of surface oxygen atoms to that of the total hydrogen consumed for the reduction of In_2O_3 becomes smaller as the reduction level increases, which explains the $\simeq$100% yield of hydrogen at higher reduction levels. When the oxide experienced too much reduction ($>\approx$85% degree of reduction), the rate of reoxidation of the reduced oxide decreased sharply (Fig. 4). The formation of indium metal particles shows a clear separation of the metal phase from In_2O_3 at >85%-degree of reduction. The drop in the rate of recovery of In_2O_3 above an 85%-degree of reduction might be ascribed to the change in the physical or chemical nature of the reduced phase due to the isolation of the metal phase from the oxide.

The Kinetics of Bromate-Cerium(III) and -Iron(II) Reactions

Toshihisa YOSHIDA* and Yataro USHIKI
Department of Chemistry, Faculty of Education, Saitama University, Urawa, Saitama 338
(Received October 31, 1981)

The bromate-cerium(III) and -iron(II) reactions in acidic media were examined with special reference to their induction periods and reaction rates. In the bromate-cerium(III) reaction, the induction period is followed by a burst of cerium(IV) formation and then a gradual formation of cerium(IV). In the bromate-iron(II) reaction, a slow decrease occurs only in acidic media, even without bromate, so it may differ from the decrease in the tris(1,10-phenanthroline)iron(II) concentration based on the oxidation by bromate. It was interpreted as the dissociation from $[Fe(phen)_3]^{2+}$ to $[Fe(phen)_2]^{2+}$ and phen. This is the induction period for iron(III) formation, which follows as the burst. The induction period and the rates of cerium(IV) or iron(III) formation can be interpreted on the basis of the mechanism for the Belousov oscillatory and the present redox reactions proposed by Noyes and his co-workers.

The Belousov reaction,[1,2] a typical oscillating reaction, is the oxidation of malonic acid with potassium bromate catalyzed by cerium(III) and (IV) ions. The mechanism of the reaction was investigated by Field and Noyes,[3] who suggested that the reaction involves both the oxidation of the cerium(III) ion by potassium bromate and an autocatalytic reaction with respect to bromous acid. This suggestion has led us to take an interest in the redox reactions between potassium bromate and cerium(III) sulfate or tris(1,10-phenanthroline)iron(II).[4]

The reactions between bromate and various reducing agents, Ce(III), $[Fe(phen)_3]^{2+}$, Co(II), Mn(II), Np(V), and V(V), had been examined qualitatively.[3,5,6] The kinetic behaviour of these systems could be described experimentally by this rate law: $-d[BrO_3^-]/dt = k_0[BrO_3^-]^2$. However, to date all attempts to understand these systems adequately in this quantitative aspect have been unsuccessful.

If the mechanism suggested by Noyes and his co-workers[3] is applied to the oxidation of cerium(III) and iron(II) with no bromide ion involved, the following set of elementary reactions are obtained:

$$BrO_3^- + HBrO_2 + H^+ \rightleftharpoons 2BrO_2^\cdot + H_2O, \quad (1)$$

$$BrO_2^\cdot + M^{n+} + H^+ \rightleftharpoons HBrO_2^\cdot + M^{(n+1)+}, \quad (2)$$

$$BrO_2^\cdot + M^{(n+1)+} + H_2O \rightleftharpoons BrO_3^- + M^{n+} + 2H^+, \quad (3)$$

$$2\,HBrO_2 \rightleftharpoons BrO_3^- + HOBr + H^+, \quad (4)$$

where M^{n+} and $M^{(n+1)+}$ are the reducing agent and its oxidized form respectively.

The observation that an induction period is followed by a burst of oxidation suggests that there is at least one elementary autocatalytic reaction, and that it corresponds to the following reaction (5). It is obtainable from two of the elementary reactions above, (1) and (2), and it contains $HBrO_2$ as the vital species:

$$BrO_3^- + HBrO_2 + 2M^{n+} + 3H^+ = 2HBrO_2 + 2M^{(n+1)+} + H_2O. \quad (5)$$

Considering that the bromate-cerium(III) and -iron(II) reactions are characterized by an induction period, the rapid formation of cerium(IV) or iron(III) at the inflection point on a kinetic curve and the slow formation of cerium(IV) had been examined in connection with the above suggestion by Noyes *et al.*[3] The purposes of this paper are to present our results on the reduction of bromate by cerium(III) or $[Fe(phen)_3]^{2+}$ ions and to explain these systems, as in a previous paper.[7]

Experimental

The potassium bromate, $Ce_2(SO_4)_3 \cdot 8H_2O$, $FeSO_4 \cdot 7H_2O$, and 1,10-phenanthroline monohydrate of a guaranteed reagent grade were obtained from the Wako Pure Chemical Industries, Ltd., Japan. Especially, the $[Fe(phen)_3]^{2+}$ stock solution was prepared by mixing $FeSO_4 \cdot 7H_2O$ and 1,10-phenanthroline monohydrate in a 1 : 3 mole ratio. The ionic strengths of the aqueous reaction solutions were usually controlled by means of a 1.5 mol dm^{-3} portion of sulfuric acid for cerium(III) and a 0.5 mol dm^{-3} portion of sulfuric acid for iron(II) in such a way that their concentrations were far higher than the concentration of either the potassium bromate or the cerium sulfate and $[Fe(phen)_3]^{2+}$ employed. Each sulfuric acid solution was degassed before use.

The bromate-cerium(III) reaction was allowed to run in a nitrogen atmosphere and in the dark; the potassium bromate and cerium(III) sulfate were each dissolved in a degassed sulfuric acid solution. Mixing the two solutions initiated the bromate-cerium(III) reaction, the progress of which was followed by recording the absorbance at 320 nm for the cerium(IV) ion, the molar absorptivity at this wavelength being 5520 mol^{-1} dm^3 cm^{-1}.[8] The bromate-iron(II) reaction was also allowed to run in a nitrogen atmosphere and in the dark; the $[Fe(phen)_3]^{2+}$ stock solution was diluted in a degassed sulfuric acid solution. The mixing of the bromate and the iron(II) solutions initiated the bromate-iron(II) reaction. The concentration of the $[Fe(phen)_3]^{2+}$ stock solution was determined spectrophotometrically at 509 nm, at which point the molar absorptivity of $[Fe(phen)_3]^{2+}$ is 11100 mol^{-1} dm^3 cm^{-1},[9] but some correction of this molar absorptivity was needed based on that of $[Fe(phen)_3]^{3+}$, about 500 mol^{-1} dm^3 cm^{-1}. The wavelength of the maximum absorption of $[Fe(phen)_3]^{3+}$ was found to be 590 nm.[10] The progress of this reaction was followed by recording the absorbance at 509 nm for the iron(II) ion. A Hitachi Model 125 spectrophotometer equipped with a temperature controller was used. The reaction vessel was directly connected to the cell of this spectrophotometer by tubing with a circulating pump.

The duration of the induction period was highly dependent on the ages of both the bromate- and cerium(III)-sulfuric acid solutions, but after the induction the change in cerium(III) was almost independent of the ages of either solution. Reproducible results for the duration of the induction period were obtained by the use of a cerium(III)-sulfuric acid solution which had been aged for 1 h and a potassium bromate-sulfuric

acid solution which had been aged for 24 h. On the other hand, the dilution of the $[Fe(phen)_3]^{2+}$ stock solution was carried out before use. All these solutions were prepared in a nitrogen atmosphere and in the dark. The reaction rate was not affected by stirring.

Results and Discussion

The progress of the bromate-cerium(III) reaction consists of three stages: (1) An induction period, (2) a burst in cerium(IV) formation, and (3) a gradual formation of cerium(IV).[7,11] The duration of the induction period is inversely proportional to the initial bromate concentration, and the rate of the fast formation of cerium(IV) is proportional to the square of the initial bromate concentration, whereas both quantities are independent of the initial cerium(III) concentration. In the slow formation of cerium(IV), the steady-state treatment can be applied with success, even to the concentration of the bromous ion, as well as to those of radical species.[7] The details of the kinetic behaviour of the bromate-cerium(III) reaction were reported in a previous paper.[7]

Dissociation of $[Fe(phen)_3]^{2+}$. After the mixing of the bromate and the iron(II) solution, a slow decrease of the absorbance at 509 nm occurs in the beginning only in acidic media, and this decrease occurs also without bromate. If only $[Fe(phen)_3]^{2+}$, without bromate, is left alone in acidic media for 22 h at 25 °C, the absorbance in the range from 800 to 370 nm disappears completely. The spectra of the products in the reaction without bromate and in the reaction with bromate were identical. This decrease is independent of the acid concentration, at least in the range from 0.1 to 1.0 mol dm^{-3} sulfuric acid.[10,12] It has been postulated as the dissociation from $[Fe(phen)_3]^{2+}$ to $[Fe(phen)_2]^{2+}$ and phen,[5,10] and its mechanism has been postulated to be the step-by-step dissociation of the ligand from the complex. For the bromate-iron(II) reaction, this dissociation is considered to be in progress during the burst of $[Fe(phen)_3]^{3+}$ formation. Therefore, it must be considered to be parallel to the $[Fe(phen)_3]^{3+}$ formation. This rate of decrease based on the dissociation to $[Fe(phen)_2]^{2+}$ is proportional to the concentration of $[Fe(phen)_3]^{2+}$ and is independent of the bromate and acid concentrations. The rate-determining step for the dissociation of the complex can be postulated to be the loss of the first ligand molecule.[10]

Table 1. The dissociation rate constants to $[Fe(phen)_2]^{2+}$ from $[Fe(phen)_3]^{2+}$ in 0.10 mol dm^{-3} aq H_2SO_4

$[Fe(phen)_3]^{2+}_0$ / mol m^{-3}	$k \times 10^5$ / s^{-1}		Temperature / °C
0.153	7.45		25.1
0.118	7.03		25.1
0.101	7.77	7.51±0.35	25.1
0.0512	7.28		25.1
0.0242	8.02		25.1
0.150	16.2		30.7
0.151	4.22		21.7
0.150	0.999		14.7

The details of the dissociation rate are summarized in Table 1. Körös[5] and Shakhashiri[10] had reported this dissociation rate constant at 25 °C (k; first-order dependency to $[Fe(phen)_3]^{2+}$ concentration) to be $(7.54 \pm 0.42) \times 10^{-5}$ and 7.50×10^{-5} s^{-1} respectively. Our constant is in good agreement with their values. It is much smaller than the following burst-rate constant for the oxidation to $[Fe(phen)_3]^{3+}$. The activation energy for this dissociation is 123 kJ/mol.

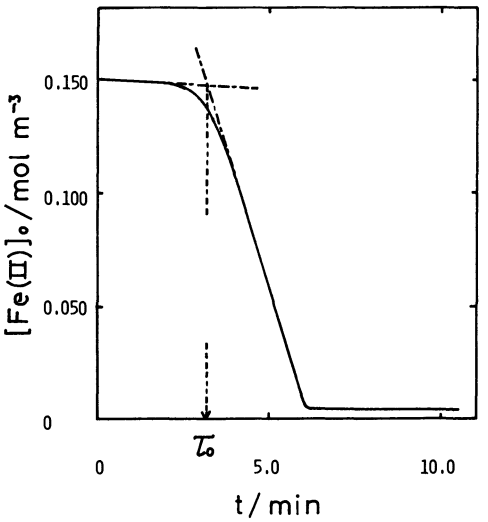

Fig. 1. Kinetic behavior of the bromate–iron system. Reaction-temperature 25 °C, $[BrO_3^-]_0 = 1.53$ mol m^{-3}, $[Fe(II)]_0 = 0.151$ mol m^{-3}, $[H^+] = 1.0$ mol dm^{-3}. Induction period (time, τ_0) defined by a dotted line.

Figure 1 shows the typical behaviour of $[Fe(phen)_3]^{2+}$ concentration with time. Let the induction period, τ_0, be defined as the time of intercept on the initial, slow and decreasing slope (dissociation) by the tangent (burst of iron(III) formation) drawn at the inflection point on the kinetic curve, as is shown in Fig. 1.

Induction Period. For the bromate-cerium(III) reaction, Thompson[6] and Kasperek[11] obtained a similar but qualitative dependence of the induction period on the initial bromate and acid concentrations. We have previously attempted to explain our quantitative results on the basis of the elementary steps given above.[3] The following steps may be considered:

$$BrO_3^- + HBrO_2 + H^+ \xrightarrow{k_1} 2BrO_2^\cdot + H_2O, \qquad (1')$$

$$BrO_2^\cdot + M^{n+} + H^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} HBrO_2 + M^{(n+1)+}, \qquad (2)$$

$$2HBrO_2 \xrightarrow{k_4} BrO_3^- + HOBr + H^+, \qquad (4')$$

where $BrO_2^\cdot$ is a radical species. As the amount of unstable $BrO_2^\cdot$ is assumed to be extremely small in comparison with those of the other species, the reverse of Step (1) and the slow Step (3) can be disregarded.[3] In acidic solutions, HOBr easily converts to Br^-, so the reverse of Step (4) can also be disregarded.[12] Moreover, the steady-state treatment is applied to the concentration of unstable $BrO_2^\cdot$ for the bromate-iron(II) reaction as:

$$\frac{d[BrO_2^\cdot]}{dt} = 2k_1[H^+][HBrO_2][BrO_3^-] - k_2[H^+][BrO_2^\cdot][Fe(II)] + k_{-2}[HBrO_2][Fe(III)] = 0. \quad (6)$$

The rate equations for the increase in the iron(III) concentration, the decrease in the bromate concentration, and the change in the bromous concentration are formulated as:

$$\frac{d[Fe(III)]}{dt} = k_2[H^+][BrO_2^\cdot][Fe(II)] - k_{-2}[HBrO_2][Fe(III)] = 2k_1[H^+][BrO_3^-][HBrO_2], \quad (7)$$

$$-\frac{d[BrO_3^-]}{dt} = k_1[H^+][BrO_3^-][HBrO_2] - k_4[HBrO_2]^2, \quad (8)$$

$$\frac{d[HBrO_2]}{dt} = k_1[H^+][BrO_3^-][HBrO_2] - 2k_4[HBrO_2]^2. \quad (9)$$

The concentration of $BrO_2^\cdot$ can be neglected as compared with those of the other species.[3] The following relations are assumed to hold for the initial stage, as based on the simple material and valency balances:

$$[BrO_3^-]_o + [HBrO_2]_o = [BrO_3^-] + [HBrO_2], \quad (10)$$

$$[Fe(III)] = 2\{[BrO_3^-]_o - [BrO_3^-]\}, \quad (11)$$

where the subscript o indicates the initial value.

The integration of Eq. 7 gives:

$$\ln\left\{\frac{[BrO_3^-]_o(2[HBrO_2]_o + [Fe(III)])}{[HBrO_2]_o(2[BrO_3^-]_o - [Fe(III)])}\right\} = k_1[H^+]\{[BrO_3^-]_o + [HBrO_2]_o\}t. \quad (12)$$

The concentration of the initial bromous acid is negligible as compared with that of the bromate and is at a steady value ($[HBrO_2]_o/[BrO_3^-]_o = C_1$; constant), as established through the aging adopted in the preparation of the reactions.

The induction period is obtained as follows. The relation between the time, t_f, and the concentration, $[Fe(III)]_f$, at the inflection point on the kinetic curve in Fig. 1 is obtainable from Eq. 12. On the other hand, $[BrO_3^-]_f$ and $[HBrO_2]_f$ may be obtained on the basis of $d^2[Fe(III)]/dt^2 = 0$ at the inflection point:

$$[HBrO_2]_f = C_2[BrO_3^-]_f = \frac{C_2}{C_2+1}[BrO_3^-]_o, \quad (13)$$

where the subscript f denotes the value for the inflection point and where:

$$C_2 = 1 + \frac{k_1[H^+]}{2k_4} - \sqrt{1 + \left(\frac{k_1[H^+]}{2k_4}\right)^2}. \quad (14)$$

The slope of the tangent drawn at the inflection point on the kinetic curve is determined from Eq. 7 as:

$$\frac{d[Fe(III)]_f}{dt} = 2k_1[H^+]_f \frac{C_2}{(C_2+1)^2}[BrO_3^-]_o^2. \quad (15)$$

Now, we obtain τ_0 from t_f, $[BrO_3^-]_f$, $[HBrO_2]_f$, $[Fe(III)]_f$, and the above tangent as follows:

$$\tau_o = \frac{1}{k_1[H^+][BrO_3^-]_o}\{\ln(C_2/C_1) - (C_2 + 1)\}, \quad (16)$$

which calls for τ_0 being inversely proportional to both $[H^+]$ and $[BrO_3^-]_o$; this is in good agreement with the experimental results shown in Fig. 2. In Fig. 2, results

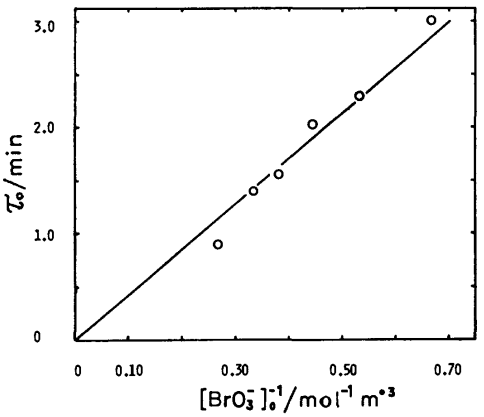

Fig. 2. Kinetic relation between τ_0 and the inverse of the initial $KBrO_3$ concentration.
Reaction-temperature 25 °C, $[Fe(II)]_o = 0.15$ mol m^{-3}, $[H^+] = 1.0$ mol dm^{-3}.

are shown for runs of the reaction with the initial iron(II) concentration of 0.150 mol m^{-3}. The induction period for a burst of iron(III) formation is inversely proportional to the initial bromate concentration, such as that of the cerium(IV) formation.[7] The induction period is independent of the initial iron(II) concentration.

The Burst of Iron(III) Formation. For the burst of iron(III) formation, the rate of iron(III) formation (R) is defined as the corrected slope of the tangent drawn at the inflection point on the kinetic curve. Figure 3 shows the relation between the corrected slope of the tangent and the square of the initial bromate concentration. The rates of iron(III) formation at 20, 25, and 30 °C are completely proportional to the square of the initial bromate concentration, whereas they are almost independent of the initial iron(II) concentration, shown in Fig. 4. These results are consistent with the interpretation based on Eq. 15. Similar results and a

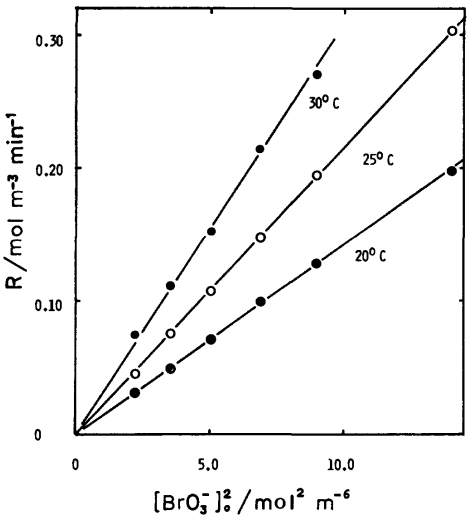

Fig. 3. Kinetic relation between the rate of burst Fe(III) formation (R) and the square of the initial $KBrO_3$ concentration.
$[Fe(II)]_o = 0.15$ mol m^{-3}, $[H^+] = 1.0$ mol dm^{-3}. Different reaction-temperatures shown above.

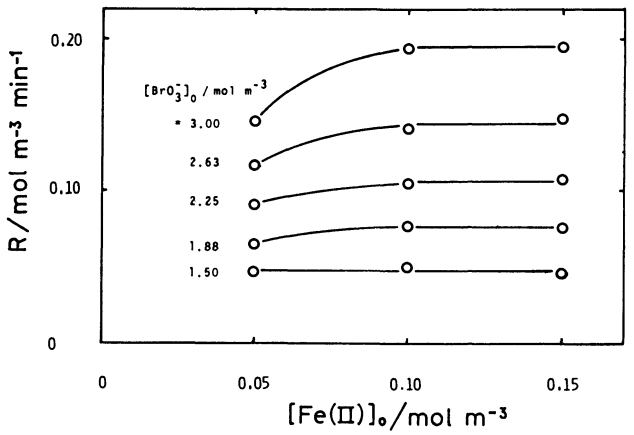

Fig. 4. Kinetic relation between the rate of burst Fe(III) formation (R) and the initial Fe(II) concentration. Reaction-temperature 25 °C, $[H^+]=1.0$ mol dm^{-3}. Various initial $KBrO_3$ concentrations shown above.

similar interpretation have been obtained for the burst of cerium(IV) formation in the previous paper.[7]

Comparison between Bromate-Cerium and -Iron Reactions. For the bromate-cerium(III) reaction, there is an induction period, followed by a burst of cerium(IV) formation, and then a gradual formation of cerium(IV). For the bromate-iron(II) reaction, a slow dissociation to $[Fe(phen)_2]^{2+}$ is observed in the beginning. It is the duration of the induction period for the iron(III) formation, which is followed by the burst of iron(III) formation.

Table 2. Apparent kinetic constants of k_r and k_r for iron and cerium systems

	k_r[a] s^{-1} mol^{-2} dm^6	k_r s^{-1} mol^{-2} dm^6	Temperature °C
Iron(II)	3.22	0.118	20
reaction	3.93	0.180	25
	4.68	0.257	30
Cerium(III)	—	5.44	20
reaction	0.772	7.44	25
	1.98	11.0	30

a) k_r is equal to $k_1/\{\ln(C_2/C_1)-(C_2+1)\}$. b) k_r is equal to $k_1C_2/(C_2+1)^2$.

For the bromate-cerium(III) and -iron(II) reactions, the details of the apparent kinetic constants are summarized in Table 2: k_r for the induction period and k_r for the burst oxidation of metal ions, based on Eqs. 16 and 15 respectively. Now, we obtain:

$$k_r = \frac{k_1}{\ln(C_2/C_1)-(C_2+1)}, \tag{17}$$

and:

$$k_r = \frac{k_1C_2}{(C_2+1)^2}. \tag{18}$$

The apparent activation energies of k_r are 27.5 for iron and 140 kJ/mol for cerium. This large difference may result from the different standard electrode potential, the E° values for the $[Fe(phen)_3]^{2+}/[Fe(phen)_3]^{3+}$ and Ce(III)/Ce(IV) couples, and the different ligands of the reaction complexes, which cause dissociation in the iron complex, but not in the cerium one. On the other hand, the apparent activation energies of k_r are 57 for iron and 52 kJ/mol for cerium. These are the same values as we obtained in neptunium from Knight's data (57—70 kJ/mol).[13] This fact may be interpreted well by the behaviour of the $BrO_2^\cdot$ radical if the oxidation rate of metal complex is controlled by the formation of the radical, as is shown in Eq. 1. Since the rate of the bromate-iron(II) ion reaction is faster than that of $[Fe(phen)_3]^{2+}$ dissociation to $[Fe(phen)_2]^{2+}$, we can also conclude that electrode transfer takes place *via* an outer-sphere path.[10]

Let us now consider how the hydrogen ion influences the burst formation of the oxidized metal ion. Knight and Thompson[13] obtained an empirical formation which summarized the variation in $2k_r[H^+]$ with the change in the hydrogen-ion concentration. The two-parameter expression, compared with Eq. 15:

$$2k_r[H^+] = \alpha[H^+]^2/(1+\beta[H^+]), \tag{19}$$

fits the data much better for the bromate-Np(V) reaction.[13]

If the $C_2(\simeq k_1[H^+]/2k_4)$ quantity is sufficiently smaller than unity, we obtain, instead of Eq. 15:

$$\frac{d[Fe(III)]_f}{dt} = \frac{\frac{k_1^2}{k_4}[H^+]^2}{1+\frac{k^1}{k^4}[H^+]}[BrO_3^-]_0^2. \tag{20}$$

In the bromate-cerium system, Noyes and his co-workers[3] reported k_1 and k_4 to be 1.0×10^4 mol^{-2} dm^6 s^{-1} and 4.0×10^7 mol^{-1} dm^3 s^{-1} respectively. Therefore, the above assumption seems to be reasonable. Equation 20 is completely consistent with Eq. 19.

The authors wish to express their cordial thanks to Professor Tominaga Keii, Science University of Tokyo, and Professor Isao Matsuzaki, Shinshu University, for their discussions, and acknowledge the help in this work by Mr. Toshio Iizuka and Mr. Hiroshi Izumi.

Correlation between Critical Solution Phenomena and Ultralow Interfacial Tensions in a Surfactant/Water/Oil System

Hironobu KUNIEDA* and Kōzō SHINODA

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai 156, Hodogaya-ku, Yokohama 240

(Received November 4, 1981)

A three-phase region consisting of surfactant (D), water (W), and oil (O) phases appeared due to the superposition of two critical phenomena of D–W and O–D in a nonionic surfactant/water/oil system. Three interfacial tensions, γ_{O-W}, γ_{O-D}, and γ_{D-W}, among the three phases were determined at various temperatures. The generalized Antonoff's rule ($\gamma_{O-W}=\gamma_{O-D}+\gamma_{D-W}$) holds approximately in the three-phase region. γ_{O-D} and γ_{D-W} disappear at the respective critical solution temperatures, and ultralow interfacial tensions are attained in the vicinity of both critical temperatures. The oil–water interfacial tension, γ_{O-W}, reaches its minimum in the midst of the temperature range of the three-phase region, and the narrower the temperature range of the three-phase region, the lower the interfacial tension. The correlation between the interfacial tensions and the types of emulsions is also discussed.

There exists a three-phase region consisting of surfactant, water, and oil phases around the transition-temperature range at which the surfactant changes from water-soluble to oil-soluble in a nonionic surfactant/water/oil system.[1] A similar three-phase region has been observed in an ionic surfactant system in the presence of salt and a co-surfactant.[2–6] Saito and Shinoda found very low interfacial tensions in a three-phase region of a nonionic surfactant system.[7] Later Healy *et al.* found ultralow interfacial tensions between a surfactant phase (they called it a middle-phase microemulsion) and a water (or oil) phase in a petroleum sulfonate system.[3,8] On the other hand, ultralow interfacial tensions in very dilute systems of ionic surfactants were reported by Wade *et al.*[9–11]

In a previous paper,[12] it was clarified that a three-phase region appears due to the superposition of three miscibility gaps *i.e.*, surfactant–oil, surfactant–water, and oil–water phases, at a constant temperature. Furthermore, it was made clear that the lower (or upper) limiting temperature of the three-phase region corresponds to the lower (or upper) critical solution temperature of surfactant–water (or surfactant–oil) phases in a nonionic surfactant system. Interfacial tensions can be expected to be very small in the vicinity of the respective critical solution temperature. Since the emulsion type changes from O/W to W/O around the three-phase region,[1] the phase inversion in emulsion may be directly related to the balance of two interfacial tensions, *i.e.*, the oil–surfactant and water–surfactant interfaces, in the three-phase region. In this context, the correlation among the phase behavior, the ultralow interfacial tensions, and the phase-inversion in emulsions has been studied.

Experimental

Materials. Pure $C_8H_{17}(OCH_2CH_2)_3OH$ was kindly donated by POLA Chemicals, while pure $C_{12}H_{25}(OCH_2CH_2)_4OH$ was obtained from Nikko Chemicals; the purities (above 98%) were confirmed by gas-chromatographic analysis. Extra-pure-grade heptane, octane, nonane, dodecane, tetradecane, hexadecane, and 2-butoxyethanol were obtained from the Tokyo Kasei Kogyo Co. and were used without further purification.

Procedures. The interfacial tensions were measured by a sessile-drop method.[13,14] After attaining equilibrium, a drop of a high-density phase was placed on a Teflon film immersed in a low-density phase. The maximum height of the sessile drop above the equator, y, was measured by means of a cathetometer. The interfacial tension was calculated by a large drop approximation as follows:

$$\gamma = gy^2\Delta\rho/2,$$

where γ is the interfacial tension; g, the gravitational acceleration, and $\Delta\rho$, the density difference between two liquids.[14] In order to reduce error, x/y (x is the radius of the sessile drop at the equator) has to be at least more than 10. The density was measured by means of a digital density meter (Anton Paar DMA 40). The procedures of the determination of phase volumes and cream volumes has been described elsewhere.[15–17]

Results and Discussion

Phase Behavior of Nonionic Surfactant in Oil–Water. A schematic ternary phase diagram for a nonionic surfactant/water/oil system at the temperature range around the three-phase region is shown in Figs. 1(a)—(c).[12] The water, surfactant and oil phases are indicated by W, D, and O respectively. The compositions of the three coexisting liquids at a constant temperature and pressure are indicated by invariant points, α (D phase), β (O phase), and γ (W phase). There is a plait point (isothermal critical point), L, in the D+O region, but not in the D+W region in Figs. 1(b) and (c), because a lower critical solution temperature on a water-nonionic surfactant axis is usually lower than this temperature. Point α shifts toward the water apex with a decrease in the temperature, and finally Points α and γ coincide with each other at the critical end point Kc ($\alpha=\gamma$) and the three-phase region disappears, as is shown in Fig. 1(a). On the Kc-β line, the critical mixture ($\alpha=\gamma$) is in equilibrium with the oil phase, β. In this case, the D+W region usually remains in the vicinity of the water-surfactant axis.[12] The boundary between D+O and O+W regions at this temperature is the Kc-β line, but we can not draw the boundary at temperatures below that of the critical end point, Kc. Therefore, the D($\simeq$W)+O notation is used for the two-phase

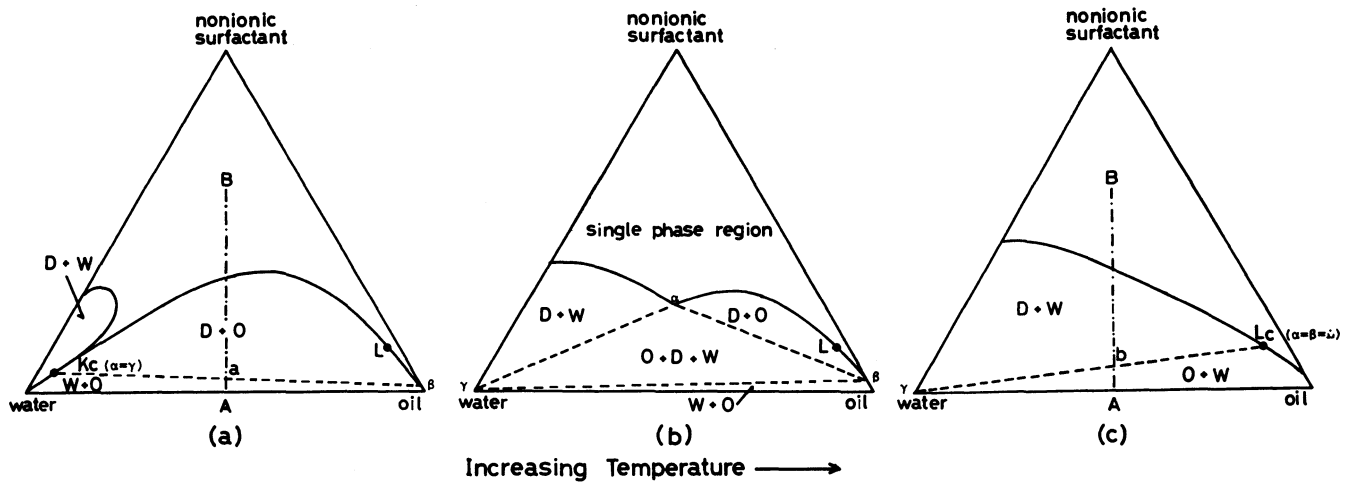

Fig. 1. Schematic phase diagram for a nonionic surfactant/water/oil system at the temperatures of a lower critical end point (Fig. 1(a)), in the midst of two critical end points (Fig. 1(b)), and of a upper critical end point (Fig. 1(c)). Kc and Lc are the lower and upper critical end points. α, β, and γ are the invariant points forming the three-phase region. O, D, and W are an oil, a surfactant, and a water phases. Points a and b correspoind to those in Fig. 2.

region at lower temperatures (*cf.* Fig. 2). D($\simeq$W) is usually called the aqueous micellar solution phase, which solubilizes oil. On the other hand, Point α shifts toward the oil apex with an increase in the temperature, and finally Points α, β, and L become identical at another critical end point, Lc ($\alpha=\beta=$L), as is shown in Fig. 1(c). Therefore, the three-phase and D+O regions disappear at this temperature, leaving the D+W and O+W regions. The W phase is nearly pure water; its composition is indicated by γ. Since we can not draw the boundary between the D+W and O+W regions at temperatures above that of the critical end point, Lc, the D($\simeq$O)+W notation is used for the two-phase region (*cf.* Fig. 2). D($\simeq$O) is usually called the nonaqueous reversed micellar solution phase, which solubilizes water.

A phase diagram consisting of equal weights of hydrocarbon and water as functions of the concentration of $C_8H_{17}(OCH_2CH_2)_3OH$ and the temperature is shown in Fig. 2. Point a in the tetradecane system, corresponds to that in Fig. 1(a), so it seems that the meniscus separating the D and W phases has just disappeared at Point a. Figure 3 shows the change in the volume fractions of respective phases as a function of the temperature in the $C_8H_{17}(OCH_2CH_2)_3OH$/water/tetradecane system. The concentration of the surfactant changes along with the broken line, a-b, in Fig. 2. The densities of the respective phases along the same line are also shown in Fig. 4. The densities of the O and W phases are almost equal to those of the pure components in the three-phase region. Accordingly, it is considered that the surfactants are singly dispersed in both phases.[7] However, the solubility of the surfactant in the O or W phase seems to increase abruptly in the vicinity of Points a and b as is shown in Fig. 4. As a

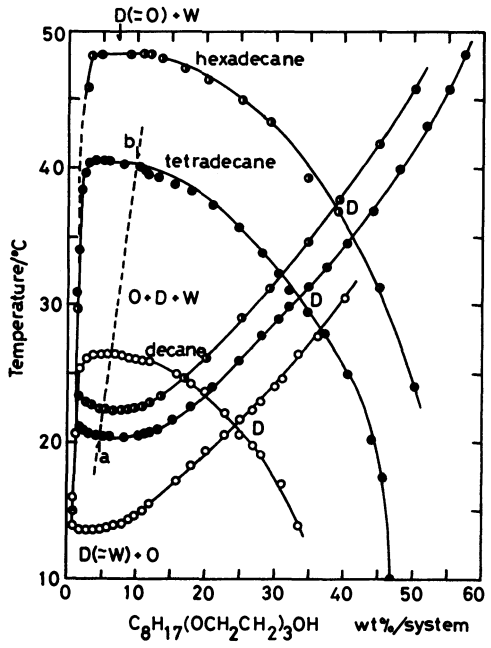

Fig. 2. Phase diagram of equal weight of water–oil containing $C_8H_{17}(OCH_2CH_2)_3OH$ as a function of temperature. The compositions correspond to the line A-B in Fig. 1.

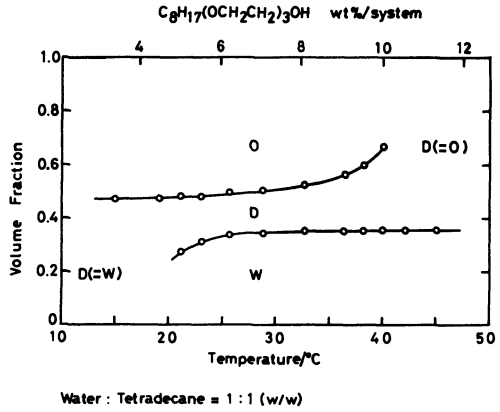

Fig. 3. The volume fractions of respective phases on the line a-b in Fig. 2.

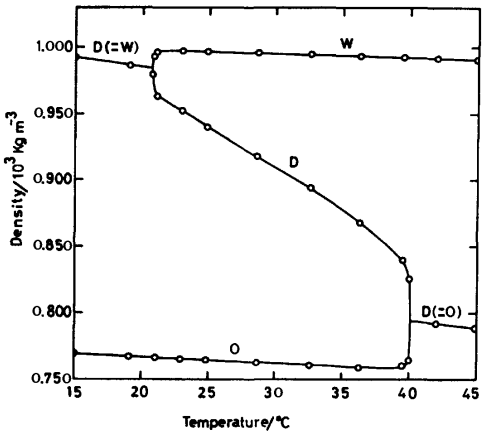

Fig. 4. The densities of respective phases on the line a-b in Fig. 2.

result, it is obvious that a three-phase region consisting of the O, W, and D phases appears in the range of two critical end temperatures, *i.e.*, a lower critical solution temperature (LCST) of the D and W phases, at which Kc exists, and an upper critical solution temperature (UCST) of the D and O phases, at which Lc exists. A similar result was obtained in an ionic surfactant system.[4,12] In the system, in which the LCST coincides with the UCST, there is a tricritical point at which the three coexisting liquids become identical.[18,19]

Correlation between Critical Solution Phenomena and Ultralow Interfacial Tensions in a Surfactant System. Since the interfacial tension becomes zero at a critical point,[20,21] and since the change in the activity of a surfactant with the concentration is very small,[22] the change in the concentration has scarcely no effect on chemical potential or interfacial tension, which is a function of the chemical potential; *i.e.*, ultralow interfacial tensions are attained in the vicinity of Point a or b in Fig. 2. Interfacial tensions between respective phases along the a-b line in Fig. 2 are shown in Fig. 5. $\gamma_{O\text{-}W}$, $\gamma_{O\text{-}D}$, and $\gamma_{D\text{-}W}$ are the interfacial tensions at the O–W, O–D, and D–W interfaces in the three-phase regions. $\gamma_{D(\simeq O)\text{-}W}$ and $\gamma_{O\text{-}D(\simeq W)}$ are the interfacial tensions at the D(≃O)–W and O–D(≃W) interfaces at temperatures above and below the critical temperatures. Naturally, $\gamma_{O\text{-}W}$, $\gamma_{O\text{-}D}$, and $\gamma_{O\text{-}D(\simeq W)}$ coincide with one another at the LCST (at Point a), while $\gamma_{O\text{-}W}$, $\gamma_{D\text{-}W}$, and $\gamma_{D(\simeq O)\text{-}W}$ coincide with one another at the UCST (Point b). $\gamma_{O\text{-}D}$ decreases with an increase in the temperature and becomes zero at Point b. On the other hand, $\gamma_{D\text{-}W}$ decreases with a decrease in the temperature and becomes zero at Point a. Accordingly, the ultralow interfacial tensions at surfactant–oil and surfactant–water interfaces are attained at temperatures in the vicinity of each critical temperature, *i.e.*, on the Lc-γ and Kc-β lines in Fig. 1. The critical point in a surfactant system usually exists in a solvent-rich region.[4,12,22,23] This is very important for such a practical purpose as the tertiary oil recovery,[8] for the amount of surfactant used to reduce the inter-

Fig. 6. Correlation between the difference in two critical end temperatures ($\Delta T = T_{UCST} T_{LCST}$) and the minima of O–W interfacial tensions in various nonionic surfactant systems. The interfacial tensions were measured at $(T_{UCST} + T_{LCST})/2$.

facial tension to the ultralow range has to be small.

At each critical temperature, a generalized Antonoff's rule, $\gamma_{O-W}=\gamma_{O-D}+\gamma_{D-W}$, automatically holds on the Lc-γ and Kc-β lines in Fig. 1,[24] because:

$$\gamma_{D-W}=0,\ \gamma_{O-W}=\gamma_{O-D} \quad \text{at LCST,} \tag{1}$$

$$\gamma_{O-D}=0,\ \gamma_{O-W}=\gamma_{D-W} \quad \text{at UCST.} \tag{2}$$

In the three-phase region, Antonoff's rule holds approximately, but, strictly speaking, γ_{O-W} is slightly smaller than $\gamma_{O-D}+\gamma_{D-W}$ as is shown in Fig. 5. A reverse inequality does not hold at true equilibrium.[24-27]

$$\gamma_{O-W}<\gamma_{O-D}+\gamma_{D-W} \quad \text{in the three-phase region} \tag{3}$$

Since a stable lens of the surfactant phase was formed at the water–oil interface after equilibrium was attained at 30 °C (50/50 water/tetradecane, $C_8H_{17}(OCH_2CH_2)_3$-OH 1.5 wt%/system), the (3) relation surely holds. The minimum was observed on the γ_{O-W} *versus*-temperature curve in the three-phase region, as is shown in Fig. 5. It is obvious from Relations 1—3 that this minimum becomes ultralow when the two critical end temperatures approach each other. If the LCST coincides with the UCST completely, γ_{O-W} becomes zero at the tricritical point at which three coexisting phases become identical, as has been described before. The correlation between the temperature difference at two critical end points ($\Delta T=T_{UCST}-T_{LCST}$) and the minima of γ_{O-W} in various nonionic surfactant systems is shown in Fig. 6. The interfacial tensions were measured at temperatures in the midst of the three-phase region. It is clear from Fig. 6 that the ultralow interfacial tension at an oil–water interface is attained in the system in which the difference in two critical temperatures is very small, and that the longer the hydrocarbon chain length of a surfactant, the lower the oil–water interfacial tension. In this case, both the oil phase and the water phase contain only a small amount of a surfactant, *i.e.*, cmc or so, as is shown in Figs, 1, 2, and 4. Therefore, the concentration of a surfactant required to reduce the interfacial tension to the ultralow range is very small.

Correlation between the Emulsion Type and Interfacial Tension. Since the three-phase region appears in the temperature range between the two critical points of the O–D and D–W phases, the interfacial tensions at the respective interfaces will be directly relevant to the inversion of the emulsion type. If γ_1 is the interfacial tension between a water phase and a surfactant monolayer adsorbed on the O–W interface, and γ_2 that between an oil phase and a surfactant monolayer, $\gamma_{O-W}=\gamma_1+\gamma_2$ holds in the three-phase region (*cf.* Fig. 7.) $\gamma_{O-D(\simeq W)}=\gamma_1+\gamma_2$ and $\gamma_{D(\simeq O)-W}=\gamma_1+\gamma_2$ also hold at temperatures below the LCST and above the UCST. As has been described before, $\gamma_{O-D(\simeq W)}$ is the interfacial tension between an aqueous micellar solution phase and an excess oil, and $\gamma_{D(\simeq O)-W}$ that between a reversed micellar solution phase and excess water. Since Antonoff's rule holds approximately in the three-phase region, the O–W interface can be regarded as a thin film of the D phase. However, strictly,

$$\gamma_{O-D}=\gamma_2+\gamma_1',\ \gamma_{D-W}=\gamma_1+\gamma_2', \tag{4}$$

where γ_1' and γ_2' are the correction terms which are not negative, judging from Eq. 3. Since Antonoff's rule holds strictly at each critical temperature, *i.e.*, $\gamma_1'=\gamma_2'=0$, the following relations hold:

$$\gamma_1=0,\ \gamma_{O-W}=\gamma_2 \quad \text{at LCST,} \tag{5}$$

$$\gamma_2=0,\ \gamma_{O-W}=\gamma_1 \quad \text{at UCST.} \tag{6}$$

γ_{D-W} may be zero or negative at a flat interface below the LCST, because the D–W interface is not stable at equilibrium. Therefore, $\gamma_1\leq 0$ and $\gamma_{O-D(\simeq W)}\leq\gamma_2$ hold below the LCST. Similarly, $\gamma_2\leq 0$ and $\gamma_{D(\simeq O)-W}\leq\gamma_1$ hold above the UCST. These relations are shown schematically in Fig. 8. The interface on the oil side of the surfactant monolayer tends to shrink, while that on the water side of the surfactant monolayer tends to expand, at temperatures below the LCST, because $\gamma_1\leq 0$ and $\gamma_2>0$, as is shown in Fig. 8. Therefore, in this temperature range, an O/W-type emulsion is formed. The case is the reverse above the UCST, so that a W/O-type emulsion is formed. $\gamma_1=\gamma_2$ holds at the temperature in the midst of a three-phase region. This temperature is the Hydrophile-Lipophile-Balanced (HLB) temperature and may correspond to the phase inversion temperature in emulsion. Since the interfacial tension curve is almost symmetrical, as is shown in Fig. 5, the phase inversion temperature (PIT) may be close to

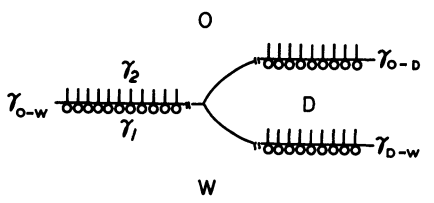

Fig. 7. Schematic O–W, O–D, and D–W interfaces. γ_1 and γ_2 are the interfacial tensions on the two sides of surfactant monolayer at O–W interface.

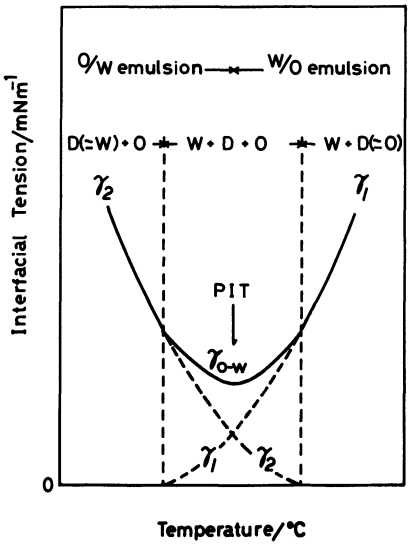

Fig. 8. Schematic change of the two interfacial tensions on the two sides of surfactant monolayer, γ_1 on the water side and γ_2 on the oil side as a function of temperature. A real curve corresponds to the interfacial tension of oil–water emulsion system.

the temperature at which γ_{O-D} and γ_{D-W} become equal. In order to confirm this reasoning, the effect of the temperature on the emulsion type was carefully determined; it is shown in Fig. 9.[28,29] It is obvious that PIT is in the midst of the three-phase region.

Spin Density Distribution and Energy Stabilization in the Cation Radicals of Multilayered Compounds

Hiroaki OHYA-NISHIGUCHI,* Atsushi TERAHARA, Noboru HIROTA, Yoshiteru SAKATA,† and Soichi MISUMI†

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

†The Institute of Scientific and Industrial Research, Osaka University, Osaka 565

(Received November 6, 1981)

The spin density distributions and the energy stabilizations in the polymer cation radicals ($R_n^{+\cdot}$) have been investigated by measuring the oxidation potentials ($E^\circ_{1/2}$) and the electron spin resonance (ESR) spectra of the cation radicals generated by the electrochemical oxidations of some multilayered compounds. $E^\circ_{1/2}$ decreased monotonically as the number of layers increased. The spin densities on the aromatic rings have been estimated from the hyperfine coupling constants with the help of the McLachlan's and INDO calculation. It was found that the spin density tends to localize in the central moieties in $R_n^{+\cdot}$. The localization of the spin density and the energy stabilization are interpreted with a simple theoretical model of $R_n^{+\cdot}$, which takes into accounts the repulsion integral (γ_1) and resonance integral (ζ) between the nearest neighbor molecules. The comparison with the experimental data has lead to the numerical estimates of $\gamma_1=0.1$ eV and $\zeta=0.4$ eV.

The dimer cation radicals ($R_2^{+\cdot}$) of some aromatic hydrocarbons are known to be formed by the reaction

$$R^{+\cdot} + R \rightleftharpoons R_2^{+\cdot}, \quad (1)$$

when R are partly oxidized chemically in liquid solution,[1] by high energy irradiation in solid solution,[2] or by chemical reaction in gaseous state.[3] Such dimer cations have been characterized by negative enthalpies of formation, spin densities equally distributed over the two moieties, and eclipsed configurations in the dimers. The negative enthalpies are possibly due to the transannular interaction between the moieties which stabilizes the dimer species.

Higher polymeric radical species $R_n^{+\cdot}$ may be formed successively by the reaction scheme

$$R_{n-1}^{+\cdot} + R \rightleftharpoons R_n^{+\cdot}, \quad (2)$$

if the enthalpy difference between $R_n^{+\cdot}$ and $R_{n-1}^{+\cdot}$ is much larger than kT and sufficient concentration of R is present. In agreement with this expectation we previously succeeded in obtaining the ESR spectrum of coronene trimer cation radical $C_3^{+\cdot}$.[1m] It was shown from the spectrum analysis that the ratio between the spin densities in the central molecule and those in the side molecules is 6 : 1 in contrast to the 2 : 1 ratio predicted by the HMO calculation. This difference was attributed to the effect of transannular interaction.

The cation radicals of multilayered compounds such as paracyclophanes can be regarded as suitable model compounds for $R_n^{+\cdot}$ in clarifying characteristic features of $R_n^{+\cdot}$ arising on polymer formation. Anthracenophane cation radical, for example, was found to be a good model of anthracene dimer cation radical.[1k]

For an ESR study of the cation radicals of multilayered compounds, electrochemical generation has some advantages over the usual chemical methods or high energy irradiation: One is that the radical generation can easily be controlled by application of a proper voltage comparable to $E^\circ_{1/2}$ of the compound under consideration from outside the ESR system. One of the present authors (H.O.) recently developed a simple two-electrode cell using a helix which is very advantageous over the commonly used electrolysis cell in obtaining the spectra of unstable radical cations.[4] In this work, we have used this cell in studying ESR spectra of the radical cations of some multilayered compounds.

Although the ESR study of the multilayered compounds provide valuable information about their electronic wave functions constructed from those of constituting moieties, the information about their orbital energies is not obtained directly. On the other hand, cyclic voltammetry (CV) is an efficient and convenient method in obtaining the oxidation and reduction potentials associated with removal of an electron from the highest occupied molecular orbital (HOMO) and addition to the lowest unoccupied molecular orbital (LUMO), respectively. We have attempted to estimate the magnitude of transannular interactions from measurements of redox potentials.

In this paper we first report the results of electrochemical measurements of the several compounds **1** to **5** in Fig. 1 in relation to the dependence of the oxidation

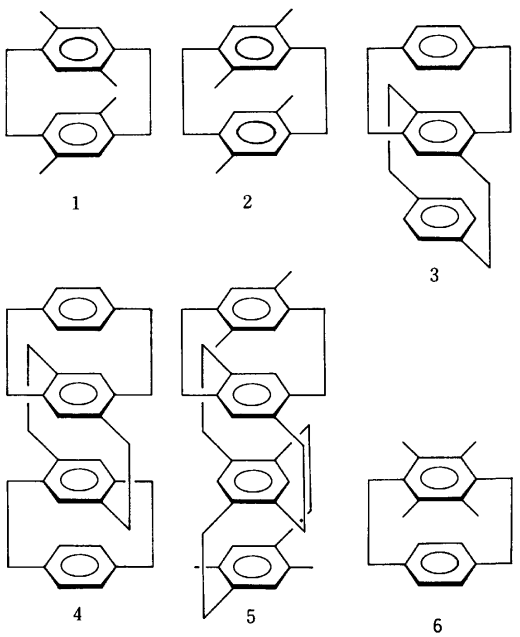

Fig. 1. Molecular structures of the multilayered compounds investigated.

potentials on the number of aromatic layers. Secondly, the ESR results of the cation radicals of these compounds are shown, and compared with those of $R_2^{+\cdot}$ and $R_3^{+\cdot}$ so far investigated. The MO calculations of the multilayered compounds were carried out using McLachlan's and INDO methods in order to interpret the observed spectra. Thirdly, we present a theoretical treatment of the spin distribution and energy stabilization in the multilayered aromatic systems, which takes into account repulsion and resonance integrals between the nearest neighbor molecules.

The model compounds such as those treated here are more amenable to detailed ESR investigations than the clustering intermediates produced in the course of chemical and biochemical reactions. Therefore, definitive ESR characterization of the multilayered compounds provides a framework for further understanding of the clustering intermediates in the chemical reactions.

Experimental

Substances shown in Fig. 1 were synthesized according to the methods described previously.[5,6] Commercially available hexamethylbenzene (**H**) and durene (**D**) were used without further purification. Purified and dried dichloromethane (CH_2Cl_2) or butyronitrile (BuCN) and tetrabutylammonium tetrafluorobotate (TBFB) of special grade for polarography were used as solvents and a supporting electrolyte, respectively. The cyclic voltammograms of the compounds, **1** to **5**, **H**, and **D**, were measured using a PAR 173 potentio/galvanostat equipped with an I/V converter, PAR 176, in conjunction with a Hewlett-Packard 3310A function generator. As a pseudo reference electrode a silver wire was used. In order to avoid the ambiguity of the potential of the reference electrode, a small amount of ferrocene was added and the position of the waves of the compounds under consideration were directly compared to that of ferrocenium/ferrocene (Fc^+/Fc) couple (0.400 V *vs.* NHE) used as an internal standard.[7] The electrochemical oxidation of the compounds for ESR measurements was carried out in the cavity using a helical working electrode made of gold wire. The details of the cell construction and the experimental procedure were given previously.[4] The appearance voltage, V_a, at which the ESR signal with modiulation amplitude of 1 G†† appears, was measured before the observation of high resolution spectra. The ESR spectra were measured with a JEOL FE-3X spectrometer, equipped with a temperature controller. Potassium nitrosylbis(sulfate) was used as a standard sample for the calibration of the magnitude and interval of the magnetic field, the accuracy of the latter being 0.005 G.

Results

The Appearance Voltages and the Oxidation Potentials of the Multilayered Compounds. V_a were measured at low temperatures at which the ESR spectra were also obtained (−70 °C to −90 °C). On the other hand, the $E^\circ_{1/2}$ were estimated from the peak potentials appeared on the anodic and cathodic sweeps (100 mV/s) by the usual method. V_a and $E^\circ_{1/2}$ of **3** to **5** nicely coinsided with each other in the range of experimental errors, but V_a of **1** and **2** become appreciably high compared with the corresponding $E^\circ_{1/2}$. This is probably due to the instability of the cation radicals produced, as pointed out in the previous paper.[4] It can be seen from Table 1 that both V_a and $E^\circ_{1/2}$ decrease as the number of the aromatic rings in the molecule n increases. In addition, $E^\circ_{1/2}$ of **1** showed an appreciable decrease from $E^\circ_{1/2}$ of **D**. This suggests the importance of the transannular interaction between the two moieties in spite of their configulation with a small overlap integral.

ESR Spectra of $1^{+\cdot}$ and $2^{+\cdot}$. After the temperature of the solution of **1** was decreased as low as −85 °C, the voltage applied between the two electrodes was increased step by step, while observing the ESR signal on an oscilloscope or a recorder. At 1.6±0.1 V well separated 13 lines with the relative intensity ratios of combinations of $_{12}C_r$ appeared. When the modulation amplitude was decreased as low as 0.063 G, each line was further split into well resolved 25 lines as shown in Fig. 2a. The analysis of this spectrum and assignment of the hfcc obtained were straight forward because of different

numbers of the equivalent protons: 6.486 G for twelve methyl-protons, 0.486 G for eight bridge-protons, and 0.334 G for four ring-protons.

The ESR signals of $\mathbf{2}^{+\cdot}$ similar to that of $\mathbf{1}^{+\cdot}$ appeared at -70 °C at 1.4 ± 0.1 V which was 0.2 V lower than that of **1**. The resolution of each group of lines is poorer than in the case of $\mathbf{1}^{+\cdot}$ because of the small difference between the two small hfcc: 6.365 G for twelve methyl-protons, 0.41 G for eight bridge-protons, and 0.43 G for four ring-protons.

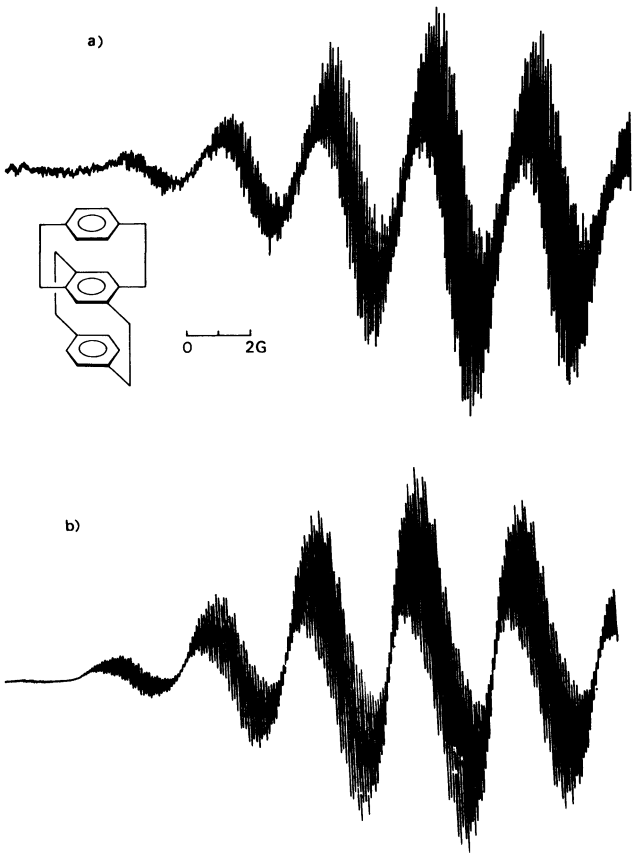

Fig. 3. The observed (a) and simulated (b) ESR spectra of $\mathbf{3}^{+\cdot}$.

The ESR Spectrum of $\mathbf{3}^{+\cdot}$. The well resolved spectrum of $\mathbf{3}^{+\cdot}$ was obtained at -56 °C (Fig. 3a). V_a (1.1 V) was lower than those of **1** and **2**. The obtained spectrum was very complex, but resolved well enough to be analyzed completely by computer simulation (Fig. 3b). 0.789 G due to two equivalent protons can be assigned unequivocally to the ring protons in the central ring in **3**. The larger hfcc, 3.279 and 3.049 G, due to two groups of equivalent four protons were not assigned uniquely, but assigned tentatively to the two four-equivalent bridge protons close to the central ring. The other hfcc can be attributable to the protons attached to the two side rings.

The ESR Spectra of $\mathbf{4}^{+\cdot}$ *and* $\mathbf{5}^{+\cdot}$. At -85 °C the ESR signals of both compounds appeared at 0.8 ± 0.1 V, which is 0.3 V lower than that of $\mathbf{3}^{+\cdot}$. They showed only one broad Gaussian-type line with the linewidths of 5.6 and 4.5 G, respectively. These radical species were very stable compared with the other species described above.

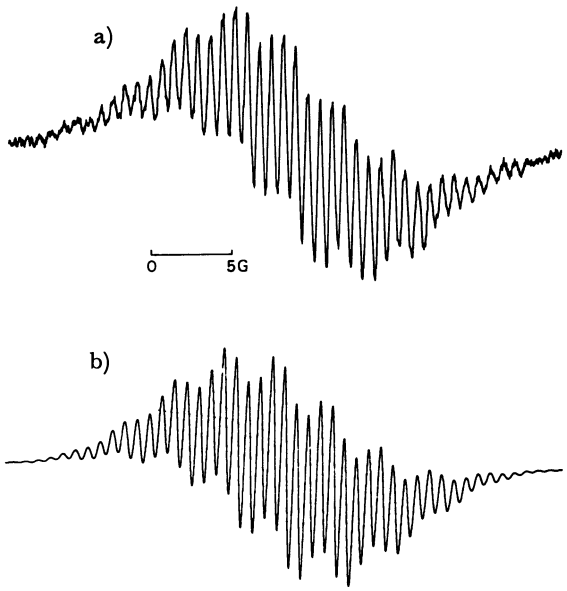

Fig. 4. The observed (a) and simulated (b) ESR spectra due to $\mathbf{1}_2^{+\cdot}$ at -112 °C.

The ESR Spectrum of $\mathbf{1}_2^{+\cdot}$. When a solution of **1** was oxidized at higher concentration and the lowest temperature available, -112°C, we observed a spectrum different from that of $\mathbf{1}^{+\cdot}$ (Fig. 4a). The conditions for obtaining this spectrum, a) high concentration, b) low temperature, and c) the beginning of the electrolysis, coincided with those for production of the dimers of typical aromatic hydrocarbons.[4] Figure 4b was obtained by the coupling constants: 3.074 G and 0.768 G for twelve-equivalent protons, and the additional unresolved couplings, 0.177 and 0.138 G for eight- and four-equivalent protons, respectively, using the Lorential lines of the widths of 0.380 G. The agreement between the simulated spectrum and the observed one is good enough to conclude that the spectrum is due to the dimer cation radical $\mathbf{1}_2^{+\cdot}$, formed according to Eq. 1. The hfcc of 3.074 G and 0.768 G are due to two different types of methyl protons, which indicates that spin densities on the central and the side rings are very different; the ratio being 4.0 : 1.

Comparison of the Hfcc with MO Calculations. Detailed molecular orbital calculations of paracyclophane and related compounds have been reported by many investigators.[8] In order to interpret the observed spectra, we have calculated hfcc by the McLachlan's and INDO methods. The usefulness of the McLachlan's method in calculating the hfcc of ordinary aromatic radical ions is well established. We have applied this method to the multilayered compounds taking into account of inter-ring interactions.

In Fig. 5 are shown the simplified molecular models (**1′** to **3′**) for **1** to **3**, used for calculation. Effects of the ethylene bridges are taken into consideration by changing the Coulomb integrals of the carbons in the rings as $\alpha(C')=\alpha_C-0.1\beta$. In our case the observed hfcc due to the methyl protons suggest a large effect of hyperconjuga-

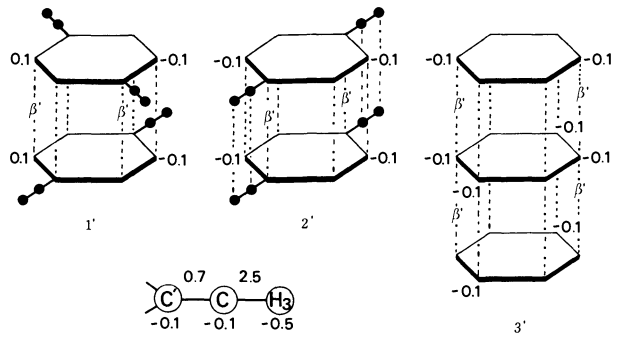

Fig. 5. The simplified molecular models, **1'**, to **3'**, for **1** to **3**, used for McLachlan's MO calculation.

tion. Therefore, the values of the Coulomb and resonance integrals of the methyl group C'–C≡H_3 were chosen as $\alpha(C')=\alpha(C)=\alpha_C-0.1\beta$, $\alpha(H_3)=\alpha_C-0.5\beta$, $\beta(C'-C)=0.7\beta$, and $\beta(C-H_3)=2.5\beta$ (hyperconjugation model[9]). In addition to those values the resonance integrals between the atoms of the upper and lower moieties in the molecule (β') were included only for pairs of carbon atoms C^l and C^u that lie on top of one another, as shown in Fig. 5. The interactions between the methyl groups in **2'** were also included.

Q values for estimating the hfcc from the calculated spin densities are somewhat ambiguous because 1) the layered configurations of the π-orbitals yield direct overlap of H atoms in the one moiety with the π-electron cloud of the other moiety, 2) each moiety does not have a planer structure, and 3) the exact configurations of the bridge protons are not known. In Table 2 are listed the hfcc calculated by this method using the following equations;

$$a_H = -24\rho_{C'} \quad \text{for ring protons,}$$

$$a_H^{CH_3} = 170\rho_{H_3} + 25\rho_{C'} \quad \text{for methyl protons, and}$$

$$a_H^{CH_2} = 6.3\rho_{C'} \quad \text{for bridge protons.}$$

The Q values for the bridge protons were estimated by $Q=50\cos\theta$,[10] where θ was calculated based on the crystallographic data of paracyclophane.[11]

Figure 6 shows the hfcc of $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$ calculated as functions of β'. The dependences of the hfcc on β' are remarkably different in the two molecules. It can be seen that the hfcc of the ring protons in $\mathbf{1}^{+\cdot}$ drastically changes from 0.65 to −3.10 G as β' increases. At $\beta'=0.03\,\beta$ the theoretical hfcc due to three kinds of protons are all in reasonably good agreements with the experimental values given in Table 2. On the other hand, the hfcc of $\mathbf{2}^{+\cdot}$ are independent of the variation of β'. Calculated values are in good agreement with the observed ones.

The hfcc of $\mathbf{3}^{+\cdot}$ were calculated in the similar manner as in the case of $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$. The best fit was obtained at $\beta'=0.04\,\beta$. The calculated values are also shown in Table 2. The largest and the second largest hfcc in the experimental data were well reproduced by those due to the bridge protons close to the central ring in spite of many ambiguities described above. The spin density is extremely localized on the central ring to those on the side rings being about 15 : 1.

The hfcc of $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$ were also calculated by the INDO method. The positions of the atoms in **1** were derived from the crystallographic data of paracyclophane.[11] In addition, we adopted a trial configuration in which the C–C bond connecting the methyl groups to the aromatic rings are parallel to the C–H bond of paracyclophane and one of the C–H bonds in the methyl group is equatorial about the rings. The hfcc of the methyl protons are averaged after the calculation because the rotations of the methyl groups about the C–C bonds are usually fast. The INDO calculation also gives the same trend of the spin distribution as

obtained by the McLachlan's method, but the numerical agreements are somewhat poorer. The main cause of the discrepancy may be due to the difference between the actual structure of $\mathbf{1}^{+\cdot}$ and that of paracyclophane.

In the INDO calculation of $\mathbf{3}^{+\cdot}$ the positions of the atoms in **3** were first derived from the crystallographic data of brominated **3** (Case 1).[12] In the second trial we used a structure in which the distance between the central moiety and the side ones were shortened by 0.2 Å (Case 2). The 1.25 A C–H bond length of the central ring protons derived crystallographically was also changed to the usual C–H bond distance of 0.98 Å in Case 2. The agreements between the experimental and calculated hfcc are poor in Case 1, but considerable improvement was achieved in Case 2. Although the largest hfcc obtained in Case 2 is large, the INDO result is in agreement with the result obtained by the McLachlan's calculation with $\beta'=0.04\,\beta$. The INDO result in Case 1 resembles to the McLachlan's result with β' smaller than $0.01\,\beta$. This may suggest that on the formation of the cation radical two side moieties are contracted to the central moiety, leading to the increased spin densities on the side moieties. The number of the atoms in **4** and **5** were too large to carry out the INDO calculations.

Theoretical Model of $R_n^{+\cdot}$

When two or more aromatic rings are stucked face to face, some transannular interactions are expected between π-electronic systems. As the whole they constitute an aggregate R_n. The spin density of $R_n^{+\cdot}$ is related to the highest occupied molecular orbital (HOMO) of R_n which are constructed by the HOMO of constituting molecules. In the following, therefore, we only consider the HOMO $\phi_i(i=1$ to $n)$ of i-th molecule in R_n, which is doubly occupied by π-electrons. The total energy of R_n can be generally given by

$$E_0^n = \int \boldsymbol{\Psi}_0 \boldsymbol{H} \boldsymbol{\Psi}_0 d\tau = 2\sum_i^n H_{ii} + \sum_i^n \sum_j^n (2J_{ij} - K_{ij}), \quad (3)$$

where H_{ij}, J_{ij}, and K_{ij} have the usual meanings.[13] Assuming that an electron is removed from ϕ_i, a configuration $\boldsymbol{\Psi}_i$ of $R_n^{+\cdot}$ is written as $\boldsymbol{\Psi}_i=|\phi_1^2\phi_1^2\cdots\phi_i^1\cdots\phi_n^2|$ and the ground state wave function $\boldsymbol{\Psi}_G^n$ of $R_n^{+\cdot}$ is expressed by a linear combination of n configurations:

$$\boldsymbol{\Psi}_G{}^n = \sum_{i=1}^n C_i \boldsymbol{\Psi}_i, \quad (4)$$

where C_i is the coefficient of the linear combination, and C_i^2 corresponds to the spin density on the i-th molecule. In order to derive the ground state energy $E_G{}^n$, one need to solve

$$(\boldsymbol{H} - E\boldsymbol{I})\boldsymbol{C} = 0, \quad (5)$$

where $\boldsymbol{H}$ is the hamiltonian matrix defined by

$$H_{ij} = \langle \boldsymbol{\Psi}_i | \boldsymbol{H} | \boldsymbol{\Psi}_j \rangle. \quad (6)$$

$\boldsymbol{I}$ is the unit matrix, and $\boldsymbol{C}$ is the column vector which consists of C_i $(i=1$ to $n)$. The diagonal elements of the matrix H_{ii} can be simply expressed in reference to $E_0{}^n$ as

$$H_{ii} = E_0{}^n - H_{ii} - \sum_j^n \{2J_{ij} - K_{ij}\}. \quad (7)$$

We assume that J_{ij} and K_{ij} have non zero values only when $j=i$ $(i=1$ to $n)$ and $j=i\pm1$ $(i=2$ to $n-1)$ and replace J_{ii} and $J_{i\,i+1}$ by γ_0 and γ_1. Then

$$H_{ii} = E_0{}^n - H_{ii} - \gamma_0 - 2\gamma_1 \quad \text{for } i = 1 \text{ and } n, \quad (8)$$

$$H_{ii} = E_0{}^n - H_{ii} - \gamma_0 - 4\gamma_1 \quad \text{for } i = 2 \text{ to } n-1. \quad (9)$$

The off diagonal elements H_{ij} is also assumed as

$$H_{ij} = \zeta \quad \text{for } j = i \pm 1, \quad (10)$$

$$H_{ij} = 0 \quad \text{for others.} \quad (11)$$

By substituting H_{ij} into Eq. 5, one can derive the determinant D_n as

$$D_n = \begin{vmatrix} -2\gamma_1-\varepsilon & \zeta & 0 & \cdots & 0 \\ \zeta & -4\gamma_1-\varepsilon & \zeta & \cdots & 0 \\ 0 & \zeta & -4\gamma_1-\varepsilon & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & & -2\gamma_1-\varepsilon \end{vmatrix} = 0, \quad (12)$$

where

$$\varepsilon = -E_0{}^n + H_{ii} + \gamma_0 - E. \quad (13)$$

It is convenient to rewrite D_n by using θ and α defined by

$$-4\gamma_1 - \varepsilon = \zeta \cdot 2\cos\theta, \quad (14)$$

$$\gamma_1 = \alpha\zeta. \quad (15)$$

Then

$$D_n = \zeta^n \begin{vmatrix} 2\cos\theta + 2\alpha & 1 & 0 & \cdots & 0 \\ 1 & 2\cos\theta & 1 & \cdots & 0 \\ 0 & 1 & 2\cos\theta & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & 2\cos\theta+2\alpha \end{vmatrix} = 0. \quad (16)$$

D_n can be expanded into a polynomial of $\cos\theta$ expressed as

$$D_n = \frac{\zeta^n(-1)^{n-2}}{\sin\theta} \times \{\sin(n+1)\theta - 4\alpha\sin n\theta + 4\alpha^2\sin(n-1)\theta\} = 0. \quad (17)$$

From this equation one can obtain n solutions $\theta_k(k=1$ to $n)$ which lead to

$$E_G{}^n = E_0 - H_{ii} - \gamma_0 - 4\gamma_1 + 2\zeta\cos\theta_1, \quad (18)$$

$$\boldsymbol{\Psi}_G{}^n = A\sum_i \{\sin i\theta_1 - 2\alpha\sin(i-1)\theta_1\}\phi_i. \quad (19)$$

It should be noted that the transannular interaction $(E_G^n - E_G^1)$ is given as a sum of the repulsion and the resonance integrals.[14] The spin density distribution at the i-th molecule is finally derived as

$$\rho_i = A^2\{\sin i\theta_1 - 2\alpha\sin(i-1)\theta_1\}^2. \quad (20)$$

In Fig. 7 the ratio of the spin densities of the central moieties to those of the side ones plotted as functions of α for the cases of $n=3$ and $n=4$.

As $n\to\infty$, the stabilization energy in reference to $R_1^{+\cdot}$, $H_n=E_G{}^n-E_G{}^1$, converges to $-4\gamma_1+2\zeta$. In Fig. 8 $2\cos\theta_1$ is plotted as a function of n. As n approaches infinity this quantity converges to 2, as can be seen from Eq. 18. On the other hand, in the limit of $\zeta=0$, Eqs. 18 and 19 are reduced to the following equations which

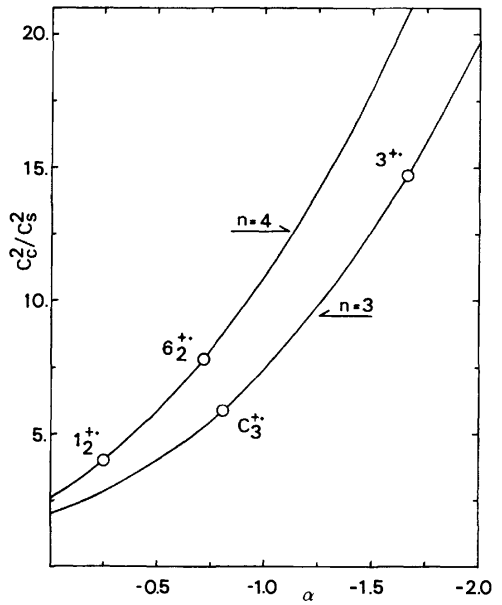

Fig. 7. The ratio of the spin densities of the central moieties to those of the side ones plotted as functions of α for the cases of $n=3$ and $n=4$.

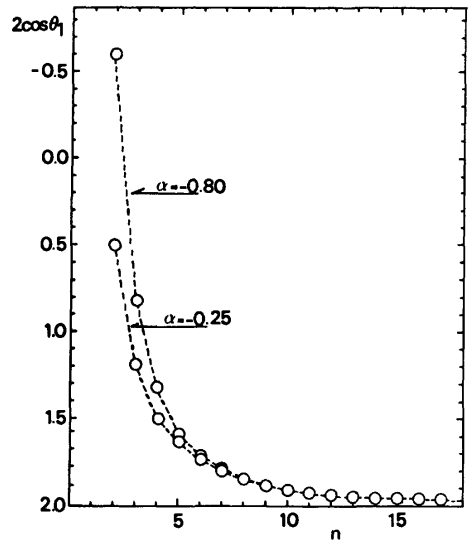

Fig. 8. $2\cos\theta_1$ plotted as functions of n for $\alpha=-0.25$ and -0.80.

are derived for the chain molecules in the Hückel treatment:[15]

$$E_j = \gamma_0 + 2\zeta\cos\theta_j, \tag{22}$$

$$\Psi_j = A\sum_i \sin i\theta_j\cdot\phi_i, \tag{23}$$

with

$$\theta_j = \frac{\pi\cdot j}{n+1}. \tag{23}$$

It should be noted in Eq. 16 that even in the case of $R_n^{+\cdot}$ in which two end molecules are different from others the determinant similar to Eq. 16 can be derived. Therefore, one can use Eqs. 18 and 19 even in the case of **3**, adjusting the parameter which includes the energy difference $H_{ii}-H_{jj}$.

Discussion

The Energy Stabilization. V_a and $E^\circ_{1/2}$ of **1** to **5** decrease in the order of **1** to **5**. This trend is consistent with that of Fig. 8 derived theoretically from Eq. 18. It is of interest to examine the magnitude of the transannular interaction of each compound in relation to this trend.

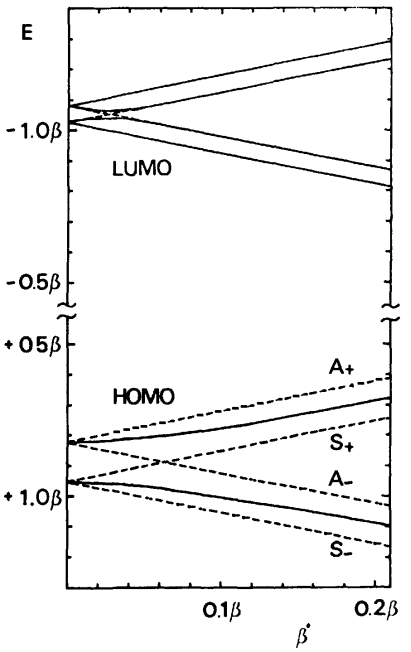

Fig. 9. β' dependences of some orbital energies including the HOMO and the LUMO calculated by HMO method; for **1** (——) and **2** (------).

Figure 9 shows β' dependence of some orbital energies including the HOMO and the LUMO of **1** and **2** calculated by the HMO method. The degenerate benzene orbitals, A and S (e_{1u}), have nodal planes perpendicular to each other, which are also perpendicular to the benzene plane. These orbital energies are split into two by substituting methyl and methylene groups to two benzene rings which results in **1** or **2**. The orbital energy of A is higher than that of S. As the transannular interaction between the two moieties M_u and M_l increases, each orbital of **2** splits further into two orbitals which are given as

$$A^{\pm} = (A^u \pm A^l)/2,$$

$$S^{\pm} = (S^u \pm S^l)/2. \tag{24}$$

The HMO and McLachlan's calculations of $\mathbf{2}^{+\cdot}$ show constant hfcc (Fig. 6) and linear change of the HMO energy with respect to the increase of β'. $\mathbf{2}^{+\cdot}$ corresponds to the usual dimeric species $R_2^{+\cdot}$ of the typical aromatic hydrocarbons with eclipsed configuration.

On the other hand, the energies of A^+ and A^- (S^+ and S^-) of **1** are almost degenerate in all range below 0.2 β, because the twisting configuration of the two moieties reduces the resonance energy between the moieties,

but an orbital mixing between $A^{\pm}$ and $S^{\pm}$ occurs through the transannular interaction. Such a mixing in **1** causes the spin density redistribution in each moiety and the lifting of the HOMO energy, as shown in Fig. 9.

The oxidation potential of durene was measured as 1.67 V. **1** consists of two durene moieties rotated each other by about 60°. Since the resonance stabilization of **1** is almost zero, one can roughly estimate the value of γ_1 using Eq. 18. As the measured value of $E^{\circ}_{1/2}$ of **1** is 1.24 V, the difference with that of durene, 0.43 V, is equal to $4\gamma_1$. Then γ_1 is estimated to be 0.11 eV. Since the interlayer distance of the compounds measured here do not change much, γ_1 of these compounds may be regarded to be the order of this magnitude.

$E^{\circ}_{1/2}$ of **2** is 0.11 V lower than that of **1**. This means that the eclipsed configuration of drurene in **2** results in an appreciable resonance interaction between the two moieties. Using Eq. 18, the difference between $E^{\circ}_{1/2}$ of **1** and that of **2** is given to be $2\zeta \cos\theta_1$, from which we can derive the numerical value of ζ provided that $2\cos\theta_1$ is estimated experimentally.

The dimeric species of **1**, $\mathbf{1}_2^{+\cdot}$, exhibited clear hf splittings with the ratio of two kinds of hfcc due to the methyl groups being 4 : 1. Assuming that the four aromatic rings in $\mathbf{1}_2^{+\cdot}$ are stacked face to face and the interactions among four moieties are equal, we obtain $\alpha=-0.25$ from this ratio with $n=4$ in Eq. 20. As γ_1 is of the order of 0.1 eV, ζ is estimated to be 0.4 eV from Eq. 15. Alternatively, the difference between $E^{\circ}_{1/2}$ of **1** and that of **2**, 0.11 V corresponds to $2\zeta\cos\theta_1$. Substituting $\alpha=-0.25$ into Eq. 18, we obtain $2\cos\theta_1=0.50$ and $\zeta=0.22$ eV. ζ estimated by these two different methods are in the same order of magnitude.

The π system of **3** consists of one durene at the center and two *p*-xylenes at both sides. The HOMO of *p*-xylene and durene are A and S respectively, each of which has a nodal plane rotated by 30° from each other. Therefore the resonance interaction is to be rather small, but $E^{\circ}_{1/2}$ of **3**, 1.08 V, is about 0.6 V lower than that of durene. This mean that the repulsion integral $4\gamma_1$ in Eq. 18 contributes considerably to the stabilization. If we adopt here $\gamma_1=0.1$ eV, the difference 0.2 eV can be regarded as the contribution from the resonance interaction.

The energy stabilization of **4** and **5** is further enhanced by the eclipsed configuration of the two durene moieties in the center of **4** and orbital mixings of the four durene moieties in **5**, as in the cases of **1** and **2**. $E^{\circ}_{1/2}$ of **4** and **5** clearly show the energy stabilization of the order of 0.9 V.

Spin Density Distribution. The transannular interaction in the staggered configuration in **1** does not so much stabilize the system, but induces the mixing between A and S, which results in the spin density redistribution. From the comparison of the observed hfcc with those of the calculated ones, we can estimate β' as 0.03 β. In the previous work,[1m] we also obtained $\beta'=0.03\,\beta$ in the case of coronene trimer cation radical $C_3^{+\cdot}$. It is remarkable that β' estimated in the two different systems coincide with each other in spite of the difference of the compounds.

About 0.5 G splittings due to the ring protons in **1** is the same magnitude as that in **2**, but the theoretical calculations (McLachlan and INDO) indicate the opposite sign. This is probably due to the fact that the small transannular interaction between the two moieties induces the spin density redistribution which converts accidentally the sign of usually negative hfcc of −0.5 G.

From the hfcc due to $\mathbf{3}^{+\cdot}$ it was found that the spin density is localized on the central moiety of durene, the ratio of the spin density in the central moiety to that of the side moieties being about 15 : 1. The theoretical treatment of such a mixed layer compound leads to a large apparent a, as indicated in Fig. 8. Dessau *et al.* obtained the hfcc of $\mathbf{D}^{+\cdot}$: 10.7 G for the twelve methyl protons and 0.8 G for the two ring protons.[16] The latter is very close to that of the central ring protons in $\mathbf{3}^{+\cdot}$ (0.789 G). Both McLachlan's and INDO calculations support such localization of the spin density, although the hfcc of the side moieties do not agree with the experimental values so well. This probably due to the fact that the hfcc of the side moieties are very sensitive to the distance between the central and side moieties. It is appropriate to conclude that most of the spin density is localized on the central durene moiety in $\mathbf{3}^{+\cdot}$.

The linewidths of $\mathbf{4}^{+\cdot}$ and $\mathbf{5}^{+\cdot}$ show only indirect evidence that the spin density localizes at the central two moieties. The four methyl substitution to **4**, which leads to **5**, produced only a small variation to the linewidth. This suggests small spin distribution on the both side rings and large spin localization on the two central rings of **4**.

The authors wish to express their thanks to Professor Suehiro Iwata of Keio University for his kind suggestions concerning the theoretical treatment of the polymer cation radicals.

Translational Energy Distribution and Relative Emission Cross Section of Excited Hydrogen Atom Produced in Electron-chloroform Collisions

Teiichiro OGAWA,* Fumihiro MIYOSHI,† and Morihide HIGO††
Department of Molecular Science and Technology, Kyushu University, Kasuga, Fukuoka 816
(Received Nobember 13, 1981)

Dissociative excitation of $CHCl_3$ and $CDCl_3$ has been investigated by means of the controlled electron impact and the high resolution emission spectroscopy. The emission spectrum shows such excited species as H, CH, CH^+, Cl^+, CCl, and HCl^+. The excitation function of H* has two thresholds, 20.5 and 41.0 eV. The emission cross spections of H* and D* reveal an isotope effect, which is dependent on the excitation energy and the principal quantum number. Translational energy distributions of H* and D* have been determined from the Doppler line shape of the Balmer-β line, and average translational energies from the half-width of the Balmer-α, β, γ, and δ lines. There are no noticeable isotope effect for the translational energy; their major peaks lie at 0—1, 4, and 6—12 eV. These findings indicate that there are at least three major processes for the formation of the excited hydrogen atom. They are assigned to dissociative excitation through the Rydberg states converging to the $(2a_1)^1$ ionic states and through doubly excited Rydberg states.

An excited molecule may decompose by itself to give an excited fragment atom. An electron-molecule collision is an efficient method to trigger dissociative excitation of the molecule. A detailed elucidation of this process has become possible through the investigation of the translational energy distributions of H* and D* obtained from the analysis of the Doppler line shape of their Balmer lines.[1,2] It has been found that there are two or more processes for dissociative excitation of H_2,[3] D_2,[4] HCl,[2] and CH_4[5] to produce the excited hydrogen atom from such molecules. The high resolution spectroscopy of H* is equally important with the mass spectroscopy of H^+ for a detailed analysis of the dissociation mechanism of highly-excited molecules.

Dissociation mechanism of chloroform has been investigated under the controlled electron impact excitation of $CHCl_3$ and $CDCl_3$.[6] The photoelectron spectrum of chloroform has been measured and discussions on the excited electronic states have been given.[7-9]

The relative value of the emission cross sections of H* to those of D* produced in the collision process is also useful for the investigation of the dissociation mechanism and is related to competition among various dissociation and ionization processes of the highly-excited molecule.[10]

In the present paper, the emission spectra of $CHCl_3$ and $CDCl_3$ have been measured with a high resolution by using a Fabry-Perot interferometer. The translational energy distributions of H* and D*, the excitation function and the relative emission cross sections have been obtained in order to discuss the mechanism of dissociative excitation of chloroform.

Experimental

The apparatus has been described previously.[2,3] The very high resolution spectrum was obtained with a Fabry-Perot interferometer (Mizojiri Optics). The $CDCl_3$ (99.8 D atom %) was obtained from Aldrich Chemical. The chloroform was used as supplied and subjected to several freeze-pump-thaw cycles before use.

Results and Discussion

Spectrum. Collisions between a chloroform molecule and an electron give photoemissions of several fragments, as are shown in Fig. 1. They are the excited hydrogen atoms (n=3,4,5,6,7,8), CH(A–X, B–X, C–X), CH^+(A–X, B–A, b–a), Cl^+, CCl(A–X), and HCl^+(A–X). The spectrum of $CDCl_3$ is similar; however, the Balmer lines are relatively weaker.

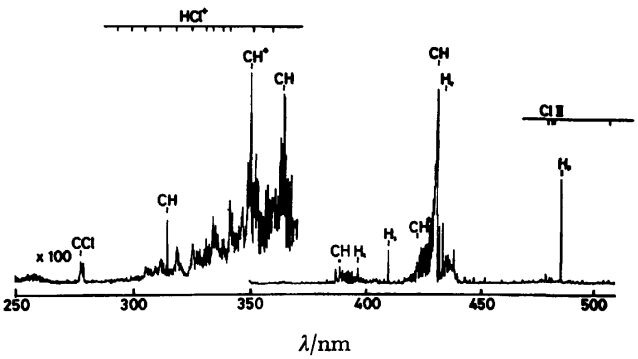

Fig. 1. Emission spectrum of chloroform by controlled electron impact. Electron energy 100 eV, electron-beam current 800 μA, spectral resolution 2 Å.

The intensities of the Balmer lines and bands of CH(A–X), CH^+(B–A), and CCl(A–X) are proportional to the electron-beam current and the gas pressure. Thus, these species should be produced in a one-electron-one-molecule primary collision. On the other hand, the square root of the emission intensity of HCl^+(A–X) is proportional to the electron-beam current (Fig. 2), although this intensity is directly proportional to the gas pressure. These results indicate that HCl^+ is produced in a two-step molecular elimination mechanism as in the case of CH_2Cl_2.[6]

Thresholds. The excitation functions of CH(A–X)

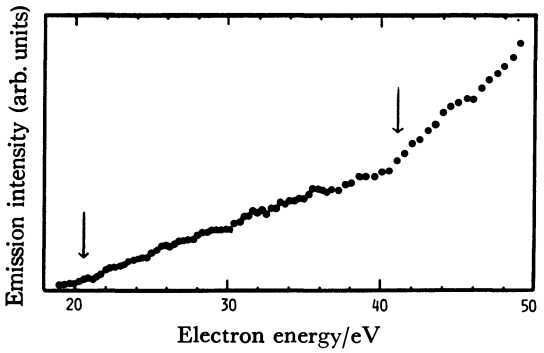

Fig. 3. Excitation function of the dissociative excitation of chloroform to yield the excited hydrogen atom (n=4).
Thresholds are indicated by arrows. The electron-beam current is 1 μA.

and H(n=4) have been measured and the latter is shown in Fig. 3. The threshold energies for the formation of CH(A) lie at 16.8±1.0 and 34.0±2.5 eV, and those of H(n=4) lie at 20.5±1.7 and 41.0±2.5 eV. These values are shown in Table 1, together with the previous results[6] and several possible dissociation processes.

The first threshold of CH(A) at 16.8 eV can be assigned to some of the processes (a), (b), or (c) in Table 1. The first threshold of H*(n=4) at 20.5 eV can be assigned to process (f), since the excited hydrogen atom carries some translational energy. The excess energy above the dissociation limit is partitioned into the translational, vibrational and rotational energies of the fragments. For the process (f), the law of conservation of momentum requires that H*(n=4) carries 99% of the total translational energy, and the residual energy should be the vibrational and rotational energies of CCl_3.

Isotope Effect. The emission cross sections of the excited hydrogen atom produced in electron-hydrogen and electron-hydrogen chloride collisions have isotope effects.[10-12] One of the main sources of this isotope effect is competition between dissociation and autoionization of superexcited states produced in the collision process.[13]

The emission spectra of H* and D* have been measured for mixtures of $CHCl_3$ and $CDCl_3$ in the equal amount; typical spectra of the Balmer-α line are shown in Fig. 4.

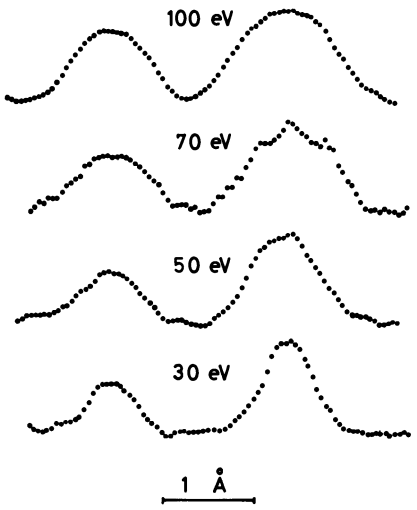

Fig. 4. High resolution spectra of the Balmer-α lines of H* and D* measured for mixtures of $CHCl_3$ and $CDCl_3$ in the equal amount. The left peak (smaller) is D* at 6561.0 Å and the right one (taller) is H* at 6562.8 Å. The resolution was 0.08—0.15 Å (Spex 1269 monochromator).

Table 1. Threshold energies for dissociative excitation of chloroform

	Process	Calculated dissociation limit	Observed threshold energy: This work	Observed threshold energy: Toyoda *et al.*[6]
(a)	$CHCl_3 \xrightarrow{e} CH(A)+Cl_2(X)+Cl(3P^5\ ^2P)$	12.0	16.8±1.0	17.6±1.0
(b)	$CH(A)+Cl_2(A)+Cl(3P^5\ ^2P)$	14.2		
(c)	$CH(A)+3Cl(3P^5\ ^2P)$	14.4		
(d)	$CH(A)+Cl_2(C)+Cl(3P^5\ ^2P)$	19.1		
(e)	$CH(A)+Cl_2(X)+Cl(4S^1\ ^4P)$	20.9		
(f)	$CHCl_3 \xrightarrow{e} H(n=4)+CCl_3(X)$	16.7	20.5±1.7	
(g)	$H(n=4)+CCl_2(X)+Cl(3P^5\ ^2P)$	19.0

40		—	0.51±0.08	0.53±0.11	0.62±0.09
30		0.50±0.08	0.52±0.08	—	0.60±0.09
Optical resolution used/Å	above 50 eV	0.13	0.08	0.08	0.08
	30, 40 eV	0.15	0.11	0.11	0.11

The relative emission cross sections (σ_D/σ_H) have been determined from the relative area of the Balmer lines; the area was measured with a planimeter. The optical resolution of the measurements is so good that we can ignore the distortion of the line shape. The relative emission cross sections are dependent on the excitation energy and the principal quantum number of the excited hydrogen atom, as are shown in Table 2.

The electron energy dependence of the relative cross sections indicates that there are two or more processes for the formation of the excited hydrogen atom and that their relative contribution is dependent on the electron energy, since the value of a single dissociation process is expected to be independent of the excitation energy.[10]

Dissociation through a repulsive potential curve has a smaller isotope effect than that through a bound potential curve, since the former is expected to be faster than the latter and, as a result, affects a smaller competition with preionization. The difference of the Franck-Condon region may be important for the dissociation through a bound curve.[14] The decrease of the observed isotope effect (approach of the value of σ_D/σ_H to 1.0) indicates that dissociation through a repulsive curve becomes more important at higher electron energies.

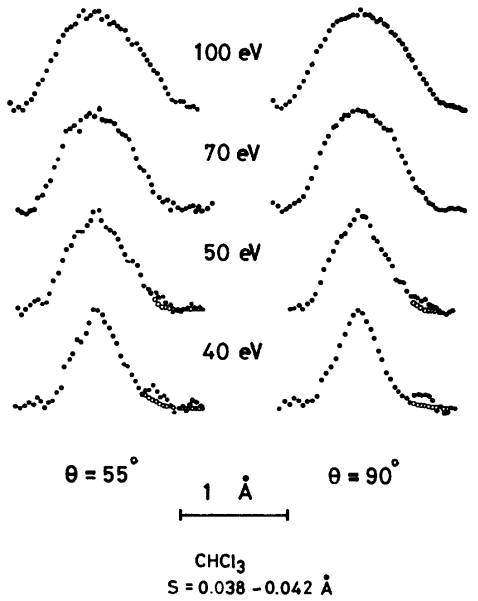

Fig. 5. Very high resolution spectra of the Balmer-β lines of H* obtained by a Fabry-Perot interferometer at a optical resolution of 0.038—0.042 Å.
Solid dots: experimental data, open circles: corrected for background radiation. Electron-beam current 800 μA.

Translational Energy Distribution. Translational energy distribution of the fragment atom has much to do with the shape of the potential curve for the formation of this fragment atom. Dissociation through a repulsive curve results in fragments with high velocity, and that through a bound curve with low velocity.

The high resolution spectra of H* from $CHCl_3$ taken with a Fabry-Perot interferometer are shown in Fig. 5. The lines are distorted by some background lines, possibly, of Cl or Cl^+. This distortion was manually corrected as shown in the Figure.

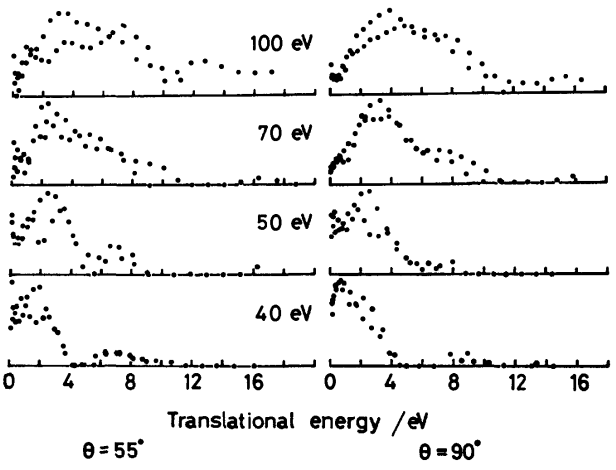

Fig. 6. The translational energy distribution of H* produced in electron-$CHCl_3$ collisions. Distributions were taken at 55° and 90° and they agree within experimental uncertainty.

The line shapes taken at 90° and 55° with respect to the electron-beam are in agreement with each other; thus, the effect of anisotropy is smaller than the experimental uncertainty. The differentiation of the line shape gives the translational energy distribution.[1,2] The results are shown in Fig. 6 for H* from $CHCl_3$ and in Fig. 7 for D* from $CDCl_3$.

The translational energy distribution excited by 100 eV electrons has a peak at about 4 eV. Upon decreasing the electron energy, the distribution shifts toward the lower energy and it has another peak at 0—1 eV when

30	0.50±0.09	0.34±0.09	—	0.35±0.10

The optical resolution (s) is 0.04—0.20 Å.

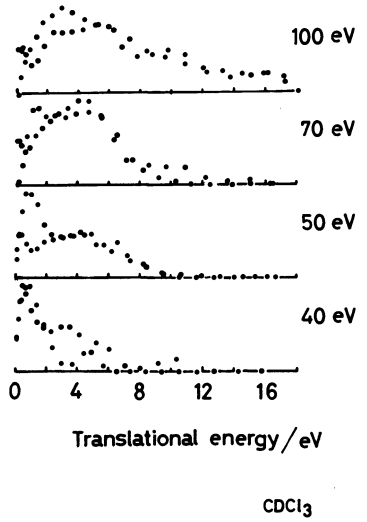

Fig. 7. The translational energy distribution of D* produced in electron-$CDCl_3$ collisions. The data were taken at 90°.

excited at 40 eV electrons. The distributions of H* and D* are, on the whole, similar; accordingly, the dissociation processes are qualitatively equal for two molecules. Furthermore, it is noteworthy that the distributions are similar to those of methane;[5] this finding suggests that dissociation processes of hydrogen from chloroform and from methane are similar. Molecules of similar structure and similar chemical bond may dissociate similarly.

Average Translational Energy. The translational energy distribution gives detailed and precise information of the kinetic character of the fragment produced in the collision processes. However, requirement of very high resolution makes it very difficult to apply the method for a weak line. Balmer-α, γ, and δ lines from chloroform are such cases. Thus, instead of the translational energy distribution, an average translational energy has been obtained through the measurement of the half-width of the Balmer lines by use of a grating monochromator.

There are two methods to take the average of the translational energy; one assumes a Maxwell distribution[15,16] and the other a δ-function distribution.[17,18] The value of the average depends substantially on the method used.[19]

$$E\,(\text{Av. }\delta\text{-function}) = 0.462\,E\,(\text{Av. Maxwell})$$

We have calculated the average translational energy with both methods and found that the average obtained by assuming a δ-function distribution agrees more with the peak of the translational energy distribution shown in Figs. 6 and 7 than the average obtained by another method does.

The observed half-widths are shown in Table 3 and the average translational energies obtained by assuming a δ-function distribution in Table 4. The results indicate that there seems no isotope effect in the average translational energy just as in the case of the distribution. This is superficially evident since the potential energy diagram should be identical for isotopic molecule; a

30	1.4±0.5	1.1±0.6	—	1.7±0.9

difference, however, has been found for hydrogen molecules.[4]

Dissociation Process. The translational energy distributions and the average translational energies of the excited hydrogen atoms produced in electron-chloroform collisions show that there are more than one major dissociation processes just as in the case of methane. Methane has the fourth component, which is very fast.[5] The translational energy distribution of chloroform (Figs. 6 and 7) may have a corresponding component at 6—12 eV region. Thus, there are at least three major components of the excited hydrogen atom from chloroform with peaks of the distribution at 0—1, 4, and 6—12 eV, respectively.

The $2a_1$ molecular orbital of chloroform, which is C–H bonding, is located at 19.8—20.8 eV vertically above the ground state.[7,8] The corresponding molecular orbital of methane lies at 22.4 eV and is concluded to play an important role for the formation of the component with the peak of the translational energy distribution at about 3 eV and with the threshold at 21.6 eV.[5] Since the first threshold of H* from chloroform is 20.5 eV, we can conclude that one of the components of H* from chloroform is produced through excitation to Rydberg states converging to the $(2a_1)^1$ ionic state, just as in the case of methane. This component has the average translational energy of about 1 eV (Table 4); this component may be different from the one which has the peak at 0—1 eV at the excitation of 40 eV.

Higher doubly excited states have been found to be important for molecular dissociation and formation of the excited hydrogen atom.[3-5] There seems to be few reports on such excited states of chloroform and neither their location nor their electronic configuration are clear. However, similarity of the translational energy distribution with that of methane suggests that similar doubly excited states with those of methane play important roles in the formation of other components of H*(D*) from $CHCl_3$ ($CDCl_3$). One of the components with the peak of translational energy distribution at 4 eV may correspond to the excited hydrogen atom with the threshold at 41.0 eV.

Concluding Remarks. The translational energy distribution of the fragment atom gives useful information of the highly excited states and their dissociation. The detailed understanding, however, becomes possible by combining various information on highly excited states, which is in serious lack for chloroform.

The authors thank professor Nobuhiko Ishibashi for encouragement. The present study was partially supported by a Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture.

Nanosecond Laser Flash Photolysis of 1-Anilinonaphthalene

Hiroki NAKAMURA,* Jiro TANAKA, Nobuaki NAKASHIMA, and Keitaro YOSHIHARA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
†*Institute for Molecular Science, Okazaki 444*

(Received December 2, 1981)

The photoionization mechanism of 1-anilinonaphthalene (1-AN) was investigated by a nanosecond laser flash photolysis and the result was compared with that of 8-anilino-1-naphthalenesulfonate (ANS). The photoionization of 1-AN in polar solvent is shown to occur through a biphotonic process *via* a triplet state; the mechanism is different from those of ANS, in which an intermediate of a charge transfer to solvent (CTTS) state was observed. Thus the major deactivation process of the lowest excited singlet state is an intersystem crossing in 1-AN, while it is a transition to the CTTS state in ANS which might be stabilized by the sulfonato group.

The fluorescence spectra, quantum yields, and lifetimes of naphthylamine derivatives, especially 8-anilino-1-naphthalenesulfonate (ANS) and 6-(*p*-toluidino)-2-naphthalenesulfonate (TNS) are extremely sensitive to their environment.[1-6] For example, ANS shows a dramatic decrease in fluorescence lifetime by increasing the solvent polarity (ethanol (12.5 ns) and water (0.2 ns)).[6] These properties have been used as probes for structural studies of biological molecules for many years.[1,3,7] Fleming *et al.*[8] proposed that the major deactivation process of the excited singlet state of ANS and 1-anilinonaphthalene (1-AN) in polar solvents may be a monophotonic ionization from their excited singlet state with a result of nanosecond laser flash photolysis. We reported that the photoionization of ANS is a biphotonic process *via* a charge transfer to solvent (CTTS) state.[9] It has been recognized that 1-AN, which has no sulfonato group, shows the red shift of fluorescence spectrum accompanying with the increase of the solvent polarity;[10] the behavior is analogous to ANS and TNS. However, 1-AN does not show a drastic decrease of fluorescence lifetime by increasing the solvent polarity.[11] It is conceivable that the sulfonato group of anilinonaphthalenesulfonate plays an important role in the deactivation process of the lowest excited singlet state in polar solvents. We studied the mechanism of photoionization of 1-AN, which has no sulfonato group, by comparing it with that of ANS.

Experimental

1-AN obtained from Nakarai Chemical Ltd. was used after twice recrystallizations from ethanol. *trans*-Stilbene and potassium iodide were used as received from Nakarai Chemical Ltd. Spectroscopic grade water, methanol, ethanol, and cyclohexane were used as solvents. The degassed samples were sealed after repeated freeze-pump-thaw degassing cycles. Fluorescence spectra were measured on a Hitachi MPF-2A spectrofluorometer located at Chemical Instrument Center of Nagoya University. Details of the laser flash photolysis and the fluorescence lifetime measurement were described previously.[6,9] The exciting source for the laser flash photolysis was a XeF excimer laser (Lambda Physik EMG-500) with an emission line at 351 nm and a pulse width of 12 ns.

Results and Discussion

Fleming *et al.*[8] found a transient absorption spectrum of 1-AN in methanol–water (1 : 1) mixed solvent which is similar to that of ANS in an aqueous solution. They proposed that the major deactivation process of 1-AN in polar solvent is a photoionization because of a similarity of transient spectrum. We also measured the transient absorption spectrum of 1-AN in a degassed methanol–water (1 : 1) mixed solvent. The spectrum which we obtained is somewhat different from that reported by Fleming *et al.* in the longer wavelength region than 580 nm as shown in Fig. 1 (curve A). Both the 420 and 800 nm bands are similar to the absorption of ANS radical which has peaks at 450 and 800 nm, respectively. These bands are assigned to the absorption of 1-AN cation radical. Furthermore we observed a transient absorption of 1-AN having a decay time identical with the fluorescence lifetime in the wavelength region above 700 nm, and these absorptions are assigned to the $S_n \leftarrow S_1$ absorption of 1-AN (Fig. 1 (curve B)).

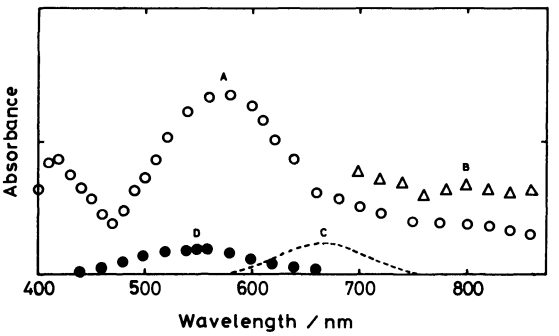

Fig. 1. Transient absorption spectra of 1-AN.
A: 70 ns after the laser pulse in a degassed methanol–water (1 : 1) mixed solvent, B: the $S_n \leftarrow S_1$ absorption, C: the absorption spectrum of solvated electron, D: the $T_n \leftarrow T_1$ absorption in cyclohexane.

The strongest absorption band with the maximum at 580 nm is not assigned to that of solvated electron because the peaks of solvated electron in water and methanol appear at 720 and 640 nm,[12,13] respectively. Moreover, we measured the transient spectrum in solution containing an electron scavenger (N_2O), which will diminish the absorption of solvated electron. The differential transient spectrum between the solution in a degassed and N_2O saturated methanol–water (1 : 1) mixed solvent gives the absorption spectrum of solvated electron with a maximum at about 670 nm as shown in Fig. 1 (curve C). Since the peak of solvated electron

is found at normal wavelength region, the absorption band at 580 nm is regarded as the $T_n \leftarrow T_1$ absorption. Furthermore the following reasons are available to support the $T_n \leftarrow T_1$ assignment.

(1) The absorption maximum lies in the position of the $T_n \leftarrow T_1$ absorption observed in cyclohexane (Fig. 1 (curve D)). The latter spectrum agreed with that reported by Fleming *et al.*[8]

(2) The dependence of the absorbance at 580 nm on the light intensity shows a linear relationship. It shows that the absorption at 580 nm is produced by a monophotonic process.

(3) The transient absorption at 580 nm is extensively quenched by adding a triplet quencher such as oxygen and *trans*-stilbene into solution. The quenching by *trans*-stilbene was investigated with varying concentration in methanol–water (4 : 1) mixed solvent. Figure 2 shows the Stern-Volmer relationship of the decay time of the absorption at 580 nm. The quenching rate obtained from the slope of this plot is 4.5×10^9 ($mol^{-1}\ s^{-1}$). The relation shows that the quenching is a diffusion-controlled process.

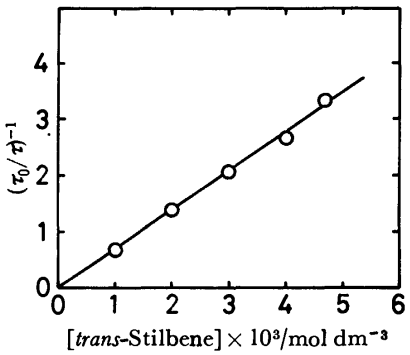

Fig. 2. Stern-Volmer plot of the decay time of the $T_n \leftarrow T_1$ absorption at 580 nm against the concentration of *trans*-stilbene in a methanol–water (4 : 1) mixed solvent.

In order to find whether the photoionization process occurs through the monophotonic or biphotonic one, we measured the dependence of the yield on the light intensity. The photoionization yield was monitored by the absorbance of 1-AN cation radical at 420 nm and the absorbance was plotted against the square of the light intensity in Fig. 3. The plot shows a linear relation, indicating that the photoionization is a biphotonic process.

Three species are conceivable as the intermediate of the biphotonic ionization; (1) the CTTS state, (2) the lowest excited singlet state, and (3) the triplet state. The CTTS state seems to be not involved because no evidence is obtained about the transient spectrum with a short lifetime. In order to find which of the singlet or the triplet excited state is the intermediate, we measured the change of the photoionization yield by adding different kind of quenchers.

The fluorescence of 1-AN was quenched by potassium iodide and we obtained the value of the quenching rate k_q from the Stern-Volmer plot ($k_q = 2.6 \times 10^8$ $mol^{-1}\ s^{-1}$). We also observed that both absorbances of the $T_n \leftarrow T_1$

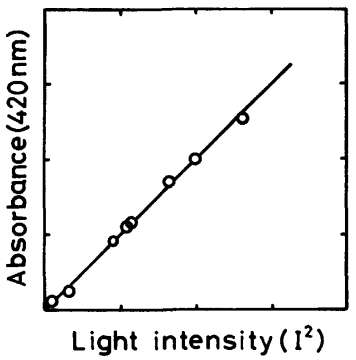

Fig. 3. Dependence of the absorbance at 420 nm on the square of the exciting light intensity in a degassed methanol–water (1 : 1) mixed solvent.

absorption and 1-AN cation radical are intensified with a linear relation by increasing the concentration of potassium iodide. This shows that potassium iodide enhances the intersystem crossing from the excited singlet state to the triplet state and the yield of the biphotonic ionization is increased. Therefore the photoionization process *via* the lowest triplet state is more probable.

Then, the change of the yield with the triplet quencher is investigated. The absorbance of 1-AN cation radical at 420 nm and the $T_n \leftarrow T_1$ absorption at 580 nm are decreased accompanying with the increase of the concentration of *trans*-stilbene. *trans*-Stilbene is a triplet quencher, therefore the photoionization is considered to take place through the triplet state. Following this result, the photoionization of 1-AN is given by the following scheme.

$$\text{1-AN}^* \xrightarrow{k_{isc}} \text{1-AN}^T \xrightarrow{h\nu} \text{1-AN}^+ + e^-_{sol}$$

$$\text{1-AN} \quad \overset{h\nu}{\underset{F}{\rightleftarrows}} \quad \text{1-AN}^* \xrightarrow{k_{isc}} \text{1-AN}^T$$

To distinguish the reaction mechanism of ANS and 1-AN in the excited singlet state, the fluorescence properties are measured and compared. Table 1 shows the fluorescence maxima and the fluorescence lifetimes of ANS and 1-AN in several solvent. The fluorescence maximum of 1-AN is shifted to the longer wavelength by increasing the solvent polarity as well as ANS. DeToma and Brand[14] reported the shift of the fluorescence maximum of 2-anilinonaphthalene in cyclo-

Table 1. Uncorrected fluorescence maxima and lifetimes in several solvent at 25°C

Solvent	ANS		1-AN			
	λ_{max} nm	τ_f ns	λ_{max} nm	τ_f ns	τ_f[a] ns	τ_f[b] ns
Water	514	0.20	461	2.6		5.0

Methanol	473	8.5	419	7.4	5.3	
Ethanol	466	12.5	412	7.6	5.6	5.75
Cyclohexane			374	5.8	4.1	4.1

a) For non-degassed samples. b) Ref. 11.

hexane–ethanol (<0.2 mol dm^{-3}) mixed solvent and we also observed the red shift of the fluorescence spectrum of 1-AN in mixed solvent of the same composition. It appears that the red shift is due to the solvent relaxation through the dipole-dipole interaction between the excited molecule and the polar solvent molecules during the lifetime of the excited singlet state, because the dipole moment of the first excited singlet state is greater than that of the ground state.[2,15]

We reported that the major deactivation process of ANS in polar solvent is the transition from the excited singlet state to the CTTS state and the $T_n \leftarrow T_1$ absorption is not detected.[9] The fluorescence lifetime of ANS is dramatically decreased by increasing the solvent polarity because the CTTS state is formed and the transition to it is enhanced in polar solvents. On the other hand the major deactivation process of the excited singlet state of 1-AN is shown to be the intersystem crossing to the triplet state, and it is less dependent on the polarity of the solvent. Hence the fluorescence lifetime of 1-AN is not shrunk significantly in polar solvent.

The biphotonic ionization occurs through the CTTS state in ANS, while it takes place *via* the triplet state in 1-AN. The difference of the photoionization mechanism between ANS and 1-AN is distinct. The presence of the sulfonato group in ANS may be connected with the formation of the CTTS state. Sadkowski and Fleming[11] suggested that the SO_3^- group of ANS forms a solvent trap through the hydrogen bond with the solvent molecules and the photoionization process from the excited ANS molecule could be interpreted by an electron transfer to the solvent trap. However we proposed the electron is transfered to the CTTS state rather than to bulk solvents before the photoionization and the SO_3^- group may stabilize the CTTS state by forming a zwitter-ion like structure. The zwitter-ion like structure is supported from the similarity of the transient absorption spectra between ANS radical and 1-AN cation radical. A similar phenomenon was reported in pyrene and pyrenesulfonic acid by Grätzel *et al.*[16]

A Co-59 Nuclear Magnetic Resonance Study of the Interaction of Lanthanoid Shift Reagents with Tris(β-diketonato)-cobalt(III) Complexes

Masatoshi HIRAYAMA,* Yoshimichi KAWAMATA, Yuki FUJII, and Yoshiharu NAKANO
Department of Chemistry, Faculty of Science, Ibaraki University 2-1-1 Bunkyo, Mito 310
(Received November 19, 1981)

$Ln(fod)_3$ (Ln=La, Pr, Nd, Sm, and Eu)-induced ^{59}Co shifts (δ_{Co}) for a series of tris(β-diketonato)Co(III) complexes were determined directly from separate observations of the free complexes and 1 : 1 adducts with $Ln(fod)_3$ at room temperature (25 °C) in $CHCl_3$; $Ln(dpm)_3$-induced shifts were also observed in CCl_4. Values of δ_{Co} corrected for the adduct-formation shifts (δ'_{Co}) are separated into contact and pseudo-contact contributions by using the intercept and slope in a linear plot of $\delta'_{Co}/\langle S_z\rangle$ *vs.* $D/\langle S_z\rangle$. It is suggested from the estimated hfs constant of ^{59}Co (≈ -0.2 G, 10^{-4} T) that the spin polarization mechanism may be predominant for the electron spin transfer from Ln ion into Co ion.

The lanthanoid shift reagents (LSR) have been extensively used for structural studies of organic substrates, but on their application to inorganic coordination complexes only a few investigations have so far been reported.[1-4] It has been found from ^1H or ^{13}C NMR studies by Lindoy *et al.*[2-4] that Ni(II) complexes of O_2N_2-donor quadridentate ligands coordinate to $Eu(fod)_3$[5] *via* two bridging donor oxygens and rapidly exchange between their free forms and 1 : 1 adducts with $Eu(fod)_3$ in $CDCl_3$ solution at room temperature,[2] while tris(β-diketonato)Co(III) complexes are bound to $Eu(fod)_3$ *via* three bridging oxygens and their exchange rates are very slow.[3,4]

These investigations prompted us to examine whether or not lanthanoid-induced shifts (LIS) can be detected at the nucleus of central metal ion of such complexes. This paper reports on LIS's of ^{59}Co measured for adducts of a series of tris(β-diketonato)Co(III) complexes with $Ln(fod)_3$ and $Ln(dpm)_3$.[5] Some of the results have been reported in a preliminary paper.[6]

Experimental

$Co(acac)_3$[5] was obtained from Tokyo Kasei Kogyo Co., Ltd. and used without further purification. Benzoylacetone was obtained commercially and *p*-methoxybenzoylacetone synthesized from *p*-methoxyacetophenone and acetic anhydride under boron trifluoride. $Co(bzac)_3$[5] and $Co(mbzac)_3$[5] were prepared according to the published method.[7] $CHCl_3$ and CCl_4 as a solvent were dried with molecular sieves before use. Eu- and $Pr(fod)_3$ were obtained from Merck Sharp and Dohme Canada Ltd. La-, Nd-, and $Sm(fod)_3$ and $Ln(dpm)_3$ (Ln= La, Pr, Nd, Sm, and Eu) were synthesized according to the literatures.[8] All the LSR's were used after being dried over P_2O_5 in a vacuum desiccator.

^{59}Co NMR spectra were recorded on a Varian CFT-20 spectrometer, equipped with a broad band accessory, at 19.104 MHz at room temperature (25 °C) using an external deuterium field-lock system. The aquisition time was taken as 0.05 s for the spectral width of 8065 Hz, the number of data points being 807. The number of transients was 100—500.

Results and Discussion

^{59}Co NMR of the Adducts of $Co(acac)_3$ with $Ln(fod)_3$. Figure 1 shows the ^{59}Co NMR spectra observed with a 0.085 mol dm^{-3} $Co(acac)_3$ solution in $CHCl_3$ at room temperature (25 °C) at a molar ratio (ρ) of $Ln(fod)_3$ (Ln=La, Pr, Nd, Sm, and Eu) to $Co(acac)_3$ of about 0.5. These spectra can be interpreted by analogy with the ^1H spectra of the $Co(acac)_3$–$Eu(fod)_3$ system measured by Lindoy *et al.*[3,4] as follows: The lower- and higher-field resonances in each spectrum can be determined to arise from the free form of $Co(acac)_3$ and its 1 : 1 adduct with $Ln(fod)_3$, respectively, by observing the change in intensity ratios of these with changing ρ. Such a separate observation of ^{59}Co shifts indicates that the chemical exchange of $Co(acac)_3$ between its free form and its 1 : 1 adduct with $Ln(fod)_3$ under these experimental conditions is very slow on the NMR time scale. No ^{59}Co resonance lines of the adducts with the later members of lanthanoid series (Gd—Yb) could be detected owing to the long T_1 of electron spin in addition to the slow exchange rate.

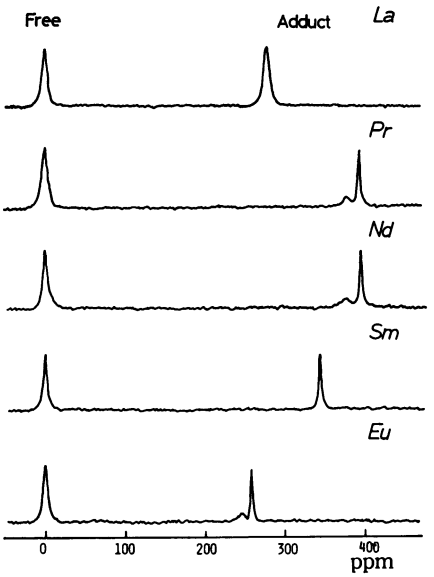

Fig. 1. The ^{59}Co NMR of free $Co(acac)_3$ and its adducts with $Ln(fod)_3$ in $CHCl_3$ at 25 °C. $\rho \approx 0.5$. High-field shifts are given as positive.

A considerable amount of large high-field shift was observed with diamagnetic $La(fod)_3$. This may not be surprising considering that the paramagnetic term of ^{59}Co shift (σ_{para}) is greatly sensitive to variation in ligand

and ligand field symmetry.[9] Thus, this high-field shift can be ascribed to a slight distortion of ligand field symmetry arising from the geometric distortion of oxygen donor atoms[3] and small changes in electron densities on these oxygens by the adduct formation. On the other hand, one may consider that this diamagnetic high-field shift corresponds to an increase in ΔE, the energy separation between the ground state and the excited $^1T_{1g}$ level of Co^{3+},[9] on going from free $Co(acac)_3$ to the adduct.

Each of the adducts with Pr-, Nd-, and $Eu(fod)_3$ gave rise to a peak of weak intensity at a slightly lower field ($\approx$20 ppm) than the main peak. The ratios of this satellite to the main peak were unchanged with changing ρ. These satellites may not be considered to arise from any impurities in $Co(acac)_3$, from the experimental result that the remaining Sm- and La-adducts studied here do not exhibit such a satellite. It has been confirmed by Lindoy *et al.* that symmetrical adducts are formed in these systems, that is, coordination of $Ln(fod)_3$ occurs *via* three β-diketone oxygen atoms at one available octahedral-face of $Co(acac)_3$ along the C_3 axis to form a 1 : 1 adduct. Thus, the possibility of coordination *via* one or two donor oxygens may be excluded and these satellites can, therefore, be presumed to be due to a small amount of geometrical isomer appearing on the adduct formation. It is generally presumed that the intramolecular rapid exchange between the *fac-* and *mer*-isomers of $Ln(fod)_3$ occurs at room temperature in $CDCl_3$ solution.[10] With the adduct formation, however, this exchange rate may be anticipated to become so slow that different effects of these isomers of $Ln(fod)_3$ on ^{59}Co shifts may separately be observed. Since the *fac*-isomer is more stable from the view of steric hindrance than the *mer*-isomer, the larger main peak may correspond to the adduct containing *fac*-$Ln(fod)_3$. The ^{59}Co shifts of these peaks relative to that of its free form (δ_{Co}) are shown in Table 1 together with its line widths ($\Delta\omega$). It is very interesting that the line widths of adducts are fairly smaller than those of free complexes for all the adducts except for the $La(fod)_3$-adduct.[11]

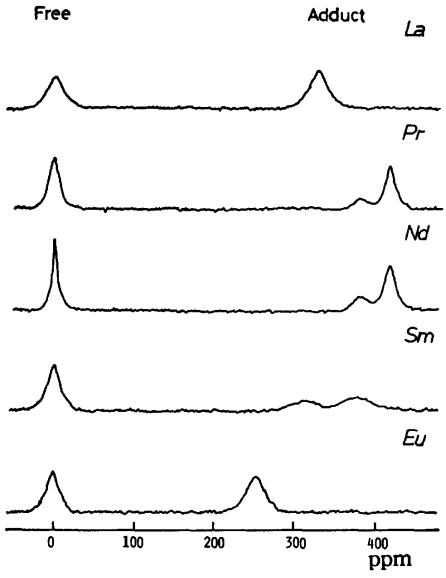

Fig. 2. The ^{59}Co NMR of free $Co(acac)_3$ and its adducts with $Ln(dpm)_3$ in CCl_4 at 25 °C. $\rho\approx0.5$. High-field shifts are given as positive.

^{59}Co NMR of the Adducts of $Co(acac)_3$ with $Ln(dpm)_3$. It was found that in $CHCl_3$ $Co(acac)_3$ is not bound to $Ln(dpm)_3$ at 25 °C, but that in CCl_4 the adducts with $Ln(dpm)_3$ are formed. This may be ascribed to the larger dielectric constant of $CHCl_3$ than that of CCl_4. The ^{59}Co spectra and LIS's of the adducts are shown in Fig. 2 and Table 1, respectively. The chemical exchange of $Co(acac)_3$ between its free form and its 1 : 1 Ln-$(dpm)_3$-adduct in CCl_4 is considerably slow, as with the $Co(acac)_3$–$Ln(fod)_3$ adduct in $CHCl_3$. In contrast to the $Ln(fod)_3$-adducts, the line widths are comparable in magnitude with those of corresponding free complexes, except for that of the $Sm(dpm)_3$-adduct which is about twice as broad as that of the free form. Furthermore, the high-field shift induced by $La(dpm)_3$ is larger by $\approx$50 ppm than that by $La(fod)_3$. This may be due to the difference in distortion of the octahedral ligand-field of Co^{3+} between these two La-adducts, which may arise from the difference in Lewis acidities and geometries of adducts.[12]

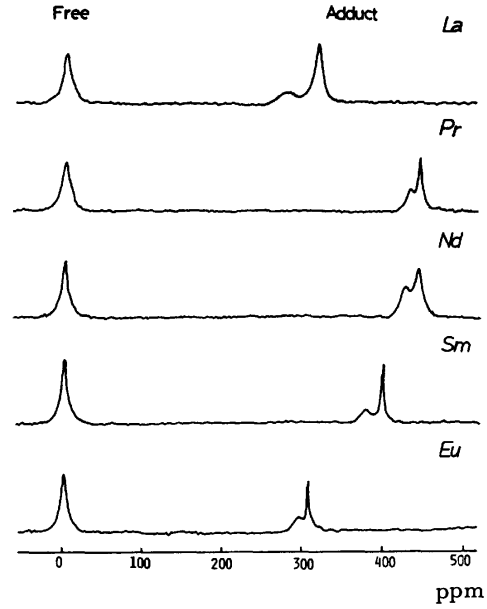

Fig. 3. The ^{59}Co NMR of free $Co(bzac)_3$ and its adducts with $Ln(fod)_3$ in $CHCl_3$ at 25 °C. $\rho\approx0.5$. High-field shifts are given as positive.

^{59}Co NMR of the Adducts of $Co(bzac)_3$ and $Co(mbzac)_3$ with $Ln(fod)_3$. Also from $Co(bzac)_3$ and $Co(mbzac)_3$ with $Ln(fod)_3$ in $CHCl_3$ at 25 °C, ^{59}Co signals assignable to the free complex and the corresponding 1 : 1 adduct with $Ln(fod)_3$ were separately observed. The spectra obtained from $Co(bzac)_3$ are shown in Fig. 3. Both of the free complexes exhibited only one line, though slightly broarder than that of $Co(acac)_3$ in $CHCl_3$, and this suggests that the shift differences between the *fac-* and *mer*-isomers of these complexes are essentially small within the line widths observed or that only the isomer of *fac*-type may exist.[13] The adduct resonances have patterns similar to those from

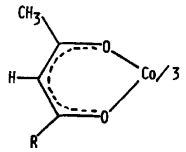
a) In ppm. Down-field shifts are given as negative. The accuracy of the observed shifts is ± 1 ppm for all the adducts except for that of Co(acac)$_3$ with Ln(dpm)$_3$ (± 2 ppm). b) Relative to free complex. Values in parentheses are for the small peaks (see text). c) The line widths of adduct peaks in Hz. d) $\delta_{Co}(La)+\alpha\cdot N$, where α is 12 ppm (Co(acac)$_3$ with Ln(fod)$_3$), 8.9 ppm (Co(acac)$_3$ with Ln(dpm)$_3$), 14.0 ppm (Co(bzac)$_3$ with Ln(fod)$_3$), and 14.5 ppm (Co(mbzac)$_3$ with Ln(fod)$_3$).



R=CH$_3$ Co(acac)$_3$
R=C$_6$H$_5$ Co(bzac)$_3$
R=*p*-CH$_3$O–C$_6$H$_5$ Co(mbzac)$_3$

Co(acac)$_3$, except for the adduct of Co(mbzac)$_3$ with La(fod)$_3$ which has only one line; that is, a satellite appears at a lower-field (15—20 ppm) than the main peak, though its intensity relative to the main peak is larger than that for Co(acac)$_3$. This two-line pattern can, therefore, be interpreted as arising from the *fac*- and *mer*-isomers of Ln(fod)$_3$-part in the adduct exchanging each other very slowly on the NMR time scale.[14] For comparison with the adduct of Co(acac)$_3$ with Ln(fod)$_3$, the larger peaks at higher-field are taken as δ_{Co}, which are listed in Table 1.

Separation of ^{59}Co LIS's into Contact (cs), Pseudo-contact (pcs), and Adduct-formation Shifts (AFS). Since it was found from an X-ray analysis of the Co(acac)$_3$–Eu(fod)$_3$ crystal[3] that this adduct has a C_3 axis, the approximation of magnetic axial symmetry can be applied to the analyses of the δ_{Co} observed above. Furthermore, the hyperfine splitting constant (A) and the geometric factor, $(3\cos^2\theta-1)r^{-3}$, (G) of ^{59}Co nucleus in the adduct are assumed to be constant along the lanthanoid series, on the basis of the reasonable expectation that the bonding nature and geometries of these adducts are almost independent of the lanthanoid metal. Thus, δ_{Co} can be expressed as

$$\delta_{Co} = A\cdot\langle S_z\rangle + G\cdot D'\cdot D + \text{AFS}, \quad (1)$$

where AFS is a diamagnetic adduct-formation shift, $\langle S_z\rangle$[15] is the projection of the total electron spin magnetization of lanthanoid ion in the direction of the external magnetic field, D'[16] is the product of the first and the third term in Bleaney's equation

$$\Delta\nu/\nu_0 = \beta^2/(60(kT)^2)\cdot(3\cos^2\theta-1)/r^3\cdot 2A_2^0\langle r^2\rangle \times g^2J(J+1)(2J-1)(2J+3)\langle J\|\alpha\|J\rangle \quad (2)$$

(a constant for a given temperature and ligand field), and D[16] is the fourth term in the above equation (a constant for a given lanthanoid). When δ_{Co} corrected for AFS is denoted as δ'_{Co},

$$\delta'_{Co} = A\cdot\langle S_z\rangle + G\cdot D'\cdot D \quad (3)$$

is obtained. By rearrangement of Eq. 3, one obtains

$$\delta'_{Co}/\langle S_z\rangle = A + G\cdot D'\cdot(D/\langle S_z\rangle). \quad (4)$$

If the assumption of constant A and G is reasonable, the $\delta'_{Co}/\langle S_z\rangle$ *vs.* $D/\langle S_z\rangle$ plot should be linear. For several systems consisting of an organic substrate and Ln(fod)$_3$, good linear relations have been obtained by several workers.[17]

An use as AFS of the La(fod)$_3$-induced shift, $\delta_{Co}(La)$, gave no linear relation in Eq. 4 for Co(acac)$_3$ with Ln(fod)$_3$. On the other hand, for the Al(acac)$_3$–Ln(fod)$_3$ system similar in structure to the present adduct,

$\delta'_{Al}/\langle S_z\rangle$ *vs.* $D/\langle S_z\rangle$ plot has given a good linearity on the use of La(fod)$_3$-induced ^{27}Al shifts as AFS.[18] This result leads us to anticipate that, in contrast to ^{27}Al shifts, ^{59}Co shifts (mainly σ_{para}) are very sensitive to even a slight change in diamagnetic electron-densities on the bridging oxygen atoms. Then, by taking δ_{Co}(La) $+a\cdot N$ as AFS where N is the number of 4f-electrons and a the contribution of a 4f-electron to AFS, a was decided so that the best linearity may be obtained. Consequently, satisfactory values for correlation coefficients were obtained by using the tabulated values for $\langle S_z\rangle$[15] and D.[16] The plot obtained is shown in Fig. 4, together with correlation coefficients (R). Also for δ_{Co} of Co(acac)$_3$ with Ln(dpm)$_3$ and Co(bzac)$_3$ and Co(mbzac)$_3$ with Ln(fod)$_3$, the same process gave good results (Figs. 4 and 5). Thus, by using the slope and intercept of the linear relation, δ'_{Co} was successfully separated into cs and pcs terms. The results are listed in Table 1.

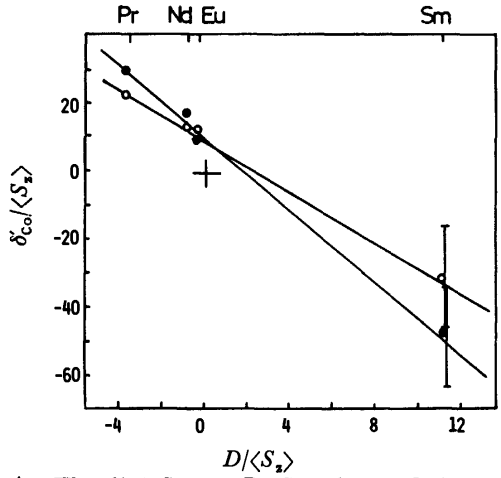


Fig. 4. The $\delta'_{Co}/\langle S_z\rangle$ *vs.* $D/\langle S_z\rangle$ plots. Co(acac)$_3$–Ln(fod)$_3$ and –Ln(dpm)$_3$ adducts are denoted by filled and open symbols, respectively.
●: R=0.980, ○: R=0.998.

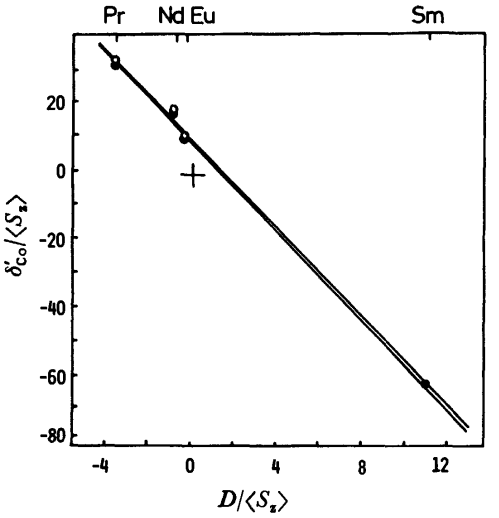

Fig. 5. The $\delta'_{Co}/\langle S_z\rangle$ *vs.* $D/\langle S_z\rangle$ plots. Co(bazc)$_3$– and Co(mbzac)$_3$–Ln(fod)$_3$ adducts are denoted by filled and open symbols, respectively.
●: R=0.987, ○: R=0.991.

Considering the use of theoretical values of $\langle S_z\rangle$ and D for the above treatment of experimental data, one cannot discuss the details of adduct geometries by comparing the slight differences between the slopes estimated for several complexes. However, it may roughly be said that the slope for the adduct of Co(acac)$_3$ with Ln(fod)$_3$ is larger than that with Ln(dpm)$_3$. The magnitude of slope estimated from Fig. 4 contains the crystal field parameter $A_2^0\langle r^2\rangle$. Since values of $A_2^0\langle r^2\rangle$ for the present systems are unknown, G cannot be estimated directly from the slope. However, if $A_2^0\langle r^2\rangle$ for Ln(fod)$_3$- and Ln(dpm)$_3$-adducts of Co(acac)$_3$ were similar in magnitude, G for the former would be larger than that for the latter. On the other hand, in the former, the coordination interaction *via* three bridging oxygens may be more pronounced because of the strong Lewis-acidity of Ln(fod)$_3$ and the Co–Ln distance can thus be expected to be shorter than the latter. The G value was calculated to be 0.0543 Å^{-3} (the distance of Co to Ln is 3.33 Å) from the X-ray crystal data,[3] on the assumption that the Co atom is located on the principal magnetic axis, as deduced on the basis of the approximation of magnetic axial-symmetry. From this value of G and the slope for the Ln(fod)$_3$-adduct given in Fig. 4, $A_2^0\langle r^2\rangle$ is calculated to be 175 cm^{-1}. This value is comparable in magnitude to those estimated for several other adducts, *e.g.*, 200—500 cm^{-1} for the γ-picoline–Ln(fod)$_3$ system in $CDCl_3$[19] and 100—150 cm^{-1} for the aniline–Ln(fod)$_3$ system in CCl_4.[20] If 175 cm^{-1} is taken also for the Co(acac)$_3$–Ln(dpm)$_3$ adduct, the Co–Ln distance for this adduct would be about 1.1 times as long as that of Ln(fod)$_3$-adduct.

A_{Co} for the Co(acac)$_3$–Ln(fod)$_3$ adduct was estimated to be about −0.2 G from Fig. 4. The amount of electron spin transferred from Ln ion into Co ion is estimated to be $\approx 2\times 10^{-4}$. The minus sign of A_{Co} and the very small amount of spin detected at the Co nucleus may imply that the spin polarization mechanism is predominant for electron spin transfer.

10) The observation of only one ^{1}H line arising from *t*-butyl protons was confirmed by a simultaneous ^{1}H NMR experiment. This is consistent with a rapid exchange between the isomers. Although it is also possible that only one of the two isomers exists, this model may be ineffective for interpretation of these satellites.

11) Two relaxation mechanisms of ^{59}Co nucleus due to quadrapole interaction and electron spins seem to be influenced each other. A discussion on this problem is in progress.

12) It may be reasonable to consider that when $CHCl_3$ or CCl_4 is used as a solvent, the difference of these solvent effects on the ^{59}Co shifts of a free complex and a corresponding adduct is similar in magnitude. Thus, for interpreting this shift difference, the solvent effect need not be taken into account.

13) Since the rate of isomerization for tris(β-diketonato)Co-(III) is generally said to be slow, it may not be considered that the observed one line corresponds to averaging *fac-* and *mer-*isomers.

14) It may not be considered that these satellites arise from the *mer*-isomer of Co-complex-part of the adduct, because of steric hindrance on the adduct formation.

A Proton Magnetic Resonance Study of Dialkyl Terephthalate Dianions

Masatoshi HIRAYAMA* and Mitsuo KANEKO
Department of Chemistry, Faculty of Science, Ibaraki University, 2-1-1 Bunkyo, Mito 310
(Received December 14, 1981)

NMR spectra were observed for green solutions formed from dimethyl, diethyl, and diisopropyl terephthalates in contact with sodium metal in THF-d_8 *in vacuo* at ambient probe temperature. A comparison of proton chemical shifts with excess charge densities calculated by the CNDO MO method supports that the green species are disodium salts of π-dianions.

It has been demonstrated by observation of NMR spectra that several unsubstituted aromatic compounds are reduced into their dianions by alkali metal *in vacuo* in aprotic solvent.[1] However, for aromatic compounds containing N- or O-hetero atom and electron-withdrawing substituents, the formation of their dianions has not so far been ascertained, probably because of their instability in solution.

Dimethyl terephthalate (DMTP), when brought into contact with Na metal in THF *in vacuo*, is at first converted into its purple-red anion radical[2] and then into a diamagnetic green species (G-species) within several minutes even if kept separated from Na metal; this species is stable for several months at room temperature even with a high concentration of starting substance of *ca.* 0.5 mol dm^{-3}. Kowata and Koizumi[3] interpreted this phenomenon in terms of UV investigation as follows: The G-species is the disodium salt $Na^+DMTP^{2-}Na^+$ of DMTP dianion formed from the sodium salt $DMTP^-Na^+$ of DMTP anion radical by the disproportionation

$$2(DMTP^-\,Na^+) \rightleftharpoons Na^+\,DMTP^{2-}\,Na^+ + DMTP.$$

Their interpretation was supported by an experimental result that the G-species has a powerful agency capable of reducing aromatic compounds such as trinitrobenzene stronger in electron affinity than DMTP. We now report ^{1}H NMR spectra successfully observed for this system.

Experimental

DMTP and diethyl terephthalate (DETP) obtained from Tokyo Kasei Kogyo Co. were used after recrystallization from benzene, and diisopropyl tetrephthalate (DPTP) was synthesized from DMTP by the exchange reaction of ester groups. THF-d_8 (Merck Sharp and Dohm Canada Ltd.) was purified by vacuum distillation after contact with Na–K alloy *in vacuo*.

^{1}H NMR spectra were measured on a Hitachi R-20A spectrometer at ambient probe temperature (34 °C) at 60 MHz in a frequency-swept mode. MO calculations were performed on HITAC-8250 at the Computer Center of Ibaraki University and on Hitachi M-200H at the Computer Center of the University of Tokyo. The program used for CNDO MO calculations is Y4CB04[4] from the library programs collected in the Computer Center of the University of Tokyo.

Results and Discussion

A 0.3 mol dm^{-3} THF-d_8 solution of DMTP was kept in contact with Na metal for 10 min *in vacuo* at room temperature and 24 h after separation from the Na metal an NMR spectrum was measured for the resulting green solution, which is shown in Fig. 1a. New resonance lines A′ and B′ appeared at higher-fields of corresponding ring (A) and methyl proton peaks (B) of unreduced DMTP, respectively, and furthermore, the intensity ratio A′/B′ was nearly equal to A/B, hence A′/A≈B′/B. On introducing air into the sample tube, the solution was caused to turn light yellow with formation of a white precipitate and the lines A and B disappeared. When methyl *p*-nitrobenzoate was introduced into the sample tube containing the G-species *in vacuo*, the formation of sodium salt of the anion radical of this ester was confirmed by observation of ESR. Also in the spectra obtained from DETP and DPTP in contact with Na in THF-d_8, the expected higher-field lines corresponding to the neutral molecule were observed and the intensity ratios A′/A, B′/B, and C′/C for ring,

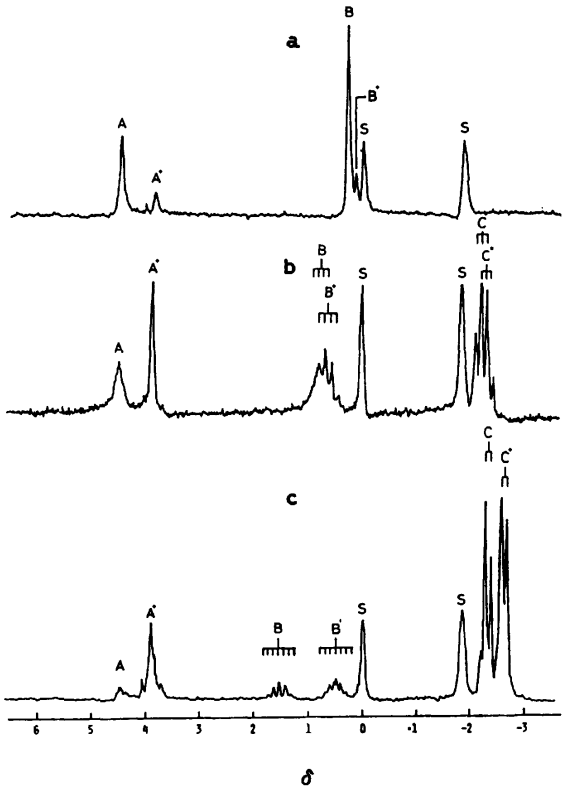

Fig. 1. NMR spectra of the dianion disodium salts of dialkyl terephthalates accompanied by the unreduced neutral molecule in THF-d_8 at 60 MHz and 34 °C. (a) DMTP, (b) DETP, (c) DPTP. The shifts are measured from the lower-shielding peak of THF. A: Ring-H, B: α-H, C: β-H, S: the solvent as an isotopic impurity. The prime letters indicate the dianion peaks.

α-, and β-protons, respectively,[5] were nearly equal to one another for both the systems, except that the intensity of A for DPTP is too small (Figs. 1b and 1c).

With all the samples, for several minutes after separation from Na metal an extensive line broadening was observed only for the peak A and then the line width became gradually sharper, while for the other protons line broadening was negligible due to smaller hfs constants than those of ring protons. These results may suggest that electron spin rapidly exchanges between the neutral molecule and the anion radical sodium salt still remaining owing to slow disproportionation. On the other hand, the line A′ remained sharp under the same conditions and this may then be considered to be ascribed to a very slow exchange of electron spin between the anion radical sodium salt and the G-species in solution.

These features of NMR spectra together with the interpretation of this reaction system based on UV spectra[3] indicate that all the lines denoted by prime letter in Fig. 1 result from dianion disodium salts. This is supported also by the fact that the lines B′ and C′ assume the same coupling patterns as those of B and C, respectively. The magnitude of $J_{\alpha\beta}$ is unchanged on going from the neutral to dianion molecule.

It has previously been decided from an ESR investigation[2] that the ester groups in the terephthalate anion radicals are fixed on the benzene plane, and this situation should also be applied to the dianion molecules. Actually, the line A′ is composed of several lines, though not completely resolved, as seen from Fig. 1 and this should be a superposition of two slightly different AA′BB′ patterns arising from *cis* and *trans* rotational isomers (Fig. 2). The center of these superposed lines is taken as the average shift of the ring protons of dianion. The shift values measured from the lower-shielding methylene peak of THF as an isotopic impurity are listed in Table 1.

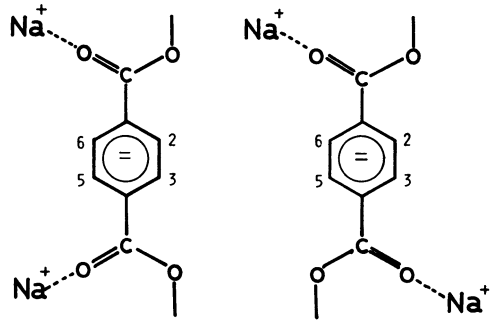

Fig. 2. The proposed structures of disodium salts of dianions of dialkyl terephthalates.

Table 1. The observed ^1H shifts of dianions

Compound		Ring-H	α-H	β-H
DMTP	Neutral[a]	4.45	0.30	
	Dianion[a]	3.84	0.16	
	$\Delta\delta_H$(obsd)[b]	−0.61	−0.14	
DETP	Neutral	4.52	0.76	−2.23
	Dianion	3.90	0.65	−2.33
	$\Delta\delta_H$(obsd)	−0.62	−0.11	−0.10
DPTP	Neutral	4.54	1.55	−2.35
	Dianion	3.89	0.53	−2.64
	$\Delta\delta_H$(obsd)	−0.65	−1.02	−0.29

a) Measured in ppm from the lower-shielding methylene peak of THF as an isotopic impurity. Negative sign denotes high-field shift. b) Shift of the dianion relative to its corresponding neutral molecule.

It has previously been established[1c,6,7] that, in simple aromatic systems, the proton chemical shift ($\Delta\delta_H$) is directly proportional to the excess π-electron density (Δq) on the carbon atom to which the proton is bonded. This may be empirically expressed by the simple linear relationship

$$\Delta\delta_H = k\,\Delta q,$$

where the constant k has been experimentally found to have a value of 10 to 11 ppm per electron.[1c,6,7] Then, proton chemical shifts provide reliable information about charge density distributions, provided that there exists no interfering effect such as the magnetic anisotropy of neighboring atoms or substituent groups. It has been predicted from theoretical consideration that the two excess electrons in the lowest vacant π-orbital of the dianion do not contribute to the ring current.[8] Therefore, no correction of the observed shift for the ring current effect is required for comparing the observed with calculated shifts. Although the anisotropy of C=O and C–O bonds for the dianion is considered to be different in magnitude from that for the neutral molecule, this effect may be neglected since these bonds are remote from the ring protons.

Thus, the π-charge densities on the carbon 2p orbitals, ρ^{π}_{2p}, were calculated by using both the CNDO and semiempirical SCF π-MO (ppp) methods. Several geometric parameters used were taken from the literature.[9] MO calculations were made for the *cis* and *trans* rotational conformers for the ester groups (Fig. 2) and ρ^{π}_{2p} was averaged over positions 2 and 6 and over the two conformers. The increase in the resulting average ρ^{π}_{2p} on going from the neutral to dianion molecule is taken as the excess charge, $\Delta\rho^{\pi}_{2p}$. The increases in the ring proton shifts corresponding to $\Delta\rho^{\pi}_{2p}$, $\Delta\delta_H$, were then calculated from $\Delta\rho^{\pi}_{2p}$ by using 10.7 ppm as k and are compared with the observed ones

Table 2. Comparison of observed shifts ($\Delta\delta_H$(obsd)) with those predicted from MO calculations ($\Delta\delta_H$(calcd)) for dimethyl terephthalate dianion[a]

		Ring-H	α-H
$\Delta\delta_H$(obsd)		−0.61	−0.14
$\Delta\delta_H$(calcd)	CNDO	−1.14(0.106)[b]	
	PPP	−1.29(0.121)[c]	
	CNDO	−1.6(0.095)[d]	−0.8(0.05)[d]

a) In ppm relative to the corresponding neutral molecule. Negative sign denotes high-field shift. b) The figure in parentheses is $\Delta\rho^{\pi}_{2p}$ (CNDO) (see text). c) The figure in parentheses is $\Delta\rho^{\pi}_{2p}$ (ppp) (see text). d) The figure in parentheses is $\Delta\rho^{H}_{1s}$ (CNDO) (see text).

($\Delta\delta_H$(obsd)) in Table 2. The result shows that $\Delta\delta_H$ (calcd) is about twice as much as $\Delta\delta_H$(obsd) for both the cases using the MO methods.

On the other hand, it has been predicted theoretically that a 6% increment of electron density on a hydrogen 1s orbital (ρ^H_{1s}) corresponds to 1 ppm high-field shift of the hydrogen. Using this relation, an attempt was made to estimate, though roughly, $\Delta\delta_H$ of ring protons from the excess charge on its 1s orbital estimated by the CNDO method, $\Delta\rho^H_{1s}$. ρ^H_{1s} was obtained from the averaging mentioned above. As shown in Table 2, the result indicates a further larger high-field shift than $\Delta\delta_H$(obsd). The same process was applied to the α-protons of methyl group but resulted in too large high-field shift.[10]

It may be resonable to consider that the counter ion effect of Na ions is responsible for this discrepancy: The hfs patterns in ESR spectra of terephthalate anion radicals have excellently been interpreted in terms of MO calculations performed on the ion pair model based on the interaction of Na ion with a carbonyl oxygen of one ester group.[2] By analogy with anion radicals, one may expect that the two Na ions bind to each of the two carbonyl oxygens of ester groups in the dianion disodium salt (Fig. 2). In this model, the bonding of Na ion to the carbonyl oxygen may increase the π-densities on the ester groups and hence may decrease those on the ring. This model is thus possibly effective for elucidation of the above discrepancy for the ring protons. However, the much larger value of CNDO $\Delta\rho^H_{1s}$ for the methyl protons than expected is difficult to be explained from this consideration and appears to be associated with the change in the anisotropy of C=O and C–O bonds on going from the neutral to dianion molecule. $\Delta\delta_H$(obsd) of the α-protons for DPTP is much larger than those for the other two compounds and this may suggest that the C–H bond of the isopropyl group in this dianion trends to be perpendicular to the molecular plane, in contrast to the case of the anion radical of this compound where this bond has been determined to be fixed on the benzene plane.[2]

It is known that for actual charged molecules the excess charge trends to be somewhat more uniformly distributed over the molecule than indicated by simple MO calculations.[1b] This effect is in competition with the trend of electron localization toward the ester groups by the bonding of Na ion. Another possible explanation for such discrepancy between the observed and calculated $\Delta\delta_H$ is related to the formation of π-π dimer dianion proposed on the basis of much larger concentrations of the starting aromatic compound than that suitable for the observation of ESR. This model is attractive since this might lead to about half $\Delta\rho$(calcd).

10) CNDO calculations were made for two rotational conformers for methyl groups in which one C–H bond is perpendicular and coplanar to the benzene plane. The excess ρ^H_{1s} for the dianion, $\Delta\rho^H_{1s}$, was estimated through the averaging of ρ^H_{1s} over the three methyl protons in each conformer.

The Estimation of the Liquid-Liquid Distribution Coefficients of Acetylacetone by Means of the Group Solution Theory

Masanao KATO*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received June 27, 1981)

The estimation of the liquid-liquid distribution coefficients of acetylacetone tautomers was attempted on the basis of the UNIFAC equation, and it was found that the calculated values of the reciprocals of the activity coefficients of tautomers in organic phases were linearly related to the distribution coefficients. It was verified that the estimation by the UNIFAC equation could be extended to the organic solvents with no characteristic parameter.

Acetylacetone (2,4-pentanedione), a well-known extractant, is extensively employed in the solvent extraction of various matallic elements. In the scheme of the extraction, the distribution of acetylacetone between two liquid phases plays an important role. The distribution ratio of metal elements is represented as a function of the partition coefficient of acetylacetone, the dissociation constant of acetylacetone in the aqueous phase, the formation constant of the metal acetylacetone complex, and the partition coefficient of the complex. From this point of view, the distribution of acetylacetone and its thermodynamic properties have been thoroughly investigated.

As a thermodynamic study, an interpretation of the distribution coefficients on the basis of the regular solution theory has been reported by Wakahayashi *et al.*;[1] they found a good correlation between the distribution coefficient of acetylacetone and the solubility parameter of organic solvents. The determination of the activity coefficients of each tautomer has also been tried in terms of the Wilson equation[2] and the UNIFAC equation[3] in our laboratory.[4,5] By the use of these analytical equations, the activity coefficients of tautomers could clearly be determined. Inoue *et al.* had also compared the activity coefficients of the tautomers with the distribution coefficients; they found a qualitative agreement between them.[4] For practical use, the Wilson parameters are required for all of the binary mixtures cencerned in the distribution experiments. That is, the vapor pressures of all the acetylacetone+organic solvent mixtures must be measured.

On the other hand, the calculation by the UNIFAC equation requires a smaller amount of parameters than those by the regular solution theory and the Wilson equation. Once the parameters are determined, these parameters can be employed for all the calculations for mixtures containing the same functional groups. In this study, the applicability of the UNIFAC equation to the estimation of the liquid-liquid distribution coefficients of acetylacetone was examined.

Theory

The UNIFAC Equation. The UNIFAC equation[3] consists of Eqs. 1 to 4. Eq. 1 represents the contribution of the size difference of the substances in the mixtures to the activity coefficients. In the original paper, it is named the combinatorial part, γ_i^C:

$$\ln \gamma_i^C = \ln \frac{\phi_i}{x_i} + \frac{z}{2} \ln \frac{\theta_i}{\phi_i} + l_i - \frac{\phi_i}{x_i} \sum x_j l_j, \quad (1)$$

and:

$$\theta_i = q_i x_i / (\sum_j q_j x_j), \quad \phi_i = r_i x_i / (\sum_j r_j x_j),$$
$$l_i = z(r_i - q_i)/2 - (r_i - 1), \quad (1a)$$

where x_i denotes the mole fraction of the i-th species; z, the coordination number; q_i, the parameter concerning the molecular surface area, and r_i, the parameter of the molecular volume. The q_i and r_i values are represented by the summation of the corresponding parameters, Q_k and R_k, for the functional groups by the following equations:

$$q_i = \sum_k \nu_k^{(i)} Q_k,$$
$$r_i = \sum_k \nu_k^{(i)} R_k, \quad (1b)$$

and

$$Q_k = A_{w,k}/(2.5 \times 10^9),$$
$$R_k = V_{w,k}/15.17, \quad (1c)$$

where $\nu_k^{(i)}$ is the number of the k group in the i-th species. $A_{w,k}$ and $V_{w,k}$ denote the van der Waals surface area and volume of the k group respectively. In Eq. 1, the required parameters are Q_k's and R_k's, and x_i is determined by the experimental conditions.

The following equations, Eqs. 2 and 3, represents the contribution of intermolecular interaction to the activity coefficients, in which γ_i^R is called the residual part, in the original paper:

$$\ln \gamma_i^R = \sum_k \nu_k^{(i)} [\ln \Gamma_k - \ln \Gamma_k^{(i)}], \quad (2)$$

$$\ln \Gamma_k = Q_k \left[1 - \ln \left(\sum_m \theta_m \Psi_{mk} \right) - \sum_m \frac{\theta_m \Psi_{km}}{\sum_n \theta_n \Psi_{nm}} \right], \quad (3)$$

where

$$\theta_m = Q_m X_m / (\sum_n Q_n X_n),$$
$$\Psi_{mn} = \exp(-a_{mn}/RT). \quad (3a)$$

The Γ_k represents the group-activity coefficient, and the additivity is postulated. The $\Gamma_k^{(i)}$ is the group-activity coefficient in the pure i species, and normalizes the activity coefficient to be unity in the pure state. The a_{mn} assesses the inter-group interaction between m and n groups; these values were summarized in the original paper in the form of a_{mn}/R. R and T are the gas constant and the temperature respectively. X_m denotes the mole

* Present address: Department of Material Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440.

fraction of the m group in the given mixtures. In Eqs. 2 and 3, the required parameters are Q_k's and a_{mn}'s.

The activity coefficient of the i-th species, γ_i, is represented by the summation of Eqs. 1 and 2 as follows:

$$\ln \gamma_i = \ln \gamma_i^{C} + \ln \gamma_i^{R}. \quad (4)$$

The Q_k and R_k values have been determined for a variety of group; the a_{mn} values have also been evaluated for the pair of principal groups. The activity coefficient in mixtures composed of well-known substances are calculated from the values of the parameters determined by Fredenslund *et al.*[6]

Distribution Coefficients. The distribution ratio, D, is generally defined by the concentration ratio of a solute in two liquid phases, ordinarily aqueous and organic phases:

$$D = C_{org}/C_{aq}. \quad (5)$$

The subscripts "org" and "aq" denote the organic and aqueous phases respectively. The distribution coefficients of tautomers of acetylacetone are represented as follows:

$$D = K_D^{E} f_{aq}/f_{org} = K_D^{K}(1-f_{aq})/(1-f_{org}), \quad (6)$$

where K_D^{E} and K_D^{K} denote the distribution coefficients of the enol and keto tautomers respectively, and where f is the enol content.

The chemical potentials, μ, of a solute in both phases are represented as follows:

$$\mu_{org} = \mu^{\circ} + RT \ln x_{org}\gamma_{org}, \quad (7)$$

$$\mu_{aq} = \mu^{\circ} + RT \ln x_{aq}\gamma_{aq}. \quad (8)$$

As the UNIFAC equation is defined for a symmetric ideal reference system, the μ°'s in Eqs. 7 and 8 are equal. The chemical potentials in both phases are equal in an equilibrium state:

$$\mu_{org} = \mu_{aq}. \quad (9)$$

Accordingly, the following relation is obtained:

$$K_{D,x} = \frac{x_{org}}{x_{aq}} = \frac{\gamma_{aq}}{\gamma_{org}}. \quad (10)$$

Equation 10 is a desirable equation, as it shows that the distribution coefficient in the symmetric ideal reference system is represented by the ratio of the activity coefficients of the solute in both phases. The distribution coefficient in molarity, K_D, is transformed to that in the mole fraction, $K_{D,x}$, by means of Eq. 11:

$$K_{D,x} = K_D v_{org}/v_{aq}, \quad (11)$$

where v denotes the molar volume of the solvents. From the above equations, it is possible to compare the activity coefficients of a given solute, calculated from the UNIFAC equation with the observed distribution coefficients.

Experimental

The acetylacetone and chlorobenzene (guaranteed reagents of commercial origin) were distilled with a distillator with 80 to 100 theoretical plates, and the middle portions were submitted to vapor-pressure measurements. Redistilled water was used. No signal due to impurities was detected on a gas chromatogram.

The apparatus for the vapor pressure measurements was previously reported by our laboratory.[7] The thermostat was controlled at 298.15±0.001 K.

The enol content of acetylacetone in water and chlorobenzene was determined from the signal area of the terminal methyl groups of each tautomer in an NMR spectrogram at 298±1 K.

The concentrations of the liquid and vapor phases were determined from their densities.

Results

The observed vapor pressures are listed in Table 1, along with the activity coefficients of the component substances. In this table, x_{acac} denotes the mole fraction of acetylacetone in the liquid phase; y_{acac}, that in the vapor phase, and p, the total pressure. Table 2 summarizes the dependence of the enol content, f, on the concentration of acetylacetone. The enol content in chlorobenzene mixtures was smoothed by the least-squares method as follows:

$$10^2 f = 2\ 538 x_{acac}^2 + 7.393 x_{acac} + 8\ 525. \quad (12)$$

No concentration dependence of the enol content in the mixtures containing water was found in diluted solutions.

Discussion

In applying the UNIFAC equation to the mixtures containing acetylacetone, the parameters for the enol tautomer should be defined as a modified value. Because the enol ring forms a resonance structure, it is reasonable to consider that it should be treated as one functional group. The details of the definition were described in Ref. 3. As more accurate data for the temperature dependence of the vapor pressure of acetylacetone were reported by Inoue *et al.*,[4] the values of a_{mn}/R were recalculated; they are listed in Table 3, along with the values reported by Fredenslund *et al.*[6] An example of the analysis by means of the UNIFAC equation is shown in Fig. 1 for acetylacetone+chlorobenzene mixtures.

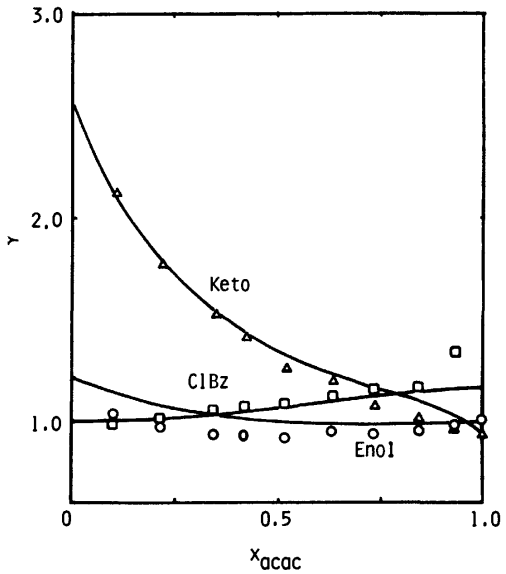

Fig. 1. Activity coefficients of the components in acetylacetone+chlorobenzene mixture at 298.15 K. ○ denotes enol tautomer, △ is keto tautomer, and □ is chlorobenzene. Solid lines represent the values calculated from the UNIFAC equation.

Correlation between $K_{D,x}$ and the Ratio of γ. As has been described above, the distribution coefficients, $K_{D,x}$, are represented as a ratio of the activity coefficients of a solute in two phases. In this study, the dependence of the distribution coefficients upon the activity coefficient in organic phases was considered.

When the activity coefficients of acetylacetone tautomers in several organic solvents were calculated by the UNIFAC equation, the concentration of acetylacetone was determined to be 10^{-3} in the mole fraction. This concentration nearly corresponds to 10^{-2} mol dm^{-3}. It has been found that the distribution coefficients of acetylacetone are independent of the concentration of acetylacetone in this concentration range.[1]

The calculated activity coefficients are listed in Table 4. In this table, D denotes the distribution coefficients of acetylacetone reported by Johansson and Rydberg.[8] The f_{org} values estimated from the equation reported by Pawling and Bernstein[9] are used because of the scarcity of experimental data. $K^{E}_{D,x}$ and $K^{K}_{D,x}$ denote the distribution coefficients of enol and keto tautomers respectively in the mole fraction. In Table 4, the systems containing benzene, toluene, chloroform, carbon tetrachloride, and chlorobenzene were used for the determination of the a_{mn}/R values. However, the activity coefficients in the mixtures of xylene, mesitylene, ethylbenzene, and some alkanes were calculated without any characteristic parameter for solvent molecules.

Figure 2 shows the correlation between $K^{E}_{D,x}$ and the

reciprocal of the activity coefficient of the enol tautomer, $1/\gamma^{E}_{org}$. The open circles denote a system with no characteristic parameter. The linearity of this figure is satisfactory. The correlation is represented by the least-squares method as follows:

$$K^{E}_{D,x} = 171.04/\gamma^{E}_{org} + 30.69. \quad (13)$$

The correlation coefficient was 0.992, omitting the chloroform system. Figure 3 shows the similar plots for the keto tautomer. The correlation by the least-squares method, except for chlorobenzene, mesitylene and chloroform, was as follows:

$$K^{K}_{D,x} = 12.43/\gamma^{K}_{org} + 0.20. \quad (14)$$

The correlation coefficient was 0.997. When only the data for chloroform were excluded,

$$K^{K}_{D,x} = 11.75/\gamma^{K}_{org} + 0.22. \quad (15)$$

The correlation coefficient was 0.986. As the amounts of the keto tautomer were very small in an organic solvent, the inaccuracy in enol contents strongly contributed to the calculated results. These two figures show that a good linear correlation exists between the

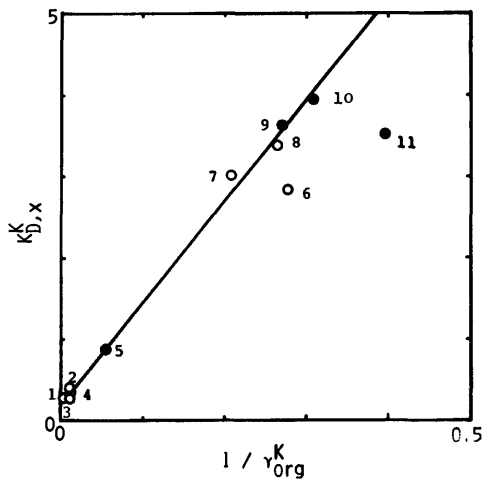

Fig. 3. Correlation between $K^{K}_{D,x}$ and $1/\gamma^{K}_{org}$ at 298.15 K. The open circles denote the systems having no characteristic parameters for solvent. The numbers are corresponding to that in Fig. 2.

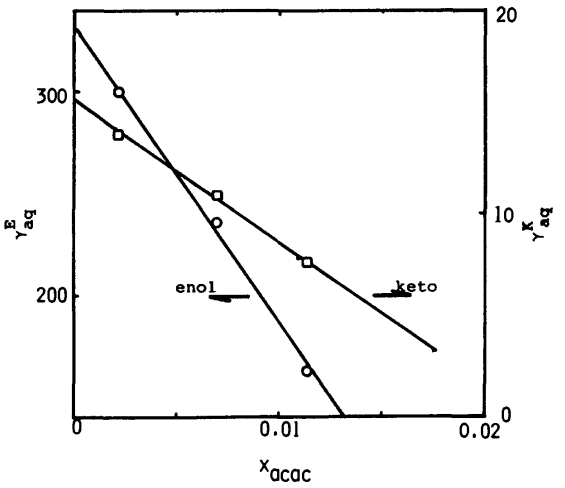

Fig. 4. Activity coefficients of acetylacetone tautomers in water at 298.15 K.

distribution coefficient and the reciprocal of the activity coefficient in the organic phase.

Comparing Eqs. 13 to 15 with Eq. 10, it is found that the slopes in Figs. 2 and 3 correspond to the activity coefficients of tautomers in the aqueous phase. As is shown in Fig. 4, the observed activity coefficient of the enol tautomer in an aqueous mixture was about 330, while that of the keto tautomer was 15.6 at an infinite dilution. The slope for the enol tautomer in Fig. 2 remarkably disagreed with the observed activity coefficient, and an intercept appeared. The disagreement of slopes indicates a smaller distribution coefficient than that calculated from the activity coefficient. The activity coefficients calculated from the UNIFAC equation were slightly greater than the observed values. The plots of Fig. 2 obtained by the use of the observed activity coefficients show a small intercept, but the same slope. As the concentration of electrolytes in the aqueous phase was 10^{-3} mol dm^{-3} of $HClO_4$,[8] it is considered that the activity coefficient of the enol tautomer takes the same value as the value in Fig. 4. In the experiment of distribution, small amounts of water were found in the organic phase. Recently, it has been found that acetylacetone, particularly its enol tautomer, associates

with water in a benzene solution.[10] This fact supports the greater activity coefficient in distribution experiments than that in vapor-pressure measurements, and smaller distribution coefficients than those calculated from the activity coefficients.

Conclusion

The activity coefficients of tautomers of acetylacetone were clearly determined by the UNIFAC equation, and it was found that the distribution coefficients were linearly related to the calculated activity coefficients. This fact shows that the UNIFAC equation is applicable to the estimation of the liquid-liquid distribution coefficients. As the UNIFAC equation can be easily extended to multi-component mixtures, it is expected that the foregoing presentation can be extended to the distribution by mixed solvents. The estimation of distribution coefficients by the UNIFAC equation can be considered to be a very useful method.

Electron Spin Resonance and Some Spectral Studies on Coordination Behaviors of Paramagnetic Metal Ions for Chelating Resins

Akira NAKASHIMA, Toshiyuki ISOBE,* and Toshikazu TARUTANI
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Fukuoka 812
(Received August 28, 1981)

Coordination behaviors of VO(II), Cr(III), Mn(II), Fe(III), Cu(II), and Gd(III) ions for the iminodiacetato group in the chelating ion-exchange resin Dowex A-1 were studied with the aid of ESR, infrared absorption, and Mössbauer spectroscopies. A comparative investigation also was made with the *o*-hydroxybenzyliminodiacetato group in the chelating resin Unicellex UR-50. The iminodiacetato group in Dowex A-1 is considered to coordinate as a tridentate ligand and form 1 : 1 chelates with metal ions, whereas the *o*-hydroxybenzyliminodiacetato group in Unicellex UR-50 coordinates as a quadridentate ligand in alkaline media and forms 1 : 1 chelates. Elucidation of spin-spin exchange interaction has led to a conclusion that the iminodiacetato groups present in the coordination pore of Unicellex UR-50 are closer to one another than those of Dowex A-1. For Fe(III) ions adsorbed in concentrated HCl media, besides the species $[FeCl_4]^-$, lower symmetric species are considered to be adsorbed with the anion exchange effect, from results of resin phase ESR and Mössbauer spectra.

Recently, new type chelating resins which are highly selective for certain metal ions have been synthesized and selective separation of metal ions has been investigated. As the selectivity is considered to depend on the chelating functional group, an investigation of the coordination behavior of metal ions for the group is of great importance in synthesis of metal ion specific resin. Commercially-available resins, Dowex A-1 and Unicellex UR-50, have different functional groups and show different coordination behaviors.

The chelating resin Dowex A-1 consists of a styrene–divinylbenzene copolymer to which iminodiacetato group is attached as chelating group. Cohen and Heitner-Wirguin suggested Cu(II) ion species adsorbed on Dowex A-1 by infrared and ESR measurements.[1,2] They assumed that Dowex A-1 acts only as an anion exchanger in concentrated HCl media and Cu(II) ion is adsorbed as $[CuCl_4]^{2-}$ or $[CuCl_3(H_2O)]^-$. In neutral and alkaline solution the functional group acts as bidentate and tridentate ligands, respectively. Their assumption was supported by Umezawa and Yamabe[3] considering the mobility of Cu(II) ions adsorbed on the resin phase and the effect of the water molecules involved in the resin phase by means of ESR spectroscopy. More recently, Hoek and Reedijk[4] suggested from ESR and electronic spectra measurements that the iminodiacetato group in Chelex 100 (analytical grade Dowex A-1) coordinates as a tridentate chelating ligand to metal ions, such as Co(II), Ni(II), and Cu(II), and that the distorted octahedral is completed by either water molecules or by carboxylate oxygens from excess neighboring iminodiacetato groups.

The chelating resin Unicellex UR-50 was made by polycondensation of *N*-(*o*-hydroxybenzyl)iminodiacetic acid with phenol and formaldehyde. Tomoshige *et al.*[5] compared the coordination behavior of the resin with that of Chelex 100 and suggested, by considering chelate stability constants of the resin with metal ions, that the phenolic hydroxyl group plays an important role in the chelating behavior. However, they gave no discussion of the adsorption structure of metal ions on the resin phase. To investigate the adsorption structure of metal ions on the resin phase would give significant information about the coordination behavior of the resin. Thus, we have made a comparison of coordination behaviors of Dowex A-1 and Unicellex UR-50 in connection with the adsorption structure of metal ions on the resins from the viewpoint of synthesis of metal ion specific resin. This paper presents a study of resin phase ESR spectra of paramagnetic metal ions, such as VO(II), Cr(III), Mn(II), Fe(III), Cu(II), and Gd(III) ions, distributions of these metal ions between the resin and solution phases, and adsorption structures of these metal ions. Furthermore, chelating behaviors of monomers, such as iminodiacetic acid (IDA) and *N*-benzyliminodiacetic acid (BIDA), are also compared with those of the resins.

Experimental

Reagents and Materials. All reagents used were of analytical grade. Stock solutions of VO(II), Cr(III), Mn(II), Fe(III), and Cu(II) ions were prepared by dissolving vanadyl dichloride, chromium(III) nitrate, manganese(II) chloride, iron(III) chloride, and copper(II) chloride in dilute hydrochloric acid solution, respectively. Their concentrations were standardized by EDTA titration. Standard solution of metal ions of desired concentration were prepared by diluting the stock solutions. The buffer solutions were as follows: pH 1 to 2, potassium chloride–hydrochloric acid; pH 3 to 6, sodium acetate–acetic acid; pH 7 to 9, tris(hydroxymethyl)-aminomethane–hydrochloric acid; pH 10, ammonium chloride–ammonia water. Deionized distilled water was used. The chelating ion-exchange resins used were Dowex A-1 (Dow Chemical Co.) in the sodium form as 50—100 mesh beads and Unicellex UR-50 (Unitika, Ltd.) in the hydrogen form as 20—50 mesh beads. The resins were conditioned and transformed into the hydrogen and sodium forms in a conventional manner, respectively. The cation exchange capacities of Dowex A-1 and Unicellex UR-50 were 3.74 and 3.57 mequiv. per g of dry resin, based upon the uptake of tetraamminecopper(II) ion which was formed in 2 mol dm^{-3} ammonia water. Nonaqueous ion-exchanger Amberlyst A-26 (Rohm and Haas) in the chloride form was used without further treatment.

Preparation of Samples and Reference Compounds. About 500 mg of dry resin, 10 cm^3 of metal ion solution and 40 cm^3 of 0.1 mol dm^{-3} buffer solution were placed in a flask and

agitated for 24 h at 20±1 °C. Metal ion concentration was 100 μg/cm³. After equilibration, the pH value was measured, the solution was filtered, and the wet resin phase (dried in a silica gel desiccator for 12 h) and the dry resin phase (dried for 2 d) were subjected to ESR spectral measurements. Only for estimation of distribution ratio the resin was rinsed rapidly with deionized distilled water except resins immersed in concentrated HCl media, then the solution and rinse were combined and analyzed for metal ion concentration by atomic absorption spectrometry except Gd(III) ion (colorimetry). Distribution ratio, D, is defined as follows and evaluated by determining the metal ion concentration in an equilibrated solution:

$$D = \frac{\text{amt. of metal ion per g of dry resin}}{\text{amt. of metal ion per cm}^3\text{ of solution}}.$$

The amount of metal ions adsorbed on the resin phase was also analyzed after elution with 2 mol dm^{-3} HCl except Cr(III) ion. The amount of Cr(III) ions on the resin phase was analyzed after ashing the resin.

$[FeCl_4]^-$ ion was prepared by extraction into diisopropyl ether from aqueous acidic chloride solution.[6] This chloro-complex was adsorbed on the anion exchanger Amberlyst A-26 in diisopropyl ether media and compared with that on Dowex A-1 in concentrated HCl media. Other reference compounds such as $(CH_3NH_3)_2[MnCl_4]$, $[(CH_3)_4N]_2[MnCl_4]$, $(CH_3NH_3)_3[FeCl_6]\cdot CH_3NH_3Cl$, $(NH_4)_2[FeCl_5(H_2O)]$, and $(CH_3)_4N[FeCl_4]$ were prepared by addition of counter ion's chloride to a concentrated HCl solution containing chloro-complex of Mn(II) or Fe(III).[7,8] IDA and BIDA complexes of Cu(II) ion were prepared by the following method: To 50 cm³ of solution containing 0.01 mol of $CuCl_2\cdot 2H_2O$ was added 100 cm³ of solution containing 0.01 or 0.02 mol of IDA or BIDA. The resulting solution was adjusted to pH 7 with 0.02 mol of $NaHCO_3$ and HCl and warmed nearly to boiling point and then absolute ethanol was added until a slight turbidity appeared. Finally, the solution was cooled in an ice-bath. The resulting crystalline material was filtered and recrystallized from a water–ethanol mixture. The obtained complexes were identified by elemental analysis as $CuIDA\cdot 3H_2O$ (Found: C, 19.39; H, 4.87; N, 5.59%. Calcd for complex: C, 19.32; H, 4.45; N, 5.63%), $Na_2Cu(IDA)_2\cdot 2.5H_2O$ (Found: C, 23.00; H, 3.36; N, 6.62%. Calcd for complex: C, 23.06; H, 3.62; N, 6.72%), and $Na_2Cu(BIDA)_2\cdot 2H_2O$ (Found: C, 44.54; H, 4.09; N, 4.74%. Calcd for complex: C, 44.94; H, 4.46; N, 4.76%).

Physical Methods and Analysis. The pH value of equilibrated solutions was measured on a Hitachi-Horiba D-5 pH meter. A Nippon Jarrell-Ash AA-781 atomic absorption and flame emission spectrophotometer was used in determination of metal ion concentration. First derivative ESR spectra were recorded on a JEOL JES-ME-3X spectrometer at X-band frequencies at room and liquid nitrogen temperatures. Resin particle samples without grinding were packed in JEOL quartz cells and their ESR spectra were measured. No change in ESR spectral shape between the wet and dry resin phases was observed, hence it follows that resin phase spectra can be obtained with the equilibrium state kept. As the amount of metal ion in the solution phase in the resin can be neglected, ESR spectra obtained are regarded as corresponding to the metal ion on the resin phase. For measurement of solution ESR spectra, a JEOL capillary cell (0.05 cm³) was used. Care was taken to keep all settings of the spectrometer knobs unchanged within a series of intensity measurements except for receiver gain amplitude.[9] Relative ESR signal intensity is defined by $(R.I.)=h_{pp}(\Delta H_{pp})^2/\text{Gain}$, where h_{pp} is peak-to-peak height in dm and ΔH_{pp} is peak-to-peak width in mT. Magnetic field was reassessed by DPPH or Mn^{2+}/MgO powder marker. Mössbauer spectra were measured by the constant acceleration method on an Austin Science Associates, Inc. Mössbauer spectrometer at room and liquid nitrogen temperatures, with a source of cobalt-57 (5 mCi) diffused into a palladium foil. The scan speed of spectrometer was calibrated using a pure iron foil, which was also used as a reference for isomer shift. All spectra were fitted to Lorentzian line shapes by computer calculation. Infrared spectra were measured in KBr pellets on a JASCO Model DS-403 G grating infrared spectrophotometer in the range 4000—200 cm^{-1}.

Results and Discussion

General. pH dependences of distribution ratio, amount of metal ions adsorbed on the resin phase, and ESR signal intensity of metal ions for Dowex A-1 and Unicellex UR-50 are shown in Fig. 1. The variation in D values with pH for Dowex A-1 is in the same tendency as that obtained by Leyden and Underwood and obviously different from that for Unicellex UR-50.[10] This difference seems to reflect the effect of the phenolic hydroxyl group at *o*- or *p*-position in Unicellex UR-50. Amounts of metal ions adsorbed on the resin phase are expressed in $(M)_R$, metal ion μg per g dry resin. With Dowex A-1 the decrease in $(Mn)_R$ values above pH 9 may suggest an inhibition of adsorption due to hydrolysis, and on the contrary, the increase in $(Fe)_R$ values above pH 8 may suggest adsorption or adherence of hydroxyl complexes and hydroxide due to hydrolysis. With Unicellex UR-50, however, the variation in $(M)_R$ values due to hydrolysis was found in higher pH regions than that for Dowex A-1. ESR signal intensities are expressed in $(R.I.)_m$, signal intensity per g of metal ion in the dry resin. The following signals were used for the estimation of h_{pp} and ΔH_{pp}: The $M_I=-1/2$ line for VO(II), the $g_{eff}\triangleq 2$ signal for Cr(III), Mn(II), and Gd(III), the $g_{eff}\triangleq 4$ signal for Fe(III), and the $g_\perp$ line for Cu(II). The order of signal intensities was Mn(II)> Cu(II)>VO(II)≈Cr(III)≈Fe(III)≈Gd(III) in all of the pH regions. For each metal ion, there was no marked difference in signal intensity between Dowex A-1 and Unicellex UR-50, except for Gd(III) ion.

Table 1 shows infrared spectral data, of which assignments were made according to the literature.[11] The method is based on the simple rule that the unionized and uncoordinated COO stretching band occurs at 1750—1700 cm^{-1} and 1200—1220 cm^{-1}, whereas the ionized and coordinated COO stretching band is at 1650—1590 cm^{-1}. For example, sodium form resin was suggested to be Type III+Type IV, having a strong absorption band at 1585 cm^{-1} and a weak absorption band at 1210 cm^{-1}. The acting resin forms are found to transform from Type I to Type IV depending on the pH of media. As described above, resin phase infrared spectra are very efficient in suggesting the acting resin form. It should be noted that all infrared spectra have the absorption due to H_2O molecule around 3400 cm^{-1}. From the weight loss after drying at 100 °C, the water content of hydrogen form Dowex A-1 was found to be 11.03%. These H_2O molecules may influence adsorption behaviors of the metal ions, together with the buffer salts, onto the resin phase.

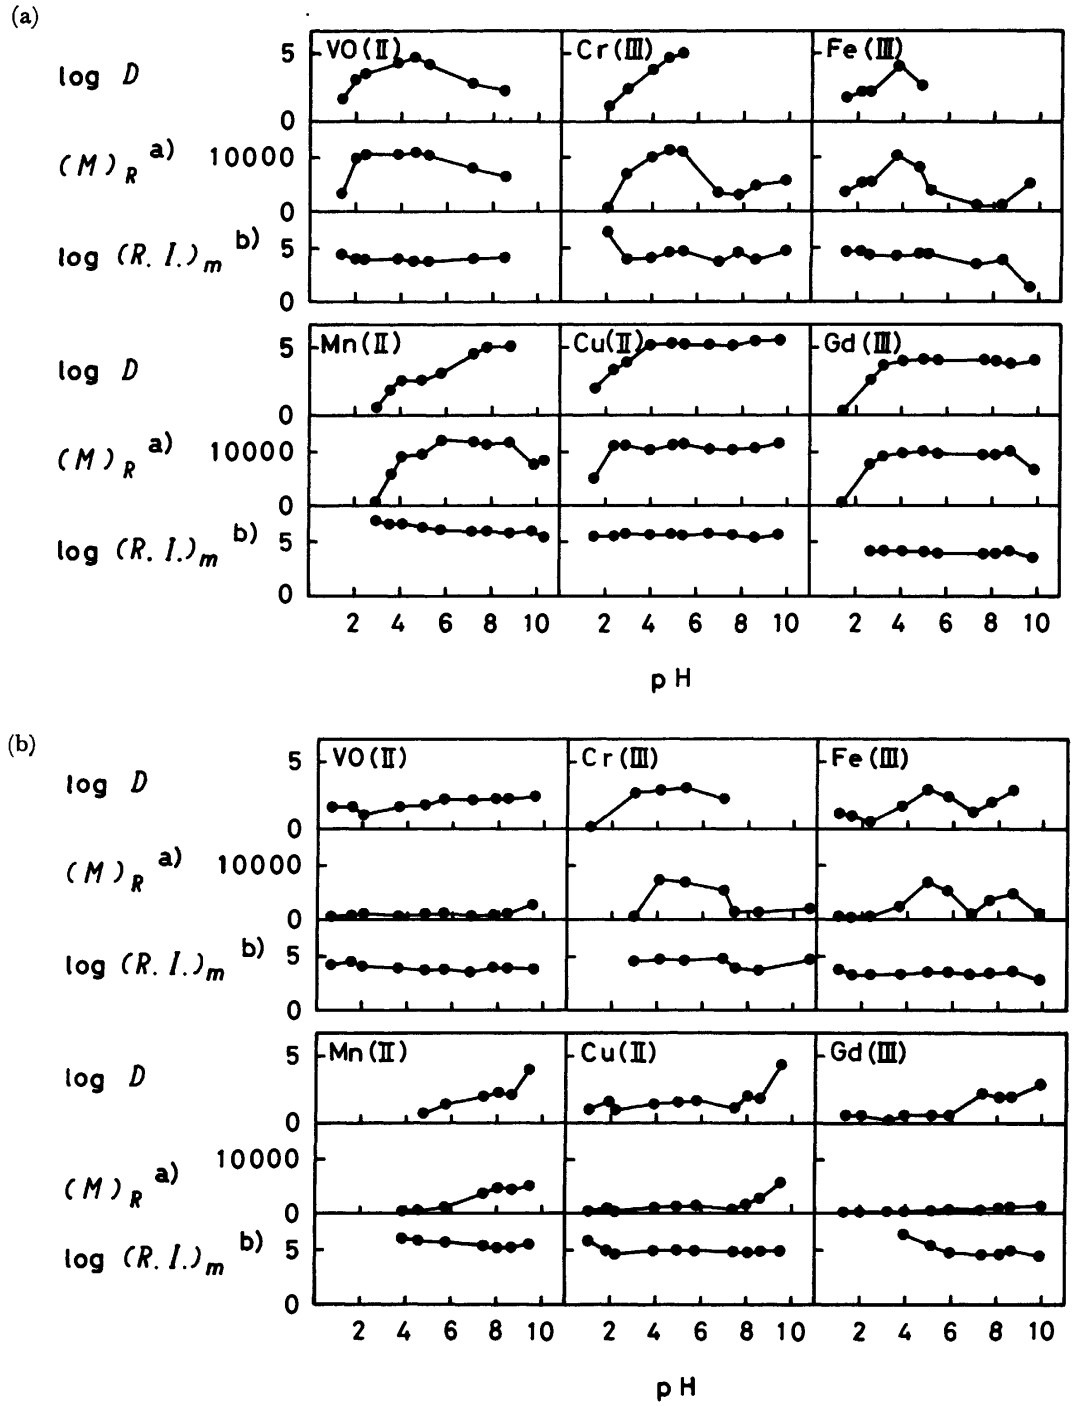

Fig. 1. pH Dependences of distribution ratios, amounts of metal ions adsorbed on (a) Dowex A-1 and (b) Unicellex UR-50 and their ESR signal intensities. a): Metal ion μg per g dry resin, b): signal intensity per g of metal ion in the dry resin.

Cu(II) Ions Adsorbed on the Resin Phase. From the results of infrared absorption bands, with both Dowex A-1 and Unicellex UR-50 acting resin forms were suggested to be Type I in concentrated HCl media, Type II+Type III in the media of pH 4, and Type III+Type IV in the media of pH 9. ESR spectra and parameters of Cu(II) ions adsorbed on the resin phase and of some reference compounds are shown in Fig. 2 and Table 2.

