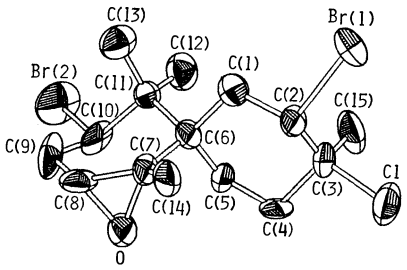

Fig. 1. A perspective view of the 7,8-epoxyhalochamigrene A-molecule, and the crystallographic numbering system.
Non-hydrogen atoms are represented as thermal ellipsoids enclosing 50% probabilities.

Of the two spiro-linked six-membered rings, the cyclohexane ring having the epoxy group takes a half-chair conformation; the Br(2), C(1), and C(12) atoms are equatorially or pseudoequatorially bonded to this ring, while the C(5) and C(13) atoms are axially or pseudoaxially oriented. On the other hand, the remaining six-membered ring has a somewhat deformed chair conformation; the Br(1), Cl, and C(11) atoms take the equatorial orientations, while the C(7) and C(15) atoms occupy the axial positions. Such a conformation of the spiro[5.5]undecane system brings the C(2)H and C(14)H_3 groups very close to each other; the C(2)···C(14) distances for the four molecules are 3.11—3.21 Å. The severe steric repulsion between these groups results in a considerable flattening of the C(5)-C(6)-C(1)-C(2) moiety (see Table 4).

In all four molecules, the C(6)-C(11) bond distance (1.58—1.62 Å) is appreciably longer than the standard C-C single-bond distance.[9] This bond lengthening is probably due to the strong steric repulsions between the bulky groups attached to the C(6) and C(11) atoms. The fact that the C(3)-C(2)-Br(1) bond angle is greater than the C(1)-C(2)-Br(1) angle on the average by 5° indicates that the Cl atom and C(15)H_3 group repel the Br(1) atom to a considerable extent. The Br(2) atom also suffers a similar steric hindrance from the C(12)H_3 and C(13)H_3 *gem*-dimethyl groups; the average difference between the C(9)-C(10)-Br(2) and C(11)-C(10)-Br(2) bond angles is 6°.

As to the valence angles at the C(3) atom, an interesting fact is found: the sum of the average C(2)-C(3)-C(4), C(2)-C(3)-C(15), and C(4)-C(3)-C(15) bond angles, 338°, is considerably larger than three times the tetrahedral angle, while all the average C(2)-C(3)-Cl, C(4)-C(3)-Cl, and C(15)-C(3)-Cl bond angles are smaller than the tetrahedral angle. This suggests that the C(3) atomic orbital used for the C(3)-Cl bond may involve a greater amount of p-character than the pure sp^3 hybrid orbital, and that, as the result, the C(3)-Cl bond may be somewhat lengthened. In fact, the average C(3)-Cl bond distance of 1.84 Å is significantly longer than the usual C-Cl distance, 1.77 Å.[9]

Crystal Structure. The most interesting point in the present structure is how the four crystallographically-independent A-, B-, C-, and D-molecules are arranged. As Fig. 2 shows, the crystal may be taken as composed of the following three kinds of molecular layers parallel to the (010) plane: (1) A layers consisting of only A-molecules and placed at $y=0$ or 1/2; (2) D layers made up of only D-molecules and situated at $y=1/4$ or 3/4; (3) BC layers containing both B- and C-molecules and lying between the A and D layers. The structure has the sequence of layers, A, BC, D, BC, A, ..., repeating after four layers.

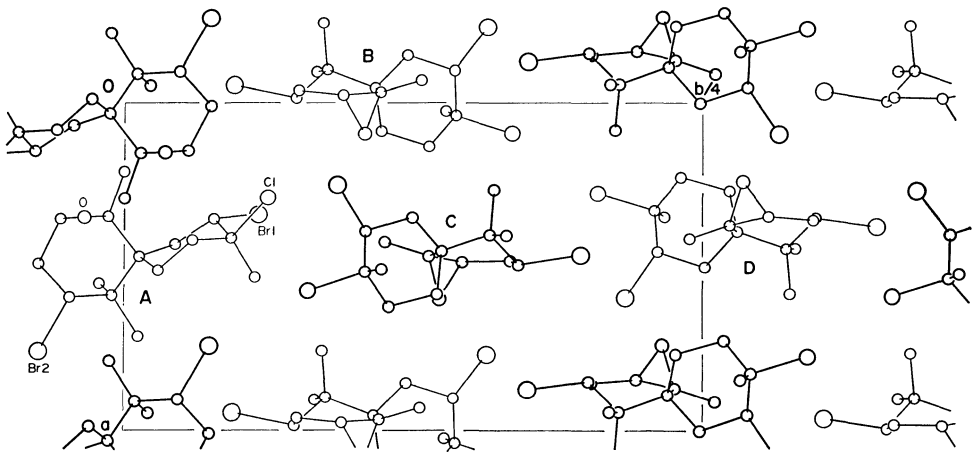

Fig. 2. The molecular arrangement viewed along the c axis.

Although the B- and C-molecules are independent, they are related to each other by an approximate two-fold screw axis along the a axis. These molecules are also related to the D-molecule by an approximate two-fold screw axis (with a translation of $b/8$) along the b axis or by an approximate two-fold rotation axis along the c axis. Consequently, the molecular arrangement in the triple molecular layer formed by adjacent BC, D, and BC layers looks as if it were part of a structure having the $P2_12_12$ space group and unit-cell dimensions of $a'=a$, $b'=b/4$, and $c'=c$. These triple molecular layers and the monomolecular A layers are alternately stacked. The orientation of the A-molecule is substantially different from those of the other three molecules; *e.g.*, the two molecules marked with A and B in Fig. 2 do not take the same orientation until either of them rotates by about 90° around a special axis lying nearly in the [$\bar{8}$10] direction.

The molecules are bonded mainly by the van der Waals interactions. The halogen atoms are arranged near either surface of the molecular layer to which they belong. The intermolecular halogen-halogen distances, which are shorter than the usual van der Waals distances, are given in Table 5. Of these, the closest Br(A1)···Br(C1), Br(A2)···Cl(C), and Cl(B)···Cl(D) contacts correspond to the apparent reductions, about 0.17 and 0.09 Å respectively, of the chlorine and bromine van der Waals radii.

Table 5. The intermolecular halogen-halogen distances shorter than the usual van der Waals distances

		l/Å
Br(A1)	Br(C1)[a]	3.720(3)
Br(A2)	Cl(C)[b]	3.497(5)
Br(C1)	Cl(A)[c]	3.729(5)
Cl(B)	Cl(D)[c]	3.260(8)

The symmetry codes are as follows: a) x, y, $-1+z$; b) $3/2-x$, $-y$, $-1/2+z$; c) x, y, z.

(Received April 21, 1982)

Ultrasonic absorption was measured in hexane solutions of octylammonium alkanoates (nonanoate, decanoate, dodecanoate, and tetradecanoate). The value of critical micelle concentration (CMC) was determined to be 0.02 M (1 M = 1 mol dm^{-3}) for all the surfactants. The excess ultrasonic absorption, observed in the solutions above the CMC, was ascribed to the association-dissociation of the monomer to and from the micelle. From the concentration dependences of the ultrasonic parameters, the mean aggregation number of the micelle, the rate constants, and the enthalpy change of the above reaction were obtained. These results were discussed in relation to the shape of the reversed micelle and the solute-solvent interactions.

A large amount of experimental information has been provided for the physicochemical properties of micelles in aqueous solution. In the field of the kinetics, two distinct reaction processes of micelle formation have been observed in different time regions:[1-4] one is a micelle formation and decomposition and the other is an association-dissociation of the monomer to and from the micelle. On the other hand, relatively little is known with regard to the micelles in organic solvents[5-8] in spite of their important roles as catalysis, solubilizing agents, and model systems for the membranes and molecular aggregations. Especially, their kinetics have rarely been studied.[8,9] The difficulty of this study seems to be due to the following reasons: (i) since the aggregation number of the micelle is very low, an abrupt and large change of the physicochemical properties of the solution cannot be expected at the CMC, and (ii) micelle formation and monomer exchange reactions are too rapid to be observed by conventional techniques. To overcome these difficulties, the ultrasonic absorption method is a very valuable technique for the study of the dynamic features of the micelle in organic solution. In the present work we applied the technique to the hexane solution of octylammonium alkanoates of different chain lengths: *i.e.*, octylammonium nonanoate (OAN), decanoate (OADe), dodecanoate (OAD), and tetradecanoate (OAT).

The purposes of this work are to decide the reaction responsible for the relaxation absorption. to obtain the kinetic parameters concerning the reaction, and to see the effect of the chain length of the detergents.

Experimental

Octylammonium alkanoates were prepared by the method already reported,[10] and dried at room temperature under reduced pressure until the weight became constant. The melting points of the detergents were satisfactorily consistent with the corresponding literature values.[11] Hexane was dried on P_2O_5 and distilled.

Ultrasonic absorption was measured by the pulse technique in the frequency range 5—95 MHz for the solutions of the concentrations from 0.05 to 0.35 M at intervals of 0.05 M at 30 °C. Details of the apparatus have been described elsewhere.[12] The sing-around method was employed for the measurement of sound velocity. The density was measured by a pycnometer.

Results and Discussion

Since many physicochemical properties of the detergent solution change at the CMC, a number of methods have been applied for the determination of the CMC. The velocity of sound, which is used in this work, is one of them: the CMC is determined from the break point of the velocity *vs.* concentration plot. As an example, the concentration dependence of the sound velocity of OAN is shown in Fig. 1, where the CMC was determined to be 0.02 M. In the same way, the value of the CMC was obtained to be 0.02 M for OADe, OAD, and OAT. Consequently, we could not observe any difference in the CMC's of the four detergents. The relationship between the alkyl chain length and the CMC is not clear in organic solution, in contrast to that in aqueous solution. Generally, the CMC increases with increase of the lipophilic part of the detergent in organic solution.[13] But the relationship is not always straightforward. In some cases, no effect was observed, *e.g.*, octylammonium alkanoates in CCl_4;[13] the present result, constant CMC irrespective to the chain length, is another example.

Ultrasonic relaxation absorptions were observed in

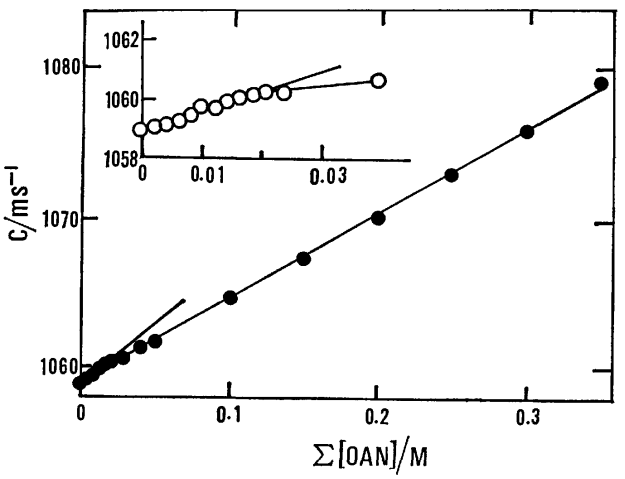

Fig. 1. Concentration dependence of the sound velocity of OAN in hexane at 30 °C.

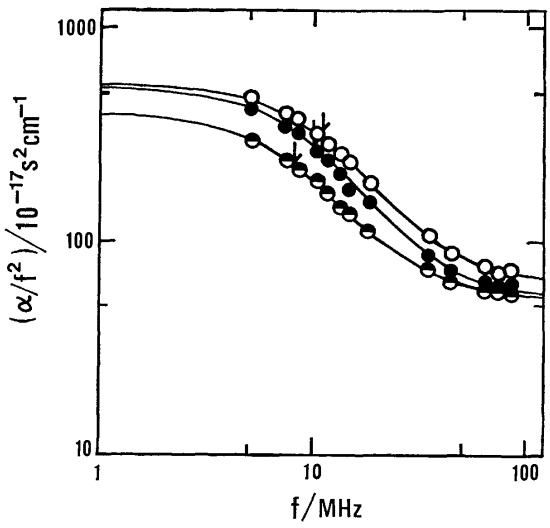

Fig. 2. Ultrasonic absorption spectra of OAT in hexane at 30 °C.
The solid lines are theoretical curves calculated by Eq. 1 with f_r, A, and B in Table 1. The arrows indicate the relaxation frequency: ◓: 0.15 M, ●: 0.25 M, ○: 0.35 M.

all the detergent solutions in the concentration range above the CMC. Representative absorption spectra of OAT are shown in Fig. 2. Similar absorption spectra were obtained in other detergent solutions. All of the spectra were represented by the single relaxation equation:

$$\alpha/f^2 = A/\{1+(f/f_r)^2\} + B, \quad (1)$$

where α is the absorption coefficient, f the frequency, f_r the relaxation frequency, A and B are the relaxing and nonrelaxing absorptions, respectively. The absorption parameters, f_r, A, and B, were determined by a computor so as to give the best fit of the experimental data to Eq. 1 and are listed in Table 1.

Since the relaxation absorption is observed only in the solutions above the CMC, it is clear that the present absorption is related to the micelle. As plausible reactions responsible for the present absorption, micelle formation and decomposition and association-dissociation of the monomer to and from the micelle were investigated. However, the micelle formation reaction,

$$nS \rightleftharpoons S_n, \quad (2)$$

(S=detergent monomer and S_n=micelle composed of n detergent molecules) could not give any satisfactory interpretations to the present data.

The association-dissociation of the monomer to and from the micelle,

$$S_n + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} S_{n+1}, \quad (3)$$

was examined as follows. By assuming that $[S_n]=[S_{n+1}]$, the equilibrium constant is given by

$$K = \frac{k_1}{k_{-1}} = \frac{1}{[S]}. \quad (4)$$

For Reaction 3, the reciprocal relaxation time, τ^{-1} is expressed by

$$\tau^{-1}(=2\pi f_r) = k_1([S]+[S_n]) + k_{-1}, \quad (5)$$

Table 1. Ultrasonic parameters of octylammonium alkanoates in hexane

and, furthermore, rewritten by Eq. 4 to be

$$\tau^{-1} = k_{-1}([S_n]/[S]+2). \quad (6)$$

With the relationship between the micelle concentration, $[S_n]$, and the overall concentration, C, of detergent,

$$[S_n] = \frac{C-[S]}{2n}, \quad (7)$$

Eq. 6 is rewritten as follows:

$$\tau^{-1} = k_{-1}\left\{\frac{C}{2n[S]}+\left(2-\frac{1}{2n}\right)\right\}. \quad (8)$$

The plots of the experimental data, τ^{-1} *vs.* C, are shown in Fig. 3. The fact that these points form a straight line indicates that the present absorption is based on Reaction 3. The values of k_{-1} and n were determined from the slope and the intercept of the straight line, respectively, and k_1 was calculated from k_{-1} and the equilibrium constant by Eq. 4. The values obtained are listed in Table 2.

Attribution of the absorption to Reaction 3 was further examined from the standpoint of absorption am-

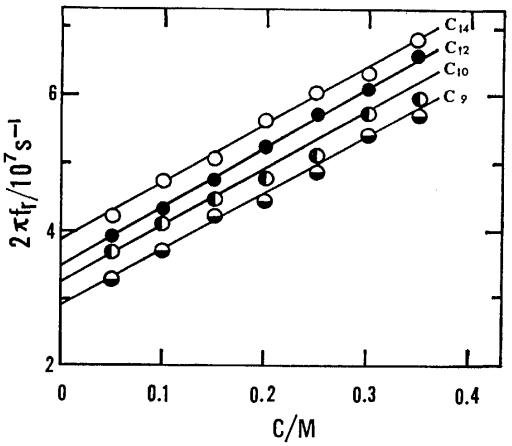

Fig. 3. Concentration dependence of the relaxation frequencies of detergent in hexane at 30 °C.

plitude. The relaxation absorption per wavelength, μ_{max}, is expressed by

$$\mu_{max} = \frac{\pi\rho C^2}{2RT}\left(\Delta V - \frac{\alpha}{\rho C_p}\Delta H\right)^2 \Gamma^{-1}, \quad (9)$$

with

$$\Gamma = \frac{1}{[S]} + \frac{1}{[S_n]} + \frac{1}{[S_{n+1}]}, \quad (10)$$

where ρ is the density, C the sound velocity, α the thermal expansion coefficient, C_p the specific heat at constant pressure and ΔV and ΔH are the standard volume change and the enthalpy change of the reaction, respectively. Since the values in the parentheses are constant for a reaction, the plot of μ_{max} *vs.* Γ^{-1} will give a straight line which goes through the origin of the coordinates. The plots for OAN are shown in Fig. 4. Similar plots were obtained for OADe, OAD, and OAT. These results are in agreement with the above prediction, and suggest that the

The dotted region means the polar core.

present relaxation absorption is based on the association-dissociation of the monomer to and from the micelle. Additional support of this assignment of the relaxation absorption will be given by the fact that the time constant of the present system falls in the range of the reported lifetime of the detergent monomers in the presence of the higher aggregates in nonpolar solvents: *i.e.*, 10^{-5}—10^{-8} s.[14]

For the reactions in organic solutions, the ΔV term is usually much smaller than the ΔH term because of the small value of ΔV and the large value of $\alpha/\rho C_p$ in the ΔH term.[15] Therefore, neglecting the ΔV term, ΔH value was obtained from the slope of the plot in Fig. 4 and is listed in Table 2.

As is well known, detergents in nonpolar solvents aggregate to form a reversed micelle, where the polar head groups locate around a polar solvent core which is often called the polar core, with the hydrocarbon chains directed outside to the solvent. Schematic second-order models of the reversed micelles of the present systems are shown in Fig. 5. In the case of OAN, since the alkyl chain length of alkanoate is about the same as that of ammonium, the lipophilic effects on them are of the same magnitude. Consequently, the surfaces of the micelle and the polar core will be as shown in Fig. 5 (a). On the other hand, in the case of OAT, the lipophilic effect on carboxylate is larger than that on ammonium. This fact will result in pulling the carboxylate out a little and enlarging the sizes of the polar core and the micelle, as shown in Fig. 5 (b). If we accept these pictures, we can attribute the increase of the aggregation number with increase of the chain length of the alkanoate, seen in Table

2, to the enlargement, or the variation of the shape, of the micelle.

Kinetics of the association-dissociation of the monomer to and from the micelle have been studied only in the aqueous solution.[16] The result indicated that there is a progressive decrease in both rate constants, k_1 and k_{-1}, with increasing the chain length of the detergent. The reason of the decrease of k_1 has been ascribed to the degree of packing, *i.e.*, how closely the monomer units are distributed on the surface of the micelle; that of k_{-1} has been thought to be due to the increase of cohesive forces between the hydrophobic ends.

These ideas were applied to the present system. With increase of the chain length of the alkanoate, the degree of packing in the micelle will decrease, in spite of the increase of the aggregation number, and therefore the detergent monomer can move into micelle more easily, *i.e.*, k_1 will increase. The increase of k_{-1} will be ascribed to the decrease of the electrostatic cohesive force between the polar head groups, which are packed less closely with increase of the chain length.

The chain length dependence of $|\Delta H|$ seems to be too small to develop a meaningful discussion now; we will attempt this after gathering the data for other surfactants in organic solvents.

(Received April 22, 1982)

Radical ions of some 9-substituted anthracene derivatives have been prepared in polymer film by γ-irradiation at 77 K. By use of the polarized absorption spectra of these radical ions, the absorption spectra have been resolved into two components (resolved spectra), the transition moments of which are polarized parallel to the molecular long and short axes, respectively. Correlation of the characteristic absorption bands is discussed briefly.

In previous papers we have shown that the stretched film technique combined with γ-irradiation is available for the polarization measurement of the radical ions of anthracene and pyrene,[1] and acridine and phenazine.[2] By qualitative analysis of the polarized absorption spectra, the polarization direction of the electronic transition band was determined and the assignments of the bands were carried out for these radical ions.

We note here the efficient preparation method for the radical ions in the films. Radical anions are produced by γ-irradiation of the poly(vinyl alcohol) film containing the solvent *s*-butylamine and the solute aromatic molecule (PVA–BuA system). For the preparation of the cation, a poly(vinyl chloride) film containing *s*-butyl chloride and aromatic molecule is irradiated (PVC–BuCl system). In order to remove the absorption due to solvated electron or positive hole, it is essential to dope the film with enough solute ($\approx 10^{-2}$ mol dm^{-3}).

In this paper we apply this method to 9-substituted anthracenes and examine the applicability of the method. Furthermore, stretched films were used and the polarized absorption spectra of the radical ions were determined and analyzed quantitatively. The resultant resolved spectra are used to discuss the correlation of the electronic transition bands in the visible region.

Experimental

Commercially available reagents, 9-methylanthracene (G.R. grade of Tokyo Kasei Co. Ltd.) and 9-bromo-, 9-nitro-, and 9-cyanoanthracene (Aldrich Chemical Co., Inc.), were used. 9-Aminoanthracene was synthesized according to the literature.[3] Poly(vinyl alcohol) film (PVA), 0.2 mm thick, and poly(vinyl chloride) film (PVC), 0.18 mm thick, were employed as before.[1] Parent compounds were doped into PVA film with the aid of a solvent, *s*-butylamine (G.R. grade of Tokyo Kasei Co. Ltd.), and into PVC film by use of *s*-butyl chloride (G.R. grade of Tokyo Kasei Co. Ltd.). For the measurement of the polarized absorption spectra, sample films PVA and PVC were stretched 3 and 4 times, respectively. These films were irradiated by ^{60}Co γ-rays for 2 h at 77 K with a dose rate of 1.0×10^{6} rad/h. Absorption spectra were measured in the range from 300 to 850 nm with a JASCO SS-50 spectrophotometer equipped with a Rochon polarizer. MO calculations were carried out for the radical ions after Zahradník and Čársky.[4] Parameters used were taken from Ishitani and Nagakura.[5]

† Present address: The Department of Materials Science and Technology, Technological University of Nagaoka, Nagaoka, Niigata 949-54.

Results and Discussion

Identification of the Absorption Spectra. 9-Methylanthracene: Figures 1a and 1b show the absorption spectra of the γ-irradiated PVA–BuA and PVC–BuCl systems of 9-methylanthracene, respectively. Dodd has reported that the characteristic absorption maxima of the 9-methylanthracene radical anion and the cation are respectively at 13750 cm^{-1} in tetrahydrofuran and at 14050 cm^{-1} in boric acid glass.[6] These maxima are well correspondent to the absorption peak at 13.7×10^{3} cm^{-1} in Fig. 1a and that at 14.2×10^{3} cm^{-1} in Fig. 1b. In addition to this, these spectra resemble strongly those of the anthracene radical anion ($A^{-\cdot}$) and the cation ($A^{+\cdot}$) in the same systems.[1] Therefore the spectra of Figs. 1a and 1b are attributed to the 9-methylanthracene radical anion ($MA^{-\cdot}$) and the cation ($MA^{+\cdot}$), respectively.

9-Bromoanthracene: Figures 1c and 1d show the absorption spectra of the γ-irradiated PVA–BuA and the PVC–BuCl systems of 9-bromoanthracene, respectively. These spectra are similar to those of the 9-bromoanthracene radical anion ($BA^{-\cdot}$) in an organic glass[7]

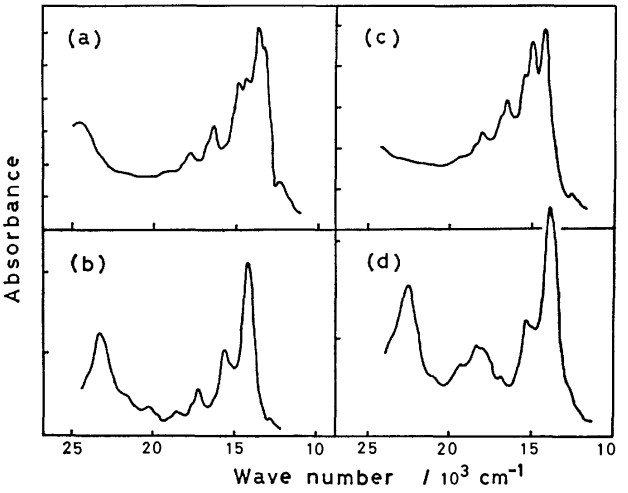

Fig. 1. Absorption spectra of 9-methylanthracene in the γ-irradiated PVA (a) and PVC (b) films, and 9-bromoanthracene in the irradiated PVA (c) and PVC (d) films, respectively.

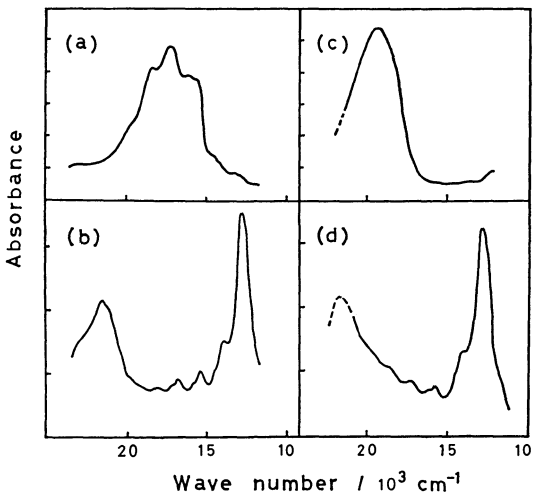

Fig. 2. Absorption spectra of 9-cyanoanthracene in the γ-irradiated PVA (a) and PVC (b) films, and 9-nitroanthracene in the irradiated PVA (c) and PVC (d) films, respectively.

and of the cation ($BA^{+\cdot}$) in a glass of 1:4 butyl chloride–methylcyclohexane.[8] Therefore, the absorption spectra of the PVA–BuA and PVC–BuCl systems are ascribed to $BA^{-\cdot}$ and $BA^{+\cdot}$, respectively.

9-Cyano-, 9-Nitro-, and 9-Aminoanthracene: Figures 2a and 2c show the absorption spectra of 9-cyano- and 9-nitroanthracene in the γ-irradiated PVA–BuA system, respectively. The spectrum of Fig. 2a resembles that of the 9-cyanoanthracene radical anion ($CA^{-\cdot}$) in dimethoxyethane, reported by Panayotov and Tsvetanov,[9] and is attributed to $CA^{-\cdot}$. The spectrum of Fig. 2c is quite different from those of $A^{-\cdot}$, $MA^{-\cdot}$, $BA^{-\cdot}$, and $CA^{-\cdot}$. As is shown in the following section, however, the resolved spectra (Fig. 5) are reasonably explained by the result calculated for the 9-nitroanthracene radical anion ($NA^{-\cdot}$). Therefore this spectrum is attributed to $NA^{-\cdot}$.

Figures 2b, 2d, and 6a show the resultant absorption spectra of 9-cyano-, 9-nitro-, and 9-aminoanthracene in the γ-irradiated PVC–BuCl systems, respectively. The former two spectra are similar to each other and also to those of $A^{+\cdot}$ and $MA^{+\cdot}$. These spectra are explained by MO calculations on the corresponding radical cations and are ascribed to their radical cations, $CA^{+\cdot}$ and $NA^{+\cdot}$. The spectrum of Fig. 6a is different from those of the other 9-substituted anthracene cations. The MO calculation for the 9-aminoanthracene radical cation ($AA^{+\cdot}$), however, explains this spectrum. Hence, this is attributed to $AA^{+\cdot}$.

Resolved Spectra. According to the symmetry of the 9-substituted anthracenes, the $\pi^*\leftarrow\pi$ electronic transition should be polarized parallel to the long or short axis in the molecular plane. By use of the polarized absorption spectra, the absorption spectrum can be resolved into two components (resolved spectra), the transition moments of which are polarized along the long and short axes.

The absorption spectrum of the symmetric and stable molecule in the PVA film can be resolved by the so-called one-parameter method developed by one of us (Y. Tanizaki).[10] This method requires the values of the stretch ratio (Rs) of the film and the dichroic ratio ($Rd:=A_{//}/A_{\perp}$). In our experiment, however, we could not determine the Rs value in the same manner as for the stable molecule because a considerable amount of the solvent, *s*-butylamine or *s*-butyl chloride, is reserved in the film for efficient preparation of the radical ions. Therefore the one-parameter method is not applicable to our case. Instead, the two-parameter method proposed by Margulies and Yogev is applied.[11] This method requires two extreme Rd values of the pure long and short axis polarized transition bands. This may be considered to be a special case of the method given by Thulstrup *et al.*[12]

The resolved spectra, A_l and A_s, are obtained by resolving the absorption spectrum A according to the following equations:

$$A_l = \frac{Rd-Rd^s}{Rd^l-Rd^s}\cdot\frac{Rd^l+2}{Rd+2}\cdot A$$

$$A_s = \frac{Rd^l-Rd}{Rd^l-Rd^s}\cdot\frac{Rd^s+2}{Rd+2}\cdot A,$$

where Rd^l and Rd^s are two extreme Rd values of the pure long and short axis polarized bands, respectively. These equations are equivalent to Eqs. 42 and 43 of Ref. 11.

In the case of the anthracenes discussed here, the long and short axes are respectively the Y and Z axes, and A_l and A_s are written as A_Y and A_Z. In the following discussion the resultant resolved spectra (A_Y and A_Z) are shown without showing the polarized absorption spectra.

As shown in Figs. 1 and 2, the absorption spectra of 9-substituted anthracenes resemble each other, except for $CA^{-\cdot}$, $NA^{-\cdot}$, and $AA^{+\cdot}$. There are characteristic bands in the region $(13—14)\times10^3$ cm^{-1} and $(22—24)\times10^3$ cm^{-1}. Considering the Rd curve behavior and the results of MO calculations, these bands are respectively assigned to Y and Z axis polarized transitions.[1] These absorption bands, however, are overlapped with other weak transition bands and are not considered to be "pure electronic transition bands." In order to calculate the resolved spectra, several sets of parameters (Rd^l and Rd^s) have been chosen by reference to the Rd values of these bands. A similar procedure has been taken for the cases of $CA^{-\cdot}$, $NA^{-\cdot}$ and $AA^{+\cdot}$. For these parameter sets, no marked changes were seen in the characteristics of the resolved spectra. Therefore one of the representative results is presented for each radical ion. These are shown in Figs. 3—6.

Anthracene: Figures 3a and 3b show the resolved spectra of $A^{-\cdot}$ and $A^{+\cdot}$. These are obtained by use of the polarized absorption spectra reported previously (Figs. 3 and 4 in Ref. 1). These resemble each other and are well explained by the calculated results shown at the bottom. For example, the intense A_Y band at 13.7×10^3 cm^{-1} and A_Z band at 24.7×10^3 cm^{-1} of $A^{-\cdot}$ are assigned to $^2B_{1g}\leftarrow{}^2B_{3u}$ and $^2B_{2g}\leftarrow{}^2B_{3u}$ transitions, respectively. The very weak absorption below 13.0×10^3 cm^{-1} is ascribed to the forbidden transition ($^2A_u\leftarrow{}^2B_{3u}$). In addition to these bands, a relatively weak

A_z band is clearly distinguished in the region (15—20) $\times 10^3$ cm^{-1}. This is assigned to the first $^2B_{2g} \leftarrow {}^2B_{3u}$ transition, as has been predicted in the previous paper.[1] Similar assignments are carried out for $A^{+\cdot}$ and these results are summarized in Table 1.

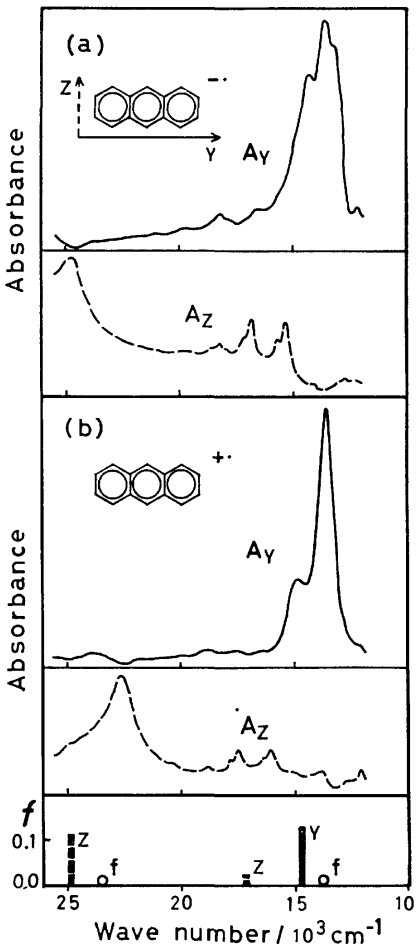

Fig. 3. Resolved spectra of anthracene radical anion (a) and cation (b).
Rd^l and Rd^s values used are 2.85 and 0.89 for (a), and 1.75 and 0.89 for (b), respectively. A_Y and A_Z represent the components polarized parallel to the long and short axes, respectively. Calculated results are shown in the bottom, where f means forbidden transition.

9-Methyl- and 9-Bromoanthracene: Figures 4a and 4b show the resolved spectra of $MA^{-\cdot}$ and $MA^{+\cdot}$. These spectra are very similar to those of $A^{-\cdot}$ and $A^{+\cdot}$. In the A_Z spectrum of $MA^{+\cdot}$, a weak band is found in the region (20—22) $\times 10^3$ cm^{-1} in addition to the characteristic bands. This is related to the second forbidden transition of $A^{+\cdot}$.

Figures 4c and 4d show the resolved spectra of $BA^{-\cdot}$ and $BA^{+\cdot}$. These spectra are also similar to those of $A^{-\cdot}$ and $A^{+\cdot}$, respectively. In A_Z spectrum of $BA^{+\cdot}$, an extra absorption appears in the region (17—21) $\times 10^3$ cm^{-1}. But we are not yet able to assign this band.

9-Cyano- and 9-Nitroanthracene: Figures 5a and 5b show the resolved spectra of $CA^{-\cdot}$ and $CA^{+\cdot}$. The calculated results for these ions are also shown at the bottom. Spectra of $CA^{+\cdot}$ resemble those of $A^{+\cdot}$, while those of $CA^{-\cdot}$ are rather different from those of $A^{-\cdot}$. The latter spectra are explained by the calculated result as follows. The first weak A_Y band below 15 $\times 10^3$ cm^{-1} is assigned to the first Y-polarized transition.

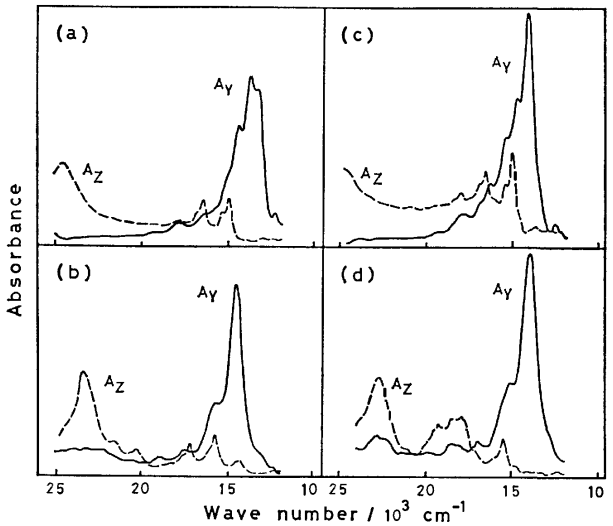

Fig. 4. Resolved spectra of 9-methylanthracene radical anion (a) (Rd^l=1.95, Rd^s=0.95) and cation (b) (1.65, 0.99), and 9-bromoanthracene anion (c) (2.10, 0.98) and cation (d) (1.41, 0.99).