In concentrated HCl media, the suggested resin form of Type I is supported by the similarity of the resin phase ESR spectra to those of anion exchanger Dowex 1×4.[2] Comparing ESR spectra of Cu(II) ions adsorbed on Dowex A-1 and Unicellex UR-50 in concentrated HCl media, we find no significant change except for the free radical signal of Unicellex UR-50. Although the cation exchange capacities of these resins are approximately the same, the amount of Cu(II) ions adsorbed on Unicellex UR-50 is about one seventieth that on Dowex A-1. This fact seems to reflect the steric

a) Cu(II) ion μg per g dry resin.

hindrance of the phenolic hydroxyl group in Unicellex UR-50. Waki *et al.*[12] suggested from distribution measurements that $[CuCl_3(H_2O)]^-$ and $[Cu_2Cl_7]^{3-}$ species are present in Dowex 1 resin phases in concentrated HCl media. However, on the basis of the ESR spectra of Cu(II) ions adsorbed on the resin phase in concentrated HCl media in this work, it is not possible to differentiate $[CuCl_3(H_2O)]^-$ and $[Cu_2Cl_7]^{3-}$ species. ESR spectra of Cu(II) ions adsorbed on the resin phase in concentrated HCl media are different from powder ESR spectra of $[CuCl_4]^{2-}$ species in solid samples.

In the media of pH 4 and pH 9, no conclusive difference in the dependence of chelation on the transformation of acting resin forms was indicated in the resin phase ESR spectra. The resin phase ESR spectra of Cu(II) ions exhibited axial spectra with $g_{//}$ and $g_{\perp}$ parts and Cu(II) ions on the resin phase were expected to be of distorted tetragonal structure. ESR parameters of the wet resin phase are almost identical with those of the dry resin phase, independent of the pH of media

Table 3. ESR parameters of the resin phases and the powders and frozen solutions of Cu(II) complexes with IDA and BIDA

Sample	Parameters g values (ΔH_{pp}/mT)

a) Cu(II) ion μg per g dry resin.

and different from those of aqua complex and cation exchange resin phase.

Other comparative investigations with some reference compounds were done. Chelating behaviors of monomers, such as iminodiacetic acid (IDA) and *N*-benzyliminodiacetic acid (BIDA), were compared with those of the resins. ESR parameters of Cu(II) ion on the resin phase and of powders and frozen solutions of Cu(II) complexes with the monomers are listed in Table 3. The chelate stability constants of IDA with Cu(II) ions were reported as $\log K_1=10.55$ and $\log K_2=5.65$, and structures of the chelates were assumed.[13] The 1 : 1 Cu–IDA chelate shows an isotropic ESR spectrum and the 1 : 2 chelate shows an anisotropic ESR spectrum. Since the resin phase ESR spectra of Cu(II) ions are similar to the powder and frozen solution ESR spectra of the 1 : 1 chelate, the iminodiacetato group in Dowex A-1 was concluded to form the 1 : 1 chelate with Cu(II) ion.

From the above results, it seems that the iminodiacetato group must chelate as a tridentate ligand to Cu(II) ions to form the 1 : 1 chelate in all of the pH regions. However, no conclusive evidence is found for chelation through the nitrogen atom. Although coordination of the phenolic hydroxyl group in Unicellex UR-50 was indicated from the increase in $(Cu)_R$ values above pH 8, the resin phase ESR spectra seemed unchange. Thus, it may be suggested that the phenolic hydroxyl group does not contribute so significantly to the structure of Cu(II) ions on the resin phase.

The hyperfine structure of the $g_{//}$ part became obscure with the increase in $(Cu)_R$ values and the isotropic spectra with $g_{iso}=2.12$ and $\Delta H_{pp}=13.4$ mT for Dowex A-1 and $g_{iso}=2.10$ and $\Delta H_{pp}=19.6$ mT for Unicellex UR-50 were observed. In the isotropic spectra, when the gain became 100 times, the peak presumably based on $\Delta M_s=\pm2$ could be observed at $g=4.38$ and $g=4.60$ for Dowex A-1 and Unicellex UR-50, respectively. This fact clearly indicates that exchange interaction must be present.

Spin-spin interaction affect the line width either as broadening (dipole-dipole interaction) or as narrowing (exchange interaction). For purely dipolar interactions between identical spins in the field of cubic symmetry, the expected line width for polycrystalline powder is

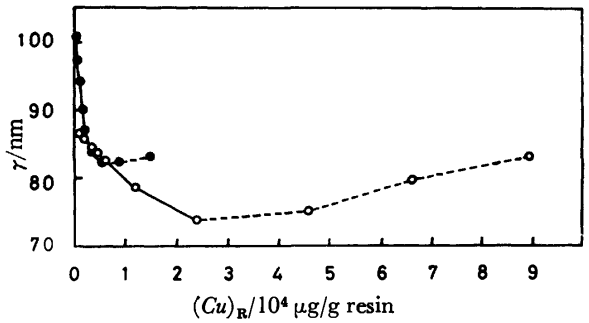

Fig. 3. Variation of distance between the neighboring spins with amount of Cu(II) ions adsorbed on the resin phases.
○: Dowex A-1, ●: Unicellex UR-50.

given by the expressions:[14]

$$r^6=\frac{3}{5}S(S+1)g^2\beta^2\frac{8.5}{\langle\Delta H^2\rangle},$$

and

$$\langle\Delta H^2\rangle=\frac{1}{4}(\Delta H_{pp})^2,$$

where, r is the distance between the neighboring spins. On the basis of the above discussion and on the assumption that the expressions be applicable to the resin phase, the distance between the neighboring spins for Cu(II) ions on the resin phase may be estimated. The variation in the distance with $(Cu)_R$ values is shown in Fig. 3. Exchange interactions may be concluded to be present above $(Cu)_R=2.4\times10^4$ μg/g resin phase for Dowex A-1 and above 0.6×10^4 μg/g resin phase for Unicellex UR-50. As previously described, nearly the same cation exchange capacities of these resins mean that the resins have almost the same amount of iminodiacetato groups. Therefore, the difference in $(Cu)_R$ value between Dowex A-1 and Unicellex UR-50 is demonstrated to be attributable mainly to the polymer matrix, that is to say, the iminodiacetato groups present in a coordination pore of Unicellex UR-50 are closer to one another than those of Dowex A-1.

Mn(II) Ions Adsorbed on the Resin Phase. In concentrated HCl media, Mn(II) ion is considered to be adsorbed on the resins with anion exchange effect in the same way as Cu(II) ion. From a comparison of resin phase ESR spectra of Mn(II) ions with powder ESR spectra of $[(CH_3)_4N]_2[MnCl_4]$ and $(CH_3NH_3)_2[MnCl_4]$,[15] of which ESR parameters are listed in Table 4, Mn(II) ions adsorbed on the resin phase in concentrated HCl media were suggested to be predominantly tetrahedral $[MnCl_4]^{2-}$.

ESR spectra of Mn(II) ions adsorbed on Dowex A-1 and Unicellex UR-50 in the media of pH 4 and pH 9 are shown in Fig. 4. In the resin phase ESR spectra of Mn(II) ions adsorbed in the media of pH 4, peaks with $g=5$ and $g=3$ were observed besides the sextet lines with $g=2$, whereas in the media of pH 9, the sextet ones smeared out and signal intensities of the peak resulting from the zero-field splitting increased. This change in ESR spectra means that Mn(II) ions in low symmetry sites increased with increasing pH of the media. The resin phase ESR spectra of Mn(II) ions

adsorbed in the media above pH 4 show very interesting patterns. Dowsing *et al.*[16-19] interpreted several ESR spectra of high-spin d^5 system in terms of a spin Hamiltonian of the form

$$\mathcal{H} = g\beta\boldsymbol{HS} + D[S_z^2-\frac{1}{3}S(S+1)] + E(S_x^2-S_y^2),$$

theoretically discussed the change of ESR spectra according to the distortion parameters, D and λ (E/D), and compared with observed spectra. Through analysis of the resin phase ESR spectra of Mn(II) ions in the media above pH 4, distortion parameters D and λ were tentatively assigned by their energy diagram. The data may fit $D=0.17$ cm^{-1} and $\lambda=0.167$ cm^{-1} for Mn(II) ions on Dowex A-1, and $D=0.29$ cm^{-1} and $\lambda=0.244$ cm^{-1} on Unicellex UR-50. Blumberg[20] showed that if $\lambda=0$ represents axial symmetry, $0<\lambda<1/3$ represents a departure toward rhombic symmetry, $\lambda=1/3$ represents the maximum possible rhombic symmetry, $1/3<\lambda<1$ represents a convergence toward axial symmetry again and $\lambda=1$ represents entirely axial symmetry. On the basis of the above discussion, therefore, Mn(II) ions adsorbed on the resin phase in the media above pH 4 were suggested to be of rhombic symmetry lowered from octahedral and axial symmetries perhaps by the substitution of coordinated H_2O molecules for hydroxide ions. The difference between the ESR spectra of Dowex A-1 and Unicellex UR-50 resin phases shows that the phenolic hydroxyl group in Unicellex UR-50 strongly influences the coordination structure of Mn(II) ions.

Fe(III) Ions Adsorbed on the Resin Phase. The dry resin phase ESR spectra of Fe(III) ions adsorbed in concentrated HCl media and $[FeCl_4]^-$ adsorbed on Amberlyst A-26 in diisopropyl ether media are shown in Fig. 5 and the analyzed data are listed in Table 5. For comparison, powder ESR spectral parameters of $(CH_3NH_3)_3[FeCl_6]\cdot CH_3NH_3Cl$, $(NH_4)_2[FeCl_5(H_2O)]$, and $(CH_3)_4N[FeCl_4]$ and solution ESR spectral parameters of $[FeCl_4]^-$ in diisopropyl ether media are included in Table 5. The resin phase ESR spectra of Fe(III) ions adsorbed on Dowex A-1 in concentrated HCl media seem to have patterns with $g_{eff}=4$ and $g_{eff}\triangleq2$ similar to those on Dowex 1×4 and of $[FeCl_4]^-$ adsorbed on Amberlyst A-26. The $g_{eff}\triangleq2$ signal is

considered to be due to $[FeCl_4]^-$ species. On the other hand, with the resin phase ESR spectrum of Fe(III) ions adsorbed on Unicellex UR-50 in concentrated HCl media, the intensity of the $g_{eff}\triangleq 2$ signal is not so large as that of Dowex A-1. It is apparent that the $g_{eff}\triangleq 4$ signal is not attributable to the coordination by the iminodiacetato group because of the similarity to the resin phase ESR spectra of Fe(III) ions adsorbed on Dowex 1×4 in concentrated HCl media and on Amberlyst A-26 in diisopropyl ether media, as can be seen in Fig. 5.

ESR signals close to $g=4$ often occur in biological materials and clay minerals. Castner *et al.*[21] proposed $D=0$ and $E\neq 0$ to account for the $g=4.27$ spectrum found for iron(III) ions in glass. Griffith[22] showed that d^5 ion is in special environments, then D need not be zero but shall be small. The special environments are tetrahedral MA_2B_2, distorted octahedral MA_6, and octahedral MA_3B_3. Of these environments, the $g_{eff}\triangleq 4$ signal is attributable to tetrahedral MA_2B_2. From the above discussion, since the resin phase ESR spectrum of Fe(III) ions adsorbed in concentrated HCl media shows two signals with $g_{eff}\triangleq 4$ and $g_{eff}\triangleq 2$, the MA_2B_2 species, in addition to the MA_4 species, $[FeCl_4]^-$ is considered to be present. That is, besides the species $[FeCl_4]^-$ simply adsorbed with the anion exchange effect, lower symmetric anion species such as a mixed ion cluster bridging by Cl atoms may be considered to be adsorbed.

Figure 6 shows the ESR spectra of Fe(III) ions adsorbed on Dowex A-1 and Unicellex UR-50 in the media of pH 4 and pH 9. In the resin phase ESR spectra of Fe(III) ions adsorbed on Dowex A-1 in the media above pH 8, a broad signal with $g_{eff}\triangleq 2$ and $\Delta H_{pp}\triangleq 100$ mT and a weak signal with $g_{eff}\triangleq 4$ were observed. As this broad signal is similar to that of Fe(III) hydroxide powder, of which a spectrum is included in Fig. 6, most of Fe(III) ions on the resin phase are considered to exist as hydroxyl complex or hydroxide. In the resin phase ESR spectra of Fe(III) ions adsorbed on Unicellex UR-50, however, a broad signal with $g_{eff}\triangleq 2$ was not observed and the $g_{eff}\triangleq 4$ signal intensity increased in the pH region where hydroxide forms. The $g_{eff}\triangleq 4$ signal in the media of pH 4 was analyzed in the same way with Mn(II) ion. The data may be $D>0.23\ cm^{-1}$ and $\lambda=-1/3\ cm^{-1}$. Therefore, the Fe(III) ions adsorbed on the resin phase in the media of pH 4 are suggested to be of rhombic symmetry similarly to Mn(II) ions. For comparison, an ESR spectrum of Fe(III)-porphine complex, which is characterized by strong axial symmetry, is also shown in Fig. 6.[16] Although the $g_{eff}\triangleq 4$ signal for pH 4 is apparently similar to that for concentrated HCl media, it must be emphasized that the adsorbed species are different.

Especially for Fe(III) ions, resin phase Mössbauer spectra were observed by using metallic iron-57 and spectral parameters at room temperature are listed in Table 6. The Mössbauer parameters suggest that the iron adsorbed on the resin phase in concentrated HCl media is trivalent of high-spin configuration and of tetrahedral symmetry[23] and a small peak that shows lower symmetric species was observed in a Mössbauer spectrum at liquid nitrogen temperature, whereas those for the iron adsorbed in the media of pH 4 suggest that

TABLE 6. MÖSSBAUER PARAMETERS FOR IRON ADSORBED ON THE RESIN PHASES

Sample	I.S.[a] mm s^{-1}	Q.S.[a] mm s^{-1}	L.W.[a] mm s^{-1}
A-1, concd HCl	0.19	0.36	0.24
A-1, pH 4.00	0.37	0.65	0.72
A-1, pH 9.00	0.37	0.80	0.53
UR-50, concd HCl		n.d.	
UR-50, pH 4.00	0.45	0.82	0.76
UR-50, pH 9.00	0.41	0.87	0.56

a) I.S.: Isomer shift; Q.S.: quadrupole splitting; L.W.: line width.

the iron on the resin phase is trivalent of high-spin configuration and very distorted symmetry of tetrahedron rather than octahedron as judged from the value of isomer shift. In the media of pH 9 the parameters are similar to those of iron(III) hydroxide.[24] This fact suggests the adherence of hydroxide in addition to the adsorption of hydroxyl complex and accounts for the increase in $(Fe)_R$ values and for the appearance of the broad ESR signal with $g_{eff} \triangleq 2$.

The Mössbauer parameters at room temperature for the iron adsorbed on Unicellex UR-50 in the media of pH 4 suggest that the iron on the resin phase is trivalent of high-spin configuration and distorted octahedral symmetry. All Mössbauer spectra were also measured at the liquid nitrogen temperature but no significant suggestion was obtained.

From the above discussion, it may be concluded that the iminodiacetato group in Dowex A-1 coordinates as a tridentate ligand to Fe(III) ion and a distorted tetrahedron is completed by water molecules, whereas in Unicellex UR-50 the phenolic hydroxyl group also coordinates in alkaline media and a distorted octahedron is completed by water molecules.

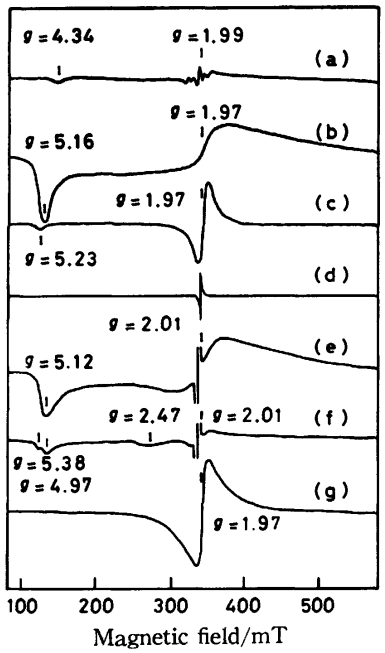

Fig. 8. ESR spectra of Cr(III) ions adsorbed on Dowex A-1 and Unicellex UR-50 and hydroxide.
(a): A-1, concd HCl, dry, (b): A-1, pH 3.90, dry, (c): A-1, pH 8.50, dry, (d): UR-50, concd HCl, dry, (e): UR-50, pH 4.04, dry, (f): UR-50, pH 8.38, dry, (g): Cr(III) hydroxide.

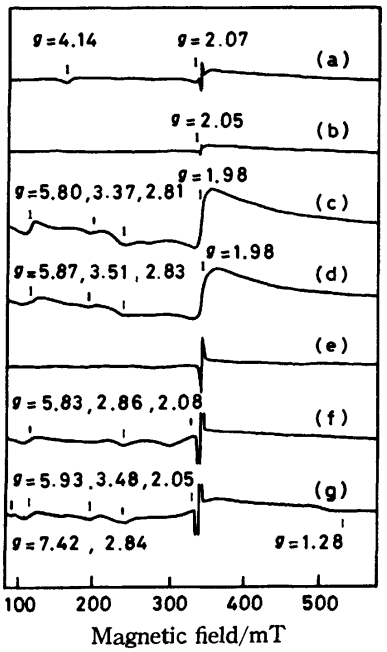

Fig. 9. ESR spectra of Gd(III) ions adsorbed on Dowex A-1, Dowex 1×4 and Unicellex UR-50.
(a): A-1, concd HCl, dry, (b): 1×4, concd HCl, dry, (c): A-1, pH 3.91, dry, (d): A-1, pH 8.55, dry, (e): UR-50, concd HCl, dry, (f): UR-50, pH 3.84, dry, (g): UR-50, pH 8.59, dry.

Other Paramagnetic Metal Ions Adsorbed on the Resin Phase. ESR spectra of VO(II), Cr(III), and Gd(III) ions adsorbed on the resin phase are shown in Figs. 7, 8, and 9. VO(II) ions adsorbed on the resin phase show anisotropic spectra and ESR parameters for VO(II) ions on Dowex A-1 and Unicellex UR-50 are virtually unchanged. In the resin phase infrared spectra of VO(II) ions adsorbed on Dowex A-1 and Unicellex UR-50 in the media of pH 9, V–O stretching bands were observed at 970 and 1010 cm^{-1}, respectively. This fact may reflect the coordination of the phenolic hydroxyl group in Unicellex UR-50. VO(II) ions adsorbed on Dowex A-1 and Unicellex UR-50 are considered to be of distorted tetragonal symmetry completed by water molecules.

In the resin phase ESR spectra of Cr(III) ions adsorbed on Dowex A-1 in the media of pH 4, signals with $g \triangleq 5$ and $g=1.97$ resulting from the zero-field splitting were observed. In the resin phase ESR spectra of Cr(III) ions adsorbed on Unicellex UR-50 in alkaline media, the $g \triangleq 5$ signal splitted into $g=5.28$ and $g=4.93$ and the $g \triangleq 2.5$ signal appeared. This fact may reflect the coordination of the phenolic hydroxyl group in Unicellex UR-50.

Gd(III) ions adsorbed on Dowex A-1 and Unicellex UR-50 also show signals resulting from the zero-field splitting. The difference in $(Gd)_R$ values and resin phase ESR spectral patterns between Dowex A-1 and Unicellex UR-50 also may reflect the coordination of the phenolic hydroxyl group in Unicellex UR-50.

The authors are grateful to Unitika Ltd, for the supply of Unicellex chelating resin.

Phase Equilibria in the Gd_2O_3–V_2O_3–V_2O_5 System at 1200 °C

Kenzo KITAYAMA* and Takashi KATSURA
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received September 16, 1981)

The phase equilibria in the Gd_2O_3–V_2O_3–V_2O_5 system are studied at 1200 °C by changing the oxygen partial pressure from −0.68(air) to −12.50 in terms of log P_{O_2}. In this system, Gd_2O_3, $GdVO_4$, $GdVO_3$, $0.81Gd_2O_3 \cdot 0.19V_2O_5$, V_2O_3, V_3O_5, V_4O_7, V_5O_9, V_6O_{11}, V_7O_{13}, and VO_2 are stable. $GdVO_4$ and $0.81Gd_2O_3 \cdot 0.19V_2O_5$ have nonstoichiometric compositions. The crystallographic properties of the latter are determined with reference to the indices of a certain compound, $4Tm_2O_3 \cdot V_2O_5$. On the basis of the phase equilibria, the Gibbs free energy of these two reactions: $31/50\ Gd_2O_3 + 19/50\ GdVO_3 + 19/100\ O_2 = Gd_{1.62}V_{0.38}O_{3.38}$ and: $GdVO_3 + 1/2\ O_2 = GdVO_4$ are determined to be 57.0 and 127.8 kJ respectively.

The phase equilibria in the Ln_2O_3–V_2O_3–V_2O_5 systems (Ln=Sm, Lu, and Er) at 1200 °C have been established.[1–3] In these systems, the existence of V_nO_{2n-1}(n=3—7) was confirmed between V_2O_3 and VO_2. In addition to the above vanadium oxides, in the Sm_2O_3–V_2O_3–V_2O_5 system, $5Sm_2O_3 \cdot V_2O_5$ ($Sm_{10}V_2O_{20}$), $SmVO_3$, and $SmVO_4$; in the Lu_2O_3–V_2O_3–V_2O_5 system, $LuVO_3$, $LuVO_4$, $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8, and in the Er_2O_3–V_2O_3–V_2O_5 system, $ErVO_3$, $ErVO_4$, and $4Er_2O_3 \cdot V_2O_5$ ($Er_8V_2O_{17}$) were stable as the ternary compounds. Different patterns of the phase diagram were obtained as results of differences in the coexisting compounds.

In the present study, Gd_2O_3 was chosen as one of the Ln_2O_3 compounds, because Gd is the first one in the heavy-lanthanoid series from the viewpoint of the electron configuration.

In the Gd_2O_3–V_2O_3 system, only $GdVO_3$ is well known as a double-oxide phase. However, the system has not yet completely been studied because of the instability of V_2O_3 in an atmosphere of air. The crystallographic properties of $GdVO_3$ have been investigated by many researchers.[4–6] It is an orthorhombic system, like the other rare-earth vanadites except $LaVO_3$ and $CeVO_3$.[4,6]

The Gd_2O_3–V_2O_5 system was studied by Brusset *et al.*[7,8] in the temperature range from 600 to 1500 °C. They found two compounds, $4Gd_2O_3 \cdot V_2O_5$ and $5Gd_2O_3 \cdot V_2O_5$, as intermediate phases above 1150 °C in addition to $GdVO_4$. The spacing and relative intensities of the two compounds were also included in one of the reports,[7] but the assignment of the indices was not successful.

The objectives of the present study are: (1) to establish the detailed phase equilibria in the Gd_2O_3–V_2O_3–V_2O_5 system at 1200 °C in order to clarify the stable ternary compounds, (2) to calculate the Gibbs free energy of the reactions of the ternary compounds which were found in the phase diagram, and (3) to ascertain whether or not there exists a linear relationship between the Gibbs free energy of the reactions and the ionic radius of the lanthanoid, as is found in the Ln–Fe–O.[9]

Experimental

Analytical grades of Gd_2O_3 (99.9%) and V_2O_5, which had been obtained by heating guaranteed-grade NH_4VO_3 at 500 °C in air for about 24 h, were used as the starting materials. The desired ratios of Gd_2O_3/V_2O_5 were obtained by mixing the appropriate quantities thoroughly in an agate motar under ethyl alcohol. The mixtures thus made were treated by the procedures described previously.[1] The apparatus and procedures for controlling the oxygen partial pressures, keeping the furnace at a constant temperature, the method of thermogravimetry, the criterion for an equilibrium establishment, the method of identifing solid phases after quenching, the method of lattice-constant measurement, and the method of wet chemical analysis were the same as those described in previous papers.[1,10–13]

The oxygen partial pressure of −12.50 in terms of log P_{O_2} was chosen as the reference oxygen partial pressure, because even samples which contain less than 50% of Gd_2O_3 in mole are stable in composition in this reference atmosphere at 1200 °C.

Results and Discussion

Phase Equilibria. Ten samples with Gd_2O_3/V_2O_5 mole ratios of 86/14, 81/19, 76/24, 7/3, 6/4, 1, 4/6, 2/8, and 1/9 were prepared for use in the thermogravimetric experiment. In Fig. 1, the relationship between the oxygen partial pressure and the weight change, W_{O_2}/W_T, is shown; W_{O_2} is the weight gain of the sample from the reference-state atmosphere of log P_{O_2}=−12.50, and W_T is the total weight gain that the sample would get if the V_2O_3 in the sample changed to V_2O_5. The experimental results for four representative samples, 86/14, 8/2, 7/3, and 2/8, are shown in Fig. 1.

In Table 1, the results of the identification of the phases are shown: the first column shows the compositions of the starting materials; in the second and third are shown the experimental conditions of the oxygen partial pressure in terms of log P_{O_2} and the experimental duration respectively; in the fourth are shown the phases, as identified by means of an X-ray powder diffractometer using Cu $K\alpha$ radiation.

Based upon the above experimental results, a phase diagram of the system at 1200 °C is depicted in Fig. 2. The following phases are present under the present experimental conditions except in the V_2O_3–V_2O_5 system: Gd_2O_3(R), $Gd_{1.62}V_{0.38}O_{3.38}$(A), $GdVO_3$(L), and $GdVO_4$(K). The compounds in the V_2O_3–V_2O_5 system are the same as those in the previous report.[1]

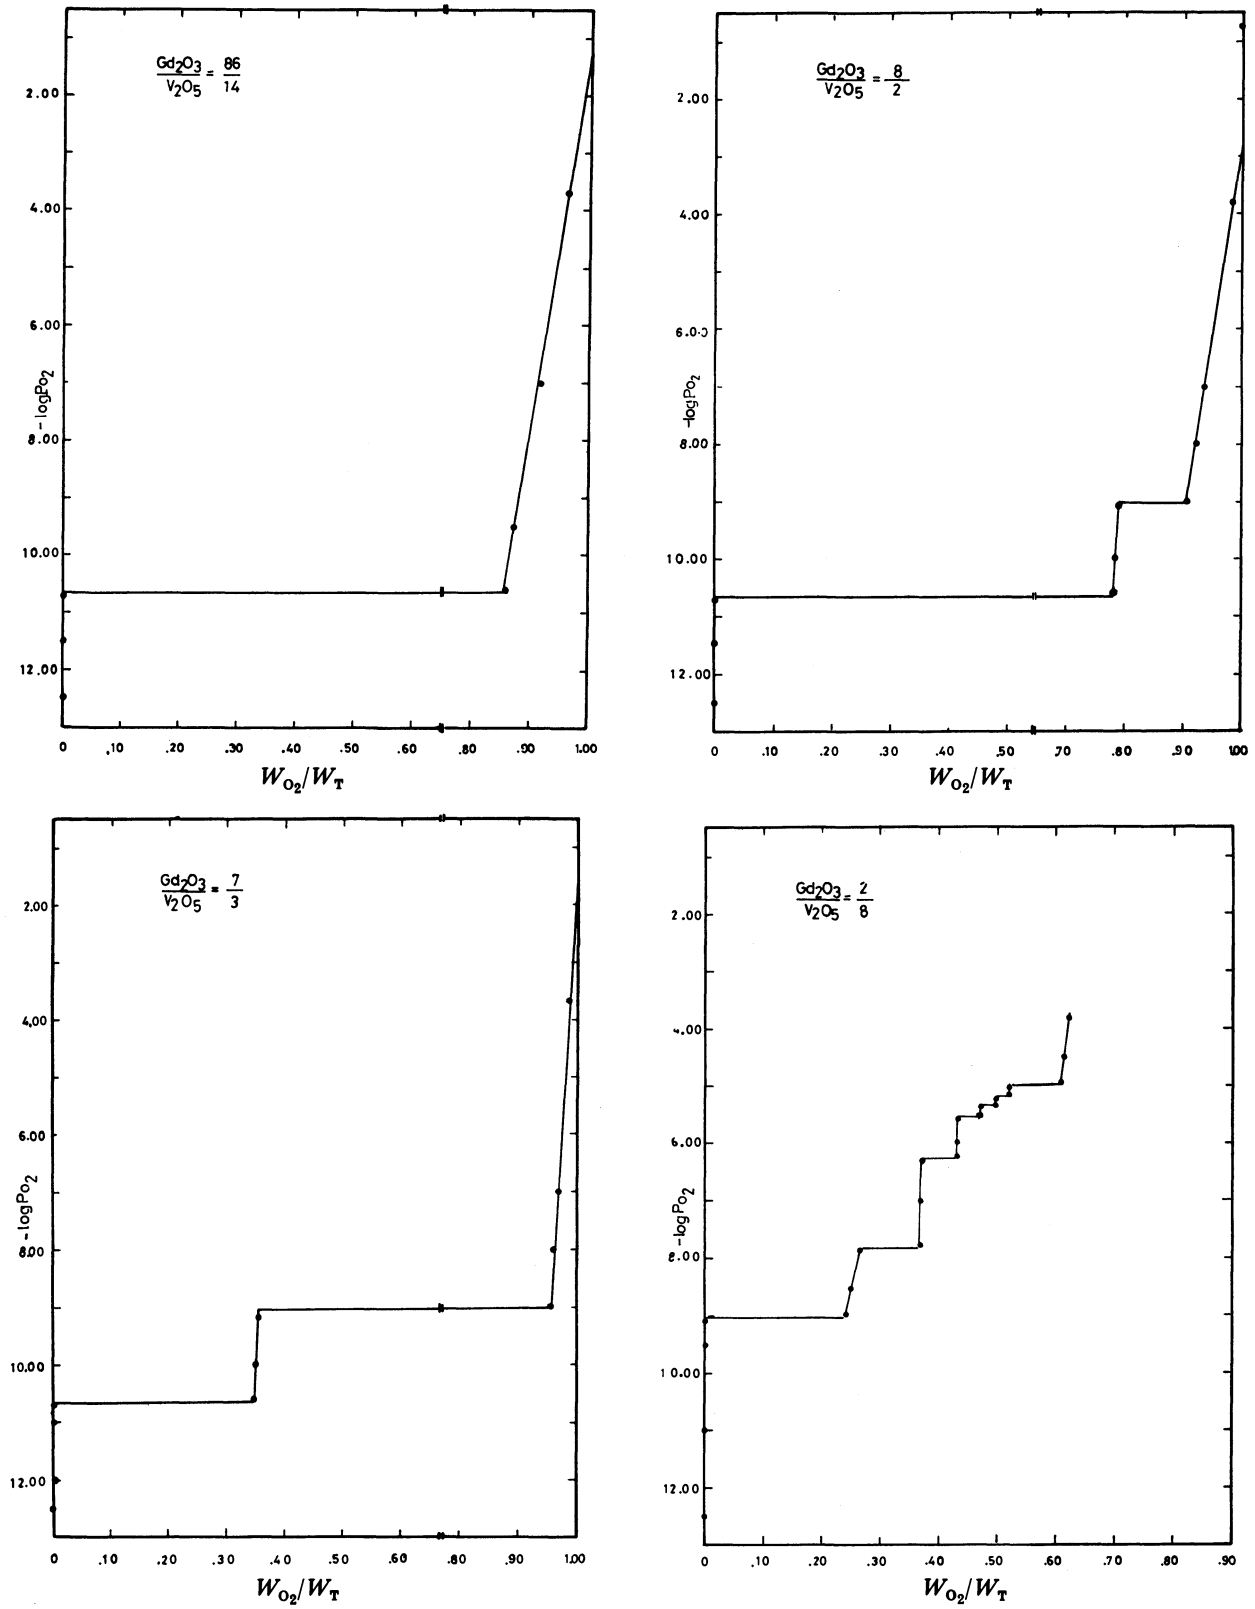

Fig. 1. The relationship between $-\log P_{O_2}$ and the weight gain (W_{O_2}/W_T) of the sample.
(a): Gd_2O_3/V_2O_5=86/14, (b): Gd_2O_3/V_2O_5=8/2, (c): Gd_2O_3/V_2O_5=7/3, (d): Gd_2O_3/V_2O_5=2/8.

Compound A has no round mole ratio such as the $4Gd_2O_3 \cdot V_2O_5$ reported by Brusset *et al.*[7,8] A straight line that connects the experimental points tends toward the $0.81Gd_2O_3 \cdot 0.19V_2O_5$ composition point rather than toward $4Gd_2O_3 \cdot V_2O_5$. This result is also supported by the results of the thermogravimetry of the sample 8/2 (Fig. 1-2). That is, the abrupt change occured at -9.06 in $\log P_{O_2}$. In order to support the fact by quenching method, we tried to make two phases quenched samples (A+$GdVO_3$) and (A+$GdVO_4$) at

TABLE 1. IDENTIFICATION OF PHASES

Starting material (mol%)		$-\log P_{O_2}$	Time / h	Phases[a)]

		5.30	41.5	$GdVO_4+V_6O_{11}$
		5.10	91.5	$GdVO_4+V_7O_{13}$
		4.50	39.0	$GdVO_4+VO_2$

a) A: $Gd_{1.62}V_{0.38}O_{3.38}$.

$\log P_{O_2}=-10.00$ and in air. However, peaks of $GdVO_3$ and $GdVO_4$ are too weak to identify the phases.

Compounds A and $GdVO_4$ have non-stoichiometric compositions. The relationship between the oxygen partial pressure and the compositions are represented by the following equations: $N_O/N_A=5.83\times10^{-3}\log P_{O_2}+8.83\times10^{-3}$ for Compound A and $N_O/N_K=1.50\times10^{-3}\log P_{O_2}+4.5\times10^{-3}$ for $GdVO_4$. Here, N_O/N_A and N_O/N_K denote the mole fraction ratio of the oxygen to the oxide component, shown by the letters A and K, and the deviation from the stoichiometry. Non-stoichiometry was not found for $GdVO_3$ under those experimental conditions.

In Table 2, the compositions of the compound, as calculated from the results of the thermogravimetry, the symbols of the compounds, the stability ranges of the compounds in terms of the oxygen partial pressure

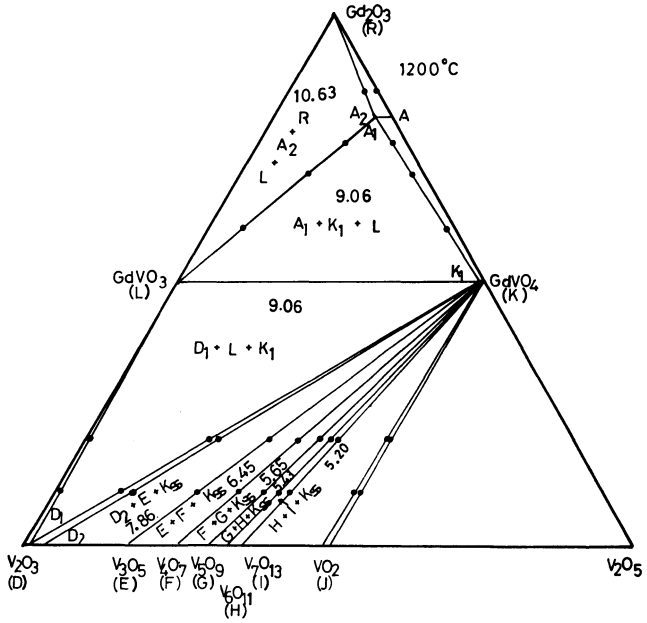

Fig. 2. Phase equilibria in the Gd_2O_3–V_2O_3–V_2O_5 system at 1200 °C. Numerical values in three solid phases regions are the oxygen partial pressure in $-\log P_{O_2}$ in equilibrium. Abbreviations are the same as those in Table 2.

	$GdVO_{3.99}$	K_1	9.06	0

a) The stability range in $\log P_{O_2}$ may be higher than −0.68. b) This value was obtained by extrapolation using the experimental values.

Table 4. Unit-cell dimensions of the compounds

Sample	$-\log P_{O_2}$	a/Å	b/Å	c/Å	β/°	V/Å^3	Ref.
$Gd_{1.62}V_{0.38}O_{3.38}$	10.00	10.69±0.06	8.70±0.05	16.4±0.3	99.5±0.7	1504±27	
	0.68	10.70±0.07	8.77±0.08	16.3±0.3	99.6±0.9	1503±35	
$GdVO_3$	12.00	5.341±0.003	5.605±0.003	7.634±0.003		228.5±0.2	
		5.341	5.606	7.630			5
		5.342	5.604	7.637		228.6	6
$GdVO_4$	8.50	7.210±0.001		6.347±0.001		330.0±0.1	
	0.68	7.207±0.001		6.344±0.001		329.5±0.1	
		7.216±0.003		6.351±0.003			8
		7.211		6.350		330.2	15

in $\log P_{O_2}$, and the activities of the components are tabulated. The activities of all the components in the solid solutions are calculated by using the Gibbs-Duhem equation. A detailed method of the calculation has been described in the paper of Kimizuka and Katsura.[13]

The assignment of indices for Compound A was tried with the aid of previous data on $4Tm_2O_3 \cdot V_2O_5$.[14] In Table 3, the results of the assignment of indices, the relative intensities, and the spacings of the sample are tabulated, together with the spacings and relative intensities of $4Gd_2O_3 \cdot V_2O_5$ obtained by Brusset *et al.*[7] There are other weak and broad peaks that are not shown in Table 3. Though Brusset *et al.* did not present the indices, the two substance have similar spacings.

The lattice constants of three samples, A, $GdVO_3$, and $GdVO_4$ are tabulated in Table 4. The figures in second column are the oxygen partial pressure used in preparation of the quenched samples. The present values are in good agreement with those of the previous reports. The experimental errors in the lattice constants of Compound A are, however, still large. Refinement will be done in the near future.

Calculation of Gibbs Free Energy of Reactions. On the basis of the phase equilibria, the Gibbs free energy of reactions, referred to the following equations:

$$31/50Gd_2O_3 + 19/50GdVO_3 + 19/100O_2 = Gd_{1.62}V_{0.38}O_{3.38} \quad (1)$$

and:

$$GdVO_3 + 1/2O_2 = GdVO_4 \quad (2)$$

can be calculated from this equation: $\Delta G^\circ = -RT \ln K$, where R is the gas constant; T, the absolute temperature, and K, the equilibrium constant of the reaction. The activities of $Gd_{1.62}V_{0.38}O_{3.38}$ and $GdVO_4$ at the A_2 and K_1 compositions (Table 2) in both solid solutions may be equal to unity. Values of 57.0 and 127.8 kJ were obtained for Reactions 1 and 2 respectively.

Anion Exchange Separation of Hard Acid-metals Using HF-H_3BO_3 Media

Takeo ADACHI

Analytical Chemistry Laboratory, Japan Atomic Energy Research Institute, Tokai, Ibaraki 319-11

(Received October 2, 1981)

The properties of HF–H_3BO_3 media and the distribution coefficients of eighteen metals have been investigated to achieve the separation of hard acid-metals by the anion exchange method. As the addition of boric acid to hydrofluoric acid solution reduces the free fluoride ion concentration to about one hundredth, it is possible to control the formation of metal fluoride complexes in a way favorable for the separation. The BF_4^- and BF_3OH^- produced in this media are adsorbed strongly to the resin and reduce the relative adsorbabilities of metal fluoride complexes remarkably. Using these properties of HF–H_3BO_3 media and the adsorbabilities of other anions, a new anion exchange method for the separation of hard acid-metals has been proposed. The new method is especially useful for the separation of titanium, zirconium, niobium, and tantalum. Distribution coefficients and elution behaviors of metal ions are not affected by the increase of the amount of metals because of the buffer action relating to the fluoride ion in HF–H_3BO_3 media.

Most ion exchange separations of hard acid-metals[1] such as titanium, zirconium, niobium, tantalum, tungsten, molybdenum, and tin have been done using anion exchange resins[2] (unless otherwise devised[3]), because these metals are easily hydrolysed in the absence of complexing agents and tend to form stable anion complexes in the presence of complexing agents.

As anion complexes of these metals have similar chemical properties, the separation of these metals is not easy, and many efforts have been attempted.[4–13] The following three points are considered to be essential for the satisfactory separation:

(1) Select a proper complexing agent forming metal complexes whose chemical properties depend on the kind of metals.

(2) Choose coexisting anions and their concentrations to control the relative adsorbabilities of metal anionic complexes on the resin.

(3) Control the concentration of complexing agents, to adjust the stage of complex formation.

As for point (1), such complexing agents as fluoride,[14,15] oxalate,[11–13] and thiocyanate[16–18] have been investigated. Fluoride has been most frequently adopted in the practical separations of hard acid-metals, probably because the stability constants of fluoride complexes depend on the kind of metals most strongly. Even in hydrofluoric acid (more than 0.1 M, 1 M=1 mol dm^{-3}), however, sufficient separation is not expected unless other anions are present, since the difference in the adsorbabilities of fluoride complexes on a fluoride-form resin are not large enough.[14]

As for point (2), such a mixed solvent as HF–HCl[4–7] or HF–HNO_3[8–10] has been proposed for the separation of hard acid-metals. The adsorbability of a chloride or nitrate ion on the anion exchange resin is much stronger than that of fluoride ion. With the strong adsorbability of chloride or nitrate, the relative adsorbabilities of metal fluoride complexes are weakened and the separation of hard acid-metals becomes possible.

As for point (3), Kraus *et al.*[19] controlled the stage of chloride complex formation by adjusting the concentration of hydrochloric acid suitably and proposed the anion exchange separation of transition metals (including a few hard acid-metals).

If one would apply point (3) to the separation of hard acid-metals in the media containing fluoride ions, the concentration of fluoride ion must be kept fairly low and constant, because these metals form fully fluorinated complexes such as ZrF_6^{2-} and TiF_6^{2-} in hydrofluoric acid more than 0.1 M. In solutions which contain fluoride ion in less than 10^{-4} M, partially fluorinated complexes such as ZrF_5^- and TiF_4 are expected to form.[3]

In hydrofluoric acid solution or HF–HCl and HF–HNO_3 mixtures, however, it is not easy to maintain the fluoride ion concentration low and constant all through the procedures, since fluoride ions may be consumed by the relatively large amounts of metal ions or supplied from metal fluoride complexes adsorbed on the resin and fluoride-form resin.

The author reported in a previous paper[3] that the fluoride ion concentration can be kept low (10^{-4} to 10^{-5} M) in HF–H_3BO_3 media according to the formation of fluoroboric acids, though the concentration of hydrofluoric acid is rather high (more than 0.1 M). In the media, the fluoride ion concentration is kept constant by the buffer action based on the dissociation of fluoroboric acids even when large amounts of metal ions are present.

In the present paper, the separation of hard acid-metals is discussed in HF–H_3BO_3 media in relation to the above mentioned properties of HF–H_3BO_3 media and the adsorbabilities of coexisting anions, while referring to points (2) and (3).

Experimental

Chemicals and Apparatus. Standard solutions of metal ions were prepared by the procedures mentioned in the previous paper.[3] Other chemicals and apparatus were also the same as used previously.

Ion Exchange Resin. A strongly basic anion exchange resin, Diaion SA # 100, product of Mitsubishi Chemical Ind. Ltd. (8% DVB, 75 to 150 μm, Cl^--form) was used. After washing the resin in a column with five times volume of 3 M HNO_3 and with distilled water untill the effluent was free from nitrate ions, the resin was dried to constant weight at 70 °C and stored in a vacuum desiccator.

Determination of Distribution Coefficient. *Method I*: Fifty ml of a definite concentration of hydrofluoric–nitric acid solution or hydrofluoric–boric–nitric acid solution containing 2×10^{-4} M of a metal ion was added to a 150 ml polyethylene

bottle containing 0.5 g of the dried resin. The bottle was then shaken gently for 24 h at room temperature (the equilibrium is attained within 4 h). After filtration of the resin, the metal ion concentration in the solution was determined by a suitable method as previously described.[3]

The distribution coefficient, K_d, was determined by the following equation:

$$K_d = (\text{Amount of metal ion in resin/Amount of metal ion in solution}) \times (\text{ml of solution/g of resin}) \quad (\text{ml/g})$$

Method II: Fifty ml of 0.2 M hydrofluoric acid solution containing 2×10^{-4} M of a metal ion was added to a 150 ml polyethylene bottle containing 0.5 g of the dried resin. The bottle was then shaken for 24 h at room temperature. After discarding the solution the resin was washed with 10 ml of 10^{-2} M HF, and 50 ml of a definite concentration of HF–HNO_3 solution or HF–H_3BO_3–HNO_3 solution was added to the bottle. Subsequent procedures were the same as in Method I.

Column Operation. About 4 g of the dried resin in NO_3^--form which had been swelled with distilled water was packed in a polyethylene column (8 mmϕ × 180 mm) and the column was conditioned with about 50 ml of 0.2 M HF. After addition of a test solution containing 1 mg of a metal ion in 0.2 M HF, an eluent of a definite composition was passed through the column. The effluent was collected with a fraction collector and the concentration of the metal ion in each fraction was determined by the methods previously mentioned.[3]

Results

The following experimental results were obtained in solutions containing more than 10^{-2} M in HNO_3 in order to prevent the hydrolysis of hard acid-metals, unless otherwise mentioned.

Distribution Coefficients. Distribution coefficients K_d of Ti(IV), Zr(IV), Nb(V), and Ta(V) were investigated by Method I in solutions which contained various concentrations of hydrofluoric acid (C_{HF}) both in the presence and in the absence of 0.5 M H_3BO_3. The results are illustrated in Fig. 1.

The K_d values of these metals in HF–H_3BO_3 media are smaller than those in HF. In both media, the K_d values of these metals are increased with the increase of C_{HF} up to 10^{-2} M. In solutions containing more than 10^{-2} M of HF, the K_d in HF–H_3BO_3 media are decreased with increasing C_{HF}, whereas those in HF are almost unchanged with C_{HF}. The K_d values in both media at any C_{HF} decrease with increasing nitric acid concentration (C_{HNO_3}).

The K_d values obtained by Method II are similar to those by Method I as shown in Fig. 2.

The K_d of other metals in HF–H_3BO_3 media containing HNO_3 are presented in Table 1. In the third and fourth columns in Table 1, K_d in solutions containing various concentrations of H_3BO_3 ($C_{H_3BO_3}$) and 0.1 M HF, and K_d in solutions containing various C_{HF} and 0.5 M H_3BO_3 are listed.

At constant C_{HF} (column 3 in Table 1), the K_d of W(VI), Nb(V), Hf(IV), Zr(IV), Mo(VI), Ti(IV), and Sn(IV) remarkably decrease when the $C_{H_3BO_3}$ is changed from 10^{-2} to 0.1 M. The decrease of K_d of Ta(V) with increasing C_{HF}, however, is not noticeable.

At constant $C_{H_3BO_3}$ (column 4 in Table 1), the K_d of Hf(IV) or Sn(IV) is at a maximum when C_{HF} is at around 10^{-2} M, but the K_d of W(VI) and Mo(VI) are large even when C_{HF} is at 10^{-3} M and decrease monotonously with the increase of C_{HF}. This is similar to the results for Ti(IV), Zr(IV), Nb(V), and Ta(V) (Fig. 1). The large K_d values of W(VI) and Mo(VI) at low C_{HF} may be due to the fact that these metals exist as such anions as WO_4^{2-} and $Mo_7O_{24}^{6-}$ even in the absence of complexing agents.

The K_d of V(V), V(IV), U(VI), Al(III), Cr(III), and Fe(III) are small at most of C_{HF} and $C_{H_3BO_3}$.

According to the Ringbom's criterion for ion exchange separation by column filtration (*i.e.* K_d of an adsorbed ion is larger than 10^2 to $10^{2.5}$ and that of the emerging ion is less than $10^{0.5}$ to 10^1),[20] the following results are expected from the K_d values in Fig. 1 and Table 1 for the column separation of hard acid-metals; (a) In 0.1 M HF–10^{-2} M HNO_3, hard acid-metals such as Ta(V), W(VI), Nb(V), Hf(IV), Zr(IV), Mo(VI), Ti(IV), Sn(IV), V(V), and U(VI) are retained in the column and V(IV) and Fe(III) are eluted from the column. Al(III) and Cr(III) are retained loosely or eluted slowly. (b) In 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3, among the metals retained in the column in (a), V(V) and U(VI) are eluted and Ti(IV) and Sn(IV) are eluted slowly. Mo(VI) is retained loosely. (c) In 0.1 M HF–0.5 M H_3BO_3–0.1 M HNO_3, among the metals retained in (b), Hf(IV) and Zr(IV) are eluted and Mo(VI) is eluted slowly. W(VI) and Nb(V) are retained loosely. (d) In 0.5 M HF–0.5 M H_3BO_3–0.1 M HNO_3, among the metals retained in (c), W(VI) and Nb(V) are eluted. Ta(V) cannot be eluted by the media mentioned above.

Although the media mentioned in (a) to (d) are chosen as an example, other possibilities for separation are obtained by selecting C_{HF}, $C_{H_3BO_3}$, and C_{HNO_3} properly.

Effect of Concentrations of HCl, H_2SO_4, HNO_3, and $HClO_4$ on K_d of Metals in HF–H_3BO_3 Media. The effects of various acids and their concentrations on the K_d of Ti(IV), Zr(IV), Nb(V), and Ta(V) in 10^{-2} M HF–0.5 M H_3BO_3 are presented in Fig. 3. In this experiment the anion exchange resin used had been converted to the respective anion form, as in the coexisting acids (*e.g.* when coexisting acid is $HClO_4$, the resin was converted to the ClO_4^--form).

Although the K_d values of all metals examined decrease with increasing the acid concentration regardless of the kind of acids, the degree of the effect of coexisting acids on K_d depends on the kind of acids; the effect is most serious with $HClO_4$.

The effect of concentration of sulfuric acid on K_d is gentle compared with those of other acids.

The K_d values of Nb(V) and Ta(V) are decreased

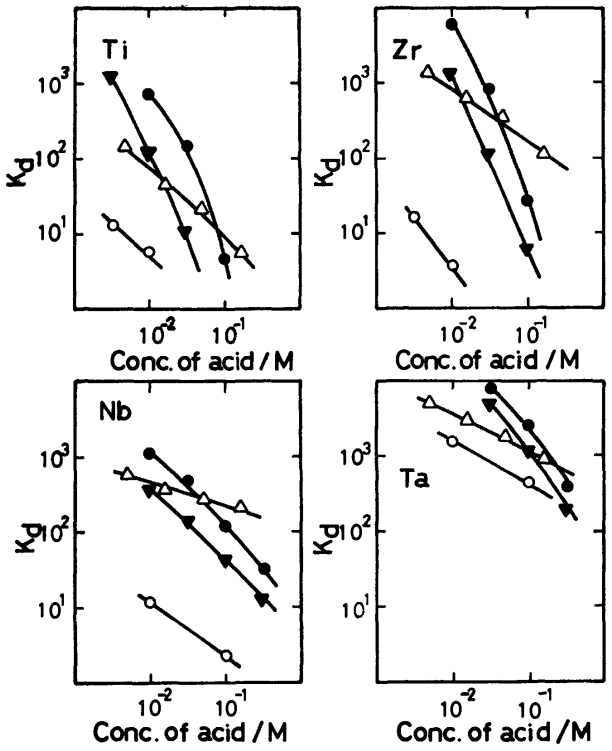

Fig. 3. Effect of concentration of coexisting acids on K_d of Ti(IV), Zr(IV), Nb(V), and Ta(V) in 10^{-2} M HF–0.5 M H_3BO_3.
●: HCl, △: H_2SO_4, ▼: HNO_3, ○: $HClO_4$.

more gently with the increase of acid concentration than those of Ti(IV) and Zr(IV).

Elution Behavior. In order to determine the practical conditions for the separation of Ti(IV), Zr(IV), Nb(V), and Ta(V), the elution behavior in HF–H_3BO_3 media was investigated after adsorption of these metals in a column (4 g of the dried resin, 8 mmϕ × 180 mm) in 0.2 M HF prior to the elution experiment. The flow rate of elution was adjusted to be 1.0 to 1.5 ml min^{-1}. The elution curves are shown in integrated form in Fig. 4.

As expected from the K_d values obtained by the batch method (Fig. 1 and Table 1), the mutual separation of these metals is possible by the column method as follows.

Ti(IV) is eluted when 100 ml of 10^{-2} M HF–0.5 M H_3BO_3–3×10^{-2} M HNO_3 or 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3 is passed through the column, while Zr(IV), Nb(V), and Ta(V) are retained in the column even with 400 ml of these eluents (Fig. 4, (a)). Ti(IV) and Zr(IV) are eluted with 100 ml of 10^{-2} M HF–0.5 M H_3BO_3–0.1 M HNO_3 or 0.1 M HF–0.5 M H_3BO_3–0.1 M HNO_3, and Nb(V) is eluted with 300 ml of these eluents (Fig. 4, (b)). Ti(IV), Zr(IV), and Nb(V) are eluted with 100 ml of 0.5 M HF–0.5 M H_3BO_3–0.1 M HNO_3, while Ta(V) is not eluted with 300 ml of the eluent (Fig. 4, (c)). Ta(V) is eluted with 100 ml of 1 M HF–0.5 M H_3BO_3–5 M HNO_3 (Fig. 4, (d)-4), since the K_d value for Ta(V) in the medium is about 10.

The successive separation of Ti(IV), Zr(IV), Nb(V), and Ta(V) can be achieved when the media mentioned in (a) to (c) in Fig. 4 are properly combined as (d) in

Fig. 4, as long as the amount of each metal is less than 1 mg.

Effect of Amount of Metal Ions on K_d and Elution Behavior of Metals. In HF–H_3BO_3 media, the free fluoride ion concentration is extremely low, as mentioned in the previous paper.[3] Therefore, the K_d values might be affected by the amount of metal ions owing to the deficiency of fluoride ions caused by the complex formation of large amount of metals with fluoride and/or the surplus of fluoride ions which are released from the large amount of metal fluoride complexes. This would occur especially when metals are adsorbed to the column in rather concentrated hydrofluoric acid in the beginning of the elution procedure.

The effect of the amount of Zr(IV) on K_d of Zr(IV) investigated by the batch method is summarized in Table 2. In this experiment, 2 g of the dried resin was used in order to keep the loading less than 0.1 and the solution of Zr(IV) was made free from fluoride ion. The C_{HF} was chosen so that the K_d of Zr(IV) is around 10^2 at 1 mg level of Zr(IV), *i.e.* 10^{-3} M C_{HF} in the absence of H_3BO_3 and 0.1 M C_{HF} in the presence of 0.5 M H_3BO_3.

The K_d obtained by equilibrating the media containing Zr(IV) with the resin (Method I in Table 2) is decreased by the increase of the amount of Zr(IV) from 0.25 to 50 mg, when 10^{-3} M HF–10^{-2} M HNO_3 is used as the medium. But the K_d is not changed with the amount of Zr(IV) up to 20 mg, when 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3 is used as the medium.

The K_d obtained by equilibrating zirconium-free media with the resin on which Zr(IV) had been adsorbed in 0.2 M HF (Method II in Table 2) is extremely large compared with that by Method I and is more than 5×10^3 regardless of the amount of Zr(IV) when 10^{-3} M HF–10^{-2} M HNO_3 is used as the medium. On the other

Table 2. Effect of the amount of metal ions on distribution coefficients by batch method

a) Determined by equilibrating the medium containing a metal ion with the resin. b) Determined by equilibrating the metal-free medium with the resin on which a metal ion had been adsorbed in 0.2 M HF.

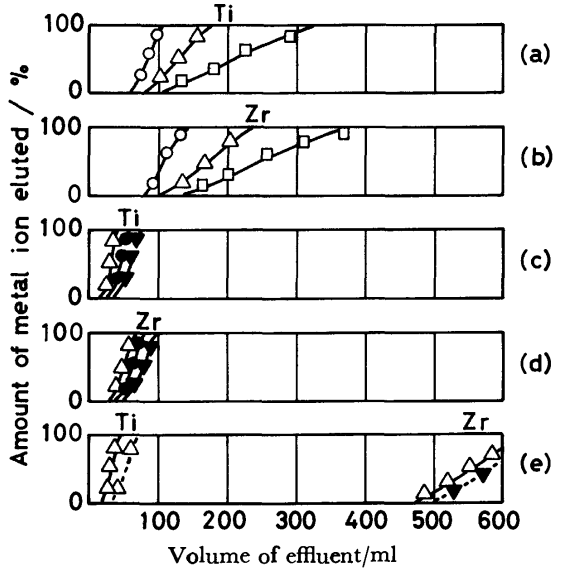

Fig. 5. Effect of amount of metal ions on elution behaviors of Ti(IV) and Zr(IV).
(a) and (b): 10^{-3} M HF–0.1 M HNO_3, (c) and (e): 0.1 M HF–0 5 M H_3BO_3–10^{-2} M HNO_3, (d): 0 1 M HF–0 5 M H_3BO_3–0.1 M HNO_3. Amount of metal ions; ○: 0.25 mg, △: 1 mg, □: 5 mg, ●: 10 mg, ▼: 50 mg.

hand, when 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3 is used as the medium, the K_d by Method II is identical with that by Method I and is not affected by the amount of Zr(IV) up to 50 mg.

The reason why the K_d value in HF–H_3BO_3–HNO_3 media does not change may be attributed to the F^--buffer action of this media, as mentioned in the previous paper.[3]

The large K_d obtained by Method II in 10^{-3} M HF–10^{-2} M HNO_3 cannot be explained clearly, but it may be due to the irreversible adsorption of Zr(IV)–fluoride complexes and/or the change of C_{HF} caused by the partial dissociation of highly fluorinated zirconium complexes on the resin.

The K_d of Nb(V) in 0.1 M HF–0.5 M H_3BO_3–0.1 M HNO_3 is the same regardless of the equilibrating method used and the amount of Nb(V), up to 20 mg.

The effect of the amount of Zr(IV) or Ti(IV) on their column elution behavior is shown in Fig. 5. These metals had been adsorbed to the column in 0.2 M HF prior to this elution experiment. Though the elution of Ti(IV) or Zr(IV) was extremely retarded by the increase of metal ions in 10^{-3} M HF–0.1 M HNO_3 (Figs. 5(a) and (b)), the elution was hardly affected by increasing the amount of the metal ions up to 50 mg, when 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3 or 0.1 M HF–0.5 M H_3BO_3–0.1 M HNO_3 was used as the eluent (Figs. 5(c) and (d)). Less than 50 mg of coexisting Zr(IV) hardly affected the elution behavior of 1 mg of Ti(IV) in 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3 (Fig. 5(e)).

Discussion

The K_d values of metals for the anion exchange resin in solutions involving complexing agents are generally expressed by the equation presented by Helfferich.[21] The equation can be modified into Eq. 1, by considering the adsorption of a metal ion M^{n+} to A^{a-}-form anion exchange resin in a solution containing fluoride ions as a complexing agent:

$$K_d = \sum_{j=0}^{N}[x_j(K_A^{MF_j})^{1/a}([A^{a-}]_r/[A^{a-}])^{j-n/a}], \quad (1)$$

$$x_j = [F^-]^j\beta_j/(1+[F^-]\beta_1+\cdots+[F^-]^N\beta_N). \quad (2)$$

Here j is the number of fluoride ions complexed with the metal ion M^{n+}, N is the maximum coordination number of fluoride ion for M^{n+}, x_j is the molar fraction of MF_j to the total metal species in the solution, $K_A^{MF_j}$ is the selectivity coefficient of MF_j to A^{a-}, $[A^{a-}]_r$ and $[A^{a-}]$ are the concentration of anion A^{a-} in resin and solution and β_j is the cumulative stability constant of MF_j.

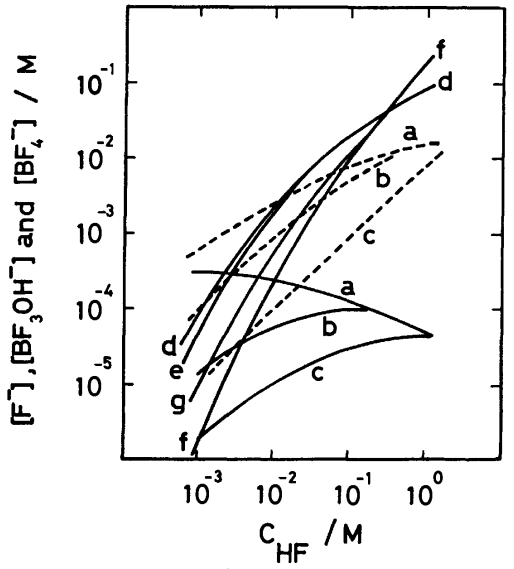

Fig. 6. Concentration of F^-, BF_3OH^-, and BF_4^- in HF and HF–H_3BO_3 media containing HNO_3.
——: HF–0.5 M H_3BO_3, ------: HF. a, b, and c: $[F^-]$ (a: without HNO_3, b: with 10^{-2} M HNO_3, c: with 0.1 M HNO_3), d and e: $[BF_3OH^-]$ (d: without HNO_3, e: with 0.1 M HNO_3), f and g: $[BF_4^-]$ (f: without HNO_3, g: with 0.1 M HNO_3).

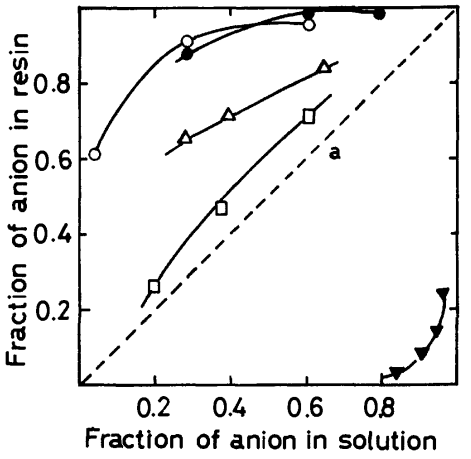

Fig. 7. Exchange of anions with Cl^- in the resin.
Diaion SA # 100: 1.0 g. Amount of acids: 0.5 to 20 mmol in 20 ml of solution. ○: BF_4^-, ●: ClO_4^-, △: NO_3^-, □: SO_4^{2-}, ▼: F^-.

As is evident from Eq. 1, the K_d value is a function of x_j, which is controlled by $[F^-]$ in the solution (Eq. 2), of $(K_A^{MF_j})^{1/a}$ which indicates the relative adsorbability of MF_j to A^{a-} (and hence, the value depends on the kind of anion), and of $([A^{a-}]_r/[A^{a-}])^{j-n/a}$, which depends on the valency and the concentration of anion A^{a-}.

Concentrations of free fluoride ion and other anions which exist in hydrofluoric acid and HF–H_3BO_3 media containing HNO_3 are calculated by the procedure described in the previous paper.[3] These are illustrated in Fig. 6; the dissociation constants of hydrofluoric acid and fluoroboric acids were used.

Figur 6 and the dependency of K_d on C_{HF} shown in Fig. 1 can be explained as follows: In solutions containing less than 10^{-2} M HF and 10^{-2} M HNO_3 with and without 0.5 M H_3BO_3, the resin stays as NO_3^-–form because the concentration of anions in solution other than nitrate is low and, hence, the second and third terms in Eq. 1 can be considered as constant at a definite C_{HNO_3}. Therefore, the increase of K_d with increasing C_{HF} up to 10^{-2} M may be ascribed to the change of x_j term, that is, to the increase of anionic metal fluoride complexes.

As an example, the species of Zr(IV) fluoride complexes and their fractions x_j in HF–H_3BO_3 media are calculated using the stability constants of Zr(IV) fluoride complexes.[22] The free fluoride ion concentration in the media of 0.5 M H_3BO_3–10^{-2} M HNO_3 containing 10^{-3} or 10^{-2} M HF is $10^{-5.0}$ or $10^{-4.3}$ M, respectively (see Fig. 6). The molar fraction of major species of Zr(IV) in solutions containing $10^{-5.0}$ M or $10^{-4.3}$ M of free fluoride ion are 35% of ZrF_4, 15% of ZrF_5^-, and 2% of ZrF_6^{2-} or 30% of ZrF_4, 55% of ZrF_5^-, and 15% of ZrF_6^{2-}, respectively. Consequently, the increase of the K_d of Zr(IV) with increasing C_{HF} is mainly due to the increase of the fraction of ZrF_5^- (and ZrF_6^{2-}).

The decrease of K_d with the increase of C_{HF} in HF–H_3BO_3 media containing more than 10^{-2} M HF (see Fig. 1) cannot be explained by the change of x_j because the free fluoride ion concentration slightly increases with the increase of C_{HF} (Fig. 6), but may be attributed to the change of the second and third terms in Eq. 1. Because the concentration of BF_4^- and BF_3OH^- increases remarkably with increasing C_{HF} in the solutions which are more than 10^{-2} M HF and 0.5 M H_3BO_3 (Fig. 6), it is suspected that BF_4^- and BF_3OH^- are adsorbed rather strongly on the resin, reducing the relative adsorbabilities of the metal fluoride complexes.

The adsorbability of BF_4^- was investigated and compared with the adsorbabilities of ClO_4^-, NO_3^-, SO_4^{2-}, and F^- according to Wheaton *et al.*[23] After equilibrating 1.0 g of Cl^--form dry anion exchange resin with 20 ml of various concentrations of HBF_4, $HClO_4$, HNO_3, H_2SO_4, or HF for 24 h at room temperature, the amount of chloride ion desorbed from the resin was determined by the Volhard method.[24] Assuming the amount of chloride desorbed is equivalent to the anions adsorbed, the molar fractions of the anion examined both in resin and solution are calculated (Fig. 7). In Fig. 7, the curve of an anion which lies above line (a) suggests the stronger adsorbability of the anion than that of chloride ion.[23] It is seen from Fig. 7 that the adsorbability of BF_4^- is very strong and is comparable to that of ClO_4^-. The order of adsorbabilities of anions is as follows:

$$BF_4^- \simeq ClO_4^- > NO_3^- > SO_4^{2-} > Cl^- > F^-. \quad (3)$$

Although the adsorbability of BF_3OH^- cannot be determined experimentally because of the difficulty of the preparation of BF_3OH^- free from BF_4^-,[25] it is considered that BF_3OH^- has the similar adsorbability to that of BF_4^- since the structure and the ionic charge of BF_3OH^- resemble those of BF_4^-.[25]

According to the considerations mentioned above, the decrease of K_d with the increase of C_{HF} in HF–H_3BO_3 media containing more than 10^{-2} M HF (Fig. 1) may

be attributed to the increase of BF_4^- and BF_3OH^- which are strongly adsorbed on the resin. And the decrease of K_d with the increase of $C_{H_3BO_3}$ in HF–H_3BO_3 media containing more than 10^{-2} M H_3BO_3 (column 3 in Table 1) may also be attributed to the increase of BF_4^- and BF_3OH^-.

The effects of coexisting acids and their concentrations on K_d (Fig. 3) may also be due to the difference in the adsorbabilities of the anions included in the coexisting acids. The different adsorbability given by various kinds of anions changes the second term in Eq. 1, $(K_A^{MF_j})^{1/a}$, and the concentrations of anions affect the third term in Eq. 1, $([A^{a-}]_r/[A^{a-}])^{j-n/a}$.

Based on the above discussions, the separation of Ti(IV), Zr(IV), Nb(V), and Ta(V) in HF–H_3BO_3 media shown in Fig. 4(d) is interpreted as follows: Metals in 0.2 M HF are adsorbed on the resin as fully fluorinated complexes. When the eluent, 0.1 M HF–0.5 M H_3BO_3–10^{-2} M HNO_3, is introduced to the column, metal complexes tend to be transformed to partially fluorinated complexes and the K_d values of these metals are reduced, because the concentration of free fluoride is extremely low in the medium. With this eluent Ti(IV), whose K_d is the smallest among these metals in this medium, is eluted from the column. With the increase of C_{HNO_3} in the eluent, the amount of NO_3^- adsorbed on the resin is increased, and Zr(IV) is eluted. When C_{HF} is increased from 0.1 M to 0.5 M, BF_4^- or BF_3OH^-, whose adsorbabilities are stronger than that of NO_3^-, is increased and Nb(V) is eluted. Since the adsorbability of Ta(V) fluoride complexes is extremely strong, a medium containing strong adsorptive anions in rather high concentration such as 1 M HF–0.5 M H_3BO_3–5 M HNO_3 is required to elute Ta(V).

Generally, in the separation of hard acid-metals by anion exchange, mixtures of HF (more than 0.1 M) and fairly concentrated HCl[4–7] or HNO_3[10] are used as eluents. Using these media, however, a separation such as that of Ti(IV) from Zr(IV) is difficult, because the adsorbabilities of fully fluorinated complexes of these metals resemble each other. Although for the elution of Ta(V) a solution of salt in high concentration such as 1 M NH_4F–4 M NH_4Cl[4,7] or a mixture of concentrated acids such as 5 M HF–12 M HNO_3[10] are employed in the works of HF–HCl or HF–HNO_3 media, it is difficult to remove the large amount of salts from the effluent and the concentrated acids decompose the resin. Using HF–H_3BO_3 media proposed in the present paper, these disadvantages are eliminated.

In conclusion, there is a buffer action relating to fluoride ion based on the dissociation of fluoroboric acids in HF–H_3BO_3 media, as discussed in the previous paper.[3] Therefore, despite the low fluoride ion concentration in HF–H_3BO_3 media, the separation can be attained without any effect of the amount of metal ions (up to 50 mg) as illustrated in Table 2 and Fig. 5.

The author wishes to thank Professor Taitiro Fujinaga, Drs. Tooru Kuwamoto, Kakuzo Tada, Hiroshi Hashitani, Sorin Kihara, and Mr. Hideyo Yoshida for their helpful discussions and useful suggestions.

(Received October 5, 1981)

The analytical procedure for the separation and quantification of various phosphorus oxoacids was investigated by the capillary type isotachophoresis. The various phosphorus oxoacids, such as linear-, cyclic-, and lower phosphorus oxoacids, were separated at pH 5.5 with a 0.01 mol dm^{-3} hydrochloric acid–histidine–0.1% triton X-100 mixture as the leading electrolyte and a 0.01 mol dm^{-3} hexanoic acid as the terminating electrolyte. The PU value increased in the order of $P_{3m}<P_{4m}<P_3<P_2<\overset{1}{P}<\overset{3}{P}<P_1$. The calibration curves for the various phosphorus oxoacids were linear in the range of 0.5—3.5 μg as phosphorus oxoacids. Coefficients of variation for the measured phosphorus oxoacids were less than 2% except for P_3. Separation times were approximately 15 min. This procedure was applied to the ground phosphates.

Phosphorus oxoacids and their salts have an important role as fertilizers, detergents, watersofteners *etc.* As they have many varieties, paper- and ion exchange chromatography have been used for the separation and quantification of them. A disadvantage of these method is that they are laborious and time consuming.

Recently, more rapid and less laborious methods were developed by the use of a high liquid chromatography and an automatic phosphate analyzer.[1–4]

In the present paper, a procedure for the separation and quantification for chain-, cyclic-, and lower phosphorus oxoacids by isotachophoresis is described to remove the above disadvantage. It is applied to the ground phosphates.

Mikkers, *et al.*[5–7] have also attempted an isotachophoresis of phosphates, but they have only analyzed chain phosphates.

Experimental

Samples. Reagent-grade sodium phosphinate monohydrate ($NaPH_2O_2\cdot H_2O$; $\overset{1}{P}$) was used. Sodium phosphonate (Na_2PHO_3; $\overset{3}{P}$) and sodium dihydrogenorthophosphate (NaH_2PO_4; $\overset{5}{P}$ or P_1) were obtained by heating Wako's reagents to dehydrate water of crystallization. Tetrasodium pyrophosphate ($Na_4P_2O_7$; P_2), pentasodium triphosphate ($Na_5P_3O_{10}$; P_3) and trisodium *cyclo*-triphosphate ($Na_3P_3O_9$; P_{3m}) were prepared by heating sodium orthophosphate, purified by recrystallization, and dehydrated water of crystallization. Tetrasodium *cyclo*-tetraphosphate ($Na_4P_4O_{12}$; P_{4m}) was prepared according to the method of Bell *et al.*[8]

All phosphorus oxoanions were standardized by paper chromatography. The ground samples were obtained by grinding $Na_2H_2P_2O_7$ and $Na_5P_3O_{10}$, respectively, for the specified lengths of time in an AGA-type Ishikawa's mill with an agate mortor.

Apparatus and Procedure. A Shimadzu Capillary Tube Isotachophoretic Analyzer IP-2A was used. The isotachophoretic tubes for the separation composed of a main capillary column (0.5 mm i.d., 100 mm in length) and a pre-column (1.0 mm i.d., 100 mm in length). The conditions of the isotachophoretic analysis are given in Table 1. After the electric driving current of 200 μA was applied for 12 min to shorten the analytical time, that of 100 μA was done. The potential gradient detector was used. Paper chromatography was performed as reported previously.[9]

Table 1. Operational system for separation of phosphorus oxoacids

	Electrolyte

Chart speed	40 mm min^{-1}	

Results and Discussion

The separation of the various phosphorus oxoanions is affected by the pH of leading solution. The relationship between the pH of the leading solution and the *PU* value, which is an indicator in qualitative analysis, is shown in Fig. 1. When the *PU* values of oxoanions are close, a mixed zone of them is formed. It can be seen from Fig. 1 that the separation at pH 4.5, 5.5, and 6.0 is unfavourable, but good separation is obtained in the range of pH 5.3—5.7. Therefore, seven varieties of the phosphorus oxoacids were separated at pH 5.5.

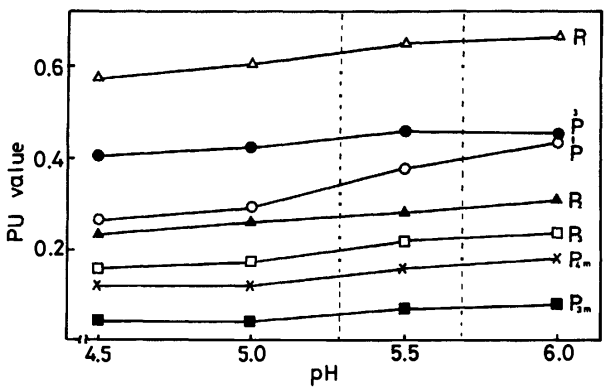

Fig. 1. Effect of pH of leading electrolyte on *PU* value.

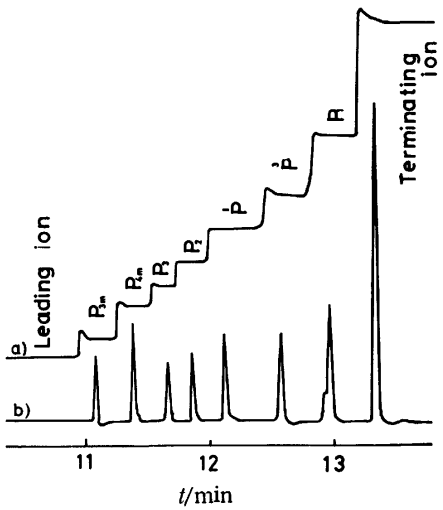

Fig. 2. Isotachopherogram of various phosphorus oxoacids.
a): Potential gradient, b): differential potential gradient.

Figure 2 shows the isotachopherogram of the various phosphorus oxoacids. An order of the *PU* value is $P_{3m}<P_{4m}<P_3<P_2<{}^{1}P<{}^{3}P<P_1$. These results indicate that the electrophoretic mobility of the chain phosphate ion increased with an increase in the number of phosphorus atoms, that of the cyclic phosphate ion decreased with an increase in the number of phosphorus atoms, and that of the lower phosphorus oxoanion with different oxidation numbers decreased with an increase of oxidation numbers.

TABLE 2. REPRODUCIBILITY AND MOLAR RESPONSE FOR VARIOUS PHOSPHORUS OXOACIDS

	PU value		Zone length		Molar response[c]
	$\bar{X}$[a](n=8)	*CV*[b] %	$\bar{X}$[a](n=8) mm	*CV*[b] %	10^8 mm mol^{-1}
${}^{1}P$	0.394	1.02	36.8	1.09	5.57(0.95)
${}^{3}P$	0.498	0.80	29.3	1.02	5.28(0.90)
${}^{5}P(P_1)$	0.661	0.76	34.1	1.76	5.85(1.00)
P_2	0.305	2.95	19.4	1.55	7.38(1.26)
P_3	0.233	2.58	15.2	5.26	7.79(1.33)
P_{3m}	0.074	1.35	24.2	0.83	10.57(1.81)
P_{4m}	0.170	2.35	22.1	0.90	12.85(2.20)

a) Average value. b) Coefficient of variation ($CV=\sigma/\bar{X}\times100$). c) Value in parentheses is relative molar response (as $P_1=1.00$).

Table 2 shows the reproducibilities of the *PU* value and the zone length, and molar response. All coefficients of variation (*CV*%) of the *PU* value were less than 3% and those of the zone length were less than 2% except for P_3. A high *CV* value (5.25%) of P_3 is due to only one abnormal data. If this abnormal data is removed, the *CV* value of P_3 is 2.22%. The molar response for the various phosphorus oxoacids in Table 2 was calculated from the zone length on the isotachopherogram and the amount of injected phosphorus oxoacids. The value in parentheses represents the relative molar response which is the value converted as that of P_1 is 1.00. It can be seen from these results that the relative molar response of both chain- and cyclic phosphates increased with an increase in the number of phosphorus atoms of the phosphates, that of the cyclic phosphates is higher value than that of the chain phosphates, and that of phosphorus oxoacids with different oxidation numbers doesn't depend on the oxidation numbers.

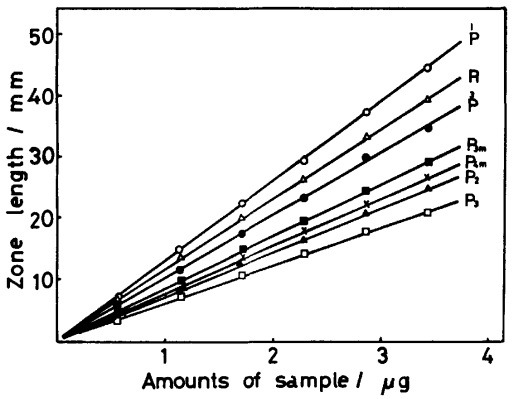

Fig. 3. Calibration curves of various phosphorus oxoacids.
Chart speed: 40 mm min^{-1}.

Figure 3 shows the calibration curves for seven varieties of phosphorus oxoacids. These phosphorus oxoacids were injected simultaneously. Linear relationship were obtained over the range of 0.5—3.5 μg of sodium salts of phosphorus oxoacids, but the calibration curve was nonlinear above 3.5 μg because the phosphorus oxoanions with adjacent *PU* values formed the mixed zone. When a single phosphorus oxoacid was injected, a linear relationship was obtained over a wide range of the amount of phosphorus oxoacids, 0.5—30.0 μg.

As the linear region of the calibration curve depends on the volume of the capillary tube, it is preferable to select an adequate capillary tube to obtain good results.

Application

The procedure mentioned above was applied to the separation and quantification of the ground phosphates.

The P–O–P linkages of the chain phosphates, such as pyro- and triphosphate, were severed to shorter chain

phosphates due to grinding.[10] Therefore, the ground samples contained the different chain-length phosphates were obtained by grinding for different times.

Figure 4 is the representative isotachopherogram of the ground triphosphate. The results of the isotachophoresis of these ground samples have been summarized in Tables 3 and 4. These results are comparable with those of paper chromatography.

†*Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo-cho, Mito, Ibaraki 310*

(Received October 7, 1981)

The crystal and molecular structure of the title complex $(-)_{435}$-Λ_{RS}-β_2(mer)-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)]·3H$_2$O, has been determined by single crystal X-ray analysis. The crystals are orthorhombic, space group $P2_12_12_1$, with unit cell dimensions $a=19.247(8)$, $b=14.162(4)$, $c=10.329(4)$ Å, and $Z=4$. The structure was solved by the heavy-atom method and refined by block-diagonal least-squares technique, using 1624 independent reflections, to the final *R*-value of 0.080. The molecular structure is of a Λ_{RS}-*cis*-β_2(mer) type in which two coordination sites of a distorted octahedron are occupied by the *N*-Bz-L-ala group and the others by the quadridentate α-Me-sal$_2$en Schiff-base ligand in a nonplanar configuration. The Co–O and Co–N bon lengths, 1.938(12) and 1.989(15) Å respectively, of the *N*-Bz-L-ala group are significantly longer than the usual values. The molecule is distinctly strained as shown by the bond angles of the ligands and those of the cobalt(III) coordination polyhedron. The water molecules form a hydrogen bonded chain linking phenolate and carboxylate oxygens of different molecules along the crystallographic c axis.

The crystal structures of Schiff-base metal complexes have been studied extensively.[1] However, there are only a few structures in which the quadridentate Schiff-base ligands took a nonplanar configuration.[2-6] Recently, studies of several metal complexes with quadridentate Schiff-base ligands in *cis*-configuration have shown that they exhibit stereoselective effects in coordinating optically active amino acids.[7,8] In order to elucidate these effects more clearly, we have synthesized a series of mixed complexes of the type [Co(α-Me-sal$_2$en)(AA)] where α-Me-sal$_2$en is the dianion of the quadridentate *N,N'*-ethylenebis(α-methylsalicylideneaminato) ligand and AA is the anion of one of the following amino acids: *N*-methyl-L-alanine, *N*-benzyl-L-alanine (abbreviated as *N*-Bz-L-ala), and *N*-benzyl-*N*-methyl-L-alanine.[9] This paper reports the result of an X-ray diffraction study of the crystal and molecular structure of $(-)_{435}$-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)]·3H$_2$O, which is the predominant isomer at equilibrium conditions.

Experimental

Preparation of Compound. $(-)_{435}$-*cis*-β_2(mer)-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)]·3H$_2$O was prepared by a method described elsewhere.[9] From a mixed solution of methanol and water (1 : 1), dark green crystals were obtained. Found: C, 58.36; H, 6.10; N, 7.29%. Calcd for $C_{28}H_{30}CoN_3O_4$·2.5H$_2$O: C, 58.33; H, 6.12; N, 7.29% and for $C_{28}H_{30}CoN_3O_4$·3H$_2$O: C, 57.43; H, 6.20; N, 7.18%. From comparison with the X-ray result, these values suggest that a partial dehydration occurred. $(M)_{435}=-4.38\times10^4$° ($c=1.0\times10^{-3}$ mol dm^{-3}; chloroform solution).

Crystallographic-data Collection. The size of the crystal used for the X-ray measurement was $0.35\times0.28\times0.17$ mm^3. The systematic absences for $h00(h=2n+1)$, $0k0(k=2n+1)$, $00l(l=2n+1)$ indicated the space group $P2_12_12_1$. The determination of cell dimensions and the collection of intensity data were carried out on a Rigaku AFC-5 automated four-circle diffractometer with Mo *Kα* radiation ($\lambda=0.71069$ Å) monochromated by a graphite plate. The unit cell dimensions were refined by a least-squares method with 20 reflections ($2\theta>22$°). The crystal data were as follows: orthorhombic, space group $P2_12_12_1$, $a=19.247(8)$, $b=14.162(4)$, $c=10.329(4)$ Å, $D_m=1.35$ g cm^{-3} (by flotation in a $ZnCl_2$ solution), $Z=4$, and $D_c=1.38$ g cm^{-3}. The intensity data were collected in the ω-2θ scan mode up to $2\theta=50$° with the scan rate of 8°/min (50 kV, 170 mA). The scan range was $(1.2+0.5\tan\theta)$°. Of the 2119 unique observed reflections, 1624 reflections with $|F_o|\geq3\sigma(F_o)$ were used for the structure determination. Corrections for the absorption effect were neglected (μ(Mo *Kα*)=6.9 cm^{-1}).

Determination and Refinement of Crystal Structure

The structure was solved by the heavy-atom method and refined by the block-diagonal least-squares method. Three kinds of water molecules were found from a difference Fourier map after the other non-hydrogen atoms were located. The refinement using anisotropic

$B_{eq}=8\pi^2(U_{11}+U_{22}+U_{33})/3$. The anisotropic thermal parameters for the non-hydrogen atoms have been preserved by the Chemical Society of Japan.

a) These values were fixed at $B=6.0$/Å^2 during the least-squares calculations.

thermal parameters for the non-hydrogen atoms reduced the R value (defined as $\sum||F_o|-|\sum|F_c||/\sum|F_o|$) to 0.097. At this stage, all the hydrogen atoms were located from a difference Fourier map. The final refinement including the contribution of these hydrogen atoms with isotropic temperature factors converged to the R value of 0.080. The effect of the anomalous dispersion of the Co atom was included in the calculation.[10] The final difference map showed no peaks higher than 0.5 electrons/Å^3. Atomic scattering factors were taken from Ref. 10. All the computations were carried out by a HITAC M-180 computer at the Hiroshima University Information Processing Center. The computer programs used were FOUR-MMM[11] and HBLS-IV with a slight modification.[12] An ORTEP drawing was carried out by a computer system XTL in a Syntex R3 automated diffractometer.[13] The final atomic parameters are summarized in Table 1 with averaged isotropic temperature factors. The anisotropic thermal parameters and complete lists of the $|F_o|$ and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8222).

Results and Discussion

The projections of the crystal structure along the c and b axes with the numbering scheme are shown in Figs. 1 and 2. The crystals are built up of discrete [Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)] molecules and waters of crystallization.

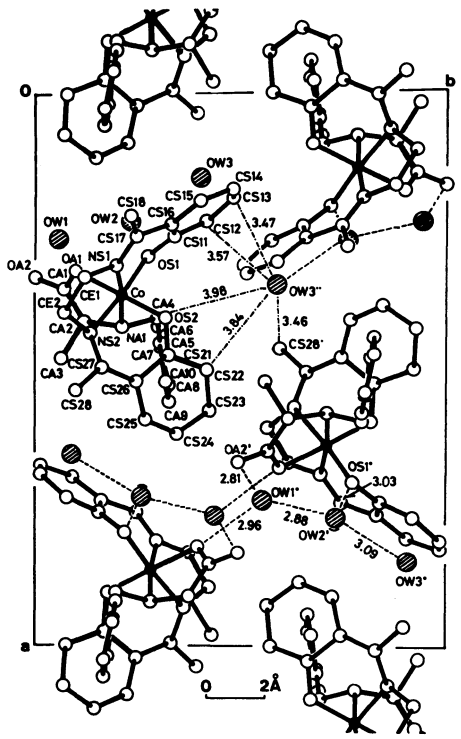

Fig. 1. A perspective drawing of the contents of the unit cell viewed down the c axis. The hydrogen bonds are indicated by bloken lines. Hydrogen atoms are omitted for clarity.

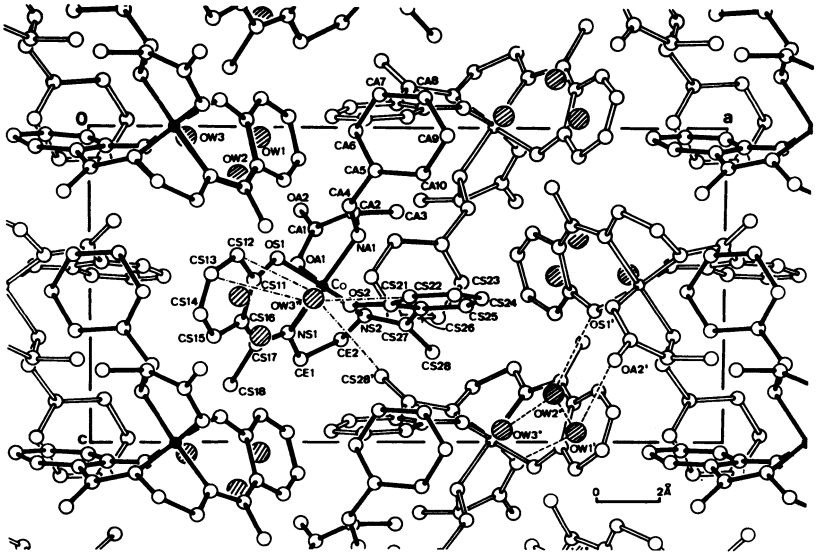

Fig. 2. A perspective drawing of the contents of the unit cell viewed down the b axis with the numbering scheme.

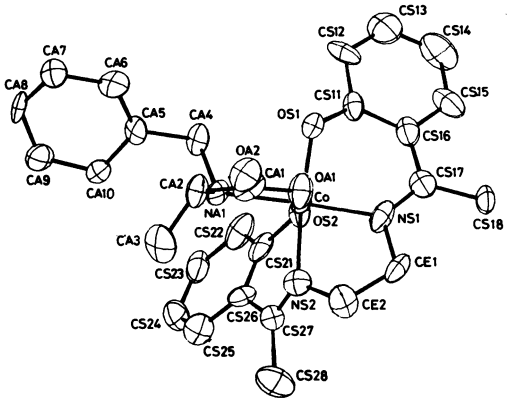

Fig. 3. An ORTEP drawing of the complex molecule. All atoms are drawn with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

Molecular Structure. The ORTEP drawing of the complex molecule is shown in Fig. 3 where the thermal ellipsoids are depicted with a 50% probability. The molecular structure of [Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)] has a close resemblance to that of [Co(α-Me-sal$_2$en)(L-isoleu)].[6] The *N*-benzyl-L-alaninate anion is nitrogen- and oxygen-bonded bidentate, and the α-methyl-sal$_2$en group has the *cis*-β_2 configuration[14] of a quadridentate ligand. The co-ordination polyhedron around the central cobalt atom is a meridional N_3O_3 structure in which the oxygen atom(OA 1) of the *N*-Bz-L-ala group is situated on the *trans* position of the oxygen atom(OS 2) of the phenolate moiety sal(2).

The absolute configuration of the complex molecule is *Λ*[15] as deduced from the known absolute configuration of the asymmetric carbon atom of the L-alaninato skeleton as an internal reference.[16] The arrangement of the group around the nitrogen atom(NA 1) of the *N*-benzyl-L-alaninato ligand is an *R* configuration and those around the asymmetric carbon atom(CA 2) is an *S* configuration. Thus, the structure of the complex molecule is denoted as *Λ*$_{RS}$-*cis*-β_2(mer) type.

Bond lengths and bond angles in the complex molecule are listed in Table 2 together with their estimated standard deviations. The Co–O and Co–N bond lengths of α-Me-sal$_2$en ligand are in agreement with those in the nonplanar [Co(salen)(acac)] derivatives within the experimental error.[2,3] The corresponding distances of the *N*-Bz-L-ala group, Co–OA1 1.938(12) and Co–NA1 1.989(15) Å, are significantly longer than those reported in Co(III) amino acidato chelates; Co–$O_{av.}$ 1.885(9) and Co–$N_{av.}$ 1.945(10) Å in (−)-mer-[Co(L-ala)$_3$][17] and Co–O 1.892(7) and Co–N 1.920(9) Å for L-phenylalaninato group in [Co(acac)$_2$(L-phala)].[18]

The bond angles around the cobalt atom are approximately in agreement with those in [Co(salen)(acac)][3] and [Co(salen)(bzacac)].[2] The chelate angle for the *N*-Bz-L-ala group, OA1–Co–NA1 85.2(6)°, is normal.

A perspective drawing of the complex molecule projected down the axis through the middle point of NS1-NS2 atoms and the cobalt atom is depicted in Fig. 4. Bailay *et al.* mentioned that the strain of the *cis*-β_2 type salen ligand is apparent in: (i) Angular strain in the "en" chelate ring, (ii) the nonplanar coordination geometry around the azomethine nitrogens, and (iii) the angular strain in the salicylideneamine moiety sal(2).[2] The highly strained conformational state about the "en" ring and the coordination geometry around the azomethine nitrogens (NS1 and NS2) are clearly shown in Fig. 4. The strain in the sal(2) moiety is also noticed by comparison with the sal(1) moiety in Fig. 4 and the sal(2) moiety in Fig. 3.

Calligaris *et al.* showed another representation for giving the degree of strain in these molecules.[3] Based on their representation, the angles between the planes passing through sal(1), sal(2), and the ala moieties, and the planes of the three equatorial planes of the octahedron around the cobalt atom are illustrated in Fig. 5.

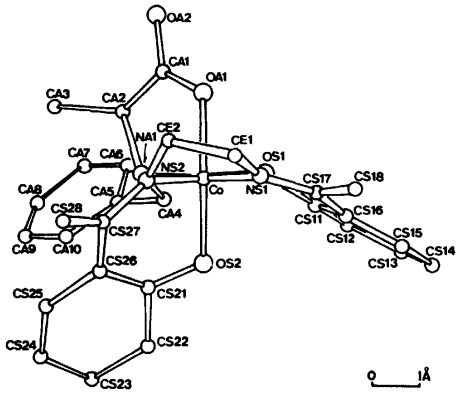

Fig. 4. Structure of the complex molecule viewed down the axis through the middle point of NS1-NS2 atoms and the cobalt atom.

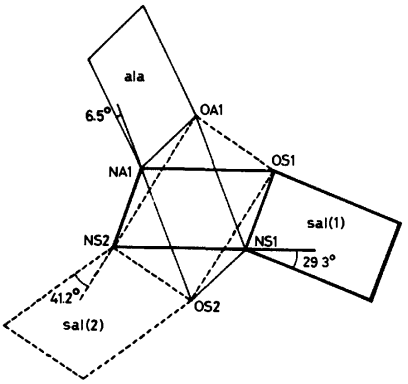

Fig. 5. A schematic drawing of the dihedral angles between the least-squares planes.

Comparison between these values, which are summarized in Table 3, and those found in [Co(salen)(acac)], 5.0, 29.3, and 17.9° for sal(1), sal(2), and acac respectively, indicates that the strain caused by the *cis*-β_2-salen skeleton in the present complex is distinctly higher than that in [Co(salen)(acac)].

The coordination of the bulky *N*-benzyl-L-alaninato ligand is probably responsible for this difference, as evidenced by the long Co–O and Co–N bond distances in the *N*-Bz-L-ala group. Two short intramolecular

nonbonded contacts are found between the methylene carbon atom(CA4) of *N*-Bz-L-ala group and the oxygen atoms of the α-Me-sal$_2$en ligand: CA4–OS1 2.760(21) and CA4–OS2 3.187(20) Å.

A new question thus arises. Why the fairly bulky amino nitrogen atom of *N*-Bz-L-ala(NA1) coordinates in the somewhat crowded position which is *trans* to the nitrogen atom NS1 in the equatorial plane instead of in the less crowded position *trans* to the apical oxygen atom(OS2)?

In relation to this, it is noteworthy that the structure of chloro(pyridine)[*N*,*N*'-tetramethylenebis(salicylideneaminato)]rhodium(III), in which the sal$_2$trien group acts as a quadridentate chelated ligand and takes a common *cis*-β type structure, belongs to the meridional coordination about the arrangement of mononegative coordination atoms(Cl^-, O^-, O^-) and the neutral nitrogen atoms(N(py), N(sal$_2$trien), N(sal$_2$trien)).[5] In the structure of μ-peroxo-bis{[3,3'-bis(salicylideneamino)dipropylaminato]cobalt(III)}, again the coordination around the cobalt atom takes a meridional N_3O_3 type.[19] Moreover, our X-ray studies on (−)$_{435}$-(L-isoleucinato)[*N*,*N*'-ethylenebis(α-methylsalicylideneaminato)]cobalt(III) 1.5H_2O has clearly shown that the structure is Λ_L-*cis*-β_2-mer(N_3O_3) type.[6] Therefore, as far as we know, all the structures of the related complexes so far determined by X-ray analyses are of meridional type. Thus, it can be inferred that the preference for the meridional coordination plays an important role in determining the molecular structures of these complexes.

There were many studies on the stereoselectivity or stereospecificity of [Co(N_4)(AA)] complexes with a chiral amino acid.[20] In comparison with these *cis*-β_2-[Co(N_4)(AA)] complexes, the stereoselectivity of *cis*-β_2-type cobalt(III) Schiff-base complexes is surprisingly high: for example, in the present *N*-Bz-L-ala complex, the stereoselectivity for the Λ_{RS}-*cis*-β_2(mer) configuration is almost 100%.[9] Recently, Yamaguchi *et al.* reported that the structure of (+)$_{589}$-[Co(*R*-ala)(*SS*-pyht)]$^{2+}$, which is the predominant isomer at the equilibrium conditions, is a Λ_R-*cis*-β_2 type.[21] The complex has no significant nonbonded interaction between the tetramine moiety and the alaninato ligand. In contrast to this, our present cobalt(III) Schiff-base complex has several significant nonbonded interactions between the α-Me-sal$_2$en moiety and the *N*-Bz-L-ala group though this isomer is the most favorable one at the equilibrium conditions.[9] The intramolecular nonbonded distances are as follows: CA4–OS1 2.760(21), CA4–Co 2.947(17), CA4–OS2 3.187(20), NA1–CA10 3.190(24), NA1–CS21 3.003(23) and NA1–CS26 3.143(22) Å.

If the absolute configuration around the *N*-Bz-L-amino nitrogen atom(NA1) changes from *R* to *S* and remaining part of the molecule is fixed, several abnormally short contacts appear around the methylene

Selected intermolecular distances around OW3 atom (*l*/Å)			
OW3^{iii}···OS2	3.98(3)	OW3^{iii}···CS13	3.47(3)
···CS22	3.84(3)	···CS14	3.76(4)
···CS12	3.57(3)	···CS28^{vii}	3.46(4)

Roman numerals as superscripts refer to the following equivalent positions, relative to the reference atom at (x,y,z): i$(1/2-x, -y, -1/2+z)$, ii$(x, y, 1+z)$, iii$(1/2-x, 1-y, 1/2+z)$, iv$(1/2-x, -y, 1/2+z)$, v$(1-x, -1/2+y, 1/2-z)$, vi$(1/2+x, 1/2-y, 1-z)$, vii$(1-x, 1/2+y, 3/2-z)$. D; Hydrogen donor, A; hydrogen acceptor.

carbon atom(CA4) of the *N*-Bz moiety. The shortest intramolecular distance calculated in this Λ_{SS} model is only 2.10 Å for CA4–CS26(sal(2)). On contrast to this, the inversion of the absolute configuration around the α-carbon atom(CA2) of *N*-Bz-L-ala group from *S* to *R* introduces a fairly small repulsive effect. The shortest distance in this Λ_{RR} model is 2.64 Å for CA2(R)–CA4. Thus, our presumption about the thermodynamic stabilities among the diastereoisomers of the present complex,[9] $\Lambda_{RS} \gg \Lambda_{RR} > \Lambda_{SS}$, can be verified clearly.

Crystal Packing and Water of Crystallization. The selected intermolecular distances including the hydrogen bonding modes are summarized in Table 4. Three water molecules of crystallization(OW1, OW2, and OW3) make a columnar structure around the two-fold screw axis along the c-direction, and provide crystalline stability by forming strong hydrogen bonds. The hydrogen bonding network of these water molecules, including three other oxygen atoms(two(OA1 and OA2) come from the *N*-Bz-L-ala group and one(OS1) from the sal(1) moiety), is shown in Fig. 1 and Fig. 2 by the dotted lines.

Three benzene rings are present in this molecule. The packing modes around these benzene rings in the present crystal are as follows: (i) The benzene ring of the sal(1) moiety has close contacts with the water molecule OW3(see Table 4), and (ii) the remaining two benzene rings(one comes from the *N*-Bz-L-ala and the other from the sal(2) of the α-Me-sal$_2$en) are stacked nearly perpendicular to each other along the crystallographic c axis.

The intermolecular bond distances around the water molecule OW3 are summarized in Table 4. It is interesting to note that this water molecule lies nearly on a line which passes through the central cobalt atom and the middle point of the OS1 and OS2 oxygen atoms as shown in Fig. 2. Therefore, the central area of the OS1–Co–OS2 plane is covered with the water molecule OW3, and this water molecule prohibits other molecules from approaching along this direction.

The packing feature around the water molecule OW3 is also responsible for the thermal dehydration behavior of this crystal. The elemental analysis shows that partial dehydration should occur in this crystal. There are strong interactions around the water molecules OW1 and OW2 as shown in Table 4. In contrast, only one short contact is found around the OW3; OW3–OW2 3.09(3) Å. Additionally, the averaged isotropic temperature factor for OW3 (B_{eq}=15.4 Å^{-2}) is considerably larger than those obtained for OW1(5.9) and OW2(9.4). Thus, it can be concluded that the partial dehydration mainly occurs at the position of OW3.

(Received October 12, 1981)

The crystal structures of (−)$_{589}$-[Cr(NCS)$_2$(tn)$_2$]1/2[Sb$_2$(+)-tart$_2$]·2H$_2$O (**1**) and (−)$_{589}$-[Co(NCS)$_2$(tn)$_2$]1/2-[Sb$_2$(+)-tart$_2$]·2H$_2$O (**2**) have been determined from the X-ray diffraction data. The structures were solved by the Patterson-Fourier method and refined by the least-squares method to R=0.043 (**1**) and 0.070 (**2**) for 2659 and 1826 reflections respectively. The two crystals are isomorphous with each other. The complex cations in **1** and **2** have a similar geometry. Their absolute configuration is Λ, and agrees with that assigned from the CD spectra in comparison with those in the first d-d band region of bis(ethylenediamine)cobalt(III) complexes. The six-membered chelate rings are of chair conformation. The chairs are flattened more than expected from the conformational analysis.

As a part of studies of circular dichroism(CD)-structure correlation of metal complexes involving 1,3-propanediamine,[1,2] we describe here X-ray structure analyses of (−)$_{589}$-bis(isothiocyanato)bis(1,3-propanediamine)chromium(III) bis[μ-(+)-tartrato(4−)]-bis[antimonate(III)] dihydrate (−)$_{589}$-[Cr(NCS)$_2$(tn)$_2$]-1/2[Sb$_2$(+)-tart$_2$]·2H$_2$O (tn=1,3-propanediamine, [Sb$_2$(+)-tart$_2$]$^{2-}$=bis[μ-(+)-tartrato(4−)]-bis[antimonate(III)] anion) and its cobalt(III) analogue (−)$_{589}$-[Co(NCS)$_2$(tn)$_2$]1/2[Sb$_2$(+)-tart$_2$]·2H$_2$O. Preliminary communication on the cobalt(III) complex has already been reported.[3]

Experimental

X-Ray Data Collection. The crystal of (−)$_{589}$-[Cr(NCS)$_2$(tn)$_2$]1/2[Sb$_2$(+)-tart$_2$]·2H$_2$O (**1**) is red and hexagonal tablet. The (−)$_{589}$-[Co(NCS)$_2$(tn)$_2$]1/2[Sb$_2$(+)-tart$_2$]·2H$_2$O complex (**2**) crystallizes in dark red prisms. The compounds **1** and **2** were prepared and resolved by Kawaguchi and his co-workers.[4,5] Preliminary oscillation and Weissenberg photographs showed the space group and approximate unit-cell dimensions for each crystal. The unit-cell dimensions were refined by least-squares analyses of the θ values of 32 reflections for **1** and 23 for **2**. The crystal data for **1** and **2** are given in Table 1. Intensity data were collected at room temperature on a Philips PW1100 automated diffractometer, using graphite-monochromated Mo $K\alpha$ radiation. During the data collection, three standard reflections were monitored every 4 h to check the stability and orientation of each crystal. Both compounds remained quite stable. Each data set was corrected for Lorentz-polarization[6] and absorption effects.[7]

Structure Solution and Refinement. The structure of **2** was first solved by the Patterson-Fourier techniques. Since the two crystals **1** and **2** are isomorphous, the structure solution for **1** was straightforward. Refinement of the structures was carried out by using the block-diagonal least-squares method. The function minimized was $\sum w(F_o-|F_c|)^2$, where $w=1/\sigma^2(F_o)$ was used. In the final cycle of refinement, all the parameter shifts were less than 0.8σ for **1** and 0.4σ for **2**. Neutral-atom scattering factors for the Sb, Cr, Co, S, O, N, and C atoms were taken from Ref. 8, with anomalous dispersion corrections for Sb, Cr, and Co atoms. The final R values were 0.043 for **1** and 0.070 for **2**. No attempt was made to locate hydrogen atoms. No chemically significant peaks were observed on final difference Fourier maps for **1** and **2**. Maximum peaks were 1.0 e Å^{-3} for **1** and 1.5 e Å^{-3} for **2**.

The absolute configurations of (−)$_{589}$-[Cr(NCS)$_2$(tn)$_2$]$^+$ and (−)$_{589}$-[Co(NCS)$_2$(tn)$_2$]$^+$ were determined on the basis of the known configuration of the (+)-tartric acid. The $F_o-|F_c|$ Tables for **1** and **2** and the anisotropic temperature factors are preserved by the Chemical Society of Japan (Document No. 8223). The final atomic coordinates are given in Table 2. Figures 1 and 2 were drawn by the use of ORTEP.[9] All the computations were performed by a FACOM 230-60 computer at Osaka City University using programs in the UNICS.[10]

Results and Discussion

The perspective views of (−)$_{589}$-[Cr(NCS)$_2$(tn)$_2$]$^+$ and (−)$_{589}$-[Co(NCS)$_2$(tn)$_2$]$^+$ are given in Fig. 1. They have a similar structure and their absolute configuration is Λ, which is consistent with the assignment from the CD data obtained by Kawaguchi and his co-workers.[4,5] Each complex cation has an approximate two-fold axis of rotation passing through the central metal and bisecting the N(NCS)–M–N(NCS) (M=Cr, Co) angle. The six-membered chelate rings are of chair conformation. The chairs in each complex have the Λpa[11](BB)[12] conformation and fold apart from one another (Fig. 1). Geue and Snow[12] calculated that the Λpa(BB) conformer is energetically more stable than the Λap(AA)

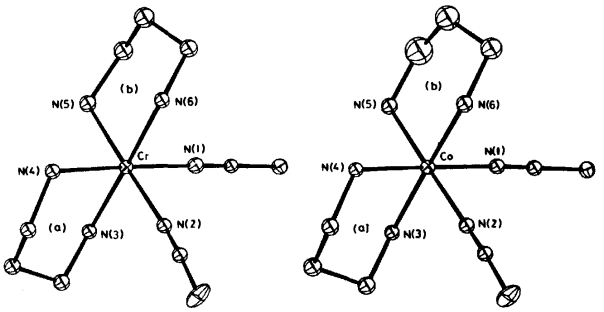

Fig. 1. The absolute configurations of the complex cations: (−)$_{589}$-[Cr(NCS)$_2$(tn)$_2$]$^+$ (left) and (−)$_{589}$-[Co(NCS)$_2$(tn)$_2$]$^+$ (right). The "a" ring is the "p" conformer and the "b" ring has the "a" form.

and Λpp(AB) conformations. They also indicated that no flattening should occur for two rings in Λpa(BB) conformation. However, we observed the flattening of the chairs in the crystals. Table 3 compares the tortion angles and bond angles calculated by Geue and Snow with those of the present work. The chairs of (a) and (b) in **1** and (a) in **2** have a similar geometry and are flattened more than expected from the calculation. The chair (b) in **2** shows a much pronounced flattening in comparison with the former three, and consequently the geometries of two rings in **2** are significantly different from each other. Since these flattenings are not predicted by the conformational analysis, the chair conformation in the present complexes presumably results from the

a) Roman numeral Superscripts refer to the following equivalent positions: I x, y, z; II $x, y, 1+z$; III $1/2-x, -1/2+y, 1-z$; IV $1/2+x, 1/2-y, 2-z$; V $-1/2+x, 1/2-y, 1-z$.

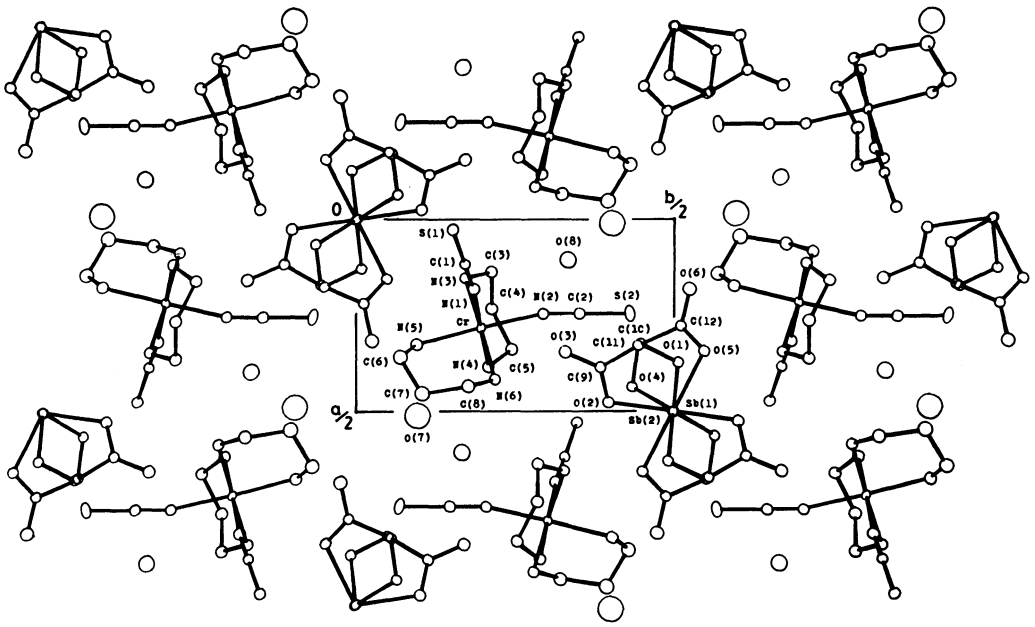

Fig. 3. The crystal structure of **1** viewed down the c axis, showing the atom numbering scheme.

crystal packing.

The bond distances between the metal ion and the ligator atoms are slightly larger in **1** than in **2**.[13] The average M–N bond distances are Cr–N(amine) 2.092 Å, Cr–N(NCS) 2.000 Å, Co–N(amine) 1.994 Å, and Co–N(NCS) 1.920 Å. These values are in agreement with those previously reported.[11–13] Deviations of the M–N(1)–C(1) bonds (Cr–N(1)–C(1)=170.7°, Co–N(1)–C(1)=173.1°) from 180° are less than the M–N(2)–C(2) bonds (Cr–N(2)–C(2)=166.4°, Co–N(2)–C(2)=166.3°). The isothiocyanato groups are approximately linear. The chelate bite angle (88.5°) in **1** is slightly less than 90°, but in **2** the value is 90.9° (Table 4).

The CD spectra of Λ-$(-)_{589}$-$[Cr(NCS)_2(tn)_2](NCS)$ and Λ-$(-)_{589}$-$[Co(NCS)_2(tn)_2](ClO_4)$ are given in Fig. 2. The CD pattern in the first d-d band region is

similar to each other and to the corresponding bis(ethylenediamine)cobalt(III) complexes.[14,15] Therefore, by analogy with bis(ethylenediamine)cobalt(III) complexes, each positive CD peak at higher wave-number could be assigned to the combined A and B components derived from the E_a component of the parent trigonal complex and each negative CD peak in the lower wave-number to the B component. Mason's criterion[16] that the absolute configuration of bis(ethylenediamine) cobalt(III) complex should be *Λ* if the CD of the combined A and B components are positive in sign, appears to hold in the present cases. It is noticed, however, that in *Λ*-$(-)_{589}$-$[Co(NCS)_2(tn)_2]^+$, the absolute configuration is related to the sign of the less dominant CD peak in the first absorption band region.

The $[Sb_2(+)\text{-tart}_2]^{2-}$ anion has a crystallographically imposed two-fold axis of rotation which passes through the two Sb atoms. The geometry of $[Sb_2(+)\text{-tart}_2]^{2-}$ anion is identical with those previously reported.[17]

Figure 3 gives the crystal structure of **1**. The crystals **1** and **2** are isomorphous. Each crystal consists of *Λ*-$(-)_{589}$-$[M(NCS)_2(tn)_2]^+$ cations, $[Sb_2(+)\text{-tart}_2]^{2-}$ anions, and water molecules, which are mainly bound by the N–H···O and N–H···S hydrogen bonds. Short contact distances are given in Table 4.

(Received October 16, 1981)

The thermal dehydration reactions of lanthanoid(III) malonate hydrates $Ln_2mal_3 \cdot nH_2O$ (Ln=Ce—Lu; mal=$CH_2(COO)_2$; n=6 for Ce—Eu and 8 for Gd—Lu) were investigated mainly by the thermogravimetries under conventional conditions and in atmosphere of water vapor at a constant reduced pressure and a superslow heating rate. The latter conditions were useful especially to detect the formation of new intermediate hydrates, and to determine the dehydration temperatures with accuracy. The main features of the results could be reasonably understood in view of the effects of the lanthanoid contraction.

The lanthanoid elements (Ln) are characterized by an overall decrease in size of atoms or ions with increasing atomic number. In the case of Ln^{3+} ions, the effects of this "lanthanoid contraction" appear most dramatically, and its influences on the coordination number (C.N.) and geometry are the unifying concept in the chemistry of Ln(III) compounds.[1,2] Lanthanoid(III) ions have unoccupied inner orbitals, but the ligand field stabilization caused by their presence is said to be much smaller than in the case of 3d-transition metal ions.[3] The C.N. of Ln^{3+} is normally 6 to 9, and the metal-ligand bonds are mainly ionic.

In aqueous solutions, most of Ln^{3+} compounds are labile, but it is said that their coordination spheres seek to achieve a compromise between the most spherical shielding for Ln^{3+} and the minimum interligand repulsion.[2]

In the solid state, polymorphs are often formed because of the small energy differences among possible structures of high C.N., and it is known that, in certain cases, one or two of the ligands are in "partial coordination," to reduce the overcrowdedness of the coordination sphere.[4] Thus the influences of the lanthanoid contraction observed in the solid state may look quite different from those[5] observed in solution.

In the present paper, such influences upon the thermal dehydration reaction of Ln^{3+} malonate hydrates in the solid state will be discussed mainly on the basis of thermogravimetric data.

Experimental

Preparation of $Ln_2mal_3 \cdot nH_2O$. Aqueous solutions of $LnCl_3$ (0.24 mol dm^{-3}) and Na_2mal (0.36 mol dm^{-3}) were mixed quickly at room temperature. Each precipitate obtained was allowed to stand overnight in contact with the mother liquor, washed several times with water by decantation, and filtered. It was further washed with ethanol and ether, and dried at room temperature. Contents of Ln, C, and H in the samples are given in Table 1.

Themogravimetry (TG) and Differential Thermal Analysis (DTA). The TG and DTA curves were obtained with a Shinku Riko TGD-3000 differential thermal microbalance at a heating rate of 3 °C/min in a dry nitrogen stream of 30 cm^3/min, and also at a superslow heating rate of 2 °C/h in water vapor at 10 Torr (1 Torr≈133 Pa).[6] About 20 mg of the powdered sample was used for each run.

IR and X-Ray Diffraction. The infrared spectra in the frequency region of 400—4000 cm^{-1} were obtained by the

a) The metal contents were determined by titration with EDTA and Xylenol Orange in the pH range of 5.1—5.6.

KBr disk method with a Hitachi 215 infrared spectrometer and the powder X-ray diffraction analysis was made with a Rigaku Denki DS X-Ray diffractometer.

Results and Discussion

The samples prepared can be formulated as $Ln_2mal_3 \cdot nH_2O$, where $n=6$ for Ce—Eu and 8 for Gd—Lu (*cf.* Table 1). Hansson has studied the crystal structures of $Nd_2mal_3 \cdot 6H_2O$,[7] $Nd_2mal_3 \cdot 8H_2O$,[8] and $Eu_2mal_3 \cdot 8H_2O$;[9] the hexahydrates and octahydrates prepared in the present study showed essentially the same X-ray diffraction patterns as those of Hansson's $Nd_2mal_3 \cdot 6H_2O$ and $Eu_2mal_3 \cdot 8H_2O$, respectively. The infrared spectra were also divided into two different groups of Ce—Eu and Gd–Lu.

It must be mentioned here that most of these hydrates were already prepared by Azikov *et al.*, who also obtained their TG curves, and stated that their infrared spectra can be divided into two proups of Ce—Gd and Tb—Lu.[10,11] The accuracy of their data, however, is seemingly not very high, and their classification of Gd is not very convincing. Therefore, the TG and DTA behaviors of these hydrates were studied in more detail to get better structural correlations.

TG and DTA in N_2 at the Heating Rate of 3 °C/min. Among the TG and DTA curves of all the samples obtained, those of Eu, Gd, Ho, and Lu are shown in Fig. 1 as typical examples. As seen in the curve of Eu, all the hexahydrates lose their waters in a single step, whereas the octahydrates lose them in two steps, which can be distinguished more clearly with the heavier lanthanoids.

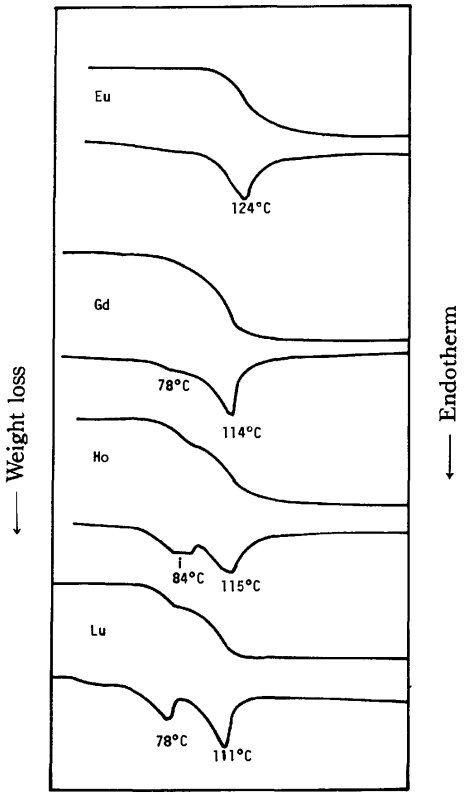

Fig. 1. TG and DTA curves of $Ln_2mal_3 \cdot nH_2O$ in N_2. The temperatures in the figure correspond to DTA peaks.

This difference in the mode of dehydration can be related with the structural data of these hydrates. It is known that the two Ln^{3+} in $Ln_2mal_3 \cdot 6H_2O$ are equivalent, and all the waters in them are coordinated to the Ln^{3+}, so that the hexahydrates can be represented as $[Ln_2mal_3(H_2O)_6]$ in which the C.N. of each Ln^{3+} is 9.[7] On the other hand, two waters in $Ln_2mal_3 \cdot 8H_2O$ are coordinated to one Ln^{3+} with C.N. 8, and three to another with C.N. 9, and the remaining three are held as lattice waters in two different ways.[9] Thus the octahydrates can be represented as $[Ln_2mal_3(H_2O)_5] \cdot 2H_2O \cdot \underline{H_2O}$.

Therefore, we can roughly say that, upon dehydration, the hexahydrates lose all of the coordination waters in a single step, but the octahydrates lose the lattice waters in the first step, and then the coordination waters in the second. Closer observations, however, reveal some more facts of interest.

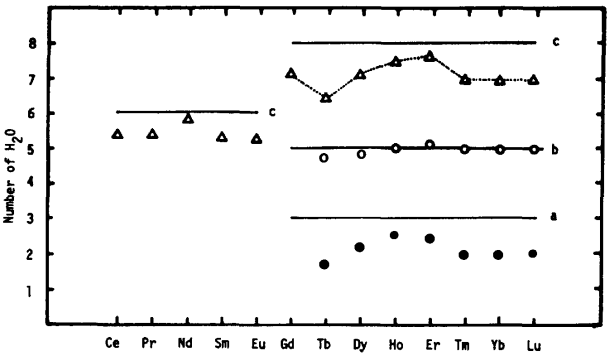

Fig. 2. Numbers of H_2O lost in the complete dehydration (△), and those lost in the first (●) and second (○) step, respectively, which were determined by TG in N_2. The solid lines indicate the theoretical values for lattice waters (a), coordination waters (b) and total waters (c).

When the numbers of H_2O lost by the complete dehydration are plotted against the symbols of Ln arranged in the order of increasing atomic number (Fig. 2), it is seen that they are somewhat smaller than expected; in the case of the octahydrates they are not exactly 8, and in most cases, nearly 7. This fact indicates that, among the waters in it, one of the lattice waters (the underlined one in the above formula) is held especially weakly, and easily lost from the sample in advance of the TG measurement.** So we represent the whole change as follows:

$$[Ln_2mal_3(H_2O)_5] \cdot 2H_2O \cdot H_2O \xrightarrow[I]{-H_2O}$$

$$[Ln_2mal_3(H_2O)_5] \cdot 2H_2O \xrightarrow[II]{-2H_2O}$$

$$[Ln_2mal_3(H_2O)_5] \xrightarrow[III]{-5H_2O} Ln_2mal_3.$$

** TG measurement on fresh samples in static air indicates, in all cases, an approximately quantitative loss of water.

Step I seems to occur very easily, so that it is either not observed on the TG curves (Lu, Yb, and Tm), or seemingly appears in combination with Step II (Ho and Er). The temperature difference between Steps II and III becomes smaller with the decrease of atomic number (or increase of ion size) of Ln as shown in Fig. 1, showing that the difference between the two kinds of waters in these hydrates decreases in the same way. We can imagine that, as the coordination sphere of Ln^{3+} expands in this direction, the lattice waters will gradually get involved in it, or get more "coordinated" in nature. This will be the reason why there is no distinct break between Steps II and III with Gd; when Ln^{3+} becomes still larger, all the waters get coordinated, forming the hexahydrates.

As to the hexahydrates, the numbers of waters lost by their complete dehydration are again somewhat smaller than expected, mostly being 5—5.5 instead of 6.** As mentioned above, all these hydrates contain their waters in a highly crowded coordination sphere (C.N. 9), and the energy difference between possible structures of C.N. 9 and C.N. 8 will be small. So it is conceivable that a small part of it is easily "squeezed out" of the coordination sphere and lost in advance of the TG study, as the case of the lattice water of the octahydrate. After this initial loss, however, the remaining waters are lost in a single step, as expected from their original formula $[Ln_2mal_3(H_2O)_6]$.

TG Analysis in Water Vapor of Constant Reduced Pressure at a Superslow Heating Rate. In order to see the nature of the steps in more detail, the TG curves were obtained in an atmosphere of water vapor at a constant reduced pressure (10 Torr) at a superslow heating rate of 2 °C/h. This technique, developed by us and reported in the preceding paper,[6] was found to be especially useful to study the dehydration of hydrated salts (such as $CuSO_4 \cdot nH_2O$), since (1) each of the dehydration steps becomes notably steeper, and more easily distinguishable, and (2) the whole pattern of the TG curve becomes remarkably similar to the true equilibrium weight-temperature relation under the specified water vapor pressure.

The comparison of the two curves in Fig. 3, which are given for examples, shows that this technique can be applied effectively to the present case. As expected, the steps of Curve A are very much steeper, in comparison with Curve B. The first step on A seems to correspond to the tail of Step I mentioned in the preceding section. Closer comparison of these curves shows that, although the total of the waters lost on Curve B is about 7(=2+5), those estimated from Curve A is about 6.7(=0.4+2.3+4). Under the present conditions, therefore, the eight waters are not lost in the order of (1)-2-5, but approximately (2)-2-4 by way of a tetrahydrate. Since the original hydrate contained only 3 lattice waters, a structural change is expected to occur when it is heated extremely slowly at a constant water vapor pressure (under quasi equilibrium conditions). In the course of the heating, a coordination water is squeezed out of the coordination sphere, and the dehydration proceeds as if the original complex should be formulated as $[Ln_2mal_3(H_2O)_4] \cdot 2H_2O \cdot 2H_2O$, losing $2H_2O$ at first,*** and then 2 and $4H_2O$ at the two main steps, respectively.

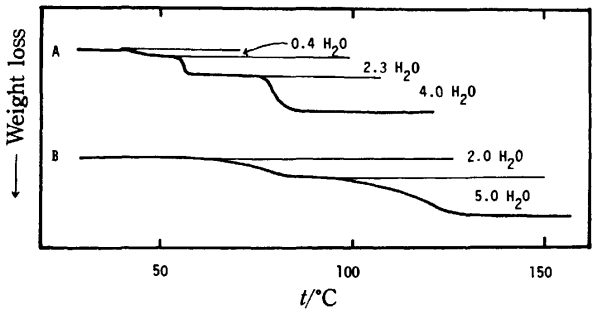

Fig. 3. TG curves of $Lu_2mal_3 \cdot 8H_2O$ obtained under two different conditions: (A) at a heating rate of 2 °C/h in water vapor at 10 Torr and (B) at a heating rate of 3 °C/min in N_2 stream of 30 cm^3/min. In both cases, some water molecules were lost before the TG measurements.**

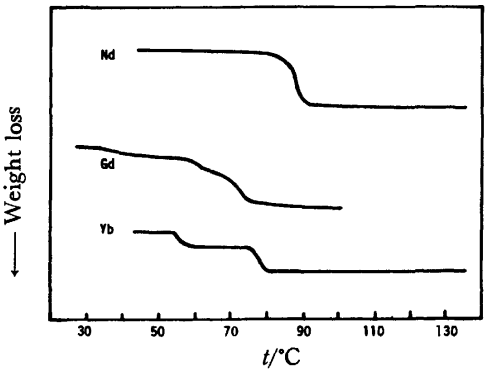

Fig. 4. TG curves of $Ln_2mal_3 \cdot nH_2O$ at the superslow heating rate in the water vapor.

Typical TG curves of other hydrates obtained under the same conditions are shown in Fig. 4. The curves of all the hexahydrates (Ce—Eu) are similar to that of Nd, in which all the coordination waters are lost in a single step. Stepwise release of waters is observed at Gd, but here the curve is dull. The curves of Tb—Yb are more or less similar, and show two clear steps as can be seen on the curve of Yb. Then comes Lu, with one more additional step as mentioned above.

The numbers of H_2O lost with each sample are now plotted in Fig. 5, just as in Fig. 2. The numbers corresponding to the complete dehydration of the octahydrates are 5 to 6, showing that they lose much of its lattice waters in advance of the TG measurement.*** About 2 H_2O among them are then lost in the first TG step, and 3 to 4 in the second. On the other hand, the hexahydrates lose about one of its coordination waters in advance, just as in the case of the TG in N_2, and then all the rest of it in a single step.

Although at present it is difficult to explain the

*** In the present case, these molecules seemingly escape from the sample during the preliminary evacuation which takes a few hours before the start of the TG measurement.

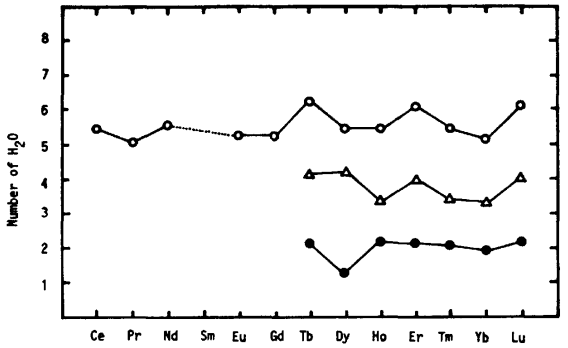

Fig. 5. Numbers of H_2O lost in the complete dehydration (○), and those lost in the first (●) and second (△) step, respectively, which were determined by TG with the superslow heating rate in the water vapor. The dehydration did not proceed completely with Sm, probably owing to the recombination of water vapor under these conditions.

complicated "ups and downs" among these numbers (see later), it is fairly certain that the mode of dehydration of the octahydrate is dependent on the atmosphere and heating rate, and the patient "squeezing" (*i.e.*, very slow heating in a diffuse water vapor) can release more water than the hasty one (*i.e.*, quick heating under 1 atm of N_2) which can only sweep out the lattice water.

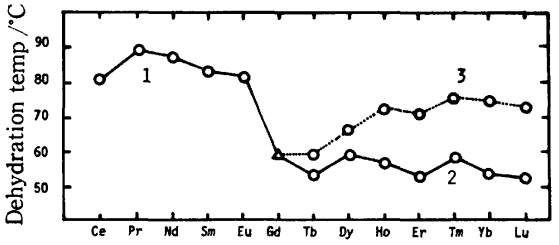

Fig. 6. Dehydration temperatures (t_i) obtained from TG with the superslow heating rate in the water vapor. As to the meaing of (1)—(3), see text. The value of Gd is given by (△), because here the two steps overlap.

The initial weight-loss temperature (t_i), or the temperature from which the TG curve begins to drop, may be taken as a measure of the relative strengths of Ln^{3+}–OH_2 bonds. In the TG studies in N_2, it was quite hard to determine exact t_i values, because all the steps observed were too dull (*cf.* Fig. 1). In the present case, the steps are much steeper (*cf.* Fig. 3), so we can quite accurately determine the t_i values for most of the steps observed, and plot them as shown in Fig. 6. The t_i values thus obtained can roughly be divided in three groups, *i.e.*: (1) Ce to Eu (hexahydrates); (2) Gd to Lu (octahydrates), 1st step; (3) Gd to Lu, 2nd step. The t_i's in the groups (1) and (3) are the temperatures at which the coordination waters hegin to escape. In both cases, in general, the t_i first rises, and then drops through a flat maximum, in the order of increasing atomic number. This can be understood as a balance between the two counteracting tendencies, *i.e.*, the strengthening of Ln^{3+}–OH_2 bond resulting from the decrease in size of Ln^{3+}, and the increase in interligand repulsion caused by the same effect. In previous studies[12,13] on lanthanoid dimethyl sulphoxide, tetrahydrothiophene 1-oxide and *N,N,N',N'*-tetramethylurea complexes, their general TG–DTA behaviours could also be explained by these two tendencies.

However, the sudden drop of the t_i at Gd (or the double periodicity between the former half and the latter half of the Ln sequence) can not be explained in such a simple way, because the lanthanoid contraction continues with little break from Ce to Lu.[14] Such "gadolinium break" has been often found among the thermodynamic data of lanthanoid complex formation in solution.[15] As one of the reasons for such a break, a change in C.N. has been suggested in the case of the formation constants of Ln^{3+} complexes with various amino polycarboxylates.[5] However, in the present case, this view is inconsistent with the trends of the t_i, since the ions of Gd—Lu with the smaller C.N. (see above) is expected to bind H_2O more strongly, and to bring about an elevation of t_i's.

By the way, among these hydrates, it is natural to suppose that the Ln^{3+}–OH_2 coordinate bonds will become weaker, when the Ln^{3+}–mal^{2-} bonds become stronger. By the X-Ray analysis,[7,9] it is known that there are two kinds of malonate ions in the hexahydrate, a chelated one and an open and bridging one, while all malonate ions in the octahydrate are chelated. These facts lead to the view that the ions of Gd—Lu are probably more suitable in size for the formation of chelate rings than those of Ce—Eu. The drop of the t_i for the malonate hydrates of the former ions thus may be due to the much more rigid Ln^{3+}–mal^{2-} bondings in them, which is reflected on the more pronounced chelation, in comparison with those in the hydrates of the latter ions.

The t_i's in the group(2) are the temperatures at which the waters squeezed out of the coordination sphere begin to escape, and generally drop from Gd to Lu, although some irregularities are observed. This kind of waters become more and more loosely held when the coordination waters lost at the last step become more and more firmly bound. The irregularities observed seem to be related to the number of H_2O contained in the hydrates, *i.e.*, the t_i's of the hydrates with more H_2O are relatively lower (*cf.* Fig. 5). These "ups and downs" may be related to the differences in the $4f^n$ electronic configurations, whose influences upon thermodynamic properties of Ln^{3+} were reviewed.[16]

In conclusion, we can say that, although the obtained results look highly complicated, their main features can be reasonably understood in view of the effects of the lanthanoid contraction.

Our cordial thanks are due to Mrs. Hiroko Yokobayashi, College of General Education, Tohoku University, for her great help in this work.

Potentiometric Study of Thermodynamic Parameters of Complexing of Lithium Ion-Basic Aprotic Solvents and Sodium Ion-Macrocyclic Polyethers in Acetonitrile

Toshio NAKAMURA,* Yasuke YUMOTO, and Kosuke IZUTSU
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received October 28, 1981)

Formation constants of the 1 : 1 complexes of lithium ion in acetonitrile (AN) with DMF, DMSO, DMA, and HMPA and of sodium ion in AN with 15-crown-5 (15C5), 18-crown-6 (18C6), dibenzo-18-crown-6 (DB18C6), and cryptand 211 (Cryp 211), were determined at 10, 25, and 40 °C by potentiometric methods with a cation-sensitive glass electrode. From the change of the formation constants with temperature, thermodynamic parameters ΔG°_{298}, ΔH°_{298}, and $-T\Delta S^\circ_{298}$, were obtained. ΔG°_{298}, ΔH°_{298}, and $-T\Delta S^\circ_{298}$, all in kJ mol^{-1}, for Li^+-solvent complexes were, respectively, -7.9, $-9._0$, $+1._1$ for DMF, -9.7, $-10._1$, $+0._5$ for DMSO, -10.0, $-9._9$, $-0._1$ for DMA, and -18.9, $-15._8$, $-3._1$ for HMPA, and those for Na^+-macrocyclic polyether complexes, -28.4, $-24._1$, $-4._5$ for 15C5, -27.2, $+1._6$, $-28._7$ for 18C6, -28.6, $-14._3$, $-14._2$ for DB18C6, and -51.9, $-53._8$, $+2._1$ for Cryp 211. Some features about the roles of enthalpy and entropy terms in complexing have been discussed.

In the previous papers,[1-5] we reported the successive formation constants of complexes of several univalent cations in acetonitrile (AN) with other donor solvents. They were obtained potentiometrically at 25 °C by using a univalent cation-sensitive glass electrode (Beckman 39047). In this paper, intending to understand the complexing phenomena in more detail, we have determined at several different temperatures the formation constants of lithium ion in AN with some basic aprotic solvents and obtained the values of ΔG°_{298}, ΔH°_{298}, and $-T\Delta S^\circ_{298}$ for the reaction shown by Eq. 1:

$$Li^+_S + D = Li^+_D, \tag{1}$$

where Li^+_S is the lithium ion solvated only by AN and Li^+_D that complexed by one molecule of solvent D. We have also obtained similar thermodynamic parameters for the complexing (Eq. 2) of the sodium ion in AN with some macrocyclic polyethers by a potentiometric method:

$$Na^+_S + L = Na^+_L, \tag{2}$$

where Na^+_S is the sodium ion solvated only by AN and Na^+_L that complexed by macrocyclic polyether L. The general construction of the cell used for the measurements was as follows:

$$\mathrm{Ag}\left|\begin{matrix}5\times10^{-3}\ \mathrm{M\ AgNO_3} + \\ 10^{-2}\ \mathrm{M\ Et_4NClO_4(AN)}\end{matrix}\right\|\begin{matrix}5\times10^{-2}\ \mathrm{M} \\ \mathrm{Et_4NClO_4(AN)}\end{matrix}\Bigg\|$$
$$10^{-3}\ \mathrm{M\ M^+ClO_4^-} + 10^{-2}\ \mathrm{M}\,\Big|\,\text{Cation-sensitive}$$
$$\mathrm{Et_4NClO_4(AN + D\ or\ L)}\,\Big|\,\text{glass electrode}$$
(Cell I)

where M^+ was Li^+_S for reaction (1) and Na^+ for reaction (2).

Complexing of the Lithium Ion in AN with Other Aprotic Solvents. The formation constant, K_1 in mol^{-1} dm^3, for reaction (1) is defined by

$$K_1 = \frac{(Li^+_D)}{(Li^+_S)[D]}, \tag{3}$$

where (Li^+_S) and (Li^+_D) are the activities of Li^+_S and Li^+_D, respectively, and [D] is the concentration of solvent D. The values of K_1 at 10, 25, and 40 °C were determined by the same method as those in the previous papers.[1-5] From the relation between $R\ln K_1$ and $1/T$, ΔH°_{298} was obtained using the SALS program of the Tokyo University Computer Center. The value of $-T\Delta S^\circ_{298}$ was obtained with the following relation:

$$-RT\ln K_1 = \Delta G^\circ_{298} = \Delta H^\circ_{298} - T\Delta S^\circ_{298}. \tag{4}$$

Complexing of the Sodium Ion in AN with Macrocyclic Polyethers. The formation constant, K in mol^{-1} dm^3, for the 1 : 1 complexing of the sodium ion in AN with a macrocyclic polyether L (Eq. 2) is defined by

$$K = \frac{(Na^+_L)}{(Na^+_S)_L[L]}, \tag{5}$$

where $(Na^+_S)_L$ and (Na^+_L) are the activities of Na^+_S and Na^+_L, respectively, and [L] is the concentration of L. Here, the activity coefficient of the sodium ion is assumed not to change on complexation. Then we may write Eq. 5 as follows:

$$K = \frac{[Na^+_L]}{[Na^+_S]_L[L]}, \tag{6}$$

There exist following relations:

$$[Na^+_L] = [Na^+_S]_{\mathrm{Init}} - [Na^+_S]_L, \tag{7}$$

$$[L] = C_L - [Na^+_L], \tag{8}$$

where $[Na^+_S]_{\mathrm{Init}}$ and $[Na^+_S]_L$ are the concentrations of Na^+_S before and after the addition of L to Cell I, and C_L shows the total concentration of L added. Equation 6 can then be written as follows:

$$K = \frac{[Na^+_S]_{\mathrm{Init}} - [Na^+_S]_L}{[Na^+_S]_L\{C_L - [Na^+_S]_{\mathrm{Init}} + [Na^+_S]_L\}}. \tag{9}$$

Here, $[Na^+_S]_{\mathrm{Init}}$ and $[Na^+_S]_L$ are related with the electrode potentials, E_{Init} before the addition of L and E_L after the addition of L, by the following equation:

$$E_L = E_{\mathrm{Init}} + \frac{RT}{F}\ln\frac{[Na^+_S]_L}{[Na^+_S]_{\mathrm{Init}}}. \tag{10}$$

To obtain K, the sodium ion in AN was titrated with a solution of L in AN up to about three times the equivalence point and the potential change during the titration was plotted. K-values which precisely fitted with the titration curves were obtained by successive approximation method. From the values of K at 10, 25, and 40 °C, values of ΔG°_{298}, ΔH°_{298}, and $-T\Delta S^\circ_{298}$ for Eq. 2 were obtained as above.

Experimental

The apparatus and experimental techniques were the same as those described before,[1,2] except that more effort was made to keep all parts of the cell assembly, including the reference electrode, precisely (within±0.2 °C) at the desired temperatures.

Nakarai's reagent grade dibenzo-18-crown-6 (DB18C6) was purified by extraction with chloroform and recrystallization from ethanol. 18-Crown-6 (18C6), 15-crown-5 (15C5), and cryptand 211 (Cryp 211) were the Merck products and were used without further purification. Hexamethylphosphoric triamide (HMPA) was a products of Johoku Chemical Industry Co. Ltd. and was purified by distilling three times under vacuum, first from barium oxide, second by the addition of small amount of sodium metal, and last without additives.[6] This HMPA was used within an hour after the purification. Other solvents and reagents were the same as those used in the previous reports.[1,2]

Results and Discussion

Before running the present experimental work, the cation-sensitive glass electrode was confirmed to respond in a Nernstian way to the activities of sodium and lithium ions in AN at 10, 25, and 40 °C. The value of the activity coefficient y used was calculated from the Debye-Hückel equation, $\log y = -AI_c^{1/2}/[1+BaI_c^{1/2}]$ ($A=1.82(\varepsilon T)^{-3/2}\times 10^6$ mol$^{-1/2}$ dm$^{3/2}$ (deg K)$^{3/2}$, $B=5.03(\varepsilon T)^{-1/2}\times 10^{10}$ dm$^{1/2}$ mol$^{-1/2}$ (deg K)$^{1/2}$, $a=5\times 10^{-9}$ dm, and I_c=ionic strength). As the dielectric constant at 10, 25, and 40 °C, respectively, 39.1, 36.7, and 34.3 were used.[7] The density of HMPA was measured to be 1.03_3, 1.02_1, and 1.00_7 g cm^{-3} at 10, 25, and 40 °C, respectively. For the densities of other solvents, we referred to literature values.[8]

Complexing of the Lithium Ion in AN with Other Aprotic Solvents. The values of K_1 for the complexing of *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), *N,N*-dimethylacetamide (DMA), and HMPA are shown in Table 1. Each value is the average of more than four determinations. Maximum concentrations of solvent D added to Cell I were 0.08 M for DMF, 0.045 M for DMSO, 0.05 M for DMA, and 0.005 M for HMPA. The relation between $R\ln K_1$ and $1/T$ for each solvent is linear, as shown in Fig. 1, and makes possible to obtain ΔH°_{298} and $-T\Delta S^\circ_{298}$. These values, calculated by using the SALS program and Eq. 4, are also shown in Table 1. It is interesting to note that, in each case, the enthalpy term plays an important role and the role of the entropy term is relatively small in determining the free energies. These results seem to be reasonable if the complexation reaction of Eq. 1 is considered to be the exchange of one solvated AN molecule with one molecule of added solvent D.

To obtain reliable ΔH°_{298}, K_1 at each temperature should be determined at least within errors of several percent. The present potentiometric method could give such K_1-values for the complexing of lithium ion with

basic aprotic solvents, as is apparent from Fig. 1 and Table 1. But the application of this method becomes somewhat difficult for the complexing of lower formation constants. We have run similar experiment for complexing of the sodium ion, but the precision of K_1 was not sufficiently good. Qualitatively, however, the smaller ΔG°_{298} for the sodium complexes could be attributed mainly to the smaller ΔH°_{298}. Work is now in progress for the complexing of other univalent cations.

Complexing of the Sodium Ion in AN with Macrocyclic Polyethers. Thermodynamic parameters for the complexing of sodium ion in AN with such macrocyclic polyethers as 15C5, 18C6, DB18C6, and Cryp211 were determined by titrating sodium ion in 0.01 M Et_4NClO_4–AN with 0.01 M Et_4NClO_4–AN solution containing 0.02—0.04 M of macrocyclic ligands. Titrations were carried out at 10, 25, and 40 °C. Some examples of the titration results are shown in Fig. 2. Curve(A) is for the titration with 18C6 and Curve(B) for that with Cryp211. In each case, the formation constant K, which fitted well with the titration results, could be found by the successive approximation method; the solid curves were obtained from Eqs. 9 and 10 using such K values. Thus the assumption of the 1 : 1 complexing is proved to be reasonable. Curve(C) in Fig. 2 is for the titration of lithium ion with Cryp211 In this case, the formation constant of Li^+–Cryp211, is expected to be larger than 10^{10} from the potential jump at the equivalence point, but it is impossible to find a K-value which fits exactly with the experimental results. This may be due to the fact that the response of the glass electrode deviates somewhat from the Nernstian one at such low activities of lithium ion in the presence of Cryp211. The values of K of the sodium complexes are shown in Table 2. log K for the complexes of Na^+–DB18C6 and Na^+–18C6 at 25 °C were 5.00 and 4.76, respectively, in good agreement with the literature values of 4.8_5—5.0_0 for Na^+–DB18C6 and 4.5_5 for Na^+–18C6.[9]

The relations between $R\ln K$ and $1/T$ are plotted in

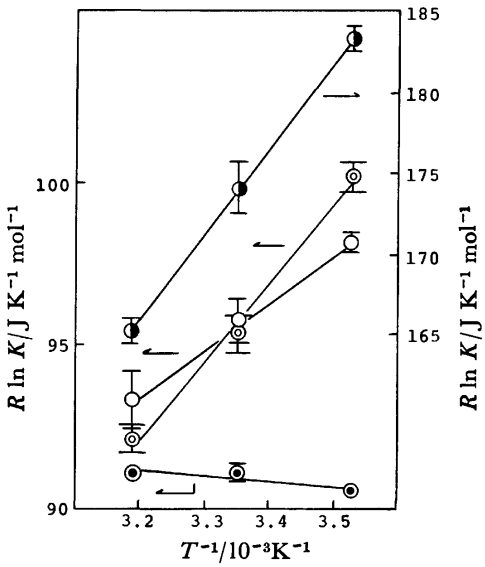

Fig. 3. Relation between $R\ln K$ for the reaction $Na^+ + L = Na_L^+$ and $1/T$.
L=15C5 (◎), 18C6 (◉), DB18C6 (○), and Cryp 211 (◑).

Fig. 3, and thermodynamic parameters obtained by the SALS program and Eq. 4 are shown in Table 2. Except for the complex with Cryp211, the formation constants are approximately the same order of magnitudes, but it is interesting to note that the factors determining the free energies of complex formation are quite different from one complex to another. For the complex with 15C5 the enthalpy term plays a predominant role, while for the complex with 18C6 the entropy term is predominant. For the complex with DB18C6, the contributions from both factors are approximately the same. The small contribution of the enthalpy term for the 18C6 complex has been found by Popov[10] in the calorimetric investigation of the lithium ion complexing ($\Delta H^\circ_{298} \approx 0$ and $-T\Delta S^\circ_{298} = 13.3$ kJ mol^{-1}). For Na^+–Cryp211, most of the free energy of formation was determined by the ethalpy term.

Because of the importance of complexes with macrocyclic polyethers, reports concerning the thermodynamic parameters of the complexing are recently increasing. Various methods, such as NMR,[10-12] conductometry,[13,14] potentiometry,[15] and calorimetry,[10,16] have been applied in several solvents. In order to discuss the mechanism of the complexing, however, the data are still too scarce. The present potentiometric method will be very convenient to obtain further information on this problem.

The Flow-injection Analysis of D-Glucose Using a Flow-cell with Immobilized Peroxidase and Its Application to Serum

Tadashi HARA,* Motohiro TORIYAMA, and Masakatsu IMAKI†
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
†*Horiba, Ltd., Kissyoin, Minami-ku, Kyoto 601*
(Received October 31, 1981)

The D-glucose concentration in a serum sample of less than 0.01 cm^3 could be continuously determined at the rate of about 20 samples/h by the use of a chemiluminescent reaction between luminol and hydrogen peroxide, a flow-cell with immobilized peroxidase, and a column with immobilized glucose oxidase. By immobilizing peroxidase as a chemiluminescent catalyst inside the flow-cell, simplification could be achieved with regard to apparatus, reagents and operation. The detection limit of hydrogen peroxide was about 5×10^{-6} mol dm^{-3}, and the calibration curves for both hydrogen peroxide and D-glucose were approximately linear in the range of 5×10^{-5}—1×10^{-3} mol dm^{-3}, a range which corresponded to the glucose concentration, 0.1—18 mg cm^{-3}, obtained by diluting serum to 50 times its initial volume.

The present study was carried out with the object of establishing a simple, rapid, and economical method by which D-glucose in a sample could be determined continuously by measuring the chemiluminescence (CL) emitted on a flow-cell with immobilized peroxidase (EC 1.2.1.7)(PO).

Generally speaking,[1] CL analysis is superior to fluorometric or absorptiometric analysis in the following points: 1) High sensitivity, 2) a wide dynamic range, 3) a simple apparatus (needs no spectrometer), and 4) an easy establishment of a continuous analysis system.

Several reports[2,3] on the chemiluminescent determination of glucose have, therefore, been published; in them, the glucose in a sample is first converted to hydrogen peroxide (H_2O_2) with fixed glucose oxidase (EC 1.1.3.4) (GO) and then determined by measuring the intensity of the CL emitted by the reaction between the H_2O_2 and 5-amino-2,3-dihydro-1,4-phthalazinedione(luminol) in the presence of potassium hexacyanoferrate(III) ($K_3[Fe(CN)_6]$) as a catalyst.

However, this method requires a considerable amount of $K_3[Fe(CN)_6]$, an environmental pollutant; moreover, it makes it imposible to recycle the used $K_3[Fe(CN)_6]$. These problems can, however, be overcome by the use of a flow-cell with immobilized PO, for PO acts on the reaction between H_2O_2 and luminol as a catalyst.[4] Though Freeman *et al.*[5] developed a CL fiber-optic probe for a batch-by-batch measurement of H_2O_2 by immobilizing the PO in a polyacrylamide gel on the end of a fiber-optic, the probe can not be used for a continuous measurement of H_2O_2 because the enzyme phase prepared by immobilizing PO and luminol by physical entrapment in a polyacrylamide gel has to be kept with a definite concentration of the luminol solution. With the use of the flow-cell with immobilized PO which has previously been proposed by the present authors, the following advantages can be expected: 1) A simple system for a how-injection analysis can be easily constructed; 2) the reagents necessary for an analysis can be minimized; 3) waste treatment becomes easier than in conventional methods in which $K_3[Fe(CN)_6]$, cupper(II), cobalt(II), and so on are used as catalysts, and 4) an improvement is made in the selective measurement of glucose because of the PO specificity for H_2O_2.

In the present paper, a flow-cell with immobilized PO has been successfully applied to the determination of glucose and then extended to serum.

Experimental

Immobilization of Glucose Oxidase. GO (Toyobo, grade II, 100 U/mg) was immobilized on 80—120 mesh of porous glass beads (CPG-10, pore size 7500 nm) in accordance with the diazotization method of Weetall[6] after the introduction of an aminoalkyl group[7] onto the porous glass beads.

Immobilization of Peroxidase. Five procedures were tried for the immobilization of PO, and the following procedure was found to be most satisfactory: A glass disk 12 mm in diameter and 1.8 mm thick, with one ground plane, was refluxed for 6 h in a 2% (3-aminopropyl)ethoxysilane solution in toluene. The glass-disk was dried at 60 °C after washing with toluene, and then refluxed for 6 h in a chloroform solution containing 5% triethylamine and 10% *p*-nitrobenzoyl chloride. The glass-disk was washed with chloroform and dried. The nitro group on the glass-disk was reduced by refluxing for 1 h with a 5% sodium dithionite solution. After the glass-disk has been washed with water, it was dipped in a 1 mol dm^{-3} hydrochloric acid solution, 3 cm^3 of a 0.5 mol dm^{-3} sodium nitrite solution was added at 0 °C over 15 min, and the mixture was reacted for an additional 15 min. The glass-disk was picked up, washed with a 5% sulfamic acid solution and water in that order, and immediately dipped in a 5 cm^3 solution of PO (Toyobo, grade III, 102 U/mg) at the concentration of 1 mg cm^{-3}, the PO have previously been made to react with

the glass-disk for 48 h at 3 °C. Thus, the glass-disk with immobilized PO was obtained.

All the reagents were of an analytical grade and were used without further purification.

Procedure. The determination of glucose was done with the apparatus shown in Fig. 1. A Teflon-made tube (1 mm i. d.) and Teflon-made joints (GU-2F and GT-2F, Gasukuro Kogyo) are used for piping. The flow path between (d) and (i) is about 80 cm long. Figure 1(a) is filled with a 1.0×10^{-3} mol dm^{-3} luminol solution (pH 8.6) containing a 10^{-4} mol dm^{-3} EDTA solution and a boric acid–potassium chloride–sodium hydroxide buffer solution, and (b), with a potassium dihydrogenphosphate–sodium hydroxide buffer solution (pH 7.1). These solutions are both fed in at the rate of 0.99 cm^3 min^{-1} by means of a pump (c) (Tokyo Rikakikai, MP-12, Micro Tube Pump). By the use of the present pump, two flows can be driven simultaneously, and pulsation in a flow after mixing is minimized, thus resulting in the stabilization of a base line on a recorder chart. The capacity of the sampling loop (e) is about 0.2 cm^3, and each definite volume of the sample solution is injected into a column (g) by rotating a six-way cock (d). After being passed through a 100 mm × 3 mm i.d. column (g) charged with DEAE-cellulose (Nakarai Chemicals, 0.89 mequiv. g^{-1}), the sample solution is introduced into a 250 mm × 3 mm i.d. column (h) charged with the glass beads with immobilized GO; in this column, the β-D-glucose in a sample is converted to gluconic acid and H_2O_2 by means of an enzyme reaction. The H_2O_2 evolved is mixed with a luminol solution immediately before it enters the flow-cell (i) with immobilized PO, and the resulting solution is brought to pH 8.4 by means of the previous calibration. The CL emitted by the chemiluminescent reaction on the flow-cell with immobilized PO is converted to the photocurrent with a photomultiplier (j) (Hamamatsu TV, R-374), and the photocurrent is amplified with a Horiba OPE-402 amplifier, followed by recording with a recorder (Matsushita Communication Industrial, VP6521A). The determination of glucose in a sample is done from the peak height on a recorder chart.

The flow-cell with immobilized PO is shown in Fig. 2. The internal volume of the flow-cell is about 0.2 cm^3, and the glass-disk (d) with immobilized PO is installed as in Fig. 2.

Results and Discussion

Immobilization of Peroxidase. In order to immobilize PO onto the flow-cell (Fig. 1(i)), an investigation was carried out with regard to the following five procedures: 1) Fixation onto the porous glass beads (CPG-10; 80—120 mesh; pore size, 7500 nm) by the glutaraldehyde method[8] after the introduction of an aminoalkyl group; 2) fixation onto the same aminoalkylated porous glass beads as 1) by the diazotization method;[6] 3) fixa tion onto the 6-Nylon disk by the glutaraldehyde method[9] after the partial hydrolysis of 6-Nylon; 4) fixation by physical entrapment[10] into a gel made of alubumin and glutaraldehyde, and 5) fixation onto the glass-disk by the diazotization method.

The glass beads with PO immobilized by Procedures 1) and 2) were charged respectively in Tygon tubes (2 mm i.d.); the tubes were subsequently coiled spirally and used as flow-cells. However, they were not sensitive enough for the present purpose, for the light generated by the chemiluminescent reaction was scattered to all directions. Both the 6-Nylon disk and the gel immobilized with PO by Procedures 3) and 4) were set as in Fig. 2(d) and used as flow-cells. They were first senstive enough, but rapidly became low in sensitivity with the lapse of time because of the lowering of the enzyme activity. The glass-disk with PO immobilized by procedure 5) was best in both the intensity of CL and its life, a and it still showed stable activity as a chemiluminescent catalyst even after analyses of up to 300 samples.

Effect of Luminol Concentration. The relationship between the luminol concentration and the CL intensity is shown in Fig. 3. As can be seen there, the maximum intensity of CL was obtained by the use of a 1.0×10^{-3} mol dm^{-3} luminol solution.

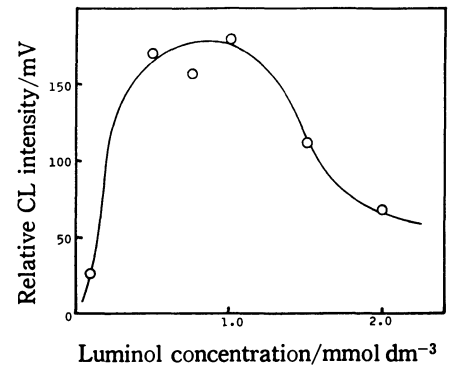

Fig. 3. Effect of luminol concentration on CL intensity.
Experimental conditions: flow rate 1.98 cm^3 min^{-1}; pH 7.8. Sample: 1.03×10^{-4} mol dm^{-3} H_2O_2.

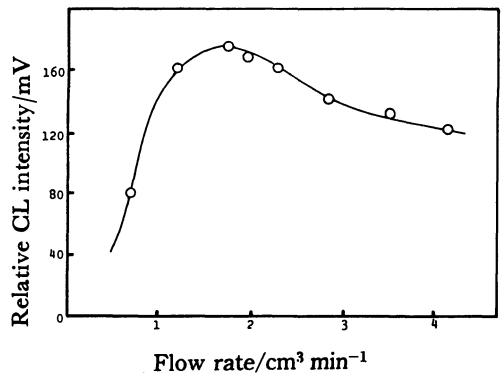

Fig. 4. Effect of flow rate on CL intensity.
Experimental conditions: 1.0×10^{-3} mol dm^{-3} luminol; pH 7.8. Sample: 1.03×10^{-4} mol dm^{-3} H_2O_2.

Effect of Flow Rate. The flow rate is an important parameter and has a close relation with the sensitivity, the precision, and the speed in flow-injection analysis. The relationship between the flow rate of a sample solution and the intensity of CL is shown in Fig. 4. The maximum in Fig. 4 is characteristic for the present flow-cell with immobilized PO, while the maximum intensity of CL appeared around a flow rate of 1.8 cm^3 min^{-1}. This phenomenon is explained as follows: 1) The intensity of CL at a flow rate less than about 1.8 cm^3 min^{-1} increases with an increase in the flow rate because the amounts of luminol and H_2O_2 fed into the flow-cell within a definite period increase with an increase in the flow rate, and the flow rate does not seriously affect the diffusion amounts of luminol and H_2O_2 to the enzyme phase, and 2) the intensity of CL at a flow rate of more than about 1.8 cm^3 min^{-1} decreases with an increase in the flow rate because the amounts of luminol and H_2O_2 fed into the flow-cell within a definite period increase with an increase in the flow rate, but the diffusion amounts of luminol and H_2O_2 into the enzyme phase are considerably lowered with an increase in the flow rate. The reaction rate between luminol and H_2O_2 on the present flow-cell with immobilized PO can be expected to be very large, since the reaction between luminol and H_2O_2 in the presence of free PO has been reported by Cormier *et al.*[4] to proceed to completion within 0.2 s. This confirms the usefulness of the present flow-cell with immobilized PO for the determination of glucose.

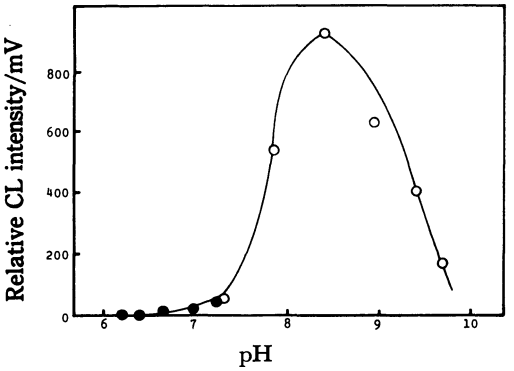

Fig. 5. Effect of pH on CL intensity.
Experimental conditions: 1.0×10^{-3} mol dm^{-3} luminol; flow rate 1.98 cm^3 min^{-1}; ●: KH_2PO_4–NaOH buffer solution, ○: H_3BO_3–KCl–NaOH buffer solution. Sample: 1.03×10^{-4} mol dm^{-3} H_2O_2.

Effect of pH. The catalytic activity of free PO shows its maximum around pH 6, whereas the quantum yield of CL between luminol and H_2O_2 shows its maximum around pH 11.[11] Therefore, the optimum pH for the maximum intensity of CL should be expected in the reaction between luminol and H_2O_2 in the presence of PO. The relationship between the pH of a solution and the intensity of CL is shown in Fig. 5. As can be seen from Fig. 5, the maximum intensity was obtained around pH 8.4.

On the basis of these experimental results, the experimental conditions for the maximum intensety of CL were chosen as follows: Flow rate, 1.98 cm^3 min^{-1}; luminol concentration, 1.0×10^{-3} mol dm^{-3}, and pH, 8.4.

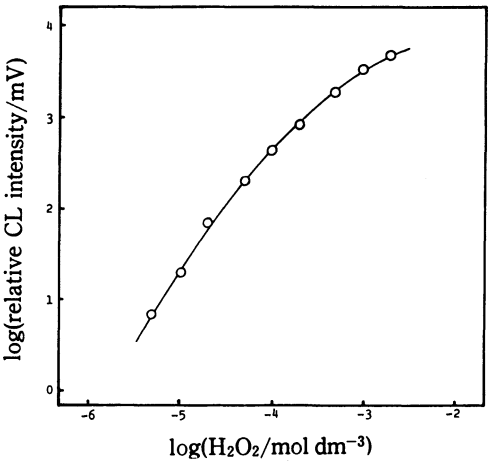

Fig. 6. Calibration curve for H_2O_2.

Calibration Curve of H_2O_2. The calibration curve of H_2O_2 as a sample is shown in Fig. 6. The time necessary for an analysis by means of the present apparatus with a DEAE-cellulose column and an immobilized GO column was about 3 min, while it was 30 s when an apparatus without the above columns was used. Since the band broadening of a sample was observed when it was passed through those columns, a sample was injected every 3 min to avoid overlapping of peaks. The detection limit for H_2O_2 was about 5×10^{-6} mol dm^{-3}, more or less inferior to that obtained by the use of $K_3[Fe(CN)_6]$ as a catalyst. The calibration curve was approximately linear between 5×10^{-5} mol dm^{-3} and 1×10^{-3} mol dm^{-3} H_2O_2. The intensity of CL at a H_2O_2 concentration of more than 1×10^{-3} mol dm^{-3} deviated from the straight line, but this was due to the fact that the experiment was carried out at a definite concentration of the luminol solution, while the chemiluminescent reaction gradually depended on the concentration of the luminol solution. At a H_2O_2 concentration of less than 5×10^{-5} mol dm^{-3}, the slope of the calibration curve shown by the log-log plot approaches 2, but this phenomenon is similar to that obtained by the CL fiber optic probe proposed by Freeman *et al.*[5]

Calibration Curve of D-*Glucose.* The calibration curve of D-glucose as a sample is shown in Fig. 7. The intensity of CL in Fig. 7 was smaller than the corresponding intensity in Fig. 6. This is mainly attributed to the fact that D-glucose is composed of about 66% of β-D-glucose, 34% of α-D-glucose, and a trace amount of aldehyde-type D-glucose, while only the β-D-glucose is made to react with GO. The large deviation from the straight line at a concentration of D-glucose of more than 1×10^{-3} mol dm^{-3} may be attributed to the treatment capacity of the column with immobilized GO. According to the present apparatus, an approximately linear calibration curve is obtained in the concentration range of 5×10^{-5}—1×10^{-3} mol dm^{-3} glucose.

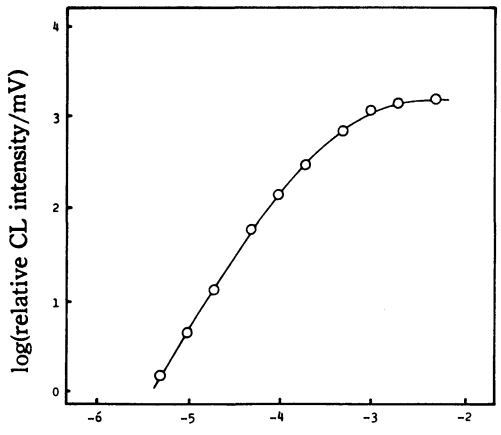

Fig. 7. Calibration curve for glucose.

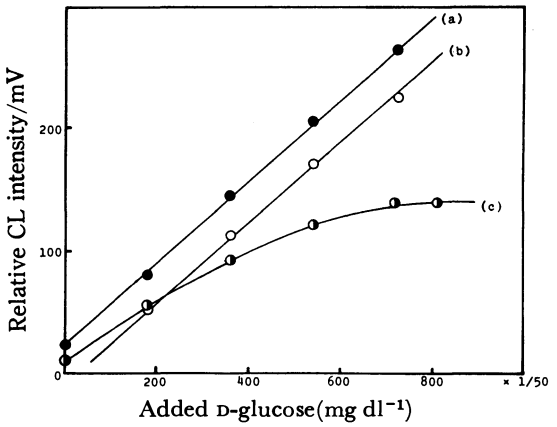

Fig. 8. Calibration curve for glucose added to serum. a: Serum+D-glucose, b: D-glucose, c: serum+D-glucose (without using a DEAE-cellulose column).

Determination of D-*Glucose in Serum.* About 1 mg cm^{-3} of glucose is contained in a normal human serum. Therefore, the concentration of glucose in a serum is brought to around 10^{-4} mol dm^{-3} by diluting it to 50 times its initial volume; it can be expected to be determined by the use of the linear part of the calibration curve in Fig. 7. Then, the relationship between the amount of glucose added and the intensity of the CL was examined after Hyland Control Serum I had been diluted to 50 times its initial volume. The results obtained are shown in Fig. 8. When an experiment was done without using a column(g) (Fig. 1), serum proteins were captured on the glass-disk with immobilized PO. This resulted in markedly lowering the intensity of CL (Fig. 8(c)), and no correlation was found between, the amount of glucose added and the intensity of the CL after analyses of 20 samples.

In order to avoid the capture of serum proteins on the above-mentioned glass-disk, a 100 mm × 3 mm i.d. column charged with various capturing agents was placed between a six-way cock (Fig. 1(d)) for sampling and a column (Fig. 1(h)) with immobilized GO. The efficiency of the capturing agents for the capture of serum proteins was examined by the use of: 1) Glass beads (80—120 mesh), 2) active charcoal (35—60 mesh), 3) silica gel (60—80 mesh), 4) activated alumina (about 200 mesh), and 5) DEAE-cellulose. Glass beads were not effective for the capture of serum proteins. Active charcoal captured serum proteins as well as glucose, and no serum proteins were observed on the glass-disk with immobilized PO. Here, the peak on a recorder chart showed tailing phenomenon and the intensity of the CL was considerably smaller than the expected value. Silica gel, activated alumina, and DEAE-cellulose were more or less effective for the removal of the interference of serum proteins, but DEAE-cellulose was most excellent in peak height and reproducibility (Fig. 8(a)).

The CL observed without adding glucose to serum in Fig. 8(a) is attributed to the glucose contained in Hyland Control Serum I. There was a parallel relationship between the calibration curve (Fig. 8(a)) obtained by adding glucose to Hyland Control Serum I and the calibration curve (Fig. 8(b)) obtained by glucose alone, where the difference between the intensities of the two lines corresponded approximately to a 1 mg cm^{-3} of glucose concentration in serum.

Judging from the complexity of serum composition, the standard addition method in which, for example, two serum samples are diluted to 50 times their initial volume with water and a definite concentration of a glucose solution respectively, seems to be most recommendable for the rapid and exact determination of glucose in serum by the present method.

It is concluded from the above results that a glucose concentration in serum of less than 0.01 cm^3 can be continuously determined at the rate of about 3 min/sample by the present method, in which a flow-cell with immobilized PO is used.

A Calorimetric Study on the Relative Thermal Stability in Some Nickel(II) Complexes Containing *N,N'*- or *N,N*-Diethylethylenediamine

Ryokichi Tsuchiya,* Akira Uehara, and Yoshiyuki Ohtsuka
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received November 24, 1981)

The enthalpy changes (ΔH) in the reaction of $Ni(AA)_2X_2 \cdot nH_2O$ type complexes with aqueous potassium cyanide were calorimetrically measured at 25 °C, where AA is *N,N'*-diethylethylenediamine (*NN'*-deen) or *N,N*-diethylethylenediamine (*NN*-deen); X is Cl^-, Br^-, I^-, or NO_3^- ion; and *n* is 0 or 2. On the basis of the enthalpy data measured, the thermal stability was compared among chloride, bromide, iodide, and nitrate in the following each group of compounds: $Ni(NN'\text{-deen})_2X_2 \cdot 2H_2O$, $Ni(NN'\text{-deen})_2X_2$, $Ni(NN\text{-deen})_2X_2 \cdot 2H_2O$, and $Ni(NN\text{-deen})_2X_2$. The thermal stability was found to decrease in the order, chloride>bromide>nitrate>iodide in each group. Comparison of the enthalpy data between the chlorides of the *NN'*-deen and *NN*-deen complexes revealed the difficulty of anation in the latter rather than in the former. $[Ni(NN\text{-deen})_2(H_2O)_2]Br_2$ was, when heated, converted into $[Ni(NN\text{-deen})_2]Br_2$ without anation differing from the chloride. The difference was also discussed on the basis of the enthalpy data.

Nickel(II) complexes are fascinating compounds from the viewpoint that they have a possibility to take various coordination structures easily capable of transforming to each other in the solution and in the solid phase.[1] The equilibria and mutual conversions are most familiarly investigated among their tetrahedral, square planar, and octahedral configurations.[2]

We have already reported that the compounds $[Ni(NN'\text{-deen})_2(H_2O)_2]X_2$ (*NN'*-deen: *N,N'*-diethylethylenediamine; X: Cl^-, Br^-, I^-, or NO_3^- ion) undergo anation to form $[NiX_2(NN'\text{-deen})_2]$ upon heating in the solid phase still keeping the octahedral environment.[3] On the other hand, the complexes $[Ni(NN\text{-deen})_2(H_2O)_2]X_2$ (*NN*-deen: *N,N*-diethylethylenediamine; X: Cl^- or Br^-) display some different thermal reactions from the *NN'*-deen complexes: *i.e.*, the chloride undergoes anation in a manner similar to the corresponding *NN'*-deen compounds, but the bromide deaquates to form square planar complexes. In addition, in the case of the iodide and nitrate, we always failed in attempting to prepare the octahedral diaqua complexes like the chloride or bromide, but exclusively obtained the square planar $[Ni(NN\text{-deen})_2]X_2$.[4]

It is therefore worthwhile to know why such differences take place in the thermal reaction. The present study was undertaken (1) to measure calorimetrically the enthalpy changes (ΔH) in the reaction of $Ni(AA)_2X_2 \cdot nH_2O$ (AA: *NN'*- or *NN*-deen; X: Cl^-, Br^-, I^-, or NO_3^- ion; *n*: 0 or 2) with aqueous potassium cyanide, (2) to compare the thermal stability of these complexes on the basis of the enthalpy changes obtained, and (3) to try to interprete the difference of the features appearing in the thermal reactions in the solid phase.

Experimental

Preparation of Complexes. $Ni(NN'\text{-deen})_2X_2 \cdot nH_2O$,[5] and $Ni(NN\text{-deen})_2X_2 \cdot nH_2O$[6] (X=$Cl^-$, Br^-, I^-, and NO_3^-; *n*=0 and 2) were prepared by the known method and identified by the chemical analysis and the electronic spectra.

Calorimetric Measurements. In order to discuss the thermal stability of these complexes, the enthalpy changes in the reaction of them in the powder state with potassium cyanide solution were measured with Tokyo-Riko twin isoperibol calorimeter TIC-2S at 25 °C. In each run, the diamine complexes employed were accurately weighed in the range of order of 1×10^{-4} mol and the aqueous potassium cyanide employed was 100 cm^3 of 6×10^{-2} mol dm^{-3} solution. The reactions proceeded quantitatively, for example, according to the Eqs. 1 and 2, and the enthalpy changes (ΔH) for each reaction were estimated as mentioned in the later section.

Results and Discussion

Thermal Stability in the NN'*-deen Complexes.* The enthalpy changes for the *NN'*-deen and *NN*-deen complexes measured are summarized in Table 1. The enthalpy changes for the reaction of diaquabis(*NN'*-deen)chromium(III) chloride and bromide with potassium cyanide solution are given as below,

$$[Ni(NN'\text{-deen})_2(H_2O)_2]Cl_2(s) + 4CN^-(aq) = Ni(CN)_4^{2-}(aq) + 2NN'\text{-deen}(aq) + 2Cl^-(aq) + 2H_2O(l) \quad \Delta H = -128\ 8\ kJ\ mol^{-1} \quad (1)$$

$$[Ni(NN'\text{-deen})_2(H_2O)_2]Br_2(s) + 4CN^-(aq) = Ni(CN)_4^{2-}(aq) + 2NN'\text{-deen}(aq) + 2Br^-(aq) + 2H_2O(l) \quad \Delta H = -103.3\ kJ\ mol^{-1}. \quad (2)$$

Table 1. Enthalpy changes for the reaction of nickel(II)-bis(diamine) complexes with CN^- (kJ mol^{-1})[a]

X^-	AA=*NN'*-deen		*NN*-deen	
Cl^-	Oh	Oh'	Oh	Oh'
	−128.8	−143.5	−121.4	−155.6
Br^-	Oh	Oh'	Oh	Sq
	−103.3	−128.3	−96.2	−102.0
I^-	Oh	Oh'	Sq	
	−81.6	−177.8	−111.6	
NO_3^-	Oh	Oh'	Sq	
	−91.3	−124.3	−113.6	

a) Oh designates the octahedral diaquabis(diamine) complexes $[Ni(AA)_2(H_2O)_2]X_2$, Oh', the octahedral diacidobis(diamine) complexes $[NiX_2(AA)_2]$produced by the anation of the former, and Sq means the square-planar bis(diamine) complexes $[Ni(AA)_2]X_2$.

By combining these two enthalpy changes with the following values,

$Cl^-(aq) = Cl^-(g)$ $\Delta H = -76.5$ kJ mol^{-1} [7]

$Br^-(aq) = Br^-(g)$ $\Delta H = -110.5$ kJ mol^{-1},[8]

the enthalpy change for the reaction,

$$[Ni(NN'\text{-deen})_2(H_2O)_2]Cl_2(s) + 2Br^-(g) = [Ni(NN'\text{-deen})_2(H_2O)_2]Br_2(s) + 2Cl^-(g),$$

was calculated as ΔH=42.5 kJ mol^{-1}. This value corresponds to the difference of lattice energy between the chloride and bromide: this result reflects that the bromide is thermally more unstable by this value than the chloride.

In the same way, by using the enthalpy data measured for the iodide (ΔH=$-$81.6 kJ mol^{-1}) and nitrate (ΔH=$-$91.3 kJ mol^{-1}) and those for the following changes,

$I^-(aq) = I^-(g)$ $\Delta H = -154.0$ kJ mol^{-1} [9]

$NO_3^-(aq) = NO_3^-(g)$ $\Delta H = -128.9$ kJ mol^{-1},[10]

the enthalpy changes for the substitution reaction of the chloride by iodide or nitrate ion were obtained as follows:

$$[Ni(NN'\text{-deen})_2(H_2O)_2]Cl_2(s) + 2X^-(g) = [Ni(NN'\text{-deen})_2(H_2O)_2]X_2(s) + 2Cl^-(g)$$

$\Delta H = 107.9$ kJ mol^{-1} for X = I^-

$\Delta H = 67.4$ kJ mol^{-1} for X = NO_3^-

These values are the difference of the lattice energies between the iodide or nitrate and the chloride.

As seen from Table 1, the enthalpy changes for the octahedral diacido complexes $[NiX_2(NN'\text{-deen})_2]$ formed by the anation of the octahedral diaqua complexes $[Ni(NN'\text{-deen})_2(H_2O)_2]X_2$ were measured as $-$143.5, $-$128.3, $-$117.8, and $-$124.3 kJ mol^{-1} for the chloride, bromide, iodide, and nitrate, respectively. By analogous calculations to the diaqua complexes, the enthalpy changes for the following substitution reactions were estimated. These values correspond to the

$$[NiCl_2(NN'\text{-deen})_2](s) + 2X^-(g) = [NiX_2(NN'\text{-deen})_2](s) + 2Cl^-(g)$$

$\Delta H = 52.8$ kJ mol^{-1} for X = Br^-

$\Delta H = 129.4$ kJ mol^{-1} for X = I^-

$\Delta H = 85.7$ kJ mol^{-1} for X = NO_3^-

decrements of lattice energy of the bromide, iodide, and nitrate from that of the chloride. As expected from the equation of lattice energy by Kapustinskii,[11] the lattice energy decreases as the radius of anion increases if the cation is the same. The radius of Cl^-, Br^-, I^-, and NO_3^- are 1.18,[12] 1.96,[12] 2.16,[13] and 1.89 Å,[14] respectively. The order of decrement of lattice energy observed in the diaqua and diacido complexes is, therefore, parallel to the increasing order of the radius except for the case of the nitrate.

The enthalpy level diagram for the *NN'*-deen complexes by using the enthalpy data obtained above is illustrated in Fig. 1. It is obvious from the figure that the thermal stability decreases in the order, chloride> bromide>nitrate>iodide, both in the diaqua and diacido series. The enthalpy changes in the dehydration

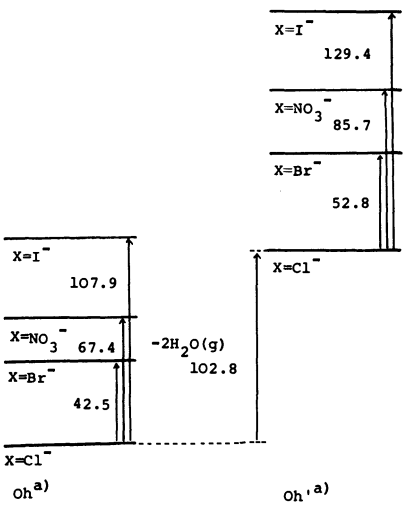

Fig. 1. Enthalpy level diagram for the *NN'*-deen complexes. The numerals are expressed by the unit of kJ mol^{-1}.
a) These designations are the same as those employed in Table 1.

followed by the anation were obtained by combining the heat of vaporization of water with the enthalpy changes measured for the reaction of $[Ni(NN'\text{-deen})_2(H_2O)_2]X_2$ or $[NiX_2(NN'\text{-deen})_2]$ type complexes with potassium cyanide solution. The value found in the dehydration of the chloride is 102.8 kJ mol^{-1} (Fig. 1).

Thermal Stability in the NN*-deen Complexes.* The enthalpy changes for the reaction of $[Ni(NN\text{-deen})_2(H_2O)_2]Cl_2$ and $[Ni(NN\text{-deen})_2(H_2O)_2]Br_2$ with aqueous potassium cyanide corresponding to Eqs. 1 and 2 were measured as ΔH=$-$121.4 kJ mol^{-1} and ΔH=$-$96.2 kJ mol^{-1}, respectively, in a manner similar to those for the *NN'*-deen complexes (Table 1). The difference of the lattice energy between the chloride

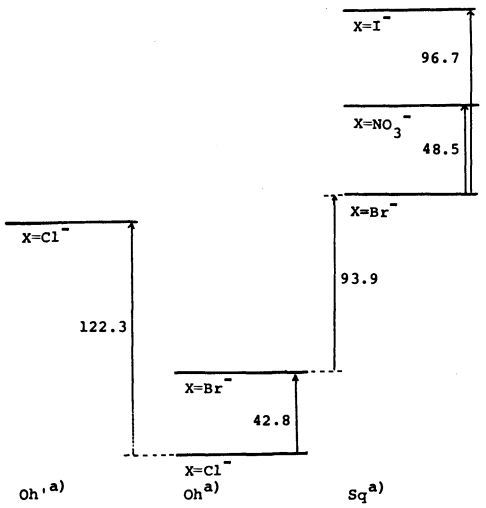

Fig. 2. Enthalpy level diagram for the *NN*-deen complexes. The numerals are expressed by the unit of kJ mol^{-1}.
a) These designations are the same as those employed in Table 1.

and bromide was estimated as ΔH=42.8 kJ mol^{-1}. The enthalpy level diagram for the *NN*-deen complexes, including the latter value, is presented in Fig. 2.

In the thermal reaction of the *NN'*-deen complexes in the solid phase, the anation was generally found, but only a slight difference was shown in ease of anation depending upon the kind of anations. It is probably due to the lesser steric effect of two equatorial ethyl groups in *NN'*-deen upon anation relative to *NN*-deen. On the contrary, the *NN*-deen complexes have at least one axial ethyl group in each *NN*-deen chelate ring, and hence notable steric effect may be expected. For example, as stated in the introduction, the chloride of the *NN*-deen complex undergoes anation, whereas the corresponding bromide is converted into square planar complex after losing the coordinated water.

The enthalpy change in the dehydration accompanied by the anation, from [Ni(*NN*-deen)$_2$(H_2O)$_2$]Cl_2 to [$NiCl_2$(*NN*-deen)$_2$], was obtained as ΔH=122.3 kJ mol^{-1} in the same way as that for the corresponding *NN'*-deen complex. In [Ni(*NN*-deen)$_2$(H_2O)$_2$]Br_2, on the other hand, the enthalpy change in the dehydration followed by the formation of square planar complex without anation was obtained as ΔH=93.9 kJ mol^{-1} by employing the measured value for [Ni(*NN*-deen)$_2$]-Br_2, ΔH=−102.0 kJ mol^{-1} (Table 1, Fig. 2). In the iodide and nitrate, the diaqua complexes were not obtained, but prepared only in anhydrous square planar configuration as mentioned in the introduction. For these square planar complexes, the differences of lattice energies of the iodide and the nitrate from the bromide were calculated as ΔH=96.7 and 48.5 kJ mol^{-1}, respectively. From Fig. 2, the thermal stability for the square planar complexes decreases in the order, bromide>nitrate>iodide.

Difference in Thermal Stability between the NN'*-deen and* NN*-deen Complexes.* The enthalpy change for the reaction of [Ni(NN'-deen)$_2$(H_2O)$_2$]Cl_2 with aqueous potassium cyanide expressed by Eq. 1, ΔH=−128.8 kJ mol^{-1}, and that for the reaction of the corresponding *NN*-deen complex, ΔH=−121.4 kJ mol^{-1} (Table 1), were combined with the following values:

NN'-deen(l) = *NN'*-deen(aq)	ΔH = −48.5 kJ mol^{-1}
NN'-deen(l) = *NN'*-deen(g)	ΔH = 37.6 kJ mol^{-1}
NN-deen(l) = *NN*-deen(aq)	ΔH = −44.0 kJ mol^{-1}
NN-deen(l) = *NN*-deen(g)	ΔH = 37.0 kJ mol^{-1}.

Here, the heats of dissolution of *NN'*-deen (ΔH=−48.5 kJ mol^{-1}) and *NN*-deen (ΔH=−44.0 kJ mol^{-1}) were measured with the calorimeter, and the heats of vaporization of *NN'*-deen (ΔH=37.6 kJ mol^{-1}) and *NN*-deen (ΔH=37.0 kJ mol^{-1}) were calculated from their boiling points and Trouton's constant. The enthalpy change in the reaction,

[Ni(*NN'*-deen)$_2$(H_2O)$_2$]Cl_2(s) + 2*NN*-deen(g)
= [Ni(*NN*-deen)$_2$(H_2O)$_2$]Cl_2(s) + 2*NN'*-deen(g),

was thus calculated as ΔH=2.8 kJ mol^{-1}. The enthalpy change for substituting *NN'*-deen by *NN*-deen in the bromide was obtained as ΔH=3.1 kJ mol^{-1} in the same way as that employed in the chloride.

Figure 3 illustrates the enthalpy level diagram for the

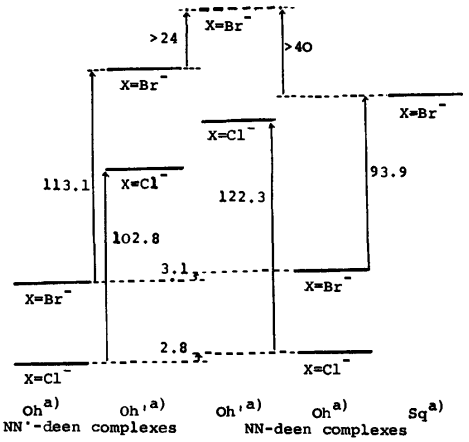

Fig. 3. Enthalpy level diagram for the chlorides and bromides of the *NN'*-deen and *NN*-deen complexes. The numerals are expressed by the unit of kJ mol^{-1}. a) These designations are the same as those employed in Table 1.

chlorides and bromides of the *NN'*-deen and *NN*-deen complexes. It is found from the figure that the enthalpy (ΔH=122.3 kJ mol^{-1}) required for [Ni(*NN*-deen)$_2$-(H_2O)$_2$]Cl_2 to form [$NiCl_2$(*NN*-deen)$_2$] is greater than that (ΔH=102.8 kJ mol^{-1}) for [Ni(*NN'*-deen)$_2$(H_2O)$_2$]-Cl_2 to form [$NiCl_2$(*NN'*-deen)$_2$]. This suggests that the former undergoes anation with more difficulty than the latter. It is probably due to the presence of an exial ethyl group in the *NN*-deen complex and its absence in the *NN'*-deen complex. Such a difference between *NN*-deen and *NN'*-deen complexes is also expected in the bromide, but we were unable to estimate the difference because [$NiBr_2$(*NN*-deen)$_2$] was not prepared. It is, however, assumed that the anation of [Ni(*NN*-deen)$_2$(H_2O)$_2$]Br_2 is not so easy as that of the corresponding chloride because bromide ion has larger radius than chloride ion. Therefore, the enthalpy level for the imaginary [$NiBr_2$(*NN*-deen)$_2$] may be expected to be higher by >24 kJ mol^{-1} than that of the corresponding *NN'*-deen complex as shown by a broken line (Fig. 3). In addition, as seen obviously in the diagram, the enthalpy level for the imaginary [$NiBr_2$(*NN*-deen)$_2$] is much higher (>40 kJ mol^{-1}) than that for [Ni(*NN*-deen)$_2$]Br_2. This might be the reason why [Ni(*NN*-deen)$_2$(H_2O)$_2$]Br_2 is, when heated in the solid phase, converted into the square planar complex without anation.