Table 1. Calculated and experimental results for anthracene radical ions[a]

	Transition energy ($\times 10^3$ cm^{-1})			Polarization[b]			Symmetry		Oscillator strength (Calcd)
	Calcd	Obsd		Calcd	Obsd				
		Anion[c]	Cation[d]		Anion	Cation	Anion	Cation	
1	13.7	<13.0	<13.0	f			Au	B_{1g}	0.000

6	26.7			f			A_u	B_{1g}	0.000

a) Calculated result is available for the radical anion and cation. b) Y and Z are molecular long and short axes, respectively; f means that the transition is forbidden. c) In γ-irradiated poly(vinyl alcohol) film. d) In γ-irradiated poly(vinyl chloride) film.

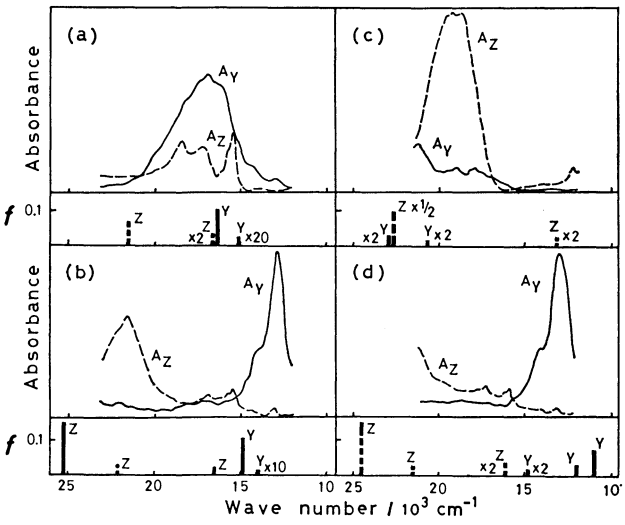

Fig. 5. Resolved spectra of 9-cyanoanthracene radical anion (a) ($Rd^l=1.68$, $Rd^s=0.99$) and cation (b) (1.51, 0.99), and 9-nitroanthracene anion (c) (1.20, 0.88) and cation (d) (1.44, 0.99). Calculated results are shown in the bottom.

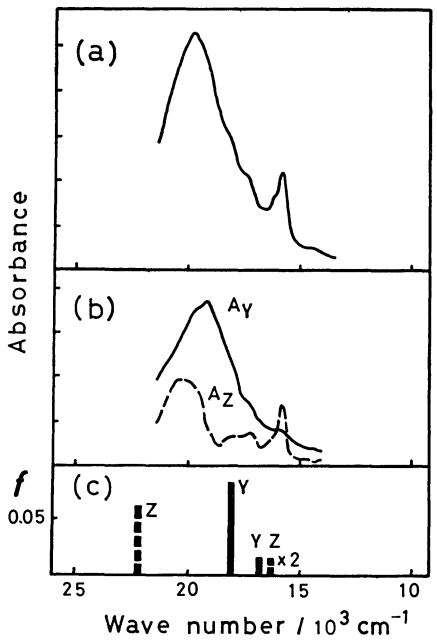

Fig. 6. Absorption spectrum of 9-aminoanthracene in the γ-irradiated PVC film (a) and its resolved spectra (b) ($Rd^l=1.42$, $Rd^s=0.90$).
Calculated results are shown in the bottom.

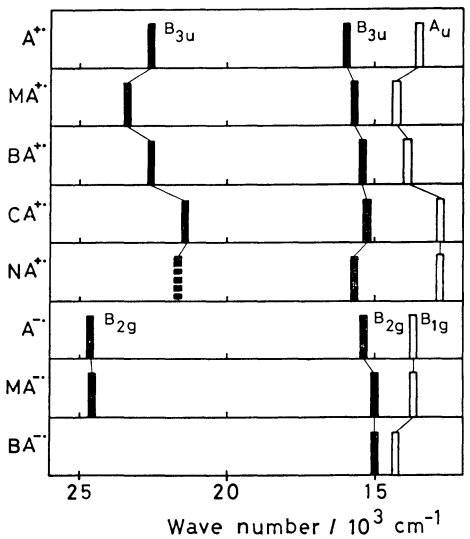

Fig. 7. Correlation diagram of the characteristic absorption bands of 9-substituted anthracenes in the visible region.
Full and open columns represent the short axis- and long axis-polarized transition bands, respectively.

The sharp A_Z peak at 15.5×10^3 cm^{-1} should be assigned to the first Z-polarized transition. The broad intense A_Y band in the region $(15—20)\times10^3$ cm^{-1} is ascribed to the second Y-polarized transition. The A_Z peak at about 18.5×10^3 cm^{-1} is tentatively assigned to the second Z-polarized transition.

Figures 5c and 5d show the resolved spectra of NA$^{-\cdot}$ and NA$^{+\cdot}$. Spectral characteristics of NA$^{+\cdot}$ are similar to those of A$^{+\cdot}$, while those of NA$^{-\cdot}$ are quite different from those of other anions. The NA$^{-\cdot}$ spectra are, however, analyzed based on the result calculated for NA$^{-\cdot}$ as follows. The A_Z band below 15×10^3 cm^{-1} and the intense A_Z band in the region $(17—21)\times10^3$ cm^{-1} are assigned to the first and the second Z-polarized transitions. The A_Y band in the region $(16—20)\times10^3$ cm^{-1} and that above 20×10^3 cm^{-1} are assigned to the first and the second Y-polarized transitions. Thus the spectrum of Fig. 2c is reasonably attributed to NA$^{-\cdot}$.

9-Aminoanthracene: Figure 6b shows the resolved spectra of AA$^{+\cdot}$. These spectra are quite different from those of other cations. These are explained by the calculated result as follows. The A_Y band below 17×10^3 cm^{-1} and the intense A_Y band in the region $(17—21)\times10^3$ cm^{-1} are ascribed to the first and the second Y-polarized transitions. A_Z bands in the region $(15.5—18)\times10^3$ cm^{-1} and at about 20×10^3 cm^{-1} are attributed to the first and the second Z-polarized transitions.

Correlation of Electronic Transition Bands. As is discussed in the section about the resolved spectra, the three characteristic absorption bands of anthracene radical ions are correlated respectively to those of the substituted anthracene ions. This situation is shown in Fig. 7, where full and open columns represent the A_Y and A_Z bands, respectively. Their positions show the absorption maximum or first peak of the bands. The spectra of CA$^{-\cdot}$, NA$^{-\cdot}$, and AA$^{+\cdot}$ have a different appearance than those of other ions. Therefore the electronic transitions of these ions are discussed qualitatively by making reference to SCF MO's of A$^{-\cdot}$ and A$^{+\cdot}$.

SCF MO's related to the visible absorptions of CA$^{-\cdot}$ and NA$^{-\cdot}$ are shown in Fig. 8, and are correlated with those of A$^{-\cdot}$. The correlation of MO's of CA$^{-\cdot}$ (or NA$^{-\cdot}$) with those of A$^{-\cdot}$ is obtained by expanding the wavefunctions of CA$^{-\cdot}$ (or NA$^{-\cdot}$) by those of A$^{-\cdot}$ and substituent group, as follows:

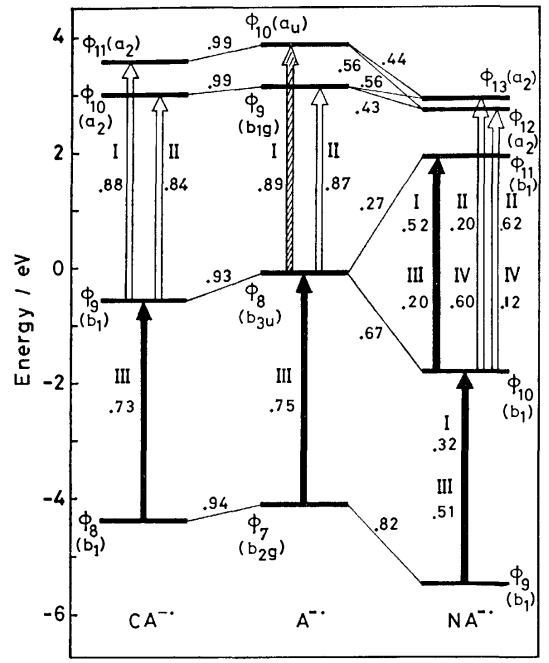

Fig. 8. Correlation diagram of MO's of 9-cyano and 9-nitroanthracene radical anions ($CA^{-\cdot}$ and $NA^{-\cdot}$) with those of anthracene radical anion ($A^{-\cdot}$). The figures along the joining fine lines are contribution weight from the MO's of $A^{-\cdot}$ to those of $CA^{-\cdot}$ and $NA^{-\cdot}$. The figures along the vertical arrows are contribution weight from the configuration to each transition. See text.

$$\phi_1(CA^{-\cdot} \text{ or } NA^{-\cdot}) = \sum_m C_m^1 \phi_m(A^{-\cdot}) + \sum_n C_n^1 \phi_n(CN \text{ or } NO_2).$$

Contribution of ϕ_m ($A^{-\cdot}$) to $\phi_1(CA^{-\cdot}$ or $NA^{-\cdot})$ is given by the square of the coefficient, $(C_m^1)^2$. These values are shown along the correlating lines between MO's.

It is found that ϕ_8, ϕ_9, ϕ_{10}, and ϕ_{11} of $CA^{-\cdot}$ are well correlated to ϕ_7, ϕ_8, ϕ_9, and ϕ_{10} of $A^{-\cdot}$, respectively. The contribution of CN group-MO is less than 7% for these MO's. These MO's are related to the main configurations of the visible transitions of $CA^{-\cdot}$ and $A^{-\cdot}$ as follows:

$$\Psi_I(A^{-\cdot}) = (0.89)^{1/2}\Phi_{8-10} + \cdots \quad (^2A_u \leftarrow {}^2B_{3u})$$
$$\Psi_{II}(A^{-\cdot}) = (0.87)^{1/2}\Phi_{8-9} + \cdots \quad (^2B_{1g} \leftarrow {}^2B_{3u})$$
$$\Psi_{III}(A^{-\cdot}) = (0.75)^{1/2}\Phi_{7-8} + \cdots \quad (^2B_{2g} \leftarrow {}^2B_{3u})$$
$$\Psi_I(CA^{-\cdot}) = (0.88)^{1/2}\Phi_{9-11} + \cdots$$
$$\Psi_{II}(CA^{-\cdot}) = (0.84)^{1/2}\Phi_{9-10} + \cdots$$
$$\Psi_{III}(CA^{-\cdot}) = (0.73)^{1/2}\Phi_{8-9} + \cdots .$$

Contributions of these configurations (squares of the coefficient) are also shown along the vertical transition arrows. Considering these contributions and correlation of MO's, it is understood that the first three transitions of $CA^{-\cdot}$ are well correlated with those of $A^{-\cdot}$. But it should be noticed here that the energy depression of $\phi_8(A^{-\cdot})$ is larger than those of the other MO's($A^{-\cdot}$) on CN group substitution. Therefore the transition energies of I and II transitions increase, while that of III decreases. As a result these transition bands overlap one another

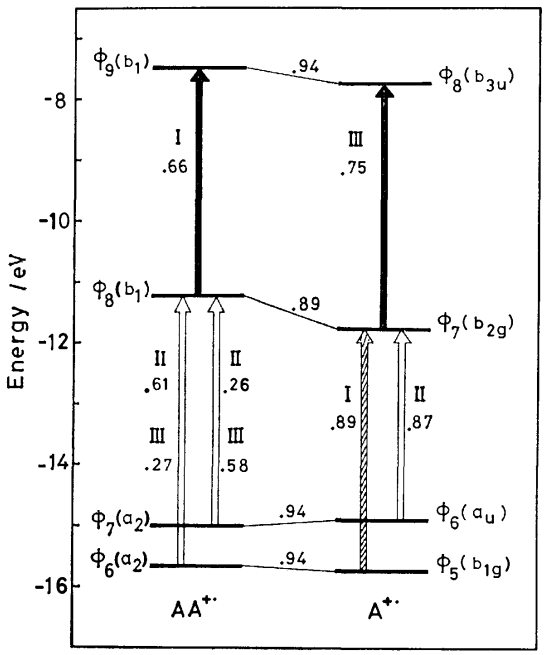

Fig. 9. Correlation diagram of MO's of 9-aminoanthracene ($AA^{+\cdot}$) and anthracene radical cations ($A^{+\cdot}$). See the captions of Fig. 8.

and the appearance of the $CA^{-\cdot}$ spectrum is different from those of other anions.

In the case of $NA^{-\cdot}$, the situation is quite different. The most characteristic point is the great participation of the vacant orbital of NO_2 in the visible transitions. Contributions from NO_2 vacant orbital to $\phi_9(NA^{-\cdot})$ and $\phi_{10}(NA^{-\cdot})$ are 12 and 17%, while that to $\phi_{11}(NA^{-\cdot})$ is 46%. This is caused by a strong coupling of the vacant NO_2 orbital with $\phi_8(A^{-\cdot})$. As a result, transition bands with quite different character appear in the spectrum of $NA^{-\cdot}$. The first four transitions are represented as follows:

$$\Psi_I(NA^{-\cdot}) = (0.52)^{1/2}\Phi_{10-11} + (0.32)^{1/2}\Phi_{9-11} + \cdots$$
$$\Psi_{II}(NA^{-\cdot}) = (0.62)^{1/2}\Phi_{10-12} + (0.20)^{1/2}\Phi_{10-13} + \cdots$$
$$\Psi_{III}(NA^{-\cdot}) = (0.51)^{1/2}\Phi_{9-10} + (0.20)^{1/2}\Phi_{10-11} + \cdots$$
$$\Psi_{IV}(NA^{-\cdot}) = (0.60)^{1/2}\Phi_{10-13} + (0.12)^{1/2}\Phi_{10-12} + \cdots .$$

Therefore I and III transition bands have the character of charge transfer state from anthracene to the nitro group.

The SCF MO diagram of $AA^{+\cdot}$ and $A^{+\cdot}$ is shown in Fig. 9. As in the case of $CA^{-\cdot}$, MO's of $AA^{+\cdot}$ are well correlated with those of $A^{+\cdot}$. Contributions of amino group to MO's of $AA^{+\cdot}$, ϕ_6—ϕ_9, are less than 11%. It should be noticed that the energy increase of $\phi_7(A^{+\cdot})$ is larger than those of other MO's($A^{+\cdot}$). Therefore, to a first approximation, energies of configurations $\Phi_{5-7}(A^{+\cdot})$ and $\Phi_{6-7}(A^{+\cdot})$ increase while that of $\Phi_{7-8}(A^{+\cdot})$ decreases. The MO's shown in Fig. 9 are related to first three transitions of $AA^{+\cdot}$ and $A^{+\cdot}$ as follows:

$$\Psi_I(A^{+\cdot}) = (0.89)^{1/2}\Phi_{5-7} + \cdots \quad (^2B_{1g} \leftarrow {}^2B_{2g})$$
$$\Psi_{II}(A^{+\cdot}) = (0.87)^{1/2}\Phi_{6-7} + \cdots \quad (^2A_u \leftarrow {}^2B_{2g})$$
$$\Psi_{III}(A^{+\cdot}) = (0.75)^{1/2}\Phi_{7-8} + \cdots \quad (^2B_{3u} \leftarrow {}^2B_{2g})$$

$$\Psi_{I}(AA^{+\cdot}) = (0.66)^{1/2}\Phi_{8-9} + \cdots$$

$$\Psi_{II}(AA^{+\cdot}) = (0.61)^{1/2}\Phi_{6-8} - (0.26)^{1/2}\Phi_{7-8} + \cdots$$

$$\Psi_{III}(AA^{+\cdot}) = (0.58)^{1/2}\Phi_{7-8} + (0.27)^{1/2}\Phi_{6-8} + \cdots.$$

Therefore I and II transition bands of $A^{+\cdot}$ shift to blue while III to red on amino group substitution. As a result these transition bands overlap one another. This situation can be understood by the resolved spectra of $AA^{+\cdot}$.

Conclusion

Radical anions and cations of 9-methyl-, 9-bromo-, 9-cyano-, and 9-nitroanthracene have been prepared by γ-irradiation of the PVA–BuA and PVC–BuCl systems of their parent compounds. Cations of 9-aminoanthracene have also been prepared in the PVC–BuCl system. The stretched film technique combined with γ-irradiation has been applied to these radical ions. Resolved spectra have been obtained by analyzing the polarized absorption spectra quantitatively.

(Received April 30, 1982)

Concentration-jump kinetic studies of the aqueous poly(acrylic acid)–copper(II) system reveal the presence of a relaxation phenomenon in the time range of 10^2 ms. Kinetic data under various pH's and compositions, together with the potentiometric results, indicate that this relaxation effect is due to the following complex-formation reaction:

$$CuL_2 + L_2^{2-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Cu(L_2)_2^{2-},$$

where L_2^{2-} is a coordination unit consisting of two adjacent carboxylato side groups on the polymer chain. The specific features of the pH dependence of the τ^{-1} value are discussed in relation to the degree of dissociation of the carboxyl groups. The rate and stability constants of the reaction are determined to be: $k_2 = 5.6 \times 10^3$ M^{-1} s^{-1} (1 M = 1 mol dm^{-3}), $k_{-2} = 0.7$ s^{-1}, and K_2 $(= k_2/k_{-2}) = 7.9 \times 10^3$, at pH 7.0, $I \approx 0$, and 25 °C. The overall complex-formation mechanism, involving the very rapid formation of CuL_2, is discussed.

The metal–polymer complex has been the subject of increasing interest recently[1–3] in the fields of the coordination chemistry, biochemistry, and industrial applications. Although there has been a considerable accumulation of experimental results available about metal–polymer systems, most of them have been limited to the equilibrium properties of the systems (based on the measurements by spectrophotometry, potentiometry, ESR, viscosity, and so on) or their catalytic effects. Only a few kinetic studies[4,5] of metal–polymer interactions have been done up to the present.

In the present work, we studied the kinetics of the poly(acrylic acid)–copper(II) system, since the polymer is one of the simplest polyelectrolytes consisting of a uniform arrangement of carboxyl groups and since the nature of the system has been comparatively well known.[6–11] The stopped-flow experiments on this system revealed the presence of a relaxation effect in the time range of 10^2 ms; this is slower by almost three orders of magnitude than the temperature-jump relaxation phenomenon reported in the same system.[4] The relaxation effect is also unusually slow compared with those for the complex formation of copper(II) with simple ligands.[12] The apparent slowness may reflect the restriction of the movement of the side groups on the polymer as well as electrostatic repulsions between the polymer chains. It is the purpose of this work to elucidate the metal–polymer interactions through the kinetic treatment of the relaxation process. The kinetic information obtained will be helpful in understanding the dynamic behavior of metal–polymer systems.

Experimental

Materials. Poly(sodium acrylate), abbreviated as NaPAA, was synthesized[13] from acrylic acid of a reagent grade (Wako Pure Chem., Ltd.), dialized against deionized-distilled water, lyophilized, and finally vacuum-dried at 60 °C for 12 h. The degree of polymerization was determined to be 1400 from the intrinsic viscosity in 2 M NaOH solution.[14] All the other chemicals were of a reagent grade and were used without further purification.

Sample solutions were prepared from aqueous stock solutions of 0.1 M $CuSO_4$ and 0.1 M NaPAA. Here and hereafter, the concentration of NaPAA (or PAA) will be expressed by the residue mole. The pH of the solutions was controlled with NaOH. No neutral salt was added to the solutions; thus, all the experiments were carried out under an approximately zero ionic strength ($I \approx 0$). Bromophenol Blue, Bromocresol Green, Methyl Red, and Bromocresol Purple were used as colorimetric pH-indicators for the kinetic measurements covering the pH range of 4—7. All the solutions were prepared by using deionized-distilled water.

Equilibrium Measurements. The absorption spectra in the UV range of 190—360 nm were recorded on an Union Giken SM-401 spectrophotometer equipped with a data-processing unit. Quartz cells with a path length of 10 mm were used. The concentration of free copper ions in PAA–copper solutions was potentiometrically determined by using a Hitachi-Horiba M-5 pH-meter equipped with a copper-ion electrode (Model 8006-05T).

Kinetic Measurement. The stopped-flow apparatus was a modification of the Union Giken gas pressure-driven type.[15] It was constructed by assembling a mixing unit (Union Giken UO-001) and an optical detection system. The optical path length of the observation cell, equipped with quartz windows, was 10 mm. The reaction signal (transmittance against the time) was stored in a digital memory and then recorded on an X-Y recorder. The dead time of the apparatus was 1.7 ms at a driving pressure of 5 atm and a mixing volume ratio of 1:1. The flow system was thermostatted at 25.0±0.5 °C.

Results and Discussion

The concentration-jump experiments were carried out by mixing the $CuSO_4$ solution (containing a pH-indicator) and the NaPAA solution. The pH's of both solutions were adjusted to appropriate values to give a definite pH value after mixing. The observed signal curves exhibited a single exponential time-dependence and enabled us to adopt the usual relaxation treatment. All the relaxation times, τ, quoted in this study are the means of several measurements; the maximum errors are about ±15%. A representative relaxation

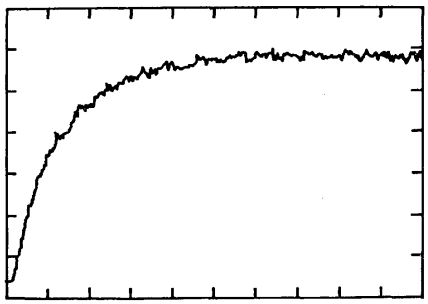

Fig. 1. Relaxation effect in the PAA–copper(II) system; ΣPAA$=1.25\times10^{-3}$ M, ΣCu$=1.25\times10^{-4}$ M, pH 7.0, and $I\approx0$, with 1.0×10^{-5} M Bromocresol Purple as an indicator.
The observation wavelength is 592 nm. The abscissa scale is 200 ms per division, and the vertical scale is in arbitrary unit of absorbance. The relaxation curve corresponds to a decrease in absorbance with time.

effect is shown in Fig. 1. Here, ΣPAA and ΣCu indicate the total concentrations of PAA and copper, respectively. The relaxation curve shows a decrease in the absorbance with the time, indicating a pH decrease due to the deprotonation from carboxyl groups on PAA. The deprotonation can be ascribed to the perturbation of the dissociation equilibrium of the acid groups induced by the complex formation of copper with PAA. Blank experiments of mixing solutions of PAA and an indicator or of diluting a copper-indicator solution with water showed no relaxation effect in the same time range. Therefore, the relaxation phenomenon observed is really to be associated with the PAA–copper interactions.

Additional concentration-jump experiments were carried out without using an indicator. The observation wavelength was 257 nm, at which the PAA–copper(II) system showed an absorption maximum due to complexation, while neither PAA nor copper exhibited any significant absorbance. The relaxation time measured was similar to the τ obtained for the sample with an indicator, but the signal amplitude was much smaller than that in the latter experiment. The relaxation curve showed an increase in the absorbance with the time, indicating the formation of PAA–copper complexes. The above results exhibit that the same phenomenon was observed by the two-type experiments. The presence of another reaction process, which is too fast to be observed by the stopped-flow apparatus, can be conjectured by a comparison of the observed signal amplitude with the total absorption change on mixing the PAA and copper solutions; the faster process contributes most of the absorbance change, while the slower observed process contributes only a small part of it.

Taking into account the results of the earlier equilibrium studies,[6–11] the PAA–copper complexation may proceed *via* the following reaction scheme:

$$\mathrm{Cu} + \mathrm{L_2} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{CuL_2}, \quad (1)$$

$$\mathrm{CuL_2} + \mathrm{L_2} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{Cu(L_2)_2}, \quad (2)$$

where the charges are omitted for the sake of simplicity and where L_2 denotes a coordination unit consisting of two adjacent carboxylato groups on a polymer chain. In the above reaction scheme, Eq. 1 is a very fast complex-formation reaction to which the temperature-jump relaxation effect has been ascribed.[4] Therefore, it may be reasonable to ascribe the rapid absorption change, which occurred within the dead time of the present concentration-jump experiments, to the CuL_2 complex formation through Eq. 1.

The result of the potentiometric measurements showed that almost all copper ions bind to PAA and that no free Cu^{2+} remains in the mixed solutions at the pH values higher than 4.5. Therefore, the observed relaxation effect is very likely attributable to the interactions involving uncomplexed carboxylato groups on PAA and copper ions already bound to the polymer sites, *i.e.*, Eq. 2. This assignment was supported by the pH dependence of the reciprocal relaxation time, τ^{-1}, for the solutions of 2.5×10^{-3} M ΣPAA and 2.5×10^{-4} M ΣCu (after mixing). Figure 2 shows the experimental results. In the low pH-region, the τ^{-1} increases with an increase in the pH. With a further increase in pH, the value of τ^{-1} attains its maximum at pH 5.3 and then finally decreases. If we ascribe the observed relaxation effect to Eq. 2, we can easily explain the above features of the pH dependence of τ^{-1}. When the pH increases, the deprotonation of the carboxyl group, HL, on PAA increases the concentration of the uncomplexed carboxylato group, L, resulting in an increase in the L_2 concentration. This effect causes an increase in the τ^{-1} in the lower pH-region. With a further increase in pH, the electrostatic repulsion caused by the high population of the uncomplexed carboxylato groups on PAA prevents the approach of the second coordination unit to form the $Cu(L_2)_2$ complex. This effect explains the decrease in

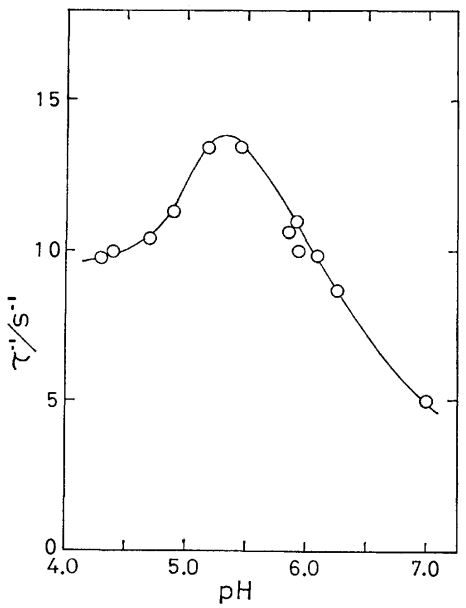

Fig. 2. The pH dependence of the relaxation time for the PAA–copper(II) system; ΣPAA$=2.50\times10^{-3}$ M and ΣCu$=2.50\times10^{-4}$ M, at 25 °C and $I\approx0$.

a) Solutions contain 1.0×10^{-5} M Bromocresol Purple as an indicator.

τ^{-1} observed in the higher pH-region.

Since the kinetic behavior of PAA varies so much with the pH, as has been described above, the kinetic experiments should be carried out at a constant pH for a quantitative analysis to be made. Thus, the concentration-jump experiments were carried out at pH 7.0 by varying the concentrations of both ΣPAA and ΣCu. The values of τ^{-1} thus obtained are listed in Table 1. The experimental data in Table 1 exhibit the following kinetic features: i) when the concentrations of the polymer (ΣPAA) and copper(II) (ΣCu) simultaneously increase under a constant mixing ratio R ($=\Sigma$PAA/ΣCu), the τ^{-1} value increases; ii) the value of τ^{-1} increases with an increase in the polymer concentration at a constant copper(II) concentration, and iii) it decreases with an increase in the copper(II) concentration at a constant polymer concentration.

Below, we will perform a relaxation analysis of the kinetic data in Table 1. From Eq. 2, the rate equation is given by;

$$d[Cu(L_2)_2]/dt = k_2[CuL_2][L_2] - k_{-2}[Cu(L_2)_2], \quad (3)$$

where the square brackets denote the molar concentrations. By assuming that the carboxyl group, HL, the uncomplexed carboxylato group, L, and the coordinated ligand-unit are randomly distributed over a polymer chain, the concentration of the uncoordinated ligand-unit, L_2, may be expressed in terms of the concentration [L] multiplied by the probability for one definite L to find another L at its adjacent position on the polymer:[16]

$$[L_2] = \frac{[L]^2}{[L]+[HL]+[CuL_2]+2[Cu(L_2)_2]}. \quad (4)$$

The protolytic reactions of acid groups on PAA and of the pH-indicator reach equilibrium much faster than the metal-complex reactions, and they can be assumed to be in equilibrium at all times of the relaxation process. Thus, we may use the equilibrium relations:

$$K_a = ([H][L]/[HL])z^{n-1}, \quad (5)$$

$$K_{In} = [H][In]/[HIn], \quad (6)$$

where In denotes the anionic form of the indicator; K_a and K_{In} are the dissociation constant of HL and that of the indicator, respectively. The quantity z in Eq. 5 is the ratio of the populations of charged to uncharged groups on the polymer.[7] Taking into account the metal complexation, it is given by:

$$z = \{[L]+2[Cu(L_2)_2]\}/\{[HL]+2[CuL_2]+2[Cu(L_2)_2]\}. \quad (7)$$

For the relaxation treatment of Eq. 2, the coupling effect of Eq. 1 can be ruled out, since the potentiometric results indicate that the concentration of the free copper(II) ion is negligibly small in the final equilibrium solutions. Thus, we have the conservation relations:

$$\Sigma Cu = [CuL_2] + [Cu(L_2)_2], \quad (8)$$

$$\Sigma PAA = [L] + [HL] + 2[CuL_2] + 4[Cu(L_2)_2]. \quad (9)$$

By expanding Eq. 3 in the vicinity of the equilibrium concentrations and by using Eqs. 4—9 together with the electroneutrality condition, the relaxation time is found to be:

$$1/\tau = k_2 B,$$

$$B = [CuL_2]\left(\frac{[L_2]}{[L]}\right)\left(\frac{4}{1+\alpha} - \frac{[L_2]}{[L]}\right) + [L_2] + \frac{1}{K_2}, \quad (10)$$

where K_2 ($=k_2/k_{-2}$) is the equilibrium constant of Eq. 2 and where:

$$\alpha = \frac{[H]}{\gamma[L]+K_a z^{1-n}+(n-1)(1+z)\beta},$$

$$\beta = \frac{[H][L]}{[L]+2[Cu(L_2)_2]}, \quad (11)$$

$$\gamma = \frac{K_{In}+[H]}{K_{In}+[H]+[In]}.$$

The quantity α expresses the contributions from the rapid protolytic reactions to the relaxation time. However, under the present experimental conditions, the values of α were less than 3×10^{-3}, too small to be significant in Eq. 1.

The experimental data in Table 1 were fitted to Eq. 10 by optimizing the adjustable parameters, K_2 and k_2, so as to minimize the root-mean-square percentage deviation between the calculated and observed values of τ^{-1}. The calculations were carried out using an iterative computer routine. As is shown in Fig. 3, the calculated τ^{-1} values agree fairly well with the experimental values (the r.m.s. % deviation=9.5). The K_2, k_2, and k_{-2} values thus determined are shown in Table 2, together with the equilibrium parameters used.

In relation to the $Cu(L_2)_2$ formation through Eq. 2, the following two possibilities may be considered.[10,11] One is the $Cu(L_2)_2$ complex formation *via* the intra-polymer reaction; the reacting CuL_2 and L_2 units lie on the same polymer chain, and the complex formation proceeds by means of the bending of the polymer chain. The other is the inter-polymer complex formation; the reacting CuL_2 and L_2 units lie on different polymer chains, and the reaction occurs by the approach of the two polymer chains. In the present kinetic treatment, we assumed, as a first approximation, the random distribution of the reacting units (*i.e.*, CuL_2 and L_2) in solution; thus, we could not discriminate the contributions from the two types of com-

plex formation. For a detailed treatment of the reaction mechanism, we need knowledge of the local distribution of the polymer sites in solution. Therefore, we must be satisfied at present with the determination of the overall rate constants, as given in Table 2.

The rate constant of the $Cu(L_2)_2$ formation (k_2 in Table 2) is by three to four orders of magnitude smaller than the formation-rate constant of CuL_2,[4] *i.e.*, $k_1=(0.93-1.7)\times10^8\ M^{-1}\ s^{-1}$, and also than those of the copper(II) complexes of simple ligands.[12] The unusually small value of k_2 may reflect the electrostatic repulsion between the negatively charged polymer chains, which prohibits the approach of the reacting units in either intra- or the inter-polymer complex formation. Here, it may be worthwhile to consider the reactivity of the polymer from another point of view. According to the Eigen mechanism,[12] the rate constant of the metal-complex formation is described in terms of the association constant, K_o, of the ion-pair formation and the first-order rate constant, k_o, of the water release from the inner-coordination sphere of the metal. Thus, by applying this idea to the present case, we obtain: $k_2=K_ok_o$. An oxygen-17 NMR study of the hexaaquacopper(II) ion[18] gave the rate constant of water exchange as: $k_o=2\times10^8\ s^{-1}$ (at 25 °C). A comparison of this value with that of k_2 obtained in this study gives an estimate for K_o of the extremely small value of 10^{-5}. This result also supports the strong hindrance of the approach of the reaction partners of CuL_2 and L_2.

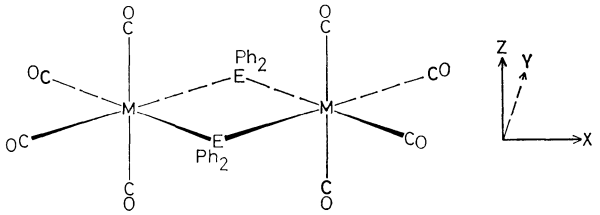
(Received May 12, 1982)

The anion radical of $V_2(CO)_8(\mu\text{-}PPh_2)_2$ and the cation radical of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2$ are generated by chemical reduction of the vanadium complex with $LiBHEt_3$ or potassium naphthalenide and by radiochemical oxidation of the manganese complex in frozen Freon mixture, respectively. Their anisotropic ESR spectra show that the V_2P_2 and the Mn_2As_2 rhomboids are planar. Their g and hyperfine splitting tensors are analyzed on the basis of a qualitative molecular orbital scheme for metal-metal bonds developed from a hypothesis that metal-ligand interactions are larger than metal-metal interactions. The odd electron orbital of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ is assigned to the metal-metal π^* MO and the odd electron density on the vanadium d AO is estimated as 0.21. The odd electron of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ is concluded to be accomodated in the metal-metal σ^* MO and odd electron densities on manganese and arsenic atoms are evaluated as $\rho(\text{Mn d})=0.25$ and $\rho(\text{As p})=0.08$ or 0.16, respectively. Order of magnitude estimates of orbital energy differences between metal-metal MO's are obtained from analyses of g tensors as $\varepsilon(\pi^*)-\varepsilon(\sigma)\simeq 0.4$ and $\varepsilon(\pi^*)-\varepsilon(\delta)\simeq 0.9$ eV for the anionic divanadium complex and $\varepsilon(\sigma^*)-\varepsilon(\delta^*)\simeq 1.1$ and $\varepsilon(\sigma^*)-\varepsilon(\pi)\simeq 1.4$ eV for the cationic dimanganese complex.

There has been considerable recent interest in electronic structures of complexes of $M_2(CO)_8(\mu\text{-}PR_2)_2$ with D_{2h} geometries where M is vanadium, chromium or manganese. Metal-metal bond lengths are shown by Vahrenkamp[1] to be consistent with formal bond orders of 2, 1 and 0 deduced from the 18 electron rule for the vanadium, the chromium and the manganese complexes, respectively. Molecular orbital (MO) calculations by Teo, *et al.*[2] and Shaik, *et al.*[3] gave $\pi^2\delta^2\sigma^2\delta^{*2}$ double bond, $\pi^2\delta^2\delta^{*2}\sigma^2\pi^{*2}$ single bond and $\pi^2\delta^2\delta^{*2}\pi^{*2}\sigma^2\sigma^{*2}$ no bond configurations for metal-metal bonds of the vanadium, the chromium and the manganese complexes, respectively.



A preliminary ESR study of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ has been reported from this laboratory,[4] and its odd electron orbital has been assigned to the b_{3u} MO with a metal-metal σ^* character and consisting mainly of the Mn $d_{x^2-y^2}$ and As p_x atomic orbitals (AO), with which calculated MO schemes[2,3] are consistent. We have been trying to extend the study to ion radicals of bioctahedral molybdenum, which is located in the same column as chromium in the periodic table, and vanadium complexes. Meanwhile, Madach and Vahrenkamp[5] reported that $V_2(CO)_8(\mu\text{-}PMe_2)_2$ can be reduced chemically into a stable anion radical and that its solution ESR spectrum shows hyperfine splittings due to pairs of vanadium and phosphorus nuclei. The extended Huckel MO calculation[3] predicted that its odd electron will occupy the metal-metal π^* MO, into which the phosphorus valence shell AO's are symmetry-forbidden to mix. The phosphorus splitting in the solution ESR spectrum was thus mentioned as somewhat confusing.[5] Since metal d AO's play dominant roles in the formation of metal-metal bond rather than metal s AO's, anisotropic spectra are more informative for the study of electronic structure of the anion radical. We report here a study of anisotropic ESR spectra of frozen solutions of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ and $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ in order to obtain quantitative informations about their electronic structures.

Results

$V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$. When a dilute benzene solution of $V_2(CO)_8(\mu\text{-}PPh_2)_2$ is mixed with an equimolar amount of potassium naphthalenide at room temperature, a paramagnetic vanadium complex is formed immediately after the mixing. The solution exhibits an isotropic ESR spectrum split into a 15-fold multiplet of 23.4×10^{-4} cm^{-1} due to a pair of equivalent vanadium nuclei (99.8% natural abundance, $I=7/2$) split further into triplets of 6.0×10^{-4} cm^{-1} due to a pair of equivalent phosphorus nuclei (100%, $I=1/2$) at $g=2.019$. The spectrum is quite similar to that of $V_2(CO)_8(\mu\text{-}PMe_2)_2^{-\cdot}$[5] and is attributed to $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$.

The same anion radical is formed gradually in 0.5—1 h when the parent complex is reacted in benzene with 2—3 equivalents of $LiBHEt_3$. This slow formation of the anion radical suggests that this radical may be generated by electron transfer from an intermediate(s) formed in a foregoing step(s) rather than by direct electron transfer from the hydroborate to the parent neutral complex. The anisotropic spectra of the anion radical in benzene solutions frozen at 77 K are obtained at X-, K-, and Q-bands (Fig. 1). These anisotropic spectra fit a rhombic spin Hamiltonian in which two vanadium nuclei are magnetically equivalent and three principal directions of the g tensor and those of the vanadium hyperfine splitting tensor are parallel to each other. This spin Hamiltonian shows that the V_2P_2 rhomboid of the anion radical is planar corresponding to a D_{2h} geometry of the anion radical, otherwise even the two vanadium nuclei can not be magnetically equivalent in the anisotropic spectra.[6] The principal values of the g tensor are:

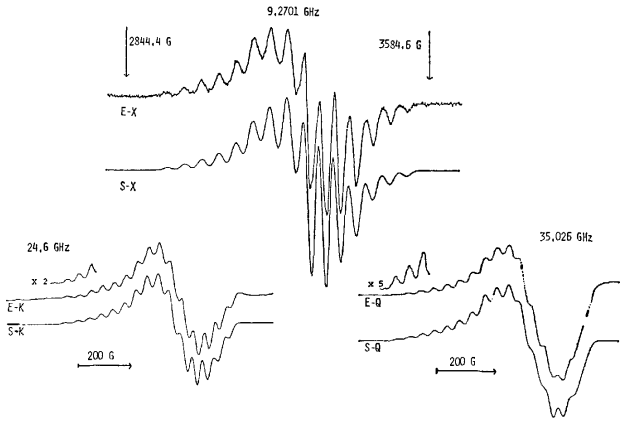


Fig. 1. Experimental (E-) and simulated (S-) ESR spectra of frozen benzene solutions of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ observed at X- (X), K- (K), and Q-bands (Q) at 77 K.

$$g_{\alpha\alpha} = 2.001,$$
$$g_{\beta\beta} = 2.018,$$
$$g_{\gamma\gamma} = 2.038,$$

and those for the vanadium splitting tensor are:

$$|A_{\alpha\alpha}(V)|/hc = |A_{\beta\beta}(V)|/hc = (15\pm2)\times10^{-4}\ cm^{-1},$$
$$|A_{\gamma\gamma}(V)|/hc = 39.2\times10^{-4}\ cm^{-1},$$

where α, β, and γ designate the rectangular axes for the spin Hamiltonian. It should be pointed out that the vanadium splitting tensor is axially symmetric. Hyperfine splittings due to the phosphorus nuclei are unfortunately hidden behind the line width in the anisotropic spectra.

$Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$. The analysis of the ESR spectra of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ has been reported in the preliminary report.[4] The principal values of the g tensor are:

$$g_{\alpha\alpha} = 2.031,$$
$$g_{\beta\beta} = 2.025,$$
$$g_{\gamma\gamma} = 2.001,$$

and those for the manganese and arsenic hyperfine splitting tensors are:

$$|A_{\alpha\alpha}(Mn)|/hc = |A_{\beta\beta}(Mn)|/hc \leqq 3\times10^{-4}\ cm^{-1},$$
$$|A_{\gamma\gamma}(Mn)|/hc = 43.0\times10^{-4}\ cm^{-1},$$
$$|A_{\alpha\alpha}(As)|/hc = 14.4\times10^{-4}\ cm^{-1},$$
$$|A_{\beta\beta}(As)|/hc = 41.5\times10^{-4}\ cm^{-1},$$
$$|A_{\gamma\gamma}(As)|/hc = 39.9\times10^{-4}\ cm^{-1}.[4]$$

Discussion

Qualitative Molecular Orbital Scheme for Metal-Metal Bond. The results of molecular orbital calculations of $M_2(CO)_8(\mu\text{-}PH_2)_2$[2,3] can be reproduced qualitatively from a hypothesis that metal-ligand interactions are larger than metal-metal interactions (Fig. 2). Larger interactions are considered first and weaker ones are taken into account thereafter. The present qualitative molecular orbital scheme starts from an electronic structure for a mononuclear fragment with a pseudoctahedral geometry, then two mononuclear

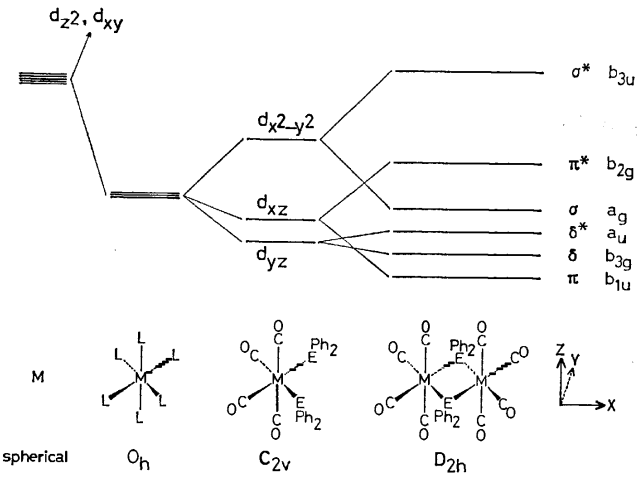

Fig. 2. Construction of qualitative metal-metal MO's for $M_2(CO)_8(\mu\text{-}EPh_2)_2$.
The σ^* MO is the odd electron orbital of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ with eleven d electrons. The π^* MO is the odd electron orbital of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ which has nine d electrons. Relative orbital energy levels of δ^* and π MO's for the divanadium anion and those between σ and δ MO's for the dimanganese cation do not have much significances.

fragments are combined together through weak metal-metal interactions into the bioctahedral complex, $M_2(CO)_8(\mu\text{-}ER_2)_2$.

When the mononuclear fragment is octahedral (O_h), the e_g d orbitals (d_{z^2} and d_{xy}) are located above the t_{2g} d orbitals ($d_{x^2-y^2}$, d_{xz}, and d_{yz}) in the energy diagram. When the symmetry of the fragment is lowered to the pseudoctahedral one (C_{2v}), the degeneracy of the t_{2g} orbitals is broken and the orbital energy sequence is expected to be $d_{x^2-y^2} > d_{xz} > d_{yz}$. The orbital energy of the d_{yz} is the lowest because this orbital interacts with vacant π^* MO's of three carbonyl ligands and its interaction with lone pair orbitals of the ligands is symmetry-forbidden. The $d_{x^2-y^2}$ orbital has the highest energy, since this orbital interacts with π^* MO's of only two carbonyls and with lone pair orbitals of six ligands whereas the d_{xz} orbital interacts with vacant π^* MO's of three carbonyls and lone pair orbitals of the two axial carbonyls.

When a pair of pseudoctahedral fragments are joined together to from a bioctahedral (D_{2h}) dimetallic complex, bonding and antibonding pairs of MO's with metal-metal σ, π, and δ symmetries are formed from the t_{2g} d orbitals through relatively weak metal-metal interactions. Among these six MO's, the σ^* MO has been calculated to have the highest orbital energy, and the π^* MO has the second highest energy.[2,3] The energies of the metal-metal MO's derived from the e_g d orbitals (d_{xy} and d_{z^2}) are far higher than those of the metal-metal MO's arising from the t_{2g} d orbitals ($d_{x^2-y^2}$, d_{xz}, and d_{yz}). This is because of the aforementioned hypothesis.

In $V_2(CO)_8(\mu\text{-}PR_2)_2$, eight "d electrons" from a pair of V(I) ions occupy the lowest four metal-metal MO's giving a double bond configuration of $\pi^2\delta^2\delta^{*2}\sigma^2$. Upon one electron reduction of this complex, the odd

electron enters into the metal-metal π^* MO. The formal metal-metal bond order of the resulted anion radical is 1.5. In $Mn_2(CO)_8(\mu\text{-}AsR_2)_2$, twelve "d electrons" from a pair of Mn(I) ions occupy the six metal-metal MO's derived from the t_{2g} d orbitals, resulting in an electronic configuration of $\pi^2\delta^2\delta^{*2}\sigma^2\pi^{*2}\sigma^{*2}$ with a formal metal-metal bond order of zero. Upon one electron oxidation of this dimanganese complex, the odd electron remains in the σ^* MO. The formal metal-metal bond order of the resulted cation is 0.5.

The purposes of the present study are (i) examination of the validity of the present qualitative MO scheme in interpretations of ESR spectra, (ii) experimental estimation of the weight of d AO's in metal-metal MO's, and (iii) experimental estimation of differences between energies of metal-metal MO's.

Symmetry of Odd Electron Orbital of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$. A shift of a principal value of a g tensor, g_{xx} for example, from the free electron value of $g_e=2.0023$ has the following form:[7]

$$\Delta g_{xx} \equiv g_{xx} - g_e = 2\sum_n^{*p} \langle\psi_p|\sum_k \zeta_k l_{kx}|\psi_n\rangle \times \langle\psi_n|\sum_k l_{kx}|\psi_p\rangle/(\varepsilon_p-\varepsilon_n), \quad (1)$$

where ψ and ε are the MO and its orbital energy with the subscripts of p and n standing for the odd electron orbital and for the other MO's, respectively, l_{kx} is the x component of the orbital angular momentum of an electron on the k-th atom, and ζ_k is its one-electron spin-orbit coupling constant. The y or z principal value can be expressed by changing x in this equation into y or z.

The large anisotropy in the vanadium hyperfine splitting tensor indicates that odd electron densities on vanadium 3d AO's are large. Orbital energy differences between the odd electron orbital and MO's with dominant metal characters, which appear as the denominator in Eq. 1, are smaller than those for ligand MO's in the present MO scheme. Thus the sign of the g shift in Eq. 1 can be predicted by taking only l-s couplings in vanadium atoms into account, although the l-s coupling constant for 3d AO's of V(I) (136 cm^{-1})[8] is not distinguishably large in comparison with those for phosphorus 3p (231 cm^{-1}),[9] oxygen 2p (152 cm^{-1})[9] and carbon 2p (28 cm^{-1})[9] AO's.[10] In this approximation, all the numerators in Eq. 1 are zero or positive and signs of g shifts can be correlated directly with those of denominators in Eq. 1. A vacant ψ_n induces a negative g shift and a doubly occupied ψ_n results in a positive g shift as long as the ψ_n and the odd electron orbital share a non-zero matric element of l-s couplings in the metals.

In the present qualitative MO scheme, the odd electron of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ is accomodated in the π^* (b_{2g}, d_{xz}*) MO. The unique axis of the axially symmetric vanadium splitting tensor should be the molecular y axis. Table 1 summerizes the shifts of the principal values of the g tensor from g_e predicted by Eq. 1 and the qualitative MO scheme in Fig. 2. For example, the shift of g_{yy} from g_e, Δg_{yy}, arises from the doubly occupied σ (a_g, $d_{x^2-y^2}$) MO and an unoccupied a_g MO consisting mainly of d_{z^2} AO's. Since

Table 1. g Shift of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ with electronic configuration of $(\pi b_{1u})^2(\delta b_{3g})^2$-$(\delta^* a_u)^2(\sigma a_g)^2(\pi^* b_{2g})^1$ based on Eq. 1

$\Delta g_{\alpha\alpha}$	l_α[a]	ψ_n[b]	Occptn. of ψ_n	Sign of $\Delta g_{\alpha\alpha}$
Δg_{xx}	$l_x(b_{3g})$	b_{1g}, d_{xy}	unocc.	+
Δg_{yy}	$l_y(b_{2g})$	a_g, $d_{x^2-y^2}$, σ / a_g, d_{z^2}	unocc. / occ.	+
Δg_{zz}	$l_z(b_{1g})$	b_{3g}, d_{yz}, δ	occ.	+

a) Component of l and its symmetry in D_{2h}. b) MO's which share non-zero matrix elements of l_α with the odd electron orbital, $\psi_p=\pi^*$. The notation of [b_{3g}, d_{yz}, δ], for exsample, indicates that ψ_n is the b_{3g} MO constructed from V d_{yz} AO's and that ψ_n is the metal-metal δ MO.

metal-metal electronic interactions are assumed to be smaller than metal-ligand interactions, the σ MO contribution is expected to dominate and a positive value of Δg_{yy} is expected.

These theoretical expectations deduced from the qualitative MO scheme in Fig. 2 are consistent with the experimental results under the assignment of the spin Hamiltonian axes of α, β, and γ to the molecular axes of x, z, and y, respectively.

Odd Electron Distribution in $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$. The odd electron density on the vanadium d_{xz} AO, $\rho(V\,xz)$, can be correlated with the vanadium hyperfine splitting tensor with corrections for second order effects of unquenched orbital angular momenta of electrons as follows:[11,12]

$$\left.\begin{aligned} A_{xx}(V) &= a(V) - B(V\,xz)\rho(V\,xz) \\ &\quad - (7/4)B(V\,xz)\Delta g_{xx} \\ &\quad - (3/8)B(V\,xz)(\Delta g_{yy}-\Delta g_{zz}) \\ A_{yy}(V) &= a(V) + 2B(V\,xz)\rho(V\,xz) \\ &\quad - (7/4)B(V\,xz)\Delta g_{yy} \\ &\quad - (3/8)B(V\,xz)(\Delta g_{xx}+\Delta g_{zz}) \\ A_{zz}(V) &= a(V) - B(V\,xz)\rho(V\,xz) \\ &\quad - (7/4)B(V\,xz)\Delta g_{zz} \\ &\quad + (3/8)B(V\,xz)(\Delta g_{xx}+\Delta g_{yy}) \end{aligned}\right\} \quad (2)$$

$$a(V) = Q_V(V)\rho(V\,s) + Q_I(V)\rho(V\,xz), \quad (3)$$

where $2B(V\,xz)$ is the parallel splitting constant of a vanadium nucleus with a unit odd electron density on its d_{xz} AO and $a(V)$ is the vanadium Fermi contact term arising from the odd electron density on the vanadium 4s AO, $\rho(V\,s)$, and from the spin polarization of the inner shell s electrons which is proportional to $\rho(V\,xz)$. The coefficient, $Q_V(V)$ or $Q_I(V)$, is the Fermi contact term of a vanadium nucleus with a unit odd electron density on its 4s AO or on its 3d AO. The valence orbital parameters of $Q_V(V)$ and $2B(V\,xz)$ have been evaluated as 1390×10^{-4} and -83.4×10^{-4} cm^{-1}, respectively.[13] The inner shell parameter, $Q_I(V)$, can be estimated as $-(100\pm20)\times10^{-4}$ cm^{-1} from theoretical and experimental studies on ESR of mononuclear vanadium complexes.[14]

The isotropic vanadium splitting of 23.4×10^{-4} cm^{-1}, observed in the solution ESR spectrum, indicates that all the signs of the principal values of the vanadium

splitting tensor are identical. Since the odd electron in the metal-metal π^* MO is symmetry-forbidden to delocalize onto vanadium 4s AO's, the Fermi contact term of the vanadium nuclei, $a(V)$, arises only from the inner shell spin polarization and should be negative due to the negative value of $Q_I(V)$. These analyses result in the assignment of negative signs to all the principal values of the vanadium splitting tensor. By using Eq. 2, the Fermi contact term and the odd electron density on the vanadium d_{xz} AO are estimated as $a(V)/hc=-24.3\times10^{-4}$ cm^{-1} and $\rho(V\ xz)=0.21$ respectively. Since $\rho(V\ s)=0$, Eq. 3 and the estimate of $\rho(V\ xz)=0.21$ give $a(V)/hc=(-16.8--25.2)\times10^{-4}$ cm^{-1}, which is consistent with the above estimation of $a(V)/hc=-24.3\times10^{-4}$ cm^{-1} deduced from the analysis with Eq. 2. Present analyses are self-consistent. The relatively small odd electron density on the vanadium $3d_{xz}$ AO implies a rather extensive π back donation from metals to carbonyl π^* MO's and/or mixing of vanadium $4p_z$ AO's into the metal-metal π^* MO. Since vanadium 4p AO's are rather diffuse, the odd electron densities on these AO's do not give much influences on g and hyperfine splitting tensors.

Orbital Energy Differences. Since the odd electron orbital is the metal-metal π^* MO and the odd electron density on the vanadium d_{xz} AO is 0.21, this orbital can be expressed as follows:

$$\pi^* = \sqrt{0.21}d_{xz}(V_1) + \sqrt{0.21}d_{xz}(V_2) + \cdots, \quad (4)$$

where the subscripts for V are numberings for the vanadium atoms. By assuming that the other MO's with dominant metal characters are localized on the metals and taking l-s couplings only in the metals into account, Eq. 1 correlates experimental g shifts with orbital energy differences as following:

$$\Delta g_{\beta\beta} = \Delta g_{zz} = 2\langle\pi^*|\zeta(l_{1z}+l_{2z})|\delta\rangle\langle\delta|l_{1z}+l_{2z}|\pi^*\rangle / [\varepsilon(\pi^*)-\varepsilon(\delta)] \quad (5)$$

$$\Delta g_{\gamma\gamma} = \Delta g_{yy} = 2\langle\pi^*|\zeta(l_{1y}+l_{2y})|\sigma\rangle\langle\sigma|l_{1y}+l_{2y}|\pi^*\rangle / [\varepsilon(\pi^*)-\varepsilon(\sigma)], \quad (6)$$

where ζ is the l-s coupling constant of d AO's of V(I) (136 cm^{-1})[8] and l_{1z} is the z component of the orbital angular momentum around the vanadium atom 1 and so on. We have neglected the contribution to Δg_{yy} from the unoccupied a_g MO consisting of vanadium d_{z^2} AO's in Eq. 6 (*vide supra*). Analyses of the g shifts with Eqs. 5 and 6 give estimates of orbital energy differences as $\varepsilon(\pi^*)-\varepsilon(\delta)\simeq0.9$ and $\varepsilon(\pi^*)-\varepsilon(\sigma)\simeq0.4$ eV. Because of approximations adopted here, these differences should be regarded as estimates of order of magnitudes. These values are in fair agreement with values of $\varepsilon(\pi^*)-\varepsilon(\delta)\simeq0.5$ and $\varepsilon(\pi^*)-\varepsilon(\sigma)\simeq0.6$ eV obtained by an extended Huckel calculation of $V_2(CO)_8(\mu\text{-}PH_2)_2$.[15]

$Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$. Analyses of ESR parameters of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ have led to conclusions that the odd electron occupies the metal-metal σ^* MO and that its densities on the 4s and $3d_{x^2-y^2}$ AO's of the manganese atoms and the arsenic $4p_x$ AO's are $\rho(Mn\ s)=0.004$, $\rho(Mn\ x^2-y^2)=0.25$ and $\rho(As\ x)=0.08$ or 0.16, respectively.[4] The ambiguity in the estimate of $\rho(As\ x)$ is due to the uncertainty of the signs of the experimental principal values of the arsenic splitting tensor.

Orbital energy differences can be estimated from g shifts by using the following equations:

$$\Delta g_{xx} = 2\langle\sigma^*|\zeta(l_{1x}+l_{2x})|\delta^*\rangle\langle\delta^*|l_{1x}+l_{2x}|\sigma^*\rangle / [\varepsilon(\sigma^*)-\varepsilon(\delta^*)] \quad (7)$$

$$\Delta g_{yy} = 2\langle\sigma^*|\zeta(l_{1y}+l_{2y})|\pi\rangle\langle\pi|l_{1y}+l_{2y}|\sigma^*\rangle / [\varepsilon(\sigma^*)-\varepsilon(\pi)], \quad (8)$$

where ζ is the l-s coupling constant of Mn(I) 3d AO's (254 cm^{-1})[8] and the other notations have similar significances as in Eqs. 5 and 6. The experimental g shifts of $\Delta g_{xx}=0.029$ and $\Delta g_{yy}=0.023$ lead to order of magnitude estimates of the orbital energy differences of $\varepsilon(\sigma^*)-\varepsilon(\delta^*)\simeq1.1$ and $\varepsilon(\sigma^*)-\varepsilon(\pi)\simeq1.4$ eV. These estimates are comparable with energy differences of $\varepsilon(\sigma^*)-\varepsilon(\delta^*)\simeq1.2$ and $\varepsilon(\sigma^*)-\varepsilon(\pi)\simeq1.3$ eV calculated for $Mn_2(CO)_8(\mu\text{-}PH_2)_2^{+\cdot}$ with the nonparameterized MO method by Teo and his coworkers.[2]

Concluding Remarks. Magnitudes of negative shifts of Δg_{zz} of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ (−0.001) and of Δg_{xx} of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ (−0.001) are far smaller than shifts of the other principal values of g tensors of both radicals. These results indicate that the energy separation between e_g and t_{2g} d orbitals in the mononuclear fragment is far larger than those among the six metal-metal MO's derived from t_{2g} d orbitals upon the formation of the dinuclear complex.

The analyses of the hyperfine splitting tensors of arsenic and manganese nuclei of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ have indicated that the metal-metal σ^* MO consists of 50% of the manganese $d_{x^2-y^2}$ components and 16 or 32% of arsenic p_x components. The proposal that the Mn $d_{x^2-y^2}$ orbital in the C_{2v} mononuclear fragment has the highest orbital energy among the t_{2g} d orbitals is based on this relatively large mixing between the arsenide lone pair orbitals and the manganese $d_{x^2-y^2}$ orbitals. The weight of the vanadium d_{xz} AO's in the metal-metal π^* MO of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ is 42% which is not very large. Since vanadium is electropositive and the carbonyl ligand is a good π accepter, most of the remaining part of the π^* MO would be carbonyl π^* MO's.

Finally, we discuss on the isotropic splitting by phosphorus nuclei resolved in the solution ESR spectrum of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$. The odd electron in the metal-metal π^* MO is symmetry forbidden to delocalize onto the valence shell AO'S of the phosphorus atoms. The odd electron density on the vanadium d_{xz} AO's would induce spin polarization of electrons in σ bonds between the vanadium and phosphorus atoms, which should result in negative spin densities on the phosphorus 3s AO's. The observed isotropic phosphorus splitting constant of 6.0×10^{-4} cm^{-1} corresponds to the phosphorus 3s spin density of (−)0.0014. This spin density is not an unacceptable value as induced by spin polarization. This explanation predicts that the sign of the isotropic splitting constant of the phosphorus nucleus should be negative.

Experimental

$V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$. $V_2(CO)_8(\mu\text{-}PPh_2)_2$[16] (1 mg, 2 μmol) was dissolved in dry benzene (0.8 ml) in a quartz

ESR sample tube under argon. When a tetrahydrofuran solution of potassium naphthalenide (0.05 mol dm^{-3}, 50 μl, 2.5 μmol) was added to this solution, a strong ESR signal of $V_2(CO)_8(\mu\text{-}PPh_2)_2^{-\cdot}$ appeared immediately and lasted for days at room temperature. When a tetrahydrofuran solution of $LiBHEt_3$ (Aldrich Super-Hydride, 1 mol dm^{-3}, 5 μl, 5 μmol) was added to the benzene solution of the neutral divanadium complex, an ESR signal of the divanadium anion radical grew slowly in 0.5—1 h.

$Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$. $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2$[17] (*ca.* 0.4 mg) was dissolved in Freon mixture ($CFCl_3$: CF_2Br-CF_2Br=1:1 volume ratio)[18] (0.7 ml) under vacuum and irradiated with 2 Mrad of ^{60}Co γ-rays at 77 K. ESR spectra of $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ were measured at low microwave powers (0.1—0.5 mW) after appropriate annealings of irradiated samples. A competitive positive hole capture between $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2$ and isoquinoline was performed by γ-irradiations of Freon mixture solutions (0.7 ml) containing $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2$ (0.05 mg, 0.06 μmol) and isoquinoline (7 μl, 0.05 μmol or 70 μl, 0.5 μmol). The irradiated sample containing the smaller amount of isoquinoline gave a superimposed ESR spectrum of signals due to $Mn_2(CO)_8(\mu\text{-}AsPh_2)_2^{+\cdot}$ and the isoquinoline cation radical,[19] and the other sample gave signals arising only from the isoquinoline cation radical.

ESR Measurements. The spectrometer and monitoring of microwave frequencies and field sweeps for measurements of X-band ESR spectra have been mentioned earlier.[11] K- and Q-band spectra were obtained on JEOL PE-2K and PE-3Q spectrometers, respectively. Q-band microwave frequencies were measured with a Shimada Rika 2A550 resonant cavity wavemeter. The K-band microwave frequency appearing in Fig. 1 is a nominal one. Field sweeps in K- and Q-band spectra were calibrated with hydrogen atom signals in irradiated samples (g=2.0022, a_H/hc=471.7×10^{-4} cm^{-1}) after higher order corrections for the hyperfine interaction.

Simulations. ESR spectra were simulated on a FACOM M200 computer with a FORTRAN program prepared according to a second order perturbation solution[20] for a rhombic spin Hamiltonian.

We thank Mr. M. Kohno (JEOL) for his measurements of Q-band ESR spectra, and Professor N. Hirota and Dr. H. Ohya-Nishiguchi (Kyoto University) for giving us a chance to use a Q-band ESR spectrometer. Samples were exposed to γ-rays at the Research Laboratory of Radioisotopes of Kyoto University. Spectrum simulations were performed on a FACOM M200 computer at the Data Processing Center of Kyoto University.

Multiphoton Ionization Spectrum of *p*-Terphenyl in a Supersonic Free Jet

Jun-ichi MURAKAMI,† Katsuhiko OKUYAMA, and Mitsuo ITO*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received May 24, 1982)

The one-photon absorption spectrum of *p*-terphenyl vapor was observed in a supersonic free jet by using multiphoton ionization spectroscopy. In the spectrum were observed the progressions of the in-phase and out-of-phase torsional vibrations of the benzene rings. It was concluded that *p*-terphenyl has a planar structure in the first excited singlet state, whereas it is twisted in the ground state.

It has long been predicted that there exist low-lying hidden electronic excited states in polyphenyls[1,2] and their identifications have been of continuing interest for the spectroscopists. However, the electronic absorption spectra of polyphenyls in vapor are completely diffuse at room temperature due to excitation of low-frequency vibrations, which prevents conclusive assignment of the excited states. It was recently demonstrated for biphenyl, however, that the diffuseness can be removed in a supersonic free jet.[3] In the jet spectrum the well-resolved vibrational structure was observed and its analysis led us definite assignment of the S_1 and S_2 states and revealed the planar structure in the excited states. The success for biphenyl seems to promise that the systematic study of the electronic spectra of polyphenyls is possible by using a supersonic free jet. In this paper we report the one-photon electronic absorption spectrum of *p*-terphenyl in a supersonic free jet. In the case of *p*-terphenyl, the molecule has two torsional vibrations of the in-phase and the out-of-phase mode and the conjugation between the benzene rings is expected to be stronger than in biphenyl. It seems interesting to study how these effects are reflected in the electronic spectrum.

Experimental

The spectrum was observed by multiphoton ionization spectroscopy. Because of the high sensitivity, this method is quite suitable for observing the spectrum of a molecule with very low vapor pressure such as *p*-terphenyl. The ionization potential of *p*-terphenyl is 7.8 eV and the lowest excited state lies at about 4 eV. Hence in the excitation with the second harmonic of the visible dye laser ($\approx$300 nm), one can obtain the one-photon resonant two-photon ionization spectrum of the molecule. *p*-Terphenyl vapor obtained by heating the sample at 400 K was seeded in 3 atm He gas and the mixed gas was expanded from a pulsed nozzle (400 μm diameter) which is synchronized with a N_2 laser pumped scanning dye laser (Rhodamine B). The experimental setup is the same as reported in our previous works.[4,5] *p*-Terphenyl was zone-refined and was free from impurities, which was confirmed by their layer chromatography and gas chromatography with several developing solvents.

Results and Discussion

In Fig. 1 is shown a part of the observed one-photon resonant two-photon ionization spectrum of *p*-terphenyl in a supersonic free jet. The frequencies of the observed bands and their assignments are listed in Table 1. As is seen from the figure and table, the simple vibrational structure appears in the cold spectrum in contrast to the broad spectrum at room temperature. The observed spectrum consists of the two progressions A and B (see Fig. 1) and their combinations (see Table 1). Since both A and B progressions start from the same band at 32460 cm^{-1} and no prominent vibrational structure was observed to the red of the band, we assign it to be the 0-0 band of the first singlet excited state (S_1).

The frequency intervals of the A and B progressions are 62 and 89 cm^{-1}, respectively, and the spacings are almost constant for the two progressions (see Table 1). In the case of biphenyl,[3] the observed low-frequency vibration ($\approx$60 cm^{-1}) was assigned to the torsional mode of the benzene rings from the isotopic

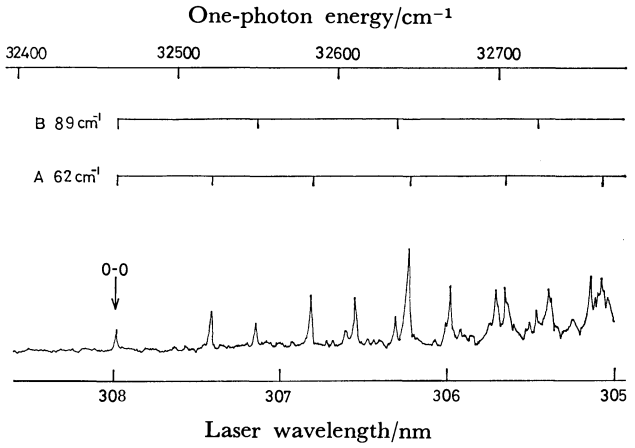

Fig. 1. The one-photon resonant two-photon ionization spectrum of *p*-terphenyl in a supersonic free jet.

ratio of the vibrational frequency. The low-frequency vibrations of *p*-terphenyl are also considered to be the torsional ones. In the case of *p*-terphenyl, however, there exist two torsional vibrations of the in-phase and the out-of-phase mode. Hence it seems quite reasonable to assign 62 and 89 cm^{-1} of the A and B progressions to the in-phase and out-of-phase torsional vibrations. In order to establish the assignment, the **GF** matrix calculation was made with the simplified force field of $V=(1/2)K\{(\Delta\tau_1)^2+(\Delta\tau_2)^2\}+K_{12}(\Delta\tau_1)(\Delta\tau_2)$, where $\Delta\tau$ is internal coordinate of the torsion of the interphenyl bond. It was found that a reasonable set of the force constants is obtained only when 62 and 89 cm^{-1} are assigned to the out-of-phase and in-phase modes, respectively. The force constants obtained are $K=1.7\times10^{-12}$ dyn cm/rad† and $K_{12}=-0.3\times10^{-12}$ dyn cm/rad. It is interesting to note that the value of K is ≈1.4 times larger than the corresponding force constant of biphenyl ($K=1.2\times10^{-12}$ dyn cm/rad). This is consistent with the expectation that conjugation between the benzene rings is stronger in *p*-terphenyl than in biphenyl.

Another interesting information obtained from the observed spectrum is the molecular geometry of *p*-terphenyl in the S_1 state. The harmonic torsional progressions of A and B suggest that *p*-terphenyl has a planar or a perpendicular form in the S_1 state. The fact that the S_1 state of *p*-terphenyl (33000 cm^{-1}) lies much lower in energy than that of biphenyl[4] implies the more extensive conjugation between the benzene rings in the former molecule than in the latter. The biphenyl molecule in the S_1 state has the planar structure owing to the predominance of the conjugation over the repulsion between the ortho-hydrogens.[4] We therefore can conclude that *p*-terphenyl also has a planar structure in the S_1 state.

Although the geometry of *p*-terphenyl vapor in the electronic ground state is not known yet, the molecule is considered to have a twisted structure as in the solution.[6] The twisted structure of the S_0 state is also consistent with the observed progression of torsional vibrations in the S_0-S_1 absorption spectrum, since the final state S_1 is planar as discussed above. The facts that only several members of the torsional progression were observed and that the 0-0 band appeared strongly are in contrast with the case of biphenyl where the torsional progressions with more than 20 quanta were observed and the 0-0 band was too weak to be observed. This strongly indicates from the Franck-Condon principle that although both biphenyl and *p*-terphenyl in vapor have a planar structure in the excited states, the dihedral angle of the latter is smaller than that of the former ($\approx42°$) in the ground states. The smaller dihedral angle for *p*-terphenyl is consistent with the result that in solution the angle is 10° compared with 20° in biphenyl.[6]

The authors wish to thank Prof. N. Mikami for his valuable discussions.

(Received December 17, 1981)

The crystal structure of the title compound, $C_{38}H_{18}$, has been determined by X-ray analysis. The space group is Pa, with unit cell dimensions $a=31.276(4)$, $b=3.7818(4)$, $c=21.663(3)$ Å, $\beta=124.22(1)°$ and $Z=4$. The structure was solved by the direct method and refined by full-matrix least-squares methods to an R value of 0.073 for 2619 reflections. Two crystallographically independent molecules are largely distorted from a planar structure due to the repulsions between the crowded hydrogen atoms, with different conformations to each other. The molecules are stacked face-to-face by van der Waals forces to form column structures along the b axis.

On treating naphthanthrone(6*H*-benzo[*cd*]pyren-6-one, hereafter abbreviated as NT) with copper powder, three condensed polycyclic aromatic hydrocarbons, diphenanthro[5,4,3-*abcd*:5′,4′,3′-*jklm*]perylene(DPP) (**1**), anthra[2,1,9,8-*ijklm*]benzo[*uv*]naphto[*defg*]pentaphene (**2**), and anthra[2,1,9,8-*hijkl*]benzo[*de*]naphtho[2,1,8,7-*stuv*]pentaphene (**3**) have been obtained.[1] All of these

1

3

have eleven benzene rings. These hydrocarbons are stereochemically interesting, because they exhibit great steric hindrance between hydrogen atoms attached to carbon atoms indicated by asterisks, which is usually known as 1···7 interaction. They are also very important in the field of organic semiconductors due to their high photoconductivity.[2] However, the deficiency of information on their structures does not permit a detailed explanation of physical properties. The X-ray analysis was undertaken in order to elucidate the structure of anthra[2,1,9,8-*hijkl*]benzo[*de*]-naphtho[2,1,8,7-*stuv*]pentaphene (**3**) and to compare its conformation with those of the related molecules.