Solvent Dependence of the Circular Dichroism Spectra of Some *cis*-Dianionobis(ethylenediamine)cobalt(III) Complexes

Ushio SAKAGUCHI, Hiroshi NAKAZAWA, Kazuhisa SAKAI, and Hayami YONEDA*

(Received December 17, 1981)

The circular dichroism spectra of some *cis*-bis(ethylenediamine)cobalt(III) complexes have been measured in several solvents. Among these complexes, the diisothiocyanato complex was found to exhibit a marked solvent dependence; the dominant circular dichroism band in the lowest energy spin-allowed transition region changed its sign upon going from, *e.g.*, water, dimethyl sulfoxide, methanol, or acetone to pyridine or its analogues. Coupled with the proton NMR spectra and a similar solvent dependence of the circular dichroism spectra of nitroisothiocyanatobis(ethylenediamine)cobalt(III) and diisothiocyanatobis(ethylenediamine)chromium(III) complexes, we ascribed the origin of the sign inversion of the diisothiocyanato complex to the stereoselective hydrogen bonding of *cis* N–H_B with pyridine-like molecules, where *cis* N–H_B is the hydrogen bonded to the nitrogen atom *cis* to NCS^- and directed off the molecular twofold axis.

It has been known for some time that the optical activity of some organic compounds is solvent dependent and this effect has been used, for example, for conformational analysis.[1] In the field of coordination chemistry, however, no systematic studies have been made on the effect of solvents upon the optical activity of metal complexes.[2] Recently, Bosnich and Harrowfield[3] found that the circular dichroism (CD) spectra of bobalt(III) complexes of the type *trans*-$[Co(N)_4(X)_2]^+$ are particularly sensitive to solvents, where $(N)_4$ represents chiral quadridentate amine ligands. Depending upon the solvent, some of these complexes changed even the sign of rotational strength of the lowest energy spin-allowed $^1A_{1g}$ to $^1T_{1g}(D_{4h})$ circular dichroism, which owes its origin to the so-called vicinal effect. Although they examined many closely related systems extensively, no definite conclusion was reached about the origin of the large CD variations observed. Subsequently, Hawkins *et al.*[4] investigated the CD and proton NMR spectra of some *trans*-$[Co(R\text{-pn})_2(X)_2]^{n+}$ and related complexes in several solvents, where *R*-pn is (*R*)-1,2-propanediamine. They ascribed the prominent solvent dependence of the CD spectra to the stereoselective hydrogen bonding that is formed between the equatorial amino hydrogens of the complex cation and the solvent molecule, rendering the coordinated nitrogens asymmetric.

Though several other scattered examples can be found in the literature[5] which describes significant solvent variation of CD spectra of metal complexes, no further attempt appears to be made at the elucidation of the solvent variation *per se*. In the above, we confined our interest to such systems that contain no chiral solvents, because in chiral solvents additional sources of complication might arise due to, *e.g.*, induced CD,[6] asymmetric transformation,[7] or the Pfeiffer effect.[8]

We have studied the CD spectra of some optically stable *cis*-dianionobis(ethylenediamine)cobalt(III) complexes, *cis*-$[Co(en)_2(X)_2]^{n+}$, in several solvents, where en=ethylenediamine and $(X)_2$=$(CN)_2$, $(NO_2)_2$, $(NCS)_2$, $(N_3)_2$, oxalate, acetylacetonate, $(NH_3)_2$, and en. These substituents range from strong- to weak-field ligands in the spectrochemical series. The diisothiocyanato and dicyano complexes were found to exhibit marked solvent dependences; the dominant and minor CD bands, respectively, changed their signs in some solvents. This paper describes the results of such studies and discusses, in particular, the origin of the CD variation of the diisothiocyanato complex with solvents.

Experimental

Materials. The literature methods were used for the preparation and optical resolution of *cis*-$[Co(en)_2(X)_2]^{n+}$ complexes, where $(X)_2$=$(CN)_2$,[9] $(NO_2)_2$,[10] $(NCS)_2$,[11] $(N_3)_2$,[12] en,[13] acetylacetonate,[14] $(NH_3)_2$,[15] and oxalate.[16] The methods for the preparation and optical resolution of the chromium(III) analogue *cis*-$[Cr(en)_2(NCS)_2]^+$ and *cis*-$[Co(en)_2(NO_2)(NCS)]^+$ were those of House[11] and Yamazaki *et al.*,[12] respectively. Each of these complexes was obtained in the form of chloride, bromide, iodide, perchlorate, and tetraphenylborate (BPh_4^-) by metathesis. For complexes containing monodentate ligands, ion-exchange chromatography with SP-Sephadex C-25 resin was used to confirm the absence of any *trans* impurities. The identity of these complexes was confirmed by unpolarized absorption spectra, proton NMR spectra, and CD spectra.

The nonaqueous solvents used for the CD measurements were of spectroscopic grade or of highest grade commercially available, mostly from Katayama Chemical Industries Co., Ltd. (Osaka) or Tokyo Kasei Kogyo Co., Ltd. (Tokyo), and used as supplied. Dimethyl-d_6 sulfoxide (DMSO-d_6, 99 atom% D minimum) and pyridine-d_5 (99 atom% D minimum) were purchased from E. Merck (Darmstadt).

Measurements. The CD spectra were obtained on a JASCO J-40CS recording spectropolarimeter at ambient temperature. Tetraphenylborate salts were used throughout for nonaqueous solvents and the complex concentration was typically 1.1×10^{-3} to 2.7×10^{-3} mol dm^{-3}.

Proton magnetic resonance spectra were run on a JEOL JNM-PMX60 spectrometer at 36 °C or on a JEOL PS-100 spectrometer at ambient temperature. Chemical shifts were referenced to internal tetramethylsilane (TMS).

Results and Discussion

The utility of CD spectra in assigning the stereochemistry and the absolute configuration of metal complexes relies upon the structure-spectrum correlation in the d-d transition and/or exciton band region.[17]

The correlation has now been believed to be well established both theoretically and experimentally, especially for configurational CD spectra. Usually, the configurational effects dominate over the conformational and vicinal effects for five-membered chelate ring systems.[17] The CD spectra due to the latter two effects have been shown,[3-5] in some complexes, to vary with solvents. For configurational CD spectra, however, no examples appear to be reported in which the sign of rotational strength changes with solvents. This spectral stability seems to be the basis of the utility of configurational CD spectra in the determination of absolute configuration. The absolute configuration of *cis*-$[Co(en)_2(X)_2]^+$ complexes has been determined based on the sign of the rotational strength of the dominant CD band in the first d-d transition region.[18] Thus, if the sign of the rotational strength of the dominant CD band changed with the environment or the medium for unknown reasons, it might lead to the undesired situation where CD spectra are unreliable and useless in the study of the stereochemistry and absolute configuration of metal complexes.

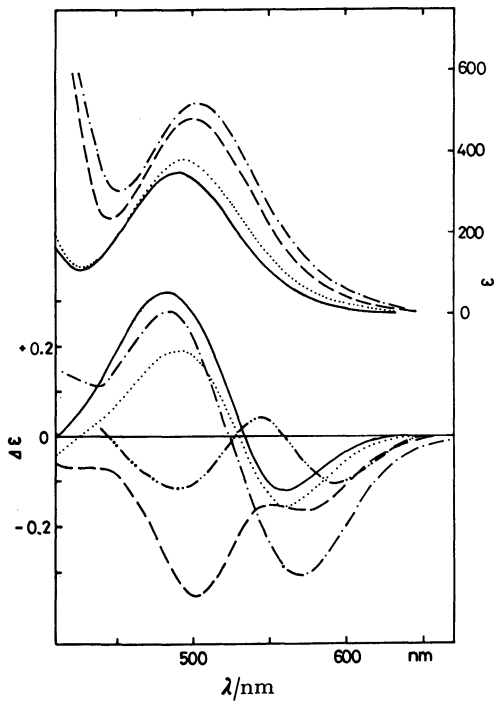

Fig. 1. The unpolarized absorption and CD spectra in the first d-d transition region of *Λ-cis*-$[Co(en)_2(NCS)_2]^+$ in water (——), DMSO (·····), THF (-·-·-·-), and pyridine (------), and the CD spectrum in nitrobenzene (-·-·-·-·-).

Diisothiocyanato Complex. Figure 1 shows the absorption and CD spectra of *Λ-cis*-$[Co(en)_2(NCS)_2]^+$ in several solvents, including water (solid curve) and pyridine (broken curve). The counter anions were chloride and BPh_4^- in water and nonaqueous solvents, respectively. In the absorption spectra, it is noted that the peak position and the intensity of the first d-d band are affected by solvents to some extent. Though the CD spectra in water, DMSO, and tetrahydrofuran (THF) differ in magnitude, their shapes are not so drastically different, as with ordinary solvents like methanol, acetone, and acetonitrile. The lowest energy CD peak, which was assigned[18] to the B_1 transition, has a minus sign in these solvents, while the higher energy component, assigned to the A_2+B_2 transition, is plus. These notations follow those of McCaffery, Mason, and Norman.[18] In contrast to these minus-plus couplets, the pyridine solution yielded a minus-minus couplet; the sign of the dominant CD band is changed from plus to minus, while leaving the minor CD band relatively unaffected. This may be the most spectacular example ever reported. If we judge simply from the sign of the dominant CD band, the pyridine spectrum is almost enantiomeric to the water or DMSO spectrum.

The CD variation shown in Fig. 1 does not seem to be primarily due to the counter anions. The CD spectrum in water did not show any noticeable change upon changing the counter anion from chloride to perchlorate. Also, addition of ten-fold excess of sodium perchlorate did not affect the spectrum in water. It is only addition of ten-fold excess of chloride to the DMSO solution that gave rise to measurable, though small, CD changes.[19] The tetraphenylborate anion is believed to show little tendency to ion association in nonaqueous solvents with bulk dielectric constants greater than 15.[20] Note that the dielectric constants of pyridine, THF, and DMSO are about 13, 7, and 47, respectively. Thus, we may safely eliminate the possibility of the counter anions generating these CD variations. That the observed CD change is not an artifact nor due to any chemical reactions was confirmed by the stability of the

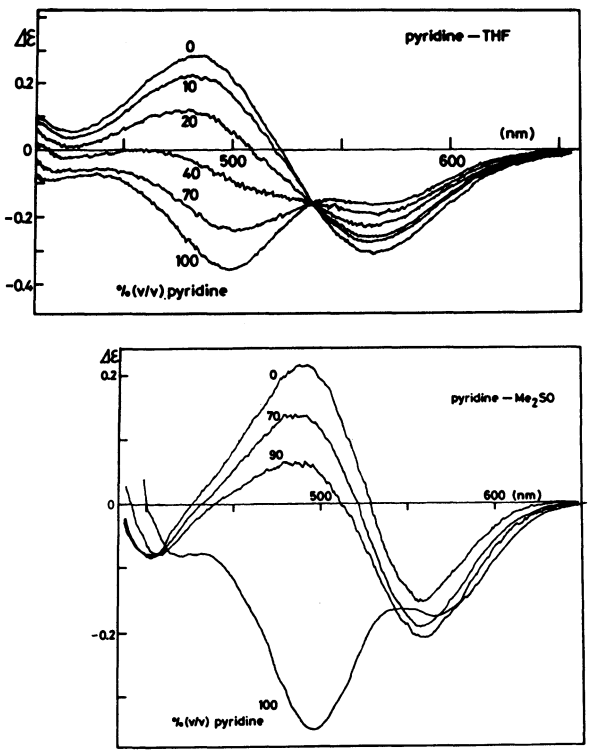

Fig. 2. The CD change of *Λ-cis*-$[Co(en)_2(NCS)_2]BPh_4$ as a function of the pyridine content in pyridine/THF (upper) and pyridine/DMSO (lower) mixed solvents.

spectra against time and by recovering the identical compound from the pyridine solution.

In order to see what type of spectrum is obtained in a mixed solvent, we measured the CD spectrum of the diisothiocyanato complex as a function of solvent composition. The results are given in Fig. 2 for the combination of pyridine/THF and pyridine/DMSO. The figure clearly indicates that the band positions are not affected greatly but the sign of the dominant CD band changed with the solvent composition. The change is, however, not a smoothly varying function of the solvent composition and a strong preference for one component can be recognized. For example, the 70%(v/v) pyridine solution in pyridine/DMSO systems yielded the CD spectrum similar to that of DMSO rather than the pyridine spectrum. This indicates that the immediate solvation sphere of the complex cation is not a smoothly varying function of the solvent composition, a phenomenon known as preferential solvation.[21] Thus, the observed CD changes are not primarily due to a change in the energy positions of the bands but due to the immediate solvation of the complex cation, causing the inversion of the intrinsic sign of the dominant band. Further, all the CD curves obtained for the pyridine/THF systems have isodichroic points, which is evidence for the presence of only two species in solution and therefore the presence of a substantial, well-defined entity that generates the sign inversion. Thus, the changes observed in Figs. 1 and 2 result most probably from some specific solute-solvent interaction. To see the nature of this interaction, we examined (i) the effect of other pyridine-like solvents, (ii) whether or not two isothiocyanato groups are essential to the sign inversion of the dominant band, and (iii) the effect of the central metal ion, by replacing cobalt(III) by chromium(III).

Figure 3 gives the CD spectra of the diisothiocyanato complex in various solvents, mostly nitrogen-containing heterocycles. From this figure, the following points will be noted. The solvents that cause the sign inversion of the dominant band are unsaturated *N*-heterocycles and the nitrogen center should not be sterically crowded.

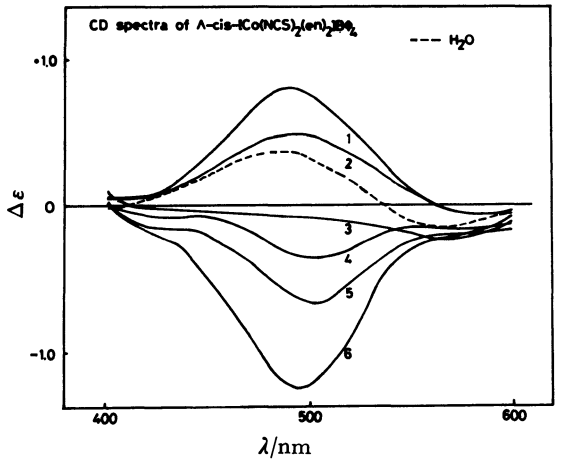

Fig. 3. The CD spectrum of *Λ-cis*-$[Co(en)_2(NCS)_2]BPh_4$ in piperidine (1), pyrrolidine (2), α-picoline (3), pyridine (4), 3,5-lutidine (5), and quinoline (6).

For example, solvents that contain a saturated nitrogen center, such as *N*-methylmorpholine, piperidine, pyrrolidine, and aniline, do not give rise to inversion. The sterically crowded 2,6-lutidine solvent behaves similarly, whereas the less crowded 3,5-lutidine solvent does cause the inversion. These structural features necessary for the inversion suggest that the nitrogen centers are interacting with the complex cation through their lone electron pairs. Further, since only unsaturated or aromatic solvents caused the inversion, these unsaturated parts of the solvent molecules too should be considered to interact with the complex cation. This latter point will be discussed later. The site of interaction with a lone electron pair may be either the isothiocyanato group or the N–H group of the complex cation. But the former group is anionic and its interaction with a lone electron pair is unlikely. Interaction with the N–H group(s) of the complex cation is thus the only possibility. The donor power of pyridine and its derivatives are rather large[22] and the acidity of the coordinated amino groups are also comparatively high, allowing for, *e.g.*, pK_a measurements,[23] electrophilic attach by several Lewis bases at deprotonated amino groups,[24] and the exchange with deuterium in neutral deuterium oxide solution.[25] Therefore, the hydrogen bonding between pyridine and coordinated amino group(s) is highly likely. In fact, the same type of interaction with pyridine has been postulated by Hawkins *et al.*[2,4] to play a major role in the solvent variations of the CD spectra of some *trans*-$[Co(N)_4(X)_2]^{n+}$ type of complexes.

a) From TMS internal standard. Numbers in parentheses refer to shoulders. Accuracy ±0.07 ppm.

In order to ascertain the actual site of hydrogen bonding with pyridine, we investigated the amine portion of the proton NMR spectrum of *cis*-$[Co(en)_2(NCS)_2]^+$. Table 1 lists the amine proton chemical shifts of *cis*-$[Co(en)_2(NCS)_2]X$ in DMSO-d_6, where X was varied from BPh_4^- through ClO_4^-, I^-, Br^- to Cl^-. We can note a particular hydrogen whose chemical shift is, among others, susceptible to the counter anion. As for other *cis*-$[Co(en)_2(X)_2]^+$ complexes with $(X)_2$= $(CN)_2$, $(NO_2)_2$, oxalate, malonate, $(Cl)_2$, and $(N_3)_2$, the chemical shift changes of this particular hydrogen brought about by the counter anions are considered to be due to the ion-pair formation with the counter anions *via* hydrogen bonding.[19,26] Thus, this hydrogen can be assigned to the amine hydrogen that is bonded to the nitrogen atom *trans* to NCS^- and pointing approximately parallel to the molecular C_2 axis. This hydrogen will be called *trans* H_A. The other *trans* hydrogen, *trans* H_B, is thus assigned to the peak at about δ 4.50 and the

low field AB quartet to two *cis* hydrogens.

Table 2 gives the chemical shifts of amine hydrogens of *cis*-$[Co(en)_2(NCS)_2]BPh_4$ in mixed pyridine-d_5/DMSO-d_6 solvents. As the pyridine content in the solvent increases, *trans* hydrogens and one of the *cis* hydrogens move to low fields by about 1.28 and 0.64 ppm, respectively. In contrast, the other *cis* hydrogen suffers a downfield shift of as great as about 2.20 ppm by pyridine and it appears in neat pyridine at about δ 8.30, which is downfield of even the phenyl resonances of BPh_4^-. This may be taken as evidence for the stereoselective hydrogen bonding at *cis* N–H by pyridine. This *cis* hydrogen, pertaining to the stereoselective hydrogen bonding, may be *cis* $N-H_B$, the *cis* hydrogen directing off the molecular C_2 axis, in analogy with the assignment made previously for the acetylacetonato- and diazidobis(ethylenediamine)cobalt(III) complexes.[19,26] Comparison of the values of Table 2 and the CD variation of Fig. 2(b) provides additional evidence for the stereoselective hydrogen bonding. The chemical shifts of the other *cis* hydrogen, *cis* $N-H_A$, and the two *trans* hydrogens are monotonic functions of the pyridine content, whereas the *cis* $N-H_B$ hydrogen suffers downfield shifts from pyridine in a manner quite similar to the CD variation due to pyridine in pyridine/DMSO systems. The similarity of the chemical shift variation of *cis* $N-H_B$ and the CD variation in pyridine/DMSO systems suggests strongly that this hydrogen plays a key role in the sign inversion of the dominant CD band.

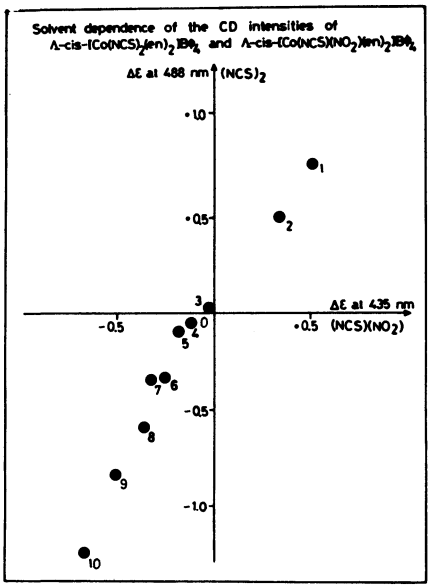

Fig. 4. The correlation of the CD intensities of *Λ-cis*-$[Co(en)_2(NCS)_2]BPh_4$ and *Λ-cis*-$[Co(en)_2(NO_2)(NCS)]BPh_4$ in various solvents, including piperidine (1), pyrrolidine (2), pyrrole (3), aniline (4), α-picoline (5), β-picoline (6), pyridine (7), 3,5-lutidine (8), isoquinoline (9), and quinoline (10).

Table 3 gives the CD data of the monoisothiocyanato complex, *Λ-cis*-$[Co(en)_2(NO_2)(NCS)]^+$, and the chromium(III) complex, *Λ-cis*-$[Cr(en)_2(NCS)_2]BPh_4$. The reason for substitution of one NCS^- by NO_2^- is that among several *Λ-cis*-$[Co(en)_2(X)_2]^{n+}$ complexes investigated, the CD spectrum of the dinitro complex was the least sensitive to the change in solvents (see below). The solvent dependence of the CD spectrum of the monoisothiocyanato complex is very similar to that of the diisothiocyanato complex. This correlation will be seen most clearly by Fig. 4, in which the CD intensity of the diisothiocyanato complex in a solvent is plotted against that of the monoisothiocyanato complex in the same solvent. In this plot, we used the wavelengths at which the CD intensities change significantly with solvents. As seen from Fig. 4, the correlation is very good and more importantly, the change in the CD intensity of the diisothiocyanato complex is

Table 3. CD peaks of *Λ-cis*-$[Co(en)_2(NO_2)(NCS)]BPh_4$ and *Λ-cis*-$[Cr(en)_2(NCS)_2]BPh_4$

				510	−0.27

approximately twice as large as that of the mono complex. This indicates (i) that the isothiocyanato group is essential to the CD change, as is also trivial from the fact that the CD changes of the other *cis*-$[Co(en)_2(X)_2]^+$ complexes examined here were much smaller, if any (see below), and (ii) that the two isothiocyanato groups interact independently with pyridine-like molecules. In the case of *Λ-cis*-$[Cr(en)_2(NCS)_2]$-BPh_4, the CD variation is not so drastic as to produce an enantiomeric spectrum but the essential features of the cobalt(III) complexes are retained; the order of increasing tendency to invert the dominant CD band observed here (pyrrolidine≪pyridine<3,5-lutidine< quinoline) parallels that of the di- and mono-isothiocyanato complexes of cobalt(III). This suggests that the sign inversion as observed for the cobalt(III) complexes is due to specific ligand-solvent interactions. It should be pointed out that the above order and a similar order in Fig. 4 can not be correlated in a simple way with common solvent parameters, such as the dielectric constant, dipole moment, E_T or Z value, or the basicity.[22]

From all the above observations, we propose a model for the interaction of the isothiocyanato complexes with pyridine-like molecules in solution, as illustrated schematically in Fig. 5. For convenience, this figure is drawn for pyridine and *Λ-cis*-$[Co(en)_2(NCS)_2]^+$. The nitrogen lone electron pair of pyridine is involved in the *cis* N–H_B···N type hydrogen bonding, as deduced from the NMR spectra. A crystal structure analysis[27] established that the Co(III)–NCS bond is linear, indicating Co–N≡C–S^- as the dominant resonance form. Molecular models show that the pyridine ring

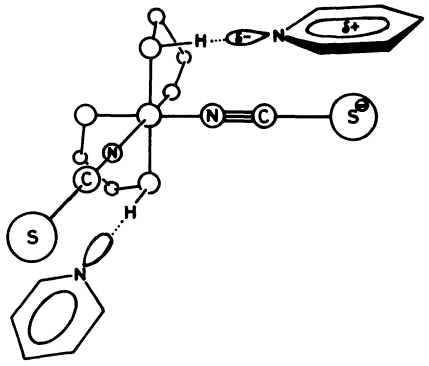

Fig. 5. The proposed model for the interaction of *Λ-cis*-$[Co(en)_2(NCS)_2]^+$ and pyridine.

a) ox: Oxalate. b) acac: Acetylacetonate. c) Insoluble.

can be situated over the sulfur atom, which carries a negative charge. In this model, the aromatic ring is tentatively assumed to interact with the negatively charged sulfur atom, which is reminiscent of the case of tetrabutylammonium bromide in nitrobenzene, where the bromide anion was assumed to be situated on the aromatic phenyl group.[28] The production of such a well-defined entity in solution may alter the CD spectrum of the complex cation either by rendering the hydrogen-bonded N–H center asymmetric (vicinal effects[17]) or by simply attaching a large "*N*-substituent" (regional rules[29]) which is orientated stereospecifically. Such a two-site interaction would be conceivable not only for pyridine but also for other aromatic molecules, if they satisfy steric requirements for this type of interaction. For example, nitrobenzene may interact in a similar fashion, though this molecule appears a little too large for such an interaction and its basicity is very much weaker than the basicity of pyridine.[22] In fact, the nitrobenzene solution gave the CD spectrum which is a weaker imitation of the pyridine spectrum rather than the water or DMSO spectrum, as shown in Fig. 1.

Other Complexes. We describe briefly the effect of solvents upon the CD spectra of the other complexes. Table 4 summarizes the absorption and CD data of all the bis(ethylenediamine) type of complexes examined here. The dicyano complex shows a relatively large CD variation especially for DMSO; the higher-energy B_1 transition, which was placed in water at 366 nm, appears to have shifted to a longer wavelength and changed the sign of its rotational strength in DMSO. The spectrum of the dinitro complex undergoes a comparatively small variation upon changing the solvents. The CD intensity of the higher-energy dominant band of the diazido complex[30] is enhanced by a factor of more than four upon going from water to DMSO, THF, or pyridine. For the oxalato and acetylacetonato complexes, prominent solvent effects are noted also for the higher-energy transitions rather than for the lower-energy ones. The peak positions and the intensities of the first d-d band of all the complexes are affected by these solvents. The origin and the nature of these spectral variations are not clear as yet.

Orbital Tilting Due to Destabilizing Four-electron and Stabilizing Two-electron Orbital Interactions. An Elucidation of *Exo-endo*-nonequivalency of π-MO Extension of Norbornene

Suketaka Ito* and Akikazu Kakehi
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received April 25, 1981)

A new concept, "Orbital Tilting," leading to hybridization change, was introduced on the basis of the destabilizing and the stabilizing secondary orbital interaction. The predominant π-MO extension of norbornene in the *exo*-direction was elucidated by application of the concept to the orbital system.

The *exo*-stereoselectivity in electrophilic addition to norbornene has been ascribed to π-HOMO extending predominantly in the *exo*-direction.[1] The nonequivalent orbital extension was rationalized in terms of the perturbation of etheno-π and -σ orbital through the orbital interaction with the methano-bridge.[1a,b] The orbital interaction results in the mixing between the unperturbed etheno-π and the etheno-σ MO or the basis 2p and 2s AO, which is the ground of the nonequivalency of the π-MO extension. Thus the *exo-endo*-nonequivalency of the π-MO extension can be understood as a problem of hybridization change.

According to Woodward and Hoffmann,[2] the cyclization of conjugated polyenes such as that of *s-cis*-butadiene to cyclobutene is represented in terms of the inclinations of both terminal methylenes. The inclination of methylene groups implies a tilt of orbitals, and the HOMO-LUMO interaction scheme[3] and other MO-theoretical treatments[2,4] rationalize the conrotatory cyclization of butadiene. In these treatments, however, only the tilt of p-π-type orbitals are considered; thus, the concomitant hybridization change is not handled in principle.[5]

In the present paper, on the basis of the HOMO-LUMO maximum overlapping principle,[3] we introduce a new concept, "Orbital Tilting," which involves the tilt of (s,p)-hybrid σ-type orbitals and leads to hybridization change.[6] The norbornene π-MO with predominant extension in the *exo*-direction is derived by application of the concept to an orbital system with an originally equivalent π-MO extension.

Results

Orbital Tilting and Hybridization Change. Let us consider a chemical system involving a methylene carbon (in sp^2 hybridization) bonded to another carbon in sp^2-sp^2 σ mode (χ_1 for the sp^2-hybrid AO of the methylene carbon, χ_2 for that of the other) and a group with an sp^2-hybrid orbital (χ_3) which is going to overlap in a σ symmetry with the p-type orbital (p) located in the methylene carbon (Fig. 1). Since a localized bonding σ_{CC} level is underlain by a bonding σ_{CH} level and the antibonding counterpart of σ_{CC} underlies that of σ_{CH} in ordinary hydrocarbons,[7] the order of orbital levels of the system under consideration is given as $\sigma^*_{CH}>\sigma^*_{CC}(=\chi_1-\chi_2)>p>\chi_3>\sigma_{CC}(=\chi_1+\chi_2)>\sigma_{CH}$. In this orbital system, χ_3 can interact with p upon approach and also with the localized σ-type orbitals. When the interaction between χ_3 and the σ orbitals located in the C–H bond regions is neglected as a first approximation,[8] the σ^*_{CC} orbital takes part as the next LUMO (NLUMO) or LUMO in the orbital interaction leading to hybridization change. According to the occupancy of p and χ_3,[9] four types of orbital interaction can be applied to the orbital system represented in Fig. 1: (1) A two-electron system (both χ_3 and p are unoccupied); (2) a four-electron system (χ_3 is occupied and p unoccupied); (3) a four-electron system (χ_3 is unoccupied and p occupied); (4) a six-electron system (both χ_3 and p are occupied).[10]

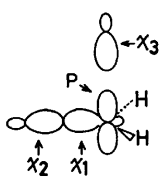

Fig. 1. Four-center orbital system leading to orbital tilting.

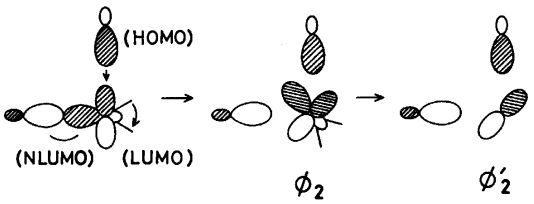
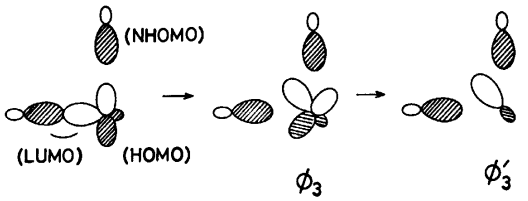
On the basis of the frontier orbital[3] or the perturbation concept,[11] these orbital systems can be treated in the following way. In Case 2, the interaction of χ_3 (HOMO) with p (LUMO) stabilizes the system, which is represented by the in-phase combination of χ_3 and p. Secondary stabilization may arise from the overlap between χ_3 (HOMO) and σ^*_{CC} (NLUMO). The orbital arrangement of σ^*_{CC} should be selected in such a way that χ_3 and χ_1 are in-phase (χ_3 and χ_2 are out-of-phase) (Fig. 2a); because χ_1 is located closer to χ_3 than χ_2 is and the in-phase overlap between χ_1 and χ_3 stabilizes the system. In this situation, as shown in Fig. 2a, the interaction of χ_1 with χ_3 and that of χ_2 with the bottom lobe of p are attractive. The HOMO-LUMO-NLUMO maximum overlap may be realized[12] by orbital tilting when the methylene group is inclined in the symmetrically bisecting plane to the configuration in which the two hydrogen atoms are more remote from the approaching group with local χ_3. Since χ_1 becomes orthogonal to the out-of-phase combination of χ_2 and χ_3 in the MO representation after orbital tilting (ϕ_2 in Fig. 2a), ϕ_2 should be revised to ϕ'_2, which is just the delocalized HOMO in the orbital system. In Case 3, the orbital system is occupied in the reverse manner of that in Case 2; however, since p (HOMO) interacts with σ^*_{CC} (NLUMO) through χ_3 (LUMO), the mode of orbital interaction should be equivalent to that of Case 2.

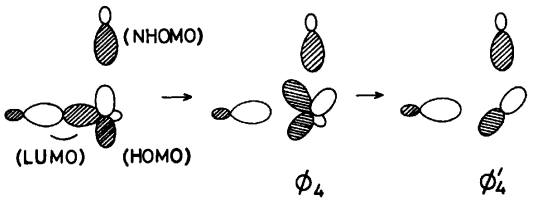
In Case 4, the interaction of χ_3 (NHOMO) with p



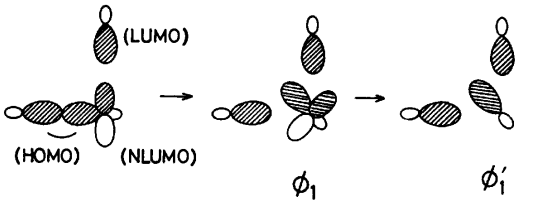
(a) Interaction of σ_{CC}* as NLUMO.



(b) Interaction of σ_{CC}* as LUMO (Type I).



(c) Interaction of σ_{CC}* as LUMO (Type II).



(d) Interaction of σ_{CC} as HOMO.

Fig. 2. Orbital tilting in the four-center orbital system.

(HOMO) destabilizes the system; this situation is represented by the out-of-phase combination of χ_3 and p. This representation is consistent with that of the semi-delocalized HOMO in the initial state. For stabilization, the following two alternative terms are available: One may arise from the overlap between p (HOMO) and σ^*_{CC} (LUMO), in which χ_2 and the bottom lobe of p are in-phase (Type I), and the other may arise from the overlap between χ_3 (NHOMO) and σ^*_{CC} (LUMO), in which χ_3 and χ_1 are in-phase (Type II). Since the magnitude of stabilization is dependent upon both the extent of orbital overlapping and the difference between the energy levels of orbitals, these circumstances are somewhat equivocal. However, the former stabilization term is probably dominant in view of the closer energy level of p to σ^*_{CC} and of the bonding character between χ_3 and χ_2. The situation of orbital interaction in this manner is given in Fig. 2b. The interaction of p with χ_2 becomes attractive; the HOMO-LUMO maximum and the HOMO-NHOMO minimum overlap may be achieved compatibly by orbital tilting in a manner similar to that of Cases 2 and 3. In the MO representation after orbital tilting (ϕ_3 in Fig. 2b), p is orthogonal to the in-phase combination of χ_2 and χ_3; accordingly, ϕ_3 should be revised to ϕ'_3, which is the delocalized HOMO in this orbital system. For this orbital system, the delocalized LUMO (ϕ'_4) can be derived in the same way from the alternative orbital representation in which σ^*_{CC} is given in such a way that χ_3 and χ_1 are in-phase (Fig. 2c).

For Case 1, σ_{CC} is the HOMO and χ_3 and p are the LUMO and the NLUMO, respectively. In the MO representation, χ_3 and σ_{CC} are in-phase; similarly, χ_3 and p are in-phase, for the in-phase combination of χ_3 and p designates the semi-delocalized LUMO. The orbital interaction can be treated analogously; this treatment is given in Fig. 2d. Since ϕ'_1 is the HOMO for the four-center two-electron system, it lies in the bottom level. Similarly, from the fact of electron occupation, it is evident that the energy ordering is $\phi'_1<\phi'_2<\phi'_3<\phi'_4$.[13]

On the one hand, since the constituent p and χ_1 in ϕ_1—ϕ_4 are based on the atomic p and the hybrid sp^2 orbital, they can be re-hybridized into a new equivalent basis set, $(\lambda\chi_1-p)/\sqrt{1+\lambda^2}$ $(=\chi_4)$ and $(\chi_1+\lambda p)/\sqrt{1+\lambda^2}$ $(=\chi_5)$. In the orbital system after re-hybridization, χ_4 overlaps with χ_2 and χ_5 with χ_3, where $\lambda\approx1$. The orbital system after re-hybrodization is represented schematically in Fig. 3 by an example.[14] Consequently, the two hybridization-changed C–C σ bonds are represented with the sets of bond orbitals, $(\chi_2+\chi_4)/\sqrt{2}$ and $(\chi_2-\chi_4)/\sqrt{2}$, and $(\chi_3+\chi_5)/\sqrt{2}$ and $(\chi_3-\chi_5)/\sqrt{2}$, respectively.

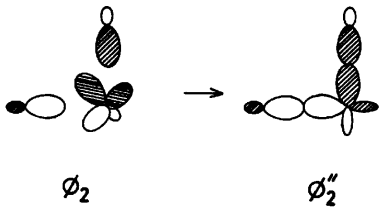


Fig. 3. Re-hybridization.

Predominant Extension of π-HOMO and π-LUMO in the Exo-direction in Norbornene System. We assume first a bicyclo[2.2.1]hept-2-ene structure in which its π-MO originally extends *exo-endo*-equivalently. For this system, the hyperconjugative four-electron interaction between the methano-bridge methylene and the double bond (through space) may be considered. As has been well known, the hyperconjugative effect of simple alkyl and alkylene groups is electron-donating.[15] The hypothetical unperturbed bicycloheptene system is represented in Fig. 4 with three localized π_{CH_2} orbitals (χ_{11}, χ_{12}, and χ_{13}) and one π orbital. In this orbital system, the three localized π_{CH_2} orbitals give a new set of semi-delocalized

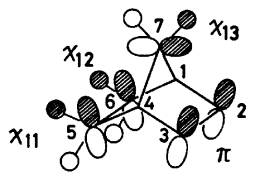

Fig. 4. Bicyclo[2.2.1]hept-2-ene system represented with unperturbed π and π_{CH_2} orbitals.

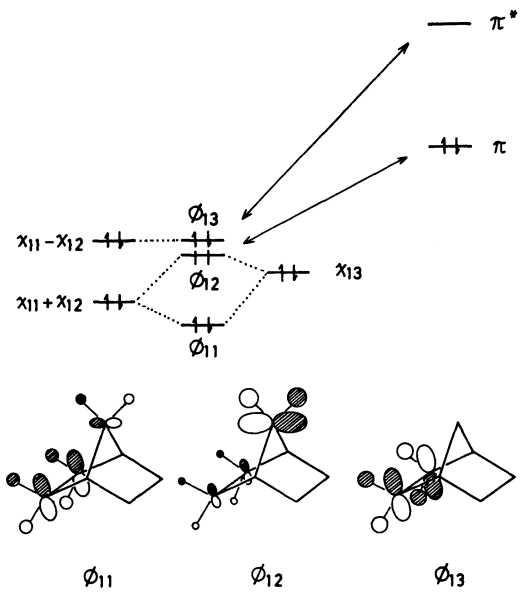

Scheme 1.

orbitals, ϕ_{11}, ϕ_{12}, and ϕ_{13}, according to the orbital interaction principle[11] (Scheme 1).

Since the orbital interaction between χ_{11} and χ_{12} is stronger than those of other combinations, ϕ_{13} should be underlain by ϕ_{12}, in which χ_{13} is the predominant contributor. According to the property of orbital symmetry, ϕ_{12} can interact with π in a four-electron fashion and ϕ_{13} with π^* in a two-electron fashion, and the interaction between ϕ_{11} and π can be considered weak and negligible in view of the difference in energy level.[16] The fact that the energy levels of ϕ_{12} and π are closer than the energy levels of ϕ_{13} and π^* suggests that the interaction of ϕ_{12} with π is dominant over that of ϕ_{13} with π^*. In this orbital system, the decrease of NHOMO (ϕ_{12})-HOMO (π) overlap and the increase of HOMO (ϕ_{13})-LUMO (π^*) overlap, both leading to the stabilization of the system, may be realized by orbital tilting, when the etheno group is inclined around the C_2–C_3 σ axis in the direction from the *exo-* to the *endo-*side to a certain extent keeping the C_2–C_3 and the two C–H σ bonds unchanged. The localized σ_{CC} bond orbitals located in C_1–C_2 and C_3–C_4 ought to be deformed by orbital tilting because, without this deformation, the etheno group cannot be inclined at all while the C_2–C_3 and the two C–H bonds are conserved.

When the σ orbitals located in C_1–C_2 and C_3–C_4 are represented in a semi-delocalized manner on the basis of sp^2 hybrids, the resulting low-lying vacant level (σ_{13}^*) may interact, upon orbital tilting, with ϕ_{12} in a stabilizing manner and with the low-lying filled level (σ_{11})[17] in a destabilizing manner. The stabilization arising from the interaction of ϕ_{12} with σ_{13}^* can be considered to dominate over the destabilization arising from that with σ_{11} in view of energy-level closing; however, both terms may be small because of their weak interaction. The MO representation for the orbital interaction between ϕ_{12} and π is given in Fig. 5, in which the low-lying vacant level (σ_{13}^*) is represented. The situation of orbital interaction resembles that of Case 4 described above, except that no formation of bond is involved; thus, the orbital system after tilting can be treated in the same manner and each constituent sp^2 hybrid and p orbital involved in σ_{13}^* and π are re-hybridized to give a new set of unequally hybridized orbitals. One pair of the new hybrids, consisting of a large fraction of the original sp^2 hybrids and a small fraction of the p orbital, lie in the $C_1C_2C_3C_4$ coplane and overlap with the local hybrid orbitals in C_1 and C_4 to lead to the generation of $\sigma_{13}^{*\prime}$ which corresponds to σ_{13}^*. The low-lying filled level, σ_{11}', is obtained analogously by considering the participation of σ_{11}. The other pair, consisting of a large fraction of p and a small fraction of sp^2 hybrids, should be in-phase and has its predominant extension in the exo-direction unquestionably, as seen in Fig. 5. This in-phase combination of the pair thus obtained (π' in Fig. 5) is the HOMO of norbornene system.

In a similar manner, the LUMO of norbornene with its predominant extension in the exo-direction can be derived from the orbital system involving ϕ_{13}, π^*, σ_{12}, and σ_{14}^*.[18]

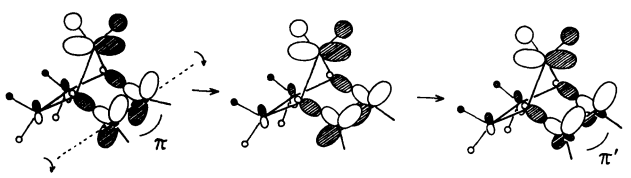

Fig. 5. Derivation of norbornene π-HOMO with predominant extension in the *exo*-direction.

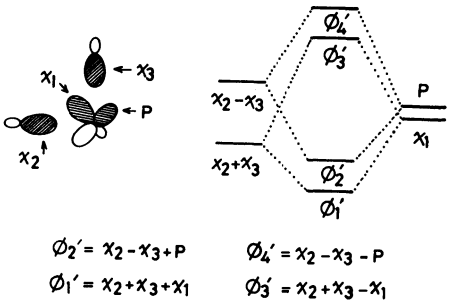
Discussion

Orbital tilting does not mean the physical inclination of orbitals (only the shift of nuclei takes place actually), of course, but it merely an artificial device in analogy with orbital hybridization. However, orbital tilting is specified in such a way that the HOMO-HOMO minimum and the HOMO-LUMO maximum overlap may be realized; therefore, this method has its theoretical grounds in the perturbation or the frontier orbital theory. In this connection, it should be noted that the delocalized MO's, ϕ_1', ϕ_2', ϕ_3', and ϕ_4', obtained above by orbital tilting can be given alternatively by the qualitative LCAO method and that the relative energy levels are consistent with the assignment stated above (Scheme 2). As seen in Fig. 3, the re-hybrids by orbital tilting



Scheme 2.

are in sp^5 hybridization, which are slightly different from the situation actually observed. This difference results from neglecting the interaction of σ orbitals located in the C–H bond regions, and is not serious.

In the method based on the orbital mixing rule, delocalized orbitals are considered for the purpose of predicting orbital extension[1a,b] or hybridization change,[6] which leads to configuration altering.[19] On the other hand, in the present method, the orbitals are represented in a localized manner and the configuration is altered so that the orthogonality of orbitals may be conserved approximately: The alteration of configuration results in hybridization change. A recognition of hybridization change on the basis of localized MO's may be feasible and reasonable;[20] for the localized MO's represented with bond orbitals correspond best with classical chemical structures and hybridization itself is based on local AO's. The merit of the concept of orbital tilting is the ease with which one can infer the alteration of configuration accompanied by hybridization change or molecular deformation.

As has been seen above, the norbornene π MO with predominant extension in the *exo*-direction can be derived from the unperturbed etheno-π MO involved in bicyclo[2.2.1]hept-2-ene structure by application of the concept of orbital tilting, due to the secondary interaction with the methano-bridge methylene as the main hyperconjugative entity.[21] Since it is generally accepted that the stability of norbornen-7-ylium ion and the instability of norbornen-7-ide ion are due to the homoconjugation[22] of the ion center with the double bond, the (homo)hyperconjugation of methano-bridge methylene with the double bond can be expected *a priori* in the bicycloheptene structure. On the other hand, if other conditions such as the extent of orbital overlapping can be regarded as equivalent, the hyperconjugative effect of the methano- and ethano-bridge in the neutral system may be dominant over that of methylenes because the energy level of a localized σ_{CC} orbital is higher than that of a localized σ_{CH}. However, from the view point of orbital symmetry, the hyperconjugative effect of methano- and ethano-bridging bond can be expected to operate in the same manner[23] as that of methylene C–H bonds.

The inclination of etheno group around the C_2–C_3 σ axis causes the hydrogen atoms attached to C_2 and C_3 to shift slightly downward from the $C_1C_2C_3C_4$ coplane (Fig. 5): This situation accords with the result of MO-theoretical calculation for norbornene[1c] and for bicyclo[2.2.1]hept-2-yl.[24]

The conformational properties and geometries of small and simple hydrocarbon molecules have been analyzed in terms of the four-electron destabilizing or the two-electron stabilizing interaction *via* hyperconjugation;[25] the same principle should be applicable also to more complex, rigid molecules. Thus, the hyperconjugative effect on the double bond results in the molecular deformation, which is the origin of the predominant extension in the *exo*-direction for π MO in norbornene system.

5) In the reverse reaction (the ring opening), the rotation of sp^3 hydrids are considered, but their hybridization change has not also been dealt with.

6) The hybridization change in the nucleo- or electrophilic addition to an unsaturated carbon has been dealt with by Fukui (*Kagaku To Kogyo*, **29**, 470 (1976); "Kagaku-hanno To Denshi No Kido," Maruzen, Tokyo (1976), p. 188) on the basis of the sigma-pi interaction (K. Fukui and H. Fujimoto, *Bull. Chem. Soc. Jpn.*, **39**, 2116 (1966).

7) W. L. Jorgensen and L. Salem, "The Organic Chemist's Book of Orbitals," Academic Press, New York (1973), p. 14.

8) Neglecting the interaction of σ orbitals located in the C–H bonds implies that the two σ_{CH} and the two σ^*_{CH} levels are regarded as orthogonal to other levels throughout the course of reaction.

9) Single occupation is excluded from the scope of this argument.

10) In all cases, the number of electrons includes two electrons which occupy the σ_{CC} orbital.

11) Ref. 7, p. 10.

12) The destabilization arising from the decreased in-phase overlap between χ_3 and p is repaired by the stabilization arising from the increased in-phase overlap between χ_2 and p.

13) The energy ordering is in accord with that of group orbitals for CH_2: $\sigma_{CH_2}<\pi_{CH_2}<\sigma^*_{CH_2}<\pi^*_{CH_2}$. See Ref. 7, p. 7.

14) MO's ϕ_1''—ϕ_4'', which are equivalent to ϕ_1—ϕ_4, are formulated approximately as follows:

$$\phi_1'' = (\chi_3+\chi_5)/2 + (\chi_2+\chi_4)/2,$$
$$\phi_2'' = (\chi_3+\chi_5)/2 - (\chi_2+\chi_4)/2,$$
$$\phi_3'' = (\chi_3-\chi_5)/2 + (\chi_2-\chi_4)/2,$$
$$\phi_4'' = (\chi_3-\chi_5)/2 - (\chi_2-\chi_4)/2.$$

15) I. Fleming, "Frontier Orbitals and Organic Chemical Reactions," John Wiley and Sons, New York (1976), p. 48.

16) From the fact that ϕ_{12} has its largest amplitude in C_7, the hyperconjugative effect of methano-bridge methylene should predominate over that of ethano-bridge methylenes.

17) The high-lying counterparts, σ_{12} (filled) and σ_{14}^* (vacant), interact with π^* upon orbital tilting.

18) The σ type orbitals, σ_{12}' and $\sigma_{14}'^*$ corresponding to σ_{12} and σ_{14}^*, are also obtained.

19) That is to say, the alteration of configuration is treated as the result of a hybridization change.

20) Another advantage of identifying a chemical process on the basis of localized MO's has been in a method for predicting pericyclic reactions: S. Ito, A. Kakehi, and Y. Tanaka, *Bull. Chem. Soc. Jpn.*, **48**, 2855 (1975).

21) The predominant extension of bicyclo [2.1.0]pent-2-ene in the *exo*-direction[1a,b] can be likewise derived on the basis of the secondary four-electron interaction between π and the

Walsh σ_{CC} orbital extending in the *exo*-direction.

22) S. Winstein, *Quart. Revs.*, **23**, 141 (1969). See also: J. B. Grutzner and W. L. Jorgensen, *J. Am. Chem. Soc.*, **103**, 1372 (1981); E. Kaufmann, H. Mayr, J. Chandrasekhar, and P. v.R. Schleyer, *ibid.*, **103**, 1375 (1981); and references cited therein.

23) The same result can be obtained by orbital tilting, when the σ MO's for the methano- and the ethano-bridging bonds are represented with group-type orbitals (shown below) in a semi-delocalized manner, or with each (2s, 2p) hybrid located in C_5, C_6, and C_7 by postulating that the interaction between π MO and the local sp^2-type hybrids in C_1 and C_4 are very weak.

Photoreduction of Aminoanthraquinones by an Electron Transfer *via* the Upper Excited nπ* Triplet State

Haruo INOUE,* Kiyoshi KAWABE, Noboru KITAMURA, and Mitsuhiko HIDA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received July 8, 1981)

The photoreduction of 2-piperidinoanthraquinone (**1**) by an electron transfer from hydroxide ion in aqueous 2-propanol was reinvestigated. The reaction proceeded actively on irradiation at 365 nm, but very weakly on irradiation at 420 nm. The fluorescence of **1** was not affected by hydroxide ion. 1,3-Cyclohexadiene as a triplet quencher retarded the photoreduction. All results revealed that the reactive state of **1** in the photoreduction is not the intramolecular excited CT state, but the upper excited nπ* triplet state. Kinetic studies indicated that the rate of deactivation from the $T_2(^3n\pi^*)$ level of **1** is unusually slow ($k_d = 1.7 \times 10^8\ s^{-1}$). The photoreduction *via* the upper excited $T_2(^3n\pi^*)$ level was also observed in 1-amino- and 1-piperidinoanthraquinone, while 2-aminoanthraquinone did not exhibit any reactivity. Wavelength-dependencies (313 nm, 365 nm, and >420 nm irradiations) of the photoreductions were also observed.

Anthraquinone derivatives have four ππ* absorption bands in the wavelength range between 220 nm and 350 nm, and also an nπ* band at longer wavelength near 400 nm. When electron donating substituents such as hydroxyl, amino, and methylamino groups are introduced into the nucleus, a new ππ* absorption band, an intramolecular charge transfer band, appears in the visible region.[1] In the photochemistry of anthraquinone derivatives, it has long been emphasized that the excited triplet nπ* state is very reactive, while the intramolecular CT state has little reactivity.[2] Recently we have found a new photosubstitution reaction of aminohaloanthraquinones with amines under irradiation with visible light and demonstrated that the intramolecular CT state is reactive in the reaction.[3] A. K. Davies *et al.* also postulated that the intramolecular CT state is reactive in the photoreduction of 2-piperidinoanthraquinone (**1**) by an electron transfer from hydroxide ion or alkoxide ion on irradiation with the light of $\lambda = 365$ nm.[4] However, an ambiguity remains in their conclusion about the reactive state; another possibility of the photoreduction *via* the upper excited $T_2(^3n\pi^*)$ level can not be excluded. The results of our reinvestigation of this photoreduction of **1** by hydroxide ion showed that the reaction proceeds not *via* the intramolecular CT state but *via* the upper excited $T_2(^3n\pi^*)$ state, contrary to Davies' conclusion. We also examined the photoreduction *via* the upper excited nπ* level of other anthraquinones (1-aminoanthraquinone (**2**), 2-aminoanthraquinone (**3**), 1-piperidinoanthraquinone (**4**) and we observed dramatic wavelength dependencies (313 nm, 365 nm, and >420 nm irradiations) on the photoreduction in these anthraquinones including 2-SO_3Na (**5**) and 1-SO_3Na (**6**) derivatives.

Experimental

Materials. *2-Piperidinoanthraquinone (1)*: 2-Chloroanthraquinone (10 g) and piperidine (150 ml) were heated to reflux for 8 h. The excess piperidine was evaporated from the reaction mixture and the residual red crystals of **1** were washed thoroughly with water and dried. The yield was 12.3 g. The crude **1** was purified by repeated recrystallizations from ethanol–benzene mixture (4 : 1 v/v); mp 164—165 °C; Found: C, 78.18%; H, 5.71%; N, 4.63%. Calcd for $C_{19}H_{17}NO_2$: C, 78.31%; H, 5.89%; N, 4.80%. 1-Aminoanthraquinone (**2**) (Sumitomo Chemical Co.) was purified by column chromatography (Al_2O_3/toluene) and repeated recrystallizations from benzene; mp 252—253 °C; Found: C, 75.31%; H, 3.86%; N, 6.44%. Calcd for $C_{14}H_9NO_2$: C, 75.32%; H, 4.06%; N, 6.27%. 2-Aminoanthraquinone (**3**) (Sumitomo Chemical Co.) was purified by the procedures recommended by Maki[5] using 82% aqueous sulfuric acid; mp 302 °C; Found: C, 75.24%; H, 3.78%; N, 6.02%. Calcd for $C_{14}H_9NO_2$: C, 75.32%; H, 4.06%; N, 6.27%. 1-Piperidinoanthraquinone (**4**): 1-Chloroanthraquinone (15 g) and piperidine (225 ml) were refluxed for 2.5 h. After evaporating off the excess piperidine, the red crystals of **4** were washed thoroughly with water and dried. The yield was 17.3 g. The crude **4** was passed through a silica-gel column (hexane–acetone, 3 : 1 v/v) and recrystallized repeatedly from ethanol; mp 124 °C; Found: C, 78.24%; H, 5.88%; N, 4.67%. Calcd for $C_{19}H_{17}NO_2$: C, 78.31%; H, 5.89%; N, 4.80%. Both sodium anthraquinone-2-sulfonate (**5**) and sodium anthraquinone-1-sulfonate (**6**) (Sumitomo Chemical Co.) were purified by respective salting-outs and repeated recrystallizations from water until molar absorption coefficients in their UV spectra became constant. 2-Propanol and methanol were purified as reported previously.[3] 1,3-Cyclohexadiene (Tokyo Kasei, GR) was further purified by fractional distillation before use.

Procedure. Each sample (4 ml) was degassed in a quartz cell by repeated freeze and thaw procedures and was irradiated with a high pressure mercury lamp (Toshiba H-400P or USHIO USH-500D) through the following filter systems; Toshiba UV-D25 glass filter and aqueous solution of K_2CrO_4 (0.27 g/dm³) Na_2CO_3 (1.0 g/dm³) (optical length: 1 cm) for the irradiation by monochromatic light of 313 nm; Toshiba UV-DIA glass filter and naphthalene (5.0×10^{-2} mol/dm³) in 2-propanol (optical length: 1 cm) for irradiation at 365 nm. The visible and UV absorption spectra of the irradiated reaction mixtures were recorded by a Shimadzu UV-200 spectrophotometer. The number of photons absorbed by each sample was determined by the use of a chemical actinometer of potassium tris(oxalato)ferrate(III).[6] In a typical case, the numbers of photons of the incident light of 313 nm and 365 nm were 3.2×10^{15} quanta/s and 1.6×10^{16} quanta/s, respectively.

Results

Photoreduction of 2-Piperidinoanthraquinone (1) in Alkaline

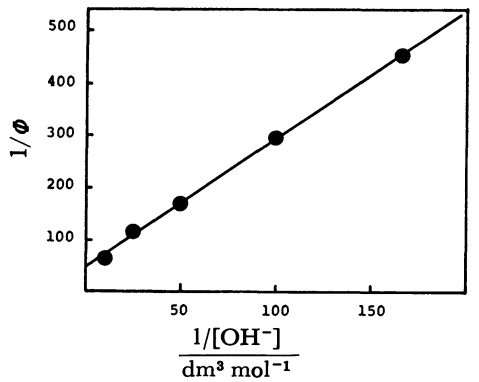

Fig. 1. Effect of the concentration of hydroxide ion on the quantum yield of the photoreduction of **1**; [**1**]: 1.00×10^{-4} mol/dm³ in 4 : 1 2-propanol–water mixture under nitrogen atmosphere; irradiation light: $\lambda=365$ nm.

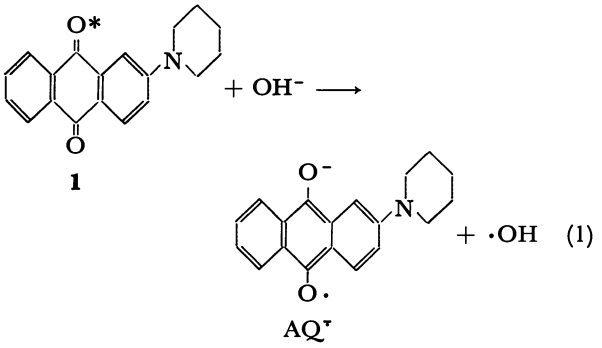
Aqueous 2-Propanol. When **1** (1.00×10^{-4} mol/dm³) and sodium hydroxide (5.00×10^{-2} mol/dm³) in 4 : 1 2-propanol–water mixture was irradiated with monochromatic light of $\lambda=365$ nm under nitrogen atmosphere, the absorption bands at $\lambda=402$, 476, and >650 nm, assigned to the radical anion of **1**, increased. Isosbestic points were observed at $\lambda=377$, 498, and 570 nm. Introduction of air to the irradiated reaction mixture caused rapid disappearance of the radical anion of **1**, and **1** was recovered unchanged. A similar effective photoreduction was also observed in aqueous acetonitrile which is considered to have little reactivity toward a conventional hydrogen atom abstraction (Φ(in 4 : 1 acetonitrile–water)/Φ(in 4 : 1 2-propanol–water)=0.56 when [NaOH]=5×10^{-2} mol/dm³). As shown in Fig. 1, the reciprocal of the quantum yield for the production of the radical anion of **1** was found to be linear with the reciprocal of the total amount of hydroxide ion added to the reaction system. These results suggest that the radical anion of **1** is produced not by a conventional hydrogen abstraction by the excited **1** from the solvent followed by a deprotonation (Eqs. 2 and 3), but by a direct electron transfer from the hydroxide ion (Eq. 1).



$$AQ^* + H\text{-}\underset{|}{\overset{|}{C}}\text{-} \longrightarrow AQH\cdot + \cdot\underset{|}{\overset{|}{C}}\text{-} \quad (2)$$

$$AQH\cdot + OH^- \longrightarrow AQ^- + H_2O \quad (3)$$

The radical anion of **1** was stable in the reaction system for more than 1d. Hence it was supposed that most of the hydroxyl radical, a powerful oxidizing agent, produced in the reaction system along with the radical anion of **1** (Eq. 1) would abstract a hydrogen atom from 2-propanol to produce water and acetone (Eq. 4). In the irradiated reaction mixture acetone was really detected by GLC analysis (column/PEG-20M; 40 °C).

$$OH\cdot + (CH_3)_2CHOH \longrightarrow H_2O + (CH_3)_2\dot{C}OH \quad (4)$$

$$(CH_3)_2\dot{C}OH + AQ \longrightarrow (CH_3)_2C{=}O + AQH\cdot \quad (5)$$

The radical anion of **1** is also produced by a deprotonation of the semiquinone radical (AQH·) generated in Eq. 5. If the photoreduction of **1** by hydroxide ion proceeds *via* the ^{1}CT level as proposed by Davies *et al.*,[4] **1** should be photoreduced on irradiation with light of $\lambda>420$ nm which excites **1** exclusively to its ^{1}CT level. The fluorescence of **1** should be quenched by the addition of hydroxide ion to an extent predicted from the linear plot of Fig. 1. However, as shown in Table 1, the radical anion of **1** was only very weakly produced on irradiation with light of $\lambda>420$ nm, and the fluorescence intensity of **1** was not affected by the presence of hydroxide ion to an extent predicted from the linear plot of Fig. 1. However, as shown in Table 1, the radical anion of **1** was only very weakly produced on irradiation with light of $\lambda>420$ nm, and the fluorescence intensity of **1** was not affected by the presence of hy-

365	1.0
>420	0.003

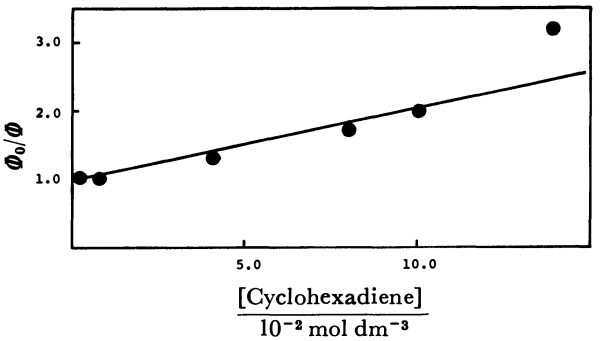

Fig. 2. Stern-Volmer plot for the quenching effect of 1,3-cyclohexadiene on the photoreduction of **1**; [**1**]: 1.00×10^{-4} mol/dm³ in 4 : 1 2-propanol–water mixture under nitrogen atmosphere; [OH⁻]: 0.1 mol/dm³; irradiation light: $\lambda=365$ nm.

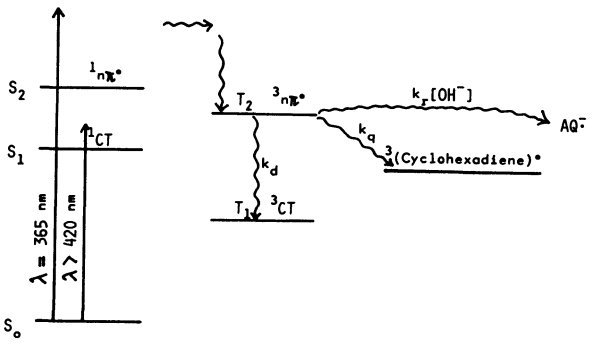

Fig. 3. Energy state diagram of **1** and the reaction scheme of the photoreduction by hydroxide ion.

droxide ion (1×10^{-3}—1×10^{-1} mol/dm^3). These results clearly indicate that the photoreduction of **1** does not proceed *via* the ^{1}CT level, but *via* the upper excited level. Moreover, the photoreduction was retarded by the addition of 1,3-cyclohexadiene as a triplet quencher[22] and a linear Stern-Volmer plot was obtained with the Stern-Volmer constant, $k_q\cdot\tau=20$ dm^3/mol (Fig. 2). Since the triplet level of 1,3-cyclohexadiene ($E_T=217$ kJ/mol) is higher than the $T_1(^3CT)$ of **1** and lower than the $T_2(^3n\pi^*)$,[7] 1,3-cyclohexadiene can be considered to quench the $T_2(^3n\pi^*)$ level of **1**. It is concluded that the photoreduction of **1** by an electron transfer from hydroxide ion proceeds *via* the $T_2(^3n\pi^*)$ level of **1**. These conclusions are schematized in Fig. 3. The quantum yield (Φ) for the production of the radical anion of **1** can be written as

$$\Phi = 2\Phi_T\,(365\text{ nm})\frac{k_r[OH^-]}{k_d+k_r[OH^-]}, \qquad (6)$$

and the Stren-Volmer equation is

$$\Phi_0/\Phi = 1 + \frac{k_q[CHD]}{k_d+k_r[OH^-]}, \qquad (7)$$

where $\Phi_T(365\text{ nm})$ denotes the triplet yield upon the irradiation of the light of $\lambda=365$ nm, k_i [i=r, d, and q] represents each rate constant in Fig. 3, and CHD refers to 1,3-cyclohexadiene. Equation 6 and the ratio of the slope to the intercept in the plot of Equation 1 indicate $k_d/k_r=5.0\times10^{-2}$ mol/dm^3. Equation 7 indicates that the Stern-Volmer cons tant in the plot of Fig. 2 is $k_q/(k_d+k_r[OH^-])=20$ dm^3/mol ($[OH^-]=0.1$ mol/dm^3). Supposing that the quenching rate constant k_q by 1,3-cyclohexadiene is diffusion controlled (10^{10} dm^3 mol^{-1} s^{-1}), the rate constants of $k_r=3.3\times10^9$ dm^3 mol^{-1} s^{-1} and $k_d=1.7\times10^8$ s^{-1} are obtained.[23] From the intercept in the linear plot of Fig. 1, $\Phi_T(365\text{ nm})$ is found to be 1.0×10^{-2}.

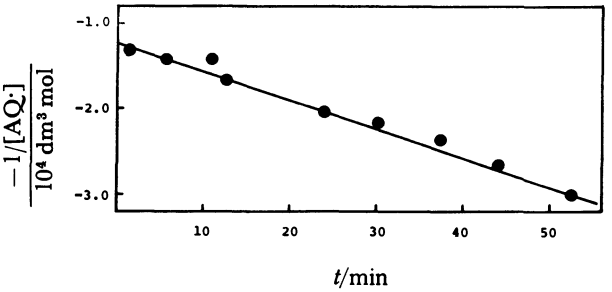

Fig. 4. Decay of the radical anion ($AQ^{\cdot}$) of **2** generated in the photoreduction by hydroxide ion; [**2**]: 1.00×10^{-4} mol/dm^3 in 4 : 1 2-propanol–water mixture under nitrogen atmosphere; [OH^-]: 5.0×10^{-2} mol/dm^3; irradiation light: $\lambda>300$ nm.

Photoreduction of other Anthraquinones in Alkaline Aqueous Alcohol. Such ready photoreduction of **1** by hydroxide ion *via* the upper excited $T_2(^3n\pi^*)$ level prompted our investigation of other anthraquinones such as **2**, **3**, **4**, **5**, and **6**. The results are summarized in Table 2. **2** (1.00×10^{-4} mol/dm^3) and sodium hydroxide (5.00×10^{-2} mol/dm^3) in 4 : 1 2-propanol–water mixture was irradiated with the light of $\lambda>300$ nm under nitrogen atmosphere. The corresponding radical anion of **2** ($\lambda_{max}=389$, 482 nm) was also readily produced with the irradiation, having isosbestic points

at λ=320, 510, 551 nm. Introduction of air to the irradiated reaction mixture also caused rapid disappearance of the radical anion of **2** and **2** was recovered unchanged. However the radical anion of **2** was unstable in 2-propanol–water and gradually disappeared with a second order decay constant of k=2.8 dm^3 mol^{-1} s^{-1} as shown in Fig. 4. This may be due to the following second order decay process of dismutation (Eq. 8). Of

$$AQ^{\cdot} + AQ^{\cdot} \xrightarrow{k} AQ^{2-} + AQ \quad (8)$$

the solvent compositions examined (aqueous solutions of methanol, ethanol, and 2-propanol), 1 : 1 methanol–water mixture was found to stabilize the radical anion for several hours. The visible absorption spectra of the reaction system in 1 : 1 methanol–water mixture are shown in Fig. 5. The corresponding radical anion of **2** alone was produced during the first 400 minutes of irradiation through a soda glass filter which only transmitted radiation of λ>300 nm (Fig. 5(a)). On prolonged irradiation the absorption intensities at λ=389 nm, 475 nm, and >650 nm gradually decreased and then, upon the irradiation through UVD-33S glass filter which transmitted radiation of 280 nm<λ<400 nm, the radical anion disappeared rapidly with the production of the dianion of **2** (λ_{max}=395 nm) having new isosbestic points at λ=388, 392, and 425 nm (Fig. 5(b)). Further irradiation of the reaction system by a 500 W high pressure mercury lamp without a glass filter also caused a disappearance of the dianion with an increment of the absorption intensity near 370 nm which might be characterized by the production of aminoanthrone derivative[8] (line(8) in Fig. 5(b)). As summarized in Eq. 9, the photochemical reduction of **2** proceeded *via* three steps. At an early stage of the photoreaction the radical anion of **2** is produced from **2** (Process I; Fig. 5(a)) and after the complete conversion of **2** into the radical anion, the dianion of **2** is produced from the radical anion (Process II; Fig. 5(b)). Finally, an end product which may be aminoanthrone is produced from the dianion of **2** (Process III). The

$$AQ \xrightarrow{h\nu} AQ^{\cdot} \xrightarrow{h\nu} AQ^{2-} \xrightarrow{h\nu} \text{aminoanthrone} \quad (9)$$

spectra in Fig. 5(a) indicate that the absorption coefficients of the radical anion of **2** at the λ_{max} of 389 and 475 nm in 1 : 1 methanol–water mixture are 53200 and 76000 dm^2/mol respectively. As is shown in Fig. 6, a plot of the reciprocal of the quantum yield of the photoreduction of process I versus the reciprocal of the concentration of hydroxide ion added to the reaction system gave a fairly straight line. The ratio of the slope to the intercept in the plot was found to be 1.5×10^{-2} mol/dm^3. Hence the radical anion of **2** is also supposed to be produced by a direct electron transfer from hydroxide ion to the excited **2** in a manner similar to the case of **1**. As mentioned above, irradiation with light of 313 nm was effective for the photoreduction of **2**. On the other hand, neither visible light irradiation (>420 nm), which excited **2** to ^{1}CT level, nor irradiation with light of 365 nm which excited **2** to $^1n\pi^*$ level induced photoreduction of **2**. Moreover the fluorescence intensity of **2** was hardly affected by hydroxide ion; the Stern-Volmer constant of the fluorescence quenching by hydroxide ion was smaller than 4 dm^3/mol. These results clearly indicate that the photoreduction of **2** by an electron transfer from hydroxide ion proceeds through the upper excited state which can be populated by 313 nm excitation. Though the quenching experiments by appropriate triplet quenchers could not be carried out because of their insolubilities in 1 : 1 methanol–water mixture, by analogy with the case of **1**, it is well supposed that the upper excited triplet $n\pi^*$ (T_2) level of **2** is responsible for the photoreduction. The value of the intercept in the plot of Fig. 6 indicates the triplet yield upon irradiation of the light of 313 nm, Φ_T(313 nm), to be 0.5×10^{-2}. A mixture of **3** (1.0×10^{-4} mol/dm^3) and sodium hydroxide (5.0×10^{-2} mol/dm^3) in 1 : 1 methanol–water mixture was irradiated with light of λ=313 nm, 365 nm and λ>420 nm under nitrogen atmosphere, respectively. Contrary to our expectation, in every case **3** did not react at all, even with prolonged irradiation at 313 nm. This unexpected result seems very interesting and will be discussed later.

The photoreduction of **4** (1.0×10^{-4} mol/dm^3) in 4 : 1 2-propanol–water mixture in the presence of hydroxide ion (5.0×10^{-2} mol/dm^3) gave its dianion (λ_{max}=408 and 493 nm) alone. Both quantum yields in the presence and the absence of hydroxide ion were almost the same to each other; in the latter case 1-piperidino-9,10-anthracenediol was produced. These results were in accord with those reported by Davies *et al.*[4] Since the production of 1-piperidino-9,10-anthracenediol from **4** at neutral conditions is believed to be due to hydrogen abstraction from 2-propanol, the dianion formation at alkaline conditions is also considered to be caused by hydrogen abstraction by the excited **4** in its triplet $n\pi^*$ state, followed by a deprotonation (Eqs. 2 and 3) in contrast to the reactions of **1** and **2**. The dianion of **4**, however, was produced effectively even in alkaline aqueous acetonitrile solution. This indicates that the electron transfer mechanism from hydroxide ion was also operating in the photoreduction of **4** along with the hydrogen abstraction mechanism. The dependency of the photoreduction of **4** on the wavelength of irradiation was similar to that of **2**: The reaction was only induced with irradiation of light of λ=313 nm and **4** did not react at all upon irradiation of the light of λ=365 nm

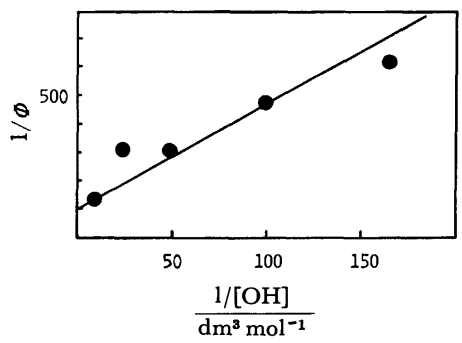

Fig. 6. Effect of the concentration of hydroxide ion on the quantum yield of the photoreduction of **2**; [**2**]: 1.00×10^{-4} mol/dm^3 in 1: 1 methanol–water mixture under nitrogen atmosphere; irradiation light: λ=313 nm.

and $\lambda>420$ nm, respectively. Hence the upper excited triplet $n\pi^*$ state (T_2), which can be populated by 313 nm excitation is probably responsible for the photoreduction of **4**. Compound **5** is a good sensitizer for the photosensitized oxidation and its photochemistry has been most intensively studied.[2] The triplet ($^3n\pi^*$) yield of **5** is known to be unity and the quantum yield for the formation of 9,10-dihydroxy-2-anthracenesulfonate from **5** by a hydrogen abstraction is also unity at neutral condition.[9] In alkaline solution or in the presence of an appropriate electron donor, photoreduction by an electron transfer mechanism is also significant.[10] Irradiation of **5** (1.0×10^{-4} mol/dm^3) in the presence of sodium hydroxide (5.0×10^{-2} mol/dm^3) in 1 : 1 methanol–water mixture with the light of $\lambda>300$ nm induced an effective formation of the radical anion of **5** ($\lambda_{max}=400$ and 502 nm) as a sole end product. The quantum yield for the formation of the radical anion of **5** was not affected by the concentration of hydroxide ion ($0.1—6\times10^{-3}$ mol/dm^3) and by the wavelength of irradiation ($\lambda=313$ and 365 nm). Compound **6** has been classified as a poor sensitizer.[11] When **6** (1.0×10^{-4} mol/dm^3) and sodium hydroxide (5.0×10^{-2} mol/dm^3) in 1 : 1 methanol–water mixture was irradiated with light of $\lambda>300$ nm, the radical anion of **6** ($\lambda_{max}=400$ and 497 nm) was produced at an early stage of the reaction. The radical anion produced was stable in the dark for several hours in 1 : 1 methanol–water. On prolonged irradiation, the dianion of **6** was further produced from the radical anion after the complete conversion of **6** into the radical anion. The spectral changes were similar to those of the reaction of **2**. The absorption coefficient of the radical anion of **6** at 497 nm in 1 : 1 methanol–water was estimated to be 45100 dm^2/mol. Studzinskii *et al.* reported that the quantum yield for the production of the radical anion was independent of the wavelength of irradiation in alkaline aqueous alcohols.[12] However, careful investigation revealed a slight wavelength dependency; Φ365 nm/Φ313 nm$=0.91\pm0.05$. A plot of the reciprocal of the quantum yield versus the reciprocal of the concentration of hydroxide ion added to the reaction system gave a fairly straight line with a value of 7.6×10^{-2} mol/dm^3 for the ratio of the slope to the intercept. This suggests that the radical anion formation in alkaline aqueous methanol is mainly induced by an electron transfer from hydroxide ion. The values of the intercept in the plot also indicate the triplet ($^3n\pi^*$) yield upon irradiation with light of 313 and 365 nm, Φ_T(313 nm) and Φ_T(365 nm) to be 9.4×10^{-2} and 8.5×10^{-2}, respectively. It is easily understood that the low reactivity of **6** (classified as a poor sensitizer) is mainly ascribable to such a low intersystem-crossing efficiency of $^1n\pi^*$ states.

Discussion

The energy state diagram of anthraquinone derivatives (**1**—**4**), having an electron-donating group, is depicted in Fig. 7.[2,13] The first absorption band in the visible region for each derivative corresponds to the lowest excited singlet state (S_1 : ^{1}CT) and the absorption band near $\lambda=300$ nm to the $\pi\pi^*$ singlet state overlying

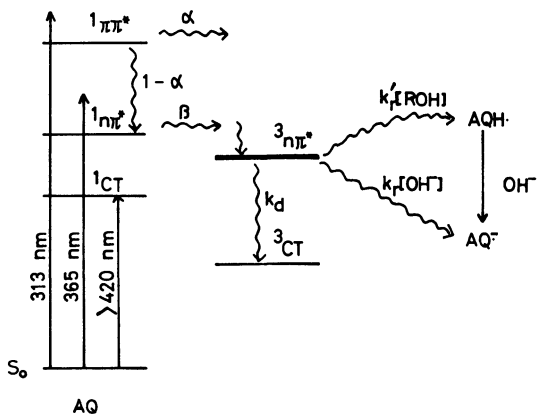

Fig. 7. Energy state diagram of the anthraquinone derivatives having electron donating substituents.

the $n\pi^*$ state. On the other hand the energy state diagram of **5** and **6** have no intramolecular CT level.[2,13] In the case of anthraquinone the $n\pi^*$ (^{1}U) and the higher $\pi\pi^*$ (^1L_b) levels have the energy of 24000 and 30000 cm^{-1}, respectively.[14] Taking account of both mechanisms of electron transfer from hydroxide ion and hydrogen abstraction from the solvent *via* the $n\pi^*$ level, the quantum yield of the photoreduction is given by Eq. 10.

$$\Phi \propto \Phi_T\left(\frac{k_r[OH^-]+k_r'[ROH]}{k_d+k_r[OH^-]+k_r'[ROH]}\right), \qquad (10)$$

where Φ_T denotes the $n\pi^*$ triplet yield upon the irradiation of the light of appropriate wavelength, k_d the rate constant of the deactivation of the $^3n\pi^*$, k_r the rate constant of electron transfer, and k_r' the rate constant of hydrogen abstraction. From Fig. 7 the triplet yields upon the irradiation of the light of $\lambda=313$ nm are expressed by Eqs. 11 and 12, respectively,

$$\Phi_T(313\text{ nm}) = \alpha + (1-\alpha)\beta, \qquad (11)$$

$$\Phi_T(365\text{ nm}) = \beta, \qquad (12)$$

where α and β denote the apparent individual intersystem crossing efficiencies of the higher $^1\pi\pi^*$ and $^1n\pi^*$ states respectively. By solving equations 11 and 12 the values of α and β can be estimated from the triplet yields summarized in Table 2. The values of α and β for **2** are 5×10^{-3} and zero, while those for **6** are 9.8×10^{-3} and 8.5×10^{-2}. High efficiency of the intersystem crossing of $^1n\pi^* \rightsquigarrow {}^3n\pi^*$ of **5** ($\beta=1.0$) renders it impossible to estimate the value of the intersystem crossing, α, from the higher level. The absence of the wavelength dependency between 313 and 365 nm in the case of **1** with low Φ_T value ($\Phi_T=1.0\%$) apparently indicates the absence of the intersystem crossing from the higher $^1\pi\pi^*$ state. However, as indicated in Table 2, the second absorption band ($\lambda_{max}=352$ nm) of **1** is largely red-shifted as compared with other derivatives. Hence the respective irradiation of the light of 313 and 365 nm may excite **1** to the same level of the higher $^1\pi\pi^*$ overlying the $^1n\pi^*$. More precise investigation on the wavelength dependency of the photoreduction of **1** may be required. The value of k_d of **1** indicates the lifetime of the $T_2(^3n\pi^*)$ state to be 5.9×10^{-9} s in 4 : 1 2-propanol–water mixture. The lifetime of the $T_2(^3n\pi^*)$

of **2** in 1 : 1 methanol–water is also estimated to be longer than 6.7×10^{-9} s from the value of $k_d/k_r = 1.5\times10^{-2}$ mol/dm^3, supposing k_r to be diffusion controlled (10^{10} dm^3/mol s) as a maximum limit. These values are longer as compared with those of T_2 of anthracenes (2—5×10^{-10} s),[15] naphthalene (1.7×10^{-11} s).[16] In the study of the photoreduction of 1-dimethylaminoanthraquinone by hydrogen abstraction, Davies *et al.* pointed out that anthraquinone derivatives might have a lifetime long enough to photoreact in their upper excited $T_2(^3n\pi^*)$ level.[17] 1-Amino-2,4-dibromoanthraquinone is also known to have a long-lived $T_2(^3n\pi^*)$ state in benzene.[18] These long lifetimes of $T_2(^3n\pi^*)$ in spite of upper excited levels are considered to be characteristic of aminoanthraquinones. The rate of internal conversion from T_2 with 0 vibrational level to T_1 with n isoenergetic vibrational levels, $k_{ic}(T_2\rightarrow T_1)$, which nearly equals the rate of deactivation, k_d, is theoretically given by Eq. 13.[19]

$$k_{ic}(T_2\rightarrow T_1) \propto \langle\psi_{T_2}|J|\psi_{T_1}\rangle^2\cdot|\textstyle\sum_n\langle\chi_{T_2 0}|\chi_{T_1 n}\rangle|^2, \qquad (13)$$

where ψ_{T2} and ψ_{T1} are the electronic wave functions of T_2 and T_1, J is the nuclear kinetic energy operator, and $\chi_{T_2 0}$ and $\chi_{T_1 n}$ are the nuclear wave functions of the corresponding states. The orthogonality between the $T_2(^3n\pi^*)$ and $T_1(^3CT)$ states can cause a poor electronic term in Eq. 13. The second term of Eq. 13 is the well known Franck-Condon factor and is largely affected by the energy gap between the two states.[20] Since the $T_2(^3n\pi^*)$ levels of aminoanthraquinones have been considered to have similar energies to that of the $^3n\pi^*$ of anthraquinone (259 kJ/mol)[2] and the $T_1(^3CT)$ levels were reported to lie in the range of 236—201 kJ/mol (**3**), 197—176 kJ/mol (**1** and **2**), and $<$123 kJ/mol (**4**),[7] the energy gaps between the T_2 and T_1 of these aminoanthraquinones are estimated to have larger values than 62 kJ/mol (**1** and **2**) and 136 kJ/mol (**4**), while that of **3** is in the range of 23—58 kJ/mol. These rather large energy gaps (except that of **3**) may also cause a poor Franck-Condon factor resulting in the long life of the $T_2(^3n\pi^*)$ levels. The lifetime of the $T_2(^3n\pi^*)$ of each derivative may be in the order of **4**$>$**1**$\approx$**2**$>$**3** in accord with the order of the energy gap. The lifetime of the $T_2(^3n\pi^*)$ of **3** may be too short for any reactions to be observed. While the $T_2(^3n\pi^*)$ of **1** and **2** may have moderate lifetimes to permit only rapid process of electron transfer to compete, the $T_2(^3n\pi^*)$ of **4** may have sufficient long one even for rather slow reaction of hydrogen abstraction[21] to proceed.

Photochemical Electron Transport from Water Layer to Organic Layer *via* Sodium Anthraquinone-2-sulfonate by Stepwise Two Photon Excitation†

Haruo INOUE* and Mitsuhiko HIDA
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received July 9, 1981)

Photochemical electron transport from hydroxide ion to organic acceptor molecule *via* an anthraquinone derivative as an electron carrier was investigated in homogeneous, cationic micellar, and cationic reversed micellar systems. In homogeneous alkaline aqueous ethanol, the photochemically generated radical anion of sodium anthraquinone-2-sulfonate (**1**) was stable against further irradiation with visible light (λ>450 nm), while the dianion of **1** was reversibly converted to the radical anion by visible light irradiation. The reversible conversion was accelerated by the addition of an organic acceptor molecule such as 1,4-dicyanobenzene. In a cationic hexadecyltrimethylammonium micellar system, an effective photoreduction of **1** by an electron transfer from hydroxide ion concentrated on the micellar surface to the excited **1** located in the surface area of the micelle was observed. In a reversed micellar system an electron was effectively transported from the water layer to the organic layer; an electron was transfered from hydroxide ion in the water layer incorporated in a benzylhexadecyldimethylammonium reversed micelle to **1** at the micellar surface by irradiation with light of λ=365 nm. Successive visible light irradiation (λ>450 nm) caused an electron ejection from the radical anion of **1** to benzonitrile as a bulk phase solvent. The possibility of the incorporation of carbon dioxide into the acceptor cycle of the electron transport system was also examined. In pyridine solution, carbon dioxide caused the disappearance of the reduced species of **1** on visible light irradiation (λ>450 nm). Trace amounts of dihydropyridinedicarboxylic acid derivatives were obtained.

Recently many intensive studies have been made on photochemical electron transport systems in relation to the photochemical conversion of solar energy.[1] Considerable attention has been paid to the photochemical splitting of water into hydrogen and oxygen using semiconductors,[2] metal complexes,[3] and chlorophylls.[4] Photochemical reductions of carbon dioxide[5] and nitrogen[6] have also been examined. Various different approaches to the photochemical electron transport system including water molecules are required in order to achieve more effective conversion of solar energy.

It is of interest to investigate the photochemical redox reactions including the water molecules as an electron donor and some quinone as an electron carrier with a view to approaching artificial photosynthesis. It is well known that anthraquinones are readily photoreduced by an electron transfer from hydroxide ion to produce the corresponding radical anion ($AQ^{\cdot-}$) as a stable product.[7,8,19] Then, it may be possible to formulate an electron transport system as depicted in Fig. 1; that is, light irradiation of the anthraquinones would evoke the oxidation of hydroxide ion equilibrated with water and successively the electron would be transfered from the radical anion ($AQ^{\cdot-}$) to another molecule step by step. The successive visible light irradiation of the resultant radical anion ($AQ^{\cdot-}$) is expected to raise the reductive power of $AQ^{\cdot-}$ itself and this photoredox system may cover a wide range of redox potential by stepwise two photon excitation. On the basis of this view point, we attempted to construct an electron transport system including anthraquinones as carrier of electron in homogeneous, cationic micellar, and cationic reversed micellar systems. The photoreduction by an electron transfer through the cationic micellar surface was actually observed to take place and an effective irreversible electron transport from the water layer to the organic layer could be attained in the cationic reversed micellar system. Furthermore, the possibility of the incorporation of carbon dioxide into the acceptor cycle of the electron transport system was examined.

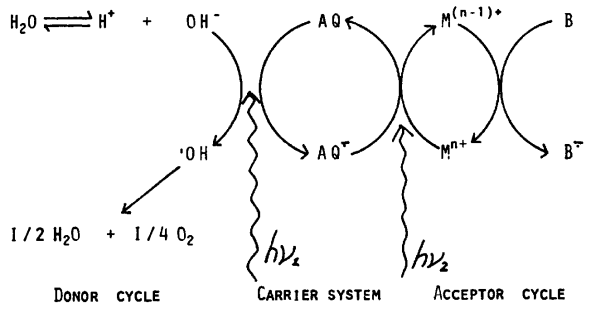

Fig. 1. Electron transport cycle including anthraquinone derivative (AQ) as a carrier and water as an electron donor by stepwise two photon excitation.

† A part of this study was presented in *Chem. Lett.*, **1979**, 107.

Experimental

Materials. Sodium anthraquinone-2-sulfonate (**1**),[19] sodium 1-aminoanthraquinone-2-sulfonate (**2**),[9] and 2-piperidinoanthraquinone (**3**)[19] were purified as reported elsewhere. Anthraquinone (**4**) (Sumitomo Chemical Co.) was passed through silica-gel column and recrystallized repeatedly from benzene; mp 285—286 °C, Found: C, 80.58%; H, 3.78%. Calcd for $C_{14}H_8O_2$: C, 80.76%; H, 3.87%. Sodium 1-amino-4-butylaminoanthraquinone-2-sulfonate (**5**) was obtained by the photoamination of sodium 1-amino-4-bromoanthraquinone-2-sulfonate with butylamine.[10] 1-Acetylaminoanthraquinone (**6**) was prepared by acetylation of 1-aminoanthraquinone with acetic anhydride and was purified by

repeated recrystallization from 1 : 1 toluene–ethanol mixture; mp 220—221 °C; Found: C, 72.42%; H, 3.95%; N, 5.27%. Calcd for $C_{16}H_{11}NO_3$: C, 72.47%; H, 4.15%; N, 5.28%. 1-Lauroylaminoanthraquinone (**7**) was prepared by the reaction between 1-aminoanthraquinone and lauroyl chloride in pyridine solution and was purified by passing through a silica, gel column and the repeated recrystallization from 2 : 5 benzene–ethanol; mp 132.5—133.5 °C; Found: C, 76.96%; H, 7.79%; N, 3.38%. Calcd for $C_{26}H_{31}NO_3$: C, 77.01%; H, 7.71%; N, 3.45%. Hexadecyltrimethylammonium bromide (CTAB) (Tokyo Kasei, EP) was recrystallized twice from water. Hexadecyltrimethylammonium hydroxide (CTAH) (10% in methanol; Tokyo Kasei) and benzylhexadecyldimethylammonium hydroxide (CDBAH) (10% in methanol; Tokyo Kasei) were used without further purification. Bis(ethylenediamine)copper(II) sulfate was prepared from copper(II) sulfate and ethylenediamine.[11] 1,4-Dicyanobenzene (Tokyo Kasei; G. R.) was used without further purification. Benzonitrile was dried with phosphorus pentoxide and fractionally distilled under a nitrogen atmosphere before use. Pyridine was refluxed with potassium hydroxide and fractionally distilled under a nitrogen atmosphere. Ion exchanged neutral water was used for the preparations of micellar solutions except where otherwise stated.

Procedures. Each sample of non-micellar and cationic micellar solution was degassed in a quartz cell by repeated freeze-thaw procedures. The reversed micellar reaction mixture was prepared by the following procedures; an appropriate amount of CDBAH methanol solution was placed in a Schlenck flask and the methanol was evaporated completely. Benzonitrile and **1** were added to the flask and the mixture was stirred vigorously. The suspension of the mixture was brought into solution by adding small amount of water (≈0.5 v/v%). The dissolved oxygen was removed by bubbling with nitrogen for at least 30 min or by the repeated freeze-thaw procedures. Monochromatic light of $\lambda=365$ nm and visible light of $\lambda>450$ nm were generated by a 500 W high pressure mercury lamp (USHIO USH-500D) through UV-DIA (Toshiba) and VY-45 (Toshiba) glass filters, respectively. The visible and UV absorption spectra of the irradiated reaction mixtures were measured by a Shimadzu UV-200 spectrophotometer. GC-Mass spectra were measured by a JMS D-100 (JEOL) mass spectrometer equipped with Thermon-100 and SE-30 columns.

Results and Discussion

Photochemical Electron Transport in Aqueous Alcohol. Sodium anthraquinone-2-sulfonate (**1**) (1.0×10^{-4} mol/dm^3) in the presence of hydroxide ion (NaOH=6.0×10^{-2} mol/dm^3) in 1 : 1 ethanol–water mixture was irradiated with monochromatic light of $\lambda=365$ nm under a nitrogen atmosphere. The visible absorption spectra of the reaction system are shown in Fig. 2. The radical anion ($AQ^{\cdot}$) of **1** alone was produced during the initial irradiation for 90s (Process I in Fig. 2). On prolonged irradiation the radical anion disappeared, along with the formation of the dianion of **1** (AQ^{2-}) (Process II in Fig. 2). The radical anion ($AQ^{\cdot}$) and dianion (AQ^{2-}) produced were stable for several hours in the dark. The spectral changes in the processes I and II had different isosbestic points. These results indicated that the dianion (AQ^{2-}) was produced by the further irradiation with light ($\lambda=365$ nm) to the radical anion ($AQ^{\cdot}$). Contrary to our expectation the radical anion

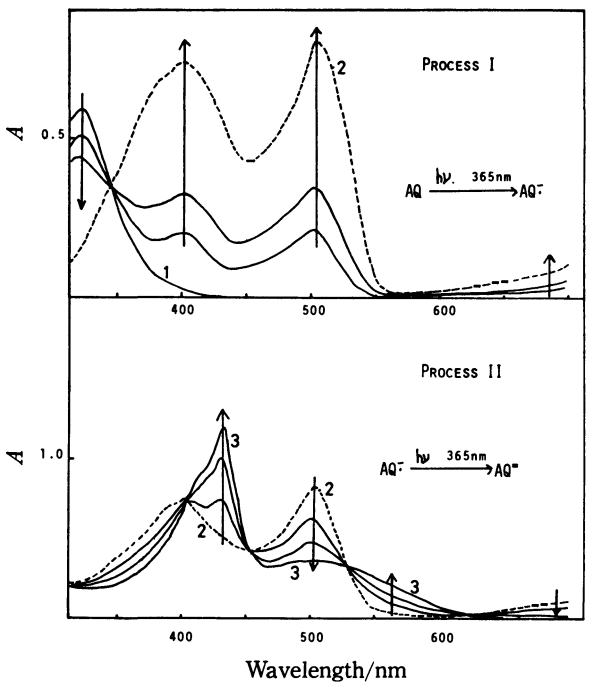

Fig. 2. Absorption spectra of the reaction system of the photoreduction of **1** under nitrogen atmosphere; [**1**]: 1.0×10^{-4} mol/dm^3 in 1 : 1 ethanol–water mixture; [OH$^-$]: 6.0×10^{-2} mol/dm^3; irradiation light: $\lambda=365$ nm; 1: 0 s; 2: 90 s; 3: 30 min.

($AQ^{\cdot}$) was stable against its selective excitation by further visible light irradiation ($\lambda>450$ nm) even in the presence of an acceptor molecule, such as 1,4-dicyanobenzene (DCB) (1×10^{-2} mol/dm^3). However, the dianion (AQ^{2-}) was reversibly reconverted to the radical anion ($AQ^{\cdot}$) on visible light irradiation ($\lambda>450$ nm) with the same isosbestic points in process II. Thus,

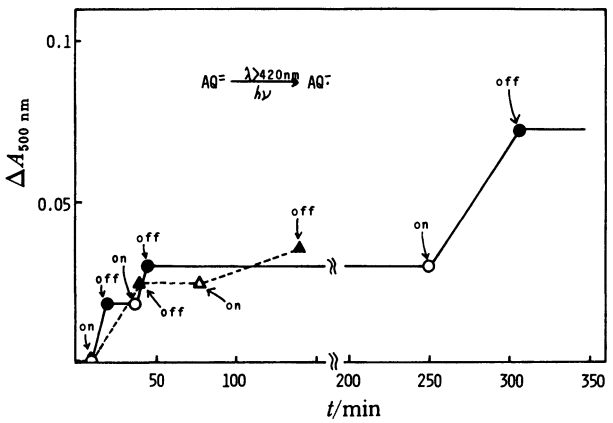

Fig. 3. Effect of the irradiation of visible light ($\lambda>420$ nm) on the reversible reconversion from the dianion (AQ^{2-}) to the radical anion ($AQ^{\cdot}$) of **1**; the amount of the reconversion was monitored at $\lambda=500$ nm; "on": light is on; "off": light is off;

	[**1**] mol/dm^3	[OH$^-$] mol/dm^3	[CN-⬡-CN] mol/dm^3
—○—●—	1.0×10^{-4}	6.0×10^{-2}	1.0×10^{-2}
---△---▲---	1.0×10^{-4}	6.0×10^{-2}	0

the photochemical ejection of an electron from the dianion (AQ^{2-}) was observed on the visible light irradiation. As indicated in Fig. 3, this reverse change from AQ^{2-} to $AQ^{\cdot}$ was accelerated by the addition of DCB as an electron acceptor; similar tendencies, though to a lesser extent, were also observed on the addition of benzonitrile, pyridine, and bromobenzene. Though it was revealed that under these conditions in 1 : 1 ethanol–water mixture the radical anion ($AQ^{\cdot}$) was mainly produced by a hydrogen abstraction from ethanol rather than an electron transfer from hydroxide ion,[12] the dianion (AQ^{2-}) was also produced from the radical anion ($AQ^{\cdot}$) in alkaline aqueous solution, indicating that hydroxide ion can also act as an electron donor in the process II. These results imply that an electron transport system including the reversible cycle $AQ^{\cdot} \rightleftharpoons AQ^{2-}$ can be constructed under appropriate conditions (Fig. 4). As a whole three photons are concerned with the electron transport.

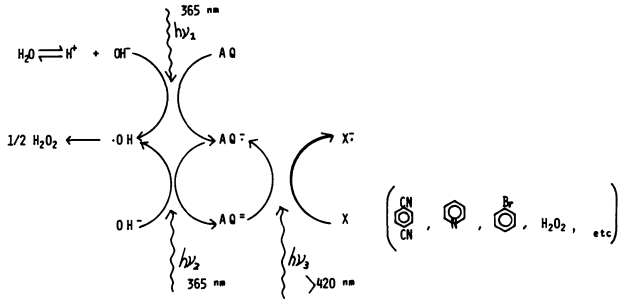

Fig. 4. Electron transport cycles including the reversible cycle of $AQ^{\cdot} \rightleftharpoons AQ^{2-}$.

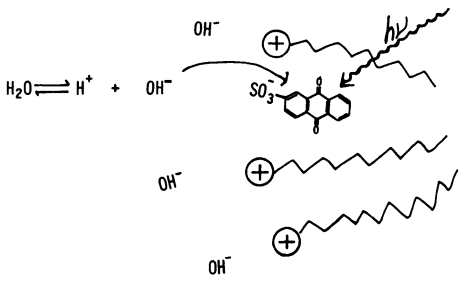
Photochemical Electron Transport in Cationic Micellar System. It is most important to establish a suitable donor system in Fig. 1 for an effective electron transport. Since cationic micelles are known to concentrate hydroxide ion on their surface[13] and may be preferable for charge seperation,[14] the reactions in a cationic micelle were examined. When **1** (1.0×10^{-4} mol/dm^3) was irradiated with light of $\lambda = 365$ nm in a cationic hexadecyltrimethylammonium bromide (CTAB) (8.0×10^{-3} mol/dm^3) micelle[15] in water (pH 5.70) under a nitrogen atmosphere, effective simultaneous productions of both the radical anion ($AQ^{\cdot}$) and the dianion (AQ^{2-}) of **1** were observed on irradiation. On the other hand, the photoreaction in the same cationic micelle in phosphate buffer solution (pH 6.88) afforded the corresponding 9,10-anthracenediol (AQH_2) (Fig. 5). Since the equilibrium in Eq. 1 is well known to lie well over to the right in neutral and acidic media,[16] the difference between the reactions in water and phosphate buffer solution strongly indicated that the micro pH value around the micellar surface in phosphate buffer solution was kept neutral, while that in water was raised to that in an alkaline medium in spite of the bulk phase solvent being acidic. No hydroxylated compound

$$AQ^{2-} + 2H^+ \rightleftharpoons AQH_2 \qquad (1)$$

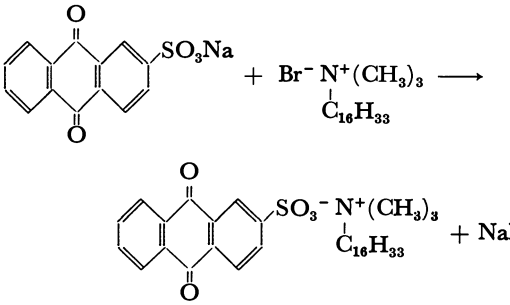
was observed in contrast to the reaction in aqueous solution.[17] The radical anion ($AQ^{\cdot}$) and the dianion (AQ^{2-}) of **1** in aqueous ethanol were rapidly oxidized to **1** in the instant of introducing air to the reaction system, while they are reasonably stable in the cationic micelle for *ca.* 30 min even with the vigorous stirring under an air atmosphere. A similar apparent protective effect of a micelle against the oxidation of the reduced species had also been observed in an anionic micellar system.[18] In a hexadecyltrimethylammonium hydroxide (CTAH 2×10^{-2} mol/dm^3) system in which the micellar surface is thought to be covered with hydroxide ion, the photoreduction was promoted by a factor of *ca.* 100 as compared with that in neutral aqueous solution

Table 1. Photoreduction in aqueous solution

	Surfactant	Product	Relative reactivity
	None	AQH_2	1.0
	CTAB (8×10^{-3} mol/dm)	$AQ^{\cdot}$,AQ^{2-}	5.5
	CTAH (2×10^{-2} mol/dm)	$AQ^{\cdot}$,AQ^{2-}	100
	CTAB (8×10^{-3} mol/dm^3)	AQH_2	$\ll 1.0$



(Table 1). When anthraquinone (**4**), which was assumed to be incorporated in the micellar interior, was used in place of **1**, the photoreduction was hardly observed. CTAB formed 1 : 1 complex with **1** to precipitate quantitatively at the concentration below its cmc according to Eq. 2 (Found: C, 69.22%; H, 8.85%;



(2)

N, 2.42%. Calcd for $C_{23}H_{49}NSO_5$: C, 69.31%; H, 8.64%; N, 2.45%). These results indicated that an electron might be transfered effectively from the hydroxide ion concentrated at a micellar surface to the excited **1** located in the surface area of the cationic micelle. The production of the radical anion was not affected at all by addition of $Cu(en)_2^{+2}$ (3×10^{-4} mol/dm^3) that has lower reduction potential ($E_0 = -0.35$ V *vs.* NHE), but was completely suppressed by the addition of $CuSO_4$ (2×10^{-4} mol/dm^3) that has a higher reduction potential (E_0=through the micellar

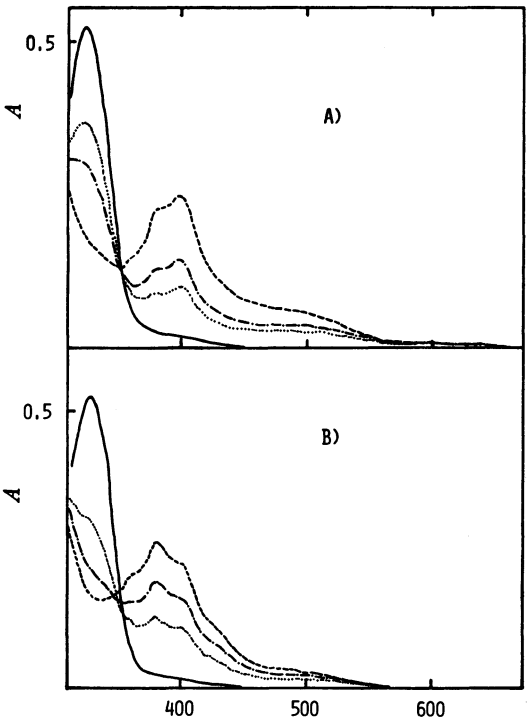


Fig. 5. Absorption spectra of the reaction system of the photoreduction of **1** in CTAB micelle; [**1**]: 1.0×10^{-4} mol/dm^3; [CTAB]: 8.0×10^{-3} mol/dm^3; irradiation light: $\lambda=365$ nm;

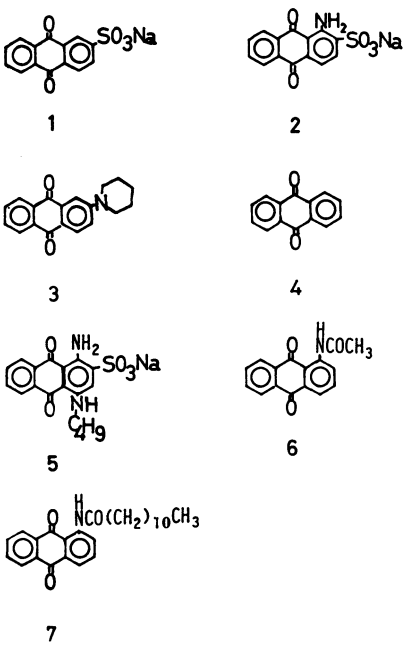
—○—	1.0×10^{-4}	8.0×10^{-3}	2.0×10^{-4}	0
—△—	1.0×10^{-4}	8.0×10^{-3}	0	3.0×10^{-4}

0.159 V) (Fig. 6). This strongly suggested the presence of the electron transfer such as $OH^- \rightarrow AQ \rightarrow Cu^{2+}$ surface. When DCB (1×10^{-2} mol/dm^3) was added to the micellar system as an acceptor molecule, the photochemical ejection of an electron from the dianion (AQ^{2-}) was accelerated, indicating that an electron was irreversibly transported from hydroxide ion to an acceptor molecule *via* **1** or reduced **1** by the stepwise UV ($\lambda=365$ nm) and visible light ($\lambda>450$ nm) irradiations. Since aminoanthraquinones are known to be photoreduced by an electron transfer from hydroxide ion in their upper excited $n\pi^*$ triplet states in homogeneous solution,[19] their photoreduction in CTAB and CTAH micelles were also examined. However, sodium 1-aminoanthraquinone-2-sulfonate (**2**), 2-piperidinoanthraquinone (**3**), sodium 1-amino-4-butylaminoanthraquinone-2-sulfonate (**5**), 1-acetylaminoanthraquinone (**6**), and 1-lauloylaminoanthraquinone (**7**) were all ineffective for photoreduction. The reason for those inactivities is not clear. Small differences of their solubilization sites in the cationic micelle from that of **1** may cause the differences of the reactivities.



Electron Transport in Cationic Reversed Micelle. It is well known that some surfactant molecules in non-aqueous solutions form reversed micelles which can solubilize considerable quantities of water and have inverse structures from those formed in water.[20] In search of a more effective electron transport system, the reaction in a reversed micellar system was attemped, in which the bulk phase solvent itself was expected to act as an acceptor in high concentration. **1** (1×10^{-4} mol/dm^3) in the presence of benzylhexadecyldimethylammonium hydroxide (CDBAH) (1×10^{-2} mol/dm^3) and water (0.5 v/v%) in benzonitrile was irradiated by the monochromatic light of $\lambda=365$ nm. After sufficient formation of the radical anion ($AQ^{\cdot}$) was observed, the selective excitation of the radical anion by visible light ($\lambda>450$ nm) irradiation for about 3 min caused a rapid disappearance of the radical anion itself (Fig. 7). As indicated in Fig. 8, the radical anion again

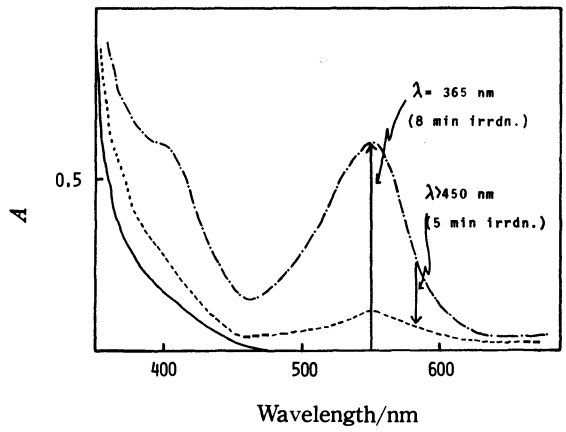


Fig. 7. Absorption spectra of the reaction system of the photoreduction of **1** in CDBAH reversed micelle dispersed in benzonitrile; [**1**]: 1.0×10^{-4} mol/dm^3; [CDBAH]: 2.5×10^{-2} mol/dm^3; [H_2O]: 0.5 v/v% in benzonitrile; (——): before irradiation; (·····): 8 min irradiation with the light of $\lambda=365$ nm; (------): 5 min irradiation with the light of $\lambda>450$ nm subsequently.

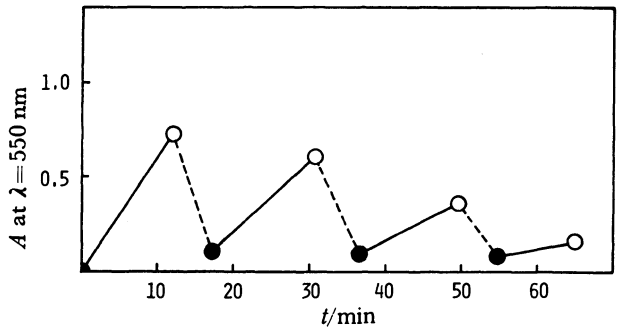

Fig. 8. Effect of the repeated irradiations of UV ($\lambda=365$ nm) and visible ($\lambda>450$ nm) light on the production of the radical anion ($AQ^{\cdot-}$) of **1** in CDBAH reversed micelle dispersed in benzonitrile; [**1**]: 1.0×10^{-4} mol/dm^3; [CDBAH]: 2.5×10^{-2} mol/dm^3; [H_2O]: 0.5 v/v % in benzonitrile; the absorbance at $\lambda=550$ nm was monitored; (●——): UV light ($\lambda=365$ nm) was irradiated; (○——): visible light ($\lambda>450$ nm) was irradiated.

appeared on 365 nm irradiation and disappeared on visible light ($\lambda>450$ nm) irradiation repeatedly. A small amount of hydrogen peroxide (5.4×10^{-5} mol/dm^3) was really detected in the reaction system after the photoreaction, suggesting that the greater part of the hydroxyl radical produced in the reaction system might abstract a hydrogen atom from the surfactant molecule. Moreover, a GC-Mass measurement (column; SE-30, 180 °C) of the irradiated reaction mixture indicated the presence of a trace amount of dihydrodimer (*m/e*; 208, 121, 103) and trimer (*m/e*; 309, 103) of benzonitrile which might be produced from the radical anion of benzonitrile as observed in electrochemical reduction.[21,22] These results strongly suggested that an effective irreversible electron transport was attained from the water layer incorporated in the reversed micelle to the organic layer benzonitrile as solvent and that **1** acted as an electron carrier at the micellar

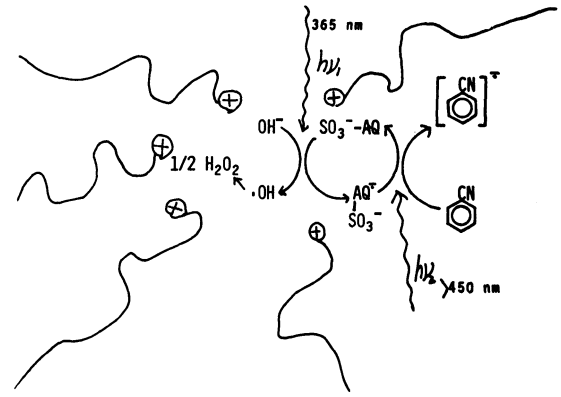

Fig. 9. Electron transport in reversed micellar system.

interface by the stepwise two photon excitation. These conclusions are illustrated in Fig. 9. However, the electron transfer cycle lost its ability to transfer an electron in the repeated cycles as observed in Fig. 8, though repeated short time irradiations seemed to improve the apparent number of transfer cycles. Side reactions such as photohydroxylation[17] and photodesulfonation[23] of **1** may cause this fatigue-like phenomenon. However, the fact that no hydroxylated compound was detected in the reaction system, and **4** as a possible product in the case of desulfonation *via* the radical anion ($AQ^{\cdot-}$) of **1**, also acted as a carrier, ruled out the above possibilities. The main reason may be that the hydroxide ion in the water layer incorporated in a reversed mecelle is consumed during the photoreduction and the resultant acidification renders the system inactive. Hence we attempted the reaction in a two phase system, in which benzonitrile solution of **1** and CDBAH was placed over the water layer including potassium hydroxide. In this two phase system, it is expected that the water core of the reversed micelle in the benzonitrile organic layer is always washed with fresh alkaline aqueous solution by vigorous stirring and the system is refreshed. In accordance with the expectation, the apparent number of transfer cycles was greatly improved to more than twenty in the two phase system. Though more detailed studies are required, it will be useful to carry out the reaction in such a two phase system.

The Possibility of the Incorporation of Carbon Dioxide into the Electron Transport. Next we examined the possibility that carbon dioxide might be incorporated into the electron transfer cycle. In order to obtain a high concentration and activation of carbon dioxide, pyridine was used as solvent. **1** and CTAB or CTAH (2.0×10^{-2} mol/dm^3) with a small amount of water (0.5 v/v%) in pyridine were irradiated by light of $\lambda=365$ nm. The radical anion and dianion of **1** were produced on irradiation. Then, visible light of $\lambda>450$ nm was irradiated successively. When the pyridine solution had been saturated with carbon dioxide, the reduced species decreased with visible light irradiation. On the other hand, under a nitrogen atmosphere without carbon dioxide, no such tendency for the disappearance of the reduced species of **1** was observed. After the photoreaction under carbon dioxide, potassium hydroxide was added to the reaction mixture and the solvent was evaporated. The residual mixture was then

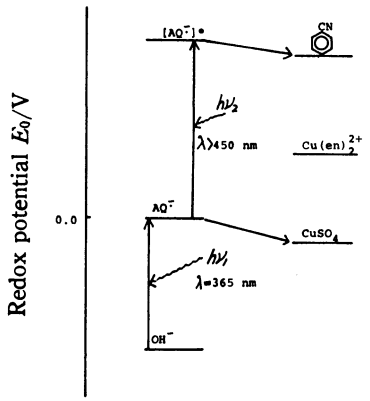

Fig. 10. Flow of electron in the electron transport system including **1** as a carrier by stepwise UV and visible light irradiations.

acidified with sulfuric acid and esterified with 1-butanol. GC-Mass spectra (column; Thermon 100, 150 °C) of the hexane solution extracted from the esterified reaction mixture indicated the presence of trace amounts of products (*m/e*; 281, 207, 57) which might be assigned to isomers of a dibutyl ester of dihydropyridinedicarboxylic acid. Since carbon dioxide did not affect the initial productions of the reduced species of **1**, carbon dioxide participated in the process after the photoreduction, that is, carbon dioxide could be incorporated in the acceptor cycle of the electron transport system to produce the addition products with pyridine.

In an attempt to establish an artificial photosynthesis which produces carbohydrate from water and carbon dioxide under illumination with sunlight, it is required to prepare a redox system which can cover a wide range of redox potential in order to carry an electron from hydroxide ion (E_0=2.0 V) to carbon dioxide (E_0 is in the neighborhood of −2 V) photochemically by one electron processes, if we use only organic materials without multi-electron conversion system such as semiconductors. As summarized in Fig. 10, the redox system including **1** as a carrier was demonstrated in this study to cover a wide range of redox potential (*ca.* 4 V) and may be useful for the purpose.

We would like to thank Dr. K. Anda and his colleagues of the Tokyo Metropolitan Industrial Technic Institute for their kind measurement of the GC-Mass spectra.

Interaction of Amylose with Iodine. I. Characterization of Cooperative Binding Isotherms for Amyloses

Masako YAMAMOTO, Takayuki SANO,† and Tatsuya YASUNAGA*,†
Department of Home Economics, Hiroshima Women's University, Hiroshima 734
†*Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730*
(Received July 20, 1981)

The interaction of amylose with iodine was investigated as a function of degree of polymerization (DP) of amylose by amperometric titration, and the binding isotherms were obtained. The intrinsic equilibrium constant and cooperative parameter were determined with a one-dimensional Ising model for amyloses of various DPs. The inflection of the plot of the intrinsic equilibrium constant *vs.* DP observed at about DP 60 suggests that a helical segment of amylose consists of anhydroglucose residues less than 60. The discontinuity of the cooperativity at about DP 60 was interpreted by two kinds of cooperative effects, intra- and interhelical effects. These results suggest that the interrupted helix is a good model for the amylose structure in aqueous solution. The temperature dependencies of the cooperative parameters show that the cooperativity of amylose-iodine complexation is entropy-controlled.

The structure of amylose in aqueous solution has not yet been established, in spite of its important role for food and industry. Figure 1 shows three representative structural models proposed for amylose in aqueous solution. Model A is a random coil structure,[1] model B is a deformed helix structure,[2,3] and model C is an interrupted helix structure composed of the helix regions with intervals of random coils between them.[4,5] These studies clarified that the iodine staining characteristics, *e.g.*, maximum wavelength λ_{max}, or iodine binding capacity I_b, increases with DP of amylose.[6,7] These results were interpreted by the increase of the affinity for iodine, which implies the existence of a cooperative effect for the complexation, *i.e.*, neighboring iodine forms a more stable complex.[8] A quantitative analysis of the cooperative effect was introduced by Schneider and Cronan.[9] They examined precisely the binding isotherms of iodine to high DP amylose from the standpoint of the cooperative phenomenon and determined the intrinsic equilibrium constant and cooperative parameters. However, no quantitative investigation of the effect of DP on these parameters has been performed.

In the present study, the effect of DP of amylose on the intrinsic equilibrium constant and the cooperative parameter was studied by the amperometric titration, with special emphasis on the change in cooperativity. These results are discussed from the point of view of the structure of amylose in aqueous solution.

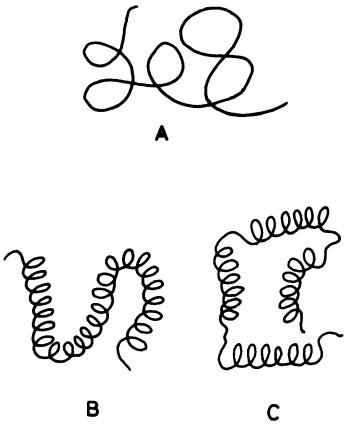

Fig. 1. Proposed models for amylose structure in aqueous solution. A) Random coil structure,[1] B) deformed helix structure,[2,3] and C) interrupted helix structure.[4,5]

Experimental

Materials. Potato amylose was purchased from Pierce Chemical and purified by precipitation three times from 1-butanol. The DP was evaluated to be 1100 by gel-filtration chromatography on Sepharose 4B gel. Degraded amyloses were obtained by hydrolysis of the above amylose with α-amylase[10] and fractionated in a dimethyl sulfoxide–ethanol solvent system. Further purification was done by gel chromatography[11] on Sephadex G-25 and G-75. The DP of each fraction was determined by the relationship between λ_{max} and DP reported by Banks *et al.*[12] The results are listed in Table 1 together with I_b. All solutions containing amylose were freshly prepared immediately before measurements.

Table 1. Properties of the amylose samples

DP	K_{av}[a]	λ_{max} / nm	I_b[b] / mg
27±2	0.24	510	1.5
32±1	0.31	530	4.7
42±3	0.41	545	8.6
57±5	0.51	570	12.6
76±3	0.65	588	15.0
142±20	0.88	610	18.1
1100±50	1.0	620	19.6

a) Elution constant[15] for a Sephadex G-75 gel. b) The amount of iodine binding to 100 mg of amylose.

Measurements. In the amperometric titration, an apparatus similar to that described by Kainuma *et al.*[13] was used in conjunction with two bright platinum electrodes. A solution of 50 cm^3 of amylose (0.5 mM** anhydroglucose) was titrated by adding 30 mm^3 portions of 10 mM iodine solution at constant concentrations of KI (50 mM) and KCl (50 mM) at 75 s intervals. The temperature was controlled at 20.0 °C by circulating thermostatically controlled water around the cell.

** In this paper 1 M = 1 mol dm^{-3}.

Results and Discussion

The binding isotherms of the amylose-iodine system were obtained for a series of amyloses, from DP 27 to 1100 by amperometric titration; these are shown in Fig. 2. As can be seen, the maximum amount of bound iodine increases with increase of DP of amylose.

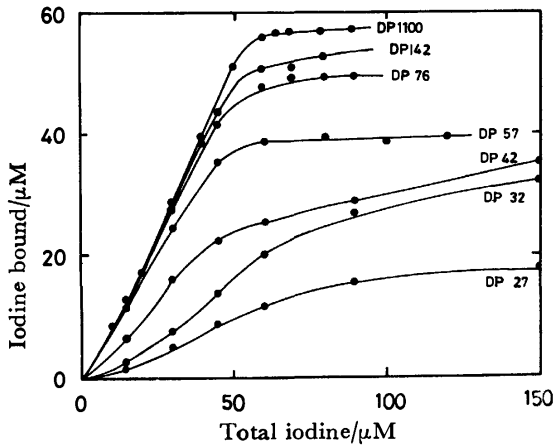

Fig. 2. Binding isotherms of iodine for a series of amyloses obtained by the amperometric titration at 20 °C. Concentration: amylose; 0.5 mM, and KI; 50 mM.

The binding equilibrium of amylose-iodine system is written as

$$A + (I_3^-)_f \rightleftarrows (I_3^-)_b, \quad (1)$$

where A is the binding site, and $(I_3^-)_f$ and $(I_3^-)_b$ are the free and bound triiodide, respectively.[14] The Scatchard equation for reaction (1) is given by

$$r/C_f = K_{app}(n-r), \quad (2)$$

where r and n are the amount of bound iodine and the maximum amount of bound iodine per glucose residue, respectively, C_f is the concentration of free iodine,[16] and K_{app} is the apparent equilibrium constant. Representative Scatchard plots are shown in Fig. 3. All of the amylose-iodine systems are indicative of the cooperativity in the complex formation.[18] If the complexation is independent of cooperativity, the plot

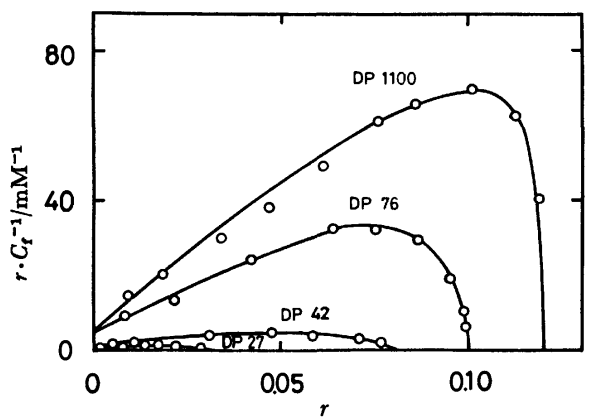

Fig. 3. Representative Scatchard plots of binding isotherms of iodine to amyloses. Solid lines show the theoretical curves obtained by Eq. 3.

Table 2. Binding parameters of the complex formation

DP	$\frac{n}{10^{-2}}$	$\frac{K_0}{10^3\ M^{-1}}$	K_{st}
27	3±1	4.7±0.2	5±1
32	7±1	4.9±0.1	6±1
42	8±2	7.9±0.1	7±1
57	9±1	15±5	9±2
76	10±2	14±1	40±5
142	10±1	14±1	50±10
1100	12±1	14±2	85±10

should show a straight line with negative slope, as can be seen in Eq. 2. The values of n were obtained from the intercept at $r/C_f=0$ in Fig. 3, and are listed in Table 2. The continuous elevation of n with DP will be due to the decrease of the "terminal effect" which means that each end of amylose does not make helix structure and so iodine can not bind there. According to the one-dimensional Ising model of McGhee and von Hippel,[19] the Scatchard equation (2) can be rewritten as

$$\frac{r}{C_f} = K_0(n-r)\left\{\frac{n-2r+R}{2(n-r)}\right\}^2, \quad (3)$$

with $R = \{(n-2r)^2+4K_{st}r(n-r)\}^{1/2}$,

where K_0 is the equilibrium constant for the intrinsic binding of iodine to amylose site (intrinsic equilibrium constant) and K_{st} is the cooperative parameter expressing the first nearest neighboring interaction between bound iodines.

The values of K_0 and K_{st} were determined so as to give the best fit of the data to the Scatchard equation, these are also listed in Table 2. The values of K_0 and K_{st} for amylose of DP 1100 were in good agreement with the corresponding values obtained by Schneider and Cronan.[9]

The value of K_0 increases with DP up to DP 60 and then remains constant, as shown in Fig. 4. With increase of a helical region, the iodine included in the center of a helix will be stabilized gradually, due to the interruption

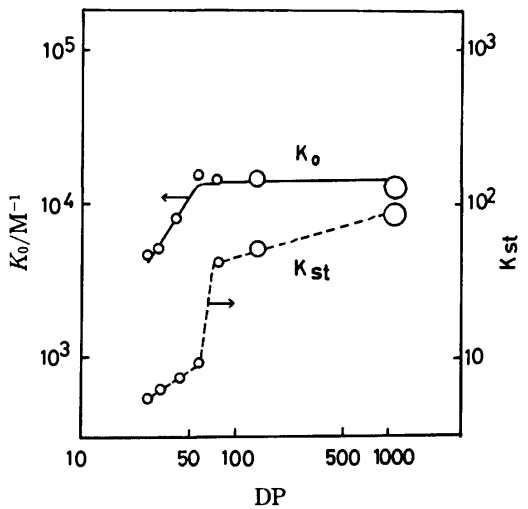

Fig. 4. The DP dependencies of the binding parameters of the amylose-iodine complex.

of the dissociation. According to this idea, the behavior of K_0 in Fig. 4 indicates that the length of a helix increases with DP up to a definite DP and then becomes constant, and suggests the model C in Fig. 1 as the amylose structure in aqueous solution. Furthermore, the length of the helical segment in the unit of DP (hereafter denoted by LHS) was estimated to be less than 60. Compared with the literature values of LHS, ranging from 66 to 140,[20-23] our value is smallest. Inconsistencies in the literature values have been ascribed mainly to the distribution of the DP of amylose.[23] However, some of them will be induced by the differences of the physical quantities used for the determination of the LHS.[24] Since the physical quantities which have been used so far were the values under the saturated condition of iodine, they should be affected significantly by the cooperativity. The value of K_0, on the contrary, does not contain any contribution from the cooperativity and is influenced only by the DP of amylose. Therefore, we believe that K_0 is the most preferable parameter for the determination of the LHS.

The value of K_{st} increases with DP of amylose up to DP 60, at this point it steeply jumps and then gradually increases, as shown in Fig. 4. Such discontinuous behavior of K_{st} can be interpreted by introducing two kinds of cooperative effects. One is the effect within a helical segment (intrahelical effect) which comes out in the region of DP up to 60, where amylose has only one helical segment. The other is the effect between different helical segments (interhelical effect) which comes out only above DP 60 where the amylose consists of more than two helical segments. This idea about cooperativity also supports the model C in Fig. 1 as the structure of amylose in aqueous solution.

Thermodynamic parameters for the intrinsic equilibrium constant and cooperativity were obtained for two kinds of amyloses (DP 42 and DP 1100). Figure 5 shows the Scatchard plots for the amylose of DP 1100

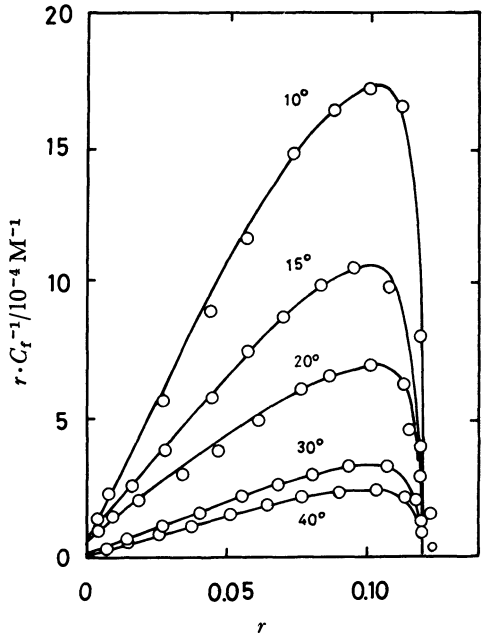

Fig. 5. The Scatchard plots of amylose (DP 1100)–iodine complex at different temperatures.

TABLE 3. EFFECT OF THE TEMPERATURE ON THE BINDING PARAMETERS OF THE COMPLEX FORMATION

Temp/°C	DP 42		DP 1100	
	K_0 / $10^3\,M^{-1}$	K_{st}	K_0 / $10^3\,M^{-1}$	K_{st}
10±0.1	16±3	7±1	24±1	85±10
15±0.1	10±1	7±1	15±1	85±10
20±0.1	7.9±0.1	7±1	14±1	85±10
30±0.1	3.9±0.7	7±1	4.7±0.3	85±10
40±0.1	—	—	3.5±0.3	85±10

TABLE 4. THERMODYNAMIC PARAMETERS OF THE COMPLEX FORMATION

Parameter	DP 42	DP 1100
ΔH_0/kJ mol^{-1}	−50	−50
ΔG_0/kJ mol^{-1}	−22	−37
ΔS_0/J K^{-1} mol^{-1}	−94	−42
ΔH_{st}/kJ mol^{-1}	0	0
ΔG_{st}/kJ mol^{-1}	−5.4	−11
ΔS_{st}/J K^{-1} mol^{-1}	19	38

measured at different temperatures. The magnitude of the plots decreases with increase of temperature, while the shape does not change. The values of K_0 and K_{st} for the two amyloses are listed in Table 3. From the temperature dependencies of K_0 and K_{st}, thermodynamic parameters were estimated, they are summarized in Table 4. It is noteworthy that the cooperative enthalpy change ΔH_{st} is zero for both amyloses and, therefore, the cooperativity is controlled not by enthalpy but by entropy.

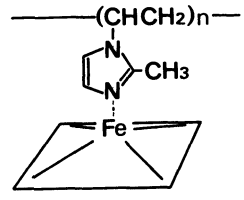
The Preparation of Protoheme Mono-*N*-[5-(2-methyl-1-imidazolyl)pentyl]amide and Its Oxygenation

Eishun TSUCHIDA,* Hiroyuki NISHIDE, Yoshinori SATO, and Manabu KANEDA
Department of Polymer Chemistry, Waseda University, Tokyo 160
(Received August 5, 1981)

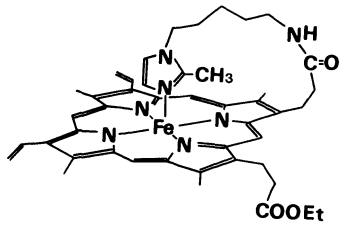
Iron(II)protoporphyrin IX *N*-[5-(2-methyl-1-imidazolyl)pentyl]amide ethyl ester (**1**) and its derivatives (**2**—**4**) were prepared. They predominantly form pentacoordinate heme complexes in organic and aqueous solutions, based on their 2-methylimidazole-ligand and spacer *N*-pentylamide groups. Oxygen adducts of **1**—**4** were rapidly formed on exposure to oxygen in *N*,*N*-dimethylformamide (DMF) at −30 °C, and their life-times were more than 30 min.

It is interesting to attempt to synthesize an iron–porphyrin complex with an oxygen-binding ability. Much recent work has been reported on such attempts, and two approaches have been partially successful. The first is the elegant steric modification of porphyrin: porphyrins have been replaced with "picket fence groups,"[1] "crown ether groups,"[2] "strap groups,"[3] *etc.*[4,5] The second approach is to attach the iron–porphyrin complex to a polymer chain.[6–8] By these means, a reversible oxygen bnding has been achieved in aprotic solvents or in the solid state, but in an aqueous medium all the iron–porphyrin derivatives have been irreversibly oxidized.



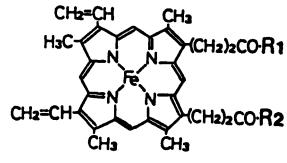
Scheme 1.

Recently, the present authors have found that the heme (iron(II)-protoporphyrin IX) complex with poly-(1-vinyl-2-methylimidazole) (PMI) (Scheme 1) forms the oxygen adduct even in an aqueous solution at −30 °C.[9] It is very important for oxygen binding in an aqueous solution that the heme complex has pentacoordinate structure the sixth coordination site of which is vacant to bind oxygen.[10]

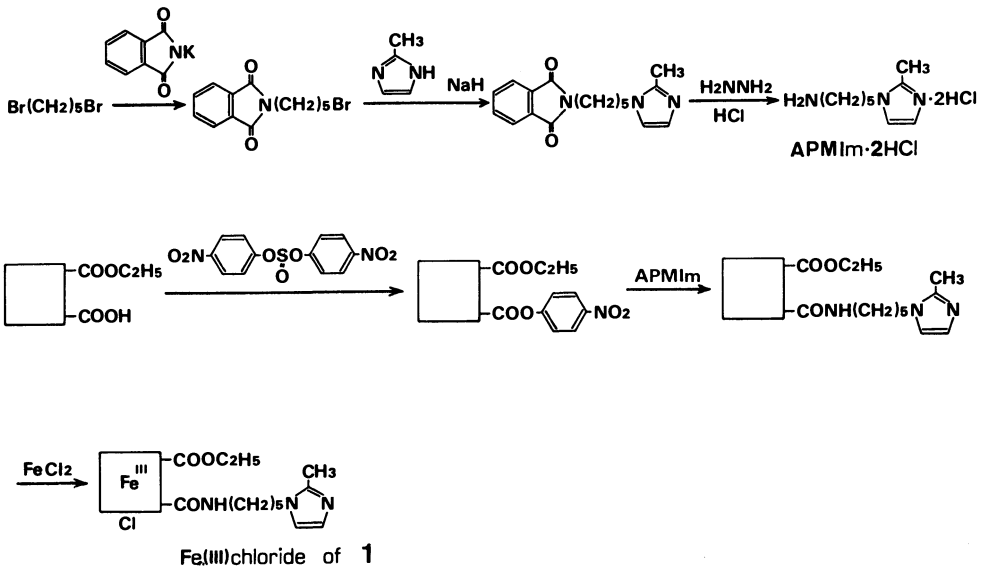


Scheme 2.

In this work, we synthesized heme derivatives having a 2-methylimidazole-ligand with *N*-pentylamide groups, **1**—**4**, which are expected to preferentially form the pentacoordinate heme complexes, as is shown in Scheme 2. A series of heme derivatives with covalently bound imidazole-ligands has already been studied by Traylor.[11–13] The mesoheme *N*-[3-(1-imidazolyl)propyl]amide ethyl ester derivative (**6**) is typical and forms the oxygen adduct in an aprotic, organic solvent.[12] However, the solution of **6** gave the visible spectrum of hexacoordinate heme, the sixth ligand having been derived from the solvent, and was irreversibly oxidized in aqueous media. On the other hand, the heme derivative with the 2-methylimidazole-ligand with an *N*-propylamide group has also been reported. However, the 2-methylimidazole-ligand could not coordinate to the central iron-ion because the *N*-propylamide group was too short, and the tetracoordinate heme complex was predominantly formed. From these results and the geometrical consideration of heme derivatives shown in Scheme 2, we selected the *N*-pentylamide group as a spacer group which bonds the 2-methylimidazole-ligand with heme and synthesized **1** and their derivatives: **2** as a water-soluble derivative, **3** as a bis(ligand)-type derivative, and **4** as a polymer-bound derivative. The coordination structure and oxygen binding ability of these heme derivatives (**1**—**4**)



Compound	R_1	R_2
Heme	OH	OH
1	$NH(CH_2)_5$-(2-methylimidazolyl)	OC_2H_5
2	$NH(CH_2)_5$-(2-methylimidazolyl)	OH
3	$NH(CH_2)_5$-(2-methylimidazolyl)	$NH(CH_2)_5$-(2-methylimidazolyl)
4	$NH(CH_2)_5$-(2-methylimidazolyl)	Gly-PEG
5	$NH(CH_2)_3$-(2-methylimidazolyl)	OC_2H_5
6	$NH(CH_2)_3$-imidazolyl	OC_2H_5
7	$NH(CH_2)_3$-imidazolyl	$NH(CH_2)_3$-imidazolyl



Scheme 3.

were studied in comparison with those of the previously reported Traylor's heme derivatives (**5**, **6**, and **7**) and with those of the polymer-heme complexes.

Results and Discussion

1 was obtained by the reaction of 1-(5-aminopentyl)-2-methylimidazole and the protoporphyrin IX monoethyl ester. The reaction process is illustrated in Scheme 3. **2** was obtained by hydrolyzing **1**. **3** was similarly prepared from 1-(5-aminopentyl)-2-methylimidazole and protoporphyrin IX, while **4** was obtained from **2** and poly(ethylene glycol)glycine[14] by using dicyclohexylcarbodiimide. The analytical data are given in the Experimental section.

The ultraviolet and visible absorption spectra of **1**, **5**, and **6** in the DMF solution (volume ratio DMF/H_2O= 9/1) are shown in Fig. 1. The visible spectrum of **1** was characterized by a single-peak absorption at 557 nm, the coordination structure of which was assigned to the pentacoordinate one; the iron(II) ion was in a high-spin state like myoglobin (557 nm). The molar absorption coefficients (ε) of **1** were 2.3×10^5 at 433 nm and 1.4×10^4 at 557 nm, nearly equal to those of the pentacoordinate heme complex with a large excess of 2-methylimidazole. On the other hand, the spectrum of **5** was broadened considerably, much like that of the tetracoordinate heme complex. This means that the 2-methylimidazole-ligand could not coordinate sufficiently to the central iron(II) ion, probably because of its shorter spacer group (*N*-propylamide group), and the pentacoordinate structure was not completed. **6** showed a double-peak absorption in the visible region (530 and 560 nm, Fig. 1) assigned to the hexacoordinate and low-spin heme complex, as had been reported by Traylor.[11] Although **6** formally has one imidazole-ligand, it forms the hexacoordinate heme complex in solution. The solvent molecule combines with the sixth coordination site of heme.[11] From these results, it may be concluded that **1** more predominantly forms the pentacoordinate heme complex than **5** and **6** do.

[Fe(II)]=0.1 mmol dm^{-3}, ——: **1**, —·—: **5**, -----: **6**, ·····: heme.

2 and **3** in aqueous solutions also showed the single-peak absorption at 557 nm, and the pentacoordinate structure was stable in the concentration range from about 0.01 to 10 mmol dm^{-3}. The visible spectrum of **3**, with two 2-methylimidazole-ligands, was identical to that of **1**. This means that one of the 2-methylimidazole pair coordinates to the central iron ion, while the other 2-methylimidazole-ligand can not coordinate to the sixth coordination site of heme. This behavior was like that of 2-methylimidazole-heme which took the pentacoordinate structure even if a large excess of 2-methylimidazole existed. This result was in contrast to that for **7**, which took the very stable hexacoordinate structure.

The oxygenation ability of each complex was measured in DMF-H_2O(9/1) at −30 °C. Except for **7**, all the heme complexes gave the oxygen adduct. As an

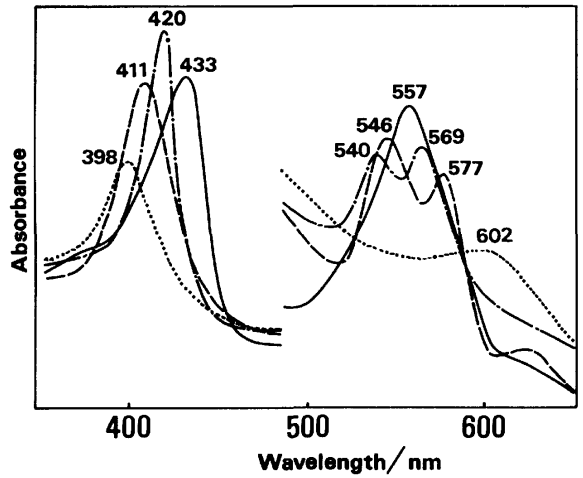

Fig. 2. Ultraviolet and visible spectra of **1** in DMF–H_2O(9/1) at −30 °C.
[**1**]=0.1 mmol dm^{-3}, ——: deoxy complex, ------: O_2-adduct, —·—: CO-adduct, ·····: oxidized complex.

example, the spectrum of the oxy-**1** complex (Fig. 2) was identified as that of the oxygen adduct by means of the following results: (i) The spectrum changed to that of the heme-CO complex when carbon monoxide was bubbled through the solution, and (ii) returned to the deoxy complex when nitrogen gas was introduced.

One must pay careful attention to the residue of the sodium dithionite which is used to prepare the heme complex (see Experimental section), because it often complicates the spectrum of the heme complex under aerobic conditions. The contribution of sodium dithionite and its residue to this reversible oxygenation was denied by the following results: (i) A small excess of sodium dithionite was used for reduction, and no trace of it remained before the oxygen exposure. (ii) The porphyrin ring of heme was degrated, and no oxygenation was observed in the presence of a large excess of dithionite. (iii) Organic reductants, such as L-ascorbic acid or D-glucose, were also effective reducing agents in forming an oxygen complex.

1—**4**, which took the pentacoordinate deoxy structure, immediately bound oxygen. Figure 3(a) shows the isosbestic spectral change in **1** after exposure to oxygen. In contrast, **6** reacted slowly with oxygen, while **7** did not react at all. It may be concluded from these results that the rate of the oxygenation reaction of the pentacoordinate heme complex is high, for the sixth coordination site, *i.e.*, the oxygen-binding site, is vacant.

The oxygen adduct of heme derivatives degraded to form a high-spin hemin complex (weak absorption at about 602 nm) through isosbestic points (528, 590 nm) as is shown in Fig. 4. The degradation obeyed first-order kinetics, and the life-time of the oxygen adduct was calculated by means of the following equation: $1/\tau=(1/t)\ln[(A_0-A_\infty)/(A_t-A_\infty)]$, where τ indicates the life-time of the oxygen adduct and where A_0, A_t, and A_∞ are the absorbance of the visible spectrum of heme-oxygen adduct at the beginning, at after time t, and when the degradation is complete respectively. The life-time is summarized in Table 1.

Table 1. Life-times of the oxygen adducts at −30 °C

Complex	Life-time/min	
	In DMF–H_2O (9/1)	In H_2O–ethylene glycol (1/1)
PMI-heme[a]	63	25
1	32	—
2	—	Oxidized
3	72	1
4	35	Oxidized
2-Methylimidazole-heme[b]	6	Oxidized
6	98	Oxidized
7	Oxidized	Oxidized

a) [2-Methylimidazole residue]/[heme]=500. b)[2-Methylimidazole]/[heme]=5000.

The life-time of oxy-**1** was much longer than that of the 2-methylimidazole-heme system; **1** could give oxygen adduct with not only a large formation rate, but also a long life-time. Table 1 shows that **3** and PMI-

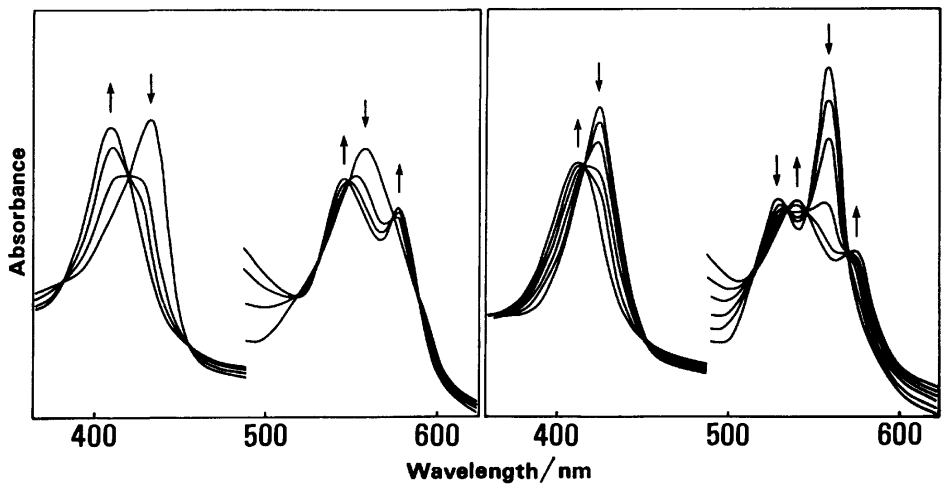

Fig. 3. Oxygenation of **1** (a) and **6** (b) in DMF–H_2O(9/1) at −30 °C. After exposing to oxygen: 0, 0.5, 1, and 2 min for (a); 0, 1, 2, 5, 10, and 15 min for (b).

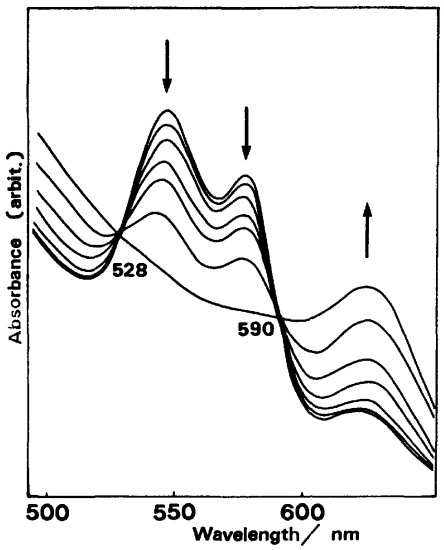

Fig. 4. Degradation of the oxygen adduct of **1** in DMF–H_2O(9/1) at −30°C. After 0, 5, 10, 20, 30, 60 min, and 1 d.

heme form more stable oxygen adducts, which approach the oxy-**6** studied by Traylor. 2-Methylimidazole residue that exists near the sixth coordination site of heme makes a good contribution to the stabilization of the oxygen adduct.

The oxygenation reaction was also checked in H_2O–ethylene glycol (1/1) at −30 °C. PMI-heme and **3**, which gave stable oxygen adducts in DMF–H_2O (9/1), could also form oxygen adducts even in an aqueous medium, though they were not so stable. The reasons for the oxygen-binding ability of PMI-heme and **3** in an aqueous medium are presumed to be as follows: (i) PMI-heme and **3** form pentacoordinate, high-spin-state complexes with large formation constants, and the rates of oxygenation are high, and (ii) the polymer-ligand, PMI, or the unchelated 2-methylimidazole sterically occludes heme and provides an effective hydrophobic environment which surrounds the oxygen adduct.

The synthesis and oxygen-binding ability of polymer-bound **1** will be presented in a subsequent paper.

Experimental

*Synthesis of Iron(III)protoporphyrin IX Mono-*N*-[5-(2-methyl-1-imidazolyl)pentyl]amide Ethyl Ester Chloride (Iron(III) Chloride of **1**) and the Corresponding Amide Acid (Iron(III) Chloride of **2**).* 1-(5-Aminopentyl)-2-methylimidazole (AMPIm) was prepared by a Gabriel reaction. Potassium phthalimide (74 g, 0.4 mol) was suspended in 1,5-dibromopentane (300 g, 1.3 mol), after which the mixture was allowed to react at 190—200 °C for 12 h. The mixture was steam-distilled to remove the unreacted 1,5-dibromopentane. *N*-(5-Bromopentyl)phthalimide (BPP) was extracted with chloroform, dried (Na_2SO_4), evaporated to dryness, and then recrystallized from ethanol; pale yellow crystals (yield, 59.8 g).

50% oily sodium hydride (4.80 g) was suspended in dry toluene (100 ml). 2-Methylimidazole (8.21 g, 0.10 mol) was added to this suspension, and the mixture was refluxed for 5 h under nitrogen. Then, BPP (29.6 g, 0.10 mol) was added, and the mixture was allowed to react for 15 h under reflux. After filtration, the solution was evaporated to dryness. The brown oily product was chromatographed on a silica-gel column (about 300 mesh, 5 cm × 45 cm for operating 1.5 g). The fourth fraction with chloroform–methanol (20 : 1) was collected (R_f=0.19 with chloroform–methanol (20 : 1)) and evaporated to dryness. *N*-(5-Phthalimidopentyl)-2-methylimidazole (PPIm): pale yellow powder; yield, 17.8 g (59.9%), IR; ν_{ring} 1621 (phenyl), 1620 (imidazole), $\nu_{C=O}$ 1780, 1720 cm^{-1}. Found: C, 69.1; H, 6.58; N, 13.9%. Calcd for $C_{17}H_{19}N_3O_2$: C, 68.7; H, 6.40; N, 14.1%.

PPIm (17.7 g, 59.5 mol) was dissolved in methanol (250 ml). Hydrazine monohydrate (2.98 g, 59.5 mol) was added to this solution, which was then refluxed for 15 h. Then water (200 ml) was added, and the methanol was removed by evaporation. Concd hydrochloric acid (200 ml) was added to this aqueous solution, and the mixture was refluxed for 2 h. After cooling to 0 °C, the white precipitate was filtered off. The filtrate was evaporated to dryness, and the crude product was recrystallized from ethanol. 1-(5-aminopentyl)-2-methylimidazole dihydrochloride (APMIm 2HCl): pale yellow crystals; yield 12.1 g (84.7%) ^1H NMR (DMSO-d_6, δ): imidazole C–H, 7.5, 7.7(2H); $-(CH_2)_5-$, 1.3—1.8(6H), 2.7(2H), 4.1(2H); $-CH_3$, 2.6(3H); $-NH_3^+$, 8.2(3H). Found: C, 45.1; H, 7.88; N, 17.4; Cl, 29.6%. Calcd for $C_9H_{19}N_3Cl_2$: C, 45.0; H, 7.92; N, 17.5; Cl, 29.6%. IR: ν_{ring} 1605 (imidazole), $\nu_{NH_3^+}$ 3000, 2510, 2420 cm^{-1}.

On the other hand, the protoporphyrin IX monoethyl ester (PMEE) was prepared as follows. Protoporphyrin IX sodium salt (4.5 g, 7.4 mmol) and phosphorus pentachloride (2.4 g, 11.5 mmol) were dissolved in chloroform (250 ml), and the mixture was stirred for 30 min at 30 °C. Ethanol (15 ml) was added, and this mixture was stirred for 30 min, after which more ethanol (15 ml) was added. The reaction was conveniently followed by examining the TLC (silica-gel, chloroform–methanol (10 : 1)). The amount of the second fraction, based on PMEE, increased as the esterification proceeded. The reaction was finished after 45 min, and chloroform (200 ml) and water (1.5 ml) were added to this solution. The pH was then controlled to 6.0 by adding triethylamine. After washing with water, the chloroform layer was filtered and concentrated. The crude product was chromatographed on a silica-gel column (5 cm × 20 cm for operating 2 g). The column was eluted with chloroform until the eluent was very pale. The PMEE was obtained with chloroform–methanol (15 : 1) as the first fraction; 30% yield.

Protoporphyrin IX mono-*N*-[5-(2-methyl-1-imidazolyl)-pentyl]amide ethyl ester (PMImPe) was synthesized as follows. PMEE (2.7 g, 4.5 mmol) was dissolved in a mixture of DMF (30 ml) and pyridine (30 ml), after which bis(*p*-nitrophenyl) sulfite (5.9 g, 18 mmol) was added . After stirring for 18 h at room temperature, the solution was concentrated by evaporation. The residue was dissolved in chloroform, and the insoluble part was removed by filtration. After concentration, PMImPe was precipitated from diethyl ether–petroleum ether (1 : 1). The brown, powdered product was chromatographed on a silica-gel column (4 cm × 20 cm for operating 1 g) eluted with benzene–acetone (25 : 1). The *p*-nitrophenyl ester was obtained as the main fraction in a 65.9% yield.

The *p*-nitrophenyl ester (0.85 g, 1.2 mmol) and PMEE (0.25 g, 1.5 mmol) were dissolved in chloroform (30 ml), and the mixture was stirred for 1 d at room temperature. After concentration, the residue was dissolved in chloroform, and the mixture was filtered. Then PMImPe was precipitated

from diethyl ether. PMImPe: brown powder; yield, 733 mg (83.6%). IR: $\nu_{C=O}$ 1640, 1550 (amide), 1730 (ester). Found: C, 73.1; H, 7.21; N, 13.2%. Calcd for $C_{45}H_{53}N_7O_3$; C, 73.1; H, 7.17; N, 13.3%. ^{1}H NMR ($CDCl_3$, δ): ring $-CH_3$, 3.55—3.80(12H); imidazole $-CH_3$, 0.30(3H), imidazole $-H$, 4.7(1H) propionic α-CH_2, 4.10(4H); propionic β-CH_2, 3.15 (4H); α-CH_2, 0.90(2H); β-CH_2, 0.20(2H); γ-CH_2, 2.35(2H); δ-CH_2, 1.95(2H); ε-CH_2, 2.83(2H); NH, 5.8(1H); *meso*-H, 9.6—9.9(4H); vinyl-H, 5.0—5.5, 6.9(3H); OC_2H_5, 4.10(2H), 2.05(3H); pyrrole-H, 4.50(2H).

By the incorporation of the iron ion in PMImPe, iron(III)-protoporphyrin IX mono-*N*-[5-(2-methyl-1-imidazolyl)pentyl]amide ethyl ester chloride (iron(III) chloride of **1**) was obtained. PMImPe (300 mg, 0.36 mmol) was dissolved in DMF (300 ml). $FeCl_2 \cdot nH_2O$ (180 mg) was added to this solution, and the mixture was heated to 70 °C under nitrogen for 1 h. The solvent was removed by evaporation, and the residue was extracted with a chloroform–methanol (3 : 1) mixture. The crude product was chromatographed on a basic alumina column (3 cm × 15 cm), eluted with chloroform–methanol (30 : 1). The first and second fractions (iron(III) chloride and μ-oxo dimer of **1**) were collected and brought to dryness. Iron(III) chloride of **1**: brown powder; yield, 172 mg (51.2%). Found: C, 65.1; H, 6.10; N, 11.8; Cl, 4.35%. Calcd for $C_{45}H_{51}N_7O_3FeCl$: C, 65.2; H, 6.16; N, 11.8; Cl, 4.29%.

By hydrolyzing PMImPe, iron(III) chloride of **2** was obtained. Iron(III) chloride of **1** (350 mg) was dissolved in methanol (15 ml). NaOH (2 mol dm^{-3}, 6 ml) was added to this solution, and the mixture was stirred for 12 h at room temperature. Water (10 ml) was added to this solution, and the methanol was removed by evaporation. The solution was acidified to pH 4.0 by adding dilute hydrochloric acid, and extracted with chloroform. The chloroform layer was dried (Na_2SO_4), and then the solvent was removed by evaporation. Iron(III) chloride of **2**: brown powder; yield, 280 mg (80%). IR: $\nu_{C=O}$ 1500, 1620 (amide), 1720 (carboxylic acid) cm^{-1}. Found: C, 64.7; H, 5.92; N, 12.1; Cl, 4.50%. Calcd for $C_{43}H_{47}N_7O_3FeCl$: C, 64.5; H, 5.87; N, 12.2; Cl, 4.44%.

Synthesis of Iron(III)protoporphyrin IX Bis[N-[*5-(2-methyl-1-imidazolyl)pentyl*]*amide*] *Chloride (Iron(III) Chloride of 3).* Protoporphyrin IX (1.12 g, 2 mmol) and bis(*p*-nitrophenyl) sulfite (4.0 g, 12.3 mmol) were dissolved in 50 ml of DMF–pyridine (1 : 1), after which the solution was allowed to react for 18 h at room temperature. After filtration, the solution was concentrated. The residue was dissolved in dichloromethane, and the insoluble part was removed by filtration; then the solution was poured into diethyl ether–petroleum ether (1 : 1). The crude product was chromatographed on a silica-gel column (3 cm × 20 cm for operating 1 g). The bis(*p*-nitrophenyl ester) was obtained in a 73% yield as the first fraction with dichloromethane–acetone (60 : 1).

The bis(*p*-nitrophenyl ester) (150 mg, 0.18 mmol) and APMIm (4.0 g, 12.3 mmol) were dissolved in a mixture of DMF–dichloromethane (1 : 1) (8 ml), after which the solution was allowed to react for 12 h at room temperature. The resulting solution was concentrated and washed with diethyl ether to remove the *p*-nitrophenol. The crude product was chromatographed on a silica-gel column (1.5 cm × 12 cm). The third fraction chloroform–methanol (4 : 1) was collected and brought to dryness. Protoporphyrin IX bis[*N*-[5-(2-methyl-1-imidazolyl)pentyl]amide] ($P(MImPe)_2$): Found: C, 72.7; H, 7.43; N, 16.3%. Calcd for $C_{52}H_{64}N_{10}O_2$: C, 72.6; H, 7.44; N, 16.3%. IR: $\nu_{C=O}$ 1650, 1555 (amide) cm^{-1}.

The corresponding iron(III) complex of $P(MImPe)_2$ (iron(III) chloride of **3**) was obtained by the above mentioned procedure in a 52% yield. Found: C, 65.7; H, 6.59; N, 14.7; Cl, 3.77%. Calcd for $C_{52}H_{62}N_{10}O_2FeCl$: C, 65.7; H, 6.53; N, 14.7; Cl, 3.74%.

Synthesis of Iron(III)protoporphyrin IX N-[*5-(2-Methyl-1-imidazolyl)pentyl*]*amide* N′-[*ω-Hydroxypoly(ethyleneoxy) carbonylmethyl*]*amide (Iron(III) Chloride of 4).* Iron(III) chloride of **2** was combined with $H_2NCH_2CO(OCH_2CH_2)_nOH$ (Gly-PEG) by the following procedure. Iron(III) chloride of **2** (120 mg, 0.15 mmol) and 1-hydroxybenzotriazole (30 mg, 0.22 mmol) were dissolved in DMF (4 ml). Dicyclohexylcarbodiimide (33 mg, 0.16 mmol) was added to this solution at 0 °C, after which the mixture was allowed to react for 30 min. Gly-PEG (0.5 g, 0.05 mmol of the functional group) and *N*-methylmorpholine (5.5 mg) were then dissolved in DMF (3 ml) and added to this solution. The mixture was stirred for 2 d at room temperature. After concentration, the residue was dissolved in chloroform, and the insoluble part was removed by filtration; then the solution was poured into diethyl ether–ethyl acetate (2 : 1). The crude product was chromatographed on a Sephadex LH-60 column (3 cm × 40 cm for operating 0.2 g). The first fraction with methanol was collected and brought to dryness. The product was reprecipitated from a chloroform–diethyl ether system twice. The degree of incorporation of the complex unit into the functional group of the polymer was determined to be 71% from the absorbance at 385 nm of a chloroform solution of iron(III) chloride of **4** referred to that of the iron(III) chloride of **1**.

Iron(III) chlorides of **5**, **6**, and **7** were synthesized according to Traylor's method.

Other Chemicals. The 2-methylimidazole was purified by recrystallization twice from benzene. The DMF for spectroscopic measurement was treated with molecular sieves (4 Å), and distilled under reduced pressure before use. The ethylene glycol added as antifreeze for spectroscopic measurement was distilled under reduced pressure before use.

Fe(II) Complex Solution. The Fe(III) complex was dissolved in a solvent (DMF/H_2O or pH 10 buffer/ethylene glycol). In the case of PMI-heme and 2-methylimidazole-heme, the ligand was added in this step. Nitrogen gas was bubbled through this solution, and an aqueous solution of sodium dithionite ($[Na_2S_2O_4]/[Fe(III)]=5$) was added to obtain the Fe(II) complex solution.

Measurements. The electronic absorption spectrum was measured with a Union Giken SM-401 spectrophotometer.

This work was partially supported by a Grant-in-Aid for Scientific Research No. 56209024 from the Ministry of Education, Science and Culture, Japan.

The Effect of Polyhydric Alcohols on the Thermal Denaturation of Lysozyme as Measured by Differential Scanning Calorimetry

Yukihisa FUJITA,* Yasuchika IWASA, and Yukinao NODA
Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663
(Received September 3, 1981)

The thermal denaturation of lysozyme in aqueous solutions of polyhydric alcohols at pH 2 was investigated by differential scanning calorimetry (DSC). The polyhydric alcohols employed were inositol, sorbitol, xylitol, erythritol, glycerol, and ethylene glycol. These alcohols tended to enhance the thermal stability of lysozyme; both the temperature and the enthalpy of denaturation increased almost linearly with increasing alcohol concentration. The increase in denaturation temperature at a given alcohol concentration was a linearly increasing function of the number of hydroxyl groups per alcohol molecule. The denaturation enthalpy at identical temperature increased only slightly by the addition of polyhydric alcohol. The hypothesis may be supported that the dominant mechanism by which polyhydric alcohols stabilize proteins to thermal denaturation is through their effect on the water structure, which determines the strength of the hydrophobic interactions between the nonpolar groups of the protein.

The folding, structural stability, and dynamics of globular proteins are thought to be extensively controlled by the interactions of the protein with water. Various substances affect the protein-water interactions when added to aqueous protein solutions and consequently alter the structural stability of proteins.[1-3] There have been many investigations which show the stabilizing effect of polyhydric alcohols and sugars on the native conformation of proteins. Simpson and Kauzmann[4] observed that the extent of denaturation of ovalbumin in urea solutions was reduced in the presence of glycerol or sucrose. The influence of polyhydric alcohols and sugars on the rate of subunit dissociation of tetrameric L-asparaginase in the presence of urea was investigated by Shifrin and Parrott.[5] Gerlsma and Stuur[6] showed by spectrophotometric measurements that polyhydric alcohols raised the thermal transition temperature of lysozyme and ribonuclease. A similar effect of polyhydric alcohols has also been observed for chymotrypsinogen.[7,8] However, the manner in which polyhydric alcohols and sugars induce the increased thermal stability of proteins or reduce the extent of denaturation by other reagents is poorly understood.

The application of differential scanning calorimetry (DSC) to the investigation of thermally induced conformational transitions of protein has provided valuable information on the mechanism of protein denaturation; this has been recently reviewed by Biltonen and Freire[9] and Privalov.[10] The extensive calorimetric investigation of the thermal denaturation of lysozyme has been reported by Privalov and Khechinashvili.[11] The reversible nature of the denaturation has been established. Recently, the DSC study of the thermal denaturation of lysozyme in sugar solutions has been reported by Uedaira and Uedaira.[12]

We have been investigating the effect of various substances on the thermal stability of globular proteins by means of DSC. In the previous paper,[13] the effect of monohydric alcohols on the thermal denaturation of lysozyme was reported. The denaturation temperature of lysozyme in monohydric alcohol solutions decreased gradually with increasing alcohol concentration, which became more pronounced with increasing hydrocarbon content of alcohol. On the other hand, the denaturation enthalpy passed through a maximum with increasing alcohol concentration and the maximal value decreased with increasing hydrocarbon content of alcohol. A similar behavior has been observed with sulfoxides.[14] These tendencies may be interpreted in terms of the mixed hydrophobic-hydrophilic character of monohydric alcohols and sulfoxides.

In the present paper, the effect of polyhydric alcohols on the thermal denaturation of lysozyme has been investigated by means of DSC and the results are compared with those of monohydric alcohols.

Experimental

Materials. The hen egg-white lysozyme used was a salt-free, six-times-recrystallized preparation obtained from Seikagaku Kogyo Co. The molecular weight of lysozyme was taken to be 14307. Analytical grade inositol, sorbitol, and xylitol were purchased from Nishio Kogyo Co. and reagent grade *meso*-erythritol from Merck. Spectral grade glycerol and ethylene glycol were obtained from Wako Pure Chemicals. These polyhydric alcohols were used without further purification.

Methods. The stock solution of lysozyme was prepared with 0.1 mol dm^{-3} glycine buffer at pH 2.0 containing 0.1 mol dm^{-3} NaCl and if necessary the pH was adjusted by adding HCl. The protein concentration was determined spectrophotometrically using an extinction of $E^{1\%}_{1cm}=26.9$ at 280 nm in 0.1 mol dm^{-3} glycine buffer at pH 3.0.[15] A Hitachi 323 automatic recording spectrophotometer was used. Polyhydric alcohol was added by weight.

Thermal measurements were performed with a Daini Seikosha SSC-560U differential scanning calorimeter (conduction type) at protein concentrations of 2.39—2.47%. The sample (0.06 cm^3) was hermetically sealed in a silver vessel. A heating rate of 1 K min^{-1} was typically used, although some measurements were performed at 0.2, 0.5, and 2.5 K min^{-1} to check the effect of the heating rate. The calorimeter was calibrated with indium, benzophenone, and benzoic acid.

Results and Discussion

Figure 1 shows the DSC curves for the thermal denaturation of lysozyme in aqueous solutions (pH 2) containing different amounts of sorbitol at a heating rate of 1 K min^{-1}. In every measurement, a reproducible

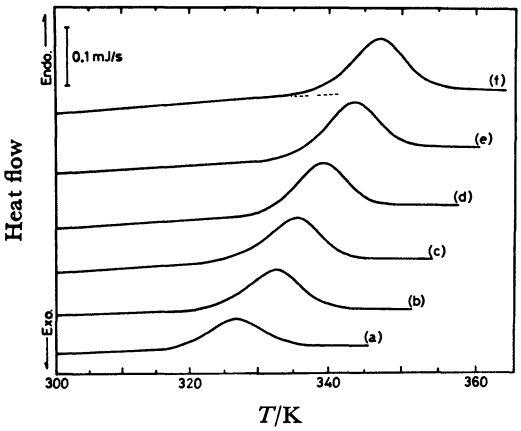

Fig. 1. DSC curves at heating rate of 1 K min^{-1} for the thermal denaturation of lysozyme in aqueous sorbitol solutions at pH 2.
The sorbitol concentrations are (a): 0, (b): 0.95, (c): 1.45, (d): 1.98, (e): 2.56, and (f): 3.04 mol dm^{-3}.

endothermic peak was observed occurring over a temperature width of 23—25 K. The endothermic peak shifted to higher temperature with increasing sorbitol concentration, while the peak area became larger and also the peak width slightly larger. The denaturation temperature, T_d, was estimated by assuming that the area under the thermogram was proportional to the amount denatured, and T_d defined as the temperature at which the protein is half-denatured. The difference between the estimated T_d and the peak temperature of the transition peak did not exceed 0.6 K in every measurement. The denaturation enthalpy, ΔH_d, was estimated by measuring the area between the transition peak and a base line fitted by inspection.

In order to check the effect of the heating rate, the thermal denaturation of lysozyme in aqueous solution and in aqueous sorbitol solutions was measured at heating rates of 0.2, 0.5, and 2.5 K min^{-1} other than 1 K min^{-1}. There was no significant difference in the denaturation enthalpies obtained at different heating rates. The denaturation temperature, however, showed a slight dependence on the heating rate; the denaturation temperature increased slightly with increasing heating rate. The values extrapolated to zero heating rate were lower than those obtained at a heating rate of 1 K min^{-1} by 0.4—0.6 K, which were in fair agreement with the denaturation temperature obtained by Gerlsma and Stuur[6] from spectrophotometric measurements.

The effect of polyhydric alcohols on the denaturation temperature of lysozyme is shown in Fig. 2. The T_d increased almost linearly with increasing concentration of alcohol and the increase became more pronounced with an increase in the number of hydroxymethyl groups in the alcohol. It is evident that these alcohols stabilize the protein against thermal denaturation. This tendency of polyhydric alcohols differ clearly from that of monohydric alcohols. As described in the previous paper,[12] monohydric alcohols lower the denaturation temperature of lysozyme, which becomes more pronounced with increasing alcohol concentration and increasing hydrocarbon content of the alcohol. That is, monohydric alcohols unstabilize the native structure of the protein. The unstabilizing effect of monohydric alcohols has been generally interpreted in terms of the hydrophobic interactions between the nonpolar groups of the protein and the alkyl chain of alcohol.[16,17]

The dependence of the denaturation enthalpy of lysozyme on the concentration of polyhydric alcohols is shown in Fig. 3. In every case studied, the ΔH_d was

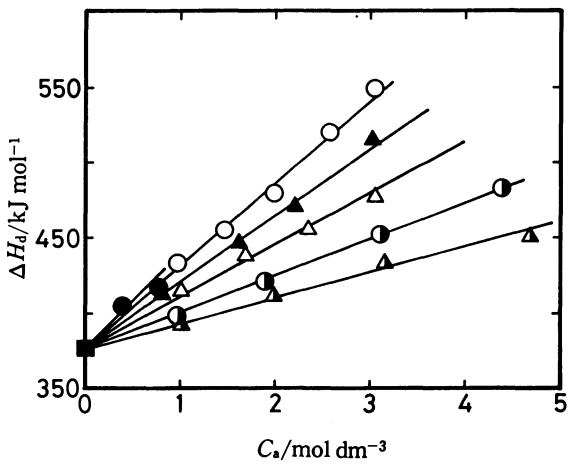

Fig. 3. The denaturation enthalpy of lysozyme as a function of concentration of polyhydric alcohol.
The symbols used are identical with those in Fig. 2.

enhanced by the addition of polyhydric alcohol. The ΔH_d increased almost linearly with increasing alcohol concentration. The increase in ΔH_d for a given concentration of alcohol becomes more pronounced as the number of hydroxymethyl groups of the added alcohol increase. The effect of the polyhydric alcohols on the denaturation enthalpy also differs from that of monohydric alcohols. As has been reported by Velicelebi and Sturtevant[17] and us,[13] the ΔH_d of lysozyme in the presence of monohydric alcohol shows a complex

dependence on the alcohol content; the ΔH_d passes through maximum with increasing alcohol concentration and the maximal value decreases with an increase in the hydrocarbon content of alcohol. A comparison between the results with polyhydric and monohydric alcohols suggests that the second and additional hydroxyl groups in the polyhydric alcohols play an important role in their stabilizing influence on the thermal denaturation of protein.

At a constant concentration of alcohol, the increase of T_d and ΔH_d with inositol were larger than those with sorbitol. This indicates that the stabilizing ability of inositol with a cyclic structure on the thermal denaturation of lysozyme is higher than that of sorbitol with a linear structure. This configuration effect may be analogous to the effect induced by branching the alkyl chain of monohydric alcohols. It has been established that the lowering of the denaturation temperature of globular proteins by monohydric alcohols with branched alkyl chain is smaller than that by the corresponding straight-chain alcohols.[13,18] It is possible that cyclization causes the increase in the content of hydroxymethyl groups per molecular chain and consequently brings about the high stabilizing ability of inositol on the thermal stability of lysozyme.

Figure 4 shows the plot of the increase in the denaturation temperature of lysozyme at an identical alcohol concentration of 1 mol dm^{-3}, ΔT_d, against the number of hydroxyl groups of the polyhydric alcohols used. As can been seen, the ΔT_d shows the linear dependence

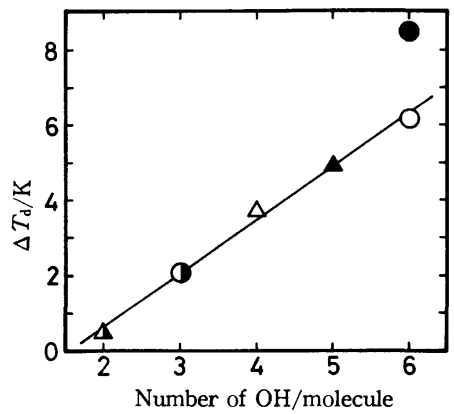

Fig. 4. Plot of the increase in the denaturation temperature of lysozyme at an identical alcohol concentration of 1 mol dm^{-3} against the number of hydroxyl groups of polyhydric alcohols.

on the number of hydroxyl groups of the polyhydric alcohols used with the exception of inositol. From the slope in Fig. 4, the T_d of lysozyme is raised by 1.4 K per hydroxyl group in the linear polyhydric alcohols, which is considerable larger than that measured by Gerlsma and Stuur.[6] A similar relation has been found with sugars as well as with polyhydric alcohols. Uedaira and Uedaira[12] have recently reported that the T_d of lysozyme in aqueous sugar solutions increases almost linearly with an increase in the number of equatorial hydroxyl groups in the sugar. From the direct dependence of ΔT_d on the number of hydroxyl groups of alcohols, it is presumed that there is no direct molecular interaction between the protein and the polyhydric alcohol, since any direct interaction would depend on the molar concentration.

The dependence of the denaturation enthalpy of lysozyme on the denaturation temperature in the presence of polyhydric alcohol is shown in Fig. 5. For

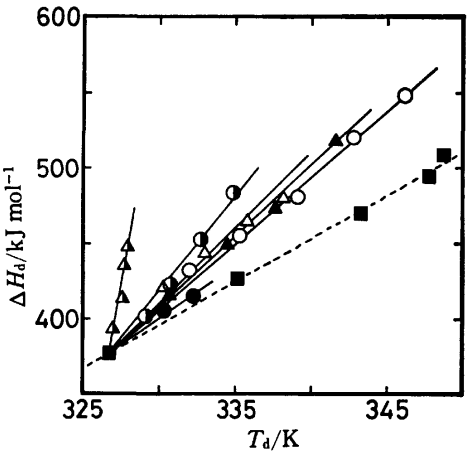

Fig. 5. The dependence of the denaturation enthalpy of lysozyme on the denaturation temperature.
The symbols used are identical with those in Fig. 2.

all the alcohols, the ΔH_d showed the linear function of T_d. This is similar to the behavior reported by Pfeil and Privalov[19] with variations of T_d produced by variation of the pH and addition of guanidinium chloride. However, there is a difference in the dependence of ΔH_d on T_d for each polyhydric alcohol. The slope of ΔH_d *vs.* T_d in the presence of alcohol decreased with an increase in the number of hydroxyl groups in the alcohol. This also suggests that the stabilizing effect of polyhydric alcohols on the thermal denaturation of protein is closely related to the number of hydroxyl groups in the alcohol.

Since ΔH_d is dependent on temperature, as mentioned above, the effect of polyhydric alcohols on ΔH_d must be estimated by comparison of the variation of ΔH_d with alcohols at identical temperature. In order to obtain the temperature dependence of ΔH_d in the absence of polyhydric alcohol, we also measured the thermal denaturation of lysozyme in glycine buffer solutions at different pH values and in acetate buffer solution at pH 5.0. These results are summarized in Table 1 together with those obtained by other investigators from calorimetric studies. Taking into account the difference in the measurement conditions such as heating rate, protein concentration, and ionic strength, our results are in good agreement with those obtained by other investigators. The dependence of ΔH_d on T_d in the absence of alcohol is shown in Fig. 5 together with that in the presence of alcohol. From the slope of this function, the temperature dependence of the denaturation enthalpy of lysozyme in the absence of alcohol, $(d\Delta H_d/dT_d)$, was obtained to be 5.6 kJ K^{-1} mol^{-1}, which was in rough agreement with that obtained from

Table 1. The denaturation temperatures and enthalpies of lysozyme at different pH values obtained by calorimetric studies

pH[a)]	T_d / K	ΔH_d / kJ mol^{-1}
1.0	319.2[b)]	234[b)]

5.4	349.7[e)]	577[e)]

a) The following buffer solutions were used: 0.1 mol dm^{-3} glycine buffer for pH 2.0, 2.5, 3.0, and 3.8; 0.1 mol dm^{-3} acetate buffer for pH 5.0. b) O'Reilly and Karasz.[20)] c) Privalov and Khechinashvili.[11)] d) Velicelebi and Sturtevant.[17)] e) Delben and Crescenzi.[21)]

precision measurement by Pfeil and Privalov.[19)] Assuming that $(d\Delta H_d/dT_d)$ remains identical with the value in the absence of alcohol at all alcohol solutions used, the denaturation enthalpy of lysozyme in the presence of alcohol at a given temperature, $\Delta H_d°(a)$, is expressed as follows:

$$\Delta H_d°(a) = \Delta H_d + (d\Delta H_d/dT_d)(T_d° - T_d), \quad (1)$$

where ΔH_d and T_d are the observed enthalpy and temperature of denaturation in the presence of alcohol and $T_d°$ is a given temperature. Then, the variation of denaturation enthalpy by the addition of polyhydric alcohol at identical temperature, $\Delta(\Delta H_d°)$, can be evaluated by the following equation,

$$\Delta(\Delta H_d°) = \Delta H_d°(a) - \Delta H_d°(w), \quad (2)$$

where $\Delta H_d°(w)$ is the denaturation enthalpy in the absence of alcohol at same temperature.

Figure 6 shows the dependence of $\Delta(\Delta H_d°)$ on polyhydric alcohol concentration at 326.7 K which is the denaturation temperature of lysozyme in aqueous solution at pH 2.0. Although these plots show appreciable scatter, it is obvious that the $\Delta(\Delta H_d°)$ is a slight

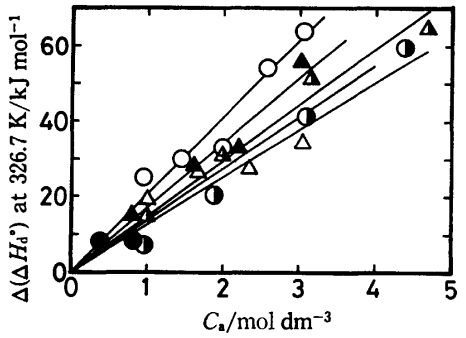

Fig. 6. The variation of the denaturation enthalpy of lysozyme with polyhydric alcohols at an identical temperature, 326.7 K, as a function of concentration of polyhydric alcohol.
The symbols used are identical with those in Fig. 2.

increasing function of alcohol concentration. However, the $\Delta(\Delta H_d°)$ value should be considerably smaller as compared with that presumed from the large increase in T_d. Substantially, the $\Delta(\Delta H_d°)$ values in the range of lower concentration of alcohol are within the experimental error in ΔH_d. Therefore, it is difficult to consider that the increase in the free energy change of denaturation by the addition of polyhydric alcohol results from only the slight increase of the denaturation enthalpy. These polyhydric alcohols for which data are available have lower dielectric constants than pure water.[22)] Thus, electrostatic interactions are stronger in these solutions than in water, which causes the denaturation enthalpy to increase. However, this contribution to the stabilizing effect appears to be relatively small.

It is interesting that the effect of polyhydric alcohols is different from that of monohydric alcohols. There have been many investigations which show the direct interaction of monohydric alcohols with protein.[23)] The unstabilizing effect of monohydric alcohols on the native structure of protein has been generally interpreted in terms of the interaction between protein and alcohol. Bull and Breese[24)] have reported from their study on the binding of alcohols to protein using equilibrium dialysis that monohydric alcohols are strongly bound to protein, but there is no direct binding of polyhydric alcohols to protein. Our presumption based on the direct dependence of ΔT_d on the number of hydroxyl groups of the added polyhydric alcohols is strongly supported by their observations. Therefore, it is conceivable that there exist other interactions which stabilize the native structure of protein in the system protein–alcohol–water. It is likely that polyhydric alcohols interact principally with the other component in the system, that is, water.

From thermodynamic studies of transfer of amino acids from water to aqueous solutions of polyhydric alcohols, Gekko and Noguchi[25)] have recently found that the enthalpy change of the transfer is positive for nonpolar side chains of amino acids and that polyhydric alcohols decrease the solubility of nonpolar groups by an unfavorable enthalpy effect. According to their findings, it is presumed that the added polyhydric alcohols dominantly affect the hydrophobic interactions between the nonpolar groups of protein. Back *et al.*[26)] have also reported that the hydrophobic interactions between pairs of hydrophobic groups are stronger in aqueous glycerol solutes than in pure water. Since hydrophobic interaction is a result of a rearrangement of the water molecules surrounding hydrophobic groups, it is likely that there is a relation between the effect of the added solutes on hydrophobic interaction and their effect on the structure of water. The effect of polyhydric alcohols on hydrophobic interaction and consequently on the thermal stability of protein may depend upon how they affect the structure of water.

There is no completely unambiguous numerical measure of "structure making" or "structure breaking" by a solute, but a change in the extent to which water is structured is accompanied by a volume change.[27)] According to Oakenfull and Fenwick,[28)] the effect of solute on the water structure is closely related with its

partial molar volume. The structure-making effect of polyhydric alcohols determined from their partial molar volume enhances in the order sorbitol>xylitol> erythritol>glycerol>ethylene glycol, that is, increasing number of hydroxyl groups per alcohol molecule. The structure-making effect of inositol, a cyclic alcohol, is larger than that of sorbitol. The stabilizing ability of polyhydric alcohols on the thermal denaturation of lysozyme also increases in the same order.

These results suggest the hypothesis that the dominant mechanism by which polyhydric alcohols stabilize protein against thermal denaturation is through their effect on the structure of the water, which, in turn, determines the strength of the hydrophobic interactions.

Synthesis of [3.3](1,3)Ferrocenophane and Its Derivatives

Akira KASAHARA,* Taeko IZUMI, Yoshio YOSHIDA, and Iwao SHIMIZU
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received September 22, 1981)

[3.3](1,3)Ferrocenophane-1,15-diene-3,14-dione was synthesized *via* the base-catalyzed condensation of 1,3-ferrocenedicarbaldehyde with 1,3-diacetylferrocene utilizing the high dilution technique. The reduction of the compound with $LiAlH_4$–$AlCl_3$ and the subsequent catalytic hydrogenation led to the formation of [3.3](1,3)-ferrocenophane. The transannular π-electronic interactions between the two ferrocene moieties in these compounds were examined on the basis of NMR and electronic spectra.

Recently, cyclophane compounds in which two or more aromatic rings are mutually stratified have been investigated, with emphasis on transannular π-electronic interactions.[1] However, there are only a few investigations of ferrocenophane having transannular π-electronic interactions: [2.2]Ferrocenophane-1,13-diyne,[2] [2.2]-ferrocenophane-1,13-diene,[3] [2]paracyclo[2]paracyclo-[2](1,1')ferrocenophane derivatives,[4] [3.3](1,1')-ferrocenophane-1,15-diene-3,14-dione,[5] [5.5](1,1')ferrocenophane derivatives,[5] and [0]metacyclo[2]-metacyclo[0](1,1')ferrocenophan-7-ene.[6] Benedikt and Schlögl[7] have recently reported on the synthesis of [2.2](1,2)ferrocenophane and Yamakawa *et al.*[8] have described the synthesis of [2.2.2](1,3)ferrocenophanetriene.

The synthetic methods and structures as well as chemical and physical properties of [2.2]metacyclophanes[9] and [3.3]metacyclophanes[10] have been widely investigated: Based on this and similar experiences in the metallocene field it seemed of considerable interest to prepare and study related metallocenophanes, especially in the ferrocenophane series. According to its molecular geometry, ferrocene cannot accommodate two ethylene bridges between two ferrocene units in the 1,3-positions such as in [2.2]metacyclophane; however, [3.3](1,3)ferrocenophane seemed to be —according to molecular models—a promising target for synthetic and structural investigations. This paper deals with the preparations of four [3.3](1,3)ferrocenophane derivatives (**1**, **2**, **3**, and **4**) having transannular π-electronic interactions.

Experimental

Materials and Measurement. Melting points were not corrected. All the reactions were performed under nitrogen. 1,3-Diacetylferrocene (**5**) was prepared according to the method described by Nesmeyanov *et al.*[11] The IR, NMR, mass, and electronic spectra were recorded with a Hitachi 215, a Hitachi R-22, a Hitachi RMU-6M, and a Hitachi EPS-

3T spectrometer, respectively.

Dimethyl 1,3-Ferrocenedicarboxylate (7). To a solution of 23 g (0.58 mol) of sodium hydroxide in 140 ml of water was dropwise added 26 g (0.16 mol) of bromine at 0—10 °C with stirring. Then 70 ml of dioxane was added in portions. At a temperature of 0—5°C, 7.0 g (0.026 mol) of **5** was added in small portions to the vigorously stirred solution. After the addition was over, stirring was continued for one additional hour at 0—5 °C. The reaction mixture was filtered, the filtrate was washed with CH_2Cl_2, and the aqueous layer was heated up to 80 °C. After cooling, acidification with 10% HCl gave orange red crystals, 1,3-ferrocenedicarboxylic acid (**6**) (3.6 g, 50% yield), mp 228 °C (decomp) (lit,[8] mp 227. 5 °C (decomp)). IR (KBr): 3100, 1675 (-C=O), 1100, 1000 cm^{-1}. MS: *m/e* 274 (M^+).

A suspension of 7.0 g of crude **6** in 150 ml of methanol containing 1 ml of concd H_2SO_4 was heated under reflux for 28 h. After removal of the solvent, the residue was taken up with $CHCl_3$ and chromatographed on silica gel with benzene. The crude product was recrystallized from benzene–hexane to give 6.9 g (90% yield) of **7**, mp 155—157 °C (lit,[8] mp 155—156 °C). IR (KBr): 3100, 1710 (ester), 1100, 1000 cm^{-1}. MS: *m/e* 302 (M^+).

1,3-Bis(hydroxymethyl)ferrocene (8). To a solution of 2.2 g (0.053 mol) of $LiAlH_4$ in 150 ml of dry diethyl ether was added dropwise a solution of 4.5 g (0.015 mol) of **7** in 50 ml of dry diethyl ether at room temperature with stirring. After the solution was heated under reflux for an additional 4 h, the reaction mixture was decomposed with a small amount of cold water. Yellow crystalline **8**, mp 115—116 °C (lit,[8] mp 115—117.5 °C), was obtained in 95% yield (3.5 g). IR (KBr): 3400, 3200, 3100, 1100, 1000, 905 cm^{-1}. MS: *m/e* 246 (M^+).

1,3-Ferrocenedicarbaldehyde (9). Active manganese(IV) dioxide (30 g) was added to a solution of **8** (3.0 g, 0.012 mol) in $CHCl_3$ (200 ml) and the resulting mixture was stirred in the dark for 12 h. After filtration, the red solution was evaporated and the dry residue was chromatographed on silica gel with benzene. Bright red crystals, mp 69—70 °C (lit,[8] yellow oil), were obtained in 91% yield (2.7 g). IR (KBr): 3100, 1670 (-C=O), 1100, 995, 920, 905 cm^{-1}. NMR ($CDCl_3$): δ=4.34 (5H, s, H_a), 5.13 (2H, m, H_b), 5.40 (1H, m, H_c), 10.03 (2H, s, -CHO). Found: C, 59.58; H, 4.25%; M^+, 242. Calcd for $C_{12}H_{10}O_2Fe$: C, 59.54; H, 4.16%; M, 242.

[3.3](1,3)Ferrocenophane-1,15-diene-3,14-dione (1). To a solution of **9** (2.4 g, 0.01 mol) in ethanol (150 ml) containing 15 g of potassium hydroxide was dropwise added a solution of 2.7 g (0.01 mol) of **5** in ethanol (160 ml) by a motor driven syringe pump over 4 h at room temperature. The resulting mixture was stirred at 55 °C for an additional 2 h, and then evaporated *in vacuo*. The residue was extracted with $CHCl_3$ (300 ml) to isolate the desired product from the polycondensation products (**10**). The $CHCl_3$ extracts were washed with brine to neutralize them and then dried over anhydrous $MgSO_4$. After removal of the solvents, the residue was chromatographed on silica gel with benzene–ether to give 0.6 g 10% yield of **1**, deep red crystals, mp 230—232 °C (decomp). IR (KBr): 3100, 1650 (-C=O), 1100, 995, 920, 905, 815 cm^{-1}. MS: *m/e* 476 (M^+), 238 (*m/2e*), 56 (Fe^+). Found: C, 65.51; H, 4.18%. Calcd for $C_{26}H_{20}O_2Fe_2$: C, 65.58; H, 4.23%; M, 476.

[3.3](1,3)Ferrocenophane-1,16-dione (2). An ethanol (100 ml) solution of **1** (0.5 g) was hydrogenated with PtO_2 at room temperature under ordinary pressure. The reaction mixture was filtered to remove the catalyst and the filtrate was evaporated. The residue was chromatographed over silica gel with benzene–hexane to give 0.45 g (90% yield) of **2**, orange red needles,mp 183—184 °C(decomp). IR(KBr): 3100,

1670 (-C=O), 1100, 1000, 920, 905 cm^{-1}. MS: *m/e* 480 (M^+), 240 (*m/2e*), 56 (Fe^+). Calcd for $C_{26}H_{24}O_2Fe_2$: C, 65.03; H, 5.03%; M, 480.

[3.3](1,3)Ferrocenophane-1,15-diene (3). A dry diethyl ether solution (100 ml) of **1** (0.40 g) was added to a suspension of $LiAlH_4$ (0.2 g) and $AlCl_3$ (0.8 g) in dry diethyl ether (50 ml). After refluxing for 4 h, the excess reagent was decomposed with moist ether and then with water. After the resulting reaction mixture was extracted with ether, the ether extracts were washed with water, saturated sodium hydrogencarbonate solution, and finally brine, and then dried over anhydrous $MgSO_4$. The removal of the solvent left 0.25 g (65% yield) of **3**, orange yellow crystals, mp 196—197 °C (decomp). IR (KBr): 3100, 1100, 1000, 925, 905, 800 cm^{-1}. MS: *m/e* 448 (M^+), 224 (*m/2e*), 56 (Fe^+). Found: C, 69.55; H, 5.23%. Calcd for $C_{26}H_{24}Fe$: C, 69.67; H, 5.38%: M, 448.

[3.3](1,3)Ferrocenophane (4). Reduction of **2** (0.20 g) with $LiAlH_4$–$AlCl_3$ in anhydrous diethyl ether was carried out in the the same way as described for **3**, and 0.11 g of **4** (60% yield), yellow crystals, mp 202—203 °C (decomp), was obtained. Catalytic hydrogenation of **3** with PtO_2 in ethanol also led to the formation of **4** in 75% yield. IR (KBr): 3100, 1100, 995, 925, 905 cm^{-1}. MS: *m/e* 452 (M^+), 226 (*m/2e*), 56 (Fe^+). Found: C, 68.91; H, 6.08%. Calcd for $C_{26}H_{28}Fe_2$: C, 69.05; H, 6.24%; M, 452.

1,3-Bis[2-(ferrocenylcarbonyl)vinyl]ferrocene (11). To a solution of **9** (2.4 g, 0.01 mol) in ethanol (150 ml) containing 15 g of potassium hydroxide was dropwise added a solution of acetylferrocene (4.6 g, 0.02 mol) in ethanol (150 ml). The resulting mixture was stirred at 55 °C for an additional 2 h, and then evaporated *in vacuo*. The extracts with $CHCl_3$ were washed with an aqueous solution of HCl, saturated sodium hydrogencarbonate solution, and brine, then dried and evaporated. The residue was chromatographed over silica gel with benzene–chloroform to afford **11**, red crystals, mp 220—221 °C (3.5 g, 53% yield). IR (KBr): 3100, 1650 (-C=O), 1590, 970 (*trans* -CH=CH-), 1100, 1000, 920, 905 cm^{-1}. Found: C, 65.21; H, 4.48%; M^+, 662. Calcd for $C_{36}H_{30}O_2Fe_2$: C, 65.29; H, 4.56%, M, 662.

1,3-Bis[2-(ferrocenylcarbonyl)ethyl]ferrocene (12). An ethanol–dioxane (200 ml, 1 : 1) solution of **11** (0.9 g) was hydrogenated with PtO_2 at room temperature. The reaction mixture was filtered to remove the catalyst, and the filtrate was evaporated. The residue was chromatographed over silica gel to give 0.8 g of **12** (92% yield), orange red crystals, mp 128—130 °C. IR (KBr): 3100, 1660 (-C=O), 1100, 1000, 920, 905 cm^{-1}. Found: C, 64.73; H, 5.05%; M^+, 666. Calcd for $C_{36}H_{34}O_2Fe_2$: C, 64.86; H, 5.14%; M, 666.

1,3-Bis(3-ferrocenyl-1-propenyl)ferrocene (13). The reduction of **11** with $LiAlH_4$–$AlCl_3$ was carried out in the same way as described for **3**, and orange yellow crystals of **13**, mp 113—115 °C, were obtained in 57% yield. IR (KBr): 3100, 1620, 960 (*trans* -CH=CH-), 1100, 1000, 925, 900 cm^{-1}. Found: C, 68.23; H, 5.48%; M^+, 634. Calcd for $C_{36}H_{34}Fe_2$: C, 68.11; H, 5.40; M, 634.

1,3-Bis(3-ferrocenylacryloyl)ferrocene (14). The base-catalyzed condensation reaction of ferrocenecarbaldehyde (4.3 g, 0.02 mol) with **5** (2.7 g, 0.01 mol) was carried out in the same way as described for **11**, and red crystals of **14**, mp 237—238 °C (decomp), were obtained in 60% yield. IR(KBr): 3100, 1645 (-C=O), 1600, 980 (*trans* -CH=CH-), 1100, 1000, 920, 905 cm^{-1}. Found: C, 65.17; H, 4.41%; M^+, 662. Calcd for $C_{36}H_{30}O_2Fe_2$: C, 65.29; H, 4.56%; M, 662.

1,3-Bis(3-ferrocenylpropionyl)ferrocene (15). The catalytic hydrogenation of **14** with PtO_2 in ethanol–dioxane was carried out in the same way as described for **12**, and orange yellow crystals of **15**, mp 188—190 °C, were obtained in 90% yield. IR (KBr): 3100, 1665 (-C=O), 1100, 1000, 920, 905 cm^{-1}. Found: C, 64.80; H, 5.02%; M^+, 666. Calcd for $C_{36}H_{34}O_2Fe$: C, 64.86; H, 5.14%; M, 666.

1,3-Bis(3-ferrocenylallyl)ferrocene (16). The reaction of **14** with $LiAlH_4$–$AlCl_3$ was carried out in the same way as described for **3**, and an orange yellow oil of **16** was obtained in 48% yield. IR (oil film): 3100, 1615, 955 (*trans* -CH=CH-), 1100, 1000, 925, 900 cm^{-1}. Found: C, 68.17; H, 5.45%; M^+, 634. Calcd for $C_{36}H_{34}Fe_2$: C, 68.11; H, 5.45%; M, 634.

1,3-Bis(3-ferrocenylpropyl)ferrocene (17). The catalytic hydrogenation of **16** was carried out in the same way as described for **3**, and a yellow oil of **17** was obtained in 94% yield. IR (oil film): 3100, 2950, 1100, 1000, 925,905 cm^{-1}. Found: C, 67.86; H, 6.11%; M^+, 638. Calcd for $C_{36}H_{38}Fe_2$: C, 67.74; H, 6.00%; M, 638.

Results and Discussion

Synthesis. All of the [3.3](1,3)ferrocenophanes (**1**, **2**, **3**, and **4**) were prepared by the synthetic sequence shown in Scheme 1. As spectral reference compounds, 1,3-disubstituted ferrocene derivatives (**11**—**17**) were synthesized (see Scheme 2).

In connection with the synthesis of the ferrocenophanes (**1**—**4**), it became desirable to synthesize 1,3-ferrocenedicarbaldehyde (**9**)[12] in quantity. A treatment of 1,3-diacetylferrocene (**5**) with sodium hypobromite in dioxane–H_2O below 10 °C, led to the formation of 1,3-ferrocenedicarboxylic acid (**6**) in 50% yield. Then, 1,3-bis(hydroxymethyl)ferrocene (**8**) was synthesized in 95% yield by the usual $LiAlH_4$ reduction of dimethyl ester (**7**), which was prepared by acid-catalyzed esterification of **6**. The oxidation reaction of **8** in chloroform with active manganese dioxide led to the formation of **9** in good yield.

Under high dilution conditions, a base-catalyzed (ethanolic KOH) condensation of **5** with **9** gave the desired [3.3](1.3)ferrocenophane-1,15-diene-3,14-dione (**1**), accompanied by polycondensation products (**10**). On the other hand, using potassium *t*-butoxide or potassium ethoxide as a base catalyst, the reaction led only to the formation of **10**. The catalytic hydrogenation of **1** afforded [3.3](1,3)ferrocenophane-1,16-dione (**2**) and the reduction of **1** with $LiAlH_4$–$AlCl_3$ gave [3.3](1,3)ferrocenophane-1,15-diene (**3**). Furthermore, both the reduction of **2** with $LiAlH_4$–$AlCl_3$ and the catalytic hydrogenation of **3** afforded the same product: [3.3](1,3)ferrocenophane (**4**).

Structures and Spectra. The NMR spectral data of **1**—**4** and the reference compounds (**11**—**17**) are summarized in Table 1. The structural assignment for **1** is based on spectral evidence and the elemental analyses. The mass spectrum shows two prominent peaks; a molecular ion at *m/e* 476 and a doubly charged ion at *m/2e* 238. This fragmentation pattern is normally observed in [2.2]- and [3.3](1,1')ferrocenophane.[2,3,5] The IR spectrum in **1** exhibits the characteristic absorptions of the carbonyl (1650 cm^{-1}) and *cis* olefinic groups (815cm^{-1}), and of the 1,3-disubstituted ferrocene ring (925 and 905 cm^{-1}).[13] The NMR spectrum of **1** is also consistent with a cyclophane structure and the *anti* orientation of the cyclopentadienyl rings. The chemical

TABLE 1. NMR DATA OF [3.3](1,3) FERROCENOPHANE DERIVATIVES (**1**—**4**) AND REFERENCE COMPOUNDS (**11**—**17**) IN $CDCl_3$ (δ)

shifts for H_a and H_c protons of the cyclopentadienyl rings are found respectively at 0.70 and 1.17 ppm upfield relative to those (H_a and H_c) of the reference compounds, 1,3-bis(2-ferrocenylcarbonylvinyl)ferrocene (**11**) and 1,3-bis(3-ferrocenylacryloyl)ferrocene (**14**). These upfield shifts are expected due to the position of protons (H_a and H_c in **1**) relative to the shielding cone of the nearby cyclopentadienyl ring. On the other hand, the shifts of H_b (Δ, 0.06 ppm) and H_d (Δ, −0.25 ppm) in **1** are negligible, compared with those (H_b and H_d) in **11** or **14**. The smaller upfield shift of the H_b and H_d relative to the H_a and H_c protons is consistent with the *anti* structure for **1** (see Fig. 1). Figure 2 shows the electronic spectra of **1**, **11**, and **14**. In the spectrum of ferrocene itself, the long wavelength bands at 325 and 440 nm can be assigned with some certainty to (d-d) type transitions within the ligand field formalism.[14] The electronic spectrum of **1** is consistent with a cyclophane structure and exhibits three broadened maxima at λ_{max}(dioxane) 308, 422, and 504 nm. Similar to the

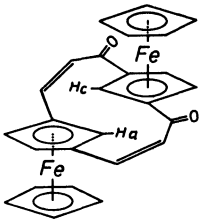

Fig. 1. Conformation of [3.3](1,3)-ferrocenophane (**1**).

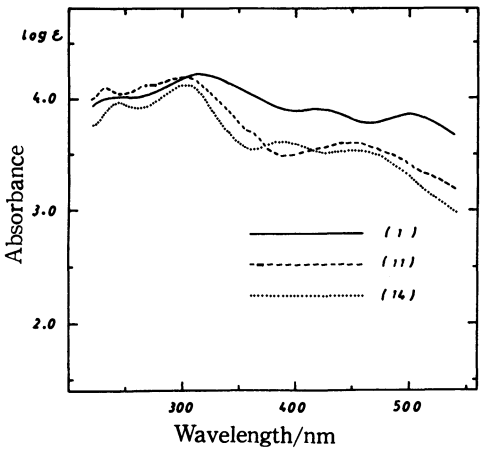

Fig. 2. Electronic spectra of **1**, **11**, and **14** in dioxane.

electronic spectra of other cyclophanes there are observed a general broadening of all bands in the spectrum and hyperchromic and bathochromic shifts of the long wavelength band relative to **11** or **14**. This is probably due to some transannular interaction between the two ferrocene moieties.

The structure of **2** can be assigned to *anti*-conformation by a comparison of its NMR data with those of the reference compounds: 1,3-Bis(2-ferrocenylcarbonylethyl)ferrocene (**12**) and 1,3-bis(3-ferrocenylpropionyl)ferrocene (**15**). Similar to the case of **1**, the upfield shifts of H_b (Δ, −0.01 ppm) and H_d protons (Δ, 0.07 ppm) in **2**, compared with those in **12** and **15**, are explained by the *anti*-structure, in which the internal cyclopentadienyl protons (H_a and H_c) lie in close proximity to the π-cloud (and the cone of shielding) of the opposed cyclopentadienyl moiety. Furthermore, the NMR spectrum of **2** contained H_a at δ 3.87 ppm, indicating an upfield shift (0.53 ppm) with respect to the diene **1** which is characteristic of such pairs of cyclophanes (with saturated and unsaturated bridges).[14] The IR spectrum of **2** also exhibits bands due to the carbonyl group (1670 cm^{-1}) and the 1,3-disubstituted ferrocene rings (920 and 905 cm^{-1}), and the mass spectrum shows two prominent peaks: one due to a molecular ion (*m/e* 480) and the other to a doubly-charged ion (*m/e* 240). In the electronic spectra of **2**, compared with those of **12** and **15**, all the absorption curves exhibit common features of cyclophane, *viz.*, broarding, bathochromic, and hyperchromic shifts, caused by the transannular electronic interaction (see Fig. 3).

In compound **3**, the IR spectrum reveals the presence

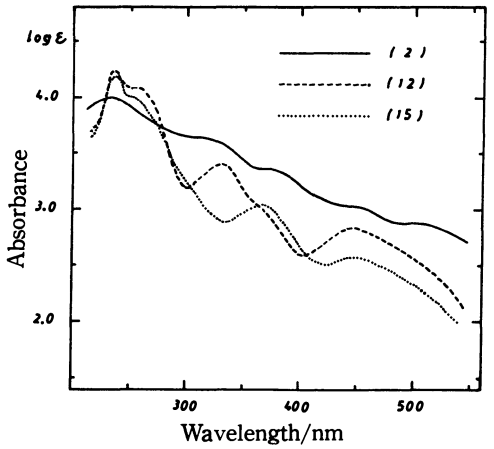

Fig. 3 Electronic spectra of **2**, **12**, and **15** in dioxane.

of *cis* olefinic bonds (800 cm^{-1}) and 1,3-disubstituted ferrocene ring (925 and 905 cm^{-1}), and in the mass spectrum, the most intense peaks is that due to the parent ion of *m/e* 448; the remaining two prominent peaks are *m/e* 224 and 56, corresponding to a doubly-charged ion and Fe^+. In the NMR spectrum of **3**, the upfield shifts of H_a (Δ, 0.25 ppm) and H_c protons (Δ, 0.22 ppm) and the downfield shifts of H_b (Δ, −0.18 ppm) and H_d protons (Δ, −0.01 ppm), compared with the corresponding ones in the reference compounds: 1,3-bis(3-ferrocenyl-1-propenyl)ferrocene (**13**) and 1,3-bis(3-ferrocenyl-2-propenyl)ferrocene (**16**), are also explained by the *anti*-structure. The upfield shifts of H_a and H_c protons in **3** are not marked, compared with those of compounds **1** and **2**. In Fig. 4, however, the electronic absorption curve becomes relatively structureless, with bathochromic shifts and increased intensity of the bands near 340 and 450 nm, compared with those of the reference compounds **13** and **16**. This indicates that the two ferrocene moieties in **3** interact strongly with each other.

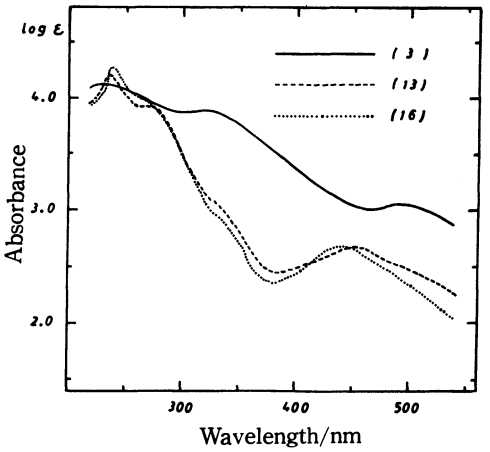

Fig. 4. Electronic spectra of **3**, **13**, and **16** in dioxane.

The spectrum of **4** exhibits bands at 925 and 905 cm^{-1}, which are characteristic of the 1,3-disubstituted ferrocene ring. By comparison with the NMR spectrum

of the reference compound, 1,3-bis(3-ferrocenylpropyl)-ferrocene (**17**), the upfield shifts of H_a protons (Δ, 0.22 ppm) and the small upfield shifts of H_b protons (Δ, 0.02 ppm) are consistent with the *anti*-structure for **4**, similarly to the cases of **1**, **2**, and **3**. The electronic spectrum of **4** (Fig. 5) exhibits two broadened maxima in the visible region, at λ_{max}(dioxane) 320 and 488 nm, and there is observed a general broadening and a bathochromic shift (48 nm) of the long wavelength band relative to **17**. These are probably due to some transannular π-electronic interactions between the two ferrocene moieties.

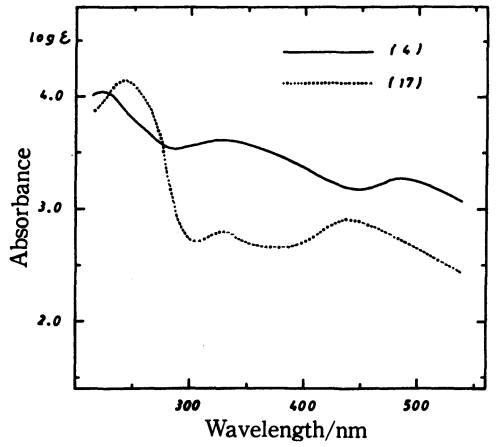

Fig. 5. Electronic spectra of **4** and **17** in dioxane.

The Lewis acid-catalysed reaction of 1-trimethylsiloxy-1,3-cyclohexadienes with aldehydes and trialkyl orthoformates afforded the corresponding 4-substituted 2-cyclohexenones. A new reaction of 2,4,6-trienones with *m*-chloroperbenzoic acid followed by the reduction with zinc in acetic acid gave 7-hydroxy-3,5-dienones. Utilizing these efficient reactions, megastigma-4,6,8-trien-3-ones, 3-hydroxy-β-ionol, 3-hydroxy-β-ionone, 5,6-epoxy-3-hydroxy-β-ionol, and 3-oxo-α-ionol were successfully synthesized.

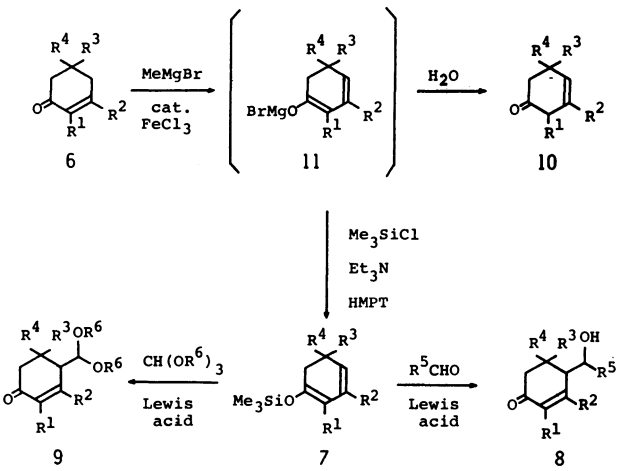
A large number of megastigmane derivatives, which are considered to be carotenoid metabolites having 13 carbon atoms, have been isolated successively from various tobacco leaves as neutral aroma constituents. Most of them have an oxygen function at the C-3 position in their cyclohexane rings, such as megastigma-4,6,8-trien-3-ones (**1**),[1] 3-hydroxy-β-ionol (**2**),[2] 3-hydroxy-β-ionone (**3**),[3] 5,6-epoxy-3-hydroxy-β-ionol (**4**),[4] and 3-oxo-α-ionol (**5**).[5] Recently, **1** and **3** were also found in Kudzu oil (Pueravia lobata Ohwi).[6] A number of synthetic methods for these megastigmane derivatives have been reported,[7] because they are considered to be potent flavoring components of tobacco and are frequently utilized as intermediates leading to carotenoids such as zeaxanthin. However, there still remain many problems, such as starting material, overall yield, and synthetic route.

In this paper, we will report a simple and efficient synthesis of **1** *via* the intermediate (**8a**) starting from readily available isophorone (**6a**), and an efficient conversion of **1** into **2**—**5** by way of an other intermediate (**13**).

Results and Discussion

The Lewis acid-catalysed aldol-type reactions of silyl enol ethers with various electrophiles such as carbonyl compounds, acetals, and trialkyl orthoformates were studied by Mukaiyama *et al.*[8] Recently, attention is focused on the reaction of dienoxysilanes with various electrophiles, which is a most useful means of organic synthesis because of its high selectivity of γ-attacking products. Mukaiyama and Ishida reported the $TiCl_4$-promoted reaction of 1-trimethylsiloxy-1,3-butadiene with acetals giving 5-alkoxy-2-enals.[9] In the course of our studies, some reports on the Lewis acid-catalysed reaction of dienoxysilanes with various electrophiles have appeared.[10]

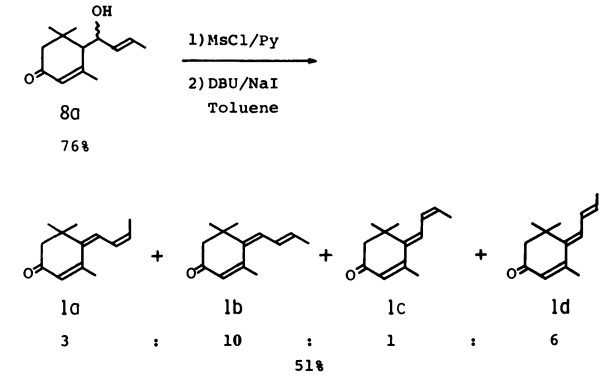
In order to apply to the syntheses of the desired megastigmane derivatives, we attempted to react 1-trimethylsiloxy-1,3-cyclohexadienes (**7**) with aldehydes or trialkyl orthoformates in the presence of Lewis acid. As a method to synthesize **7**, the reaction of 3-cyclohexenones (**10**) with lithium diisopropylamide and subsequent trapping with trimethylchlorosilane has been known, we discovered a simple synthetic method of **7** from 2-cyclohexenones (**6**) by application of the method of Kharasch *et al.*[11] Consequently, 1-hydroxyalkylated cyclohexenones (**8**) or dialkoxymethylated cyclohexenones (**9**) could be regioselectively synthesized from **6** *via* **7** as in the following (Scheme 1):



Scheme 1.

These results are listed in Tables 1 and 2.

3,5,5-Trimethyl-1-trimethylsiloxy-1,3-cyclohexadiene (**7a**) was employed to introduce an oxygen function into the C-3 position of the megastigmane skeleton. From **7a**, **1** was synthesized as in the following (Schemes 1 and 2):



Scheme 2.

Table 1. Preparation of 1-trimethylsiloxy-1,3-cyclohexadienes (7) from 2-cyclohexenones (6)

2-Cyclohexenone (6)	Product (7)					Yield[a] %

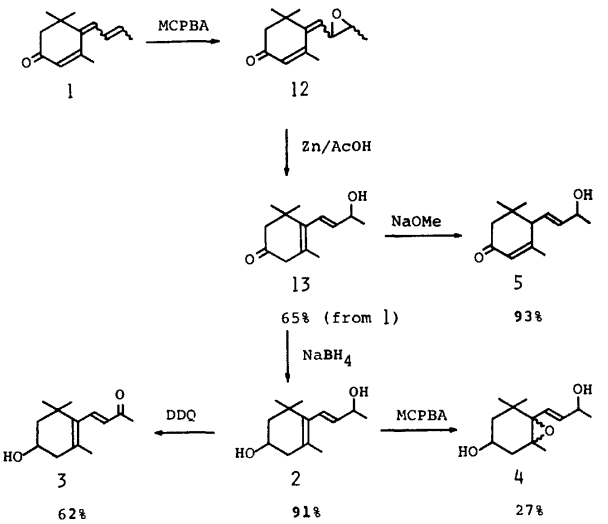
Isophorone (**6a**)	**7a**	H	CH_3	CH_3	CH_3	80
l-Carvone (**6b**)	**7b**	CH_3	H	C(CH_3)CH_2	H	72

a) Isolated yields.

Treatment of 3-oxo-α-damascol (**8a**) with methanesulfonyl chloride and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)[12] gave a mixture of **1a—d** in 51% total yield. The four isomers (**1a—d**), all of which occur in nature, were found in the ratio 3 : 10 : 1 : 6, determined by gas chromatography. All spectral data of the four isomers, isolated by means of preparative gas chromatography (20% PEG 20M), were consistent with those in the literature.[1]

In the process of transforming **1** to ionone-type compounds (**2—5**), there are two problems: the introduction of an oxygen function into the C-9 position and the isomerization of double bonds from the C-4 and C-6 positions to the C-5 and C-7 positions. We resolved the problems by the synthesis of a key intermediate (**13**), which was obtained by the regioselective epoxidation of **1** with *m*-chloroperbenzoic acid in dichloromethane, followed by the selective reduction with zinc in acetic acid in 65% yield (Scheme 3). The isomers of the epoxy compound (**12**) were not isolated, but the position of epoxy function was confirmed by measurement with NMR. (This was based upon the result that two olefin protons of the C-8 and C-9 positions of **1** disappeared). The epoxy ring cleavage accompanying isomerization of double bonds was caused by treatment of **12** with zinc in acetic acid. The isomerization of double bonds of **13** to conjugated system did not take place under these conditions. Concerning the similar reduction of 4,5-epoxy-2-enones under acidic conditions, two methods have been reported.[13] But their products were not unconjugated 5-hydroxy-3-enones but conjugated 5-hydroxy-2-enones, and the corresponding 2,4-dienones were also produced as by-products. In our synthesis of 7-hydroxy-3,5-dienone (**13**) from 6,7-epoxy-2,4-dienone (**12**), **13** could be selectively obtained as the sole product in good yield without any contamination of conjugated products. It is thought that this selectivity is due to either the conjugated effect of diene or the characteristic property of megastigmane skeleton.

The syntheses of **2—5** from **1** are shown in Scheme 3. Treatment of 3-oxo-β-ionol (**13**) with sodium borohydride in ethanol or sodium methoxide in methanol gave 3-hydroxy-β-ionol (**2**) or 3-oxo-α-ionol (**5**) in 91% or 93% yield, respectively. All spectral data of **2** and **5** were consistent with those in the literature.[2,5] 3-Hydroxy-β-ionone (**3**) and 4,5-epoxy-3-hydroxy-β-ionol (**4**) had been synthesized from **2** by Mori[14] and Takagi *et al.*,[4] respectively.



Scheme 3.

In conclusion, megastigmane derivatives oxidized at the C-3 position (**1—5**) were efficiently synthesized starting from readily available isophorone (**6a**) by using a regioselective aldol-type reaction of dienoxysilanes (**7**) and selective transformation of 2,4,6-trienone (**1**) into 7-hydroxy-3,5-dienone (**13**) in each key step.

Experimental

All the boiling points are uncorrected. The IR spectra were recorded with a JASCO IRA-2 spectrometer. The NMR spectra were measured with a Hitachi R-24A spectrometer, using tetramethylsilane as the internal standered. The mass spectra were determined with a Hitachi RMU-6E mass spectrometer.

Preparation of 3,5,5-Trimethyl-1-trimethylsiloxy-1,3-cyclohexadiene (7a). To a mixture of 2 M (1 M = 1 mol dm^{-3}) ether solution of methylmagnesium bromide (400 ml, 0.8 mol) and iron(III) chloride (2.0 g), a solution of isophorone (**6a**) (83 g, 0.60 mol) in dry ether (100 ml) was added dropwise at −20 °C, and the mixture was stirred for 0.5 h at −20 °C. Trimethylchlorosilane (87 g, 0.80 mol), triethylamine (60 ml), and hexamethylphosphoric triamide (HMPT) (60 ml) were successively added at 0 °C and the mixture was stirred for 24 h at room temperature. The mixture was poured into cold water and extracted with hexane. The extract was washed with a saturated solution of $KHSO_4$, a saturated solution of $NaHCO_3$, and brine, and then dried over $MgSO_4$. After removal of the solvent, the residue was distilled to give **7a** (101 g, 80%). Bp 88—89 °C/16 Torr (1 Torr = 133.322 Pa); IR (neat) 1655, 1595, and 850 cm^{-1}; NMR ($CDCl_3$) δ=0.22 (9H, s), 0.99 (6H, s), 1.68 (3H, d, J=2.0 Hz), 2.03 (2H, d, J=1.0 Hz), 4.87 (1H, m), and 4.96 (1H, m); MS (70 eV), *m/e* (%), 210 (M^+, 24), 195 (100), 179 (45), 105 (26), 75 (31), 73 (69), and 45 (26). Found: C, 68.63; H, 10.38%. Calcd for $C_{12}H_{22}SiO$: C, 68.51; H, 10.54%.

Preparation of 5-Isopropenyl-2-methyl-1-trimethylsiloxy-1,3-cyclohexadiene (7b). In the same manner, *l*-carvone (**6b**) (57 g, 0.38 mol) was treated with methylmagnesium bromide (2 M ether solution, 225 ml, 0.45 mol), iron(III) chloride (1.0 g), trimethylchlorosilane (49 g, 0.45 mol), triethylamine (35 ml), and HMPT (35 ml). The work-up described above gave **7b** (61 g, 72%). Bp 111—112 °C/17 Torr; IR (neat) 1670, 1640, 1585, 920, 890, and 843 cm^{-1}; NMR ($CDCl_3$) δ=0.20 (9H, s), 1.65 (3H, m), 1.76 (3H, m), 2.18 (1H, m), 2.36 (1H, m), 3.13 (1H, m), 4.80 (2H, m), 5.37 (1H, dd, J=9.5, 3.0 Hz), and 5.80 (1H, dd, J=9.5, 2.4 Hz); MS (70 eV), *m/e* (%), 222 (M^+, 21), 207 (17), 181 (15), 165 (18), 91 (21), 75 (24), 73 (100), and 45 (35). Found: C, 70.24; H, 9.79%. Calcd for $C_{13}H_{22}SiO$: C, 70.21; H, 9.97%.

Reaction of Dienoxysilanes (7) with Aldehydes Using $TiCl_4$ or $BF_3 \cdot OEt_2$. *General Procedure*: A solution of $TiCl_4$ (3.80 g, 20 mmol) or $BF_3 \cdot OEt_2$ (2.84 g, 20 mmol) in dry dichloromethane (5 ml) was added dropwise to a cold solution (−60 °C) of **7** (20 mmol) and aldehyde (24 mmol) in dry dichloromethane (20 ml). After being stirred for 2 h at −60 °C, the mixture was quenched with water. The dichloromethane layer was further stirred with a 10% solution of $(CO_2H)_2$ for 24 h at room temperature and washed with a saturated solution of $NaHCO_3$ and brine, and then dried over $MgSO_4$. After evaporation of the solvent, the residue was subjected to silica-gel column chromatography (hexane–ether) to afford **8**.

3-Oxo-α-damascol (8a): Two stereoisomers (*threo-erythro*), **8aA** and **8aB**, were prepared. **8aA**: IR (neat) 3450, 1650, and 970 cm^{-1}; NMR ($CDCl_3$) δ=1.02 (3H, s,) 1.13 (3H, s), 1.64 (3H, d, J=5.0 Hz), 1.90 (1H, d, J=18.0 Hz), 2.11 (3H, d, J=1.5 Hz), 2.32 (1H, d, J=3.5 Hz), 2.45 (1H, d, J=18.0 Hz), 3.30 (1H, broad s), 4.57 (1H, dd, J=7.0, 3.5 Hz), 5.60 (2H, m), and 5.98 (1H, broad s); MS (70 eV), *m/e* (%), 208 (M^+, 3), 193 (3), 190 (3), 149 (9), 138 (47), 123 (45), 96 (69), 95 (51), 82 (35), 81 (61), 70 (45), 69 (42), 41 (100), and 39 (77). Found: C, 74.77; H, 9.87%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%. **8aB**: IR (neat) 3370, 1645, and 985 cm^{-1}; NMR ($CDCl_3$) δ=1.00 (3H, s), 1.16 (3H, s), 1.70 (3H, dd, J=5.0, 1.5 Hz), 1.8—2.0 (1H, m), 1.98 (3H, d, J=1.5 Hz), 2.05 (1H, d, J=1.5 Hz), 2.78 (1H, d, J=18.0 Hz), 3.42 (1H, broad s), 4.67 (1H, m), 5.60 (2H, m), and 5.98 (1H, broad s); MS (70 eV), *m/e* (%), 208 (M^+, 3), 193 (3), 190 (2), 149 (8), 138 (47), 123 (43), 96 (70), 95 (53), 82 (47), 81 (61), 70 (47), 69 (38), 41 (100), and 39 (81). Found: C, 74.68; H, 9.51%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

4-(1-Hydroxy-2-methylpropyl)-5-isopropenyl-2-methyl-2-cyclohexenone (8b): *Trans*-isomer (**8bA**) and *cis*-isomer (**8bB**) were separated. **8bA**: IR (neat) 3460, 1660, and 895 cm^{-1}; NMR ($CDCl_3$) δ=0.95 (3H, d, J=6.5 Hz), 0.99 (3H, d, J=6.5 Hz), 1.76 (6H, m), 2.0—3.1 (6H, m), 3.55 (1H, m), 4.85 (2H, m), and 6.73 (1H, m); MS (70 eV), *m/e* (%), 150 (M^+−72, 100), 135 (93), 109 (74), 108 (63), 107 (51), 73 (79), 55 (79), 43 (72), and 41 (60). Found: C, 75.48; H, 9.78%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%. **8bB**: IR (neat) 3500, 1660, and 890 cm^{-1}; NMR ($CDCl_3$) δ=0.96 (6H, d, J=6.5 Hz), 1.76 (3H, m), 1.86 (3H, m), 2.2—3.1 (6H, m), 3.56 (1H, m), 4.48 (2H, m), and 6.65 (1H, m); MS (70 eV), *m/e* (%), 204 (M^+−18, 4), 150 (M^+−72, 100), 135 (59), 109 (49), 108 (93), 107 (68), 73 (56), 55 (59), 43 (73), and 41 (51). Found: C, 75.83; H, 9.72%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97%.

4-(α-Hydroxybenzyl)-5-isopropenyl-2-methyl-2-cyclohexenone (8c): *Trans*-isomer (**8cA**) and *cis*-isomer (**8cB**) were separated. **8cA**: IR (neat) 3450, 1665, and 895 cm^{-1}; NMR ($CDCl_3$) δ=1.70 (3H, m), 1.77 (3H, m), 2.3—3.2 (5H, m), 4.85 (1H, m), 4.94 (2H, m), 6.53 (1H, m), and 7.30 (5H, s); MS (70 eV), *m/e* (%), 257 (M^++1, 3), 256 (M^+, 1), 187 (5), 150 (100), 135 (43), 109 (40), 108 (31), 107 (100), 91 (21), 79 (79), and 77 (60). Found: C, 79.43; H, 7.66%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%. **8cB**: IR (neat) 3400, 1660, and 900 cm^{-1}; NMR ($CDCl_3$) δ=1.73 (6H, m), 2.2—3.1 (5H, m), 4.75—4.95 (3H, m), 6.82 (1H, m), and 7.25 (5H, s); MS (70 eV), *m/e* (%), 256 (M^+, 0.3), 255 (M^+−1, 1), 187 (2), 150 (96), 135 (41), 109 (35), 108 (27), 107 (100), 91 (22), 79 (75), and 77 (59), Found: C, 79.49; H, 7.70%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

Reaction of Dienoxysilanes (7) with Trialkyl orthoformates Using $TiCl_4$ or $BF_3 \cdot OEt_2$. *General Procedure*: To a cold solution (−60 °C) of **7** (20 mmol) and trialkyl orthoformate (26 mmol) in dry dichloromethane (20 ml), a solution of $TiCl_4$ (3.80 g, 20 mmol) or $BF_3 \cdot OEt_2$ (2.84 g, 20 mmol) in dry dichloromethane (5 ml) was added. After being stirred for 1 h at −60 °C, the mixture was quenched with methanol (5 ml). The mixture was poured into water and extracted with dichloromethane after separation of the organic layer. The extract was washed with a saturated solution of $NaHCO_3$ and dried over $MgSO_4$. After evaporation of the solvent, the residue was subjected to silica-gel column chromatography (hexane–ether) to afford **9**.

4-Dimethoxymethyl-3,5,5-trimethyl-2-cyclohexenone (9a): IR (neat) 1665, 1120, and 1075 cm^{-1}; NMR ($CDCl_3$) δ=1.02 (3H, s), 1.11 (3H, s), 1.95 (1H, d, J=17.0 Hz), 2.06 (3H, d, J=1.5 Hz), 2.24 (1H, d, J=3.0 Hz), 2.57 (1H, d, J=17.0 Hz), 3.39 (3H, s), 3.42 (3H, s), 4.53 (1H, d, J=3.0 Hz), and 5.95 (1H, broad s); MS (70 eV), *m/e* (%), 181 (M^+−31, 2), 180 (M^+−32, 4), 165 (5), 137 (7), 125 (7), 75 (100), 47 (15), 41 (12), and 39 (10). Found: C, 67.62; H, 9.70%. Calcd for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

4-Diethoxymethyl-3,5,5-trimethyl-2-cyclohexenone (9b): IR (neat) 1660, 1630, 1120, and 1065 cm^{-1}; NMR ($CDCl_3$) δ=1.04 (3H, s), 1.13 (3H, s), 1.16 (3H, t, J=7.0 Hz), 1.23 (3H, t, J=7.0 Hz), 1.95 (1H, d, J=17.0 Hz), 2.10 (3H, d, J=1.5 Hz), 2.23 (1H, d, J=3.0 Hz), 2.65 (1H, d, J=17.0 Hz), 3.3—4.0 (4H, m), 4.75 (1H, d, J=3.0 Hz), and 5.95 (1H, broad s); MS (70 eV), *m/e* (%), 195 (M^+−45, 6), 139 (8), 123 (10), 111 (15), 103 (88), 75 (81), and 47 (100). Found: C, 70.20; H, 9.88%. Calcd for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07%.

4-Diethoxymethyl-5-isopropenyl-2-methyl-2-cyclohexenone (9c): GLC (10% PEG 20M) indicated two stereoisomers, **9cA** (*trans*-isomer) and **9cB** (*cis*-isomer). The analytically pure samples of both isomers were prepared by preparative GLC (20% PEG 20M). **9cA**: IR (neat) 1670, 1110, 1060, and 895 cm^{-1}; NMR ($CDCl_3$) δ=1.18 (3H, t, J=7.0 Hz), 1.25 (3H, t,

J=7.0 Hz), 1.76 (6H, m), 2.2—3.1 (4H, m), 3.3—4.0 (4H, m), 4.45 (1H, d, J=3.0 Hz), 4.85 (2H, m), and 6.88 (1H, m); MS (70 eV), *m/e* (%), 207 (M^+−45, 2), 135 (13), 103 (86), 75 (73), and 47 (100). Found: C, 71.11; H, 9.31%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%. **9cB**: IR (neat) 1670, 1110, 1060, and 895 cm^{-1}; NMR ($CDCl_3$) δ=1.17 (3H, t, J=7.0 Hz), 1.22 (3H, t, J=7.0 Hz), 1.80 (6H, m), 2.0—3.1 (4H, m), 3.2—4.0 (4H, m), 4.42 (1H, d, J=5.0 Hz), 4.84 (2H, m), and 6.80 (1H, m); MS (70 eV), *m/e* (%), 207 (M^+−45, 4), 135 (14), 103 (75), 75 (67), and 47 (100). Found: C, 71.15; H, 9.42%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

*Preparation of Megastigma-4,6,8-trien-3-ones (**1a**—**d**).* The reaction of **8a** (6.24 g, 30 mmol) with methanesulfonyl chloride (6.87 g, 60 mmol) was carried out in pyridine (25 ml) at 0 °C for 2 h. The mixture was quenched with cold 2 M HCl and extracted with ether. The extract was washed with a saturated solution of $NaHCO_3$ and brine, dried over $MgSO_4$, and then concentrated. The residue was added to a cold solution (0 °C) of DBU (9.12 g, 60 mmol), NaI (4.50 g, 30 mmol), and toluene (30 ml) and the mixture was refluxed for 1 h. The mixture was poured into cold 2 M HCl and extracted with ether. The extract was washed with a saturated solution of $NaHCO_3$ and brine, and then dried over $MgSO_4$. After removal of the solvent, the residue was distilled to give a mixture (2.90 g, bp 120—130 °C/4 Torr, 51%) of **1a**, **1b**, **1c**, and **1d** in *ca.* 3 : 10 : 1 : 6 ratio. The analytically pure samples of four isomers were prepared by preparative GLC (20% PEG 20M).

*(6Z, 8Z)-Megastigma-4,6,8-trien-3-one (**1a**)*: IR (neat) 1665, 1630, 1590, and 730 cm^{-1}; NMR ($CDCl_3$) δ=1.25 (6H, s), 1.82 (3H, dd, J=7.0, 1.5 Hz), 2.23 (3H, d, J=1.5 Hz), 2.30 (2H, s), 5.70 (1H, m), 5.90 (1H, broad s), and 6.2—6.8 (2H, m); MS (70 eV), *m/e* (%), 190 (M^+, 100), 175 (82), 148 (82), 147 (79), 133 (79), 122 (59), 119 (68), 105 (68), 91 (91), 79 (55), 77 (61), 69 (76), 55 (61), 41 (98), and 39 (82).

*(6Z, 8E)-Megastigma-4,6,8-trien-3-one (**1b**)*: IR (neat) 1665, 1635, 1595, and 970 cm^{-1}; NMR ($CDCl_3$) δ=1.19 (6H, s), 1.86 (3H, dd, J=7.0, 1.5 Hz), 2.28 (3H, d, J=1.5 Hz), 2.29 (2H, s), 5.89 (1H, dd, J=14.0, 7.0 Hz), 5.92 (1H, broad s), 6.25 (1H, d, J=11.0 Hz), and 6.55 (1H, dd, J=14.0, 11.0 Hz); MS (70 eV), *m/e* (%), 190 (M^+, 74), 175 (61), 148 (75), 147 (70), 133 (82), 122 (41), 119 (63), 105 (60), 91 (78), 79 (48), 77 (52), 69 (68), 55 (49), 41 (100), and 39 (59).

*(6E, 8Z)-Megastigma-4,6,8-trien-3-one (**1c**)*: IR (neat) 1665, 1582, and 725 cm^{-1}; NMR ($CDCl_3$) δ=1.36 (6H, s), 1.83 (3H, dd, J=7.0, 1.5 Hz), 2.13 (3H, d, J=1.5 Hz), 2.35 (2H, s), 5.92 (1H, broad s), and 5.5—7.0 (3H, m); MS (70 eV), *m/e* (%), 190 (M^+, 97), 175 (67), 148 (76), 147 (76), 133 (82), 122 (55), 119 (55), 105 (64), 91 (79), 79 (48), 77 (55), 69 (73), 55 (52), 41 (100), and 39 (73).

*(6E, 8E)-Megastigma-4,6,8-trien-3-one (**1d**)*: IR (neat) 1670, 1630, 1585, and 968 cm^{-1}; NMR ($CDCl_3$) δ=1.35 (6H, s), 1.89 (3H, dd, J=7.0, 1.5 Hz), 2.08 (3H, d, J=1.0 Hz), 2.35 (2H, s), 5.91 (1H, broad s), 5.94 (1H, dd, J=14.5, 7.0 Hz), 6.50 (1H, d, J=11.5 Hz), and 6.75 (1H, dd, J=14.5, 11.5 Hz). MS (70 eV), *m/e* (%), 190 (M^+, 100), 175 (81), 148 (98), 147 (92), 133 (98), 122 (54), 119 (77), 105 (65), 91 (94), 79 (52), 77 (63), 69 (81), 55 (60), 41 (100), and 39 (81).

*Preparation of 3-Oxo-β-ionol (**13**).* To a cold solution (0 °C) of **1** (2.25 g, 12 mmol) in dry dichloromethane (50 ml) was added *m*-chloroperbenzoic acid (2.59 g, 15 mmol) and the mixture was stirred at 0 °C for 2 h. The mixture was washed with a 1% solution of NaOH and brine, dried over $MgSO_4$, and concentrated. The residue was added to a mixture of zinc powder (3.92 g, 60 mg atom) and acetic acid (20 ml) at room temperature. After the mixture was stirred for 2 h at room temperature, the precipitate was filtered off and washed with ether (100 ml). The filtrate was washed with a saturated solution of $NaHCO_3$ and brine, dried over $MgSO_4$, and then concentrated. Purification by silica-gel column chromatography (hexane–ether) afforded **13** (1.61 g, 65%). IR (neat) 3400, 1720, 1660, and 975 cm^{-1}; NMR ($CDCl_3$) δ=1.06 (6H, s), 1.33 (3H, d, J=6.0 Hz), 1.76 (3H, s), 2.39 (2H, s), 2.86 (2H, s), 3.57 (1H, s), 4.43 (1H, quintet, J=6.0 Hz), 5.61 (1H, dd, J=16.0, 6.0 Hz), and 6.07 (1H, d, J=16.0 Hz); MS (70 eV), *m/e* (%), 208 (M^+, 5), 190 (15), 175 (12), 135 (30), 133 (24), 121 (26), 109 (29), 108 (46), 107 (34), 91 (36), and 43 (100).

*Reduction of **13** to 3-Hydroxy-β-ionol (**2**).* To a suspension of $NaBH_4$ (0.076 g, 2 mmol) in ethanol (10 ml) was added **13** (0.801 g, 3.9 mmol) at room temperature. After the mixture had been stirred for 1 h at room temperature, the mixture was quenched with cold 5% $(CO_2H)_2$ and extracted with ether. The extract was washed with a saturated solution of $NaHCO_3$ and brine, dried over $MgSO_4$, and then concentrated. Purification by silica-gel column chromatography (hexane–ether) afforded **2** (0.734 g, 91%).

*Isomerization of **13** to 3-Oxo-α-ionol (**5**).* To a solution of NaOMe (0.010 g) in methanol (5 ml) was added **13** (0.243 g, 1.2 mmol) at room temperature, then the mixture was stirred for 10 min at room temperature, poured into cold water, and extracted with ether. The extract was washed with brine, dried over $MgSO_4$, and then concentrated. Purification by silica-gel column chromatography (hexane–ether) afforded **5** (0.225 g, 93%).

The authors wish to express their thanks to Professor Teruaki Mukaiyama, The University of Tokyo, for his helpful discussions.

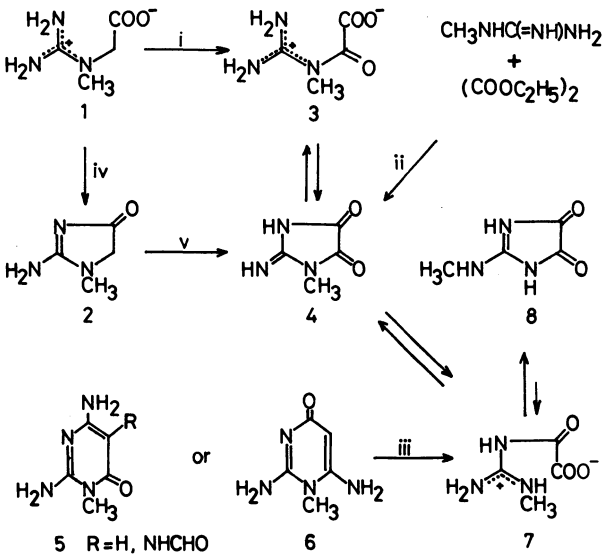
2-Methylamino-4,5-imidazoledione. A Revised Structure for Creatone, Methylparabanic Acid Imide, and (3-Methylguanidino)glyoxylic Acid

Hiroshi YAMAMOTO* and Wolfgang PFLEIDERER†
Department of Chemistry, Faculty of Science, Okayama University, Okayama 700
†Universität Konstanz, Fakultät für Chemie, D-7750 Konstanz, Germany
(Received November 18, 1981)

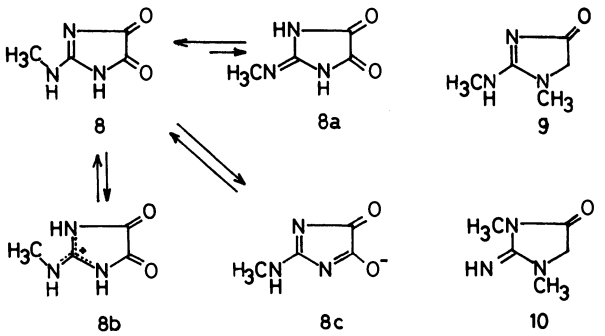
The previous structures presented for the $Hg(OAc)_2$ oxidation product of creatine, the condensation product of methylguanidine and diethyl oxalate, and the peracid oxidation product of 1-methyl-2-amino-dihydropyrimidines are all replaced by a revised formulation, 2-methylamino-1*H*-imidazole-4,5-dione on the basis of the pK_a values (0.62 and 7.87) and the spectra. The equilibria between this thermodynamically controlled product and the previous formulations are discussed.

Creatine (**1**) is present in the muscular tissue of many vertebrates, mostly as phosphocreatine, which plays an important role in energy transfer and storage.[1] It has been reported[2,3] that the action of mercury(II) acetate on **1** afforded a single product (creatone) (mp 203—204°C decomp), to which the structure of (1-methylguanidino)-glyoxylic acid (**3**) was assigned (Scheme 1). The same product was also isolated from beef and regarded as a constituent of muscle tissue.[4] Traube and Gorniak,[5] meanwhile, briefly reported a condensation product (mp 205—207 °C decomp) of methylguanidine and diethyl oxalate; the structure of "1-methylparabanic acid imide" (2-imino-1-methylimidazolidine-4,5-dione) (**4**) was simply presented for this product, without any proof.

During our study of the oxidative pyrimidine→1,3,5-triazine rearrangement, we found that the action of performic acid on 2,4-diamino-1-methyl-1,6-dihydro-pyrimidin-6-ones (**5**) and the 6-amino-4-oxo isomer (**6**) afforded a 20—25% yield of colorless needles (mp 200 °C decomp), to which the Zwitter ion structure, (3-methylguanidino)glyoxylic acid (**7**), was assigned on the evidences of the elemental analysis and spectral data



Scheme 1. Reaction pathways for the formation of **8** from **1**, **2**, **5**, **6**, and methylguanidine–diethyl oxalate. i, $Hg(OAc)_2$, Refs. 2, 3. ii, Ref 5. iii, H_2O_2/HCOOH. Ref. 6. iv, H^+. v, $Hg(OAc)_2$.



Scheme 2. Tautomeric forms and equilibria of **8**.

(UV, IR, and ^{1}H-NMR).[6] However, the close similarity of the melting points and the solubilities (in water) among the products, **3**, **4**, and **7**, led us to reinvestigate those structures.

We have now found that both creatone (**3**) prepared[3] from **1** and the condensation product[5] (**4**) were identical with our specimen,[6] derived from **5** and **6**, on the evidence of the spectroscopic data (IR, NMR) and the mixed melting points. Creatinine (**2**), an important end product of nitrogen metabolism,[7] also produced the identical substance more rapidly than **1** upon treatment with mercury(II) acetate. The revised structure of 2-methylamino-1*H*-imidazole-4,5-dione (**8**) was then assigned to the common product on the basis of the spectral data, as will be shown below.

The repeated elemental analysis of the specimen of **8** dried at 120 °C/0.05 Torr** over P_2O_5 showed an analytical figure corresponding to $C_4H_5N_3O_2$ instead of $C_4H_7N_3O_3$, which had previously been reported.[2,3,6] The EI high-resolution and chemical-ionization mass spectra clearly confirmed the molecular formula ($C_4H_5N_3O_2$), and the characteristic fragmentation peaks were those at *m/e* 99 and 71 due to the successive loss of two CO groups from the molecular ion. The presence of imino and two kinds of carbonyl groups were confirmed by the IR spectrum (3200, 1710, and 1630 cm^{-1}). Because of the sparing solubility in other suitable solvents (*e.g.*, DMSO-d_6, D_2O, or pyridine-d_5), the NMR spectrum of **8** was taken in trifluoroacetic acid (TFA); the signals are recorded in Table 1. In TFA-*d*, the doublet at 3.31 collapsed into a singlet,

** 1 Torr≈133.332 Pa.

Table 1. Physical properties of some imidazole derivatives

a) δ values in TFA at 30 °C, with TMS as the internal standard; s, singlet; d, doublet; q, quartet; m, multiplet; b, broad. b) The numbering of **1** corresponds to that of **2** for the purpose of comparison. On setting aside the sample solution in TFA at 25 °C, **1** gradually changes to **2** ($t_{1/2}$ *ca.* 3 d), which, in contrast, remains unchanged. c) 2H. d) The assignment has been made because **2** probably exists as the monocation in TFA. e) The spectra are of compounds, **3**, **4**, and **7**, all of which are identical and exist as the monocation **8b** in TFA. f) J=5.0 Hz. g) 3H. h) 1H. i) Measured with a Hitachi EPS 3T Recording Spectrophotometer. j) Monocation (+), neutral species (0), monoanion(−). k) From Ref. 17. l) From Ref. 8. m) From Ref. 9. n) Determined spectroscopically according to Ref. 16. o) Extrapolated value since the anionic species gradually decomposes during the measurement. p) From Ref. 10.

and the broad multiplet and the quartet disappeared, suggesting the presence of a CH_3NH– (or $CH_3\overset{+}{N}H$=) group in the molecule. Structures **3** and **4** were thus eliminated because their *N*-methyl signal may be expected to be a singlet, as was observed in the spectra of the two starting materials, **1** and **2**, in the same solvent (see Table 1).

Creatinine (**2**) was shown to exist mainly in the amino-oxo form rather than the universally written 2-imino-1-methylimidazolidin-4-one form by comparing the pK_a value and other physical properties with those of such related compounds as **9** and **10** (see Table 1).[8–11] The pK_a values and UV spectra of **8** were thus measured; the results are summarized in Table 1. Although the neutral species of **8** was completely stable in water at 25 °C, both cationic and anionic species were gradually degraded——*e.g.*, $t_{1/2}$ 3 d (in 1 mol dm^{-3} HCl) and 70 min (at pH 9—13). The extremely low value (0.6) of the basic pK_a of **8** and the stability of its neutral species in water point to the amino-oxo form (**8**) rather than the tautomeric imino form (**8a**) (Scheme 2), since the exocyclic imono group may be expected to be more basic and unstable in a protic solvent, as is shown in the case of **10**, which gradually isomerized to **9** in boiling methanol.[10] The UV absorption maximum of **8** in acid and the NMR doublet signal of the methyl group in TFA suggest the resonance-stabilized form **8b** for the monocation. The large bathochromic shift (30 nm) observed in the UV absorption maximum in alkaline solutions indicates that **8** probably becomes a fully conjugated diazacyclopentadienone form, **8c**, which in turn tends to decompose readily to oxalic acid and methylguanidine.

The oxidation of **1** and **2** with mercury(II) acetate presumably proceeds in a manner similar to that of the dehydrogenation of cyclic tertiary amines[12] to give **4**, which is in equilibrium with the ring-opened forms **3** and **7** (Scheme 1). The latter should provide **8** upon a recyclization similar to the Dimroth rearrangement,[13] and the predominant formation of the final product **8** could be explained by its thermodynamical stability compared with other isomers (**3**, **4**, and **7**). The formation of **8** from the pyrimidines, **5** and **6**, is initiated by the peroxy acid degradation to afford a common intermediate **4** or **7**, followed by a similar equilibrium transformation. The same equilibrium scheme was also applied to the condensation product of methylguanidine and diethyl oxalate, as is shown in Scheme 1.

Many rearrangements have been known[14] involving the fission of a heterocyclic ring and ring closure in the alternate direction catalyzed by acid, base, heat, light, or miscellaneous reagents. The present rearrangement at such a low temperature can be classified, to the best of our knowledge, as a rare example of thermodynamically controlled ring transformation of the imidazole-ring system.[15]

Experimental

The ^{1}H-NMR spectra were measured in TFA with a Hitachi High-resolution NMR Spectrometer, R-20A (60 MHz), at 30 °C. The IR spectra were taken with a Nihon-Bunko IR-S spectrometer. The mass spectra were measured at the Department of Chemistry, the University of Alberta, with an A. E. I. MS 50 ultra-high-resolution instrument (for the accurate mass measurement) and an A. E. I. MS 12 appararus (for the chemical ionization with NH_3). The measurements of the ionization constants were carried out spectrophotometrically in 0.01 mol dm^{-3} buffers by the usual method.[16]

The microanalyses were performed using a Yanagimoto CHN Corder, MT-2. Substances stated to be identical were compared by means of mixed-melting-point determinations, their spectra (IR, NMR), and TLC (silica gel; developed with DMF–MeOH–$CHCl_3$, 1 : 5 : 15). The melting points are uncorrected.

The Oxidation of Creatinine (2). To a solution of 1.13 g (10 mmol) of **2** in 80 ml of water was added 11.2 g (35 mmol) of mercury(II) acetate, after which the mixture was allowed to stand at room temperature; after *ca.* 3 h, colorless leaflets began to separate, and 4.82 g (15 mmol) more of $Hg(OAc)_2$ was added after 1 d. The precipitate was filtered off after 3 d and washed with a small amount of cold water; the pH of the supernatant solution was 3 throughout this period. The filter cake was suspended in 100 ml of water and saturated with hydrogen sulfide gas with stirring. The black mercury sulfide was filtered by gravity and washed with boiling water (20 ml). The combined filtrate and washings were evaporated to dryness *in vacuo*, and the residue was washed with 80% aq *t*-BuOH, giving 0.56 g (38%) of **8** as a colorless powder: mp 197—199 °C decomp (from 50% aq ethanol); IR (KBr), 3200 (NH), 1710 (C=O), 1630 (C=N–CO=), 1450, 1370, 1190, 1160, 790, and 680 cm^{-1}; EI high-resolution MS, *m/e* (rel intensity), 127 (89; M^+), 99 (100; M−CO), 71 (54; M−2CO), 58 (34), 56 (75; MeNHC≡N), and 55 (71; MeNCN); CI (NH_3) MS, *m/e* (rel intensity), 147 (0.8; P+2), 146 (5.5; P+1), 145 [100; P(M+NH_4^+)], 128 (2.8), 102 (1.0), and 86 (6.9).

Found (for material dried over P_2O_5 at 120 °C/0.05 Torr for 7 h): C, 37.42; H, 4.21; N, 32.83%; *m/e*, 127.0381. Calcd for $C_4H_5N_3O_2$: C, 37.81; H, 3.97; N, 33.06%; *m/e*, 127.0382.

The product was identical with the specimen[6] obtained from **5** and **6**.

The Oxidation of Creatine (1). The procedure fo Greenwald[3] was followed; after *ca.* 10 h, colorless leaflets began to separate. The product similarly obtainep after 8 d (20%yield, mp 197—199 °C decomp) was identical with **8**.

The Condensation of Methylguanidine and Diethyl Oxalate. Traube and Gorniak[5] reported the product **4** without describing the experimental procedure in detail. Thus, the reaction was carried out as follows: a solution of sodium ethoxide was prepared by dissolving 0.30 g (13 mmol) of sodium in 10 ml of absolute ethanol. To this were added, under argon at 5 °C, 1.42 g (13 mmol) of methylguanidine hydrochloride and 1.9 g (13 mmol) of diethyl oxalate. The resulting white suspension was stirred at 20 °C for 5 h. The mixture was taken to pH 4 by the careful addition of 5 mol dm^{-3} AcOH at 5 °C and subsequently concentrated *in vacuo*. The residue was suspended in methanol (20 ml) and filtered off, giving 0.80 g (47%) of **8** as colorless leaflets; mp 203—205 °C decomp (from 50% aq ethanol).

We wish to thank Dr. M.-A. Armour of the University of Alberta for the high-resolution mass spectra.

Oxidative *S*-Dealkylation Reaction of Sulfide Catalyzed by Co(II)(bzacen)

Yoshihito WATANABE, Tatsuo NUMATA, and Shigeru OAE*
Department of Chemistry, The University of Tsukuba, Niihari-gun, Sakura-mura, Ibaraki 305
(Received December 10, 1981)

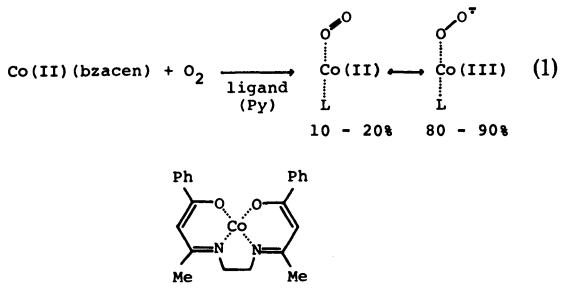
In the oxygenation reaction of alkyl sulfides with Co(II)(bzacen)–O_2 system, oxidative S–C bond cleavage (*S*-dealkylation) was found to take place exclusively. The reactivity of *S*-dealkylation reaction was dependent markedly on both acidity of α-methylene and steric hindrance of alkyl sulfide. The peroxo-Co(III) species is presumed to be the intermediate in this *S*-dealkylation reaction.

Although mechanisms of many reactions with hydrolytic enzymes have been understood fairly well now, those of the reactions with both mono- and di-oxygenases are by no means well-understood,[1-3] since many of the oxygenation intermediates in the reactions with oxygenases are unstable and hence not well-characterized. Therefore, numerous nonenzymatic models have been designed to investigate the nature of many enzymatic oxygenations.[4,5]

Meanwhile, as a model of the active site of myoglobin and oxymyoglobin "picket fence porphyrin"–iron(II) complexes have been synthesized and fully characterized by Mössbauer spectroscopy, magnetic susceptibility, and X-ray crystallography analysis.[6-8] These picket fence porphyrin–iron complexes can bond with molecular oxygen to give endo-on type complexes. Model oxygenation systems of another types are cobalt–Schiff base complexes.[9,10] However, only a few oxygenation reactions of aromatic compounds with metal-molecular oxygen complexes have been examined.[11,12] Meanwhile, sulfides bearing electron-withdrawing group were found recently by us to be oxygenated in the presence of a Co(II)–Schiff base complex affording exclusively the *S*-dealkylation products.[13]

In the meantime, in the oxygenation of divalent sulfur compounds with cytochrome P-450 monooxygenase, we have demonstrated that both dealkylation and *S*-oxygenation reactions take place *via* the sulfenium radical as the common intermediate formed in the rate-determing one electron transfer from sulfur atom to the "oxenoid" intermediate.[14,15] The "oxenoid" intermediate is believed to be the metal–mono-oxygen complex ($Fe{=}O^{3+}$).[16] Thus, it is of interest to examine the nature of the reaction with metal-molecular oxygen complex as compared to that with cytochrome P-450 in the oxygenation of various sulfides.

This report described a detailed account on the oxygenation of divalent sulfur compounds with Co(II)-(bzacen), [*N*,*N*′-bis(2-benzoyl-1-methylethylidene)ethylenediamine], which is known to ninteract with molecular oxygen to give ligand–Co(II)–O_2 complex that was found to be the endo-on type complex by X-ray study (Eq. 1).[17]



Results and Discussion

When a β-keto sulfide (**1a**, 0.40 mmol) was incubated aerobically in a 16 mL of methanol solution containing Co(II)(bzacen) (0.10 mmol) for 30 min at room temperature, the oxygenation was found to complete. The products were analyzed by GLC by removing the catalyst by adsorption through an ion exchange resin [Dowex 50W-8 (H^+ form)]. After GLC measurement and replacing methanol by dichloromethane, treatment of the mixture with an excess diazomethane to determine carboxylic acids gave methyl esters which were also analyzed by GLC (Scheme 1). In the oxygenation reaction, oxidative cleavage of S–C bond of the sulfide (**1a**) took place exclusively to afford only the corresponding carbonyl compound (**2a**) and diphenyl disulfide (**3**) in good yields (Scheme 1). The oxidative cleavage of other sulfides each having an acidic α-methylene (**1b—d**) was also found to proceed catalytically in methanol solution at room temperature but required a longer reaction time to complete the oxygenation reaction (Table 1). As shown in Table 1, the reaction proceeds faster with the sulfide bearing a higher acidic α-methylene group.[15] Benzyl phenyl sulfide (**1f**) and thioanisole (**1g**) were not oxygenated under these conditions. Thus, the reactivity of the oxidative *S*-dealkylation appears to depend strongly on the acidity of α-hydrogen of the alkyl sulfide.

comparable to that of the sulfide (**1b**), seemingly supporting the hypothesis that one of the most important factors is the acidity of the α-methylene, since both pK_a's of methylene proton of **6** and **1b** are quite similar (pK_a; $PhCO\underline{CH_3}$ 24.7, $NC\underline{CH_3}$ 31.3, $PhS(O_2)\underline{CH_2}OPh$ 27.9, $PhS(O_2)CH_2SPh$ 20.3).[18,19]

Meanwhile, the steric effect on the reactivity has been examined systematically with various α-substituted β-, keto sulfides (**4**) which are listed in Table 2. When 2-(phenylthio)cyclohexanone (**4a**) was incubated for 16h diphenyl disulfide (**3**) and 1,2-cyclohexanedione (**8a**) were obtained in good yields. The oxygenation of 2-(phenylthio)propiophenone (**4c**) with the Co(II)-(bzacen)–O_2 system required 23 h to be completed in methanol, eventually affording diphenyl disulfide (**3**) quantitatively and 1-phenyl-1,2-propanedione (**8c**) in 50% yields, respectively. Although phenyl group would activate the α-proton of **4b** which would hence be more

acidic than α-proton of **1a**, the reactivity of *S*-dealkylation of **4d** is substantially decreased. In the case of a most crowded β-keto sulfide, *i.e.*, 3-(phenylthio)-*dl*-camphor (**4e**), which is an *endo* and *exo* mixture, the oxygenation was not found to proceed for both *endo* and *exo* sulfides even though the reaction mixture was incubated for 48 h (Table 3).

These observations clearly indicate that the steric hindrance is second important factor for the *S*-dealkylation reaction. As shown previously, oxygenations catalyzed by cobalt(salen) are related to the electron donor character of the substrate and the steric hindrance would reduce the donor character of the substrates.[11]

In order to understand the whole feature of oxidative *S*-dealkylation reaction, several experiments have been carried out.[13] In the kinetic experiments of oxygenation of **1a** with Co(II) (bzacen) in methanol, the rate of the reaction was found to be of first order dependence both on the concentration of the sulfide (**1a**) and that of the catalyst; the plot of the amounts of the formation of the diphenyl disulfide (**3**) against time gave a sigmoidal curve shown in Figs. 1 and 2. On the other hand, an equimolar amount of molecular oxygen was found to be consumed by the reaction (Fig. 3).

These results suggest that the oxygenation reaction catalyzed by Co(II)(bzacen) has a pre-equilibrium which may be the process of coordination of sulfide to cobalt like a ES complex in the actual enzymatic reaction.

We cannot conclude whether or not the formation of the first complex (S·Co) involves the coordination of molecular oxygen, however, Fig. 3 suggests the participation of molecular oxygen in a ES like complex which eventually gave the products.

$$\underset{(E)}{S + Co} \overset{O_2}{\rightleftharpoons} \underset{(ES)}{S\cdot Co\cdot O_2} \longrightarrow P + Co \qquad (3)$$

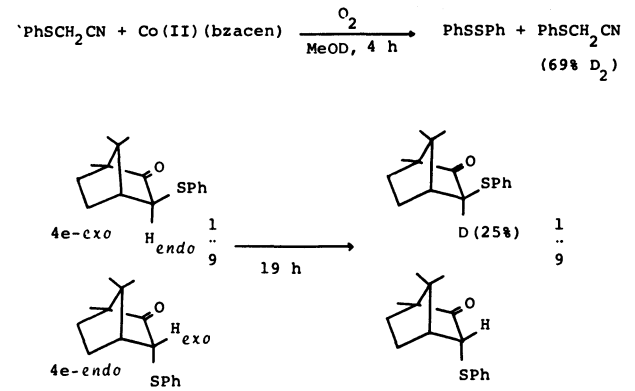
The effect of *p*-substituent on benzene ring of **1b** on this biomimetic oxygenation was examined to demonstrate the participation of divalent sulfur atom in the first equilibrium of the coordination. When the *p*-substituent was electron-donating group, the induction period of the oxygenation of **1b** was found to be shortened, however, the rate of formation of diaryl disulfide (**3**) after the induction period was not affected at all by the substituent. Meanwhile, an electron-withdrawing substituent prolonged only the induction period as shown in Fig. 4. The effect of *p*-substituent on benzene

ring may be explained in that the initial step of the oxygenation is the coordination of divalent sulfur atom to cobalt as an axial ligand.

Cyanomethyl phenyl sulfoxide (**5**) did not react at all under the same reaction conditions clearly suggesting that cobalt coordinates to divalent sulfur atom but not α-methylene position in the first step of oxygenation, since α-methylene proton is activated more by the sulfinyl group than sulfenyl group.

The effect of solvent was quite substantial; *e.g.*, the reaction in methanol was markedly faster than in pyridine. The reaction of **1a** in pyridine proceeded only 2% while the reaction in methanol was completed in the same period. These solvent and steric effects are similar to those in the oxygenation of indole derivatives by Co(II)(salen)–O_2 system.[11]

When the reaction of **1b** was carried out in methanol-d_1, the recovered sulfide was found to retain only 69% of deuterium at α-methylene carbon after 50% conversion of sulfide (**1b**) to diphenyl disulfide (**3**) (4 h, room temperature, Co(II)/**1b**=1). The H-D exchange reaction between the substrate and methanol-d_1 indicates that the reversible deprotonation step to give carbanion is involved in the oxygenation reaction. When an *endo* and *exo* mixture of very crowded 3-(phenylthio)-*dl*-camphor (**4e**) (*endo* : *exo*=1 : 9) was incubated with Co(II)(bzacen) in methanol-d_1 for 19 h to examine the H-D exchange, the starting sulfide (**4e**) was recovered quantitatively, however, 25% of *endo*-proton (less hindered proton) and 0% of *exo*-proton was deuterated (Scheme 2). The same reaction was found to take place when the reaction of sulfide (**4e**) with D_2O was carried out in the presence of pyridine as base, *i.e.*, only 28% of *endo*-proton was deuterated.



Scheme 2.

Meanwhile, oxidative dealkylation reaction of sulfides (**1a** and **1b**) was also found to take place with strong bases under oxygen atmosphere but very slowly without catalyst; *e.g.*, **1a** gave **2a** (10%), **3** (10%) and **1a** (85% recovered) upon treatment of **1a** with NaH in THF under oxygen atmosphere at room temperature for 20 min (Eq. 4).

In these reactions, peroxy intermediate (**9**) would be formed prior to give *S*-dealkylation products (Eq. 5). The products distribution in the autoxidation of sulfides supports that in the oxygenation of sulfides with Co(II)-(bzacen), a similar peroxy-intermediate (**10**) would be

$$\underset{\mathbf{1a}}{PhSCH_2COPh} + NaH \xrightarrow[\substack{THF,\ r.t.\\ 20\ min}]{O_2} PhSSPh + OHCCOPh + recov. \quad (4)$$

$$\underset{\mathbf{1b}}{PhSCH_2CN} + t\text{-}BuOK \xrightarrow[\substack{DMSO,\ r.t.\\ 30\ min}]{O_2} PhSSPh + recov.$$

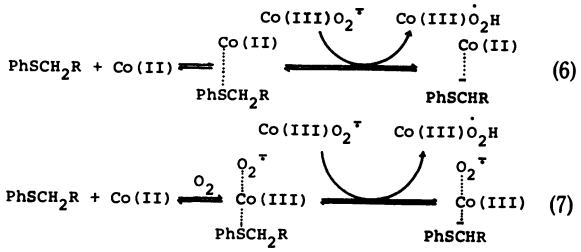
$$\mathbf{3}\ 30\% \qquad 70\%$$

formed as described in other cobalt-Schiff base induced oxygenations of *t*-butylsubstituted phenols and indoles.[11,12,23]

$$PhSCH_2R + :B \xrightarrow{Ar} PhS\dot{C}HR \xrightarrow{O_2} [PhS\dot{C}HR\ O_2^{\cdot}] \longrightarrow \left[\begin{array}{l} PhSHR \\ O\text{-}O^- \end{array}\right] \rightarrow\rightarrow PhSSPh + RCHO \quad (5)$$

9

These observations suggest that the reaction proceeds through an initial formation of a dual or a ternary complex to activate α-methylene proton which may be abstracted by the superoxo-intermediate to give an α-carbanion



In the oxygenation of *t*-butyl-substituted phenols, Nishinaga *et al.* suggested the direct hydrogen abstraction by superoxo-Co(III) complex (Eq. 9) to be the rate-determining step, followed by subsequent fast electron transfer from the divalent Co(II) complex to the substrate radical (Eq. 10).[11,12,23]

$$Co(II) + O_2 \rightleftharpoons Co(III)O_2^{\cdot} \quad (8)$$

$$Co(III)O_2^{\cdot} + R\text{–}H \longrightarrow Co(III)^{-}O_2H + R\cdot \quad (9)$$

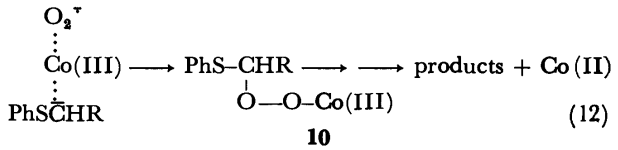
$$Co(II) + R\cdot \xrightarrow{fast} R^{-}Co(III) \quad (10)$$

$$R^{-}Co(III) + O_2 \longrightarrow ROO^{-}Co(III) \quad (11)$$

On the other hand, Jefford and Cadby[3] pointed out the cobalt–Schiff base complex to localize the π-anion charge into an orbital with more [sp^3] character; *i.e.*, cobalt–Schiff base complex catalyzes the reaction of carbanion with molecular oxygen to afford peroxy intermediate.

We cannot conclude which process is involved in the actual oxygenation pathway; *i.e.*, direct deprotonation or hydrogen abstraction and subsequent electron transfer to afford the carbanion, however, all these results would support the direct deprotonation mechanism as indicated in Eqs. 6 and 7.

Finally, the superoxo-Co(III)–carbanion complex is presumed to give peroxo-intermediate (**10**) and the products (Eq. 12).

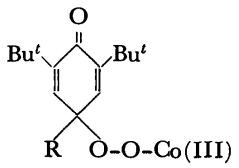


10 (12)

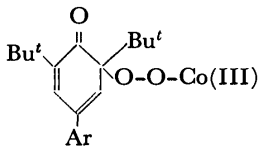
Although a few mechanisms are conceivable for the production of peroxy intermediate (**10**), Nishinaga *et al.* already isolated peroxy intermediates such as (**11**) and (**12**), which seem to support the formation of (**10**) in the oxygenation of sulfide with Co(II)(bzacen).[12,23]

After the oxygenation being carried out, a direct measurement of the ^{1}H NMR spectrum was attempted, however no clear signal was observed due to the presence of paramagnetic material which would be Co(II)(bzacen). Thus, Co(II)(bzacen) can catalyze the oxygenation reaction of sulfide. These results seem to support the mechanistic scheme shown in Eq. 12; *i.e.*, Co(II)(bzacen) is left after the reaction.

Incidentally, all these substrates (**1a—d**) are not susceptible to oxidation with superoxide with 18-crown-6 system.



11



12

Experimental

Reagent. All reagents and solvents used in this study were of guaranteed grades and used without further purification. Methanol-d_1 (min. 99%) and deuterium oxide (min. 99.75%) were purchased from Merck.

General. Melting points were measured on a Yanaco instrument and uncorrected. The boiling points were observed on a Büchi K-R (Kugel Rohr). NMR spectra were recorded on a Hitachi Perkin Elmer R 20 spectrometer in $CDCl_3$ and CCl_4 using TMS as the internal standard. GLC analyses were taken with Hitachi 163 Gas Chromatography (10% SE 30, 2 m glass column). TLC and column chromatography were carried out with Kieselgel GF_{254} Type 60 and Kieselgel 60 (70—230 mesh) (Merck), respectively.

Preparation of Sulfides ***1*** *and* ***4****.* Preparation of unsubstituted sulfides (**1a—e**) were already reported in our recent paper.[15] *p*-Substituted **1b**'s (methyl and chloro) were obtained by treatment of *p*-substituted thiophenol with chloroacetonitrile in the presence of potassium hydroxide according to the ordinary procedure described previously,[24] and isolated through SiO_2 column chromatography (eluent; benzene). Mp and ^{1}H NMR (δ-value, ppm): *p*-$CH_3C_6H_4SCH_2CN$; 160 °C/2 mmHg** (lit, 120.5—127.5 °C/1.0 mmHg),[25] 2.31 (3H, s) 3.41 (2H, s) 7.00 (2H, d, J=8.3) 7.29 (2H, d, J=8.3). *p*-$ClC_6H_4SCH_2CN$; 88—99 °C (from hexane) (lit, 88—90 °C),[26] 3.48 (2H, s) 7.25 (2H, d, J=9.6) 7.33 (2H, d, J=9.6). α-Substituted β-keto sulfides (**4a—e**) were synthesized by treating benzenesulfenyl chloride with corresponding alkyl ketones in the presence of butyllithium or sodium hydride in tetrahydrofuran.

Benzenesulfenyl Chloride. Chlorine gas was bubbled into a dichloromethane solution of diphenyl disulfide at 0 °C for 20 min to give benzenesulfenyl chloride quantitatively.[27] The reaction mixture was condensed by evaporation of both solvent and excess chlorine *in vacuo* without warming. Benzenesulfenyl chloride was used without further purification.

*Preparation of 3-(Phenylthio)-*DL*-camphor (****4e****).* A solution of butyllithium (0.2 mol) in 10 mL of dry hexane was added to a solution of DL-camphor (4.5 g, 0.03 mol) in dry tetrahydrofuran (40 mL) at −72 °C and stirred for 10 min. After introduction of benzenesulfenyl chloride (2.8 g, 0.02 mol) into the reaction mixture at −72 °C, the solution was warmed to room temperature slowly for 1 h and stirred for 1 h additionally. The solution was evaporated under reduced pressure and the mixture was washed with water and extracted with chloroform. The chloroform layer was dried over anhydrous magnesium sulfate. The recovered DL-camphor was separated by distillation at 110 °C (bath temp)/2 mmHg. 3-(Phenylthio)-DL-camphor (**4e**) was isolated through SiO_2 column chromatography (2.9 g, 50% yield). From the ^{1}H NMR spectroscopic analysis, 90% of phenylthio group in **4e** was found to be substituted at *exo* position. When the reaction was carried out at −20 °C, the ratio of *exo* : *endo* was 65 : 35. Other sulfide (**4**) were also prepared similarly and their physical data were listed in Table 2.

Phenylglyoxal and Benzoylformic Acid. Phenylglyoxal and benzoylformic acid were synthesized according to the procedure described in Organic Synthesis.[28,29]

*Synthesis of Phenacyl Phenyl Ether (****5****).* A mixture of phenacyl chloride (6.0 g, 0.039 mmol) and phenol (4.0 g, 0.042 mol) in benzene (40 mL) was added to a solution of sodium hydroxide (1.6 g, 0.067 mol) and tetrabutylammonium chloride (140 mg, 0.5 mmol) in water (40 mL). The solution was refluxed for 10 h and acidified with 6 mol dm^{-3} HCl (pH 4). The solution was extracted with chloroform and the extract was washed with water and dried over anhydrous magnesium sulfate. After evaporation of solvent, the residue was chromatographed on SiO_2, using hexane–benzene (4 : 5) as eluent. The desired product was recrystallized from ethanol. Mp and ^{1}H NMR in $CDCl_3$; 73—74 °C (lit, 71—72 °C),[30] 4.93 (2H, s) 6.7—7.0 (3H, m) 7.0—7.5 (2H, m) 7.3 (5H, brs).

Preparation of Co(II)(bzacen). *Bzacen*; N,N′-*Bis(2-benzoyl-1-methylethylidene)ethylenediamine*: A solution of benzoylacetone (20 g, 0.2 mol) in abs. ethanol (25 ml) was refluxed for 5 min and ethylenediamine (6.0 g, 0.1 mol) in 6 mL of abs. ethanol was added dropwise slowly. After additional reflux for 15 min, the reaction mixture was cooled to room temperature to give a white precipitate in a quantitative yield. The product was recrystallized from ethanol (mp 182—184 °C; lit, 180.5 °C).[31]

Co(II)(bzacen): After refluxing a solution of bzacen (2.0 g, 5.7 mmol) in dry acetone for 2 h under argon atmosphere, anhydrous cobalt(II) chloride (0.75 g, 5.7 mmol) was added and the solution turned green at once. Then, sodium hydroxide (0.75 g, 5.7 mmol) was added to the reaction mixture which was refluxed until the precipitate turned red completely (about 7 h). The reaction mixture was cooled to 0 °C and filtrated. The precipitate was washed with cold water and decantation with methanol 3 times gave Co(II) bzacen) in 60% yield (mp 262—263 °C decomp; lit. 265 °C decomp).[31]

*Oxygenation Reaction of Phenacyl Phenyl Sulfide (****1a****) with Co(II)-(bzacen).* A solution of 105 mg of sulfide (**1a**) (0.46 mmol) in 16 mL of methanol was added to 44 mg of Co(II)-(bzacen) and the mixture was stirred, monitoring time to time the decrease of sulfide (**1a**) by TLC (benzene : hexane= 1 : 1). The reaction mixture was stirred for 30 min and poured into an ion exchange resin (Dowex-50W H^+ form, methanol suspension) and then stirred for 5 min. After filtration, the filtrate was evaporated. The residue was diluted

** 1 mmHg≈133.322 Pa.

with dichloromethane (8 mL) and products [phenylglyoxal (**2a**), methyl benzoate, and diphenyl disulfide (**3**)] were analyzed by GLC. Then the solution was cooled with ice bath and excess diazomethane (ether solution) was added to the solution which was then kept standing for 2 h at 0 °C. Then the reaction mixture was analyzed by GLC again (methyl benzoate and methyl benzoylformate) by comparison with those of authentic samples. PhSSPh (quant), $PhCOCHO$ (81%), $PhCOCO_2H$ (13%), $PhCO_2H$ (4.5%), and $PhCO_2Me$ (1.2%).

The other sulfides were oxygenated in the same procedure.

*The Reaction of Sulfide (**1**) with KO_2.* To a solution of sulfide (**1**) (0.1 mmol) in chloroform, 7 mg, of KO_2 (0.1 mmol) was added at room temperature under argon atmosphere and 26 mg of 18-crown-6 (0.1 mmol) in 4 mL of chloroform. The mixture was stirred for 26 h at room temperature. TLC and GLC measurements showed that sulfide (**1**) was inert to KO_2.

*The Autoxidation of Sulfides (**1a**) and (**1b**) in the Presence of Base. Oxygenation of Phenacyl Phenyl Sulfide (**1a**):* To a solution of **1a** (110 mg, 0.5 mmol) in 30 mL of dry tetrahydrofuran, sodium hydride (17 mg, 0.7 mmol) was added at −72 °C under argon atmosphere and the mixture was stirred for 30 min. Then the mixture was warmed to room temperature slowly and oxygen was bubbled for 20 min with stirring. After evaporation of solvent, the residue was extracted with chloroform. The extract was washed with 2 mol dm^{-3} HCl solution and dried over anhydrous magnesium sulfate. The products were determined by GLC [PhSSPh (10%), PhCOCHO (10%), and recovered (85%)].

*Oxygenation of Cyanomethyl Phenyl Sulfide (**1b**).* A solution of **1b** (149 mg, 1 mmol) and potassium *t*-butoxide (157 mg, 1.4 mmol) in 30 mL of dry dimethyl sulfoxide was stirred at −72 °C under argon atmosphere for 30 min and was warmed to room temperature. Oxygen was bubbled then into the reaction mixture for 30 min and the solution was evaporated. The products were analyzed by GLC. [PhSSPh (30%) and recovered (70%)].

*The H-D Exchange Reaction of Sulfides (**1b**) and (**4e**) with Co(II)(bzacen).* A mixture of sulfide (**1b**) (60 mg, 0.4 mmol) and Co(II)(bzacen) (162 mg, 0.4 mmol) in 2 mL of methanol-d_1 was incubated for 4 h at room temperature under oxygen atmosphere. Co(II)(bzacen) was removed by ion exchange resin and the supernatant was evaporated. The residue was extracted with chloroform and washed with water. The chloroform layer was dried over anhydrous magnesium sulfate and evaporated. The residue was subjected to SiO_2 column chromatography and eluted with hexane. The ^1H NMR spectrum of the recovered sulfide (**1b**) (*ca.* 50%) was determined to estimate the content of deuterium [$PhSCH_2(D_2)CN$; 69% deuterated]. A mixture of sulfide (**4e**) (110 mg, 0.42 mmol, *exo* : *endo*=9 : 1) and Co(II)(bzacen) (100 mg, 0.25 mmol) in 10 mL of methanol-d_1 was stirred for 19 h. After the usual work-up, the extent of the H-D exchange was also estimated by ^1H NMR (25% of *endo*-proton was deuterated).

*The H-D Exchange Reaction of Sulfide (**4e**) in the Presence of Pyridine.* A solution of sulfide (4e) (110 mg, 0.42 mmol *exo* : *endo*=9 : 1) and deuterium oxide (10 mmol) in pyridine, (20 mL) was stirred for 40 h under argon atmosphere at room temperature. The solution was acidified then to pH 4 by adding 4 mol dm^{-3} HCl into the solution at 0 °C which was extracted with chloroform. The chloroform layer was washed with 1 mol dm^{-3} HCl to remove a small amount of residual pyridine and dried over anhydrous magnesium sulfate. Chloroform was removed under reduced pressure and the deuterium content was determined by ^1H NMR (28% of *endo*-proton was deuterated).

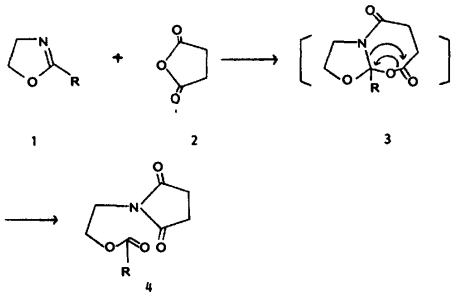
Addition Reaction of Carboxylic Anhydrides to the Carbon-Nitrogen Double Bond of Unsubstituted Cyclic Imidates

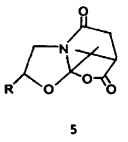
Shiro KOBAYASHI, Michihisa ISOBE, and Takeo SAEGUSA*
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received December 18, 1981)

Acyclic and cyclic (SAn and GAn) carboxylic anhydrides were added at room temperature to the C=N bond of unsubstituted cyclic imidates of 2-oxazoline (OZO) and 5,6-dihydro-4*H*-1,3-oxazine (OZI) to give addition products quantitatively. In contrast to these findings, the reactions of acetyl halides with OZO and OZI yielded ring-opened products and the reactions of carboxylic anhydrides with 2-benzyl-2-oxazoline (BzOZO) afforded also the ring-opened products. The bicyclic addition product of OZO with SAn is equilibrated with a mixture of starting materials. The stereochemistry of addition products having a six-membered ring system is discussed.

Reactions of substituted 2-oxazolines with carboxylic anhydrides have been reported in several papers.[1-4] In these reactions amide and imide derivatives were formed. For example, the reaction of 2-substituted 2-oxazoline (**1**) with succinic anhydride (**2**, SAn) gave a succinimide product (**4**), probably through an intermediate (**3**) which is an addition product of **2** onto the reactive C=N bond[5] of **1** and isomerized to **4**.[3] In the specific combination of 2-isopropyl-2-oxazolines and maleic anhydride, products **5** have been obtained,



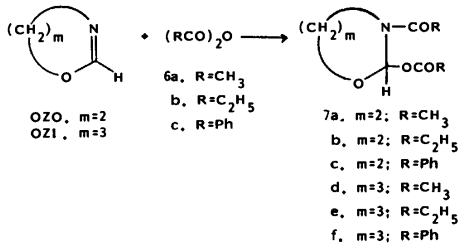
which has been claimed to correspond to the above intermediate **3**.[4]



The present paper describes the addition reactions of carboxylic (acyclic and cyclic) anhydrides onto the C=N double bond of unsubstituted five- and six-membered cyclic imidates of 2-oxazoline (OZO) and 5,6-dihydro-4*H*-1,3-oxazine (OZI), respectively. Products exactly correspond to the intermediate **3** which has been assumed in the previous study.[3] It should be noted also that prior to the present work unsubstituted OZO and OZI had not been employed for the reaction with carboxylic anhydrides probably due to the difficulties of their preparation. In the polymerization chemistry, however, OZO and OZI have recently been used extensively as a monomer of cationic ring-opening polymerization to produce poly(*N*-formylaziridine) and poly(*N*-formylazetidine) respectively.[6]

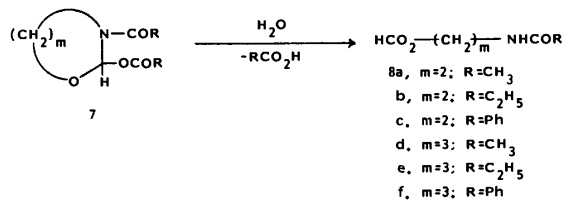
Results and Discussion

Reactions of OZO and OZI with Acyclic Carboxylic Anhydrides. In $CHCl_3$ or CH_2Cl_2, OZO and OZI reacted with acyclic carboxylic anhydrides (**6**) at room temperature to give addition products (**7**). In all

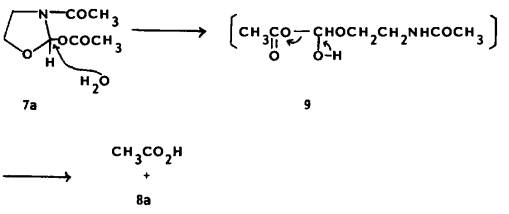


combinations, products **7a**—**f** were produced quantitatively. The structure of **7** was determined by IR and NMR spectroscopy, elemental analysis, as well as hydrolysis experiments of **7**.

Products **7** were readily hydrolyzed with an equimolar amount of water to give quantitatively formate derivatives (**8**) with elimination of one molecule of carboxylic acid. Products **8** were purified by distillation *in vacuo* and the structure was determined by IR and NMR spectroscopy and by elemental analysis. The production

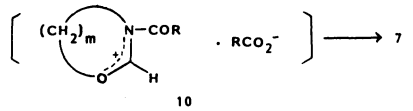


of **8a**, for example, is explained by the following course of reaction from **7a** and water through an intermediate **9**:



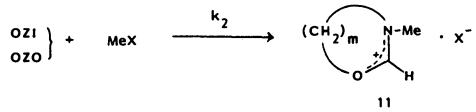
Results of hydrolysis experiments are taken to support the structure of the addition products **7**.

The addition reaction of **6** to the C=N bond of OZO or OZI proceeded much faster with OZI than with OZO, *i.e.*, the reactions of OZI with **6** finished within several minutes at room temperature whereas those of OZO with **6** took one day at the same temperature. This difference is due to the difference in nucleophilic reactivity of OZI and OZO in the formation of intermediate **10**, which is probably a rate-determining step.



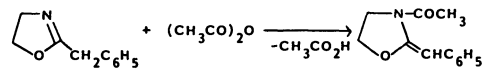
10

For example, our previous study has shown that the nucleophilic reaction of OZI with MeX (X=I and *p*-$CH_3C_6H_4SO_3$) producing *N*-methyl onium **11** proceeded about 12 times faster than that of OZO reflected by the second order rate constant (k_2).[7]



11

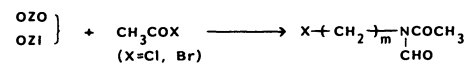
In the reaction of 2-substituted 2-oxazoline, *e.g.*, 2-benzyl-2-oxazoline (BzOZO), with acetic anhydride, the addition product corresponding to **7** was not produced but a new product (**12**) was obtained with liberation of an equimolar amount of acetic acid. This



BzOZO **12**

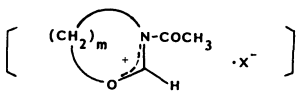
phenomenon constitutes a sharp contrast with the result of OZO. Only unsubstituted OZO gave addition products.

In previous studies, various nucleophiles have been used in the reaction with 2-substituted 2-oxazolines, *e.g.*, alkyl halides, molecular chlorine, chloroformate esters, and acyl chlorides.[1,5,8] In these reactions all the products were ring-opened ones and no addition product at the C=N bond was formed. In order to examine the behavior of unsubstituted cyclic imidates, reactions of OZO and OZI with acetyl halides were carried out and found to give ring-opened products **13** but not an addition product corresponding to **7**. With



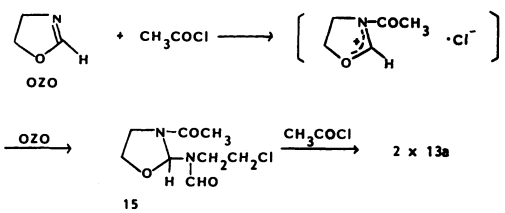
13a, m=2; X=Cl
b, m=2; X=Br
c, m=3; X=Cl
d, m=3; X=Br

an equimolar feed reactions of OZO–CH_3COCl, OZI–CH_3COCl, and OZI–CH_3COBr systems gave **13** quantitatively within a few minutes in CH_2Cl_2, which was confirmed by NMR of the reaction mixture. The reaction probably involves an onium intermediate **14**.



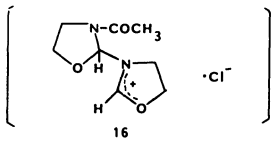
14

In the combination of OZO–CH_3COCl (1 : 1), on the other hand, it was found that the 2 : 1 reaction product (**15**) was first formed and then **15** was gradually converted to **13a** within one day at room temperature by reacting further with CH_3COCl. **15** was actually isolated



15

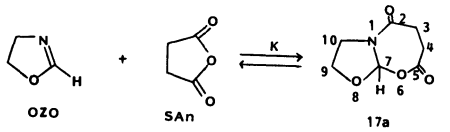
from the OZO–CH_3COCl (2.5 : 1) reaction system. **15** was formed *via* the intermediate **16** derived from **14a** and OZO. The reaction mechanism of **15** with CH_3COCl has not been fully understood.



16

Thus, the reaction mode of acetyl halides with OZO and OZI is quite different from that of carboxylic anhydrides. The reaction mode of OZO and OZI toward acetyl halides, however, is analogous to that of 2-substituted 2-oxazolines toward acyl chlorides.[8]

Reactions of OZO and OZI with Cyclic Carboxylic Anhydrides. It was found by NMR study that the reaction of OZO with succinic anhydride (SAn) produced a bicyclic adduct 6,8-dioxa-1-azabicyclo-[5.3.0]decane-2,5-dione (**17a**), a product corresponding to **7** in the case of cyclic carboxylic anhydrides, and that **17a** is present in solution in equilibrium with starting materials of OZO and SAn. It has been unsuccessful



OZO SAn **17a**

so far to isolate **17a** in pure form. The NMR spectrum of the reaction system shows a new peak at δ 7.1 ascribed to the specific methine proton of **17a** beside a signal at δ 6.8 due to the methine proton of OZO. When the temperature was varied the intensities of these two signals changed. This change was reversible with the temperature variation. Therefore, the equilibrium constant (K, $1 \cdot mol^{-1}$) could be determined. Figure 1 shows the temperature dependency of K measured at −25, 35, 50, and 80 °C. From the observed plot of $\ln K$ *vs.* $1/T$, enthalpy (ΔH) and entropy (ΔS) values were calculated from the following equation:

$$-RT \ln K = \Delta H - T\Delta S$$

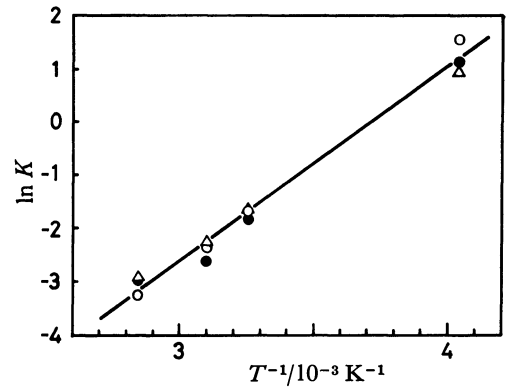


Fig. 1. Temperature dependency of the equilibrium constant $K(1\cdot mol^{-1})$: the total amount of OZO+SAn =2.0 mmol in 0.4 ml of CD_3CN: OZO/SAn ratio; ○, 2.0; △, 1.0; ●, 0.5.

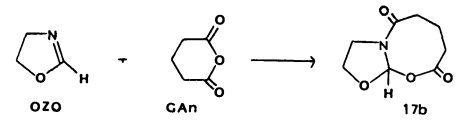
as $\Delta H = -30$ kJ mol^{-1} and $\Delta S = -110$ J K^{-1} mol^{-1}.

To support the structure of **17a**, the IR spectrum of the reaction mixture of OZO–SAn in CH_2Cl_2 showed a new band at 1730 cm^{-1} ascribable to the ester group and no band around 1580 cm^{-1} assignable to a carboxylate anion was observed.

The reaction of OZO with glutaric anhydride (GAn) yielded a bicyclic addition product, 7,9-dioxa-1-azabicyclo[6.3.0]undecane-2,6-dione (**17b**) quantitatively, which was obtained as a white solid. It is considered that the reaction equilibrium goes far to the right in this system. **17b** is insoluble in most organic solvents and hence NMR spectrum of the compound has not been obtained.

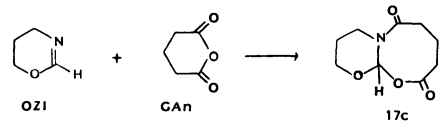


The hydrolysis of **17b** readily occured and gave a formic ester **18a**, which was taken to support the structure of **17b**.

$$\textbf{17b} \xrightarrow{H_2O} HCO_2CH_2CH_2NHCOCH_2CH_2CH_2CO_2H$$

18a

The reaction of OZI with GAn was exothermic, which was completed in a few minutes at room temperature to give a white solid of 7,9-dioxa-1-azabicyclo[6.4.0]-dodecane-2,6-dione (**17c**). The reaction equilibrium lies far to the side of product in this system, too.

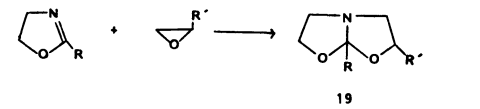


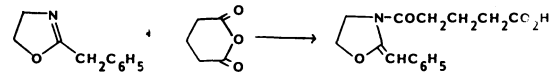
Similarly to **17b** the hydrolysis of **17c** gave **18b**, supporting the structure of **17c**.

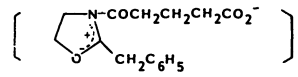
$$\textbf{17c} \xrightarrow{H_2O} HCO_2CH_2CH_2CH_2NHCOCH_2CH_2CH_2CO_2H$$

18b

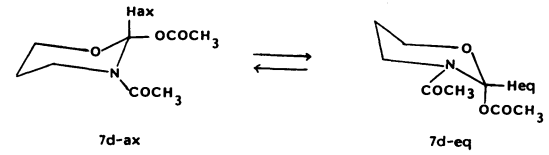
Formation of bicyclic addition products (**17**) is interestingly compared with that of bicyclic amide acetals (**19**) from 2-substituted 2-oxazolines and epoxides, where epoxides add to the C=N bond of the oxazolines.[9] In comparison with the results of unsubstituted cyclic imidates of OZO and OZI the reaction of BzOZO with GAn was examined. The reaction gave **20**, which is not a bicyclic addition product of GAn onto the C=N bond of BzOZO but corresponding to the product **12**. An intermediate **21** is probably involved.







Stereochemistry of Cyclic Addition Products Having Six-membered Ring. Addition products of five-membered ring system, *e.g.*, **7a** and **17a**, showed a single peak of the methine proton at δ 7.1 in the NMR spectra ($CDCl_3$ solvent). In contrast, the methine proton of addition products derived from six-membered OZI, *e.g.*, **7d** and **17c**, appeared as two peaks. The peak of the higher field at δ 7.1 and that of the lower field at δ 7.5 are ascribed respectively to the axial and equatorial methine proton of a six-membered chair form,[10] *e.g.*,



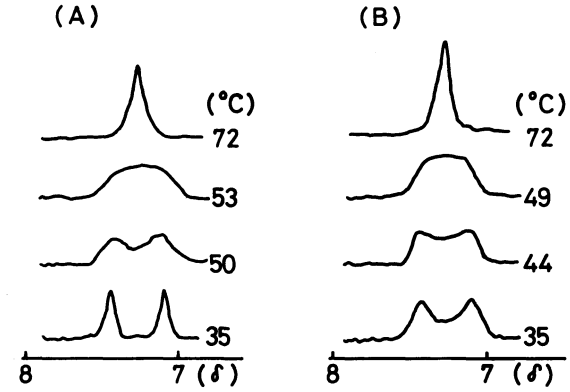


Fig. 2. Temperature-dependent NMR signals of the methine proton of **7d** (A) and **17c** (B) in CD_3CN.

With variation of temperature in CD_3CN, in which two methine signals at δ 7.1 and 7.5 appear as shown in Fig. 2, the coalescence time (T_c) was obtained as 53 °C for **7d** and 49 °C for **17c**, respectively. Then, the free-energy of activation ($\Delta F^{\neq}$) of the interconversion like **7d**-ax⇆**7d**-eq was calculated to be 69.4 kJ mol^{-1} for **7d** and 68.6 kJ mol^{-1} for **17c**, respectively.[11] These $\Delta F^{\neq}$ values are somewhat higher than those obtained for cyclohexane derivatives.[11a]

Experimental

Materials. Solvents of CH_2Cl_2, $CHCl_3$, $CDCl_3$, CH_3CN CD_3CN, and DMSO-d_6 were purified by distillation under nitrogen. 2-Oxazoline (OZO),[6a] 5,6-dihydro-4*H*-1,3-oxazine (OZI),[6b] and 2-benzyl-2-oxazoline (BzOZO)[12] were obtained according to the reported procedures. Acetic and propionic anhydrides were dried over $CaCl_2$ and distilled. Benzoic anhydride was purified by recrystallization from diethyl ether. Succinic (SAn) and glutaric (GAn) anhydrides were recrystallized from $CHCl_3$ and $CHCl_3$–diethyl ether, respectively. Acetyl chloride and bromide were purified by distillation under nitrogen after drying over $CaCl_2$.

Measurements. NMR spectra were recorded at 60 MHz on a Hitachi R-20B spectrometer. IR spectra were taken on a Hitachi EPI G31 spectrophotometer.

Reaction of OZO and OZI with Acyclic Carboxylic Anhydrides (6). A typical run was as follows. A mixture of OZO and acetic anhydride (**6a**) (10 mmol each) in 4 ml of $CHCl_3$ was allowed to react at room temperature for 24 h under nitrogen. At this point it was confirmed by NMR of the mixture that the reaction was completed to yield addition product (**7a**) quantitively. The product **7a** was isolated by distillation *in vacuo* using Kugelrohl to give **7a** (1.63 g, 94% yield). Likewise, **7b** (91%), **7d** (92%), and **7e** (89%) were obtained. The quantitative production of **7c** and **7f** was confirmed by NMR of the reaction system carried out in $CDCl_3$ but the isolation of **7c** and **7f** has not been succeeded.

Data for the structural determination of products **7** are as follows. **7a**: bp 95—96 °C/0.13 Torr (1 Torr=133.322 Pa); IR (neat): 1730 and 1660 cm^{-1}; NMR ($CDCl_3$): δ 2.05 (s, 6H), 3.64 (t-like, 2H), 4.23 (t-like, 2H), and 7.08 (s, 1H). Found: C, 48.25; H, 6.37; N, 8.15%. Calcd for $C_7H_{11}NO_4$: C, 48.55; H, 6.40; N, 8.09%. **7b**: bp 110—112 °C/0.15 Torr; IR (neat): 1735 and 1665 cm^{-1}; NMR ($CDCl_3$): δ 1.15 (t, 6H), 2.33 (q, 4H), 3.65 (t-like, 2H), 4.21 (t-like, 2H), and 7.10 (s, 1H). Found: C, 53.89; H, 7.41; N, 6.97%. Calcd for $C_9H_{15}NO_4$: C, 53.72; H, 7.51; N, 6.96%. **7c**: NMR($CDCl_3$): δ 3.84 (2H), 4.25 (2H), and 7.1—8.1 (11H). **7d**: bp 83—84 °C/0.09 Torr; IR (neat): 1720 and 1660 cm^{-1}; NMR ($CDCl_3$): δ 1.73 (2H), 2.08 (6H), 3.0—4.5 (4H), and 7.1+7.5 (1H). Found: C, 51.09; H, 7.25; N, 7.47%. Calcd for $C_8H_{13}NO_4$: C, 51.33; H, 7.00; N, 7.48%. **7e**: bp 109—111 °C/0.15 Torr; IR (neat): 1730 and 1660 cm^{-1}; NMR ($CDCl_3$): δ 1.15 (t, 6H), 1.75 (2H), 2.36 (q, 4H), 3.5—4.5 (4H), and 7.1+7.5 (1H). Found: C, 55.74; H, 7.96; N, 6.33%. Calcd for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51%. **7f**: NMR ($CDCl_3$): δ 1.4—2.5 (2H), 3.1—4.6 (4H), and 7.0—8.2 (11H).

Hydrolysis of Addition Products (7). A typical example of hydrolysis of **7a** was carried out as follows. To 3.24 mmol of **7a** 5.6 mmol of water was added and stirred at room temperature. The hydrolysis took place exothermically. After 10 min the vacuum distillation with Kugelrohl gave 3.90 g (92% yield) of **8a**. Furthermore, 1.90 g (97% yield) of acetic acid was obtained in the trap cooled in a Dry-Ice bath during the distillation. Analogous procedures for **7b**—**f** gave respectively **8b** (96%), **8c** (85%), **8d** (90%), **8e** (87%), and **8f** (80%).

The structure of these six hydrolysis products was determined based on the following data. **8a**: bp 83—85 °C/0.1 Torr; IR (neat): 3280, 3070, 1725, 1660, 1545, and 1180 cm^{-1}; NMR ($CDCl_3$): δ 2.00 (s, 3H), 3.45 (2H), 4.20 (t, 2H), 7.05 (br s, 1H), and 7.98 (s, 1H). Found: C, 46.01; H, 7.01; N, 10.70%. Calcd for $C_5H_9NO_3$: C, 45.80; H, 6.92; N, 10.68%. **8b**: bp 116—118 °C/0.3 Torr; IR (neat): 3280, 3070, 1720, 1650, 1540, and 1180 cm^{-1}; NMR ($CDCl_3$): δ 1.13 (t, 3H), 2.17 (q, 2H), 3.48 (2H), 4.18 (t, 2H), 6.9 (br s, 1H), and 7.95 (s, 1H). Found: C, 49.76; H, 7.85; N, 9.73. Calcd for $C_6H_{11}NO_3$: C, 49.65; H, 7.64; N, 9.65%. **8c**: bp 158—162 °C/0.25 Torr; IR (neat): 3300, 3070, 1725, 1650, 1540, and 1180 cm^{-1}; NMR ($CDCl_3$): δ 3.65 (2H), 4.27 (t, 2H), 6.58 (br s, 1H), 7.4 (5H), and 7.94 (s, 1H). Found: C, 62.50; H, 5.89; N, 7.24%. Found: C, 63.99; H, 6.26; N, 6.55%. Calcd for $C_{11}H_{13}NO_3$: C, 63.76; H, 6.32; N, 6.76%.

Reaction of BzOZO with Acetic Anhydride. BzOZO and acetic anhydride (**6a**) (10 mmol) each were allowed to react in 4 ml of CH_2Cl_2 at room temperature for 30 min. Evaporation of the solvent gave a white solid of **12** which was purified by recrystallization from a $CHCl_3$/diethyl ether mixed solvent (1.40 g, 96% yield); mp 128—129 °C; IR (KBr): 1675 and 1640 cm^{-1}; NMR ($CDCl_3$): δ 2.10 (s, 3H), 3.65 (t-like, 2H), 4.10 (t-like, 2H), 6.07 (s, 1H), and 7.1 (5H). Found: C, 70.72; H, 6.40; N, 6.86%. Calcd for $C_{12}H_{13}NO_2$: C, 70.92; H, 6.45; N, 6.89%.

Reactions of OZO and OZI with Acetyl Chloride or Bromide. In 0.5 ml of $CDCl_3$, OZO, or OZI (1 mmol) and acetyl chloride or bromide (1 mmol) were mixed. By NMR the reaction was found to finish within several minutes except for the OZO–acetyl chloride system which took one day for the completion of the reaction. The product (**13**) was isolated by using Kugelrohl and data for the structure determination are given as follows. **13a**: bp 81—83 °C/0.25 Torr; IR (neat): 1725 and 1670 cm^{-1}; NMR ($CDCl_3$): δ 2.42 (s, 3H), 3.58 (t, 2H), 4.01 (t, 2H), and 9.08 (s, 1H). Found: C, 40.30; H, 5.60; N, 9.48%. Calcd for $C_5H_8NO_2Cl$: C, 40.15; H, 5.39; N, 9.36%. **13b**: bp 96—98 °C/0.20 Torr; IR (neat): 1725 and 1670 cm^{-1}; NMR ($CDCl_3$): δ 2.43 (s, 3H), 3.40 (t, 2H), 4.03 (t, 2H), and 9.08 (s, 1H). Found: C, 30.82; H, 4.12; N, 7.06%. Calcd for $C_5H_8NO_2Br$: C, 30.95; H, 4.16; N, 7.22%. **13c**: bp 85—87 °C/0.30 Torr; IR (neat): 1725 and 1665 cm^{-1}; NMR ($CDCl_3$): δ 1.98 (m, 2H), 2.40 (s, 3H), 3.50 (t, 2H), 3.77 (t, 2H), and 9.09 (s, 1H). Found: C, 44.33; H, 6.28; N, 8.65%. Calcd for $C_6H_{10}NO_2Cl$: C, 44.05; H, 6.16; N, 8.56%. **13d**: bp 104—107 °C/0.25 Torr; IR (neat); 1725 and 1670 cm^{-1}; NMR ($CDCl_3$): δ 2.05 (m, 2H), 2.43 (s, 3H), 3.35 (t, 2H), 3.78 (t, 2H), and 9.12 (s, 1H). Found: C, 34.92; H, 4.85; N, 6.82%. Calcd for $C_6H_{10}NO_2Br$: C, 34.64; H, 4.84; N, 6.73%.

A mixture of OZO (10 mmol) and acetyl chloride (4 mmol) was allowed to react in 3.2 ml of $CHCl_3$ at room temperature for 24 h. The evaporation of $CHCl_3$ and unreacted OZO

gave a 2 : 1 reaction product **15** (92% yield), which was further purified by silica-gel TLC (ethanol solvent). IR (neat): 1660, and 1100 cm^{-1}; NMR ($CDCl_3$): δ 2.95 (s, 3H), 3.5—4.4 (m, 8H), 6.18 (s, 1H), and 8.36 (s, 1H). Found: C, 43.38; H, 6.08; N, 12.65%. Calcd for $C_8H_{13}N_2O_3Cl$: C, 43.55; H, 5.94; N, 12.70%. An attempt to distill **15** with Kugelrohl *in vacuo* resulted in decomposition to give **13a**

Reaction of OZO with GAn. All operations were performed under nitrogen. In 4 ml of CH_3CN,OZO (10 mmol) and GAn (10 mmol) were mixed at 0 °C. A white solid precipitated after several minutes. Then, the solid product (**17b**) was separated using a sintered-glass filter and washed several times with CH_2Cl_2 (1.73 g, 93% yield): mp 87—88 °C; IR (KBr): 1735 and 1670 cm^{-1}. Found: C, 51.66; H, 6.01; N, 7.75%. Calcd for $C_8H_{11}NO_4$: C, 51.89; H, 5.99; N, 7.56%.

Reaction of OZI with GAn. All operations were carried out under nitrogen. A mixture of OZI (10 mmol) and GAn (10 mmol) was stirred at 0 °C in 4 ml of CH_2Cl_2. The reaction mixture immediately become viscous. After 30 minutes dry diethyl ether (5 ml) was added to the system, well shaken and kept at −25 °C for 2 h. Then, the system was separated into two layers. The lower layer was dissolved in 4 ml of CH_2Cl_2. This solution was added to a large amount of diethyl ether to separate a viscous liquid material. This reprecipitation procedure was repeated twice. The separated viscous liquid product (**17c**) became a white solid after drying *in vacuo* (1.75 g, 88% yield): mp 53—55 °C; IR (KBr): 1715, 1650, and 1090 cm^{-1}; NMR ($CDCl_3$): δ 1.4—2.7 (8H), 3.2—4.6 (4H), and 7.1+7.5 (1H). Found: C, 51.33; H, 7.04; N, 6.71%. Calcd for $C_9H_{13}NO_4(H_2O)_{0.6}$: C, 51.47; H, 6.82; N, 6.67%.

Hydrolysis of 17b and 17c. **17b** (or **17c**) (5 mmol) was reacted with 30 mmol of water. The hydrolysis finished immediately. The evaporation of excess water gave a viscous liquid. This liquid was dissolved in CH_3CN and poured into a large amount of diethyl ether to separate the liquid again. This procedure of purification was repeated three times to give an oily product **18a** (or **18b**) in almost quantitative yield. **18a**: IR (neat): 3280, 3070, 1720, 1640, 1550, and 1180 cm^{-1}; NMR (CD_3CN): δ 1.5—2.5 (m, 6H), 3.30 (q-like, 2H), 4.04 (t, 2H), 6.63 (br s, 1H), and 7.89 (s, 1H). Found: C, 47.35; H. 6.61; N, 7.01%. Calcd for $C_8H_{13}NO_5$: C, 47.29; H, 6.45; N, 6.89%. **18b**: IR (neat): 3280, 3070, 1725, 1640, 1560, and 1180 cm^{-1}; NMR (CD_3CN): δ 1.4—2.5 (m, 8H), 3.14 (q-like, 2H), 4.05 (t, 2H), 6.78 (br s, 1H), and 7.91 (s, 1H). Found: C, 48.96; H, 7.35; N, 6.47%. Calcd for $C_9H_{15}NO_5$: C, 49.76; H, 6.96; N, 6.45%.

Reaction of BzOZO with GAn. A mixture of BzOZO and GAn (5 mmol each) in CH_3CN (2 ml) was kept at room temperature for 20 h to give needle crystals **20**, which was separated and washed with CH_2Cl_2 (0.72 g, 52%): mp 63—64 °C (from DMSO); IR (KBr): 1690, 1630, and 1120 cm^{-1}; NMR (DMSO-d_6): δ 1.5—2.7 (m, 6H), 3.88 (t-like, 2H), 4.29 (t-like, 2H), 6.25 (s, 1H), and 6.7—7.4 (m, 5H). Found: C, 65.41; H, 6.31; N, 5.28%. Calcd for $C_{15}H_{17}NO_4$: C, 65.44; H, 6.22; N, 5.09%.

Effects of Chelating Agents on the Preparation of Benzenediols by Oxidation of Phenol with Peracetic Acid

Tohru Tsuchiya,* Kazuhiro Ikehira, and Juichi Imamura

Catalyst Division, National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki, 305

(Received October 28, 1980)

The oxidation of phenol with peracetic acid has been investigated in connection with the industrial preparation of benzenediols. The effects of 25 additives, such as derivatives of monomeric and condensed phosphoric acid, chelating agents, and salts of polybasic carboxylic acids, were examined; derivatives of condensed phosphoric acid were found to be most effective. The oxidation of phenol (213 mmol) with peracetic acid (21 mmol) in the absence of the additives gave 1,2- and 1,4-benzenediols in only 5.8% and 7.6% yields, respectively. But in the presence of 2.0×10^{-7} mol of potassium diphosphate the yields of 1,2- and 1,4-benzenediol were 47% and 31%, respectively. The improvement in the yields by the additives is attributable to the masking of a trace of metals, especially iron and cobalt, present in the reaction mixture. These metals tend to catalyze the further oxidation of the benzenediols formed.

Benzenediols are important feedstocks in chemical industries and are extensively used as powerful reducing agents in the photography industry. 1,2-Benzenediol has been manufactured by means of alkali-fusion of 2-chlorophenol,[1] and 1,4-benzenediol by reduction of *p*-benzoquinone or by autooxidation of 1,4-bis(1-methylethyl)benzene.[2,3]

Preparation of benzenediols by oxidation of phenol with peroxides is important because it protects the enviroment from heavy metals or strong acid pollution. Many studies on this process have been described in patent applications.[4-9] On the other hand, the peroxy acid oxidation of phenol has been studied as a model reaction in the oxidative treatment of monomeric lignin[10] and in the metabolism of aromatic compounds *in vivo*.[11]

In cases of industrial preparation of benzenediols by oxidation of phenol with peracetic acid, it is recognized that the methods for the preparation of peracetic acid seriously affect the yields of benzenediols.[12] In order to suppress undesirable reactions such as the further oxidation of benzenediols, many additives have been tested:

1. Acids[6] (sulfuric acid, phosphoric acid, condensed phosphoric acids, hydrogen fluoride, and ion-exchanging resins of the sulfonic acid type);
2. Stabilizers for peroxides[12-14] (2,6-bis(hydroxymethyl)pyridine, 8-quinolinol, and dioctyl dihydrogendiphosphate);
3. Chelating agents[12-13] (iminodiacetate, nitrilo triacetate, ethylenediamine tetraacetate, citrate and tartarate); and
4. Vicinal benzenepolyols[9] (1,2-benzenediol and 1,2,3-benzenetriol).

This article describes the effects of both additives and metal ions.

Experimental

Materials. Peracetic acid was prepared by means of autooxidation of acetaldehyde in acetone by using 1,2,3,4-benzenetetracarboxlic acid as a catalyst.[15] After a stabilizer[14a] was added, acetaldehyde was evaporated and the residue was concentrated under a reduced pressure. After the addition of butyric acid, the solution was distilled under a reduced pressure (1.3 kPa) on a water bath of 30 °C. The distillate contained about 50 wt% of peracetic acid and acetic acid without water or hydrogen peroxide. This solution of peracetic acid can be stored in a refrigerator with no change for several months in the absence of stabilizers. This solution was diluted just before use with guaranteed grade acetic acid, and the concentration of peracetic acid was determined by iodometric titration.

Guaranteed grade phenol, glacial acetic acid, potassium diphosphate, and all other additives and metal salts except for octamethyldiphorphoric tetramide[16] were commercially supplied and used without purification.

General Reaction Procedure. Twenty grams (213 mmol) of phenol was stirred at 60 °C, under a nitrogen atmosphere, in a 100 ml two necked flask equipped with a dropping funnel and a thermometer. An acetic acid solution (11 ml) of peracetic acid (21 mmol) and an additive was added dropwise to the phenol through the dropping funnel within 10 min; the reaction mixture was kept at 60 °C for 2 h and then cooled in an ice water bath and analyzed by VPC. The conversion of phenol and the yields of benzenediols were all calculated based on the amount of peracetic acid used. Quinones and other further oxidized compounds were not analyzed.

Conditions of VPC Analysis. Phenol and 1,2- and 1,4-benzenediols were determined with a 1 m column packed with Tenax-GC at programmed temperatures from 150 °C to 200 °C (the rate of temperature increace; 6 °C min^{-1}); chlorobenzene was used as an internal standard and helium as a carrier gas (flow rate: 60 ml min^{-1}). The values of 1.0, 1.8, 6.6, and 8.5 min were observed as retention times of chlorobenzene, phenol, 1,2-benzenediol and 1,4-benzenediol, respectively.

Results and Discussion

The Oxidation in the Presence of Additives. Figure 1 illustrates a typical change in the conversion of phenol and in the yields of benzenediols as a function of the increasing amount of potassium diphosphate. As the amount of additive is increased, the total yield of benzenediols increased up to a constant value (Y_{max}), while the ratio of 1,2-benzenediol to the 1,4-isomer increased from 0.6 to 1.5. No improvement in the yields of benzenediols was observed with the addition of an amount larger than X_{max}, the amount of additive needed to get Y_{max}. From the industrial viewpoint, an additive with a greater Y_{max} and a smaller X_{max} is desirable. Figure 2 shows the effects of some additives on the total

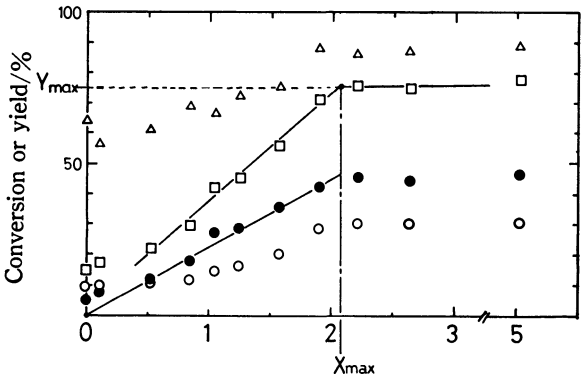

Fig. 1. Effects of potassium diphosphate on the conversion of phenol and the yields of 1,2- and 1,4-benzenediols.
△: Conversion of phenol, □: total yield of benzenediols, ●: yield of 1,2-benzenediol, ○: yield of 1,4-benzenediol. Phenol: 213 mmol, peracetic acid: 21 mmol, 60 °C, after 130 min.

yields of benzenediols.

Table 1 summarizes the X_{max}'s and Y_{max}'s of some additives tested. This table indicates the excellence of condensed phosphates as additives. For example, in the presence of 2.0×10^{-7} mol of potassium diphosphate, 9.6 mmol (47%) of 1,2-benzenediol and 6.6 mmol (31%) of 1,4-benzenediol were obtained, while in the absence of the additive, the yields of 1,2- and 1,4-benzenediol were only 1.2 mmol (5.8%) and 1.6 mmol (7.6%), respectively. Chelating agents, such as ethylenediamine tetraacetate and diethylenetriamine pentaacetate, were good additives. Derivatives of monomeric phosphoric acid and 1,2,3-benzenetriol were also good additives. The effects of diammonium hydrogenphosphate can be attributable to trace contaminants of

a) Phenol: 213 mmol, peracetic acid: 21 mmol, 60 °C, after 130 min, in the presence of 2.4×10^{-7} mol of the salts.

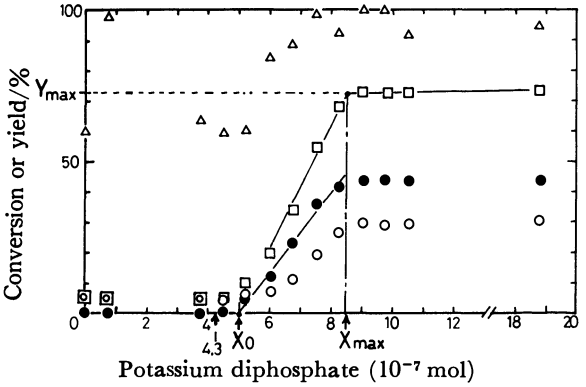

Fig. 3. Effects of potassium diphosphate on the conversion of phenol and the yields of 1,2- and 1,4-benzenediol in the presence of 4.3×10^{-7} mol of iron(III) nitrate. △: Conversion of phenol, □: total yield of benzenediols, ●: yield of 1,2-benzenediol, ○: yield of 1,4-benzenediol. Phenol: 213 mmol, peracetic acid: 21 mmol, 60 °C, after 130 min.

derivatives of condensed phosphoric acid. This same effect is seen for a mixture of methyl dihydrogenphosphate and dimethyl hydrogenphosphate. On the other hand, bases, salts of organic polybasic acids, and ligating reagents such as acetylacetone and 8-quinolinol showed little effect. Crown ethers (15-crown-5, dibenzo-18-crown-6 and perhydrodibenzo-24-crown-8) were also tested, but they did not improve the yields of benzenediols.

These facts show that additives mask the effects of trace metal ions in the system.[17] The indicated additives with higher Y_{max} and lower X_{max} values mask the metal ions better.

The Oxidation in the Presence of Transition-metal Salts. The effects of transition-metal salts on the oxidation were tested. Table 2 shows that the addition of iron(II) or cobalt(II) salts depressed the yield of 1,2-benzenediol and had little effect on the yield of 1,4-benzenediol. On the other hand, the table also shows that salts of chromium(III), manganese(II), nickel(II), and zinc had little effect on the yields of both benzenediols.

In the presence of peracetic acid, transition-metal ions are in their higher oxidation states[18] and the benzenediols to be oxidized form complexes with these transition metal ions.[19-24] Therefore, it is reasonable that metal ions accelerate the further oxidation of benzenediols formed in this reaction.[25-27]

The Oxidation in the Presence of Both Potassium Diphosphate and a Transition-metal Salt. In order to clarify the relation between additives and metal ions in this system, phenol was oxidized in the presence of both diphosphate and a transition-metal salt.

Figure 3 illustrates the effect of potassium diphosphate on the conversion of phenol and the yields of 1,2- and 1,4-benzenediols in the presence of iron(III) nitrate (4.3×10^{-7} mol). In these cases, even upon increasing the amounts of potassium diphosphate up to X_0 (5.0×10^{-7} mol) no 1,2-benzenediol was obtained, and almost no change was observed in the yield of 1,4-benzenediol. Here X_0 means the smallest amount of potassium

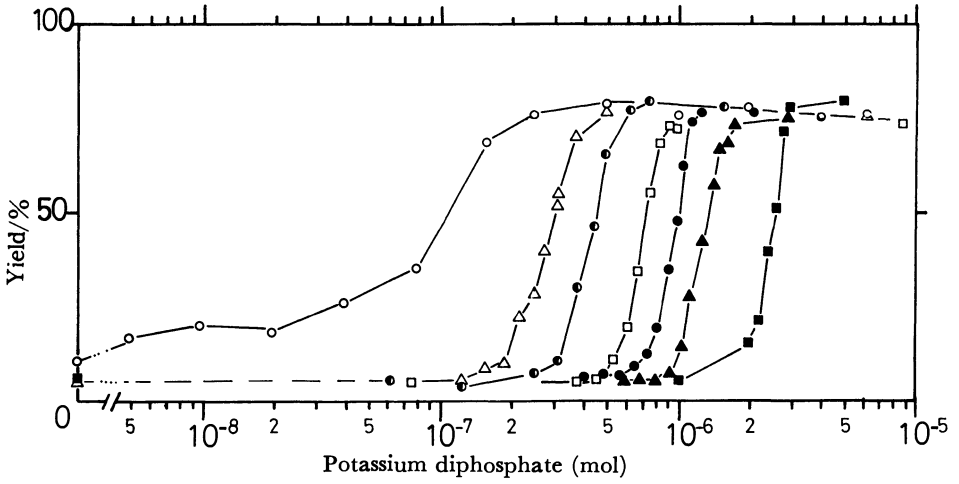

Fig. 4. Effect of potassium diphosphate in the presence of iron(III) nitrate on the total yield of benzenediols.

diphosphate needed for producing 1,2-benzenediol. The increase in the yields of benzenediols was observed with increasing amounts of diphosphate beyond X_0; the yields were saturated at the last stage.

Figure 4 shows the change in the total yield of benzenediols, in the presence of iron(III) nitrate (0—1.7×10^{-6} mol) and potassium diphosphate. The salts of cobalt and manganese exhibited the same kinds of feature, but the salts of chromium, nickel, copper, and zinc did not suppress the formation of 1,2-benzenediol. These findings are summarized in Figs. 5 and 6, which show that plots of X_{max}'s and X_0's against the amount of metal added are almost linear; their gradients are shown in Table 3.

Table 3. The gradients of the plots of X_{max}'s and X_0's against the amount of transition-metal salts added[a)]

Metal salts	$X^{b)}_{max}$/Metal	$X^{c)}_0$/Metal

Zinc(II)	0.69	−0.18

a) Phenol: 213 mmol, peracetic acid: 21 mmol, 60 °C, after 130 min. b) The smallest amount of potassium diphosphate needed for giving the maximum yields of benzenediols. c) The smallest amount of potassium diphosphate needed for producing 1,2-benzenediol.

These findings support the explanation that these additives mask the metal ions contaminating the reaction mixture and that the presence of free metal ions, especially iron and cobalt, suppress the yields of benzenediols.

Quantitative Measurement of Metals Originally Present in the Reaction Mixture. After the reaction, X-ray flouresence was used to determine the concentration of iron in the reaction mixture; it was determined to be 180 mg m^{-3}. By flameless-atomic-absorption spectroscopy the concentrations of copper and cobalt were also determined to be 6.5 mg m^{-3} and less than 0.5 mg m^{-3}, respectively.

The intersections of the plots of X_{max}'s with the ordinate, in Fig. 5, correspond to the smallest quantitions of diphosphate needed for maximizing the yields of benzenediols when no metal was added. The amount of metal ions originally contained in the system can be estimated from this intersection and the gradients. This was calculated to be 173 mg m^{-3} if all of the metal contained was assumed to be iron; this value was in good agreement with that of 180 mg m^{-3} obtained from X-ray-fluorescence measurement.

On the basis of these findings, it is concluded that there was a trace of iron in the system, and that this catalyzed the further oxidation of benzenediols formed. The additives masking metal ions, consequently, improve the yields of benzenediols. From an industrial point of view, such a masking-reagent is useful for instant removal of these metal ions.

The authors wish to express their thanks to Mr. S. Nakamura and Mrs. N. Fudakawa for their X-ray-fluorescence and atomic-absorption analysis on metals.

Liquid-phase Oxidation of Anthracene in Acetic Acid by Use of Copper(II) Chlorocomplexes. II.[1] Kinetic Study

Jinya KOSHITANI,* Toshio KADO, Yoshio UENO, and Takatoshi YOSHIDA
Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received June 18, 1981)

A kinetic study was performed on the oxidation of anthracene by use of copper(II) chlorocomplexes, which were produced in reactions of copper(II) acetate with lithium chloride in acetic acid. When the pressure of oxygen was high enough that the rate of oxidation was not affected, the result was as follows:

$$-\frac{dO_2}{dt} \propto [RH]^1 [Cu_2(OAc)_4]_0^{1/2} [LiCl]_0^{1/2-0}.$$

A kinetic approximation to the experimental result was attempted.

It is known that metal ions[2-4] decompose hydrolithium chloride in acetic acid.

$$ROOH + M^{(n+1)+} \xrightarrow{k_1} ROO\cdot + H^+ + M^{n+} \quad (1)$$

$$ROOH + M^{n+} \xrightarrow{k_2} RO\cdot + OH^- + M^{(n+1)+} \quad (2)$$

peroxides and that metal ions[5,6] in their higher valency may oxidize substrates and generate free radicals. On the other hand, it is known that copper(II) chlorocomplexes[7-19] are formed in reactions of Cu^{2+} with Cl^- in molten salts, and in aqueous and nonaqueous solutions. We previously reported that liquid-phase oxidation[1] of anthracene was effected by these chlorocomplexes, producing mainly anthraquinone. It is interesting to learn the role of these chlorocomplexes at the initiation stage of the oxidation.

$$RH + M^{(n+1)} \xrightarrow{k_3} RH^+ + M^{n+} \quad (3)$$

$$RH^+ \xrightarrow{k_4} R\cdot + H^+ \quad (4)$$

The mechanism of autoxidation of anthracene is complex and not yet clearly explained in spite of great interest. In this paper, we report a kinetic study of the oxidation of anthracene by use of copper(II) chlorocomplexes formed by the reactions of copper(II) acetate with

Experimental

The experimental procedures were the same as those described in the previous paper,[1] with the following exceptions. Gas compositions of the mixtures of oxygen and nitrogen in the reaction vessels were determined on a Yanagimoto model GCG 550-TF gas chromatograph with TCD detector, using helium gas as a carrier. The reactions were performed according to the method of Morimoto and Ogata.[20] The reactions, except for the experiments on the effect of partial pressure of oxygen, were performed under 6.1×10^{-1} bar partial pressure of oxygen, at which pressure the rates of oxidations were not affected. Iodometry was performed in a nitrogen atmosphere.

Results and Discussion

Kinetics. How the initial rates of oxygen absorption depend on concentrations of anthracene, initially added copper(II) acetate, and initially added lithium chloride is shown in Table 1. The rate is expressed as

$$-\frac{dO_2}{dt} = k_{obsd}[RH]^1 [Cu_2(OAc)_4]_0^{1/2} [LiCl]_0^{1/2}$$

Table 1. Effect of concentrations of anthracene, copper(II) acetate, and lithium chloride on initial rate of oxygen absorption at 90 °C

at $[LiCl]_0$ of 0.0001—0.01 mol dm^{-3}. The rate is

$$-\frac{dO_2}{dt} = k'_{obsd}[RH]^1 [Cu_2(OAc)_4]_0^{1/2}$$

at $[LiCl]_0$ of 0.01—0.03 mol dm^{-3}. The rate shows zeroth-order dependence with respect to $[LiCl]_0$ in a large excess of $[LiCl]_0$. The dependency of this rate on the partial pressure of oxygen is shown in Fig. 1. The rate was nearly proportional to the partial pressure of oxygen of 1.3×10^{-1}—4.8×10^{-1} bar, while the rate was zeroth-order with respect to the partial pressure of oxygen of 4.8×10^{-1}—6.1×10^{-1} bar.

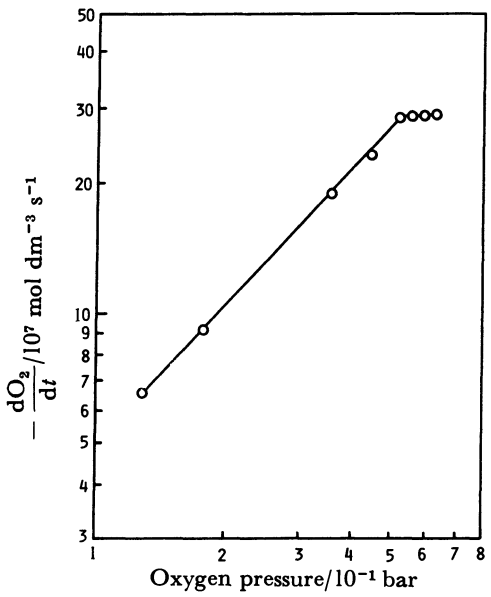

Fig. 1. Effect of oxygen pressure on initial rate of oxygen absorption at 90 °C.
[RH]: 0.05 mol dm^{-3}, $[Cu_2(OAc)_4]_0$: 0.005 mol dm^{-3}, $[LiCl]_0$: 0.01 mol dm^{-3}.

Reaction. No induction period was observed. The possibility of the accumulation of peroxide was investigated at [RH] of 0.05 mol dm^{-3} under the high pressure of oxygen. The amount of peroxide in the solution was determined to be very small on the basis of iodometry, taking the consumption of sodium thiosulfate by the initially added copper(II) acetate into account. Since the variation of the spectrum at the early stage of the reaction was small, there was presumably no prominent variation in kinds or amounts of species of copper(II) salts and copper(II) chlorocomplexes during this period. The amount of oxygen absorption was measured during the period, and the rate of oxygen absorption was calculated. After the period, the absorption near 685 nm was found to increase. This was because a portion of the copper(II) chlorocomplexes or of the monomer of copper(II) acetate changed to the dimer[21,22] of copper(II) acetate again.

Kinetic Approximation. On the basis of kinetics, a tentative mechanism was deduced. M^{2+} and M^+ represent copper(II) ion as active species and copper(I) ion as active species, respectively. Within the range of $[LiCl]_0$ of 0.001—0.01 mol dm^{-3}, the following is assumed:

$$[M^{2+}] \propto [Cu_2(OAc)_4]_0^{1/2}\,[LiCl]_0^{1/2}.$$

And within the range of $[LiCl]_0$ of 0.01—0.03 mol dm^{-3}, the following is assumed:

$$[M^{2+}] \propto [Cu_2(OAc)_4]_0^{1/2}.$$

As shown in Eqs. 3 and 4, RH may react with M^{2+} to give R·.[23,24] R· and oxygen molecule combine to give ROO·.

$$R\cdot + O_2 \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} ROO\cdot \qquad (5)$$

ROO· reacts with RH to give ROOH and R·.

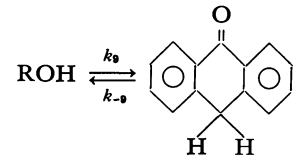
$$ROO\cdot + RH \xrightarrow{k_6} ROOH + R\cdot \qquad (6)$$

As shown in Eqs. 1 and 2, ROOH reacts with M^{2+} and M^+. RO· is generated from ROO· and then reacts with

$$2ROO\cdot \xrightarrow{k_7} 2RO\cdot + O_2 \qquad (7)$$

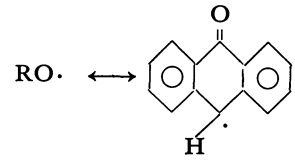
$$RO\cdot + RH \xrightarrow{k_8} ROH + R\cdot \qquad (8)$$

RH. Equation 9 has been reported for the keto-enol tautomerism between 9-anthrol and anthrone.[25-28]

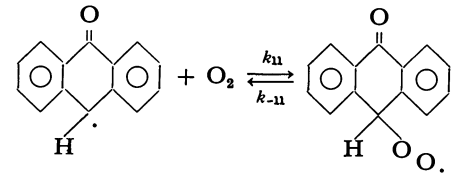


(9)

RO· resonates in the following way and may react with an oxygen molecule.[29-32] By reference to works,[32-34]

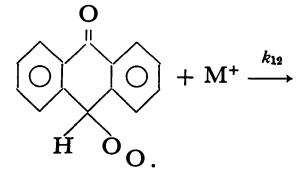


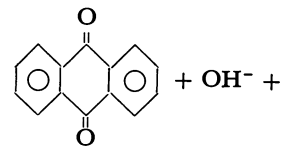
(10)



(11)

we thought that the peroxyl radical may react with M^+.





(12)

Steady-state treatment is applied in Eqs. 1—12. On the basis of the experimental results,

$$\frac{d[ROOH]}{dt} \approx 0,$$

$$-\frac{d[M^{2+}]}{dt} \approx 0.$$

Therefore,

$$-\frac{dO_2}{dt} \approx (k_1[ROOH][M^{2+}] + k_3[RH][M^{2+}]) \times \left(\frac{3}{2} + \frac{1+\frac{k_{-11}}{k_{12}[M^+]}}{2k_{11}[O_2]} \times k_8[RH]\right),$$

$$\frac{d[anthraquinone]}{dt} \approx k_1[ROOH][M^{2+}] + k_3[RH][M^{2+}],$$

$$\frac{d[anthrone]}{dt} \approx \frac{1+\frac{k_{-11}}{k_{12}[M^+]}}{k_{11}[O_2]} \times k_8(k_1[ROOH][M^{2+}] + k_3[RH][M^{2+}])[RH].$$

Since, on the basis of the experimental result, [ROOH] may be very small,

$$\frac{k_3[RH]}{[ROOH]} \gg k_1.$$

The relation between the rate of production of anthrone and the rate of production of anthraquinone is represented:

$$\frac{d[anthrone]}{dt} = G \times \frac{d[anthraquinone]}{dt},$$

where G is a function. Therefore,

$$\frac{-\frac{dO_2}{dt}}{\frac{d[anthraquinone]}{dt}} \approx \frac{1}{2}(3 + G).$$

Here, G may be determined experimentally. For example, G is nearly constant at the early stage of the oxidation shown in Fig. 1,[1)] with a value of around 1.4. Therefore, at the early stage of the oxidation,

$$-\frac{dO_2}{dt} \approx 2.2k_3[RH][M^{2+}],$$

$$\frac{d[anthraquinone]}{dt} \approx k_3[RH][M^{2+}],$$

$$\frac{d[anthrone]}{dt} \approx 1.4k_3[RH][M^{2+}],$$

$$\frac{-\frac{dO_2}{dt}}{\frac{d[anthraquinone]}{dt}} \approx 2.2.$$

The results of these calculations fit the experimental facts in Fig. 1.[1)]

Further, selective production of anthraquinone without production of anthrone could be explained in this mechanism without Eqs. 8 and 9; in this case no approximation is necessary.

Manufacture of High Pure Titanium(IV) Oxide by the Chloride Process. I. Kinetic Study on Leaching of Ilmenite Ore in Concentrated Hydrochloric Acid Solution

Hisashi Tsuchida,† Eiichi Narita,* Hitoshi Takeuchi, Masahiro Adachi, and Taijiro Okabe

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
†Mizusawa Factory, Mizusawa Industrial Chemicals, Ltd., Tsuruoka, Yamagata 999-75

(Received October 2, 1981)

Kinetic study of the leaching of powdered ilmenite ore was carried out in highly concentrated hydrochloric acid (11.3—11.6 mol dm^{-3}) at temperatures of 30 to 80 °C. The changes in shape and grain size of the ore particles with progress of the leaching was simultaneously observed with X-ray diffraction and electron microscope techniques. Titanium and iron were dissolved in a nearly stoichiometric ratio; the rate of the dissolution was significantly affected by the temperature of the acid solutions. From the analysis of the dissolution rates on the basis of the core-model, it was found that the dissolution rates at temperatures of 30 to 50 °C were well expressed by the rate equation based on the rate-determining step of the surface chemical reaction. The apparent activation energies were 81.2 kJ mol^{-1} for titanium and 73.2 kJ mol^{-1} for iron. The rate-determining step of the dissolution was changed at a temperature of about 50—60 °C; the dissolution rates at temperatures of 60 to 80 °C were limited by the diffusion of the dissolved metal ions through a residual layer of the ore. However, the rates after 2 or 3 h at high temperatures deviated from the rate equation because of the precipitation of hydrous titanium(IV) oxide on the surface of the ore by hydrolysis of the dissolved titanium(IV) ion.

Titanium(IV) oxide is used as a raw material of the white pigment which is utilized extensively in paints, paper, porcelain, and fibers. Some new uses based on being an n-type semiconductor, for example an electrode or a catalyst have recently been tried.

Titanium(IV) oxide is produced industrially by the sulfuric acid leaching of its minerals and the subsequent thermal hydrolysis of titanium(IV) sulfate solutions; this is commonly known as the sulfate process. It is also produced by the vapor phase oxidation of titanium(IV) tetrachloride.[1,2] Although the manufacture of titanium-(IV) oxide by this latter process is gradually increasing, the former is still the most widely used.[2] The sulfate process, however, has serious disadvantages because the treatments of crude iron(II) sulfate and of the waste acid solution are difficult.[3] On the other hand, hydrochloric acid, which is very useful for decomposition of natural ores, allows comparatively easier recovery of the useful free acid from its waste solution than does sulfuric acid. In practice, the recovery of free hydrochloric acid from the waste solutions of steel cleansing is now feasible.[4—8] Accordingly, if it becomes possible to leach ilmenite ore in hydrochloric acid, the closed system of the manufacturing process of titanium(IV) oxide will be achieved. The pressurized leaching of ilmenite ore in hydrochloric acid solutions is now carried out to upgrade the ore, in which a large portion of iron is dissolved.[9—11] Titanium can also be dissolved in concentrated hydrochloric acid solutions by keeping the leaching solution at temperatures below about 90 °C.[12—14] In addition, the recovery of a number of metal ions by liquid-liquid extraction from hydrochloric acid solutions is considerably easier than that from sulfuric acid solutions.[15,16] The authors, therefore, intended to develop a new manufacturing process of high pure titanium(IV) oxide, which would be based on the leaching of ilmenite ore in concentrated hydrochloric acid solutions and the selective solvent extraction of titanium(IV) from the leaching solution by neutral organophosphorus compounds.

In this study, we investigated the leaching kinetics of powdered ilmenite ore in concentrated hydrochloric acid. Static leaching studies of ilmenite ore in hydrochloric acid solutions were performed by earlier workers[12—14] in order to obtain optimum conditions, but only a few reports on the kinetic study (using diluted hydrochloric acid solutions of 3 mol dm^{-3}) have been presented[17] and there is still a lack of the essential information in the kinetics of the dissolution behavior of titanium and iron in concentrated hydrochloric acid with respect to the leaching mechanism.

Experimental

Unless otherwise stated, the ilmenite ore having a grain size range of 250 to 325 mesh was used in this study. The chemical composition after the sample was dried by heating at 110 °C is shown in Table 1. In one part of the experiments, the ilmenite ore having a grain size of 150—250 mesh, whose chemical composition was the same as that shown in Table 1 was also used. The leaching experiments of the powdered ilmenite ore were carried out in the highly concentrated HCl solutions of 11.3—11.6 mol dm^{-3} at temperatures of 30 to 80 °C. A 0.5 dm^3 three-necked flask equipped with a reflux condenser, a thermometer, and a stirrer was used as a reaction vessel. Five g of the ilmenite ore was suspended in 200 cm^3 of leaching solution, temperature-regulated at 30—80 °C; this

Table 1. Chemical composition of the ilmenite ore

Constituent	Content / wt%
TiO_2	52.0
Fe[a)]	27.2

Cr_2O_3	0.04

a) $FeO+Fe_2O_3$.

was stirred continuously with a mechanical stirrer. The dissolution rates of titanium and iron were determined by pipetting about 5 cm^3 of the suspension from the flask as regular time intervals, filtering out the insoluble residue, and chemically analyzing the supernatant solution. Titanium and iron were determined by colorimetric methods.[18] The X-ray diffraction patterns were obtained by using a Rigaku Denki Geigerflex 2013 with Ni filtered Cu *Kα* radiation, with 30 kV and 10 mA. The surface observation was performed by using a Hitachi-Akashi Scanning Electron Microscope MSM 4C-102.

Results and Discussion

Analysis of Dissolution Rate. The electron micrographs of the ilmenite ore and the insoluble residues obtained from the suspension after the leaching experiment at 60 °C are shown in Fig. 1. Although the surface of the residues became rather porous during the leaching, no prominent changes were observed in the grain size and shape of the ores after the leaching. In this experiment, about 85% of the titanium and 90% of the iron in the ore were dissolved after 5 h. With these major constituents, most of the manganese and magnesium also dissolved. But the chemical analysis of the residue indicated that large amounts of aluminum, chromium, and silicon were still in it. However, the amounts of these residual minor constituents are not enough to maintain the grain size and shape of the ore particles. Therefore, a small portion of the dissolved titanium ion seemed to precipitate continuously by the hydrolysis at the ilmenite surface and to maintain the grain size and shape of the ore particles with other residual minor constituents during the leaching reaction. This assumption was supported experimentally by the result that the dissolution rate of titanium was slightly smaller than that of iron, although titanium and iron were dissolved in a near stoichiometric ratio. As described later, the X-ray diffraction patterns of the insoluble residues indicated the presence of rutile, anatase, and Ti_2O_3. On the other hand, at lower temperatures, the grain size of the ore particles was changed and gradually became smaller with the progress of the leaching, because of the absence of any precipitation of titanium oxides.

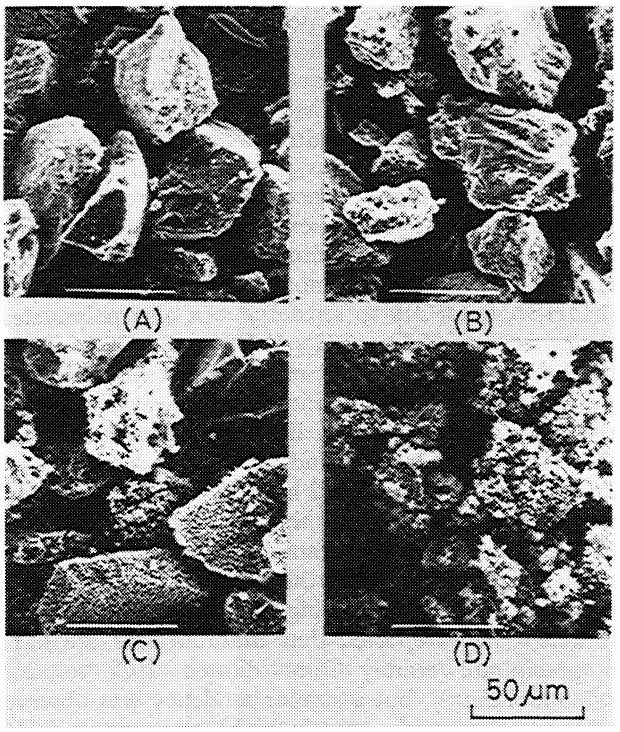

Fig. 1. Scanning electron micrographs of ilmenite ore and reaction residues.
HCl: 11.6 mol dm^{-3}, temperature: 60 °C, stirring speed: 400 min^{-1}. (A): ilmenite ore, (B): residue (0.5 h), (C): residue (2 h), (C): residue (5 h).

Accordingly, the dissolution rates of titanium and iron were analyzed on the basis of the extraction type core-model under the assumption that the ore is a homogeneous spherical solid phase.

The dissolution reaction of the ilmenite ore in hydrochloric acid solution is written as:

$$FeTiO_3 + 4HCl = TiOCl_2 + FeCl_2 + 2H_2O. \quad (1)$$

The reaction in Eq. 1 can be represented simply as Eq. 2:

$$A(l) + bB(s) = \nu P(l). \quad (2)$$

When the reaction percentage of component P was represented as x and the steady state of the reaction was assumed, the following Eq. 3 was obtained as the rate equation:

$$\frac{dx}{dt} = \frac{3\nu C_A}{\rho_P R} = \frac{1}{\frac{1}{k_L} + \frac{R}{D_e}\{(1-x)^{-1/3}-1\} + \frac{1}{k_C}(1-x)^{-2/3}}. \quad (3)$$

Three rate-determining steps were studied: the diffusion in liquid film, the diffusion in residual layer, and the surface chemical reaction.[19] However, the diffusion in liquid film should not be the rate-determining step because the dissolution rate of titanium and iron was apparently not zero-order and was not affected by the stirring speed, as described in the next paragraph. Therefore, the following two equations were obtained

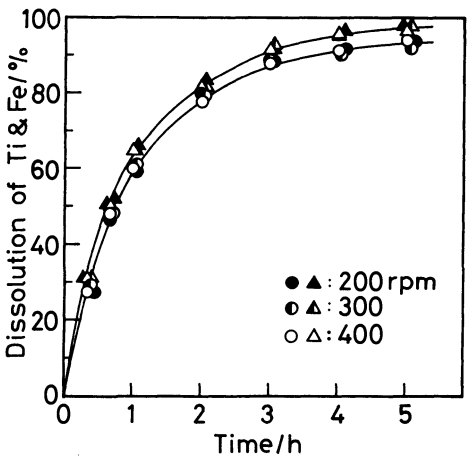

Fig. 2. Effect of stirring speed on the dissolution rates of Ti and Fe of ilmenite ore in concentrated HCl solution. HCl: 11.4 mol dm^{-3}, temperature: 70 °C. ○, ◐, ●: Ti, △, ◭, ▲: Fe.

for each rate-determining step by integration of Eq. 3.

i) For diffusion in residual layer (k_L, $k_C \gg D_e/R$)

$$1 + 2(1 - x) - 3(1 - x)^{2/3} = \frac{6\nu C_A k_C}{\rho_P R^2} t, \quad (4)$$

ii) for surface chemical reaction (k_L, $D_e/R \gg k_C$)

$$1 - (1 - x)^{1/3} = \frac{C_A k_C}{\rho_P R} t. \quad (5)$$

Effect of Stirring Speed. Figure 2 shows the effect of stirring speed on the dissolution rate of titanium and iron in 11.4 mol dm^{-3} HCl solution at 70 °C. The diffusion in liquid film was not the rate-determining step of the reaction in Eq. 1. The dissolution rate of iron was slightly faster than that of titanium, but both were in a nearly stoichiometric ratio. On the basis of the data, subsequent experiments were carried out at the stirring speed of 400 min^{-1}.

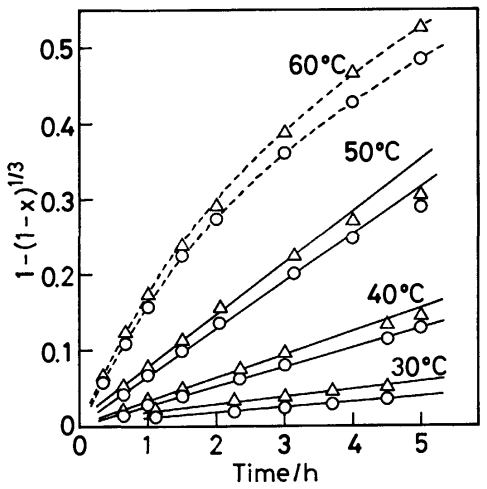

Fig. 3. Effect of temperature on the dissolution rates of Ti and Fe of ilmenite ore in concentrated HCl solution. $\{1-(1-x)^{1/3}\}$ *vs.* t.

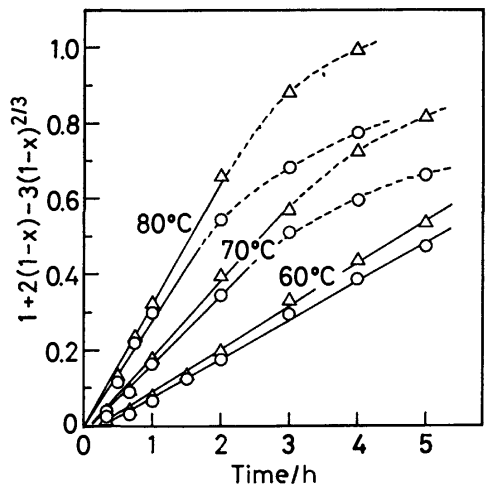

Fig. 4. Effect of temperature on the dissolution rates of Ti and Fe of ilmenite ore in concentrated HCl solution. $\{1+2(1-x)-3(1-x)^{2/3}\}$*vs.* t.
HCl: 11.6 mol dm^{-3}, stirring speed: 400 min^{-1}. ○: Ti, △: Fe.

Effect of Temperature. Figures 3 and 4 show the effect of temperature on the dissolution rates of titanium and iron in 11.6 mol dm^{-3} HCl solution at temperatures of 30 to 80 °C. The dissolution rates at 30—50 °C shown in Fig. 3 were well expressed by Eq. 5, which is based on the rate-determining step of the surface chemical reaction; namely, there was a good linear relationship between $\{1-(1-x)^{1/3}\}$ and t. However, the linear relationship was no longer observable in the dissolution rate at 60 °C. This result indicates that the leaching reaction at temperatures above 60 °C was not limited by the surface chemical reaction. The rate constants, k_C, for the leaching reactions were calculated from the slopes of the straight lines in Fig. 3 and are given in Table 2. The apparent activation energies calculated from the Arrhenius plots of k_C were 81.2 kJ mol^{-1} for titanium and 73.2 kJ mol^{-1} for iron.

Table 2. Kinetic parameters of the leaching of ilmenite ore in concentrated HCl solution at low temperature

Temp / °C	$k_C \times 10^6$/m h^{-1}	
	Ti	Fe
30	1.23	1.72
40	3.83	4.29
50	9.20	10.4
Activation energy/kJ mol^{-1}	81.2	73.2

On the other hand, the dissolution rates at 60—80 °C shown in Fig. 4 were also well expressed by Eq. 4, which is based on the rate-determining step of the diffusion in the residual solid layer. That is to say, the surface chemical reaction at temperatures above 60 °C became so fast that the dissolution rates were limited by the diffusion in the residual layer. In this case, the diffusion rate of H_3O^+ was presumed to be quite fast because we used highly concentrated hydrochloric acid solution in the leaching experiments. Accordingly, the diffusion of Ti^{4+} (titanium ions present in aqueous solutions were not only mononuclear species such as $Ti(OH)^{3+}$, $TiO(OH)^+$, $Ti(OH)_3^+$ but also polynuclear species such as $(TiO)_8(OH)_{12}^{4+}$ [20]) and Fe^{2+} produced by the surface chemical reaction of the unreacted core was the rate-determining step. However, as shown in Fig. 4, there was not a linear relationship between $\{1+2(1-x)-3(1-x)^{2/3}\}$ and t in the dissolution curves after 4 h at 70 °C or after 3 h at 80 °C. This deviation from the rate equation was thought to be dependent on the precipitation of the titanium(IV) oxide on the ore particles by hydrolysis of the titanium ion present in the leaching solution at high temperatures. Earlier workers[17] have reported that titanium ions are liable to precipitate readily from diluted HCl solutions ($<$0.3 mol dm^{-3}), but a similar tendency was observed to happen frequently even in highly concentrated HCl solutions.The X-ray diffraction patterns and the electron

$$TiOCl_2 + H_2O = TiO_2 + 2HCl$$

micrographs of the reaction residues obtained after the leaching experiment at 70 °C were shown in Figs. 5 and

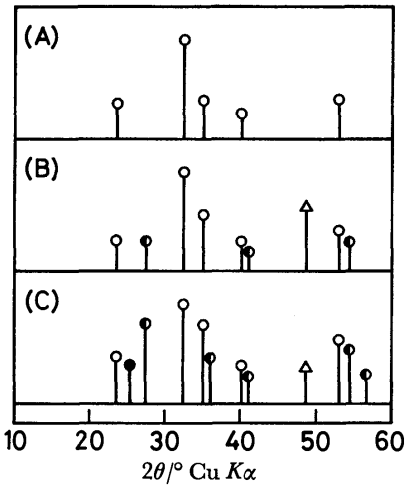

Fig. 5. X-Ray diffraction patterns of ilmenite ore and reaction residues.

6, respectively. The intensity of the diffraction peaks based on ilmenite decreased as the leaching continued, while the peaks of rutile gradually appeared. The peaks based on anatase and Ti_2O_3[21] were also observed in the X-ray diffraction patterns of the residues, though they were minor peaks. Ti_2O_3 was presumed to be produced by hydrolysis of Ti(III) ion formed by the reduction of Ti(IV) ion with chloride ion during the leaching. The times of formation of rutile as an insoluble matter were consistent with that of the deviation of titanium dissolution curves from the rate equation shown in Fig. 4. It can therefore be said that the hydrolysis of a part of dissolved titanium ion and the change in thickness of the residual layer have caused the deviation of the titanium dissolution curves. The deviation of the iron dissolution curves from the rate equation was also observed to follow that of titanium. This tendency was considered to depend upon the adsorption of dissolved iron ion and the change in thickness of the residual layer by the precipitation of titanium(IV) oxide. The

effective diffusion coefficient, D_e, was calculated from the slopes of the straight lines in Fig. 4 and is given in Table 3. The apparent activation energies calculated from the Arrhenius plots of D_e were 48.9 kJ mol^{-1} for titanium and 53.7 kJ mol^{-1} for iron.

Effect of Ore Grain Size. Figure 7 shows the result obtained by using the powdered ilmenite ore of 150—250 mesh in 11.6 mol dm^{-3} HCl solution at 50 and 80 °C. The dissolution rate at 50 °C was well expressed by Eq. 5, while the initial dissolution rate at 80 °C was expressed by Eq. 4. On the basis of the data, the following reaction constant, k_C, and effective diffusion coefficient, D_e, for titanium were calculated: $k_C(50\ °C) = 9.38 \times 10^{-6}$ and $D_e(80\ °C) = 6.03 \times 10^{-10}$. These values agreed approximately with the results obtained by using the ilmenite ore of 250—325 mesh, as shown in Tables 2 and 3. It can therefore be said that the rate analysis used in this study was reasonable.

Nomenclature

b = Stoichiometrical coefficient (—).
C_A = Hydrochloric acid concentration in the solution (kg mol m^{-3}).
D_e = Effective diffusion coefficient in the residual layer of the particle (m^2 h^{-1}).

k_C=Rate constant for the reaction Eq. 2 (m h^{-1}).
k_L=Mass transfer coefficient (m h^{-1}).
R=Particle radius (m).
t=Time (h).
x=Reaction percentage (−).
ρ_P=Mole density (kg mol m^{-3}).
ν=Stoichiometrical coefficient (−).

Thermochemical Hydrogen Production by the Magnesium-Sulfur-Iodine Cycle

Susumu MIZUTA* and Toshiya KUMAGAI

Energy Chemistry Division, National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

(Received November 6, 1981)

A new thermochemical cycle, consisting of (i) redox reaction of sulfur dioxide and iodine with magnesium oxide in aqueous phase, (ii) hydrolysis of magnesium iodide, (iii) thermal decomposition of magnesium sulfate, and (iv) thermal dissociation of hydrogen iodide, is presented for hydrogen production. The key reactions (i) and (ii) are experimentally verified.

Among a number of thermochemical cycles so far proposed for hydrogen production, the sulfur-iodine cycle has been considered as one of the most promising. This cycle comprising (i) redox reaction of sulfur dioxide and iodine, (ii) thermal decomposition of sulfuric acid, and (iii) thermal dissociation of hydrogen iodide is expressed by the following sequence,

$$I_2(c) + SO_2(g) + 2H_2O(l) \longrightarrow H_2SO_4(aq) + 2HI(aq), \quad (1')$$

$$H_2SO_4(g) \longrightarrow H_2O(g) + SO_2(g) + (1/2)O_2(g), \quad (2')$$

$$2HI(g) \longrightarrow H_2(g) + I_2(g). \quad (3')$$

The key operation for the cycle consists in the separation process of the acid mixture (H_2SO_4–HI) formed by Reaction 1′ since simple distillation causes the reverse reaction resulting in evolution of I_2 and SO_2. Thus, several proposals have been made on the separation: addition of excess iodine to form polyiodides (HI_x),[1] use of nickel metal,[2] and electrolytic promotion[3] of Reaction 1′.

The present authors have examined an addition of a series of metal oxides (Fe_2O_3, CoO, NiO, CuO, ZnO, PbO, MgO *etc.*), whose sulfates decompose at relatively low temperatures (<1200 °C), to the acid mixture. As a result of preliminary experiments, following points were obtained:

(i) Metal oxides are easily dissolved into the acid mixture by heating, however, the reverse reaction takes place as the solution gets concentrated when the amount of metal oxide is less than the equivalent to the acids.

(ii) Neither HI vapor nor H_2 is observed to be evolved directly from the solution.

(iii) For complete prevention of the reverse reaction, the amount of metal oxide should be equivalent to that of the acids. In other words, the formation of metal sulfate and iodide is considered to be inevitable.

Since a separation of the metal sulfate and iodide solution is another troublesome operation for the cycle, effects of the addition of metal oxide seemed unfavorable. However, the present authors noticed that it would be unnecessary to separate the sulfate and iodide in the case of magnesium oxide, because the temperature required for the thermal decomposition of $MgSO_4$ (1100 °C) is far apart from that for the hydrolysis of MgI_2 (400 °C). Such a temperature difference between these reactions was considered to have a possibility of allowing HI and SO_3 to be evolved separately.

Thus, a new thermochemical cycle using magnesium, sulfur, and iodine was designed as follows:[4–6]

$$2MgO(c) + SO_2(aq) + I_2(c) \xrightarrow{70\,^\circ C} MgSO_4(aq) + MgI_2(aq), \quad (1)$$

$$MgSO_4(aq) + MgI_2(aq) \xrightarrow{400\,^\circ C} MgSO_4(c) + MgO(c) + 2HI(g) + nH_2O(g), \quad (2)$$

$$MgSO_4(c) \xrightarrow{1100\,^\circ C} MgO(c) + SO_2(g) + (1/2)O_2(g), \quad (3)$$

$$2HI(g) \xrightarrow{300\text{—}700\,^\circ C} H_2(g) + I_2(g). \quad (4)$$

Each of the reactions was studied in this work. Experimental verifications were particularly focused on the key reactions 1 and 2.

Reaction Characteristics and Experimental Verification

Reaction 1(Redox Reaction of SO_2 and I_2 with MgO in Aqueous Phase). Iodine powder 552 mg was added to 2 cm^3 of approximately 6.8 wt% SO_2 aqueous solution in a beaker and the mixture was agitated until a colorless solution was obtained. Then, 174 mg of MgO powder, prepared by the decomposition of $MgSO_4$, was added to the resulting mixed acid solution at 70 °C with stirring. The magnesium oxide was easily dissolved to make a transparent solution after several minutes.

This mixed solution was subjected to EDTA chelate analysis, sulfate gravimetry, and thiosulfate iodometric titration for concentrations of Mg^{2+}, SO_4^{2-}, and I^- ions, respectively. Molar ratio $[Mg^{2+}] : [SO_4^{2-}] : [I^-] = 2.0 : 1.0 : 2.0$ was obtained. Thus, 100% yield and high reaction rate were verified for this reaction.

Reaction 2(Hydrolysis of MgI_2 Hydrate). X-Ray Analysis: In order to grasp an outline of Reaction 2, an X-ray analysis was made on solid phases. A mixed solution of $MgSO_4$ and MgI_2 produced by Reaction 1, was heated in a quartz boat in an atmosphere of N_2 at 100, 200, 240, 300, 350, or 1100 °C. Each of the solid residues was examined by X-ray analysis. Results are shown in Fig. 1. Since magnesium iodide and magnesium hydroxyiodides are extremely hygroscopic or easily oxidized in air, samples were kept in an N_2 atmosphere during measurement.

Based on the results shown in Fig. 1, changes in solid phases in course of Reaction 2 is expressed by

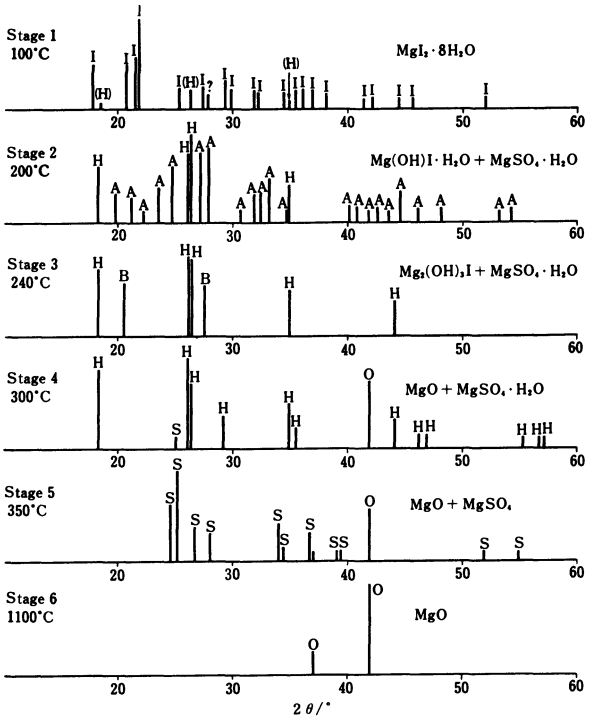

Fig. 1. Changes in X-ray diffraction patterns during heating of a mixed solution of MgI_2 and $MgSO_4$ (Cu $K\alpha$).
I: $MgI_2 \cdot 8H_2O$, H: $MgSO_4 \cdot H_2O$, A: $Mg(OH)I \cdot H_2O$
B: $Mg_2(OH)_3I$, S: $MgSO_4$, O: MgO.

$$MgSO_4(aq) + MgI_2(aq)$$
$$\longrightarrow MgSO_4 \cdot H_2O + MgI_2 \cdot 8H_2O$$
$$\longrightarrow MgSO_4 \cdot H_2O + Mg(OH)I \cdot H_2O$$
$$\longrightarrow MgSO_4 \cdot H_2O + (1/2)Mg_2(OH)_3I$$
$$\longrightarrow MgSO_4 \cdot H_2O + MgO$$
$$\longrightarrow MgSO_4 + MgO \longrightarrow 2MgO.$$

Thus, the hydrolysis of $MgI_2 \cdot 8H_2O$ and the dehydration or thermal decomposition of $MgSO_4 \cdot H_2O$ were found to separately proceed, as far as the result of X-ray analysis is concerned.

Thermal Analyses: A mixed solution of $MgSO_4 + MgI_2$ was also analyzed by TG and DTA from 25 to 1200 °C in a stream of argon at a heating rate of 200 °C/h. Results are shown in Fig. 2, where each arrow shows the theoretical weight calculated by using atomic weights for possible products. The plateaus observed at 130, 210, 260—300, and 350 °C correspond exactly to

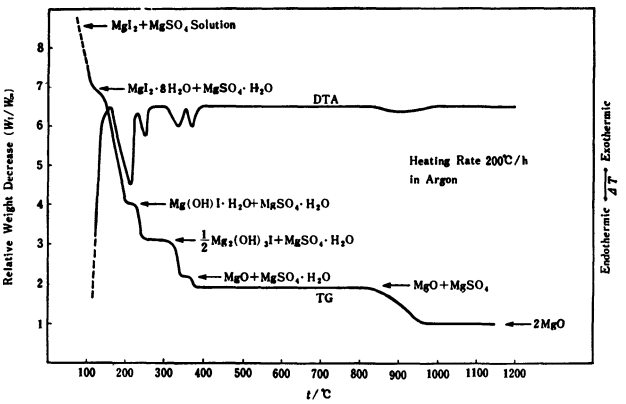

Fig. 2. TG and DTA curves for heating a mixed solution of MgI_2 and $MgSO_4$.

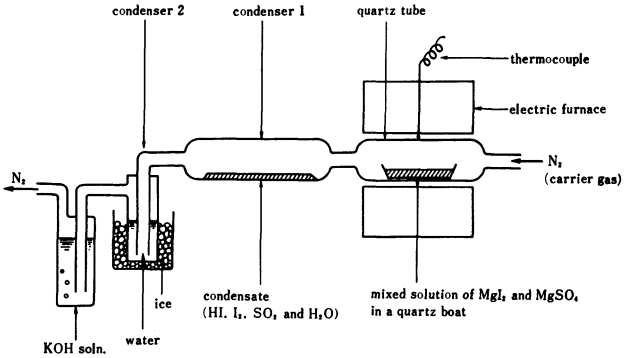

Fig. 3. Apparatus for hydrolysis of a mixed solution of MgI_2 and $MgSO_4$.

$MgSO_4 \cdot H_2O + MgI_2 \cdot 8H_2O$, $MgSO_4 \cdot H_2O + Mg(OH)I \cdot H_2O$, $MgSO_4 \cdot H_2O + (1/2)Mg_2(OH)_3I$, and $MgSO_4 \cdot H_2O + MgO$, respectively, while the one at 400—800 °C lies slightly lower than the calculated position for $MgSO_4 + MgO$, *i.e.*, the weight decrease observed for the reaction at 350—400 °C is slightly larger than the theoretical.

At any rate, general tendency of the results of thermal analyses may be considered to be in good agreement with those of X-ray analysis. To clarify the details of the reactions in the range 300—400 °C, a further study resorting to chemical analyses was performed as described below.

Chemical Analysis: Products of Reaction 2 were chemically analyzed. As shown in Fig. 3, a mixed solution of $MgSO_4$ and MgI_2 in a quartz boat was

TABLE 1. RESULTS OF CHEMICAL ANALYSIS FOR HYDROLYSIS OF A MIXED SOLUTION OF MgI_2 AND $MgSO_4$[a]

Heating mode	No. 1[b]			No. 2[c]			
Species determined	Distillate (25—430 °C)	Residue	Total	Distillate 1 (25—300 °C)	Distillate 2 (300—430 °C)	Residue	Total
I^-	1.85[d]	0.02[d]	1.99	1.62[d]	0.24[d]	0.02[d]	1.99
I_2	0.12	0		0.06	0.05	0	
SO_4^{2-}	0	1.91	2.01	0	0	1.92	2.01
SO_3^{2-}	0.04	0.06		0	0.06	0.03	
R[e]		$R=0.050$			$R=0.045$		

a) The figures give quantities in mmol. b) Direct heating (see text). c) Two-step heating (see text).
d) Calculated by I_2 ($I^-/2$). e) $R \equiv SO_3^{2-}/(SO_4^{2-}+SO_3^{2-})$.

heated in an N_2 atmosphere. Evolved vapors of I_2, HI, and SO_2 were collected in condensers while a solid residue in a quartz boat was dissolved in HCl.

The amounts of I_2, and I^- and the total amount of SO_3^{2-} and SO_4^{2-} for each reaction product were determined by thiosulfate iodometric titration and sulfate gravimetry. The amount of SO_3^{2-} was determined by back-titration of excess free iodine after adding a measured amount of I_2 to the sample.

Results for the cases of direct heating up to 430 °C (designated No. 1) and of heating in two steps of 25→300 and 300→430 °C (designated No. 2) are shown in Table 1. For the case of No. 2, evolution of SO_2 was undetected in the range of 25—300 °C whereas considerable amounts of I_2 and SO_2 were generated at 300—430 °C. A slight amount of I_2 formation would be attributable to the thermal dissociation of HI, though, this I_2 formation is only assumed to result from the reverse reaction of Reaction 1 since the total amount of I_2 evolved is almost equal to that of SO_3^{2-}. The contribution of the reverse reaction was calculated to be $R=0.050$ for No. 1 and $R=0.045$ for No. 2, where R (reverse reaction factor) is defined by

$$R \equiv \frac{SO_3^{2-}}{SO_3^{2-}+SO_4^{2-}}. \quad (5)$$

Thus, it is concluded that 95% of each of HI and H_2SO_4 was successfully separated by the addition of MgO.

Discussions on Reaction 2: As results of X-ray, thermal, and chemical analyses, total reactions are conclusively expressed as follows:

$$MgSO_4(aq) + MgI_2(aq) \xrightarrow{100\,^\circ C} MgSO_4\cdot H_2O(c) + MgI_2\cdot 8H_2O(c), \quad (2\text{-}1)$$

$$MgSO_4\cdot H_2O(c) + MgI_2\cdot 8H_2O(c) \xrightarrow{150\text{—}200\,^\circ C} MgSO_4\cdot H_2O(c) + Mg(OH)I\cdot H_2O(c) + HI(g) + 6H_2O(g), \quad (2\text{-}2)$$

$$MgSO_4\cdot H_2O(c) + Mg(OH)I\cdot H_2O(c) \xrightarrow{220\text{—}250\,^\circ C} MgSO_4\cdot H_2O(c) + (1/2)\,Mg_2(OH)_3I(c) + (1/2)\,HI(g) + (1/2)\,H_2O(g), \quad (2\text{-}3)$$

$$MgSO_4\cdot H_2O(c) + (1/2)\,Mg_2(OH)_3I(c) \xrightarrow{300\text{—}340\,^\circ C} MgSO_4\cdot H_2O(c) + MgO(c) + (1/2)\,HI(g) + (1/2)\,H_2O(g), \quad (2\text{-}4)$$

$$MgSO_4\cdot H_2O(c) + MgO(c) \xrightarrow{360\text{—}380\,^\circ C} MgSO_4(c) + MgO(c) + H_2O(g). \quad (2\text{-}5)$$

This reaction sequence is also supported excellently by the results of hydrolysis of pure $MgI_2\cdot 6H_2O$ previously reported by the present authors.[7]

The reverse reaction was observed to proceed at 300—430 °C within an extent of 5%; as least 95% of reactants was consumed in accordance with this sequence. A slight amount of some complex compound (Mg–I–SO_4) capable of causing the reverse reaction, though undetectable by X-ray analysis, might be present in the mixture of MgI_2 and $MgSO_4$ hydrates after drying the mixed solution.

Reaction 3 (Thermal Decomposition of $MgSO_4$). Thermal decomposition of $MgSO_4$ is reported[8] to take place as follows:

$$MgSO_4(c) \longrightarrow MgO(c) + SO_2(g) + (1/2)O_2(g). \quad (3)$$

The present experiments also confirmed the complete conversion of $MgSO_4$ into MgO at 1100 °C as shown in Figs. 1 and 2. Decomposition of SO_3 to SO_2 and O_2 is reported to proceed to almost 100% conversion at 1100 °C.[9]

Reaction 4 (Thermal Dissociation of HI). Thermal dissociation of HI is well known to occur according to

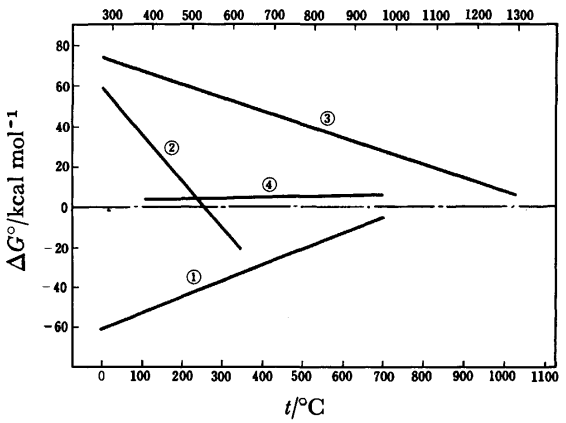

Fig. 4. Free energy change (ΔG°) *vs.* temperature plot for Reactions 1—4.
(1) $I_2(c)+SO_2(g)+2MgO(c)+6H_2O(l)\rightarrow MgI_2\cdot 6H_2O(c)+MgSO_4(c)$, (2) $MgI_2\cdot 6H_2O(c)\rightarrow MgO(c)+2HI(g)+5H_2O(g)$, (3) $MgSO_4(c)\rightarrow MgO(c)+SO_2(g)+(1/2)O_2(g)$, (4) $2HI(g)\rightarrow H_2(g)+I_2(g)$.

Table 2. Enthalpy, entropy, and freee nergy changes (ΔH°_{298}, ΔS°_{298}, and ΔG°) for Reactions 1—6[a]

Reaction	ΔH°_{298}/kcal mol^{-1} [b]	ΔS°_{298}/cal mol^{-1} K^{-1} [b]	ΔG°/kcal mol^{-1} [b]
1	−83.5	−81.1	−59.3 at 298 K

3	+92.5	+68.3	+0.6 at 1400 K
4	+2.3	−5.3	+5.6 at 700 K
5	−14.9	−34.4	−4.7 at 298 K
6	−51.5	−142.0	−9.5 at 298 K
Total	+68.3	+39.0	

a) (1) $I_2(c)+SO_2(g)+2MgO(c)+6H_2O(l)\longrightarrow MgI_2\cdot 6H_2O(c)+MgSO_4(c)$, (2) $MgI_2\cdot 6H_2O(c)\longrightarrow MgO(c)+2HI(g)+5H_2O(g)$, (3) $MgSO_4(c)\longrightarrow MgO(c)+SO_2(g)+1/2O_2(g)$, (4) $2HI(g)\longrightarrow H_2(g)+I_2(g)$, (5) $I_2(g)\longrightarrow I_2(c)$, (6) $5H_2O(g)\longrightarrow 5H_2O(l)$. b) 1 cal=4.184 J.

$$2HI(g) \longrightarrow H_2(g) + I_2(g). \quad (4)$$

The extent of conversion is reportedly 18—29% at 600—1000 K according to Bodenstein.[10]

Thermodynamic Calculation

The enthalpy change (ΔH°_{298}), entropy change (ΔS°_{298}) and free energy change (ΔG°) for each of the processes involved in the present cycle were calculated based on the thermochemical data by Barin and Knacke[11] and estimated values for $MgI_2 \cdot 6H_2O$.[7] The results are shown in Fig. 4 and Table 2.

Conclusion

1) A new thermochemical cycle for hydrogen production (Magnesium-Sulfur-Iodine cycle) was successfully presented on the basis of a combination of MgO and a sulfur-iodine scheme.

2) The feasibility of the two key reactions, (i) redox reaction of SO_2 and I_2 with MgO in aqueous phase and (ii) hydrolysis of MgI_2 hydrate, were experimentally verified. Conversion was found to be 100% for reaction (i) at 70 °C and 95% for reaction (ii) at 400 °C, respectively. Sufficiently high reaction rates were observed for both the reactions.

3) For this cycle it is unnecessary to separate the mixed solution of $MgSO_4$ and MgI_2, that is, HI and SO_3 are separately evolved at different temperatures. Therefore, the material flow-sheet can be so simple, as shown in Fig. 5.

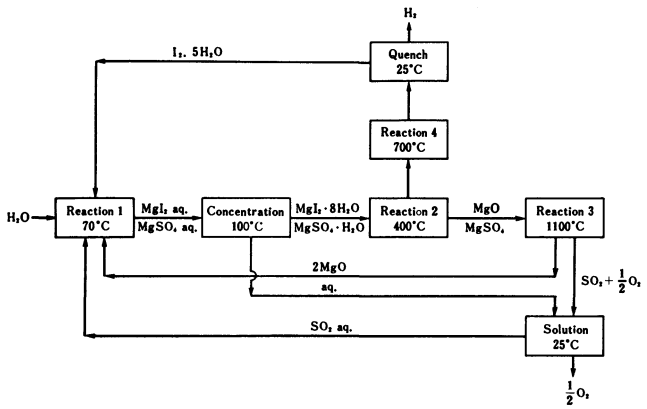

Fig. 5. Material flow in magnesium-sulfur-iodine cycle.

Application of Regular Solution Theory to Extraction of Salicylaldehyde Oxime Chelates

S. Narayanan and G. N. Rao*

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi 110016, India

(Received August 6, 1981)

The distribution coefficients of salicylaldehyde oxime and its metal chelates, namely of Co(II), Cu(II), and Zn(II) were determined between aqueous acetate phase (μ=0.1) and eight 'inert' organic solvents at 25 °C. On the basis of regular solution theory, the correlation between the distribution coefficients of the ligand (P_{HA}) and that of the metal chelates (P_M) expressed by log $P_M = n$ log P_{HA} + const, was shown to be valid satisfactorily in most of the systems. Hexane and cyclohexane showed abnormal behaviour in extraction with Cu(II), while with Zn(II) extraction to the desired level was not possible with these two solvents. A good correlation was also observed between the distribution coefficient of salicylaldehyde oxime and the 'solubility parameter' of the solvents and the solutions are shown to be regular.

In the solvent extraction of metal complexes, studies have been made qualitatively in several systems. Also in many studies the solvents have been chosen semiempirically without understanding what physicochemical properties of the solvent govern the distribution of the species. The solvent plays an important role not only in the effective separation of the species from a mixture but also in synergistic studies, organic phase reactions, kinetics of extraction *etc.* Thus, role of solvent is quite important and a quantitative approach on the basis of regular solution theory[1] has been made. Studies have revealed that the distribution coefficient of a species can be correlated with the solubility parameter of the organic solvent. Also a correlation can exist between the distribution coefficients of the ligand and its metal chelate when the nature of their interaction with solvent molecules are same. Such correlations have been established by Suzuki, Akiba, and others in their studies with thenoyltrifluoroacetone with different metals and different solvents[2-7] and by Honjo *et al.* with thiothenoyl trifluoroacetone.[8] Similar relations for benzoyltrifluoroacetone and for 4-benzoyl-5-methyl-2-phenyl-4-pyrazolin-3-one (BMPP) have been recently established.[9] The present study on above lines has been described with salicylaldehyde oxime as the ligand. Salicylaldehyde oxime has been specifically selected due to its characteristic nature of being biprotonic, and having fair solubility in water, these two properties being absent in the ligands studied so far.

Experimental

Material. Salicylaldehyde oxime (Merck) was used as supplied without further purification.

Carbon tetrachloride, chlorobenzene, cyclohexane (all BDH), chloroform, dichloromethane, hexane (all Merck), benzene (IDPL), and toluene (Rechem) were purified whenever necessary and used.

Co(II), Cu(II), and Zn(II) solutions were prepared from cobalt acetate, copper(II) sulfate, and zinc sulfate respectively (all A. R. grade).