Experimental

The compound was prepared by the method described in the previous paper,[1] and purified by recrystallization from chlorobenzene, chromatography on activated alumina, and sublimation in vacuum. The crystal used for X-ray work was grown from an *o*-dichlorobenzene solution. Preliminary unit cell dimensions and space group ($P2_1/a$) were obtained from oscillation and Weissenberg photographs. However, a careful reexamination of the Weissenberg photographs of b and c axes exposed for a long time (about 200 h) revealed that the 030 reflection had weak but significant intensity. Therefore, the true space group should be Pa. The unit cell dimensions were refined by the least-squares method on the basis of 2θ values measured on a Rigaku automated four-circle diffractometer (16 reflections, $2\theta \leqq 25°$). The crystal data are listed in Table 1. Intensity data up to $2\theta \leqq 125°$ were collected on the diffractometer with Ni-filtered Cu $K\alpha$ radiation ($\lambda=1.5418$ Å). An $\omega/2\theta$ scan technique was employed with a scan rate of 4° min^{-1} in 2θ. Three standard reflections were monitored after every 50 measurements; the net counts of these reflections did not change significantly over the period of data collection. A total of 2619 independent reflections, ($|F_o| \geqq 3\sigma(|F_o|)$), was used for the structure determination. Corrections for Lorentz and polarization factors were made, but not for absorption.

Structure Determination

The first trial structure was obtained by the MULTAN 78 program,[3] on the assumption of the space group $P2_1/a$. As the ten peaks occupying the centers of the benzene rings on the E-maps could be interpreted not to be false but true ones, we assumed that the crystal was disordered and molecules took alternative positions randomly. Refinement by the least-squares methods reduced the R value to 0.23. But further refinement was impossible on this model.

A new model with space group Pa was constructed from the old model with $P2_1/a$ by removing the crystallographic center of symmetry. The refinement was carried out by the block-diagonal least-squares method. After the R value converged to 0.133, the full-matrix least-squares program SHELX 76[4] was applied, where some rigid groups and bond lengths were under constraint. When the R value deduced to 0.102, the usual refinement without constraint were carried out by the block-diagonal least-squares method. The final R was 0.073 for 2619 observed reflections. No peaks higher than 0.4 eÅ^{-3} was found on the final difference map. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5] The final atomic parameters and their estimated standard deviations are listed in Table 2. served and calculated structure factors, parameters of hydrogen atoms and thermal parameters for non-hydrogen atoms are kept in the office of the chemical society of Japan (Document No. 8250). The computation was done on the M-180 computer at Tokyo Institute of Technology and on the M-200H computer at the Computer Center of the University of Tokyo.

Results

Figure 1 illustrates the crystal structure viewed along the b axis. There exist two crystallographically independent molecules, A and B, in an asymmetric unit. Figure 2 shows the perspective drawing of the A molecule. A similar figure has been obtained for the B molecule. Molecules are largely distorted from a planar structure due to the repulsions between crowded hydrogen atoms. The numbering scheme is indicated in Fig. 3, together with the average values of the two corresponding bond lengths in the A and B molecules. Individual bond lengths and angles for each molecule are listed in Tables 3 and 4, respectively. The average C–C length of 1.413(10) Å is similar to 1.41(1) Å in NT,[6] 1.407(6) Å in 7*H*-benzo[*hi*]chrysen-7-one,[7] and 1.409(9) Å in tetrabenzo[*a,cd,j,lm*]perylene (TBP).[8] Although the values of the bond lengths and angles are not so reliable due to the pseudo symmetry described above, a similar distortion of the NT moiety is observed; the bond lengths of C(20)–C(21), C(36)–C(37), and C(11)–C(12) increases in that order (1.37→1.42→1.48 Å). They correspond to the sequences observed in TBP (1.348→1.418→1.474 Å) and DPP (1.37→1.43→1.49 Å).[9]

Although the C–C–C bond angles range from 115°

to 129°, the three bonds around each carbon atom are nearly coplanar. The large difference in the bond angle C(10)-C(11)-C(12), 128.7° in A and 120.9° in B, will be discussed in the next section.

The molecules are stacked face-to-face by van der Waals forces to make column structures along the b axis. Figure 4 shows the overlapping mode of the A molecules; the situation for the B molecule is close to this. A list of the equations of several planes and their dihedral angles is deposited in the office of the Chemical Society of Japan. The deviations of the atoms from the mean plane of the whole molecule range from 0.92 to −0.60 Å. The interplanar spacings are 3.67 Å in A and 3.66 Å in B, which are

The e.s.d.'s range from 0.6 to 0.8°.

comparable to 3.84 Å in DPP.[9]

The molecules can also be regarded as two nearly planar NT skeletons connected by the central benzene ring. The deviations from the mean planes of the NT skeletons a, b are shown in Fig. 5. In both molecules, the planarity of (a) is better than that of (b). This brings about a wider interplanar spacing between (b)'s than that between (a)'s. Their values are 3.48 and 3.57 Å in A and 3.46 and 3.57 Å in B for (a) and (b) stackings, respectively. Each pair of NT skeletons in the A and B molecules makes an angle of 22.3° and an angle of 23.0°, respectively. The mean plane of the central benzene ring makes an angle of 5.7° with (a) and of 17.0° with (b) in A. The corresponding ones are 9.2° and 14.3° in B. Both central benzene rings take conformations of twisted

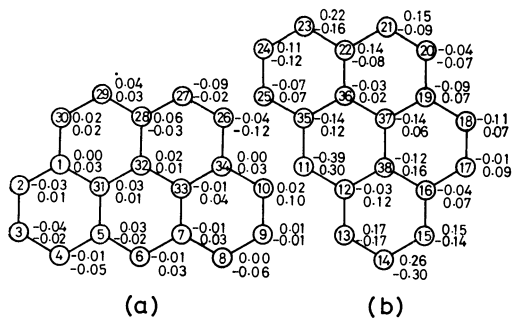

Fig. 5. Distances (l/Å) of atoms from the mean planes of (a) and (b) skeletons; upper and lower values of each pair refer to those in the A and B molecules, respectively.

boat form.

Discussion

The present study has established the structure of 3 and a large distortion from a planar structure occuring from the 1···7 interaction. Relief of such repulsion can be achieved by two modes of distortion as shown in Fig. 6; one is the enlargement of the C(3)–C(4)–C(5) angle, an angle-expansion mode, and the other is the twisting of the two C–C bonds opposite to each other, a twist mode. We define the values α and β to estimate the degree of the distortion as shown in Fig. 6. They are closely related to each other to avoid the 1···7 repulsion; β decreases with the increase of $(\alpha-120°)$.

In the present molecules, α and β of A are 128.7° and 30.1°, wheareas those of B are 120.9° and 37.6°, respectively. These values are significantly different for the two molecules. The repulsion has been relieved to equal extent, since the distance of C(9)···C(13) is 2.94 Å in A and 2.96 Å in B.

Four related molecules have been reported, as shown in Fig. 7, where the asterisks indicate the 1···7 interaction. The values of α and β, and the non-bonded distances between 2 and 6 carbon atoms are listed in Table 5. The four molecules are divided into two classes; an approximate two-fold axis exists perpendicular to the molecular plane in (1)—(3), whereas it lies in the molecular plane in (4). In each molecule of the former class, the two 1···7 repulsions may prevent the enlargement of α from 120° and should bring about the twisting mode. For the molecule of the latter class, on the other hand, only a repulsion may allow the angle-expansion mode to be taken.

Considering the values of α and β, the A and B molecules in the present crystal belong to the former and latter classes, respectively. The molecule has only a 1···7 repulsion between H(C9) and H(C13), but it has a fairly strong 1···6 repulsion between H(C24) and H(C27) opposite to the 1···7 repulsion. The distances between H(C24) and H(C27) are nearly the same as those of H(C9)···H(C13) for both molecules; 1.87(9) and 1.91(9) Å for A and 2.01(9) and 2.00(9) Å for B.†† The present molecule may be described as an intermediate between the two classes. Consequently, both modes of distortion characteristic of the two classes can occur and the two molecular conformations will probably be observed in solution.

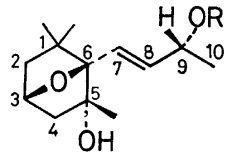
(Received January 11, 1982)

The relative configuration of natural 3,6-epoxy-5-hydroxy-5,6-dihydro-β-ionol, $C_{13}H_{22}O_3$, a principal tobacco constituent, has been established by an X-ray crystal structure analysis of its *p*-nitrobenzoate, $C_{20}H_{25}NO_6$, as (±)-(1*R*,2*R*,5*S*)-2,5-epoxy-2-[(1*E*,3*S*)-3-hydroxy-1-butenyl]-1,3,3-trimethyl-1-cyclohexanol. The derivative crystallizes in space group $P\bar{1}$ with $a=11.618(1)$, $b=12.373(2)$, $c=7.934(1)$ Å, $\alpha=108.43(1)$, $\beta=108.89(1)$, $\gamma=95.95(1)°$ and $Z=2$. The crystal structure was solved by the direct phasing method and refined by the block-diagonal least-squares method to the final *R* index of 0.073 for 2550 reflections. The hydrogen bondings linking the two molecules placed in pairs around a crystallographic center of symmetry are disordered over two sites in the crystal.

A novel flavor substance, (−)-3,6-epoxy-5-hydroxy-5,6-dihydro-β-ionol (**1**), was initially found in the volatile fraction of air-cured Japanese Suifu tobacco.[1] Enzell *et al.* also isolated the compound **1** from sun-cured Greek tobacco and established the relative configurations at C-3, C-5, and C-6, but the configuration at the remaining asymmetric center, C-9, remained unsettled.[2] In order to establish this relative configuration at C-9, the crystalline *p*-nitrobenzoate derivative **2** was synthesized and subjected to a single crystal X-ray diffraction analysis. A brief account on this work has appeared previously.[3]



1 R=H

2 R=*p*-Nitrobenzoyl

Experimental

The title compound was crystallized from a hexane solution as colorless plates elongated along the b direction. A well-shaped crystal of dimensions $0.05\times0.3\times0.2$ mm³ was mounted with the b axis coincident with the goniometer ϕ axis and used for the X-ray measurements. Preliminary unit cell dimensions and space group information were obtained from oscillation and Weissenberg photographs. Accurate cell dimensions were obtained by a least-squares fit of the 2θ values of 25 reflections measured on a Rigaku automated four-circle diffractometer. Intensity data were also collected on this instrument using graphite-monochromated Cu $K\alpha$ radiation and 2θ-ω scanning mode at a rate of $10°(\omega)$/min with a scan range of $(0.8+0.142\tan\theta)°(\omega)$. As a check on the crystal and electronic stability, three representative reflections were measured after every 50 measurements. The intensities of these standards decreased gradually during the data collection. A total of 2550 unique reflection intensities were collected up to $2\theta=120°$ with the criterion $F\geqq3\sigma(F)$; these were corrected for crystal deterioration and for Lorentz and polarization effects, but not for absorption.

Crystal Data. $C_{20}H_{25}NO_6$, M.W.=375.41, triclinic, space group $P\bar{1}$, $a=11.618(1)$, $b=12.373(2)$, $c=7.934(1)$ Å, $\alpha=108.43(1)$, $\beta=108.89(1)$, $\gamma=95.95(1)°$, $V=996.51$ Å³, $D_m=1.24$, and $D_x=1.252$ Mg m^{-3} for $Z=2$, μ(Cu $K\alpha$)=7.76 cm^{-1}.

Structure Determination and Refinement

The structure was solved by the multiple-solution tangent formula program MULTAN 78.[4] The phase set with the highest combined figure of merit gave a reasonable structure containing all the atoms except one. Successive Fourier and difference Fourier maps revealed all the remaining atoms including hydrogen atoms. The parameters were refined by the block-diagonal least-squares program HBLS V.[5] The final refinement in which anisotropic temperature factors were assumed for the non-hydrogen atoms and isotropic ones for the hydrogen atoms gave $R=0.073$ for 2550 reflections. In the refinement the function minimized was $\Sigma\omega(|F_o|-|F_c|)^2$ with $\omega=(\sigma^2(F_o)+a|F_o|+b|F_o|^2)^{-1}$ where $\sigma(F_o)$ is the standard deviation based on counting statistics. The final values of *a* and *b* were −0.1262 and 0.0029 respectively. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[6] Final positional and thermal parameters of the atoms are listed in Tables 1 and 2.[7]

Discussion

A stereodrawing of the molecule is shown in Fig. 1. Figure 2 shows the atomic labelling and the bond lengths and angles for non-hydrogen atoms. Bond lengths and angles involving hydrogen atoms are shown in Table 3. The conformations around the C(6)–C(1) and C(6)–C(5) bonds are shown in Fig. 3 as the Newmann projections. Further details of the molecular geometry are given in Table 4. The estimated standard deviations of the bond lengths for non-hydrogen atoms are 0.006—0.009 Å, while those of the bond angles are 0.4—0.6°.

Since the atoms C(3) and C(6) are bridged by an epoxyl O(1) atom, the cyclohexane ring adopts a boat conformation. The epoxyl bridge plane C(3)–O(1)–C(6) bisects the cyclohexane ring at the dihedral angles of 124.8° and 118.2° to the C(6)–C(1)–C(2)–C(3) plane and C(3)–C(4)–C(5)–C(6) planes respectively. The O(2)H and C(12)H_3 groups are axially attached to the cyclohexane ring; this severe 1,3-

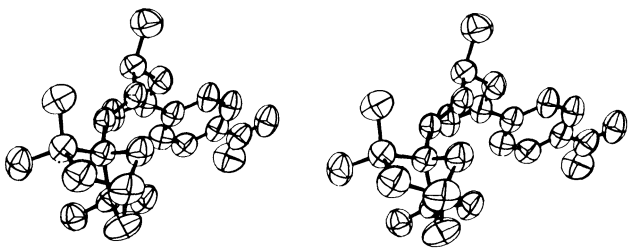

Fig. 1. A stereodrawing of the molecule viewed along the b axis.
The thermal ellipsoids correspond to 50% probability.

diaxial interaction results in an enlargement of the C(6)-C(5)-O(2), C(1)-C(6)-C(5), and C(6)-C(1)-C(12) bond angles (114.5, 114.4, and 116.8° respectively). In the side chain, the atoms C(6), C(7), C(8), and C(9) make a plane, the C(8) and O(1) atoms being synperiplanar about the C(6)-C(7) bond, while the atoms C(10) and O(3) deviate significantly from this plane onto the opposite sides; the torsion angles C(7)-C(8)-C(9)-C(10) and C(7)-C(8)-C(9)-O(3) are 132.9° and −110.0° respectively. The mean C–C length of 1.549 Å in the cyclohexane ring agrees well with the expected value and the three methyl carbons also have a reasonable mean bond length of 1.543 Å. The epoxyl O(1)-C(3) and O(1)-C(6)

a) X, Y, and Z are coordinates expressed by the following equation

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \begin{pmatrix} a & b\cos\gamma & c\cos\beta \\ 0 & b\sin\gamma & -c\cos\alpha^{*}\sin\beta \\ 0 & 0 & c\sin\alpha^{*}\sin\beta \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}.$$

b) Atoms not included in the calculation of the plane.

distances (1.463 Å and 1.435 Å) and C(3)-O(1)-C(6) angle (96.3°) compare well with the values 1.443 Å, 1.452 Å and 96.2° for a toxisterol epoxide[8)] and the values 1.448 Å, 1.459 Å and 97.0° for triterpenoid baccharis oxide.[9)] The C(7)-C(8) double bond length of 1.326 Å and the two neighboring C(sp^2)-C(sp^3) bond lengths of 1.480 Å and 1.481 Å are also reasonable. All bond lengths and angles in the *p*-nitrobenzoate moiety are normal.

The molecular arrangement of the crystal is shown in Fig. 4. The molecules are placed in pairs around a center of symmetry, connected by two kinds of hydrogen bonds. As shown in Fig. 5, the final difference Fourier synthesis phased by all the atoms except H(O2) atom gave two peaks (H1(O2) and H2(O2)) at the positions expected for the H(O2) atom. From the facts that the electron density map shows heights of 0.4 and 0.3 e/Å^3 at the H1(O2) and H2(O2) peaks respectively and that the both O(2)-H1(O2) and O(2)-H2(O2) directions are favorable for hydrogen-bond formation, it was concluded that the two kinds of hydrogen bond exist at random; *i.e.*, when the O(2)H hydroxyl group donates its proton to the O(2)′ atom of the molecule connected by the crystallographic center of symmetry at (1/2, 1/2, 1/2), the hydrogen bond O(2)′-H2(O2)′···O(4) is formed, while when the O(2)H group donates its proton to the O(4)′ atom, the O(2)′-H1(O2)′···O(2) hydrogen bond is formed. As a result of the random distribution of these hydrogen bonds, the crystal is kept centrosym-

The Complex Formation of Poly(*N*-vinylpyrrolidone) with Manganese Dodecyl Sulfate in Water Studied by ESR

Masayuki AIZAWA,* Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 4, 1982)

ESR measurements of Mn^{2+} ions in aqueous manganese dodecyl sulfate ($Mn(DS)_2$) solutions with or without 0.05% poly(*N*-vinylpyrrolidone)(PVP) were carried out at 30 °C. The dependences of linewidths and of absorption intensities on the $Mn(DS)_2$ concentration in ($Mn(DS)_2$+0.05% PVP) solutions changed abruptly at a concentration where a PVP–$Mn(DS)_2$ complex begins to form. The same dependence in $Mn(DS)_2$ solutions was found around the CMC of $Mn(DS)_2$ in water. From the quantitative analysis of the data obtained, it was concluded that the $Mn(DS)_2$ molecules in the complex form a nearly micelle-like aggregate, and that most of Mn^{2+} ions bound onto the micelle-like aggregate or the $Mn(DS)_2$ micelle exist in the Stern layer. In addition, the PVP concentration dependence of the similar quantities in ($Mn(DS)_2$+PVP) solutions with a constant $Mn(DS)_2$ concentration suggested that the polymer–surfactant complex changes its structure at higher PVP concentrations.

In the past three decades, many investigators have been engaged in the study of the interaction between nonionic polymers and surfactants in water.[1] By applying various types of measurements (viscosity,[2–5] surface tension,[4,6,7] solubilization,[5–8] electric conductivity,[3–5] ionic activity,[5,9] *etc.*[10,11]) details of the interaction and its mechanism have become increasingly clear. One of the important observations reported so far is that a type of complex formation occurs between some polymers and surfactants; this was first suggested by the fact that the viscosity curve of some polymer solutions with surfactants resembles that of polyelectrolyte solutions.[12]

Since the complex can solubilize hydrophobic compounds,[1,8] its structure was presumed to have a hydrophobic region. The most acceptable structural model at present[1,7,9,10] has surfactants bound onto a polymer to form a micelle-like structure. The full description of the structure, however, has not yet been achieved completely. Several problems remain to be solved: the number of surfactant ions in one micelle-like aggregate;[10] the degree of dissociation of the counterions from the complex;[5] the binding mode of the polymer to the surfactants which constitute the micelle-like aggregate.[11]

Recently, magnetic resonance methods have been widely applied to study micellar solutions.[23] For example, the binding manner of ions to a micellar surface has been studied by the ESR measurement of manganese(II) ions (Mn^{2+} ions) introduced as counterions[13–15] or probe-ions[16] into micellar solutions. This method can yield information on the hydrophilic region of micelles in contrast with the spin-probe or spin-label method with nitroxide radicals which gives mainly information on the hydrophobic region of the micelles. If one uses surfactants which contain Mn^{2+} ions as counterions, this method is free from disturbing the system under investigation. In addition, ESR measurements by this method can easily be applied to systems with lower sample concentrations. In contrast, the NMR method requires a higher concentration owing to its lower sensitivity.[11]

The aim of the present paper is to investigate the behavior of Mn^{2+} ions in (polymer+surfactant) solutions by the ESR method to clarify the binding state of Mn^{2+} ions in the polymer–surfactant complex in comparison with the behavior of Mn^{2+} ions in $Mn(DS)_2$ solutions. In order to obtain the degree of dissociation of Mn^{2+} ions from the complex, absorption intensities of ESR signals will be measured. Linewidths of ESR signals will also be measured so as to establish the binding state of Mn^{2+} ions in the complex.

Experimental

Manganese dodecyl sulfate ($Mn(DS)_2$) was synthesized from commercial sodium dodecyl sulfate of specially prepared reagent grade and manganese chloride of guaranteed reagent grade according to Miyamoto's method.[17] The $Mn(DS)_2$ was purified by several recrystallization from water.

Poly(*N*-vinylpyrrolidone)(PVP) which was purchased from Nakarai Chemicals Ltd. was purified by dialysis using cellophane tubing.

Surface tension measurements by a capillary rise method were carried out at 25±0.05 °C to ascertain the purity of $Mn(DS)_2$ and the existence of the interaction between PVP and $Mn(DS)_2$ in water.

The ESR spectra were recorded at 30±0.5 °C on a JEOL model FEIX spectrometer equipped with a variable temperature accessory.

The ESR signal of solid DPPH was used as an external reference in the calculation of the absorption intensities of Mn^{2+} ions in a series of sample solutions.

Results and Discussion

In Fig. 1, the values of the surface tension of aqueous $Mn(DS)_2$ solutions are plotted against the molar concentration of $Mn(DS)_2$, *m*. Obviously there is no minimum in the resultant curve. From the break point on its curve, the value of the CMC of $Mn(DS)_2$ in water was estimated to be 1.4 mmol kg^{-1} which is slightly higher than that reported in the literature.[18]

A similar plot of aqueous ($Mn(DS)_2$+0.05% PVP) solutions is also illustrated in Fig. 1; in this case, *m* is the number of moles of $Mn(DS)_2$ per kilogram of a 0.05% aqueous PVP solution. This plot is evidently different from that of aqueous $Mn(DS)_2$ solutions. It has two break points whose concentrations do not coincide with the CMC of $Mn(DS)_2$ in water. This fact indicates that $Mn(DS)_2$ interacts with PVP

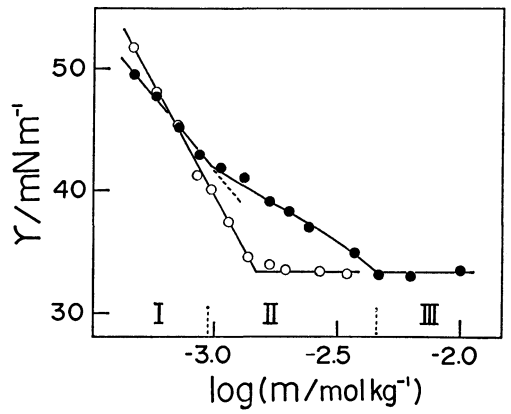

Fig. 1. Surface tension *vs.* log(m/mol kg^{-1}).
○: $Mn(DS)_2$ solutions, ●: ($Mn(DS)_2$+0.05% PVP) solutions.

in some manner.

If one interprets the two break points according to the previous studies on the interaction between sodium dodecyl sulfate and some nonionic polymers,[4,7] a kind of complex formation between $Mn(DS)_2$ and PVP starts at the concentration of the lower break point, m_1, and continues to the concentration of the higher one, m_2. Above m_2, micelles of $Mn(DS)_2$ are produced in the solution without further complex formation. Thus, chemical species in the solution vary with m in the following way: in region I ($m<m_1$), Mn^{2+} ions and dodecyl sulfate ions (DS^- ions); in region II ($m_1 \leqq m<m_2$), Mn^{2+} ions, DS^- ions, and complexes formed between PVP and $Mn(DS)_2$ (P-S complexes); in region III ($m_2<m$), Mn^{2+} ions, DS^- ions, P-S complexes, and $Mn(DS)_2$ micelles. These three concentration regions are indicated by roman numerals above the abscissa in the figure.

ESR spectra of Mn^{2+} ions ($S=5/2$ and $I=5/2$) obtained in the present study were composed of six unequivalent lines; each of which contains five unresolved lines. Since the fourth line from the low field side is nearly Lorentzian, its linewidths and absorption intensities were measured as a function of m.

Figure 2(a) shows the dependence of the peak-to-peak linewidth, W_{pp}, on m in two systems; the one is aqueous $Mn(DS)_2$ solutions, and the other is aqueous ($Mn(DS)_2$+0.05% PVP) solutions. In appearance, there is little difference between the two systems; W_{pp} is nearly constant to $m = ca.$ 1 mmol kg^{-1}, and then increases with m. Since this concentration approximately corresponds to the CMC of $Mn(DS)_2$ in water or to the concentration, m_1, at which the P-S complex begins to form in the ($Mn(DS)_2$+0.05% PVP) solutions, the increase in W_{pp} reflects the formation of micelles or P-S complexes.

According to Garrett and Morgan,[19] the broadening of W_{pp} of Mn^{2+} complexes in solutions is caused by the decrease in perturbational correlation time and/or by the alteration in the time-dependent spin Hamiltonian of Mn^{2+} ions. When Mn^{2+} ions are bound onto the surface of the micelle-like region, both effects can be expected to occur.

The similarity of the W_{pp}-m plot between the two

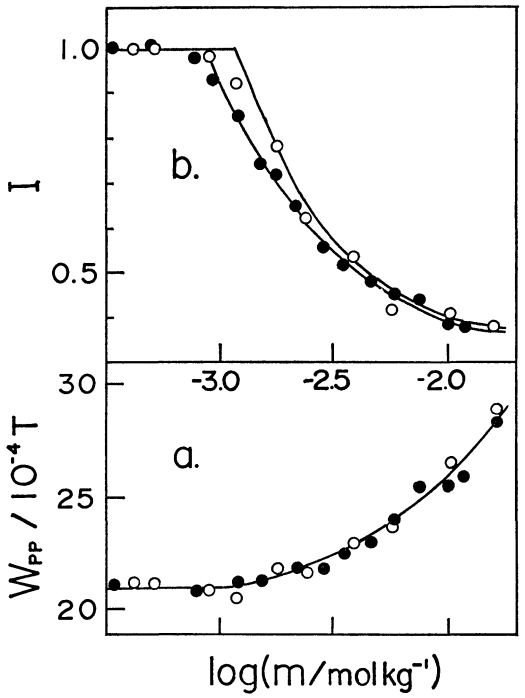

Fig. 2. (a) Linewidth *vs.* log(m/mol kg^{-1}). (b) Normalized intensity *vs.* log(m/mol kg^{-1}). ○: $Mn(DS)_2$ solutions, ●: ($Mn(DS)_2$+0.05% PVP) solutions.

systems, therefore, may imply that there is little difference in the binding state of Mn^{2+} ions; it suggests that $Mn(DS)_2$ molecules bound onto the PVP aggregate to form a micelle-like structure.

Normalized absorption intensities, I, of Mn^{2+} ions in the two systems are shown as a function of m in Fig. 2(b); here, I was obtained by the normalization of values which resulted from dividing absorption intensities, I_A, by m. The I_A was calculated through the following relation which holds for Lorentzian line shapes:

$$I_A \propto h_{pp} \times W_{pp}^2, \quad (1)$$

where h_{pp} is the peak-to-peak height.

A small difference in the behavior of the I-m curve can be seen between the two systems owing to the rate of change in I being greater than that in W_{pp}. In the case of $Mn(DS)_2$ solutions, I takes a constant value (=1.0) below m=1.1 mmol kg^{-1} which is nearly equal to the CMC, and then decreases steeply to a saturation value ($\approx$0.35). On the other hand, in the case of ($Mn(DS)_2$+0.05% PVP) solutions, the steep decrease in I begins at $m=0.9_4$ mmol kg^{-1} which is approximately equal to m_1 in Fig. 1. At higher concentrations, the I-m curve approaches gradually to that of $Mn(DS)_2$ solutions.

According to the previous ESR studies on Mn^{2+} complexes in solutions,[20,21] the loss of signal intensity of Mn^{2+} ions is attributed to the extreme broadening of the linewidths beyond detection. This broadening is caused by a large distortion from the octahedral symmetry of $Mn(H_2O)_6^{2+}$ on the formation of unsymmetrical inner-sphere complexes.

If one considers, on the basis of a simple micellar model, that Mn^{2+} ions in $Mn(DS)_2$ micellar solutions

exist in three regions; the Stern layer, the diffuse layer, and the bulk water, Mn^{2+} ions "bound" onto the micelles are those in the two layers. Since Mn^{2+} ions in the Stern layer form inner-sphere complexes with DS^- ions constituting micelles, they are responsible for the intensity loss. On the other hand, those in the diffuse layer which form outer-sphere complexes with the DS^- ions contribute to the broadening of linewidths in Fig. 2(a).

By analyzing the intensity loss in Fig. 2(b) on the basis of the simple idea, one can proceed to a quantitative discussion.

Denoting the degree of dissociation of Mn^{2+} ions from $Mn(DS)_2$ micelles by α, and the fraction of Mn^{2+} ions in the diffuse layer in total Mn^{2+} ions bound onto micelles by β, I_A is combined with α and β by the following relation;

$$I_A \propto m_f + \alpha(m-m_f) + \beta(1-\alpha)(m-m_f), \quad (2)$$

where m_f is the concentration of free $Mn(DS)_2$ being in equilibrium with the $Mn(DS)_2$ in a micellar state. The second and the third term represent the contribution from Mn^{2+} ions dissociating from micelles and those in the diffuse layer, respectively.

Dividing the right hand side of Eq. 2 by m, I is derived as follows:

$$I = \frac{m_f}{m} + \alpha\left(1-\frac{m_f}{m}\right) + \beta(1-\alpha)\left(1-\frac{m_f}{m}\right)$$

$$= (1-\alpha-\beta+\alpha\beta)\frac{m_f}{m} + \alpha + \beta - \alpha\beta. \quad (3)$$

Moreover, by simple transformation of Eq. 3, the following equation is obtained;

$$m(1-I) = (\alpha\beta+1-\alpha-\beta)(m-m_f). \quad (4)$$

Supposing that $Mn(DS)_2$ molecules bound onto PVP form a micelle-like aggregate, in the case of ($Mn(DS)_2$+0.05% PVP) solutions, the equations similar to Eqs. 3 and 4 can be described as follows:

$$I = (1-\alpha^p-\beta^p+\alpha^p\beta^p)\frac{m_f^p}{m} + \alpha^p + \beta^p - \alpha^p\beta^p, \quad (5)$$

$$m(1-I) = (\alpha^p\beta^p+1-\alpha^p-\beta^p)(m-m_f^p), \quad (6)$$

where α^p, β^p, and m_f^p are the corresponding quantities to α, β, and m_f in Eqs. 3 and 4.

Plots of I *vs.* m_f/m and I *vs.* m_f^p/m based on Eqs. 3 and 5 respectively are shown in Fig. 3. Here, the concentrations at the break points in Fig. 2(b) were used as the constant values of m_f and m_f^p; that is, m_f=1.1 mmol kg^{-1} and m_f^p=0.9$_4$ mmol kg^{-1}. In the strict sense, m_f^p varies from 0.9$_4$ mmol kg^{-1} to 1.1 mmol kg^{-1} in region II with an increase in m. The present assumption that m_f^p takes a constant value of 0.9$_4$ mmol kg^{-1}, however, does not introduce serious errors in the calculation of m_f^p/m in Eq. 5 and ($m-m_f^p$) in Eq. 6, since the difference between the two values of m_f^p (=0.1$_6$ mmol kg^{-1}) is much smaller than the value of m_2 (=4.6 mmol kg^{-1}); the errors become largest at m_2. Roman numerals above the abscissa indicate the regions corresponding to the three concentration regions in Fig. 1. The two plots in the figure are depicted by the same straight line in regions II and III; in the plot of I *vs.* m_f^p/m, there is no inflection at the boundary between region II and region III.

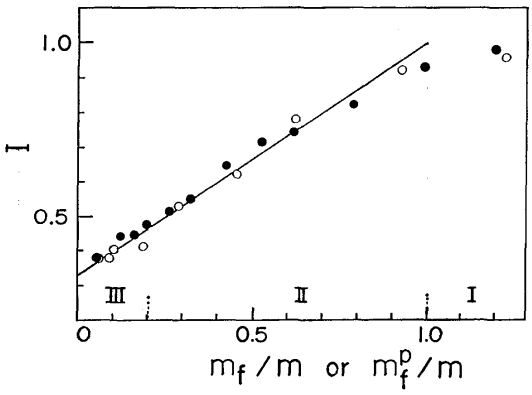

Fig. 3. Plots of I in $Mn(DS)_2$ solutions *vs.* m_f/m: (○), and I in ($Mn(DS)_2$+0.05% PVP) solutions *vs.* m_f^p/m: (●).

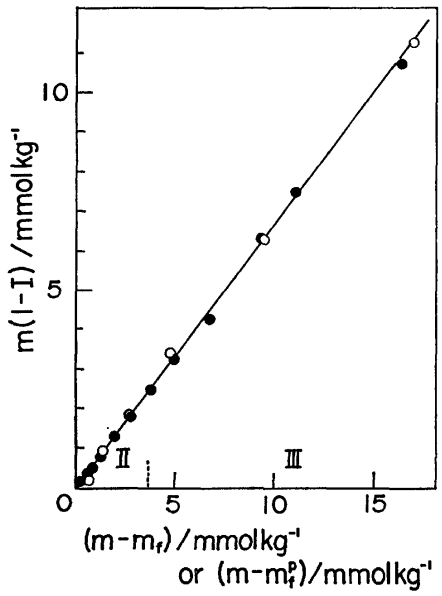

Fig. 4. Plots of $m(1-I)$ in $Mn(DS)_2$ solutions *vs.* ($m-m_f$): (○), and $m(1-I)$ in ($Mn(DS)_2$+0.05% PVP) solutions *vs.* ($m-m_f^p$): (●).

Similarly, plots of $m(1-I)$ *vs.* ($m-m_f$) and $m(1-I)$ *vs.* ($m-m_f^p$) based on Eqs. 4 and 6 respectively are shown in Fig. 4. The two plots are evidently on the same line with no inflection in regions II and III as well as in Fig. 3.

Thus, the results obtained in Figs. 3 and 4 indicate that $\alpha \approx \alpha^p$ and $\beta \approx \beta^p$; in other words, the binding manner of Mn^{2+} ions onto the micelle-like aggregate is similar to that of Mn^{2+} ions onto the $Mn(DS)_2$ micelles.

From the dependence of m_1 or CMC on the hydrocarbon chain length of surfactants, Arai and coworkers[7] have reported that the free energy of transferring a CH_2 from aqueous solution to the micelle-like aggregate in the P-S complex agrees with the result in the simple micellar solutions without added polymers. It can, therefore, be supposed that the structure of this micelle-like aggregate is almost identical with that

of an ordinary micelle.

It is clear from Eqs. 3 and 4, that the simultaneous determination of α and β from the y-intercept and the slope of the straight lines (Figs. 3 and 4) is impossible; the value of β was therefore estimated by the use of a value for α reported by Satake and coworkers.[22] From electric conductivity data, they estimated α of magnesium dodecyl sulfate ($Mg(DS)_2$) micelles to be 0.21 in a 0.1 mol dm^{-3} $MgSO_4$ solution.

The use of this value for $Mn(DS)_2$ micelles in the present study is permissible for the following two reasons; one is the similar chemical character of Mn^{2+} ions and Mg^{2+} ions,[24] and the other is the weak effect of added electrolytes on the aggregation number of dodecyl sulfate ions in micelles of bivalent metal dodecyl sulfates.[22]

Substituting this value (=0.21) for α in the following equation which is obtained by analysis of the lines in Figs. 3 and 4:

$$\alpha + \beta - \alpha\beta = 0.32, \quad (7)$$

the value of β is estimated to be 0.14.

The magnitude of this β value implies that most of Mn^{2+} ions bound onto micelles exist in the Stern layer as inner-sphere complexes with DS^- ions. Since β^p is nearly equal to β, the same conclusion can also be derived in the case of the micelle-like aggregate in P–S complexes.

In order to investigate whether the structures of P–S complexes change or not with an increase in the PVP concentration, the linewidths and relative intensities of the ESR signal of Mn^{2+} ions in ($Mn(DS)_2$+PVP) solutions with various amounts of PVP were measured at a constant $Mn(DS)_2$ concentration.