Procedure. Determination of Distribution Coefficient (P_{HA}) of Salicylaldehyde Oxime: Aqueous solution of salicylaldehyde oxime of suitable concentration was prepared at pH=1 and its absorbance measured at 258 nm in a spectrophotometer (SP-700A PYE UNICAM) and the molar absorptivity coefficient was determined (ε=8400). Solution of salicylaldehyde oxime of known concentration in the desired organic solvent was equilibrated with aqueous phase (pH=1) and the absorbance of suitable aliquot of aqueous phase was measured. Knowing ε=8400, and the concentration in the aqueous phase, by difference the concentration in organic phase was determined and hence the distribution coefficient. The values of P_{HA} with different solvents are presented in Table 1.

Determination of Distribution Ratio (K_d) of the Metal Salicylaldehyde Oxime Chelate: Ten milliliters of the aqueous phase containing the acetate buffer at appropriate pH and the metal ion at 10—20 ppm level was equilibrated with 10 ml of the desired organic solvent containing salicylaldehyde

Table 1. Distribution coefficients of salicylaldehyde oxime and extraction constants of metal salicylaldehyde oxime

No.	Solvent	δ[a]	ε[b]	log P_{HA}	log K_{ex}		
					Co(II)	Cu(II)	Zn(II)
1	Cyclohexane	8.2	2.0	−0.59	−7.32±0.02	2.62±0.04[c]	d)
2	Hexane	7.3	1.9	−0.53	−7.50±0.02	2.82±0.10[c]	d)

oxime (10^{-2} M; 1 M=1 mol dm^{-3}) for 5 min. After equilibration, pH of aqueous phase was measured and the concentration of metal in the aqueous phase was determined by atomic absorption spectrophotometer (SP-191 PYE UNICAM) and then the distribution ratio was determined. Experiments were also done with varying ligand concentration (2×10^{-3} M to 10^{-2} M) in the organic phase while maintaining a fixed pH in the aqueous phase.

Results and Discussion

The extraction equilibria for the distribution of a bivalent metal (M) with a ligand (HA) can be written as:

$$HA_{aq} \rightleftharpoons HA_{org} : P_{HA}, \quad (1)$$

$$HA_{aq} \rightleftharpoons H^+_{aq} + A^-_{aq} : K_a, \quad (2)$$

$$M^{2+}_{aq} + nA^-_{aq} \rightleftharpoons MA^{(2-n)+}_{n,aq} : \beta_n, \quad (3)$$

$$MA_{2,aq} \rightleftharpoons MA_{2,org} : P_M, \quad (4)$$

where the subscripts org and aq represent the species in the organic and aqueous phase respectively. The symbol on the right side represents the equilibrium constant for that particular step.

Under the conditions when the concentration of the metal chelate is sufficiently low compared to that of the metal, M^{2+}, in the aqueous phase and if the metal species exist as MA_2 chelate in the organic phase then the distribution ratio, K_d, of the chelate can be given as:

$$K_d = P_M\beta_2(A^-)^2, \quad (5)$$

where A^- is the anion of the ligand and its concentration can be determined from the expression

$$[A^-] = \frac{[HA]_{org,ini}}{[P_{HA}+1][H^+]/K_a+1}. \quad (6)$$

The experimental extraction behaviour of metal complexes can be followed through theoretical plots and slope analysis. Plots of $\log K_d$ *vs.* pH and $\log K_d$ *vs.* log of ligand concentration indicate the number of hydrogen ions released and the number of ligand molecules involved respectively, during the complexation process. Further, plots of $\log K_d$ *vs.* pA (pA= $-\log [A^-]$) can be drawn at fixed pH or at fixed ligand concentration. These plots give negative slopes indicating the number of ligand molecules participating in the simple complexation process. The distribution coefficient (P_M) of the chelate, generally, cannot be measured experimentally and it is related to the measurable distribution ratio, K_d, as a function of pA. Mathematically,

$$K_d = P_M \cdot f[A^-] \quad (7)$$

Thus, if the value of distribution ratio could be known at a fixed pA, it is possible to relate the distribution coefficient of the chelate with the distribution coefficient of ligand and the relation

$$\log P_M = n \log P_{HA} + \text{const}, \quad (8)$$

could be validated as expected from regular solution theory.[12]

In the present work the correlation shown by Eq. 8 has been found to obey satisfactorily with the three metals studied.

Co(II)–Salicylaldehyde Oxime System. The extraction takes place in the pH range 5.6 to 6.6 in all the eight solvents. Slope analysis of plots, discussed already, gave values of two indicating release of two hydrogen ions and involvement of two molecules of salicylaldehyde oxime. It is thus obvious that one hydrogen ion is released from each ligand molecule. The mechanism can be written as:

$$Co^{2+}_{aq} + 2(H_2\cdot sal)_{org} \rightleftharpoons Co(H\cdot sal)_{2\,org} + 2H^+_{aq}, \quad (9)$$

where $(H_2\cdot sal)$ represents one salicylaldehyde oxime molecule.

The values of extraction constants, $\log K_{ex}$, for the above reaction for different solvents have been calculated from the relation

$$\log K_{ex} = \log K_d - 2\text{pH} - 2\log [H_2\cdot sal] \quad (10)$$

and are presented in Table 1.

Salicylaldehyde oxime has fair solubility in water. A correction is to be applied since the actual value of the ligand concentration will be less than that taken for equilibration in the organic phase. Utilising the P_{HA} values, the solubility correction has been incorporated while computing the values of K_{ex} presented in Table 1.

Plots of $\log K_d$ *vs.* pA also give negative slope of two for all solvents. Figure 1 indicates such plots for some solvents. From these plots, the values of $\log K_d$ at a fixed pA were plotted against $\log P_{HA}$, and it was found that there is a satisfactory regularity with most of the solvents.

Cu(II)–Salicylaldehyde Oxime System. The extraction takes place in acidic range *i.e.*, pH range 1 to 2 in all solvents. Slope analysis confirms the mechanism similar to the extraction in Co(II) system shown in Eq. 9, in all solvents except hexane and cyclohexane. These two solvents, however, show different behaviour and they give slope value of ≈ 3 in $\log K_d$ *vs.* pH and $\log K_d$ *vs.* $\log [H_2\cdot sal]$ plots. This indicates involve-

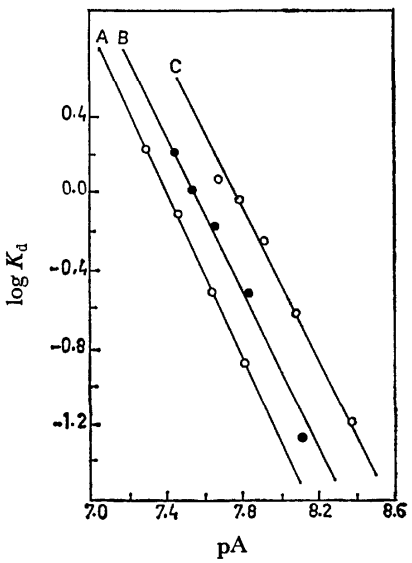

Fig. 1. Variation of distribution ratio of cobalt–salicylaldehyde oxime chelate as a function of pA.
A: Benzene; $(HA)_0=10^{-1}$ M, B: chlorobenzene; pH= 6.4, C: dichloromethane; pH=6.6.

ment of three molecules of ligand and release of three hydrogen ions and the complex will be anionic. Since extraction does take place into the organic phase, this anion perhaps forms an ion pair chelate, of the type $Cu(H\cdot sal)_3^-\cdot H^+$ where the H^+ probably coming from the aqueous phase. The mechanism is probably

$$Cu^{2+}_{aq} + 3(H_2\cdot sal)_{org} \rightleftharpoons 3H^+_{aq} + Cu(H\cdot sal)_{3,aq} \longrightarrow Cu(H\cdot sal)_3^-\cdot H^+_{org}. \quad (11)$$

The formation of higher complexes involving three ligand molecules may be due to nature of these two solvents. These two solvents, show more resemblance to aqueous phase so far as the distribution coefficient of salicylaldehyde oxime with these two solvents are concerned. The P_{HA} values are so low that the anion concentration of salicylaldehyde oxime can be expected to be high in the aqueous phase resulting in the formation of higher complexes. In the case of both solvents at higher pH (>2) the extraction declines and this can be attributed to low availability of H^+ to form ion pair. The values of log K_{ex} with different solvents are given in Table 1.

In the log K_d *vs.* log P_{HA} plot, shown in Fig. 2, there is satisfactory regularity. Hexane and cyclohexane show abnormal deviation and it is difficult to pinpoint the reason with the present information.

Zn(II)–Salicylaldehyde Oxime System. Dahl, in his studies[10] has emphasized the importance of reagent concentration in the extraction of Zn(II) with various solutions of salicylaldehyde oxime. The present studies also indicated requirement of different ligand concentration in different solvents, 5×10^{-2} M solution of salicylaldehyde oxime in benzene, toluene, chlorobenzene, and carbon tetrachloride and 10^{-1} M solution were needed in chloroform and dichloromethane for extraction which was in the pH range 6.4 to 7.6; in case of cyclohexane, however, it was noted that quantitative extraction could not be achieved with 10^{-1} M or even slightly higher concentration. Still higher concentration rendered the ligand insoluble in these two solvents and hence no satisfactory extraction could be done with hexane and cyclohexane.

Analysis of plots reveal interesting results. With toluene, chloroform, and dichloromethane the extraction mechanism was similar to those noted in Co(II) and Cu(II) system. But with carbon tetrachloride, benzene and chlorobenzene slope analysis indicated release of two hydrogen ions and involvement of only one ligand molecule in the complexation. This indicates the release of the two hydrogen ions from the same salicylaldehyde oxime molecule and the mechanism can be written as:

$$Zn^{2+}_{aq} + (H_2\cdot sal)_{org} \rightleftharpoons Zn(sal)_{org} + 2H^+_{aq}. \quad (12)$$

The extraction constant values are shown in Table 1.

In the plots of log K_d *vs.* log P_{HA}, slope of two was observed for toluene, chloroform, and dichloromethane while for carbon tetrachloride, benzene, and chlorobenzene slope of one was noted. This is in conformity with the predicted mechanism of involvement of only one molecule of ligand for the latter three solvents. It can be seen from Fig. 3 that there is good regularity with all solvents.

The molar volume of salicylaldehyde oxime was determined to be 100±5.0 through density measurement using petroleum ether as solvent. This experimental value was checked to be correct by the graphical method employed for β-diketones by Wakahayashi *et al.*[11,12] and later by Kojima *et al.*[13] Knowing the molar volume, the solubility parameter (δ) of salicylaldehyde oxime in different solvents, using hexane as standard, was calculated employing Siekierski-Olszer equation.[14] The solubility parameter value was found to be 13.0±0.8. A plot between the distribution coefficient of the ligand and the solubility parameter of the solvents gave a parabolic curve, as Fig. 4 shows, and this is in accordance with regular solution theory. The points in the figure for different solvents are on the same side since $\delta_{ligand} > \delta_{solvent}$ for all the solvents and since all points fall in the parabola with no deviation it can be concluded that the solutions of salicylaldehyde oxime in different solvents are regular.

The basis for regular solution theory is on the concept of solubility parameter. The importance of this in relation to other parameters like dielectric constant was also investigated, on the basis of Pearson's cor-

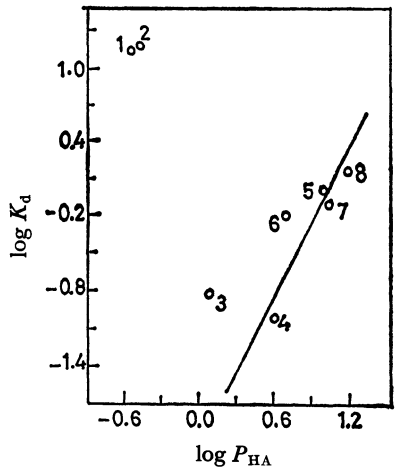

Fig. 2. Correlation between the distribution coefficient of salicylaldehyde oxime and that of its copper chelate. The numbers in the figure correspond to those in Table 1.

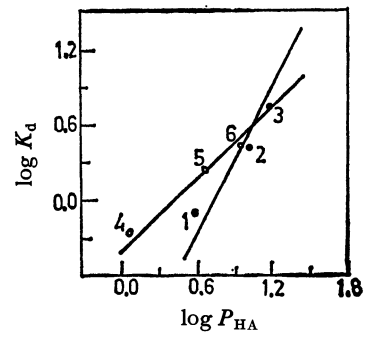

Fig. 3. Correlation between the distribution coefficient of salicylaldehyde oxime and that of its zinc chelate at a fixed pA.
1: Toluene, 2: chloroform, 3: dichloromethane (at pA=6.2), 4: carbon tetrachloride, 5: chlorobenzene, 6: benzene (at pA=15.0).

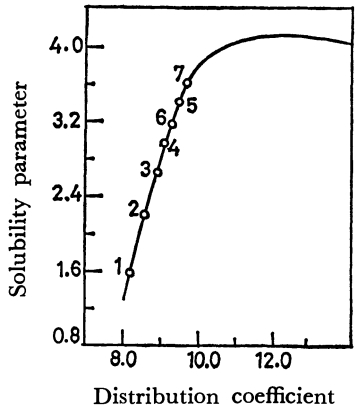

Fig. 4. Distribution of salicyladehyde oxime as a function of solubility parameter of organic solvents based on Siekierski-Olszer equation using Hexane as standard.
1: Cyclohexane, 2: carbon tetrachloride, 3: toluene, 4: benzene, 5: chlorobenzene, 6: chloroform, 7: dichloromethane.

relation coefficient. The correlation coefficient is used to measure the degree of linear correlation between two variables. Pearson's correlation coefficient is given by

$$\text{Correlation coefficient} = \frac{\sum \delta x . \delta y}{\sqrt{\sum(\delta x)^2 \times \sum(\delta y)^2}},$$

where δx is deviation from the mean of one of the first variable and δy is the deviation from the mean of the corresponding second variable. When the correlation coefficient is $+1$ there is a positive correlation between the two variables and all the points fall exactly on a line. If the points are completely random on the graph the correlation coefficient will be zero. In the present study, in the plot between $\log P_{HA}$ and δ, the solubility parameter, the correlation coefficient is obtained as $+0.88$ while in the plot of $\log P_{HA}$ *vs.* ε, the dielectric constant the value is $+0.58$. Thus, the values P_{HA} are much better correlated with solubility parameter than with dielectric constant.

In conclusion, it may be said that for a ligand like salicylaldehyde oxime, regular solution theory appears to be valid from the present studies and it is thus possible to make choice of appropriate solvent for extraction.

The Thermodynamics of Ion Exchange of Singly Charged Cobalt(III) Complex with Sodium Ions on Cation Exchange Resin

Katsumi KUROTAKI* and Shoichi KAWAMURA
Division of Chemistry, National Institute of Radiological Sciences, 4-9 Anagawa, Chiba 260

(Received April 25, 1981)

Synopsis. Thermodynamic values of the ion exchange of $[Co^{III}L_4B_2]^+$ (L=NH_3, ethylenediamine/2 (=en/2), or dimethylglyoximato(1−) anion/2 (=dmgH/2); B=NO_2^-, NCS^-, $CO_3^{2-}/2$, NH_3, or $C_2H_5NH_2$) with Na^+ on Dowex AG 50W-X2 resin were determined at 25 °C by measurements of selectivity coefficient and heat of exchange. Heats and entropies are negative for the uptake of $[Co(NH_3)_4(NO_2)_2]^+$ and $[Co(en)_2B_2]^+$, while they are positive for the uptake of $[Co(dmgH)_2(C_2H_5NH_2)_2]^+$.

In our previous paper,[1] we determined thermodynamic values of ion exchange of trivalent metal complex ions and pointed out that heats and entropies of ion exchange, which are related to the interaction of these ions with water, are functions of polarization charge densities at the surface of these ions. On the other hand, several investigators have reported affinities of some singly charged cobalt(III) complex ions against ion exchange resins.[2-4] However, the thermodynamics of these ion exchange reactions have not yet been studied. In this paper, thermodynamic values of ion exchange of singly charged cobalt(III) complex ions on Dowex AG 50W-X2 are determined and interactions of these ions with water are discussed.

Experimental

Materials. The poly(styrenesulfonic acid) cation exchange resin (Dowex AG 50W-X2, 50—100 mesh, Bio Labo.) was obtained in the sodium form after conditioning, and dried in air current. Cobalt(III) complex chlorides were prepared by the literature methods.[5,6]

Equilibrium Measurements. Batch method was employed to measure the selectivity coefficient; 0.2 g of sodium form resin was equilibrated with 40 cm^3 of 0.04 mol dm^{-3} mixed salt solution containing the complex and sodium chlorides of several compositions (ionic strength of equilibrium solution is 0.04). Equilibration was achieved within a few hours by agitating at 25±0.1 °C. Concentrations of complex and sodium ions in aqueous phase were determined from optical absorbance and from radioactivity of ^{22}Na, respectively.

Heat of Exchange. A twin type conduction calorimeter of a commercial model (Lesca Co., Tokyo, CM-204S) was employed to measure the heat of ion exchange; 0.2—1.0 g of sodium form resin was weighed into sample holding tubes of sample and reference calorimeters, and then added 5 cm^3 of water to eliminate the heat of swelling, while 40 cm^3 of 0.05 mol dm^{-3} salt solution and water were introduced into the sample and reference cells. After thermal equilibrium, the resins in sample holding tubes were mixed with the salt solution and water in the cells. The heat evolved was recorded as a differential electromotive force.

Results and Discussion

The selectivity coefficient of ion exchange, $X^+ + NaR = Na^+ + XR$, can be defined as

$$K_c' = N_X m_{Na} / N_{Na} m_X,$$

where N and m are the mole fraction in resin and the molality of solution of subscript ions, X^+ and Na^+, respectively. Selectivity coefficients plotted against the mole fraction of complex ion in resin (*i.e.*, Kielland plots) are shown in Fig. 1. All of the Kielland plots are nearly linear. The preferential uptake of $[Co(en)_2(NO_2)_2]^+$, $[Co(en)_2(NCS)_2]^+$, $[Co(NH_3)_4(NO_2)_2]^+$, and $[Co(dmgH)_2(NH_3)_2]^+$ increases with increasing mole fraction of these ions in resin, that is, the slope of Kielland plots of these ions is positive. This trend can be explained in terms of the cluster formation of these ions and resin matrix.[7,8]

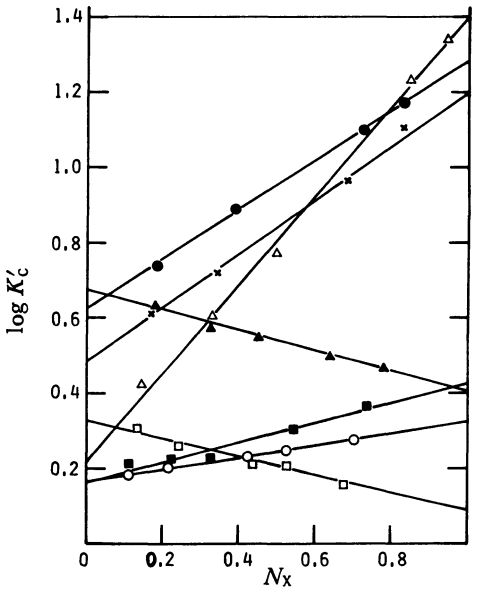

Fig. 1. Selectivity coefficients as functions of ionic compositions in resin.
●: *cis*-$[Co(en)_2(NO_2)_2]^+$, ○: *trans*-$[Co(en)_2(NO_2)_2]^+$, ▲: $[Co(en)_2CO_3]^+$, △: *cis*-$[Co(en)_2(NCS)_2]^+$, ×: *cis*-$[Co(NH_3)_4(NO_2)_2]^+$, ■: $[Co(dmgH)_2(NH_3)_2]^+$, □: $[Co(dmgH)_2(C_2H_5NH_2)_2]^+$.

The free energy $\Delta G°$ and entropy $\Delta S°$ of ion exchange are calculated by

$$\Delta G° = -RT\int_0^1 \ln K_c'[\gamma(Na^+)/\gamma(X^+)]dN_X$$

$$\Delta G° = \Delta H° - T\Delta S°.$$

Since the ionic strength of aqueous phase is sufficiently low (0.04), the values of $\gamma(Na^+)/\gamma(X^+)$ are approximated to 1. Standard heats of exchange $\Delta H°$ are approximated to heats of exchange ΔH, since the heat content terms are small. Thermodynamic values of ion exchange are

Table 1. Thermodynamic values of ion exchange for $A^+ + NaR = AR + Na^+$ on Dowex AG 50W-X2 at 25 °C (I=0.04)

Cation	$\Delta G°$	$\Delta H°$	$\Delta S°$
	kJ mol^{-1}	kJ mol^{-1}	J K^{-1} mol^{-1}
cis-$[Co(NH_3)_4(NO_2)_2]^+$	−4.81	−11.92	−23.8
cis-$[Co(en)_2(NO_2)_2]^+$	−5.52	−8.99	−11.7
trans-$[Co(en)_2(NO_2)_2]^+$	−1.38	−3.77	−8.0
trans-$[Co(en)_2(NCS)_2]^+$	−4.39	−8.74	−14.6
$[Co(en)_2CO_3]^+$	−3.05	−5.61	−8.4
$[Co(dmgH)_2(NH_3)_2]^+$	−1.67	−1.59	+0.4
$[Co(dmgH)_2(C_2H_5NH_2)_2]^+$	−1.17	+3.14	+14.6

presented in Table 1.

The exothermic heats cause the preferential uptake of $[Co(NH_3)_4(NO_2)_2]^+$ and $[Co(en)_2B_2]^+$ (Table 1). This trend can be explained in terms of strong interaction between these ions and resin matrix. *cis*-$[Co(en)_2(NO_2)_2]^+$ has a larger dipole moment than *trans*-$[Co(en)_2(NO_2)_2]^+$. This causes the more exothermic heat and stronger affinity of the former than those of the latter.

It was recognized that ions are classified into three groups on the basis of ion-water interaction: (a) Electrostrictive structure makers such as Na^+, (b) structure breakers such as Cs^+, and (c) hydrophobic structure makers.[9,10] Since the structure maker increases the structural order of water near itself, its removal from aqueous phase gives a positive entropy. Furthermore, as an ion of the same charge becomes more structure making, the water content of its form resin increases, that is, the extent of dehydration of ion by transfer from the aqueous to resin phase decreases.[1,11-13] These facts suggest that the sign and magnitude of the entropy of ion exchange gives a reliable indication of the structure altering property of an ion.

Table 1 shows that the values of $\Delta S°$ for $[Co(dmgH)_2B_2]^+$ are positive and they become more positive with alkyl chain. A similar behaviour was shown in ion exchanges of tetraalkylammonium ions.[13] The alkyl (hydrophobic) groups of the dmgH ligands are in contact with water. Furthermore, the dmgH ligands coordinated in plane are hydrogen bonded with one another and therefore, the anionic groups are not localized. These facts suggest that $[Co(dmgH)_2B_2]^+$ has a hydrophobic structure making property which causes its preferential uptake against the resin.

The values of $-\Delta S°$ of $[Co(en)_2B_2]^+$ and $[Co(NH_3)_4(NO_2)_2]^+$ are larger than that of Cs^+ with Na^+ on Dowex 50 (2% DVB).[12] This fact shows that $[Co(en)_2B_2]^+$ and $[Co(NH_3)_4(NO_2)_2]^+$ are structure breakers. Interestingly, it has been shown that $[Co(en)_3]^{3+}$ is a hydrophobic structure maker.[10] Water dipoles near an anion are oriented in the opposite direction to those near a cation. Therefore, the water structure near anion ligands of $[Co(en)_2B_2]^+$ should be disturbed in a wide range. Thus, $[Co(en)_2B_2]^+$ as well as $[Co(NH_3)_4(NO_2)_2]^+$ acts as a structure breaker. The order of structure breaking tendencies of $[Co(en)_2B_2]^+$ is $NCS^- > NO_2^- > CO_3^{2-}/2$. This order seems to accord with the structure breaking tendencies of these anions. *cis*-$[Co(NH_3)_4(NO_2)_2]^+$ is more structure breaking than *cis*-$[Co(en)_2(NO_2)_2]^+$, since $-\Delta S°$ of the former is larger than that of the latter. This trend accords with the relation between $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$.[1]

The Gibbs Free Energy of the Formation of the $Al(OH)_4^-$ Ion at Elevated Temperatures

Byong-Tae CHANG
Department of Chemistry, Faculty of Science, Korea University, Kodaira, Tokyo 187
(Received July 16, 1981)

Synopsis. The Gibbs free energy of the formation of the $Al(OH)_4^-$ ion, $\Delta G_f^\circ[Al(OH)_4^-]$, has been determined from the solubility data of alumina hydrates at temperatures up to 300 °C. According to the results of thermodynamical calculations, $\Delta G_f^\circ[Al(OH)_4^-]$ is -1305.3 kJ/mol at 25 °C, and it decreases almost linearly with an increase in the temperature. Its temperature dependence between 25 and 300 °C can be expressed as follows: $\Delta G_f^\circ[Al(OH)_4^-] = -1152.7 - 3.318T - 5.64\times10^{-4}T^2 + 1.202T\log T$.

The Gibbs free energy of the formation of the $Al(OH)_4^-$ ion, $\Delta G_f^\circ[Al(OH)_4^-]$, is very important in understanding thermodynamically the alumina production by the Bayer process, the aqueous geochemistry of aluminous minerals, and the corrosion of aluminum in alkaline solutions. Previously, various values for $\Delta G_f^\circ[Al(OH)_4^-]$ at 25 °C have been reported by many investigators.[1-6] Unfortunately, these values are very discrepant, ranging from -1297.2 to -1314.2 kJ/mol. Furthermore, $\Delta G_f^\circ[Al(OH)_4^-]$ at elevated temperatures has not yet been presented. The alumina extraction from bauxite and the formation of alumina minerals proceed usually at a high temperature. It is, therefore, important to know $\Delta G_f^\circ[Al(OH)_4^-]$ at high temperatures.

The present author previously determined the ionic solubility products, K_s, of gibbsite[7] and boehmite[8] in the alkaline pH range by applying an extending Debye-Hückel equation to their solubility data in NaOH solutions. The purpose of this paper is to determine $\Delta G_f^\circ[Al(OH)_4^-]$ at temperatures from 25 to 300 °C, based on K_s°.

The dissolution processes of alumina hydrates are given by the following equations:

a) For gibbsite,

$$Al(OH)_3(s) + H_2O(l) = Al(OH)_4^-(l) + H^+(l), \quad (1)$$

$$K_{s,1}^\circ = a_{Al}a_H/a_w, \quad (2)$$

$$\Delta G_1^\circ = -RT\ln K_{s,1}^\circ. \quad (3)$$

b) For boehmite,

$$AlOOH(s) + 2H_2O(l) = Al(OH)_4^-(l) + H^+(l), \quad (4)$$

$$K_{s,2}^\circ = a_{Al}a_H/a_w^2, \quad (5)$$

$$\Delta G_2^\circ = -RT\ln K_{s,2}^\circ, \quad (6)$$

where a_{Al}, a_H, and a_w are the activities of $Al(OH)_4^-$, H^+ ions, and water, and where ΔG_1° and ΔG_2° are the Gibbs free energy changes in Reaction 1 and 4 respectively.

The temperature dependences of log K_s° can be expressed throughout the temperature range as follows:

a) For gibbsite,

$$\log K_{s,1}^\circ = -22.11 - 3.368\times10^{-3}T - 5835.9/T + 6.390\ln T. \quad (7)$$
$$(313.2 \leq T \leq 443.2\ K)$$

b) For boehmite,

$$\log K_{s,2}^\circ = -29.64 - 8.149\times10^{-3}T - 2263.0/T + 4.3721\ln T. \quad (8)$$
$$(353.2 \leq T \leq 573.2\ K)$$

The above equations are the results of the least-square treatment of the data for K_s° obtained in Refs. 7 and 8.[9]

According to Eq. 1 or 4,

$$\Delta G_f^\circ[Al(OH)_4^-]_1 = \Delta G_1^\circ + \Delta G_f^\circ[Al(OH)_3] + \Delta G_f^\circ(H_2O) - \Delta G_f^\circ(H^+), \quad (9)$$

$$\Delta G_f^\circ[Al(OH)_4^-]_2 = \Delta G_2^\circ + \Delta G_f^\circ(AlOOH) + 2\Delta G_f^\circ(H_2O) - \Delta G_f^\circ(H^+). \quad (10)$$

The Gibbs free energy of the formation of a substance for which heat capacity data are available can be calculated by the usual thermodynamical method. For gibbsite, boehmite, and water, highly accurate heat capacity data have been presented in the literature.[10,11] It is most important and most difficult to evaluate $\Delta G_f^\circ(H^+)$ exactly at high temperatures. In this paper, the $\Delta G_f^\circ(H^+)$ values were calculated approximately by using the "correspondence principle" presented by Criss and Cobble.[12] They demonstrated that reliable estimates of "absolute" (*i.e.* "third law") ionic entropies and heat capacities can be made using their correspondence principle.

The thermodynamic data necessary to evaluate ΔG_f° are listed in Table 1. It should be noted that an ionic entropy of the hydrogen ion at 25 °C, which is usually defined as zero based on the conventional scale, was assigned to 20.92 J/K mol according to the correspondence principle.

TABLE 1. SELECTED STANDARD THERMODYNAMIC DATA FOR GIBBSITE, BOEHMITE, WATER, AND HYDROGEN IONS

Substance	$\Delta G_{f,298}^\circ$ / kJ mol^{-1}	S_{298}° / J K^{-1} mol^{-1}	c_p° / J K^{-1} mol^{-1}

Table 2. The Gibbs free energies of formation for gibbsite, boehmite, water, H^+, and $Al(OH)_4^-$ ions at elevated temperatures

	$\Delta G^\circ_{f,T}$/kJ mol^{-1}						
T/K	298.15	333.15	373.15	423.15	473.15	523.15	573.15
$Al(OH)_3$	−1154.9	−1157.6	−1160.9	−1165.8	—	—	—
AlOOH	−915.0	−916.8	−919.2	−922.7	−926.7	−931.1	−936.0
$H_2O(l)$	−237.2	−239.8	−243.1	−247.7	−252.7	−258.1	−263.9
$H^+(l)$	0	0.5	0.6	−0.3	−2.6	−6.0	−10.1
$Al(OH)_4^-$ a)	−1304.7	−1310.3	−1315.5	−1320.0	—	—	—
$Al(OH)_4^-$ b)	−1305.2	−1309.2	−1314.2	−1320.7	−1326.8	−1332.6	−1338.7

a) $\Delta G^\circ_f[Al(OH)_4^-]_1$ obtained from Eq. 9. b) $G^\circ_f[Al(OH)^\circ_4]_2$ obtained from Eq. 10.

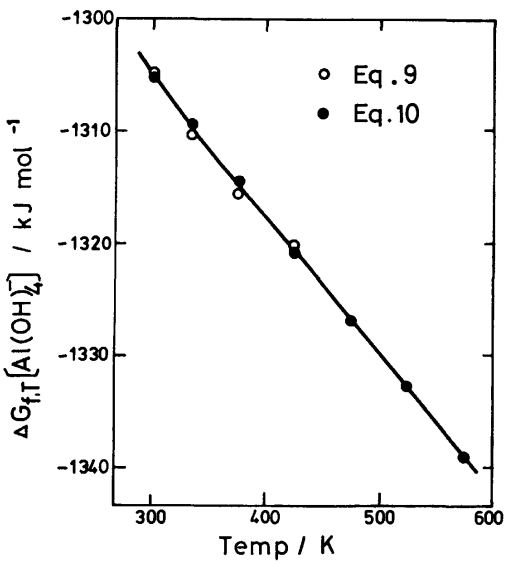

Fig. 1. Temperature dependence of the Gibbs free energy of formation for $Al(OH)_4^-$ ion at temperatures between 25 and 300 °C.

Table 2 gives the results of calculation of the free energies of formation at elevated temperatures for the species in Table 2. The $\Delta G^\circ_f(H_2O)$ values at high temperatures were obtained using the heat capacities of pure water[11] under its saturated vapor pressure at each temperature above 100 °C.

In the temperature range from 25 to 150 °C, $\Delta G^\circ_f[Al(OH)_4^-]_1$ and $\Delta G^\circ_f[Al(OH)_4^-]_2$ are consistent with each other within 1.3 kJ/mol. As is shown in Fig. 1, $\Delta G^\circ_f[Al(OH)_4^-]$ decreases almost linearly with the increase in the temperature; its temperature dependence between 25 and 300 °C can be expressed, after the least-square treatment, as follows:

$$\Delta G^\circ_f[Al(OH)_4^-] = -1152.7 - 3.318\,T - 5.64 \times 10^{-4}T^2 + 1.202\,T\log T. \quad (11)$$

The value of $\Delta G^\circ_f[Al(OH)_4^-]$ at 25 °C is −1305.3 kJ/mol, which agrees very well with the value of −1305 kJ/mol recently reported by Hemingway.[5]

Effect of Polymorphic Transition on Molecular Diffusion in Some Molecular Complexes, as Evidenced by Exchange Reaction Rate and by Electrical Resistivity

Tamotsu INABE and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received October 29, 1981)

Synopsis. Marked increases in electron donor and acceptor-exchange reaction rates and also large differences in the temperature dependence of the electrical resistivity of polycrystalline compactions between the first and the second heating processes indicate the enhanced molecular diffusion near and above the polymorphic transition temperatures of some molecular complexes.

The appearance of isomorphous high-temperature forms upon polymorphic transitions in over twenty molecular complexes consisting of aromatic hydrocarbons and various electron acceptors has been ascribed to the onset of molecular rotation.[1] In this connection, these complexes bear some similarity to plastic crystals, which are composed of globularly shaped and orientationally disordered molecules. As plastic crystals are known to show diffusion coefficients approximately 10^4 times higher than normal crystals when compared at their melting points,[2] an appreciable increase of the translational mobility upon the transitions might be expected for the above-mentioned molecular complexes. Attempts were made to follow such changes in some selected complexes by measurements of electron donor and acceptor-exchange reaction rates covering the transition temperature and also by comparison of the electrical resistivity of polycrystalline compactions between the first and the second heating processes.

The following three 1 : 1 complexes seemed to suit the study of the exchange reactions because of their relatively low transition temperatures and large entropy changes: pyrene-2,4-dinitrotoluene (Py–DNT), 53.5 °C, 37 J mol^{-1} K^{-1}; pyrene-2,4,6-trinitrotoluene (Py–TNT), 59 °C, 36 J mol^{-1} K^{-1}; fluoranthene-2,4,6-trinitrochlorobenzene (Fl–TNC), 54 °C, 54 J mol^{-1} K^{-1}. The acceptors employed for the exchange reactions were 2,4,7-trinitrofluorenone (TNF) and 4,6-dinitrobenzofuroxan (DNBF). They are stronger as acceptors than any in the complexes and have melting points higher than those of the complexes. Because of the former condition, the complex formed by the exchange reaction gives a charge-transfer absorption band in a region separated from that of the original complex. The latter condition was expected to mean that the molecules in the added component compound would be less mobile than those in the complex. The donor-exchange reaction was examined with the combination of Fl–TNC and Py. Py is stronger as a donor than Fl and its melting

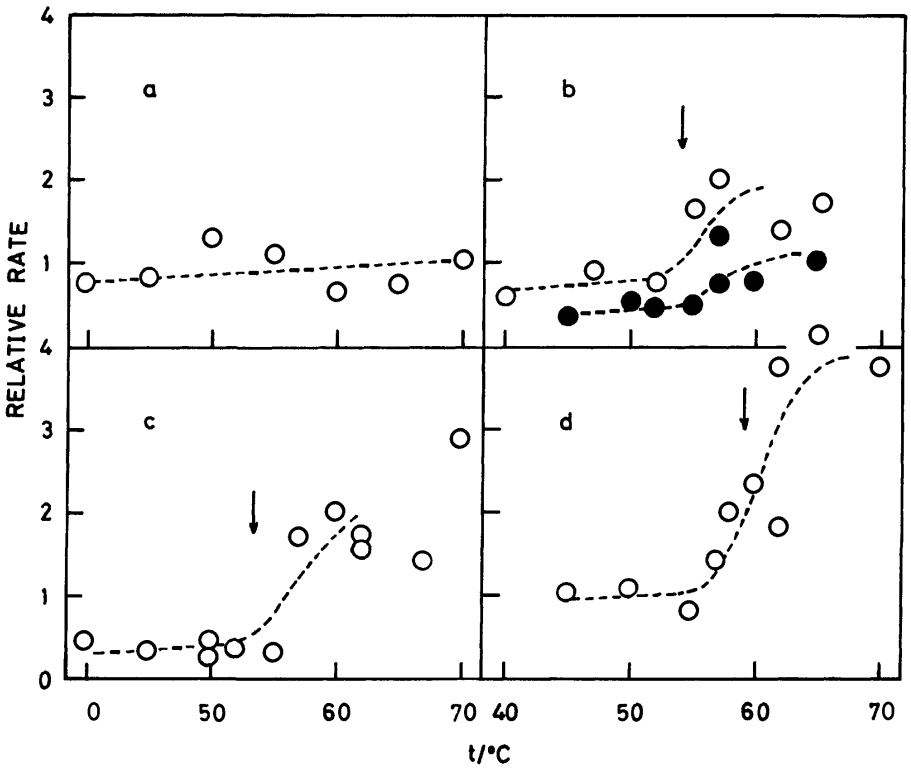

Fig. 1. Relative rates of the exchange reactions between (a) fluoranthene-3-nitrophthalic anhydride and 4,6-dinitrobenzofuroxan, (b) fluoranthene-2,4,6-trinitrochlorobenzene and 4,6-dinitrobenzofuroxan (○) or pyrene (●), (c) pyrene-2,4-dinitrotoluene and 2,4,7-trinitrofluorenone, and (d) pyrene-2,4,6-trinitrotoluene and 2,4,7-trinitrofluorenone.

point is higher than that of Fl–TNC.

The complex and the component compound to be added to the complex were separately ground, and then mixed in a weight ratio of 45 : 1 by grinding for short time. The mixed powdered sample, packed into a holder for reflectance measurements, was kept in a thermostat. The spectrum was recorded at intervals of 10 to 120 min by means of a Beckman DK 2A spectro-reflectometer. The intensity (I) of the new charge-transfer band estimated by the Kubelka-Munk function was considered to be proportional to the concentration of the complex formed by the exchange reaction. The ratio was chosen to make the final reflectance not less than 20%. The plot of $\ln I/(I_\infty - I)$ against the reaction time gave a straight line at each temperature. The slope naturally depends on the absorption coefficient of the charge-transfer band; therefore, it may be taken as a measure of the reaction rate only for each complex.

In order to check the reliability of the procedure, the reaction between Fl–3-nitrophthalic anhydride and DNBF was studied. This complex exhibits no polymorphic transition in the measured temperature range and has a melting point lower than that of DNBF (136 °C *vs.* 172 °C). The rate appears to increase slightly by raising the temperature (see Fig. 1a). The results obtained with Fl–TNC complex are presented in Fig. 1b. Although the measured rates are rather scattered, one can clearly see an increase near and above the transition temperature indicated by the vertical arrow. Similar and more pronounced changes were observed with the reactions between the Py complexes and TNF shown in Figs. 1c and 1d.

The increase of reactivity during polymorphic transition has been noted by Hedvall.[3] He reported many examples demonstrating that the transition temperature or the temperature range coincides with the maximum reactivity. The explanation given by him is the appearance of unstable and highly-reactive transitional states during the transition. No such maximum rate could be found in the present cases; however, the observed rate increase is undoubtedly indicative of enhanced molecular diffusion upon the transition of the complex.

The electrical resistivity of polycrystalline compactions of the five complexes in this group examined earlier showed an abrupt decrease in the transition temperature range.[4] This observation resembles that made for some plastic crystals by Swiatkiewicz and Pigon.[5] Now, we wish to report that the behavior in the first heating process can be quite different from that described before if the compaction is made of a thoroughly powdered sample. The best example was provided with the Fl–2,4,6-trinitrophenol complex, which is transformed into the isomorphous form at 93.5 °C with an entropy of 42 J mol^{-1} K^{-1}. As is shown in Fig. 2, an encrease of the resistivity by a factor of about five was found in the first run just below the transition temperature. On the other hand, the change in the second heating process is normal and reproducible. The decrease in the transition temperature range is as much as by a factor of twenty. The marked difference between the two

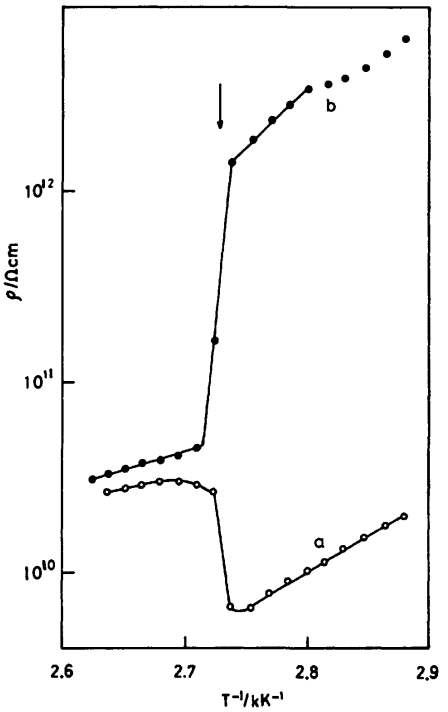

Fig. 2. Electrical resistivity changes of a polycrystalline compaction of fluoranthene-2,4,6-trinitrophenol during (a) the first heating process and (b) the second heating process.

runs can be explained if one assumes that the conduction in the compaction, which is not yet heated to the transition temperature, predominantly arises from surface current. Then, the resistivity increase near the transition temperature may be attributed to the decrease of the surface area by rapid recrystallization due to the enhanced molecular diffusion. The electrical behavior observed in the second run reflects the bulk property of the complex. Similar but less drastic changes have been recorded with the following complexes: Fl–TNC, Fl–TNT, and Fl–4-nitrophthalic anhydride. The anomalous change near the transition temperature has been reported in the work of Swiatkiewicz and Pigon on plastic crystals, and has been ascribed also to the recrystallization.

The present work was partly supported by a Grant-in-Aid for Scientific Research No. 543001 from the Ministry of Education, Science and Culture.

Liquid Crystal Formation in Binary Systems. VI.[1] Smectic Liquid Crystals Induced in *N*-[4-(Diethylamino)benzylidene]-4-ethoxyaniline-*N*-(4-Nitrobenzylidene)-4-ethoxyaniline and Related Systems

Kotaro ARAYA, Noriko HOMURA, and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received October 29, 1981)

Synopsis. The replacement of the dimethylamino group in the combinations of the 4-dimethylamino-4-alkoxy and 4-nitro-4-alkoxy derivatives of *N*-benzylideneaniline by a diethylamino group favors the induction of smectic phases in their mixtures.

In Part II of this series, we described the induction of nematic and smectic liquid crystals by mixing electron donors and acceptors of the type 4-X-C_6H_4-CH=N-C_6H_4-Y-4.[2] The donor molecules had a dimethylamino group as X or Y, while the acceptor molecules had a nitro group as X or Y. The substituents on the remaining ends were methoxyl, ethoxyl, or propoxyl groups. The stabilization of mesophases in these binary mixtures was ascribed to the parallel molecular arrangement achieved by an electron donor-acceptor interaction.

In order to obtain a better understanding of the relations between the induction of liquid crystals and molecular structure, systematic studies of the effects of substituents are obviously important. As the first step along this line, we wish to report on the liquid crystals induced by mixing the diethylamino and nitro derivatives of *N*-benzylideneaniline.

N-[4-(Diethylamino)benzylidene]-4-alkoxyanilines, hereafter abbreviated (Et_2N, RO), and *N*-(4-alkoxybenzylidene)-4-(diethylamino)anilines, (RO, Et_2N) were prepared by the condensation reaction between appropriate benzaldehyde and aniline, and had the following melting points: (Et_2N, MeO) 100 °C, (MeO, Et_2N) 89.5 °C, (Et_2N, EtO) 106 °C, (EtO, Et_2N) 107 °C, (Et_2N, PrO) 110 °C, and (PrO, Et_2N) 98.5 °C. The nitro derivatives were similarly prepared. The measurements were carried out as described in our earlier works.[1,2]

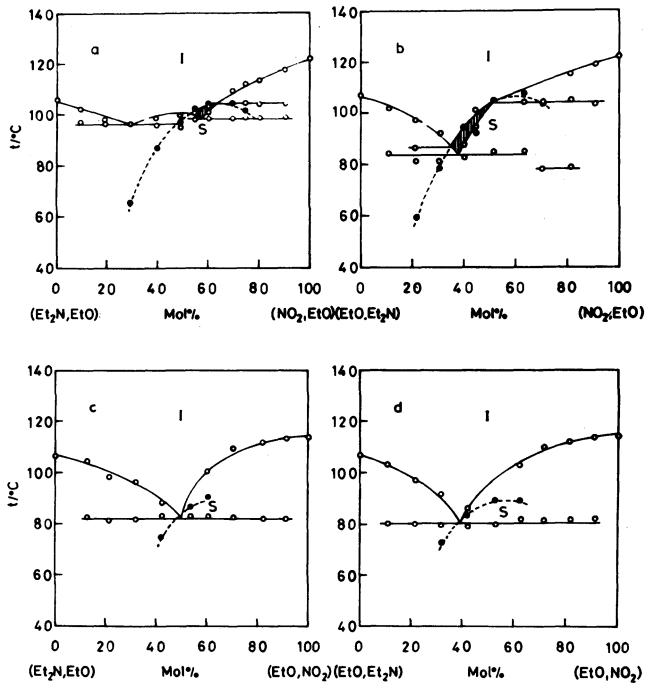

Fig. 1. Phase diagrams of (a) (Et_2N, EtO)-(NO_2, EtO), (b) (EtO, Et_2N)-(NO_2, EtO), (c) (Et_2N, EtO)-(EtO, NO_2), and (d) (EtO, Et_2N)-(EtO, NO_2) systems. The open and shaded circles are transitions recorded in the processes of heating and cooling respectively.

No liquid crystal could be found in the systems consisting of the methoxy derivatives. The results are in sharp contrast to the observation that the induction of nematic liquid crystals occurs with the corresponding dimethylamino compounds. As the diethylamino group is known to be less efficient in promoting nematic liquid crystals than the dimethylamino group,[3] the absence of nematic liquid crystals in the present systems may not be unexpected.

Figure 1 indicates that all the four combination of the ethoxy derivatives can induce smectic liquid crystals. The (Et_2N, EtO)-(NO_2, EtO) system produces a 1 : 1 solid complex which melts congruently at 100.5 °C. The induced mesophase is stable between 53 and 64 mol% of (NO_2, EtO) but it is observable as a metastable phase in a much wider range: from 20 to 75 mol%. The isotropic liquid-smectic liquid crystal (I-S) transition temperature at the former composition is as low as 65 °C. An incongruently melting complex, possibly of the 1 : 2 mole ratio, is found in the phase diagram of the (EtO, Et_2N)-(NO_2, EtO) system. The I-S transition curve meets the freezing point curve of the donor compound at 86.5 °C and 35 mol% of (NO_2, EtO) and that of the acceptor compound at a point which is not distinguishable from the peritectic point located at 104 °C and 51 mol%. The maximum lies at 106 °C and near 60 mol%.

The combination of (Et_2N, EtO) and (EtO, NO_2) gives a diagram of the eutectic type. The mesophase is observed in the range from 40 to 60 mol% and is metastable with the possible exception of a very small area near the eutectic point: 82 °C and 50 mol%. No solid complex is formed in the (EtO, Et_2N)-(EtO, NO_2) system. The induced smectic phase seems to be wholly metastable but covers a range wider than that in the (Et_2N, EtO)-(EtO, NO_2) system. The I-S transition curve passes through the eutectic point located at 81.5 °C and 39 mol% of (EtO, NO_2) and reaches the maximum at 89 °C and about 57 mol%.

We reported earlier the formation of congruently melting solid complexes in both the (Me_2N, EtO)- and (EtO, Me_2N)-(NO_2, EtO) systems and that of an

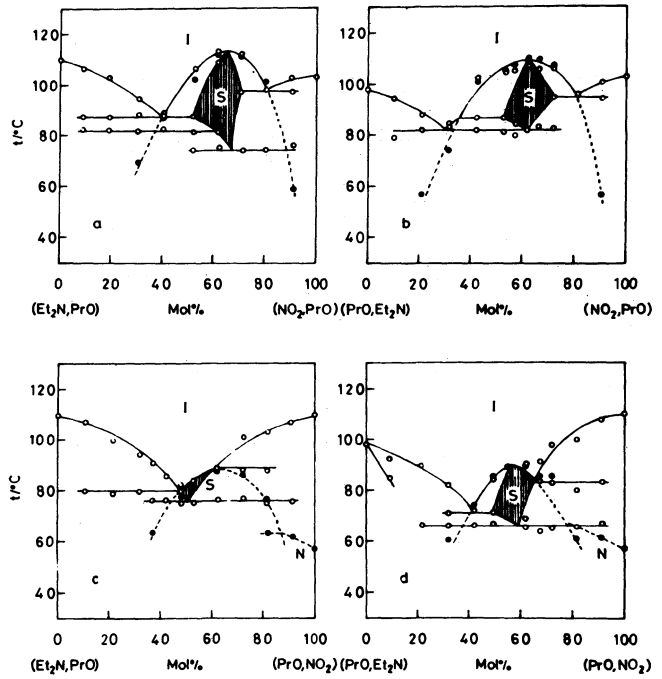

Fig. 2. Phase diagrams of (a) (Et_2N, PrO)–(NO_2, PrO), (b) (PrO, Et_2N)–(NO_2, PrO), (c) (Et_2N, PrO)–(PrO, NO_2), and (d) (PrO, Et_2N)–(PrO, NO_2) systems. As to the open and shaded circles, see the caption of Fig. 1.

incongruently melting one in the (EtO, Me_2N)–(EtO, NO_2) system and also the induction of nematic liquid crystals with all the combinations.[2] Thus, smectic mesophases appear to be markedly stabilized by the introduction of a diethylamino group instead of a dimethylamino group into the donor molecules, while nematic mesophases and solid complexes are destabilized.

As is shown in Fig. 2, the solid complex in the (Et_2N, PrO)–(NO_2, PrO) system has the composition of a 1 : 1 mole ratio and ceases to exist at 81.5 °C, giving a peritectic point at 62 mol% of (NO_2, PrO). A stable smectic liquid crystal appears in the composition range from 40 to 81 mol% and the maximum temperature of 114 °C is found at 65 mol%. The mesophase coexists with the isotropic melt except for the hatched area. The eutectic point is at 74 °C and 67 mol%. The diagram of the (PrO, Et_2N)–(NO_2, PrO) system is of the eutectic type. The I-S transition curve intersects the freezing point curve of (NO_2, PrO) at 86.5 °C and 36 mol% and at 95 °C and 81 mol%. The maximum is found at 109 °C and 62 mol%. The combination of (Et_2N, PrO) and (PrO, NO_2) also gives a diagram of the eutectic type. The maximum stabilization of the induced smectic phase is achieved at the intersection between the I-S transition curve and the freezing point curve of the acceptor compound: 89 °C and 62 mol% of (PrO, NO_2). As the melt of this acceptor compound can be supercooled to the latent I-N transition temperature (57.5 °C), the induction of the nematic liquid crystal is observable above 87 mol%. The (PrO, Et_2N)–(PrO, NO_2) system produces no solid complex. The I-S transition curve meets the freezing point curve of the donor compound at 71 °C and 41 mol% of (PrO, NO_2) and that of the acceptor compound at 83 °C and 66 mol%.

It must be emphasized that the tendencies noted with the ethoxy derivatives are more pronounced with the propoxy derivatives. First of all, the four systems of the corresponding dimethylamino compounds produce solid molecular complexes stable up to their own melting points, while only the (Et_2N, PrO)–(NO_2, PrO) system can form a solid complex with a limited stability. On the other hand, the induced smectic phases are stable in all the systems of the present compounds, contrary to those induced with the dimethylamino compounds, which are entirely metastable.

The Determination of the Ratio of Two Kinds of Hydrogen in Metal Hydrides by Means of Pulsed NMR

Shigenobu HAYASHI,* Kikuko HAYAMIZU, and Osamu YAMAMOTO
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305

(Received November 19, 1981)

Synopsis. A method is proposed by which the composition of the two kinds of hydrogen with different diffusional behavior in metal hydrides can be determined accurately by means of ^{1}H NMR; using the method, it is found that the energy difference between the two sites occupied by the two kinds of hydrogen is 7.9 kJ/mol in $VH_{0.77}$.

Metal-hydrogen alloys have recently attracted much attention as hydrogen-storage materials because they can absorb and desorb large amounts of hydrogen reversibly; many studies have been performed by various methods.[1)]

A number of phases have been observed in the metal-hydrogen systems; they are called α-, β-, and γ-phases, and so on. There exist, in most of the hydrides, wide two phase regions, where at least two kinds of hydrogen are observed by means of ^{1}H NMR spectroscopy.[2)] Even if the metal lattice is in a single phase, the existence of several kinds of hydrogen is occasionally observed within a limited temperature range. It was observed by continuous-wave (cw) NMR spectroscopy that hydrogen in the hydrides of the Va group metals consists of two components in the β-phase at about 160 K;[3–5)] the same is true of hydrogen in $ZrH_{1.99}$ at about 440 K.[6)] The nature of each component is almost unknown, and, thus far, no quantitative investigations have been made of the concentration of each component. In metal-hydrogen alloys, the existence of several kinds of hydrogen is common, and it is very important to determine the composition accurately. However, in solids it is difficult to determine the true composition accurately because of instrumental limitations.

In this paper we propose a method for accurately determining the composition by means of pulsed NMR method, making use of the difference in the spin-spin relaxation times. Then, using the method, the concentrations of two kinds of hydrogen with different diffusional behavior which are observed in the β-phase of $VH_{0.77}$ are determined.

Experimental

Vanadium hydride, $VH_{0.77}$, was prepared by a reaction between vanadium metal and hydrogen gas in an autoclave. The synthesized sample was pulverized, passed through a 200-mesh screen, and sealed in a Pyrex glass ampoule.

The equipment used for the NMR measurements was a Bruker CXP-100 pulsed spectrometer whose 90° pulse width was about 1.5 μs. The measurements were performed at 55 MHz for the ^{1}H observation. The spectra were obtained by the Fourier-transformation of the free-induction decay (FID) after 90° -pulse, the solid-echo, and the spin-echo signals.

Results and Discussion

Figure 1 shows the ^{1}H Fourier-transformed (FT) NMR spectra of $VH_{0.77}$ at 133 K obtained by the spin-echo method. The spectra are assumed to be superpositions of two components with different linewidths. Similar superimposed spectra are also obtained by the FID and solid-echo methods. These superimposed spectra are observed at temperatures between 120 and 180 K. Above 180 K, motional narrowing occurs, after which the spectra appears to consist of only one component.

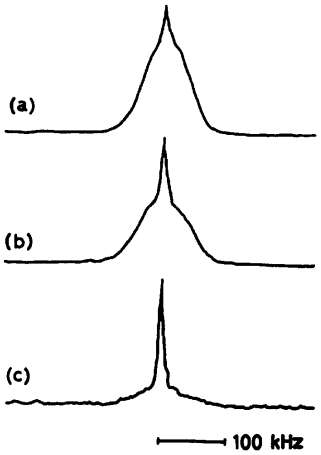

Fig. 1. FT-NMR spectra of ^{1}H in $VH_{0.77}$ at 133 K obtained by the spin-echo metod. The t_d values, which is twice the separation of the two pulses, are (a) 20 μs, (b) 30 μs, and (c) 50 μs, respectively.

The broader line is broadened mostly by the ^{1}H-^{51}V and ^{1}H-^{1}H dipole-dipole interaction, and then assumed to be Gaussian. The narrower line is assumed to be Lorentzian because it seems to be in the region of motional narrowing. The line separation is then carried out, assuming the above-mentioned line-shapes for each component. Thereafter, the ratio of the two components is obtained by integrating the area of each line. However, the ratio is not equal to the true ratio of the two kinds of hydrogen, for the line-shape of the spectra varies, depending on t_d, the time interval between the first 90°_x pulse and the beginning of the signal acquisition, as is shown in Fig. 1. The ratio of the narrower component (II) to the broader one (I) increases as t_d increases. The t_d dependence of the spectra can be explained by the well-known principles of pulsed NMR spectroscopy.[7)] The magnetization of the i-th component at the echo maximum, $M_i(t_d)$, is expressed as:

$$M_i(t_d) = M_i^\circ \exp(-t_d/T_{2i}), \quad (1)$$

where M_i° is the magnetization at $t_d=0$ and where T_{2i} is the spin-spin relaxation time of the i-th component. The observed magnetization is the sum of that of each component. Component I has a shorter T_2 than Component II, so $M_I(t_d)$ decreases faster than $M_{II}(t_d)$ as t_d increases. If we could make t_d equal to zero, the true ratio of the two kinds of hydrogen, M_{II}°/M_I°, could

be determined. This is generally impossible, however, because of instrumental limitations. The receiver cannot work for a short period, which is called "dead time," after a transmission of the radiofrequency pulse. For our equipment it is about 8 μs. The observed linewidth of the broader component in $VH_{0.77}$ is about 50 kHz, and the T_2 value is estimated to be 6 μs, which is comparable to the "dead time." However, $M_{II}^{\circ}/M_{I}^{\circ}$ can be determined by the extrapolation of $M_{II}(t_d)/M_{I}(t_d)$ to $t_d=0$, as is shown in Fig. 2. A very good linearity is obtained, and the slope is defined as a function of the two T_{2i} values.

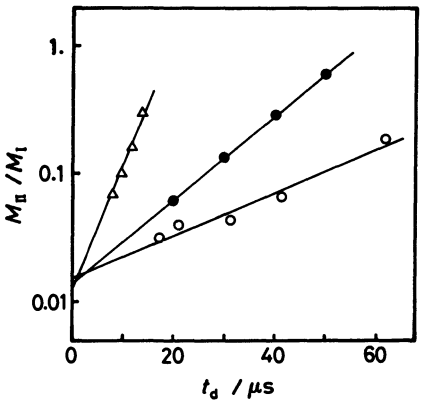

Fig. 2. The t_d dependence of the apparent ratio of the two components in $VH_{0.77}$ at 133 K.
○: Solid echo, ●: spin echo, and △: FID.

Similar t_d dependences of the line-shapes are observed by the other two methods, the solid-echo and the FID methods, as is shown in Fig. 2. The M_{II}/M_{I} values change exponentially with t_d, the slope being different in the three methods. In the solid-echo method, the magnetization of each component at the echo maximum decays with a time constant longer than T_2. The FID curve falls faster than the other two methods. If the line-shape of the FT spectra is of a Lorentzian type, the FID curve shows an exponential decay whose time constant is expressed as:

$$1/T_{2i}^{*} = 1/T_{2i} + \text{(magnetic inhomogeneity term)}. \quad (2)$$

While the broader component seems to be a Gaussian type in the present case of $VH_{0.77}$, it can be assumed to be approximately a Lorentzian type, as is shown in Fig. 2, for the linear extrapolation is possible and the extrapolated value, $M_{II}^{\circ}/M_{I}^{\circ}$, in this method is in excellent agreement with the values in the other two methods.

The agreement of the extrapolated values in the three methods, within the limits of experimental error, proves the validity of this extrapolation method for determining the ratios of each hydrogen. The first 90_x° pulse width should be taken into consideration if it is not negligible compared to t_d. It is about 1.5 μs for our equipment, though, and is negligible, considering the experimental error. The accuracy of the extrapolated

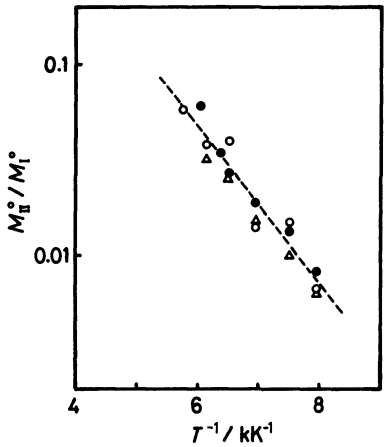

Fig. 3. The temperature dependence of the ratio of the two kinds hydrogen in $VH_{0.77}$.
○: Solid echo, ●: spin echo, and △: FID.

value becomes higher as the difference of T_{2i} decreases, due to the nature of the extrapolation method. However, a component with an extremely low concentration and a long spin-spin relaxation time will be observed by a good choice of t_d values, and then the approximate concentration of the component can be obtained by the extrapolation method described above.

Figure 3 shows the temperature dependence of the ratio of the two kinds of hydrogen in $VH_{0.77}$. The Arrhenius relation is satisfied in the temperature range from 120 to 170 K, and from its slope, the apparent energy difference of the two components is calculated to be 7.9 kJ/mol. Hydrogen atoms of Component I occupy more stable sites than those of Component II, and the exchange of hydrogen atoms between the two sites is slow. "Motional narrowing" has already occurred in Component II in the temperature range studied, but not in Component I; *i.e.*, hydrogen of Component II diffuses faster than that of Component I. Thus, we can determine the composition of different kinds of hydrogen with different diffusional behavior in metal hydrides by means of pulsed NMR spectroscopy.

Isotope Effect on Hydrogen Atom Abstraction Reaction by Recoil T Atoms in Solid n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ Mixtures. Comparison of Recoil T Atoms with D Atoms in γ-Radiolysis

(Received November 26, 1981)

Synopsis. An isotope effect on the hydrogen atom abstraction reaction by recoil T atoms in the n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures in the solid phase is compared with the reaction by D atoms in the γ-radiolysis. A small isotope effect for the recoil T atoms is explained by a track model.

So far many studies have been undertaken on hot tritium reactions in the gas phase,[1] but only a few studies have been reported for solid organic compounds. It has been reported for solid neopentane that most of the recoil T atoms react in their own tracks and the thermal diffusion of the T atoms in the bulk matrix plays only a minor role.[2] Recently a large isotope effect on the hydrogen atom abstraction by D atoms produced by γ-radiolydis has been found in n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures at 77 K.[3]

Here the isotope effect on the hydrogen atom abstraction reaction by recoil T atoms is examined in n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures in the solid phase and compared with the results for D atoms produced by γ-radiolysis of decane.

Experimental

n-$C_{10}D_{22}$ and n-$C_{10}H_{22}$ were the same as used before.[3c] ^{6}Li enriched LiF, used as a target for ^{6}Li (n, α) T, has the ^{6}Li/(^{7}Li+^{6}Li) ratio of 0.95. The details of the neutron irradiations, performed in the KUR reactor of Kyoto University[4] and the JRR-4 reactor of the Japan Atomic Energy Research Institute, were described in the previous papers.[2] The irradiation times were 54 h at 20 K and 15 s at other temperatures. HT and DT were analyzed by radio-gas chromatography (5 m ferric oxide γ-alumina column at 77 K).

Results and Discussion

Though recoil T atoms cause abstraction, replacement, and fragmentation reactions with alkanes, the discussion in this paper will be confined only to the abstraction reaction which is one of the main processes in the T atom reactions and is closely related to the reaction by D atoms in the radiolysis. An apparent overall abstraction reaction in the n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ system will be represented by the following scheme.

$$\underset{(D)}{T} + n\text{-}C_{10}D_{22} \xrightarrow{p_D} \underset{(D_2)}{DT} + C_{10}D_{21}, \quad (1)$$

$$\underset{(D)}{T} + n\text{-}C_{10}H_{22} \xrightarrow{p_H} \underset{(HD)}{HT} + C_{10}H_{21}, \quad (2)$$

where p is the relative probability of the reactions. The T and D atoms are produced by the ^{6}Li(n, α)T reaction and the radiolysis of n-$C_{10}D_{22}$, respectively. The ratios of the HT yields to the DT yields at 77 K are shown in Fig. 1 and compared with HD/D_2 ratios for D atoms.[3]

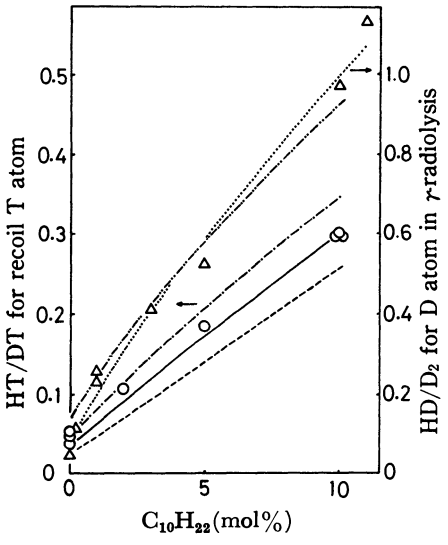

Fig. 1. Concentration dependence of HT/DT for recoil T atoms in the n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures at 77 K.
○: Experimental value for recoil T atoms, △···△, experimental value for D atoms in the radiolysis,[3a-c] –·–·–: calculated value for x=0.1, –·–·: calculated value for x=0.05, ——: Calculated value for x=0.03, – – –: calculated value for x=0.01. x is a fraction of diffusive T atoms to total recoil T atoms.

HT/DT is much lower than HD/D_2. Since 38% of the D_2 yield is formed by molecular detachment from n-$C_{10}D_{22}$ in the γ-radiolysis,[3c] HD/D_2 by the hydrogen atom abstraction reactions should be higher than the values in Fig. 1, resulting in the large difference between HT/DT and HD/D_2.

Recent studies show that thermal H atoms easily abstract H or D atom from alkanes at low temperature by a quantum mechanical tunneling.[5] Thus, both hot and thermal T atoms can abstract a hydrogen atom in Reactions 1 and 2. The ratio of relative probabilities for Reactions 1 and 2 is approximated by the following equation:

$$P = \frac{p_H}{p_D} = \frac{[HT][C_{10}D_{22}]}{[DT][C_{10}H_{22}]}. \quad (3)$$

The temperature effect on p_H/p_D for recoil T atoms is shown in Fig. 2. p_H/p_D for D atoms in the γ-radiolysis is also shown in Fig. 2.[3b,3c] Though the $(p_H/p_D)_D$ depends remarkably upon temperature, the $(p_H/p_D)_T$ shows little temperature effect.

The remarkable difference between the recoil T atom reaction and the D atom reaction in the γ-radiolysis can be explained by the following track model. The recoil T atom produced by the ^{6}Li(n, α)T reaction has an initial energy of 2.7 MeV and produces a high LET

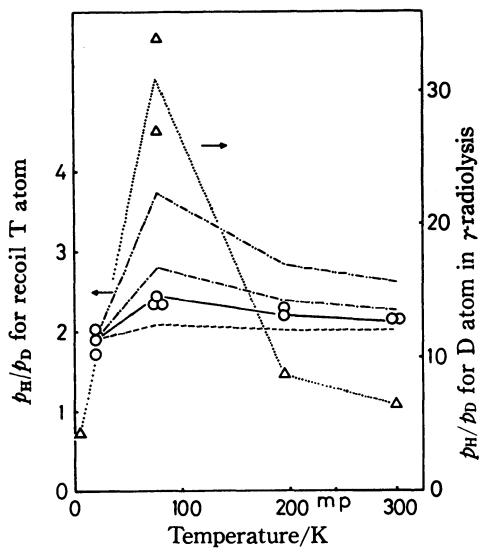

Fig. 2. Temperature dependence of p_H/p_D for recoil T atoms in the n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures.
○: Experimental value for recoil T atoms, △···△: experimental value for D atoms in the radiolysis,[3a-c] ·-·-·: calculated value for $x=0.1$, ·-·-·: calculated value for $x=0.05$, ——: calculated value for $x=0.03$, ——: calculated value for $x=0.01$. x is a fraction of diffusive T atoms to total recoil T atoms. Mp denotes a melting point of decane.

track along its trajectory in the solid phase. Some of the energetic T atoms react with n-$C_{10}D_{22}$ in the track by a hot atom reaction. However, a certain fraction of them escape reaction and finally become thermalized T atoms in the track. A fraction of the thermalized T atoms react near the end of the track, while the rest of them diffuse into the bulk matrix and react in a similar manner to D atoms in the γ-radiolysis.[6] Therefore the reaction of the recoil T atoms in the solid phase consists of two types; one occurs in the track of the recoil T atom and the other in the bulk matrix by diffusive T atoms. Then, Reactions 1 and 2 take place both in the track and in the bulk matrix. $P^t(=p_H{}^t/p_D{}^t)$ and $P^b(=p_H{}^b/p_D{}^b)$ can be defined in the track and in the bulk matrix, respectively. If x is the fraction of the T atoms, which diffuse into the bulk matrix, to the total T atoms, [HT]/[DT] can be evaluated by the following equation.

$$\frac{[HT]}{[DT]}=\frac{\dfrac{0.42(1-x)P^tm}{1+P^tm}+\dfrac{xP^bm}{1+P^bm}}{\dfrac{0.42(1-x)}{1+P^tm}+\dfrac{x}{1+P^bm}}, \quad (4)$$

where m is $[C_{10}H_{22}]/[C_{10}D_{22}]$.

It has been reported in solid neopentane that almost all the recoil T atoms react in the track at 20 K without diffusion into the bulk matrix and that 42% of the total T atoms produce hydrogen.[2b] Thus, it is assumed here that 42% of the recoil T atoms in the track reaction also produce hydrogen in the decane mixture. Then, the first and second terms in the numerator of Eq. 4 represent HT yields in the track and in the bulk matrix, respectively. The denominator represents the DT yields. Since the thermal diffusion of T atoms is suppressed at 20 K, the ratio $P(=p_H/p_D)$, calculated from [HT]/[DT] at 20 K, represents the ratio in the track reaction (P^t). P^b for diffusive T atoms may be equal to that for diffusive D atoms produced by γ-radiolysis.[6]

Then, [HT]/[DT] can be estimated in the cases of $x=0.1$, 0.05, 0.03, and 0.01 by using Eq. 4 (*cf.* Fig. 1).[7] The experimental data fit the cuves for $x=0.03$ or 0.05, suggesting that the amount of the diffusive T atoms is only 3—5% of the total T atoms. p_H/p_D can also be estimated at each temperature (*cf.* Fig. 2). The experimental data fit the curve for $x=0.03$.

In conclusion most of the recoil T atoms react in their own track and only a few percent of them diffuse into the decane matrix.

The authors wish to thank Prof. Hiroyuki Yoshida and the staff of the low temperature irradiation laboratory of the Research Veactor Institute, Kyoto University, for their fruitful advice. Part of this work was carried out under the Visiting Researchers Program of Research Reactor Institute, Kyoto University. (Received November 2, 1981)

From the view point of the effect of viscosity, the ^{35}Cl NMR line widths and the electrical conductivities were compared for the aqueous solutions of sodium chloride in the presence of polyethylene glycol. A criterion was proposed on the validity of the viscosity correction treatment for the NMR line width.

The line width of ^{35}Cl NMR, $\Delta\nu_{1/2}$, is governed by quadrupolar relaxation, and it is proportional to the product of the square of the quadrupolar coupling constant, e^2Qq, and the correlation time, τ_c, for molecular reorientation,

$$\Delta\nu_{1/2} \propto (e^2Qq)^2\tau_c. \quad (1)$$

In order to obtain information about the change in the field gradient, q, around a ^{35}Cl nucleus and to utilize the line width as a probe for investigating the condition of the nearest neighbours around a ^{35}Cl ion, the effect of τ_c on the line width has been eliminated effectively by dividing the line width by the macroscopic viscosity using the Einstein-Stokes relation, $\tau_c=4\pi a^3\eta/3kT$, where a is an ion radius, η is viscosity, and $3kT$ is thermal energy.[1,2] The validity and limitation of this viscosity correction treatment, however, have to be examined carefully, because the viscosity η should be microscopic in nature instead of macroscopic. Here we wish to present an example to discuss this problem and show a criterion on the validity of this viscosity correction treatment for the line width.

As a measure for the microscopic viscosity, we focus our attention on the electrical conductivity, κ, because it is well known that this relationship holds between the electrical conductivity and viscosity.

$$\kappa\eta = \text{constant}, \quad (2)$$

so far as Stokes' law is satisfied for a slowly moving sphere in a liquid. It is also known that this simple relation is valid only when we use the microscopic viscosity for η.[3,4]

Aqueous solutions of sodium chloride (0.1 mol kg^{-1}) in the presence of polyethylene glycol (PEG) with various molecular weights were studied, since the electrical conductivity of aqueous sodium chloride was determined in these solutions, the macroscopic viscosities of which range from 0.9 to 138 cP (1 cP=10^{-3} Pa s).[5] The composition of the solution, macroscopic viscosity, electrical conductivity, Walden product, and ^{35}Cl line width are summarized in Table 1. The results were quite straightforward. It is noticeable that both $\Delta\nu_{1/2}$ and κ^{-1} do not correlate with the macroscopic viscosity, which is illustrated in Fig. 1. These results arise from the fact that Eqs. 1 and 2 can be satisfied only for microscopic viscosity. A reasonably good linear correlation was found, on the other hand, in the $\Delta\nu_{1/2}$ against κ^{-1} plot of Fig. 2. This result indicates that $\Delta\nu_{1/2}$ and κ^{-1} are governed by the same physical quantity, namely, microscopic viscosity, although they correspond to different dynamical motions, namely, rotational and translational ones, respectively. It is also noticeable in Fig. 1 that a linear correlation could be recognized between $\Delta\nu_{1/2}$ and κ, or between κ^{-1} and η, for the entries 1, 2, and 6. The Walden products of these three are close to 1.0.

Based upon the above results, we propose a criterion to judge whether macroscopic viscosity can be used for the correction of line width in place of the microscopic one. The Walden product for a certain concentration of aqueous sodium chloride is to be determined

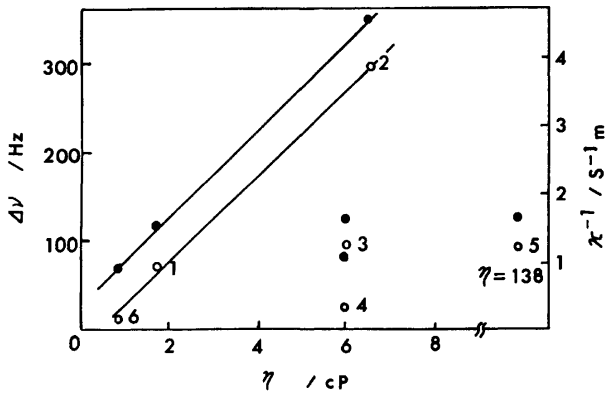

Fig. 1. Plots of the ^{35}Cl line width (○), and the inverse of electrical conductivity (●), *vs.* macroscopic viscosity η.

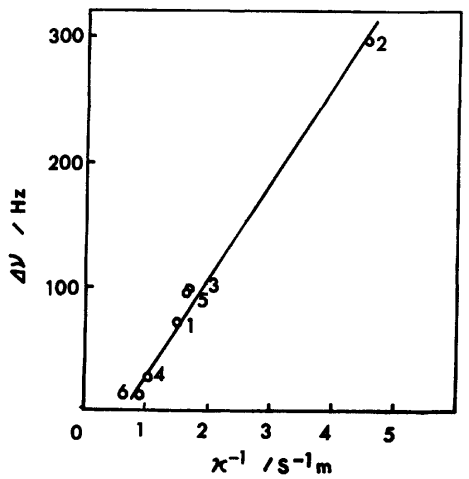

Fig. 2. The correlation between ^{35}Cl line width $\Delta\nu_{1/2}$ and the inverse of electrical conductivity κ^{-1}.

a) Concentration of sodium chloride was 0.1 mol kg^{-1} at 25 °C.

from conductivity and viscosity measurements in the absence of additives. If the Walden product of aqueous sodium chloride in the presence of additives (PEG in the present case) is close to the former value, microscopic viscosity can be replaced with macroscopic one in this solution. The idea obtained here would be quite useful for analyzing NMR line width on ionic species of quadrupolar nuclei.

Experimental

Polyethylene glycol (PEG 200, 4000, 20000) were supplied by Wako Pure Chemical Industries Ltd.[3] Sodium chloride was purchased as a special grade and used without further purification.

^{35}Cl FT-NMR was recorded on Varian's FT 80A in the same condition as described elsewhere.[2] The temperature of the probe was kept at 25±0.5 °C by the temperature variation accessary.

Zero-field Energy Levels in Near-doubly-degenerate Triplet States

Jiro Higuchi
Department of Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240

(Received November 14, 1981)

Synopsis. The zero-field energy levels in near-doubly-degenerate triplet states are discussed on molecules which are distorted so as to lose their trigonal symmetry axes. As an example, the second excited triplet states of a deformed benzene molecule are calculated from the electron spin-spin interactions.

In a previous paper,[1] the zero-field splitting (ZFS) parameters of the lowest and second excited triplet states of molecules with a trigonal symmetry axis were calculated from the electron spin-spin interactions:

$$\mathcal{H}_{ss} = \frac{\mu_0 g^2\beta^2}{4\pi}\left[\frac{(s_1\cdot s_2)}{r_{12}^3} - \frac{3(s_1\cdot r_{12})(s_2\cdot r_{12})}{r_{12}^5}\right]$$
$$= \frac{\mu_0 g^2\beta^2}{4\pi}\left[S_x^2\left(\frac{r_{12}^2-3x_{12}^2}{r_{12}^5}\right) + S_y^2\left(\frac{r_{12}^2-3y_{12}^2}{r_{12}^5}\right)\right.$$
$$+ S_z^2\left(\frac{r_{12}^2-3z_{12}^2}{r_{12}^5}\right) - (S_yS_z + S_zS_y)\frac{3y_{12}z_{12}}{r_{12}^5}$$
$$- (S_zS_x + S_xS_z)\frac{3z_{12}x_{12}}{r_{12}^5}$$
$$\left. - (S_xS_y + S_yS_z)\frac{3x_{12}y_{12}}{r_{12}^5}\right] \quad (1)$$

(μ_0: vacuum permeability; $S=s_1+s_2$: total spin) When such molecules are slightly distorted so as to lose their trigonal symmetry axes, the separations of ZFS in such near-degenerate states are not so simple, because of the interaction between these states. Although the ZFS parameters in the degenerate states were given in the previous paper,[1] the change in the zero-field (ZF) energy levels in such conformations was not discussed in detail. Also, no similar discussion has yet been carried out for aromatic molecules,[2] possibly because of a lack of experimental evidence. In the present work, therefore, the influence of such molecular deformation upon the ZF energy levels in near-doubly-degenerate triplet states is studied semi-quantitatively. In the course of this study, the ZFS's were simply evaluated by assuming them to originate from the electron spin-spin interactions, $\mathcal{H}_{ss}$.

In discussing near-doubly-degenerate states, a set of the corresponding near-degenerate real orbital functions is expressed as Ψ_X and Ψ_Y, which are orthogonal with each other and which are assumed to be symmetric with respect to the x and y axes respectively, and antisymmetric with respect to the y and x axes respectively [the x and y axes are perpendicular to the trigonal symmetry axis (z)]. It may be noted here that the ZF energy levels should not be calculated separately using each of these near-degenerate orbital parts because of the non-zero off-diagonal element of $\langle\Psi_X|-2x_{12}y_{12}/r_{12}^5|\Psi_Y\rangle$. Therefore, the basis set chosen consist of the following six functions:

$$|\Psi_X{}^3\Theta_X\rangle,\ |\Psi_X{}^3\Theta_Y\rangle,\ |\Psi_X{}^3\Theta_Z\rangle,$$
$$|\Psi_Y{}^3\Theta_X\rangle,\ |\Psi_Y{}^3\Theta_Y\rangle,\ \text{and}\ |\Psi_Y{}^3\Theta_Z\rangle. \quad (2)$$

Here,

$$^3\Theta_X = 2^{-1/2}[\beta(1)\beta(2) - \alpha(1)\alpha(2)]$$
$$^3\Theta_Y = 2^{-1/2}i[\beta(1)\beta(2) + \alpha(1)\alpha(2)] \quad (3)$$
$$^3\Theta_Z = 2^{-1/2}[\alpha(1)\beta(2) + \beta(1)\alpha(2)].$$

If the spin-free Hamiltonian is expressed as $\mathcal{H}_0$, the matrix of the Hamiltonian $\mathcal{H}=\mathcal{H}_0+\mathcal{H}_{ss}$ with the above six basis functions may be described as follows:

$$\begin{array}{c} \\ \langle\Psi_X{}^3\Theta_X| \\ \langle\Psi_X{}^3\Theta_Y| \\ \langle\Psi_X{}^3\Theta_Z| \\ \langle\Psi_Y{}^3\Theta_X| \\ \langle\Psi_Y{}^3\Theta_Y| \\ \langle\Psi_Y{}^3\Theta_Z| \end{array} \begin{array}{c} \begin{array}{cccccc} |\Psi_X{}^3\Theta_X\rangle & |\Psi_X{}^3\Theta_Y\rangle & |\Psi_X{}^3\Theta_Z\rangle & |\Psi_Y{}^3\Theta_X\rangle & |\Psi_Y{}^3\Theta_Y\rangle & |\Psi_Y{}^3\Theta_Z\rangle \end{array} \\ \begin{pmatrix} W_X+\frac{1}{3}D_X-E_X & 0 & 0 & 0 & -F_{XY} & 0 \\ 0 & W_X+\frac{1}{3}D_X+E_X & 0 & -F_{XY} & 0 & 0 \\ 0 & 0 & W_X-\frac{2}{3}D_X & 0 & 0 & 0 \\ 0 & -F_{XY} & 0 & W_Y+\frac{1}{3}D_Y-E_Y & 0 & 0 \\ -F_{XY} & 0 & 0 & 0 & W_Y+\frac{1}{3}D_Y+E_Y & 0 \\ 0 & 0 & 0 & 0 & 0 & W_Y-\frac{2}{3}D_Y \end{pmatrix} \end{array} \quad (4)$$

where:

$$W_i = \langle\Psi_i|\mathcal{H}_0|\Psi_i\rangle \qquad (i = X, Y) \quad (5)$$

$$D_i = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle\Psi_i\left|\frac{r_{12}^2-3z_{12}^2}{r_{12}^5}\right|\Psi_i\right\rangle$$

$$E_i = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle\Psi_i\left|\frac{y_{12}^2-x_{12}^2}{r_{12}^5}\right|\Psi_i\right\rangle \qquad (i = X, Y) \quad (6)$$

and

$$F_{XY} = \frac{3\mu_0 g^2\beta^2}{16\pi hc}\left\langle\Psi_X\left|\frac{-2x_{12}y_{12}}{r_{12}^5}\right|\Psi_Y\right\rangle.$$

When Ψ_X and Ψ_Y are perfectly degenerate, that is, $W_X=W_Y=W^\circ$, the following relations are obtained:

$$D_X = D_Y = D^\circ$$
$$\text{and} \qquad E_X = -E_Y = F_{XY} = E^\circ \quad (7)$$

As a result, the energies of the ZF levels obtained are two single and two doubly degenerate ones:

$$W = \frac{1}{3}D^\circ + 2E^\circ, \frac{1}{3}D^\circ, \frac{1}{3}D^\circ,$$
$$\frac{1}{3}D^\circ - 2E^\circ, -\frac{2}{3}D^\circ, \text{and} -\frac{2}{3}D^\circ, \quad (8)$$

relative to W°. Since the representation of the spin function $^3\Theta_i$ (i=X, Y, Z) is the same as that of the corresponding component of angular momentum (*e.g.*, E_{1g} and A_{2g} for the D_{6h} symmetry), the above numbers of single and doubly degenerate levels can be deduced from a consideration of the group theory. For example, in the case of the $^3E_{1u}$ state of benzene with the D_{6h} symmetry,

$$E_{1u} \times (A_{2g} + E_{1g}) = A_{1u} + A_{2u} + E_{1u} + E_{2u}. \quad (9)$$

The above conclusion should not be changed if the complex orbital parts of $2^{-1/2}[\Psi_X \pm i\Psi_Y]$ are used instead of the real functions of Ψ_X and Ψ_Y.

When the molecule is distorted very slightly so as to lose a trigonal symmetry axis and the electronic energy

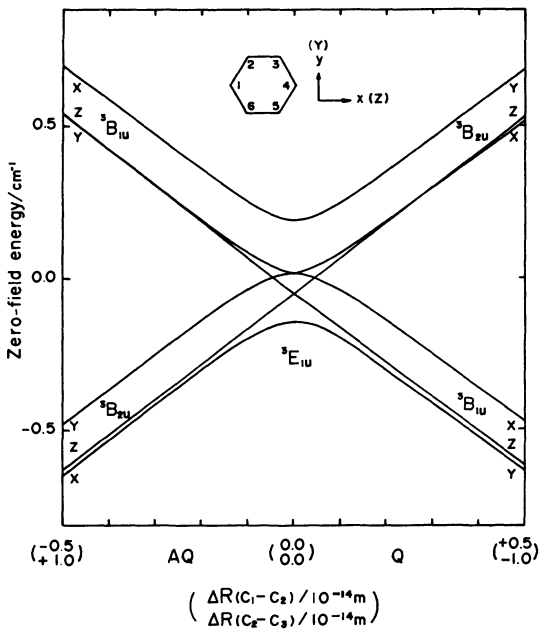

Fig. 1. Zero-field energy levels in the second excited triplet states of benzene with antiquinonoidal(AQ) and quinonoidal (Q) forms. The axis system for D_{2h} symmetry is indicated in parentheses.

separation between these near-degenerate states, $\Delta W = |W_X - W_Y|$, becomes the same order as $|F_{XY}|$, the ZF energy levels except for $|\Psi_X{}^3\Theta_Z\rangle$ and $|\Psi_Y{}^3\Theta_Z\rangle$ are somewhat complicated because of the considerable contribution of F_{XY}, as can be seen in Fig. 1. However, when the molecule is further distorted with an energy separation of $\Delta W \gg |F_{XY}|$, the energies of these states with ZFS may be approximately expressed as:

$$W = W_X - \frac{2}{3}D_X,$$

$$W_X + \frac{1}{3}D_X \pm E_X + F_{XY}{}^2/(W_X - W_Y),$$

$$W_Y - \frac{2}{3}D_Y, \text{ and}$$

$$W_Y + \frac{1}{3}D_Y \pm E_Y - F_{XY}{}^2/(W_X - W_Y). \quad (10)$$

As a result, the apparent D values observable in these states are:

$$D_X{}^\dagger = D_X + F_{XY}{}^2/(W_X - W_Y)$$

and (11)

$$D_Y{}^\dagger = D_Y - F_{XY}{}^2/(W_X - W_Y),$$

while the E values are not changed from E_X and E_Y respectively. As $D_X \approx D_Y$ in these near-degenerate states, the difference in the apparent D values may possibly be useful as a factor in estimating the molecular distortion. In the above cases, the principal magnetic x and y axes are not perfectly parallel to any symmetry axis of the molecule, for example, the x and y axes of the distorted benzene molecule shown in Fig. 1. On the other hand, when the magnetic field is applied not parallel to the trigonal symmetry axis (z), the energy levels are more complicated because of the mixing of more than two basis functions (2).

As a typical example, Fig. 1 shows the ZF energy levels of distorted benzene in the second excited triplet states with the D_{2h} symmetry. The coordinate system and the numbering of the constituent carbon atoms are taken as shown in Fig. 1. The conformation of the distorted molecule is assumed to be as follows: (i) All the bond angles are unchanged from those of the ground state with the D_{6h} symmetry;[3] and (ii) the bond lengths are changed as follows:

$$\Delta R(C_1\text{–}C_2) = \Delta R(C_3\text{–}C_4) = \Delta R(C_4\text{–}C_5)$$
$$= \Delta R(C_6\text{–}C_1) = -\Delta R(C_2\text{–}C_3)/2 = -\Delta R(C_5\text{–}C_6)/2.$$

The calculations carried out for the electronic energy and for the ZFS parameters were quite the same as those of Treatment (C) in the previous paper.[1] Further, the influence on the change of bond angels was examined on the assumptions that: (i) all the C–C bond lengths are unchanged from those of the ground state;[3] and (ii) the bond angles are changed as follows:

$$\Delta\angle C_6C_1C_2 = \Delta\angle C_3C_4C_5 = -2\Delta\angle C_1C_2C_3$$
$$= -2\Delta\angle C_2C_3C_4 = -2\Delta\angle C_4C_5C_6 = -2\Delta\angle C_5C_6C_1.$$

In this case, the trend of the ZF energy levels due to the changes in the bond angles is very close to that due to the changes in the bond lengths within the ranges shown in Fig. 1 if one reads $\Delta\angle C_6C_1C_2 \approx \pm(2.7\times10^{-2})°$ for $\Delta R(C_1\text{–}C_2) = \pm 0.1\times10^{-14}$ m, respectively.

In general, the excited molecules trapped in host glasses or crystals are more distorted than the distortion discussed here.[4] As a result, it may actually be impossible to observe transitions among ZF energy levels in degenerate triplet states, while there remains some possibility of detecting molecules with a very slight Jahn-Teller distortion in the gas phase. Although the experimental technique has not yet been improved for observing the magnetic resonance of the second excited triplet states of aromatic molecules, the present relation expected in near-degenerate triplet states may be of interest in discussing the molecular deformation due to environmental influence in orbitally degenerate phosphorescent triplet states of molecules such as aromatic ions, ESR experiments on which were made by de Groot *et al.*[5]

The author wishes to thank Professor Takashi Itoh, Ochanomizu University, for his helpful suggestion.

Selective Transport of Potassium Ions against Their Concentration Gradient by Pentaethylene Glycol Derivative Containing Both 8-Quinolyl and *o*-Carboxylphenyl Terminal Groups[1]

Kazuhisa HIRATANI

Industrial Products Research Institute, Higashi 1-chome, Yatabe-machi, Tsukuba-gun, Ibaraki 305

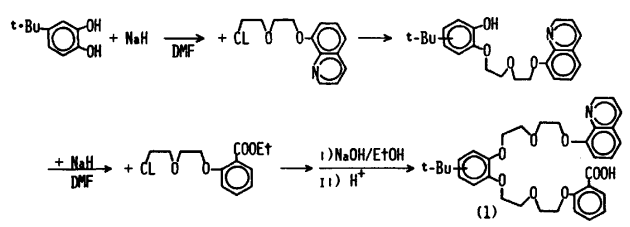
(Received June 8, 1981)

Synopsis. A pentaethylene glycol derivative containing both 8-quinolyl and *o*-carboxylphenyl terminal groups can transport potassium ions selectively against the concentration gradient in liquid membrane systems containing more than one alkali ion species in aqueous solution. Uptake of cations by this synthetic ionophore from the aqueous solution into the organic layer is confirmed to be important for exhibiting this excellent selectivity toward potassium ions.

Some of the noncyclic polyether compounds have been reported to be selective carriers of cations in the liquid membrane system.[2] The author and coworkers have recently reported that the oligoethylene glycol derivatives containing both basic quinolyl and acidic carboxyl terminal groups exhibit the selective uptake of an alkali ion into chloroform.[3] They also exhibit the transport of alkali ions against the concentration gradient in the presence of single cation species in the aqueous solution; the properties of complexation and transport are largely dependent on the length of the oxyethylene chain.[4] In this study the author wishes to report the selective transport of potassium ions in aqueous solutions containing some other alkali ion species through liquid membranes by a synthetic polyether (**1**).

Results and Discussion

The pentaethylene glycol derivative (**1**), in which the 4-*t*-butyl *o*-phenylene group is introduced among the oxyethylene chains, was prepared by the procedure described below. It is a glassy solid (pale yellow): $UV_{max}(CHCl_3)$ 286 nm (ε=8300); IR (neat) 3250 and 2550 (carboxyl OH), 1740—1680 (broad, carboxyl C=O), and 1160—1080 cm^{-1} (ether C–O–C); NMR ($CDCl_3$) δ=8.93 (1H, m, aromatic), 8.15 (1H, m, aromatic), 8.02 (1H, m, aromatic), 7.5—6.8 (10H, m, aromatic), *ca.* 7.5 (1H, broad, COOH), 4.5—3.7 (16H, m, O–CH_2–CH_2–O), and 1.28 (9H, s, C–CH_3). Found: C, 69.91; H, 6.23; N, 2.54%. Calcd for $C_{34}H_{39}N_1O_8$: C, 69.25; H, 6.67; N, 2.38%.



Transport of alkali ions across a chloroform liquid membrane by the synthetic ionophore (**1**) was carried out in a previously-described U-type cell[4] at 25±0.2 °C. The solution was stirred at 200 min^{-1}. The amounts of the metal ion transported from Phase I (an alkaline aqueous solution) to Phase II (an acidic aqueous solution) were determined by atomic absorption analysis for lithium, sodium, and potassium ions, and flame analysis for rubidium and caesium ions.

The experimental results are shown in Figs. 1 and 2. In the control experiment (without ionophore) the ion transport was confirmed to be negligible even after 2 d.[4] As indicated in Fig. 1,[5] in the ion transport experiment for the single alkali ion species, the difference of the transport capability of the ionophore (**1**) for each alkali ion seems to be small. Surprisingly, the transport phenomena for the three alkali ion species (Li, Na, and K) existing together, as shown in Fig. 2, are quite different from that in Fig. 1. Under these conditions, potassium ions were selectively transported by **1**, while little transport of lithium ions was detected in Phase II and the amount of sodium ions transported was less than 1/4 of the amount of potassium ions. The ionophore

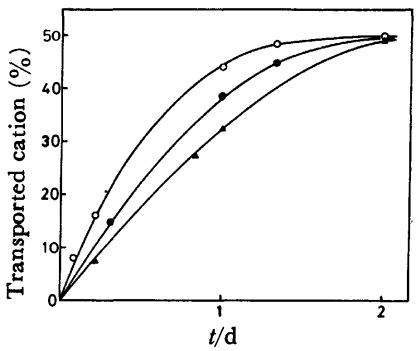


Fig. 1. Ion transport by **1** for single cation species.[5] Phase I: 15 ml of 0.1 M alkali hydroxide aqueous solution; Phase II: 15 ml of 0.1 M alkali chloride +0.1 M HCl aqueous solution; Phase III: 30 ml of chloroform containing 1.5×10^{-4} mol of **1**. —○—: K^+, —●—: Na^+, —▲—: Li^+.

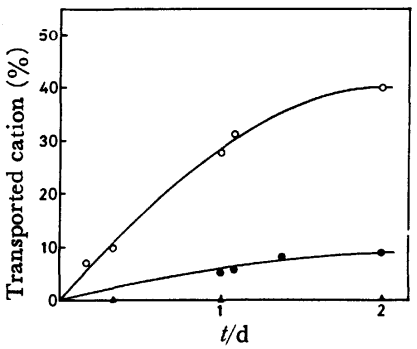

Fig. 2. Ion transport by **1** for lithium, sodium, and potassium ion species existing together. Conditions: see Table 1. —○—: K^+, —●—: Na^+, —▲—: Li^+.

Table 1. Ion transport by 1 through chloroform membrane

Coexistent cations	Transported cation after 2 d (%)[d] Li (1.32)	Na (1.90)	K (2.66)	Rb (2.98)	Cs (3.38)	Total	Selectivity for K^+
Li/Na/K (1 : 1 : 1)[a]	≈0	9	40	—	—	49	K/Li≫10 K/Na=4.4
Na/K/Ca (1 : 1 : 1)[b]	—	5	36	—	8	49	K/Na=7.2 K/Cs=4.5
K/Rb (1 : 1)[c]	—	—	33	17	—	50	K/Rb=1.9

a) Phase I: 15 ml of 0.1 M LiOH+0.1 M NaCl+0.1 M KCl aqueous solution; Phase II: 15 ml of 0.1 M LiCl+0.1 M NaCl+0.1 M KCl+0.1 M HCl aqueous solution; Phase III: 30 ml of chloroform containing 1.5×10^{-4} mol of **1**. b) Phase I: 15 ml of 0.1 M NaOH+0.1 M KCl+0.1 M CsCl aqueous solution; Phase II: 15 ml of 0.1 M NaCl+0.1 M KCl+0.1 M CsCl+0.1 M HCl aqueous solution; Phase III: 30 ml of chloroform containing 1.5×10^{-4} mol of **1**. c) Phase I: 15 ml of 0.1 M KOH+0.1 M RbCl aqueous solution; Phase II: 15 ml of 0.1 M KCl +0.1 M RbCl+0.1 M HCl aqueous solution; Phase III: 30 ml of chloroform containing 1.5×10^{-4} mol of **1**. d) The values in parentheses are the ionic diameters (Å) of each cation.

(**1**) also exhibits a large selectivity toward potassium ions both for sodium, potassium, and caesium ions existing together and for potassium and rubidium ions existing together; these latter have almost the same ionic diameter, 2.66 and 2.98 Å respectively (see Table 1).

From Table 1, the order of the cation selectivity of **1** is as follows: $K^+>Rb^+>Cs^+\approx Na^+>Li^+$. And in every case, the total amounts cations transported reach finally about 50% after two days. It is considered that hydrochloric acid not only is consumed to release the cation transported into Phase II from Phase III (an organic layer), but also reacts with alkali hydroxide in Phase I to give the alkali halide, because hydrochloric acid can be carried as the quinolinium salt of **1** in the reverse direction from Phase II to Phase I across Phase III.[4]

In Table 2 are shown the results of uptake of alkali ions into the organic layer from aqueous solution in the presence of the ionophore (**1**). These results correspond to those of the transport experiment (see Table 1). Thus, it is considered that the step of the uptake of the cation into the chloroform layer from Phase I is important for exhibiting the excellent selectivity with 9 toward potassium ions in these transport experiments. The detailed mechanism of the cation selectivity of **1** is now under investigation.

Experimental

General Procedure of Ion Transport. In the cell was placed 30 ml of chloroform containing 1.5×10^{-4} mol of **1**. The two kinds of aqueous solutions used for Phases I and II were subsequently poured into the appropriate side. The cell was placed in a water bath. The transport of alkali ions was initiated by the addition of the aqueous solutions. At each time point, 50-μl of solution was withdrawn from each phase, and the concentration of cation was adjusted by using a measuring flask and determined by atomic absorption or flame analysis.

Table 2. Extraction of alkali ions into chloroform layer

a) For single ion species.

Alkali ion species	Li	Na	K	Rb	Cs
Decrease of cation in aq solution (%)	39	43	43	41	41

Initial aqueous layer: 1.0 ml of 0.1 M alkali hydroxide; Organic layer: 0.05 mmol of **1** in 2.0 ml of $CHCl_3$.

b) For multiple ion species.

Alkali ion species	Li Na K	Na K Cs	K Rb
Decrease of cation in aq solution (%)	3 7 36	5 32 7	32 17
Composition of cation in 1.0 ml of initial aqueous layer	0.1 M LiOH +0.1 M NaCl +0.1 M KCl	0.1 M NaOH +0.1 M KCl +0.1 M CsCl	0.1 M KOH +0.1 M RbCl
Organic layer	0.05 mmol of **1** in 2.0 ml of $CHCl_3$		

Extraction of Alkali Ion with 1 into Chloroform. In a 5-ml microvial, which contained a small stirrer, was placed 2.0 ml of chloroform containing 0.5×10^{-4} mol of **1** and 1.0 ml of an aqueous solution containing one or more alkali ions, as described in Table 2. After the solution was stirred at room temperature for 1 d, the concentration of alkali ions in the upper aqueous solution was determined by atomic absorption or flame analysis.

Extraction of Lead(II) in Aqueous Halide-Perchlorate Solutions with Trioctylphosphine Oxide in Hexane

Satoshi KUSAKABE and Tatsuya SEKINE*
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 23, 1981)

Synopsis. The stability and the extractability with trioctylphosphine oxide(L) in hexane of lead(II) halide complexes in 1 mol dm^{-3} Na(ClO_4) were studied. The complexes were stable and more extractable in the following order of the ligands: $Cl^- < Br^- < I^-$. The maximum numbers of the ligand (n) in the complexes PbX_n^{2-n} were 2(Cl^-), 3 (Br^-), and 4 (I^-). The chemical forms of the extracted species with L were in all cases $Pb(ClO_4)_2L_2$, $PbX(ClO_4)L_3$, and PbX_2L_2.

The solvent extractions of lead(II) in aqueous 1 mol dm^{-3} Na(X, ClO_4) ionic media (where X^- is Cl^-, Br^-, or I^-) with 2-thenoyltrifluoroacetone (TTA) in carbon tetrachloride and with trioctylphosphine oxide (TOPO) in hexane have been measured at 25 °C and the stability constants of the PbX_n^{2-n} species as well as their extraction constants with the latter extractant were calculated.

Experimental and Statistical

Experiments were made in the same way as described previously[1] except that sodium halides were used instead of sodium thiocyanate. The initial aqueous concentration of lead(II) was always 1×10^{-4} mol dm^{-3}. The distribution ratio of lead(II) is defined by:

$$D = [Pb(II)]_{org}/[Pb(II)] \quad (1)$$

$$= K_{TTA,O}[H^+]^{-2}[Htta]_{org}^2/(1 + \beta_1[X^-] + \beta_2[X^-]^2 + \cdots + \beta_n[X^-]^n) \quad (2)$$

$$D[H^+]^2[Htta]org^{-2}/K_{TTA,O} = D/D_0 = 1/(1 + \sum \beta_i[X^-]^i), \quad (3)$$

where D_0 is the distribution ratio in the absence of halide ions. The stability constants may be calculated from the decrease in the distribution ratio as a function of the ligand concentration.

The distribution ratio in the extraction with TOPO(L) from these solutions could be represented by:

$$D = \sum [PbX_n(ClO_4)_{2-n}L_m]_{org}/[Pb^{2+}](1 + \sum \beta_i[X^-]^i) = \sum K_{ex\ n,m}[X^-]^n[ClO_4^-]^{2-n}[L]_{org}^m/(1 + \sum \beta_i[X^-]^i), \quad (4)$$

where $n=0$ to 2, $m=4-n$, and the extraction constants are defined by:

$$K_{ex\ n,m} = \frac{[PbX_n(ClO_4)_{2-n}L_m]_{org}}{[Pb^{2+}][X^-]^n[ClO_4^-]^{2-n}[L]_{org}^m}. \quad (5)$$

The free TOPO concentration at equilibrium, $[L]_{org}$, can be related to its initial concentration, $[L]_{org,I}$, as:

$$[L]_{org,I} = [L]_{org} + \sum m[PbX_n(ClO_4)_{2-n}L_m]_{org} + 3[NaClO_4L_3]_{org} = [L]_{org} + \sum mK_{ex\ n,m}[X^-]^n[ClO_4^-]^{2-n}[L]_{org}^m + 3K_{ex\ Na}[ClO_4^-][L]_{org}^3. \quad (6)$$

The extraction constants of lead perchlorate, $K_{ex\ 0,4}$, and sodium perchlorate, $K_{ex\ Na}$ with TOPO in hexane have been reported to be $10^{6.92}$,[1] and $10^{1.01}$,[2] respectively. By using a least squares program including a successive approximation procedure of the free TOPO concentration on the basis of Eqs. 4 and 6, the stability constants and the extraction constants were calculated.

Results and Discussion

In the lead(II) extraction with TTA from aqueous solutions above 0.04 mol dm^{-3} of iodide, the recovery of the metal was not quantitative and dark-red precipitations were found on the interface. Thus the chelate extraction from the iodide solutions was made only in the concentration range lower than this. The extraction of lead(II) from the 1 mol dm^{-3} Na(X, ClO_4) solutions with TOPO in hexane as a function of the ligand concentration in the aqueous phase is shown in Figs. 1 and 2. Precipitations of iodide were not observed in the case of TOPO extraction, but loss of the metal from the two phases was found when TOPO concentration was 2×10^{-3} mol dm^{-3} and the iodide concentration was 0.1 to 0.2 mol dm^{-3}. For this reason, those data were not included in the data analysis.

In the chloride and bromide systems, a set of stability constants which could explain both the TTA and TOPO extraction data were obtained; these are listed in Table 1. In the iodide system, the TTA extraction could be carried out only in the lower ligand concentration range and thus only β_1 could be obtained. On the other hand, the TOPO extraction could cover the whole concentration range and the values β_1, β_2, β_3, and β_4

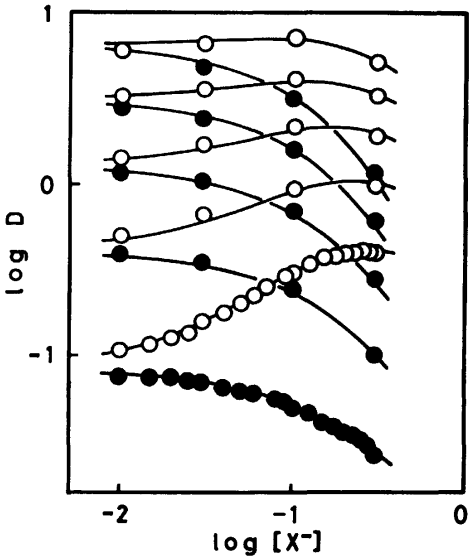

Fig. 1. Extraction of Pb(II) in 1 mol dm^{-3} Na(X, ClO_4) with TOPO in hexane, where $X^- = Cl^-$ (●) and Br^- (○). The initial concentration of TOPO in the organic phase was 0.03, 0.025, 0.02, 0.015, and 0.01 mol dm^{-3} from the top to bottom, respectively. The solid curves were calculated by Eqs. 4 and 6 using the constants in Table 1.

Table 1. Summary of the stability and extraction constants of lead(II) halide complexes

X^-	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$	$\log \beta_4$	$\log K_{ex1,3}$	$\log K_{ex2,2}$
Cl^-	0.83±0.20	1.3	nil	nil	5.52±0.21	3.5
Br^-	0.93±0.21	1.6±0.3	2.0	nil	6.52±0.15	5.57±0.11
I^-	1.29±0.15	1.8	3.0	3.9	8.0	8.35±0.11

The possible error is 3σ. When the possible error is not given, it is larger than 0.3. The $K_{ex\ n,m}$ (Eq. 5) were calculated by means of Eq. 4, using the above stability constants and the value of $K_{ex\ 0,4}=10^{6.92}$.

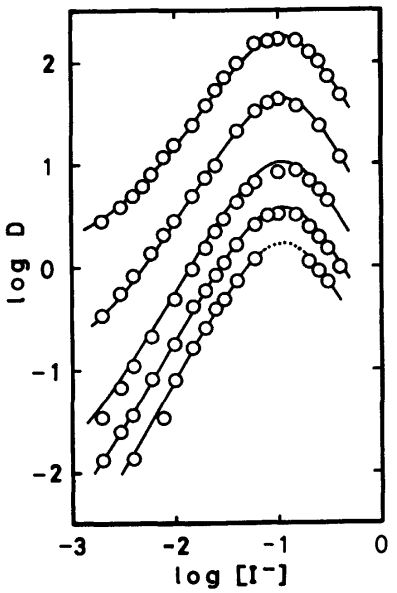

Fig. 2. Extraction of Pb(II) in 1 mol dm^{-3} Na(I, ClO_4) solutions with TOPO in hexane. The initial concentration of TOPO in the organic phase was 0.02, 0.01, 0.005, 0.003, and 0.002 mol dm^{-3} from the top to bottom, respectively. The solid curves were calculated by Eqs. 4 and 6 using the constants in Table 1.

were obtained. However, the possible errors of these constants are not small. The extraction constants with TOPO of the lead(II) species listed in Table 1 were also computed from these data.

The stability constants of lead(II) halide complexes in the present paper agreed well with the literature values obtained under the identical conditions by means of polarography.[3,4] The first complexes, PbX^+, are more stable than the thiocyanate complex ($\beta_1=10^{0.49}$).[1] The sum of the number of the ligand and TOPO molecules in the extracted species was always four, although that of the thiocyanate complexes was four or five.[1] Similar numbers were reported in the extraction of zinc(II) from perchlorate–halide[5] and –thiocyanate[6] systems. This suggests that the ligand ions and TOPO molecules are coordinated with the metal ion in the halides but some of the ligand ions are electrostatically attracted in the extracted thiocyanate species.

The extraction of lead(II) under the same concentration of TOPO and a certain given ligand ions was in the order of $I^->SCN^->Br^->Cl^-$, while the stabilities of the lead complexes in the aqueous phase was $I^->Br^->Cl^->SCN^-$. In the case of zinc(II),[5] the order of the stability in the aqueous solution was $SCN^->Cl^->Br^->I^-$ and that of the extraction was $SCN^->I^->Br^->Cl^-$. The orders found with zinc(II) were explained in the previous paper in terms of the size and the stability of the halide and thiocyanate complexes. The extractability of the unchanged complexes with TOPO is represented by:

$$MX_2 + 2L(org) \rightleftarrows MX_2L_2(org)$$

$$K^*_{ex\ 2,2} = [MX_2L_2]_{org}[MX_2]^{-1}[L]_{org}^{-2} = K_{ex\ 2,2}/\beta_2. \quad (7)$$

The following values of $K^*_{ex2,2}$ were obtained from the results in Table 1: $10^{2.2}$, $10^{4.0}$, and $10^{6.6}$ for $PbCl_2$, $PbBr_2$, and PbI_2, respectively. Dihalogenozinc(II) complexes are too unstable to be measured, but it should be reasonable to assume that the β_2 values are smaller than unity. Thus from Eq. 7, the $K^*_{ex2,2}$ values for dihalogenozinc(II) complexes should be larger than the $K_{ex2,2}$ values, ($10^{3.64}(ZnCl_2)$, $10^{4.51}(ZnBr_2)$, and $10^{6.12}(ZnI_2)$).[5] From the range of these $K^*_{ex2,2}$ values, the dihalogenolead(II) complexes are assumed to be less extractable with TOPO than the corresponding zinc(II) complexes, although they are thermodynamically more stable than the corresponding zinc(II) complexes.

The extractability of uncharged complexes with solvating extractants such as TOPO is affected by both of the partition coefficient of the unchanged complexes and by their tendency to solvate in the organic phase,[7] but since the values $[PbX_2]_{org}/[PbX_2]$ for hexane containing no TOPO were too small to be determined, no conclusion about this problem could be reached in this study.

Effect of Molecular Size on the Association of *p*-Quinone Anion and Lithium Ion in *N,N*-Dimethylformamide

Tsutomu NAGAOKA,* Satoshi OKAZAKI, and Taitiro FUJINAGA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received September 29, 1981)

Synopsis. Ion pair formation effects of metal ions on the electro-reduction of *p*-quinones in *N,N*-dimethylformamide were studied systematically by polarography. The formation constants of 1 : 1 and 1 : 2 associates, as evaluated by the $1/F_0^2$-weighted least squares method, decrease with increase in the anion size.

In a previous paper,[1] the authors presented effects of the carbonyl group geometry on ion association of several types of carbonyl compound anions and metal cations. The degree of the half-wave potential shifts due to the ion pair formation was observed in the order of *p*-quinones<ketones<*o*-quinones with various uni- and bivalent metal cations. The interaction between the anion and cation can be considered to occur mainly near the carbonyl oxygen of the anion. Taking into consideration the probability of two ions to come into contact, stronger association is expected for the *p*-quinone ion pairs than for the ketone ones. However, the experimental results showed the contrary and, therefore, it was concluded that the factor affecting the ion pair formation of these compounds is not the number of carbonyl groups but their geometry (*i.e.*, charge localization).

In the present paper, we will discuss another factor affecting the association behavior of carbonyl compound anions, *i.e.*, their anion size, studied by polarography. *p*-Quinones were studied because their half-wave potential shifts due to ion pair formation are not large and, therefore, the above effect could be expected to be predominant compared to the geometry effect. In these systems, however, formation of 1 : 2 associates as well as 1 : 1 ones must be taken into consideration.

Experimental

Reagent grade *p*-quinones were used without further purification except for 9,10-anthraquinone which was recrystalized twice from ethanol. Reagent grade *N,N*-dimethylformamide (DMF, Nakarai Chemicals Co.) was distilled by the method described previously.[2] Polarographic measurements were made with a PAR model 173 and a Yanaco P-1000 at 25 °C. The potential scan rate used was 0.5 mV/s and the initial potential was measured to 0.1 mV with a Digital Multimeter TR-6854 (Takeda Riken Co.). The measured value of potential gave a precision of about 0.5 mV. Numerical calculation was carried out on a FACOM M-200 computer at the data processing center of Kyoto University with time sharing services.

Results and Discussion

All *p*-quinones studied underwent 2 one-electron reductions and generated stable mono- and dianions. In the presence of excess alkali metal ion, it is known from ESR studies in ether that 1 : 2 associates as well as 1 : 1 ones are formed.[3] In a previous study,[1] their presence was confirmed by polarography even in the dipolar solvent of DMF, provided the metal ion was present in large excess.

The polarographic half-wave potential shift, $\Delta E_{1/2}$, due to ion pair formation can be explained by the following mechanism: after the first one-electron reversible reduction, the following equiliblium formulas are possible:

$$Q^{-\cdot} + M^+ \rightleftharpoons Q^{-\cdot}M^+, \quad (1)$$

$$Q^{-\cdot}M^+ + M^+ \rightleftharpoons Q^{-\cdot}(M^+)_2, \quad (2)$$

where $Q^{-\cdot}$, M^+, $Q^{-\cdot}M^+$, and $Q^{-\cdot}(M^+)_2$ represent a *p*-quinone anion, a metal cation, 1 : 1 associates and 1 : 2 associates, respectively. Accordingly, 59 and 118 mV potential shifts should be observed at 25 °C for the quantitative formation of 1 : 1 and 1 : 2 associates with tenfold increase in the metal ion concentration, respectively. For the evaluation of association constants from the polarographic results, the $1/F_0^2$-weighted least squares method described by Momoki *et al.* was applied.[1,4] The variation in the junction potential between a reference electrode and the solution with the metal ion concentration was found to be negligible from the following experimental result: the half-wave potential due to the reduction of potassium or sodium perchlorate remained constant with various concentrations of lithium perchlorate where the ionic strength of the solution was adjusted to 0.3 M (1 M=1 mol dm^{-3}) with tetraethylammonium perchlorate. As seen from Fig. 1, $\Delta E_{1/2}$ was largest for 1,4-benzoquinone and

a) Ionic strength was adjusted to 0.3 M with tetraethylammonium perchlorate. b) K_1 and K_2 represent formation constants of 1 : 1 and 1 : 2 associates, respectively.

decreased with increase in molecular size. The associates of 1 : 2 were also formed at higher lithium ion concentrations. Table 1 shows the results of the above calculation together with 95% confidence levels based on Student's T. From this table, it is obvious that the formation constants of both the 1 : 1 and 1 : 2 associates decrease with increase in anion size. Although the 1 : 1 associate has a zero net charge, the second cation can approach it because it constitues an electrostatic dipole.

For the association between two spherical univalent ions, the Fuoss equation can be applied[5)] and the formation constant, K_A (M^{-1}), is expressed by

$$K_A = (4\pi La^3 \times 10^{27}/3)\exp(e^2/4\pi\varepsilon_0\varepsilon_r akT), \quad (3)$$

where L, a, and ε_r represent the Avogadro constant, the contact distance between two ions (m), and the relative permittivity of the solvent, respectively, and the other symbols are used with usual meanings. In Table 1, the a-values for 1 : 1 associates calculated from the experimental results are also given. Applying the Fuoss equation, we ignored the solvent dielectric saturation effect, which often makes the ε_r-value decrease in the case of relatively small ions. This will cause relatively large increase in the contact distance a. Although it is also difficult to estimate a-values of actual ion pairs, reasonable correlations were obtained between the calculated a-values and the anion molecular sizes. From the formation constant 1.0×10^4 M^{-1} of Li+-9, 10-phenanthraquinone$^{-\cdot}$ ($PQ^{-\cdot}$) evaluated in our previous study,[1)] an a-value of 1.0×10^{-10} m was estimated. Since the van der Waals' radius of the oxygen atom is about 1.4×10^{-10} m, the lithium ion appears to interact solely with carbonyl oxygens of $PQ^{-\cdot}$. Therefore, it can be proposed that the association behavior of *o*-quinone anions is not influenced by their size. It was confirmed from the fact that the $\Delta E_{1/2}$'s of 1,2-naphtoquinone and PQ are 197 and 201 mV in the presence of 0.1 M lithium perchlorate in DMF, respectively.[1)] Consequently, for the anions having large formation constants (charge-localized anion), their association constants are determined only by the geometry of carbonyl groups of the anion. On the other hand, for the anions possessing small formation constants (charge-delocalized anion in aprotic polar solvents), the most important factor influencing the association constant can be said to be the molecular size. In the case of the latter, the carbonyl oxygen plays no important role in comparison with the former, and the latter can be considered as being almost spherical in shape. In conclusion, in the *p*-quinone anions their ring portions interact with the cation as well as the carbonyl oxygens, as suggested by the large a-values. This interaction becomes weak as their anion sizes increase, which, of course, cause their formation constants to be small.

Comparison of Association Constants Derived from CD and UV Measurements. The Case of Λ-Tris(ethylenediamine)-cobalt(III) and Λ-Tris((1*R*, 2*R*)-1,2-cyclohexanediamine)cobalt(III) with Thiosulfate Ion

Hayami YONEDA,* Katsuhiko MIYOSHI, and Hitoshi MATSUKAWA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730
(Received October 9, 1981)

Synopsis. The association constant K_A determined by CD measurement is much smaller than that by UV measurement for the Λ-$[Co(en)_3]^{3+}$–$S_2O_3^{2-}$ system in water, whereas the two kinds of measurements yield almost the same K_A values for the Δ-$[Co(l\text{-chxn})_3]^{3+}$–$S_2O_3^{2-}$ system. These results are discussed in relation to possible interaction modes involved.

Absorption (AB) and circular dichroism (CD) spectra of metal-amine complex cations like $[Co(en)_3]^{3+}$ are changed in shape and/or magnitude upon addition of polarizable oxoanions such as PO_4^{3-}, $S_2O_3^{2-}$, SeO_3^{2-}, and SO_4^{2-}.[1,2] These changes have been utilized to investigate outer-sphere interactions of these complexes with added anions in solution.[3,4] Norden[5] was the first to demonstrate that CD change (in the visible region) gives an appreciably smaller association constant K_A than AB change (in the UV region) for the $[Co(en)_3]^{3+}$–(*R*,*R*)-tartrate^{2-} system in water. Taura[6] has recently presented the same trend in K_A values of $[Co(en)_3]^{3+}$ with (*R*,*S*)-tartrate^{2-} ion. The anomalous trend pointed out anew by Yamatera[7] remains still unsolved. In the present study, association constants of two chiral complexes, Λ-$[Co(en)_3]^{3+}$ and Δ-$[Co(l\text{-chxn})_3]^{3+}$ (*l*-chxn=(1*R*,2*R*)-1,2-cyclohexanediamine), with $S_2O_3^{2-}$ ion were determined by CD and AB measurements under identical conditions, and were compared with each other.

Experimental

Materials. Λ-$[Co(en)_3]^{3+}$ and Δ-$[Co(l\text{-chxn})_3]^{3+}$ prepared as chloride salts[8] were identified by their AB and CD spectra. Optically active $[Co(Hbg)_3]^{3+}$ and $[Co(tri)_2]^{3+}$ (Hbg=biguanide and tri=tribenzo[*b*,*f*,*i*][1,5,9]triazacyclododecine) were also prepared according to the procedures described in the literature.[9,10] All the other chemicals used were of reagent grade.

Measurements. AB and CD changes of aqueous solutions of the chiral complexes (2.0×10^{-3} mol/dm^3) were recorded at 25±0.1 °C on Shimadzu UV-200 and JASCO J-40CS spectrometers, as a function of the concentration of $Na_2S_2O_3$ (2.50×10^{-3} to 2.75×10^{-2} mol/dm^3). Ionic strength *I* was adjusted with NaCl and not with $NaClO_4$ because of low solubility of $[Co(l\text{-chxn})_3](ClO_4)_3$. Freshly prepared sample solutions were subjected to spectral measurements which were carried out at 460, 315, or 300 nm. No spectral changes with standing time over 1 h were detected, and interference due to Cl^- ion added was found negligible at each wavelength. A standard analysis[5,11] of the data thus obtained gave the association constant K_A.

Results and Discussion

Figure 1 shows AB and CD spectra of Δ-$[Co(l\text{-chxn})_3]^{3+}$ in aqueous solutions with and without $Na_2S_2O_3$. In addition to the usual changes in the AB (UV region) and CD (visible region) spectra, an appreciable CD change is observed in the UV region, which is also attributed to ion association with $S_2O_3^{2-}$ ion.[4] Essentially the same spectral changes are found in the Λ-$[Co(en)_3]^{3+}$ system. Thus, we attempted to determine the association constant K_A by utilizing these CD changes in the UV region as well as the usual spectral changes.

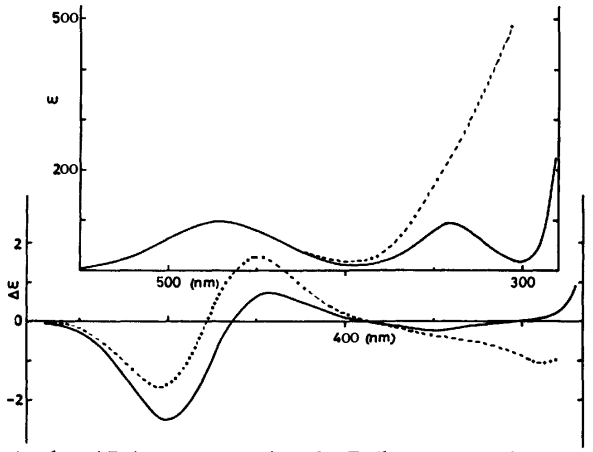

Fig. 1. AB (upper curves) and CD (lower curves) spectra of aqueous Δ-$[Co(l\text{-chxn})_3]^{3+}$ (2.0×10^{-3} mol/dm^3) in the absence (solid curves) and presence (dotted curves) of $Na_2S_2O_3$ (2.5×10^{-2} mol/dm^3).

Table 1. Association constants K_A with $S_2O_3^{2-}$ ion at I=0.1 (NaCl) in water at 25 °C

K_A	Λ-$[Co(en)_3]^{3+}$	(λ/nm)	Δ-$[Co(l\text{-chxn})_3]^{3+}$	(λ/nm)
K_{UV}	59.0±0.5	(300)	70.4±0.3	(315)
	59.6±0.7	(300)	70.0±0.5	(315)
$K_{CD(V)}$	43.7±0.4	(460)	69.0±0.4	(460)
	44.5±0.7	(460)	69.1±0.5	(460)
$K_{CD(UV)}$	51.5±0.4	(300)	61.6±0.5	(315)
	51.1±0.5	(300)	62.9±0.4	(315)

In Table 1 are given the K_A values obtained by the two independent measurements, where K_{UV}, $K_{CD(V)}$, and $K_{CD(UV)}$ refer to the association constants derived from the AB (UV region), CD (visible region), and CD (UV region) measurements, respectively. The most strinking finding in Table 1 is that $K_{CD(V)}$ is appreciably smaller than K_{UV} for the $[Co(en)_3]^{3+}$ system as already observed with (*R*,*R*)-tartrate^{2-} [5] and (*R*,*S*)-tartrate^{2-},[6] while the two values are the same within our experimental errors for the $[Co(l\text{-chxn})_3]^{3+}$ system.

In Table 2 are summarized the K_A values of Λ-

Table 2. Association constants K_A of Λ-$[Co(en)_3]^{3+}$ with some anions at $I=0.1$ ($NaClO_4$) in water at 25 °C

Anions	K_A		Ref.
(*R*,*R*)-Tartrate^{2-}	K_{UV}	26±2	5,14
		22.5±0.4	6
	$K_{CD(V)}$	16±3	5
		13.6±0.2	6,11b
(*R*,*S*)-Tartrate^{2-}	K_{UV}	60.7±0.7	6
	$K_{CD(V)}$	39.6±0.5	6,11b
SO_4^{2-}	K_{UV} [b]	49±2	14
	$K_{CD(V)}$	30.3±0.4	a)

a) H. Yoneda *et al.*, unpublished work. b) $K_{UV}=70\pm2$ for the Λ-$[Co(d\text{-pn})_3]^{3+}$–SO_4^{2-} system at $I=0.1$ (Ref. 14).

$[Co(en)_3]^{3+}$ with some anions reported by earlier workers. It seems a general observation that $K_{CD(V)}$ is smaller than K_{UV} as far as $[Co(en)_3]^{3+}$ is concerned. Here, we assume that the CD change in the visible region is due to the asymmetry around the coordinated N atoms, which is newly generated through the hydrogen-bonding of the N–H protons with added oxoanions along the C_3 axis of the complex.[1a,4b,12] This assumption is supported indirectly by the fact that $[Co(Hbg)_3]^{3+}$ and $[Co(tri)_2]^{3+}$, either having no N–H proton directed parallel to their C_3 axis, do not suffer any CD change in the visible region upon addition of some oxoanions.[9] If the above assumption is valid, it follows that the $K_{CD(V)}$ value reflects predominantly the magnitude of ion-pair formation with anions along the C_3 axis.

The K_{UV} value, on the other hand, contains all the contributions from the association modes which give rise to the interionic charge transfer (CT) band(s) in the UV region. Since the above-mentioned association mode along the C_3 axis contributes to the CT band,[13] the AB change (UV region) is expected to detect association modes not only along the C_3 axis but also along other directions, K_{UV} thus being greater than $K_{CD(V)}$ for the $[Co(en)_3]^{3+}$ system.

If the same interpretation is applied to the $[Co(l\text{-chxn})_3]^{3+}$ system, the K_A values given in Table 1 suggest that this complex interacts with $S_2O_3^{2-}$ ion along the C_3 axis only. In fact, the association modes other than that along the C_3 axis are sterically prohibited for this complex owing to the bulky chxn ligands. However, since $[Co(l\text{-chxn})_3]^{3+}$ adopts a rigid lel_3 conformation with three N–H protons oriented favorably for hydrogen-bonding along the C_3 axis, greater $K_{CD(V)}$ and K_{UV} values are expected for this complex than for conformationally less rigid $[Co(en)_3]^{3+}$. This expectation is actually fulfilled as seen in Table 1. Similarly, a greater K_{UV} value with SO_4^{2-} ion has been reported[14] for Λ-$[Co(d\text{-pn})_3]^{3+}$ with a lel_3 conformation than for Λ-$[Co(en)_3]^{3+}$. Finally, let us discuss the $K_{CD(UV)}$ values obtained for the first time in the present study. Mason *et al.*[4] proposed for some time that the CD change in the first d-d transition results from the electronic interaction with the interionic CT band, which exhibits an accompanying CD change upon addition of oxoanions (Fig. 1). If their proposal is valid, the CD change in the visible region should be proportional to that in the CT region. In other words, the $K_{CD(UV)}$ value is expected to be equal to the $K_{CD(V)}$ value. Contrary to this expectation, $K_{CD(UV)}$ is in the middle of K_{UV} and $K_{CD(V)}$ for the $[Co(en)_3]^{3+}$ system, whereas it is slightly smaller than K_{UV} or $K_{CD(V)}$ for the $[Co(l\text{-chxn})_3]^{3+}$ system. As a result, the significance of these $K_{CD(UV)}$ values is not clear at present. Wavelength dependence of the K_A values might give some insight into these problems.

Synopsis. A six-coordinate diaqua nickel(II) complex with the title macrocyclic ligand, $[Ni(H_2O)_2(S,S\text{-L})]Cl_2$, has been synthesized and its structure has been determined by the X-ray analysis. Coordination geometry about the Ni is of *cis*-NiO_2N_4 type with the macrocyclic ligand folded.

It is well known that a certain tetraazamacrocyclic nickel(II) complex exists as an equilibrated mixture of four-coordinate and diaquated six-coordinate species in an aqueous solution. However, in the case of a nickel(II) complex with 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane, $[NiL]^{2+}$, neither the occurrence of such an equilibrium nor the existence of a diaqua six-coordinate complex had been reported until our previous study[1] on the complex having the optically active ligand. We found in the circular dichroism (CD) spectral study of $[Ni(S,S\text{-L})]^{2+}$ that a very small amount of six-coordinate diaqua complex exists in a dilute perchloric acid solution of *α*-$[Ni(S,S\text{-L})](ClO_4)_2$, where *S,S*-L denotes 7*S*,14*S*-form of the ligand L and a symbol "*α*" designates in this case that chiral secondary amine nitrogens adopt 1*R*,4*R*,8*R*,11*R*-configuration.[2] From the CD band positions, the structure about the Ni of the six-coordinate species was tentatively assigned to be of *cis*-NiO_2N_4 type.

In this study, we isolated successfully the diaqua six-coordinate complex, *cis*-$[Ni(H_2O)_2(S,S\text{-L})]Cl_2$. The blue diaqua complex is obtained from an acetonitrile solution of *cis*-$[NiCl_2(S,S\text{-L})]$, which contains an appropriate amount of water. When the acetonitrile contains an insufficient amount of water, green crystals of *cis*-$[NiCl_2(S,S\text{-L})]$ are recovered. When the water content is too much, a yellow compound (probably four-coordinate $[Ni(S,S\text{-L})]Cl_2$) is obtained. The diaqua complex was obtained only when secondary amine nitrogens are in the *α*-form.

Figure 1 shows a stereoscopic view of $[Ni(H_2O)_2(S,S\text{-L})]^{2+}$. Coordination geometry about the Ni is of *cis*-NiO_2N_4 type, two water molecules occupying the *cis* positions. The ligand L is folded about N(4)–Ni–N(11), as is in the crystals of $[Ni(OAc)(rac\text{-L})](ClO_4)$[3] and $[\{Ni(S,S\text{-L})\}_2(H_2O)(d\text{-tart})](ClO_4)_2\cdot 2H_2O$.[1] Each chelate ring adopts the most strain free conformation: all the six-membered rings take the chair form with the single methyl groups in equatorial positions; all the five-membered rings are in the gauche conformation. Table 1 lists bond lengths and angles about the Ni. Other structural parameters are deposited as supplementary data.[4] Chloride ions are hydrogen-bonded to coordinated water molecules, giving one dimensional chains along the c-axis.[4]

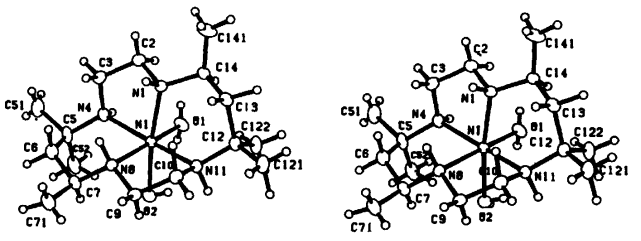

Fig. 1. A stereo view of the structure of *cis*-$[Ni(H_2O)_2(S,S\text{-L})]^{2+}$.

Figure 2 shows nujol-mull solid state absorption (AB) spectra of *cis*-$[Ni(H_2O)_2(S,S\text{-L})]Cl_2$ ($\tilde{\nu}_{max}$/cm^{-1}: 10100, 17000, 27100) and *cis*-$[NiCl_2(S,S\text{-L})]$ ($\tilde{\nu}_{max}$/cm^{-1}: 8550, 15700, 25400). They are very similar to each other except that the AB maxima of *cis*-$[NiCl_2(S,S\text{-L})]$ are shifted to longer wavelengths. The green dichloro complex gives the same AB spectrum in the solid state

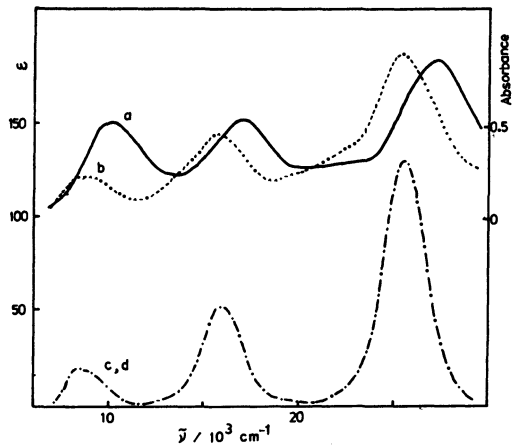

Fig. 2. Nujol-mull solid state absorption spectra of *cis*-$[Ni(H_2O)_2(S,S\text{-L})]Cl_2$ (a) and *cis*-$[NiCl_2(S,S\text{-L})]$ (b) [right-hand ordinate], and absorption spectra of *cis*-$[Ni(H_2O)_2(S,S\text{-L})]Cl_2$ (c) and *cis*-$[NiCl_2(S,S\text{-L})]$ (d) in acetonitrile [left-hand ordinate].

as in the acetonitrile solution [$\tilde{\nu}_{max}/cm^{-1}$ (ε): 8500(20.9), 15800(53.4), 25600(130)]. On the other hand, when the diaqua complex is dissolved in acetonitrile, nitromethane, or acetone, it gives green solution. The spectrum of the solution is exactly the same as that of *cis*-$[NiCl_2(S,S\text{-L})]$. The ionic diaqua complex turns the dichloro complex and exists as a chargeless complex in such organic solvents.

The positions of AB maxima of the solid state spectrum of *cis*-$[Ni(H_2O)_2(S,S\text{-L})]Cl_2$ are the same as those for the triplet species of α-$[Ni(S,S\text{-L})](ClO_4)_2$ in dilute perchloric acid.[2]

Experimental

Materials. cis-[*NiCl*$_2$(S,S-*L*)]: To an acetonitrile solution (50 cm^3) containing 0.5 g of α-$[Ni(S,S\text{-L})](ClO_4)_2$[1] was added an excess of tetrabutylammonium chloride (0.5 g). The solution was rotoevaporated to *ca.* 10 cm^3. Green precipitates were filtered and washed with a minimum amount of acetonitrile (yield, 0.4 g). Found: C, 45.73; H, 9.02; N, 13.51%. Calcd for $NiC_{16}H_{36}N_4Cl_2$: C, 46.41; H, 8.76; N, 13.53%.

cis-[*Ni*(H_2O)$_2$(S,S-*L*)]Cl_2: 0.4 g of *cis*-$[NiCl_2(S,S\text{-}L)]$ was dissolved in 30 cm^3 of acetonitrile containing two drops of water. Blue prismatic crystals of *cis*-$[Ni(H_2O)_2(S,S\text{-L})]Cl_2$ were obtained upon standing the solution in a refrigerator for a few days. (yield, 0.1 g). Found: C, 42.66; H, 8.87; N, 12.41%. Calcd for $NiC_{16}H_{40}N_4O_2Cl_2$: C, 42.69; H, 8.96; N, 12.45%. When an amount of water present in the solvent acetonitrile is insufficient or too much, the desired compound cannot be isolated.

X-Ray Analysis. The intensity measurement and the structure analysis were carried out in the same way as described previously.[1] A specimen with dimensions 0.28 mm×0.13 mm×0.10 mm was used for the X-ray work. Crystal data: orthorhombic, $P2_12_12_1$, a=14.070(3), b=18.022(3), c=8.876 (2) Å, U=2250.6(8) Å^3, Z=4, D_m=1.34, D_X=1.33 g cm^{-3}, μ(Mo $K\alpha$)=11.1 cm^{-1}. All the hydrogen atoms located by the difference synthesis were included in the final refinement with the isotropic temperature factors. The final R indices were R=0.033 and R_w=0.035. Table 2 lists the atomic coordinates.[5]

Measurements. Absorption spectra in solution were measured with a Hitachi 340 spectrophotometer. Solid state absorption spectra were taken as Nujol mulls on a Hitachi 323 spectrophotometer equipped with an attached integrating sphere.

(Received June 11, 1981)

Synopsis. On treatment with a mixture of thiocarboxylic acid and perchloric acid in acetic anhydride, cyclopropenone gave acylthiocyclopropenium perchlorate in a good yield. Bis(acylthio)cyclopropene also yielded the salt under similar reaction conditions. The salt was stable under nitrogen at low temperatures, but was easily hydrolyzed to yield the corresponding cyclopropenethione.

The chemistry of cyclopropenone and their derivatives has attracted considerable attention in the past two decades.[1] Cyclopropenium ions substituted with tris(alkylthio), triamino, or triaryl groups have been isolated as stable crystals.

In a previous paper[2] the present authors have shown the reaction of cyclopropenones, **1**, with thiocarboxylic acids in the presence of strong acids. The reaction in dichloromethane yields the corresponding cyclopropenethiones, **4**, in good yields, while the reaction in ethanol gives bis(acylthio)cyclopropenes, **2**. In this communication we will show two easy routes for the preparation of acylthiocyclopropenium ions, **3**, which are believed to be intermediates for the reaction of **1** with thiocarboxylic acid to yield **4**.

Although it has been reported that unsubstituted cyclopropenone yields a 1 : 2 addition product, **5**, by a reaction with thioacetic acid, no precise study has been made.[3]

No reaction was observed between **1a** and thioacetic acid without a strong acid. When a mixture of **1a**, thioacetic acid, and 70% perchloric acid in acetic anhydride was allowed to stand at room temperature, colorless needles appeared within a few minutes. One hour later crystals were collected. Similarly, the treatment of **1b** with a mixture of thiocarboxylic acids and perchloric acid in acetic anhydride yielded the crystalline products. The structure of the products was confirmed to be **3** on the basis of their ^{13}C- and ^{1}H-NMR and IR spectra, molecular-weight determination, and the subsequent acid hydrolysis.

The ^{13}C chemical shifts for some **3** ions, together with the cyclopropene derivatives, are given in Fig. 1. The assignments were made by considering the signal multiplicities from off-resonance decoupling experiments or from coupled spectra, line intensities, and chemical shifts in comparison with substituted cyclopropenium ions. The chemical shifts for ring carbons of trimethyl-, tris(*t*-butylthio)-, and triphenylcyclopropenium ions are observed at δ 179.3, 156.1, and 155.4 (154.0)[4] ppm respectively.[1] The ^{13}C chemical shifts for carbonium ions are interpreted in terms of the charge densities.[5] Figure 1 indicates that positive charges on the carbons of the cyclopropenium ions would be furnished in this order with respect to the substituents: Me>MeS>Acylthio≥Ph.

The reaction of **2** with perchloric acid in acetic anhydride also yielded **3**. The results are collected in Table 1.

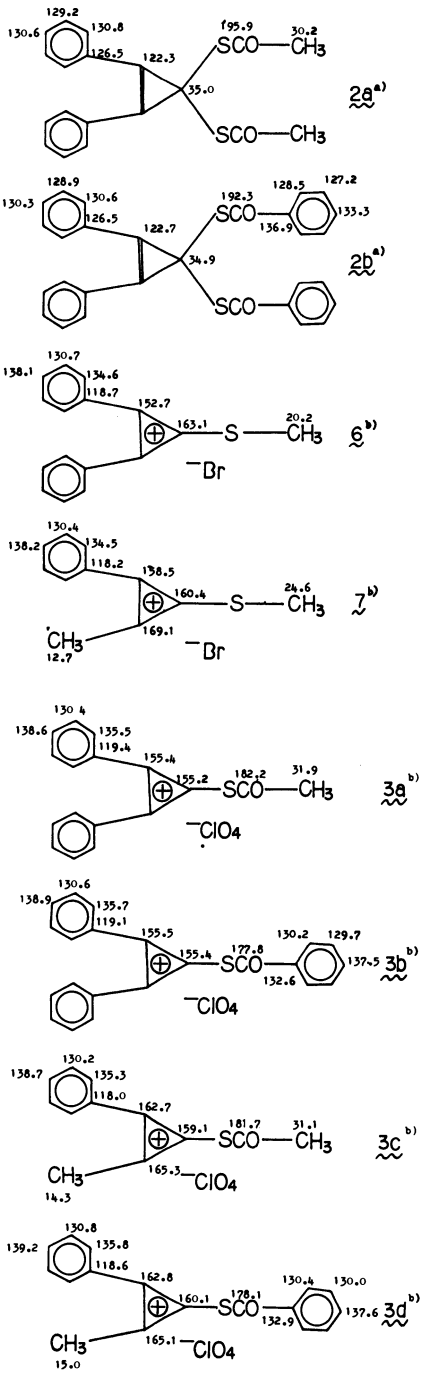

Fig. 1. Selected ^{13}C-NMR data.
a) Solvent: $CDCl_3$, b) solvent: $CDCl_3$–CF_3CO_2H (1 : 0.1—0.3 v/v).

Although the **3** salts were stable under nitrogen at low temperatures, the **3** were easily hydrolyzed under acidic

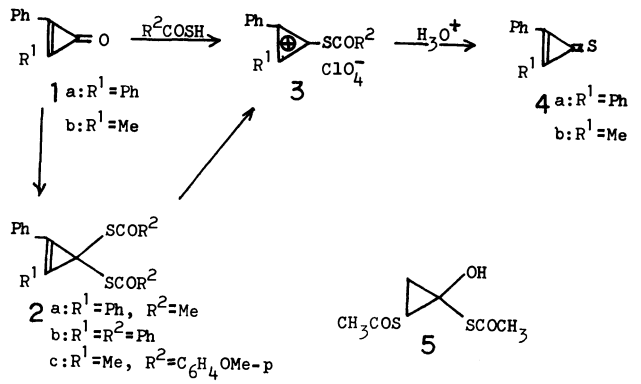
a) In $CDCl_3$–CF_3CO_2H (10 : 1 v/v).



conditions at room temperature to yield the corresponding cyclopropenethione, **4**, in fairly good yields.

Experimental

General. The ^{13}C FT NMR spectra were recorded on a JEOL JNM FX-60 spectrometer (15.04 MHz), and ^1H-NMR spectra, on a Hitachi Perkin Elmer R-24 (60 MHz). The IR spectra were recorded on a JASCO A-3 spectrometer.

Preparation of 3 from 1. To a solution of perchloric acid (70%, 1.1 mmol) in acetic anhydride (3 cm^3), we added **1** (1 mmol) to give a clear solution. Thiocarboxylic acid (1.1 mmol) was then added to the mixture, and the stirring was continued at room temperature. The colorless needles which appeared in the reaction mixture within 5 min were collected after 1 h, washed with dry benzene, and dried *in vacuo*.

Preparation of 3 from 2. To a solution of perchloric acid (70%, 1.1 mmol) in acetic anhydride (3 mmol), we added **2** (1 mmol) at room temperature, and then we stirred the mixture well. The colorless needles which appeared were collected and treated as above.

Hydrolysis of 3. To a cold mixture of 2 mol dm^{-3} hydrochloric acid and dichloromethane (10 cm^3 each), we added **3** (1 mmol). The reaction mixture was stirred well for 30 min, and the organic layer was separated. The condensation of the solution and recrystallization gave **4** in good yields: **4a** from **3a** in a 96% yield and from **3b** in a 90% yield, and **4b** from **3c** in a 89% yield respectively. The structures of **4a** and **4b** were confirmed by a comparison of their mp's and ^1H-NMR spectra with those of authentic samples.[2)]

Molecular-weight Determination. The molecular weights of **3** were determined as follws: an exactly weighed amount of **3** (*ca.* 200 mg) was dissolved in dry ethanol (5 cm^3). To the solution under nitrogen we added an excess amount of potassium hydroxide in ethanol (5% solution). The resulting mixture was stirred well for 20 min. The precipitated potassium perchlorate (the solubility in ethanol: 0.008% at 21 °C) was collected in a glass-sintered filter, washed with dry ethanol and benzene under nitrogen, dried at 100 °C, and weighed. The observed (calcd) molecular weights for **3a—e** were **3a**: 360 (365), **3b**: 442 (427), **3c**: 316 (303), **3d**: 352 (365), and 373 (395). Studies of the elemental and mass spectroscopic analyses of **3a—e** were unsuccessful because of the decomposition of the samples.

(Received August 29, 1981)

Synopsis. The ruthenium(II) complex, $[Ru(cod)py_4](BPh_4)_2$ (cod=1,5-cyclooctadiene, py=pyridine) has been shown to catalyze the reduction of oxidized nitrogen compounds with CO and H_2O. In this reaction, primary, secondary, and tertiary nitroalkanes are converted into amides, ketones, and amines, respectively. Nitrosobenzene and picoline *N*-oxides are also reduciable to amines in good yields.

Much attention has been devoted to the reduction of organic molecules with CO and H_2O without using molecular hydrogen. The reduction of nitrobenzenes with this system has been thoroughly investigated,[1-3] yet the reductions of other compounds have rarely been known.[4-5] We have previously reported that the ionic ruthenium(II) complex, $[Ru(cod)py_4](BPh_4)_2$ (**1**), is an efficient catalyst for the reduction of nitrobenzenes with CO and H_2O. In this paper, we describe the application of this catalytic system to the reduction of some compounds containing oxidized nitrogen.

Unlike the reduction of nitrobenzenes, 1-nitropropane reacted with CO and H_2O in the presence of **1** to give mainly propionamide. Small amounts of propionitrile and propylamine derivatives such as $CH_3CH_2CH_2$-$NHCOCH_2CH_3$ and $(CH_3CH_2CH_2)_2NCHO$ were formed as organic by-products, but propylamine was not detected. As an inorganic product a small quantity of ammonium hydrogencarbonate was found. For this reaction the presence of both CO and H_2O was essential. However, either the presence of a large excess of H_2O or the application of a high pressure of CO resulted in decrease in the yield of the amide but increase in the formation of ammonium hydrogencarbonate. The favorable reaction conditions were as follows: CO=15 atm, H_2O/RNO_2=2 mol/mol. 1-Nitrohexane was similarly reduced to the corresponding amide and nitrile.

Interestingly, the reaction of secondary nitroalkane, 2-nitropropane, gave acetone and acetone oxime. This oxime formation suggests that oximes may be one of the intermediates in the reaction of primary and secondary nitro compounds. In fact, under these conditions acetone oxime was hydrolyzed to acetone in 66% yield. Propionaldehyde oxime was also converted into a mixture of propionamide (63%) and propionitrile (4%). This is the Beckmann rearrangement of aldoxime, which has been known to be catalyzed by some transition metal complexes.[6] For this reaction, neither CO nor H_2O was needed, while the product ratio was affected; the yield of propionitrile was increased up to 47% in the absence of CO and H_2O, whereas propionamides was formed in 36% yield.

On the other hand, the reaction of 2-nitro-2-methylpropane gave *t*-butylamine exclusively. The difference between tertiary and secondary or primary nitroalkanes seems to be attributed to the hydrogens on the α-carbon atom. It may be deduced that at the first stage of the catalysis a nitroso compound is formed as an intermediate. Actually, nitrosobenzene was readily reduced to aniline in a high yield compared with the reduction of nitrobenzene (76%). The reaction scheme is illustrative as follows.

Table 1. Reduction of nitroalkanes with CO and H_2O catalyzed by $[Ru(cod)py_4](BPh_4)_2$[a]

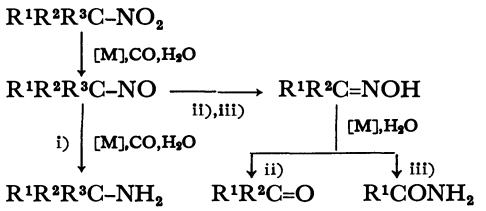
a) Reaction conditions: complex **1** (0.1 mmol), substrate (20 mmol), H_2O (40 mmol), THF (5 ml), 140 °C, 20 h. b) The yields were determined by GC using internal standards. c) Isolated yields. d) H_2O (100 mmol) was used. e) At 170 °C.

Table 2. Catalytic reduction of oxidized nitrogen compounds

Substrate	Condition[a]	Product	Yield/%[b]
Nitrosobenzene	A	Aniline	82
β-Picoline *N*-oxide	A[c]	β-Picoline	89
γ-Picoline *N*-oxide	A[c]	γ-Picoline	99
m-Nitrobenzonitrile	B	*m*-Aminobenzonitrile	93
m-Nitroacetophenone	B	*m*-Aminoacetophenone	81
m-Nitrobenzaldehyde	B	Poly(nitrilo-1,3-phenylenemethylidyne)	100[d]

a) Condition A: complex **1** (0.2 mmol), substrate (20 mmol), H_2O (40 mmol), THF (5 ml), CO (50 atm), 100 °C, 20 h; Condition B: complex **1** (0.05 mmol), substrate (10 mmol), H_2O (20 mmol), THF (5 ml), CO (50 atm), 150 °C, 20 h. b) GC yields. c) H_2O was not used. d) Isolated yield.



i) R^1,R^2,R^3 = alkyl. ii) R^1,R^2 = alkyl, R^3 = H.
iii) R^1 = alkyl, R^2,R^3 = H.

The applications of the catalyst **1** to the reductions or various organic compounds such as 1-hexane, methyl cinnamate, acetophenone, benzonitrile, *N*-benzylidenecyclohexylamine, triphenylphosphine oxide, and diphenyl sulfone were attempted, but these compounds were virtually inert under Condition A shown in Table 2. Picoline *N*-oxides were exceptionally reduciable to picolines, though the presence of H_2O is not required. These results indicate that the catalysis of **1** is selective to the reduction of compounds containing oxidized nitrogen. Consequently, it was possible to achieve the selective reduction of the nitro group of substituted nitrobenzenes containing cyano or carbonyl group.

Experimental

GC-MS spectra were recorded on a Hitachi M-52 spectrometer. ^{1}H-NMR spectra were recorded with a Varian T-60A spectrometer. All liquid compounds were distilled under an atmosphere of nitrogen before use.

General Procedure. All reactions were carried out in a stainless steel autoclave of 65 ml capacity, heated by an external rocking electric oven. A THF solution of $[Ru(cod)(py_4](BPh_4)_2$, substrate, and H_2O was placed in the autoclave, which was subsequently charged with CO. After heating for 20 h, the autoclave was cooled to room temperature. The reaction mixture was analyzed by the GC method using an internal standard. The identification of the products was accomplished by GC/MS, IR, and ^{1}H-NMR techniques, and by comparison with those of authentic samples. Some spectral data were as follows; $CH_3CH_2CH_2NHCOCH_2CH_3$: MS, 115 (M^+); IR (cm^{-1}), 3350 (ν_{NH}), 1640 (ν_{CO}); ^{1}H-NMR (CCl_4, δ), 0.9 (t, CH_3CCN), 1.5 (h, CH_2CN), 3.1 (q, CH_2N), 1.1 (t, CH_3CCO), 2.2 (q, CH_2CO), 7.6 (b, NH); $(CH_3CH_2CH_2)NCHO$: MS, 129 (M^+); IR (cm^{-1}), 1660 (ν_{CO}); ^{1}H-NMR (CCl_4, δ), 0.9 (t, CH_3), 1.5 (h, CH_2CN), 3.2 (t, CH_2N), 8.0 (s, CHO).

Synthesis and Lithiation of 2-Alkylthio- and 2-Arylthio-1,3-dithiolanes

Shigeo TANIMOTO,* Tatsuo OIDA, Hideyuki IKEHIRA, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received September 24, 1981)

Synopsis. Several 2-alkylthio- and 2-arylthio-1,3-dithiolanes were synthesized by the reaction of 2-ethoxy-1,3-dithiolane with aliphatic and aromatic thiols in the presence of $ZnCl_2$. The lithiation of 2-alkylthio-1,3-dithiolanes with butyllithium in tetrahydrofuran followed by the addition of alkyl halides gave unsymmetrical dialkyl trithiocarbonates in moderately good yields.

Although the so-called six-membered cyclic trithioorthoformates (derivatives of 1,3-dithiane) have been studied[1] intensively, little is known about the five-membered analogues (derivatives of 1,3-dithiolane). To our knowledge, only a few compounds are reported in the literature. Nakayama[2] described the replacement of the butoxy-group of 2-(3-methylbutoxy)-1,3-benzodithiole by alkylthio- and arylthio-groups producing 2-alkylthio- and 2-arylthio-1,3-benzodithioles. The others are 2-phenylthio-1,3-dithiolane and 2,2′-[1,2-ethanediylbis(thio)]bis(1,3-dithilane); the former was synthesized in 1976 by Yoshida and his co-workers,[3] who obtained this compound by the thiolysis of the *N*-tosylsulfilimine derived from 1,3-dithiolane, and the latter is most easily available,[4] but it appears to be far from general. Recently, we described a process for the introduction of a formyl moiety to some phenols.[5] This procedure involved the reaction of the phenols with 2-ethoxy-1,3-dithiolane[4] in the presence of $BF_3 \cdot Et_2O$ and subsequent hydrolysis of the resulting 1,3-dithiolan-2-ylated phenols. We have now found that the reaction of aromatic thiols with 2-ethoxy-1,3-dithiolane proceeds smoothly by using $ZnCl_2$ as a catalyst to afford 2-arylthio-1,3-dithiolanes; in this case no nuclear substitution products are formed. This sulfur-for-oxygen interchange reaction proved to be quite general even when aliphatic thiols were used, although in the cases with low-boiling aliphatic thiols the reaction had to be performed with a large excess of the thiols. If the aliphatic thiols are not used in excess, the products are often isolated in an impure state. Thus an interchange reaction of 2-ethoxy-1,3-dithiolane with aliphatic and aromatic thiols was demonstrated; it was analogous to that observed previously in the case of 2-(3-methylbutoxy)-1,3-benzodithiole.[2] The results are summarized in Table 1.

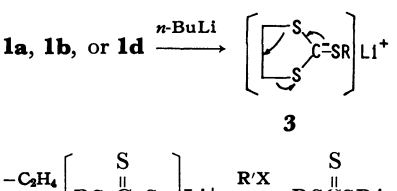
a) Yield of isolated product based on 2-ethoxy-1,3-dithiolane. b) Isolated by distillation under reduced pressure. c) Isolated by column chromatography on silica gel.

The removement of the trithioorthoformate proton of 2-alkylthio- and 2-arylthio-1,3-dithiolanes could be achieved by observing at −5——10 °C and by the addition of an easily available metalating agent such as butyllithium. In reaction with 2-alkylthio-1,3-dithiolanes, the initially formed anion is assumed to be **3**, which decomposes to ethylene and alkyl trithiocarbonate anion (**4**), and the latter is subsequently alkylated by alkyl halides to afford the unsymmetrical dialkyl trithiocarbonates (**5**).[6—8]



R = $CH_3(CH_2)_2$, $CH_3(CH_2)_3$, $C_6H_5CH_2$
R′X = CH_3I, C_2H_5I, $CH_3(CH_2)_2I$, $CH_3(CH_2)_3I$, $C_6H_5CH_2Br$

In cases where the experiments using 2-arylthio-1,3-dithiolanes were performed in the same way as that applied to 2-alkylthio-1,3-dithiolanes, the similarly formed aryl trithiocarbonate anion (**7**) undergoes further fragmentation to afford carbon disulfide and arenethiolate anion (**8**), presumably due to the electron-withdrawing effect of the benzene ring. The anion (**8**) would be then trapped by methyl iodide. In three cases where Ar=C_6H_5, *p*-$CH_3C_6H_4$, *m*-$CH_3C_6H_4$ in 2-arylthio-1,3-dithiolanes, none of the corresponding aryl methyl trithiocarbonates were recognized, but **9a**, **9c**, and **9e** were obtained in 75, 97 and 84% yield, respectively. It is also confirmed that **7** is unstable and decomposes similarly even at −78 °C. Thus an obvious difference in behavior between 2-alkylthio- and 2-arylthio-1,3-

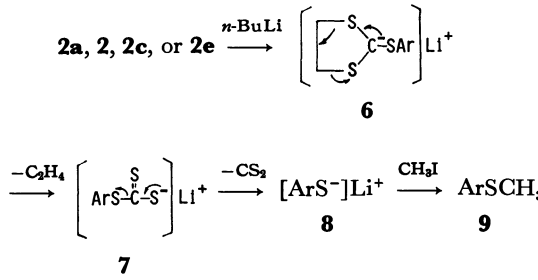
dithiolanes has been noted.



a: Ar = C_6H_5, **c**: Ar = *p*-$CH_3C_6H_4$, **e**: Ar = *m*-$CH_3C_6H_4$

Experimental

Reaction of 2-Ethoxy-1,3-dithiolane with a Thiol. The reaction was carried out by stirring a mixture of 2-ethoxy-1,3-dithiolane (5.0 g, 33.3 mmol), a thiol (33.6 mmol) (100 mmol was used in the cases of low-boiling aliphatic thiols, *i.e.*, in Runs 1, 2, and 3 in Table 1) and $ZnCl_2$ (4.6 g, 33.8 mmol) at room temperature for 24 h. The mixture was poured into a large quantity of dilute aqueous NaOH and extracted with several portions of ether. The combined ethereal extracts were washed repeatedly with dilute aqueous NaOH, dried, filtered, and concentrated *in vacuo* to give a residue. The product was isolated by distillation under reduced pressure or by column chromatography on silica gel, using 10% ether–hexane as the eluent.

Conversion of a 2-Alkylthio-1,3-dithiolane to an Unsymmetrical Dialkyl Trithiocarbonate (5). To a stirred solution of a 2-alkylthio-1,3-dithiolane (5.0 mmol) dissolved in tetrahydrofuran (20 ml), under nitrogen at −5—−10 °C, was added a 1.56 molar solution (3.8 ml, 5.9 mmol) of butyllthium in hexane; the stirring was continued for 20—30 min at that temperature. A solution of an alkyl halide (10 mmol) (6—7 mmol was used in the case of benzyl bromide) in tetrahydrofuran (2—3 ml) was added, and the mixture was stirred at −5—−10 °C for 1 h and further at room temperature for 4 h. Water (30 ml) and a saturated aqueous solution (30 ml) of ammonium chloride were added, and the mixture was extracted with several portions of ether. The combined ethereal extracts were dried, filtered, and concentrated *in vacuo* to give a residue, which was distilled under reduced pressure to afford an unsymmetrical dialkyl trithiocarbonate. Only in the case of Run 1 (Table 2) was the product isolated by column chromatography.

Stereoselective Micellar Catalysis. II. Kinetic Properties of Optically Active Micellar Catalysts for Cleavage of Amino Acid Ester Derivatives

Yasuji IHARA* and Reiko HOSAKO

Yamaguchi Women's University, 3-2-1 Sakurabatake, Yamaguchi 753

(Received June 29, 1981)

Synopsis. Stereoselective reactions of the enantiomers of *N*-acylamino acid *p*-nitrophenyl esters with *N*-decanoyl-(D or L)-histidine (DecHis) in an optically active surfactant (DMEBr) derived from (*l*)-ephedrine were studied at 25 °C and pH 7.30 in comparison with those of simple surfactant, hexadecyltrimethylammonium bromide (CTABr). The mixed micelles of DecHis and DMEBr are effective stereoselective catalysts and the catalytic effects are determined mainly by the nucleophilic reactivity of the optically active histidine residue of DecHis.

Surfactant micelles have been extensively investigated as favorable models for enzyme catalysis;[1] particularly, several esterolysis reactions have been performed with optically active micellar systems in order to gain further insight into stereoselective properties of enzymic reactions.[2]

In our previous papers,[3] we showed that functional mixed micelles of optically active catalysts containing a histidine residue and hexadecyltrimethylammonium bromide (CTABr) are very effective stereoselective catalysts for cleavage of enantiomeric substrates, and a mechanism was suggested for reaction in mixed micelles involving acylation of the optically active histidine residue.

In this paper, we describe kinetic results for cleavage of amino acid ester derivatives in a mixed micellar system formed from *N*-decanoly-(D or L)-histidine (DecHis) and an optically active cationic surfactant (DMEBr) having the hydroxyl function at the polar head, and results are compared with those observed in the mixed micelles with CTABr.

Surfactant

DMEBr

Experimental

Materials. Hexadecyltrimethylammonium bromide (CTABr) was purified by established methods.[4] *N*-Dodecyl-*N*-methyl-*l*-ephedrinium bromide (DMEBr) and *N*-decanoyl-(D or L)-histidine (DecHis) were prepared and purified by standard methods.[5] *N*-Benzoyl-L-histidine (BzHis) was obtained from Sigma Chemical Co. The substrates, *p*-nitrophenyl esters of *N*-benzyloxycarbonyl-D-alanine, and *N*-methoxycarbonyl-D and L-phenylalanine were synthesized by the dicyclohexylcarbodiimide method.[6] Other *p*-nitrophenyl esters of *N*-benzyloxycarbonyl amino acids were purchased from Sigma Chemical Co., and were used without further purification. The purity of these esters was confirmed by kinetic analysis.

Kinetic Measurements. The cleavage of *p*-nitrophenyl esters was performed at pH 7.30, 0.02 mol dm^{-3} of phosphate buffer, and 25 °C in 0.83% CH_3CN–H_2O, and the formation of the *p*-nitrophenolate anion was followed spectrophotometrically at 400 nm. The pseudo-first-order rate constants were obtained from plots of $\log(A^{\infty}-A^{t})$ *vs.* time (t) by use of the least-squares method. Correlation coefficients were >0.999.

Results and Discussion

Optically active DMEBr micelles showed considerably different catalytic efficiencies for the hydrolysis of enantiomeric *p*-nitrophenyl α-methoxyphenylacetate.[7] However, no appreciable stereoselectivity was observed for the above esters in the presence of a simple optically active surfactant, hexadecyldimethyl-(α-methylbenzyl)ammonium bromide.[8]

In this study, substrates, ZPheONp, ZAlaONp, and MocPheONp, were hydrolyzed in the presence of

a) In 6.00×10^{-3} mol dm^{-3} DMEBr or CTABr, at pH 7.30, 0.02 mol dm^{-3} of phosphate buffer, and 25 °C. [DecHis] = 0.40—5.33×10^{-4} mol dm^{-3} and [substrate] = 1.0×10^{-5} mol dm^{-3}, unless otherwise specified. Values in parentheses are for D-substrates. The k_c values are calculated by the least-squares method and generally have correlation coefficients of over 0.99. b) [PNPA or PNPH] = 1.0×10^{-4} mol dm^{-3} and [DMEBr] = 5.00×10^{-2} mol dm^{-3}.

6.00×10^{-3} mol dm^{-3} DMEBr at pH 7.30 and 25 °C (Table 1). DMEBr micelles show slightly different catalytic efficiencies in the hydrolysis of the enantiomeric substrates; D substrates are more reactive than L enantiomers. In CTABr micelles there was no difference between the rates of hydrolysis of the enantiomeric substrates within experimental error.[3]

The catalytic effects of L-DecHis and L-BzHis for ZPheONp hydrolysis were first examined by varing the DMEBr concentration at pH 7.30 and 25 °C (Table 2). At higher ratios the rates decrease but the stereoselective effect is almost unchanged when L-DecHis is diluted with DMEBr. A similar effect is observed in the mixed micelles of L-BzHis and DMEBr. Therefore, the stereoselective kinetic analysis was carried out at a fixed surfactant concentration (6.00×10^{-3} mol dm^{-3}). The catalytic second-order rate constants (k_c) were obtained from the linear slope of a plot of the observed pseudo-first order rate constants (k_ψ) against catalyst concentration under the condition: [surfactant] > [catalyst] > [substrate]. Table 3 summarizes results for the cleavage of the substrates by (D or L)-DecHis in the presence of DMEBr. For comparison, (D or L)-DecHis–CTABr catalyzed rates also are determined and listed in Table 3.

From Table 3, it is apparent that there is no rate difference between D- and L-DecHis for cleavage of nonspecific substrates, such as *p*-nitrophenyl acetate (PNPA) and hexanoate (PNPH), and optically inactive substrate (ZGlyONp). On the other hand, it is found that L-DecHis reacts more selectively than D-DecHis with L substrates, and D-DecHis with D substrates. The pattern of stereoselective effects for the optically active substrates in the mixed (D or L)-DecHis–DMEBr micelle is similar to that found in the mixed (D or L)-DecHis–CTABr. These results show that the stereoselectivity is determined mainly by the nucleophilic reactivity of the optically active histidyl residue of DecHis. It is well known that the imidazolyl and hydroxyl groups act as nucleophiles giving acylated products, and that the imidazolyl group is more reactive than the hydroxyl group under neutral conditions. Thus, reaction rates with the mixed DecHis–DMEBr micelle are two orders of magnitude higher than those with the DMEBr micelle alone at pH 7.30.

A comparison of the rate constants between mixed micelles with DMEBr and CTABr indicates that both the reactivity and stereoselectivity of ZPheONp are essentially the same, but that the rates of less hydrophobic substrates such as ZAlaONp bring about 2-fold decreases with the extent of stereoselectivity also decreasing from 2.0 to 1.4—1.6. Although the reactions with mixed D-DecHis–CTABr and L-DecHis–CTABr micelles produced the same differences between D and L substrates in the opposit direction within experimental error, the D-DecHis–DMEBr and L-DecHis–DMEBr micelles show slightly different catalytic efficiencies in the reactions with D and L enantiomers.

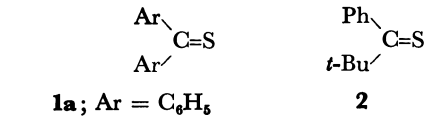
(Received December 17, 1981)

Synopsis. Electrochemically generated anion radicals of thioketones were allowed to react with alkyl halides (or tosylate). Electronic structure of the anion radical is discussed on the basis of the products.

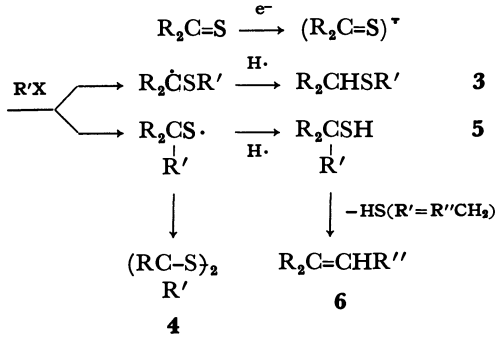
It was reported that the polarization of thiocarbonyl group is largely affected by the substituent, and it is not uncommon that the dipole is oriented from positive sulfur to negative carbon.[1,2] It has also been proposed that the electronic structure of anion radical of thioketone reflects the electronic effect of the substituent; an anion radical from an aromatic thioketone being in carbanion-like structure, whereas that from an aliphatic thioketone being in thiolate-like structure.[3,4] However, the electronic structure of anion radical of thioketone is still ambiguous because the proposition bases on the behavior of transient reaction intermediate. Minoura and his co-worker reported the reactions of sodium thiobenzophenone thioketyl.[5] However, obviously the reaction does not represent the reaction of thiobenzophenone thioketyl since the anion radicals disproportionate easily into a dianion and a neutral molecule under the reaction conditions. At the same time, the anion radical from metal thioketyl is not free from large influence of the counter cation.[6] In order to understand intrinsic nature of anion radicals from thioketones, we generated them by cathodic reduction of thioketones, and studied their reactions with alkyl halides.

Results and Discussion

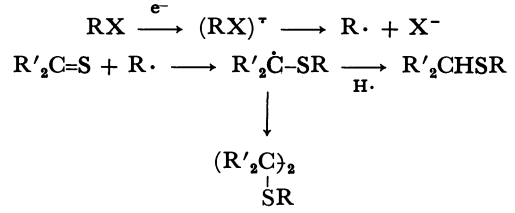
Appropriate amounts of thiobenzophenone (**1a**), 4,4'-dimethoxythiobenzophenone (**1b**), or thiopivalophenone (**2**) and an alkyl halide or tosylate were dissolved in acetonitrile and subjected to cathodic reduction



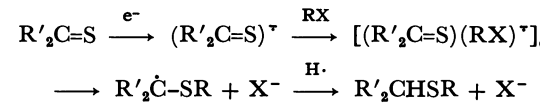
1a; Ar = C_6H_5
1b; Ar = *p*-$MeOC_6H_4$



(−1.6 V *vs.* SCE) in the presence of tetraethylammonium perchlorate as supporting electrolyte. After the color of thioketone had disappeared completely, reaction products were analyzed. Results are summarized in Table 1. Since the reduction potentials of **1** (≈−1.0 V *vs.* SCE) and **2** (≈−1.3 V *vs.* SCE) are lower than those of alkyl halides,[7] the electrochemical reduction may reduce thioketone rather than the alkyl halide. Initial reduction of thioketone is also supported by the fact that the reaction with **1** affords *C*-alkylated product(s); diaryl or aryl alkyl thioketone is known to be a very efficient free-radical scavenger,[8] and if the alkyl halide were the species to be reduced initially, all products should be *S*-alkylated ones. However, it is plausible



that the anion radical of thioketone transfers an electron to the alkyl halide within a solvent cage when they encounter each other, as proposed for the reaction of thiolate anion and alkyl halide.[9]



Although not major, the formation of *C*-alkylated product(s) from **1**, but not from **2**, suggests that the anion radical of diaryl thioketone has more carbanion-

	$BrCH_2$–CH_2CH_2Cl	—[e]	27[f]				

a) $Ar_2C=O$. b) Methyl *p*-toluenesulfonate. c) Trace amount. d) One mmol of **2** and 4 mmol of an alkyl halide were used. e) Overnight (≈20 h). f) ω-Chloro sulfide was obtained.

like character than alkyl aryl thioketone accordantly with the previous proposal.[2,3] Olefinic products are formed only when **1b** is subjected to the reaction, probably because electron-releasing effect of two *p*-methoxyl groups facilitates El-type elimination of hydrogen sulfide from the thiol resulted by *C*-alkylation.

It is interesting, in summary, to note that one can obtain *C*-alkylated product(s) when a neutral alkyl aryl or dialkyl thioketone is treated with a carbanion, whereas only *S*-alkylated product is obtained by the same reaction with diaryl thioketone.

Experimental

Materials. Thioketones were prepared according to the literature procedure.[10] Tetraethylammonium perchlorate, alkyl halides, and methyl tosylate were purchased from a commercial source (Nakarai Chem. Co.). Acetonitrile was distilled three times on phosphorus pentaoxide and once on potassium carbonate, then kept in a bottle filled with dry argon and capped by a silicon-rubber stopper.

Procedure. In both arms of a H-shaped electrolytic cell, each 5 cm^3 of acetonitrile containing 100 mg of tetraethylammonium perchlorate was placed. Then 0.25 mmol of a thioketone and 1 mmol of an alkyl halide (or tosylate) were dissolved in the cathode. Platinum electrodes were used. The reaction was run under a constant voltage of -1.6 V (*vs.* SCE) at room temperature. After the color of thioketone had disappeared, the solution in the cathode was taken out, quenched with water, and extracted three times with dichloromethane. The organic layer was washed once with saturated aqueous sodium chloride and dried over anhydrous sodium sulfate, then the solvent was removed *in vacuo*. The material thus obtained was chromatographed on a HPLC (silica gel) and product isolated were identified and quantitatively analyzed by NMR and mass spectroscopy.

Dynamic Structure of Pyrimidine-polyribonucleotides in Solution. ^{1}H NMR Studies[1)]

Atsuko YAMADA-NOSAKA,*,† Yoshio NOSAKA,*,† Kazuyuki AKASAKA, and Hiroyuki HATANO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

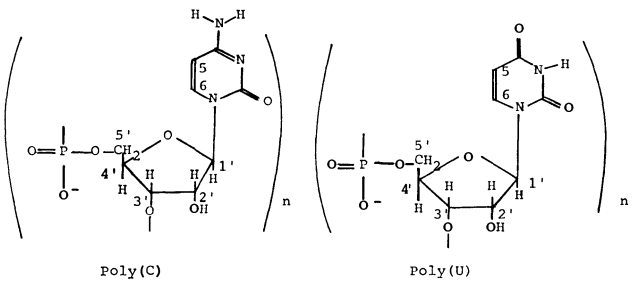
(Received June 25, 1981)

Temperature dependent conformations and molecular motions of pyrimidine polyribonucleotides, poly(C) and poly(U), have been studied in ^2H_2O solutions (pH 5.8±0.3, 5—72 °C) by measuring ^{1}H NMR intensities, chemical shifts, coupling constants, and spin-lattice relaxation times. Below 50 °C, poly(C) exists as a slowly exchanging mixture of double-stranded and single-stranded forms of which only the single-stranded form is observable by ^{1}H NMR. In this temperature range, the single-stranded poly(C) shows a strong base-stacking with dominated C_3'-*endo anti* conformation, whereas above 50 °C it takes partly C_2'-*endo* conformation with destabilization of the helical structure. Poly(U) exists as single strand within the whole temperature range studied, and the bases are nearly unstacked with 58% of C_2'-*endo* conformer. Poly(U) is more flexible than poly(C), which was characterized with rotational correlation times in the order of 10^{-9}—10^{-10} s.

Conformation of synthetic homopolynucleotides has been studied by many investigators as the first step toward the understanding of the structure of nucleic acids. In aqueous solution, each homopolynucleotide shows unique behaviour characteristic of its purine and pyrimidine bases.[2,3)] Nuclear magnetic relaxation measurements of ^{31}P showed different motions for different polynucleotides.[4)] However, their detailed structures in solution are still unknown although some of their structures in fiber states have been analyzed by X-ray diffraction.[5–7)]

At neutral pH, poly(C) takes single-stranded helix stabilized by base stacking, while at acidic pH (pH<5.0) it exists as a double-stranded helix in which the bases are held together by three hydrogen bonds, one of which can be formed only when a proton is added to N-3 for each pair of bases.[8–10)] In general, the ordered double helical form of high polymers does not give a high resolution NMR spectrum.[2)] Our previous ^{31}P NMR study[11)] exhibits that at acidic pH the signal is too broad to be observed presumably due to the double-stranded form, while at an intermediate pH between acidic and neutral the exchange between the double-stranded and single-stranded forms is slow in the NMR time scale, so that the single-stranded form and possibly partially double-stranded form can be observed.

In the present work, temperature dependence of ^{1}H chemical shifts, coupling constants and spin-lattice relaxation times of poly(C) and poly(U) were measured and the conformational features of single-stranded poly(C) are discussed together with those of poly(U) known to exist as a random coiled structure.



Poly(C) Poly(U)

† Present address: Department of Materials Science and Technology, The Technological University of Nagaoka, Nagaoka, Niigata 949-54.

Experimental

The potassium salts of poly(C) and poly(U) (molecular weight>10^5) were purchased from Sigma Chemical Company. The samples were dialysed against a large volume of 0.1 M (1 M=1 mol dm^{-3}) sodium chloride to remove low molecular species and paramagnetic metal ions. The solution was lyophilized and the residue was dissolved in ^2H_2O (99.7%). The lyophilization and addition of ^2H_2O were repeated three times to reduce ^1H_2O background. About 3 mM of EDTA was added to remove the effect of the remaining paramagnetic metal ions. No buffer was used. The final pH of the solution was 5.8±0.3 (direct pH meter reading). The samples were evacuated on a vacuum line and sealed in an NMR sample tube of 5 mm diameter. The final concentration of poly(U) and poly(C) were 92 mM and 53 mM in monomer unit, respectively, as determined from the optical absorption at 261 nm and 269 nm by using the molar extinction coefficients of 9600 and 6300 for poly(U) and poly(C), respectively.[12)]

Spin-lattice relaxation times (T_1) were measured at 100 MHz on a JEOL PFT Fourier transform NMR spectrometer using the inversion recovery pulse sequence (180°-t-90°). T_1 values were deduced with a non-linear least square fit method. Chemical shifts and coupling constants of poly(C) were measured at 360 MHz on a Bruker HX-360 spectrometer. Relative peak area was determined at 360 MHz by averaging the values obtained by three independent methods, *i.e.* measurement of peak height, integration of the peak area, and weighing the spectral sheet.

Results and Discussion

Poly(C). Figure 1(a) shows the peak area of the three protons (H_5, H_6, and H_1') of poly(C) at pH 5.8 as a function of temperature. It is noted that the peak area of each of the three protons shows an abrupt increase at about 45 °C. The loss of signal intensity below 45 °C seems to be best interpreted as due to the formation of the double-stranded form of poly(C) whose ^{1}H NMR signals are too broad to be observed. Moreover, the exchange between the single-stranded form and the double-stranded form of poly(C) must be slow in the NMR time scale,[11,13)] so that the observed signals correspond to the poly-

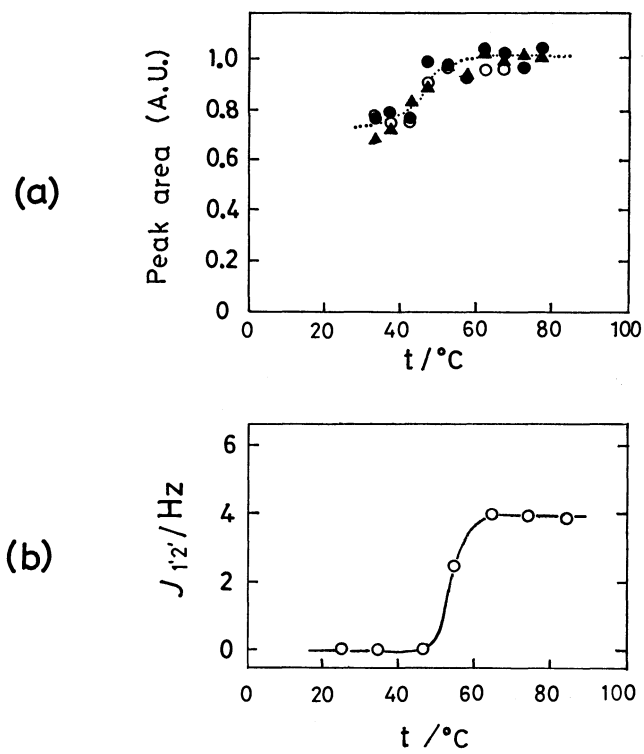


Fig. 1. Temperature dependence of ^{1}H NMR parameters of poly(C) measured at 360 MHz (53 mM in ^2H_2O, pH=5.8±0.3, [Na^+]=0.1).
(a): Peak area of H_5 (●), H_6 (▲), and $H_{1'}$ (○),
(b): coupling constant $J_{1'2'}$.

(C) in the single-stranded form and possibly in the partially double-stranded form. This interpretation is in accordance with the earlier observation that, in the acidic pH range, the signal intensity of ^{31}P resonance decreases upon protonation of poly(C) by the formation of a double strand.[11]

Figure 1(b) shows that the coupling constant between $H_{1'}$ and $H_{2'}$ ($J_{1'2'}$) is almost nil below 50 °C. From the Karplus relation, this result means that the dihedral angle ($\angle H_{2'}C_{2'}C_{1'}H_{1'}$) is close to 90°, *i.e.*, that the ribose ring of the single-stranded poly(C) takes exclusively $C_{3'}$-*endo* (N) conformation below 50 °C. $J_{1'2'}$ shows a sharp increase in the narrow temperature range of 50—65 °C, and above 65 °C becomes constant at 3.9 Hz. The increase in the coupling constant reflects the increase in the population of the $C_{2'}$-*endo* (S) conformer under the assumption of a rapid equilibrium between N and S conformers.[14] The population of the S conformer above 65 °C is then estimated to be 42% by using the equations given by Altona and Sundaralingam.[14]

In contrast, the chemical shifts of the three protons of poly(C) increase rather monotonically in the temperature range of 28—70 °C as shown in Fig. 2. This observation implies that at low temperature these protons receive strong deshielding effects from the ring currents of neighbouring bases, but that the effects are relieved at higher temperatures by gradual unstacking of bases, in agreement with the conclusion obtained from other methods.[13,15,16]

Lee and co-workers have suggested that the base

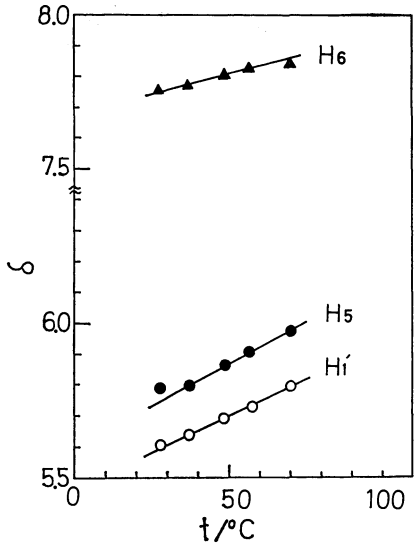

Fig. 2. Temperature dependence of chemical shifts of H_5, H_6, and $H_{1'}$ of poly(C) as measured from an internal standard of DSS (H_6 ▲, H_5 ●, $H_{1'}$, ○).

stacking arrangement prohibits the ribose ring to take the S-conformation, based on the fact that the ribose ring of dinucleotides has a large fraction of N-conformer corresponding to the increase in the fraction of base stacking.[17] The present results have shown that, similarly in poly(C), a single helical or partial double helical form with stacked bases and exclusive N ribose conformation is highly stabilized at low temperature, but that upon destacking of bases, poly(C) is allowed to take the S-conformation.

We may conclude that under the present experimental conditions, the conformational equilibria in poly(C) could be summarized in the following schemes:

$$\left.\begin{array}{ccc} \mathrm{Poly(C)_N^*} + \mathrm{H^+} & \overset{\text{rapid}}{\rightleftharpoons} & \mathrm{Poly(C)_N^*H^+} \\ \Big\| \text{rapid} & & \Big\| \text{rapid} \\ \mathrm{Poly(C)_S^*} + \mathrm{H^+} & \overset{\text{rapid}}{\rightleftharpoons} & \mathrm{Poly(C)_S^*H^+} \end{array}\right\} \quad (>65\,^\circ\mathrm{C}), \qquad (1)$$

$$\mathrm{Poly(C)_N^*} + \mathrm{H^+} \overset{\text{rapid}}{\rightleftharpoons} \mathrm{Poly(C)_N^*H^+} \quad (<50\,^\circ\mathrm{C}), \qquad (2)$$

$$\mathrm{Poly(C)_N^*} + \mathrm{Poly(C)_N^*H^+} \overset{\text{slow}}{\rightleftharpoons} \mathrm{Poly(C)_N^*H^+Poly(C)^*} \quad (<50\,^\circ\mathrm{C}), \qquad (3)$$

where Poly(C)* and Poly(C)*H$^+$Poly(C)* represent the single- and double-stranded forms of poly(C), respectively, and subscripts N and S represent N and S conformers of the ribose, respectively.

Figure 3 shows the temperature dependence of T_1's of H_5, H_6, and $H_{1'}$ of poly(C). In spite of the remarkable change of the coupling constant in the range of 50—60 °C, T_1 shows no abrupt change in the corresponding temperature range. Akasaka showed that the dynamic structure of a polynucleotide can be studied from the temperature dependence of T_1.[18] Namely, in an isotropic motional approach with a single τ_c, the T_1 minimum occurs at a rotational correlation time τ_c of 9.9×10^{-10} s at 100 MHz, and by using this τ_c and the minimum value of T_1, relevant interproton distances can be obtained. As shown in

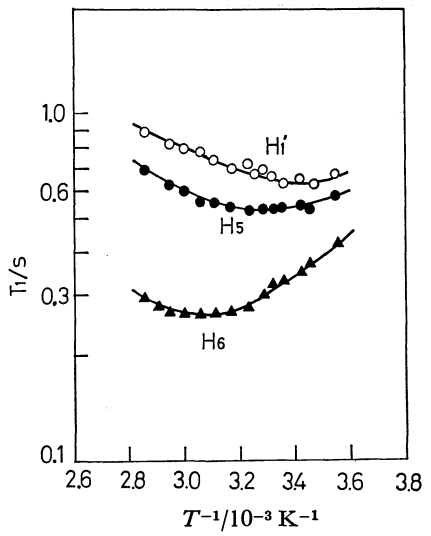

Fig. 3. Semilogarithmic plots of spin-lattice relaxation times (T_1) of poly(C) against reciplocal absolute temperature (H_6 ▲, H_5 ●, $H_{1'}$ ○).

Fig. 3, T_1's of all the three protons of poly(C) go through minima. However, they occur at different temperatures.

In principle, the occurence of different $T_{1\,min}$ temperatures indicates the possibility of differential motions of the three protons. The effect does not seem to arise from the cross-relaxation effect among protons,[19] since around $T_{1\,min}$, where $\omega\tau_c \approx 1$ holds, the cross-relaxation term is close to nil. By taking a simple approach of isotropic motion, the value of r_{iobsd} was obtained for each proton from the minimum values of T_1 (see Appendix), and the results are shown in Table 1.

The values of r_{iobsd} may be compared with r_{icalcd} calculated with atomic coordinates given for 5'-CMP,[20] by taking into account of dipolar interactions within the same nucleotide unit only. The r_{icalcd} values were computed for different torsional angles about the glycosidic bond (χ) varied at an interval of 10° and the dihedral angle ($\angle C_{3'}C_{4'}C_{5'}O_{5'}$) ($\phi$) at interval of 30°, respectively. The ribose conformation was fixed to $C_{3'}$-*endo*. The values of r_{icalcd} for H_6 was not calculated since T_1 for H_6 goes through minimum above 50 °C where the fraction of $C_{2'}$-*endo* conformer cannot be neglected.