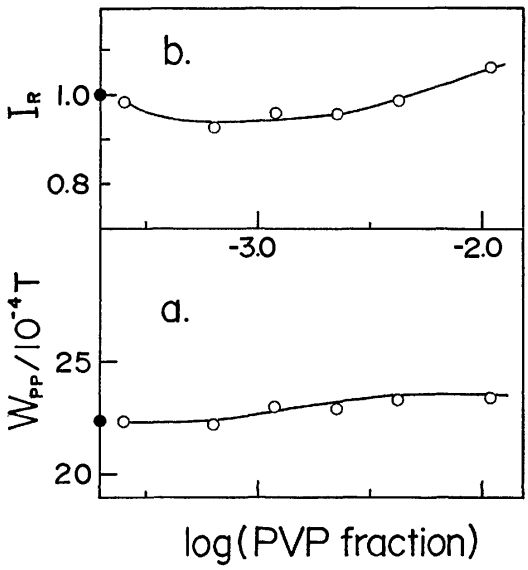

Fig. 5. (a) Linewidth *vs.* log(weight fraction of PVP). (b) Relative intensity *vs.* log(weight fraction of PVP). $Mn(DS)_2$ concentration=3.21 mmol kg^{-1}. Closed circles represent the values of the $Mn(DS)_2$ solution without PVP.

If the structure assumed for the complexes in the above discussion remains unchanged with increase in the PVP concentration, W_{pp} will increase slightly, whereas I will decrease asymptotically, for the concentration m_1 gradually decreases with the increase in the PVP concentration.[11]

The results where m=3.21 mmol kg^{-1} are shown as a function of the weight fraction of PVP in Fig. 5; the relative intensity, I_R, means the ratio of I_A in ($Mn(DS)_2$+PVP) solutions to that in the $Mn(DS)_2$ solutions without PVP. Obviously, the curves depicted in the figure are not the predicted ones. W_{pp} in Fig. 5(a) is nearly constant below 0.2%, and then increases slightly, while I_R decreases asymptotically to 0.2%, but above that concentration it increases evidently.

This behavior may suggest a structural change of the P–S complex at higher PVP concentrations; the structure may transform into one with a weak binding potential for Mn^{2+} ions.

The Solvent Extraction of Silver and Thallium(I) Picrates by Crown Ethers

Yasuyuki TAKEDA,* Masashi NEMOTO, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received March 16, 1982)

Extraction constants of silver and thallium(I) picrates and those of 12-crown-4 (12C4) and benzo-15-crown-5 (B15C5) with silver and thallium(I) picrates have been determined between benzene and water at 25 °C. Ion-pair complex-formation constants ($K_{MLA,o}$) of 12C4 and B15C5 with silver and thallium picrates in the benzene solution have been calculated and compared with those of 15-crown-5 (15C5), 18-crown-6 (18C6), dibenzo-18-crown-6 (DB18C6), and dibenzo-24-crown-8 (DB24C8). The $K_{MLA,o}$ sequences of the crown ethers with Ag^+ and Tl^+ are 15C5, 18C6>DB18C6>B15C5>DB24C8≫12C4 and 18C6≫DB18C6>DB24C8>15C5>B15C5≫12C4, respectively. For both Ag^+ and Tl^+ systems, the relative sizes of the cation and the crown ether cavity, the number of donor oxygen atoms in the crown ether ring, the basicity of donor oxygen atom, and the flexibility of the crown ether are important factors in determining stabilities of the complexes with these crown ethers in the benzene solution.

Crown ethers form stable stoichiometric complexes with Ag^+ and Tl^+ as well as with alkali metal ions. The complexing-power of crown ethers for Ag^+ and Tl^+ has been investigated by solvent extraction.[1-5]

In the present study, the extraction constants of silver and thallium(I) picrates and those of 12-crown-4 (12C4) and benzo-15-crown-5 (B15C5) with silver and thallium(I) picrates have been determined between benzene and water at 25 °C. Ion-pair complex-formation constants of 12C4 and B15C5 with silver and thallium picrates in the benzene solution have been calculated and compared with those of 15-crown-5 (15C5),[1] 18-crown-6 (18C6),[1] dibenzo-18-crown-6 (DB18C6),[2,4] and dibenzo-24-crown-8 (DB24C8)[5] in order to study the factors governing the stabilities of these complexes.

Experimental

The 12C4 (Wako-Pure Chemicals, Ltd.) was used without further purification. The method of purification of the B15C5 (Merck Japan Ltd.) has been described in the literature.[6] The purity of $AgNO_3$ and $TlNO_3$, and the concentrations of the picric acid solutions were determined by KCl, EDTA, and alkaline titrations, respectively. Analytical-grade benzene was washed twice with distilled water. All the experiments were conducted at 25±0.2 °C. Most of the experimental procedures were similar to those in the previous papers.[1,2] The concentrations of $AgNO_3$, $TlNO_3$, picric acid, 12C4, and B15C5 were $(2—6)\times10^{-3}$, $(1—9)\times10^{-3}$, $1\times10^{-3}—1.5\times10^{-2}$, $6\times10^{-3}—3.9\times10^{-1}$, and $5.9\times10^{-5}—3.9\times10^{-2}$ mol dm^{-3}, respectively. All the extractions were carried out in the pH range of 2.0—2.7.

Results

In an equilibrium between an aqueous solution of a univalent metal ion (M^+) and a picrate ion (A^-), and benzene, and its solution of a crown ether (L), the following equilibrium constants may be defined:

$$K_{ex}(MA) = [MA]_o[H^+]/[M^+][HA]_o \quad (1)$$

$$K_{ex}(MLA) = [MLA]_o[H^+]/[M^+][L]_o[HA]_o \quad (2)$$

$$K_{D,L} = [L]_o/[L] \quad (3)$$

$$K_{ex}(HA) = [HA]_o/[H^+][A^-] \quad (4)$$

$$K_{ML} = [ML^+]/[M^+][L] \quad (5)$$

$$K'_{ex} = [MLA]_o/[ML^+][A^-], \quad (6)$$

where the subscript "o" and the lack of subscript denote the organic and the aqueous phase, respectively; square brackets indicate the molar concentrations. Thus, $K_{ex}(MLA)$ can be written as follows:

$$K_{ex}(MLA) = K_{D,L}^{-1}K_{ex}(HA)^{-1}K_{ML}K'_{ex}. \quad (7)$$

In the absence of the crown ether, the distribution ratio of the metal may be written as

$$D = [MA]_o/[M^+]. \quad (8)$$

The substitution of Eqs. 1 and 4 into Eq. 8 gives:

$$D = K_{ex}(MA)K_{ex}(HA)[A^-]. \quad (9)$$

The log D *vs.* log[A^-] plot in Fig. 1 shows a straight line with a slope of 1. This indicates that the K_{ex}(MA) can be represented by Eq. 1. The value of [A^-] in Eq. 9 was calculated from Eq. 10:

$$[A^-] = ([HA]_t-[MA]_o)/\{1+(K_{HA}+K_{ex}(HA))[H^+]\}, \quad (10)$$

where $K_{HA}=1.9_5$,[7] $K_{ex}(HA)=247$,[8] and the subscript "t" denotes the total concentration. When the extraction system contains a crown ether, D may be represented by:

$$D = [MLA]_o/([M^+]+[ML^+]). \quad (11)$$

In the case of $[M^+]\gg[ML^+]$, Eq. 11 becomes:

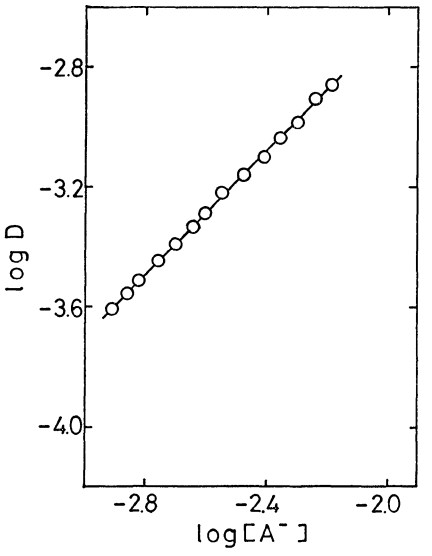

Fig. 1. Plot of log D *vs.* log[A^-] for the Tl^+ system.

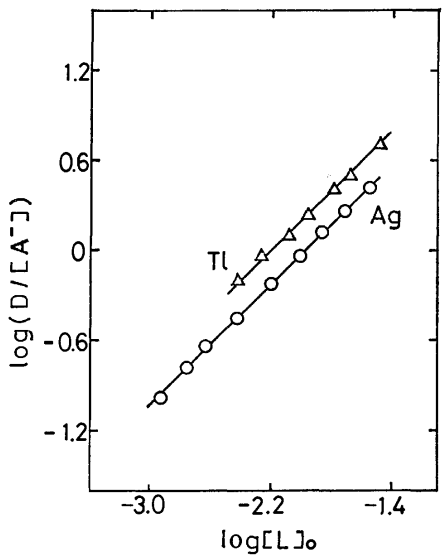

Fig. 2. Plot of $\log(D/[A^-])$ *vs.* $\log[L]_o$ for the 12C4–Ag^+ and Tl^+ systems.

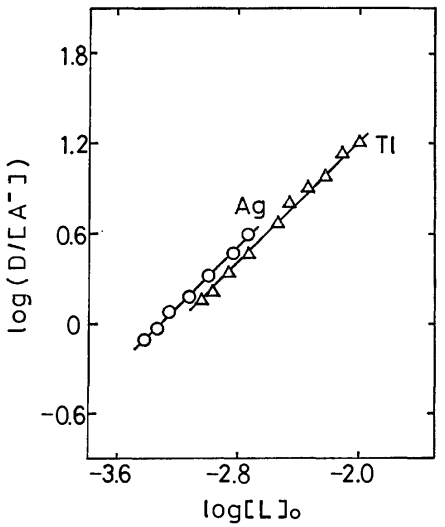

Fig. 3. Plot of $\log(D/[A^-])$ *vs.* $\log[L]_o$ for the B15C5–Ag^+ and Tl^+ systems.

$$D = K_{ex}(MLA)K_{ex}(HA)[A^-][L]_o. \quad (12)$$

The $\log(D/[A^-])$ *vs.* $\log[L]_o$ plots in Figs. 2 and 3 show a linear relationship with a slope of 1 in every case, indicating that 12C4 and B15C5 form 1:1 complexes with Ag^+ and Tl^+. The values of $[A^-]$ and $[L]_o$ in Eq. 12 were calculated from Eqs. 13 and 14 respectively:

$$[A^-] = ([HA]_t - [MLA]_o)/\{1 + (K_{HA} + K_{ex}(HA))[H^+]\} \quad (13)$$

$$[L]_o = ([L]_t - [MLA]_o)/(1 + K_{D,L}^{-1}). \quad (14)$$

The equilibrium constants obtained from these data are listed in Table 1.

Table 1. Equilibrium constants at 25 °C

	$\log\{K_{ex}(MA)K_{ex}(HA)\}$

12C4	1.14	1.40
15C5[1]	3.65	3.00
B15C5	4.63	4.53

Discussion

Although a Ag^+ ion is much more strongly hydrated than a Tl^+ ion, for the benzene system, silver picrate is more extractable than thallium picrate and, for the chloroform system, the extractability of the former is equal to that of the latter (Table 1). In the cases of both Ag^+ and Tl^+, the picrate is more extractable by benzene than by chloroform. The reason why the Ag^+ ion is more extractable than the Tl^+ ion for the benzene system and the Ag^+ ion is more extractable by benzene than by chloroform may be due to the strong interaction of the Ag^+ ion with the π-electrons of a benzene molecule.

The crystal ionic radius of Ag^+ (1.26 Å[9]) is nearly equal to that of K^+ (1.33 Å[9]) and that of Tl^+ (1.40 Å[9]) is almost identical with those of K^+ and Rb^+ (1.48 Å[9]). However, in the cases of both 12C4 and B15C5, the $\log K_{ex}(MLA)$ value of Ag^+ is much larger than that of K^+ (12C4: −1.82,[10] B15C5: −0.46[6]) and that of Tl^+ is much greater than those of K^+ and Rb^+ (12C4: −2.10,[10] B15C5: −0.95[6]). The covalent bond[11] of Ag^+ and Tl^+ ions with oxygen atoms of the crown ether is one of the reasons for the above phenomena.

The $\log(K_{ML}K'_{ex})$ value sequences of 12C4, 15C5, and B15C5 with Ag^+ and Tl^+ are B15C5>15C5≫12C4 and B15C5≫15C5≫12C4, respectively (Table 1). Since both 12C4 and 15C5 are rigid and the sizes of Ag^+ and Tl^+ are larger than the cavity sizes of 12C4 (1.0—1.3 Å[12]) and 15C5 (1.7—2.2 Å[12]), the magnitude of the $\log K_{ML}$ value may largely depend on the number of donor oxygen atoms of the crown ether. Thus, for both Ag^+ and Tl^+, the $\log K_{ML}$ value for 15C5 is larger than that for 12C4. The size of the 15C5 complex with the same metal ion (Ag^+ and Tl^+) is larger than that of the 12C4 complex. Moreover, 15C5 may more effectively screen the surface charge of the metal ion trapped in its cavity than 12C4 because of its larger size. Consequently, for both Ag^+ and Tl^+, the $\log K'_{ex}$ value of 15C5 is larger than that of 12C4. The fact that the $\log(K_{ML}K'_{ex})$ value of 15C5 is greater than that of 12C4 is in agreement with the above discussion. In an aqueous solution, B15C5 complexes with Ag^+ and Tl^+ may be more unstable than 15C5 complexes

owing to the two aromatic ether oxygen atoms. Since the B15C5 complex with the same metal ion has a larger molar volume than the 15C5 complex, the former may be more extractable by benzene than the latter. It thus appears that, in the case of both Ag^+ and Tl^+, the $\log(K_{ML}K'_{ex})$ sequences of B15C5 and 15C5 depend completely on the $\log K'_{ex}$ sequences.

$K_{ex}(MLA)/K_{ex}(MA)$ $(=K_{MLA,o})$ represents the ion-pair complex-formation constant of the crown ether with silver or thallium picrate in a benzene solution. Since the complex-formation reaction is an ion-pair complex-formation reaction, the anion has a large influence on the stability of the complex compared with the reaction between a free metal ion and a crown ether. The $\log K_{MLA,o}$ sequences of the crown ethers with Ag^+ and Tl^+ are 15C5, 18C6>DB18C6> B15C5 > DB24C8 ≫ 12C4 and 18C6 ≫ DB18C6 > DB24C8>15C5>B15C5≫12C4, respectively (Table 2). This indicates that, for both the Ag^+ and Tl^+ systems, the relative sizes of the cation and crown ether cavity; the number of donor oxygen atoms in crown ether ring; the basicity of donor oxygen atom; and the flexibility of the crown ether are important factors in determining the stabilities of the complexes.

TABLE 2. $\log(K_{MLA,o}/mol^{-1}\,dm^3)$ VALUES IN BENZENE AT 25 °C

	Ag^+	Tl^+
12C4	2.22	2.90
15C5	4.71[2)]	4.48
B15C5	3.59	3.91
18C6	4.70[2)]	6.98
DB18C6	3.82[2)]	5.17
DB24C8	3.35[2)]	4.74

Although Ag^+ fits more closely into the 12C4 and B15C5 cavities than Tl^+, the $\log K_{MLA,o}$ value of Tl^+ is larger than that of Ag^+. This may be attributed to the fact that silver picrate is strongly solvated by benzene. However, in the case of 15C5, the Ag^+ complex is more stable than the Tl^+ complex. This can be considered to reflect the increase in basicity of the two donor oxygen atoms on going from B15C5 to 15C5. The reason why, in the cases of 18C6, DB18C6, and DB24C8, the Tl^+ complex is much more stable than the Ag^+ complex may be attributed to the strong solvation of silver picrate by benzene and the more optimal size of Tl^+ for each of the cavities of these crown ethers than Ag^+.

Kinetic Studies of the Electron Transfer Reactions in Iron(II) and Iron(III) Systems. XII. The Ratios of the Reaction Rates of the Outer-sphere *vs.* Inner-sphere Electron Transfer Mechanisms in the Presence of X^- ($X^-=Cl^-$, SCN^-, and N_3^-) in Aqueous Solutions, as Judged from the Kinetics of the Dissociation Reactions of FeX^{2+}

Goro WADA,* Tomiko INATANI, and Sachiko ICHIMURA

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received February 3, 1982)

The electron transfer reactions between Fe^{2+} and FeX^{2+} ($X^-=Cl^-$, SCN^-, or N_3^-) may take place through the inner- or outer-sphere mechanism or through both in parallel. The process of the outer-sphere mechanism is just equivalent to the process of dissociation of FeX^{2+} catalyzed by Fe^{2+} in appearance. When the overall rate constant of the electron transfer reaction and the rate constant of Fe^{2+}-assisted dissociation reaction of FeX^{2+} are denoted by k_E and k_o respectively, the fraction r of the outer-sphere mechanism to the total is given in terms of $r=2k_o/k_E$. Thus, the r values were determined with the results that $r(Cl^-)=44\%$ at $I=1.5$ M (1 M=1 mol dm^{-3}) and 25 °C, $r(SCN^-)=100\%$ at $I=0.5$ M and 25 °C, and $r(N_3^-)=0\%$ at $I=0.55$ M and 10 °C. These facts suggest that r depends considerably upon the bridging ability of X^-; formation of binuclear intermediate may be favored by the symmetrical structure and the size of X^-, which make the inner-sphere mechanism easier with the stronger coordinate bond and the weaker electric repulsion between the two reactants beyond the bridging ligand.

The electron transfer reactions between iron(II) and iron(III), $Fe^{II}+Fe^{III}\rightarrow Fe^{II}+Fe^{II}$, have been known to be accelerated by the presence of some anions, X^-, in aqueous perchloric acid media.[1-8] In such catalytic actions, X^- usually coordinates to iron(III) to form a precursor complex, FeX^{2+}, which participates in the electron transfer reaction *via* either of the two paths shown as follows:

$$FeX^{2+} + F^{2+} \quad \text{(Path-I)}$$

$$Fe^{2+} + FeX^{2+} \rightleftharpoons Fe^{3+} + FeX^{+} \quad \text{(Path-O)}$$

The former of the two paths is called the inner-sphere mechanism, in which X^- bridges the two reacting ions and is transferred from Fe(III) to Fe(II) as an atom or radical (X) transfer, leaving an electron of X^- on Fe(III), while the latter path is the outer-sphere mechanism, in which an electron of Fe(II) is directly transferred to Fe(III) without accompanying any ligand substitution in the first coordination spheres of both ions. Generally, the two reaction mechanisms may compete with each other, with a certain ratio, the outer-sphere *vs.* inner-sphere mechanism, depending upon the properties of the bridging anion ligand X^- in aqueous solution.

Since the chemical species appearing as the reactants or products in the Path-I are identical in both sides, the rate constants of the forward and reverse reactions are equally k_1, while the Path-O is not a symmetric reaction with the product species different from the reactant ones, so that the rate constant of the forward reaction k_o should be unequal to that of the reverse reaction k_o'.

Now, let us consider an aqueous solution containing Fe(II), Fe(III), and X^-; all of the probable chemical species being at equilibrium. If the electron transfer reactions, both Path-I and Path-O, are simultaneously occurring in this system, the overall reaction rate, R, can be expressed by the sum of the three individual rates.

$$R = k_i[Fe^{2+}][FeX^{2+}] + k_o[Fe^{2+}][FeX^{2+}] + k_o'[Fe^{3+}][FeX^{+}] \quad (1)$$

Since the reaction system is at equilibrium, the concentrations of all the species in it must be individually kept constant. Although FeX^+ produced is very labile and is going soon to decompose, any probable side-reaction is quite indifferent to the reverse process of Path-O. Generally, the reverse process has the same mechanism as that of the forward process. Therefore, the rate of the forward reaction in Path-O should be equal to that of the reverse one at equilibrium.

$$k_o[Fe^{2+}][FeX^{2+}] = k_o'[Fe^{3+}][FeX^{+}] \quad (2)$$

By using the relationship of Eq. 2, Eq. 1 then becomes[8]

$$R = (k_1+2k_o)[Fe^{2+}][FeX^{2+}] \quad (3)$$

and the apparent overall rate constant k_E of the electron transfer reaction is expressed as follows:

$$k_E = k_1 + 2k_o. \quad (4)$$

If both k_E and k_o are separately determined for a reaction system in the presence of X^-, we can define the fraction r of the outer-sphere mechanism to the overall reaction rate.

$$r = \frac{2k_o}{k_E} \quad (5)$$

In order to determine k_E, the radioactive isotope ^{59}Fe has been frequently used as a tracer by several workers since the first investigation by Silverman and Dodson.[1] For the determination of k_o, on the other hand, an idea is useful as described below.

When the dissociation reaction of FeX^{2+}, $FeX^{2+}\rightarrow Fe^{3+}+X^-$, is accelerated by the presence of Fe^{2+}, it looks like that Fe^{2+} acts as a catalyst for the dissociation reaction:

$$FeX^{2+} + Fe^{2+} \xrightarrow{k_d} Fe^{3+} + FeX^{+} \quad \text{(Path-D)}$$

Reaction Path-D is seemingly a ligand exchange reaction of X^-, but it is just the same reaction with Path-O in appearance. Consequently, the observed k_d is equivalent to k_o of the outer-sphere electron transfer in Path-O.

In the present investigation, the kinetics of the catalytic dissociation of FeX^{2+} was studied, and the values of r were determined in the cases of Cl^-, SCN^-, and N_3^- and were interpreted by virtue of the nature of these anions. For the case of Cl^-, Sutin and his coworkers[8] estimated the r value earlier, which will be compared with the present results.

Experimental

Materials. *$Fe(ClO_4)_2$*: The preparative method was described elsewhere.[9]

$Fe(ClO_4)_3$: Aqueous perchloric acid solution of $Fe(ClO_4)_2$ was oxidized to $Fe(ClO_4)_3$ by adding approximately equivalent amount of H_2O_2. The precipitated crystals of $Fe(ClO_4)_3$ were filtered, washed by chloroform, and dried in vacuum.

NaCl, KSCN, NaN_3, and $NaClO_4$: Commercial reagents of the purest grade were recrystalized from their aqueous solutions, respectively.

Water: Tap water was purified by double distillation after being deionized through ion-exchange resin.

Procedure. Kinetic measurements were carried out by use of a Yanako stopped-flow spectrophotometer Model SPS-1 connected with an Iwatsu memoriscope MS-5019A. The reaction compartment was thermostated at a given reaction temperature. The dissociation reaction of FeX^{2+} in the presence or absence of Fe^{2+} was initiated by mixing two solutions A and B, containing Fe^{3+}, X^-, $HClO_4$, and $NaClO_4$ in A and Fe^{2+} or none, $HClO_4$, and $NaClO_4$ in B, respectively. Sodium perchlorate was used for adjusting the ionic strength of the reaction media. The reaction rate was followed by the decrement in absorbance due to the disappearance of FeX^{2+}, at wavelengths 370 nm for $FeCl^{2+}$, 460 nm for $FeSCN^{2+}$ and FeN_3^{2+}, respectively.

The apparent dissociation rate constant k_{app} was obtained from the linearity of $\ln([FeX^{2+}]-[FeX^{2+}]_e)$ *vs.* time t by the following relationship:

$$\ln\frac{[FeX^{2+}]-[FeX^{2+}]_e}{[FeX^{2+}]_o-[FeX^{2+}]_e} = -k_{app}t. \quad (6)$$

Since FeX^{2+} in solution A was in equilibrium with free Fe^{3+} and X^- before mixing with solution B, the equilibrium was suddenly perturbed and forced to shift towards a new equilibrium by dilution, with the forward (dissociation) rate constant k and the reverse (recombination) one k'. If the formation constant of FeX^{2+} is denoted by K_x ($=[FeX^{2+}]/[Fe^{3+}][X^-]$), K_x is equal to k'/k and, thus, k is given by the following equation:

$$k = \frac{k_{app}}{1+K_x([Fe^{3+}]_e+[X^-]_e)}. \quad (7)$$

The notations [ ]$_o$ and [ ]$_e$ in Eqs. 6 and 7 denote the concentrations at the initial time and at the equilibrium, respectively.

Results and Discussion

An example of a plot of $\ln([FeN_3^{2+}]-[FeN_3^{2+}]_e)$ against reaction time t is shown in Fig. 1. The observed straight line represents Eq. 6 very well, from

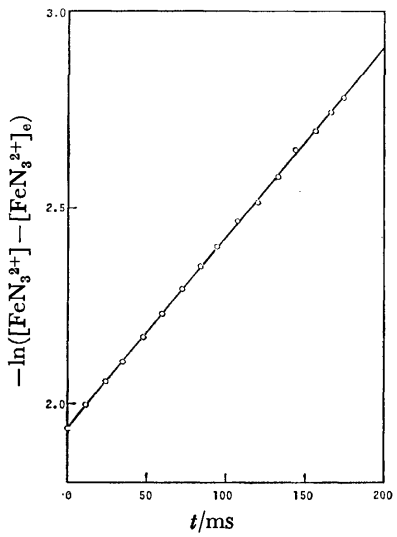

Fig. 1. Linear relationship of $-\ln([FeN_3^{2+}]-[FeN_3^{2+}]_o)$ *vs.* t at $[Fe(ClO_4)_3]_t=[NaN_3]_t=1.96\times10^{-3}$ M, $[Fe(ClO_4)_2]_t=0$, $[HClO_4]_t=0.01$ M, $I=0.55$ M at 10 °C.

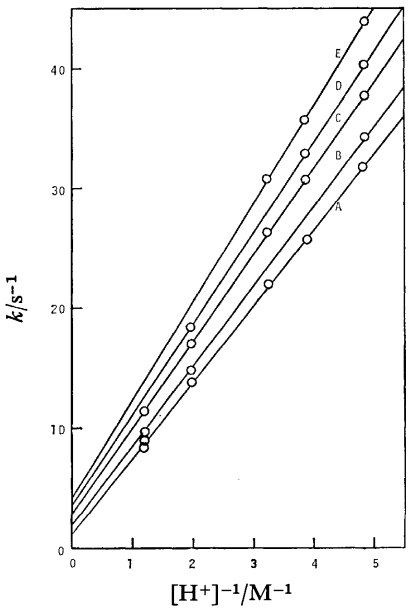

Fig. 2. Linear relationship of k *vs.* $[H^+]^{-1}$, at $[Fe^{3+}]_t=4.63\times10^{-3}$ M, $[Cl^-]_t=4.58\times10^{-3}$ M, $[H^+]=0.2$—0.8 M, $I=1.5$ M at 25 °C.
A: $[Fe^{2+}]_t=0$, B: $[Fe^{2+}]_t=0.05$ M, C: $[Fe^{2+}]_t=0.01$ M, D: $[Fe^{2+}]_t=0.15$ M, E: $[Fe^{2+}]_t=0.20$ M.

the slope of which k_{app} can be calculated. On account of the relatively low value of the formation constants, $K_{Cl}=3.0\times10^{10}$) and $K_{SCN}=4.2\times10^2$,[11] both at $I=0$ and 25 °C, k is considered to be approximately equal to k_{app} from Eq. 7 for $X^-=Cl^-$ or SCN^-. In the case of N_3^-, however, the situation is more complicated as will be described below.

Dissociation of $FeCl^{2+}$ and $FeNCS^{2+}$ Catalyzed by Fe^{2+}. The reaction rate was found to be dependent upon the concentration of perchloric acid, either in the absence or presence of Fe^{2+}. Since the rate constant k is in linear relationship with the reciprocal of hydrogen

ion concentration at $[Fe^{2+}]_t=0$—0.2 M ($[\ ]_t$ represents the total concentration), as shown in Fig. 2, the reaction scheme and the rate equation are given as follows:

$$\begin{array}{ccc} & \xrightarrow{k_1} Fe^{3+} + X^- & \text{(i)} \\ FeX^{2+} & \\ & + Fe^{2+} \xrightarrow{k_3} Fe^{3+} + FeX^+ & \text{(iii)} \\ H^+ \uparrow\downarrow -H^+ & & \\ & \xrightarrow{k_2} Fe(OH)^{2+} + X^- & \text{(ii)} \\ Fe(OH)X^+ & \\ & + Fe^{2+} \xrightarrow{k_4} Fe(OH)^{2+} + FeX^+ & \text{(iv)} \end{array}$$

$$k = k_1 + \frac{k_2K_H}{[H^+]} + \left(k_3 + \frac{k_4K_H}{[H^+]}\right)[Fe^{2+}], \quad (8)$$

where the individual rate constants are denoted by k_1, k_3, k_2, and k_4 respectively, and the hydrolysis constant of FeX^{2+} is expressed as $K_H=[Fe(OH)X^+][H^+]/[FeX^{2+}]$. In the absence of Fe^{2+}, k_1 and k_2K_H are determined from the intercept and the slope of the straight line obtained by plotting the observed k against $[H^+]^{-1}$, respectively. In the presence of Fe^{2+}, the linear relationship of $\{k-(k_1+k_2K_H/[H^+])\}/[Fe^{2+}]$ against $[H^+]^{-1}$ gives k_3 and k_4K_H from the intercept and the slope of the straight line, respectively, the linearity being shown in Fig. 3.

The experimental results thus obtained are listed in Table 1 for both $X^-=Cl^-$ and SCN^-. From the table, it is clear that Fe^{2+} catalyzes the dissociation

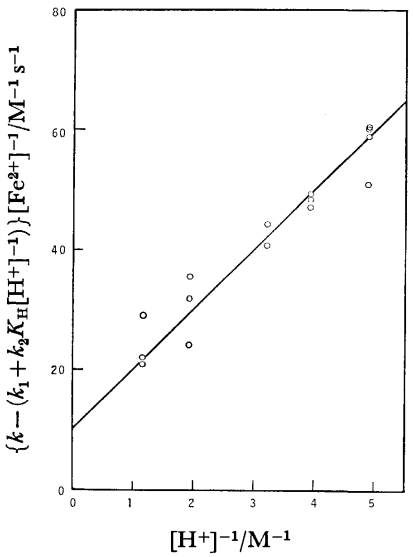

Fig. 3. Linear relationship of $\{k-(k_1+k_2K_H[H^+]^{-1})\}[Fe^{2+}]^{-1}$ *vs.* $[H^+]^{-1}$, the conditions being the same as in Fig. 2.

reaction of FeX^{2+} in both systems, and that the reaction is more accelerated by Fe^{2+} in the $FeNCS^{2+}$ system than in the $FeCl^{2+}$ system, according to the value of k_3/k_1. Further, the unhydrolyzed species, FeX^{2+}, is more easily accelerated to dissociate that the hydrolyzed one, $Fe(OH)X^+$, because k_3/k_1 is larger than k_4/k_2. Anyway, the rate constant k_3 for Reaction iii coincides with the rate constant k_o in the electron transfer reaction through the outer-sphere mechanism, Path-O, which is really the rate constant aimed in the present study.

Dissociation of FeN_3^{2+} Catalyzed by Fe^{2+}. In the reaction system containing N_3^-, the equilibrium, $H^+ + N_3^- \rightleftarrows HN_3$, has to be taken into account, in addition to the equilibria of the complex formation between Fe^{3+} and N_3^-, and of the hydrolysis of Fe^{3+}, in order to calculate the concentrations of free Fe^{3+}, N_3^-, and other relevant species. The equilibrium constants used are as follows: $K_{N_3}=[FeN_3^{2+}]/[Fe^{3+}][N_3^-]=2.7\times10^4$ M^{-1},[5,12] $K_a=[H^+][N_3^-]/[HN_3]=3.0\times10^{-5}$ M,[5] and $K_h=[Fe(OH)^{2+}][H^+]/[Fe^{3+}]=6.7\times10^{-3}$ M[6] at $I=0.55$ M and 10 °C. The reaction temperature chosen was 10 °C, because of the fact that the rate-determining step in the electron transfer reaction between Fe^{2+} and FeN_3^{2+} is the first stage among the successively occurring elementary processes below 13 °C, above which temperature the reaction mechanism would be more complicated.[5]

The rate measurements were performed at $[Fe(ClO_4)_3]_t=[NaN_3]_t=1.96\times10^{-3}$ M, $[HClO_4]_t=0.01$—0.5 M, $[Fe(ClO_4)_2]_t=0$—0.08 M, $I=0.55$ M and 10 °C. The observed k_{app} was transformed into k according to Eq. 7, since the values of the denominator on the right-hand side in Eq. 7 are no longer regarded to be nearly equal to unity for $X^-=N_3^-$, under the present conditions. When all the observed k's are plotted against $[H^+]$, k first decreases rapidly with the increase in $[H^+]$ in its low concentration range, and then k grows up almost linearly with a mild slope at higher $[H^+]$ range. Moreover, another linear relationship is also seen between k and $[H^+]^{-1}$ only within the lower $[H^+]$ range, $[H^+]=0.01$—0.075 M, namely $[H^+]^{-1}=13$—100 M^{-1}, as is shown in Fig. 4. Many observed points appear within the limited range as shown in the figure, independently of $[Fe^{2+}]$. Accordingly, the rate constant k can be expressed by Eq. 9, in which a term proportional to $[H^+]$ is supplemented to Eq. 8. This supplemented term may correspond to Reaction v, as shown below.

$$k = k_1 + \frac{k_2K_H}{[H^+]} + \left(k_3 + \frac{k_4K_H}{[H^+]}\right)[Fe^{2+}] + k_5[H^+], \quad (9)$$

Table 1. The individual rate constants for the dissociation reactions of $FeCl^{2+}$, $FeNCS^{2+}$, and FeN_3^{2+} catalyzed by Fe^{2+}

X^-	I / M	Temp / °C	k_1 / s^{-1}	k_2K_H / M s^{-1}	k_3 / M^{-1} s^{-1}	k_4K_H / s^{-1}	k_5 / M^{-1} s^{-1}	k_3/k_1 / M^{-1}	k_4/k_2 / M^{-1}
Cl^-	1.5	25	1.3	6.3	10.0	9.9	—	7.7	1.6
SCN^-	0.5	25	0.80	0.21	23	1.1	—	29	5.2
SCN^-	1.5	25	0.39	0.16	30	2	—	77	13
N_3^-	0.55	10	5.3×10^{-2}	1.4×10^{-2}	≈0	≈0	8.5×10^{-2}	0	0

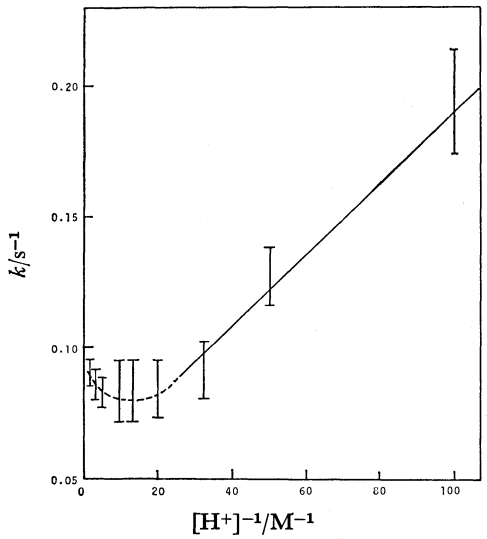

Fig. 4. Linear relationship of k *vs.* $[H^+]^{-1}$, at $[Fe^{3+}]_t = [N_3^-]_t = 1.96\times10^{-3}$ M, $[H^+]=0.01$—0.05 M ($[H^+]^{-1}=100$—20 M^{-1}), $I=0.55$ M, and 10 °C.
About 20 observed points scattering randomly between the two limiting values indifferent to the concentrations of existing Fe^{2+}, $[Fe^{2+}]_t=0.025$, 0.050, or 0.075 M, at each $[H^+]^{-1}$ values.

$$FeN_3^{2+} + H^+ \xrightarrow{k_5} Fe^{3+} + HN_3. \qquad (v)$$

Reaction v is a hydrogen ion-assisted dissociation of FeN_3^{2+}, where H^+ acts similarly as a catalyst in place of Fe^{2+} in Reaction iii.