On computation r_{icalcd} showed little dependence on ϕ. Therefore, the curves in Fig. 4 show r_{icalcd} as a function of χ for a fixed ϕ (=60°).[21] For H_5, r_{icalcd} and r_{iobsd} coincide in the whole region of χ within the experimental errors of T_1 (±5%), as is expected from the chemical structure of cytidine base

Table 1. r_{iobsd}'s deduced from minimum values of T_1 by using Eq. 3 in Appendix

	r_{iobsd}/Å		
	H_6	H_5	$H_{1'}$
Poly(C)	2.16±0.12	2.43±0.14	2.50±0.14
Poly(U)	2.15±0.12	2.48±0.15	2.48±0.15

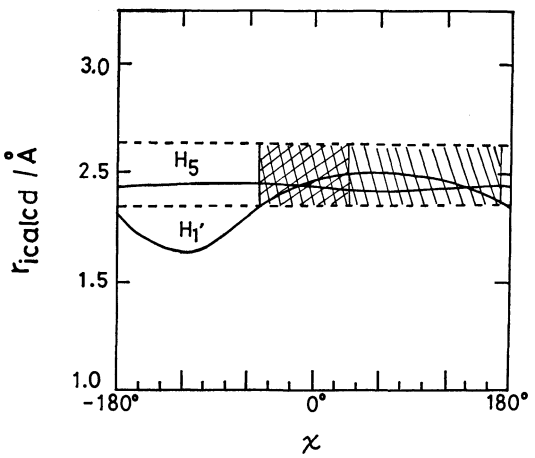

Fig. 4. r_{icalcd}'s $(\sum_j r_{ij}^{-6})^{-1/6}$ are plotted against torsional angle about glycosidic bond (χ).
Ribose ring and ϕ are fixed to $C_{3'}$-*endo* and 60°, respectively. The region where r_{icalcd} and r_{iobsd} coincide within experimental errors is shown by hatched line for $H_{1'}$. The cross-hatched area shows the allowed and plausible region obtained by taking account of the van der Waals exclusion.

where T_1 of H_5 is mainly determined by the dipolar interaction with H_6. The hatched region between the dotted lines in Fig. 4 shows where r_{icalcd} and r_{iobsd} of $H_{1'}$ coincide within experimental errors of T_1. The allowed region of χ for van der Waals contact was estimated to be −130°—40°, where the exclusive atomic radii for H and O were taken to be 0.95 and 1.1 Å, respectively. Therefore, the allowed and plausible region of χ for $H_{1'}$ is in the range of −50°—40° as is represented by the cross-hatched area in Fig. 4, showing that the orientation of the base is restricted to *anti*.

This result is consistent with the theoretical calculation in mononucleotides which predicts that the most probable value of χ for the pyrimidine base lies in the range of 0°—30° for the $C_{3'}$-*endo* sugars.[21] In solution, mononucleotides are shown to exist as equilibrium mixtures of *syn* and *anti* conformers with preference of *anti*. However, in CpC the angle decreases with increasing stacking of base.[17] Our conclusion that single-stranded poly(C) takes predominantly $C_{3'}$-*endo anti* orientation of the base at low temperatures is in accordance with these results. A consistent result has also been presented for single stranded poly(C) in the fiber state by X-ray analysis ($C_{3'}$-*endo anti*, χ=80°).[7] The fraction of *syn* conformers, however, might not be neglected above 50 °C, in view of the coexistence of a substantial fraction of $C_{2'}$-*endo* ribose conformers (42%).

Poly(U). In contrast with poly(C), no temperature dependence of peak area of protons was observed for poly(U). As shown in Fig. 5, neither the chemical shifts of H_5 nor H_6 of poly(U) show significant temperature dependence, indicating that the base-stacking is negligible in this polymer, in accordance with the reported random coil property of poly(U).[2,3]

Temperature dependence of coupling constant $J_{1'2'}$

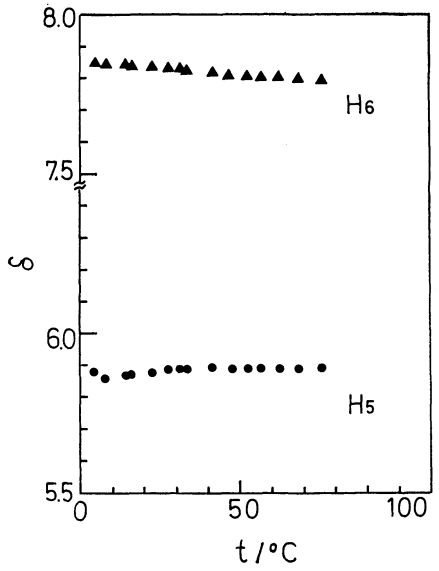

Fig. 5. Temperature dependence of chemical shifts of H_5 and H_6 of poly(U) as measured from an internal standard of DSS (H_5 ●, H_6 ▲).

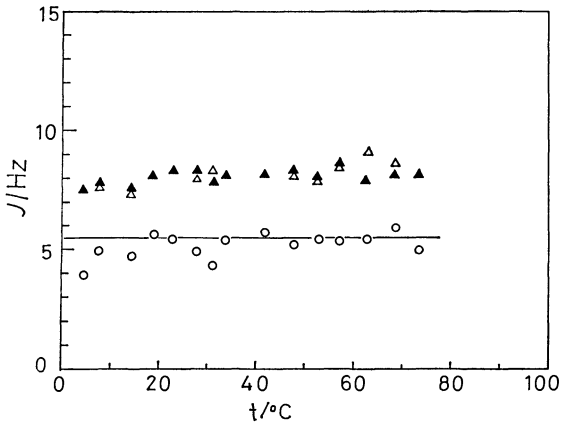

Fig. 6. Temperature dependence of coupling constants $J_{1'2'}$ and J_{56} of poly(U).
$J_{1'2'}$ ○, J_{56} (measured on H_5 signal) △ J_{56} (measured on H_6 signal) ▲.

of poly(U) is shown in Fig. 6 together with that of J_{56}. $J_{1'2'}$ is measured on the $H_{1'}$ signal under homo-decoupling H_6 proton, since the H_5 and $H_{1'}$ signals partially overlap in poly(U). Since J_{56} shows little temperature dependence, it appears safe to conclude that $J_{1'2'}$ is also invariant with temperature within the experimental accuracy of ±1.5 Hz. Based on the detailed analysis of coupling constants of ribose protons at 36 °C at 220 MHz by Kreishman and Chan,[22] Davies and Danyluk have estimated ring-conformer population of poly(U) to be 42% and 58% for N and S conformers, respectively.[23] The result of Fig. 6 shows that such conformation of the ribofranosyl ring of poly(U) does not change within the temperature range studied. Richards and co-workers[24] reported that poly(U) could undergo a co-operative transition to an order form below 15 °C. However, since their optical experiments were performed under high salt concentration, it could not be compared directly with the present results.

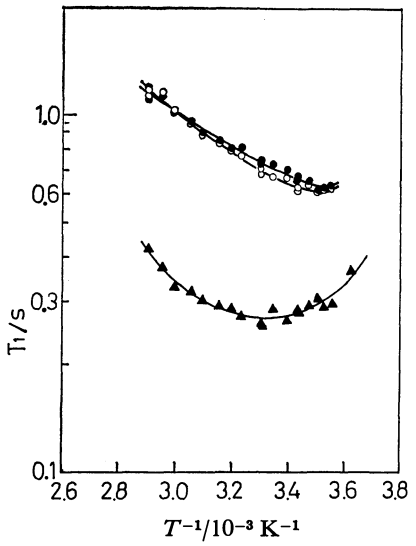

Fig. 7. Semilogarithmic plots of spin-lattice relaxation times (T_1) of poly(U) against reciprocal absolute temperature (H_5 ●, H_6 ▲, $H_{1'}$ ○).

Figure 7 shows the temperature dependence of T_1 for H_5, and H_6, and $H_{1'}$. T_1 of the three protons go through minima, but at different temperatures. Interproton distances, r_{lobsd} were obtained similarly as in poly(C) (Table 1). These distances must reflect local conformation of poly(U). The r_{lcalcd} values were computed for many conformers and compared with r_{lobsd} similarly as for poly(C). As the result, the base orientation of poly(U) is restricted to *anti* and *syn*.

The population of S conformer above 65 °C is 16% higher in poly(U) than in poly(C). This would arise from the fact that poly(U) is free from base stacking at all the temperatures studied, whereas poly(C) takes partial base stacking even above 65 °C as judged from Fig. 2, where N conformer is preferable to S conformer discussed for poly(C).

From the T_1 values, rotational correlation times τ_c were estimated to be in the order of 10^{-10}—10^{-9} s, corresponding to the local motions of polynucleotides.[4,18,25,26] The higher flexibility of poly(U) is implied from the fact that $T_{1\,\text{min}}$ of poly(U) protons appear at lower temperature than those of poly(C). The above observation is in accordance with the earlier conclusion from ^{31}P T_1 measurements.[4]

Appendix

When T_1 of a proton i is determined by dipolar interaction which is modulated by an isotropic rotation of the molecule with a characteristic time constant τ_c, the following equation is given for the interacting protons separated by a fixed distance r,[27]

$$\frac{1}{T_1} = \sum_j \frac{\gamma^4\hbar^2}{r_{ij}^6}\left(\frac{3}{10}\frac{1}{1+\omega^2\tau_c^2}+\frac{12}{10}\frac{1}{1+4\omega^2\tau_c^2}\right)\tau_c, \qquad (1)$$

where γ and ω are the gyromagnetic ratio and Larmor angular frequency of a proton, respectively, and suffix i and j represent the observed proton and the other proton interacting with proton i, respectively. Equation 1 predicts that T_1 goes through a minimum when $\omega\tau_c \simeq 0.62$ or $\tau_c =$

9.9×10^{-10} s. Therefore, for T_1 at the minimum, Eq. 1 could be rewritten as follows,

$$\frac{1}{T_{1\,\mathrm{min}}} = \sum_j \frac{\gamma^4\hbar^2}{r_{ij}^6}\times 6.81\times10^{-10}. \quad (2)$$

Accordingly, with the minimum value of T_1 we can evaluate interacting proton-proton distance in a form of

$$r_{\mathrm{lobsd}} = (T_{1\,\mathrm{min}}\gamma^4\hbar^2\times6.81\times10^{-10})^{1/6} \quad (\text{in Å}). \quad (3)$$

Chemical shifts and coupling constants of poly(C) were measured at 360 MHz at the Max-Planck Institut für Medizinische Forschung, Heidelberg, FRG. The authors are grateful to Professor K. H. Hausser for this opportunity.

Studies on Molecular Motion in Lyotropic Mesophases of Hexaethylene Glycol Dodecyl Ether–D_2O System by ^{13}C Nuclear Magnetic Resonance

Shigeru MITA,* Shoichi KONDO, and Masatami TAKEDA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 7, 1981)

The ^{13}C spin-lattice relaxation time(T_1) and the resonance line width corresponding to T_2* were measured for each of the carbons in hexaethylene glycol dodecyl ether–water(D_2O) system, which exists as two distinct lyotropic mesophases(neat and middle phase). The line width is very narrow in the isotropic state, such as in organic solvents and in a lower concentration aqueous solution, whereas in a mesophase and in a higher concentration aqueous solution, the line width of the alkyl chain was broadened. Here the line widths for glycol carbons were about an order of magnitude smaller than for an alkyl chain, demonstrating the difference of molecular motion. The chemical shifts of the alkyl chain in the middle phase were different from those in the isotropic state; this difference was clearly shown in the spectrum of the middle/isotropic coexistent phase. ^{13}C-T_1 was not sensitive enough to differentiate between the isotropic and the lyotropic phase at room temperature. It was found that T_1 did not equal T_2* for any of the methylene carbons, the difference being most marked for the terminal methyl carbon in the alkyl chain. The orientational order in the phases had an influence on the T_2* values.

One of the most fruitful techniques used to study lyotropic mesophases is magnetic resonance.[1] Proton nuclear magnetic resonance (^1H NMR) and relaxation measurements have been used to study the interaction of an ester with a polyethylene glycol alkyl ether as a nonionic surfactant.[2] It is difficult by ^1H NMR to measure separately the hydrophilic and hydrophobic parts of a mesophase because of the overlapping and the broadening of resonance lines.[2,3]

^{13}C Nuclear magnetic resonance (^{13}C NMR) has become an important tool in the investigation of the microstructure and molecular dynamics of liquid crystals.[3] The ^{13}C spin lattice relaxation time T_1 can readily be measured for all resolved resonances from partially-relaxed Fourier transform spectra. Ribeiro and Dennis measured ^{13}C NMR and T_1 values in isotropic states for octaethylene glycol dodecyl ether and suggested there were differences in mobility of the various groups in the surfactant.[3] The present study examines the ^{13}C-T_1 and the line width in an aqueous system of hexaethylene glycol dodecyl ether ($C_{12}EG_6$), as a function of aqueous concentration in D_2O and temperature in both the isotropic micellar solution and the mesophase. The $C_{12}EG_6$–water system is known to form two distinct lyotropic mesophases (neat and middle phase).[1,4] The results yield considerable information concerning the motional behavior of the hydrophilic and hydrophobic part of the miceller phases.

Experimental

Samples. Hexaethylene glycol dodecyl ether was obtained from Nikko Chemical Co., Ltd. and used without further purification. Purity of the sample is ≧99% by gas chromatography. NMR measurements were made for an undiluted liquid $C_{12}EG_6$; sample A comprised 90% $C_{12}EG_6$ and 10% D_2O (Merck, Uvasol 99.75%) by weight; sample B was a neat phase comprising 72% $C_{12}EG_6$ and 28% D_2O; sample C contained 65% $C_{12}EG_6$; sample D as a middle phase contained 50% $C_{12}EG_6$, and sample E, 10% $C_{12}EG_6$.[4] These samples were prepared according to the phase diagram established by Clunie *et al.*[4]

NMR Measurements. ^{13}C NMR spectra were measured at 25.03 MHz on a JEOL PFT-100 NMR spectrometer equipped with a PG-100 pulse programmer and a JEOL temperature controller. Samples were studied under conditions of complete proton noise decoupling or the gated decoupling, which minimize the rise of temperature in the sample by proton irradiation. The temperature of the sample in the probe was selected and maintained within ±1 K in accuracy in the range of 301 to 348 K.

Values of T_1 were measured using the inversion recovery method (T-180°-t-90°) over a 2 kHz band width with 8192 time domain data points. The 90° pulse length was calibrated prior to each set of experiments and varied between 20—25 μs. The delay time T was more than 5 times the longest T_1 value. For the relaxation time measurements, the sample was put into a spherical glass, and sealed after being degassed by freezed-thaw cycles. All such sample tubes were equilibrated for more than one weak at room temperature.[1]

Results and Discussion

Assignment of ^{13}C NMR Spectra. In Fig. 1, the ^{13}C NMR spectrum and tentative assignments are shown for the carbons in undiluted liquid $C_{12}EG_6$ at room temperature. The identification of the alkyl

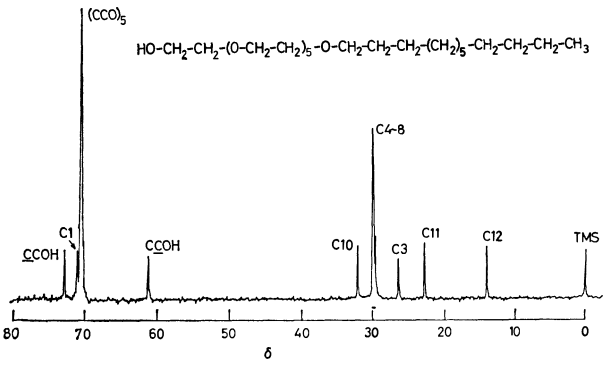

Fig. 1. ^{13}C NMR spectrum and assignment of undiluted liquid of $C_{12}EG_6$ at 301 K.

chain carbons in $C_{12}EG_6$ is based on assignments for $C_{10}OH$ and for other aliphatic compounds. Comparing the $C_{12}EG_6$ spectrum with that of $C_{12}OH$, we find no signal in the $C_{12}EG_6$ spectrum at the position of the C2 carbon of $C_{12}OH$. The C2 signal was shifted upfield and overlapped with the C4—9 signal by an increase of the electron density of C2 in $C_{12}EG_6$, owing to the oxyethylene group. Rebeiro and Dennis have assigned the C2 carbon to the signal which is assigned here to the C3 carbon.[3] The assignment for the carbons of the oxyethylene group has been made by ^{13}C NMR measurements of polyethylene glycol dodecyl ethers ($C_{12}EG_n$, n=1—8) and of compounds with several oxyethylenes and otherwise agreed with that of Ribeiro and Dennis.[3]

^{13}C NMR Spectra in the Mesophase. Sample B was measured by ^{1}H NMR at 100 MHz. At temperatures below the transition point of 343 K, there are two very much broadened peaks of alkyl chain and oxyethylene group in the ^{1}H NMR spectrum. It is difficult by ^{1}H NMR to separate the alkyl chain and the oxyethylene group.[4] In Fig. 2 are shown ^{13}C NMR spectra of a neat phase and of the isotropic phase for sample B. The upper spectrum, corresponding to the neat phase, and the lower spectrum in the isotropic phase at 348 K were obtained from the same solution. The lower spectrum was almost the same as the undiluted liquid spectrum in Fig. 1. In Fig. 3 are shown the ^{13}C NMR spectra of samples A, D, and E. The ^{13}C NMR spectrum in the middle phase for sample D is substantially the same as that in the neat phase in Fig. 2(1).

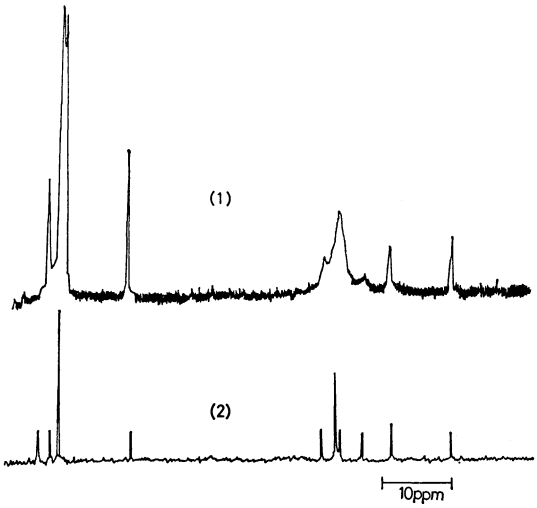

Fig. 2. ^{13}C NMR spectra for $C_{12}EG_6$ 75 w/w% in D_2O.
(1): Neat phase at 338 K, (2): isotropic phase at 348 K.

(1): 90% $C_{12}EG_6+D_2O$, (2): 50% $C_{12}EG_6$, (3): 10% $C_{12}EG_6$.

In the neat and the middle phase spectra, the peaks arising from the carbons of the alkyl chain are much broader than those of the isotropic phase spectrum. The ^{13}C peaks of the oxyethylene group are slightly broadened. It is considered for mesophases that the alkyl chains overlap and that the paraffinic layer is rigid. The line width narrowing for the oxyethylene group is presumed to be due to a diffusional motion of this group, which is loosely restrained because of a hydration to the oxyethylene group. A low angle X-ray diffraction study on the $C_{12}EG_6$–H_2O system by Corkill et al. supported this assumption.[2] Samples A and E are both in the isotropic phase at room temperature. In the spectrum of sample E, the peaks of the alkyl chain are shown to be slightly broadened and the line shapes are different from those of the neat and middle phase. The spectrum of sample A is similar to that of the undiluted liquid $C_{12}EG_6$ and to that of the isotropic phase of sample B.

Chemical Shift. The data of chemical shifts for all samples are summarized in Table 1. Previously, it was shown that the peaks of the alkyl chain in the isotropic phase are displaced downfield by 0.5 ppm from those in the lyotropic neat and middle meso-

phases. On the other hand, ^{13}C chemical shifts of the oxyethylene group do not differ for the lyotropic and isotropic states. In Fig. 4, all oxyethylene group signals except that of terminal oxyethylene for sample C are coincident. But each alkyl carbon signal consists of two resonance lines, as shown in Fig. 4. The lower-field peaks in this region were assigned to the alkyl carbons in the isotropic phase and the upper field peaks to the middle phase, by comparing the chemical shifts in samples B, D, and C. Thus, this spectrum suggests that the state corresponds to a middle/isotropic coexistent phase denoted as an interpenetrated broad boundary in the phase diagram by Clunie *et al.*[4]

Spin-lattice Relaxation Times. In Table 2 are summarized the ^{13}C spin-lattice relaxation times, T_1s, of the undiluted liquid, and samples B and D at several temperatures. At room temperature, samples B and D form the neat and middle phase, respectively. Small differences in magnitude of T_1 values were observed among carbons in the middle phase, indicating that there are small differences in mobility in the molecule. We compared the T_1 values for the phases:

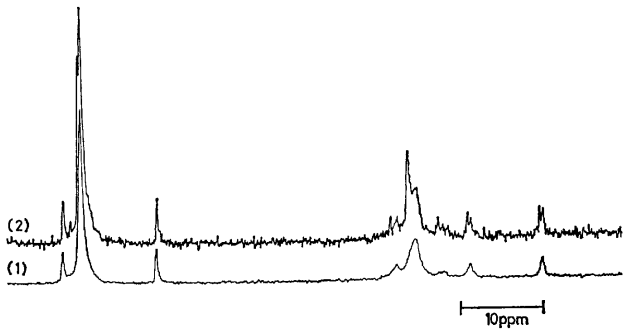

Fig. 4. ^{13}C NMR spectra of 65% $C_{12}EG_6+D_2O$ system (sample C).
(1): Middle phase at 296 K, (2): middle/isotropic coexistent phase at 298 K.

T_1(C12) of the neat phase is smaller than that of the isotropic and the middle phase. The T_1(C*COH) and T_1(CC*OH) values for the carbon (marked by the asterisk) of the middle phase are greater than that of the other phase. However, there is collectively no large difference in the T_1 values between phases. This result suggests that the mobility of a molecule in each phase is similar.

In 1-decanol or decylammonium trifluoroacetate, there is an increase in ^{13}C-T_1 on going from the carbons adjacent to an OH or NH_3 group to the terminal carbon in a molecule chain; this restriction is caused by intermolecular hydrogen bonding.[5,8] The alkyl chain has this tendency in our system. Ribeiro and Dennis had measured ^{13}C-T_1 of $C_{12}EG_8$ in micelles with D_2O as a good hydrogen bonding solvent.[3] They found that all T_1 values in aqueous solution are much smaller than those in the organic solvents.[2] There was little difference in ^{13}C-T_1 values of the corresponding carbons in the $C_{12}EG_6$ undiluted liquid, the neat phase, and the middle phase, as shown in Table 2.

Temperature dependences of T_1(C-11) and T_1-(C*COH) for the sample B and the undiluted liquid are shown in Fig. 5. T_1(C-11) plot for sample B has a minimum point at 308 K. The other curves show an inflection at about 301 K. It seems that this temperature is near to that of a minimum point of T_1. The plots of sample B show some scatter between 338 K and 343 K. This scatter agrees with the phase transition point from the neat to the isotropic phase.

Spin-Spin Relaxation Time. If a line shape is Lorentzian, a spin-spin relaxation time T_2^* is generally given by

$$T_2^* = 1/\pi \cdot \Delta\nu,$$

where $\Delta\nu$ is the half-height line width. T_2^* values calculated from this relationship are given in Table 3 T_2^* values of the undiluted liquid are longer than

those of the other states, but T_2* values of each signal for the neat phase are similar to those for the middle phase. In the undiluted liquid, T_2* values for alkyl carbons were three to eight times greater than those in mesophase, but the values of T_2* for the oxyethylene group do not change between the undiluted liquid and the mesophase.

The Relationship between ^{13}C-T_1 *and* ^{13}C-T_2* *Values.* There is a disparity between the values of ^{13}C-T_1 and ^{13}C-T_2*. Figure 6 shows the nT_1/T_2* ratio for each carbon at 301 K which is close to the temperature of T_1 minimum for the carbons of oxyethylene

in the mesophases. In this case the relation of $T_1 > T_2$ should be held acoording to the classical work of Bloembergen *et al.*[9] On the other hand, when the temperature of T_1 minimum for alkyl carbons is higher than 301 K, the T_1 value can be expected to be much greater than the T_2* value. It is found that this expectation is actually valid, as shown in Fig. 6. The ratios of nT_1/T_2* for oxyethylene carbon are almost invariably less than fifty-six, while the ratios of alkyl carbons are more than a hundred.

In contrast to the mesophases, for the undiluted liquid the ratios of both oxyethylene carbons and alkyl carbons, except for terminal ethyl carbons, are almost constant (in the range of about 17 to 25), and less than the value for oxyethylene in mesophases. This result has been attributed to the fact that the undiluted liquid of low viscosity had narrow line widths for all carbons. It is interesting to note that the ratio of methyl carbon is higher than that of the other carbons.

The authors take this opportunity to express their thanks to Professor Roger S. Porter of University of Massachusetts for many helpful suggestions.

Adsorption of Ethylene Oxide on Cab-O-Sil Silica, Reactive Silica, and Oxygen-treated Reactive Silica

Noriyuki SOTANI

College of Liberal Arts, Kobe University, Tsurukabuto, Nada-ku, Kobe 657

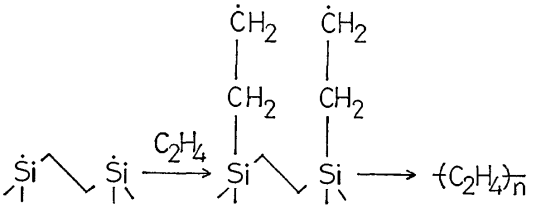
(Received July 16, 1981)

Ethylene oxide reacted with surface Si–OH of Cab-O-Sil silica to form Si–O–CH_2–CH_2–OH, while ethylene oxide was adsorbed on the silicon radicals of the reactive silica, and the oxygen radicals of the oxygen-treated reactive silica on which the adsorbed species polymerized to form $(-CH_2-O-CH_2-)_n$.

It is well known that ethylene oxide radicals are formed by pyrolysis[1] and photolysis,[2–4] and that these radicals can be easily polymerized without catalyst. The polymerization reaction of ethylene oxide occurs on various oxides, hydroxides and metal carbonates.[5–7] Furukawa *et al.*[5] have carried out a large number of experiments using solid catalysts. Ethylene oxide is easily polymerized under the influence of water and other substances containing labile hydrogen atoms such as amines and alcohols. The hydroxyl group appears to be the active centers in the polymerization reaction of ethylene oxide.[8] This polymerization occurs as an ionic type reaction.[9] On the other hand, a non-acid solid, for instance, silica gel with 5.6% of water bound on the surface is inactive in this polymerization.[9]

The polymerization product of ethylene oxide was studied by X-ray diffraction technique[10,11] and infrared spectroscopy,[12,13] and was confirmed to be a polyethylene glycol. In the presence of a strong acid or base catalyst the successive addition of ethylene oxide molecules yielded a polyethylene glycol. Aldehyde was presumably formed through oxyethylene biradicals.[14]

Reactive silica (RS) shows high reactivity in chemisorbing a variety of gases,[15–19] and it has been shown that acetylene, ethylene, several alkenes,[20,21] and ethylene oxide[22] are polymerized on its surface. Surface structure unlike those found on ordinary silica is formed. The high activity is thought to arise from the presence of unusual reaction center on the silica surface, *i.e.*, a pair of silicon radicals,[23] shown schematically in the following structure (I). Acetylene,



(I) (II)

ethylene, and several alkenes are adsorbed on silicon radicals of RS, and acetylene, ethylene and alkene radicals are formed as shown in structure (II). These radicals are easily polymerized[19–21] and these polymerization should be a radical type reaction.

Polymerization of ethylene oxide on RS can be expected to be a radical type reaction. Therefore, the present author studied the adsorption of ethylene oxide on Cab-O-Sil silica, RS and oxygen-treated reactive silica(ORS), and tried to find the difference in the reaction mechanisms on these silicas and the mechanism of the polymerization reaction.

Experimental

RS was prepared from Cab-O-Sil silica (obtained from G. Carbot Co., Boston, Mass.). It was methoxylated by using methoxy-containing compounds,[18] of which trimethoxymethane (trimethyl orthoformate, TMM) was the most efficient.[19] The methoxylated samples were pyrolyzed and then degassed at high temperature.[16,17] ORS was obtained from RS by exposing it to dry oxygen.[17] The samples were treated in the cell described elsewhere[17] and the conventional high vacuum technique was employed. Infrared spectra were recorded on Perkin Elmer Models 421 and 621 spectrometers.

Ethylene oxide (Eastman Kodak "pure grade") was degassed at liquid nitrogen temperature and distilled several times prior to the use.

Results

Cab-O-Sil Silica. Ethylene oxide was added to Cab-O-Sil silica, which was treated in about 100 Torr of wet oxygen at 650 °C for 1 h and was degassed at 700 °C for 1 h. When the silica was exposed to ethylene oxide, infrared absorption bands appeared immediately at 3350, 3085, 3066, 3007, 2970, 2929, 2870, 2720, 1736, 1468, and 1455 cm^{-1}, in addition to the band at 3747 cm^{-1} due to OH stretching vibration attached to surface Si atoms (Si–OH)[15–17] as shown in Fig. 1(A). Figure 2 shows the changes in intensities of the bands at 3747, 3350, and 2929 cm^{-1} when ethylene oxide was added to the silica. The band intensity was determined after 20 min. The intensity of the 3747 cm^{-1} band decreased with the increase of pressure of ethylene oxide. On the other hand, the intensities of the bands at 3350 and 2929 cm^{-1} increased with the increase of the pressure. This result shows that these three bands strongly correlate with each other. Namely, this means that the surface OH of Cab-O-Sil silica was reacted with added ethylene oxide and that a new adsorbed species showing the bands at 3350 and 2929 cm^{-1} was formed.

The sample adsorbed with ethylene oxide was degassed for 5 min at room temperature and at 105 °C. The bands at 3085, 3066, 3007, 2970, 2720, and 1736 cm^{-1} disappeared completely by degassing, but the bands at 3747, 3350, 2955, 2925, 2878, 1468, and 1451 cm^{-1} were maintained as shown in Figs. 1(B) and (C), and they still remained at 400 °C (Fig.

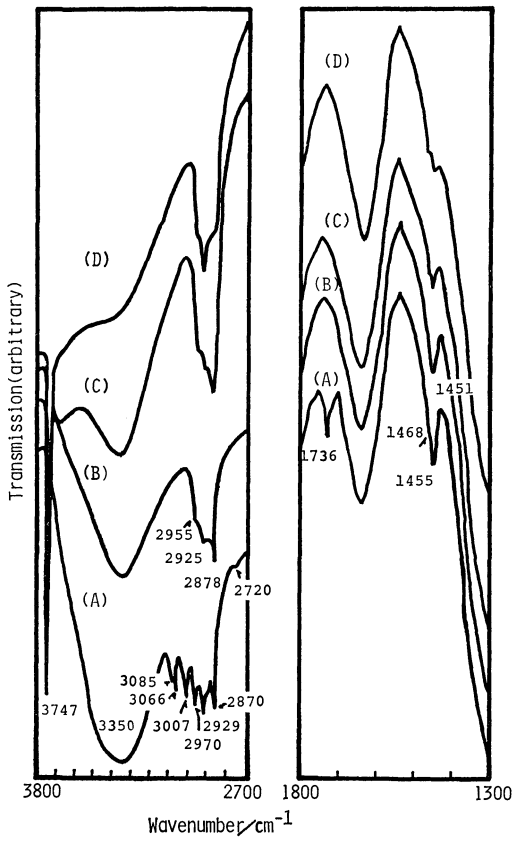


Fig. 1. IR spectra of ethylene oxide adsorbed on Cab-O-Sil silica.
A: 95 Torr† ethylene oxide at room temperature for 15 h, B: degassed at room temperature for 5 min, C: degassed at 105 °C for 5 min, D: degassed at 400 °C for 5 min.

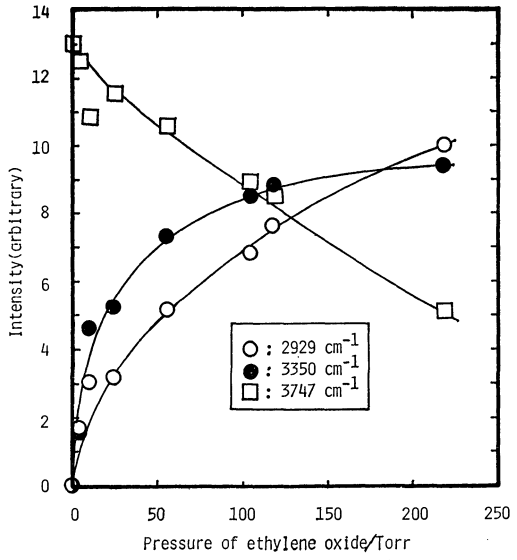

Fig. 2. Changes in intensities of the bands at 3747 (□), 3350(●), and 2929(○) cm^{-1} with pressure of ethylene oxide.

1(D)). The bands at 2720 and 1736 cm^{-1} are characteristic frequencies of aldehyde,[24] which is weakly adsorbed. The bands at 3085, 3066, 3007, and 2970 cm^{-1} are identified with typical bands of gaseous

† 1 Torr≈133.322 Pa.

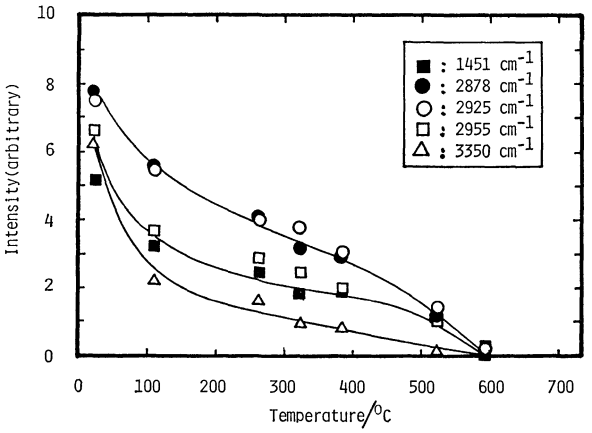

Fig. 3. Changes in intensities of the bands at 3350 (△), 2955(□), 2925(○), 2878(●), and 1451(■) cm^{-1} with evacuation temperature.

ethylene oxide reported by Potts,[25] which are CH_2 stretching vibration. The fact that the bands at 3085, 3066, 3007, and 2970 cm^{-1} disappeared easily by degassing at room temperature means that ethylene oxide kept its ring structure and was weakly adsorbed on Cab-O-Sil silica.

Figure 3 shows the change in band intensities by degassing at different temperatures. The band intensities at 3350, 2955, 2925, 2878, and 1451 cm^{-1} gradually decreased with elevation of degassing temperature. From Figs. 2 and 3, it is clear that the band at 3747 cm^{-1} correlates strongly with the bands at 3350, 2955, 2925, 2878, and 1451 cm^{-1}. Considering these results two types of adsorbed ethylene oxide are presumed, that is, one is the weakly adsorbed ethylene oxide molecules which keep a ring structure, and the other, the new adsorbed species reacts with surface OH which shows the band at 3350, 2955, 2925, 2878, and 1451 cm^{-1}.

RS (Reactive Silica). Sixty five Torr of ethylene oxide was added to RS. Figure 4(A) shows an infrared spectrum of ethylene oxide introduced on RS, which shows the bands at 3092, 3063, 3025, 3007, 2960, 2931, 2917, 2865, and 1450 cm^{-1}. Among these, the intensities of the bands at 3092, 3063, 3025, 3007, and 2917 cm^{-1} decreased as the time went on, on the other hand, the intensities of the bands at 2960, 2931, 2865, and 1450 cm^{-1} increased. Figure 5 shows the changes in intensities of the bands at 3063, 3007, 2931, 2865, and 1450 cm^{-1} by the same procedure. It is clear that the intensities of the bands at 2931, 2865, and 1450 cm^{-1} increased with the decrease of the band intensities at 3063 and 3007 cm^{-1}. The bands at 3063 and 3007 cm^{-1} are typical of ethylene oxide molecules.[25] Namely, Fig. 5 shows that the weakly adsorbed ethylene oxide molecules were converted into the new adsorbed species on RS.

The sample exposed to ethylene oxide vapor was degassed at room temperature for 5 min. The bands due to ethylene oxide disappeared completely, the bands at 2960, 2876, and 1455 cm^{-1} were maintained and a new band at 1465 cm^{-1} appeared as shown in Fig. 4(B). No further change was observed by degassing at room temperature for 1 h. The band at 2876

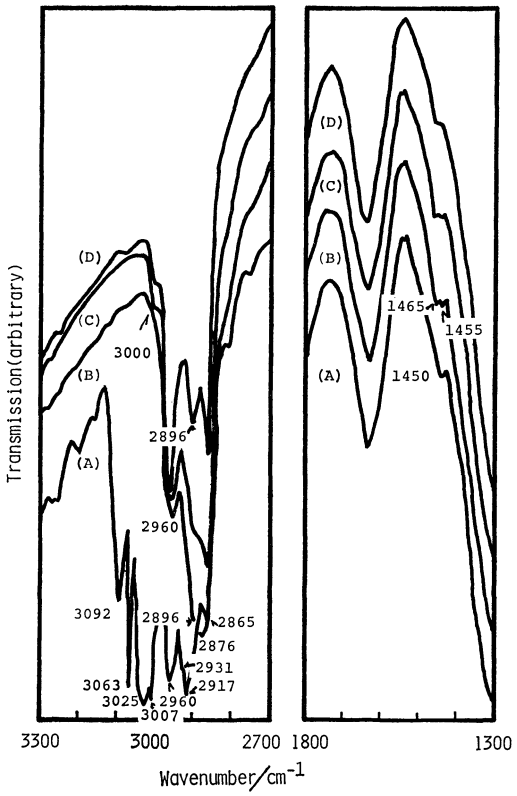

Fig. 4. IR spectra of ethylene oxide adsorbed on RS. A: 65 Torr ethylene oxide at room temperature, B: degassed at room temperature for 5 min, C: degassed at 200 °C for 5 min, D: degassed at 440 °C for 5 min.

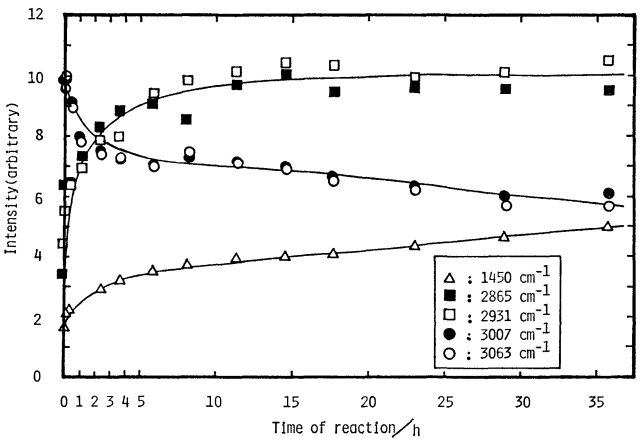

Fig. 5. Changes in intensities of the bands at 3063(○), 3007(●), 2931(□), 2865(■), and 1450(△) cm^{-1} with the time of reaction.

cm^{-1} split into two bands (2896 and 2865 cm^{-1}), and a new small band appeared at 3000 cm^{-1} by degassing at 200 °C and at higher temperatures even though the band intensities were changed as shown in Figs. 4(C) and (D).

As in the case of adsorption of ethylene oxide on Cab–O–Sil silica, the bands at 3092, 3063, 3025, 3007, and 2917 cm^{-1} disappeared easily and completely by degassing at room temperature. These bands due to gaseous ethylene oxide molecules having a ring structure as reported by Potts,[25] and by Lord and Nolin.[26]

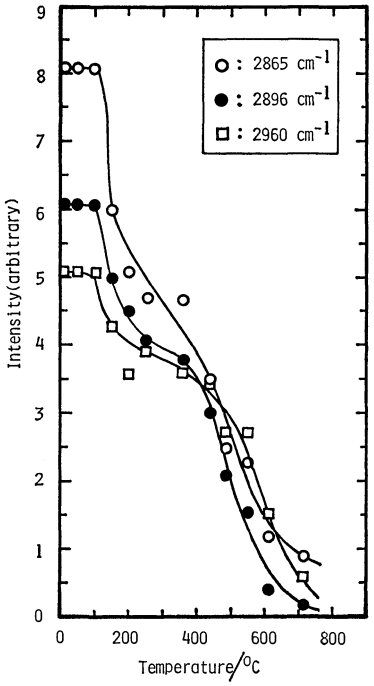

Fig. 6. Changes in intensities of the bands at 2960(□), 2896(●), and 2865(○) cm^{-1} with evacuation temperature.

This means that ethylene oxide is weakly adsorbed on RS.

Figure 5 shows the changes in intensities of the bands at 3063, 3007, 2931, 2865, and 1450 cm^{-1}. The intensities of the 3063 and 3007 cm^{-1} bands due to ethylene oxide molecules decreased at room temperature with the time of reaction. On the contrary, the intensities of the bands at 2931, 2865, and 1450 cm^{-1} increased. This result suggests that the weakly adsorbed ethylene oxide is converted into another new type of adsorbed species. While the intensities of both bands at 2931 and 2865 cm^{-1} increased similarly, but, as shown in Fig. 4, the band at 2931 cm^{-1} disappeared by degassing at room temperature, and the band at 2865 cm^{-1} was maintained even by degassing at 720 °C. Considering these results, there exist two different species showing the 2931 cm^{-1} band and the 2865 cm^{-1} band.

Figure 6 shows the changes in intensities of the bands (2960, 2896, and 2865 cm^{-1}) with evacuation temperature. No change was observed under 150 °C, but the intensities of three bands decreased above 150 °C. These bands were kept even at 720 °C. From Figs. 5 and 6, it is assumed that there are two kinds of adsorbed species on RS. One is the weakly adsorbed species, and the other, the strongly adsorbed one. Therefore, it is reasonable to consider that the weakly adsorbed species having the band at 2931 cm^{-1} was converted into another strongly adsorbed species having the bands at 2960, 2896, and 2865 cm^{-1}. Namely, the species having the band at 2931 cm^{-1} is assumed to be an intermediate on RS.

ORS (Oxygen-treated Reactive Silica). RS chemisorbs O_2 at room temperature, the reaction being complete within a few second. Oxygen-chemisorbed

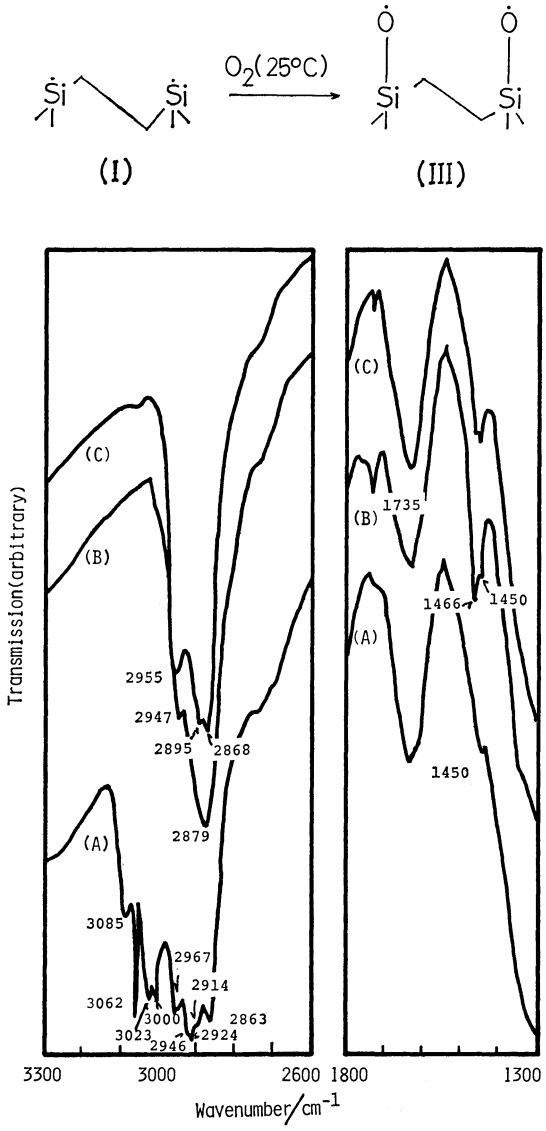

Fig. 7. IR spectra of ethylene oxide adsorbed on ORS. A: 71 Torr ethylene oxide at room temperature for 17 h, B: degassed at room temperature for 5 min, C: degassed at 460 °C for 5 min.

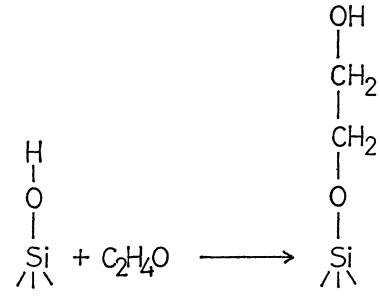
RS has a pair of oxygen radicals in structure (III).[17] It shows high activity and reacts with various gases as in the case of RS.[17]

Figure 7(A) shows the spectrum of ethylene oxide added to ORS at room temperature. The bands at 3085, 3062, 3023, 3000, 2967, 2924, 2914, 2863, 1735, and 1450 cm^{-1} were observed. Among these the bands at 3085, 3023, 3000, 2967, 2924, and 2914 cm^{-1} disappeared by degassing at room temperature, but the band intensity at 1735 cm^{-1} increased. The band at 1450 cm^{-1} split into two bands (1466 and 1456 cm^{-1}). By degassing at 460 °C, the band at 2947 cm^{-1} shifted to 2955 cm^{-1} and the band at 2879 cm^{-1} split into two bands (2895 and 2868 cm^{-1}) as shown in Fig. 7(C). These bands are similar to those in the case of RS except the one at 1735 cm^{-1}.

Discussion

Cab–O–Sil Silica. It is well known that the band at 3747 cm^{-1} is due to the surface OH(Si–OH).[15–17] The intensity of the 3747 cm^{-1} band decreased with the increase of those of the 3350 and 2929 cm^{-1} bands which were kept even by degassing at 600 °C as shown in Fig. 3. As mentioned above, this means that ethylene oxide reacts with surface OH. If the adsorbed species interacts with surface OH, the band due to OH shifts to lower frequencies by hydrogen bonding. In that case ethylene oxide should be adsorbed on the different site from surface OH, and this species was adsorbed weakly on Cab–O–Sil silica. This adsorbed species should be removed easily by degassing at room temperature. In the case of OH bonded to hydrocarbon such as alcohol (R–OH), the OH stretching vibration shifts to lower frequencies by hydrogen bonding and appears at near 3300 cm^{-1}.[8,27,28] The band at 3350 cm^{-1} just falls in this range and this may result from OH attached to the end of hydrocarbon. Therefore, it should be concluded that ethylene oxide reacted with the surface OH of Cab–O–Sil silica to form the new adsorbed species having the end OH group.

Considering that the ethylene oxide ring opens at C–O and fragment $-CH_2-CH_2-O-$ reacts with surface ≡Si–OH, the reaction product should have structure (IV). This is what is called an ionic type reaction. Structure(IV) is very similar to ethylene glycol except for the fact that one of the end OH groups is replaced with Si atom. Kanbayashi and Nukada[29] reported that the bands due to ethylene glycol appeared at 2947, 2924, 2881, and 1462 cm^{-1}. The bands at 2955, 2925, 2878, and 1451 cm^{-1} observed in this work (Fig. 1(B)) show little shift from those of ethylene glycol. These differences result from strong adsorption on Si atom of Cab–O–Sil silica like structure(IV). Indeed, Fig. 3 proved the presence of the strong adsorption species.



(IV)

The results and reasons mentioned above lead to the following conclusions; (i) Ethylene oxide is weakly adsorbed on Cab–O–Sil silica, forming a ring structure. That is, this is physical adsorption; (ii) Small amount of aldehyde is formed; (iii) Ethylene oxide reacts with the surface OH to form the adsorption species of structure (IV) which is similar to ethylene glycol. This is an ionic type reaction.

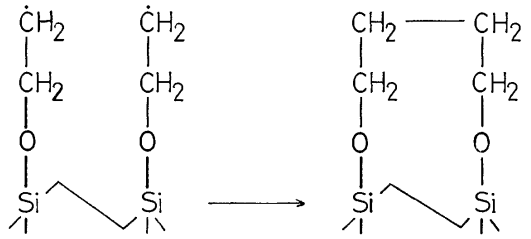
RS and ORS. As shown in Fig. 4, the bands at 3063 and 3007 cm^{-1} disappeared completely by degassing at room temperature, and at the same time the band at 2931 cm^{-1} also disappeared completely. The bands at 3063 and 3007 cm^{-1} are characteristic bands due to ethylene oxide having a ring structure, but the band at 2931 cm^{-1} is not. That is, the weakly adsorbed ethylene oxide molecule on RS is converted into the species having the band at 2931 cm^{-1}. On the other hand, the intensity of the band at 2931 cm^{-1} increases with the increase of the band intensities at 2865 and 1450 cm^{-1}, but the weakly adsorbed species having the band at 2931 cm^{-1} differs markedly from those having the bands at 2865 and 1450 cm^{-1} and also differs from the one resulted on Cab-O-Sil silica. Therefore, the author may safely predict that the species having the band at 2931 cm^{-1} is an intermediate of the reaction.

According to Markova,[30] adsorption species of ethylene oxide on $Mg(OH)_2$ showed three bands at 3055, 2925, and 2880 cm^{-1}. By degassing at room temperature the band at 3055 cm^{-1} disappeared completely and the band at 2925 cm^{-1} gradually disappeared by degassing at 180—200 °C. Only the band at 2880 cm^{-1} was kept. He proposed that the band at 3055 cm^{-1} was due to the characteristic of gaseous ethylene oxide which was physically adsorbed, and the bands at 2925 and 2880 cm^{-1} were due to valence vibration of CH_2 groups of the polymer molecule. Especially, he reported that the band at 2925 cm^{-1} was due to the band of the intermediate between ethylene oxide monomer and polymer.

The intensities of the bands at 2931 and 2865 cm^{-1} increased as shown in Fig. 5. The band at 2865 cm^{-1} was kept by degassing at room temperature and even at higher temperatures as shown in Fig. 6, while the band at 2931 cm^{-1} disappeared by degassing at room temperature. It is clear that the species having the band at 2865 cm^{-1} was formed when the species having the band at 2931 cm^{-1} existed. Namely, the species having the band at 2931 cm^{-1} plays an important role in inducing the species having the band at 2865 cm^{-1}. In addition to the results by Markova,[30] this result leads to the conclusion that the species having the 2931 cm^{-1} band is the intermediate. This result was recognized in the case of ORS.

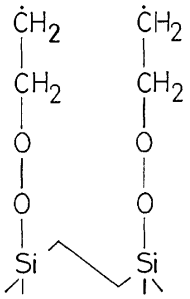
As shown in Fig. 6, the intensities of the bands at 2960, 2896, and 2865 cm^{-1} were kept by degassing under 200 °C, but those decreased above 200 °C. On the other hand, a new band appeared at 3000 cm^{-1} and the shoulder at 2896 cm^{-1} appeared clearly. Namely, as shown in Figs. 4(C) and (D), three strong bands at 2960, 2896, and 2865 cm^{-1} appeared clearly. The intensities of these bands decreased similarly by degassing above 200 °C, and these bands were kept even by degassing at 720 °C. This result means that the species was strongly adsorbed on RS. In the case of ethylene oxide adsorption on ORS, the band appeared at 1735 cm^{-1} by degassing at room temperature and was kept at higher temperatures as shown in Fig. 7. But the other bands behaved similarly as those of RS except the band at 3000 cm^{-1}.

Ethylene oxide ring opens in two ways as $-CH_2-CH_2-O-$(V) and $-CH_2-O-CH_2-$(VI). Usually, ethylene oxide reacts with hydrogen atoms such as alcohols, amines, hydroxyl groups and strong acids by cleavage at the C-O linkage and forms $-CH_2-CH_2-OH$ structure (V'). That is, this proceeds as an ionic type reaction. Indeed, as described above, in the case of Cab-O-Sil silica, ethylene oxide reacts with surface OH and forms $Si-O-CH_2-CH_2-OH$. RS and ORS have no hydrogen or hydroxyl group, but they have silicon radicals(I) and oxygen radicals(III). Therefore, it is easy to predict that reaction of ethylene oxide on RS and ORS differs from that on Cab-O-Sil silica. Low reported[16,17] that silicon radicals of RS and oxygen radicals of ORS reacted with various gases in the same way. Especially, radicals were formed on RS and ORS such as ethylene radicals (structure (II)) and these radicals were polymerized on them. Low also reported[21] that ethylene reacted with oxygen radicals of ORS to form species (VII) and then species (VIII). If species (V) reacted with



(VII) (VIII)

silicon radicals(I), species (VII) should be formed and then species (VIII). But there was no evidence, *i.e.*, there was no band for which Low[21] assigned species (VII) and species (VIII). On the other hand, if species (V) reacted with oxygen radicals of ORS, a peroxide having structure (IX) should be formed. If peroxide (IX) was formed, the band due to CH vibra-



(IX)

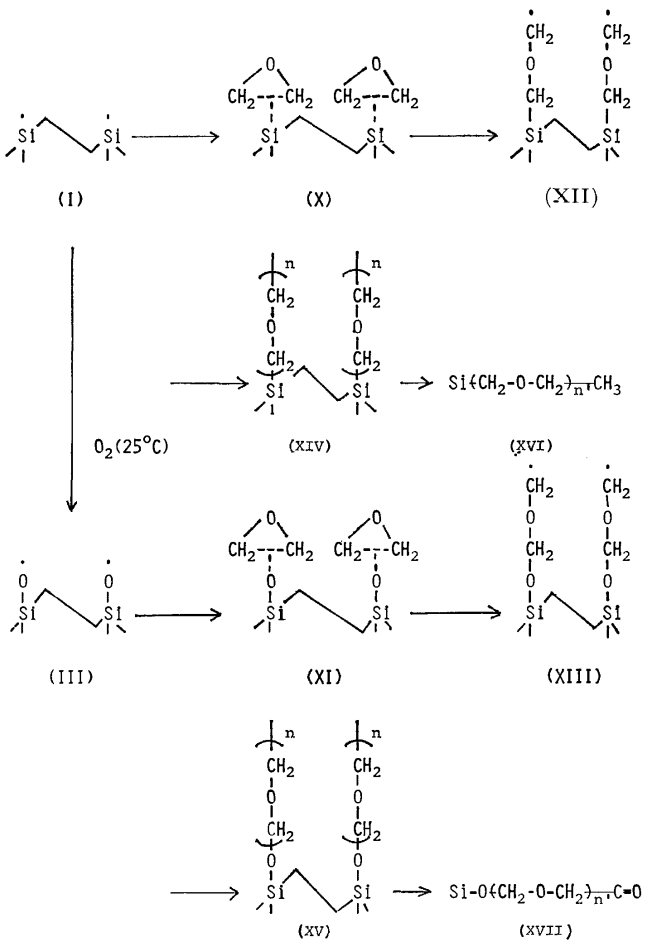
tion was expected to shift to lower frequencies than that of ethoxide by effect of oxygen atom, but there was no evidence of the shift as shown in Fig. 7. Namely, the bands due to vibration of CH_2 group show no difference between the cases of RS and ORS. Therefore, there is little probability that species (IX) exists.

Generally, CH stretching vibration in CH_2 groups appears at 2940—2915 and 2870—2845 cm^{-1}.[24,31-34]

But the bands due to CH_2 in ether as the structure of R–O–CH_2– shift to higher frequencies at 2955—2922 and 2878—2835 cm^{-1}.[31,34] According to Miyazawa *et al.*[13] polyethylene glycol has the –CH_2–O–CH_2– repeating unit and shows the bands at 2950, 2890, 1470, and 1453 cm^{-1}. Naccache *et al.*[9] reported that the polymer of ethylene oxide showed the bands at 2943, 2887, 1467, and 1455 cm^{-1}. The bands observed in the present work (Fig. 4(B): 2960, 2876, 1465, and 1455 cm^{-1}, and Fig. 7(B): 2947, 2879, 1466, and 1456 cm^{-1}) are very similar to those by Miyazawa *et al.*[13] and Naccache *et al.*[9] The structure of –CH_2–O–CH_2– is, therefore, expected.

The band at 2876(ORS;2879) cm^{-1} splits into two bands at 2896(ORS;2895) and 2865(ORS;2865) cm^{-1} by degassing at high temperature and these band intensities decreased similarly as shown in Fig. 6. From the result mentioned above, it is speculated that polymerization of ethylene oxide proceeds at high temperature. At the same time, a new band appeared at 3000 cm^{-1} on RS and 1735 cm^{-1} on ORS. The former predicts the existence of CH_3 group, and the latter C=O group. These groups should be formed by depolymerization at higher temperature.

Considering the above results, it is concluded as follows; (i) Ethylene oxide is weakly adsorbed on RS and ORS, forming a ring structure. This is physical adsorption; (ii) The intermediate is formed on silicon and oxygen radicals as species (X) and (XI), which are adsorbed weakly; (iii) Species (X) and (XI) open its ring at C–C bond as a radical type reaction to form species (XII) and (XIII), and, then, they are polymerized as species (XIV) and (XV), (iv) One of species (XIV) and/or (XV) depolymerizes at higher temperatures to form species (XVI) and/or (XVII).



The author is very grateful to Professor Manfred J. D. Low of New York University for his giving the chance to study at his laboratory and for his obliging permission to present this paper. The author is also grateful to Mr. Koji Watanabe of Kobe University for his kind suggestions with respect to this manuscript.

Circular Dichroism of *N*-Acetyl-L-amino Acid Methylamides with Aromatic Side Groups

Hiroatsu MATSUURA,* Kodo HASEGAWA,†,†† and Tatsuo MIYAZAWA†,†††

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

† *Institute for Protein Research, Osaka University, Yamadaoka, Suita, Osaka 565*

(Received August 21, 1981)

The circular dichroism (CD) and its temperature dependence were studied on *N*-acetyl-L-phenylalanine methylamide, *N*-acetyl-L-tyrosine methylamide, and *N*-acetyl-L-tryptophan methylamide, as model molecules of aromatic amino acid residues in proteins. The CD spectra indicated that the increase in temperature and the decrease in solvent polarity give a similar effect on the amide $\pi^* \leftarrow n$ transition. The CD behavior of the tryptophan derivative was different from that of the phenylalanine and tyrosine derivatives, suggesting that the bulkier indolyl side group interacts with the peptide backbone in a different way. The noticeable temperature dependence of the CD intensities in the 250—300 nm region observed for the phenylalanine and tryptophan derivatives suggested the coexistence of various conformers at higher temperatures.

Protein molecules contain chromophoric groups such as amides, disulfides, and aromatic groups. Although the amides and aromatic groups themselves possess planes of symmetry, they are made optically active by the asymmetric configuration of the amino acid residues and the asymmetric arrangement of these chromophoric groups. Accordingly, the optical activity depends on the conformation of the groups surrounding the chromophores. Studies on circular dichroism (CD) of model molecules of proteins, containing aromatic side groups are, therefore, important in understanding the relation between the conformation and the optical rotation of the amide and aromatic groups. The CD spectra of phenylalanine, tyrosine, tryptophan, and their derivatives of *N*-acetyl amino acid amides and *N*-acetyl amino acid ethyl esters have been studied by several investigators. However, since amino and carboxyl groups of amino acids are involved in forming the peptide bonds of protein main chains, the most appropriate model molecules of amino acid residues in proteins are *N*-acetyl amino acid methylamides ($CH_3CONHCHRCONHCH_3$). Accordingly, in the present study, the CD and ultraviolet absorption spectra of *N*-acetyl-L-phenylalanine methylamide (AcPheMA), *N*-acetyl-L-tyrosine methylamide (AcTyrMA), and *N*-acetyl-L-tryptophan methylamide (AcTrpMA) have been measured in a temperature range between −70 and 50 °C.

The CD spectra of *N*-acetyl-L-phenylalaninamide (AcPheA), *N*-acetyl-L-tyrosinamide (AcTyrA), and *N*-acetyl-L-tryptophanamide (AcTrpA), and their related compounds have previously been studied by Shiraki,[1] and Strickland *et al.*[2-7] Strickland *et al.* measured the CD spectra at 25 and −196 °C and analyzed the vibrational structure. They suggested that the observed temperature dependence of the spectra was related to the shift of equilibrium of various conformers. In the present study, temperature dependence of the CD spectra of AcPheMA, AcTyrMA, and AcTrpMA was studied in a wavelength region between 200 and 300 nm in aqueous, methanol, and 1,4-dioxane solutions, and a change in intensity of the CD bands assignable to the amide and aromatic chromophores was examined. The results were also compared with those obtained for the primary amides of AcPheA, AcTyrA, and AcTrpA.

Experimental

AcPheMA, AcTyrMA, and AcTrpMA were prepared from the corresponding *N*-acetyl amino acid ethyl esters by the following method. Each of the esters was dissolved in methanol. Vapor of methylamine was then blown into the methanol solution until concentration of methylamine was about 25%. After being kept for 2 or 3 d, the reacting solution of *N*-acetyl-L-phenylalanine ethyl ester with methylamine yielded white needle crystals of AcPheMA, which was then recrystallized from methanol. For the derivatives of L-tyrosine and L-tryptophan, methylamine and methanol were evaporated after the reaction to give pale yellow powders. Repeated recrystallization from a mixture of ethanol and hexane gave white powders of AcTyrMA or AcTrpMA. Elemental analyses gave the following results. AcPheMA. Found: C, 65.48; H, 7.51; N, 12.94%. Calcd for $C_{12}H_{16}N_2O_2$: C, 65.43; H, 7.32; N, 12.72%. AcTyrMA. Found: C, 61.01; H, 7.01; N, 12.01%. Calcd for $C_{12}H_{16}N_2O_3$: C, 61.00; H, 6.83; N, 11.86%. AcTrpMA. Found: C, 64.70; H, 6.80; N, 16.15%. Calcd for $C_{14}H_{17}N_3O_2$: C, 64.85; H, 6.61; N, 16.20%.

The CD spectra were measured with a JASCO J-20 spectropolarimeter and the ultraviolet absorption spectra with a Hitachi 124 spectrophotometer. Molar ellipticity $[\theta]$, in $10^{-2\circ}$ M^{-1} cm^{-1} $= {}^\circ$ cm^2 $dmol^{-1}$, was calculated by a relationship, $[\theta]=3300\ (\varepsilon_l-\varepsilon_r)$, where ε_l and ε_r are molar absorption coefficients for the left- and right-circularly polarized lights, respectively. The CD intensity was calibrated against the intensity ($\varepsilon_l-\varepsilon_r=2.20$ M^{-1} cm^{-1})** of the 290.5 nm band of an aqueous solution of (+)-10-camphorsulfonic acid. Sample cells of path lengths of 5 and 10 mm were used for a wavelength region of 230—300 nm, while cells of path lengths of 0.1 and 1 mm were used for a region of 200—250 nm to reduce absorptions of solvents. The path length of the 0.1 mm cell was corrected by the ultraviolet absorption of a standard aqueous solution of potassium chromate.

The temperature of the sample cells was controlled with two kinds of constant-temperature apparatus.[8] For the measurements at −70 °C, a low-temperature cell was used

** 1 M = 1 mol dm^{-3}.

with Dry Ice-acetone as coolant. Inside the low-temperature cell, a sealed sample cell was fixed to cooled copper block. The outer cell was kept vacuum to prevent the sample cell from condensation of water vapor. For temperatures higher than −10 °C, a brass-block cell holder was used. Through the brass block, externally temperature-controlled water or ethanol was circulated to keep the cell holder at constant temperature. Nitrogen gas was blown onto the sample-cell surface to avoid water-vapor condensation for temperatures below room temperature.

Results and Discussion

N-Acetyl-L-phenylalanine Methylamide (AcPheMA). The CD spectra of AcPheMA measured in methanol at various temperatures are shown in Figs. 1 and 2. The ultraviolet absorption spectrum measured in methanol at 22 °C is very similar to the absorption spectrum of AcPheA in methanol–glycerol at 25 °C (Fig. 1 of Ref. 2). The CD spectral pattern in the wavelength region longer than 250 nm are essentially the same for the temperature range from −7 to 57 °C; three negative CD bands assignable to the phenyl group were observed at 255, 261.5, and 267.5 nm. The intensities of the three CD bands increased as temperature was lowered. At −70 °C, these bands have intensities threefold stronger than those at 57 °C, and three positive CD bands appeared at 251.5, 257.5, and 264 nm. Also, two shoulders appeared at 260 and 266 nm in the CD spectrum measured at −70 °C, but no corresponding absorption bands were detected at 22 °C. These spectral features of AcPheMA resemble those of AcPheA measured by Strickland *et al.*[2] The difference in intensity of the CD vibronic bands observed at −70 °C and higher temperatures suggests the coexistence of various conformers at higher temperatures, as in the case of AcPheA.

The CD bands observed in the 240—270 nm region are assigned to the vibrational structure of the $^1B_2 \leftarrow {}^1A_1$ electronic transition of the phenyl group. The vibronic assignments of the absorption and CD bands of AcPheMA were attempted in the light of the analysis for AcPheA.[2] The observed bands and their possible assignments are summarized in Table 1. The 0-0 band and the bands associated with the 0+930 cm^{-1} mode have a negative CD sign, while the 0+520 cm^{-1} progression observed only at −70 °C has a positive sign. The shoulders at 260 and 266 nm belong to the 0+180 cm^{-1} progression. The 0+180 cm^{-1} transition may be assigned to the B_1 vibrational mode, since this vibrational transition is electronically forbidden (total wavefunction is A_2). The absorption bands of the 0+180 cm^{-1} progression were, in fact, observed for neither AcPheMA nor AcPheA. The CD bands in the 240—250 nm region are likely to be distorted by overlapping tails of the phenyl $^1A_1 \leftarrow {}^1A_1$ and amide $\pi^* \leftarrow$n bands with band centers around 220 nm. This effect will be discussed later in detail.

In the CD spectrum of the methanol solution, a negative extremum was observed at 235—250 nm (Fig. 1). As temperature was raised, the intensity of this extremum increased with a blue shift, contrary to the $^1B_2 \leftarrow {}^1A_1$ bands whose intensities decreased. Judging from the band shape and the wavelength, this band is not likely to be due to the phenyl $^1B_2 \leftarrow {}^1A_1$ vibronic transition. In fact, no absorption band was observed in this wavelength region. This band at 235—250 nm is probably an apparent extremum formed as a residual difference between the overlapping tails of the shorter-wavelength CD bands assignable to the phenyl $^1A_1 \leftarrow {}^1A_1$ and amide $\pi^* \leftarrow$n transitions with the CD signs different from each other. Accordingly, temperature dependence of the CD spectrum in the 200—240 nm region was examined (Fig. 2). The CD extremum at about 220 nm for the methanol

solution showed appreciable dependence on temperature; its intensity increased about 1.5 times as temperature was lowered from 40 to −5 °C. This band was also found to be sensitive to the solvent. The CD intensity in water is about 40% stronger than in methanol, as seen in Fig. 2. Similar spectral changes have been noted by Barel and Glazer[9] for AcPheA in water and ethylene glycol–water (9:1). These authors considered that this spectral change was due to the change in solvent polarity and that the intensity decrease of the 220 nm band and the intensity increase of the 240 nm band were related to the dependence of the amide $\pi^* \leftarrow$n optical rotation on the solvent polarity. Thus, the solvent-polarity dependence and the temperature dependence of the CD spectrum of AcPheMA is quite similar in the 200—250 nm region.

In order to examine temperature dependence of the amide $\pi^* \leftarrow$n CD band free from the overlap of other bands, the CD spectrum of *N*-acetyl-L-leucine methylamide (AcLeuMA), $CH_3CONHCH(CH_2CH(CH_3)_2)CONHCH_3$, was measured in methanol at 0, 22, and 40 °C (Fig. 3). The spectral change with the increase in temperature resembles the spectral change with the decrease in solvent polarity.[10] Similar observations have been reported of the temperature dependence of the CD spectrum for *N*-acetyl-L-alanine ethylamide[11] and of the solvent dependence for *N*-acetyl-L-alaninamide.[9] Accordingly, it may be concluded that the increase in temperature and the decrease in solvent polarity give a similar effect on the amide $\pi^* \leftarrow$n transition. In order to confirm the above conclusion, the CD spectra of AcPheMA in water and 1,4-dioxane, whose polarities are higher and lower, respectively, than methanol, have also been measured. The aqueous-solution spectrum did not show a remarkable change in the 240 nm region as temperature was raised. This quite small spectral change may be due to the 215 nm positive band whose intensity is strong enough to screen the intensity change of the amide $\pi^* \leftarrow$n band. In 1,4-dioxane, on the other hand, a very strong negative CD band was

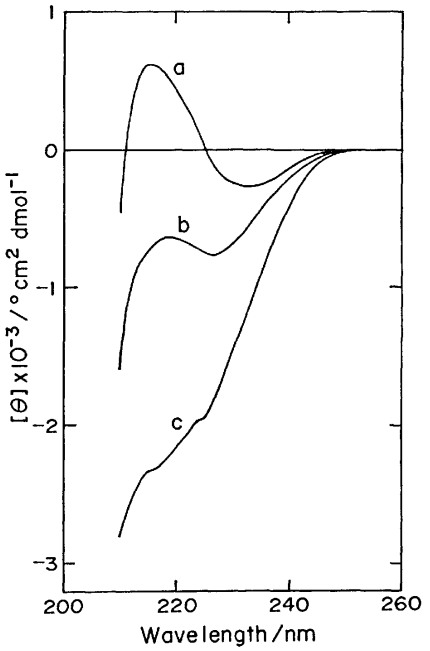

Fig. 3. CD spectra of *N*-acetyl-L-leucine methylamide (AcLeuMA) in methanol.
a: 0 °C, b: 22 °C, c: 40 °C.

observed at 233 nm (Fig. 4), which was blue-shifted with progressive intensity enhancement from 240 nm in methanol. These spectral observations indicate that the apparent negative CD extremum of AcPheMA around 240 nm is formed as a result of the overlap of the two CD bands with different signs. The CD spectra of AcPheA have been measured by Shiraki[1] in water, methanol, and 1,4-dioxane. The spectral changes with solvent are similar to those for AcPheMA studied in the present work, but the spectral patterns of AcPheA resemble the AcPheMA spectra measured at higher temperatures.

From the above considerations of the temperature and solvent dependence of the CD spectra, it is sug-

gested that the hydrogen bonds between the amide group of AcPheMA and solvent molecules affect the amide $\pi^*\leftarrow$n transition. However, further studies are necessary to conclude whether the hydrogen bonding causes the conformational change or only the change of the electronic state of the amide group.

N-Acetyl-L-tyrosine Methylamide (AcTyrMA). The CD spectra of AcTyrMA measured in methanol at various temperatures are shown in Figs. 5 and 6. In the wavelength region of 260—290 nm, a negative extremum was observed at 278.5 nm with shoulders at 282.5 and 287 nm at room temperature. These bands are assigned to the vibrational structure of the phenolic $^1B_2\leftarrow{}^1A_1$ transition, similarly to the 240—270 nm bands of AcPheMA assigned to the phenyl $^1B_2\leftarrow{}^1A_1$ transition. The 278.5 and 282.5 nm CD bands of AcTyrMA correspond to the absorption bands at 277 and 283 nm observed with the same condition. The 287 nm CD shoulder, with no counterpart in the absorption spectrum, may be assigned to the 0-0 transition, with reference to the assignment of the 286 nm CD band of AcTyrA to the 0-0 transition.[3] As seen in Fig. 5, the shoulders at 282.5 and 287 nm became better resolved when temperature was lowered to −70 °C, and the peak intensity of the former was comparable to the intensity of the main peak at 278.5 nm. However, no remarkable spectral change with temperature was observed in this wavelength region. The CD spectrum at 40 °C was essentially the same as the spectrum at 22 °C. Thus, the temperature dependence of the spectral feature from −70 to 40 °C is much less than that for AcPheMA or AcTrpMA. The CD spectra in water and 1,4-dioxane were also similar to the spectrum of the methanol solution, with no appreciable spectral change with temperature. The resemblance of the CD and absorption spectra of AcTyrMA and other L-tyrosine derivatives in this wavelength region is accounted for by the reasoning that all of the vibronic bands have the same CD sign[3]

and that the rotational strength is nearly proportional to the dipole strength. In *N*-acetyl-L-tyrosine ethyl ester (AcTyrEE), the CD sign of this vibronic progression is different between the methanol and 1,4-dioxane solutions.[3] The fact that the very little variation of the CD spectra of AcTyrMA measured for various conditions suggests that the mobility of the *p*-hydroxyphenyl groups in AcTyrMA is more restricted than in AcTyrEE.

In the wavelength region shorter than 250 nm, a positive CD band appeared at 227.5 nm in methanol (Fig. 6), corresponding to the strong absorption band at 226 nm ($\varepsilon_{max}=12000\ M^{-1}\ cm^{-1}$). This band is probably due to the phenolic $^1A_1 \leftarrow {}^1A_1$ transition. The aqueous-solution CD spectrum exhibits a peak at 225 nm (blue-shifted by 2.5 nm) with an intensity about 50% stronger than in methanol. The intensity of this CD band in methanol increased as temperature was lowered, similarly to the temperature dependence of the 220 nm CD band of AcPheMA. This spectral change is ascribed to the dependence of the $\pi^* \leftarrow n$ transition on temperature. This is supported by the observation that in a 1,4-dioxane–methanol mixture (2:1, v/v) an apparent negative CD band appeared around 246 nm at 55 °C, but no distinct peak at 17 °C (Fig. 7). These observations of the spectral changes with temperature may be compared with the solvent effect on the CD spectra of AcTyrA observed in water, methanol, and 1,4-dioxane.[1] The effects of the increase in temperature and the decrease in solvent polarity resemble closely each other, as in AcPheMA.

N-Acetyl-L-tryptophan Methylamide (AcTrpMA). The CD spectra of AcTrpMA measured in methanol at various temperatures are shown in Figs. 8 and 9. It should be mentioned that in AcTrpMA the absorption strength relative to the rotational strength is much stronger than in AcPheMA or AcTyrMA. Accordingly, the solution concentration and the path length were limited in the measurements, giving very weak CD signals and consequently low signal-to-noise ratios. As temperature was lowered to −70 °C, the CD intensity in the longer-wavelength region increased progressively and the vibronic bands were well resolved (Fig. 8). The vibronic bands in this region are assigned to the $^1L_a \leftarrow {}^1A$ and $^1L_b \leftarrow {}^1A$ transitions of the indolyl side group. The low-temperature spectrum has

two distinct positive peaks at 283.5 and 291 nm and a shoulder at 280 nm. An additional shoulder was observed around 270 nm at low temperature. These spectral features resemble those of the CD spectrum of AcTrpA.[5] The peaks of AcTrpMA at 283.5 and 291 nm are assigned to the 0+850 cm^{-1} $^1L_b \leftarrow {}^1A$ band and the 0—0 $^1L_b \leftarrow {}^1A$ band, respectively, with reference to the assignment of the corresponding CD bands of AcTrpA at 283 and 290 nm.[5] The noticeable difference in the CD spectra at room and lower temperatures suggests the coexistence of various conformers at higher temperatures, as in the case of AcPheMA. The CD spectrum of AcTrpMA in water in the 240—300 nm region resembles the aqueous-solution spectrum of L-tryptophan with unblocked amide and carboxyl groups;[12] three positive peaks with similar intensities were observed at 272, 281, and 291 nm.

In the spectral region of 200—240 nm, a positive CD band appeared at 223.5 nm in methanol and at 220 nm in water (Fig. 9), corresponding to the strong absorption band ($\varepsilon_{max}=45000\ M^{-1}\ cm^{-1}$) at 221.5 nm

in methanol. With the decrease in temperature, the intensity of this CD band increased but the peak position remained almost unshifted, indicating that this band of AcTrpMA is due largely to the transition of the indolyl side group ($^1L_b \leftarrow {}^1A$ transition). A noticeable spectral feature in Fig. 9 is that the CD curve of the methanol solution crosses over the base line at about 210 nm to the negative region. This observation shows the presence of a negative CD band in the shorter-wavelength region, in striking contrast to an anticipated positive band for AcPheMA (Fig. 2) or AcTyrMA (Fig. 6). Another spectral feature to remark for AcTrpMA is the appearance of a negative band at 237 nm at −70 °C. This spectral change appears to be opposite to the temperature effect on the apparent band of AcPheMA or AcTyrMA observed at 230—240 nm. However, the band at 237 nm is also ascribable to the overlap of two CD bands with different signs, as suggested by its wavelength. These peculiar spectral patterns for AcTrpMA lead to an inference that the CD behavior of the amide $\pi^* \leftarrow n$ and $\pi^* \leftarrow \pi$ transitions is different from that for AcPheMA or AcTyrMA. The difference is probably related to the bulkier indolyl group, which may interact with the peptide backbone in a way different from the phenyl or *p*-hydroxyphenyl group.

The authours wish to express their thanks to Dr. Toshio Takagi, Institute for Protein Research, Osaka University, for his valuable discussions and advices throughout the present work.

Synthesis and Alkali-cation Complexing Properties of 12-Crown-4 Derivatives†

Takeshi MIYAZAKI, Shozo YANAGIDA,* Akira ITOH, and Mitsuo OKAHARA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received September 9, 1981)

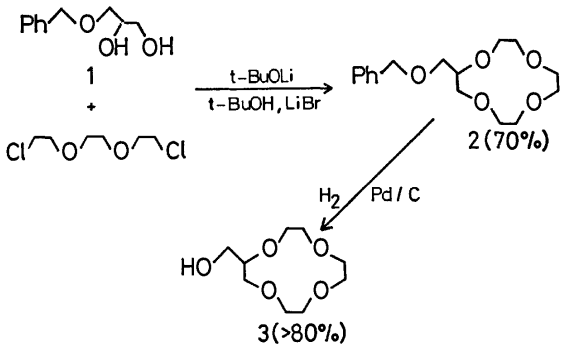
Benzyloxymethyl-12-crown-4, a precursor of hydroxymethyl-12-crown-4, is prepared in an excellent yield by the reaction of 3-benzyloxy-1,2-propanediol with 1,8-dichloro-3,6-dioxaoctane in the heterogeneous *t*-BuOLi/*t*-BuOH/LiBr·$2H_2O$ reaction system. The hydrogenolysis in the presence of *p*-toluenesulfonic acid leads to a good yield of hydroxymethyl-12-crown-4. The sandwich-type 2:1 complexation with Na^+ of 12-crown-4 and hydroxymethyl-12-crown-4 derivatives was discussed on the basis of the stability constants and the solvent extraction in the CH_2Cl_2–water system.

Among a series of macrocyclic ethers, twelve-membered macrocycles, 12-crown-4 and its derivatives, long drew little attention because of their weak complexation due to their small cavity size and because of the difficulty in their preparation. Steiner and his group first reported that 12-crown-4 forms crystalline complexes with alkali and alkaline-earth metal salts and clarified some of their crystalline structure by means of X-ray crystallography.[1,2] We have been interested in their findings that the 2:1 sandwich-type complexes of 12-crown-4 are formed with NaCl and NaOH and have square-antiprismatic coordination structures. In our previous ^1H NMR studies of polyethers,[3] we found that, in methanol, 12-crown-4 showed an unusual downfield shift of protons in the presence of Na^+, and that the 2:1 complex with NaSCN including water of crystallization is formed in aqueous methanol and can be recrystallized in acetone. With these facts in view, the present work was undertaken in order to clarify the characteristic interaction of 12-crown-4 macrocycles with Na^+. Although we previously reported a method for the preparation of hydroxymethyl crown ethers,[4] this paper will describe another facile synthesis of hydroxymethyl-12-crown-4 and its derivatives from commercially available starting materials, and will discuss their complexation with alkali metal cations in comparison with those of 15-crown-5 derivatives.

Results and Discussion

Synthesis of Hydroxymethyl-12-crown-4(3). The cyclization reactions to 12-crown-4 were generally in low yields because of the side reactions producing cyclic or acyclic oligomers.[5] As a route to hydroxymethyl-12-crown-4(**3**), we investigated the reactions shown in Scheme 1, and tried to determine whether a high yield of cyclization to benzyloxymethyl-12-crown-4(**2**) could be achieved under the influence of high dilution and the template effect of Li^+.[6]

3-Benzyloxymethyl-1,2-propanediol(**1**) can be prepared by the benzylation of commercially available 2,2-dimethyl-4-hydroxymethyl-1,3-dioxolane, followed by the hydrolysis of the dioxolane ring. The diol(**1**) was allowed to react with triethylene glycol ditosylate



Scheme 1.

in a 1:1 molar ratio in the presence of lithium bases. As is shown in Table 1, the use of *t*-butyl alcohol as a solvent gave satisfactory results for the cyclization. Further, when commercially available 1,8-dichloro-3,6-dioxaoctane was employed instead of the ditosylate with an equimolar quantity of LiBr·H_2O, the cyclization occurred almost quantitatively, giving an excellent yield of the 12-crown-4(**2**), although a long reaction time was required (see Run Nos. 7 and 8). Without LiBr·H_2O, however, no cyclization was observed after a 9-day reaction, indicating that the halogen-exchange reaction to the bromide and its moderate reactivity are possibly favorable for the cyclization. The employment of lithium iodide, however, was accompanied by an unidentified by-product having a smaller retention volume in GLPC analysis, leading to a low yield (*ca.* 15% GLPC yield).

It is worth noting that a drop-by-drop addition of the diol(**1**) to a *t*-butyl alcohol solution of *t*-BuOLi immediately causes the turbidity of the finely dispersed lithium salt of the diol(**1**); thus, the reaction system is heterogeneous through the reaction. The heterogeneous intermolecular cyclization was extended to the synthesis of benzyloxymethyl-15-crown-5 from the diol(**1**) and 1,11-dichloro-3,6,9-trioxaundecane. An excellent yield(74%) was confirmed in the *t*-BuOLi/*t*-BuOH/LiBr·H_2O reaction system rather than in the *t*-BuONa/*t*-BuOH system(65%). Recently Czech[7] and Gokel *et al.*[8] have independently reported the same cyclization. Lower yields, 35% and 62%, were noted in the reaction systems with dichloride/NaOH/dioxane and with ditosylate or bis(methanesulfonate)/NaH/THF, respectively. Benzyloxymethyl-18-crown-6 could be isolated in a 46% yield according to the

† A preliminary report of this work was presented at the 19th Annual Meeting of the Japan Oil Chemists' Society, Hiroshima, October 1980.

present method, using 1,14-dichloro-3,6,9,12-tetraoxatetradecane.

The *t*-BuOLi/LiBr/*t*-BuOH reaction system was extended to the synthesis of unsubstituted 12-crown-4 from ethylene glycol and 1,8-dichloro-3,6-dioxaoctane. However, the quantitative cyclization was not confirmed by GLPC analysis; *i.e.*, the dichloride was left unreacted even after a 10-day reaction, and some by-products with a longer retention volume were formed with 12-crown-4. This was also true for the reaction of triethylene glycol and 1,8-dichloro-3,6-dioxaoctane under the same conditions. The yield of 18-crown-6(4 h, <10%) was quite inferior to those of such homogeneous reactions at *t*-BuOK/KBr/*t*-BuOH reactions system(20 h, 51%). In view of these facts, the quantitative cyclization to the benzyloxymethyl-12-crown-4 may be attributed to the heterogeneous reaction on the dispersed Li salt of the diol(**1**), in which the coupling by the attack of the primary alkoxide of the diol(**1**) and the subsequent intramolecular attack of the secondary alkoxide, must occur advantageously under the influence of the template effect of Li^+. A similar heterogeneous metal template synthesis has already been disclosed for the synthesis of 18-crown-6.[9,10]

The benzyl group of the benzyloxymethyl-12-crown-4 can be readily removed by hydrogenolysis on the Pd-carbon catalyst in the presence of a catalytic amount of *p*-toluenesulfonic acid, giving more than an 80% yield of hydroxymethyl-12-crown-4. The hydrogenolysis is very slow in the absence of *p*-toluenesulfonic acid. The co-catalysis of *p*-toluenesulfonic acid was discovered by the observation of the smooth debenzylation of the crude benzyloxymethyl-12-crown-4 obtained using the ditosylate. Matsui and Koga[11] previously reported the debenzylation of the 18-crown-6 derivatives by means of hydrogenolysis in acetic acid. It seems likely that protic acids catalyze the hydrogenolysis of benzyloxy macrocyclic ethers.

Hydroxymethyl-12-crown-4 can be alkylated in good yields by a reaction using alkyl bromide, potassium *t*-butoxide as the base, and *t*-butyl alcohol as the solvent.

Stability Constants of 12-Crown-4 Complexes with Na^+ and K^+ in Methanol. Employing potentiometry using ion-selective electrodes, the stability constants, *i.e.*, the equilibrium constants for complexation, of 12-crown-4 and its derivatives have been determined in methanol. According to the Frensdorff equations,[12] the stability constants, K_1' for 1:1 complexation and K_2' for 2:1 complexation, and K_2'/K_1' were precisely determined. For purposes of comparison, those of 15-crown-5 and benzyloxymethyl-15-crown-5 have also been determined (Table 2). The results show that, as for all Na^+ complexes with 12-crown-4 derivatives, the K_2' values are from 2 to 6 times larger than K_1', indicating the stronger tendency of the 2:1 complexation of 12-crown-4 in methanol as well as in the crystalline complexes with Na^+ salts. The proportions of 2:1 complexation have been calculated; they are

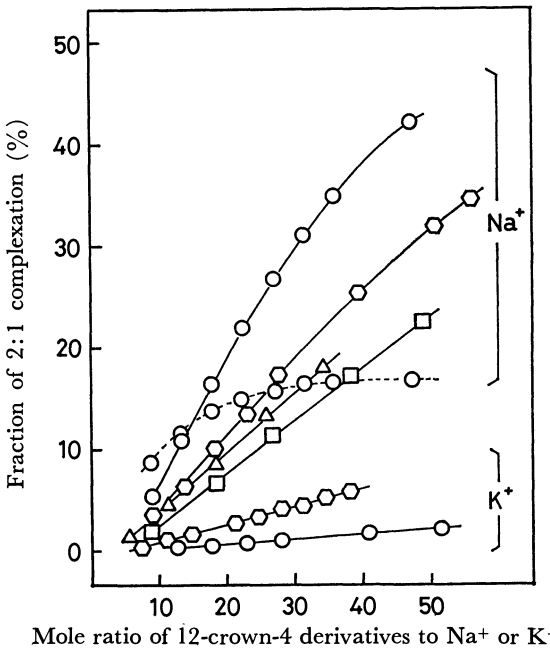

Fig. 1. Fraction of 2:1 complexation *vs.* mole ratio of 12-crown-4 derivatives to Na^+ or K^+.
—○—: 12-Crown-4, —◇—: benzyloxymethyl-12-crown-4, —□—: hydroxymethyl-12-crown-4, —△—: octyloxymethyl-12-crown-4, ···○···: fraction of the 1:1 complexation of 12-crown-4 with Na^+.

shown graphically in Fig. 1, along with that of the 1:1 complexation of 12-crown-4(see the dotted line in Fig. 1). The sandwich-type complexation increases with an increase in the ratio of the 12-crown-4 to Na^+. These findings, then, demonstrate that the sandwich-type complexation of 12-crown-4 derivatives gradually overcomes the solvation of methanol to Na^+, even if the large-side group causes steric interference in the 2:1 complexation.[13] Much the same, but a more remarkable, tendency has recently been observed for 12-crown-4 in propylene carbonate.[14]

In contrast, the stability constants for K^+ and the small or negligible proportion of the 2:1 complexation for K^+ (Fig. 1) suggest that 12-crown-4 derivatives are rather inclined to form 1:1 complexes with K^+ in methanol, contrary to the formation of the solid 2:1 complex of 12-crown-4 with KCl.[1] This is also true for the complexation of 15-crown-5 derivatives with Na^+ and K^+ in methanol. Thus, the characteristic complexation of 12-crown-4 with Na^+ is apparently due to the contribution of their sandwich-type complexation.

It is interesting to note that, although the log K_1' values of 15-crown-5 are almost the same for both Na^+ and K^+, the log K_2' value for K^+ is larger than that for Na^+. The selective complexation of 15-crown-5 with K^+ is also related to a sandwich-type complexation, just as in the case of 12-crown-4 for Na^+.

The effect of a benzyloxymethyl group on complexation with K^+ is worth noting. The stability constant, K_2', for K^+ of benzyloxymethyl-12-crown-4 is about ten times larger than that of 12-crown-4, while benzyloxymethyl-15-crown-5 has a smaller K_2' than 15-crown-5. In other words, the benzyloxymethyl group bound to 12-crown-4 strengthens the 2:1 complexing of K^+. The same effect of a benzyloxymethyl group has also been confirmed in the following solvent extraction.

Extraction of Alkali Picrates. The sandwich-type complexation of 12-crown-4 derivatives with Na^+ has also been derived from solvent extraction using dichloromethane as the solvent. 12-Crown-4 is lipophilic enough for it to be used as an extractant, because 95% of the crown in water can be removed by one extraction with chloroform(see Experimental section). However, because of the low stability constants, 12-crown-4 derivatives were used in a large excess against the picrates. The degree of extraction and the distribution ratio have been determined for alkai picrates; they are summarized in Table 3.

Compared with the extraction of 15-crown-5, 12-crown-4 derivatives all show weak extraction abilities, as expected. However, their selective extraction for Na^+ has now been confirmed. 12-Crown-4 and dodecyloxymethyl-12-crown-4 are the most selective. Benzyloxymethyl-12-crown-4(**2**) also extracts potassium picrate to a comparable extent, which is consistent with its large stability constant, K_2', for K^+ in methanol. It seems likely that the benzyloxymethyl group serves as a π donor for the 2:1 sandwich-type complexation especially with K^+.[15]

Extraction with 12-crown-4 was recently reported in a benzene–water system.[16] The stoichiometry of the extracted Na^+ species was determined to be 1:1. To ascertain the stoichiometry in the present extraction, the logarithm of the distribution ratios was plotted against the logarithm of the ratio of the 12-crown-4 to the picrate (Fig. 2). The coordination number of the crown in the extracted species can be determined from the slope of the line. A curved line is obtained, indicating that the coordination number changes ap-

a) EX(%): Degree of extraction, D: distribution ratio.

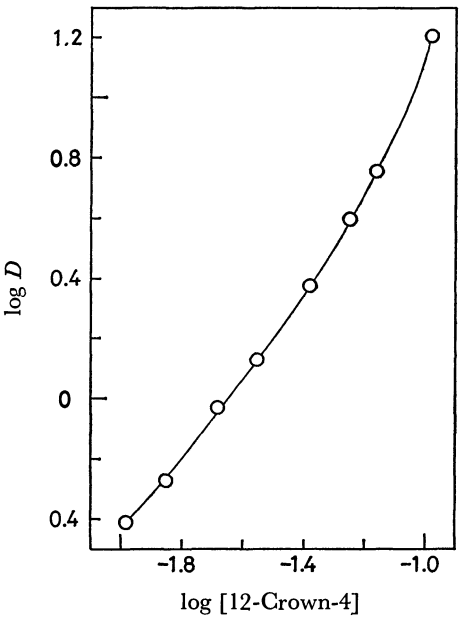

Fig. 2. Distribution ratio of sodium picrate *vs.* concentration of 12-crown-4.

proximately from 1 to 2 as the concentration of the crown increases. This is probably due to the increasing sandwich-type complexation.

The selective complexation of 12-crown-4 derivatives for Na^+ has now been confirmed due to the 2:1 sandwich-type complexation. The specific complexation for Na^+ might be related to the fulfillment of the Na^+ coordination geometry.[2]

In view of the facile synthesis and the sandwich-type interaction of 12-crown-4 macrocycle, hydroxymethyl-12-crown-4 may be utilized as a new functional substituent causing a Na^+-promoted bimolecular interaction.

Experimental

Materials. 3-Benzyloxymethyl-1,2-propanediol (**1**) was prepared according to Howe and Malkin.[17] The 1,11-dichloro-3,6,9-trioxaundecane, 1,14-dichloro-3,6,9,12-tetraoxatetradecane, and triethylene glycol ditosylate were prepared by the chlorination of tetraethylene glycol and pentaethylene glycol with $SOCl_2$, and by the reaction with tosyl chloride, respectively. The 12-crown-4 (Bokusui Brown Co., Ltd.) and 15-crown-5 (Nakarai Chemical Ltd.,) were purified by distillation. All the other reagents and solvent were obtained commercially and were used without further purification.

Measurement of Spectra. The ^1H NMR, IR, and mass spectra were obtained using JEOL LMN-PS-100, Hitachi 260-10, and Hitachi RMU-6E spectrometers respectively. GLPC analyses were carried out on a Shimadzu GC-4BPT apparatus using Silicone SE-30 on a Diasolid L (60—80 mesh) (4 mm × 1 m).

Preparation of Benzyloxymethyl-12-crown-4 (2). A 3—1 three-necked flask equipped with a reflux condenser, an addition funnel, and a magnetic stirrer was charged with *t*-butyl alcohol (1500 ml) and metal lithium (5.7 g, 0.82 mol). After an hour's reflux under stirring, 3-benzyloxy-1,2-propanediol (50 g, 0.27 mol) was added drop by drop, causing the solution to become cloudy because of the precipitation of the lithium salts of 3-benzyloxy-1,2-propanediol (**1**). To the above heterogeneous solution we added 1,8-dichloro-3,6-dioxaoctane (51.4 g, 0.27 mol) and $LiBr \cdot H_2O$ (28.8 g, 0.27 mol) successively. The heterogeneous reaction mixture was refluxed and stirred until the dichloride almost disappeared upon GLPC analysis (12 d). After the bulk of *t*-butyl alcohol had been evaporated under reduced pressure, a 100-ml portion of water was added to the residue. After neutralization, the product was extracted three times with a 100-ml portion of diethyl ether. The extract was dried and condensed under reduced pressure. The resulting liquid was distilled under reduced pressure, giving 56.9 g of benzyloxymethyl-12-crown-4 (**2**) (70% yield): bp 120—130 °C/0.03 Torr (1 Torr=133.322 Pa); IR (neat, NaCl plates), 3035 (w), 2930 (s), 2870 (s), 1500 (w), 1460 (m), 1135 (s), 1100 (s), 740 (m) cm^{-1}. ^1H NMR ($CDCl_3$), δ 3.48—3.90 (m, 17H), 4.55 (s, 2H), 7.25 (s, 5H); mass spectrum (*m/e* rel intensity) 296 (M^+), 205 (6), 175 (28), 146 (17) 133 (11), 91 (100), 87 (81), 73 (19), 59 (26), 45 (90). Found: C, 64.73; H, 8.16%. Calcd for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16%. Under comparable conditions, benzyloxymethyl-15-crown-5 and 18-crown-6 were prepared by the reaction of 3-benzyloxymethyl-1,2-propanediol with 1,11-dichloro-3,6,9-trioxaundecane and 1,14-dichloro-3,6,9,12-tetraoxatetradecane respectively: Benzyloxymethyl-15-crown-5 (74% yield); bp 160—180 °C/0.01 Torr (Kugelrohr); IR (neat, NaCl plates) 3035 (w), 2870 (s), 1500 (w), 1460 (w), 1125 (s), 740 (m), 700 (m) cm^{-1}: ^1H NMR ($CDCl_3$) δ 3.48—3.90 (m, 21H), 4.55 (s, 2H), 7.25 (s, 5H); mass spectrum (*m/e*, rel intensity) 340 (M^+, 6), 249 (10), 219 (11), 177 (3), 146 (18), 133 (14), 91 (100), 87 (98), 73 (18). Found: C, 63.49; H, 8.55%. Calcd for $C_{18}H_{28}O_6$: C, 63.51; H, 8.21%. Benzyloxymethyl-18-crown-6 (46% yield), bp 190—195 °C/0.03 Torr (Kugelrohr); IR (neat, NaCl plates) 3040 (w), 2860 (s), 1455 (m), 1355 (m), 1300 (w), 1250 (m), 1105 (s), 955 (m), 840 (m), 740 (m), 700 (m). ^1H NMR ($CDCl_3$) δ 3.48—3.90 (m, 25H), 4.52 (s, 2H), 7.30 (s, 5H). Mass spectrum (*m/e*, rel intensity), 384 (M^+), 293 (13), 263 (7), 175 (10), 146 (10), 133 (20), 91 (94), 87 (100), 73 (28), 59 (28). Found: C, 62.20; H, 8.48%. Calcd for $C_{20}H_{32}O_7$: C, 62.47; H, 8.38%.

Preparation of Hydroxytmethyl-12-crown-4 (3). Benzyloxymethyl-12-crown-4 (**2**) (4.5 g, 0.022 mol) and 10 ml of 1,4-dioxane were placed in a 20-ml test tube equipped with a hydrogen inlet. To the solution we then added 0.1 g of Pd–carbon (5%) (Mitsuwa Pure Chemicals) and 50 mg of *p*-toluenesulfonic acid. Hydrogen gas was passed through the solution at 50 °C for 5 h. After the filtration and removal of 1,4-dioxane by means of a rotary evaporator, the residue was distilled under reduced pressure to yield 2.6 g of hydroxymethyl-12-crown-4 (81%): bp 112—113 °C/0.02 Torr [lit,[4] 115 °C/0.04 Torr] IR (neat, NaCl plates), 3250 (s), 2930 (s), 2870 (s), 1135 (s), 1100 (s) cm^{-1}: ^1H NMR ($CDCl_3$) δ 3.05 (s, 1H), 3.45—3.90 (m, 17H); mass spectrum (*m/e*, rel intesity), 206 (M^+), 188 (3), 175 (21), 133 (6), 103 (5), 87 (51), 45 (100). Found: C, 52.14; H, 9.09%. Calcd for $C_9H_{18}O_5$: C, 52.41; H, 8.80%.

Preparation of Dodecyloxymethyl-12-crown-4. Hydroxymethyl-12-crown-4 (1.0 g, 4.9 mmol) was allowed to react with dodecyl bromide (1.57 g, 6.4 mmol) at 70 °C for 10 h, using lithium *t*-butoxide (0.71 g, 6.3 mmol) as the base and *t*-butyl alcohol (15 ml) as the solvent. After the subsequent removal of the solvent, water was added and the mixture was neutralized and extracted with diethyl ether. After the usual work-up, dodecyloxymethyl-12-crown-4 (1.4 g, 78% yield) was obtained: bp 150 °C/0.03 Torr, ^1H NMR ($CDCl_3$) δ 0.88 (t, 3H), 1.27 (bs, 20H), 3.35—3.50 (m, 19H); mass

spectrum, 374 (M^+). Found: C, 67.15; H, 11.37%. Calcd for $C_{21}H_{42}O_5$: C, 67.34; H, 11.30%. Octyloxymethyl-12-crown-4 was similarly prepared (85% yield): bp 125 °C/0.04 Torr, ^1H NMR ($CDCl_3$) δ 0.88 (t, 3H), 1.27 (bs 12H), 3.33—3.90 (m, 19H); mass spectrum, 318 (M^+). Found: C, 64.26; H, 10.64%. Calcd for $C_{17}H_{34}O_5$: C, 64.12; H, 10.76%.

Measurement of Stability Constant. According to Frensdorff's method based on potentiometry with cation-selective electrodes, the stability constants for 1:1 and 2:1 complexes of the crown ethers were determined for Na^+ and K^+. The solvent was absolute methanol (less than 0.1% water) (Wako Pure Chemicals Industry, Ltd.) The following Tohkoh Chemical measuring electrodes were used after step-by-step conditioning: the sodium-ion electrode (Na1100) and a reference electrode (MR-501C) for Na^+, and the potassium-ion electrode (K1200) and a reference electrode (CR-501C) for K^+. The emf was measured with a Beckman 4500 digital pH meter. The R values[10] were computed by minimizing the deviation of average K_1' values within 1% using an NEC PC-8001 computer. Seven to 9 measurements were included in regression analysis.

Solvent Extraction. In a stoppered, 30-ml glass tube we placed 10 ml of a dichloromethane solution containing an extractant (1.05×10^{-2} M or more), 5 ml of an alkali hydroxide solution (0.02 M), and 5 ml of a picric acid solution (1.4×10^{-4} M). The solution was shaken for 10 min at 25 °C and then left standing in a thermostated water bath (at 25 °C±0.5) for 12 h. The picrate concentration in the water phase was determined at 354 nm by means of a Shimadzu UV 200 spectrophotometer ($\varepsilon=1.414\times10^4$ $cm^{-1}M^{-1}$).

Table 4. The extraction of sodium picrate by means of 12-crown-4

Concentration of 12-crown-4	Extraction (%)	Distribution ratio (D)
1.05×10^{-2}	28.2	0.3929
1.40×10^{-2}	35.2	0.5421
2.10×10^{-2}	48.2	0.9292
2.80×10^{-2}	57.4	1.3471
4.20×10^{-2}	70.5	2.3911
5.60×10^{-2}	79.8	3.9607
7.00×10^{-2}	85.1	5.7155
10.50×10^{-2}	94.2	16.3625

The extraction percentages and the distribution ratios were determined at different concentrations of 12-crown-4 (Table 4).

Determination of Lipophilicity of 12-Crown-4. 12-Crown-4 (0.055 g), dissolved in 0.552 g (*ca.* 0.5 ml) of D_2O, was extracted with 0.727 g (*ca.* 0.5 ml) of $CDCl_3$. The concentration of 12-crown-4 in the aqueous phase was determined by ^1H NMR, using nitromethane as the internal reference. Ninety-five percent of the 12-crown-4 was extracted by $CDCl_3$ just as in the case of 15-crown-5.

The authors wish to express their thanks to Mr. Masaie Fujino for his kind advice on computation by means of a PC-8001 computer.

Photoreduction of Silver Ion in a Titanium Dioxide Suspension

Hiroshi HADA,* Yoshiro YONEZAWA, and Masahiko SAIKAWA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received September 19, 1981)

Quantum yields ranging from 0.084 to 0.191 were obtained for the reduction of Ag^+ by irradiation of light at 365 nm on a TiO_2 surface in aqueous solutions containing 1×10^{-4} to 1×10^{-2} mol dm^{-3} $AgClO_4$. Some features of the reduction were preliminarily examined with the aid of an electrochemical measurement of TiO_2 sinter. It is proposed that some conduction-band electrons, produced in the TiO_2 by irradiation, transfer to Ag^+ adsorbed on the TiO_2 surface and that positive holes react with water molecules. The photoreduction of Ag^+ is optically sensitized by addition of Uranine. The apparent quantum yield (the number of reacted ions/the number of photons incident to the suspension) of the dye-sensitized photoreduction of Ag^+ is 0.01.

Photodeposition of metals at semiconductor surface is interesting in that it is related to many applications including the solar energy conversion: the solid-state photogalvanic cell capable of storing light energy in the form of deposited metal and supplying electrical energy from it;[1] semiconductor photocatalysis and anticorrosion of semiconductors;[2-6] non-silver halide imaging materials of interesting use.[7,8] However, only a few reports have dealt with the mechanism of the photodeposition.[9] This may be first because even deposition of colloidal metal by either photolysis or radiolysis of aqueous solution of metal ions is rather a complex reaction as revealed by several investigators,[10,11] and second because deposited metal may considerably change semiconductor surface in its physical and chemical properties. For these reasons, investigations on photodeposition of metals are limited to SnO_2–, ZnO–, and TiO_2–Ag^+ systems,[9,12,13] TiO_2–Pd^{2+} system,[14] TiO_2–Pd^{2+} and –$PtCl_6^{2-}$ systems,[15] TiO_2– and WO_3–Cu^{2+} systems,[16] and TiO_2–$PtCl_6^{2-}$, –$PdCl_4^{2-}$, –Ag^+, and –Cu^{2+} systems.[17] As to dye-sensitized reduction of metal ions, only a few reports have been published which treat TiO_2–Ag^+–triphenylmethane dye[9] and ZnO–Ag^+–xanthene dye systems,[13] apart from a qualitative study for photographic application.[18]

We have been interested in photochemical reactions of the ZnO–Ag^+ system and carried out photochemical and electrochemical studies on photoreduction of Ag^+ both in ZnO suspension and at ZnO sinter surface.[13] We have found that the net photochemical reaction induced by irradiation of UV-light obeys the local-cell mechanism. In photochemical reactions at TiO_2 surface, positive holes produced by optical excitation of TiO_2 will not induce dissolution of the semiconductor itself, in contrast to the ZnO system, which suggests some different situation involved in this case. We thus investigated photoreduction of Ag^+ in a TiO_2 aqueous suspension by using 365 nm light, which is within the fundamental absorption band of TiO_2, and examined optical sensitization of this reaction by Uranine. Also, we carried out preliminary measurements of electrochemical properties of the TiO_2–aqueous solution interface. We have thus clarified several characteristics of the photoreduction of Ag^+ at TiO_2 surface.

Experimental

The experimental set-up and procedure were almost the same as those previously reported for the ZnO–Ag^+ aqueous suspension.[13] The TiO_2 used was a highly purified powder offered from Teikoku Kakou Co., Okayama. This material had a surface area of 7.3 m^2/g-TiO_2, an average particle size of 0.5 μm, and low-level impurities of Nb, Al, and P (below 0.01%). In an 50 ml aqueous solution containing 1×10^{-4} to 1×10^{-2} M† $AgClO_4$ and 0.5 M KNO_3 was suspended 0.5 g TiO_2 powder. For the study of dye-sensitized reduction, Uranine was added to the aqueous suspension. Before the reaction, dissolved oxygen was purged by introduction of high-purity nitrogen gas.

The same combination of the light source, monochrometer, and glass filter as in our previous work[13] was used to select either the 365 nm light (designated TiO_2-light) or 500 nm light (dye-light). The half-band width of the monochromator was about 20 nm. Irradiation was commenced after the adsorption equilibrium of Ag^+ at the TiO_2 surface had been established. After irradiation, the amount of photoreduced silver was determined by atomic absorption spectrometry with a Jarrel-Ash AA-780 spectrophotometer. The number of incident photons was 1.10×10^{15} cm^{-2} s^{-1} for TiO_2-light and 2.00×10^{15} cm^{-2} s^{-1} for dye-light.[19] The transmittance and reflectance for suspensions were measured with Shimadzu spectrophotometers, MPS-5000 and QV-50 equipped with an integrating sphere, respectively. The quantum yield of photoreduction of Ag^+ for the unsensitized system and the apparent quantum yield for the dye-sensitized system were evaluated by use of the equation:

$$\Phi_{Ag} = \frac{1}{Q}\frac{d[Ag]}{dt}, \quad (1)$$

where Φ_{Ag} is the quantum yield for the unsensitized system or the apparent quantum yield for the dye-sensitized system, d[Ag]/dt is the initial rate of formation of the reduced silver (atoms s^{-1}), and Q is either the number of the photons absorbed by the suspension (unsensitized system) or of those incident to the suspension (sensitized system) (photons s^{-1}). The amount of Ag^+ adsorbed at adsorption equilibrium was determined after TiO_2 powder had been immersed in a solution of 1×10^{-4} to 1×10^{-2} M $AgClO_4$ plus 0.5 M KNO_3 for 3 h under constant stirring.

Electrochemical measurements on a TiO_2 sinter electrode were carried out in the conventional manner.[20,21] A pellet from TiO_2 powder was placed on a disk 12 mm in diameter and 0.5 mm thick and then sintered at 1300 °C for 2 h in air. After cooling to room temperature, the pellet was reduced at 600 °C in a hydrogen atmosphere for 2 h. Indium was evaporated onto one face of the sinter to provide an ohmic contact, and a copper wire was soldered on it. Then, all surfaces, except the other face of the sinter to be exposed to the electrolyte solution (*ca.* 0.64 cm^2), were cov-

† 1 M = 1 mol dm^{-3}.

ered with epoxy resin. The electrode prepared in this manner was dipped into aq HNO_3 for 30 s and washed in water before use. The construction of the electrochemical cell and electrochemical measurements were carried out by employing the same procedures previously described.[13] The number of incident photons on the electrode (TiO_2-light) was 9.00×10^{14} cm^{-2} s^{-1}. The electrolyte solutions were composed of 0.5 M KNO_3 or a mixed solution of 0.5 M KNO_3 and 1×10^{-5} to 1×10^{-3} M $AgClO_4$. High purity nitrogen gas was bubbled through the solution in order to remove oxygen before the measurement.

Results

Photoreduction in the Unsensitized System. The dependence of the amount of reduced silver on the irradiation time of TiO_2-light for the TiO_2–Ag^+ aqueous suspension is given in Fig. 1. The reduced silver resulting from thermal reduction in the dark was about 0.15 μmol irrespective of either irradiation time or $AgClO_4$ concentration. This value was previously subtracted before constructing this figure. Quantum yields of the photoreduction of Ag^+ are 0.191 ± 0.014 ($AgClO_4$; 1×10^{-2} M), 0.159 ± 0.005 (2×10^{-3} M), 0.090 ± 0.003 (1×10^{-3} M), 0.090 ± 0.003 (5×10^{-4} M), and 0.084 ± 0.0 (1×10^{-4} M). The pH of the suspension was about 4.5. The quantum yields obtained here are in the same magnitude as those reported for TiO_2 thin film–Ag^+ system.[9] However, the dependence of Φ_{Ag} on the initial Ag^+ concentration, C_{Ag^+}, significantly deviates from the Stern-Volmer relation proposed by Fleischauer *et al.* (Fig. 2).

The adsorption of Ag^+ on the TiO_2 surface was measured at 20 °C, the adsorption isotherm being given in Fig. 3. The equilibrium concentration of Ag^+ in the aqueous phase, $C^{eq}_{Ag^+}$, and the equilibrium amount of Ag^+ adsorbed on the surface of 1.0 g TiO_2, N_{Ag^+}, satisfy Freundlich's adsorption formula at $AgClO_4$ concentrations less than 5×10^{-3} M:

$$N_{Ag^+} = A(C^{eq}_{Ag^+})^{1/n}, \quad (2a)$$

$$\log N_{Ag^+} = \log A + \frac{1}{n}\log C^{eq}_{Ag^+}, \quad (2b)$$

●: $[AgClO_4]=1\times10^{-2}$ M, ◑: 2×10^{-3} M, ○: 1×10^{-3} M, □: 5×10^{-4} M, and △: 1×10^{-4} M.

where A and n are constants. The adsorption index $1/n$ is 0.78. However, at higher concentrations, N_{Ag^+} began to increase more steeply than expected from Eq. 2. Substitution of N_{Ag^+} for C_{Ag^+} in Fig. 2 could scarcely improve the linear relation of Stern-Volmer plot (Fig. 2).

We tried to clarify the behavior of positive holes through detection of increase in the dissolved oxygen in the aqueous phase during the photoreaction. A 200 ml aqueous suspension composed of 2.0 g of TiO_2, 0.5 M KNO_3, and 1×10^{-3} M $AgClO_4$ was prepared.

N_{Ag^+} and $C^{eq}_{Ag^+}$ denote the amount of adsorbed Ag^+ on TiO_2 surface and the concentration of Ag^+ in aqueous phase.

After bubbling nitrogen, the suspension was irradiated by 365 nm light from a 500 W high-pressure mercury lamp (Ushio Denki Type USH-500D), and the increase in dissolved oxygen was recorded on an oxygen meter (Nisshin Rika Model OX-36). After 30 min irradiation, the increase of dissolved oxygen and the amount of reduced silver were registered as 8.2 μmol and 39.6 μmol, respectively. The observed O_2/Ag ratio is close to the theoretical value of 1/4. With suspensions containing no $AgClO_4$, on the contrary, dissolved oxygen after irradiation was at somewhat a lower level than that before irradiation. These facts lead to a conclusion that the positive hole produced by TiO_2-light can react with water and generate oxygen in the presence of Ag^+.[22-24]

Photoreduction in the Dye-sensitized System. The dependence of the amount of photoreduced silver on the irradiation time is given in Fig. 4. The concentrations of $AgClO_4$ and Uranine were 1×10^{-4} and 1×10^{-5} M, respectively. The apparent quantum yield of the photoreduction of Ag^+ is 0.01. The optical absorption spectrum of Uranine solution and the diffuse reflection spectrum of TiO_2 suspension were recorded on an MPS-5000 spectrophotometer (Fig. 5). The dependence of apparent quantum yield on the wavelength of incident light (photochemical action spectrum) was determined from the amount of photoreduced silver after 2 h irradiation. It has a maximum at *ca.* 500 nm (Fig. 5).

Discussion

Reaction Scheme for the Unsensitized System. In our previous paper,[13] we examined, with a help of electrochemical study, a simple reaction scheme proposed by Fleischauer *et al.*[9] and concluded that the scheme is capable of interpreting the general feature of Ag^+ reduction at ZnO surface. Such a simple scheme, as it is, is not applicable to the present TiO_2–Ag^+ system, as seen from the significant departure from linear plot shown in Fig. 2. Nevertheless, aside

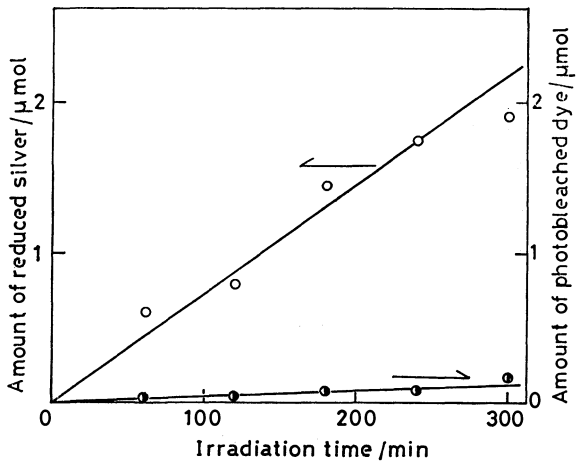

Fig. 4. Growth of the amount of reduced silver in TiO_2 suspension containing $AgClO_4$, KNO_3, and Uranine with irradiation of 500 nm light (○——○). Growth of the amount of photobleached dye is also given (◑——◑).

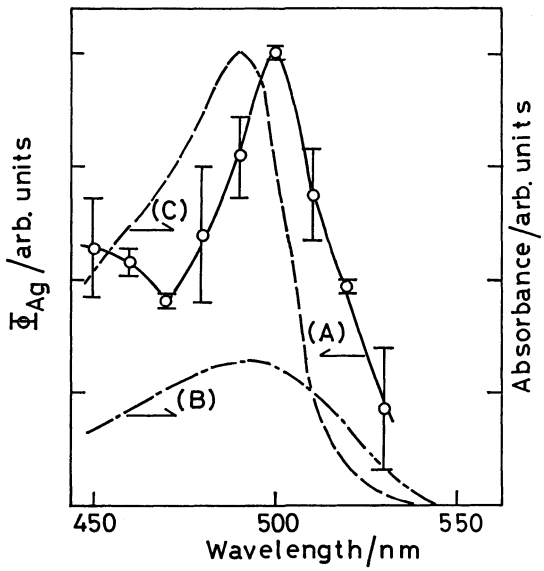

Fig. 5. Photochemical action spectrum for sensitized reduction of Ag^+ on TiO_2 (A) and absorption spectra of Uranine adsorbed on TiO_2 (B) and in aqueous solution (C).

from the detailed mechanism, it is natural to assume, as the above scheme does, that the photoreduction at semiconductor surface will proceed under the local-cell condition, *i.e.*, that the rate of net cathodic reaction is equal to that of net anodic reaction in the photostationary state.

To examine this assumption, we carried out the present photoelectrochemical study on the TiO_2 sinter electrode. Figure 6 shows polarization curves of the TiO_2 electrode in 0.5 M KNO_3 solutions with and without 5×10^{-4} M $AgClO_4$. The curves indicate both the current measured in the dark and the partial anodic photocurrent as obtained by subtracting the current measured in the dark from the current measured under irradiation. The irradiation did not affect the cathodic current in our study, contrary to the finding of Sprünken *et al.*[25] Therefore, the partial anodic photocurrent indicates the real anodic element of the current under irradiation. From these curves, we have obtained both the zero-current-potential, E_{zcp}, at which the total current under irradiation is zero, and the cathodic current at this potential, i_{dzcp}. If all the cathodic current contributes to the reduction of Ag^+, we can estimate the rate of photoreduction of Ag^+ on this electrode from the value of this current. Indeed, the rate evaluated in this manner at 1×10^{-3} M $AgClO_4$ is in accord with the value obtained by the chemical-analysis method for the same electrode system, within the limit of experimental error. Therefore, almost all the cathodic current at the zero-current-potential can be said to contribute to the silver reduction.

Now, let us assume that the results on the TiO_2 suspension can be analyzed through electrochemical study of the TiO_2 sinter. On the local-cell model for the photoreduction at TiO_2 surface, the electrode

(A) ●——●: Partial anodic photocurrent without $AgClO_4$, (B) ●——●: dark cathodic current without $AgClO_4$, (C) ○——○: partial anodic photocurrent with $AgClO_4$, (D) ○——○: dark cathodic current with $AgClO_4$. E_{zcp} and i_{dzcp} denote the zero-current-potential and the corresponding cathodic current in solution with $AgClO_4$.

potential (Fermi level) of the TiO_2 immersed in a solution under irradiation is equal to the E_{zcp}. According to Fig. 6, the upward band bending still exists in the space-charge layer of TiO_2, because the onset potential of the partial anodic photocurrent of the TiO_2 electrode is more negative than E_{zcp}. Furthermore, the photopotential measurement on this electrode showed that the electrode potential shifts to a more positive value when the TiO_2-light is cutoff. From these facts, the surface barrier of the TiO_2 in the $AgClO_4$ solution seems to be much smaller under irradiation of TiO_2-light. The photoelectrons in the conduction band can react with the adsorbed Ag^+ over the surface barrier, which is considerably smaller than that in the dark.

We have determined the quantum efficiency of the photocurrent at $E=E_{zcp}$, $\Phi_{h\nu}$, as

$$\Phi_{h\nu} = \frac{1}{eI} i_{dzcp}, \tag{3}$$

which corresponds to the quantum yield of the photoreduction of Ag^+ at the TiO_2 sinter surface. Here, I denotes the number of photons incident to the electrode surface and e the elementary electric charge. A linear relation is observed between the logarithms of $\Phi_{h\nu}$ and C_{Ag^+} (Fig. 7). We have next examined a similar relation between Φ_{Ag} and N_{Ag^+} for the TiO_2 suspension. The linearity shown in Fig. 7 seems to be better than that in Fig. 2. If we note a small amount of the Ag^+ adsorbed on the TiO_2 sinter surface, we may state that log (Φ_{Ag^+}) for both the TiO_2 suspension and sinter systems depends linearly on log (N_{Ag^+}). Such a relation seems to be characteristic

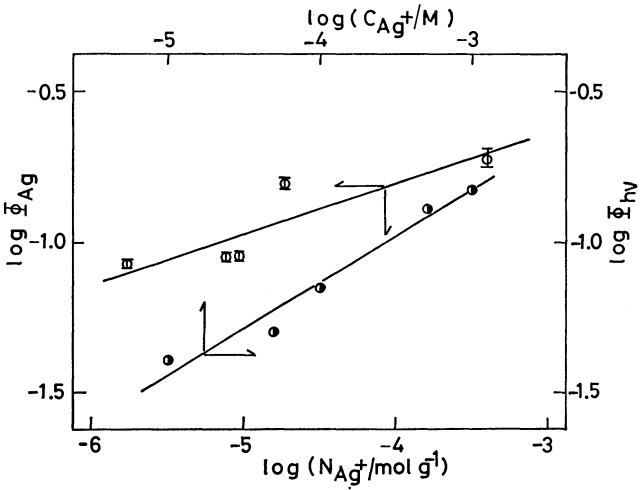

Fig. 7. Relation between the quantum yield and the concentration of $AgClO_4$.
◑——◑: Logarithmic plot between the quantum yield Φ_{Ag} and N_{Ag^+}, ◑——◑: logarithmic plot between the quantum efficiency of the photocurrent $\Phi_{h\nu}$ and C_{Ag^+}.

of the TiO_2–Ag^+ reaction systems studied here. It contrasts markedly with a Stern-Volmer relation previously reported for ZnO– and TiO_2–Ag^+ systems.[9,13] We have further found that E_{zcp} depends linearly on log(C_{Ag^+}) and that i_{dzcp} is proportional to $I^{0.64}$ irrespective of the Ag^+ concentration. These findings will offer a clue to the mechanism of photoreduction at the TiO_2–Ag^+ system. However, the details of actually operative reaction mechanisms will considerably change depending on physicochemical properties of semiconductor surfaces. It is, therefore, desirable to employ the same semiconductor sample for both photochemical and electrochemical studies; a research along this line is now in progress.

The Mechanism of Dye Sensitization. Though there have been many studies on the dye-sensitization of TiO_2 electrode,[26–29] little is known about the sensitized photoreaction at TiO_2 surface. We have shown in Fig. 4 that silver reduction proceeds by dye-light in the presence of both TiO_2 and Uranine. However, the amount of photoreduced silver after 4 h irradiation of dye-light was only 0.1 μmol in the absence of Uranine and it was still as small as about 0.15 μmol even when Uranine–$AgClO_4$ aqueous solution was irradiated by dye-light for 2 h. Such findings further support the role of both TiO_2 and Uranine in this reaction. The photochemical action spectrum in Fig. 5 may suffer the influence of the filter effect due to the optical absorption of dye molecules in the solution bulk. However, apart from the somewhat longer wavelength maximum in the photochemical action spectrum, the general features of these three spectra may be considered not to be so different from one another, if we note the relatively large half-width of the monochromator employed. The sensitized reaction at TiO_2 surface will be initiated by either electron transfer (the electron transfer mechanism) or energy transfer (the energy transfer mechanism) from excited dye molecules to TiO_2, which results in increase in the

concentration of conduction-band electrons. Then, conduction-band electrons are transferred to the Ag^+ adsorbed on the surface. In this way, TiO_2 serves to accept electrons and send them to Ag^+ in such a manner that the reverse electron transfer is prevented from proceeding.

It was observed that a photobleach of dye occurs in the course of silver reduction. The amount of photobleached dye in the suspension was determined by employing the same procedures previously described[13] and is given in Fig. 4. Apparent quantum yield of the photobleach is only 0.0005. However, a similar reaction proceeds to some extent even in the absence of Ag^+, because the photobleached dye in the TiO_2–Uranine system amounted to 0.12 μmol after 5 h irradiation of dye-light. It is remarkable that the amount of photoreduced silver after more than 2 h irradiation is larger than the amount of Uranine initially added to the suspension. To interpret the discrepancy between them, we may as well take into consideration complicated reactions of dye molecule following its sensitizing action, including its regeneration, at least in the case of the electron transfer mechanism for spectral sensitization. Similar phenomena have been reported for the ZnO–Ag^+–Uranine system by us.[13] The mechanism of the sensitized reduction of Ag^+ seems to be much more complicated than that of the unsensitized one and must be far beyond the simple local-cell consideration.

The authors wish to thank Teikoku Kakou Co., for kindly providing us with the TiO_2 powder. This work was carried out with a financial support from the Ministry of Education, Science and Culture of Japan (Grant-in-Aid No. 311607).

The Synthesis and Electrical Resistivities of Complexes of Cation–TCNQ–Salts with Crown Ethers, Cryptands, and 1,13-Di(8-quinolyl)-1,4,7,10,13-pentaoxatridecane

Katsumi Matsuoka, Takashi Nogami,* Tsuruyoshi Matsumoto, Hidekazu Tanaka, and Hiroshi Mikawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565

(Received July 24, 1981)

Cation–TCNQ complexes with crown ethers, cryptands, and 1,13-di(8-quinolyl)-1,4,7,10,13-pentaoxatridecane were isolated. The cations include alkali-metal, and alkyl- and arylammonium ions. Nine types of complexes were isolated. These complexes are classified into two groups: complexes containing neutral TCNQ, and the complexes not containing neutral TCNQ. The electrical resistivities of the compaction samples were mainly measured at room temperature. The complexes containing neutral TCNQ were much more conductive than the other type of complexes; they exhibit resistivities of 8.2—10^3 Ω cm. The complexes of 1,13-di(8-quinolyl)-1,4,7,10,13-pentaoxatridecane contained methanol when we synthesized them from methanol solution.

We previously reported the synthesis and electrical resistivities of many alkali-metal and alkaline-earth-metal cation–TCNQ–crown ether complexes.[1-4] By using crown ether, we could isolate the complex salts, $[M^{n+}(TCNQ^-)_n]_m(TCNQ)_i(\text{crown ether})_j$, which contain neutral TCNQ, as well as simple salts, $[M^{n+}(TCNQ^-)_n]_m(\text{crown ether})_i$. A comparison of the electrical conductivities of the crown ether–TCNQ complexes with those of the original TCNQ salts, $M^{n+}(TCNQ^-)_n$, shows that simple salts are much less conductive than the original TCNQ salts.[1,2] On the other hand, complex salts including the alkali-metal cation are about 10 times more conductive than the corresponding original TCNQ salts, M^+TCNQ^-.[1,2] In the case of the complex salts including alkaline-earth-metal cations, however, most of them were much more conductive than the original TCNQ salts, $M^{2+}(TCNQ^-)_2$. The fact that the conductivities of the complex salts including alkaline-earth-metal cations were higher than those of the alkali-metal cations was explained by the closer distance between TCNQ molecules in the former complexes.[3]

1,13-Di(8-quinolyl)-1,4,7,10,13-pentaoxatridecane (usually called simply "Kryptofix-5") is an acylic polyether with two quinolyl groups at both ends of the molecule, and it has a property of coordinating metal cations by means of its five oxygens and two nitrogens.[5] The electrical conductivities of TCNQ–"Kryptofix-5" complexes are interesting in connection with famous good conductor, quinolinium–TCNQ complex.[6] We have now isolated several alkali-metal cation–TCNQ–"Kryptofix-5"-complexes.

Crown ethers are known to include ammonium ions.[7] We have previously reported several ammonium–TCNQ–crown ether complexes.[1,2] We have now synthesized alkyl- and arylammonium–TCNQ–crown ether complexes in order to see the effect of the substituent groups on the electrical conductivities.

We measured the electrical resistivities of the several types of new complexes mentioned above with the compaction samples, mainly at room temperature. We also measured the diffuse-reflection spectra of the new complexes in order to ascertain the electronic interaction between TCNQ molecules.

Experimental

Materials. The crown ethers, cryptands, and 1,13-di(8-quinolyl)-1,4,7,10,13-pentaoxatridecane were purchased from Tokyo Kasei Kogyo Co. Ltd.

Synthesis of the Complexes. The following four methods were employed for the synthesis of the complexes.

Method 1: Most of the complexes not containing neutral TCNQ (Types A, B, and H in Fig. 1) were obtained by the reactions of cation TCNQ salts with crown ethers. The details have been presented previously.[2]

Method 2: Most of the complexes containing neutral TCNQ (Types C and I in Fig. 1) were obtained by the reactions of cation-TCNQ salts, neutral TCNQ, and crown ether. The details have been presented previously.[2]

Method 3: The quinolinium-type "Kryptofix-5" complexes (Types D, E, and F in Fig. 1) were obtained by this method. This method is subdivided into four subtypes: (*3-1*) "Kryptofix-5" and 2,3,5,6-tetramethyl-1,4-benzenediol (1:2.1 molar ratio) were dissolved in acetonitrile. To this solution we then added an acetonitrile solution of TCNQ (3—4 molar ratio); this mixtures was then refluxed for 10 min, and the hot solution was filtered. After the solution had been kept at 0 °C for a few hours, the precipitate was filtered, washed with a small amount of acetonitrile and diethyl ether, and dried in a vacuum. (*3-2*) "Kryptofix-5" was dissolved in dioxane, and the solution was heated to 60 °C. To the solution we then added an equimolar amount of aqueous hydrogen iodide, and the "Kryptofix-5"-hydroiodide precipitated was collected quickly. (When the filtration was done too slowly, we obtained a reddish brown oil.) In this case, the solvent was distilled out completely, and then hexane was added to the oil which remained; we thus obtained the powder of "Kryptofix-5"-hydroiodide. The hydroiodide was then dissolved in a small amount of water, and an aqueous solution of Li^+TCNQ^- (2.1 molar ratio) was added through a filter paper. The precipitate was collected, washed with water, and dried in a vacuum. (*3-3*) To the acetonitrile solution of the complex obtained by Procedure (*3-1*) or Procedure (*3-2*), we added acetonitrile solutions of alkali metal TCNQ salt (equimolar amount) and TCNQ (1—3 molar ratio). The solution was heated for 10 min, and the hot solution was filtered. The filtrate was allowed to stand at room temperature and then kept 0 °C for several hours. The precipitate was collected, washed with a small amount of acetonitrile, and dried in a vacuum. (*3-4*) The complexes

obtained by Method 1 or Method 2 were dissolved in acetonitrile, and 2,3,5,6-tetramethyl-1,4-benzenediol (2.1 molar fraction) was added. The solution was heated to dissolve the reactants, and then an acetonitrile solution of TCNQ (3—4 molar ratio) was added. After the solution had been refluxed for 10 min, the hot solution was filtered. The filtrate was allowed to stand at room temperature and then kept at 0 °C for several hours. The precipitate was collected, washed with a small amount of acetonitrile, and dried in a vacuum.

Method 4: Ammonium–TCNQ–crown ether complexes (Type G in Fig. 1) were obtained by the same procedures as in Method 1. In this case, however, we obtained complexes containing neutral TCNQ. The solvents we used were methanol in the case of the methylammonium complex and 2-propanol in the cases of the other complexes.

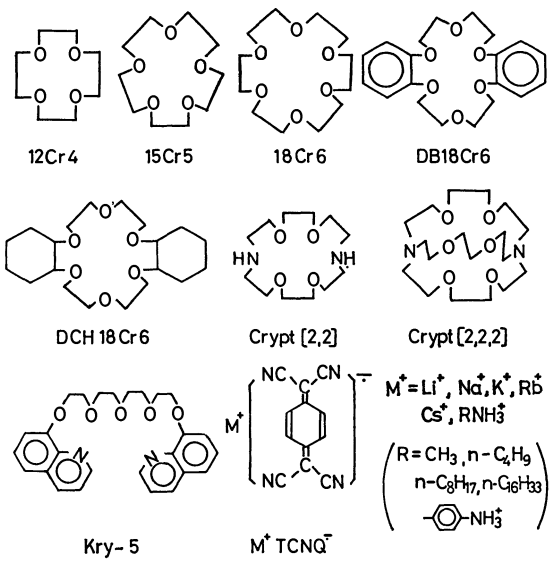
Measurements of the Electrical Resistivities. The room-temperature resistivities of the complexes were measured by the procedures described before.[2] The temperature dependence of the resistivity was measured by means of a type-D cryomini refrigerator (Osaka Sanso Co., Ltd).

Measurements of Diffuse Reflection Spectra. The diffuse reflection spectra of the complexes were measured by means of a Hitachi 340 recording spectrophotometer, with an integrating sphere attached.

Differential Thermal Analysis and Thermogravimetry. Differential thermal analysis was done by the use of a Dainiseikosha SSC 560 apparatus, and thermogravimetry, by the use of a Rigaku Thermoflex.

Results and Discussion

Isolation of the Complexes. The following crown ethers, cryptands, acyclic polyether, and cation-TCNQ salts were used for the preparation of the complexes: 12-crown-4, 15-crown-5, 18-crown-6, dibenzo-18-crown-6, "dicyclohexyl-18-crown-6"[8], cryptand[2.2], cryptand[2.2.2], "Kryptofix-5"[9], Na^+TCNQ^-, K^+TCNQ^-, Rb^+TCNQ^-, Cs^+TCNQ^-, $CH_3NH_3^+TCNQ^-$, $n\text{-}C_4H_9NH_3^+TCNQ^-$, $n\text{-}C_8H_{17}NH_3^+TCNQ^-$, $n\text{-}C_{16}H_{33}NH_3^+TCNQ^-$, and *p*-phenylenediammonium TCNQ; their structures are shown below. In this figure, Cr, DB, DCH, Crypt, and Kry-5 indicate crown ether, dibenzo and perhydrodibenzo groups, crystand, and



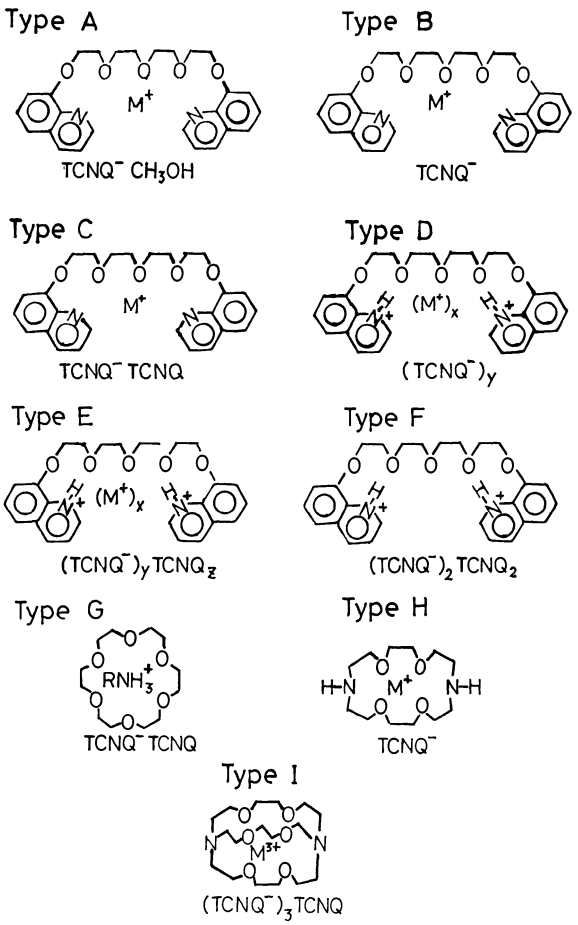


Fig. 1. Nine kinds of complexes isolated.

"Kryptofix-5" respectively. We have isolated nine kinds of complexes; they are designated as Types A, B, C, D, E, F, G, H, and I.[10] Figure 1 shows the structures of these complexes. All the complexes are stable and have a good solubility in many organic solvents; this may be useful for their practical application. Table 1 lists the complexes isolated and their yields, melting points, analytical data, synthetic methods, appearances, and resistivities.

Cation–TCNQ–"Kryptofix-5" Complexes: Types A, B, C, D, E, and F are included in these complexes. The complexes, of Types C, D, E, and F contain neutral TCNQ, while those of the Types A and B do not contain neutral TCNQ.

The complexes of Types A and B were isolated by means of procedures described before.[2] It is noteworthy that the complex of Type A contained one molecule of methanol when we crystallized it from a methanol solution. However, when we used other solvents, such as ethyl acetate or ethanol, we obtained solvent-free complexes (Type B). The colors of the complexes of Type A were yellow green. On the other hand, the colors of the complexes of Type B were purple. When the Type-A complexes were heated under vacuum, the corresponding complexes of Type B were obtained, hence giving rise to the color change. In order to see the conversion from Type A to Type B, we performed differential thermal analyses and thermogravimetries of Type-A complexes;

a) Pressed pellt sample. b) We could not obtain the complex with a stoichiometric composition. c) We could not obtain a good analytical agreement.

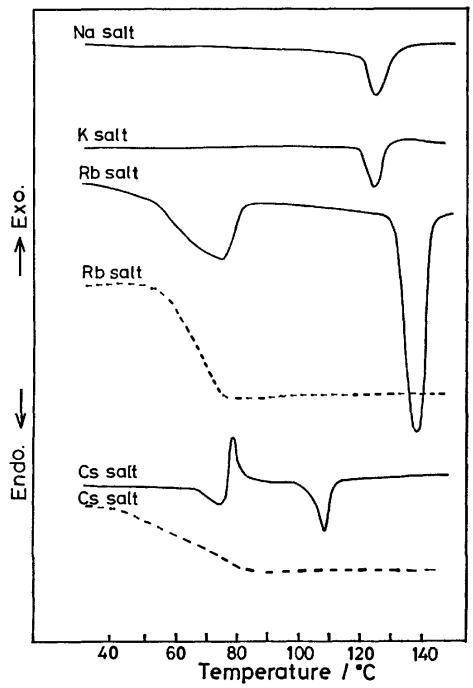

Fig. 2. Differential thermal analysis and thermogravimetry of the methanol-containing "Kryptofix-5" complexes.
——: Differential thermal analysis, ……: thermogravimetry.

the results are shown in Fig. 2. The sodium and potassium complexes in Type A showed only one endothermic signal at their melting points, and the weight losses were not observed. On the other hand, the rubidium and cesium complexes of Type A showed two endothermic signals. The lower-temperature signals were accompanied by weight losses. The higher-temperature signals correspond to the melting points. Thus, methanol is bound more tightly in the sodium and potassium complexes than in the rubidium and cesium complexes in Type A.

The Type-C complexes were isolated by means of procedures described before.[2)] Unfortunately, except for the potassium complex, they did not give the stoichiometric compositions.

The Type-D and Type-F complexes were obtained principally by two methods: by the reaction of "Kryptofix-5", 2,3,5,6-tetramethyl-1,4-benzenediol, and neutral TCNQ, and by the reaction of "Kryptofix-5"-dihydroiodide and Li+TCNQ$^-$. We obtained metal containing (Type D) and metal-free (Type F) complexes with quinolinium structures. The Type-F complexes and sodium and potassium complexes of Types D and E gave stoichiometric compositions. However, the rubidium and cesium complexes in Type D gave nonstoichiometric compositions. The complexes in Types C, D, and F were black.

Substituted Ammonium–TCNQ–Crown Ether Complexes: The complexes of Type G are included in these complexes. Several alkyl- and arylammonium–TCNQ salts were obtained by the reactions of the corresponding ammonium iodides with Li+TCNQ$^-$. Their reactions with crown ether in methanol gave Type-G complexes. To our surprise, all the complexes contained neutral TCNQ, whereas we did not add neutral TCNQ to the reaction system. The reason for this remains to be clarified.

Miscellaneous Complexes: The complexes of Types H and I were obtained by means of procedures described before.[2)] The Type-I complexes containing Ce^{3+} and Sm^{3+} did not give good analytical agreements.

Electrical Resistivities of the Complexes. We measured the electrical resistivities of the complexes isolated with the compaction samples, mainly at room temperature; the results are shown in Table 1.

Cation–TCNQ–"Kryptofix-5" Complexes: The complexes of Types A, B, and D, none of which contain neutral TCNQ, were poor conductors and exhibited resistivities of 10^8—10^{10} Ω cm. On the other hand, the complexes of Types C, E, and F, which contain neutral TCNQ, were much more conductive than the

former type of complexes and exhibited resistivities of the order of $10^1\,\Omega$ cm. The resistivities of the complexes of Types E and F were less than $10\,\Omega$ cm. The best conductor was found in the Type-E complexes possessing Cs ions, which exhibited $8.2\,\Omega$ cm. Unfortunately, we could not obtain these complexes as single crystals. The temperature dependence of the resistivities of Kry-5-2H$^+$(Rb$^+$)$_x$(TCNQ$^-$)$_y$(TCNQ)$_z$ and Kry-5-2H$^+$(Cs$^+$)$_x$(TCNQ$^-$)$_y$(TCNQ)$_z$ measured between 125 K and 250 K showed semiconducting properties; the activation energies were 0.05 eV and 0.06 eV respectively.[11]

Substituted Ammonium–TCNQ–Crown Ether Complexes: The resistivities of most of the substituted ammonium–TCNQ–crown ether complexes were 10^2—$10^3\,\Omega$ cm. However, (18-crown-6)$C_8H_{17}NH^+_3$TCNQ$^-$TCNQ showed a very low conductivity. When we see the effect of the alkyl groups on the electrical resistivities, we find that (18-crown-6)$C_4H_9NH_3^+$TCNQ$^-$TCNQ is more conductive than (18-crown-6)$CH_3NH_3^+$TCNQ$^-$-TCNQ and (18-crown-6)$C_8H_{17}NH_3^+$TCNQ$^-$TCNQ.

Miscellaneous Complexes: As has been described in the Introduction, multivalent cation–TCNQ–crown ether complexes can be expected to be highly conductive materials. In line with this, Sm^{3+}(TCNQ$^-$)$_3$-TCNQ crypt[2.2.2] was a relatively good conductor ($68\,\Omega$ cm); it was *ca.* 300 times more conductive than the original salts, Sm^{3+}(TCNQ$^-$)$_3$ ($2\times10^4\,\Omega$ cm).[6]

Electronic Diffuse Reflection Spectra of the Complexes. We measured the electronic diffuse reflection spectra of the complexes isolated in order to ascertain the electronic interaction between TCNQ molecules in the solid state.[12]

Type-A and Type-B Complexes: As has been discussed above, we obtained methanol-containing complexes (Type A) and methanol-free complexes (Type B). Figure 3 shows the diffuse reflection spectra of both types of complexes. (Kry-5)K$^+$TCNQ$^-$CH$_3$OH and (Kry-5)K$^+$TCNQ$^-$ were chosen as typical examples in this figure, together with the absorption spectrum of K$^+$TCNQ$^-$ in an acetonitrile solution. The reflection spectrum of the methanol-containing complex has a characteristic vibrational structure, which resembles the absorption spectrum of K$^+$TCNQ$^-$ in an acetonitrile solution. This fact suggests that TCNQ$^-$ is isolated in this complex. On the other hand, the methanol-free complex showed two broad absorption bands in the near-IR region. The lower-energy band may have mainly the charge-transfer character between TCNQ anion radicals, while the higher-energy band has mainly the local excitation character within TCNQ anion radicals, like many TCNQ salts.[13]

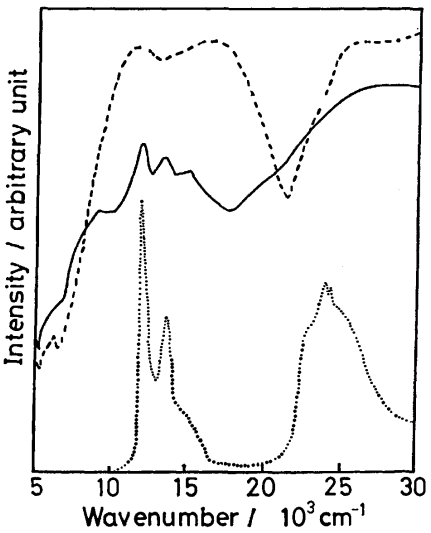

Fig. 3. Electronic diffuse reflection spectra and electronic absorption spectrum of the complexes.
----: Kry-5 K$^+$TCNQ$^-$, ——: Kry-5 K$^+$TCNQ$^-$-CH$_3$OH, ·····: K$^+$TCNQ$^-$ in acetonitrile solution.

Type-C, E, F, G, and I Complexes: All the complexes containing neutral TCNQ have absorption bands below 7×10^3 cm^{-1}; this may be ascribable to the charge-transfer transition from the TCNQ anion radical to neutral TCNQ.

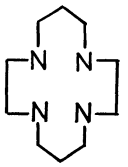
Correspondence between the Electrical Resistivities of the Complexes and Their Electronic Reflection Spectra. As has been discussed above, the complexes containing neutral TCNQ (Types C, E, F, G, and I) are much more conductive than those not containing neutral TCNQ (Types A, B, D, and H). All the complexes of the first type have absorption bands below 7×10^3 cm^{-1}, originating from the charge-transfer transition from TCNQ$^-$ to TCNQ. This fact shows that TCNQ$^-$ and TCNQ are located close together in the complex. Since electrons flow through TCNQ molecules under an electric field, the reduced Coulomb repulsion force between mobile electrons[14] because of the existence of neutral TCNQ gives rise to relatively high conductivities for the former type of complex.

Many complexes of the latter type (Types B, D, and H) have two absorption bands at the near-infrared region (charge-transfer transition between TCNQ$^-$ molecules); this fact suggests the dimer structure of TCNQ$^-$ molecules. In this case, it is well known that a band-gap is formed;[14] this results in the poor conductivity, in line with the experimental observations.

The absorption spectra of the Type-A complexes showed that TCNQ$^-$ is isolated in the complexes; this fact gives rise to the poor conductivities of Type-A complexes.

Summary of the Electrical Resistivities of a Series of Cation–TCNQ–Crown Ether Complexes

Comparison of the Electrical Resistivities. We previously synthesized about 100 kinds of cation–TCNQ–crown ether complexes and measured their electrical resistivities, mainly with the compaction samples at room temperature.[1–4] The cations we used were alkali-metal ions, alkaline-earth-metal ions, alkyl- and arylammonium ions, and transition-metal ions. We classified the complexes into two groups: the complexes containing neutral TCNQ, and the complexes not containing neutral TCNQ. The former type of complexes were semiconductors and were much more conductive than the latter type of complexes; most of the latter type of complexes were insulators. We



"Cyclam"

used not only crown ethers, cryptands, and "Kryptofix-5," but also 1,5,8,12-tetraazacyclotetradecane (usually called "cyclam"), since the latter compounds can include many transition-metal ions.[15]

As a summary of our work, we compared the electrical resistivities of the cation–TCNQ–crown ether complexes with the original TCNQ complexes; this is shown schematically in Fig. 4. The upper half of this figure shows the resistivity range of the cation–TCNQ–crown ether complexes, classified by the cations. We have shown only the resistivity ranges of the complexes containing neutral TCNQ, since they are relatively good conductors. The lower half of Fig. 4 shows the resistivity ranges of the original TCNQ complexes, also classified by the cations.

Roughly speaking, many of the alkali-metal–TCNQ–crown ether complexes are about 10 times more conductive than the original alkali-metal–TCNQ complexes. It is interesting to note that the alkali-metal–TCNQ–"Kryptofix-5" complexes are from about 1000 to about 10000 times more conductive than the alkali-metal–TCNQ complexes. All the alkaline earth metal–TCNQ–crown ether complexes are more conductive (up to 1000 times) than the alkaline earth metal–TCNQ complexes.[6] Many of the ammonium–TCNQ–crown ether complexes are about 10 to 100 times more conductive than the corresponding original TCNQ complexes.[6] Thus, most of the cation–TCNQ–crown ether complexes are more conductive than the corresponding original TCNQ complexes. However,

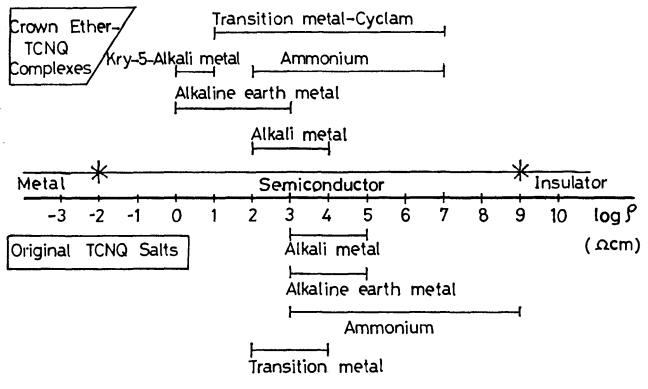


Fig. 4. Comparison of the electrical resistivities of cation–TCNQ–crown ether complexes with those of the corresponding cation–TCNQ complexes.

we could not find any significant improvement in the conductivities of transition metal–TCNQ–"cyclam" complexes[4] as compared with transition metal–TCNQ complexes.[6] The most striking difference in the chemical properties of the cation–TCNQ–crown ether complexes from the original TCNQ complexes is that the former complexes are very soluble to the organic solvents, whereas the solubilities of the latter complexes are very low. This fact may be useful for the practical application of the cation–TCNQ–crown ether complexes.

We are grateful to Miss Junko Maenaka, Mr. Kazuaki Muneishi, and Miss Yuriko Sako, Faculty of Engineering, Osaka University, for the elemental analysis.

Experimental and Calculated Magnetic Circular Dichroism Spectra of Iron(II) Low Spin Hemoglobin and Myoglobin with CO, NO, and O_2

Takao YAMAMOTO,† Tsunenori NOZAWA, Akira KAITO,†† and Masahiro HATANO*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received October 5, 1981)

The ratios of the apparent Faraday A terms to the dipole strengths (A'/D) were obtained from the experimental magnetic circular dichroism (MCD) data for the iron(II) low spin derivatives of human hemoglobin and its α and β chains, and myoglobins (whale and bovine). The observed MCD peak height and trough depth exhibit the decreasing order of $CO > O_2 > NO$ in the Soret band and $O_2 > CO > NO$ for the Q band. The moment analysis also showed the decreasing order of the A'/D values of $CO > O_2 > NO$ in the Soret bands for all hemoglobin and myoglobin derivatives experimentally studied. The molecular orbital calculation of the porphyrin π electron system based on the PPP CI approximation method demonstrated that the calculated spectra for the pyrrole nitrogen core-charge of 1.5 showed characteristics for the CO complex of hemoglobin and myoglobin, and that the NO and O_2 complexes could be simulated by the calculations for the core charge values smaller than 1.5 (*i.e.* 1.4—1.3). These results suggest that the change in the porphyrin π electronic state which is caused by the electronic interaction between the diatomic molecule such as CO, NO, or O_2 and the heme iron can be explained by the change in the σ core charge in the pyrrole nitrogen possibly through changes in the electronic states of the heme iron.

All complexes of hemoglobin and myoglobin with CO, NO, and O_2 exhibit the Soret and Q electronic absorption spectra characterized as the iron(II) low spin complexes.[1] However, appreciable differences among the complexes have been detected by several techniques. The quadrupole splitting in Mössbauer spectra for the CO complexes ($\Delta E_Q = 0.36$ mm s^{-1}) is typical of the iron(II) low spin heme, while that for the O_2 complexes ($\Delta E_Q = -2.2$ mm s^{-1}) is rather similar to those for the iron(III) low spin complexes.[2,3] In resonance Raman spectra the CO, NO, and O_2 complexes of hemoglobin gave somehow different energies for the porphyrin vibration band.[4,5] Furthermore, the IR frequencies of ligand diatomic molecules, O_2, CO, and NO exhibited different relative change on binding with the heme iron.[6-8]

Since the magnetic circular dichroism (MCD) technique has been revealed to be a very powerful technique to explore the electronic structures of hemoproteins,[9,10] the technique has been applied to the hemoproteins complexes with the above diatomic molecules to get insight on the electronic structures of these heme complexes. Although many previous papers have presented MCD spectra on the CO, NO, and O_2 complexes of hemoglobin and myoglobin,[11-20] there has been no quantitative analysis among them. In this paper the magnitudes of the Faraday parameters for the Soret and Q bands were extracted from the experimental MCD spectra on various hemoglobin and myoglobin derivatives, and were compared with the theoretically calculated data to analyze the effect of the diatomic molecules as ligands on the heme electronic states.

Experimental

Whale myoglobin (type II) and human hemoglobin (type IV) were purchased from Sigma. Bovine myoglobin was generous gift of Dr. Y. Sugawara of Tohoku University. Each separated chain of human hemoglobin was prepared by the method of Bucci and Franticelli.[21]

Myoglobin and hemoglobin in phosphate buffer (0.01 mol dm^{-3}, pH 7.0) were reduced by a small amount of sodium dithionite and the excess reductant was removed by passing the solution through a Sephadex G-25 column (30 cm height and 3 cm ϕ). Myoglobin (Mb) and hemoglobin (Hb) became to MbO_2 and HbO_2 during this process. CO complexes were prepared by bubbling CO gas to MbO_2 and HbO_2 solutions for 3 min. MbNO and HbNO were made by adding sodium dithionite and sodium nitrite to MbO_2 and HbO_2 solutions.

The concentrations of hemoglobin and myoglobin were determined by the usual pyridine hemochromogen method by using $\varepsilon_{557} = 32000$.[1]

The MCD spectra were taken with a JASCO circular spectrodichrometer model J-20A equipped with a JASCO electromagnet which produces as high as 1.14 T magnetic field. MCD magnitude is expressed by the molar ellipticity per Tesla (T) ($[\theta]_M/10^4$ degree mol^{-1} dm^3 m^{-1} T^{-1} or 10 degree m^2 mol^{-1} T^{-1}).

The method of moments[22,23] was used to extract Faraday parameters.

The transition energies, oscillator strengths and Faraday parameters were calculated on the basis of PPP CI method, the details of which have been reported previously.[24,25]

Results and Discussion

Figure 1 demonstrates the absorption and MCD spectra for the CO, NO, and O_2 complexes of the β chain of human hemoglobin. The complexes of diatomic molecules with human hemoglobin and its α chain as well as myoglobins from bovine and whale also exhibit similar spectra (not shown). General features in the electronic absorption and MCD spectra of the CO, NO, O_2 complexes of hemoglobin and

† Present address: Kawamura Research Institute, 2-7-8, Kamikizaki, Urawa, Saitama 338.

myoglobin are similar and bear characteristics of the iron(II) low spin hemoproteins in that the MCD spectra show apparent Faraday A terms for the Soret, Q_{0-0} and Q_{v-0} bands.[9,10] However, the magnitudes and relative intensities of the Soret to the Q_{0-0} were seen to be different significantly among them. The apparent MCD magnitudes (the peak height and the trough depth) show the decreasing order of CO>O_2>NO for the Soret bands and O_2>CO>NO for the Q_{0-0} bands. It is also noted that the Soret MCD's of the CO complexes are larger than those of the Q bands, while for the O_2 complex the MCD spectra in the Q region are larger than those in the Soret region, and that for the NO complex the Soret and Q MCD have similar magnitudes.

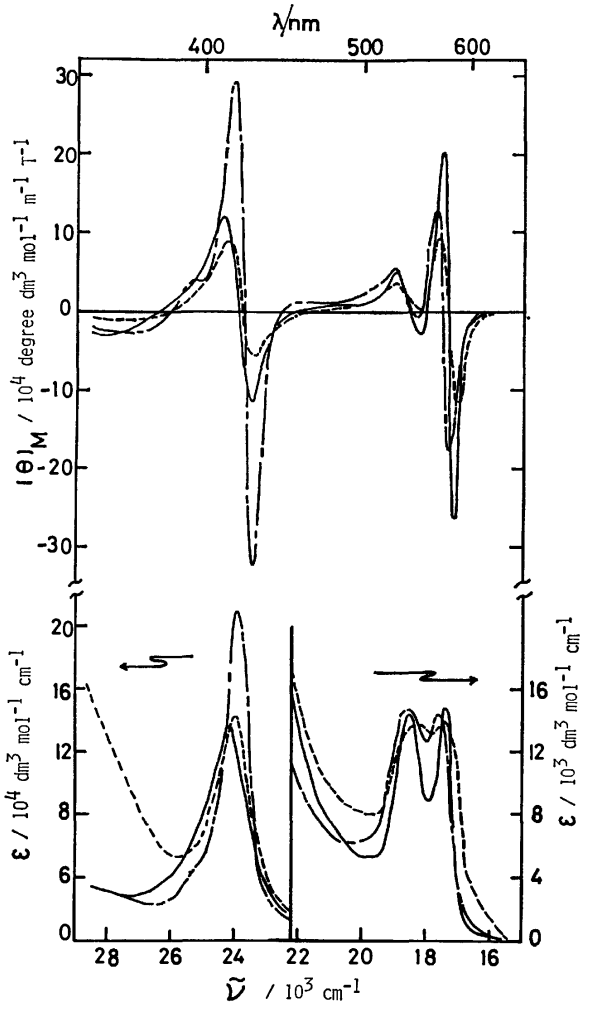

Fig. 1. The MCD and electronic absorption spectra of the CO (———), NO (– – –), and O_2 (——) complexes of the β chain of the human hemoglobin. Concentration: 4×10^{-6} mol dm^{-3} (for the Soret region) and 4×10^{-5} mol dm^{-3} (for the Q region), cell length: 1 cm, magnetic field: 1.14 T, temperature: 1 °C.

The quantitative magnitudes of the MCD spectra were evaluated by the quantities A'/D, where A' and D represent the magnitude of the apparent Faraday A term[26] and the dipole strength of the electronic transition in the electronic absorption spectra.[22-25] The experimental A'/D values obtained by use of the method of moment[22,23] are summarized in Tables 1 and 2. The A'/D values for the Soret band for all the hemoglobin and myoglobin studied here show the same decreasing order of CO>O_2>NO in each hemoprotein. On the contrary the orders of A'/D for the Q_{0-0} and Q_{v-0} bands are rather random. Since the random order of the A'/D values for the Q_{0-0} and Q_{v-0} seems to be due to the difficulty in resolving the superimposed bands, the comparison of the A'/D values in the Q band region could not be done.

Table 2 shows that CO, O_2 ,and NO complexes have the Soret A'/D values of (0.30—0.19)β,[27] (0.15—0.10)β, and (0.09—0.03)β, respectively, for all the hemoglobin and myoglobin studied. The A'/D values for the Soret band in Tables 1 and 2 reveal that the α chain of hemoglobin gave larger A'/D values for all the three complexes than the β chain, and that the β chain showed similar A'/D values to those for human hemoglobin, and bovine and whale myoglobin. For example the O_2 complexes for human hemoglobin, its β chain, bovine and whale myoglobin gave the similar Soret A'/D values which are smaller than that of the α chain of human hemoglobin by (0.07—0.12)β. The difference of this order is significant and may imply some peculiar electronic structure for the O_2 complex of the α chain of human hemoglobin as compared with those of human hemoglobin, its β chain, bovine and whale myoglobin. It is also interesting to note that the A'/D values for the O_2 complex of the α chain of human hemoglobin exhibit similar magnitude of that for the CO complexes of the β chain, bovine myoglobin and human hemoglobin.

Our previous theoretical studies have succeeded in calculating the reasonable values of Faraday parameters of the iron(II) low spin type heme-chromophore for the Soret and Q transitions by use of the PPP CI MO method.[24] Although the calculation was rather simple one which neglects the orbitals of the iron and the axial ligands, it can predict the experimental apparent Faraday A terms for the π-π^* transitions. This is somewhat rationalized by the fact that the iron(II) low spin complex does not show the contribution from the Faraday C term. The Faraday parameters of the iron(II) low spin complexes on the Soret and Q bands were determined to be Faraday A and B terms which predominantly come from the porphyrin π electron system.

The present experimental results which show subtle but clear differences in the A'/D values in the Soret band region among CO, O_2, and NO complexes which will be better examined by the calculation including the orbitals of iron and axial ligands. However, since the Soret band for the iron(II) low spin complexes mainly depends on the π-electronic systems, a simple calculation which neglects these orbitals was used to examine the possible reasons for the axial ligand dependence on the A'/D values in the Soret MCD bands.

Within the framework of our π-electron approximation which neglects the iron and axial ligand orbitals, the effect of axial ligands can be included by changing the α-electron population on the pyrrole nitrogen atoms through the iron orbitals. Thus the core-charge of the nitrogen atom, *i.e.*, the α-electron density on the nitrogen atom will be altered by the effect of the axial ligands. For example the extent of the electron back-donation which depends on the π^* orbital level of the diatomic molecules will determine the strength of the α coordination of the axial ligand to the central iron, and further control the degree of the α coordination of the pyrrole nitrogen to the heme iron. Thus, the axial ligands (diatomic molecules) will vary the core-charge of the pyrrole nitrogen. Under these consideration the calculations of the A'/D values using the different nitrogen core-charges of 1.5, 1.4, 1.3, 1.2, 1.1, and 1.0 were examined. Only the core-charge values of 1.5, 1.4, and 1.3 gave reasonable A'/D values for the Soret and Q bands, and the calculated results are shown in Table 3. With these calculated A'/D values and the calculated energies of the splitting in the Soret and Q transitions, the expected MCD peak and trough magnitudes were calculated by assuming the gaussian band shape. The results are shown in Fig. 2 which shows that the calculated MCD's for the decreasing nitrogen core-charge values from 1.5 to 1.3 can reproduce at least the relative magnitudes of the Soret and Q MCD bands for the CO, NO, and O_2 complexes. Unfortunately the calculated energy difference between the Soret and Q bands as well as the calculated absolute magnitude and the splitting between plus and minus components in the Soret and Q bands did not correspond strictly to the experimental results, the reason for which may be partly due to the neglect of the iron(II) and ligand orbitals in the present stage of calculations.

Table 4 summarizes the π bond orders in the ground

Table 4. The calculated π bond orders of the model protoheme for several nitrogen core charge values

Core-charge	π Bond order[a] C_β-C_β	C_α-C_β	C_α-N	C_α-C_m
1.5	0.756—0.805	0.439—0.482	0.485—0.493	0.604—0.622
1.4	0.762—0.812	0.429—0.471	0.509—0.518	0.603—0.617
1.3	0.766—0.817	0.421—0.462	0.528—0.539	0.600—0.614

a) The symbols C_α, C_β, and C_m in the table denote the α cabon, β carbon of the pyrrole and the meso carbon of the porphyrin.

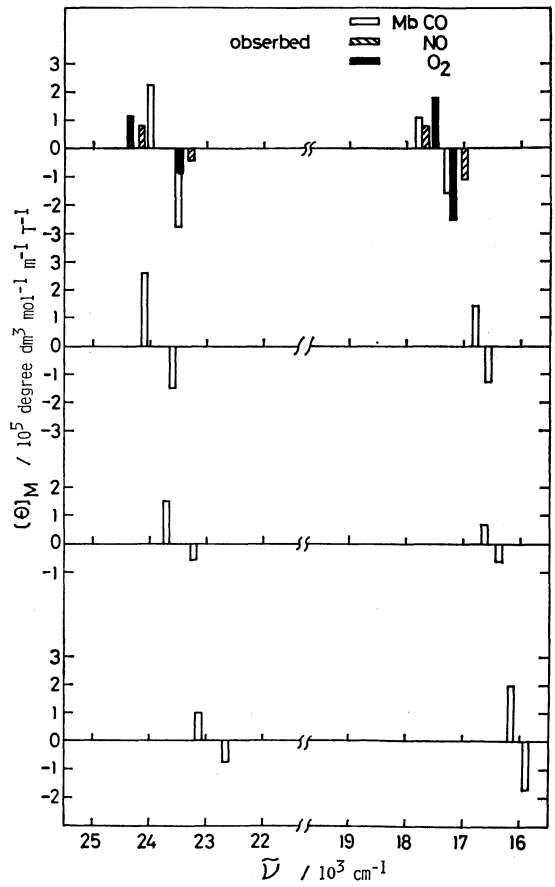

Fig. 2. The stick diagram of the experimental and calculated MCD spectra for the CO, NO, and O_2 complexes of hemoglobin and model protoheme. The calculated spectra were based on the A' values and the splitting energies from the PPP π electron calculation assuming the gaussian band shapes, and the experimental bandwidth. The top column is the experimental data, and from the second to the bottom colums are the calculated data for the pyrrole nitrogen core-charge of 1.5, 1.4, and 1.3, respectively.

states for the calculation with the varied nitrogen core-charge values. The larger changes in the π bond order in the pyrrole (0.010—0.012, −0.018——0.020, and 0.043—0.046 for C_β–C_β, C_α–C_β, and C_α–N, respectively) with varying the nitrogen core-charge from 1.5 to 1.3 were compared with the smaller changes in the C_α–C_m bond (0.004—0.008). Among all, the bond order change in the C_α–N is prominent and is two to three times as large as those in other pyrrole bonds. These calculated results can be compared with the resonance Raman spectral results as follows. The band IV in the heme resonance Raman spectral lines which is one of the spin and oxidation markers appears at 1372, 1375, and 1380 cm^{-1} for the CO, NO, and O_2 hemoglobin complexes, respectively.[4,5] Since the band IV was assigned to be dependent primarily on the C_α–N bond stretching, the above experimental frequencies indicate that the C_α–N bond order increases in the order of the CO, NO, and O_2 complexes. This order shows a similar trend with the calculated bond orders for the decreasing nitrogen core-charge values from 1.5 to 1.3. This means that some factors which induce the bond order changes of the porphyrin pyrrole C_α–N bond in the iron(II) low spin hemoprotein with diatomic molecules could be also explained by the PPP-CI calculations with the varied nitrogen core-charge values.

In conclusion the subtle but clear differences in the MCD's among the CO, NO, and O_2 complexes of the iron(II) low spin hemoproteins were found to be explained by considering the change in the core-charge of the pyrrole nitrogen which might be induced by axial ligands through the iron orbitals. The calculation also demonstrated the π bond order changes in the pyrrole C_α–N bond with the pyrrole nitrogen core charge variation, which seemed to refect on the heme resonance Raman spectral line IV.

The authors would like to express their thanks to Prof. Y. Yoneyama, Dr. S. Matsukawa, and Dr. K. Mawatari (Kanazawa University) for the kind guidances in preparing the α and β chains of human hemoglobin. The authors ackowledge support from Grant-in-Aid for Scientific Research of Japanese Government.

26) Since heme b in myoglobin has not true C_{4v} symmetry when all the substituents on the periphery of the porphyrin are taken into consideration, the porphyrin lowest unoccupied e orbitals (C_{4v}) slightly split into two closely positioned orbitals in the actual symmetry lower than C_{4v}. Hence there can not be expected true Faraday *A* term. However as the calculation indicated (A. Kaito, *et al.*, *Chem. Phys. Lett.*, **52**, 154 (1977)) the Faraday *B* terms predominantly mix among these split two orbitals gave an S-shaped MCD band which is a mimic Faraday *A* term. In this paper this apparent *A* term has been treated just like true Faraday *A* term.

Molecular Structure of [2](2,5)(7,7,8,8-Tetracyanoquinodimethano)-[2](1,4)naphthalenophane†

Takashi Mizuma,†† Kunio Miki, Yasushi Kai, Nobuo Tanaka,††† and Nobutami Kasai*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received October 23, 1981)

Molecular structure of [2.2](1,4)naphthalenophane containing 7,7,8,8-tetracyanoquinodimethan moiety as an electron acceptor has been determined by means of X-ray diffraction. Crystals belong to monoclinic system, space group Cc with four molecules per unit-cell; $a=9.770(1)$, $b=15.176(2)$, $c=13.299(2)$ Å, $\beta=98.43(1)°$. The structure was established by the direct method and refined by the full-matrix least-squares to $R=0.035$ for 1217 non-zero reflections. The [2.2]paracyclophane skeleton has the usual structure; a half of the naphthalene moiety has a boat-form, the six-membered ring of the TCNQ moiety also has a boat-form, and two $C(CN)_2$ portions in the TCNQ moiety are bent out and slightly twisted from the six-membered ring. The other half of the naphthalene ring free from the bridging is planar and are slightly bent out from the [2.2]paracyclophane skeleton.

As a part of a series of structural studies on layered cyclophanes, molecular structures of [2.2]paracyclophanes containing 7,7,8,8-tetracyanoquinodimethan (TCNQ) moiety as an electron acceptor have been determined;[1] they are [2](2,5)(7,7,8,8-tetracyanoquinodimethano)[2]paracyclophane (TCNQ-X) and 14,17-dimethoxy[2](2,5)(7,7,8,8-tetracyanoquinodimethano)-[2]paracyclophane (TCNQ-X(OMe)$_2$). In relation with these structures, this paper will deal with the molecular structure of [2](2,5)(7,7,8,8-tetracyanoquinodimethano)[2](1,4)naphthalenophane (TCNQ-N^{1,4}), in which a TCNQ and a naphthalene moieties are contained as an electron acceptor and electron donor respectively.

Experimental

A dark violet, needle crystal of TCNQ-N^{1,4} with approximate dimensions of $0.08\times0.15\times0.25$ mm^3 was used. The unit-cell dimensions were determined by the least-squares fit of 2θ values of high order reflections. The systematic absence of reflections showed that the corresponding space group is either Cc or C2/c. The value of calculated density of the crystal [$D_c=1.309$ g cm^{-3}] for $Z=4$ exclude the possibility of the space group C2/c, which was later confirmed by the structure determined.

Crystal Data. $C_{26}H_{16}N_4$, *F.W.* 384.44, monoclinic, space group Cc, $a=9.770(1)$, $b=15.176(2)$, $c=13.299(2)$ Å, $\beta=98.43(1)°$, $V=1950.5(3)$ Å^3, $D_c=1.309$ g cm^{-3} for $Z=4$.

Integrated intensities were measured on a Rigaku automated, four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. The $\theta-2\theta$ scan technique was applied at a scan rate of 4° min^{-1} in 2θ; scan width was $\Delta2\theta=(2+0.30\tan\theta)°$. Backgrounds were counted for 7.5 s at both ends of a scan. A total of 1232 (1217 non-zero) reflections was collected. Usual Lp corrections were made but absorption correction was ignored [μ(Cu $K\alpha$)$=6.35$ cm^{-1}].

Structure Solution and Refinement

The structure was solved by the direct method (*MULTAN* 74).[2] Twelve ring carbon atoms which consist of the [2.2]paracyclophane skeleton of the molecule could be located on the *E* map. The location of these atoms was confirmed to be consistent with the result of three-dimensional Patterson function. The Fourier synthesis revealed 28 carbon atoms out of 30, and the successive Fourier synthesis revealed the remaining carbon atoms.

The structure was refined isotropically by the block-diagonal least-squares method (*HBLS* V).[3] When the *R* value reduced to 0.14, anisotropic thermal parameters were introduced for all the non-hydrogen atoms. Ten strong reflections, of which intensities were considered largely affected by the counting loss of the scintillation counter and/or affected by the extinction, were excluded from the subsequent refinement. The refinement was continued by the full-matrix least-squares procedure.[4] At the later stage, all the hydrogen atoms located on a difference Fourier synthesis, were also included in the refinement, isotropic temperature factors being used. Finally, the *R* index converged to 0.035 ($R_w=0.045$) for 1217 non-zero reflections. The weighting schemes used at the final stage were $w=\{\sigma^2(F_o)+0.0523|F_o|+0.0025|F_o|^2\}^{-1}$ for $|F_o|>0$ and $w=2.2827$ for $|F_o|=0$. σ is the standard deviation obtained by the counting statistics of reflection intensities. Atomic scattering factors used for the C, N, and H atoms were taken from International Tables for X-Ray Crystallography, Vol. IV.[5] Computations were carried out on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University. Final atomic parameters are listed in Table 1.**

Results and Discussion

Molecular Structure. Perspective and side views of the present TCNQ-N^{1,4} molecule (*ORTEP* II)[7] and those of TCNQ-X for comparison are shown in Figs. 1 and 2. Selected bond distances and bond angles are given in Fig. 3.

The [2.2]paracyclophane skeleton in the TCNQ-N^{1,4} molecule has the similar structure as those in

† Structural Chemistry of Layered Cyclophanes. VIII.

†† Present address: Fuji-FACOM Corporation, 23-5 Nishishinbashi 3 chome, Minato-ku, Tokyo 105.

††† Present address: Institute for Protein Research, Osaka University, Yamadaoka, Suita, Osaka 565.

** Tables of observed and calculated structure factors and anisotropic thermal parameters are kept at the Chemical Society of Japan, Document No. 8236.

TCNQ-X and TCNQ-X$(OMe)_2$. Almost all of the bond distances and bond angles in the TCNQ-$N^{1,4}$ molecule are equal to the corresponding distances and angles in the TCNQ-X within the limits of errors. The better coincidence is observed between two molecules in the TCNQ portion than in the other portions. A few exceptions are observed: the C(4)–C(9) and C(9)–C(10) distances [1.427(4) and 1.426(4) Å] are longer than the corresponding ones in the TCNQ-X[1.386(6) and 1.385(6) Å].

The upper six-membered ring of the [2.2]paracyclophane skeleton, which is a half of the naphthalene moiety, takes a boat form: the planes defined by the C(3), C(4), and C(12) atoms and by the C(9), C(10), and C(11) form angles of 12.7 and 11.8° respectively with the mean plane made by the C(4), C(9), C(11), and C(12) atoms. The other half of the naphthalene moiety, formed by the C(4) to C(9) atoms, is planar within 0.007 Å, and slightly bent up by 4.2° from the

N (3) ··· N (1) [b]	3.465 (7)	Key: a, $1+x$, y, z;	
C (16) ··· C (4) [b]	3.489 (4)	b, x, $1-y$, $-0.5+z$;	
C (21) ··· C (3) [b]	3.430 (4)	c, x, $1-y$, $0.5+z$.	

plane made by the C(4), C(9), C(11), and C(12). The C(3)–C(2) and C(10)–C(13) bonds are further bent down by 11.0 and 12.6° from planes defined by the C(3), C(4), and C(12) atoms and by the C(9), C(10), and C(11), respectively.

The TCNQ moiety has a twisted structure. The central six-membered ring is in a boat form, the planes formed by the C(17), C(18), and C(19) atoms and by the C(15), C(16), and C(20) are bent up from the mean plane defined by the C(16), C(17), C(19), and C(20) by 15.8 and 14.4°, respectively. On the other hand, both of the two $C(CN)_2$ portions slightly bent down from the mean plane. The C(17)–C(21) and C(20)–C(24) vectors respectively make angles of 10.7 and 9.2° with the mean plane formed by the C(16), C(17), C(19), and C(20) atoms. Two $C(CN)_2$ planes have tilt angles of 12.4 and 9.4° to the mean planes mentioned above. The deviations of C(14)–C(15)–C(20), C(15)–C(20)–C(24), C(20)–C(24)–C(26), C(1)–C(18)–C(17), C(18)–C(17)–C(21), and C(17)–C(21)–C(23) angles[av. 124.4°] from 120° are observed, which are considered as due to the repulsions between $C(CN)_2$ portions and $-(CH_2)_2-$ bridges.

Two $-(CH_2)_2-$ bridges are twisted: the torsion angles about their central C–C bonds are 29.8 and 26.2°.

As described above, the electron donor and electron acceptor moieties in the present molecule are no more planar after they were linked by two $-(CH_2)_2-$ bridges: a half of the naphthalene moiety deformed into a boat form and the TCNQ moiety changed into a twisted structure. These deformations probably caused the electronic state in these moieties unfavorable to the charge-transfer interaction. In the similar manner little charge-transfer interaction between the benzene and TCNQ and *p*-methoxybenzene and TCNQ moieties respectively in the TCNQ-X and TCNQ-X-$(OMe)_2$ molecules can be explained well.

Crystal Structure. A perspective view[7] of the crystal structure is shown in Fig. 4. Short intermolecular atomic contacts less than 3.5 Å are given in Table 2. Most of them are involved between the neighboring TCNQ moieties.

The authors wish to express their deep thanks to Professor Soichi Misumi and his co-workers, Institute of Scientific and Industrial Research, Osaka University for the supply of crystals and their helpful discussions.

(Received October 29, 1981)

The surface free energies of two kinds of graphite fluorides, $(CF)_n$ and $(C_2F)_n$, were estimated from the contact angles of several liquids. The contact angles of water on flaky $(CF)_n$ and $(C_2F)_n$ were 117° and 116°, respectively, being slightly larger than that for poly(tetrafluoroethylene), while the values for tablets of powdery $(CF)_n$ and $(C_2F)_n$ were 143° and 141°, respectively, which indicates that powdery graphite fluoride is hardly wetted by water. From the contact angles obtained, the surface free energies were estimated to be *ca.* 18 mJ/m² for both flaky $(CF)_n$ and $(C_2F)_n$, *ca.* 2 mJ/m² for powdery $(CF)_n$ and *ca.* 3 mJ/m² for powdery $(C_2F)_n$. These differences depend on the surface conditions such as the packing of fluorine atoms, the roughness and porosity. From the contact angles for the tablets of $(CF)_n$–polyethylene mixtures, it is suggested that the anode effect in the fluorine or aluminium electrolysis takes place when the surface of carbon anode is partially covered by graphite fluoride.

During the electrolysis of molten KF·2HF or alumina in cryolite melt, it sometimes happens that the cell voltage suddenly increases with arc-discharging. This phenomenom is called the anode effect, on which a number of mechanisms have been reported by many investigators.[1,2]

Watanabe *et al.* proposed that the anode effect is attributed to the formation of graphite fluoride film on the surface of carbon electrode.[3–5] The formation of graphite fluoride on carbon anode surface extremely decreases the wettability of molten salt owing to its low surface free energy. On the basis of the mechanism, various experiments have been performed.[6–9] Graphite fluoride was detected on the surface of carbon anode after the anode effect from ESCA spectra.[10–11] Furthermore, during the studies on the relationship between composition and structure of graphite fluoride, it was found that a new compound, poly(dicarbon monofluoride), $(C_2F)_n$, is formed at a relatively low reaction temperature.[12] This compound might also be concerned with the anode effect besides $(CF)_n$.

The present study was carried out to clarify the roles of graphite fluorides on the anode effect. The extent of wetting between anode and electrolyte was evaluated physically from the surface free energies obtained from the contact angles of several liquids on two kinds of graphite fluorides at room temperature.

Experimental

Material. The following four samples of graphite fluorides were prepared. (1) Flaky poly(carbon monofluoride), $(CF)_n$ with F/C ratio of 1.0 was prepared by the direct fluorination of natural graphite (produced in Madagascar, purity: more than 99%) having a sieve size of 1.981—0.833 mm under F_2 pressure of 26664 Pa at 630 °C for 2 d. (2) Powdery $(CF)_n$ with F/C ratio of 1.1, prepared from petroleum coke of less than 37 μm, was supplied by Daikin Kogyo Co. Ltd. (3) Flaky poly(dicarbon monofluoride), $(C_2F)_n$ with F/C ratio of 0.65 was prepared by the fluorination of flaky natural graphite (1.981—0.833 mm) under F_2 pressure of 101325 Pa at 380 °C for 14 d. (4) Powdery $(C_2F)_n$ with F/C ratio of 0.65 was prepared by the fluorination of natural graphite of less than 37 μm under F_2 pressure of 101325 Pa at 380 °C for 3 d. All the samples were analyzed by X-ray diffractometry and their compositions were determined from elemental analysis of carbon and fluorine. For the purpose of comparison, flaky natural graphite with a sieve size of 1.981—0.833 mm, grafoil made by compressing exfoliated graphite from Union Carbide Corporation, poly(tetrafluoroethylene) (PTFE) supplied by Daikin Kogyo Co. Ltd. and polyethylene(PE) of E. Merck were used for the contact angle measurement.

Liquids used for the contact angle measurement were distilled water, reagent grade glycerol, formamide, 1,4-butanediol, hexadecane and 17% and 31% NaOH solutions.

Contact Angle Measurement. All the measurements were made at 30 °C using the CA-D type contact angle meter of Kyowa Kagaku Co. Ltd. For the flaky samples, the liquids were dropped onto them immediately after peeling off the thin layer with plastic adhesion tape. For the powdery samples, they were compressed and molded under a pressure of *ca.* 49 MPa to the tablets of 13 mm diameter and supplied for the contact angle measurement. The measurements for each sample were repeated 10 to 20 times and their average value was taken.

Results and Discussion

Surface Free Energy. Table 1 shows the contact angles of several liquids on each samples and water drops on the typical samples are shown in Fig. 1. It is of interest that water shows an extremely large contact angle on the tablet of graphite fluoride. The contact angles for PTFE and PE are in good agreement with the results measured by other investigators.[13–15] The data of water on natural graphite and grafoil are slightly larger than the values (60—86°) measured by others.[16–18] The difference of the data between natural graphite and grafoil would be attributed to the surface conditions such as the roughness and porosity. The large deviations in the data for flaky graphite fluorides might be due to the surface roughness and cracks made by fluorination, or/and the groups of $=CF_2$ and $-CF_3$ produced around the crack. Furthermore, the liquids with a surface tension lower than that of 1,4-butanediol penetrated into the flakes through the cracks. It was impossible to measure the contact angles of the liquids with a low surface tension such as hexadecane, since the powdery graphite fluorides were also too poor in cohesiveness

Table 1. Contact angles for graphite fluorides and other samples at 30 °C

to make a tablet without pore.

It was attempted to estimate the critical surface tensions, γ_c, from the Zisman plots in Fig. 2 using the data in Table 1. In Fig. 2, the surface tensions of the liquids, γ_L, at 20 °C were adopted because the values at 30 °C were not available. The difference in the data between 20 °C and 30 °C would be negligibly small, being less than 2 mN/m.[19] The critical surface tension is determined from a point where the extrapolated line of Zisman plot intersects the abscissa of cos $\theta=1$, which is approximately equal to the surface free energy. As shown by the dashed lines in Fig. 2, the critical surface tensions of PTFE and PE are 18 and 31 mN/m, respectively.[20] It is also known that the Zisman plot consists of two lines for nonpolar and polar liquids. Although graphite fluorides could not be measured for the nonpolar liquids in this work, if the samples without crack and pore were prepared, their Zisman plots for the nonpolar liquids would give a line with a slope similar to the dashed line for PTFE. Accordingly, it is suggested that the critical surface tensions for flaky graphite fluorides, $(CF)_n$ and $(C_2F)_n$ are nearly equal to that of PTFE. As shown in Fig. 3, two kinds of graphite fluorides have different structures, however, the packings of fluorine atoms on the basal plane are

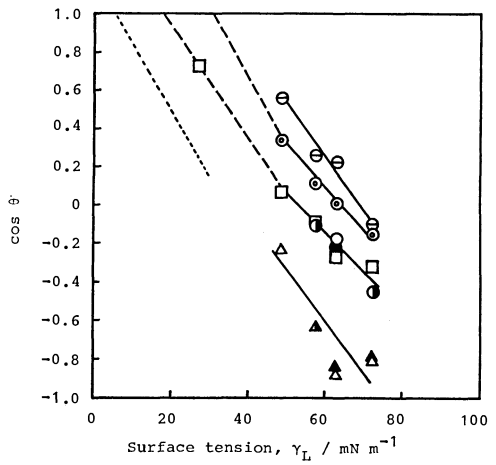

Fig. 2. Zisman plots for $(CF)_n$, $(C_2F)_n$, graphite, PTFE, and PE.
○ $(CF)_n$, flake, ●: $(C_2F)_n$, flake, △: $(CF)_n$, tablet, ▲: $(C_2F)_n$, tablet, ⊖: graphite, □: PTFE, ◎: PE, ……: perfluorolauric acid monolayer.

equal to each other, being *ca.* 1.9×10^{19} F/m^2 (The packing for PTFE is calculated to be *ca.* 3.2×10^{19} F/m^2 along the long chain and *ca.* 1.0×10^{19} F/m^2 at the chain edge.[21]). It is therefore reasonable that

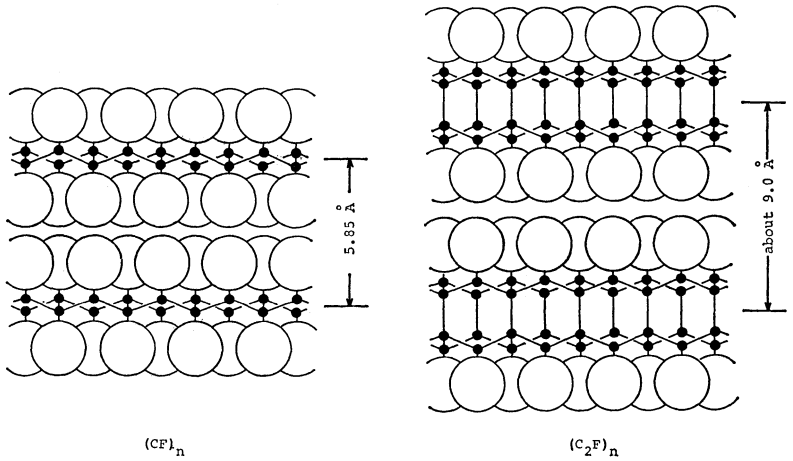

Fig. 3. Crystal structures of $(CF)_n$ and $(C_2F)_n$.
●: Carbon atom, ○: fluorine atom.

two kinds of flake samples have the same surface free energy.