Figure 4 looks like indicating that the rate constant k is probably unaffected by the concentration of Fe^{2+} within the experimental errors. The least squares method based on 128 observations give the most probable individual rate constants as follows:

$$k_1 = (5.34\pm0.22)\times10^{-2}\ s^{-1}$$
$$k_2K_H = (1.37\pm0.05)\times10^{-2}\ s^{-1}$$
$$k_3 = (0.00\pm0.43)\times10^{-1}\ M^{-1}\ s^{-1}$$
$$k_4K_H = (0.02\pm0.09)\times10^{-2}\ s^{-1}$$
$$k_5 = (8.52\pm0.72)\times10^{-2}\ M^{-1}\ s^{-1}.$$

With fairly large errors, k_3 and k_4K_H should be regarded as zero, suggesting that the FeN_3^{2+} dissociation is not catalyzed by Fe^{2+}. These rate constants are listed in Table 1, along with those for $X^-=Cl^-$ and SCN^-.

The Ratio of Outer-sphere Mechanism in the Electron Transfer Reaction. As has been described above, the electron transfer reaction between Fe^{2+} and FeX^{2+} proceeds through either the inner-sphere or the outer-sphere mechanism or through both. The observed k_3 gives directly the rate constant k_o in the outer-sphere path. In Table 2, the overall rate constant k_E reported by previous workers, the outer-sphere rate constants k_o, and their ratios r defined by Eq. 5 are listed. According to the table, the electron transfer between Fe^{2+} and $FeNCS^{2+}$ occurs wholly through the outer-sphere path. On the contrary, the electron transfer between Fe^{2+} and FeN_3^{2+} occurs wholly through the inner-sphere path, while that between Fe^{2+} and $FeCl^{2+}$ undergoes both paths competitively.

TABLE 2. THE TOTAL AND THE OUTER-SPHERE RATE CONSTANTS, k_E AND k_o, AND THEIR RATIO r OF THE ELECTRON TRANSFER REACTION

X^-	I / M	Temp / °C	k_o / $M^{-1}\ s^{-1}$	k_E[a] / $M^{-1}\ s^{-1}$	r / %
Cl^-	1.5	25	10	45[6,8]	44
SCN^-	0.5	25	23	41.5[3]	≈100
N_3^-	0.55	10	≈0	4.75×10^3 [5]	≈0

a) Corrected to the given temperatures and ionic strengths.

To compare the two redox mechanisms, N_3^- and SCN^- have been frequently used, on the basis that the former ion is capable of bridging two reactants, resulting in the inner-sphere mechanism, whereas the latter ion is not.[13,14] The assumed intermediate complex in the inner-sphere mechanism bridged by N_3^- may be $[Fe\text{-}N\text{-}N\text{-}N\text{-}Fe]^{4+}$ with a linear and symmetric structure. On the other hand, SCN^- is linear, but not symmetric having a larger S atom on one end than an N atom on the other end. Thus, the coordination of S with Fe^{2+} in the binuclear structure, $[Fe^{III}\text{-}N\text{-}C\text{-}S\text{-}Fe^{II}]$, will be sterically unfavorable as a bridging ligand.

An additional condition is required for the inner-sphere mechanism that at least one of the two reactants should be substitution-labile, and this is fully satisfied in Fe^{2+}. Since the rate constant for the solvent water exchange reaction on Fe^{3+}_{aq} has been known to be $1.6\times10^2\ s^{-1}$ at 25 °C, that on Fe^{2+}_{aq} may be larger than this value.[15] In this connection, the large value of $k_E(N_3^-)/k_E(SCN^-)$ ratio is usually believed to give a firm indication of the inner-sphere mechanism for $CoX(NH_3)_5^{2+}/Fe^{2+}_{aq}$,[16] $CoX(NH_3)_5^{2+}/Eu^{2+}_{aq}$,[17] *etc.*

For Cl^-, both mechanisms are probable. Chloride ion has more than two lone electron-pairs which may be favorable to bridge the two reactants, leading to the inner-sphere path, so-called "chlorine atom transfer." But in the Cl^--bridged binuclear intermediate, $[Fe\text{-}Cl\text{-}Fe]^{4+}$, the nuclear distance between the two metal ions is too short to overcome the Coulombic repulsion between electric charges of the same sign, as compared with the case of N_3^- with the longer nuclear distance between the two iron ions, this fact being unfavorable to the inner-sphere mechanism. After all, the two mechanisms compete with each other in the Cl^- system. Sutin and his co-workers[8] carried out similar experiments, and concluded that the electron transfer between Fe^{2+} and $FeCl^{2+}$ proceeded mainly by a chloride-bridged inner-sphere activated intermediate at $I=3.0$ M and 25 °C, ignoring the process between Fe^{2+} and $Fe(OH)Cl^+$, namely the fourth term $(k_4K_H/[H^+])[Fe^{2+}]$ in Eq. 8, in the dissociation reaction of $FeCl^{2+}$. The forward and reverse reactions for the systems Co^{II}(chelate) and $Fe^{III}(CN)_5X$ are also considered to have trends of taking place through both mechanisms.[18] This is probably due to the fact that the bridging ligand, CN^-, is not only unsymmetric but also still too small to separate the electric charges on two reacting ions in its binuclear intermediate, inspite of its strong coordinating ability.

If the activation energies of the electron transfer reaction differed to a considerable extent between the two mechanisms, the ratio r would vary with temperature, and finally the reaction would go almost 100% *via* one of the two mechanisms at appropriately elevated or lowered temperatures. The systems of SCN^- and N_3^- observed above are just instances of such two limiting cases, respectively, while the Cl^- system may probably be transient between the two.

In conclusion, the symmetry and the length or size of the bridging ligand may be important factors to decide an inner-sphere mechanism or an outer-sphere one, or both in parallel.

Difference between Reaction Mechanisms of Outer-sphere Electron Transfer and Ligand Exchange. In the above descriptions, the electron transfer reaction through the outer-sphere mechanism (Path-O, k_o) and the dissociation reaction catalyzed by Fe^{2+} (Path-iii, k_3) are expressed by an identical equation.

$$Fe^{2+} + FeX^{2+} \longrightarrow Fe^{3+} + FeX^{+}$$

When one of the iron species is labeled by the isotopic tracer ^{59}Fe (represented by *Fe), however, two distinctly different reactions will become possible. If only one electron is really transferred from Fe^{2+} to FeX^{2+} with no change in chemical bondings (the outer-sphere electron transfer), the reaction is expressed as follows:

$$Fe^{2+} + {}^*FeX^{2+} \longrightarrow Fe^{3+} + {}^*FeX^{+}. \qquad (E)$$

On the other hand, if X^- is transferred from FeX^{2-} to Fe^{2+} without altering their oxidation states (the ligand exchange), the labeled Fe(III) remains still as Fe(III).

$$Fe^{2+} + {}^*FeX^{2+} \longrightarrow FeX^{+} + {}^*Fe^{3+} \qquad (S)$$

These two chemical reactions, E and S, involve quite different elementary processes with each other, but in the present experimental method, we cannot distinguish between them explicitly.

Since the unimolecular dissociation reaction of FeX^{2+}, $FeX^{2+} \rightarrow Fe^{3+} + X^-$ (k_1), has been revealed to be very slow as shown in Table 1,[19] Reaction S might be reasonably supposed to occur in a way that Fe^{2+} encounters directly with FeX^{2+} before the spontaneous decomposition of FeX^{2+}, forming an inner-sphere intermediate. If so, N_3^- may be considered to be most favorable for Reaction S due to its largest bridging ability among three ligand anions. This expectation, however, is denied by the results in Table 1 which informs us that k_3 is almost zero in the case of N_3^-. Therefore, Reaction S may be impossible, and the acceleration of the FeX^{2+} dissociation by Fe^{2+} proceeds probably through the outer-sphere electron transfer due to Path-O, with the rate constant k_3 which is essentially the same with k_o.

When Mg^{2+}, Co^{2+}, Ni^{2+}, or Mn^{2+} was used in place of Fe^{2+} in the $FeCl^{2+}$ dissociation reaction, the reaction was found to be little affected by the presence of these ions.[8] This fact indicates that these metal ions except Fe^{2+} work neither as Cl^- acceptor (Reaction S) nor as electron donor (Reaction E). Only Fe^{2+} can catalyze the dissociation reaction of $FeCl^{2+}$ *via* the electron transfer process of the outer-sphere mechanism.

Reaction Process of Vanadium Tetrachloride with Ammonia in the Vapor Phase and Properties of the Vanadium Nitride Formed

Yuzo Saeki,* Takashi Shimizu, Akimasa Yajima, and Ryoko Matsuzaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received February 19, 1982)

The reaction products of gaseous VCl_4 with ammonia were $VCl_4 \cdot 4NH_3$ at 200 °C, $VCl_4 \cdot 4NH_3$, VN_x, and NH_4Cl at 250—550 °C, and VN_x and NH_4Cl at 600—1000 °C. At 1100 °C, small amounts of VCl_2 and HCl were formed in addition to VN_x and NH_4Cl. The N/V atomic ratio, x, of the VN_x formed was 1.20 at 600 °C, 1.15 at 700 °C, 1.14 at 800 °C, and 1.13 at 900 and 1000 °C. The lattice constants of the VN_x formed were shown. The reaction process of gaseous VCl_4 with ammonia can be represented as follows: The reaction of gaseous VCl_4 with ammonia first occurs to form $VCl_4 \cdot 4NH_3$. Above about 215 °C, the reaction of $VCl_4 \cdot 4NH_3$ with ammonia also occurs to form VN_x. At 1100 °C, in addition to these reactions, the reaction of gaseous VCl_4 with hydrogen formed by the thermal dissociation of ammonia occurs to form VCl_2. On heating the VN_x, formed by the vapor-phase reaction, at temperatures higher than 500 °C in an argon atmosphere, the value of x decreased with the increase in the heating temperature to 1.03 at 900—1000 °C.

The vapor-phase reaction of transition metal chlorides with ammonia has recently become important for the preparation of fine powders of transition metal nitrides, which are acquiring importance as new industrial materials. Concerning the formation of vanadium nitride powders by the vapor-phase reaction of vanadium tetrachloride (VCl_4) with ammonia, Hojo *et al.*[1] have studied the preparation of fine vanadium nitride powders by a vapor-phase reaction of the VCl_4–NH_3–H_2–N_2 system at 700—1200 °C with emphasis on the effects of reaction conditions on particle size and chemical composition. However, no information is at present available on the reaction process of VCl_4 with ammonia in the vapor phase.

In this paper, the reaction products of gaseous VCl_4 with ammonia at 200—1100 °C were examined in detail. In order to elucidate the reaction process of gaseous VCl_4 with ammonia, the behavior of $VCl_4 \cdot 4NH_3$, which was newly-found during the reaction process, on heating in an ammonia stream and the thermal dissociation of ammonia under the experimental conditions in this work were examined. The N/V atomic ratios, lattice constants, and thermal stability in an argon atmosphere of the vanadium nitrides formed at various temperatures were examined. The vanadium nitrides formed were also examined by electron microscopy.

Experimental

Materials. The VCl_4 used was prepared by the reaction of vanadium (V>99.8%, Atomergic Chemetals Corp., U.S.A.) with chlorine at 500 °C.[2] The chemical analysis gave V, 26.4; Cl, 73.5% (calcd for VCl_4:V, 26.43; Cl, 73.57%). The Ammonia was dried by passing it over sodium hydroxide granules.

Experimental Procedures. A transparent quartz reaction tube (1000 mm length) was used for examining the reaction products of gaseous VCl_4 with ammonia at various temperatures. Gaseous VCl_4 was formed by heating liquid VCl_4 (22 g) at 125 °C and carried by a stream of argon (50 cm³/min) into the reaction zone (28 mm i.d., 250 mm length) held at a specified temperature. The VCl_4 inlet tube consisted of two concentric tubes. Gaseous VCl_4 carried by argon was introduced through the inner tube and the outer tube was used for introducing argon (50 cm³/min) as a sheath gas to prevent formation of vanadium nitride deposits at the chloride inlet tube. Ammonia was simultaneously introduced at a flow-rate of 100 cm³/min into the reaction zone through a separate tube. The mean flow-rate of gaseous VCl_4 was 6.0 cm³/min. A quartz tube was inserted inside the reaction tube to make the removal of the reaction product easier. The reaction was allowed to proceed for 2 h.

The by-product ammonium chloride (NH_4Cl) which deposited outside the reaction zone together with the vanadium nitride formed was separated by heating the mixture in an argon stream at 400 °C (the sublimation point of NH_4Cl: 339 °C)[3] for 10—15 h.

Analytical. The vanadium, chlorine and ammonia contents of the product formed were determined by chelatometric titration,[4] gravimetric method as AgCl, and the Kjeldahl method, respectively, after dissolving the sample in dilute nitric acid.

X-Ray analysis of the solid product was performed with an X-ray powder diffractometer equipped with a proportional counter using Ni filtered Cu radiation. The sample chamber of the diffractometer was maintained under a dry nitrogen atmosphere, if necessary, to prevent any contamination of the sample with atmospheric moisture during the irradiation. The lattice constant of the vanadium nitride was calculated based on the X-ray diffraction data obtained by using silicon powders as an internal standard under a scanning speed of 1/2—1/4°/min.

The sensitivity of the quartz helix used for thermogravimetry (TG) was approximately 72 mm/g. The sample (0.2 g) was heated at a rate of 2.5 °C/min and the flow-rate of ammonia was maintained at 50 cm³/min.

The N/V atomic ratio of the vanadium nitride formed was evaluated as follows: The sample vanadium nitride was oxidized to V_2O_5 by heating in an oxygen atmosphere up to 550 °C, using a Shimazu high-sensitive thermal balance Model TGA31. The amount of vanadium in the sample was calculated from the amount of V_2O_5 formed. The amount of nitrogen was determined as the difference between the amount of initial sample and that of the vanadium. The value of the N/V atomic ratio was evaluated with an accuracy within ± 0.01.

Throughout this work, the VCl_4 and the reaction products were handled in an argon atmosphere to prevent any contamination with atmospheric moisture.

Results and Discussion

Reaction Products of Gaseous Vanadium Tetrachloride with Ammonia. The products formed by heating gaseous VCl_4 in an ammonia stream at various temperatures were examined by X-ray analysis[5-7] and chemical analysis. Reaction temperatures above 200 °C were employed, because gaseous VCl_4 was generated at 125 °C. The results are shown in Table 1. Unreacted VCl_4 was not observed throughout the temperature range in this work. The products were obtained inside and outside the reaction zone below 550 °C. The portion of the product obtained outside the reaction zone increased with the increase in the reaction temperature and above 600 °C all the products were obtained outside the reaction zone.

The product formed at 200 °C showed a hitherto unknown X-ray diffraction pattern which was different from those of known vanadium compounds. The chemical analysis of the product gave V, 19.3; Cl, 54.5; NH_3, 26.2%. The ratio of V:Cl:NH_3 was calculated to be 1:4.06:4.06. This result was considered to indicate that the product formed at 200 °C had a composition of $VCl_4 \cdot 4NH_3$ (calcd for $VCl_4 \cdot 4NH_3$: V, 19.53; Cl, 54.36; NH_3, 26.11%). But the observed values for chlorine and ammonia were slightly higher than the calculated values. The evaporation of VCl_4 on heating liquid VCl_4 is accompanied by the decomposition of liquid VCl_4, $VCl_4(l) \rightarrow VCl_3(s) + 1/2Cl_2(g)$.[8] The resulting chlorine was considered to react with ammonia to form NH_4Cl. Accordingly, the amount of chlorine formed by heating liquid VCl_4 at 125 °C for 2 h was examined. The result showed that 0.07 g of chlorine was formed during the heating. From this result, the product formed at 200 °C was considered to be $VCl_4 \cdot 4NH_3$ containing a small amount of NH_4Cl. The chemical analysis of the sample obtained after the removal of the NH_4Cl from the product at 190 °C in an ammonia atmosphere gave V, 19.5; Cl, 54.3; NH_3, 26.0%. From the results, the product formed at 200 °C was confirmed to have the composition of $VCl_4 \cdot 4NH_3$.

The products formed at 250 and 300 °C were identified by X-ray analysis as a mixture of $VCl_4 \cdot 4NH_3$ and a small amount of NH_4Cl. However, it was found that when the products were treated with 1 M hydrochloric acid, $VCl_4 \cdot 4NH_3$ and NH_4Cl were dissolved leaving a small residue of black powder which was identified as vanadium nitride (VN_x) by X-ray and chemical analyses. These results indicated that a small amount of VN_x was formed in addition to $VCl_4 \cdot 4NH_3$ and NH_4Cl at 250 and 300 °C. The products formed at 500 and 550 °C were identified as a mixture of VN_x and NH_4Cl by X-ray analysis. But, the formation of a small amount of $VCl_4 \cdot 4NH_3$ in addition to these products was found by chemical analysis. Contrary to the experimental results obtained for the reaction products at temperatures below 1000 °C, a small amount of VCl_2 was formed in addition to VN_x and NH_4Cl at 1100 °C. It was also found that hydrogen chloride (HCl) was formed.

Table 1. Reaction products of gaseous VCl_4 with ammonia at various temperatures

Temp/°C	Products
200	$VCl_4 \cdot 4NH_3$
250	$VCl_4 \cdot 4NH_3 \gg VN_x$; NH_4Cl
300	$VCl_4 \cdot 4NH_3 \gg VN_x$; NH_4Cl
350	$VCl_4 \cdot 4NH_3 > VN_x$; NH_4Cl
400	$VCl_4 \cdot 4NH_3 > VN_x$; NH_4Cl
450	$VN_x > VCl_4 \cdot 4NH_3$; NH_4Cl
500	$VN_x \gg VCl_4 \cdot 4NH_3$; NH_4Cl
550	$VN_x \gg VCl_4 \cdot 4NH_3$; NH_4Cl
600—1000	VN_x; NH_4Cl
1100	$VN_x > VCl_2$; NH_4Cl, HCl

Reaction Process of Gaseous Vanadium Tetrachloride with Ammonia. To elucidate the reaction process of gaseous VCl_4 with ammonia, the behavior of $VCl_4 \cdot 4NH_3$, formed during the reaction process, on heating in an ammonia stream and the thermal dissociation of ammonia[9] under the experimental conditions in this work were examined.

Behavior of $VCl_4 \cdot 4NH_3$ on Heating in an Ammonia Stream: TG of $VCl_4 \cdot 4NH_3$ (0.2 g) in an ammonia stream (50 cm^3/min) was carried out. When ammonia was introduced at room temperature, the sample gained weight gradually and reached a constant value after 6 h, showing about 10% increase in weight. After the weight increase, the sample gave the same X-ray diffraction pattern with the initial sample. When the heating of the sample was started, the sample lost weight gradually and reached the initial weight at 190 °C. The TG curve of $VCl_4 \cdot 4NH_3$ in an ammonia stream above 200 °C is shown in Fig. 1.

$VCl_4 \cdot 4NH_3$ lost weight above 215 °C. The weight loss was accompanied by the vaporization of NH_4Cl and a small amount of $VCl_4 \cdot 4NH_3$. The sample after heating up to 450 °C was found to be VN_x by X-ray analysis.

In order to obtain more detailed information on the behavior of $VCl_4 \cdot 4NH_3$ on heating in an ammonia stream, $VCl_4 \cdot 4NH_3$ (1.0 g) in a quartz boat (70 mm length, 15 mm width, 7 mm depth) was placed in a straight reaction tube (28 mm i.d., 1000 mm length). Ammonia was introduced into the reaction

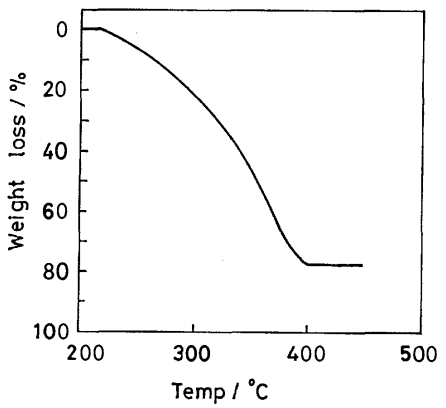

Fig. 1. TG curve of $VCl_4 \cdot 4NH_3$ in an ammonia stream.

Table 2. Experimental results for $VCl_4 \cdot 4NH_3$ on heating in an ammonia stream

Heating temp/°C	Products		Unreacted $VCl_4 \cdot 4NH_3$/%
	In the boat	Outside the boat	
250	$VN_x(<1)$	$VCl_4 \cdot 4NH_3(1)$, NH_4Cl	98
300	$VN_x(7)$	$VCl_4 \cdot 4NH_3(7)$, NH_4Cl	86
350	$VN_x(86)$	$VCl_4 \cdot 4NH_3(10)$, $VN_x(<1)$, NH_4Cl	3
400	$VN_x(92)$	$VCl_4 \cdot 4NH_3(5)$, $VN_x(2)$, NH_4Cl	<1
450	$VN_x(95)$	$VCl_4 \cdot 4NH_3(3)$, $VN_x(2)$, NH_4Cl	—

Note: the value in parentheses is mole percentage of $VCl_4 \cdot 4NH_3$ converted to the product.

tube at a flow-rate of 100 cm³/min. The sample part was then placed in the centre of an electric furnace (300 mm heating length) maintained at a specified temperature for 1 h. The products obtained inside and outside the boat were examined by X-ray and chemical analyses. The results are shown in Table 2.

The results showed that $VCl_4 \cdot 4NH_3$ reacted with ammonia to form VN_x above about 215 °C and a part of the $VCl_4 \cdot 4NH_3$ vaporized. The formation of a small amount of VN_x outside the boat was considered to indicate that the reaction of gaseous $VCl_4 \cdot 4NH_3$ with ammonia also occurred above about 350 °C.

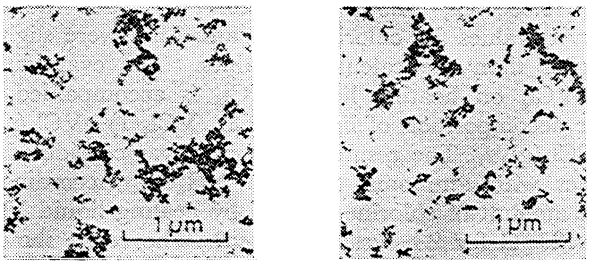
Thermal Dissociation of Ammonia: Ammonia alone was introduced at a flow-rate of 100 cm³/min into the reaction zone held at a specified temperature and the total volume of nitrogen and hydrogen, formed by the dissociation of ammonia, was measured. From the results, the percentage of the dissociated ammonia was found to be <1% at 800 °C, 1% at 900 °C, 2% at 1000 °C, and 6% at 1100 °C.

Based on the experimental results mentioned above, the reaction process of gaseous VCl_4 with ammonia was discussed. As shown in Table 1, $VCl_4 \cdot 4NH_3$ alone was formed at 200 °C. This fact indicates that the reaction of gaseous VCl_4 with ammonia first occurs to form $VCl_4 \cdot 4NH_3$. The VN_x formed by the vapor-phase reaction above 250 °C (Table 1) are considered to be due to the reaction of $VCl_4 \cdot 4NH_3$ with ammonia, because the $VCl_4 \cdot 4NH_3$ reacts with ammonia above about 215 °C to form VN_x. The formation of VCl_2 at 1100 °C (Table 1) is considered to be due to the reaction of gaseous VCl_4 with hydrogen[2] formed by the thermal dissociation of ammonia.

Properties of the Vanadium Nitride Formed. The N/V atomic ratios of VN_x formed by the vapor-phase reaction at 600—1000 °C are shown in Table 3. Prior to this examination, the VN_x obtained after the removal of by-product NH_4Cl at 400 °C in an argon stream was dissolved in dilute nitric acid and the presence of residual NH_4Cl was checked by chemical analysis.[10] From the results, the VN_x formed at 1000 °C was found to contain no residual NH_4Cl. The VN_x formed at 600—900 °C was found to contain a small amount of residual NH_4Cl; The NH_4Cl content was 0.3% for the VN_x formed at 900 °C, 2.4% at 800 °C, 2.6% at 700 °C, and 3.6% at 600 °C. But, further separation of the NH_4Cl was not possible as the N/V atomic ratio of VN_x decreased on heating at temperatures higher than 500 °C in an argon atmosphere, as described later. So, for the evaluation of the N/V atomic ratios of the VN_x formed below 900 °C, the initial weight of the sample was corrected by subtracting the amount of NH_4Cl contained, because the NH_4Cl was vaporized during the oxidation.

Table 3. N/V atomic ratio and lattice constant of the VN_x formed by the reaction of gaseous VCl_4 with ammonia

Formation temp/°C	x in VN_x	a_0/Å
600	1.20	Not determined
700	1.15	4.115
800	1.14	4.126
900	1.13	4.133
1000	1.13	4.133



(a) 900 °C (b) 1000 °C

Fig. 2. Electron micrographs of $VN_{x(x=1.13)}$ formed at 900 and 1000 °C.

It has been known that VN_x phase has a NaCl structure.[7] The lattice constant of VN_x formed at each temperature is also shown in Table 3. As X-ray diffraction lines of the $VN_{1.20}$ formed at 600 °C were relatively weak and diffuse, the exact value of the lattice constant was not calculated.

The VN_x formed by the vapor-phase reaction at 600—1000 °C was examined by electron microscopy. The typical micrographs of the VN_x are shown in Fig. 2. The VN_x formed is relatively uniform, ultrafine powders with particle diameters of the order of 1/100 μm.

Finally, to obtain knowledge of the thermal stability of the VN_x formed by the vapor-phase reaction, the N/V atomic ratio of the sample obtained by heating $VN_{1.20}$ formed at 600 °C, which had the largest N/V atomic ratio in the VN_x formed in this work, at various temperatures in an argon atmosphere was examined. The results are shown in Fig. 3. In addition,

it was found that the residual NH_4Cl in the VN_x was completely removed by the heating above 900 °C.

The results indicated that when the VN_x formed by the vapor-phase reaction was heated in an argon atmosphere at temperatures higher than 500 °C, the N/V atomic ratio decreased and became close to that of the stoichiometric nitride; The value of x was 1.03 at the heating temperatures of 900 and 1000 °C. Hojo *et al.*[1] reported that when the VN_x with $x>1$ was heated *in vacuo* up to 1150 °C, the x value reduced to 1.02.

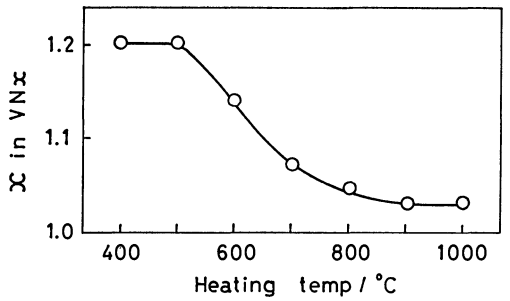


Fig. 3. N/V atomic ratio of VN_x obtained after heating $VN_{1.20}$ at various temperatures in an argon atmosphere for 1 h.

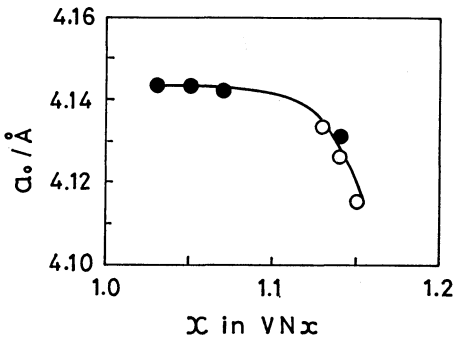

Fig. 4. Lattice constants (a_0) of VN_x with various x values.
●: From VN_x obtained after the heating of $VN_{1.20}$,
○: from VN_x formed by the reaction of gaseous VCl_4 with ammonia (Table 3).

The lattice constants of the VN_x with various x values, obtained in this work, are shown in Fig. 4.

The N/V atomic ratio of VN_x obtained after heating $VN_{1.20}$ in an argon atmosphere at each temperature was found to be lower than that of the VN_x formed by the vapor-phase reaction at the same temperature (Table 3). The difference in the N/V atomic ratio became larger with the increase in the temperature. These facts are considered to be due to the presence of nitrogen during the reaction, because the dissociation pressure of ammonia is relatively high even at low temperatures and markedly increases with the increase in the temperature.[9] This consideration was supported by the fact that no change in the N/V atomic ratio of the $VN_{1.13}$ formed at 1000 °C by the vapor-phase reaction was observed after heating at 1000 °C in an ammonia stream for 1 h.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56470058 from the Ministry of Education, Science and Culture.

Pyrolytic Sulfurization Gas Chromatography. XII. The Simultaneous Determination of the Atomic Ratio between C, H, O, and N in an Organic Compound at the Centimilligram Level

Tadashi HARA* and Fujio OKUI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received February 25, 1982)

The atomic ratio between C, H, O, and N in an ordinary organic compound and a metal organic chelate compound could be simultaneously and satisfactorily determined by the use of 30—130 μg of a sample which cannot be accurately weighed by a microbalance or an ultramicrobalance. This was done by adopting the following modifications: 1) The amount of S was reduced to 0.5 mg from the 5 mg used in the previous studies; 2) the stainless steel column in the gas chromatograph was replaced by a Teflon column; 3) the poly(vinyl chloride) and silicone rubber tubes were replaced by stainless steel and copper tubes; and 4) a correction procedure was established for the analysis of a small amount of a sample.

With the objective of establishing a new elemental analysis method by which several elements can be simultaneously determined, pyrolytic sulfurization gas chromatography(PSGC) was originated and has been investigated fundamentally by the present authors. It has been successfully applied to the simultaneous determination of the atomic ratio between C, H, O, and N in an ordinary organic compound,[1,2] a metal organic chelate compound,[3] a polymer,[4] and an organic halogen compound.[5,6]

In conventional organic elemental analysis, the atomic ratio between C, H, O, and N is determined by combining the content of C, H, and N obtained by a CHN analyzer with the content of O obtained by an oxygen analyzer. To obtain the exact atomic ratio between C, H, O, and N, a sample of more than either 1 mg or 100 μg must be weighed by a microbalance(sensitivity 1 μg) or an ultramicrobalance(sensitivity 0.1 μg) respectively. On the other hand, since one of the most remarkable characteristics of PSGC is that the atomic ratio between C, H, O, and N can be simultaneously determined without weighing the sample, the amount of sample necessary for an analysis by PSGC can be decreased to a minimum so long as the products can be detected by gas chromatography. The present study has been carried out for the purpose of decreasing the amount of sample necessary for an analysis by PSGC.

When about 50 μg of a sample, which is one tenth of the amount of a sample in the ordinary PSGC method, was analyzed by the conventional PSGC method, the carbon content was found to be less than the theoretical value. This was attributed to the partial dissolution of carbon disulfide(CS_2) into residual sulfur. Therefore, the amount of S was reduced to 0.5 mg from the 5 mg used in the conventional PSGC method. Thus, the atomic ratio between C, H, O, and N could be simultaneously determined by the use of 30—130 μg of a sample and 0.5 mg of S. In addition to ordinary compounds, metal organic chelate compounds, which are difficult to analyze even by mass spectrometry, could be analyzed with satisfactory results.

Experimental

Reagents. All the reagents used as the analytical samples were of a reagent grade for elemental analysis except for cyanoguanidine, which was of a reagent grade for the melting-point standard.

Apparatus. The displacement apparatus,[1] which had been used for the preparation of the ampule containing a sample and S, was modified as follows: As the charging tube of He, a stainless steel tube (1 mm i.d., 1.5 mm o.d.) was used instead of a poly(vinyl chloride) tube, and as the exhaust tube of air, a copper tube (4 mm i.d., 5 mm o.d.) was used instead of a silicone rubber tube. To improve the precision and accuracy of the gas-chromatographic analysis, Teflon columns were used instead of the stainless steel columns used in the previous studies.

The other equipment used in the experiment was the same as that previously reported.

Procedure. A definite volume of a powdered sample was placed in a reaction tube by the use of the sampler[1]-I, which was composed of a glass capillary tube and a plunger (13%Rh–Pt alloy, 0.2 mm diam.) used to push the sample into the reaction tube. About 0.5 mg of S was added to it by the use of the sampler-II, which was also composed of a glass capillary tube and a plunger (Ni–Cr alloy, 0.4 mm diam.). According to this procedure, S could be taken in the range from about 0.45 mg to 0.55 mg. The reaction tube containing the sample and S thus obtained was treated by the same procedure as in the previous study.[7]

Results and Discussion

Amounts of Sample and S. In order to minimize the amount of sample necessary for the PSGC analysis, the effect of the amount of the sample on the analytical values was examined by the use of alanine as a standard sample in the following manner. A known amount of a sample was made to react with 5 mg of S in an ampule, and the reaction products were analyzed by the ordinary PSGC method. The peak areas of the products were then plotted against the weight of the sample (Fig. 1). Figure 1 shows that the calibration curves of all products pass through the point of origin of the coordinate axis except for that of CS_2. Since the peak-area ratio of each product to hydrogen sulfide(H_2S) is required to be a definite value in PSGC, these ratios were also calculated

Table 1. Effect of column material on the fluctuation of the peak-area ratios[a)]

Column material	Sulfur (mg)	Sample (μg)	C.V.(%)[b)]				
			N_2	CO_2	H_2S	COS	CS_2

and plotted against the weight of the sample (Fig. 2). As can be seen from Fig. 2, the peak-area ratio of CS_2 to H_2S decreases with a decrease in the weight of the sample. These results could be explained by the fact that CS_2 as a reaction product partly remained in the residual sulfur because of its dissolution. Therefore, it was necessary to reduce the amount of S with a decrease in the amount of the sample. Almost entirely satisfactory results for 30—130 μg of the sample were obtained by the use of about 0.5 mg of S, as will be shown later.

Improvement of the Apparatus. The analytical value obtained under the experimental conditions of the conventional PSGC method gave an error increasing with a decrease in the amount of sample. In order to improve the precision and accuracy of the analytical data, 1) the column material in a gas chromatograph and 2) the displacement apparatus were modified in the following way. 1) The stainless steel columns used in the previous studies were replaced by Teflon columns under the same gas-chromatographic conditions. The present column material was compared with the previous one by analyzing *ca.* 0.5 mg and *ca.* 50 μg of alanine samples (Table 1). Judging from the results shown in Table 1, the Teflon column is superior to the stainless steel column. 2) To minimize the fluctuation in the analytical value of nitrogen (N_2)(Table 1) which seemed to be due to the contamination of air passing through the tubes of poly(vinyl chloride) and silicone rubber, the displacement apparatus was modified in the following manner. As the charging tube of He, a stainless steel tube(1 mm i.d., 1.5 mm o.d.) was used instead of a poly(vinyl chloride)tube, and as the exhaust tube of air, a copper tube(4 mm i.d., 5 mm o.d.) was used instead of a silicone rubber tube. The present displacement apparatus was compared with the previous one by analyzing *ca.* 50 μg of alanine (Table 2). Table 2 shows that the present apparatus is superior to the previous one with regard to the fluctuation of the analytical data of N_2. As a result of the above-mentioned improvements, it is suggested that the atomic ratio between C, H, O, and N for centimilligrams of a sample can be simultaneously determined with the same pre-

cision and accuracy as in the ordinary PSGC method. The following investigations were undertaken by the use of the modified apparatus.