The combination of Young's and Fowkes's equations for the interfacial tension[22,23] leads the relation between the contact angle and the surface free energy in the solid–liquid system depending only on the dispersion force.

$$\cos\theta = -1+2(\gamma_s^d\cdot\gamma_l^d)^{1/2}/\gamma_L,$$

where θ is contact angle, γ_s^d and δ_l^d are the surface free energies of solid and liquid, respectively, and γ_L is the surface tension of liquid. The calculations for water, glycerol and formamide gave the average surface free energies of *ca.* 18 mJ/m² for flaky $(CF)_n$, *ca.* 18 mJ/m² for flaky $(C_2F)_n$, *ca.* 2 mJ/m² for powdery $(CF)_n$, *ca.* 3 mJ/m² for powdery $(C_2F)_n$, *ca.* 20 mJ/m² for PTFE and *ca.* 33 mJ/m² for PE. (*cf.* published data: 19.5 mJ/m² for PTFE and 35.0 mJ/m² for PE.[23]) The surface free energies of two powdery graphite fluorides are much lower than those of the flakes, being nearly equal to that of perfluorolauric acid monolayer having the group of $-CF_3$ on the surface (γ_c=6 mN/m).[24] This might be attributable to the group of $-CF_3$ or $=CF_2$ on the edge plane of graphite fluoride crystallite as shown in Fig. 4. The surface free energy of graphite fluoride would depend on the ratio of the basal and edge planes on the surface of graphite fluoride particle.

Relation between Surface Free Energy and Anode Effect. Both of the basal and edge planes of graphite crystallite would be present at random on the surface of actual carbon electrode. Powdery graphite fluoride is preferred to investigate influence of surface covering by graphite fluoride on the anode effect or the contact angle. Since it was difficult to make a tablet from graphite and graphite fluoride because of their poor cohesiveness, PE having the surface free energy analogous to that of graphite was used as a binder on preparing a tablet.

The effect of the surface covering by graphite fluoride on the contact angles is shown in Fig. 5, together with the result of PTFE–PE system. In the latter, the contact angles increased linearly with increasing content of PTFE, which satisfied the following equation;[25]

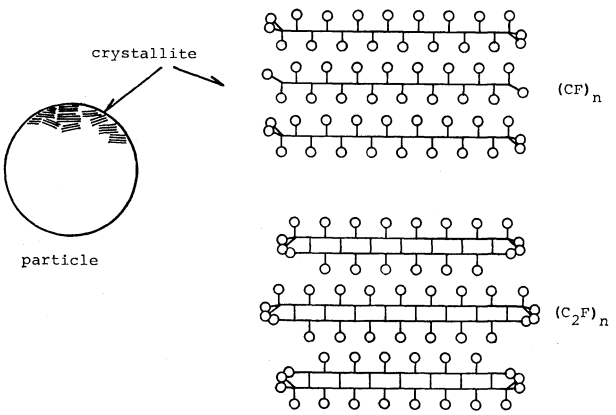

Fig. 4. Illustration of particle and crystallite of graphite fluoride.

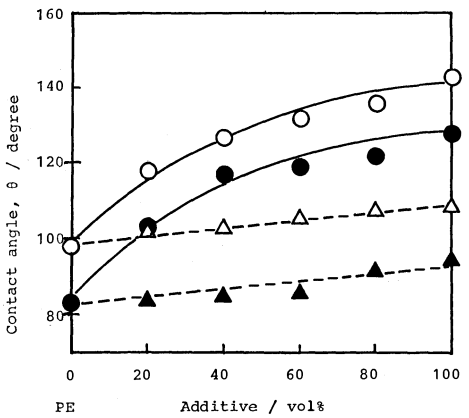

Fig. 5. Effect of additive content in the tablet on contact angle.
○: $(CF)_n$–water, ●: $(CF)_n$ formamide, △: PTFE–water, ▲: PTFE–formamide.

$$\cos\theta_{mix} = f_A\cdot\cos\theta_A + f_B\cdot\cos\theta_B,$$

where θ is contact angle, f is volume percentage of composite, A or B, and $f_A+f_B=1$. On the other hand, $(CF)_n$–PE mixture dosen't obey this relation, which would be due to the low surface free energy

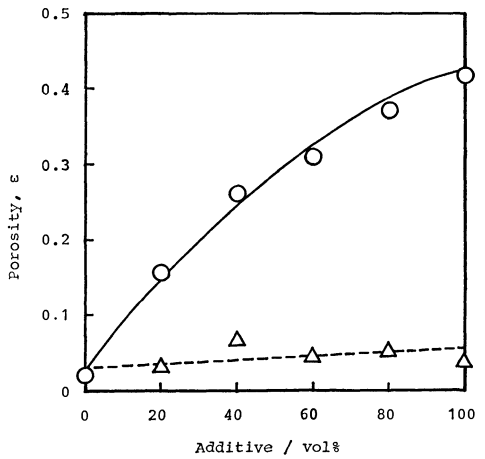

Fig. 6. Plots of porosity *vs.* additive content of $(CF)_n$–and PTFE–PE tablets pressed at *ca.* 49 MPa.
Additive: ○: $(CF)_n$, △: PTFE.

of graphite fluoride or the surface roughness or porosity of the tablet. Wenzel[26] found that when a true contact angle is larger than 90°, a larger contact angle than the true one is observed by the surface roughness, and Ito *et al.*[27] also reported the similar effect by the porosity. The porosity of $(CF)_n$–PE tablet calculated from the weight and size of tablet and the density of mixture increases with the content of $(CF)_n$ as shown in Fig. 6. In this case, the effect increasing a contact angle by porosity or roughness and another effect decreasing a contact angle by penetration of liquid through the pore would give some change to the contact angle. If a tablet having the smooth surface like that of PTFE–PE system is made, the true contact angle would be measured. In case of the tablet composed of only $(CF)_n$, no tablet with the porosity less than 0.4 could be made even under the pressure of *ca.* 490 MPa.

Although this problem still remains, it was attempted to discuss the effect of the surface covering by graphite fluoride on the anode effect on the basis of the data in Fig. 5 and the contact angles of 17 and 31% NaOH solutions with high surface tensions. The cosine of contact angle *vs.* surface tension of liquid is plotted in Fig. 7. The contact angle of molten cryolite having the surface tension of 134 mN/m at 1000 °C is reported to be in the range of *ca.* 130 to 140° on natural graphite.[1] It is likely that the contact angle increases with increasing surface tension of liquid as shown in the solid line for natural graphite in Fig. 7. In the range of $(CF)_n$ content of more than 60% for $(CF)_n$–PE system, the contact angles seem to reach constant in spite of increase in the surface tensions of liquids, which would be due to the limit of the experimental method used in this study. If a liquid behaves like a rigid sphere, its contact angle would be measured accurately up to 180°. In practice, it is known that the contact angle of mercury on PTFE is *ca.* 150° which is the critical value for wetting in contact angle measurement by sessile drop method. Thus, the contact angle for $(CF)_n$–PE tablet would vary with the surface tension of liquid as shown by the dotted lines in Fig. 7.

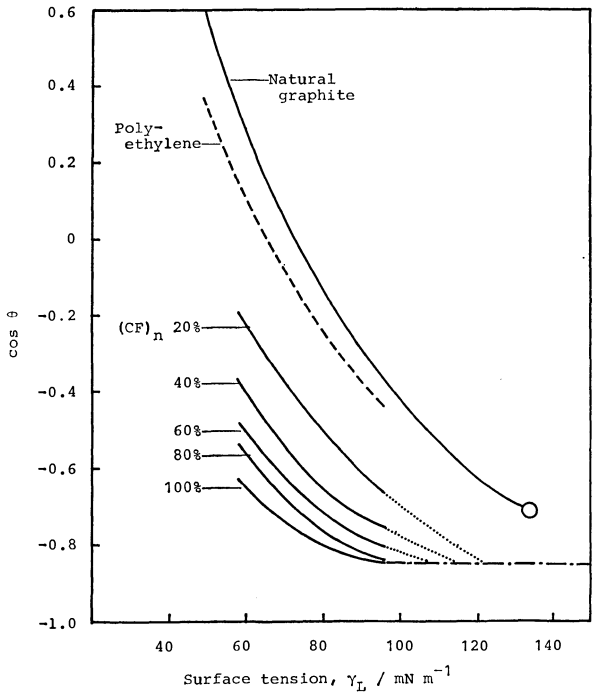

Fig. 7. Influence of $(CF)_n$ surface covering upon contact angle.

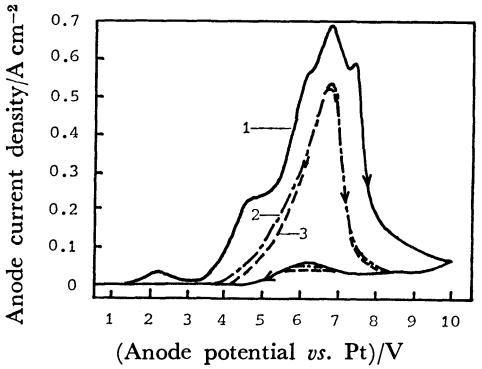

Fig. 8. Potential-sweep diagram for carbon anode in KF·2HF melt.
Sweep rate: 0.2V/s. 1: 1st sweep, 2: 2nd sweep, 3: 3rd sweep.

It is assumed that the anode effect occurs when the contact angle of molten salt on carbon anode reaches the critical value shown in Fig. 7. If the wettability of anode surface is determined by the relation between the surface tension of molten salt and the property of anode surface, the anode effect in the aluminium electrolysis is expected to occur at the surface covering of 10 to 20% by graphite fluoride on the basis of above surface tension of molten cryolite. Likewise, the anode effect in the fluorine electrolysis is expected to occur at the surface covering of 60 to 80% by graphite fluoride since the surface tension of molten KF·2HF is reported to be *ca.* 100 mN/m at 100 °C.[6]

Figure 8 shows the current-potential curves for carbon anode in molten KF·2HF.[5] In the first sweep,

OH^- ion is first discharged owing to its low discharge potential and through the discharge of F^- ion, the anode effect occurs when anode surface is covered by graphite fluoride to some extent. The second and third sweeps indicate that the anode surface partially covered by graphite fluoride remaining without decomposition is not wetted by the species including OH^- ion but wetted by the species including F^- ion, which means that the surface tension of the species including OH^- ion is higher than that of the species including F^- ion. If water exists as a molecule in molten $KF \cdot 2HF$, it should be easily adsorbed by carbon anode prior to molten $KF \cdot 2HF$ because of its low surface tension, *ca.* 60 mN/m at 100 °C. This is in conflict with the above experimental result. The wettability of anode surface under electrolysis would be dominated by other species different from the bulk species of molten $KF \cdot 2HF$ or water itself.

In order to estimate accurately the anode surface covering by graphite fluoride at the onset of anode effect, the surface tension of the dominant species present in the vicinity of anode surface must be evaluated, taking into account the other factors such as the roughness of anode surface, temperature, polarizing effect by electric current and composition of molten salt.

From the results obtained in this work, it is inferred that the partial covering of anode surface by graphite fluoride can easily cause the anode effect in the system having substantially poor wettability between carbon electrode and melt as in the case of aluminium electrolysis.

Financial support and experimental assistance from Sumitomo Aluminium Smelting Co. Ltd. are acknowledged. The authors thank Dr. Hidekazu Touhara and Dr. Akimasa Tasaka for their helpful discussions.

Photoelectrochemical Reduction of Carbon Dioxide at p-Type Gallium Phosphide Electrodes in the Presence of Crown Ether

Yasuhiko TANIGUCHI, Hiroshi YONEYAMA,* and Hideo TAMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamada-oka, Suita, Osaka 565
(Received November 6, 1981)

Reduction of carbon dioxide at p-type GaP photocathodes was investigated in lithium carbonate electrolytes. The reduction occurs in competition with hydrogen evolution and its current efficiency is enhanced by dissolving crown ether such as 15-crown-5 in the electrolyte. It is proposed that a chemical reaction pathway is involved in which the reduction of carbon dioxide is initiated by cathodically deposited lithium with formation of the anion radical of carbon dioxide.

Electrochemical reduction of carbon dioxide in aqueous solutions has been investigated by using metal cathodes of high hydrogen-overvoltage such as mercury and lead. Since Teeter and Rysselberghe[1] observed a cathodic wave due to reduction of carbon dioxide in polarograms, many investigators[2-6] have assumed that the electrochemical reduction of carbon dioxide is initiated by accepting single electron to give the anion radical of carbon dioxide. This view was confirmed by reflectance spectroscopy[5] and by measurement of photoemmission current of mercury cathodes in the presence of carbon dioxide.[6] The reduction product at mercury cathodes is in general exclusively formic acid[7] and high current yields for the reduction can be achieved by appropriate choice of electrolysis conditions.[1,4] However, the problem in using metal cathodes is that a large applied voltage of *ca.* 3 V seems to be required, as deduced from reported electrode potentials of the cathode.

Recently, photoelectrochemical reduction of carbon dioxide has been reported by Halmann[8] who used a p-type GaP photocathode to cut down the electrical energy input to a large extent. The photo-assisted reduction of carbon dioxide can also occur, even in the absence of electrical energy input, if heterogeneous reaction systems using semiconductor photocatalysts are employed,[9,10] although the rate of reduction is quite low in this case.

The present study was carried out with a view of elucidating the mechanism of the photoelectrochemical reduction of carbon dioxide at p-type GaP cathodes in lithium carbonate electrolytes. As will be reported in a separate paper,[11] lithium deposits onto illuminated p-type GaP cathodes to give Li_xGaP. This phenomenon is noticeable especially in the presence of crown ethers such as 15-crown-5 in the electrolyte. In this paper, it will be shown that the deposited lithium contributes to the reduction of carbon dioxide by providing a chemical reaction pathway in the initial stage of reduction to give the anion radical of carbon dioxide. A chemical reaction mechanism similar to this was postulated for the electrochemical reduction at mercury under a high cathodic bias in the presence of sodium cation, in which carbon dioxide reacts with sodium amalgam,[12] but no confirmative data has been presented. Rather, according to detailed studies by Park *et al.*,[4] such a mechanism is believed to be unlikely in general cases at metal electrodes.

Experimental

Single crystal wafers of zinc-doped p-type GaP, donated by Sanyo Electric Co., were used as the electrode material. The acceptor concentration determined by the manufacturer was 4×10^{17} cm^{-3}, and the (111) face was chosen as the electrode surface. The preparation of the electrode was etched in aqua regia for 2 min, and then washed with deionized water for 15 min.

Current-potential curves were obtained by employing the potential sweep method, in which a potentiostat (Hokuto Denko Model FG-2) and an X-Y recorder (Yokogawa Electric Model 3077) were used. Photoelectrolysis was carried out under potentiostatic control with the charge being measured with an electronic coulometer (Hokuto Denko Model HF-201). Techniques of anodic stripping voltammetry were used for cathodically prepolarized electrodes at a sweep rate of 0.7 V s^{-1} by allowing the relay of the function generator to be excited whenever the cathodic polarization at a fixed potential was just enough to give a desired charge. An SCE served as the reference electrode.

Electrolysis experiments were usually carried out in a 3-compartment cell, and carbon dioxide was continuously bubbled into both the anode and cathode compartments after being saturated with water vapor. In order to collect reduction products, the effluent gas was passed through a trap which was cooled in a mixture of dry ice and acetone. In the case where the production of methane was to be investigated, a sealed 1-compartment cell was used under a carbon dioxide atmosphere.

Quantitative analysis of formic acid, formaldehyde and methanol was carried out for both the electrolyte and residues in the cooled trap. Methanol was analyzed by gas chromatography using a Porapak Q column and a FID detector. Formic acid and formaldehyde were determined by a colorimetric analysis using chromotropic acid.[14] For the analysis of formaldehyde in sample solutions containing either crown ether or CO_3^{2-} or both 4 cm^3 of HCl was added to 10 cm^3 of sample solution to make the solution acidic. In the case where the solution contained crown ether, it was then distilled to get rid of the crown ether.

Formic acid was indirectly determined by first reducing it to formaldehyde,[15] by which the formaldehyde in sample solutions was increased by the amount corresponding to that of formic acid, and then subtracting the original amount of formaldehyde from the total amount determined. For this purpose, 100 mg of Mg ribbons was dropped into 0.5 cm^3 of sample solution and then 0.05 cm^3 of HCl was added to the solution ten times at intervals of 1 min, to reduce formic acid to formaldehyde. Analysis of methane was carried out by gas chromatography using a Porapak Q column.

Current yields for the formation of the analyzed components were evaluated on the assumption that they are produced according to the following reduction schemes:

$$CO_2 + 2H^+ + 2e^- \longrightarrow HCOOH, \quad (1)$$

$$CO_2 + 4H^+ + 4e^- \longrightarrow HCHO + H_2O, \quad (2)$$

$$CO_2 + 6H^+ + 6e^- \longrightarrow CH_3OH + H_2O, \quad (3)$$

$$CO_2 + 8H^+ + 8e^- \longrightarrow CH_4 + 2H_2O. \quad (4)$$

Spectroscopic measurements for the chemical reaction of carbon dioxide with lithium were carried out by using a Shimadzu MPS-5000 spectrophotometer. The cell used had a glass capillary through which carbon dioxide was bubbled.

A 500 W super high-pressure mercury arc lamp (Ushio Electric Model UXL-500) served as the light source. Light was collimated, passed through a Toshiba UV-37 filter which cut off lights of wavelengths shorter than 370 nm, and then focused so as to illuminate just the electrode surface. The intensity of the light effective for the excitation of electrode, which covered from 370 to 550 nm, was 0.05 W, as measured with a laser power meter (Coherent Radiation Model 201).

All the chemicals used were of reagent grade and no further purification was made except for the propylene carbonate, which was subjected to distillation under reduced pressure twice before use.

Results and Discussion

Current Efficiency for the Formation of Reduction Products. Figure 1 shows current-potential curves for the illuminated p-type GaP electrode obtained under nitrogen atmospheres in 0.1 mol dm^{-3} 15-crown-5. The crown ether seems to suppress the saturated photocurrent a little, but not to have any other noticeable effects on current-potential curves. A replacement of nitrogen with carbon dioxide in the bubbling gas brought about no marked change in current-potential curves.

The current efficiency for the production of formic acid, formaldehyde, and methanol was obtained with the same electrolytes as those given in Fig. 1 at three different electrode potentials, where photocurrents were greatly different in magnitude from one another. The electrolysis time chosen was 22 h. The results are shown in Fig. 2, from which it is noticed that the efficiency is enhanced by the addition of crown ether to the lithium carbonate electrolyte for all the three kinds of products. No enhancement in the current efficiency is brought about by any decomposition reactions of crown ether, because when an electrolysis was carried out under the same conditions but that an electrolyte of 0.1 mol dm^{-3} LiOH containing 0.1 mol dm^{-3} 15-crown-5 was used under a nitrogen atmosphere, no production of formic acid, formaldehyde, or methanol occurred.

According to the results given in Fig. 2, the current efficiency for the production of every product de-

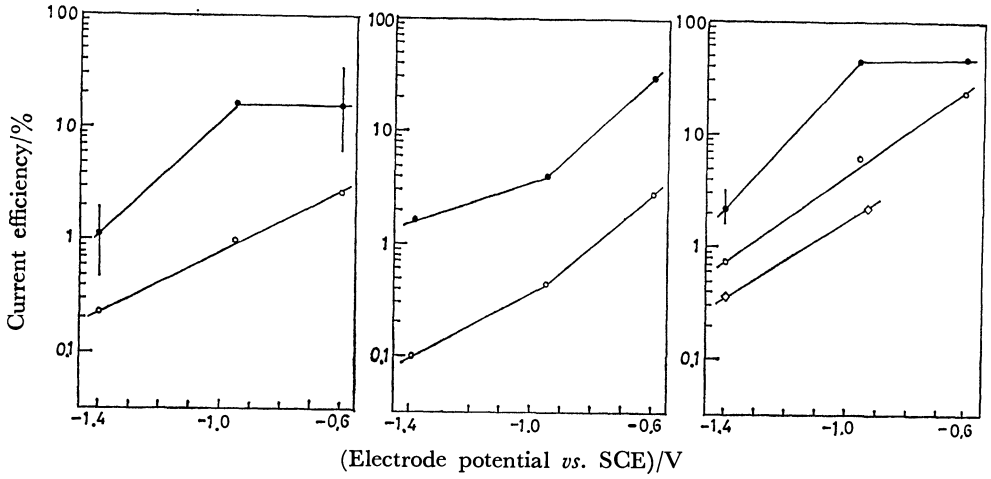

Fig. 2. The current efficiency for the production of formic acid (left), formaldehyde(middle), and methanol (right) as a function of electrode potentials.
—○—: 0.1 mol dm^{-3} Li_2CO_3 under bubbling CO_2, —●—: 0.1 mol dm^{-3} Li_2CO_3 containing 0.1 mol dm^{-3} 15-crown-5 under bubbling CO_2, —◇—: 0.1 mol dm^{-3} Li_2CO_3 containing 0.1 mol dm^{-3} 15-crown-5 under bubbling N_2.

creases with an increase in the cathodic polarization. A replacement of the bubbling gas from carbon dioxide to nitrogen caused a decrease in the current efficiency for the formation of methanol by approximately one order of magnitude, as shown in Fig. 2, which confirms the well estabilished view that major electroactive species is not CO_3^{2-} but CO_2.[16,17]

Besides the products given in Fig. 2, methane seems to be formed. Although no systematic investigation has been done, a current efficiency of *ca.* 5% was obtained for an electrolysis at −0.95 V *vs.* SCE in the presence of crown ether. It is characteristic of semiconductor photoelectrodes[8] and photocatalysts[9,10] that several reduction products are simultaneously formed.

Figure 3 shows effects of the concentration of 15-crown-5 on the production of formic acid, formaldehyde, and methanol. It is seen that the current efficiency for every product increases with an increase in the concentration of the crown ether. Since the crown ether affects the photodeposition of lithium in proportion to its concentration,[11] the results shown in this figure give an indication that the efficiency for the reduction of carbon dioxide is closely related to the feasibility of the lithium photodeposition.

Current Efficiency Obtained in the Presence of 18-Crown-6. Table 1 shows the current efficiency obtained in the presence of 18-crown-6, together with that obtained in the presence of 15-crown-5. It is seen that the current efficiency for the three kinds of products is higher in 15-crown-5 than in 18-crown-6. This difference seems to be caused by the feasibility of the lithium deposition which takes place in course of the cathodic polarization of electrode. As will be shown in detail in another paper,[11] the amount of deposited lithium increases with an increase in the cathodic charge and decreases with an increase in the molecular dimension of crown ethers. The kind of lithium salt electrolytes is not a problem for appearence of the phenomena. Typical examples of anodic stripping voltammetric waves of a cathodically prepolarized electrode in 0.2 mol dm^{-3} LiOH are given in Fig. 4 for the presence of 15-crown-5 and 18-crown-6. The anodic peak observed in the voltammogram is due to oxidation of the deposited lithium.

It is then speculated that there is a chemical reaction between carbon dioxide and deposited lithium to give the anion radical of carbon dioxide as the initial step of carbon dioxide reduction:

$$Li + CO_2 \longrightarrow Li^+ + CO_2^{\cdot-}. \quad (5)$$

In order to confirm this idea, the following experi-

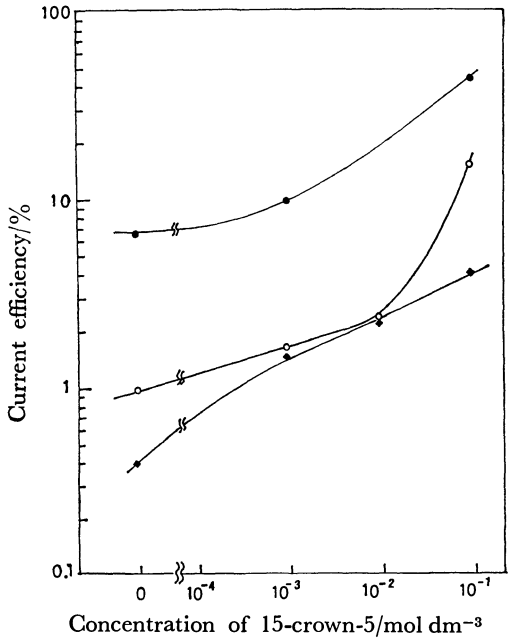

Fig. 3. Effects of the concentration of 15-crown-5 in 0.1 mol dm^{-3} Li_2CO_3 on the current efficiency for the production of formic acid (—○—), formaldehyde (—◆—), and methanol (—●—).

Table 1. Current efficiency for formation of formic acid, formaldehyde, and methanol[a]

The experiments were carried out under N_2 atmospheres.

ments were carried out.

Spectroscopic Studies on the Chemical Reaction of Carbon Dioxide with Lithium. If Reaction 5 occurs in aqueous electrolytes, the resulting anion radical will instantly react with water to give formate radical:[4,7]

$$CO_2^{\cdot-} + H_2O \longrightarrow HCO_2\cdot + OH^-. \quad (6)$$

The occurrence of Reaction 5 was then investigated in propylene carbonate solutions by taking absorption spectra characteristic of the anion radical.[5] Figure 5 shows the results obtained with a solution into which carbon dioxide was continuously bubbled. A CO_2-saturated propylene carbonate containing 0.1 mol dm^{-3} $LiClO_4$ shows no noticeable absorption in the UV region, but in the presence of lithium metal a strong absorption appeared at 265 nm which is due to $\sigma^* \leftarrow n^*$ transition of the anion radical,[5] confirming the occurrence of Reaction 5.

In order to obtain information on whether or not the deposited lithium can easily reduce formic acid to formaldehyde, similar experiments were carried out in propylene carbonate. Formic acid gave the absorption maxima at *ca.* 220 nm and formaldehyde at *ca.* 275 nm in a broad absorption band, as shown in Fig. 6. When a piece of lithium was dropped in propylene carbonate containing 64 mmol dm^{-3} formic acid and shaken vigorously under an air-tight condition for 10 min, the resulting solution gave an enhancement of the broad absorption due to formaldehyde. Simultaneously, the absorption due to formic acid was weakened. When the propylene carbonate solution initially contained a small amount of water (0.025 cm^3/10 cm^3 propylene carbonate), the absorption at 275 nm was much stronger.

Judging from these results, the reduction of formic acid to formaldehyde with lithium is likely to occur in the course of photoelectrochemical reduction of CO_2 at illuminated GaP cathodes:

$$HCOO^- + 2Li + 2H_2O \longrightarrow HCOOH + 2LiOH + OH^-. \quad (7)$$

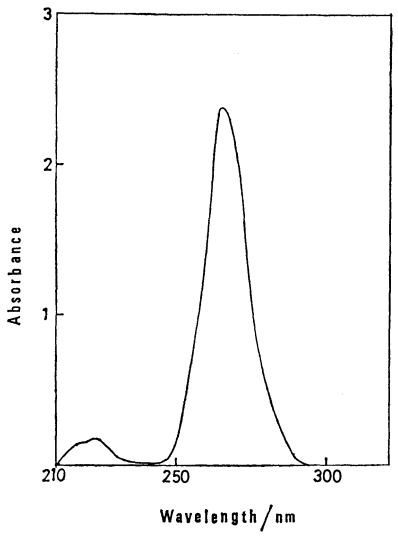

Fig. 5. An absorption spectrum showing the formation of $CO_2^{\cdot-}$ by chemical reaction of CO_2 with lithium in propylene carbonate.

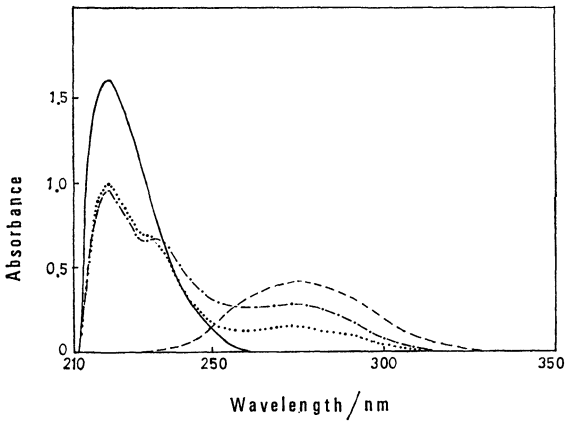

Fig. 6. Change in absorption spectra of formic acid in propylene carbonate by addition of a piece of lithium.
——: 64 mmol dm^{-3} HCOOH, ·····: after adding a piece of lithium to 64 mmol dm^{-3} HCOOH, – – –: after adding a piece of lithium and 0.025 μdm^3 of H_2O to 10 cm^3 of 64 mmol dm^{-3} HCOOH, — —: 30 mmol dm^{-3} HCHO.

In this section, we have discussed chemical reaction paths for the production of analytically determined species. However, it seems important to stress here that the reduction of carbon dioxide by purely electrochemical processes[7] is not excluded, at least in cases where no crown ether is dissolved in the electrolyte.

Energy Conversion Efficiency. The energy conversion efficiency for the photoproduction of carbon dioxide was estimated for the results given in Fig. 2 by using the following equations:

$$\eta_{ph} = \frac{[\Sigma n_i \Delta G_i^0 - VC]}{W_{ph} t} \times 100, \quad (8)$$

where n_i is the number of moles of produced species i, ΔG_i have been evaluated as

$$CO_2 + H_2O \longrightarrow HCOOH + 1/2O_2 \qquad \Delta G^0 = 270.1 \text{ kJ mol}^{-1}, \quad (9)$$

$$CO_2 + H_2O \longrightarrow HCHO + O_2 \qquad \Delta G^0 = 521.7 \text{ kJ mol}^{-1}, \quad (10)$$

$$CO_2 + 2H_2O \longrightarrow CH_3OH + 3/2O_2 \qquad \Delta G^0 = 702.5 \text{ kJ mol}^{-1}. \quad (11)$$

V is the applied voltage between the anode and cathode, C is the amount of charge consumed in the electrolysis for 22 h, W_{ph} is the optical energy input which was 0.05 W for incident photons effective for the excitation of electrode, and t the electrolysis time, 22 h. The experiments for Fig. 2 were carried out by controlling the photocathode potential but not the anode potential. In the present estimation of energy conversion efficiency, however, the anode potential needs to be evaluated, and this value was assumed here to be 0.52 V *vs.* SCE on the assumption of the oxygen overvoltage at the anode being 0.2 V, which will be achieved at the best anode (DSA) for the current density region chosen in the present study.

Table 2 gives calculated results for the total amount of formic acid, formaldehyde, and methanol produced.

TABLE 2. ENERGY CONVERSION EFFICIENCY FOR PHOTOELECTROCHEMICAL REDUCTION OF CARBON DIOXIDE IN A CELL USING A P-TYPE GALLIUM PHOSPHIDE CATHODE[a)]

Electrolyte	$E_{cathode}$ *vs.* SCE / V	q / C	Appl. V[b)] / V	VC / J	$\Sigma n_i \Delta G_i^0$ / J	W_{ph} / J	η_{ph} / %	η_t / %
0.1 M 15-Crown-5/ 0.1 M Li_2CO_3	−0.6	0.78	1.12	0.87	0.90	3960	9.1×10^{-4}	2.3×10^{-2}
	−0.95	1.7	1.47	2.5	1.40	3960	—	3.5×10^{-2}
	−1.40	37.4	1.92	71.6	3.20	3960	—	8.0×10^{-2}
0.1 M Li_2CO_3	−0.6	0.93	1.12	1.04	0.59	3960	—	1.4×10^{-2}
	−0.95	11.3	1.47	16.6	1.10	3960	—	2.8×10^{-2}
	−1.4	134	1.92	257.4	1.50	3960	—	3.5×10^{-2}

a) The efficiency was obtained for the production of formic acid, formaldehyde, and methanol. b) Applied voltage between the anode and cathode. An overpotential of 0.2 V was assumed for the oxygen evolution reaction at the anode.

The production of methane was neglected in this case, but this is not serious for the present purpose of estimating a rough order of conversion efficiency, because the methane production is believed to be minor. According to the obtained results which are given in Table 2, storage of optical energy was achieved only for one case where the electrolysis was carried out at −0.6 V *vs.* SCE in the presence of 15-crown-5. The estimated conversion efficiency in this case was as low as 9.1×10^{-4}%, which has no practical significance. In the other cases, the electrical energy input was found to exceed the sum of chemical energies produced.

Then, another measure for the total energy conversion efficiency was defined by Eq. 12, which gives the ratio of stored chemical energy to total energy input consumed for obtaining the chemicals in question:

$$\eta_t = \frac{\Sigma n_i \Delta G_i^0}{VC + W_{ph}t} \times 100. \quad (12)$$

Results obtained by applying this equation are also shown in Table 2, which indicates that the efficiency is still low even if estimated in this measure.

As indicated in Table 2, the principal cause responsible for such low conversion efficiencies is low utilization of optical energy in producing cathodic photocurrents. The low utilization is, of course, inevitable for the electrolysis at potentials where saturated photocurrents are not attained. Judging from the results shown in Fig. 1, the electrolysis at −0.6 V, for example, will give a relative utilization of optical energy of less than one twentieth that at −1.4 V. Furthermore, a gradual decrease in photocurrent, which occurs in the course of electrolysis, is very serious. If one estimates the average photocurrent in the electrolysis by dividing the amount of measured charges by the electrolysis time (22 h), the following values are obtained: 27.6 μA cm^{-2} at −0.6 V, 62.9 μA cm^{-2} at −0.95 V, and 1.38 mA cm^{-2} at −1.4 V *vs.* SCE. If these values are compared with those given in Fig. 1, it will be noticed that the degradation of electrode is serious. The major cause for bringing about such degradation is believed to be due to the incorporation of lithium which causes a noticeable decrease in quantum yield of photocurrent in the intrinsic absorption region.[11)] Similar degradation, though to a less extent, is in general caused to occur at p-type GaP photocathodes by impregnation of hydrogen.[13)] In order to achieve a high conversion efficiency of optical energy, such unstable behavior of photocathodes should be avoided.

Judging from the results given in Fig. 2, the sum of the current efficiencies for the production of formic acid, formaldehyde, and methanol is less than 100%, indicating that a hydrogen evolution took place competitively. Since hydrogen is a useful fuel which can store optical energy, η_t was again calculated for the whole cathodic reactions including the hydrogen evolution from the results shown in Table 2 on the assumption that 100% efficiency will be attained for the production of formic acid, formaldehyde, methanol, and hydrogen. The results obtained in the presence of the crown ether were 2.55×10^{-2}, 5.4×10^{-2}, and 1.1% for the cathodic potentials −0.6, −0.95, and −1.4 V, respectively, while in the absence of the crown ether η_t was 2.5×10^{-2}, 0.35, and 3.9% at −0.6, −0.95, and −1.4 V, respectively. The observed increase in η_t with an increase in the cathodic polarization in this case simply reflects the tendency that both the quantum yield of cathodic photocurrents and the current efficiency for the hydrogen evolution will increase with increasing cathodic polarization.

In the present study, unsatisfactory results were obtained in the point of energy conversion efficiency for the reduction of carbon dioxide. The results obtained, however, have revealed that carbon dioxide can be reduced at −0.6 V *vs.* SCE at p-type GaP photocathodes with current efficiency enhanced by addition of crown ether to lithium salt electrolyte. This implies that replacement of conventional metal cathodes by the present systems can save us more than 1 V of electrical energy input for the carbon dioxide reduction.

The present study was supported by Grant-in-Aid for Energy Research No. 5604011 from the Ministry of Education, Science and Culture.

A Conductance Study of Alkali Metal Ion–Benzo-15-crown-5 Complexes in Propylene Carbonate

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received November 28, 1981)

The formation constants (K_{ML^+}) for 1:1 complexes of benzo-15-crown-5 (B15C5) with alkali metal ions at 25 °C, and the enthalpy (ΔH) and entropy changes (ΔS) of the K^+–B15C5 complex in propylene carbonate (PC) have been determined conductometrically. The K_{ML^+} series of B15C5 for the alkali metal ions are given in the order $Na^+ > Li^+ > K^+ > Rb^+ > Cs^+$. The selectivity tendency of B15C5 for the alkali metal ions is consistent with the size-fit concept, however, B15C5 shows poor selectivity. Both the ΔH and ΔS values for the complexation reaction of B15C5 with K^+ are negative. In the cases of Na^+, K^+, Rb^+, and Cs^+, the size of the moving entity in PC is larger for the B15C5 complex than for the corresponding alkali metal ion, while, in the case of Li^+, that is completely the reverse.

Benzo-15-crown-5 (B15C5) forms stoichiometric complexes with alkali metal ions. Most of them are 1:1 complexes, however, B15C5 also forms 2:1 complexes with K^+, Rb^+, and Cs^+ whose sizes are larger than the cavity size of the ligand.[1,2] In a water–methanol mixed solvent system,[1] B15C5 shows poor selectivity for alkali metal ions and the 1:1 complexes of B15C5 with alkali metal ions are not so much stable. In the present paper, the enthalpy and entropy changes of the K^+–B15C5 complex as well as the formation constants of the 1:1 complexes of B15C5 with alkali metal ions at 25 °C have been determined conductometrically in propylene carbonate (PC). The results have been compared with those of the corresponding 15-crown-5 (15C5) complexes with alkali metal ions in PC.

Experimental

Materials. Benzo-15-crown-5 (Merck Japan Ltd.) was dissolved in heptane, and filtered while hot. Then it was recrystallized from heptane three times and, prior to use, dried at 40 °C in a vacuum oven. Lithium, sodium, and potassium perchlorates were obtained commercially. The method of preparing rubidium and caesium perchlorates, as well as that of purifying alkali metal perchlorates were previously described.[3] Propylene carbonate was distilled twice under nitrogen atmosphere at 2.4 kPa. The water content of the finally purified PC determined by Karl Fischer titration was less than 0.02%. The conductivity of the final product was less than $4\times10^{-8}\ \Omega^{-1}\ cm^{-1}$.

Apparatus and Procedure. The apparatus and the experimental procedures were the same as those described in the previous paper.[3] For the K^+ system, the conductance measurements were performed at 5, 10, 15, 20, 25, 30, and 35±0.02 °C.

Results

The molar conductivity, Λ, *vs.* $[L]_t/[M]_t$ plots are given in Fig. 1, where $[L]_t$ and $[M]_t$ are the total concentrations of B15C5 and an alkali metal ion respectively. It is supposed that the association between a cation and perchlorate ion in PC is negligible under these highly dilute experimental conditions and that, in the present study, B15C5 forms 1:1 complexes with alkali metal ions in PC. Since the B15C5 concentration was kept below 3.0×10^{-3} M (1 M = 1 mol dm^{-3}) during these experiments, corrections for viscosity changes were neglected. The procedure for

obtaining complex-formation constant, K_{ML^+}, of an alkali metal ion–B15C5 complex was just the same as that described in the previous paper,[3] where M^+ and L denote an alkali metal ion and B15C5, respectively. The log K_{ML^+} *vs.* T^{-1} plots for the K^+–B15C5 system in PC are given in Fig. 2. The log K_{ML^+} *vs.* T^{-1} plots show a linear relationship. The log K_{ML^+} values, and the values of enthalpy and entropy changes are listed in Tables 1 and 2, together with the literature values, respectively.

TABLE 1. $\log (K_{ML^+}/mol^{-1}\,dm^3)$ VALUES IN PC AT 25 °C

	15C5[4]	B15C5
Li^+	4.2_6	3.7_7
Na^+	3.7	4.3_5
K^+	3.4_1	2.7_8
Rb^+	3.0_4	2.3_8
Cs^+	2.6_9	2.0_3

TABLE 2. ΔH AND ΔS VALUES FOR THE COMPLEXATION OF THE POTASSIUM ION WITH CROWN ETHERS

Crown ether	Solvent	$\log K_{ML^+}$ (at 25 °C)	$-\Delta H$ / kJ mol^{-1}	$-\Delta S$ / J K^{-1} mol^{-1}
B15C5	PC	2.7_8	$26._4$	$35._4$
	H_2O[1]	0.38	9.75	26
DB24C8	PC[3]	3.7_3	$34._5$	$44._4$

Discussion

As can be seen from Table 1, the $\log K_{ML^+}$ series of B15C5 for alkali metal ions in PC are given in the order $Na^+ > Li^+ > K^+ > Rb^+ > Cs^+$. The selectivity tendency of B15C5 (cavity radius: 0.85—1.1 Å[5]) for the alkali metal ions is consistent with the size-fit concept, however, B15C5 shows poor selectivity. The B15C5 complex with the same alkali metal ion in PC is more unstable than the 15C5 complex except for the case of Na^+. This may be attributable to the fact that B15C5 has two aromatic ether oxygen atoms whose basicity is lower than that of the aliphatic ether oxygen atom. The value of enthalpy change (ΔH) of the 15C5 complex with Na^+ may be smaller than that of the B15C5 complex because of the two aromatic ether oxygen atoms. Thus, the reason why the 15C5 complex with Na^+ is more unstable than the B15C5 complex is presumably due to that the 15C5 complex may be much more entropy destabilized than the B15C5 complex.

Table 2 shows that the complexation reaction of B15C5 with K^+ in PC is exothermic and the ΔS value is negative. The smaller $-\Delta H$ and $-\Delta S$ (entropy change) values of B15C5 compared to dibenzo-24-crown-8 (DB24C8) may reflect the smaller number of donor oxygen atom and much more rigid structure of B15C5, respectively (Table 2). Very much greater $-\Delta H$ and slightly greater $-\Delta S$ values of B15C5 in PC result in the very much larger $\log K_{ML^+}$ value compared to water. The hydrogen bond between an ether oxygen atom of uncomplexed B15C5 and a water molecule may be the reason why the $-\Delta H$ value of PC is very much larger than that of water. In the previous paper,[6] it has been reported that, although the solvation power of water for the same alkali metal ion (Na^+, K^+, Rb^+, and Cs^+) is the third largest of all the solvents (acetonitrile, PC, water, methanol, DMF, and DMSO), the $\log K_{ML^+}$ value of water is the smallest for every alkali metal ion–crown ether (18-crown-6 and dibenzo-18-crown-6) system. This may also largely depend on the hydrogen bond between an ether oxygen atom of the uncomplexed crown ether and a water molecule. Since water is a three-dimensional structural solvent and PC is not, the $-\Delta S$ value of B15C5 in PC is expected to be smaller than that in water. On the contrary, Table 2 shows that $-\Delta S$ value of B15C5 in PC is larger than that in water. This fact seems to be related to that K^+ plays a net structure breaking role in water.

The Λ *vs.* $[L]_t/[M]_t$ plots in Fig. 1 show a decrease of Λ with an increase in the B15C5 concentration for Na^+, K^+, Rb^+, and Cs^+ systems, and on the contrary for the Li^+ system. This indicates that, in the cases of Na^+, K^+, Rb^+, and Cs^+, the size of the moving entity in PC is larger for the B15C5 complex than for the corresponding alkali metal ion, while, in the case of Li^+, that is completely the reverse. The Λ *vs.* $[L]_t/[M]_t$ plots for the 15C5 system in PC show the same tendency for the B15C5 system except for the case of Na^+.[4] The B15C5 complex with Na^+ is bulkier than the Na^+ ion in PC, and on the contrary for the case of 15C5.[4] Both B15C5 and 15C5 complexes with Na^+ may be scarcely solvated in a PC solution. It thus appears that the size of the moving entity of a Na^+ ion in PC is approximately equal to the size between that of the B15C5 complex with Na^+ and that of the 15C5 complex.

Distinct Activation Energies for Temporal and Spatial Oscillations in the Belousov-Zhabotinskii Reaction

Kenichi YOSHIKAWA
College of General Education, University of Tokushima, Minami-josanjima, Tokushima 770
(Received December 7, 1981)

Temperature dependence of the frequencies in temporal oscillations and of the moving-wave velocities of concentric waves in spatial oscillation in the Belousov-Zhabotinskii reaction was studied in detail using the same starting concentrations of the reactants. When cerium ions were used as catalyst, the activation energies were found to be 60—65 kJ/mol for the temporal oscillation and 46±4 kJ/mol for the spatial oscillation. The difference in the activation energies was well explained by the theoretical prediction based on kinetic-diffusion coupling. When $[Fe(phen)_3^{2+}]$ or $[Fe(bpy)_3^{2+}]$ was used as catalyst, the apparent activation energy in the temporal oscillation depends markedly on the concentration of the catalyst used.

During the last decade, sustained oscillations and traveling chemical waves in the Belousov-Zhabotinskii reaction[1,2] have received much attention as a typical cooperative phenomenon in thermal nonequilibrium. When this reaction is allowed to proceed in a well-stirred vessel, sustained oscillation of the concentrations of several chemical species occurs (referred to as the temporal oscillation). On the other hand, when the reaction is run in an unstirred shallow layer (*e.g.* in a petri dish), spatio-temporal structures of the concentrations of chemical species appear.[3] The dynamic structure that has been most commonly studied is the concentration waves with concentric symmetry (referred to as the spatial oscillation).

For the temporal oscillation, the period of the oscillation has been studied as a function of temperature by some workers,[4-8] who demonstrated an Arrhenius dependence of the frequency (inverse period) on temperature. It has also been reported[9] that the period of the oscillation varied with the catalyst used, but the reason for this has not been clarified yet. For the spatial oscillation, on the other hand, only a few experimental studies have been reported on the temperature dependence of the moving-wave velocities of the concentric chemical waves.[10-12]

The present work deals with studies of the temperature dependences of the oscillation periods in the temporal oscillation and of the velocities of the moving-waves in the spatial oscillation, using the same starting concentrations of the reagents. We demonstrated a marked difference in activation energies between the temporal and spatial oscillations. This difference is explained on the basis of the proposed chemical mechanisms.

Experimental

Materials. Reagent grade chemicals were used throughout. Iron phenanthroline (ferroin), $[Fe(phen)_3^{2+}]$, was prepared from 1,10-phenanthroline and iron(II) sulfate, and iron bipyridyl, $[Fe(bpy)_3^{2+}]$, was prepared from 2,2′-bipyridyl and iron(II) sulfate.

Measurement of Temporal Oscillations. The redox potential was measured by monitoring the e.m.f. generated by a platinum electrode and a calomel reference electrode with a Hitachi-Horiba F-7 pH/mV meter. A double junction reference electrode (Hitachi-Horiba 253A-05T) was used with the bridging solution of saturated potassium nitrate. The reacting mixture was prepared by successive additions of stock solutions of sodium bromate, malonic acid and metal-catalyst ($[Fe(phen)_3^{2+}]$ or $[Fe(bpy)_3^{2+}]$ or Ce^{3+} or Ce^{4+} or Mn^{2+}) to sulfuric acid in a 50-dm^3 beaker thermostated to a desired temperature between 10 and 45 °C. Throughout the measurement of redox potential, the reacting mixture was constantly stirred under appropriate conditions. The first oxidation peak observed was taken as the onset of the first period of oscillation. As the frequency changes slightly with time in accordance with the changes in the concentrations of the reactants, the average value for the ten periods between the 2nd and the 11th oscillations is taken as the frequency.

Measurement of Spatial Oscillations. The reaction was initiated by adding a metal-catalyst, cerium ion, to a thermostated beaker containing sulfuric acid, sodium bromate, and malonic acid. After being stirred for 5 min, the reaction mixture was poured into a thermostated petri dish with a diameter of 87 mm. The concentrations of the reactants were adjusted to the same concentrations as used for the temporal oscillation. Trigger (concentric) waves were generated by adding a small piece of poly(vinyl alcohol) (Nakarai Chemical, Av. Mol. Wt. 2200) as a pacemaker.[13] Other deformed moving-waves were considered as interferences and are therefore not discussed in this article. The oscillating reaction taking place in the petri dish was photographed at appropriate intervals, and the velocities were determined by measuring the distance from the center (the position of the pacemaker) of the concentric traveling band to the outer propagating bands. Photographs were taken using a Polaroid 600 SE camera with type 667 film under UV light.

Results

Activation Energies in Temporal Oscillations. Figure 1 exemplified the temporal oscillation of redox potential obtained when Ce^{3+} was used as catalyst. It is apparent that the period of oscillation was kept nearly constant. Therefore, the average value of the periods between the 2nd and the 11th oscillation was regarded as the "period" of a given oscillating system. The periods were measured at temperatures ranging from 10 to 45 °C. An Arrhenius plot for the oscillating frequency, F_{osc} (reciprocal of the period), is shown in Fig. 2. From the slope of the figure, 64.9± 2 kJ/mol is obtained as the activation energy, E_a, for the temporal oscillation catalyzed by cerium ion

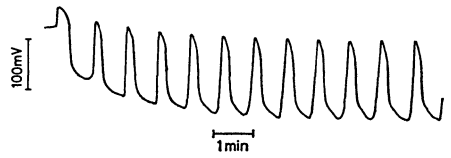

Fig. 1. Temporal oscillation of redox potenital. $[H_2SO_4]_0=0.4$ M, $[NaBrO_3]_0=0.35$ M, $[KBr]_0=0.06$ M, [Malonic Acid]$_0=0.12$ M, $[Ce(NH_4)_2(NO_3)_5]_0=0.002$ M. Temperature=25.1 °C. Volume, 20 dm^3.

($[Ce(NH_4)_2(NO_3)_5]=0.002$ M†).

We then carried out similar experiments with several different catalysts, such as [Fe(phen)$_3^{2+}$], Ce^{4+}, and Mn^{2+} at the concentration of 2 mM. An Arrhenius plot for the oscillation catalyzed by [Fe(phen)$_3^{2+}$] is shown in Fig. 3. Apparent activation energies for the temporal oscillation obtained with the different catalysts are listed in Table 1. The E_a values with Ce^{3+}, Ce^{4+}, and Mn^{2+} are essentially the same at the same concentration, 2 mM, of the catalyst, but greatly differ from the E_a value with [Fe(phen)$_3^{2+}$]. In order to study further the effects of the catalysts on the oscillation, E_a values were determined with different concentrations of the catalysts, [Fe(phen)$_3^{2+}$]

† 1 M=1 mol dm^{-3}.

Table 1. Apparent activation energies in temporal oscillations

Catalyst	Concentration / mM	Frequency[a] at 25 °C / Hz	E_a[b] / kJ mol^{-1}
[Fe(phen)$_3^{2+}$]	2	0.051	46.6
	1	0.055	44.9
	0.3	0.056	56.6[c]
	0.2	0.060	57.4[c]
	0.1	0.068	72.4[c]
[Fe(bpy)$_3^{2+}$]	0.3	0.071	71.6[c]
Ce^{3+}	2	0.021	62.4
Ce^{4+}	5	0.021	64.9
	2	0.021	64.9
	1	0.022	59.9
	0.3	0.023	59.9
	0.2	0.025	60.7
	0.1	0.025	60.7
Mn^{2+}	2	0.025	64.1

and Ce^{4+} (Table 1). The E_a values with Ce^{4+} remain nearly constant at different concentrations, while those with [Fe(phen)$_3^{2+}$] change remarkably, from 46.6 to 72.4 kJ/mol, with decreasing concentration of the [Fe(phen)$_3^{2+}$]. A possible explanation for the dependence of the E_a value on the catalyst concentration is that [Fe(phen)$_3^{2+}$] does decompose gradually in the reaction medium and that this, in turn, affects the kinetics of the oscillating reaction. Thus, the rate of the decomposition of [Fe(phen)$_3^{2+}$] in 0.4 M sulfuric acid was measured by monitoring spectrometrically the decrease of the absorption maximum at 522 nm (data not shown). For comparison, the rate of the decomposition of [Fe(bpy)$_3^{2+}$] was also measured under similar conditions. The decreasing rate of the absorption showed that the kinetic constant, k, was 0.007 min^{-1} for [Fe(phen)$_3^{2+}$] and 0.097 min^{-1} for [Fe(bpy)$_3^{2+}$] at 26 °C and that the half-life periods of these iron-complexes at 26 °C are 90 and 7.1 min, respectively. The rate of the decomposition was enhanced at elevated temperatures. It seems that the decomposition of these iron-complexes cannot be ignored during the chemical oscillations, suggesting that these iron-complexes are not suitable as a catalyst for the kinetic study of the Belousov-Zhabotinskii reaction.

Activation Energies in Spatial Oscillations. Concentric trigger waves (spatial oscillation) were generated using cerium ion as catalyst. To compare the activation energy for temporal oscillation with that for spatial oscillation, the oscillating reactions were run with the same starting concentrations of the reagents. Figure 4 shows the time dependence of the distance of each wave from the center of the cylindrical bands. The slopes in Fig. 4 represent the moving-wave velocities, v. Similar experiments were carried out at several temperatures. The results obtained

are shown as an Arrhenius plot in Fig. 5. From this figure, the apparent activation energy of 46±4 kJ/mol is obtained for the propagation of the cylindrical waves with Ce^{4+} as catalyst.

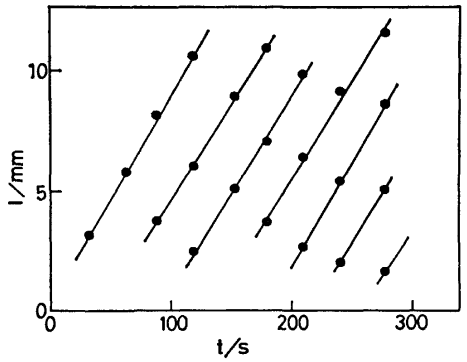

Fig. 4. Time dependence of the band position (distance from the center) in a spatial oscillating reaction with the cylindrical pattern.
The concentrations are the same as described in the legend to Fig. 1. Ce^{4+}-catalyst at 25 °C. Volume, 7 dm^3.

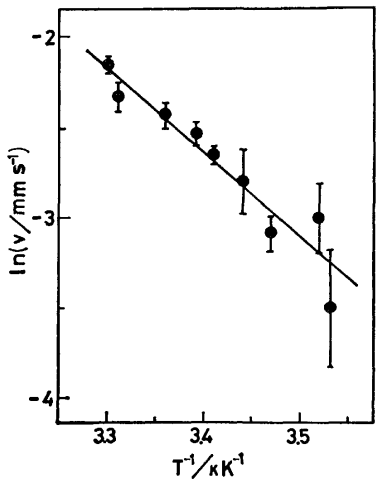

Fig. 5. Arrhenius dependence of moving-wave velocity, v.
Ce^{4+}-catalyst. The concentrations are the same as described in the legend to Fig. 1. The limits shown are estimated errors of the mean. Volume, 7 dm^3.

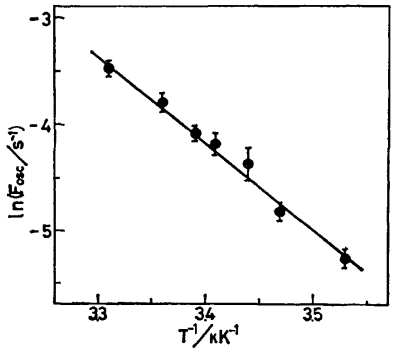

Fig. 6. Arrhenius dependence of oscillating frequency, F_{osc}, at a place 1 cm away from the center in spatial oscillation.
The data were taken from the same experiments as shown in Fig. 5. The limits shown are estimated errors of the mean.

From the photographs of the moving-wave, one can also obtain the frequencies of the chemical oscillation at a fixed position. The frequencies at the position 1 cm distant from the center were obtained and are depicted as an Arrhenius plot in Fig. 6. The activation energy was thus determined to be 69±4 kJ/mol, which is close to that for the temporal oscillation (64.9±2 kJ/mol) obtained at the same concentration of cerium ions (2 mM). The small difference in the activation energies of the frequencies between the temporal and spatial oscillations may have resulted from the different experimental conditions used, *i.e.*, continuous mixing for the former reaction and standing still for the latter.

Discussion

No attempt has been made to compare the kinetics of the temporal and spatial oscillations with the same starting concentrations of the reagents. We demonstrated that the activation energies for the two types of oscillating reactions are apparently different. We now wish to discuss these results in relation to the mechanism of the chemical oscillations.

Field and Noyes proposed[14,15] a mechanism of the spatial oscillation of the concentric wave, coupled with diffusion of the chemical species. Based on the assumption that the velocity of the band propagation is controlled by the concentration of bromide ion and bromous acid in the band front and that the traveling band of bromide ion does not affect the velocity of the band propagation, the following differential equations are obtained:[15,16]

$$\left(\frac{\partial C_A}{\partial t}\right)_x = D_A\left(\frac{\partial^2 C_A}{\partial x^2}\right)_t + k_3[H^+][BrO_3^-]C_B - k_2[H^+]C_AC_B + k_5[H^+][BrO_3^-]C_A - 2k_4C_A^2, \quad (1)$$

$$\left(\frac{\partial C_B}{\partial t}\right)_x = D_B\left(\frac{\partial^2 C_B}{\partial x^2}\right)_t - k_3[H^+][BrO_3^-]C_B - k_2[H^+]C_AC_B. \quad (2)$$

Here $C_A=[HBrO_2]$ and $C_B=[Br^-]$. The definitions of the other symbols in these equations are identical to those in Refs. 15 and 16. Experimentally, the propagating bands move with a constant velocity, as is shown in Fig. 4; then

$$v = \left(\frac{\partial x}{\partial t}\right)_{C_A, C_B}, \quad (3)$$

$$\left(\frac{\partial C_A}{\partial t}\right)_x = v\left(\frac{\partial C_A}{\partial x}\right)_t. \quad (4)$$

The autocatalytic reaction (5) with the rate constant, k_5, is rate-determining in the Belousov-Zhabotinskii reaction.[15,16]

$$BrO_3^- + HBrO_2 + H^+ \xrightarrow{k_5} 2BrO_2\cdot + H_2O. \quad (5)$$

Under the approximation that this autocatalytic term is much more important than others in the face of an advancing band, Eq. 1 can be simplified as follows:

$$D_A\frac{d^2C_A}{dx^2} - v\frac{dC_A}{dx} + k_5[H^+][HBrO_3^-]C_A = 0. \quad (6)$$

Under the condition of maximum sharpness,[15,16] an approximate solution of Eq. 6 is given as follows:

$$v = (4D_A k_5[H^+][BrO_3^-])^{1/2}. \quad (7)$$

As for the temporal oscillation, the diffusion term in Eqs. 1 and 2 can be neglected, and the autocatalytic reaction (5) is also most important for the rate of the oscillation.[17] Tyson *et al.*[18] have suggested that the period of the oscillation is determined by Reaction 5 and that the activation energy of the oscillation is nearly equal to that of Reaction 5. Quite recently, from the result of a mathematical analysis for the Belousov-Zhabotinskii reaction using "Oregonator" model, Edelson *et al.*[19] have concluded that the principal factor determining the period of the temporal oscillation is k_5 and that this reaction is almost an order of magnitude more significant than the others. Therefore, the frequency, F_{osc}, is approximately given by (8), using the rate equation of Reaction 5. In

$$F_{osc} \propto k_5[H^+][BrO_3^-]. \quad (8)$$

Eqs. 7 and 8, D_A and k_5 are temperature dependent and may be expressed as follows:

$$D_A = D_0 \exp(-E_D/RT), \quad (9)$$

$$k_5 = k_0 \exp(-E_k/RT). \quad (10)$$

E_D and E_K are the activation energies for the diffusion of A ($=HBrO_3$) and Reaction 5, respectively. The activation energy of self-diffusion of water has been experimentally reported to be 4.8 kcal/mol (20 kJ/mol).[20] Thus, it is probable that E_D is about 20 kJ/mol. In our experiment, E_K (the activation energy of F_{osc}) is about 69 kJ/mol in the spatial oscillation (Fig. 6) and about 65 kJ/mol in the temporal oscillation (Table 1) when $[Ce^{4+}]_0=2$ mM. The small difference between the activation energies may be due to the stirring effect[9] and/or to the oxygen effect.[21] From Eqs. 7, 9, and 10, the relationship between the activation energies becomes

$$E_v = \frac{1}{2}(E_D + E_k). \quad (11)$$

Here E_v is the activation energy of v in the spatial oscillation. E_v is thus calculated to be $(20+69)\div 2 = 44.5$ (kJ/mol) or $(20+65)\div 2 = 42.5$ (kJ/mol). These values agree well with the value of E_v, 46 kJ/mol, experimentally obtained in this study (Fig. 5).

It may be worthwhile to compare the activation energies obtained in this study with the previously reported values. From the measurement of the frequency of the temporal oscillation at three different temperatures (288, 298, 308 K), Körös[4] has derived an activation energy of 67.5 kJ/mol, which was the same for different catalysts: Ce^{3+}, Mn^{2+}, and $[Ru(bpy)_3^{2+}]$. Blandamer *et al.*[6] reported an activation energy of 70 kJ/mol for the frequency in the temporal oscillation, using the system of malonic acid–BrO_3^-–H_2SO_4–Ce^{3+}. Rastogi *et al.*[5] have also reported the dependence of the frequency on temperature. Though they did not report the activation energy, we can obtain an activation energy of 54 kJ/mol from the figure of the Arrhenius relation of the oscillation period given in their paper.[5] The large difference of the activation energies may be mainly due to the difference of the concentrations of the reactants and the catalyst. This may be not surprising, as the Belousov-Zhabotinskii reaction is a quite complicated system consisting of many elemental reactions. It is also to be noted that the difference of the experimental conditions causes a large difference of the frequencies of the oscillation, for example, the frequency at 25 °C is 0.05 s^{-1} in the experiment of Blandamer *et al.*[6] and 0.021—0.025 s^{-1} in our experiment. It is thus apparent that starting concentrations of the reagents should be the same if one wishes to compare the kinetics between the temporal and spatial oscillating reactions, as has been done in this study.

Thoenes[10] has reported an activation energy of 100 kJ/mol for the oscillation frequency in the spatial oscillation for the system of malonic acid–BrO_3^-–H_2SO_4–$[Fe(phen)_3^{2+}]$. As he has not shown the actual values of the frequencies at different temperatures in his paper, we can not discuss about the error or accuracy of his experiment. However, it should be pointed out again that ferroin ($[Fe(phen)_3^{2+}]$) is not suitable as the catalyst for the study of the reaction kinetics in the Belousov-Zhabotinskii reaction.

The author thanks Prof. Takeshi Waki for his encouragement and Miss Chikako Kawase for her assistance. The author is indebted to Dr. Akira Ohsaka and Mr. Toshimi Hayakawa for their helpful discussions.

Optical Studies on the Lowest Triplet State of Chromone

Yasuko YAMADA, Seigo YAMAUCHI,* and Noboru HIROTA*

Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawaoiwake-cho, Sakyo-ku, Kyoto 606

(Received January 18, 1982)

The lowest excited triplet state of chromone was investigated *via* high resolution phosphorescence spectra, phosphorescence excitation spectra and triplet lifetimes in the neat crystal, in the single crystals of durene and benzoic acid at liquid helium temperature. Including the cases in other solvents such as 3-methylpentane, methylcyclohexane and ethanol, the lowest triplet state was assigned to be $\pi\pi^*$ type contrary to the previous assignment. The triplet sublevel properties including the sublevel spectra were obtained in the benzoic acid host. T_y is radiative at the 0-0 band. T_z is radiative at the nontotally symmetric bands and is active in nonradiative transitions. These properties are discussed and compared with those of other carbonyl compounds. A brief comment on the photochemical reactions are given.

There have been some interests in the photochemical behavior of chromone (**1**) and several works have been reported in recent years.[1-4] It has been sug-

gested that the lowest excited triplet state T_1 is involved in the photochemical reactions and the orbital character ($n\pi^*$ or $\pi\pi^*$) of the T_1 state has been discussed from the photoproducts. $n\pi^*$ assignment was favored in these works.

The phosphorescence spectra and triplet lifetimes at 77 K have been reported by Hanifin and Cohen,[1] Gallivan,[5] and Brinen.[6] They assigned the lowest triplet state to be $\pi\pi^*$ type in ethanol, but $n\pi^*$ in 3-methylpentane and 2-methyltetrahydrofuran based on the spectra and the lifetimes of 15—38 ms. This assignment, however, is questionable for the following reasons. Firstly, the reported phosphorescence spectra are too complex to be assigned to $n\pi^*$ spectra.[7] Secondly, the lifetimes of 15—38 ms appear to be somewhat long as lifetimes of $^3n\pi^*$ states. Furthermore, the use of lifetimes as a criterion to decide the triplet character is sometimes ambiguous, because the lifetimes of the $\pi\pi^*$ carbonyls at 77 K may be markedly shortened by thermal mixing with higher vibronic states and second triplet ($^3n\pi^*$) states.[7]

In order to decide the character of the T_1 state unambiguously, we have taken high resolution phosphorescence emission and excitation spectra and measured the lifetimes in different host crystals at liquid helium temperature. Comparing the obtained spectra with those of typical $^3n\pi^*$ and $^3\pi\pi^*$ types, we discuss whether the T_1 state is $^3n\pi^*$ or $^3\pi\pi^*$ in nature. The lifetimes and excitation spectra are used to confirm the assignment. We also discuss a correlation between the phosphorescence properties and ΔE_{TT} (energy difference between T_1 and T_2).

In a previous work we have studied the properties of the T_1 state of coumarin (**2**) which is isomeric to chromone.[8] It was found that the decay properties of coumarin are very different from those of benzaldehyde type aromatic carbonyls. This difference was thought to arise from the large difference in ΔE_{TT}. It seemed interesting to examine the decay properties of chromone in this connection. Accordingly, we have made zero field optically detected magnetic resonance (ODMR) experiments in benzoic acid host to obtain the zero field splitting, the total decay rate constants from sublevels, the relative decay rate constants and sublevel spectra. We discuss the mechanisms of the radiative and non-radiative transitions and compare the properties with those of other carbonyls. Lastly we briefly comment on the implication of the present work on the photochemical behavior of chromone.

Experimental

Chromone, durene, and benzoic acid were purified by zone melting after recrystallization from ethanol. Single crystals were grown by the Bridgman method. The mole fractions of chromone were *ca.* 10^{-2} in the melts, but those of the samples used in the experiments were not measured.

The phosphorescence emission and excitation spectra were obtained at 4.2 K with an Osram 900 W Xe lamp, a Spex 1704 1 m monochromator and an EMI 9502 photomultiplier. The excitation spectra were observed by monitoring the total phosphorescence. The phosphorescence lifetimes were obtained at 1.4 K. The zero field ODMR and microwave induced delayed phosphorescence (MIDP) experiments were made using the mixed crystal of benzoic acid with the apparatus already described.[9] The individual triplet spin sublevel spectra were obtained by observing the time resolved spectra and MIDP spectra at 1160 ms after excitation cut-off, with a PAR 160 boxcar integrator.[10]

Results

The phosphorescence spectra of chromone obtained at 4.2 K in the neat crystal, in the single crystals of durene and of benzoic acid are shown in Fig. 1. The 0-0 band was observed at 379.29 nm, 383.08 nm, and 382.91 nm, respectively. Three sites were observed in benzoic acid as shown in the figure. The triplet lifetimes at 1.4 K are shown in Table 1. In the case of benzoic acid, the lifetime of site III is tabulated. Even at 1.4 K chromone in benzoic acid shows a single exponential decay except in the site I. The lifetime in the durene host at 77 K is 8 ms, which is markedly shorter than that at 1.4 K.

$\Delta E_{TT}(=E(T_2)-E(T_1))$ obtained from the phospho-

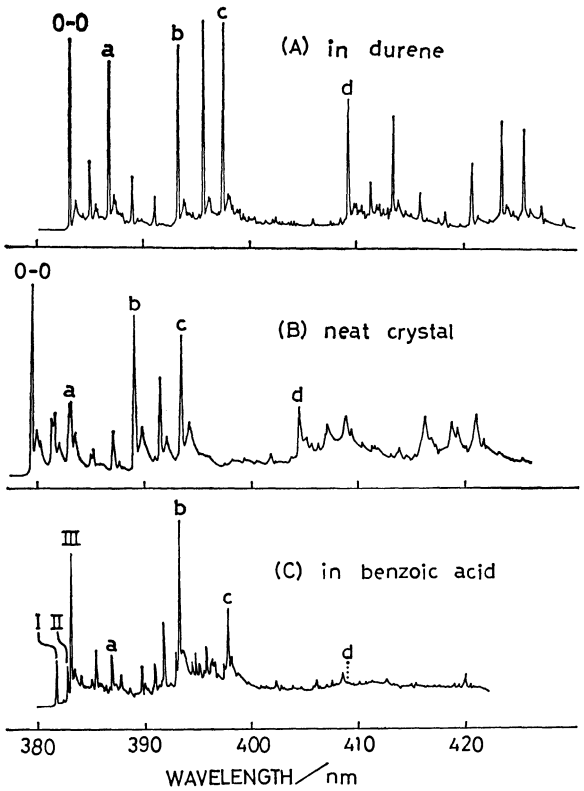

Fig. 1. Phosphorescence spectra of chromone at 4.2 K in durene(A), in a near crystal (B), and in benzoic acid(C).
I, II, and III denote the 0-0 bands of the three sites. a, b, c, and d represent 0-252 cm^{-1}, 0-682 cm^{-1}, 0-980 cm^{-1} bands (see Table 3.) and C=O stretching band respectively.

Table 1. Phosphorescence lifetimes and energy gaps between $T_1(\pi\pi^*)$ and $T_2(n\pi^*)$ states of chromone

Host	Lifetime/ms	$\Delta E_{TT}/cm^{-1}$
Durene	35	371
Neat	55	539
Benzoic acid	241	2356

rescence excitation spectra are also shown in Table 1. A typical excitation spectrum in a lower energy region is shown in Fig. 2. The 0-0 bands of the T_1 and T_2 states are assigned as shown in the figure. In the benzoic acid host, the $S_0 \rightarrow T_2$ ($n\pi^*$) absorption is buried under the $S_0 \rightarrow T_1$ absorption of the benzoic acid. In order to estimate an approximate value we used $\Delta E'_{ST}=1750\ cm^{-1}$ ($\Delta E'_{ST}=E(^1n\pi^*)-E(^3n\pi^*)$), obtained from the neat crystal. This value is known to be appropriate in a series of substituted benzaldehydes.[11]

Spin sublevel properties could be investigated only for the site I in benzoic acid, where the spin-lattice relaxation was suppressed. The zero field splitting constants, the total decay rate constants and the relative radiative decay rate constants at vibronic bands are given in Table 2. The T_z and T_y sublevel spectra are shown in Fig. 3.

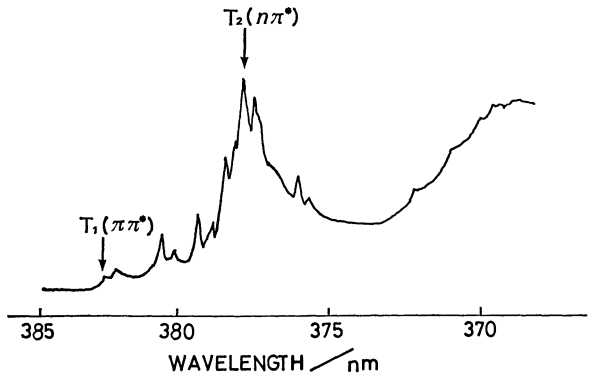

Fig. 2. Phosphorescence excitation spectrum of chromone in durene at 4.2 K.
The 0-0 bands of $T_1(\pi\pi^*)$ and $T_2(n\pi^*)$ are shown.

Vibrational analysis is summarized in Table 3.

Discussion

Assignment of the Lowest Triplet State. In many aromatic carbonyl compounds, phosphorescence spectra are quite different, depending on whether the lowest triplet states are $n\pi^*$ or $\pi\pi^*$ type.[7,12,13] If a phosphorescence state is of $n\pi^*$ character, its spectrum is very simple consisting mainly of a 0-0 band and vibronic bands involving C=O stretching vibration. Occasionally bands involving nontotally symmetric vibrations give rise to strong progressions due to molecular distortion.[14,15] On the other hand, a $\pi\pi^*$ triplet state gives a more complicated spectrum because of a $n\pi^*$—$\pi\pi^*$ vibronic coupling. Especially when a $^3n\pi^*$ triplet state is located near a $^3\pi\pi^*$ state, a spectrum is composed of many vibronic bands of comparable intensities.[13]

Keeping these facts in mind, we examine the spectra in Fig. 1. In all spectra, many strong bands appear in addition to the 0-0 band and the C=O stretching band. Any progression except the C=O stretching band is not observed. Obviously these are the characteristics of the $^3\pi\pi^*$ phosphorescence spectra. Almost all the strong bands in these spectra except the C=O band must be the bands involving nontotally symmetric vibrations. Detailed vibrational assignment is given in the later section.

The phosphorescence excitation spectra support this conclusion. The intensity of the 0-0 band of T_1 is much weaker than the vibronic bands and the 0-0 band of T_2 (Fig. 2). The phosphorescence lifetimes of 35—241 ms are also consistent with the $\pi\pi^*$ assignment. The lifetime of a $^3n\pi^*$ carbonyl is usually in the order of at most a few milliseconds.[12] Combined with all of these facts, the lowest triplet states of chromone in these hosts are definitely assigned to be of $\pi\pi^*$ character. Judging from the lifetimes and spectra, the T_1 states in 3-methylpentane and 2-methyltetrahydrofuran previously assigned to be $n\pi^*$ states are also assigned to be of the $\pi\pi^*$ type, though ΔE_{TT} is relatively small. In all other solvents we examined, hexane, methylcyclohexane, and ethanol, T_1 was found to be of $\pi\pi^*$ type.

Next we discuss a correlation between ΔE_{TT} and some properties of phosphorescence. ΔE_{TT} increases in the order, in durene, in neat crystal, in benzoic acid. The total decay rate constant and the relative intensity of the C=O band decrease in the same order. This correlation is interpreted in terms of a magnitude of the mixing between $T_1(\pi\pi^*)$ and $T_2(n\pi^*)$ states, that is, how much $^3n\pi^*$ state character is contaminated in T_1 state determines the properties of T_1 in durene and neat crystal.

Radiative and Non-radiative Mechanisms for the Triplet Spin Sublevels. With the MIDP technique, the relative radiative decay rate constants of the vibronic bands are obtained as $k_z^r(0\text{-}0):k_y^r(0\text{-}0):k_x^r(0\text{-}0)=0.24:1:0.11$ and $k_z^r(0\text{-}682\ cm^{-1}):k_y^r(0\text{-}682\ cm^{-1}):k_x^r(0\text{-}682\ cm^{-1})=1:0.12:0.03$. Together with these values, the spin sublevel spectra (Fig. 3) give the ratio of the total radiative decay rate constants as $k_y^r \gtrsim 0.3k_z^r$ ($k_i^r \equiv \sum_\nu k_i^r(\nu)$). If we use the equation $k_y \simeq 0.3k_z$ (Table 2) and the inequality $k_y^r \geq 0.3k_z^r$, we can obtain $k_y^{nr} \leq 0.3k_z^{nr}$. The spin sublevel spectra also show that the ratio of the radiative decay at the nontotally symmetric bands of strong intensities are nearly equal to that of the 0-682 cm^{-1} band. Therefore, T_y is radiative at the 0-0 band, whereas T_z is radiative at the nontotally symmetric bands and also active in the nonradiative transition. T_x is less active in both radiative and nonradiative transitions. The symmetry of the molecule is C_s and the lowest triplet state belongs to $A'(\pi\pi^*)$. If we assume that one center integral at the oxygen atom is dominant in the relevant spin orbit coupling matrix elements, the T_z and T_y sublevels couple with the $^1n\pi^*$ and $^1\sigma\pi^*$ states, respectively.

Radiative Mechanisms: The radiative mechanisms at the 0-0 band and the totally symmetric a' bands are summarized as follows,

$$T_z \xrightarrow{H_{so}(1)} {}^1n\pi^*(A'') \xrightarrow{er} S_0, \quad (1)$$

$$T_y \xrightarrow{H_{so}(1)} {}^1\sigma\pi^*(A'') \xrightarrow{er} S_0, \quad (2)$$

$$\xrightarrow{H_{so}(2)} {}^1n\pi^*(A'') \xrightarrow{er} S_0, \quad (3)$$

$$T_x \xrightarrow{H_{so}(3)} {}^1\pi\pi^*(A') \xrightarrow{er} S_0. \quad (4)$$

H_{so} and er denote a spin orbit coupling and a dipole transition, respectively. H_{so} (1), H_{so} (2), and H_{so} (3) represent matrix elements which involve one center, two center and three center atomic integrals. $\sigma\pi^*$ denotes botn $\sigma\pi^*$ and $\pi\sigma^*$ states. The contribution of the two center terms involving the $\sigma\pi^*$ states is neglected because of the weak coupling due to the large energy denominator. The magnitude of the spin orbit coupling is large in both T_z and T_y owing to one center terms. Although the energy denominator ($\Delta E_{ST}=E(S)-E(T_1)$) is favorable for T_z, the transition dipole moment for the $S_0 \rightarrow S_1$ ($n\pi^*$) transition is expected to be much smaller than those for the $S_0 \rightarrow S_1$ ($\sigma\pi^*$) transitions. Indeed, CNDO/S calculation on chromone predicts that the oscillator strengths for the $S_0 \rightarrow S_1$ ($\sigma\pi^*$) transitions are about two orders of magnitude larger than that for the $S_0 \rightarrow S_1$ ($n\pi^*$) transition. Considering these factors, we expect that T_y is more radiative than T_z at the 0-0 and a' bands. T_x will be only slightly active owing to three center terms. These expectations are born out by the observation, $k_z^r(0\text{-}0):k_y^r(0\text{-}0):r_x^r(0\text{-}0)=0.24:1:0.10$. As a result the mechanism (2) is the most important in the radiative decay at the 0-0 band.

For the nontotally symmetric bands, we must consider vibronic couplings. We will discuss the mechanisms paying attention to the result, $k_z^r(nt):k_y^r(nt)=1:0.12$ (nt denotes to nontotally symmetric vibronic bands.). The mechanisms similar to the mechanisms (1)—(4) are summarized as follows:

$$T_z \xrightarrow{a''} {}^3n\pi^*(A'') \xrightarrow{H_{so}(1)} {}^1\pi\pi^*(A') \xrightarrow{er} S_0, \quad (5)$$

$$\xrightarrow{H_{so}(1)} {}^1n\pi^*(A'') \xrightarrow{a''} {}^1\pi\pi^*(A') \xrightarrow{er} S_0, \quad (6)$$

$$T_y \xrightarrow{a''} {}^3\sigma\pi^*(A'') \xrightarrow{H_{so}(1)} {}^1\pi\pi^*(A') \xrightarrow{er} S_0, \quad (7)$$

$$\xrightarrow{a''} {}^3n\pi^*(A'') \xrightarrow{H_{so}(2)} {}^1\pi\pi^*(A') \xrightarrow{er} S_0, \quad (8)$$

$$\xrightarrow{H_{so}(1)} {}^1\sigma\pi^*(A'') \xrightarrow{a''} {}^1\pi\pi^*(A') \xrightarrow{er} S_0, \quad (9)$$

$$\xrightarrow{H_{so}(2)} {}^1n\pi^*(A'') \xrightarrow{a''} {}^1\pi\pi^*(A') \xrightarrow{er} S_0. \quad (10)$$

The difference between T_z and T_y is that T_z involves a spin orbit coupling with the $n\pi^*$ state *via* one center terms, while T_y involves spin orbit coupling with the $\sigma\pi^*$ states via one center terms and with the $n\pi^*$ state *via* two center terms. As the $\sigma\pi^*$ states are higher in energy and the two center terms are smaller, T_z is expected to be more active at the nontotally symmetric bands. This expectation was again realized by the observation, $k_z^r(nt):k_y^r(nt)=1:0.12$. Next we discuss the relative importance of $\sigma\pi^*$ and $n\pi^*$ states as the intermediate in the T_y mechanism. In the T_y radiative decay at the nontotally symmetric bands, the mechanism involving the $\sigma\pi^*$ states ((7), (9)) is likely to be more important than that involving the $n\pi^*$ state, because the magnitude of one center terms is expected to be more than 100 times of that of two center terms as found in the case of quinoxaline.[10] T_x sublevel is again less active because of the three center terms A detailed vibrational assignment is made by the sublevel spectra and fm-ODMR spectra and is shown in Table 3. In-plane (a′) and out-of-plane (a″) vibrations are distinguished.

Nonradiative Mechanisms: The mechanisms of the nonradiative transitions resemble to those of radiative transitions of vibronic bands (*cf.* mechanism (5)—(10)). The mechanisms are the following, based on the foregoing discussion.[16]

$$T_z \xrightarrow{a''} {}^3n\pi^*(A'') \xrightarrow{H_{so}(1)} S_0, \quad (11)$$

$$\xrightarrow{H_{so}(1)} {}^1n\pi^*(A'') \xrightarrow{a''} S_0, \quad (12)$$

$$T_y \xrightarrow{a''} {}^3\sigma\pi^*(A'') \xrightarrow{H_{so}(1)} S_0, \quad (13)$$

$$\xrightarrow{H_{so}(1)} {}^1\sigma\pi^*(A'') \xrightarrow{a''} S_0, \quad (14)$$

$$T_x \xrightarrow{H_{so}(3)} S_0. \quad (15)$$

As in the case of radiative transition at the nontotally symmetric bands, T_z involves the spin orbit coupling with the $n\pi^*$ states and T_y with the $\sigma\pi^*$ states, and the energy denominator favors the T_z mechanism. Similar results for $k_z^r(nt)/k_y^r(nt)$ and k_z^{nr}/k_y^{nr} are expected. As expected, T_z is most active in the nonradiative transition. Although T_x involves direct coupling with the ground state, T_x is not expected to be active, again due to three center atomic integrals.

Table 3. Vibrational analysis of the phosphorescence spectrum of chromone in benzoic acid

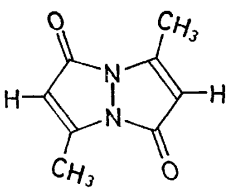
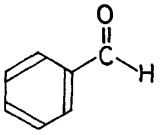
Comparison with Other Carbonyl Compounds. We compare the dynamical properties of chromone in benzoic acid with those of coumarine (**2**) in durene,[8] anti-(CH_3,H)bimane(4,8-dimethyl-1,5-diazabicyclo-[3.3.0]octa-3,7-diene-2,6-dione) (**3**) in durene[17] and benzaldehyde (**4**) in benzoic acid.[18]



3



4

In all cases, the lowest triplet states are of $\pi\pi^*$ type with relatively large ΔE_{TT} (2300—6300 cm^{-1}). In coumarin ($k_z=9.7$ s^{-1}, $k_y=2.0$ s^{-1}, $k_x=0.32$ s^{-1}; $k_z^r(0\text{-}0):k_y^r(0\text{-}0):k_x^r(0\text{-}0)=0.25:1:0.03$) and anti-bimane ($k_z=1.83$ s^{-1}, $k_y=2.99$ s^{-1}, $k_x=0.14$ s^{-1}; $k_z^r(0\text{-}0):k_y^r(0\text{-}0):k_x^r(0\text{-}0)=0.04:1:0.02$) these properties are very similar to those of chromone, T_y is radiatively active at the 0-0 band, whereas T_z is active in the nontotally symmetric bands. On the other hand in benzaldehyde ($k_z=18$ s^{-1}, $k_y=0.44$ s^{-1}, $k_x=0.46$ s^{-1}; $k_z^r(0\text{-}0):k_y^r(0\text{-}0):k_x^r(0\text{-}0)=1:0.06:0.06$) and substituted benzaldehydes, k_y is not large and T_y is less radiative even at the 0-0 band. Possible reasons for the difference between the two types of molecules are the following.

(1) The oscillator strength for the $S_0\rightarrow S_1$ ($n\pi^*$) transition is larger in benzaldehyde type molecules. This has been found experimentally[19] and is also supported by the CNDO/S calculation.

(2) The energies of the $\sigma\pi^*$ states are lower in chromone than in benzaldehyde. The oscillator strengths for the $S_0\rightarrow S_i$ ($\sigma\pi^*$) transitions for the lower energy states may be larger for chromone and coumarin as indicated by the results of CNDO/S calculation.

Comment on the Photochemical Reactions. We have assigned T_1 of chromone as $\pi\pi^*$ states in all solvents and host crystals at low temperatures. This is somewhat contradictory to the conclusion derived from the photochemical studies. In the non-polar solvents ΔE_{TT} is in the same order of magnitude as measured in the durene crystal ($\Delta E_{TT}=371$ cm^{-1}). With this value of ΔE_{TT} the ratio between the population in the $^3n\pi^*$ and that in the T_1 state in Boltzmann distribution is 0.17 at 300 K. Therefore, it is quite probable that both $^3n\pi^*$ and $^3\pi\pi^*$ type photochemical reactions take place. Although the phosphorescence spectra and lifetimes indicate the mixed character of the T_1 state, the actual $n\pi^*$ character induced by the vibronic mixing is at most 3%. Thus the thermal population of the $^3n\pi^*$ state is likely to be responsible for the $^3n\pi^*$ type reaction.

The report that the $^3n\pi^*$ type reaction takes place in methanol[3] is puzzling. ΔE_{TT} in methanol is in the same order as that in benzoic acid and the ratio of the population of the $^3n\pi^*$ state is *ca.* 10^{-5} at 300 K. It is possible that chromone in solution at 300 K has a smaller ΔE_{TT} than that estimated in solid at 4.2 K or has a considerably different configuration. However, whether or not a $^3n\pi^*$ type reaction is really taking place still seems to be uncertain.

We wish to thank Dr. Tadamasa Shida for discussions on CNDO/S calculations, and Mr. Masaaki Baba for experiments.

The Discrimination of the Oxidation States of Neptunium in Sodium Hydroxide Solutions by Means of Chromatography on Alumina

Yoshinobu SHIOKAWA*, Hajimu YAMANA, Akiko SATŌ, and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira, Sendai 980

(Received August 27, 1981)

A method of discriminating the oxidation states of Np in a NaOH solution by means of chromatography on alumina is proposed. In a NaOH solution of 0.5—1.7 M(1 M=1 mol dm^{-3}), the separation of Np(VI) from Np(VII) can be made effectively by means of chromatography on alumina. Only a little Np(VI) is adsorbed on alumina the Np(VII) adsorbed to some extent, and the Np(V), strongly, under the same conditions. By applying this chromatographic method, the method of preparing Np(VI) and Np(VII) of a tracer quantity in 1 M NaOH is established.

It has been found by polarography that the possible oxidation states of Np in a NaOH solution are the penta-, hexa-, and heptavalent states.[1] In a basic solution, the color of the Np(VII) is green, and its existence is easily confirmed by spectrophotometry because of its large extinction coefficient and high solubility.[2] On the other hand, since both Np(V) and Np(VI) have a small extinction coefficient and a low solubility,[2] the spectrophotometry cannot be used even for an ordinary concentration of Np. Therefore, a method other than spectrophotometry is required if we are to ascertain the distribution of the oxidation states of Np of a low concentration in a basic solution. However, no such method has yet been established, and the chemical behavior of Np(V), Np(VI), and Np(VII) in a basic solution is not sufficiently clarified.

In a previous paper,[3] we ourselves reported that, in a NaOH solution of 1—2 M, the Np(V) was almost completely adsorbed on zirconium(IV) hydroxide, while the Np(VI) and Np(VII) remained in the supernatant. The present study is an attempt to establish a method for discriminating, in a NaOH solution Np(VI) and Np(VII), which are indistinguishable by adsorption on zirconium(IV) hydroxide. For this purpose, column chromatography on alumina is found to be excellent. A method of preparing Np(VI) and Np(VII) of a tracer quantity in a NaOH solution is also proposed by the application of this method.

Experimental

The sodium hydroxide solution of Np was prepared from a 0.5 M nitric acid solution of Np by adding an adequate oxidant or reductant after the addition of NaOH. The NaOH stock solution was prepared by filtering its saturated solution through a Millipore Mitex filter with a pore size of 5 μm, the necessary experimental procedures were carried out in a polyethylene bag filled with nitrogen gas to avoid contamination with carbon dioxide.

Alumina (Merck aluminium oxide 60, active basic 70—230 mesh) was heated in a 2 M NaOH solution containing bromine at 80—100 °C for 1 h. After cooling, the alumina was transferred into a black glass tube with a carbon dioxide absorber of 0.6 cm in diameter and with its length adjusted to 10.0—10.2 cm. Then the alumina bed was rinsed with water and the eluent used in each run. NaOH solution of various oxidation states of Np of 1 cm^3 was carefully transferred to the top of the bed and allowed to flow through. After the tube had been washed, the eluent was allowed flow through at 0.2—0.3 cm/min.

The ^{237}Np was obtained from The Radiochemical Centre, Amersham, while the ^{239}Np tracer was prepared by milking from ^{243}Am through a cation exchanger. By measuring the ^{239}Np activity by means of a NaI scintillator or Ge detector, the neptunium was determined. The optical density was measured by means of a Hitachi 330 spectrophotometer.

Results and Discussion

Chromatographic Behavior of Np(VII) and Np(V). The chromatographic behavior of Np(VII), prepared by a conventional ozone oxidation,[4] is shown in Fig. 1 for its ordinary concentration of 4.3×10^{-4} M in 1.2 M NaOH. In this figure, the ordinate represents the ratio of the amounts of Np found in each fraction of the effluent to the total amount placed in the column. In the first peak of the chromatogram, the effluent was colorless, but in the second peak the color was the green characteristic of a heptavalent state. Moreover, the recovery of Np was 99%, which showed that almost all the Np loaded on the column was eluted. As is shown in Fig. 1, the Np(VII) of an

Influent: 4.3×10^{-4} M Np(VII) in 1.2 M NaOH, eluent: 1.1 M NaOH, recovery: 99%.

ordinary concentration prepared by ozone oxidation is separated into two parts by means of alumina chromatography.

The chromatographic behavior of Np(V), prepared by the addition of hydrazine,[3] was investigated for an extremely low concentration of 5×10^{-12} M. However, no neptunium was eluted at all, even by the use of 60 ml of the eluent (1 M NaOH+10^{-3} M $N_2H_4\cdot2HCl$). Also, the adsorption of Np(V) on 100 mg of alumina was found to be above 98% by the agitation of 4 ml of Np(V) in a 1 M NaOH solution containing hydrazine. Thus, the Np(V) in a 1 M NaOH solution may be said to be strongly adsorbed on alumina.

Chromatographic Behavior of Np(VI). A basic Np(VI) solution of an ordinary concentration is usually prepared by alkalizing an acidic Np(VI) solution without any foreign oxidants,[5] by dissolving Np(VI) salt in a solvent of interest,[2] or by electrolyzing a basic Np(VII) solution.[6] However, there is some probability of a partial formation of a pentavalent state in the basic Np(VI) solution prepared by the above-mentioned method. Here we prepared not pure Np(VI), but various mixed solutions of Np(VI) and Np(VII) by adding hydrazine to Np(VII) solutions prepared by ozone oxidation, as is tabulated in Table 1. This table shows the fraction of Np(VII) as calculated from the optical densities at 618 nm before and after the addition of hydrazine. In these mixtures of Np(VII) and Np(VI), there is no probability of the existence of the pentavalent state at all, because the reaction of Np(V)+Np(VII)→2Np(VI) is rapid and complete.[2]

The chromatographic behavior of Np(VII) and Np(VI) can be examined without any consideration of Np(V). The elution chromatograms of the mixtures are shown in Fig. 2, in which the numbers correspond to the index numbers in the first column of Table 1. As the fraction of Np(VII) in a mixture decreases, the intensity of the first peak in Fig. 2 becomes larger, and that of the second peak, smaller. The fractions of the second peak, observed by means of chromatograms, are shown in the sixth column of Table 1. These values agree fairly well with the fractional values of Np(VII) in the mixtures obtained by spectrophotometry. From Table 1 and Fig. 2, it may be concluded that the first peak in the chromatogram is due to Np(VI), and the second peak, to Np(VII), and that the intensity ratio of the two peaks corresponds to the concentration ratio of Np(VI) and Np(VII).

The difference between the D_1/D_0 ratio and the second peak fraction may result either from the reduction of Np(VII) during chromatography or from an incomplete preparation of pure Np(VII) in 1 M NaOH, as shown by controlled potential coulometry.[6]

Preparation of Tracer-scale Np(VII) and Np(VI) in a 1 M NaOH Solution. As is shown in Table 1 and Fig. 2, Np(VII) and Np(VI) of an ordinary concentration can easily be discriminated by chromatography on alumina. Here, we are concerned with the preparation of Np(VII) and Np(VI) of a tracer quantity in a 1 M NaOH solution.

Neptunium solutions from 5×10^{-4} M to an extremely low concentration were oxidized by ozone in a 1 M NaOH solution containing bromine. The chro-

matogram is shown in Fig. 3. A comparision of Fig. 3-(1) with Fig. 1, makes it obvious that Np(VII) of a higher purity is obtained by ozone oxidation in a NaOH solution containing bromine; the contamination of Np(VI) is estimated to be about 1% from the chromatogram of Fig. 3-(1). Figure 3 shows that the distribution coefficient of Np(VII) on alumina grows larger as its concentration decreases, though that of Np(VI) is apparently constant from an ordinary to an extremely low concentration. Also, Np(VII) of a tracer quantity in 1 M NaOH can be prepared by ozone oxidation in a 1 M NaOH solution containing bromine, as is shown in Fig. 3-(4).

Np(VI) in a 1 M NaOH solution may be obtained by the use of an oxidant with a formal electrode potential of about 0.45 V, because the potential in a 1 M NaOH solution is 0.59 V for a Np(VII)/Np(VI) couple[6] and 0.30 V for a Np(VI)/Np(V) couple.[7] However there are not any suitable oxidants in basic solutions. Therefore, we tried to prepare Np(VI) by oxidation with mixture of $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]$. For a $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ couple, the standard electrode potential is 0.36 V and the formal electrode potential is 0.46 V at 0.01 M NaOH and 0.52 V at 5 M NaOH.[8] By oxidation with this mixture, Np(VI) must be obtained, because the potential of the mixture will vary with the concentration ratio, Q, where $Q=[[Fe(CN)_6]^{4-}]/[[Fe(CN)_6]^{3-}]$. The preliminary spectrophotometric experiments showed that the concentrations of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$

in a mixture of them at 1 M NaOH remained almost constant over 2 d. This means that the potential of the mixture in 1 M NaOH is almost constant.

The distribution of the oxidation states of Np in the mixture was examined both by adsorption on zirconium(IV) hydroxide[3] and by chromatography on alumina. The results are shown in Table 2 and Fig. 4. As is shown in Table 2, the adsorption of Np is almost constant, independent of the standing time and the temperature, and the Np in the mixture with the concentration ratio of $Q<10$ is adsorbed a little, though much of the Np in the $[Fe(CN)_6]^{4-}$ solution is adsorbed. Since the oxidation into Np(VII) by $[Fe(CN)_6]^{3-}$ in a NaOH solution is incomplete,[9] the result of adsorption shows that the Np in a mixture with a ratio of $Q<10$ is a pure hexavalent state or a mixture of hexa- and heptavalent states. And also the results show that Np in $[Fe(CN)_6]^{4-}$ solution is a mixture of penta- and hexavalent state. The possible oxidation states of Np are shown in the seventh column of Table 2.

The chromatographic behavior of Np in $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$ solutions are shown in Figs. 4-(1) and 4-(4) respectively. Though Np(VI) exists in both solutions, Np is not eluted at all in the $[Fe(CN)_6]^{4-}$ solution, as is shown in Fig. 4-(1), while it is eluted at an intermediate position between Np(VI) and Np(VII) in the $[Fe(CN)_6]^{3-}$ solution, as is shown in Fig. 4-(4). The curious behavior can be easily explained by the concept of repeated extractions for chromatography as follows. If there are two different oxidation states of Np which are produced by a reversible redox reaction, these two states of Np are not separated by chromatography, and the elution of Np is observed at the intermediate position between intrinsic positions for each oxidation state, because Np in the mobile and stationary phase is forced to become two different oxidation states by a reversible redox reaction, and it is partly and repeatedly adsorbed or desorbed on alumina between the two phases.

Figures 4-(2) and 4-(3) show the chromatograms of Np in mixtures with the concentrations ratio, Q, of 9 and 4 respectively. Almost all the Np was eluted at an intrinsic peak position for Np(VI). Therefore, in a 1 M NaOH solution Np(VI) in a tracer quantity can be prepared by oxidation with the mixture of $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]$ having concentration ratio, Q, from 4 to 9.

Effect of the Concentration of Na_2CO_3 and NaOH on the Chromatographic Behavior of Np(VII) and Np(VI). The effects of the concentration of Na_2CO_3 and NaOH on the chromatographic behavior of Np(VII) and Np(VI) were examined. The mixtures of Np(VII) and Np(VI) were prepared by the addition of bromine. Figure 5 shows the effect of the concentration of Na_2CO_3, where Np was been prepared by heating at 80—90 °C for an hour in a 1 M NaOH solution containing bromine, so that the fraction of Np(VII) was rich. As is shown in Fig. 5, the elution peak

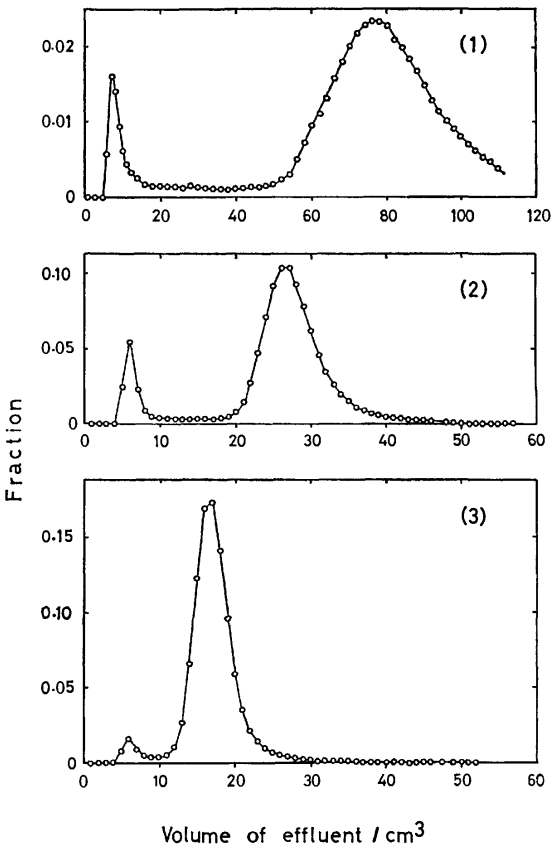

Fig. 6. Influence of the concentration of NaOH on the chromatogram of Np(VI) and Np(VII).
(1): 0.57 M NaOH+0.08 M Br_2, (2): 1.1 M NaOH +0.08 M Br_2, (3): 1.7 M NaOH+0.08 M Br_2.

position on Np(VII) is dependent on the concentration of CO_3^{2-}, but that of Np(VI) is independent of it. It is found that the discrimination between Np(VII) and Np(VI) can be made up to 0.05 M Na_2CO_3 in a 1 M NaOH solution.

Figure 6 shows the effect of the concentration of NaOH, where Np has been prepared by standing at room temperature in a 1 M NaOH solution containing bromine, so that the fraction of Np(VI) was larger. This figure shows that the discrimination can also be made in a NaOH solution of 0.5—1.7 M.

By combining the chromatography on alumina with the adsorption on zirconium(IV) hydroxide, it is possible to analyze the distribution of all the oxidation states of Np, Np(V), Np(VI), and Np(VII) in a 1 M NaOH solution.

The present work was partially supported by a Grant-in-Aid for the Encouragement of Young Scientists (No. 56740239) from the Ministry of Education, Science and Culture.

Voltammetric Studies of the Use of the Rotated Oxide Electrode as an Indicator Electrode and as a View to the Determination of EDTA and Other Complexanes

Tadayosi YOSHIMURA

Department of Industrial Chemistry, Fukui Technical College, Sabae, Fukui 916

(Received September 7, 1981)

The accessible potential ranges of rotated lead dioxide (PbO_2) and manganese dioxide (MnO_2) electrodes were investigated in supporting electrolyte solutions of 0.1 mol/l (mol/dm^3) KNO_3 at various pH values, by measuring the base currents of these oxide electrodes. The anodic and cathodic ascending potentials of both the oxide electrodes are pH-independent in a neutral solution. In each neutral system of KNO_3, $KClO_4$, K_2SO_4, and KCl, the accessible potential range of the PbO_2 electrode was from +1.4 to +0.2 V *vs.* SCE, while that of the MnO_2 electrode was from +1.2 to +0.3 V, and the lower manganese oxide electrode from +0.3 to −0.9 V. Furthermore, the applications of these electrodes to the determination of EDTA and other complexanes were examined. Both the oxide electrodes gave a good calibration curve which could establish a linear relationship to the EDTA concentration, passing through the point of origin. The rotated PbO_2 and MnO_2 electrodes seem to be useful for determining depolarizers such as the EDTA-type complxanes.

The voltammetric fundamentals of the oxide electrodes have been reported by several investigators. With regard to the Pt electrode, Kolthoff and Tanaka[1] reported the residual current-voltage curves and dissolution patterns of rotated and stationary platinum wire electrodes in supporting electrolytes. When the curves are recorded from the evolution potential of oxygen in the negative direction, a small cathodic dissolution pattern is observed starting at a potential which approximately corresponds to the equilibrium value of the platinum-platinous hydroxide electrode. Sato *et al.*[2] reported the electrodeposition and reduction of the manganese dioxide (MnO_2) electrode; two cathodic waves were observed in an acidic solution in a cathodic sweeping. Similar results were reported by Reynaud,[3] Lee *et al.*,[4] and Yoshimura:[5]

$$MnO_2 + H^+ + e^- \longrightarrow MnOOH, \quad (1)$$

$$MnOOH + 3H^+ + e^- \longrightarrow Mn^{2+} + 2H_2O. \quad (2)$$

The lead dioxide (PbO_2) electrode was reviewed by Carr and Hampson.[6] Under acidic conditions and within the anodic potential range, the primary redox equilibrium is between lead dioxide and the lead(II) ion:

$$PbO_2 + 4H^+ + 2e^- \rightleftharpoons Pb^{2+} + 2H_2O. \quad (3)$$

The electrode reactions of ethylenediaminetetraacetic acid (EDTA), other polyamine *N*-polycarboxylic acids (complexanes),[7,8] chromium(III),[9] acetylacetone,[10] 8-quinolinol,[11] and ethanol[12] have previously been reported by using the stationary MnO_2 and PbO_2 electrodes as indicator electrodes. In the case of the MnO_2 electrode,[7] a characteristic cathodic peak due to the complex formation of EDTA was observed, and two further anodic peaks or the coalesced anodic peak were at last also observed in an acidic solution. In the case of the PbO_2 electrode,[8] an anodic peak and a cathodic peak due to the complex formation of EDTA were obtained in a 0.1 mol/l KNO_3 solution. Both the cathodic and anodic peaks of these oxide electrodes increase with the increase in the complexane concentration.

For the analytical use of the PbO_2 and MnO_2 electrodes, it seems to be most useful to investigate and clarify the voltammetric behavior of the rotated oxide electrodes. In this work, the accessible potential ranges of these oxide electrodes were investigated in the supporting electrolyte solutions of 0.1 mol/l KNO_3 at various pH values; this was done by measuring the base currents of the rotated PbO_2 and MnO_2 electrodes. Furthermore, the use of these oxide electrodes for the determination of EDTA and other complexanes was examined.

Experimental

Chemicals. The chemicals used were of an analytical reagent grade. The supporting electrolyte solution used mainly was a 0.1 mol/l concentration of potassium nitrate. Since the oxide electrodes were sensitive to the anion components of most buffer solutions,[5,8] the pH of the electrolyte solution was adjusted with 0.1 mol/l nitric acid and potassium hydroxide. The variation in pH value of the solution before and after the voltammetric measurements was ±0.0039 in the pH range from near 2 to 11.[10] The nitrilotriacetic acid (NTA), ethylenediaminetetraacetic acid (EDTA), and diethylenetriaminepentaacetic acid (DTPA) were used without further purification. Redistilled water was used throughout this investigation.

Preparation of the Oxide Electrodes. The rotated lead dioxide (PbO_2) electrode was prepared by the electrolytic oxidation of 1.0 mol/l lead nitrate[8] on a platinum disk microelectrode (0.046 cm^2) at 30±2 °C, rotated with a synchronous motor at a rate of 600 min^{-1}. Similarly, the rotated manganese dioxide (MnO_2) electrode was prepared by the electrolytic oxidation of 1.0 mol/l manganese sulfate[7] on a platinum disk microelectrode (0.046 cm^2) in a 0.5 mol/l sulfuric-acid solution at 90±3 °C. The stationary MnO_2 electrode was prepared by the electrolytic oxidation of the same solution without being rotated.[7] After the electrolytic oxidation of the electrode, these oxide electrodes were washed with redistilled water and used.

Apparatus and Procedures. A Yanagimoto polarograph Model P8-AP and a Princeton Applied Research Model 174A polarographic analyzer with a three-electrode system were used for the voltammetric measurements. A Corning pH-meter Model 125 was used for the pH measurements. During all the voltammetric measurements, the rotated oxide electrode was used at a rotation rate of 600 min^{-1} with a synchronous motor, Yanagimoto Model SM6S2, except for the

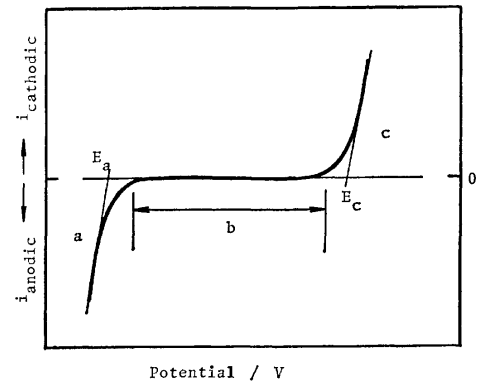

Fig. 1. Typical current-voltage curve of an indicator electrode.
a: Anodic ascending current [decomposition of medium], b: accessible potential range for an analytical application, c: cathodic ascending current [dissolution of electrode or evolution of hydrogen gas]. Ascending potential: E_a, anodic; E_c, cathodic.

investigation of the effect of the rotation rate on the redox wave. All the voltammetric measurements were carried out at a sweep rate of 5 mV/s in a thermostat of 25±0.2 °C without any deaeration of the solution. When current-voltage curves are measured at a more negative potential than zero **V** *vs.* SCE, the solution was deoxygenated by bubbling nitrogen gas. A saturated calomel reference electrode (SCE) and a platinum counter electrode were used.

Measurements of the Ascending Potential. Figure 1 shows a typical current-voltage curve of an indicator electrode; the anodic ascending current corresponds to a decomposition of the medium, while the cathodic one corresponds to a dissolution of the electrode or an evolution of hydrogen. The ascending potential was measured in the following way (see Fig. 1): the current-voltage curves of the rotated oxide electrode were recorded starting from +0.50 V both anodically and cathodically, and the ascending potential has defined as the potential of the point at which the tangent to the ascending curve of about 300 μA intersects with the tangent to the residual curve.

Results and Discussion

Accessible Potential Range. The accessible potential ranges have been studied for the assessments of the PbO_2 and MnO_2 indicator electrodes. The base currents of these rotated electrodes in 0.1 mol/l KNO_3 with various pH values are shown in Figs. 2 and 3 respectively.

The rotated PbO_2 electrode shows one cathodic wave at a pH value lower than 4 and one anodic wave at a pH value higher than 9, as is shown in Fig. 2. The anodic ascending current corresponds to oxygen evolution. The PbO_2 electrode may have the accessible potential range of +1.4 to +0.2 V in a 0.1 mol/l KNO_3 solution at pH values between 4 and 9.

On the other hand, the rotated MnO_2 electrode shows a small cathodic wave in its base current at the cathodic sweep, which corresponds to the reduction of MnO_2 to the lower manganese oxide, according to Eqs. 1 and 2. The anodic ascending current corresponds to oxygen evolution, while the cathodic

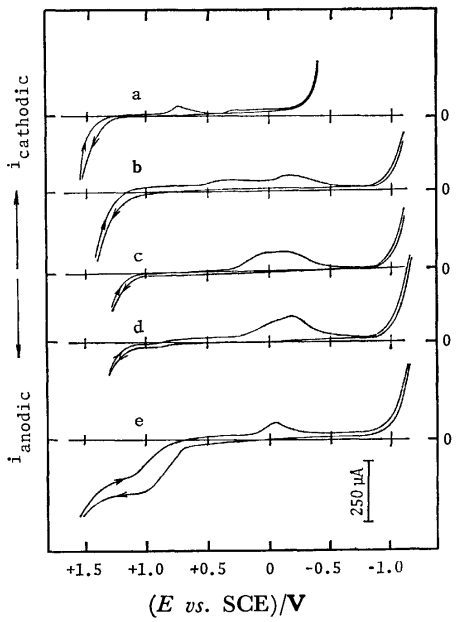

Fig. 3. Current-voltage curves of the MnO_2 electrode in 0.1 mol/l KNO_3 with various pH.
Sweep rate: 5 mV/s at a rotation rate of 600 min^{-1}.
The pH of solution: a, 1.05; b, 3.05; c, 5.74; d, 10.11; e, 11.79.

ascending current corresponds to hydrogen evolution. Thus, the accessible potential range of the MnO_2 electrode was +1.2 to +0.3 V in a 0.1 mol/l KNO_3 solution at pH values between 3 and 10.

Ascending Potentials and Self-reduction Waves of the Oxide Electrodes. In Fig. 4, the ascending potentials of the PbO_2 electrode and the half-wave potentials of the cathodic and anodic waves are plotted against the pH values. Curve a indicates the evolution potential of oxygen, while Curve b shows the ascending potential at which the PbO_2 is reduced and dissolved as Pb^{2+}, according to Eq. 3.[6] At pH values lower than 4, the cathodic wave appears and the height

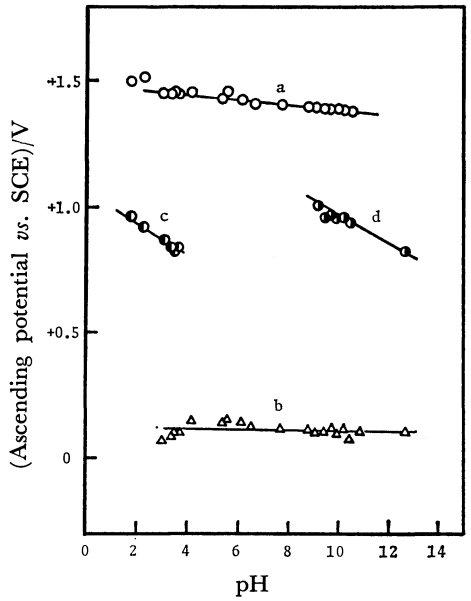

Fig. 4. Relationship between pH and wave potential of the PbO_2 electrode in 0.1 mol/l KNO_3 solution. Ascending potential: a(○), oxygen evolution; b(△), cathodic dissolution. Half-wave potential: c(◐), cathodic wave; d(◑), anodic wave.

increases with a decrease in the pH. The potential shift is −60 mV/pH (Curve c). Thus, the electrode process may be assumed to be as follows:[8]

$$PbO_2 + H^+ + e^- = PbOOH. \quad (4)$$

At pH values higher than 9, on the other hand, the anodic wave appears, and it increases with an increase in the pH values. Its potential is also shifted by −60 mV/pH, as is indicated by Curve d. Thus, the electrode process may be assumed to be as previously reported:[8]

$$PbO_2 + 2H_2O + 2e^- = Pb(OH)_2 + 2OH^-. \quad (5)$$

The ascending potential shown by Curve a is scarcely dependent on the pH of the solution. Therefore, the oxygen evolution may proceed *via* a rate-determining step, Eq. 6, as follows:

$$2PbO_2 \xrightarrow{\text{slow}} 2PbO^+ + O_2\uparrow + 2e^-, \quad (6)$$

$$PbO^+ + H_2O \xrightarrow{\text{fast}} PbO_2 + 2H^+ + e^-. \quad (7)$$

Curve b indicates that the cathodic dissolution of the PbO_2 may include a rate-determining step, Eq. 9, which is pH-independent, as follows:

$$PbO_2 + 2H^+ + e^- \xrightarrow{\text{fast}} PbO^+ + H_2O, \quad (8)$$

$$PbO^+ + e^- \xrightarrow{\text{slow}} PbO. \quad (9)$$

Similar plots are given in Fig. 5 for the rotated MnO_2 electrode. At pH values lower than 3, all the waves depend upon the pH. The ascending potential of the oxygen evolution shown by Curve a has a slope of −60 mV/pH. Thus, the following reaction may take place:

$$H_2O \longrightarrow \tfrac{1}{2}O_2\uparrow + 2H^+ + 2e^-. \quad (10)$$

The reduction potential of the MnO_2 (Curve c′) is shifted by −120 mV/pH at pH values lower than 3.

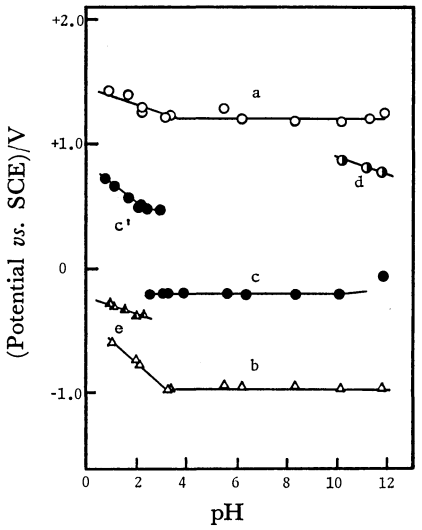

Fig. 5. Relationship between pH and wave potential of the MnO_2 electrode in 0.1 mol/l KNO_3 solution. Ascending potenital: a(○), oxygen evolution; b(△) and e(◭), hydrogen evolution. Wave potential: c and c′(●), reduction of MnO_2; d(◑), oxidation of $Mn(OH)_2$.

This result indicates that the MnO_2 on the electrode is reduced to the lower manganese state, as follows:[2]

$$MnO_2 + 4H^+ + 2e^- \longrightarrow Mn^{2+} + 2H_2O. \quad (11)$$

Curves e and b correspond to the evolution of hydrogen gas, and the simultaneous elution of the lower manganese state from the electrode, respectively. The wave height for Curve e decreased with an increase in the pH and disappeared at pH 3. The slopes of Curves b and e were −180 mV/pH and −60 mV/pH respectively. This phenomenon is too complicated to explain the reaction mechanism.

At pH values higher than 3, the potential of the oxygen evolution (Curve a) was pH-independent, indicating that the reaction scheme may be the same as that for the PbO_2 electrode:

$$2MnO_2 \xrightarrow{\text{slow}} 2MnO^+ + O_2\uparrow + 2e^-, \quad (12)$$

$$MnO^+ + H_2O \xrightarrow{\text{fast}} MnO_2 + 2H^+ + e^-. \quad (13)$$

The reduction wave of the MnO_2 appeared near −0.2 V and was pH-independent at pH values higher than 3. The same scheme as that for PbO_2 is assumed for this wave:

$$MnO_2 + 2H^+ + e^- \xrightarrow{\text{fast}} MnO^+ + H_2O, \quad (14)$$

$$MnO^+ + e^- \xrightarrow{\text{slow}} MnO. \quad (15)$$

The chemical species of MnO might not be eluted from the electrode, in contrast with the cathodic dissolution of the PbO_2 electrode. The evolution potential of hydrogen (Curve b) was also independent of the pH of the solution. This result indicates that the evolution may take place by means of the catalytic action of the oxide electrode and may include a rate-determining step, Eq. 17, as follows:

$$MnO + H_2O \xrightarrow{\text{fast}} Mn^+OH + OH^-, \quad (16)$$

$$Mn^{+}OH + H_2O + e^- \xrightarrow{slow} MnO_2 + \tfrac{2}{3}H_2\uparrow, \quad (17)$$

$$MnO_2 + 3H^+ + 2e^- \xrightarrow{fast} Mn^{+}OH + H_2O. \quad (18)$$

Tafel Slope. A useful electrode for the evolution of oxygen or hydrogen is generally estimated by means of a Tafel plot ($\eta = a + b \log [i/\mathrm{A\ m^{-2}}]$). In this investigation, the Tafel plot was examined for both the PbO_2 and MnO_2 electrodes from the ascending current-voltage curves of the evolution of oxygen and hydrogen. Figure 6 shows the relation between the pH and the *b* value of the Tafel slope of both the oxide electrodes. From Ref. 13, the Tafel slope (*b*) of oxygen evolution at the Pb/PbO_2 electrode is 0.12 V. In Fig. 6, Curve a indicates that the Tafel slope at the PbO_2 (Pt/PbO_2) electrode is constant, 0.08 V, against the pH of the solution. From Curve b of the MnO_2 (Pt/MnO_2) electrode, it was found that the *b* value of oxygen evolution is pH-dependent; this indicates that the electrode would be excellent in an acidic solution. Curve c displays the Tafel slope of hydrogen evolution at the MnO_2 electrode, on which the chemical species may be the lower manganese oxide. The *b* value is satisfactory for the electrode.

Curves: a(○), oxygen evolution at the PbO_2 electrode; b(●), oxygen evolution and c(▲), hydrogen one at the MnO_2 electrode.

Accessible Potential Ranges with Other Supporting Electrolytes. As to other systems of supporting electrolytes (constant concentration, 0.1 mol/l), each accessible potential range of both the oxide electrodes was investigated. Table 1 shows the relation between the accessible potential range at pH 5—6 and the supporting electrolyte. In each system—KNO_3, $KClO_4$, K_2SO_4, and KCl— at pH 5—6, the accessible potential range of the PbO_2 electrode was +1.4 to +0.2 V *vs.* SCE, and that of the MnO_2 electrode was +1.2 to +0.3 V, while the latter was +0.3 to −0.9 V at the lower-manganese-state electrode. The same potential ranges were obtained in the supporting electrolyte of the sodium salt instead of potassium salt.

In an acidic solution with a pH value lower than 1, the PbO_2 on the electrode was dissolved in a solution of HNO_3 and $HClO_4$, but produced insoluble films of $PbSO_4$ and $PbCl_2$ on the surface of the electrode in the solutions of H_2SO_4 and HCl respectively. This is also based upon the value of the stability constant, $\log k_1$.[14] As to the MnO_2 electrode, on the other hand, the accessible potential range was +1.4 to +0.9 V in the systems of HNO_3, $HClO_4$, and H_2SO_4, but not that of HCl (chlorine evolution).[5,7] In a basic solution, each oxide on the electrode might change to a hydroxide: $Pb(OH)_2$[8] or $Mn(OH)_2$.[5] Thus, these oxide electrodes cannot be used as dioxide electrodes, but they can be used as hydroxide electrodes.

When a buffer solution of an acetic system was used as the supporting electrolyte instead of an unbuffered solution such as KNO_3, both the oxide electrodes showed the redox waves, in spite of the small values of the stability constant,[14] as is tabulated in Table 1. Furthermore, other general buffer solutions (0.1 mol/l potassium dihydrogen phosphate, 0.1 mol/l potassium hydrogen phthalate, 0.1 mol/l potassium dihydrogen citrate, Gomori's buffer, *etc.*) were used. Similarly, both the oxide electrodes showed redox

Table 1. Accessible potential range of the rotated PbO_2 and MnO_2 electrodes in several supporting electrolyte solutions at pH 5—6

waves in all these buffer solutions. Thus, these buffer solutions were not used as supporting electrolytes in this work.

Electrolytic Behavior of EDTA and the Concentration Dependence. The behavior of EDTA and other complexanes at the rotated MnO_2 and PbO_2 electrodes was also investigated. Figure 7 displays the current-voltage curves at the Pt, MnO_2, and PbO_2 electrodes in a 0.1 mol/l KNO_3 solution in the absence and in the presence of EDTA. The anodic ascending potential of the Pt electrode became a little negative only, and an anodic wave of EDTA was not observed[15] (Curve b). At the MnO_2 electrode, the anodic wave at +1.0 V appeared only in the anodic sweep. At the PbO_2 electrode, however, the pre-wave at +0.67 V and the main-wave at +0.97 V were observed in both the anodic and cathodic sweeps.

The author has previously reported on the discovery of the anodic pre-wave of EDTA at the stationary PbO_2 electrode.[8] The concentration dependence of the anodic waves of EDTA at the rotated PbO_2 electrode are shown in Fig. 8. The heights of the anodic pre-wave and main-wave were directly proportional to the EDTA concentration. The half-potential of each wave was constant. These data were reproducible within about ±3% on repeated runs. From the measurement of the anodic wave height with the PbO_2 electrode, it was possible to determine the EDTA of a concentration down to 1×10^{-5} mol/l. Figure 9 shows the relations between the wave heights and the angular velocity ω ($=2\pi N$, N: rotation rate) at the

PbO_2 and MnO_2 electrodes. A linear relationship between the wave heights and $\omega^{1/2}$ with the PbO_2 electrode was found, as is shown by Curves a and b in Fig. 9. According to Levich's opinion,[16] it follows that the limiting diffusion current, i, of the rotated disk electrode can be obtained by the use of the following equation:

$$i = \alpha\omega^{1/2}, \tag{19}$$

where α denotes the proportionality constant. It was found that the limiting currents of both the anodic waves are diffusion-controlled, because these currents were directly proportional to the $\omega^{1/2}$, Eq. 19. The anodic pre-wave is considered to be due to the adsorption of EDTA onto the electrode.[8] The anodic main-wave may be due to the complex formation of EDTA for the electrode.[8]

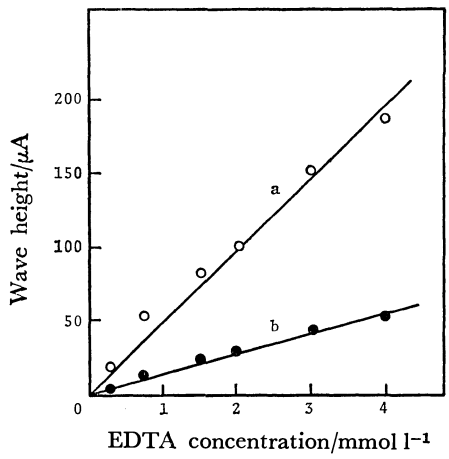

Fig.10. Relationship between wave height and concentration of EDTA in 0.1 mol/l KNO_3 solution (pH (5.9).
Lines a(○): anodic sweep; b(●): cathodic sweep.
Electrode: MnO_2 electrode at a rate of 600 min^{-1}.

For the anodic limiting current of EDTA at the rotated MnO_2 electrode, a linear concentration dependence was also found passing through the point of origin, as is shown in Fig. 10. The MnO_2 electrode showed a broader anodic wave in the anodic sweep than aid of the PbO_2 electrode. In the cathodic sweep, though no well-defined anodic wave was observed, a positive current was followed (Figs. 7-d and e). The heights of the anodic wave and the positive current in Fig. 10 were measured between the anodic current at the anodic wave potential of +1.0 V and that of the base current (Figs. 7-c, d, and e). These data obtained were reproducible within about ±5% on repeated runs. From the measurement of the anodic wave height with the MnO_2 electrode, it was possible to determine the EDTA of a concentration down to 1×10^{-5} mol/l. The effect of the rotation rate of the MnO_2 electrode on the anodic wave height was also examined. In this case, however, no linear relation was found, as is shown by Curve c in Fig. 9. This finding suggests the anodic limiting current is reaction-controlled.[16] The anodic wave is considered to be due to the complex formation of EDTA for the MnO_2 electrode.

The determination of NTA and DTPA as the EDTA-type complexanes was similar to that of EDTA with the rotated PbO_2 and MnO_2 electrodes.

Comparison with Other Methods. The techniques of the determination of complexane, such as absorption spectroscopy, chelate titrimetry, and the electroanalytical method, have been described by Ueno.[17] The determining precision of each technique is not very sharp at concentrations of a complexane lower than 1×10^{-3} mol/l. A conventional electroanalytical method, such as the polarographic method and electrometric titration, is well suited for the separation and determination of complexanes, but not for trace amounts of complexane. While the present method is an electroanalytical method, it consists of the use of an anodic limiting current dependent upon the concentration of complexane, and it is as simple as a polarographic method. This method is capable of greater precision than previously reported methods,[17] and it is well suited for small amounts, 1×10^{-5} mol/l, of complexane. The PbO_2 electrode seems to be useful for determining complexane.

Behavior of the MnO_2 Electrode in an Acidic Solution. In an acidic solution, it was found that the rotated PbO_2 electrode cannot be used as an indicator electrode, since the PbO_2 shows a self-redox wave.[8] The rotated MnO_2 electrode in the acidic solution (0.1 mol/l HNO_3) has an accessible potential range of +1.4 to +0.9 V *vs.* SCE as the rotated electrode.

The electrode reaction of complexanes on the stationary MnO_2 electrode has been reported previously;[7] a characteristic cathodic current peak of manganese dioxide which increases in the presence of complexane was observed. This is because the reduction of manganese dioxide is accelerated through the complex formation. The electrode reaction is extremely dependent on the pH of the electrolysis solution. Figure 11 shows the current-voltage curves of the rotated Pt and MnO_2 electrodes in 0.1 mol/l HNO_3 containing EDTA in anodic and cathodic sweeps. When the surface of the rotated electrode was observed during this experiment, the MnO_2 was eluted and removed at +0.85 V in the cathodic sweep (Curve d) and at +1.05 V in the anodic sweep (Curve e). At these potentials, the black color of the MnO_2 material disappeared, and the white color of the base material of platinum was observed. The MnO_2 material was removed completely from the electrode after this experiment. Thus, the rotated MnO_2 electrode is considered not to be necessary for the determination of

complexane in an acidic solution.

According to a previous paper,[7] the stationary MnO_2 electrode is adequate as an indicator electrode for the determination of complexane in an acidic solution. The accessible potential range of the stationary MnO_2 electrode was also examined against the pH of the solution. Figure 12 shows the influence of the pH on the compositional electrode potential of the stationary MnO_2 electrode, which is defined as the potential of zero-current in the cyclic current-voltage curve (E_a and E_c). The shaded parts in Fig. 12 indicate the accessible potential range of the MnO_2

electrode in the pH region of solution. As the residual current of the MnO_2 electrode became large and the electrode became voltammetrically inert at pH values higher than 3 (Fig. 12-i_r), the stationary MnO_2 electrode is considered to be suitable for use at pH values lower than 3. In the application of the stationary MnO_2 electrode, the base current and the redox wave of DTPA in the accessible potential range are shown in Fig. 13. When current-voltage curves are measured over the accessible potential range, the electrolytic process of the anodic wave is complicated. In order to study the concentration-dependence of each complexane (DTPA, EDTA, and NTA), the height of the anodic wave was measured at +1.3 from the abscissa of the zero-current level. Figure 14 shows the relation between the wave heights and the concentrations of DTPA, EDTA, and NTA in a 0.1 mol/l HNO_3 solution. Each height was directly proportional to the concentration of complexane. These data were reproducible within about ±5% on repeated runs. From the measurement of the anodic wave-height of complexane with the stationary MnO_2 electrode, it was possible to determine the quantities of complexane in concentrations down to 1×10^{-4} mol/l.

The author wishes to express his thanks to Professor Taitiro Fujinaga and Doctor Satoshi Okazaki of Kyoto University, and Professor Kazunori Takaoka of Fukui Technical College for their valuable advice and discussions throughout this work.

(Received July 25, 1981)

The structure of copper(II) tetrachloroaluminum $Cu(AlCl_4)_2$ was determined by the single-crystal X-ray diffraction technique. The crystal is triclinic: $a=6.582(6)$, $b=7.362(5)$, and $c=12.265(5)$ Å; $\alpha=89.99(5)$, $\beta=85.97(6)$, and $\gamma=89.77°$; space group $P\bar{1}$ and $Z=2$. The structure was solved by the heavy-atom method and refined by applying the block-diagonal matrix least-squares technique on 2628 independent reflections up to a final R value of 0.110. The structure consists of closely-packed centrosymmetric $Cu(AlCl_4)_2$ molecules with copper atoms tetragonally coordinated. Structural difference between $Cu(AlCl_4)_2$ and $Co(AlCl_4)_2$ is described.

Aluminium halides form complexes with various halides in gas phase, and their structures and thermal properties have been extensively studied.[1-5] However, no attempt has been made to isolate crystals of such complexes and determine their crystal structures by single-crystal X-ray analysis, except for $Co(AlCl_4)_2$.[6]

We have reported that aluminium chloride and copper(II) chloride form a 2:1 complex, $2AlCl_3 \cdot CuCl_2$, when heated together.[7] The complex is a very active catalyst for isomerization of pentane at room temperature.[8,9] Studies on the structure of this complex by ESR and Raman spectroscopy have suggested that the complex contains $(AlCl_4)^-$ units and that the coordination environment of Cu(II) ions is of distorted octahedron, though the structure of $CuCl(Al_2Cl_7)$ was proposed for the complex in gas phase.[10,11]

Though the structure of $Co(AlCl_4)_2$ has been determined by Ibers,[6] the powder X-ray pattern of the present complex[8] is different from that of $Co(AlCl_4)_2$.

In the present work, the structure of $2AlCl_3 \cdot CuCl_2$ is determined in order to obtain the structural basis for the catalytic activity of this compound.

Experimental

Suitable crystals for diffraction measurements were prepared by the chemical transport method. A mixture of $AlCl_3$ and $CuCl_2$ (0.5 g each) was sealed under vacuum in a Pyrex glass tube of about 15 cm length with a diameter of 1.5 cm. Then, the tube was partitioned into three parts, which were heated in an electronic furnance at 170, 190, and 230 °C, respectively. Fine yellow prismatic crystals were deposited on the glass wall at the middle part. The density of the crystal was determined by flotation in a mixture of CCl_4 and CH_2Br_2. Since the compound is hygroscopic, a crystal of approximately $0.2\times0.3\times0.55$ mm³ was sealed in a thin-walled glass capillary filled with nitrogen. Cell constants were obtained from the least-squares treatment on angular settings of 25 high angle reflections. Data collection was carried out on a Rigaku computer-controlled four-circle diffractometer, using the graphite-monochromated Mo $K\alpha$ radiation. The crystal data and the details of experimental conditions are summarized in Table 1. Attenuators were automatically inserted to keep the counting rate below 8000 cps. Backgrounds were counted for 10 s at each end of scan range. Intensities were corrected for the Lorentz and polarization factors but not for the absorption. Four standard reflections measured after every 100 reflections indicated no significant intensity variation throughout the experiment.

Structure Determination

The structure was solved by the heavy-atom method and atomic parameters were refined by the block-diagonal least-squares technique. The quantity minimized was $\Sigma w(|F_o| - k|F_c|)^2$ with $w=1/\sigma^2(F_o)$. Zero reflections were included in the least-squares calculation by assuming $|F_o|=F_{lim}$ $(=1.86)$ where F_{lim} is the observed threshold value, but they were omitted when $|F_c|-F_{lim}$. The final R value was 0.110 for non-zero reflections. Final atomic parameters are listed in Table 2.[12] Atomic scattering factors were taken from the International Table for X-ray Crystallography.[13] Computations were done on a HITAC M-170 computer in Tokyo Institute of Technology by use of the program system XSEN.[14] The programs

Results and Discussion

The crystal structure of the complex $2AlCl_3\cdot CuCl_2$ consists of two crystallographically independent molecules of $Cu(AlCl_4)_2$ as shown in Fig. 1. Each molecule has a crystallographic center of symmetry; molecule A is on the origin while molecule B resides at (0, 1/2, 1/2). Both molecules are approximately related by a twofold screw axis at $x=0$, $z=1/4$ or by a c glide plane at $y=1/4$, indicating a pseudo $P2_1/c$ symmetry, which was inferred from the systematically weak intensities of $0k0$ and $h0l$ reflections.

The interatomic distances and angles are listed in Table 3. There are no significant structural differences between the two molecules. Each copper atom is tetragonally coordinated by chlorine atoms with a mean Cu–Cl distance of 2.295 Å, slightly shorter than the sum of the tetrahedral covalent radii.[17] The next nearest neighboring chlorine atoms are located above and below the plane of this group at a distance of 2.951 Å as indicated with the broken lines in Fig. 1. This distance corresponds to a bond number of about 0.1,[18] implying very weak interaction. Similar situations are usually observed with many copper (II) complexes.[19] The Cu(1)→Cl(7') and Cu(2)→Cl(3) vectors make angles of 86.4° and 86.5° with the corresponding basal planes, respectively.

Each aluminium atom is tetrahedrally coordinated by chlorine atoms, and the more strongly the chlorine atom is coordinated to the copper atom, the longer the Al–Cl distance becomes as in the case of $Co(AlCl_4)_2$.[6] The uncoordinated chlorine atoms have the shortest Al–Cl distances of 2.057 and 2.060 Å. These values are smaller than those obtained for $Co(AlCl_4)_2$ (2.105 Å),[6] $C_6H_6CuAlCl_4$ (2.078 Å),[20] $(C_6H_6PdAlCl_4)_2$ (2.10 Å),[21] and $NaAlCl_4$ (2.11 Å),[22] indicating that the $AlCl_4$ tetrahedra in the present complex are the most distorted among these chloroaluminate complexes.

The interplanar angle between the Cu(1), Cl(1), Cl(2), and Cl(1), Cl(2), Al(1) planes and that between the Cu(2), Cl(5), Cl(6), and Cl(5), Cl(6), Al(2) planes are 8.3° and 8.7°, respectively. The Cu–Al distances are long and the bridging Cu–Cl–Al angles are not highly acute, implying that there is no direct metel-metel interaction.[23]

The networks composed of $AlCl_4$ tetrahedra and $CuCl_6$ distorted octahedra lie parallel to the bc plane

of the unit cell, forming a layer structure. The closest distance between the layers is about 3.60 Å for Cl(7) Cl(4) at $(1+x, y, z)$. It is equal to twice the van der Waals radius of chlorine (1.80 Å).

The crystal structures of $Co(AlCl_4)_2$[6] and $Cu(AlCl_4)_2$ are compared in Figs. 2(a) and 2(b). In both structures $AlCl_4$ groups play a dual role as monocoordinate as well as bicoordinate ligands. An important difference is the fact that the cobalt atom resides on the crystallographic two-fold axis and has *cis* configuration, 1, whereas the copper atom sits on the center of symmetry and possesses *trans* configuration, 2, as far as the monocoordinate ligands are concerned.

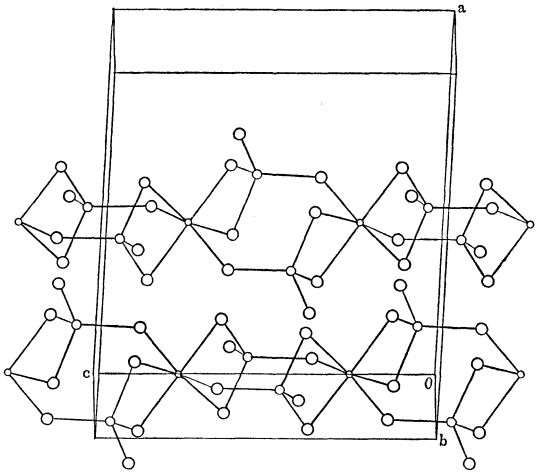

Fig. 2(a). Crystal structure of $Co(AlCl_4)_2$.

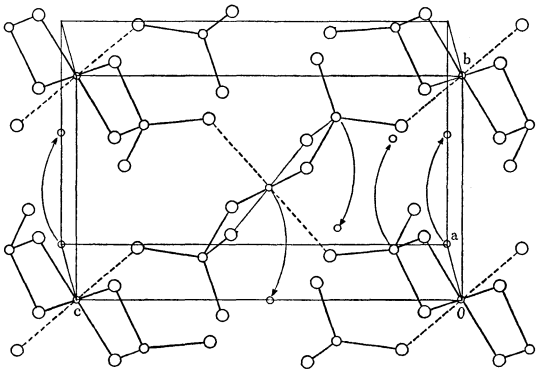

Fig. 2(b). Crystal structure of $Cu(AlCl_4)_2$.
If the copper and aluminum atoms would be transfered as indicated with arrows, the hypothetical structure could be derived as shown in Fig. 2(c).

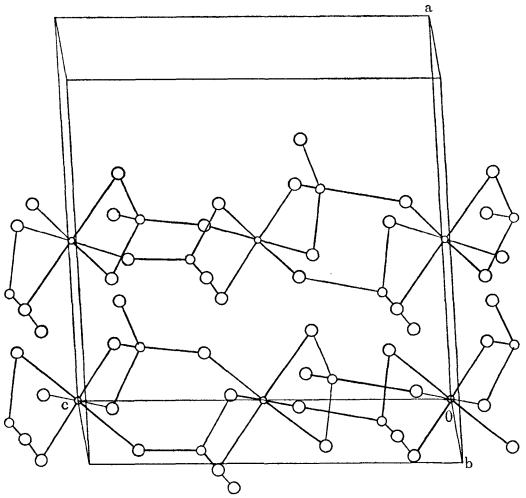

Fig. 2(c). Hypothetical crystal structure of $Cu(AlCl_4)_2$.

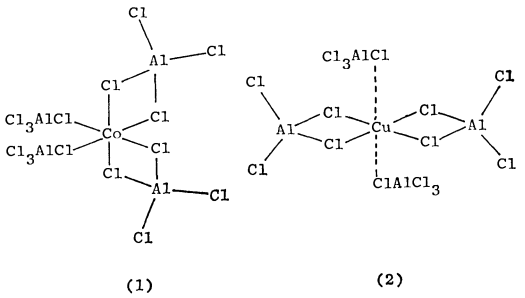

(1) (2)

The crystal structure of the present compound, like that of $Co(AlCl_4)_2$,[6] consists of layers parallel to the (001) plane, each containing atoms of one kind. The layers repeat in the sequence Cu–Cl–Al–Al–Cl. As shown in Fig. 3, the chlorine atoms are arranged in the unit cell in approximately hexagonal close-packed arrays like those observed with $Co(AlCl_4)_2$,[6] with copper and aluminium atoms occupying a part of the available octahedral and tetrahedral interstices, respectively. The volume per chlorine atom is 37.1 Å^3, which is slightly larger than the volume for $Co(AlCl_4)_2$,[6] 35 Å^3.

The essential difference between the two structures originates from the different intralayer arrangement of cobalt and copper atoms, and from the interlayer displacement of aluminium atoms in two successive layers. Thus, the hypothetical structure of $Co(AlCl_4)_2$ type could be generated from the observed structure of $Cu(AlCl_4)_2$ by simply translating metal atoms along the b axis in the way given in Fig. 2(b), though the obtained structure (Fig. 2(c)) as it is, has abnormalities in some of interatomic distances and bond angles. On the other hand, if cobalt atoms in $Co(AlCl_4)_2$ were replaced by copper atoms, these atoms would inevitably be in an octahedral geometry with nearly equal Cu–Cl distances. The structural difference between $Cu(AlCl_4)_2$ and $Co(AlCl_4)_2$[6] may result from the difference in preferred coordination geometries of the transition metals in this system.

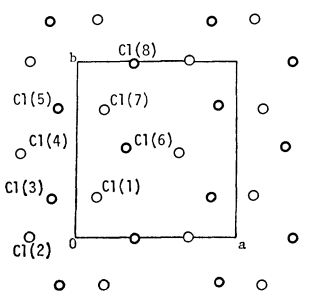

Fig. 3. Projection of chlorine layers.
The atoms drawn with thicker circles are nearer to the viewer.

The authors are grateful to Dr. Akio Takenaka for his advice in computer calculation and Professor Tominaga Keii for his helpful discussion.

Kinetic Studies of the Oxidation of L-Ascorbic Acid by the Peroxodisulfate Ion, and of Copper(II)-catalysis

Masaru KIMURA,* Akiko KOBAYASHI, and Keiko BOKU
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received October 5, 1981)

Kinetic studies of the oxidation reaction of L-ascorbic acid by the peroxodisulfate ion($S_2O_8^{2-}$) are carried out in an aqueous solution over the pH range of 3.4—4.6 at various ionic-strengths from 0.071 to 1.07 M (1 M= 1 mol dm^{-3}) with $NaClO_4$, and at four temperatures between 15 and 30 °C, at an ionic-strength of 1.07 M. The variations in the rate of the oxidation with the hydrogen-ion concentrations are consistent with the reaction schemes involving two pH-related species; ascorbic acid H_2A ($k_1=0.032$ M^{-1} s^{-1} at 25 °C, $\Delta H_1^{\ddagger}=17$ kJ mol^{-1}, $\Delta S_1^{\ddagger}=-220$ J deg^{-1} mol^{-1}) and the ascorbic anion HA^- ($k_2=0.43$ M^{-1} s^{-1} at 25 °C, $\Delta H_2^{\ddagger}=45$ kJ mol^{-1}, $\Delta S_2^{\ddagger}=-102$ J deg^{-1} mol^{-1}). A relationship of $\log k_2=-1.47+2.17\,I^{1/2}/(1+I^{1/2})$ is found with the ionic-strength (I) at 25 °C. The reaction rate is greatly catalyzed by the presence of trace amounts of the copper(II) ion; the mechanisms of the copper(II)-catalyzed reaction are discussed.

The peroxodisulfate ion is known as a powerful two-electron oxidizing agent, and its reactions with organic and inorganic substrates have been extensively studied by many researchers and reviewed by several authors.[1-4] Previously, we studied the kinetics of the oxidation reactions of oxalic acid,[5] formic acid,[6] the thallium ion,[7] and the silver(I) ion[8] by the peroxodisulfate ion in an aqueous solution. The present paper intends to propose a reaction mechanism and the kinetic parameters for the reaction between L-ascorbic acid and the peroxodisulfate ion in an acidic aqueous solution, and also to propose the kinetic properties of the copper(II) ion-catalyzed reaction for this reaction system.

Experimental

Reagents. Reagent-grade potassium peroxodisulfate was recrystallized twice from redistilled water and dried at 25 °C in a vacuum desiccator. L-ascorbic acid of a guaranteed-reagent grade of the Wako Pure Chemical Co., Ltd., was used without further purification. Solutions of peroxodisulfate and L-ascorbic acid were prepared just before each use. The sodium perchlorate used for adjusting the ionic-strength was purified by filtering the aqueous solution through filter-paper coated with activated carbon[9] and then recrystallized twice from redistilled water. The redistilled water was prepared from the deionized water by successive distillation of solutions with and without permanganate in a glass still. All the other chemicals used were guaranteed reagents of the Wako Pure Chemical Co., Ltd.

Reaction Solution. Preliminary experiments showed that (1) the rate of reaction decreased with a decrease in the pH in the reacting solution, and thus gradually became slow by the pH decrease, according to the progress of the reaction in an unbuffered solution for pH (refer to Table 1), and that (2) the rate of reaction was greatly catalyzed by a trace amount of the copper(II) ion (see Table 4 and Fig. 5); it seemed that the rate was slightly accelerated by the trace impurity of the copper(II) ion present in the reagents used (see line(2) in Fig. 3), and such a catalytic effect of the copper(II) ion was masked by the presence of ethylenediaminetetraacetate (EDTA) (see a closed mark (●) in Fig. 3 and also Table 4). Thus, we used pH buffer solutions of acetate-acetic acid involving 0.05 M in sodium acetate, and 0.005 M in disodium dihydrogen ethylenediaminetetraacetate (EDTA), as masking agents against the copper(II)-catalysis.

Kinetic Measurements. The reaction was started by mixing the peroxodisulfate solution with an L-ascorbic acid solution containing the pH buffer, EDTA, and sodium perchlorate. The pH value, ionic strength, and temperature of the reaction solution were kept constant at a given value. The reaction vessel was covered with black adhesive-plastic tape to ensure darkness and placed in a thermostat bath. Aliquot samples were withdrawn at appropriate times, and the concentration of the peroxodisulfate ion remaining was measured at 0.15 V *vs.* SCE (a saturated calomel electrode) by means of polarography in a solution of 0.05 M perchloric acid, 0.1 M sodium perchlorate, and 0.01% gelatin at 25 °C, essentially as has been described previously.[5-8] The gelatin was used as a maximum suppressor. Preliminary experiments showed that the rate of reaction between L-ascorbic acid and peroxodisulfate was so slow in a perchloric acid solution of 0.05 M that the loss of both the reactants during the period of about 5 min. needed for the measurement of the polarogram was, in practice, negligible. Since the reaction rate was not affected by the oxygen dissolved in a solution, the kinetic runs were carried out in solutions without removing the dissolved air, unless otherwise stated. The pH of the reacting solution was measured for the aliquot samples by the use of a Hitachi-Horiba M-5 pH meter. Sodium chloride was used instead of potassium chloride as the electrolyte in the reference electrode of the pH meter. The ionic strength was adjusted by the addition of sodium perchlorate. The activity coefficients f_i at varying ionic strengths (I) were obtained by using $\log f_i=-0.358\times Z_i^2\,I^{1/2}/(1+10^8\,a_i\times 0.2325\,I^{1/2})$ with $a_i=900$ pm and $Z_i=1$.[10] The activity coefficients used in this paper were 0.88 (0.071), 0.83 (0.2), 0.79 (0.47), and 0.77 (1.07), with the ionic strength in parentheses.

Results and Discussion

Stoichiometry. With concentration of 5.0×10^{-3} M for each reactant of peroxodisulfate and L-ascorbic acid, the concentrations of the reactants disappearing according to the reaction were determined at the reaction times. The results are shown in Table 1. The concentrations of peroxodisulfate and L-ascorbic acid were measured at 0.15 V *vs.* SCE and 0.375 V *vs.* SCE, respectively by means of polarography in a solution of 0.05 M perchloric acid, 0.1 M sodium perchlorate, and 0.01% gelatin at 25 °C. Under these conditions, only the reduction current of the peroxodisulfate ion was measured at 0.15 V, while the total

				Av. 0.98

a) The initial concentrations are: $[S_2O_8^{2-}]_i=[AA]_i=5.0\times10^{-3}$ M. Unbuffered solutions at an ionic strength of 0.02 M at 25 °C and in the dark.

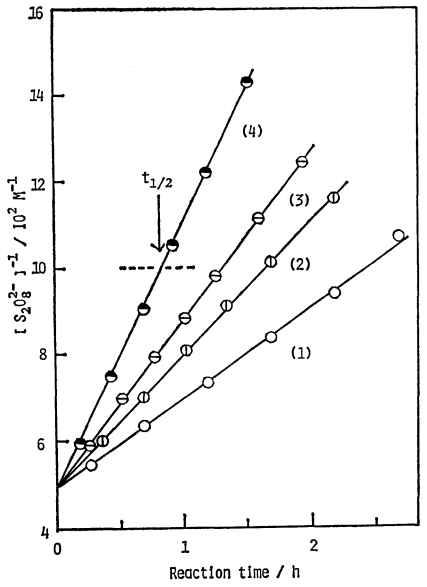

Fig. 1. Examples of plots of $[S_2O_8^{2-}]^{-1}$ *vs.* t (Eq. 1). The pH values are 3.50, 3.71, 3.90, and 4.40 for lines (1), (2), (3), and (4), respectively. Other conditions are the same as those of a) in Table 2 at an ionic strength of 0.47 M.

currents of reduction of the peroxodisulfate ion and of the oxidation of L-ascorbic acid were measured at 0.375 V. The results in Table 1 may indicate the stoichiometry to be 1:1. This stoichiometry was confirmed by kinetic experiments such as those illustrated in Fig. 1.

Kinetics of Reaction. The kinetic runs were carried out over the pH range from 3.3 to 4.6. In this pH range, the thermal decomposition of both peroxodisulfate and L-ascorbic acid was so slow that it could be neglected. When the reaction was started at the same concentrations for both reactants, the plots of $[S_2O_8^{2-}]^{-1}$ *vs.* t were rectilinear; some examples of the plots are given in Fig. 1. Thus, the empirical rate law may be written as follows:

$$-d[S_2O_8^{2-}]/dt = -d[AA]/dt = k_0[AA][S_2O_8^{2-}] \quad (1)$$

where k_0 is the observed second-order rate constant and where [AA] indicates the total concentration of all the forms of L-ascorbic acid and can be set as $[H_2A]+[HA^-]$ in the present pH range. The rate constants (k_0) were determined by treating plots of $[S_2O_8^{2-}]^{-1}$ *vs.* t with a least-squares method. The values of k_0 obtained are given in Table 2. The plots of k_0 *vs.* $K_1/(K_1+[H^+])$ showed a straight line with an intercept; some examples of the plots are given in Fig. 2. Thus, the relationship of the k_0 with $[H^+]$ is accounted for by Eq. 2, consistent with the reaction mechanisms (*v.i.*):

$$k_0 = k_1 + (k_2-k_1)\frac{K_1}{[H^+]+K_1}, \quad (2)$$

where K_1 is the first acid-dissociation constant of L-ascorbic acid of Eq. 3. The rate constants, k_1 and k_2, were determined by treating plots of k_0 *vs.* $K_1/([H^+]+K_1)$ with a least-squares method; they are listed in Table 3. The values of K_1 were necessary for making the plots such as in Fig. 2. Recently,[11] we determined the K_1 values by the pH titration of L-ascorbic acid under various conditions. The values of pK_1 used in this work are as follows: at an ionic strength of 1.07 M (with the temperature (°C) in parentheses): 4.04 (15), 4.00 (20), 3.95 (25), and 3.90 (30), and at 25 °C (with the ionic strength in parentheses): 4.09 (0.071), 4.00 (0.2), and 3.96 (0.47).

Mechanisms of Reaction. The following three schemes can be presented to account for the empirical results:

$$H_2A \overset{K_1}{\rightleftharpoons} HA^- + H^+ \quad (3)$$

Scheme 1:

$$H_2A + S_2O_8^{2-} \xrightarrow{k_1} 2SO_4^{2-} + A + 2H^+ \quad (4)$$

$$HA^- + S_2O_8^{2-} \xrightarrow{k_2} 2SO_4^{2-} + A + H^+ \quad (5)$$

Scheme 2:

$$H_2A + S_2O_8^{2-} \xrightarrow{k_1} (H_2A^+ + SO_4^{\cdot-} + SO_4^{2-}) \xrightarrow{\text{fast}} 2SO_4^{2-} + A + 2H^+ \quad (6)$$

$$HA^- + S_2O_8^{2-} \xrightarrow{k_2} (HA\cdot + SO_4^{\cdot-} + SO_4^{2-}) \xrightarrow{\text{fast}} 2SO_4^{2-} + A + H^+ \quad (7)$$

Scheme 3:

$$H_2A + S_2O_8^{2-} \xrightarrow{k_1} H_2A^+ + SO_4^{\cdot-} + SO_4^{2-} \quad (8)$$

$$H_2A + SO_4^{\cdot-} \longrightarrow H_2A^+ + SO_4^{2-} \quad (9)$$

$$S_2O_8^{2-} + H_2A^+ \longrightarrow SO_4^{\cdot-} + SO_4^{2-} + A + 2H^+ \quad (10)$$

a) The initial concentrations are 2.0×10^{-3} M for potassium peroxodisulfate and L-ascorbic acid, 5×10^{-3} M in disodium dihydrogen ethylenediaminetetraacetate (EDTA), 0.05 M in sodium acetate, and the given concentrations of acetic acid and sodium perchlorate. b) In the presence of 1% acrylonitrile; the other conditions are the same as those in a). c) In the absence of EDTA; the other conditions are the same as those in a). d) In the presence of 1×10^{-6} M in copper(II) sulfate; the other conditions are the same as those in a).

$$H_2A^+ + SO_4^{\cdot-} \xrightarrow{\text{fast}} SO_4^{2-} + A + 2H^+ \quad (11)$$

$$HA^- + S_2O_8^{2-} \xrightarrow{k_2} HA\cdot + SO_4^{\cdot-} + SO_4^{2-} \quad (12)$$

$$HA^- + SO_4^{\cdot-} \longrightarrow HA\cdot + SO_4^{2-} \quad (13)$$

$$S_2O_8^{2-} + HA\cdot \longrightarrow SO_4^{\cdot-} + SO_4^{2-} + A + H^+ \quad (14)$$

$$HA\cdot + SO_4^{\cdot-} \xrightarrow{\text{fast}} SO_4^{2-} + A + H^+, \quad (15)$$

where A represents dehydroascorbic acid; dehydroascorbic acid is known as the final product in the oxidation of L-ascorbic acid by many oxidizing agents;[12] the presence of free radicals of H_2A^+ and HA· in the oxidation of L-ascorbic acid has been confirmed by ESR measurements and kinetic investigations by many researchers.[12] Every one of the above three schemes is consistent with the empirical rate law of Eqs. 1 and 2. For the purpose of examining whether or not the reaction occurs *via* a successive one-electron transfer involving the free radicals, as in schemes 2 and 3, the acrylonitrile of a radical scavenger was added to the reaction solution at the initiation of the reaction. The results are given in Table 2 and Fig. 3; the polyacrylonitriles were not

$\Delta H_1^* = 17\pm5$ kJ mol^{-1} $\Delta S_1^* = -220\pm20$ J deg^{-1} mol^{-1}
$\Delta H_2^* = 45\pm1$ kJ mol^{-1} $\Delta S_2^* = -102\pm4$ J deg^{-1} mol^{-1}

a) The conditions are the same as those of a) in Table 2.

found in the reacting solution, and the reaction rate appeared to be a little slower than that in the absence of acrylonitrile. In most of the previous works on peroxodisulfate reactions,[5-8] the acrylonitrile was a strong retarder of the reaction rate, forming polyacrylonitrile as a white sediment. Thus, the acrylonitrile effect obtained in this work was extraordinarily different from most cases of peroxodisulfate reactions; this may indicate, at least apparently, a two-electron transfer reaction without forming radicals, *i.e.*, Scheme 1. Scheme 2 will be not very sensitive to the presence of a radical scavenger, while Scheme 3 is probably very sensitive to such a scavenger for radicals.

Temperature Dependence. The activation parameters corresponding to the specific rate constants are shown in Table 3. The values of both $\Delta H_1^{\ddagger}$ and $\Delta S_1^{\ddagger}$ are smaller than those of $\Delta H_2^{\ddagger}$ and $\Delta S_2^{\ddagger}$. Although the k_1 values were much smaller than the k_2 values over the temperature range of 15—30 °C, the k_1 should become larger than the k_2 at temperatures lower than −36 °C, which is obtained as the isokinetic temperature by using the kinetic parameters. In most of the oxidation reactions of L-ascorbic acid, the values of k_1 are much smaller than those of k_2. For example, the k_2/k_1 ratio at 25 °C (with the oxidizing agent in parentheses) is 13 (peroxodisulfate) at I=1.07 M in this work, 34 (tris(oxalato)cobaltate(III)),[11] 3.7×10^3 (tris(1,10-phenanthroline)iron(III),[11] 6×10^2 (thioureapentacyanoferrate(III)),[13] and 1.3×10^3 (hexacyanoferrate(III)).[14] The trend toward less negative $\Delta S^{\ddagger}$ values on going from H_2A to HA^- is similar to that ($\Delta S_1^{\ddagger}=-192$ J deg^{-1} mol^{-1}; $\Delta S_2^{\ddagger}=-134$ J deg^{-1} mol^{-1}) found in the reaction of L-ascorbic acid with thioureapentacyanoferrate(III).[13] The larger $\Delta H_2^{\ddagger}$ values than $\Delta H_1^{\ddagger}$ indicate the stronger hydration for HA^- than that for H_2A.

Ionic Strength Dependence. Although the ionic-strength values employed in this work lie outside the Debye-Hückel region, plots of $\log k_2$ *vs.* $I^{1/2}/(1+I^{1/2})$ showed a straight line, with a relationship of $\log k_2 = -(1.47\pm0.02) + (2.17\pm0.04)I^{1/2}/(1+I^{1/2})$. This dependence is as expected for the reaction between two ions of a like sign; the positive value of 2.17 is in good agreement with that of 2.04 which is obtained from the theoretical term of $1.02Z_aZ_b\times I^{1/2}/(1+I^{1/2})$ with $Z_a=-1$ for HA^- and $Z_b=-2$ for $S_2O_8^{2-}$.

Effect of the Copper(II) Ion. When the reaction solution did not contain EDTA, the k_0 values increased to some extent (see line(2) in Fig. 3). However, such an increase in k_0 was depressed by the presence of EDTA (see line(1) in Fig. 3) and thus, was thought to be due to the copper(II) ion present as an impurity in the reaction solution; most of the copper(II)-ion impurity may come from the acetate-buffer solutions used. Moreover, it was found that the rate of reaction between L-ascorbic acid and peroxodisulfate was greatly accelerated by the presence of trace amounts of the copper(II) ion, and that the copper(II)-catalyzed reaction rate was: (1) indifferent to the presence or absence of oxygen, (2) retarded completely by the

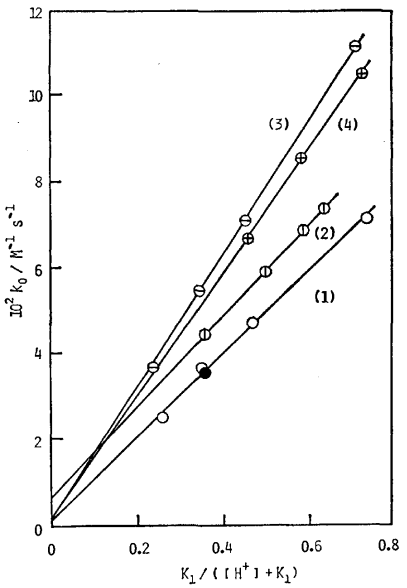

Fig. 3. Effects of acrylonitrile, EDTA, and copper(II) ion (as an impurity) on the rate constant k_0 in Eq.1 at an ionic strength 0.07 M and at 25 °C.
Line (1) indicates the results in the presence of 5×10^{-3} M in disodium dihydrogen ehthenediaminetetraacetate (EDTA); line (2) indicates the results in the absence of EDTA under the other conditions same as those in line (1); line (3) indicates the results at an ionic strength 0.2 M under the other conditions same as those in line (1); line (4) indicates the results in the presence of 1% acrylonitrile under the other conditions same as those in line (3); a plot ● in line (1) indicates a result in the presence of 1×10^{-6} M in copper(II) sulfate under the conditions same as those in line (1).

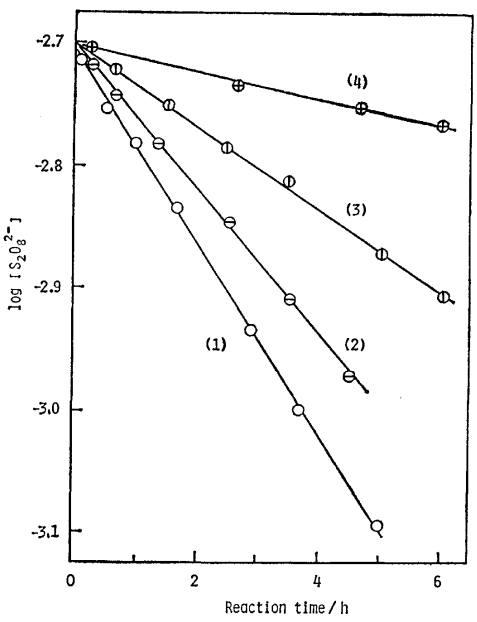

Fig. 4. Examples of plots of log $[S_2O_8^{2-}]$ *vs.* t (Eq. 16). Initial concentrations of L-ascorbic acid are 0.03, 0.02, 0.01, and 0.002 M for lines (1), (2), (3), and (4), respectively. The catalyser's concentration is 2×10^{-6} M in copper(II) sulfate. Other conditions are the same as those of a) in Table 5.

presence of EDTA, and (3) not retarded by the presence of acrylonitrile; nevertheless, polyacrylonitrile in the forms of a white sediment was obviously found in the reacting solution. These effects are shown in Table 4. When pseudo first-order conditions were satisfied, the plots of log $[S_2O_8^{2-}]$ *vs.* t were rectiliniear up to at least the half-time ($t_{1/2}$) of reaction. Some examples are given in Fig. 4. The rate constants, $k_{cat.}$, in Eq. 16 were obtained under various conditions. The results are given in Table 5. Plots of both $k_{cat.}$ *vs.* $[Cu(II)]_i$ and $k_{cat.}$ *vs.* $[AA]_i$ showed straight lines with intercepts. Some examples of plots of $k_{cat.}$ *vs.* $[Cu(II)]_i$ are given in Fig. 5. These relationships can be described by Eqs. 16 and 17:

$$-d[S_2O_8^{2-}]/dt = k_{cat.}[S_2O_8^{2-}] \quad (16)$$

$$k_{cat.} = k_a[Cu(II)]_i + (k_b + k_c[Cu(II)]_i)[AA]_i$$
$$= k_b[AA]_i + (k_a + k_c[AA]_i)[Cu(II)]_i, \quad (17)$$

where [ ]$_i$ indicates the concentration at the initial stage of reaction. The values of k_a ($M^{-1}s^{-1}$), k_b ($M^{-1}s^{-1}$), and k_c ($M^{-2}s^{-1}$) were determined at 25 °C to be: $k_a=2.0$, $k_b=5.5\times10^{-4}$, $k_c=5.6\times10^2$ at pH 2.1, and $k_a=1.5\times10^2$, $k_b=5.0\times10^{-2}$, $k_c=7.1\times10^5$ at

Table 4. Effects of oxygen, acrylonitrile (AN), and EDTA on the rate of the copper(II)-catalyzed reaction

20	—	0.73	—	—	—	2.17	3.75	4.95

a) The conditions are $[S_2O_8^{2-}]_i=2.0\times10^{-3}$ M, $[HClO_4]=0.01$ M (pH 2.1), and in solutions containing dissolved air at 25 °C (in the dark). b) The conditions are the same as those in a), but the pH value in 4.31 in the 0.05 M sodium acetate—0.1 M acetic acid solution, with no perchloric acid ($HClO_4$) added. The values of $k_{cat.}$ in this case were evaluated by using the initial slope of the plots of $[S_2O_8^{2-}]$ *vs.* t with a relationship of $-\Delta[S_2O_8^{2-}]_i/\Delta t = k_{cat.}[S_2O_8^{2-}]_i$. c) The conditions are the same as those in a), but in a solution saturated with pure nitrogen gas.

pH 4.31. The k_b corresponds to the rate constant for the uncatalyzed-reaction path, while the rate constants k_a and k_c are those for the catalyzed-reaction paths. The ratios of $k_b:k_a:k_c$ were $1:3600:1\times10^6$ at pH 2.1 and $1:3000:1.4\times10^7$ at pH 4.31. These values indicate that the copper(II) ion is very strong catalyst for the reaction between L-ascorbic acid and peroxodisulfate. It is obvious that the copper(II)-catalyzed reaction is complosed of a chain reaction of the redox cycle of Cu(I) and Cu(II), and that the origin of the reaction mechanism can be written as follows:

$$\left\{\begin{array}{c}H_2A\\ \uparrow\downarrow H^+\\ HA^-\end{array}\right\} + Cu^{2+} \rightleftharpoons Cu^+ + \text{Radicals} \qquad (18)$$

$$S_2O_8^{2-} + Cu^+ \longrightarrow Cu^{2+} + SO_4^{\cdot-} + SO_4^{2-}. \qquad (19)$$

The rate constant for Reaction 19 has been reported as $1.4\times10^3\ M^{-1}\ s^{-1}$ in 1 M potassium chloride at 25 °C,[15] about 100-fold that for Reaction 20:

$$O_2 + Cu^+ \longrightarrow Cu^{2+} + O_2^-. \qquad (20)$$

Recently, Ito *et al.*[16] reported that the rate of Reaction 18 was 5×10^5-fold faster than that of Reaction 20. Therefore, it can be said that Reaction 20 hardly ever occurs in a catalyzed reaction, even in an air-saturated solution. This is consistent with the fact that the catalyzed-reaction rate is utterly indifferent to the presence or absence of oxygen (see Table 4). The strong inhibition effect of EDTA on the catalyzed reaction is attributable to the retardation of Reaction 18 by the complex formation of EDTA with the copper (II) ion. Separate, preliminary experiments showed that Reaction 18 was retarded by either nitrilotriacetate (NTA) or oxalate as well as by EDTA. The acrylonitrile effect may be accounted for by the following reactions:

$$X + Cu^{2+} \rightleftharpoons Cu^+ + X^{\cdot+} \qquad (18)$$

$$S_2O_8^{2-} + Cu^+ \longrightarrow Cu^{2+} + SO_4^{\cdot-} + SO_4^{2-} \qquad (19)$$

$$Cu^+ + SO_4^{\cdot-} \longrightarrow Cu^{2+} + SO_4^{2-} \qquad (21)$$

$$Cu^{2+} + X^{\cdot+} \longrightarrow Cu^+ + \text{Products} \qquad (22)$$

$$X^{\cdot+} + SO_4^{\cdot-} \longrightarrow SO_4^{2-} + \text{Products}, \qquad (23)$$

where $X=H_2A+HA^-$ and $\text{Products}=A+H^+$. The backward reaction of (18) and Reaction 19 are competing with Reactions 20 and 21. Thus, when the acrylonitrile scavenged the radicals of $SO_4^{\cdot-}$ and/or $X^{\cdot+}$, the rate of the forward reactions of (18) and (19) might be accelerated. Actually, polyacrylonitrile was found in the reacting solutions upon the addition of acrylonitrile of the monomer, indicating the removal of the radicals, and the copper(II)-catalyzed reaction was a little accelerated by the presence of acrylonitrile (see Table 4). On the other hand, no clearly rational explanations could be made for the fact that the rate in the presence of 1% acrylonitrile is slightly slower than that in the 0.5% acrylonitrile; the propagating radical of an acrylonitrilepolymer may react with the copper(I) ion, competing with Reaction 19 or other competing reactions may occur.

(Received October 16, 1981)

Fundamental structure, k_F and $2k_F$ satellite reflections, and electrical properties of $Ni_{0.84}[Pt(C_2O_4)_2]\cdot 6H_2O$ (Ni–OP) were determined. Complex Ni–OP crystallizes in the orthorhombic space group Pccn with cell parameters of $a=14.296(2)$, $b=16.387(3)$, and $c=5.671(1)$ Å and $Z=4$. Ni–OP is essentially isostructural with Mg–OP ($Mg_{0.82}[Pt(C_2O_4)_2]\cdot 5.3H_2O$) and Co–OP ($Co_{0.83}[Pt(C_2O_4)_2]\cdot 6H_2O$). The space group of Mg–OP and Co–OP is Cccm. Owing to the change in the space group, there are two independent Pt chains in Ni–OP. X-Ray studies of M–OP (M=Co, Ni) show that there exist strong k_F satellite spots and weak $2k_F$ spots. One M^{2+} cation is vacant per period of the lattice modulation wave of the platinum chain, λ_{2k_F}. The periodic cation defect induces the k_F modulation waves. The $2k_F$ waves do not have a Peierls origin but are induced by the k_F modulation wave. A second order phase transition is observed at about 305 K above which the $2k_F$ spots disappear.

In recent years partially oxidized cyanoplatinates and bis(oxalato)platinate complexes have been attracting much interest because of their quasi-one-dimensional metallic behavior.

The prototype compound $K_2[Pt(CN)_4]Br_{0.3}\cdot 3.2H_2O$ (KCP(Br)) undergoes a gradual transition from a room temperature one-dimensional conductor state to a low temperature insulating state. Observations of a giant Kohn anomaly and a low temperature three-dimensional superlattice have been proposed as evidence for the Peierls transition with this compound. The nature of sinusoidal modulation of the one-dimensional platinum chain has been investigated by many workers through various neutron and X-ray diffuse scattering studies.[1–3]

One-dimensional metallic system is unstable at low temperature and exhibits lattice distortions with a wave number equal to twice the Fermi momentum ($2k_F$). The period of a Peierls distorted cell is determined by the degree of partial oxidation (DPO).[4]

Bis(oxalato)platinate salts have the formula $M_x[Pt(C_2O_4)_2]\cdot yH_2O$ (M–OP). For bivalent cations Mg^{2+}, Zn^{2+}, Mn^{2+}, Ni^{2+}, and Cu^{2+}, $0.81<x<0.84$ and $y\approx 6$.[5–8, 10,11] For monovalent cations NH_4^+, Rb^+, and K^+, $1.6<x<1.81$ and $y=1$—4.

In the present paper, fundamental structure, X-ray satellite reflections (k_F and $2k_F$), and diffuse scattering of Ni–OP are reported together with electrical conductivity measurements and 2nd-order phase transition.

Experimental

Ni–OP was prepared by the method previously reported.[6] A crystal of $0.43\times 0.36\times 0.01$ mm³ was used for data collection. Data were collected on a Rigaku automated diffractometer equipped with a graphite monochromator.

Crystal data:

$a=14.296(2)$, $b=16.387(3)$, and $c=5.671(1)$ Å,

$V=1328.54$ Å³, $Z=4$, $d_{calcd}=2.643$ g cm^{-3}, and $\mu=123.32$ cm^{-1} (Mo $K\alpha$ radiation, $\lambda=0.71069$ Å).

Intensity data were collected with monochromatized Mo $K\alpha$ radiation by the ω-2θ scan technique up to $2\theta=60°$. Corrections were made for the Lorentz and polarization factors. Data revealed systematic extinctions consistent with the orthorhombic space group Pccn. The space group of Mg–OP and Co–OP is Cccm.[5,8] Data were corrected for absorption. Initial locations of the Pt and Ni atoms were assumed from the structure of Co–OP. Positions of the oxalate ligand atoms and independent oxygen atoms coordinated to the Ni^{2+} ion were determined by the standard Fourier and least-squares refinement procedures. Site occupancies of the Ni atoms and four independent oxygen atoms of water molecules were determined by use of the full matrix least-squares program LINUS. Site occupancies are 0.415(6) for Ni, 0.90(4), 0.84(4), and 0.81(4) for the coordinated O atoms, and 1.05(4) for the uncoordinated O atoms. For the three coordinated oxygen atoms, site occupancies are almost equivalent and nearly equal to twice the Ni site occupancy. Discrepancy indexes are $R(|F_o|)=0.050$ and $Rw(|F_o|^2)=0.069$. The weighting scheme used was $w^{-1}=\sigma^2(|F_o|)+c|F_o|^2$, where the value of c is 0.02, as estimated from the fluctuation of intensities of the standard reflections. The atomic coordinates of Pt are (0.25, 0.25, 0.0177). The Z coordinate deviates ≈ 0.1 Å from the $Z=0$ point. This deviation causes the lattice change from C to P. Positional parameters determined from the final least-squares cycle are presented in Table 1. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[12] Calculations were performed on the HITAC 8800/8700 computer at the Computer Centre of the University of Tokyo. $|F_o|-|F_c|$ tables and thermal parameters are kept at the Office of this Bulletin as Document No. 8227.

Results and Discussion

Fundamental Structure. The c axis and a axis projections of the structure of Ni–OP are shown in Fig. 1. Bond lengths and bond angles are almost the same as those of Co–OP within 3σ. Slight differences of bond lengths and angles are found in the hexahydrated cations. The main structural difference

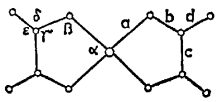
a) A: $Mg_{0.82}[Pt(C_2O_4)_2]\cdot 5.3H_2O$; B: $Co_{0.83}[Pt(C_2O_4)_2]\cdot 6H_2O$; C: $K_2[Pt(C_2O_4)_2]\cdot 2H_2O$; D: $Ni_{0.84}[Pt(C_2O_4)_2]\cdot 6H_2O$.



between Ni–OP and Co–OP (Mg–OP) is in the different space groups Pccn for Ni–OP and Cccm for Co–OP (Mg–OP). This fact indicates that there are two independent Pt chains in Ni–OP.

Within a platinum chain, oxalate ligands are staggered with respect to the ligands located directly above and below them. The staggered angles are approximately 55°. There are two platinum atoms per unit cell in the c-direction with spacing $c'=c/2=$ 2.836 Å. The Ni^{2+} ions are located between the planes containing $[Pt(C_2O_4)_2]^{x-}$ ions and are coordinated by six water molecules with slightly distorted octahedral symmetry. Table 2 shows averaged molecular structures of the anion. The Pt–O distance is 2.00(1) Å on the average. The O–Pt–O angles is 83.6(4)°, the C–O bond distance in the five-membered ring is 1.30(2) Å, and the C–C distance is on the average 1.55(2) Å. The molecular structure of partially oxidized bis(oxalato)platinate complexes with bivalent metal cations (Ni, Co, and Mg) is approximately equal to the molecular structure with $[Pt(C_2O_4)_2]^{2-}$ anion in $K_2[Pt(C_2O_4)_2]\cdot 2H_2O$.[5,8,13] In a cobalt bis(oxalato)platinate salt, a new water site which is not within the Co^{2+} coordination sphere was found. The Ni^{2+} salt also contains this additional water molecule, which was not found in the Mg^{2+} salt. The neighboring Pt chains are linked by hydrogen bonds involving the water molecules. Table 3 compares the bond lengths and angles around each cation in Ni–OP, Co–OP, and Mg–OP.

k_F, $2k_F$ Satellite Reflections. The structure was solved by using intensities of the main reflections. However, characteristic satellite reflections and diffuse scattering are observed on X-ray photographs indi-

cating that the lattice is periodically modulated. Extra reflections are located at $\boldsymbol{G}(hkl)+nk_F\boldsymbol{c}^*$ $(n=1,2,\cdots)$ and classified into three groups:

I) k_F Satellite Reflections: Intensities of the k_F satellite reflections are comparatively strong.

Satellites are located near the a* and a*±b* axes. Since some of these are accompanied by very weak 2nd order satellite reflections ($2k_F$ spots), these k_F satellites are considered to be associated with the sinusoidal modulation wave whose displacement vector is parallel to the a and a±b axes, perpendicular to the direction of wave propagation c*. The intensity of the n-th satellite spot of the sinusoidally modulated structure is proportional to the square of the Bessel function $J(2\pi(p\xi+g\eta+r\zeta))$, where (ξ,η,ζ) is the position in the reciprocal space $(\zeta=l+nk_F)$ and $p\boldsymbol{a}/a+q\boldsymbol{b}/b+r\boldsymbol{c}/c$ is the amplitude vector of the modulation wave (see Figs. 2, 3, and 4).†††

In addition to this, strong k_F satellite reflections are observed at low 2θ-values which appear not to originate from the sinusoidal modulation of lattice.

II) $2k_F$ Satellite Reflection: There are two kinds of $2k_F$ satellites.

(IIa) The 2nd order satellites originating from the transverse modulation wave with a wave vector k_F as shown in Fig. 2, which are observed around the a* and a*±b* axes.

(IIb) Satellite reflections which are weaker than k_F spots observed around the c* axis. This corresponds to a modulation satellite in Co-OP. Since these spots are observed around the c* axis, the amplitude vector of modulation may be nearly parallel to c*, which is parallel to the wave propagation vector. This is, therefore, a longitudinal modulation wave (see Figs. 2 and 4).

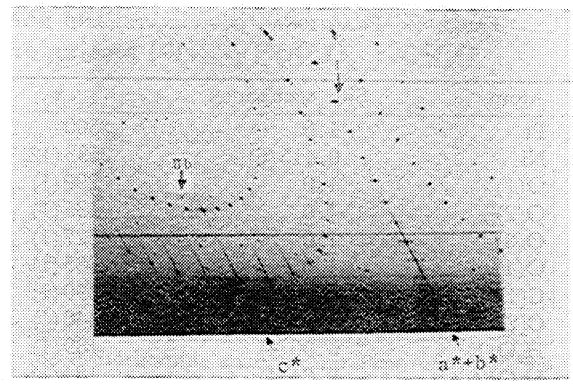

Fig. 2. Weissenberg photograph of the zero layer of the a-b axis of Ni-OP.
I and IIb satellite spots are shown.

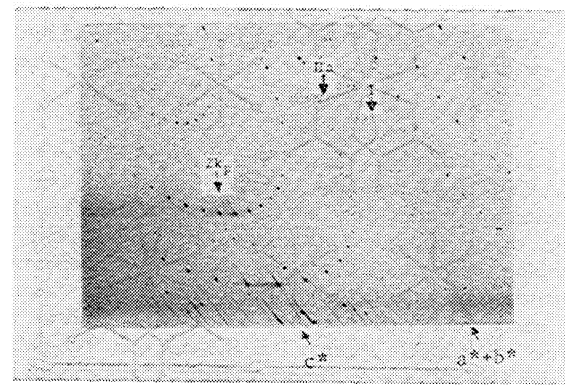

Fig. 3. Weissenberg photograph of the first layer of the a-b axis of Ni-OP showing I and IIa satellite spots and the $2k_F$- diffuse scattering (III).

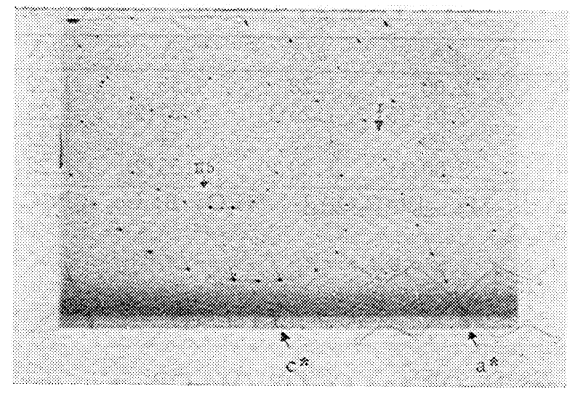

Fig. 4. Weissenberg photograph of an *h0l* reciprocal layer showing I and IIb satellite spots.

III) $2k_F$-Diffuse Scattering: This is the X-ray diffuse scattering distributing around the c* axis (see Fig. 3). As indicated by Braude *et al.*,[9-10] this scattering appears to be based on the low-frequency longitudinal lattice vibration with the Peierls origin. However, temperature dependence of the $2k_F$ diffuse scattering must be investigated in order to elucidate its origin.

The X-ray diffraction pattern described above suggests that the superstructure of Ni-OP is very complicated. The displacive periodic antiphase model of Bertinotti[14] suggests that the superstructure is formed by displacements of the oxalate ligands from the Pt

†††A. Bertinotti *et al.*[14] proposed a displacive periodic antiphase model for Co-OP. They found two kinds of satellite reflections. One appears for each $l=2n$ at h, k, $l\pm 1/2M$ where $h+k=2n+1$ and the value of M is 3.25, and the other appears at h, k, $l\pm 1/M$ where $h+k=2n$. The former corresponds to k_F spots and the latter to $2k_F$ spots. For Ni-OP, the extinction rule is more complicated and there are weak reflections which are not in accord with it.

atom in the transverse direction and that these displacements form the antiphase domain with the period $2M$.

The coexistence of $2k_F$ and k_F spots is a common feature of one-dimensional bis(oxalato)platinate complexes with bivalent cations. However, in general, the origin of $2k_F$ spots in bis(oxalato)platinate complexes with univalent cations will be a Peierls instability of the Pt chain.

Cation Distribution. In one-dimensional bis(oxalato)platinate complexes with bivalent cations, the relationship between the degree of partial oxidation (DPO) and the $2k_F$ value is as follows: DPO$=2(1-x)$, $k_F=\pi x/c$, and $2k_F'=2\pi/c-2k_F=(2\pi/c)(1-x)$. In the crystal lattice $2k_F'$ and $2k_F$ are equivalent. The wavelength of the $2k_F'$ (or $2k_F$) wave is $\lambda_{2k_F'}=c/(1-x)$. For example, when x is 0.84, $\lambda_{2k_F'}$ is $6.3c$ and $\lambda_{k_F'}$ is $12.6c$. The structure of bis(oxalato)platinate complex indicates that two cation sites exist within a tunnel. The arrangement of $[M(H_2O)_6]^{2+}$ is shown in Fig. 5. These cations cannot occupy both sites A and B (see Fig. 1b) due to a strong cation-cation Coulomb repulsion. If the cation sites are 50% occupied, each chain of $[M(H_2O)_6]^{2+}$ ions will be an ordered array of alternating vacant and occupied M sites. However, with 42% occupancy, one M^{2+} cation is vacant per one period of the $2k_F'$ wave of the platinum chain $\lambda_{2k_F'}$. Therefore, the cation site has a period of $\lambda_{k_F'}$.

This model satisfactorily explains the fact that k_F reflections are commonly observed with the bivalent bis(oxalato)platinate complexes but that they are not observed in the univalent complexes. The k_F spots are stronger than the usual $2k_F$ spots observed in the modulation structure. The presence of periodic cation defects will result in deformation of the surrounding structure. The neighboring cations and $[Pt(C_2O_4)_2]$ anions will move to fill up the vacancy and this produces modulation waves with a period of $\lambda_{k_F'}$. This may be the origin of k_F modulations.***

In one-dimensional systems, the origin of $2k_F$ waves and the lattice distortion are generally considered to have a relation to the Peierls instability. However, Braude *et al.*[10] from X-ray diffraction patterns proposed that $2k_F$ spots in Co–OP have a non-Peierls origin. In the bivalent bis(oxalato)platinate complexes, there exists a strong k_F lattice distortion, which has no direct relation to the Peierls instability.

Origin of the $2k_F$ Wave. In order to elucidate the origin of $2k_F$ satellite spots (IIb) and the relationship between $2k_F$ and k_F spots, we examined temperature dependence of X-ray diffraction spots. In Fig. 6 Weissenberg photographs at 295 K (6a) and 305 K (6b) are shown. The $2k_F$ spots disappear at 305 K, although the k_F spots are visible in this temperature range. In the bivalent complexes, the k_F spots are stronger than the $2k_F$ spots. Since periodic cation defects are the origin of k_F modulation, k_F spots can be thought to have no strong temperature dependence. From the X-ray diffraction experiments at high temperatures and the phase transition theory applied to K_2SeO_4 by Iizumi *et al.*,[15] the $2k_F$ wave may be considered to be induced by the primary k_F lattice distortion wave.†††

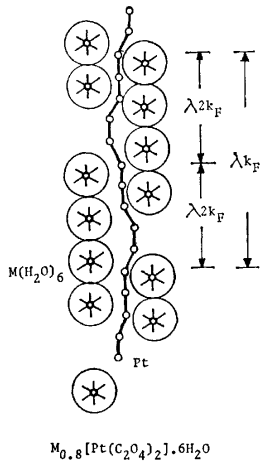

Fig. 5. The schematic arrangement of $[M(H_2O)_6]^{2+}$ is shown.
The cation is octahedrally surrounded by six water molecules. One M^{2+} cation is vacant per one period of the $2k_F$ wave of the platinum chain λ_{2k_F}. The cation site has a period of λ_{k_F}.

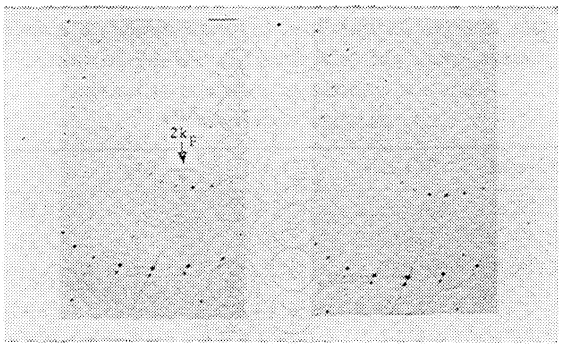
Electrical Resistivity Measurements. Results of the electrical resistivity study are shown in Fig. 7. DC resistivity was measured by use of the four probe method. Measurements were made on several specimens along the needle axis parallel to the Pt chains of crystal. Electrical contacts were made by four 0.025 mm gold wires attached with aquadag. The conductivity at room temperature is 5 $(\Omega\cdot cm)^{-1}$ and dI_NR/dT^{-1} diverges at about 305 K. This result agrees well with that of Watkins *et al.*[6] The anomaly at 305 K is in good agreement with the temperature at which the $2k_F$ spots begin to vanish. Therefore, this phase transition temperature corresponds to the temperature at which the secondary lattice distortion wave

***The k_F modulation is not simple since there are two types of k_F spots. However, the presence of transverse modulation spots suggests that k_F modulations contain a transverse sinusoidal component.

†††When there exists a lattice distortion wave with a wave vector $\boldsymbol{q}$ in the crystal, the atomic displacement is written as $\boldsymbol{u}=Q(\boldsymbol{q})\exp i\boldsymbol{q}.\boldsymbol{r}$. According to the phase transition theory applied to K_2SeO_4 by Iizumi,[15] the free energy of the modulated system is written as:

$$\mathbf{V}^{(1)}Q(\boldsymbol{q}_1)^2+\mathbf{V}^{(2)}Q(\boldsymbol{q}_2)^2+\cdots\mathbf{V}^{(n)}(\boldsymbol{q}_1,\boldsymbol{q}_2)Q(\boldsymbol{q}_1)^{n-1}Q(\boldsymbol{q}_2), \quad (1)$$

where $\mathbf{V}^{(n)}$ is the n-th energy factor, $Q(\boldsymbol{q}_1)$ is the amplitude of a primary lattice distortion which is characterized by the wave vector $\boldsymbol{q}_1$, and $Q(\boldsymbol{q}_2)$ is the amplitude of a secondary lattice distortion which is induced by the translational invariance, $(n-1)\boldsymbol{q}_1+\boldsymbol{q}_2=\boldsymbol{G}$, where $\boldsymbol{G}$ is a reciprocal-lattice vector or zero. Since the k_F spots in these bivalent bis(oxalato)platinate complexes are stronger than the usual $2k_F$ spots originating from the Peierls modulated lattice, the k_F wave can be regarded as the primary lattice distortion wave. Then the secondary lattice distortion wave is induced from the third energy term $(Q(\boldsymbol{k}_F)^2-Q(-2\boldsymbol{k}_F))$, whose wave number $\boldsymbol{q}_2$ is equal to $2\boldsymbol{k}_F$.



(a) (b)

Fig. 6 Weissenberg photograph of zero layer of diagonal axis a+b of Ni-OP at 295 K(6a) and 305 K(6b) are shown.
The exposure time of Cu $K\alpha$ radiation was 24 h. $2k_F$ spots (IIb) are visible at 295 K and vanish at 305 K.

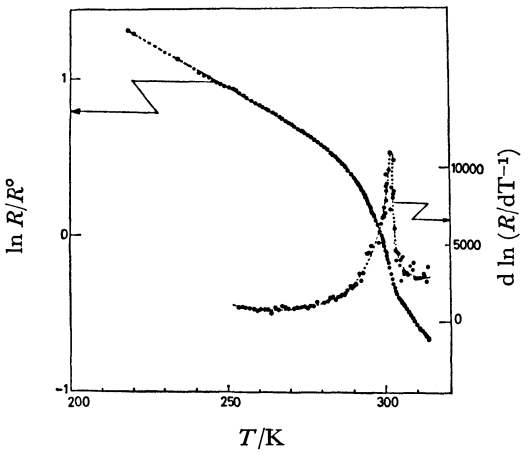


Fig. 7. The electrical resistivity measurements of Ni-OP is shown.
$dI_N R/dT^{-1}$ diverges at about 305 K. This anomaly corresponds to the temperature at which $2k_F$ spots are vanishing.

vanishes.

In order to understand lattice distortion waves of bis(oxalato)platinate complexes in crystal, precise structural studies and theoretical considerations on superstructures must be performed.

(Received October 22, 1981)

A procedure is described for the spectrophotometric determination of iron(III) at ppm levels with 5-chloro-7-iodo-8-quinolinol. Iron(III) reacts with the reagent in an acidic solution to form a water-insoluble blue-black complex, which can be quantitatively adsorbed on the surface of freshly precipitated microcrystalline naphthalene at room temperature. The separated iron(III) complex is dissolved in *N,N*-dimethylformamide, together with the naphthalene, and the absorbance of the resulting solution is measured at 480 nm. Beer's law is obeyed over the range of 5—88 μg of iron in 10 ml of the solvent. The molar absorptivity of the complex was found to be 6.3×10^3 l mol^{-1} cm^{-1} at 480 nm. The effects of various factors, such as the pH, the amounts of the reagent and naphthalene, and diverse ions, were also examined. The proposed method was satisfactorily applied to the determination of iron in several selected samples, including standard reference materials, aluminum metal, and natural water.

5-Chloro-7-iodo-8-quinolinol, which is a derivative of 8-quinolinol, forms water-insoluble colored complexes with various metal ions, such as zinc, manganese, cobalt, nickel, cadmium, and iron(III). These complexes are easily extracted into chloroform or molten naphthalene under the optimum conditions. In this work, 5-chloro-7-iodo-8-quinolinol was chosen as a complexing reagent for the spectrophotometric determination of iron(III). This reagent reacts with iron (III) in the pH range of 1.8—4.5 to form a water-insoluble blue-black complex, which is quantitatively adsorbed on microcrystalline naphthalene at room temperature. The adsorbed naphthalene mixture is dissolved in *N,N*-dimethylformamide, and the absorbance of the solution is measured at 480 nm. The proposed method is characterized by the fact that the complex is easily adsorbed on micro crystalline naphthalene by vigorous shaking for a few seconds, even at room temperature, in contrast with the naphthalene-extraction method,[1-11] in which heating above 81 °C is required. In this paper, we describe a simple and convenient spectrophotometric method for the determination of iron(III) in the N.B.S. reference materials (alloys) and environmental samples.

Experimental

Reagents. Standard iron(III) solution, 100 ppm. Prepared by dissolving 0.8635 g of ammonium iron(III) sulfate in 100 ml of 0.5 M(1 M=1 mol dm^{-3}) H_2SO_4 and by diluting to 500 ml with water.

5-Chloro-7-iodo-8-quinolinol solution, 0.2%. Prepared by dissolving 0.2 g of this reagent in 100 ml of ethanol.

Naphthalene solution, 20%. Prepared by dissolving 20 g of naphthalene in acetone and by then diluting to 100 ml.

Buffer solutions were prepared by mixing 1 M acetic acid and 1 M ammonium acetate solution at pH 3—6, and 1 M aqueous ammonia and 1 M ammonium acetate solution at pH 8—11.

Apparatus. The absorption measurements were made with a Hitachi Model 200-20 spectrophotometer with 10-mm glass cells.

All the pH measurements were done with a Toa-Dempa Model HM-6A pH meter, equipped with a combination glass and calomel electrode assembly.

Naphthalene was dried with a Tabai Model K-2 drier (Tabai Mfg. Co., Japan).

Procedure. Transfer a sample solution containing 5—88 μg of iron(III) to a tightly stoppered Erlenmeyer flask, and dilute with water to about 45 ml. Add 4.0 ml of a 0.2% 5-chloro-7-iodo-8-quinolinol solution and adjust the pH of the solution to 3.5 with 2.0 ml of an acetate buffer solution. Mix the solution well and let stand for 10 min at room temperature. Add 2.0 ml of 20% naphthalene in acetone to this sample solution as fast as possible, using a small nozzled pipet attached to a rubber bulb, and shake the mixture vigorously for 1 min. Collect the colored naphthalene mixture on a filter paper placed flat on a Teflon filter plate in a funnel or a sintered glass filter (No. 2) by filteration. Wash it with water and dry at 50—60 °C. Then dissolve the mixture in *N,N*-dimethylformamide and dilute to exactly 10 ml. Measure the absorbance of the solution in a 10-mm glass cell against the reagent blank.

Results and Discussion

Absorption Spectra. Figure 1 shows the absorption spectra of the reagent and the iron(III) complex in a naphthalene-*N,N*-dimethylformamide solution. The iron(III) complex has two absorption peak, at 480 and 620 nm. The reagent blank shows strong absorption below 375 nm.

Effect of pH. The effect of the pH on the absorbance of the complex was investigated. The pH measurements were made at room temperature after the adsorption of the complex on naphthalene. Figure 2 shows that the maximum absorbance is obtained between pH 1.8 and 4.5.

Effect of Reagent Concentration. Varying amounts of a 0.2% 5-chloro-7-iodo-8-quinolinol solution were added to a sample solution containing 50 μg of iron (III) and 2.0 ml of the buffer solution (pH 3.5). The results are shown in Fig. 3. The absorbance increased with an increase in the amount of this reagent up to 1.2 ml of the 0.2% solution. It was reasonably

constant when 1.2—7.0 ml of this solution was used.

Effect of Buffer Solution and Digestion Time. The effect of the addition of buffer solution on the absorbance was also investigated. The absorbance was unaffected by the addition of up to 5 ml of the buffer solution. The effect of the digestion time on the absorbance was then investigated by digesting the iron(III) complex for 1—30 min. It was found that the absorbance was constant for this period of digestion.

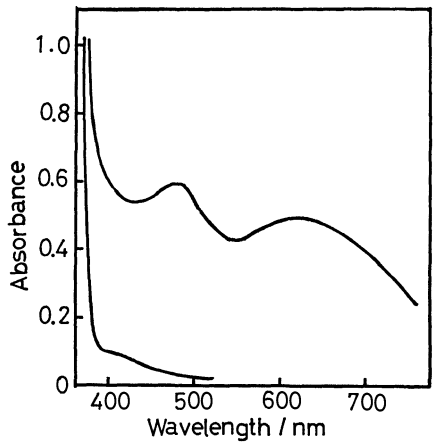

Fig. 1. Absorption spectra of reagent and iron(III)-complex in naphthalene–*N*,*N*-dimethylformamide solution.
Iron(III): 50 μg, 0.2% 5-chloro-7-iodo-8-quinolinol: 4.0 ml, pH: 3.5, 20% naphthalene–acetone: 2.0 ml, shaking time: 1 min, reference: water.

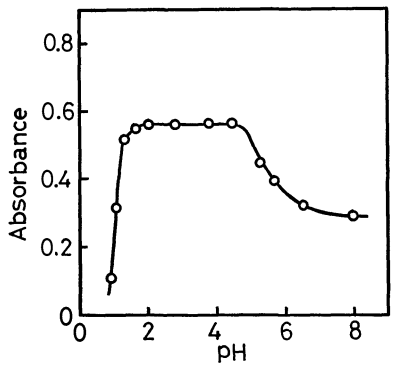

Fig. 2. Effect of pH.
Iron(III): 50 μg, 0.2% 5-chloro-7-iodo-8-quinolinol: 4.0 ml, wavelength: 480 nm, shaking time: 1 min, reference: reagent blank.

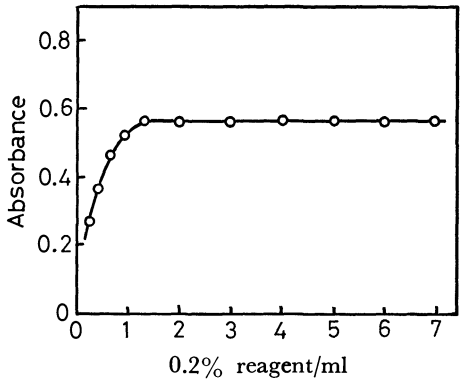

Fig. 3. Effect of reagent concentration.
Iron(III): 50 μg, wavelength: 480 nm, pH: 3.5, 20% naphthalene–acetone: 2.0 ml, standing time: 15 min, reference: reagent blank.

Effect of Naphthalene Concentration. 0.1—4.0 ml portions of 20% naphthalene in acetone were added to a sample solution containing the iron(III) complex. The results showed that the absorbance was independent of the amount of naphthalene.

Effect of Shaking and Standing Times. The effect of the shaking time on the absorbance of the complex was also examined. The rate of the adsorption of the complex on naphthalene was very fast, and no change in the degree of the adsorption was observed during the shaking period of 2—120 s. The adsorbed naphthalene mixture was dissolved in *N*,*N*-dimethylformamide. The color of the complex thus obtained is very stable, and the absorbance remained unchanged for a long time.

Calibration Curve. Based on the optimum conditions described above, a calibration curve for the iron(III) determination was prepared. A linear relationship was obtained between the concentration of iron(III) and the absorbance over the range of 5—88 μg of iron at 480 nm in 10 ml of *N*,*N*-dimethylformamide. The molar absorptivity was 6.3×10^3 l mol^{-1} cm^{-1} at 480 nm, the sensitivity being 0.009 μg/cm^2 for 0.001 absorbance. The relative standard deviation for ten replicate determinations was 0.72% for 50 μg of iron(III).

Choice of Solvent. Tests were made with various organic solvents to dissolve the adsorbed naphthalene mixture. This mixture is easily soluble in *N*,*N*-dimethylformamide, benzene, toluene, xylene, dioxane, chlorobenzene, chloroform, *o*-dichlorobenzene, acetonitrile, nitrobenzene, 1,2-dichloroethane, *etc.* at room temperature.

Effect of the Aqueous-phase Volume. Since the volume ratio of the organic to the aqueous phase is an important factor in the adsorption of the iron(III) complex on naphthalene, the effect of the volume of the aqueous phase on the absorbance was studied.

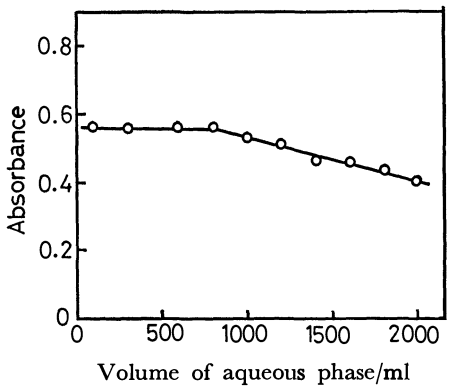

Fig. 4. Effect of volume of aqueous phase.
Iron(III): 50 μg, wavelength: 480 nm, pH: 3.5, 0.2% 5-chloro-7-iodo-8-quinolinol: 6.0 ml, 20% naphthalene–acetone: 4.0 ml, digestion time(30—35 °C): 20 min, reference: reagent blank.

Table 1. Determination of iron in standard reference materials(alloys) and environmental samples

Sample	Iron content (certified value) %	Number of determinations	Iron found	
			Present method (%)	1,10-phenanthroline method (%)
N.B.S. SRM-85b Al alloy	0.24	5	0.239±0.003	0.239±0.003
N.B.S. SRM-94c Zn alloy	0.018	5	0.017±0.001	0.017±0.001
N.B.S. SRM-158a Silicon-Bronze alloy	1.23	5	1.33 ±0.01	1.27 ±0.02
Metallic aluminum (powder)	—	5	0.135±0.001	0.139±0.002
Lake water (Kitagata, Fukui Pref.)	—	4	1.35 ±0.01 (ppm)	1.45 ±0.04 (ppm)

The results are shown in Fig. 4. Under the experimental conditions described, the absorbance remains almost constant up to about 800 ml of the aqueous phase. With further increases in the volume of the aqueous phase, however, the absorbance is gradually diminished.

Effect of Diverse Ions. The effect of diverse ions on the determination of 50 μg of iron(III) was studied. The following alkali metal salts and metal ions(present in the amounts given in parentheses) did not cause an error of more than ±5%: NaCl(8 g), Na_2SO_4 (8 g), NaI(8 g), NH_4Cl(8 g), KNO_3(7 g), sodium tartrate(5 g), sodium citrate(5 mg), sodium oxalate(3 mg), disodium EDTA(10 μg), Ca^{2+}(8 mg), Mg^{2+}(8 mg), Mn^{2+}(8 mg), Pb^{2+}(500 μg), Cr^{6+}(300 μg), Zn^{2+}(40 μg), Cd^{2+}(150 μg), Bi^{3+}(50 μg), Cu^{2+}(30 μg), Pd^{2+}(20 μg), Ni^{2+}(10 μg), Co^{2+}(5 μg). Most of the diverse metal ions gave a positive error, but the complexing reagents, such as sodium citrate, sodium oxalate, and disodium EDTA gave negative one.

Determination of Iron in Reference Materials and Environmental Samples. The proposed method was applied to the determination of iron in the reference materials, aluminum powder, and water samples. The results are in reasonably good agreement with those obtained by the standard spectrophotometric procedure employing 1,10-phenanthroline,[14] as is shown in Table 1. The analytical procedures were as follows: a 0.8279-g portion of standard aluminum alloy (N.B.S., SRM-85b) was gently dissolved in 40 ml of hydrochloric acid (1+1) and 2 ml of 30% hydrogen peroxide. The excess hydrogen peroxide was decomposed by gently heating the mixture on a boiling-water bath for a few minutes. After cooling, the volume of the sample was made up to 200 ml with water. A 5-ml aliquot was transferred to a 100-ml separatory funnel, and 50 ml of hydrochloric acid (1+3) was added. The iron(III) in this sample was extracted by vigorous shaking for 5 min with 20 ml of isobutyl methyl ketone (MIBK).[12] It was then back-extracted from the organic phase with 25 ml of water, and the proposed method was applied.

A 5.085-g portion of standard zinc alloy(N.B.S., SRM-94c) was dissolved in 60 ml of hydrochloric acid (1+1) and 1 ml of concentrated nitric acid. The excess of the acids was removed by evaporating the mixture on a boiling-water bath, and the volume of the sample made up to 200 ml with water. A suitable aliquot was transferred to a 100-ml separatory funnel, and 20 ml of hydrochloric acid (1+1) was added. The iron(III) in this sample was extracted by vigorous shaking for 3 min with 20 ml of an MIBK–isopentyl acetate(1+1) mixture.[13] The aqueous phase was drained off and discarded. The organic phase was washed first with 15 ml and then with 5 ml of hydrochloric acid(1+1). Then 20 ml of water was added to the organic phase, and the mixture was shaken for 3 min. After having been left standing for 5 min, the aqueous phase was drained off in a beaker. Again, 5 ml of water was added to the organic phase, followed by the same procedure. The combined aqueous solution was diluted to exactly 200 ml with water. To an aliquot of this sample solution, we then added 2.0 ml each of a 10% hydroxyammonium chloride solution and a 20% EDTA solution. The solution was then analyzed for iron by the proposed procedure and the 1,10-phenanthroline method.

A 108.6-mg portion of Silicon Bronze alloy(N.B.S., SRM-158a) was dissolved in 10 ml of hydrochloric acid(1+1), 1 ml of concentrated nitric acid, and 3 ml of concentrated sulfuric acid. The mixture was then gently heated on a boiling-water bath. The excess of the acids was evaporated, and then the volume of the sample was brought to 200 ml with water. This sample was used for the both methods.

Metallic aluminum powder was analyzed in the same way as in the case of the standard aluminum alloy.

Lake-water samples, adjusted to 0.1 M with hydrochloric acid immediately after collection, were filtered through a filter paper(No. 5C) to remove suspended particulates; the filtrates were analyzed for the total iron content using this method and the 1,10-phenanthroline method.[14]

(Received October 17, 1981)

The title complex was synthesized, and the structure was determined by means of the X-ray diffraction technique. The crystal is triclinic; space group $P\bar{1}$, $a=9.944(1)$, $b=14.336(2)$, $c=9.759(1)$ Å, $\alpha=107.00(1)$, $\beta=117.35(1)$, $\gamma=76.55(1)°$, $Z=2$, $D_x=1.40$, $D_m=1.36(3)$ g cm^{-3}, μ(Mo $K\alpha$)$=1.08$ mm^{-1}. The *O*-methyl dithiocarbonato ion acts as a unidentate ligand, and it is coordinated with the metal through one sulfur atom. The coordination number of the metal is 3 if the cyclopentadienyl is regarded as a unidentate ligand. A series of [(η-cyclopentadienyl)(*O*-alkyl dithiocarbonato)(trialkyl- or triarylphosphine)nickel(II)], [Ni(C_5H_5)(S_2COR)(PR'_3)], where R=CH_3, C_2H_5, $CH_3(CH_2)_2$, $(CH_3)_2CH$, or $CH_3(CH_2)_3$; R'=C_6H_5, $C_6H_5CH_2$, or $CH_3(CH_2)_3$, were also obtained. The dissociation of the phosphine ligand of the complexes in solution was studied spectrophotometrically, and it was found that the more electron-donative the alkyl group of the *O*-alkyl dithiocarbonato ligand is, the weaker the phosphorus-nickel bond is.

The title complex is unique in that three different ligands are coordinated to the metal, also as will be shown in the later part of this paper, the *O*-alkyl dithiocarbonate ion acts as a unidentate in it. 1,1-Dithioacid ions, including *O*-alkyl dithiocarbonate ions, commonly act as bidentate ligands with their sulfur atoms; however, exceptionally, the ligand acts as a unidentate in the case of $[Sn(S_2COC_2H_5)_4]$,[1] $[Sn\{S_2CN(C_2H_5)_2\}_4]$,[2] $[Ru(NO)\{S_2CN(C_2H_5)_2\}_3]$,[3] $[As(C_6H_5)_4][Pt(S_2COC_2H_5)_3]$,[4] $[Sn(C_6H_5)_3\{S_2P(OC_2H_5)_2\}]$,[5] $[Sb(CH_3)_3\{S_2CN(CH_3)_2\}_2]$,[6] and $[(C_2H_5)_4N][Cd(S_2COC_2H_5)_3]$.[7]

Therefore, the present authors started to investigate this type of complex. In the course of the study, the crystal and molecular structure of the title complex was clarified by the X-ray diffraction technique; a part of the results have already been published.[8]

Recently, Tsipis and his collaborators have reported the crystal and molecular structure as well as the NMR results of the analoguous $[Ni(\eta\text{-}C_5H_5)(S_2COC_2H_5)\{P(C_6H_5)_3\}]$.[9] They gave a qualitative interpretation of the equilibrium between two non-equivalent conformations as well as the phosphine dissociation. Their work prompted us to investigate quantitatively the effect of the alkyl group in the *O*-alkyl dithiocarbonato ligand on the dissociation of phosphine in the complex. As a result, the dissociation constants, as well as some thermodynamic data of the equilibrium were obtained.

Experimental

Synthesis of (η-Cyclopentadienyl)(O-methyl dithiocarbonato)(triphenylphosphine)nickel(II). The chemicals used were all GR-grade reagents: they were purified further by distillation or recrystallization, if necessary. The starting materials, dicyclopentadienylnickel(II) and chlorobis(triaryl or trialkylphosphine)nickel(II), were synthesized by the methods of Cordes[10] and of Venanzi[11] respectivelly. The chloro(η-cyclopentadienyl)(triphenyl-, tribenzyl-, or tributylphosphine)nickel(II) (0.84 g, 2 mmol), obtained by the method of Yamazaki *et al.*,[12] was dissolved in 25 cm^3 of dichloromethane. To the solution, solid potassium *O*-methyl dithiocarbonate (0.29 g, 2 mmol) was then added, and the mixture was stirred at room temperature. The dithiocarbonate, initially insoluble, started to react, and the color of the solution changed from dark red to deep brown due to the product dissolved in it. The reaction was completed in several minutes. The precipitated potassium chloride was filtered off, and a 30 cm^3 portion of hexane was added to the filtrate. The solution was then concentrated to about 10 cm^3 using a rotary vacuum evaporator at room temperature, and finally was left standing. The precipitated crystals were filtered off and washed with hexane; yield, 0.69 g (70%). (Recrystallized from petroleum benzine.)

Synthesis of (η-Cyclopentadienyl)(O-alkyl dithiocarbonate)(triaryl- or trialkylphosphine)nickel(II), [Ni(C_5H_5)(S_2COR)(PR'_3)] (Where R=CH_3, C_2H_5, $CH_3(CH_2)_2$, $(CH_3)_2CH$, or $CH_3(CH_2)_3$; R'=C_6H_5, $C_6H_5CH_2$, or $CH_3(CH_2)_3$). These complexes were obtained by a technique similar to that used in the synthesis of $[Ni(C_5H_5)(S_2COCH_3)\{P(C_6H_5)_3\}]$ described above. Yield: 60—85%. Since the tribenzylphosphine derivatives are relatively sensitive to air-oxidation in solution, care had to be taken not to raise the temperature higher than 50 °C during the recrystallization.

The other alkyldithiocarbamato complexes, $[Ni(\eta\text{-}C_5H_5)(S_2CNHR)\{P(C_4H_9)_3\}]$ (where R=CH_3, C_2H_5, C_6H_5, $C_6H_5CH_2$), were also obtained by the same technique; however, no triphenylphosphine derivatives of this type were obtained.

The dialkyldithiocarbamato derivatives could not be synthesized. From the reaction between $[NiCl(\eta\text{-}C_5H_5)\{P(C_6H_5)_3\}]$ and dimethylammonium dimethyldithiocarbamate, $[Ni(\eta\text{-}C_5H_5)\{S_2CN(CH_3)_2\}]$ was obtained; it was stable only below 10 °C. An attempt was made to synthesize the complexes of this type by using a ligand containing an alkyl group longer than methyl, but no stable products were obtained.

Infrared, Visible, and NMR Spectra Measurements. The infrared spectra of samples were recorded by means of a JASCO infrared spectrophotometer (type 403G), using Nujol and hexachloro-1,3-butadiene mull.

The visible spectra of the samples in a benzene solution were measured by means of a Hitachi 124 spectrophotometer

†† Present address: Department of Chemistry, Faculty of Science and Technology, Keio University, 3-14-1, Kohoku-ku, Yokohama 223.

the temperature of the cell chamber kept at 15, 20, 25, or 30 °C by means of thermostatted circulating water.

The proton NMR spectra were obtained by the use of a JNM-MH-100 type NMR spectrometer, by using chloroform-*d* as the solvent and TMS as the internal standard.

X-Ray Measurement. The single crystals of $[Ni(C_5H_5)(S_2COCH_3)\{P(C_6H_5)_3\}]$ had grown in a dichloromethane-hexane solution kept in hexane vapor for several days at the ambient temperature. The crystal used was shaped into a sphere ($\phi=0.43$ mm). Crystallographic data: $C_{25}H_{23}NiOPS_2$, F.W.=493.25, triclinic, space group $P\bar{1}$, $a=9.944(1)$, $b=14.336(2)$, $c=9.759(1)$ Å, $\alpha=107.00(1)$, $\beta=117.35(1)$, $\gamma=76.55(1)°$, $Z=2$, $D_x=1.40$, $D_m=1.36(3)$ g cm^{-3}, $\mu=1.08$ mm^{-1} for Mo $K\alpha$(0.7107 Å). The reflections with 2θ less than 60° (Mo $K\alpha$ radiation) were collected on a Rigaku automated four-circle diffractometer, the θ-2θ scan technique being employed. The 5768 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. The calculations were carried out mainly by means of the FACOM 230-48 computer at The Institute for Solid State Physics, The University of Tokyo, and partially by means of the HITAC 8700/8800 computer at The Computer Center of The University of Tokyo, using the local version of the UNICS program.[13] The atomic scattering factors were taken from Ref. 14.[14]

Structure Determination. The structure was solved by the heavy-atom method. The positions of the nickel, phosphorus, and sulfur atoms were deduced from a three-dimensional Patterson map; all the other non-hydrogen atoms successively located by means of Fourier syntheses. The positional and thermal parameters were refined by the use of the block-diagonal least-squares method. The positions of hydrogen atoms were obtained from a difference Fourier synthesis, and were also refined. In the final cycle of the refinement with anisotropic temperature factors for all the non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value was 0.030.[15]

Results and Discussion

The chemical formulae and the analytical data of the complexes, together with their melting points (or decomposition temperature), are shown in Table 1. The ir data are shown in Table 2. As the wave numbers of these peaks of the complexes are not very different from each other, the structure and the coordination mode of the ligands in them are also likely to be similar.

The final atomic parameters of [(η-cyclopentadienyl)(*O*-methyl dithiocarbonato)(triphenylphosphine)-nickel(II)] are listed in Table 3.[16] The interatomic distances and bond angles are tabulated in Table 4. A perspective drawing of the complex and the numbering scheme are shown in Fig. 1. Figure 2 gives a projection of the structure along c.

The crystal consists of discrete molecules. As may be seen from Fig. 1, the coordination number of the nickel atom is 3 if the cyclopentadienyl group is regarded as a unidentate. The dihedral angle between the cyclopentadienyl plane (the maximum deviation from the mean plane is 0.3 Å) and the plane formed by Ni, P, and S (coordinated) atoms is almost rectangluar (89.1°). The ∠P–Ni–S (coordinated) angle was close to a right angle (92.3°). All the non-hydrogen atoms of the *O*-methyl dithiocarbonato ligand and the central nickel atom are coplanar. The C(6) and O atoms of the ligand are likely to have sp^2 hybridization. The C(6)–O, C(6)–S (non coordinated), and to a lesser extent, C(6)–S (coordinated) bonds have

a multiple-bond character.

The structural data indicate that the C–S (non coordinated) is shorter than the C–S (coordinated) in the case of unidentate 1,1-dithioacid ion. The steric conformations concerned with C–O are always E, except for $[M(S_2COC_2H_5)_3]$ (M=As or Sb), where the ligands are in an intermediate state between the

chelate and unidentate types of coordination.[17,18] The conformation of the ligand in the title complex is also E.

Of the present complexes, the bond distances between nickel and ligating sulfur atoms as well as between nickel and cyclopentadienyl are almost equal to the respective values of the *O*-ethyl dithiocarbonato complexes. On the other hand, the Ni–P distances of both the complexes are slightly, but significantly, different from each other (2,160(1) *vs.* 2.184(1) Å). This fact will be discussed later.

The visible spectra of the complex in benzene solution containing an excess of phosphine ligand are shown in Fig. 3. In the figure, two isosbestic points were found at 492 and 535 nm; they remained unchanged even when the concentration of the co-ex-

Concentration of Ni(II): 0.3285×10^{-3} mol dm^{-3}, total concentration of triphenylphosphine: a) 0.3285, b) 2.04, c) 4.33, d) 7.31, e) 11.8, f) 20.2, g) 32.3, h) 49.2, i) 76.8, j) 137.9, k) 197.5×10^{-3} mol dm^{-3}.

isting phosphine was varied from 1 to 600 times (mol/mol) to that of the original 1:1 complex adduct.

Tsipis proposed the following dissociation scheme of the phosphine from the complex in order to explain the temperature variation on the NMR spectra of the complex above 56 °C:[9] $[Ni(C_5H_5)(S_2COR)(PPh_3)] = PPh_3 + [Ni(C_5H_5)(S_2COR)]$ (where Ph=C_6H_5)

The equillibrium constant, K', of this reaction was obtained from the measured absorbance of the solutions at 430 nm containing the complex and the excess of the phosphine ligand at 15, 20, 25, and 30 °C. The procedure is as follows: The equilibrium constant, K', is given by $K'=[M][L]/[ML]$ (where M=$Ni(C_5H_5)(S_2COR)$, L=PPh_3, and ML=$Ni(C_5H_5)(S_2COR)(PPh_3)$.) The total amount of $PPh_3(l)$, and $Ni(m_o)$ are expressed by $l=[ML]+[L]$ and $m_o=[M]+[ML]$ respectively. The absorbance, $A_c=\varepsilon_2[ML]+\varepsilon_1[M]$, where ε_1 and ε_2 are the absorption coefficients of M and ML respectively. The equation becomes:

$$A_c = \varepsilon_2\frac{(m_o+l+K')-\sqrt{D}}{2} + \varepsilon_1\frac{(m_o-l-K')+\sqrt{D}}{2},$$

where $D=(m_o+l+K')^2-4m_ol$ by representing [ML] and [M] in terms of l,m_o, and K'. The values of ε_1, ε_2, and K' were obtained by using the least-squares method, which minimizes $\Sigma(A_o-A_c)^2$, where A_o is observed absorbance. The calculation was carried out on a HITAC M-200H computer at The Computer Center of The University of Tokyo, using the SALS program.[20]

The K''s were converted to the equilibrium constants in molar fraction units, K**. From the van't Hoff plots for each complex, the apparent standard enthalpy, entropy, and Gibb's free energy change of the reaction were obtained; the results are shown in Table 5. As is shown in the table, all of these dissociation reactions are endothermic, and their entropy changes are all positive. The relation between $\Delta H°$ or $\Delta S°$ and the aliphatic polar substituent constants, σ*,[21] of the alkyl groups of the *O*-alkyl dithiocarbonato ligand is shown in Fig. 4. The complex involving the more electron-donative alkyl group shows lower ΔH and ΔS values. At room temperature, the complexes having the higher electron-donative alkyl group of the ligand dissociate more easily. From the equilibrium constants, it is shown that, at the ambient temperature, the complex in the solution of about 10^{-4} mol dm^{-3} dissociates almost completely (more than 99%) in the absence of an excess of ligands. The Ni–P distance in the *O*-methyl dithiocarbonato complex, which is shorter than that of the *O*-ethyl dithio-

Table 5. Standard enthalpy $\Delta H°$, entropy $\Delta S°$, and Gibb's free energy $\Delta G°$ of the reaction $[Ni(C_5H_5)(S_2COR)\{P(C_6H_5)_3\}]=[Ni(C_5H_5)(S_2COR)]+P(C_6H_5)_3$ at 25 °C.

$(CH_3)_2CH$	38.4 (12)	79 (4)	15 (2)

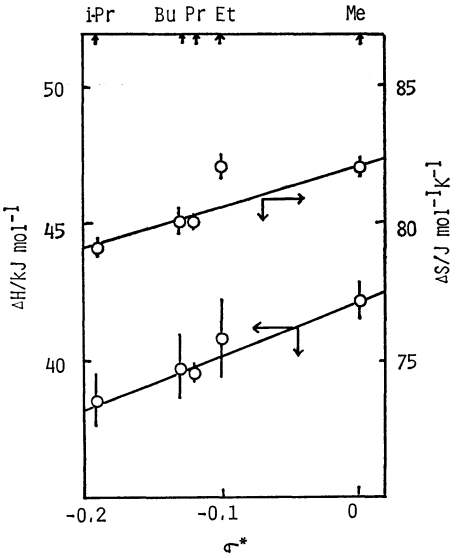

Fig. 4. Dependence of $\Delta H°$ and $\Delta S°$ of the reaction $[Ni(C_5H_5)(S_2COR)\{P(C_6H_5)_3\}]=[Ni(C_5H_5)(S_2COR)]+P(C_6H_5)_3$ on aliphatic polar substituent constants σ* of R.

** The temperature variation of the specific gravity of the solvent was also taken into consideration. The standard changes in enthalpy, *etc.*, obtained from the new K's stand for those in which all components of the equation are in the unit molar fraction.

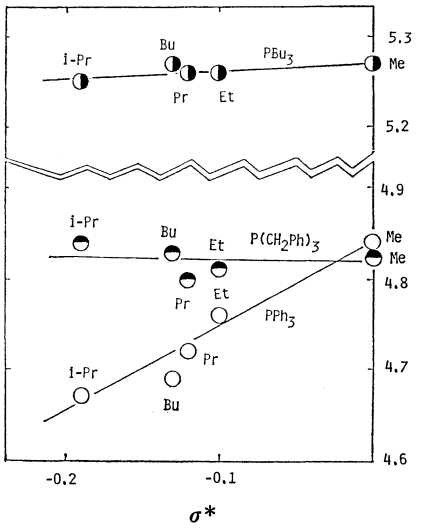

Fig. 5. Dependence of the chemical shifts of cyclopentadienyl protons on the aliphatic polar substitent constants σ^* of R in $[Ni(C_5H_5)(S_2COR)(PR'_3)]$. Abbreviations. For phosphines, Bu=$CH_3(CH_2)_3$, Ph=C_6H_5; for R of $(S_2COR)^-$, Me=CH_3, Et=CH_3CH_2, Pr=$CH_3(CH_2)_2$, *i*-Pr=$(CH_3)_2CH$, Bu=$CH_3(CH_2)_3$.

carbonato one, is explained by the fact that the methyl group is less electronegative than the ethyl group.

The relation between the chemical shifts of ^{1}H-NMR of the cyclopentadienyl proton of the complexes, and the aliphatic polar substituent constants, σ^*,[21] is shown in Fig. 5. The NMR study reveals that the dissociation of the complex in the solution is complete when the concentration of the solution is high (about 10^{-1} mol dm^{-3}), and that the cyclopentadienyl protons of complexes containing triphenylphosphine are more shielded when the alkyl group of the *O*-alkyl dithiocarbonato ligand is more electron-donative. However, this relation is not realized for the tributyl- and tribenzylphosphine complexes, as is shown in the figure. Therefore, in these cases some additional effects should be involved.

† *The Institute for Solid State Physics, The University of Tokyo, Roppongi-7, Minato-ku, Tokyo 106*

(Received November 5, 1981)

The title complex was synthesized, and the crystal structure was determined by means of the X-ray diffraction technique. The crystal is monoclinic; space group $P2_1/n$, $a=16.310(3)$, $b=6.777(1)$, $c=14.576(3)$ Å, $\beta=96.13(1)°$, $Z=2$, $D_x=1.58$, $D_m=1.55(3)$ g cm^{-3}, μ(Mo $K\alpha$)$=1.12$ mm^{-1}. The molecule has a center of symmetry, and a distorted octahedron is formed around the central cadmium atom; two *O,O'*-diethyl dithiophosphato ions (dtp) act as bidentate ligands, and each ligand forms a four-membered chelate ring with its two sulfur atoms on the equatorial plane, while two hexamethylenetetramine molecules are coordinated to the metal atom by their nitrogen atoms from the axial direction. Related adducts, Cd(II)(dtp)$_2\cdot X_n$, where X is a donor and $n=1$ or 2, were also synthesized, and their structures were compared with those of the corresponding Co(II)(dtp)$_2\cdot X_n$-type complexes.

The present authors have reported in another paper[1] that the phosphine or amine adducts of bis(*O,O'*-diethyl dithiophosphato)cobalt(II) (hereafter, abbreviated as Co(II)(dtp)$_2$; the same types of abbreviations are used for related adducts) are very stable in air; however, the original Co(II)(dtp)$_2$ is easily oxidized. We have attempted to obtain similar types of adducts of other metals in order to compare them with the corresponding cobalt(II) complexes. As the electron paramagnetic resonance spectra, especially that of the single crystal, is expected to be effective in clarifying the stabilization mechanism, we have tried to synthesize adducts that are isostructural to the cobalt(II) analogues and contain a diamagnetic metal atom. Thus, the present authors have synthesized adducts containing cadmium(II) and compared their properties and structures with those of the corresponding cobalt(II) adducts. From their chemical compositions, the general features of their infrared spectra, and then X-ray powder diffraction patterns, the adducts of cobalt(II) and of cadmium(II) are found to resemble each other, and some of them are isostructural, as will be shown later. In the other paper,[1] we have suggested the octahedral structure for some adducts from the magnetic as well as the visible spectroscopic results; however, no structural analysis has been carried out. In this connection, the structure of Cd(II)(dtp)$_2$(hex)$_2$ (where hex=hexamethylenetetramine), which is expected to be octahedral, was determined by the X-ray diffraction technique. Another reason for the selection of the hex adduct in the present study was to examine the effect of such a bulky ligand on the coordination bond. In fact, the structure analysis of the metal complex involving this amine had been carried out only for Mn(II)Cl$_2$(hex)$_2$(H$_2$O)$_2$.[2] As cadmium(II) is a diamagnetic metal, the ^{1}H-NMR technique is easily applicable to the adducts. The results of the study revealed that the adducts are not completely dissociated, even in a solution.

†† Present address: Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi 3-14-1, Kohoku-ku, Yokohama, Kanagawa 223.

Experimental

Synthesis of Bis(O,O'-diethyl dithiophosphato)cadmium(II) Adducts, Cd(II)(dtp)$_2\cdot X_n$ (Where X is a Donor, and n=1 or 2). All the chemicals used were the GR- or EP-grade reagents of Wako Pure Chemicals Co., Ltd., and no further purification was necessary. Na(dtp) was obtained from phosphorus pentasulfide by the method of Livingstone.[3] The adducts were synthesized as follows:

Synthesis of Cd(II)(dtp)$_2$ (1): Into about 400 cm^3 of ethanol, 9.12 g (40 mmol) of hydrated cadmium(II) chloride ($CdCl_2\cdot 2.5\,H_2O$) and 16.6 g (80 mmol) of Na(dtp) were added, and the mixture was refluxed for 1 h. After cooling, the deposited crude complex was filtered off and recrystallized from ethanol. Yield: 18 g (93%).

Synthesis of Cd(II)(dtp)$_2$(hex) (2): Into about 35 cm^3 of benzene, 1.93 g (4 mmol) of **1**, and 0.56 g (4 mmol) of hex were dissolved. After filtration, the filtrate was left standing for a while and then filtered once more to remove the white turbid. To the filtrate, 5 cm^3 of benzene was added, and the mixture was left standing in a desiccator containing hexane for several days. A crystalline product came out. Yield: 0.6 g (25%). Found: Cd, 18.00; C, 27.20; H, 5.19; N, 9.07%. Calcd for $CdC_{14}H_{32}N_4O_4P_2S_4$: Cd, 18.04; C, 26.99; H, 5.18; N, 8.99%.

Synthesis of Cd(II)(dtp)$_2$(hex)$_2$ (3): Into 70 cm^3 of chloroform, 3.15 g (6.97 mmol) of **1** and 1.95 g (13.9 mmol) of hex were added, and the mixture was refluxed for 1 h. After cooling, it was filtered off, and the filtrate was left standing for several days in hexane vapor. Crystallines were thus precipitated. Yield: 2.9 g (55%). (It was also obtained from the evaporation residue of a mixed solution of the starting materials by repeated recrystallizations from diisopropyl ether.) Found: Cd, 14.76; C, 31.55; H, 5.80; N, 14.65%. Calcd for $CdC_{20}H_{44}N_8O_4P_2S_4$: Cd, 14.73; C, 31.48; H, 5.81; N, 14.68%.

Synthesis of Cd(II)(dtp)$_2$(PPh$_3$) (4) (Where PPh$_3$=Triphenylphosphine): Into 30 cm^3 of chloroform, 0.97 g, (2.0 mmol) of **1** and 1.05 g (4.0 mmol) of PPh$_3$ were added, and the mixture was refluxed for 30 min. The solvent was evaporated off, and from the residue the product was extracted by ligroine. The extracted solution was ice-cooled, and the crystals came out. The crude product was recrystallized from benzene containing PPh$_3$. Yield: 1.25 g (84%). Found: Cd, 15.07; C, 42.42; H, 4.73%. Calcd for CdC_{26}-

$H_{35}O_4P_3S_4$, Cd, 15.09; C, 41.49; H, 4.74%.

Synthesis of Cd(II)(dtp)$_2$(pip) (5) (Where pip=Piperazine): This complex was synthesized by the same procedure as that for **4**, 0.8 g (1.7 mmol) of **1** and 0.45 g (5.2 mmol) of pip being used. Toluene was employed in place of benzene for the extraction. Yield: 0.45 g (48%). Found: Cd, 19.66; C, 25.43; H, 5.28; N, 5.20%. Calcd for $CdC_{12}H_{30}N_2O_4P_2S_4$: Cd, 19.75; C, 25.33; H, 5.32; N, 4.92%.

Synthesis of Cd(II)(dtp)$_2$(pyr) (6) (Where pyr=Pyrazine): Into 30 cm^3 of chloroform, 0.8 g (1.7 mmol) of **1** and 0.4 g (5.0 mmol) of pyrazine were dissolved, after which the solution was evaporated using a rotary vacuum evaporator under 80 °C. The residue was recrystallized from 1,2-dichloroethane–ligroine (20/7=v/v). Yield: 0.35 g (38%). Found: Cd, 19.89; C, 25.62; H, 4.23; N, 4.71%. Calcd for $CdC_{12}H_{24}N_2O_4P_2S_4$: Cd, 19.97; C, 25.60; H, 4.30; N, 4.98%.

Synthesis of Cd(II)(dtp)$_2$(bzt)$_2$ (7) (Where bzt=Benzothiazole): The synthesis procedure for **6** was applied, starting from 0.8 g (1.7 mmol) of **1**, and 0.5 g (3.7 mmol) of bzt. The recrystallization solvent used was ligroine–toluene (1/1=v/v). Yield: 0.75 g (60%). Found: Cd, 14.97; C, 35.07; H, 4.00; N, 3.72%. Calcd for $CdC_{22}H_{30}N_2O_4P_2S_6$: Cd, 14.92; C, 35.08; H, 4.02; N, 3.72%.

Synthesis of Cd(II)(dtp)$_2$(bza)$_2$ (Where bza=Benzylamine): The crude product was synthesized by the same method as **6**, starting from 0.8 g (1.7 mmol) of **1** and 0.5 g (4.9 mmol) of bza. The product was extracted with ligroine and it was deposited by ice cooling. Yield: 0.69 g (52%). Found: Cd, 16.00; C, 37.71; H, 5.43; N, 4.13%. Calcd for $CdC_{22}H_{38}N_2O_4P_2S_4$: Cd, 16.17; C, 38.01; H, 5.22; N, 4.03%.

X-Ray Measurements. Powder X-Ray Diffraction Patterns: They were recorded on the diffractometer, Model DX-GO-F of GEOL, in the range from 6° to 30° in 2θ, Cu $K\alpha$ radiation being used.

Single-crystal X-Ray Analysis: The single-crystal specimen of **3** for the X-ray study was grown from a chloroform–hexane solution kept in hexane vapor for several days. The crystal was shaped into a sphere (ϕ=0.34 mm) and covered by cyanoacrylate resin to prevent decomposition by atmospheric moisture. The crystallographic data are: $CdC_{20}H_{44}N_8O_4P_2S_4$, F.W.=763.21, monoclinic, space group $P2_1/n$,** a=16.310(3), b=6.777(1), c=14.576(3) Å, β=96.13(1)°, Z=2, D_x=1.58, D_m=1.55(3) g cm^{-3}, μ(Mo $K\alpha$)=1.12 mm^{-1}. The reflections with 2θ less than 60° were collected on a Rigaku automated four-circle diffractometer with Mo $K\alpha$ radiation, θ-2θ scan technique being employed. Of 4670 reflections measured, 3654 independent reflections with $|F_o| > 3\sigma(|F_o|)$ were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. The calculations were carried out mainly on the FACOM 230-48 computer at The Institute for Solid State Physics, The University of Tokyo, and partly on HITAC 8700/8800 computer at The Computer Center of The University of Tokyo, using the local version of UNICS program.[4] The atomic-scattering factors were taken from Ref. 5.[5]

Structure Determination: The structure was solved by the heavy-atom method. All the non-hydrogen atoms except for ethyl carbon atoms were deduced from a three-dimensional Patterson map, while the carbon atoms were located by successive Fourier syntheses. Their positional and thermal parameters were refined by the block-diagonal least-squares method. The positions of all the hexamethylenetetramine hydrogen atoms as well as of four ethyl hydrogen atoms were obtained from a difference Fourier synthesis; they were also refined. In the final cycle of the refinement with anisotropic temperature factors for all the non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value becomes 0.030.[6]

^{1}H-NMR Measurement. The ^{1}H-NMR spectra of their chloroform-*d* solutions were recorded on a JEOL JNM-MH-100 NMR spectrometer, using TMS as the internal standard.

Results and Discussion

The final atomic parameters for **3** are listed in Table 1,[7] while the interatomic distances, as well as the bond angles of the complex, are tabulated in Table 2. A perspective drawing of the adduct and the numbering scheme of the atoms are shown in Fig. 1, while Fig. 2 presents a projection of the structure along b.

The crystal consists of discrete molecules, and each

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

cadmium atom is at the center of symmetry. A couple of dtp ligands are coordinated to the central metal atom by their two sulfur atoms, forming four-membered chelate rings on the equatorial plane. On the other hand, two hex molecules are coordinated to the central metal atom by their nitrogen atoms from the axial direction. Thus, the cadmium(II) atom takes a six-coordinate distorted octahedral configuration.

The Cd–S distances of the present adduct are 2.704(1) and 2.682(1) Å, slightly longer than those in Cd(II) (i-Pr_2dtp)$_2$ (where i-Pr_2dtp = O,O'-diisopropyl dithiophosphato group) (2.486(7)—2.590(8) Å.[8]) This is probably because of the fact that the former is in an octahedral configuration, while the latter is in tetrahedral configuration. In the present adduct, the two P–S distances in the ligand are about the same, *ca.* 1.98 Å, and intermediate between the single bond (2.09 Å) and the double bond (1.87 Å),[9] indicating that the double bond is delocalized. The four-membered ring formed by Cd, S(1), S(2), and P atoms is almost planar. In the present complex, the S(1)–Cd–S(2) bond angle is 77.09(2)°, smaller than those of common O,O'-dialkyl dithiophosphato complexes and of their adducts,[10–24] including the Co(Me_2dtp)$_2$(PPh_3) (where Me_2dtp = O,O'-dimethyl dithiophosphato group; PPh_3 = triphenylphosphine) reported in the other paper,[1] although there are some exceptions.[13,16]

The apparent C–C distances of the ethyl groups of the present adduct were found to be 1.323(8) and 1.382(7) Å, shorter than the common C–C single bond length (1.50 Å). This is probably a result of the fact that the carbon atoms are not fixed, but have large thermal parameters, as is shown in Table 2.

The Cd–N(1) distance is 2.595(2) Å, longer than the common Cd–N distances (about 2.3 Å) in cadmium(II) complexes.[25] Similar phenomenon has also been observed in Mn(II)Cl_2(hex)$_2$(H_2O)$_2$, where Mn–N is 2.40 Å.[2] In the present case, this is probably attributable to the repulsion between the hydrogen atoms of the hex and the sulfur atoms of the dtp ligand. As is shown in Table 2, H(7-1)···S(1), H(7-2)···S(2), H(5-1)···S(1′), and H(6-1)···S(2′) are all about 2.9 Å. They are shorter than the sum of the van der Waals radii of H and S atoms (3.05 Å), suggesting a strong repulsion. Thus, the long Cd–N distance of this adducts is probably attributable to the hindrance caused by the bulky ligand. As was shown in another paper, the Co–P distance of Co(II)(Me_2dtp)$_2$(PPh_3) is also large, because of the bulky ligand.[1] In the case of smaller ligands, the metal-nitrogen distances of the amine adducts, for example, the Ni–N distances of Ni(II)(dtp)$_2$·X_n-type adducts, are not unusually long (2.06—2.11 Å);[19–23] they are not much longer than the sum of the coordination radii (2.00 Å).

In the free hex molecule, all the C–N bonds are equivalent; their length is 1.476(2) Å. In contrast, the average distance between carbon and nitrogen atoms bonded to the metal atom in the present adduct is 1.488(5) Å, and the mean length of the other N–C bonds is 1.464(5) Å. This observation suggests that electrons flow from the ligand into the metal through the coordinated nitrogen atom. The same type of elongation of the C–N bond of hex has also been reported for its adducts of borane[27] and iodine.[28]

The powder X-ray diffraction pattern of **2** was compared with that of the same type of Co(II) adduct. The diffraction patterns are shown in Fig. 3a. The peak positions, as well as their intensities, correspond with each other, except for some weak peaks. Their infrared spectra in the 400—4000 cm^{-1} region are also similar. Thus, the cadmium(II) and cobalt(II) adducts are likely to be isostructural, exhibiting a five-coordinate trigonal bipyramidal configuration.

The powder X-ray diffraction patterns of **1**, **2**, **3**, and hex were compared with each other, but no coincidence between them were recognized. This fact indicates that **2** and **3** are not mixtures, but different kinds of compounds.

The adduct **5** and Co(II)(dtp)$_2$(pip), as well as **6** and Co(II)(dtp)$_2$(pyr), are found to be isostructural with one another, and the structure of **5** resembles that of **6**; the diffraction patterns of **5**, **6**, and Co(II)-

dtp: *O,O'*-Diethyl dithiophosphato ligand; hex: hexamethylenetetramine; PPh$_3$: triphenylphosphine; pip: piperaziae; pyr: pyrazine; bzt: benzothiazole; bza: benzylamine.

$(dtp)_2(pyr)$ are shown in Fig. 3b. These cobalt(II) adducts are expected to have an octahedral configuration,[1] where two nitrogen atoms of the ligand act as donor atoms, and the ligand bridges two metal atoms. Therefore, the corresponding cadmium(II) adducts may have the same structure. The **4** and **7** adducts are not exactly isostructural to the corresponding $Co(II)(dtp)_2$ adducts, but each pair of adducts is likely to have structures resembling each other.

The chemical shifts of the ^{1}H-NMR of **1** and its adducts in a chloroform-*d* solution, together with those of the free ligands, are shown in Table 3. As expected, the signals of the dtp ethyl protons are shifted to a higher magnetic field by the formation of the adducts. On the other hand, the signals of the amine or phosphine protons of the adducts appear in a lower magnetic field than those of the corresponding ligands. This fact shows that the amine or phosphine molecules form bonds with the complex, even in a solution, or at least in equilibrium with the bonded form. Thus, the electrons appear to flow from the amine or phosphine to the dtp ligand through the central metal atom.

We gratefully acknowledged the assistance on the structure-analysis calculations by Mr. Yasuhiko Yukawa of the Faculty of Science and Technology, Sophia University.

(Received November 11, 1981)

The reaction of rare-earth sesquioxides (Ln_2O_3) with vanadium dioxide (VO_2) at 1400 °C and 50 kbar** and 30 kbar was studied. Quadrivalent vanadium ions were reduced to the trivalent state, rare-earth vanadates (III) ($LnVO_3$) being obtained. For $LnVO_3$ a typical transformation of the ABO_3-type compounds, one from the aragonite-type to the perovskite-type *via* the vaterite- or calcite-type structure was observed with a decrease in the ionic radius of the rare-earth ions. The magnetic properties of the vaterite-type $LnVO_3$ were studied.

We have previously studied the reaction of erbium sesquioxide (Er_2O_3) with vanadium dioxide (VO_2) at 1400 °C and 50 kbar and 30 kbar, and succeeded to obtain vaterite- and calcite-type $ErVO_3$.[1] Under these conditions quadrivalent vanadium ions are unstable and reduced to the trivalent state. $ErVO_3$ with the crystal structure other than the perovskite-type has been first obtained. In this paper, we report on the high-pressure reaction of the rare-earth sesquioxides (Ln_2O_3) with VO_2.

Experimental

The preparative and analytical methods were similar to those described previously.[1]

Results and Discussion

The Reaction Products of Ln_2O_3 with VO_2 at High Pressures. The Ln_2O_3–VO_2 mixtures in 1:2 were heated at 1400 °C and 50 kbar or 30 kbar. The atomic ratio of the rare-earth element to vanadium in the products was determined to be 1.0 by the fluorescent X-ray analysis. The valence states of vanadium in the products were estimated from the result of the oxygen analysis, which revealed that the quadrivalent vanadium ions in the products were reduced to the trivalent state and the formulae of the products were $LnVO_3$ in every case.

Crystal Structures of the Products. X-Ray diffraction data for aragonite-type $LaBO_3$[2] and the reaction product of the 1:2 mixture of La_2O_3 and VO_2 heated at 50 kbar for 30 min are given in Table 1. Similarity of the X-ray diffraction pattern of $LaVO_3$ to that of the aragonite-type compound suggests that the compound crystallizes in the orthorhombic system, $a=5.869$ Å, $b=8.261$ Å, and $c=5.103$ Å. The structural feature of $LaVO_3$ obtained at 30 kbar was equal to that of the product obtained at 50 kbar.

The crystal structures of $NdVO_3$ and $SmVO_3$ obtained by heating at 50 kbar and 30 kbar for 30 min belonged to the aragonite-type, same as that of $LaVO_3$. The cell parameters were $a=5.703$ Å, $b=8.032$ Å, and $c=5.011$ Å for the neodymium compound, and $a=$

** 1 bar$=10^5$ Pa.

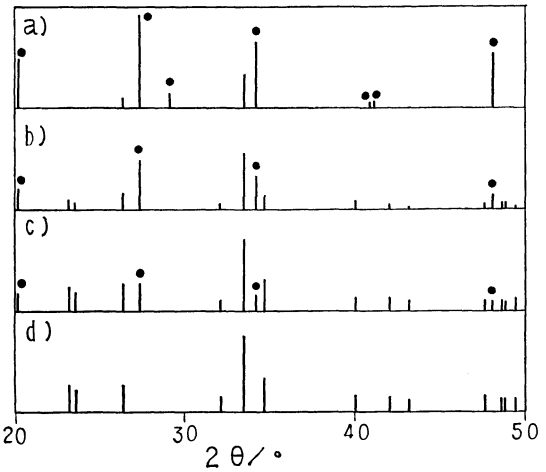

Fig. 1. X-Ray diffraction patterns for Y_2O_3–VO_2 1:2 mixtures at 1400 °C and 50 kbar.
Reaction period; a) 60 min, b) 30 min, c) 10 min, and d) perovskite-type YVO_3.

5.661 Å, b=7.992 Å, and c=5.028 Å for the samarium compound.

The crystal structure of $HoVO_3$ obtained by the reaction of the 1:2 mixture of Ho_2O_3 and VO_2 at 50 kbar for 30 min was isostructural with $HoBO_3$,[2] vaterite-type and belonged to the hexagonal system, while one obtained at 30 kbar was the calcite-type belonging to the rhombohedral (pseudo-hexagonal) system. These results are similar to those of the reaction of Er_2O_3 with VO_2.[1]

The X-ray diffraction patterns of the products obtained by the reaction of Y_2O_3–VO_2 (1:2 mixture) along with that of the perovskite type YVO_3 are shown in Fig. 1. The peaks marked by a dot can be assigned to the vaterite-type crystal. When the reaction was carried out at 1400 °C and 50 kbar for 10 min or 30 min, a mixture of perovskite- and vaterite-type YVO_3 was obtained. A prolonged reaction time (60 min) resulted in a decrease in the perovskite-type and an increase in the vaterite-type compounds.

The reaction product of Dy_2O_3–VO_2 (1:2 mixture) at 50 kbar for 30 min was the perovskite-type crystal including a trace amount of the vaterite-type compound, and those of Y_2O_3–VO_2 and Dy_2O_3–VO_2 (1:2 mixtures) at 30 kbar for 30 min were perovskite-type crystals along with a trace amount of the calcite-type compound. If the reaction time is longer for the Y_2O_3–VO_2 and Dy_2O_3–VO_2 systems, vaterite- or calcite-type crystals will be obtained.

For the reaction products of Eu_2O_3 or Gd_2O_3 with VO_2 their poor crystallinity prevented the determination of their crystal structures.

The reactions between Yb_2O_3, Tm_2O_3, and Lu_2O_3 with VO_2 at high pressures gave perovskite-type oxides.

The crystal structures of the high-pressure products as well as those of the rare-earth borates are summarized in Fig. 2. As is well known aragonite, vaterite and calcite are modifications of calcium carbonate (Fig. 3). The rare-earth borate transforms from the aragonite-type to the calcite-type structure *via* the vaterite-type structure with a decrease in ionic radius

of the rare-earth ions. For the rare-earth vanadates(III) a typical transformation observed for the ABO_3-type compounds,[3] one from the aragonite-type to the perovskite-type *via* the vaterite- or calcite-type structure was observed with a decrease in ionic radius of the rare-earth ions. That the crystal structure of the rare-earth vanadates(III) depends on the reaction pressure will be due to the difference in the compres-

sibilities of the vanadium and rare-earth ions, and at high pressure, the vanadium ions are more compressible than the rare-earth ions.

The cell parameters and the density calculated from X-ray diffraction data of the high-pressure synthesized crystals are summarized in Table 2 along with those of the perovskite-type vanadates(III).[4] In general, the increase in pressure tends to stabilize the denser phase, and the most dense ABO_3 phase is considered to have the cubic-perovskite structure.[5] $LnVO_3$ with the perovskite-type structure are orthorhombically distorted from the ideal cubic perovskite structure, and the distortion increases with decrease in the ionic radius of the rare-earth ions.[4] Since packing of the ions in the perovskite-type crystals is insufficient because of the distortion, aragonite- and vaterite-type $LnVO_3$ crystals except $LaVO_3$ have a larger density than that of perovskite-type $LnVO_3$.

Magnetic Properties of the Vaterite-type $LnVO_3$. The magnetic susceptibility measurements were performed in the temperature range 4.5—300 K. The magnetic properties of the vaterite-type YVO_3, $HoVO_3$, and $ErVO_3$ are summarized in Table 3. As the observed values of the magnetic moment for these crystals are close to those for Ln^{3+}, V^{3+} ions order antiferromagnetically in the temperature range from T_N to T_C, and the observed transformations at high temperature are attributable to their antiferromagnetic ordering. All the compounds with the vaterite-type structure were paramagnetic, the magnetic susceptibility following the Curie-Weiss law above the Neel temperature, T_N. Below the temperature, T_C, they showed ferromagnetic behavior. The value of the magnetic moment at 4.5 K suggests that this transition is attributable to the rearrangement of the antiferromagnetically ordered V^{3+} ions to the ferromagnetic state.

Fourier Transform Infrared Photoacoustic Spectroscopy of Polymers

Norio TERAMAE,* Masayuki HIROGUCHI, and Shigeyuki TANAKA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 14, 1981)

Fourier transform infrared photoacoustic spectroscopy (FTIR-PAS) was applied to the structural elucidation of several kinds of organic polymers. By using a photoacoustic detection, infrared spectra of textile fabrics and rubbers containing carbon black could be measured without destructive and troublesome sample preparations. Curing process of resol type phenolic resins was examined by FTIR-PAS and conventional KBr disk method. FTIR-PAS was found to be sensitive to the structural change of the surface of the cured resins. Helmholtz resonance effect of the photoacoustic cell and the effect of the thermal properties of samples in FTIR-PAS were also discussed.

Photoacoustic spectroscopy (PAS) has been known to be a useful method for the analysis of bulk or rugged surface materials.[1] Most of the studies on PAS, however, are limited to the uv-visible spectral region, for which powerful excitation sources are readily available. On the other hand, high power sources tunable over a wide spectral range do not presently exist in the infrared spectral region. In recent years, there has been a growing interest in PAS using Fourier transform infrared spectroscopy (FTIR),[2-11] since a FTIR spectrometer has a greater throughput of radiation than the conventional dispersive infrared spectrometer.[12] However, few discussions on the characteristics of the Fourier transform infrared photoacoustic spectroscopy (FTIR-PAS) have been made. In this study, some discussions on the factors which affect the FTIR-PAS spectra are made, and some application of FTIR-PAS to the structural elucidation of organic polymers is presented.

Experimental

The PAS system was composed of a home-made PAS attachment and a Digilab FTS-15 FTIR spectrometer.

Figure 1 shows a schematic drawing of the PAS cell employed in this study. The PAS cell was made of brass and its internal volume was approximately 0.95 cm^3. A KBr plate (3 mm thick) was used as a cell window and a 1/2 inch Bruel Kjaer 4165 condenser microphone was used as a pressure transducer. These were mounted on the PAS cell body by O-rings to ensure an air tight seal. Although KBr is one of the most transparent materials in the infrared region, it is susceptible to humidity. It should be noted that both highly transparent and wet-proof windows can not be available in the infrared region, and that the Helmholtz resonance effect affects the FTIR-PAS spectra as will be mentioned later. Therefore, the cell was designed so that the windows could be replaced easily and also that the volume in front of the microphone diaphragm could be adjusted easily in order to obtain optimum efficiency.

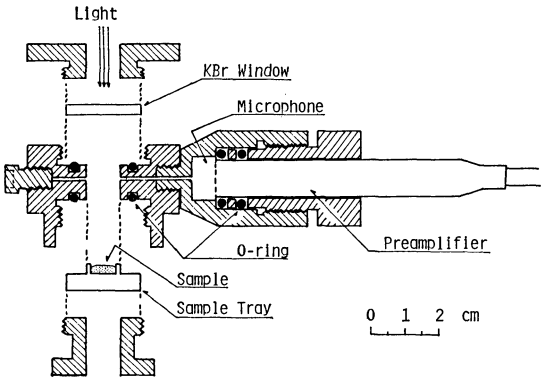

Fig. 1. Schematic drawing of photoacoustic cell.

The photoacoustic signals from the microphone attached to the PAS cell were amplified with a Brookdeal 9454 a.c. amplifier and were fed to the HgCdTe detector amplifier section of the FTIR spectrometer. All of the spectra were measured at 4 cm^{-1} resolution using 900 scans which took about 25 min.

Results and Discussion

Characteristics of FTIR-PAS. Figure 2 shows the photoacoustic spectrum of carbon black (benzene soot) and the source spectrum measured by a triglycine sulfate (TGS) detector. The carbon black PAS spectrum and the source spectrum measured by a pyroelectric detector such as TGS are known to be vir-

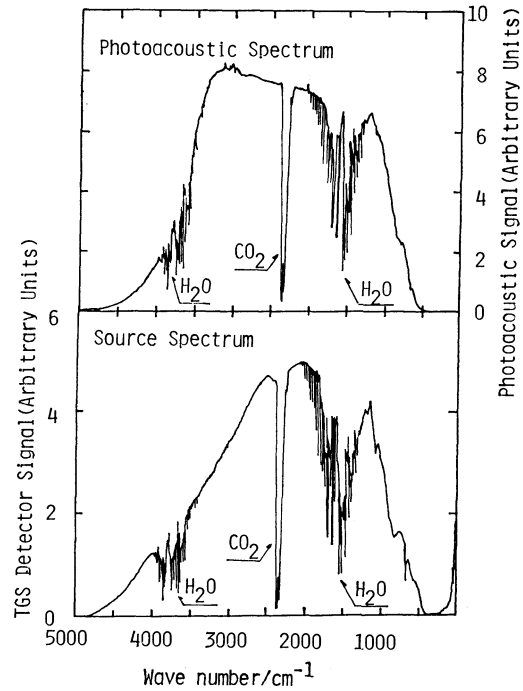

Fig. 2. Photoacoustic spectrum of carbon black (upper) and source spectrum measured by TGS detector (lower).

tually identical with each other in the dispersive PAS system with a fixed frequency light modulation.[13,14] As shown in Fig. 2, the above identity is not observed in the case of FTIR-PAS. This result can be considered to be attributed to the difference of the light modulation methods between the interferometry and the dispersive spectrometry. In the case of rapid scanning FTIR, the frequency of the radiation being emitted from the source, ν[cm^{-1}], corresponds to the modulation frequency, ω[s^{-1}], through the relationship, $\omega=2V\nu$, where V represents the velocity of the moving mirror in a Michelson interferometer.[12] Considering that the carbon black PAS signals are inversely proportional to the modulation frequencies,[15] carbon black PAS signals for FTIR-PAS must be larger in the lower wave number region. However, this expected tendency was not observed as shown in Fig. 2. Accordingly, another additional effect must be taken into consideration for the analysis of FTIR-PAS spectra. Since another type of PAS cell[2] showed a different spectral pattern of carbon black compared with the results shown in Fig. 2, the possibility of the influence of the Helmholtz resonance effect was examined by changing the volume in front of the microphone diaphragm.

The Helmholtz resonance frequency, ω_0, is given by[16]

$$\omega_0 = (v_0/2\pi)[\{(1/V_1)+(1/V_2)\}\sigma/\{L+(1/2)(\pi\sigma)^{1/2}\}]^{1/2},$$

where v_0 is the speed of sound, and V_1 and V_2 are the volume of the sample cavity and the volume in front of the microphone diaphragm, respectively. σ is the cross-sectional area of the tube of length L connecting the volume V_1 and V_2. Figure 3 shows the photoacoustic spectral changes due to the Helmholtz resonance effect when V_2 is changed from 90 to 750 mm^3. These curves were obtained by dividing the carbon black PAS spectra by the source spectrum presented in Fig. 2. As shown in Fig. 3, the peak which represents resonance frequency moves to lower wave numbers, as the volume V_2 becomes larger. The observed resonance frequencies were plotted against the $[(1/V_1)+(1/V_2)]^{1/2}$ values, and a good linear correlation was obtained as shown in Fig. 4. From the

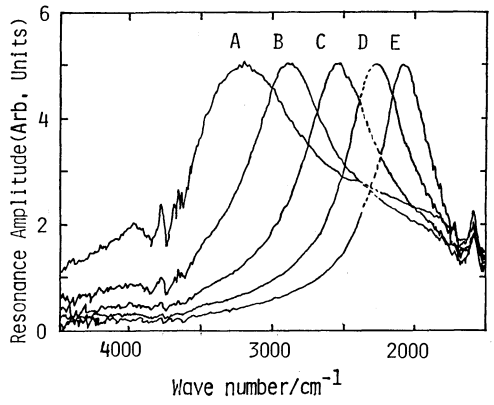

Fig. 3. Resonance effect obtained by changing the volume in front of the microphone diaphragm. The volumes, V_2, are 90(A), 150(B), 290(C), 420(D), and 750(E) in mm^3 units.

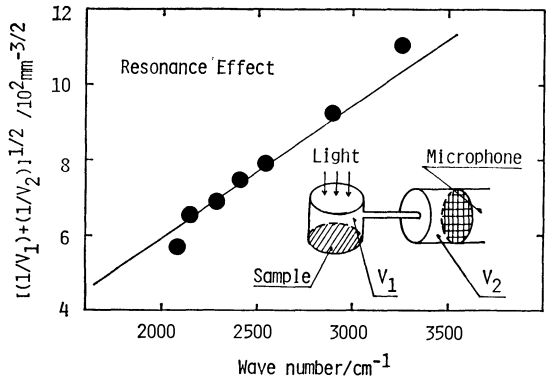

Fig. 4. Helmholtz resonance effect of the photoacoustic cell.

above-mentioned fact, the PAS signals in FTIR are considered to be influenced greatly by the Helmholtz resonance effect. Strictly speaking, the effect of the volume of sample must be taken into consideration for the normalization of FTIR-PAS spectra. However, the effect can be neglected if V_1 is sufficiently greater than V_2.

Although the above effect can be compensated when the normalization of the sample PAS spectra is carried out by using a carbon black PAS spectrum measured by the same PAS cell as a reference, the effect must be taken into account if the measurement of FTIR-PAS is carried out by the use of double beam measurement system which requires two PAS cells. Of cource, if a completely non-resonant type of PAS cell is used, the above-mentioned effect can be neglected. However, it is considered to be better to use a resonant type of PAS cell in order to improve the S/N ratio of PAS spectra, since the usual light source in the infrared spectral region is not powerful.

FTIR-PAS spectra of several kinds of polymers such as cloths, rubbers, cured resins *etc.* were measured. Although the features of these spectra were fairly similar to those of published spectra measured by a KBr method or an ATR method etc., photoacoustic signals were found to be larger in the lower wave number regions. This result can be attributed to the thermal properties of the samples, since the thermal diffusion length in the sample depends on the modulation frequency.[15] The samples investigated in this study are considered to be optically opaque and thermally thick solids, for which photoacoustic signals show $\omega^{-3/2}$ dependence, where ω is the modulation frequency. In this case, further normalization must be carried out by multiplying a factor of $\omega^{1/2}$, that is $(2V\nu)^{1/2}$, after simply dividing the raw PAS spectrum by a carbon black PAS spectrum, since carbon black PAS signals are inversely proportional to ω. The above mentioned normalizing procedures would be necessary if we wish to compare the PAS spectra with the standard spectral data such as IRDC cards.

FTIR-PAS Spectra of Polymers. Figure 5 shows the PAS spectra of nylon cloth and cotton cloth. The features of these spectra are fairly similar to those of the published spectra measured by a KBr method or a thermally pressed film method.[17] Using the

photoacoustic detection, infrared spectra of these textile fabrics can be obtained by simply putting a small piece of sample into the PAS cell. Thus, it can be said that FTIR-PAS could be a simple but still effective method for the identification of these compounds without troublesome and destructive sample preparations which are nescessary for conventional measurement techniques.

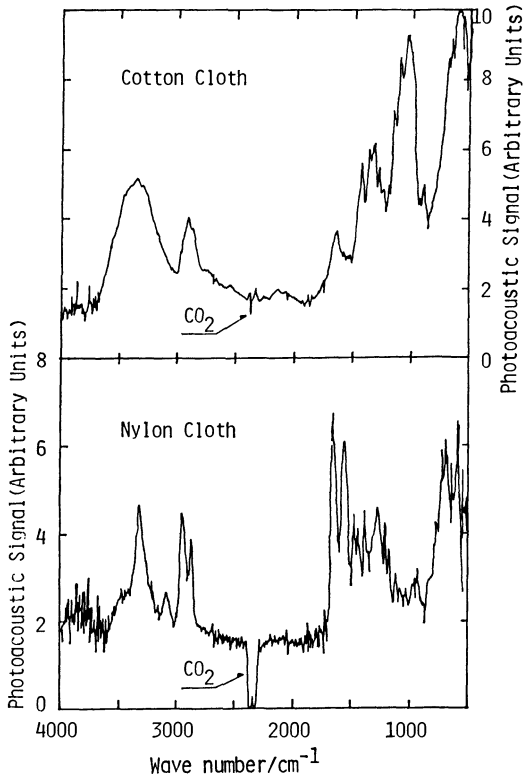

Fig. 5. Photoacoustic spectra of cotton (upper) and Nylon (lower) cloths.

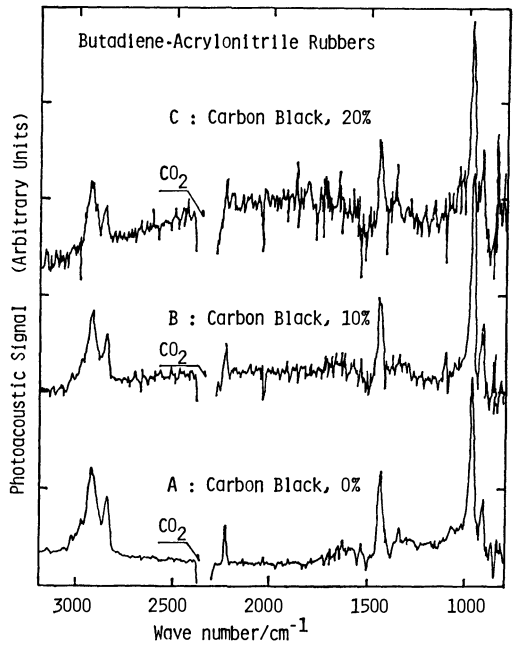

Fig. 6. Photoacoustic spectra of butadiene-acrylonitrile rubbers containing carbon black.
Carbon black content, A: 0%, B: 10%, C: 20%.

In Fig. 6, PAS spectra at the top, the middle and the bottom show butadiene–acrylonitrile rubbers containing carbon black, 20, 10, and 0%, respectively. Commercial rubbers usually contain carbon black or silica in order to enhance elasticity. The conventional measurement technique used to examine rubbers is an ATR method, which requires a specially designed apparatus,[18] capable of taking a large incident angle for obtaining spectra of the sample containing carbon black because of the high refractive indices of samples. As shown in Fig. 6, however, structural elucidation of rubbers can be made in the same manner regardless of the content of carbon black in the range of 0 to 20%. It can be seen that the S/N ratio of the PAS spectra decreases as the content of carbon black increases. This result is possibly due to the fact that the more carbon black a sample contains, the less light it receives. From the fact, FTIR-PAS would be more useful for the structural elucidation of rubbers which contain silica, since silica absorbs less light than carbon black does.

Figure 7 shows the spectral change by curing a resol type phenolic resin. These spectra were measured after heating the sample at 170 °C for 0, 15, 30, 60, and 120 min. The curing process of the resin was reported to be characterized as follows.[19] As the resin is heated, the intensity of the band due to C–O–C stretching vibrational mode at about 1050 cm^{-1} decreases, and a new band due to carbonyl stretching vibrational mode at about 1650 cm^{-1} appears. The new band is considered to be caused by the oxidation of the methylene group. The PAS spectral changes are well consistent with the above proposed curing process. In Fig. 8, spectra at the left and the right halves are the expanded spectra of the above-

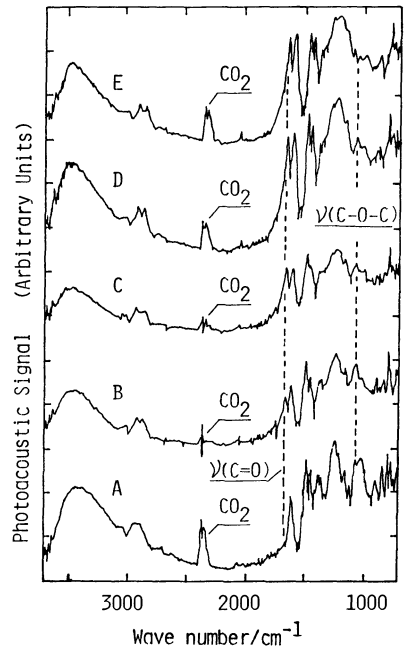

Fig. 7. Photoacoustic spectral change of resol type phenolic resin.
Heating temperature is 170 °C. Heating periods are 0(A), 15(B), 30(C), 60(D), and 120(E) min.

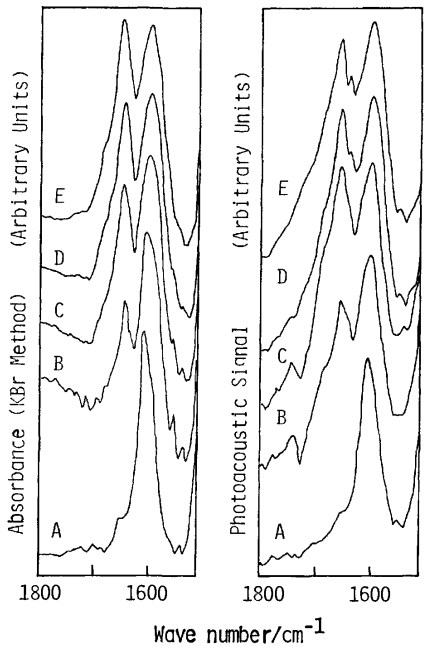

Fig. 8. Absorption spectra measured by a KBr method (left side) and photoacoustic spectra (right side) of cured resol type phenolic resins.
Heating periods are 0(A), 15(B), 30(C), 60(D), and 120(E) min.

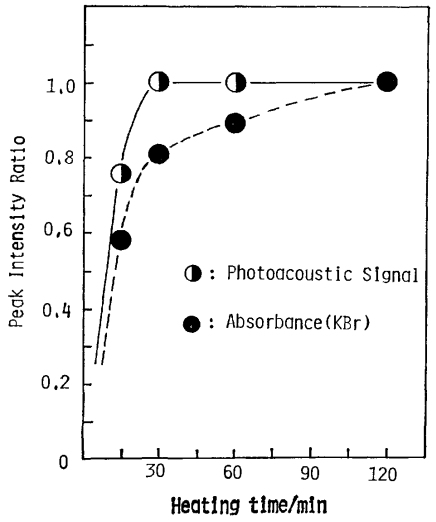

Fig. 9. Peak intensity ratio of the 1650 cm^{-1} band to the 1610 cm^{-1} band *vs.* heating time.

mentioned resins measured by absorption and photoacoustic techniques, respectively. The absorption spectra were obtained by a KBr method, in which the resins used for measuring FTIR-PAS were ground to fine powders. During the curing of resol type phenolic resins, the absorption intensity of the band at about 1610 cm^{-1} which is assigned to aromatic C=C stretching vibrational mode is said to be unchanged.[19] Therefore, in order to examine the degree of curing of the resin as well as to compare results which is obtained by the two measuring methods presented in Fig. 8, the ratio of the intensity of the carbonyl absorption band at 1650 cm^{-1} to that of the aromatic absorption band at 1610 cm^{-1} was plotted against the heating period by using absorption and photoacoustic spectra. The results are shown in Fig. 9. Comparing the two curves in Fig. 9, it is immediately seen that the ratio reaches to a constant value within 30 min by using the PAS spectral data. Whereas, as for the absorption spectral data, the ratio is gradually increases as the heating time increases. This result reflects that the PAS is sensitive to the structural change of the surface of cured resin, and that averaged information about the mixed species of cured and non-cured resins is obtained by the absorption method such as a KBr technique. If the constant value in the ratio shown in Fig. 9 is caused by the saturation effect of the photoacoustic signal,[15] the depth of the cured layer can be estimated. Assuming that the thermal diffusivity of the cured resin is 0.001 (cm^2/s), thermal diffusion length of 5.7 microns is obtained at 1650 cm^{-1} under the measuring conditions in our spectrometer.[3] Accordingly, the cured layer of several microns can be considered to be formed during the heating of 0 to 30 min. Thus, FTIR-PAS is useful for the surface characterization of cured resins. In some cases, cured resins are difficult to examine by conventional measurement techniques because of their mechanical hardness. For the analysis of such materials, FTIR-PAS is also effective, since FTIR-PAS requires minimal sample preparations.

The authors wish to express their thanks to Dr. Tsuguo Sawada and Professor Yohichi Goshi, The University of Tokyo, and Dr. Shohei Oda, Fuji Film Co., Ltd., for their helpful discussions. We also would like to thank Dr. Morio Tsuge, Sumitomo Bakelite Co., Ltd., for providing phenolic resins as samples.

Circular Dichroism Spectra of *fac*(*D*)-[Co(a)(BC)(DDD)]$^{n+}$ Type Complexes with 1,4,7-Triazacyclononane, (2*R*)-2-Methyl-1,4,7-triazacyclononane, and 1,5,9-Triazacyclododecane

Shuhei Fujinami,* Yukio Matsunami, and Muraji Shibata
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received November 16, 1981)

The complexes, [Co(L-val)(NH_3)(tacn)]$^{2+}$ (tacn=1,4,7-triazacyclononane), [Co(gly)(NH_3)(Me-tacn)]$^{2+}$ (Me-tacn=(2*R*)-2-methyl-1,4,7-triazacyclononane) have been prepared and separated into diastereomers by column chromatography. Six other complexes, [Co(a)(β-ala)(tacn)]$^{n+}$ (a=CN^-, NO_2^-, or NH_3) and [Co(a)(gly)(tacdd)]$^{n+}$ (a=NO_2^-, NCS^-, or H_2O; tacdd=1,5,9-triazacyclododecane) have also been prepared and resolved into enantiomers. By comparing the CD spectra of the L-valinato and the Me-tacn complexes with that of [Co(gly)(NH_3)(tacn)]$^{2+}$, the optical activities of [Co(a)(gly)(tacn)]$^+$ are considered to be mainly derived from chiral arrangements of four kinds of donor atoms. The change from five-membered chelate ring to a six-membered one has slight influence upon the CD spectral shapes in the β-alaninato complex, but a large influence in the tacdd complexes.

In recent studies on the CD spectra of a series of [Co(a)(gly)(tacn)]$^{n+}$ complexes (a=CN^-, NO_2^-, NH_3, NCS^-, H_2O, OH^-, N_3^-, or Cl^-; tacn=1,4,7-triazacyclononane), it has been concluded that, though two helical ring-pairs exist in the complexes, the optical activities of the complexes are mainly derived from a chiral arrangement of four kinds of donor atoms, each N donor in tacn and gly, O donor in gly, and the donor of a unidentate.[1] In this work, we aimed to confirm the above conclusion by extending the CD spectral studies to various *fac*(*D*)-[Co(a)(BC)(DDD)]$^{n+}$ complexes which contain tacn, Me-tacn(=(2*R*)-2-methyl-1,4,7-triazacyclononane) or tacdd (=1,5,9-triazacyclododecane) as DDD, and L-val or β-ala as BC. The Me-tacn complex has a preferable conformation due to the orientation of the methyl group. Therefore, the CD spectral comparison between the Me-tacn and tacn complexes will afford information about the conformational contribution to the optical activity in the latter complex. Since the L-valinate ion has a bulky isopropyl group, a large interaction between the substituent and the tacn molecule are anticipated in the [Co(a)(L-val)(tacn)]$^{n+}$ complex. Six-membered chelate rings exist in the β-alaninato and the tacdd complexes, and the CD spectra of these complexes are interesting to compare with those of [Co(a)(gly)(tacn)]$^{n+}$ which contains five-membered chelate rings.

Experimental

Ligand. 1,4,7-Triazacyclononane trihydrochloride (TACN·3HCl), (2*R*)-2-methyl-1,4,7-triazacyclononane trihydrobromide (Me-TACN·3HBr), and 1,5,9-triazacyclododecane trihydrochloride or trihydrobromide (TACDD·3HCl or TACDD·3HBr) were prepared according to the literatures.[2,3]

Preparation of Complexes. *1) (Ammine)(1,4,7-triazacyclononane)(L-valinato)cobalt(III) Chloride, [Co(L-val)(NH_3)(tacn)]Cl_2*: At first, a [Co(NCS)(L-val)(tacn)]$^+$ complex was prepared in the same way as a [Co(NCS)(gly)(tacn)]$^+$ complex,[1] by using of *mer*(*N*)-*trans*(NH_3)-[Co(CO_3)(L-val)(NH_3)$_2$][4] (3.5 g, 0.013 mol) and TACN·3HCl (3 g, 0.013 mol). At the second step, the isothiocyanato complex was oxidized with aqueous H_2O_2 (30%) at pH *ca.* 3.[1] The resulting solution was poured onto a column of SP-Sephadex C-25 in Na^+ form (3.5 cm×40 cm). The adsorbed band was eluted with a 0.05 mol/dm^3 Na_2SO_4 solution, and an orange band containing aimed bivalent cation was collected in a fraction. The effluent was concentrated at 40 °C and the eluting agent removed.

One fourth of the concentrate was dissolved in a large amount of water, and poured onto a column of SP-Sephadex C-25 in Na^+ form (2.5 cm×70 cm). By eluting with 0.075 mol/dm^3 K_2[Sb_2(*d*-tart)$_2$], the adsorbed band was separated into two components which were labelled E1 and E2 in the order of elution (these labels were also used to designate the isomers contained in each band). When the E1 band had descended to the neighborhood of the outlet of the column, the two bands were washed with water and then eluted with a 0.1 mol/dm^3 NaCl solution. The two bands were collected in each fraction. This procedure was repeated for the residual portion of the concentrate. The combined fractions were concentrated, and the eluting agent which precipitated was removed by repeated filtration. To the final filtrate was added a small amount of ethanol, and the whole was kept in a refrigerator. The crude products were recrystallized from warm water. The yield was *ca.* 0.05 g for E1, and 0.1 g for E2. Found for E1: C, 30.64; H, 7.36; N, 16.33%. Calcd for [Co(L-val)(NH_3)(tacn)]Cl_2·$2H_2O$=$C_{11}H_{32}N_5O_4Cl_2Co$: C, 30.85; H, 7.53; N, 16.35%. Found for E2: C, 31.83; H, 7.07; N, 17.16%. Calcd for [Co(L-val)(NH_3)(tacn)]Cl_2·H_2O=$C_{11}H_{30}N_5O_3Cl_2Co$: C, 32.21; H, 7.37; N, 17.07%.

2) (Ammine)(glycinato)[(2R)-2-methyl-1,4,7-triazacyclononane]cobalt(III) Perchlorate, [Co(gly)(NH_3)(Me-tacn)](ClO_4)$_2$: This complex was prepared in the same manner as a [Co(gly)(NH_3)(tacn)]$^{2+}$ complex,[1] except for the use of Me-TACN·3HCl in place of TACN·3HCl.

The reaction mixture was poured onto a column of Dowex 50W-X8 in H^+ form (5.5 cm×10 cm), and the adsorbed band was eluted by a 0.5 mol/dm^3 H_2SO_4 solution. The descended orange band was collected in a fraction, and the eluate was adjusted to pH 6 by $BaCO_3$. After filtration, the filtrate was concentrated, and small amount of ethanol was added to the concentrate. The whole system was kept in a refrigerator. The yield was about 0.1 g. Found: C, 26.31; H, 6.73; N, 17.28%. Calcd for [Co(gly)(NH_3)(Me-tacn)]SO_4·H_2O=$C_9H_{26}O_7N_5SCo$: C, 26.53; H, 6.45; N, 17.19%.

The orange crystals obtained were dissolved in water and the solution was subjected to a column chromatography on SP-Sephadex C-25 in Na^+ form (2.5 cm×110 cm). By elution with 0.05 mol/dm^3 K_2[Sb_2(*d*-tart)$_2$], the adsorbed

band was separated into three bands which were labelled B1, B2, and B3 in the order of elution (these labels were also used to designate the isomers contained in each band). When the B1 band had descended to the neighborhood of the outlet of the column, the band was washed with water and then eluted with a 0.1 mol/dm^3 NaCl solution. The absorption and CD spectra of the effluents were measured and the metal-concentrations were evaluated by atomic absorption spectrophotometry.

3) (β-Alaninato)(nitro)(1,4,7-triazacyclononane)cobalt(III) Chloride Dihydrate, [*Co(NO$_2$)(β-ala)(tacn)*]*Cl·2H$_2$O*: At the first step, a [Co(β-ala)(H$_2$O)(tacn)]$^{2+}$ complex was prepared similarly to a [Co(gly)(H$_2$O)(tacn)]$^{2+}$ complex.[1] The aqua complex could not be isolated because of the great solubility of the species in water. At the next step, a [Co(NO$_2$)(β-ala)(tacn)]$^+$ complex was derived from the aqua complex, according to the literature method.[1] Found: C, 27.41; H, 6.51; N, 17.48%. Calcd for [Co(NO$_2$)(β-ala)(tacn)]Cl·2H$_2$O=C$_9$H$_{25}$N$_5$O$_6$ClCo: C, 27.45; H, 6.41; N, 17.79%.

4) (β-Alaninato)(ammine)(1,4,7-triazacyclononane)cobalt(III) Perchlorate Monohydrate, [*Co(β-ala)(NH$_3$)(tacn)*](*ClO$_4$*)$_2$·*H$_2$O*: This complex was derived from the above [Co(β-ala)(H$_2$O)(tacn)]$^{2+}$ complex in the same manner as in the [Co(gly)(NH$_3$)(tacn)]$^{2+}$ complex.[1] Found: C, 21.13; H, 5.18; N, 13.63%. Calcd for [Co(β-ala)(NH$_3$)(tacn)](ClO$_4$)$_2$·H$_2$O=C$_9$H$_{26}$N$_5$O$_{11}$Cl$_2$Co: C, 21.18; H, 5.15; N, 13.73%.

5) (β-Alaninato)(cyano)(1,4,7-triazacyclononane)cobalt(III) Perchlorate, [*Co(CN)(β-ala)(tacn)*]*ClO$_4$*: This complex was also prepared similarly to the [Co(CN)(gly)(tacn)]$^+$ complex,[1] starting from the [Co(β-ala)(H$_2$O)(tacn)]$^{2+}$ by way of [Co(Cl)(β-ala)(tacn)](NO$_3$). The complex was isolated by column chromatography (SP-Sephadex C-25, 4.5 cm×25 cm, Na$^+$ form, by use of 0.05 mol/dm^3 NaClO$_4$ as eluent). Found: C, 29.62; H, 5.28; N, 17.56%. Calcd for [Co(CN)(β-ala)(tacn)]ClO$_4$=C$_{10}$H$_{21}$N$_5$O$_6$ClCo: C, 29.89; H, 5.28; N, 17.44%.

6) (Glycinato)(isothiocyanato)(1,5,9-triazacyclododecane)cobalt(III) Bromide 1,5-Hydrate, [*Co(NCS)(gly)(tacdd)*]*Br·1.5*H$_2$O: A [Co(gly)(H$_2$O)(tacdd)]$^{2+}$ complex was first prepared by use of *mer(N)-trnas(NH$_3$)*-[Co(CO$_3$)(gly)(NH$_3$)$_2$][5] (0.8 g, 0.0036 mol) and TACDD·3HCl (1 g, 0.0036 mol), by the method similar to that for the [Co(gly)(H$_2$O)(tacn)]$^{2+}$ complex.[1] Crystallization of the aqua complex was unsuccessful because of a great solubility of the complex species in water.

An isothiocyanato complex was then derived from the aqua complex in the same way as the [Co(NCS)(gly)(tacn)]$^+$ complex,[1] with slight modifications; an aqueous solution (20 cm^3) containing the aqua complex which had been prepared at 0.01 mol scale was adjusted to pH 2 with 20% HClO$_4$, after which KSCN (1.5 g, 0.015 mol) was added to the solution. The mixture was stirred at *ca.* 50 °C for 2 h. The resulting solution was poured onto a column of SP-Sephadex C-25 in Na$^+$ form (4.5 cm×30 cm). The adsorbed band was eluted with a 0.03 mol/dm^3 NaBr solution, and a red-violet band which descended was collected in a fraction. The eluate was concentrated by means of a rotary evaporator at 35 °C. After addition of ethanol, the solution was kept in a refrigerator. The crystal deposited was recrystallized from water. The yield was *ca.* 0.3 g. Found: C, 30.44; H, 6.06; N, 15.15%. Calcd for [Co(NCS)(gly)(tacdd)]Br·1.5H$_2$O=C$_{12}$H$_{28}$N$_5$O$_{3.5}$SBrCo: C, 30.71; H, 6.01; N, 14.92%.

7) (Glycinato)(nitro)(1,5,9-triazacyclododecane)cobalt(III) Bromide, [*Co(NO$_2$)(gly)(tacdd)*]*Br*: This complex was prepared by the same method as a [Co(NO$_2$)(gly)(tacn)]$^+$ complex,[1] except for the use of [Co(gly)(H$_2$O)(tacdd)]$^{2+}$ which had been prepared at 0.01 mol scale. The yield was *ca.* 0.3 g. Found: C, 30.48; H, 5.76; N, 16.00%. Calcd for [Co(NO$_2$)(gly)(tacdd)]Br=C$_{11}$H$_{25}$N$_5$O$_4$BrCo: C, 30.71; H, 5.76; N, 16.28%.

8) Trinitro(1,5,9-triazacyclododecane)cobalt(III), [*Co(NO$_2$)$_3$-(tacdd)*]: This complex was prepared by the same procedure as a [Co(NO$_2$)$_3$(tacn)] complex,[6] except for the use of TACDD·3HBr in place of TACN·3HBr. The crystals deposited in the course of the reaction were washed with a small amount of water. Starting from 0.1 mol TACDD·3HBr (2.96 g), the yield was *ca.* 0.1 g. Found: C, 29.26; H, 5.68; N, 22.79%. Calcd for [Co(NO$_2$)$_3$(tacdd)]=C$_9$H$_{21}$N$_6$O$_6$Co: C, 29.36; H, 5.75; N, 22.82%.

Optical Resolution. The three β-alaninato complexes, [Co(CN)(β-ala)(tacn)]$^+$, [Co(NO$_2$)(β-ala)(tacn)]$^+$, and [Co(β-ala)(NH$_3$)(tacn)]$^{2+}$, were resolved into each optical antipodes by means of a column chromatography of SP-Sephadex C-25 (2.5 cm×110 cm, Na$^+$ form), using 0.05 mol/dm^3 K$_2$[Sb$_2$(*d*-tart)$_2$] as eluent. Total resolution was attained for the ammine complex, and partial resolutions, for the cyano and nitro complexes.

All of the tacdd complexes were also resolved by means of a column chromatography of SP-Sephadex C-25 in Na$^+$ form (2.5 cm×110 cm, for the nitro and isothiocyanato complexes; 2.5 cm×130 cm, for the aqua complex). Total resolutions were attained for the nitro and isothiocyanato complexes, when the elutions were performed with 0.075 mol/dm^3 and 0.15 mol/dm^3 (saturated) K$_2$[Sb$_2$(*d*-tart)$_2$] solutions, respectively. As to the aqua complex, a 0.15 mol/dm^3 Na$_2$[Sb$_2$(*d*-tart)$_2$] solution was used as eluent. When each adsorbed band descended to four-fifths of the column height, the band was sufficiently washed with water and eluted with 0.1 mol/dm^3 NaCl or NaClO$_4$. The effluents were concentrated and submitted to the measurement of CD spectra, while the concentrations of the complex species were evaluated from the absorption spectral data.

Derivations from Optically Active Complex. $(+)^{CD}_{500}$[Co(NO$_2$)(gly)(tacdd)]$^+$ and $(+)^{CD}_{500}$[Co(NCS)(gly)(tacdd)]$^+$ could be derived from $(-)^{CD}_{500}$[Co(gly)(H$_2$O)(tacdd)]$^{2+}$ in the same way as described in *6)* and *7)*.

Measurements. The absorption spectra in aqueous solution were recorded with a Hitachi 323 recording spectrophotometer. The CD spectra were measured with a JASCO J-40C automatic recording spectropolarimeter equipped with a JASCO Model J-DPZ data processor for CD. As to [Co(gly)(H$_2$O)(tacdd)]$^{2+}$ and [Co(gly)(NH$_3$)(Me-tacn)]$^{2+}$, a Hitachi 170-50 Atomic Absorption Spectrophotometer was used in order to evaluate the metal-concentration.

Results and Discussion

1) The [*Co(L-val)(NH$_3$)(tacn)*]$^{2+}$ *Complex.* As described in Experimental, the [Co(L-val)(NH$_3$)(tacn)]$^{2+}$ complex was prepared by oxidation of a [Co(L-val)(NCS)(tacn)]$^+$ complex. When the reaction mixture of [Co(L-val)(H$_2$O)(tacn)]$^+$ and ammonia under the conditions of pH>10 and 60 °C was chromatographed on SP-Sephadex C-25 column, four bands of [Co(val)(NH$_3$)(tacn)]$^{2+}$ species appeared. The same situation was encountered by use of D-val. These facts showed that racemization of chelating L (or D)-valinate ion took place. On the other hand, aimed two diastereomers were obtained by the reaction of [Co(L-val)(NCS)(tacn)]$^+$ with H$_2$O$_2$ in an acidic solution.

The absorption and CD spectra of the diastereomers

are shown in Fig. 1, and numerical data are summarized in Table 1. The calculated vicinal and configurational contribution curves of the L-valinato complex are illustrated in Fig. 2. The vicinal contribution curve resembles that of $[Co(L\text{-val})(NH_3)_4]^{2+}$,[7] and the configurational contribution curve is similar to that of $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$.[1] This fact indicates that the earlier eluted isomer (E1) has the same absolute configurations as the $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$ isomer,[1,8] and that there is slight interaction between the isopropyl group of chelated L-val and the tacn rings. In other words, the orientation of the isopropyl group does not have much influence on the d-electron optical activity of the L-valinato complex. On this basis, it is considered that the interaction between the CH_2 group of glycinato ligand and the tacn chelate rings is small in the $(-)_{589}$-$[Co(gly)(NH_3)(tacn)]^{2+}$ complex.

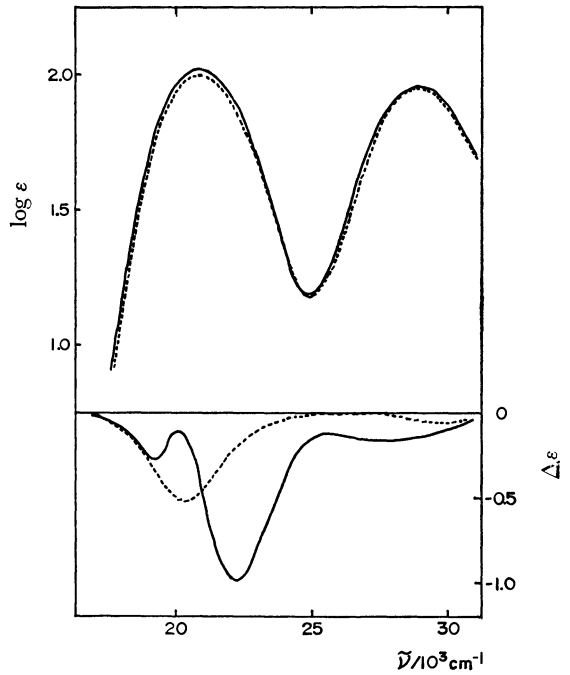

Fig. 1. Absorption and CD spectra of $[Co(L\text{-val})(NH_3)(tacn)]^{2+}$, E1 (——), E2 (·····).

2) The $[Co(gly)(NH_3)(Me\text{-}tacn)]^{2+}$ Complex. There are two coordination modes of Me-tacn, as shown in Fig. 3 (I). In the both modes, the C–CH_3

	29.0 (1.99)	27.0 (0.05)
		29.3 (−0.07)
$[Co(gly)(NH_3)(Me\text{-}tacn)]^{2+}$ (B2)	20.7 (1.95)	20.5 (1.29)
	29.0 (1.99)	27.0 (0.07)
		29.4 (−0.06)
$[Co(gly)(NH_3)(Me\text{-}tacn)]^{2+}$ (B3)	20.8 (1.97)	21.6 (1.15)
	29.0 (2.01)	27.0 (0.16)

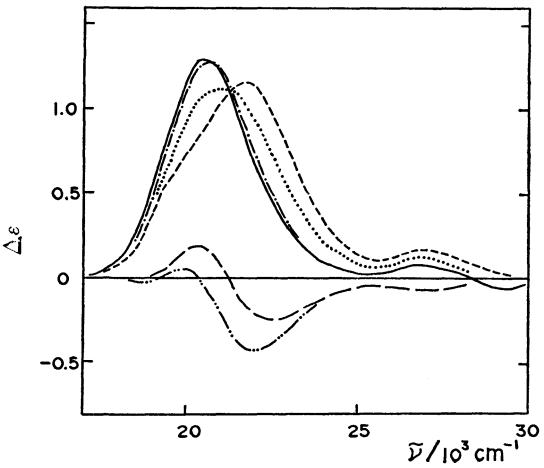

Fig. 4. CD spectra of $[Co(gly)(NH_3)(Me\text{-}tacn)]^{2+}$, B1 (·—·—), B2 (——), B3 (- - -), $[\Delta\varepsilon(B1)+\Delta\varepsilon(B3)]/2$ (·····), $[\Delta\varepsilon(B1)-\Delta\varepsilon(B3)]/2$ (— —), $(-)_{589}[Co(NH_3)(gly)(tacn)]^{2+}$ (··—··—).

bond in Me-tacn is directed to the equatorial position with respect to a mean plane of three chelate rings of Me-tacn and the chelate conformations are fixed to λ, but the configuration of the coordinated secondary nitrogen atoms in one mode is opposite to that in another mode. Since six diastereomers are possible for one mode (Fig. 3 (II)), twelve diastereomers may exist in the $[Co(gly)(NH_3)(Me\text{-}tacn)]^{2+}$ complex. The column chromatography separated three isomers of the complex, the distance between bands B1 and B2 being much smaller than that between bands B2 and B3.

The CD spectra of the diastereomers are shown in Fig. 4. The spectrum of B1 is similar to that of B2, but different from that of B3. It is assumed that the isomers with different configuration with respect to the arrangement of donor atoms are easily separable compared with those due to coordination modes or relative positions of the methyl group of Me-tacn. Therefore, the configuration of B1 is considered to be the same as that of B2 and opposite to that of B3. The conformational and vicinal contribution curve of $[Co(gly)(NH_3)(Me\text{-}tacn)]^{2+}$ was tentatively calculated from Eq. 1 and the configurational contribution curve, from Eq. 2.

$$[\Delta\varepsilon(B1 \text{ or } B2) + \Delta\varepsilon(B3)]/2 \quad (1)$$

$$[\Delta\varepsilon(B1 \text{ or } B2) - \Delta\varepsilon(B3)]/2 \quad (2)$$

As is seen in Fig. 4, the intensity of the resultant curve from Eq. 1 is higher than that of the resultant curve from Eq. 2. This corresponds to the large vicinal and conformational effects in the $[Co(Me\text{-}tacn)_2]^{3+}$ complex, the $\Delta\varepsilon$ values in the first absorption band region being *ca.* 5.[9] The calculated configurational contribution curve resembles the CD spectrum of $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$. However, the weak Cotton peak of the tacn complex observed at the lowest frequency in the first absorption band region disappeares at the calculated curve. From these observations, it is concluded that no fixed chiral conformation of chelated tacn exists in aqueous solution of $[Co(gly)(NH_3)(tacn)]^{2+}$, as described in the previous paper.[1]

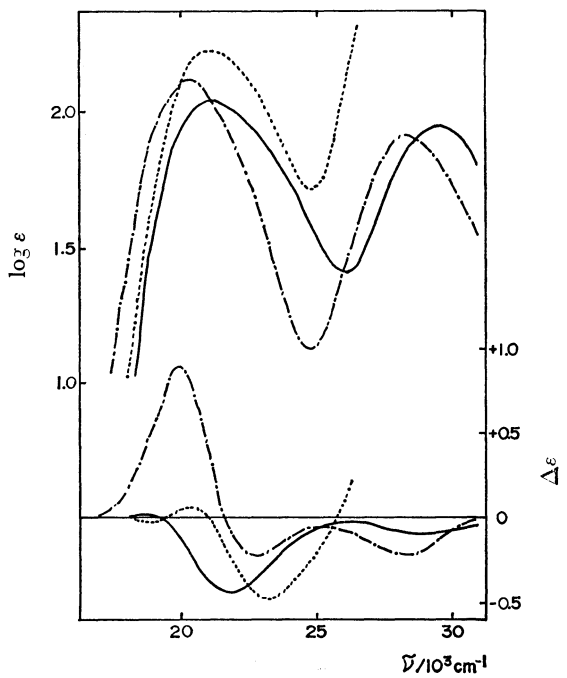

Fig. 5. Absorption and CD spectra of, $(-)^{CD}_{460}[Co(CN)(\beta\text{-ala})(tacn)]^+$ (——), $(-)^{CD}_{450}[Co(NO_2)(\beta\text{-ala})(tacn)]^+$ (·····), $(+)_{589}[Co(\beta\text{-ala})(NH_3)(tacn)]^{2+}$ (·—·—).

3) The $[Co(a)(\beta\text{-ala})(tacn)]^{n+}$ Complexes. The β-alaninato complexes were prepared similarly to the glycinato complexes. By chromatography on SP-Sephadex C-25, total resolution was achieved for the ammine complex, $[Co(\beta\text{-ala})(NH_3)(tacn)]^{2+}$, and partial resolution for the cyano and nitro complexes. The CD spectra of the earlier eluted isomers of these complexes are shown in Fig. 5, and numerical data are listed in Table 2. The $(+)_{589}[Co(\beta\text{-ala})(NH_3)(tacn)]^{2+}$ isomer exhibits two Cotton peaks with + and − signs from the lower frequency side in the first absorption band region, the positive peak being dominant. On the other hand, the corresponding $(-)_{589}[Co(gly)(NH_3)(tacn)]^{2+}$ isomer exhibits three Cotton peaks with −, +, and − signs from the lower frequency side, the negative peak at the highest frequency being dominant.[1] For the nitro complexes, both the $(-)_{589}$-glycinato and $(-)^{CD}_{450}$-β-alaninato complexes exhibit −, +, and − peaks in the first absorption band region. The CD spectrum of the $(-)_{589}$-$[Co(CN)(gly)(tacn)]^+$ complex shows a negative Cotton peak, and that of the $(-)^{CD}_{450}[Co(CN)(\beta\text{-ala})(tacn)]^+$ shows two peaks with opposite signs, the positive peak at the lower frequency being extremely weak. By comparison with the Cotton sign at the highest frequency, the absolute configurations of the earlier eluted isomers of $[Co(a)(\beta\text{-ala})(tacn)]^{n+}$ (a=NH_3, NO_2^-, or CN^-) are assumed to be the same as those of the corresponding $(-)_{589}[Co(a)(gly)(tacn)]^{n+}$ isomers.[1]

To confirm the above assumption, we attempted to determine the absolute configuration of $(-)_{589}[Co(\beta\text{-ala})(NH_3)(tacn)](ClO_4)_2\cdot HClO_4$, by an X-ray analysis. This was crystallized from the later eluted band. The absolute configuration found is shown in Fig. 6

Table 2. Absorption and CD spectral data of the earlier-eluted enantiomers

Complex	Absorption $\tilde{\nu}/10^3$ cm^{-1} (log ε)	CD $\tilde{\nu}/10^3$ cm^{-1} ($\Delta\varepsilon$)

	27.2 (1.93)	

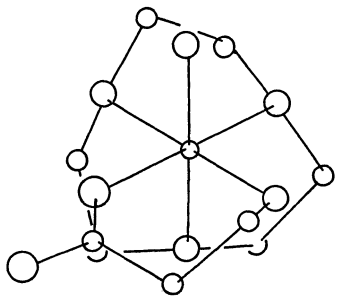

Fig. 6. Absolute configuration of $(-)_{589}$[Co(β-ala)(NH_3)(tacn)]$^{2+}$ complex.

(details will be published elsewhere). The structure of the complex closely resembles that of the corresponding glycinato complex.[7] However, the absolute configuration of the β-alaninato complex is opposite to that of the $(-)_{589}$-glycinato complex. In the previous work,[1] the absolute configuration of the [Co(a)(gly)(tacn)]$^{n+}$ complexes was determined on the basis of the Cotton sign of the dominant peak in the first absorption band region. In the present work, the absolute configuration of [Co(a)(amino acidato)(tacn)]$^{n+}$ can be determined not by the Cotton sign of dominant peak, but by the Cotton sign at the highest frequency.

A change from the five-membered glycinate chelate ring to the six-membered β-alaninate one causes the CD spectral shape to vary somewhat, especially, on the lower frequency side of the first absorption band region. It was previously assumed[1] that the optical source of the helical distributions of a NH_2–CH_2–COO^- chelate and –NH–CH_2–CH_2–NH– moieties of tacn had a small contribution to the optical activity of [Co(a)(gly)(tacn)]$^{n+}$, since the two helical ring-pairs canceled each other. The CD spectra of the β-alaninato complexes suggest that such cancellation is incomplete, but the spectra also indicate that the contribution of the helical ring-pairs is small. Thus, the main optical activities of the tacn complexes are

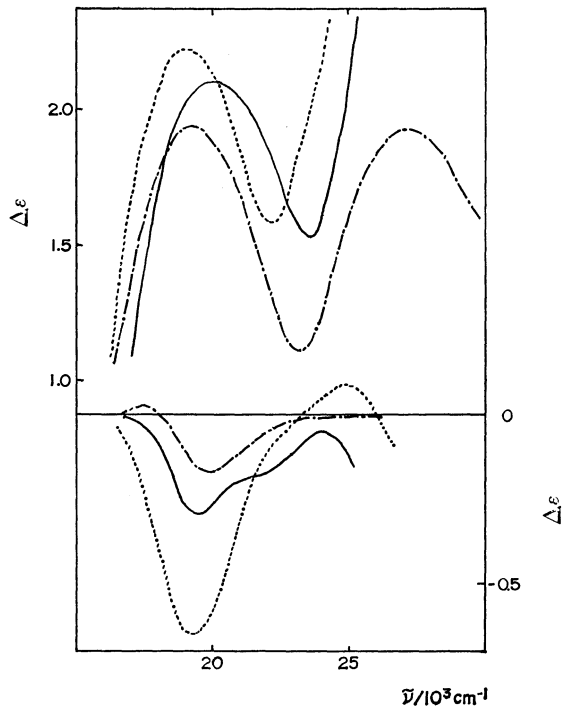

Fig. 7. Absorption and CD spectra of, $(-)_{500}^{CD}$[Co(NO_2)(gly)(tacdd)]$^+$ (——), $(-)_{500}^{CD}$[Co(NCS)(gly)(tacdd)]$^+$ (……), $(-)_{500}^{CD}$[Co(gly)(H_2O)(tacdd)]$^{2+}$ (·—·—).

considered to be derived from chiral arrangements of the donor atoms.

4) The [Co(a)(gly)(tacdd)]$^{n+}$ Complexes. Absorption and CD spectra of [Co(NO_2)(gly)(tacdd)]$^+$, [Co(NCS)(gly)(tacdd)]$^+$ and [Co(gly)(H_2O)(tacdd)]$^{2+}$ are shown in Fig. 7. At present, there are few complexes containing the tacdd ligand,[10,11] and the ligand field strength of this ligand has not been reported. The [Co(NO_2)(gly)(tacdd)]$^+$ complex exhibits the first absorption band at 20100 cm^{-1}, and the related [Co(NO_2)(gly)(tacn)]$^+$ and *fac(*NH_3*)*-[Co(NO_2)(gly)-

$(NH_3)_3]^+$,[12] at 21800 cm^{-1} and 20900 cm^{-1}, respectively. On this basis, it is found that the ligand field strengths decrease in the order, tacn>NH_3>tacdd. To obtain a ligand field parameter of tacdd (Δ(tacdd)=$3e_\sigma$), we prepared trinitro complex, $[Co(NO_2)_3(tacdd)]$, which exhibited an absorption maximum at 21300 cm^{-1} ($\log \varepsilon$=2.21). Since the absorption maximum of $[Co(NO_2)_3(tacn)]$ appears at 22700 cm^{-1}, the following relation of the ligand field parameters can be derived from an angular overlap model;[13]

$$\Delta(\text{tacdd}) = \Delta(\text{tacn}) - 2800\ (\text{cm}^{-1}).$$

The earlier eluted $(-)^{CD}_{500}[Co(NO_2)(gly)(tacdd)]^+$ complex exhibits a negative Cotton peak and a shoulder peak in the first absorption band region. The net rotatory strength of the tacdd complex is negative as well as that of the tacn complex, but the spectral shape is very different from that of the tacn complex. The CD spectra of the earlier eluted isomers, $(-)^{CD}_{500}$-$[Co(NCS)(gly)(tacdd)]^+$ and $(-)^{CD}_{500}[Co(gly)(H_2O)$-$(tacdd)]^{2+}$, show a single peak and two peaks, respectively, which resemble those of the corresponding isomers of the tacn complexes.

In the case of the tacn complexes, the earlier eluted isomers are all of the same absolute configuration.[1] This is not the case for the tacdd complexes, since the later eluted isomers, $(+)^{CD}_{500}[Co(NO_2)(gly)(tacdd)]^+$ and $(+)^{CD}_{500}[Co(NCS)(gly)(tacdd)]^+$, are derived from the earlier eluted $(-)^{CD}_{500}[Co(gly)(H_2O)(tacdd)]^{2+}$ isomer. Therefore, we were unable to determine the absolute configuration of the tacdd complexes, by CD comparison with the tacn complexes.

The reason why the CD spectra of the tacdd complexes are different from those of the corresponding acn complexes seems to be due to a large repulsive interaction between the bulky tacdd chelate and the glycinato chelate. The interaction may induce the presence of a chiral conformation of the tacdd chelate rings. It is interesting that the change from five-membered glycinate to six-membered β-alaninate chelate ring brings about only a slight variation of the CD spectral shapes, while the change from five-membered tacn to six-membered tacdd chelate ring causes a large variation. This suggests that non-ligating atoms of cyclic terdentate ligands somewhat influence the optical activity of the complexes.

A Kinetic Study of the Anation Reactions of Some Cobalt(III) Complexes Containing Macrocyclic Quadridentate Amine Ligands

Keiichi Tsukahara,* Hiroshi Oshita, Yasunobu Emoto, and Yasuo Yamamoto

Department of Chemistry, Faculty of Science, Shimane University, Nishikawatsu-cho, Matsue 690

(Received November 24, 1981)

The kinetics of the anation of *trans*-$[Co(OH)(N_4)(H_2O)]^{2+}$ by acetate ions (OAc^-) have been studied at 25 °C and at an ionic strength of 0.10 mol dm^{-3} ($LiClO_4$), and over the pH range from 3.62 to 5.17; N_4 represents a macrocyclic ligand. The reaction is considered to proceed through a dissociative mechanism. The rate constants of the loss of the coordinated water of $[Co(OH)(N_4)(H_2O)]^{2+}$ are estimated to be $(1.4\pm0.2)\times10^{-2}$ s^{-1}, $(8.9\pm1.6)\times10^{-2}$ s^{-1}, $(1.0\pm0.1)\times10^{-1}$ s^{-1}, and $(4.0\pm0.1)\times10^{-1}$ s^{-1} for [14]aneN$_4$,† Me$_6$[14]4,11-dieneN$_4$, *ms*-Me$_6$[14]aneN$_4$, and *rac*-Me$_6$[14]aneN$_4$ complexes respectively. These represent the steric acceleration by the methyl groups of the macrocyclic ligands. The anation of the [14]aneN$_4$ complex by chloride and bromide ions in acetate-buffer solutions has also been investigated. The relative effectiveness of entering groups for the coordination to the pentacoordinate intermediate follows the order: $H_2O<OAc^-<Cl^-<Br^-$. The substitution reaction of $[Co(OH)(N_4)(H_2O)]^{2+}$ is slower than the ascorbate reduction of this complex reported previously. It is concluded that the electron-transfer reaction does not proceed through an inner-sphere mechanism, but through an OH-bridged mechanism.

In a previous paper,[1] we reported that the ascorbate reduction of *trans*-diaqua cobalt(III) complexes containing macrocyclic quadridentate amine ligands (Fig. 1) proceeds through an outer-sphere mechanism; however, it has not yet been determined whether *trans*-aquahydroxo complexes are reduced through a substitution-limited inner-sphere mechanism or through an OH-bridged mechanism. The substitution reaction is an important factor in determining the electron-transfer mechanism.

Extensive investigations have been carried out on the kinetics of substitution reactions of cobalt(III) complexes of the type *trans*-$[CoX_2(N_4)]^{n+}$ (N_4=a macrocyclic quadridentate amine ligand and X=a replaceable group such as Cl^-, Br^-, or NO_2^-).[2] These reactions are considered to proceed through a dissociative mechanism; the increase of the steric crowding of methyl groups of the macrocyclic ligands accelerates the loss of the leaving group. The kinetics of the substitution reactions of the diaqua and aquahydroxo macrocyclic cobalt(III) complexes, however, have rarely been investigated except for porphyrin complexes.[3]

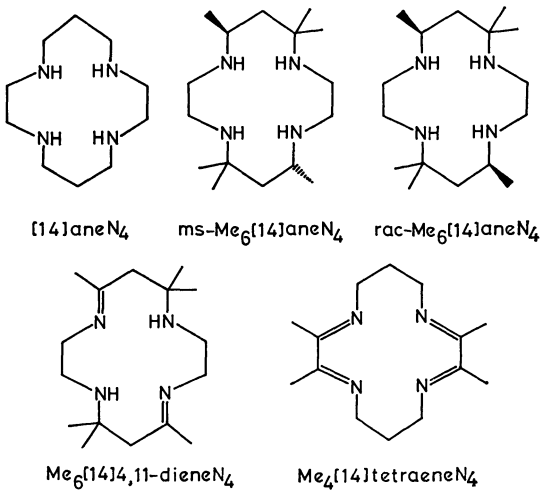

Fig. 1. Structures of tetraazamacrocycles (N_4).

In this paper we report the kinetics of the anation reaction of *trans*-$[Co(OH)(N_4)(H_2O)]^{2+}$ by an acetate ion (OAc^-), Cl^-, or Br^- and estimate the rate constants of the loss of the coordinated water of these complexes. The mechanism of the ascorbate reductions of the aquahydroxo complexes is discussed.

Experimental

Reagents. The *trans*-diaqua complexes $[Co([14]aneN_4)(H_2O)_2](ClO_4)_3$,[4] $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2](ClO_4)_3$,[5,6] $[Co(rac\text{-}Me_6[14]aneN_4)(H_2O)_2](ClO_4)_3$,[5,6] $[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2](ClO_4)_3$,[6] and $[Co(Me_4[14]tetraeneN_4)(H_2O)_2](ClO_4)_3\cdot2.5H_2O$[7] were prepared as has been described elsewhere. The acetate-buffer solutions and the $LiClO_4\cdot3H_2O$ were obtained according to the procedure reported previously.[8] All the solutions used for the measurements were prepared from redistilled water. All the other reagents used were of guaranteed grade from Wako Pure Chemical Industries, Ltd.

Kinetic Measurements. Solutions containing a cobalt(III) complex and $LiClO_4$ were added to an optical cell, which was then sealed with a serum cap. After the solution had been purged with a nitrogen atmosphere for 15 min, the reaction was initiated by the injection of the acetate-buffer solution (or the solution containing the acetate buffer and lithium halide for the anation by halide ions). The change in the absorbance with the time was followed with either a Hitachi 200-20 or a Shimadzu UV 140-02 spectrophotometer. The wavelengths used for the measurements were 290 nm ($[Co(Me_4[14]tetraeneN_4)(H_2O)_2]^{3+}$), 310 nm ($[Co(rac\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$), 320 nm ($[Co([14]aneN_4)(H_2O)_2]^{3+}$ and $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$), and 345 nm ($[Co(Me_6[14]4,11\text{-}dieneN_4)(H_2O)_2]^{3+}$). In order to ensure a pseudo-first-order condition, acetate or lithium halide was used in at least a 10^2 fold excess over the cobalt(III) complexes.

The temperature was controlled at 25.0±0.1 °C, and the ionic strength (I) was adjusted to 0.10 mol dm^{-3} with

† [14]aneN$_4$=1,4,8,11-Tetraazacyclotetradecane; *ms*- and *rac*-Me$_6$[14]aneN$_4$=*meso*- and *rac*-5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane; Me$_6$[14]4,11-dieneN$_4$=5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene; Me$_4$[14]tetraeneN$_4$=2,3,9,10-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,3,8,10-tetraene.

lithium perchlorate. The pH of the solution was measured on a Hitachi-Horiba F-7 pH meter. The $[H^+]$ was computed from the pH, using a value of 0.83 for the activity coefficients of H^+.[9]

Acid-dissociation Constants. The acid-dissociation constants of the diaqua ligands of $[Co(ms\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$ and $[Co(rac\text{-}Me_6[14]aneN_4)(H_2O)_2]^{3+}$ were determined by pH titrations with a standard sodium hydroxide solution at 25 °C and $I=0.10$ mol dm^{-3} ($LiClO_4$) under a nitrogen atmosphere. The pK values thus obtained are listed in Table 1 along with those in the literature.

Results

Reactions of $[Co(OH)(N_4)(H_2O)]^{2+}$ with Acetate. The spectral changes observed during the reaction of $[Co(OH)([14]aneN_4)(H_2O)]^{2+}$ with acetate gave four isosbestic points over the range from 370 to 700 nm (Fig. 2). The absorption maxima of the spectra after the reaction was completed were 360 nm ($\varepsilon=79$ dm^3 mol^{-1} cm^{-1}), 443 nm ($\varepsilon=34$ dm^3 mol^{-1} cm^{-1}), and 565 nm ($\varepsilon=41$ dm^3 mol^{-1} cm^{-1}), which agreed with those of the species separated by the use of an SP-Sephadex C-25 column (H^+ form). This product, which has a 2+ charge in 0.1 mol dm^{-3} $HClO_4$, is considered to be $[Co(OAc)([14]aneN_4)(H_2O)]^{2+}$. In the case of the $Me_6[14]4,11\text{-}dieneN_4$ complex, two isosbestic points (at 549 nm and 630 nm) were observed at pH 4.17. The absorption maximum of the reaction product in this system was 567 nm ($\varepsilon=37$ dm^3 mol^{-1} cm^{-1}). The reaction product in the ms-$Me_6[14]aneN_4$ system, on the other hand, had the absorption maxima at 468 nm ($\varepsilon=40$ dm^3 mol^{-1} cm^{-1}) and 577 nm ($\varepsilon=42$ dm^3 mol^{-1} cm^{-1}). These results indicate that the reactions of these complexes with acetate can be represented as follows:

$$[Co(OH)(N_4)(H_2O)]^{2+} \text{ (or } [Co(N_4)(H_2O)_2]^{3+}) + OAc^- \longrightarrow [Co(OAc)(N_4)(H_2O)]^{2+} + H_2O. \quad (1)$$

The kinetics of the reactions were studied in various concentrations of acetate (0.020—0.25 mol dm^{-3}), cobalt(III) ($(1.00—2.40)\times10^{-4}$ mol dm^{-3}), and hydrogen ions ($(0.82—8.15)\times10^{-5}$ mol dm^{-3}). The plots of $-\ln(A_\infty-A_t)$ *vs.* the time were linear for at least 90% completion; here A_∞ and A_t represent the absorbance at infinity and time t respectively. The pseudo-first-order rate constant, k_{obsd}, increased with a decrease in the acidity when the total concentrations of acetate ($[OAc]_T$) were fixed. The acid dependency of the rate in the $[14]aneN_4$ system was analyzed as the occurrence of Reactions 2—7:

$$[Co(N_4)(H_2O)_2]^{3+} \overset{K_1}{\rightleftharpoons} [Co(OH)(N_4)(H_2O)]^{2+} + H^+, \quad (2)$$

$$HOAc \overset{K_a}{\rightleftharpoons} H^+ + OAc^- \ (pK_a=4.53^{12}), \quad (3)$$

$$[Co(N_4)(H_2O)_2]^{3+} + OAc^- \overset{k_1}{\longrightarrow} \text{products}, \quad (4)$$

$$[Co(N_4)(H_2O)_2]^{3+} + HOAc \overset{k_1^H}{\longrightarrow} \text{products}, \quad (5)$$

$$[Co(OH)(N_4)(H_2O)]^{2+} + OAc^- \overset{k_2}{\longrightarrow} \text{products}, \quad (6)$$

$$[Co(OH)(N_4)(H_2O)]^{2+} + HOAc \overset{k_2^H}{\longrightarrow} \text{products}. \quad (7)$$

Then, Eq. 8 can be derived for k_{obsd}:

$$k_{obsd}=\frac{k_1^H K_a^{-1}+(k_1+k_2^H K_1 K_2^{-1})[H^+]^{-1}+k_2 K_1[H^+]^{-2}}{(1+K_1[H^+]^{-1})(1+[H^+]K_a^{-1})[H^+]^{-1}}. \quad (8)$$

The plots of the values of $k_{obsd}(1+K_1[H^+]^{-1})(1+[H^+]K_a^{-1})[H^+]^{-1}$ *vs.* $[H^+]^{-1}$ gave a quadratic curve and the intercept was nearly zero. On the other hand, the plots of the values of $k_{obsd}(1+K_1[H^+]^{-1})\times(1+[H^+]K_a^{-1})$ *vs.* $[H^+]^{-1}$ gave a straight line (Fig. 3) and the intercept was very small. Therefore, both k_1 and k_2^H terms can be neglected under the present experimental conditions.[13] The pseudo-first-order rate constants showed nonlinear dependency on the total concentrations of acetate. The rate law was as follows:

$$-\frac{d[Co(III)]}{dt}=\frac{c[OAc]_T}{a+b[OAc]_T}[Co(III)], \quad (9)$$

where $k_{obsd}=c[OAc]_T/(a+b[OAc]_T)$. The plots of k_{obsd}^{-1} *vs.* $[OAc]_T^{-1}$ gave straight lines (Fig. 4). The values of a/c and of b/c are obtained from the slope

and the intercept of this straight line respectively.

These are explained by either a dissociative mechanism (D-mechanism):

$$[Co(OH)(N_4)(H_2O)]^{2+} \underset{k^{H_2O}}{\overset{k_d}{\rightleftharpoons}} [Co(OH)(N_4)]^{2+} + H_2O, \quad (10)$$

$$[Co(OH)(N_4)]^{2+} + OAc^- \xrightarrow{k_1^{OAc}} [Co(OH)(OAc)(N_4)]^+, \quad (11)$$

$$[Co(OH)(OAc)(N_4)]^+ + H^+ \rightleftharpoons [Co(OAc)(N_4)(H_2O)]^{2+}, \quad (12)$$

or an interchange mechanism (I-mechanism):

$$[Co(OH)(N_4)(H_2O)]^{2+} + X^- \overset{Q^X}{\rightleftharpoons} \{[Co(OH)(N_4)(H_2O)]^{2+}\cdot X^-\} \xrightarrow{k_2^X} \text{products}. \quad (13)$$

These mechanisms lead to Eqs. 14a and 14b respectively (X=OAc):

$$\frac{1}{k_{obsd}} = \frac{1+[H^+]K_1^{-1}}{k_d} + \frac{k^{H_2O}(1+[H^+]K_1^{-1})(1+[H^+]K_a^{-1})}{k_d k_1^{OAc}} \times \frac{1}{[OAc]_T}, \quad (14a)$$

$$\frac{1}{k_{obsd}} = \frac{1}{k_2^{OAc}} + \frac{(1+[H^+]K_1^{-1})(1+[H^+]K_a^{-1})}{k_2^{OAc}Q^{OAc}} \times \frac{1}{[OAc]_T}, \quad (14b)$$

The values of k_d and k_1^{OAc}/k^{H_2O} or of k_2^{OAc} and Q^{OAc} obtained by means of the plots of k_{obsd}^{-1} *vs.* $[OAc]_T^{-1}$ are listed in Table 2.

The pseudo-first-order rate constants for the reactions of the $Me_4[14]tetraeneN_4$ complex with acetate and bromide ions are 1.2×10^{-6} s^{-1} at 0.10 mol dm^{-3} acetate and pH 5.17, and 6.3×10^{-7} s^{-1} at $[Br^-]=0.050$ mol dm^{-3}, $[OAc]_T=0.060$ mol dm^{-3}, and pH 5.17.

Reaction of $[Co(OH)([14]aneN_4)(H_2O)]^{2+}$ with Cl^-. The title reaction was examined in the presence of acetate. The plots of $-\ln(A_\infty-A_t)$ *vs.* the time were linear for at least 90% completion, when $[OAc]_T \gg [Cl^-]$.[14] Since the anation of $[CoCl([14]aneN_4)(H_2O)]^{2+}$ by Cl^- is very slow ($k=7.6\times10^{-7}$ dm^3 mol^{-1} s^{-1} at 25 °C),[15] the following parallel reactions are considered to occur:

$$[Co(OH)([14]aneN_4)(H_2O)]^{2+} + OAc^- \longrightarrow [Co(OH)(OAc)([14]aneN_4)]^+ + H_2O, \quad (15)$$

$$[Co(OH)([14]aneN_4)(H_2O)]^{2+} + Cl^- \longrightarrow [CoCl(OH)([14]aneN_4)]^+ + H_2O. \quad (16)$$

The pseudo-first-order rate constants show nonlinear dependency on the concentrations of Cl^- ions (Fig. 5). If the following reactions occur in addition to Reactions 10—12;

$$[Co(OH)(N_4)]^{2+} + Cl \xrightarrow{k_1^{Cl}} [CoCl(OH)(N_4)]^+, \quad (17)$$

$$[CoCl(OH)(N_4)]^+ + H^+ \rightleftharpoons [CoCl(N_4)(H_2O)]^{2+}, \quad (18)$$

Eq. 19 can be derived:

$$\frac{1}{k_{obsd}-k_{obsd}^{OAc}} = \frac{1}{k'-k_{obsd}^{OAc}} + \frac{k''}{k'-k_{obsd}^{OAc}} \times \frac{1}{[Cl^-]}. \quad (19)$$

Here k_{obsd}^{OAc} is the pseudo-first-order rate constant in the absence of Cl^-, $k'=k_d/(1+[H^+]K_1^{-1})$, and $k''=k_1^{OAc}/k_1^{Cl}+k_1^{OAc}[OAc]_T/k_1^{Cl}(1+[H^+]K_a^{-1})$. The plots of the left-hand side of Eq. 19 *vs.* $[Cl^-]^{-1}$ gave a linear relation (Fig. 5). The values of k_d and k_1^{OAc}/k_1^{Cl} were determined from the intercept and the slope of this straight line respectively. In the I-mechanism (Reaction 13), k' and k'' correspond to k_2^{Cl} and $(1+$

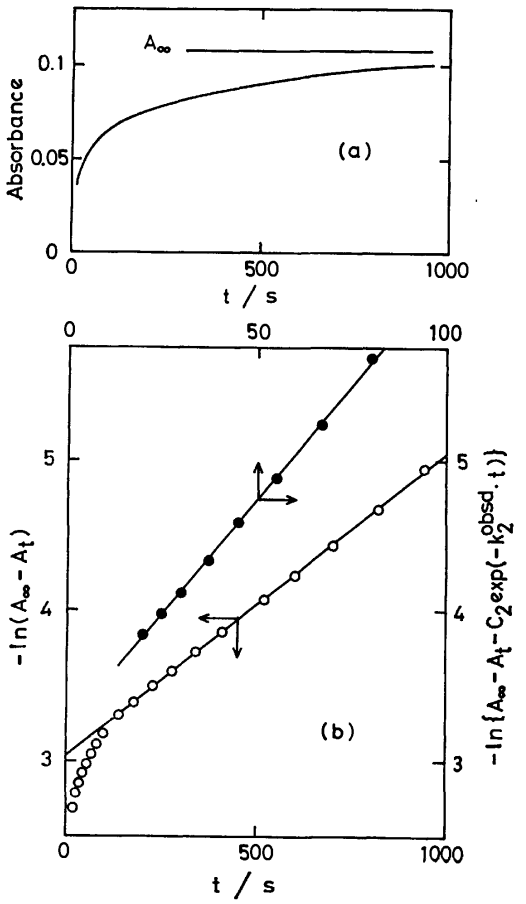

Fig. 6. Reactions of $[Co([14]aneN_4)(H_2O)_2]^{3+}$ with bromide ion at $[Co(III)]_0=7.98\times10^{-4}$ mol dm^{-3}, [Br$^-$]=0.060 mol dm^{-3}, $[OAc]_T$=0.060 mol dm^{-3}, pH, 4.71, 25 °C, and I=0.10 mol dm^{-3} ($LiClO_4$) followed at 320 nm: (a) absorbance-time profile; (b) resolution of the kinetic data into two component exponentials.

$[H^+]K_1^{-1})/Q^{Cl}+Q^{OAc}[OAc]_T/Q^{Cl}(1+[H^+]K_a^{-1})$ respectively. The data thus obtained are given in Table 2.

Reaction of $[Co(OH)([14]aneN_4)(H_2O)]^{2+}$ with Br$^-$. Figure 6 shows an example of the change in the absorbance at 320 nm against the time and of the consecutive reaction treatment[1] for the evaluation of the pseudo-first-order rate constants, k_1^{obsd} and k_2^{obsd}, for the first and second stages of the reaction. The second-stage rate constant, k_2^{obsd}, is given by the slope of the linear portion observed by means of a plot of $-\ln(A_\infty-A_t)$ *vs.* t:

$$-\ln(A_\infty-A_t) = k_2^{obsd}t - \ln C_2. \quad (20)$$

Using the values of k_2^{obsd} and C_2 thus obtained, a plot of the left-hand side of Eq. 21 against the time for the first-stage reaction gives k_1^{obsd} as a slope:

$$-\ln\{A_\infty-A_t-C_2\exp(-k_2^{obsd}t)\} = k_1^{obsd}t - \ln C_1, \quad (21)$$

where C_1 and C_2 are constant. The first-stage rate constant, k_1^{obsd}, depends on [Br$^-$], while k_2^{obsd} does not (Fig. 7). Therefore, the first-stage reaction is considered to be the simultaneous occurrence of Reactions 15 and 22:

$$[Co(OH)([14]aneN_4)(H_2O)]^{2+} + Br^- \longrightarrow [CoBr(OH)([14]aneN_4)]^+ + H_2O \quad (22)$$

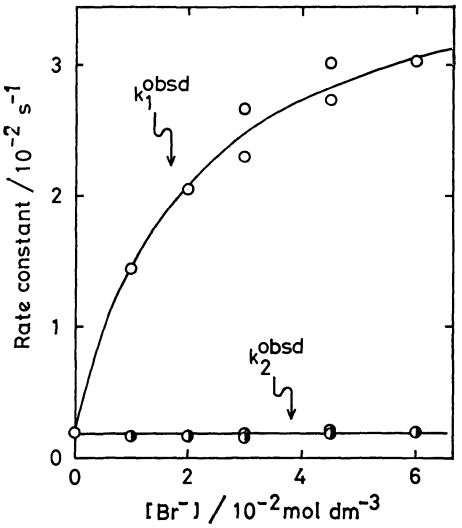

Fig. 7. Plots of k_1^{obsd} *vs.* [Br$^-$] and of k_2^{obsd} *vs.* [Br$^-$] for the [Co([14]aneN$_4$)(H$_2$O)$_2$]$^{3+}$–bromide system.

Discussion

Anation of trans-[*Co(OH)(N$_4$)(H$_2$O)*]$^{2+}$ *Ions.* There are two possible mechanisms for the anation of the [Co(OH)(N$_4$)(H$_2$O)]$^{2+}$ ions: (i) a dissociative mechanism (Eqs. 10—12) and (ii) an interchange mechanism (Eq. 13). The D-mechanism is more likely than the I-mechanism, because, if the reaction proceeds via the interchange mechanism, the large values of the ion-association constants cannot be explained (Q^{OAc} for the *ms*- and *rac*-Me$_6$[14]aneN$_4$ complexes or Q^{Cl} and Q^{Br} for the [14]aneN$_4$ complex); the expected value for a 2:1 electrolyte in water at 25 °C is about 2 dm^3 mol^{-1}. Poon[2] has demonstrated that the substitution reactions of [CoX$_2$([14]aneN$_4$)]$^+$ (X=a replaceable group such as Cl$^-$, Br$^-$, or NO$_2^-$) proceed through a dissociative mechanism.

The rate constants of the loss of the coordinated water of [Co(OH)(N$_4$)(H$_2$O)]$^{2+}$ range from 10^{-2} to 10^{-1} s^{-1} and increase in the following order: [14]aneN$_4$ < Me$_6$[14]4,11-dieneN$_4$ ≃ *ms*-Me$_6$[14]aneN$_4$ < *rac*-Me$_6$-[14]aneN$_4$. This order is similar to that of the hydrolysis of dichloro and dibromo complexes.[2] This similarity suggests that the methyl groups of the macrocyclic ligands accelerate the loss of the coordinated water. The increasing order of k_1^X/k^{H_2O} (X=OAc$^-$), [14]aneN$_4$ ≤ Me$_6$[14]4,11-dieneN$_4$ < *rac*-Me$_6$[14]aneN$_4$ < *ms*-Me$_6$[14]aneN$_4$, is coincident with the inference that [14]aneN$_4$ is more hydrophilic than the others and that its k^{H_2O} is larger. The relative effectiveness of the entering group for the coordination to the pentacoordinate intermediate follows the order: H$_2$O < OAc$^-$ < Cl$^-$ < Br$^-$.

The anation of the Me$_4$[14]tetraeneN$_4$ complex by OAc$^-$ and Br$^-$ is very slow. We have not found any reactions which signaled the rapid anation by means of a stopped-flow apparatus. However, it does not necessarily follow that the loss of the coordinated water of this complex is slow, because the Me$_4$[14]-tetraeneN$_4$ complex may have less affinity to OAc$^-$ and Br$^-$.

The substitution reaction of *trans*-[Co(OH)(N$_4$)-(H$_2$O)]$^{2+}$ obtained in this work is much faster than that of other cobalt(III) complexes;[2] this is explained by the "internal S_N1 conjugate-base mechanism" proposed by Mok and Poon.[16] As is shown in Fig. 8, the amido group, >N$^-$, can facilitate a dissociative reaction and may stabilize a tetragonal-pyramidal intermediate. The rate of the aquation of [CoCl(OH)-([14]aneN$_4$)]$^+$ is comparable with that of the loss of the coordinated water of [Co(OH)([14]aneN$_4$)(H$_2$O)]$^{2+}$ (2.1×10^{-2} s^{-1} at 25 °C);[15] therefore, the rate of the formation of the pentacoordinated intermediate may be independent of the nature of the leaving group. Interestingly, k_d of *trans*-[Co(OH)([14]aneN$_4$)(H$_2$O)]$^{2+}$ agrees with the rate constant of the N–H proton exchange of this complex (2×10^{-2} s^{-1} at 21 °C and I= 0.50 mol dm^{-3}).[10] These facts suggest that the N–H protons play a significant role in the substitution reactions of the macrocyclic cobalt(III) complexes.

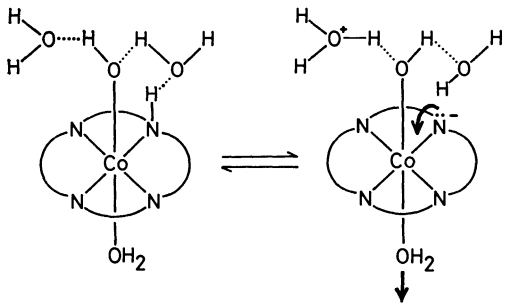

Fig. 8. Internal S_N1 conjugate-base mechanism.

Possible Structure of trans-[*Co(OH)(*rac-*M$_6$[14]aneN$_4$-(H$_2$O)*]$^{2+}$. Since the *trans*-[Co(*ms*-Me$_6$[14]aneN$_4$)-(H$_2$O)$_2$]$^{3+}$ complex has a center of symmetry with respect to the cobalt atom, there is only one possible structure for the aquahydroxo species (Fig. 9a). The *trans*-[Co(OH)(*rac*-Me$_6$[14]aneN$_4$)(H$_2$O)]$^{2+}$ complex, on the other hand, has two possible structures (Figs. 9b and 9c),[17] because *rac*-Me$_6$[14]aneN$_4$ has no axis of symmetry. We propose that the predominant structure of the *rac*-complex is (b) rather than (c). The *ms*- and *rac*-isomers are very similar in the first acid-dissiciation constants, pK_1 (Table 1). The pK_2 of the *ms*-isomer, however, is smaller than that of the

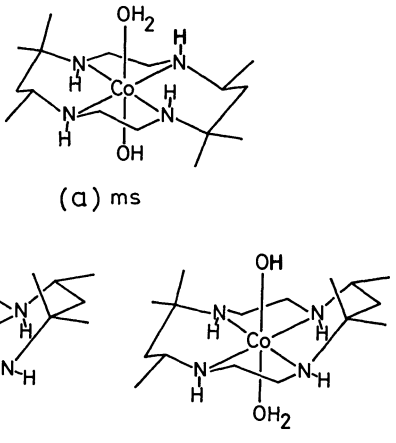

Fig. 9. Proposed structures of *trans*-[Co(OH)(Me$_6$[14]-aneN$_4$)(H$_2$O)]$^{2+}$.

rac-isomer; that is, the *ms*-dihydroxo species is more stable than the *rac*-dihydroxo species. The OH^- ligand, which faces the N–H proton, can make a chain of hydrogen bonds with the N–H proton through solvent water molecules (Fig. 8). In the *ms*-isomer two OH^- ligands are possible to make such a hydrogen bonding; in the *rac*-isomers, only one OH^- ligand is possible. Since the electronic effect of these ligands is identical, the difference in pK_2 can be ascribed to the stabilization by the hydrogen bonding. In the aquation of *trans*-$[CoCl_2(N_4)]^+$,[18] the loss of the coordinated chloride is accelerated by the increase of the steric crowding of methyl groups. The k_d of the *rac*-isomer is larger than that of the *ms*-isomer. This can be explained as the steric acceleration. The fact that k_1^{OAc}/k^{H_2O} of the *rac*-isomer is much smaller than that of the *ms*-isomer can also be explained as the steric hindrance.

Mechanism of Electron-transfer Reactions of trans-$[Co(OH)(N_4)(H_2O)]^{2+}$ *with Ascorbic Acid.* We have reported that the rate constants of the reactions of $[Co(OH)(N_4)(H_2O)]^{2+}$ with ascorbate (HA^-) range from 2.9×10 to 1.3×10^3 $dm^3\ mol^{-1}\ s^{-1}$.[1] If the reaction proceeds through an inner-sphere mechanism, the substitution reaction of $[Co(OH)(N_4)(H_2O)]^{2+}$ must be faster than the electron-transfer reaction. The kinetic data for the substitution reaction of the aqua-hydroxo complexes obtained in this work show that the ascorbate reduction of these complexes is faster than the substitution reaction. Therefore, an inner-sphere mechanism can be ruled out and the ascorbate reduction of *trans*-$[Co(OH)(N_4)(H_2O)]^{2+}$ is considered to proceed through an OH-bridged mechanism:

The Crystal Structure of $Na_2H_2[Co_4I_3O_{18}(OH_2)_6]$-$[Co_4I_3O_{16}(OH)_2(OH_2)_6]\cdot 22H_2O$

Hidetaka KONDO,† Akiko KOBAYASHI, and Yukiyoshi SASAKI*

Department of Chemistry and The Research Centre for Spectrochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 4, 1981)

The title compound has the analytical formula of $Co_4H_{36}I_3NaO_{35}$ and is seemingly well formulated as $NaH_2[Co_4I_3O_{18}(OH_2)_6]\cdot 11H_2O$. But the structure determination revealed that the crystals contain non-protonated $[Co_4I_3O_{18}(OH_2)_6]^{3-}$ and doubly protonated $[Co_4I_3O_{16}(OH)_2(OH_2)_6]^-$. The anion itself has a new variation of the Anderson structure. The almost identical three pK's of the acid, $H_3[Co_4I_3O_{18}(OH_2)_6]$, explain the formation of the present crystals by co-precipitation of two forms of the anion with different degrees of protonation. Crystals are monoclinic, space group P2/c, with $a=15.172(2)$, $b=10.874(1)$, $c=19.436(3)$ Å, $\beta=116.58(1)°$, $U=2867.6(5)$ Å^3, and $Z=2$. The final R factor was 0.036 for 7010 independent reflections.

The periodate anion has been reported to form complex anions with various transition metal cations.[1,2] The Co^{III} and I^{VII} form a highly condensed anion, $[Co_4I_3O_{18}]^{3-}$, as reported by Malaprade.[3]

On the basis of spectroscopic and stereochemical data, Ama, Hidaka, and Shimura proposed the Anderson structure for this anion, consisting of seven octahedra condensed into a flat arrangement of D_{3d} symmetry by edge-sharing.[4] Two types of the Anderson structure are known: the first one has been found in $[TeMo_6O_{24}]^{6-}$,[5] and $[IMo_6O_{24}]^{5-}$,[6] which has no constitutional water, while the second one has been reported in the cases of $[CrMo_6O_{24}H_6]^{3-}$,[7] and $[CoMo_6O_{24}H_6]^{3-}$,[8] having six non-acidic protons per molecule. Our present study has confirmed that this (tetracobaltato)triperiodate anion belongs to a new type of the Anderson structure which has twelve non-acidic protons.

Experimental

At the beginning, our aim was to prepare the free acid form of the title compound from $Na_3[Co(CO_3)_3]\cdot 3H_2O$, $HClO_4$ and $NaIO_4$. The method reported by Williams and Nyman[9] was used, but crystals of the compound having the analytical formula of $Co_8H_{72}I_6Na_2O_{70}$ were obtained and used for the present study.

Data Collection. Preliminary Weissenberg photographs showed that the crystal system is monoclinic. A systematic absence $h0l$, $l=2n+1$, indicated the space group to be either Pc or P2/c; P2/c was assumed and confirmed by the successful structure analysis.

The intensities of the reflections were measured with a Rigaku automatic four-circle diffractometer (graphite monochromator, Mo $K\alpha$ radiation, ω-2θ scan mode) up to $2\theta=60°$. The crystal used here was a parallelepiped with dimensions $0.45\times 0.1\times 0.2$ mm^3. Independent 7010 reflections, $|F_o|\geq 3\sigma(|F_o|)$, were adopted for the structure determination. The crystal data are: $Co_8H_{72}I_6Na_2O_{70}$, FW=2471.88, monoclinic, space group P2/c, $a=15.172(2)$, $b=10.874(1)$, $c=19.436(3)$ Å, $\beta=116.58(1)°$, $U=2867.6(5)$ Å^3, $Z=2$, $D_x=2.864$ g cm^{-3}, μ for Mo $K\alpha$ ($\lambda=0.71069$ Å)$=57.85$ cm^{-1}.

Structure Determination and Refinement

The structure was solved by the heavy-atom method. All the non-hydrogen atoms were refined by the block-diagonal least-squares method using anisotropic temperature factors. Almost all of the hydrogens attached to anions 1 and 2 have been located on the difference Fourier maps and treated isotropically in the refinements. One hydrogen atom of an aqua ligand bound to a cobalt atom, the cationic proton, and all of the hydrogens of the water molecules were not found. The eleven waters of crystallization are in general positions and one of them, Aq(11), are distributed in two sites, Aq(11a) and Aq(11b), by the ratio of 0.45 and 0.55. This ratio was estimated from the peak heights in the difference Fourier maps and fixed in the structure refinements. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where $w=1/[\sigma(|F_o|)^2+c^2|F_o|^2]$. The parameter c was estimatedto be 0.02 from the fluctuations of the intensities of the standard reflections during the data collection and $\sigma(|F_o|)$ was found from counting statistics. The final R values are $R=0.035$ and $R_w=0.036$, where $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w=\Sigma w||F_o|-|F_c||/\Sigma w|F_o|$. The atomic scattering factors and the corrections of anomalous dispersion were taken from International Tables for X-Ray Crystallography.[10] All the calculations were performed on a HITAC 8800/8700 computer at the Computer Centre of the University of Tokyo with a local version of UNICS.[11] The atomic fractional coordinates and the averaged bond distances and angles are listed in Tables 1 and 2. The F_o-F_c tables and anisotropic thermal parameters are kept at the office of this Bulletin as Document No. 8230.

Description of the Structure and Discussion

Structure of Polyanion. There are two forms of the anion, which are different not only crystallographically but also in the degree of the protonation. We describe the common features of the structures of both forms in this section.

The structure of the polyanion is shown in Fig. 1. The anion has principally the Anderson structure, as found in several heteropolymolybdates.[5-8] But in the present (tetracobaltato)triperiodate anion, the six peripheral sites are occupied by Co and I alternatively and there is a Co at the central heteroatom site. In general, the Anderson polyanion has three types of

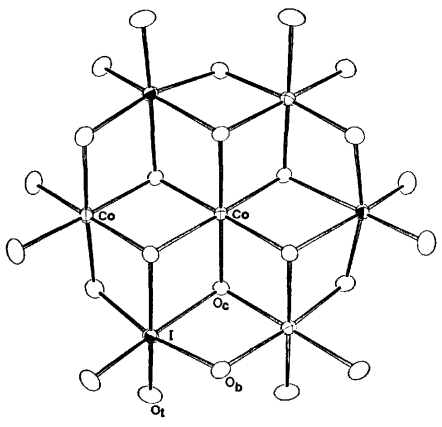

Fig. 1. Structure of $[Co_4I_3O_{18}(OH_2)_6]^{3-}$ "Anderson polyanion" (anion 1) viewed vertical to the hexagonal Co_4I_3 pseudo-plane.
The vibration ellipsoids are drawn at the 50% probability level (Johnson, 1965).[17] All the terminal oxygen atoms attached to Co are those of water molecules. The terminal oxygens attached to I are not protonated. In the anion 2 two of them are protonated.

oxygen atoms, denoted as O_t, O_b, and O_c. O_t represents the terminal oxygen bonding to one peripheral metal atom, O_b the one bridging between two peripheral metal atoms, and O_c the one coordinating to the central atom and two peripheral atoms. In this (tetracobaltato)triperiodate anion, however, there are two different O_t atoms. Half of them are the terminal oxygen atoms of Co, which are actually aqua ligands. Others are those of I which attract a proton in acidic media or form hydrogen bonds with the aqua ligands coordinated to Co atom.

The alternate arrangement of Co and I atoms at the peripheral metal sites causes the reduction of symmetry of the ion from $D_{3d}(\bar{3}m)$ of the Anderson structure to $D_3(32)$. The Co_3I_3 framework is not regularly hexagonal, while Mo_6 in $[IMo_6O_{24}]^{5-}$ is.[6]

It should be noted that there are only a few examples of structure determination of the Co^{III}–OH_2 distances. The only reliable example of Co^{III}–OH_2 distance is 1.954(1) Å, in $[Co(OH_2)(NH_3)_5]^{3+}$.[12] Our present study provides six crystallographically independent Co^{III}–OH_2 distances, 1.912—1.947(10) Å.

Crystal Structure. The crystal structure is shown in Fig. 2. The crystal contains two symmetrically independent Anderson polyanions. The first anion, referred to as anion 1, is not protonated and lies on the crystallographic two-fold axis at $x=0$, $z=1/4$ or 3/4 with the Co_4I_3 pseudo-plane almost parallel to

TABLE 2. AVERAGED BOND DISTANCES AND ANGLES IN $[Co_4I_3O_{18}(OH_2)_6]^{3-}$ (ANION 1) AND $[Co_4I_3O_{16}(OH)_2(OH_2)_6]^{1-}$ (ANION 2)
(Estimated standard deviation is given in parentheses)

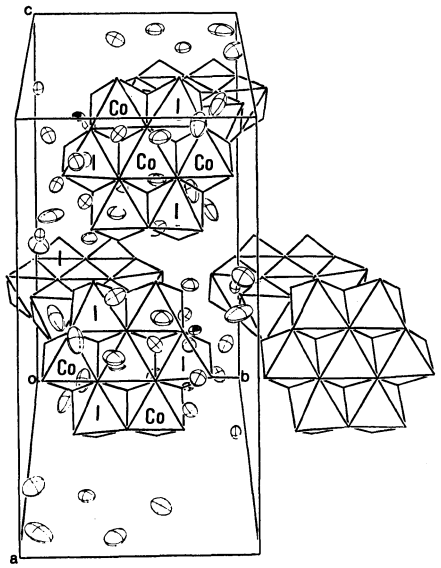

Fig. 2. Crystal structure viewed from the a*-axis. The shaded ellipsoids represent Na^+ ions and other ellipsoids are water molecules of crystallizations. Anions are shown with polyhedral models. The almost regular hexagonal shaped anions are the anion 1 and other are the anion 2.

the (001) plane. The second one, anion 2, contains two more protons and is on the diad axis at $x=1/2$, $z=1/4$ or 3/4 and almost parallel to the (100) plane. In Table 1, Co*(a1) and Co*(a2) mean the central Co atoms of anions 1 and 2 respectively and M(i), where M=Co or I, belongs to anion 1 for $1\leq i\leq 4$ and to anion 2 for $5\leq i\leq 8$.

Sodium Cation. The Na^+ ions do not interact with the polyanions directly. The Na^+ ion is coordinated by six water molecules of crystallization and forms an almost regular octahedral $[Na(OH_2)_6]^+$ ion, as is shown in Fig. 3. The distances of Na–O are 2.28—2.40(2) Å.

Anion-Anion Hydrogen Bond. As can be seen in Fig. 2, anion 1 is very close to its neighbour translated along the b-axis. Anion 2 is also in the same situation. This is because the O_t atoms of Co are aqua ligands, while those of I are oxygen atoms and inter-anionic hydrogen bonds are formed among them. As a result, 2 anions form a two-dimensional network (denoted 2D-net hereafter) parallel to the (100) plane shown in Fig. 4. These 2D-nets stack along the a-axis and the 1 anions link two 2D-nets with hydrogen bonds (Fig. 5). These inter-anionic hydrogen bonds are summarized in Table 3.

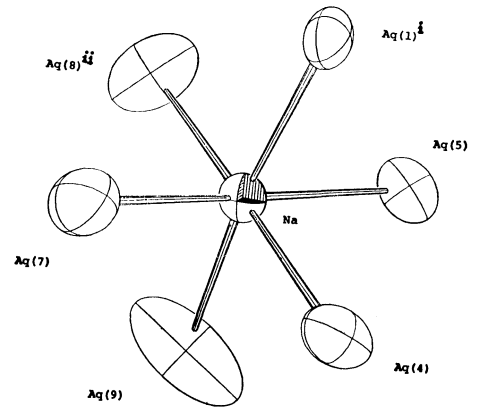

Fig. 3. The structure of the $[Na(OH_2)_6]^+$ cation.
Superscripts represent symmetry operations (i: $-x$, y, $1/2-z$; ii: x, $1-y$, $1/2+z$).

	O_t(8)	O_t(5)^i	2.565(7)

i: x, $-1+y$, z
ii: $1-x$, $1-y$, $1-z$

Protonation of the Anions. One of the terminal oxygen atoms of I(7) in anion 2 is protonated. This oxygen, O_t(7b) is very close to O_b(23), a bridging oxygen atoms of the anion 1, with the distance of 2.61(1) Å. This short distance indicates that there is a strong hydrogen bond between O_t(7b) and O_b(23). Moreover, the I(7)–O_t(7b) distance is 1.885(5) Å, which agrees with the I–OH length, 1.89(2) Å, in H_5IO_6.[13] This value is significantly larger than the other I–O_t distances, 1.783—1.824(5) Å, in the anions

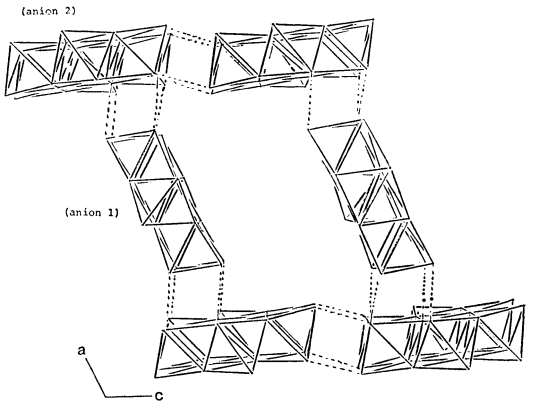

Fig. 5. Stacking scheme of the 2D-nets viewed from the b-axis.
The anion 1 acts as a girder between two 2D-nets.
Dashed lines represent inter-anionic hydrogen bonds.

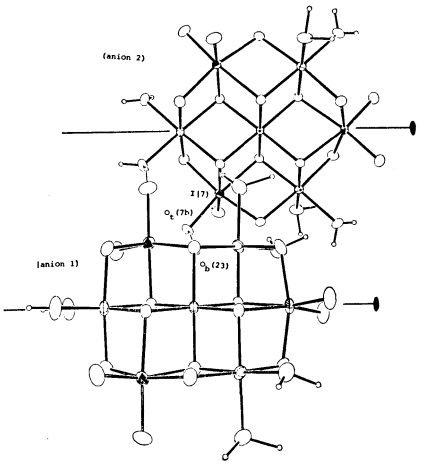

Fig. 6. Interaction of anions 1 and 2.
The protonated atom of anion 2 and the related atoms are shown. Small circles are hydrogen atoms included in the structure refinement. Fine lines are inter-anionic hydrogen bonds.

1 and 2. The minimum I–O_t length, 1.783(8) Å, is found in I(7)–O_t(7a), where O_t(7a) is the geminate O_t atom of O_t(7b). This short I(7)–O_t(7a) distance must be caused by the loose I(7)–O (7b) bond. In the difference Fourier maps, there is a peak with the height of ≈ 0.7 e/Å^3 at about 0.9 Å from O_t(7b) toward O_b(32). From these facts, we have concluded that O_t(7b) has a proton. There is no evidence for further protonation to the both polyanions. The anion 2 has a crystallographic 2-fold axis, so anion 2 is doubly protonated and should be formulated as $[Co_4I_3O_{16}(OH)_2(OH_2)_6]^{1-}$, while anion 1 is written as $[Co_4I_3O_{18}(OH_2)_6]^{3-}$. Figure 6 shows the interactions between anions 1 and 2. It has been reported that the acid is tri-basic, with virtually identical pK's (≈ 1.5).[14] Equilibrium calculations show that at the pH of 1.5, the concentrations of the four species: H_3X, H_2X^-, HX^{2-}, and X^{3-} ($X=Co_4I_3O_{18}(OH_2)_6^{3-}$) are equal in the solution.

The formation of the present crystals can be understood as the coprecipitation of H_2X^- and X^{3-}

anions; the one proton not found in this study must be present as an oxonium ion.

It is noteworthy that anion 2 is protonated at a terminal oxygen atom. There are several polyanions known to be protonated, but in most cases, the protonated sites are doubly or triply coordinated oxygen atoms, *e.g.* $[CrMo_6O_{24}H_6]^{3-}$.[7] The only exception is $[Mo_8O_{28}H_2]^{6-}$ anion, which has protonated terminal oxygen atoms.[15]

The bond distances and angles of the polyanions, except for the protonated sites, are the same as those of the Li salt determined by Lebioda, Ciechanowicz-Rutkowska, Baker, and Grochowski (1980).[16]

The authors thank Professor L. C. W. Baker for sending us his structure of the Li salt of the (tetracobaltato)triperiodate prior to the publication.

Ion-pair Extraction of Nickel(II) and Copper(II) Complexes of 8-Hydroxy-7-nitroso-5-quinolinesulfonic Acid with Zephiramine

Toyoko OZAKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 7, 1981)

The ion-pair extraction of nickel(II) and copper(II) complexes of 8-hydroxy-7-nitroso-5-quinolinesulfonic acid (H_2NQS) with zephiramine(benzyldimethyltetradecylammonium chloride) was studied. It was found that slope analysis can be used to determine the mechanism of these ion-pair extraction systems, as well as the continuous-variation method for three component systems or the mole-ratio method by choosing appropriate extraction conditions. As a result, the equation of these extraction equilibria can be represented as:

$$M^{2+} + 2HNQS^- + 2ZCl_{(o)} \rightleftharpoons M(NQS)_2Z_{2(o)} + 2H^+ + 2Cl^-$$

The extraction constants and the exchange constants were calculated.

As has previously been stated,[1] the author has applied 8-hydroxy-7-nitroso-5-quinolinesulfonic acid (H_2NQS) as a chelating reagent to the solvent extraction of the ternary complex, which is an ion-pair of water-soluble metal chelate with zephiramine (benzyldimethyltetradecylammonium chloride), in order to develop a sensitive colorimetric method for determining cobalt(II) and iron(II).

Since this reagent forms stable complexes with many other bivalent metal ions, in the present study it was applied to the solvent extraction of nickel(II) and copper(II). Subsequently, the compositions of extracted species were investigated. As a rule, the mechanism of ion-pair extraction is very complicated, as it includes a greater number of related chemical species than that of chelate extraction. For example, Kambara *et al.*[2,3] have presented a continuous-variation method for three components or a mole-ratio method to analyze the compositions of extracted species in the ion-pair extraction system. The compositions of ternary complexes of metal(Ni(II) and Cu(II)), 8-hydroxy-5-quinolinesulfonic acid (H_2QS) and zephiramine (ZCl) were reported by them to be $Ni(QS)_2(HQS)Z_3$ ($\lambda_{max}=400$ nm, $\varepsilon=1.35\times10^4$) and $Cu(QSZ)_3$ ($\lambda_{max}=410$ nm, $\varepsilon=9.45\times10^3$).

The present author has been attempted to apply a simple slope analysis, which is usually used in a chelate extraction system, to determine the compositions of extracted species in this extraction system. As a result, it could be seen that the slope analysis as well as the mole-ratio method can be successfully used for the ion-pair extraction system by choosing appropriate extraction conditions. The composition of the extracted species in this extraction system was confirmed to be 1:2:2 (M:H_2NQS:Z) for both the ternary complexes of nickel(II) and copper(II), differrent from the 1:1 complex synthesized in the auqeous phase by Aly *et al.*[4] In addition, the extraction constant of the complexes and the exchange constant between NQS and Cl^- were calculated from the distribution ratios in order to understand the extraction equilibria quantitatively.

Experimental

Reagents. Stock solutions of nickel(II) and Copper (II) (1000 ppm each) were prepared by dissolving weighed amounts of nickel sulfate and copper sulfate in water distilled and subsequentry standardized atomic absorptionmetrically, and diluted with distilled water as required.

The buffer solutions used were mixtures of a 0.2 M (1 M = 1 mol dm^{-3}) solution of sodium acetate and acetic acid for measurement at pH 3.9, and that of a 0.2 M solution of sodium borate and boric acid for measurement at pH 8.9. The ionic strength of the aqueous solutions used was kept at 0.1 with sodium sulfate and a small amount of buffer solutions, such as acetate and borate buffers. For low pH ranges, the ionic strength of the aqueous solutions was kept at 0.1 with mixtures of sodium sulfate, sulfuric acid, and sodium acetate.

All the other chemicals and apparatus used were essentially the same as those described earlier.[1]

Extraction Procedure. Ten ml of a buffered solution containing an appropriate amount of H_2NQS and nickel(II) or copper(II) was shaken with an equal volume of a chloroform solution of zephiramine. The pH value of the aqueous phase after extraction was taken as the equilibrium pH value. After a 3-min centrifugation(2000 min^{-1}), the phases were separated. The aqueous phase was immediately analyzed by atomic-absorption spectrophotometry, while the organic phase was analyzed after back-extraction into dilute hydrochloric acid.

Results and Discussion

Optimum Conditions for Extraction. The effect of the pH and the shaking time on the extraction percentage of Ni(II)–NQS and Cu(II)–NQS complexes with zephiramine were examined. Figure 1 shows that nickel and copper were quantitatively extracted in the pH ranges of 4.0—11.0 and 3.5—5.5 respectively.

A shaking time of 5 min was sufficient to establish equilibrium in all the systems.

Extraction Exchange Constant of H_2NQS Species. Since the values of the acid dissociation constants of H_2NQS are given as $pK_{a_1}<1$ and $pK_{a_2}=5.55$,[1] the dianion NQS^{2-} is the predominant H_2NQS species above pH 6.5, and the monoanion $HNQS^-$, below pH 4.5. These species are also extracted into the organic phase with zephiramine.

The equations of the extraction equilibria of H_2NQS with zephiramine can be represented as follows for both the cases:

at pH 3.9

$$HNQS^- + ZCl_{(o)} \rightleftharpoons HNQSZ_{(o)} + Cl^-, \quad (1)$$

at pH 8.9

$$NQS^{2-} + 2ZCl_{(o)} \rightleftharpoons NQSZ_{2(o)} + 2Cl^-. \quad (2)$$

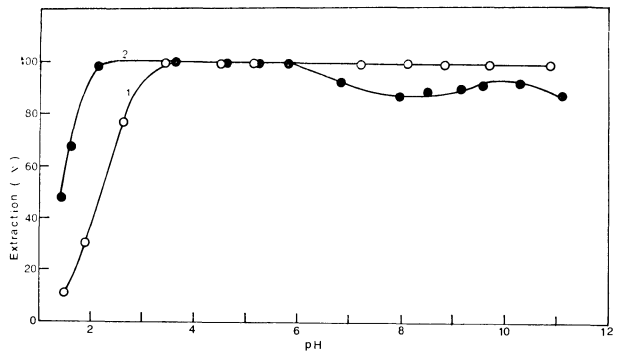

Fig. 1. The dependence of percentage extraction of nickel(II) and copper(II) complexes on the pH of the aqueous phase.
[NQS]=3.16×10^{-4} M, [ZCl]=10^{-3} M. 1: [Ni]=3.40×10^{-5} M, 2: [Cu]=3.15×10^{-5} M.

The extraction exchange constants of H_2NQS and Cl^- are given by:

$$K_{HNQS^-}^{Cl^-} = \frac{[HNQSZ]_o[Cl^-]}{[HNQS^-][ZCl]_o}, \quad (3)$$

$$K_{NQS^{2-}}^{Cl^-} = \frac{[NQSZ_2]_o[Cl^-]^2}{[NQS^{2-}][ZCl]_o^2}. \quad (4)$$

By taking logarithms of Eqs. 3 and 4, the following expression is derived:

$$\log\frac{[HNQSZ]_o}{[HNQS^-]} = \log K_{HNQS^-}^{Cl^-} - \log\frac{[Cl^-]}{[ZCl]_o}, \quad (5)$$

$$\log\frac{[NQSZ_2]_o}{[NQS^{2-}]} = \log K_{NQS^{2-}}^{Cl^-} - 2\log\frac{[Cl^-]}{[ZCl]_o}. \quad (6)$$

The total concentration of zephiramine is considered to be almost the same as that of $[ZCl]_o$ when the concentration of zephiramine far exceeds that of the reagent. The plots of $\log[HNQSZ]_o/[HNQS^-]$ *vs.* $\log[Cl^-]/[ZCl]_o$ at pH 3.9 and of $\log[NQSZ_2]_o/[NQS^{2-}]$ *vs.* $\log[Cl^-]/[ZCl]_o$ at pH 8.9 are shown in Fig. 2. The plots exhibited curves of slope −1 and slope −2 respectively, indicating that the theoretical extraction equilibria were actually established. The extraction exchange constants, as calculated from the ordinate intercept of plots in Fig. 2, are given in Table 1. Considering the values of the extraction exchange constants, it can be assumed that the reagent remains quantitatively in an aqueous phase when the concentrations of chloride are more than 10^3 and 10^2 times that of zephiramine at pH 3.9 and pH 8.9 respectively.

The Compositions of Ion-pairs of Metal–NQS Complexes with Zephiramine. The mole-ratio method and the continuous-variation method are generally used for determining the composition of an extracted ion-pair. However, it is not adequate to apply these methods to determining the ratio of zephiramine to metal when the formation constant of the ion-pair is significantly small, because they occasionally give results in which the apparent number of zephiramine related to metal is much greater than the actual one. Kambara *et al.* have presented a continuous-variation method for three-component systems with a trianglar coordinate to avoid the above-mentioned complication. The present auther has been attempted to apply a slope analysis, which is usually used in a chelate-extraction system, to settle the problem. At pH 3.9, the metal ion, M^{2+}, is extracted into chloroform by forming a water-soluble complex anion with n number of $HNQS^-$ and by subsequently aggregating with m number of zephiramine, which is necessary to maintain electrical neutrality in the organic phase.

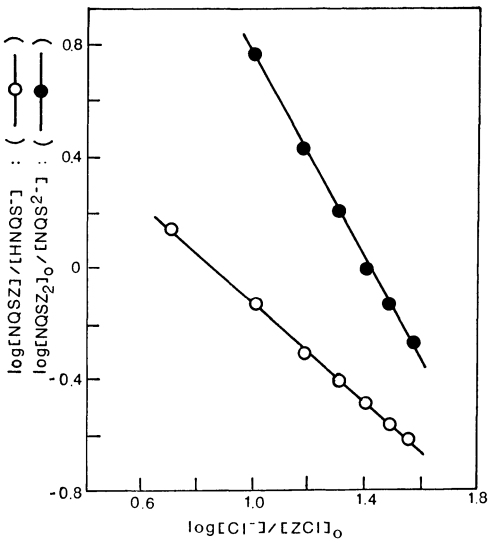

Fig. 2. Relationship between the distribution ratio of 8-hydroxy-7-nitroso-5-quinolinesulfonic acid and log $[Cl^-]/[ZCl]_o$.
[NQS]=7.9×10^{-5} M, [ZCl]=10^{-3} M.

For this extraction system, the equation can be written as:

$$M^{2+} + nHNQS^- + mZCl_{(o)} \rightleftharpoons M(NQS)_nZ_{m(o)} + mCl^- + nH^+, \quad (7)$$

where the extraction constant is given by:

$$K_{ex} = \frac{[M(NQS)_nZ_m]_o[Cl^-]^m[H^+]^n}{[M^{2+}][HNQS^-]^n[ZCl]_o^m}. \quad (8)$$

The total concentrations of NQS and zephiramine can be expressed as Eqs. 9 and 10:

$$[NQS]_{total} = [HNQS^-] + [HNQSZ]_o + n[M(NQS)_nZ_m]_o, \quad (9)$$

$$[Z]_{total} = [ZCl]_o + [HNQSZ]_o + m[M(NQS)_nZ_m]_o. \quad (10)$$

The distribution ratio of metal between the two phases is given as:

$$D = \frac{[M(NQS)_nZ_m]_o}{[M^{2+}]}. \quad (11)$$

By introducing Eq. 11 to Eq. 8, the following expression is derived:

$$\log D = \log K_{ex} + n\mathrm{pH} + m\log\frac{[ZCl]_o}{[Cl^-]} + n\log[HNQS^-]. \quad (12)$$

The ratio of metal to zephiramine is obtained as follows. When the concentration of both NQS and zephiramine are sufficiently excessive against that of the metal ion, the third term of Eqs. 9 and 10 can be omitted. When the amount of chloride ions present is more than 70 times that of zephiramine, the second terms of Eqs. 9 and 10 become negligible,

because $K^{Cl^-}_{HNQS^-}$ is given as 7.08 by Eq. 3. Under these conditions, $[HNQS^-]$ and $[ZCl]_0$ can be regarded as $[NQS]_{total}$ and $[Z]_{total}$ respectively.

Therefore, Eq. 12 can be rewritten as 13 when $[Cl^-]_{total} > [Z]_{total} \approx [NQS]_{total} \gg [M]_{total}$:

$$\log D = \log K_{ex} + n\mathrm{pH} + m\log\frac{[Z]_{total}}{[Cl^-]} + n\log[NQS]_{total}. \quad (13)$$

This equation represents the plot of $\log D$ *vs.* $\log[Z]_{total}/[Cl^-]$, with a slope corresponding to the ratio of metal to zephiramine under the conditions of a constant pH and a constant NQS concentration. The plots of $\log D$ *vs.* $\log[Z]_{total}/[Cl^-]$ for nickel(II) and copper(II) are shown in Fig. 3. As is evident from Fig. 3, the plots gave linear curves with a slope of 2 for nickel(II) and copper(II) in the anticipated ranges. This result indicates that the ratio of metal to zephiramine is 1:2 in each system.

Similarly, the ratio of metal to NQS is obtained as follows. By introducing Eq. 3 to Eq. 12, the following expression is derived:

$$\log D = \log K_{ex} - m\log K^{Cl^-}_{HNQS^-} + n\mathrm{pH} + m\log[HNQSZ]_0 + (m-n)\log[HNQS^-]. \quad (14)$$

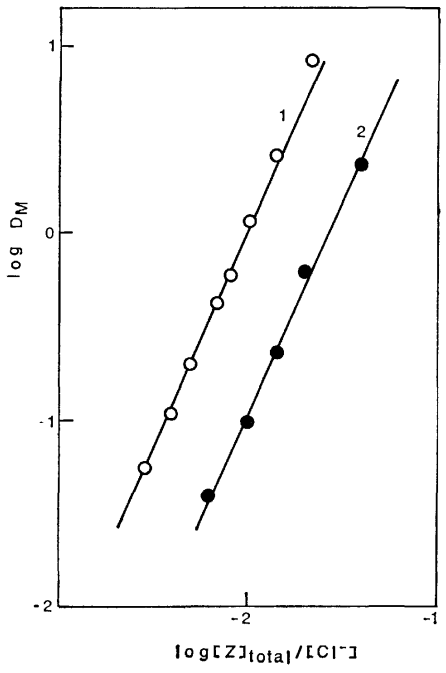

Fig. 3. Relationship between $\log D_M$ and $\log[Z]_{total}/[Cl^-]$.
$[NQS]=6.32\times10^{-4}$ M, $[ZCl]_{total}=10^{-3}$ M, pH=3.9.
1: $[Ni]=3.40\times10^{-5}$ M, 2: $[Cu]=3.15\times10^{-5}$ M.

As the terms of $[HNQS^-]$ and $[M(NQS)_nZ_m]_0$ in Eq. 9 can be neglected when the concentration of a ligand is sufficiently in excess against that of the metal ion and when moreover, the concentration of zephiramine exceeds that of the ligand, namely, $[Z]_{total} > [NQS]_{total} \gg [M]_{total}$, $[HNQSZ]_0$ can be regarded as $[NQS]_{total}$. Considering the electrical neutrality of the ion-pair, the numbers of zephiramine and ligand seem to coincide in this system.

Then, supposing $m=n$, Eq. 14 can be rewritten as follows:

$$\log D = \log K_{ex} - m\log K^{Cl^-}_{HNQS^-} + n\mathrm{pH} + m\log[NQS]_{total}. \quad (15)$$

This equation means that a plot of $\log D$ *vs.* pH gives a slope corresponding to the ratio of metal to the $HNQS^-$ of the extracted complex. The plots of $\log D$ *vs.* pH for nickel(II) and copper(II) at pH 3.9 are shown in Fig. 4. The fact that these plots give curves with a slope of 2 for both the metals indicates an M:NQS ratio of 1:2 in this extraction system. These results agree well with those obtained by the mole-ratio method, and in combination with the results presented above, they indicate that the composition of extracted complexes in the presence of zephiramine is M:NQS:Z=1:2:2. The composition of the precipitated complexes in the aqueous phase,

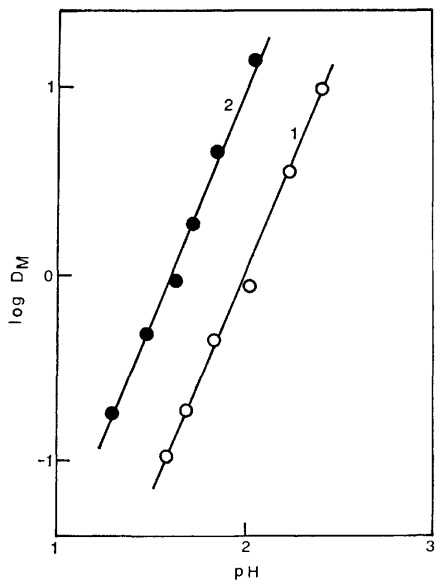

Fig. 4. Relationship between $\log D_M$ and pH.
$[NQS]=1.58\times10^{-3}$ M, $[ZCl]_{total}=10^{-2}$ M. 1: [Ni] $=3.40\times10^{-5}$ M, 2: $[Cu]=3.15\times10^{-5}$ M.

Table 1. Exchange-equilibrium constants and extraction constants for 8-hydroxy-7-nitroso-5-quinolinesulfonic acid(H_2NQS) and its metal complexes (Z; Zephiramine)

	λ_{max} / nm	Molar absorptivity / $1\,mol^{-1}\,cm^{-1}$	$\log K^{mCl^-}_{A^{m-}}$	$\log K_{ex}$
HNQS	390	2.9×10^3	0.85	—
$NQSZ_2$	440	5.3×10^3	1.42	—
$Ni(NQS)_2Z_2$	460	2.6×10^4	4.14	3.40
$Cu(NQS)_2Z_2$	455	2.5×10^4	3.16	4.10

however, was reported to be M:NQS=1:1 on the basis of the results of the IR spectra and elemental analysis, according to Aly *et al.*[4] Noriki *et al.*[5] have stated that zephiramine has the effect of changing a coordination-unsaturated chelate to an extractable coordination-saturated chelate by accelerating the replacement of water molecules with ligands in the case of magnesium oxinate. It can, therefore, be presumed that zephiramine has a similar effect in the case of NQS complexes.

The absorption maxima, the molar absorptivities, and the exchange-equilibrium constants of the extracted ion-pair complexes are listed in Table 1.

The author wishes to express her deep gratitude to Professor Taitiro Fujinaga, Assistant Professor Tooru Kuwamoto, Dr. Eiichiro Nakayama, and Dr. Etsu Yamada, all of Kyoto University, for their unfailing guidance through the course of this work. Almost all of this work has been done at the Instrumental Analysis Research Center, Kyoto University; the author is grateful to Professor Hiroyuki Hatano, the head of the Center, for his permission to use the facilities.

Binuclear Metal Complexes. XLV.[1] Synthesis and Magnetic, Spectral, and Electrochemical Studies of Strati-bis Copper(II) Complexes of Some Schiff Bases Derived from Primary Tetraamines and Salicylaldehydes

Tatsuo Izumitani, Masaaki Nakamura, Hisashi Ōkawa,* and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received December 8, 1981)

New Schiff base ligands, 1,2,3,4-tetrakis(R-salicylideneamino)-2,3-dimethylbutane (abbreviated as H_4(R-sata); R (substituent on the ring)=H, 5-Me, 5-Bu^t) and 1,2-bis(R-salicylideneamino)-1,2-bis(salicylideneaminomethyl)cyclohexane (H_4(R-sacta)), which are capable of forming "strati-bis" type binuclear copper(II) complexes, have been synthesized. Magnetic, spectral and electrochemical properties of the binuclear copper(II) complexes, Cu_2(R-sata) and Cu_2(R-sacta), were investigated in comparison with those of mononuclear copper (II) complexes Cu(R-salpn) and Cu(R-sacda), where H_2(R-salpn) is *N,N'*-bis(R-salicylidene)-1,2-propanediamine and H_2(R-sacda) 1-(R-salicylideneamino)-1-(R-salicylideneaminomethyl)cyclohexane. ESR spectra of Cu_2(sata), Cu_2(sacta) and Cu_2(5-Me-sacta) showed a seven-lined hyperfine structure whose hyperfine coupling constant ($A_\parallel \approx 85$ G, 1 G$=10^{-4}$ T) was about one half of that of the corresponding mononuclear copper(II) complex. Each electronic spectrum of these binuclear complexes showed the π-π^* transition originated from the azomethine group at a low frequency compared with that of the corresponding mononuclear complex. Cyclic voltammograms of these three complexes involved two redox couples. The first redox couple attributable to the Cu(II, II)/Cu(II,I) process is higher in potential than the Cu(II)/Cu(I) process of the corresponding mononuclear complex. These characteristics were discussed in terms of the electron-delocalization through the π-π interaction between the two [CuN_2O_2]-chromophores.

Recently, much attention has been devoted to electrochemical investigations of copper complexes in which two metal ions are bound in close proximity, in the hope to clarify the redox function of copper proteins.[2-6] Reduction of binuclear copper(II) complexes into the corresponding copper(I) complexes occurs *via* two monoelectronic steps[2,5] or one dielectronic step.[3,4,6] In most of these complexes two equatorial planes of the metal ions are linked so as to be coplanar with oxygen-bridges[2-5] and there are very few electrochemical investigations on binuclear copper(II) complexes whose coordination planes face to each other.

In the preliminary report[7] we have suggested that the binuclear copper(II) complex, Cu_2(sata) (H_4(sata) denotes 1,2,3,4-tetrakis(salicylideneamino)-2,3-dimethylbutane), takes a unique configuration in which two CuN_2O_2 planes are stacked in a face-to-face manner. In this study we have prepared the binuclear copper (II) complexes, Cu_2(R-sata) (R=5-Me, 5-Bu^t), which are the homologs of Cu_2(sata) containing methyl or *t*-butyl group at the 5-position of the aromatic ring. We have also prepared the copper(II) complexes, Cu_2(R-sacta), where H_4(R-sacta) denotes 1,2-bis(R-salicylideneamino)-1,2-bis(R-salicylideneaminomethyl)-cyclohexane. Magnetic, spectral and electrochemical properties of Cu_2(R-sata) and Cu_2(R-sacta) were investigated in comparison with those of the mononuclear copper(II) complexes, Cu(R-salpn) and Cu-(R-sacda) (H_2(R-salpn)=*N,N'*-bis(R-salicylidene)-1,2-propanediamine; H_2(R-sacda)=1-(R-salicylideneamino)-1-(R-salicylideneaminomethyl)cyclohexane), respectively, in the hope to elucidate the characteristics of the binuclear copper(II) complexes stacked in the face-to-face manner.

Experimental

Syntheses. 1-Aminomethyl-1-cyclohexanamine was prepared by the method in the literature.[8] Synthesis of Cu(R-salpn) (R=H, 5-Me, 5-Bu^t) was carried out by the method of Holm.[9]

2,3-Dicyano-2,3-butanediamine. A solution of 2,3-dicyano-2,3-butanediol[10] (40 g) in methanol (300 cm^3) was chilled by means of ice-water and to this was introduced a stream of dry ammonia. After the mixture was allowed to stand overnight, the solvent and ammonia were evaporated to give 2,3-dicyano-2,3-butanediamine as white crystals. They were recrystallized from ethanol as colorless needles melting at 138—141 °C. The yield was *ca.* 15 g.

Found: C, 52.25; H, 7.42; N, 40.23%. Calcd for $C_6H_{10}N_4$: C, 52.16; H, 7.30; N, 40.55%.

1,2-Dicyano-1,2-cyclohexanediamine. This was prepared by the reaction of 1,2-dicyano-1,2-cyclohexanediol[10] and ammonia in the same way as described above. It forms colorless needles melting at 169—171 °C. The yield was *ca.* 30%.

Found: C, 58.49; H, 7.42; N, 33.93%. Calcd for $C_8H_{12}N_4$: C, 58.52; H, 7.37; N, 34.12%.

2,3-Dimethyl-1,2,3,4-butanetetramine. A suspension of $LiAlH_4$ (25 g) in dry dioxane (500 cm^3) was stirred at 70 °C, and to this was added dropwise a solution of 2,3-dicyano-2,3-butanediamine (15 g) in dry dioxane (200 cm^3) and the mixture was refluxed for three hours. The reaction mixture was cooled by ice-water and decomposed by the addition of 50 cm^3 of water and then 50 cm^3 of a 15% sodium hydroxide solution. Inorganic substances that precipitated were filtered and washed with three 50 cm^3 portions of dioxane. The filtrate and the washings were combined and to this was added hydrobromic acid (60%, 20 cm^3). On evaporating the solvent there remained 2,3-dimethyl-1,2,3,4-butanetetramine tetrahydrobromide as a yellow mass. It was dissolved in water (10 cm^3) and to this solution was added potassium hydroxide (pellets 20 g). The free tetramine thus liberated was extracted with three 100 cm^3 portions of ether, and the combined ethereal solution was dried with KOH. Evaporation of the solvent left 2,3-dimethyl-1,2,3,4-butanetetramine as pale yellow, oily substance (3 g). It was used for preparation of complexes without further puri-

fication.

1,2-Bis(aminomethyl)-1,2-cyclohexanediamine. This was prepared as yellow, oily substance by the reduction of 1,2-dicyano-1,2-cyclohexanediamine in a way similar to that described above.

Cu_2(R-sata) (R=H, 5-Me, 5-Bu^t). Synthetic methods for these complexes are practically the same. The methods were exemplified by that for Cu_2(sata) as follows. 2,3-Dimethyl-1,2,3,4-butanetetramine (0.5 g) and salicylaldehyde (1.7 g) were dissolved in ethanol (30 cm^3), and the mixture was heated at *ca.* 70 °C for 10 min. To this solution was added powdered copper(II) acetate monohydrate (1.4 g), and the mixture was stirred at 60 °C for 30 min and then allowed to stand in a refrigerator to give brown to dark green crystals. They were collected and recrystallized from a chloroform–ethanol mixture.

Cu_2(R-sacta) (R=H, 5-Me, 5-Bu^t). These complexes were obtained by a method similar to that of Cu_2(R-sata).

Cu(R-sacda) (R=H, 5-Me, 5-Bu^t). These complexes were prepared by the reaction of 1-aminomethyl-1-cyclohexanamine, salicylaldehyde, and copper(II) acetate monohydrate in a 1:2:1 mole ratio in ethanol.

Elemental analyses of Cu_2(R-sata), Cu_2(R-sacta), and Cu(R-sacda) are given in Table 1.