Sampling Amounts. Since it was difficult to weigh centimilligrams of a sample accurately by means of a microbalance, the weight of a sample was calculated approximately by the use of Eq. 1 from the analytical data:

$$W(\mathrm{mg}) = \frac{1}{F}\Sigma M(\mathrm{X})K(\mathrm{X})A(X), \quad (1)$$

where W is the weight of a sample, X is the reaction product, $M(\mathrm{X})$ is the value obtained by subtracting the amount of S from the formula weight of X, $K(\mathrm{X})$ is the calculation factor of X, $A(\mathrm{X})$ is the peak area of X, and F is the conversion factor obtained by the use of Eq. 2 from the calibration curve of H_2S in Fig. 1:

$$F = \frac{M_t}{3.50w}A(\mathrm{H_2S}), \quad (2)$$

where w is the weight of alanine, M_t is the molecular weight of alanine, and 3.50 indicates the mole number of H_2S produced from 1 mol of alanine. By the use of Eq. 1, the weight of a sample could be calculated within a relative error of about $\pm 10\%$. Sulfur in the range from about 0.45 mg to 0.55 mg was conveniently sampled by means of the sampler-II.

Effect of the Sample Amount on the Peak-area Ratio. Centimilligrams of alanine as a standard sample was made to react with *ca.* 0.5 mg of S in an ampule and then analyzed by PSGC. The peak-area ratios of the products to H_2S were plotted against the calculated weight of a sample (Fig. 3). It is apparent from Fig. 3 that the atomic ratio between C, H, O, and N in a sample can be determined by the use of a sample in the range from about 50 μg to 130 μg, for the peak-area ratios of all the products to H_2S indicated definite values.

Correction of Blank Values. As can be seen from Fig. 3, the peak-area ratio of carbonyl sulfide(COS) to H_2S increased with a decrease in the amount of a sample to less than 50 μg, while the peak-area ratio of CS_2 to H_2S decreased with a decrease in the amount of a sample to less than 30 μg. Then, the following investigation was made with regard to 1) the blank value of COS and 2) the blank value of CS_2. 1) In the ordinary PSGC, a small peak of COS was still detected in the analysis of a sample consisting of either C and H or C, H, and N, but it was neglected in the calculation of the atomic ratio because it was negligibly small. In the present study, however, a smaller amount of a sample is used, and the peak area of COS is presumed to be influenced by the peak area of COS as a blank value. Then, a 30—100 μg of cyanoguanidine, which consists of C, H, and N, was analyzed by the present method, and the value of the peak area of COS was examined. The peak area of COS as a blank value was approximately a definite value, regardless of the amount of the sample. Therefore, the peak-area ratio of COS to H_2S was calculated from the value which was obtained by subtracting the value of COS as a blank one from the analytical value of alanine as a standard sample; it was then plotted against the sample amount (Fig. 4). Figure 4 shows that the peak-area ratio of COS to H_2S comes to a definite value when the blank value is corrected. 2) The peak-area ratio of CS_2 to H_2S decreased with a decrease in the amount of the sample to less than 30 μg (Fig. 3). It was presumed that a part of the CS_2 remained in the residual sulfur in the ampule. Therefore, the effect of the amount of residual sulfur on the peak area of CS_2 was investigated by the use of the analytical data in Fig. 3 in the following manner. The amount of S(W_c) consumed by pyrolytic sulfurization reaction was calculated by means of Eq. 3:

$$W_c(\mathrm{mg}) = \frac{M_s}{F}(A(\mathrm{H_2S}) + K(\mathrm{COS})A(\mathrm{COS}) + 2K(\mathrm{CS_2})A(\mathrm{CS_2})), \quad (3)$$

where M_s is the atomic weight of S, F is the same factor as in Eq. 1, X is the reaction product, $A(\mathrm{X})$ is the peak area of X, and $K(\mathrm{X})$ is the calculation factor of X. Therefore, the amount of residual sulfur (W_r) was found approximately by Eq. 4:

$$W_r(\mathrm{mg}) = 0.5 - W_c. \quad (4)$$

The relationship between W_r and the deficient amount of CS_2, calculated from the data in Fig. 3, was plotted in Fig. 5. Figure 5 shows that the amount of CS_2 dis-

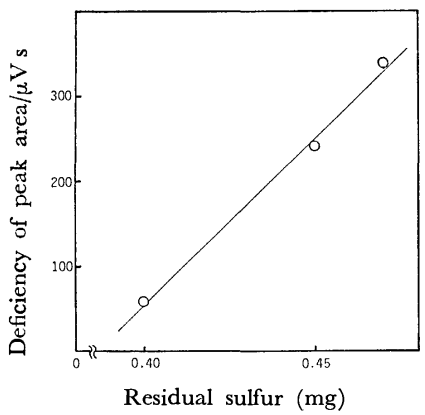

Fig. 5. Relationship between residual sulfur and deficiency of peak area of CS_2.

solved in the residual sulfur is approximately proportional to the amount of the residual sulfur. Therefore, the deficient amount of CS_2 was calculated by the use of Eq. 5, obtained from the calibration curve in Fig. 5:

$$\alpha(\mu V\,s) = 3.8\times10^{3}W_r - 1.5\times10^{3}, \quad (5)$$

where α is the deficient amount of CS_2. Judging from the results shown in Fig. 5, Eq. 5 can be applied when W_r is in the range from 0.39 mg to 0.5 mg. Thus, the atomic ratio between C, H, O, and N should be estimated by calculating α by means of Eqs. 3, 4, and 5 and by correcting the apparent peak area of CS_2. Examples of these corrections are shown in Table 3. As can be seen from Table 3, the atomic ratio between C, H, and O was markedly improved by applying the above-mentioned corrections. Both the oxygen content in cholesterol and the amount of COS produced from 62 μg of cholesterol were small, but a satisfactory result was obtained.

Analysis of Various Organic Compounds. Various organic compounds and metal organic chelate compounds were analyzed by the present procedure; the results are shown in Table 4. Table 4 indicates that the atomic ratio between C, H, O, and N can be simultaneously and satisfactorily determined by the use of centimilligrams of a sample.

The present study is expected to be especially significant for the organic elemental analysis of micro amounts of a sample which cannot be accurately weighed by a microbalance or an ultramicrobalance.

This study was supported by a Grant-in-Aid for the Special Research Project on "Trace Characterization" given by the Ministry of Education, Science and Culture.

(Received February 1, 1982)

A new spectrophotometric method for the determination of palladium after extraction of its 1-pyrrolidinecarbodithioate into molten naphthalene has been developed. Palladium forms a water-insoluble, thermally stable 1:2 complex with 1-pyrrolidinecarbodithioate which is easily extracted into molten naphthalene in the pH range of 3.0—6.0. At room temperature, solid naphthalene containing the metal-complex is dissolved in chloroform (10 ml). It has an absorption maximum in the range of 336—342 nm. Beer's law holds in the concentration range of 2.5—90.0 μg of palladium in 10 ml of chloroform solution. The molar absorptivity(1 mol^{-1} cm^{-1}) and sensitivity(μg/cm^2) are found to be 6.4×10^3 and 0.0166, respectively. Samples containing 30 μg of palladium gives a mean absorbance of 0.18 with a standard deviation of 0.0025. Other factors such as amount of reagent and naphthalene, pH, aqueous phase volume and diverse ions have been examined. The method has been applied to the analysis of some alloys.

Ammonium 1-pyrrolidinecarbodithioate has been used as an analytical reagent in the determination of various metal ions spectrophotometrically and atomic absorption spectrophotometrically after extracting their metal complexes into suitable solvents.[1-3] Recently it has been utilized in the spectrophotometric determination of copper, bismuth and cobalt after extracting their complexes into molten naphthalene.[4] The main advantages of this method are that the equilibrium distribution in the two phases is achieved in a few seconds and the metal chelates are dissolved merely by contact with the molten naphthalene. A very small amount (2 g) of the organic phase is required for the complete extraction which enhances the sensitivity as the whole of the organic phase may be taken for the analysis. This technique is especially useful for the extraction of those metal ions which form complexes with the complexing agent at high tempera ture.[5] The present communication describes conditions for the extraction of palladium with potassium 1-pyrrolidinecarbodithioate (PPDC) into molten naphthalene and its subsequent determination by spectrophotometric method after dissolution of naphthalene extract in chloroform. The interference of the various ions has been studied and the conditions have been developed for the determination of palladium in some alloys.

Experimental

Reagents. Palladium nitrate solution was prepared in redistilled water and standardized gravimetrically.[6]

PPDC solution, 0.2% was prepared by dissolving 0.2 g of PPDC in 100 ml of water.

Naphthalene and chloroform(analytical grade) were checked spectrophotometrically before use.

Alkali salt(1%) and metal salt(0.2%) solutions were prepared to study interference.

Dilute solution of perchloric acid, ammonia or acetate buffer prepared from 1 M(1 M=1 mol dm^{-3}) acetic acid and 1 M ammonium acetate were used to adjust pH.

Apparatus. An Elico pH meter and a SP-700 spectrophotometer were used.

General Procedure. An aliquot of palladium solution was taken in a beaker, to this was added 3.0 ml of reagent solution. The pH was adjusted to 4.2 with 2.0 ml of buffer solution. This solution was transferred to a 100-ml round bottomed flask and warmed on a water bath at about 60 °C and naphthalene (2 g) was added to it. The flask was stoppered and heating was continued till naphthalene melted and formed a separate liquid-layer. The flask was taken off from the water bath and stirred vigorously till the naphthalene separated out as a solid mass. Once more the naphthalene was melted, shaken vigorously and allowed to stand. The naphthalene was filtered off, dried on a filter paper and dissolved in chloroform in a 10 ml standard flask. This solution was dried by adding anhydrous sodium sulfate (2 g), and the absorbance was measured in a 1-cm cell at 340 nm against a reagent blank. A calibration curve was prepared under similar conditions.

Results and Discussion

Absorption Spectra. The absorption spectra of potassium 1-pyrrolidinecarbodithioate and palladium(II) 1-pyrrolidinecarbodithioate in naphthalene and chloroform solution were measured against water and reagent blank, respectively and are shown in Fig. 1. The palladium complex absorbs strongly in the region 336—342 nm where the reagent absorbs very little. All absorbance measurements were made at 340 nm.

Effect of pH. Extraction was carried out at different pH, other conditions as described in the general procedure being kept constant. The characteristics of all spectral curves were the same, indicating the presence of only one complex. The results are shown in Fig. 2. Optimum pH corresponds to 3.0—6.0.

Effect of Reagent Concentration. Extractions were carried out at a fixed pH but at varying reagent concentrations and it was observed that the extractions were quantitative for 1.5—6.0 ml of 0.2% of potassium 1-pyrrolidinecarbodithioate (Fig. 3). Consequently, 2.0 ml of the reagent was used in each case.

Effect of Buffer Solution. Sample solutions containing 30 μg of palladium, 3.0 ml of 0.2% PPDC solution and various amounts of the acetate buffer solution (pH 4.2) were added and the extractions were carried out by the general procedure. The absorbance remained constant for 0.5—6.5 ml of the buffer used In all the cases, 2.0 ml of the buffer was used.

Effect of Amount of Naphthalene. At fixed pH and reagent concentration, the extractions were car-

Palladium: 30 μg, wavelength: 340 nm, 1-pyrrolidinecarbodithioate: 3.0 ml (0.2%), naphthalene: 2 g, reference: reagent blank.

ried out by taking 0.5—3.5 g of naphthalene in different steps. It was observed that the absorbance remained constant for 1.0—3.0 g of naphthalene and thus 2.0 g of naphthalene was used throughout the experiment. Below 1.0 g, the extraction was incomplete while above 3.0 g of the naphthalene, it was difficult to dissolve it in a limited quantity of chloroform (10 ml).

Effect of Aqueous Phase Volume. Since the organic phase is very small (2 g) as compared to the aqueous phase (40 ml), it was essential to study the

Palladium: 30 μg, rest of the conditions were the same as in Fig. 2.

TABLE 1. EFFECT OF DIVERSE SALTS

Alkali salt added	Anion added (mg)	Absorbance 340 nm
—	—	0.180
Potassium chloride	23.80	0.180
Potassium bromide	33.60	0.178
Potassium iodide	38.25	0.181
Potassium thiocyanate	29.85	0.182
Sodium acetate	40.00	0.180
Sodium sulfate	40.00	0.180
Sodium oxalate	33.60	0.177
Potassium sodium tartrate	39.40	0.178
Sodium citrate	31.45	0.177
Sodium orthophosphate	25.60	0.178
Sodium thiosulfate	21.00	0.182
Disodium EDTA	40.00	0.178
Sodium fluoride	22.60	0.178

Pd: 30.0 μg, pH: 4.2, 0.2% PPDC: 3.0 ml, buffer: 2.0 ml.

effect of the volume of the aqueous phase on the extraction. It was observed that the absorbance remained constant upto 50 ml of the aqueous phase. Above this volume of the aqueous phase, the extraction was not quantitative.

Effect of Digestion Time. The palladium(II) 1-pyrrolidinecarbodithioate in the solution was warmed on a water-bath at 60 °C and the effect of digestion time on the absorbance was investigated between 1—20 min. It was found that the absorbance remained constant during this period. Therefore, 10 min of digestion time was selected for all measurements.

Effect of Shaking Time. The sample solution containing palladium(II) 1-pyrrolidinecarbodithioate and 2.0 g of naphthalene was warmed on a water-bath for 10 min at the temperature 60 °C and the extraction was carried out by vigorous shaking of the contents upto 30 min. It was observed that the shaking time of 1 min was sufficient for the complete extraction.

Effect of Standing Time of Chloroform Solution. The absorbance of the complex in naphthalene–chloroform was noted at an interval of 20 min and it was noted that the absorbance remained constant for more than 24 h indicating that the complex is quite stable in the extract.

Effect of Electrolytes. Various electrolytes such as sodium perchlorate, sodium nitrate, sodium sulfate, and sodium acetate (0.01—1.0 M) caused no improvement in the extraction indicating that the extraction was complete.

Composition of the Complex. The composition of palladium(II) 1-pyrrolidinecarbodithioate was established by Job's method of continuous variation and the mole ratio method. A sharp peak at 0.33 mole fraction in Job's curve and a clear break at 1:2 metal: carbodithioate ratio in the mole ratio plot suggest the extraction of $Pd(C_4H_8NCS_2)_2$ under these conditions.

Calibration Curve. With the optimum conditions described above a calibration curve was constructed for palladium complex at 340 nm. It was observed that Beer's law was obeyed over the concentration

Table 3. Determination of palladium in alloys

Alloy	Composition of alloy (%)	Amount of palladium taken/μg	Amount of palladium found/μg	Average μg	Other method[a]
Oakay	Ni:60, Pt:20, V:9.5, Pd:10.5	31.5	31.4 31.6 31.6 31.8 31.6	31.6	31.1
Platinum-Iridium	Pt:55, Ir:28, Rh:7, Cu:3, Fe:3.5, Pd:3.5	39.2	39.3 39.5 39.3 39.0 39.4	39.3	39.5

a) Average of the five determinations.

range of 2.5—90.0 μg in 10 ml of the final solution. Ten samples containing 30 μg of palladium were prepared by the general procedure gave a mean absorbance of 0.18 when measured in a 1-cm cell with a relative standard deviation of 0.0025. The molar absorptivity was calculated to be 6.4×10^3 l mol^{-1} cm^{-1} at 340 nm, and the sensitivity 0.0166 μg of palladium per cm^2 for the absorbance of 0.001.

Interference. The interference of various ions was studied in detail. Generally, 50 mg of alkali salt and 2 mg of metal ion were added individually to the aliquots containing 30 μg of palladium. Among the anions examined (Table 1) none interfered. This non-interference of the various anions may be attributed to their low stability constants as compared to palladium 1-pyrrolidinecarbodithioate.[7] Among the metal ions studied (Table 2) only Fe(III), Ni(II), Co(II), Hg(II), and Cu(II) interfered but their interference was eliminated by using suitable masking agents (Table 2). Obviously, the method is quite selective for the extraction of palladium.

Analysis of Alloy. 25—50 mg of the alloy of known composition, and 20—40 ml of aqua regia were added and the solution evaporated to about 5 ml. Concentrated hydrochloric acid (10 ml) was added, the solution was warmed, transferred to a 500 ml standard flask and made upto the mark with distilled water.[8] An aliquot was taken, 5 ml of 1% EDTA, and 3.0 ml of the reagent solutions were added. The pH of this solution was adjusted to 4.2 with 2 ml of the buffer solution and the palladium complex was extracted into molten naphthalene according to the general procedure. The results are given in Table 3 and are compared with a recent method.[9]

In conclusion, this simple and inexpensive procedure for palladium can be successfully applied to the alloy sample analysis.

The extraction with molten naphthalene is useful for the strongly hydrated oxinates of zinc,[10] magnesium[11] and cadmium,[12] and for the nioxime complexes[13] of nickel and palladium and bismuth 2-mercaptobenzothiazole complex[14] that offer a low solubility in nonaqueous solvents.

Sincere thanks of the authors are due to C. S. I. R., Delhi for the award of a fellowship to one of them (M. F. H.).

Studies on Dissolved Metalloenzymes in Lake Water. I. Identification of Alkaline Phosphatase

Kensei Kobayashi, Kimikazu Iwase, Masahiro Matsui, Masami Watanabe, Hirotaka Ueda, Kitao Fujiwara, Hiroki Haraguchi, and Keiichiro Fuwa*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 6, 1982)

Metalloenzyme (alkaline phosphatase) dissolved in lake water has been identified by means of high performance liquid chromatography (HPLC). Water samples were collected from Lake Kasumigaura in Ibaraki, and filtered with a 0.2—0.45 μm membrane filter immediately after sampling. Filtered water was concentrated to 100—2000 fold by ultrafiltration membrane which could concentrate the components of molecular weight larger than 10000. The enzymatic activity of alkaline phosphatase was measured using *p*-nitrophenyl dihydrogenphosphate as a substrate. Chelating agents added to the concentrated lake water inhibited the appearance of enzymatic activity, while the enzymatic activity was recovered with addition of zinc ion. The HPLC chromatograms of the concentrated lake water were examined, where an aqueous porous gel column was used for separation. The effluent at molecular weight of *ca.* 90000 showed specific activity of alkaline phosphatase. Zinc was also found in the same fraction. These facts suggest that alkaline phosphatase with the nature similar to procaryotes was present in the lake water.

Recently, the present authors reported that alkaline phosphatase existed as a dissolved form in sea water.[1,2] In these studies the identification of alkaline phosphatase was made by measuring the high performance liquid chromatogram as well as enzymatic activity and zinc content, and also biological significances of dissolved metalloenzymes in natural water were discussed along with the natural cycles of nutrient and trace elements. As is well known, alkaline phosphatase is one of the typical metalloenzymes containing four zinc atoms in one molecule,[3] and concerns with the phosphorus cycle in animals and microorganisms. Thus, further study on dissolved metalloenzymes in natural water may help to elucidate not only biological activities, but also elemental cycles. In addition, the identification of the chemical forms of trace metals in water has also been receiving great attention in the fields of bioinorganic and analytical chemistry.[4] In this sense, the dissolved metalloenzymes can be considered as one of the chemical forms of trace metals in water.

As was suggested in the previous papers,[1,2] alkaline phosphatase is also one of the most significant enzymes in limnology, because it may concern with the phosphorus cycles in natural water. Free dissolved phosphatase activity in pond water was first reported by Overbeck and Babenzien in 1963.[5] Reichardt *et al.* did consider the ecological importance of free phosphatase in lake water.[6] Since then, a number of investigations on phosphatase activity and its role in freshwater have been done. Furthermore, several reports on other types of enzymatic activities have been also given in terms of natural water. For example, Morrison *et al.* determined cellulase activity,[7] and Little *et al.* determined proteolytic enzymes in lake water.[8]

In this paper, the study on dissolved alkaline phosphatase has been extended to lake water. Lake Kasumigaura was chosen as the target, since it is one of the typical eutrophic lakes in Japan. The dissolved alkaline phosphatase activity was measured and identification of the enzyme was discussed along with the enzymatic properties.

Experimental

Chemicals. *E. coli* alkaline phosphatase (Boehringer-Mannheim, No. 15429) whose specific activity was 20 U mg^{-1} was used as a standard enzyme. *p*-Nitrophenyl dihydrogenphosphate was dissolved in 0.6 M tris(hydroxymethyl)-methanamine hydrochloride (pH 8.0; abbreviated as Tris buffer) (1 M=1 mol dm^{-3}). Chloride salts were used as metal(II) ion standards. Calibration proteins for the molecular weight (M. W.) standard of HPLC are as follows: Urease (Jack bean; M. W.: 480000);[9] aldolase (rabbit muscle; M. W.: 161000);[10] alkaline phosphatase (*E. coli*; M. W.: 89000);[11] carbonic anhydrase (Bovine erythrocytes; M. W.: 31000);[12] and ribonuclease (Bovine pancreas; M. W.: 13700).[13]

Instruments. A Shimadzu UV-210A spectrophotometer with a SFU-6 semi-auto flow cell unit was used for the measurements of enzymatic activity. The optical path of the absorption cell was 10 mm. A Shimadzu LC-3A high performance liquid chromatography with a SPD-2A spectrophotometric detector was used for HPLC-separation. Zinc concentration was determined by a Jarrell-Ash Model 975 Plasma Atom Comp. Ultrafiltration and incubation for activity measurements were all performed under the controlled temperature by a thermostatic bath circulator (Model TRL-111SP; Thomas Scientific Co., Ltd.).

Sampling and Filtration of Lake Water. The sampling stations in Lake Kasumigaura are located as shown in Fig. 1. In Stations 4 and 9, water samples were collected from depths of 0.5, 1.5, and 5.0 m; in the other stations, only from a depth of 0.5 m. Samples were taken once a month starting in April, 1980.

Water samples were also collected from the Shinobazu pond in Tokyo.

The water was filtered through a glass-fiber membrane filter (pore size: 1.0 μm) and then a Toyo Kagaku UK-4 membrane filter (pore size: 0.2 μm) as soon as possible after collection, in order to remove microorganisms. Enzymes in thus filtered water are hereafter called *dissolved enzymes.*

Concentration of Lake Water Samples. As enzyme levels in lake water are too low to be analyzed by the chromatographic technique, the filtered water samples were concentrated using the ultrafiltration technique. An Amicon YM-10 or UM-10 type membrane, or a Toyo Kagaku UK-10 type membrane, through which only molecules with a mo-

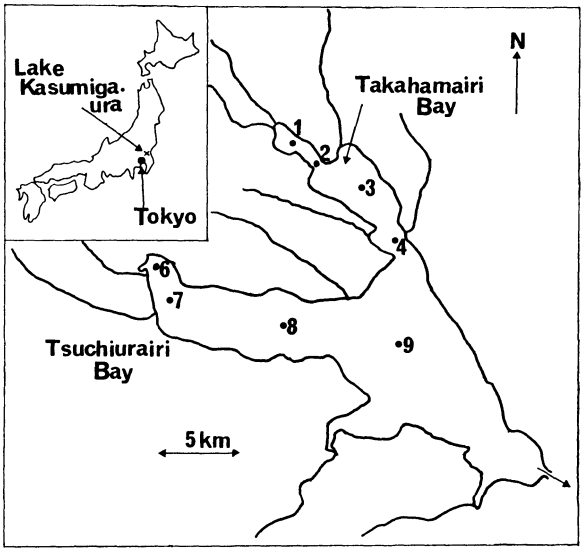

Fig. 1. Sampling stations in Lake Kasumigaura.

lecular weight over 10000 can be concentrated, was attached to an Amicon ultrafiltration cell (Model 202), in which samples were concentrated to 1/100—1/2000 of their original volumes. Samples were kept at about 4 °C throughout the operation.

Measurements of Phosphatase Activity. The enzymatic reaction of alkaline phosphatase for the substrate *p*-nitrophenyl dihydrogenphosphate proceeds as follows:

$$O_2N\text{-}C_6H_4\text{-}OPO_3H_2 + H_2O \longrightarrow O_2N\text{-}C_6H_4\text{-}OH + H_3PO_4. \quad (1)$$

The absorbance of the product, *p*-nitrophenol, was measured at 410 nm.[14] Assay procedures were as follows: The substrate solution (volume: V_1) and either a water sample or distilled water (blank) (volume: V_2) were mixed and then kept at 25 °C. After an interval of time, t, the absorbance of the mixture at 410 nm was measured using spectrophotometer equipped with a 10-mm long light path cuvette. When the absorbance of the sample-mixture and the blank-mixture, and the absorption coefficients of the substrate (S) and the product (P) at 410 nm are A, A_0, ε_S, ε_P, respectively, the enzymatic activity of the water sample, α, is given in Eq. 2:

$$\alpha = \frac{(A-A_0)(V_1+V_2)}{(\varepsilon_P-\varepsilon_S)V_2 t}. \quad (2)$$

When V_1, V_2, and t were taken as 4 cm^3, 1 cm^3, and 1440 min, respectively, in measuring unconcentrated samples, and $(\varepsilon_P-\varepsilon_S)$ is determined as 16200 mol^{-1} dm^3, the value of α is shown in Eq. 2′:

$$\alpha = 2.1 \times 10^{-7} (A-A_0) \text{ mol dm}^{-3} \text{ min}^{-1}. \quad (2')$$

Separation and Detection Using High Performance Liquid Chromatography (HPLC). The HPLC separation was performed using a Shimadzu W-71 aqueous porous gel column (7.9 mm i.d.×50 cm), with which molecules can be separated according to their molecular weight (range 10000—500000). Two types of the carriers were used, *i.e.*, a) 0.2% KH_2PO_4-KOH buffer (pH 7.3) for general separation, and b) 0.01 M Tris·HCl buffer (pH 8.0) for the distribution measurement of phosphatase activity, since phosphate inhibits phosphatase activity. The flow rate of the carrier was 1.0 cm^3 min^{-1}, and the solutes in the effluent were detected with the absorbance at 210 nm (general) and 280 nm (for protein). Chromatography was carried out at room temperature. Chromatographic effluents were collected by a fraction collector every 0.3—0.5 min.

Results and Discussion

Phosphatase Activity in Lake Waters. Table 1 shows the phosphatase activity of the water in Lake Kasumigaura. All the activity measurements were performed for the untreated samples. Activity values varied with sampling seasons and sampling points from less than 0.4 to 9.0 nmol dm^{-3} min^{-1}. The average value of activity, 1.4 nmol dm^{-3} min^{-1}, is comparable to the value in Lake Kinneret reported by Berman[15] and the value in the Shinobazu pond, Tokyo, measured by the present authors, and higher than the level in sea water samples.[16]

Characterization of Phosphatase Activity in Lake Water. Phosphatase activity in the lake water was inhibited

by treating with chelating agents such as ethylendiaminetetraacetic acid (EDTA) or 2,6-pyridinedicarboxylic acid (PDA). However, it is well known that such inhibited activity may be recovered by adding metal ions, such as zinc(II) and cobalt(II). The recovery effect of metal ions added to *apo-lake water* (the sample treated with chelating agents) is summarized in Table 2. Phosphatase activity was completely recovered when zinc(II) was added, and partly when cobalt(II) or manganese(II) was added. When heated over 80 °C, the sample completely lost activity. These results suggest that phosphatase activity in lake water originates from the zinc-metalloenzyme *alkaline phosphatase.*

In Fig. 2, the pH dependence of dissolved alkaline phosphatase activity in Lake Kasumigaura is shown. The maximum activity of *lake water* alkaline phosphatase was obtained at pH 8.9, which was a little higher than that of *E. coli* alkaline phosphatase (8.0).

The variations of phosphatase activity of *lake water* alkaline phosphatase, and of *E. coli*, with temperature and substrate concentration were also examined. The apparent activation energy (E_a) and the Michaelis constant (K_m) were estimated from the Arrhenius and the Michaelis plots.[6] The results are summarized in Table 3. Both the E_a and K_m of *lake water* alkaline phosphatase were different from those of *E. coli* alkaline phosphatase. This may indicate that *lake water* alkaline phosphatase is similar to that of *E. coli*, but exactly not the same.

Separation by HPLC. The HPLC chromatogram of concentrated lake water using 0.2% phosphate buffer

Table 2. Recovery ratio of phosphatase activity in lake water

Apo-sample(mm^3)[a]	Metal ion[b]	Relative activity %
50	None	0
50	Manganese(II)	41
50	Cobalt(II)	32
50	Nickel(II)	4
50	Copper(II)	9
50	Zinc(II)	100
50	Cadmium(II)	4

a) Concentrated (×400) lake water dialyzed against 0.01 M 2,6-pyridinedicarboxylic acid (pH 7.0). Lake water was sampled in Lake Kasumigaura in August, 1980. b) 50 μg of each metal ion was added in the form of chloride salt.

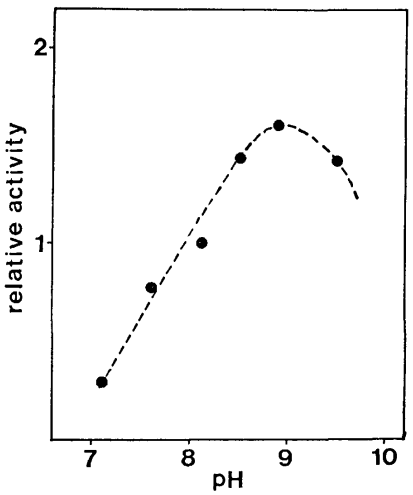

Fig. 2. pH dependence of dissolved alkaline phosphatase activity in lake water.
Activity was measured using 1 mM *p*-nitrophenyl dihydrogenphosphate in 0.1 M Tris–HCl buffer at various pH, at 30 °C. The sample was collected in Lake Kasumigaura (Sta. 2) on November 20, 1980.

Table 3. Apparent activation energies and Michaelis constants of alkaline phosphatases

Source of alkaline phosphatase	Apparent activation energy[b] E_a/kcal mol^{-1}	Michaelis constant[c] K_m/μM
Lake water[a]	6.93	1.0
E. coli	8.73	1.5

a) Concentrated lake water collected in Lake Kasumigaura (Sta. 2) on November 20, 1980. b) Obtained with the Arrhenius plot. Activities were measured using 1 mM *p*-nitrophenyl phosphate in 0.1 M Tris·HCl buffer (pH 8.1), at various temperatures (0—30 °C). c) Obtained with the Michaelis plot. Activities were measured using *p*-nitrophenyl dihydrogenphosphate of various concentrations (1 μM—1 mM) in 0.1 M Tris·HCl buffer (pH 8.1) at 30 °C.

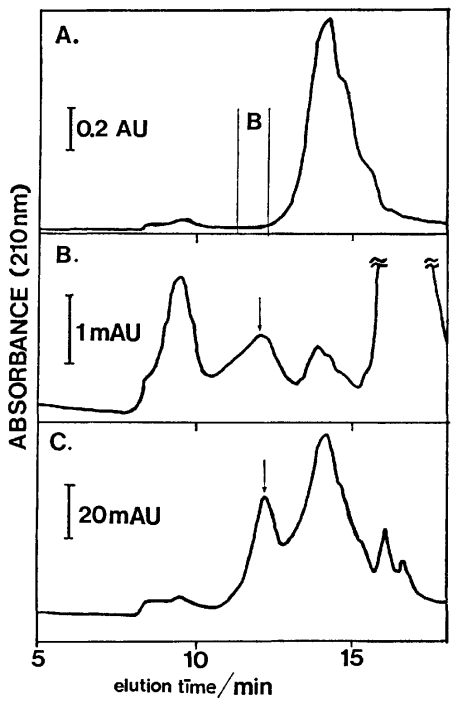

Fig. 3. Chromatograms of lake water.
Column: Shimadzu W-71 (7.9 mm i.d. × 50 cm), flow rate: 1.0 mL min^{-1}, carrier: 0.2% KH_2PO_4–KOH (pH 7.3), sample: concentrated (×500) lake water from Lake Kasumigaura sampled in February, 1980, temperature: at room temperature. (A): Lake water only, 100 μL; (B): fraction of (A) between 11.3 and 12.3 min; (C): (A) +20 μg of *E. coli* alkaline phosphatase.

(pH 7.3) as a carrier is shown in Fig. 3(A). As has been reported in the previous papers,[1,2] the chromatogram peak of alkaline phosphatase is located near 12 min. However, no marked peak could be noticed near the elution time of alkaline phosphatase in the chromatogram (A). Then, the effluent between 11.3 and 12.3 min of A was collected and concentrated. The chromatograph of the fractionated effluent was again examined under the same conditions, and the chromatogram B was obtained. In the chromatogram B, some apparent peak can be observed at the elution time at *ca.* 12 min. The chromatogram C is that of concentrated lake water spiked with *E. coli* alkaline phosphatase, which provided the elution peak at 12 min. From the comparison between the chromatograms B and C, the peak near 12 min in the chromatogram B corresponds to the distinct peak at the elution time of *E. coli* alkaline phosphatase. Fig. 4 shows the chromatograms of concentrated lake water detected both by absorbance and phosphatase activity, using 0.01 M Tris buffer (pH 8.0) as the carrier. There is a sharp peak of activity, and its elution time is the same as that of *E. coli* alkaline phosphatase. Zinc could also be found in this fraction. These results suggest that phosphatase activity in lake water originates from the alkaline phosphatase, whose molecular weight is close to that of *E. coli* alkaline phosphatase.

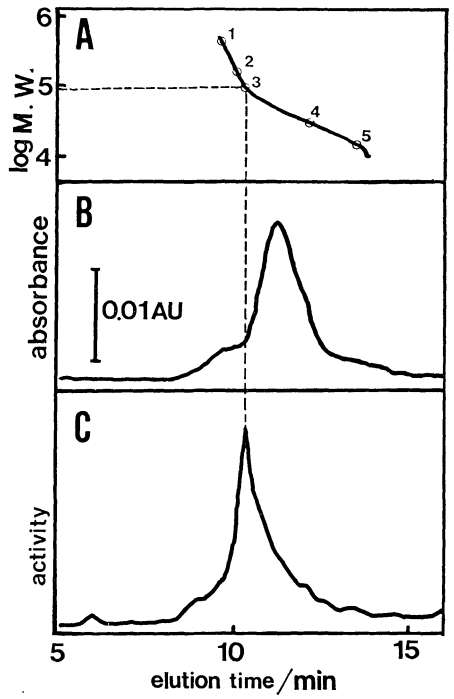

Fig. 4. Distribution of phosphatase activity of lake water.
Column: Shimadzu W-71 (7.9 mm i.d. × 50 cm), flow rate: 1.0 mL min^{-1}, carrier: 10 mM Tris buffer (pH 8.0), sample: concentrated (×2,300) lake water from Lake Kasumigaura sampled in August, 1980, 100 μL, temperature: 25 °C. (A) Calibration curve by standard enzymes [1, Urease (Jack bean; M. W.: 480000); 2, aldolase (rabbit muscle; M. W.: 161000); 3, alkaline phosphatase (*E. coli*; M. W.: 89000); 4, carbonic anhydrase (Bovine erythrocytes; M. W.: 31000); 5, ribonuclease (Bovine pancreas; M. W.: 13700)]; (B) chromatogram detected in absorbance at 280 nm; (C) distribution of phosphatase activity.

Conclusion

The results described above lead us to the conclusion that dissolved zinc-metalloenzyme alkaline phosphatase, which may be provided by procaryotes, is present in Lake Kasumigaura. It has been known that alkaline phosphatase of eucaryotes (molecular weight around 150000) is usually larger than the alkaline phosphatase of procaryotes (molecular weight around 90000).[17] As Lake Kasumigaura is known to be an algae-rich lake, a large portion of the alkaline phosphatase in the lake would be provided by algae, such as *Microcystis*. Further work to identify the isozymes using electrophoresis, *etc.* is in progress.

In Lake Kasumigaura, the concentration of alkaline phosphatase-formed zinc has been calculated as about 0.2 ng dm^{-3} (0.2 ppt), using the value of standard *E. coli* alkaline phosphatase, that is, almost one ten-thousandth of the total zinc in the lake water.

In consequence, the existence of active dissolved alkaline phosphatase may be related to the phosphorus cycles in the lake water, as has been discussed in other lakes.[15,18–20] The study on the correlation between the dissolved alkaline phosphatase and phosphorus concentration/cycle in the eutrophic lake including Lake Kasumigaura should be biochemically and ecologically important and interesting.

The present authors thank Dr. Akira Otsuki, Division of Chemistry and Physics, the National Institute for Environmental Studies, for his kind advice in limnology and for the sampling arrangement in Lake Kasumigaura.

This research has been supported by Grant-in-Aid for Special Project on Trace Characterization under Grant No. 510804 from the Ministry of Education, Science and Culture.

Selective Determination of Histamine in Urine by Solvent Extraction with Tetrabromophenolphthalein Ethyl Ester and Atomic Absorption Spectrophotometry

Tadao SAKAI,* Noriko OHNO, Takashi WAKISAKA, and Yoshinori KIDANI†

Department of Chemistry, Gifu College of Dentistry, Takano 1851, Hozumi-cho, Gifu 501-02

†*Faculty of Pharmaceutical Sciences, Nagoya City University, 3-1, Tanabedori, Mizuho-ku, Nagoya, Aichi 467*

(Received March 8, 1982)

A simple determination method of histamine in urine by solvent extraction and atomic absorption spectrophotometry has been established. The method is based on the formation of histamine–Cu(II) chelate cation, followed by the extraction of ion-associates with tetrabromophenolphthalein ethyl ester into 1,2-dichloroethane. Histamine in urine can be successfully determined without separation and purification from other histamine derivatives and amines. A linearity is obtained in the concentration range $(0.4—4)\times10^{-5}$ M (1 M=1 mol dm^{-3}) histamine in aqueous solutions. The relative deviation is *ca.* 1.8%.

It is well known that histamine is produced from histidine in the presence of histidine decarboxylase and stored in the mast cells. The activity is considerably noted because histamine in mammalian tissues shows an important physiological action in the central nervous system. Therefore, the measurements of histamine in urine, tissues and brain are of great importance in clinical chemistry.

Fluorimetry with column chromatography,[1] high-performance liquid chromatography,[2] high-performance liquid chromatography with fluoresence detection[3] and radioisotope technique using ^{14}C-histamine for the assay and activity measurements of histamine and its derivatives in urine and tissues were reported. However, these procedures were somewhat complicated for the separation and purification.

The present paper describes a simple and selective atomic absorption spectrophotometric method without separation and purification of other biogenic amines and histamine derivatives for the assay of histamine in urine. The method is based on the formation of chelate compounds between Cu(II) and histamine and solvent extraction with hydrophobic tetrabromophenolphthalein ethyl ester (TBPE) into 1,2-dichloroethane. Acetylcholine and serotonine at the concentration of $(3—6)\times10^{-4}$ M do not cause errors. Catecholamines such as adrenaline and noradrenaline at the concentrations less than 6×10^{-5} M do not interfere, either.

Experimental

Reagents. Reagent solutions were prepared from reagent grade chemicals and distilled water, and they are stored in polyethylene bottles. Histamine standard solution of 1×10^{-2} M was prepared by dissolving 1.8407 g of histamine dihydrochloride (M.W. 184.07) to make the solution 1 L with distilled water. A 5×10^{-3} M copper(II) chloride solution was prepared by dissolving 0.8524 g of copper(II) chloride dihydrate in distilled water to make it 1 L. A 4×10^{-3} M TBPE ethanol solution was prepared by dissolving 0.2800 g of tetrabromophenolphthalein ethyl ester potassium salt in hot ethanol to make it 100 ml. A borate-phosphate buffer solution(pH 9.0) was prepared by adding 1 M NaOH to a 0.3 M potassium dihydrogenphosphate solution containing 0.1 M sodium borate. 1,2-Dichloroethane was used as an extractant.

Apparatus. A Nippon Jarrell-Ash, Model AA-780, atomic absorption spectrophotometer equipped with 10-cm slit burner and a cupric hollow-cathode lamp(Hamamatsu TV Co., Ltd.) was used and peak hights were recorded with a Yanako Model YR-110 chart recorder. Hitachi-Horiba, Model F-7II, pH meter was used for pH measurements. An Iwaki shaker, Model KM, was used for the solvent extraction.

Recommended Procedure. Take 2 ml of sample solutions containing about 90 μg/ml of histamine, 1.5 ml of 5×10^{-3} M copper(II) chloride solution, 5 ml of a buffer solution (pH 9.0) and 2 ml of a TBPE solution into a 50 ml calibrated flask, and dilute the mixture to 50 ml with water. Transfer the aqueous solution into a 100 ml separatory funnel and shake it for 5 min with 10 ml of 1,2-dichloroethane. Keep the funnel standing for 15 min and then separate the organic layer. Run off the extract into a glass tube through a filter paper to remove water droplets. Add 4 ml of ethanol to 1 ml of the extracts. Record the absorption signal at 3247 Å after mixing the solution. Take the peak height as the analytical signal. Run a reagent blank at the same instrumental settings and subtract it from the analytical values. Linear relationship between the absorbance of the extract and the concentration of histamine was held for the concentration range of $(0.4—4)\times10^{-5}$ M histamine in aqueous solutions.

Results and Discussion

Analytical Conditions for Copper Determination. The operating conditions used for copper determination were as follows: lamp current, 9 mA; wavelength, 3247 Å; flow-rate of acetylene, 1.75 l/min; flow-rate of air, 8.5 l/min; burner height, 23 mm; absorption-sens, 0.1 and burner length, 10 cm.

Effect of pH on Extraction. It was reported[5] that histamine formed the complexes with transition metal ions such as copper, zinc, cobalt, nickel, and iron. Of these metals, however, it was found that the height of the absorption peak given by the extract was considerably increased when copper(II) was present in the aqueous solution. Therefore, the effect of pH on the extraction in the presence of copper(II) was studied by extracting Cu(II)–histamine chelate cations with TBPE anion from a series of aqueous buffer solution of various pH. Figure 1 shows that the atomic absorption of copper(II) in the extracts was maximum and constant over the pH range of 8.5—10, whereas in the absence of histamine, copper(II) was not ex-

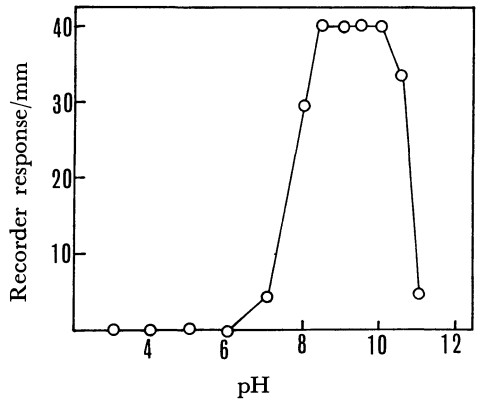

Fig. 1. Effect of pH on extraction.

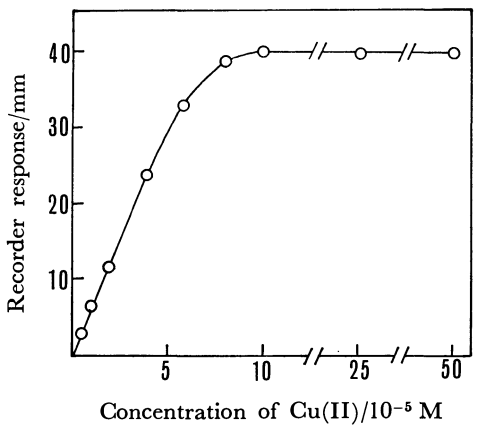

Fig. 2. Effect of copper(II) concentration.
Histamine: 3×10^{-5} M, TBPE: 1.6×10^{-4} M, pH: 9.0.

tracted with TBPE. In both acidic and alkaline media, the atomic absorption of copper(II) was markedly decreased. This may be caused by the decrease of Cu(II)–histamine complex formation in the acidic medium (pK_a for histamine, 5.1[6]), as well as copper(II) hydroxide precipitation in the alkaline medium. Extraction is recommended to carry out at pH 9.0.

Effect of Copper(II) Concentration. Various amounts of copper(II) were added to aqueous solutions of histamine and the extraction was carried out as described above. Figure 2 shows that 3-fold molar ratio of Cu(II) to histamine is enough to obtain maximum and constant atomic absorption. A copper(II) concentration of 1.5×10^{-4} M is recommended when histamine concentration is 3×10^{-5} M.

Effect of Counter Ions for the Extraction. Hydrophobic anions such as perchlorate, tetraphenylborate (TPB), picrate and TBPE were studied as a counter ion for the extraction of hydrophilic Cu(II)–histamine cations. The ion-associates with perchlorate and picrate anions were not extractable into nitrobenzene, though it has a higher dielectric constant. On the other hand, the addition of TPB showed a high atomic absorption, but the peak height was remarkably decreased when TPB concentration was maintained more than 1×10^{-4} M, because the concentrated TPB and histamine produce white precipitates in the aqueous

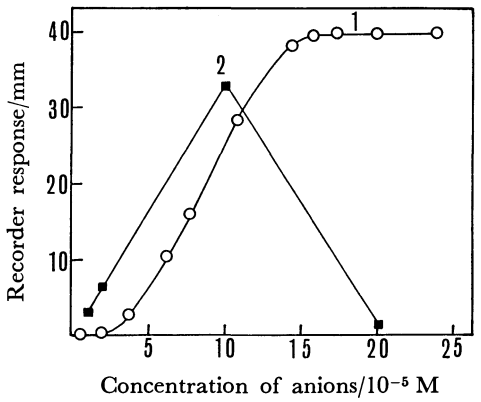

Fig. 3. Effect of TBPE and TPB concentrations on extraction.
1: TBPE, 2: TPB, histamine: 3×10^{-5} M, Cu(II): 1.5×10^{-4} M, pH: 9.0.

phase. Figure 3 shows that the extraction of Cu(II)–histamine–TBPE ion-associates was maximum and constant, when TBPE used was more than 1.5×10^{-4} M (5-fold molar ratio to histamine). Excess amounts of phosphate buffer did not give any influence on the atomic absorption, but separation of two layers became incomplete when the addition of the buffer solution was less than 1 ml. The previous papers[7] described that ion-associates with TBPE was the most extractable species into 1,2-dichloroethane.

Effect of Shaking Time and Stability of the Extract. Extraction was completed quantitatively within 30 s, and shaking for up to 15 min did not produced any further change in absorption signal, and which was remained almost constant for at least 5 h after extraction.

Calibration Curve and Precision. Under the optimum conditions, the calibration curve was made with a histamine standard solution containing 1.5×10^{-4} M copper(II) chloride solution. It shows a good linearity over the range of $(0.4—4)\times10^{-5}$ M (0.736—7.36 μg/ml) histamine with an aqueous/organic solvent volume ratio of 5. The relative standard deviation (ten determinations) was estimated to be 1.8% for 3×10^{-5} M histamine.

Interferences of Diverse Substances. To the solution containing 3×10^{-5} M histamine and 1.5×10^{-4} M copper(II) chloride solutions, various amounts of foreign compounds were added and their influences were examined. The results are summarized in Table 1. Inorganic substances, such as sodium chloride, potassium chloride, sodium nitrate, sodium carbonate, and sodium sulfate did not show any interference. Furthermore, calcium, magnesium, cobalt, lead, nickel, zinc, iron, and iodide ions of 5-fold molar excess over 3×10^{-5} M histamine did neither show any influence. Though citrate ion interfered considerably with the determination, it was minimized by addition of calcium ions at a concentration almost equal to that of citrate ion.

Histidine, serotonine, acetylcholine and imidazole-4-acetic acid, being analogous to histamine and giving a strong influence on other measurements,[1,3] did not interfere with histamine in 10—20 fold ratio. Of bio-

TABLE 1. EFFECT OF VARIOUS SUBSTANCES ON DETERMINATION OF HISTAMINE

Substances	Mole ratio [Ion]/[HA]	Mole ratio [Ion]/[Cu(II)]	Recovery of histamine %

Histamine taken: 3×10^{-5} M, Cu(II) taken: 1.5×10^{-4} M, TBPE: 1.6×10^{-4} M, pH on extraction: 9.0, solvent: 1,2-dichloroethane

genic amines, catecholamines such as adrenaline, noradrenaline and dopamine which coexist with histamine in biological materials did not interfere less than 1—2 fold ratios to 3×10^{-5} M histamine. Histamine is a major component in biological materials and the content ratio for [Adrenaline]/[Histamine(HA)] is 0.03; for [Noradrenaline]/[HA], 0.2; [Dopamine]/[HA], 0.02 in heart and the corresponding ratios are 0.06, 0.4, 0.02 in spleen.[8] Consequently, about 5 μg/ml levels of histamine in tissues and urine can be selectively determined by this method.

Composition of the Extracted Species. In order to clarify the composition of the extracted species, continuous variation plots were made. The results shown in Figs. 4 and 5 reveal that a 1:1 chelate cation is formed between Cu(II) and histamine, and that in the organic phase a 1:3 ion-associate is formed between Cu(II)–histamine cations and TBPE anions. Moreover, an ion-associate was dried at reduced pressure for 48 h and the powdery precipitates obtained was analyzed. Found: C, 39.7; H, 2.4; N, 2.0; O, 8.6; Br, 46.6; Cu, 1.0%. Calcd for Cu(II)–histamine–TBPE associate: C, 39.7; H, 2.2; N, 1.3; O, 9.1; Br, 45.8; Cu, 1.9%. Thus the results obtained by the

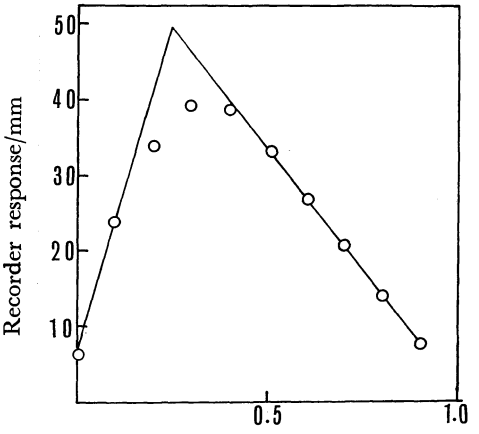

Fig. 5. Continuous variation plots.
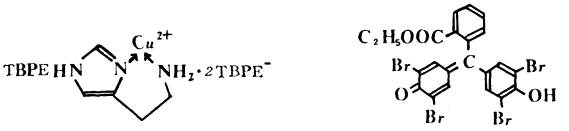
[HA]+[TBPE]=2×10^{-4} M, Cu(II): 2×10^{-4} M, pH: 9.0.



Ion-associate with TBPE TBPE molecule

Chart 1.

two methods suggest that the chemical formula of the extracted species may be formulated as [Cu(II)–histamine]·$(TBPE)_3$. The ion-associate produced is assumed to show its structure in Chart 1 because the absorption spectrum of the associate with TBPE showed the charge transfer complex type in our previous paper,[7] being a maximum wavelength at 515 nm.

Application to Histamine Determination. Known amounts of histamine standard solution were added in human urine. Sample solutions containing 92 μg of histamine were analyzed by the proposed method. The results obtained were 81 μg and 79 μg histamine for two samples (3 determinations) and the recoveries were 88 and 86%, respectively. On the other hand,

5 mg/ml of histidine dihydrochloride was injected intravenously to two rats (about 150 g, ♂). Urine was withdrawn after 24 h and histamine in urine was determined by this method. 58 μg histamine could consequently be found in 50 ml of the recovered urine.

The recovery of histamine by the proposed method is not high enough as we expected. However, the procedure is very simple and this is available for the practical determination of histamine in biogenic amines, as the selective method.

Preparation and Electrochemical Behaviors of Phenoxide-coordinated Iron(III) Porphyrins

Hiroshi Sugimoto,* Nobuhiro Ueda, and Masayasu Mori

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558

(Received March 23, 1982)

A new series of iron(III) porphyrins having various phenoxide anions as the axial ligand, [Fe^{III}(porphyrin)-(4-X-$C_6H_4O^-$)] (porphyrin=octaethylporphyrin and tetraphenylporphyrin; X=OCH_3, CH_3, H, C_6H_5, Cl, Br, $COCH_3$, CN, CHO, and NO_2) were synthesized. All these complexes are five-coordinated high-spin complexes ($S=5/2$). Their electrochemical behaviors were investigated by the cyclic voltammetry and the controlled potential coulometry. The complexes showed significantly negative potentials for the Fe^{II}/Fe^{III} redox couple (−0.4——0.8 V). A good linear relationship was found between the half-wave potentials of the Fe^{II}/Fe^{III} redox couple and the Hammett σ-values of the substituent X. A new characteristic feature is the appearance of the redox peaks of the coordinated phenoxide anions near the redox couple of the porphyrin ring oxidoreduction. The role of the tyrosine-67 in the enzymatic mechanism for cytochrome c is discussed.

As to the biological functions of cytochrome c such as its electron transferring activities, some hypotheses were presented on the basis of the crystallographic data of its several variant forms.[1,2] All of these hypotheses point out the importance of the interaction between the heme (iron porphyrin) and the tyrosine-67 residue, where the phenol group or its anionic form may act as the one-electron donor to the ferric porphyrin through the ionic interaction (tyr-67)$^-$..... (heme)$^+$ to give ferrous porphyrin and tyrosine radical.[2] It, therefore, seemed to be considerable interest to evaluate qualitatively the strength of the ionic interaction by use of model complexes.

For this purpose, we systematically prepared a series of iron(III) porphyrin complexes having phenoxide anions substituted at the 4-position (*para*-position), and investigated their basic physicochemical properties, particularly electrochemical behaviors.

Experimental

Syntheses of Complexes, General Procedures. To a dichloromethane solution of (octaethylporphyrinato)iron(III) acetate,[3] [Fe^{III}(oep)(OAc)] or (tetraphenylporphyrinato)iron-(III) acetate, [Fe^{III}(tpp)(OAc)] (100 mg) was added a dichloromethane solution of phenol derivatives (100 mg). Due to the low solubility in dichloromethane, *p*-hydroxybenzaldehyde and methyl *p*-hydroxybenzoate were dissolved in methanol, and biphenyl-4-ol was dissolved in acetone. After stirring for about 3—4 h, the solvent was removed to dryness. The residual solid was washed with acetonitrile and recrystallized from dichloromethane–methanol (1:1 vol/vol) or dichloromethane–acetonitrile (1:1 vol/vol) to give purple crystals in about 60—80% yields. The elemental analyses, and the spectral data of UV-VIS and IR are summarized in Tables 1, 2, and 3, respectively.

Cyclic Voltammetry and Controlled Potential Coulometry. Dichloromethane was dried and distilled over CaH_2 before use. As a supporting electrolyte, tetrabutylammonium per-

chlorate (TBAP) was used after being subjected twice to recrystallization from benzene. Cyclic voltammograms were obtained on a HA-104 potentiostat (Hokuto Denko) in combination with a HB-107A function generator (Hokuto Denko). A three-electrode system was used which consisted of platinum working and counter electrodes and a commercial saturated calomel electrode (SCE) separated from the bulk of solution by a bridge filled with the solvent containing supporting electrolyte. The bridge had its solution changed periodically to avoid aqueous contaminants from entering the cell *via* SCE. All solutions were purged of oxygen by passing purified nitrogen through them for 10 min just before

taking cyclic voltammograms. After the degassing a blanket of nitrogen was kept over the solution. The half-wave potential $E_{1/2}$ was taken as that potential lying midway between the oxidation and reduction peaks for a given couple. All experiments were carried out at room temperature (15 °C) and the potentials reported refer to the SCE. The scan rate was constantly 100 mV/s. The controlled potential coulometry was carried out on a HA-104 potentiostat with a HF-201 coulomb-amperehour meter (Hokuto Denko). The number of electron was obtained as the mean value of three experiments.

Results and Discussion

The acetate ion of the starting complexes could be easily replaced by various types of phenoxide anions.

$$[Fe^{III}(porphyrin)(OAc)] + HO\text{-}C_6H_4\text{-}X \longrightarrow [Fe^{III}(porphyrin)(4\text{-}X\text{-}C_6H_4O^-)]$$

The substituents X were varied from the most electron donating OCH_3 to the most electron-withdrawing NO_2.

The coordinated phenoxide anions could be easily confirmed by the characteristic IR bands[4] as summarized in Table 3. These complexes showed UV-VIS spectra (Fig. 1) similar to those of the typical iron(III) high-spin complexes.[5] Compared with the acetate complex, the Soret band of these complexes shifted toward longer wavelength region by about 10 nm, and the so-called charge-transfer band around 600—650 nm shifted toward shorter wavelength region by about 20—30 nm. These absorption maxima are similar to those of fluoro complex, $[Fe^{III}(oep)F]$.

All of these complexes showed magnetic susceptibilities of about 5.9 BM at room temperature, indicating that these phenoxide complexes are of five-coordinated high-spin ($S=5/2$) type.

Although the absorption maxima of the charge-transfer band were expected to be a good indicator of the strength of the interaction between iron(III) porphyrin-phenoxide anion, the effect of substituent X was found to be small. Since the redox potential of the cobalt(III)[6] or iron(III) porphyrins[7] are also known to be sensitive to the nature of the counter anions, such quantities of the phenoxide complexes were measured by the cyclic voltammetry. The half-wave potentials thus obtained are summarized in Table 4. In order to eliminate the complication by the coordination of polar solvent molecules,[7] the cyclic voltammograms were obtained in dichloromethane. As in the case of usual iron(III) porphyrins,[7] two quasi-reversible redox couples were observed at −0.5——0.8 V and +1.1—+1.2 V. From the electrospectrochemistry and the controlled potential coulometry, these couples could be assigned to the Fe^{II}/Fe^{III} and Fe^{III}/Fe^{IV} or porphyrin ring oxidoreduction as shown in Fig. 2, reflecting the effect of the substituents on the porphyrin ligand. The values of octaethylporphyrin derivatives were more negative by about 0.1 V than those of tetraphenylporphyrin derivatives. The Fe^{II}/Fe^{III} redox values were found to be significantly dependent on the kind of substituent X in the phenoxide anion and ranged over −0.8——0.4 V. These values are much negative compared with usual iron(III) complexes,[7] in particular the values of 4-methoxyphenoxide complexes are probably the most negative ones reported so far in iron(III) porphyrins. As shown in Fig. 3, there are good linear correlation between the half-wave potentials and the Hammett σ-values of substituent X.

a) Inflection. b) Not observed. c) Ref. 7.

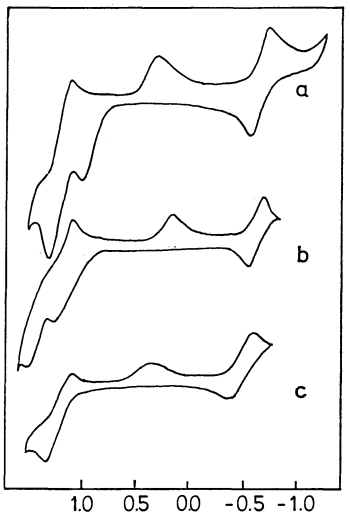

Fig. 2. Cyclic voltammograms of (a) [Fe^{III}(tpp)(4-CH_3O-$C_6H_4O^-$)], (b) [Fe^{III}(tpp)(4-C_6H_5-$C_6H_4O^-$)], and (c) [Fe^{III}(tpp)(4-CN-$C_6H_4O^-$)] in CH_2Cl_2.

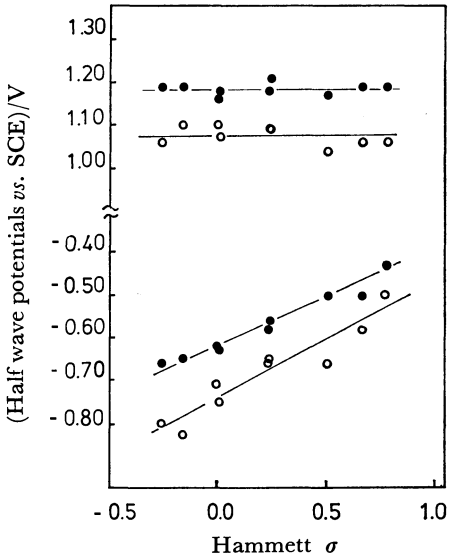

Fig. 3. The correlation between the half-wave potentials of [Fe^{III}(porphyrin)(4-X-$C_6H_4O^-$)] and the Hammett σ-values of substituent X; (○) octaethylporphyrin derivatives and (●) tetraphenylporphyrin derivatives.
The σ-values adopted are follows; X=CH_3O(−0.268), CH_3(−0.170), H(0.00), C_6H_5(−0.01), Cl(+0.227), Br(+0.232), CN(+0.660), CH_3CO(+0.502), NO_2-(+0.778).

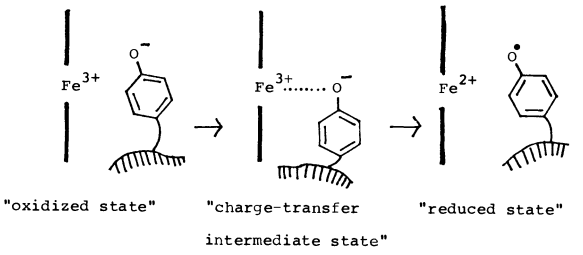
On the other hand, the redox couple at +1.1—+1.2 V showed no correlation with Hammett σ-values of X. This probably means that the redox couple is assignable to the redox process on the porphyrin ring rather than on metal.[7]

A new characteristic feature in these phenoxide complexes is the appearance of an additive oxidation and corresponding reduction peaks near the redox potential of porphyrin ring. These new oxidation peaks are remarkably dependent on the kind of substituent X. In 4-methoxyphenoxide complexes, the peaks could be clearly observed as a separated peak at about +0.9 V (Fig. 2a). These peaks were proved to be a one-electron process by the controlled potential coulometry and could be unambiguously assigned to the oxidation of coordinated phenoxide anions. The peak positions are consistent with those of the corresponding free phenols or phenoxide anions found in the literatures.[8] Such additive peaks have never been observed in iron(III) porphyrins, because the electrochemical studies so far dealt with iron(III) porphyrins with electrochemically inert halide ions or another inorganic anions. Very recently we reported that the catecholate complexes of iron(III) porphyrins had similar oxidoreduction peaks of coordinated catecholate anions.[9] As the electron-donating character of the substituent X decreases, the peak shifted to a more positive region finally to overlap the peak of porphyrin ring oxidation (Fig. 2b) and give a single peak (Fig. 2c). The overlapped peak at about +1.1—+1.2 V had doubled in current.

Very negative values of the Fe^{II}/Fe^{III} redox couple of these phenoxide complexes suggest that the strong electron donation, *i.e.*, the charge-transfer occurs from the phenoxide anions to iron(III) ion.

$$Fe^{3+} \leftarrow L^- \longleftrightarrow Fe^{2+}\text{----}L\cdot$$

Moreover, the coordinated phenoxide anions are subjected to the one-electron oxidation at more negative voltage than that of the porphyrin ring oxidation. These facts suggest the important catalytic role of the phenoxide anions (tyrosine-67) as a deliverer of electrons in enzymatic mechanism.[2] It is reasonably sup-



posed that phenoxide group of tyr-67 in the enzyme can be brought so close to the ferric heme moiety probably due to the conformation change of the peptide chain that the electron transfer smoothly proceeds resulting ferrous heme and phenoxide radical as illustrated above.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

(Received April 7, 1982)

The crystal structure of the title complex, which was chromatographically obtained as the first eluted isomer, has been determined by the X-ray diffraction method. The dark-brown needle crystal was hexagonal, space group $P6_1$, $a=21.035(5)$, $c=6.459(3)$ Å, $Z=6$, and the final R value was 0.076 for 1504 non-zero reflections. Of three possible isomers for the (diethylenetriamine)(L-penicillaminato)cobalt(III) complex, the complex isolated has *trans*(N_1N) configuration. The average Co–N distance for the nitrogen atoms bonded cis to the sulfur atom is 1.961 Å, whereas the trans Co–N length is 2.007 Å.

Some cobalt(III) complexes with thiolato ligands such as penicillamine and cysteine have been investigated for their stereochemical and biochemical interests.[1–3] It appears that the presence of a thiolato donor atom in the coordination sphere induces an extreme specificity concerned with the formation of possible isomers.[2,3] This work deals with the stereochemistry of the mixed cobalt(III) complex with the L-penicillaminate (L-pen) and diethylenetriamine (dien) ligands, where L-pen functions as a tripod-like terdentate ligand and has a similar framework to the L-cysteinate ion. For the [Co(L-pen)(dien)]$^+$ complex having a thiolato donor atom, three geometrical isomers are possible. They are designated as *trans*(N_1N), *trans*(N_1O), and *trans*(N_1S) with respect to the coordinated atoms as shown in Fig. 1. These isomers belong to a *cis*(*SO*)-[Co(N)$_4$(S)(O)] type and it is difficult to assign spectrochemically their geometrical configurations.

The present paper deals with the crystal and molecular structure of [Co(L-pen)(dien)]Cl·H_2O which was isolated from the first eluate by means of a column chromatographic separation. The trans effect due to the coordinated thiolato donor atom in the L-pen ligand is also discussed. A preliminary report has been presented.[4]

Experimental

(Diethylenetriamine)(L-penicillaminato)cobalt(III) chloride was prepared by a modification of a method in the literatures.[5] To a suspension containing 5.4 g of [$CoCl_3$(dien)][6] in 100 cm^3 of water was added a solution containing 5.1 g of silver nitrate in 20 cm^3 of water. The precipitated silver chloride was filtered off. After nitrogen gas was vigorously bubbled into the filtrate for 30 min, an aqueous solution containing 3.0 g of L-penicillamine was added to it. The nitrogen gas was constantly bubbled into the mixture at room temperature for about 20 h. The reaction mixture was poured onto a column (30 mm × 1000 mm) containing cation exchange resin (Dowex 50W-X8, 200—400 mesh, Na^+ form). After the column had been swept with water, the adsorbed band was eluted with 0.075 mol dm^{-3} aqueous solution of NaCl. Three brown bands were eluted in succession. The first eluate was concentrated to a small volume with a rotary evaporator below 15 °C. The deposited NaCl was filtered off and a large amount of ethanol–acetone (1:2) mixture added to the filtrate. The solution was kept in a refrigerator overnight. The crude crystals were collected by filtration. The dark-brown needle crystals were obtained by recrystallization from a small amount of water by adding acetone.

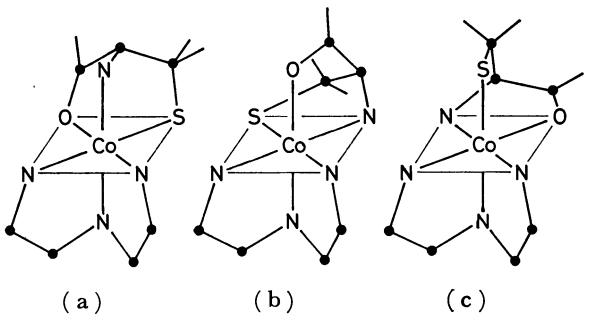

Fig. 1. Three possible isomers of [Co(L-pen)(dien)]$^+$; (a) *trans*(N_1N), (b) *trans*(N_1O), and (c) *trans*(N_1S).

Preliminary photographic examination established a hexagonal unit cell containing six chemical units of [Co(L-pen)(dien)]Cl·H_2O. The systematic absence led to the space group $P6_1$. The least-squares refinement of setting angles of 41 reflections, measured on a Rigaku Denki automatic four circle diffractometer (AFC-5) using Mo $K\alpha$ radiation monochromatized by a graphite plate, led to the cell constants: $a=21.035$ (5) Å, $c=6.459$ (3) Å. The calculated density of 1.46 g cm^{-3} agrees with the observed density of 1.49 g cm^{-3} by the flotation method.

The intensity data up to $2\theta<55°$ were collected by use of ω-2θ scanning technique, the scanning rate being 4° in ω per minute. During the course of the data collection, three reflections were monitored every 100 reflections. The intensity data were converted to the F_o data in the usual manner. Absorption corrections were not applied. The standard deviations were estimated by counting statistics. A total of 1504 independent reflections with $F_o>3\sigma(F_o)$ were retained as observed, and employed in solving and refining the structure.

The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra, with a JASCO J-20 spectropolarimeter. All measurements were carried out in aqueous solution at room temperature.

Determination of Crystal Structure

The position of the cobalt atom was obtained from the three-dimentional Patterson function. Fourier and

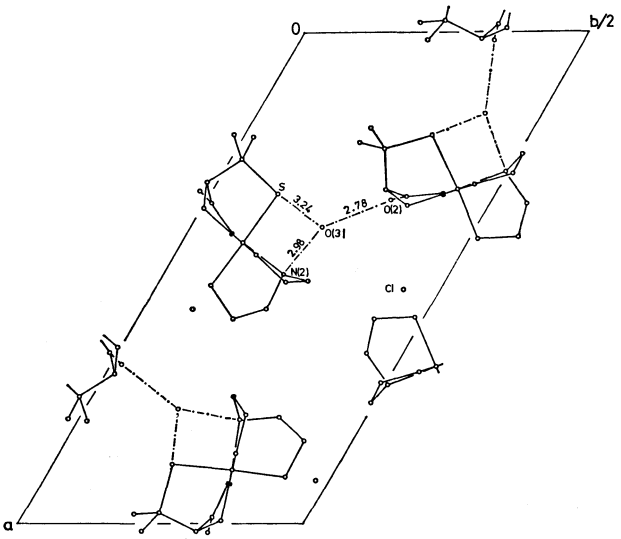

Fig. 3. A projection of the crystal packing viewed along the c axis.

difference-Fourier maps based on the cobalt atom revealed the rest of the structure. The structure was refined by a full-matrix least-squares refinement of the positional and anisotropic thermal parameters (program RFINE by L. W. Finger, which was modified by H. Horiuchi (1979), was used). The final R values in the space groups $P6_1$ and $P6_5$ converged 0.076 and 0.077, respectively, using the anomalous scattering factors. Taking the known absolute configuration of the L-penicillaminate in the complex into consideration, the space group must be $P6_1$. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[7] The calculations were carried out on a FACOM M-200 computer at the University of Tsukuba. The final atomic parameters and their standard deviations are given in Table 1. A list of the anisotropic thermal parameters and a table of the observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8248).

Results and Discussion

Description of the Structure. A perspective drawing of the complex cations obtained is given in Fig. 2 and their packing mode is illustrated in Fig. 3. The atomic numbering scheme is given in Figs. 2 and 3. The bond lengths and angles with their estimated standard deviations in the complex ions are listed in Table 2. The coordination geometry around the cobalt atom is approximately octahedral. The L-penicillaminate and diethylenetriamine coordinate facially to the cobalt atom as terdentate ligands. The nitrogen atom of the L-pen ligand occupies the trans position to the imino nitrogen atom of the dien ligand. Therefore, this cation is determined to have a *trans(N$_1$N)* configuration as shown in Fig. 1 (a).

The bond lengths and angles are similar to those for the cobalt(III) complexes with diethylenetriamine and/or sulfur-containing amino carboxylates.[2,8-12] The averages of the cobalt-ligand bond lengths are 2.255 (5) Å for Co–S, 1.926 (9) Å for Co–O, and 1.972 (11) Å for Co–N. The Co–N distance involving the nitrogen atom bonded trans to the sulfur atom is 2.007 Å and the average cis Co–N distance is 1.961 Å, giving a difference between trans and cis distances of 0.046 Å. This fact suggests that the trans effect due to the coordinated sulfur atom and the difference (0.046 Å) corresponds with those of the cobalt(III) complexes with the thiolato ligands such as 2-aminoethanethiolate.[13]

The crystal structure consists of the complex cations, chloride anions, and water molecules. As shown in Fig. 3, a water molecule O(3) atom is surrounded by the three atoms: *e.g.*, the oxygen O(2) atom of the complex cation and the sulfur S and nitrogen N(2) atoms of the other complex cation. The O(3)–O(2) or O(3)–N(2) distance is mostly less than 3 Å and O(3)–S one is 3.24 Å. These distances suggest that those are hydrogen bonds.

In order to examine the conformations of chelate rings, the displacements of relevant atoms from the chelate ring plane, which is defined by the central

cobalt atom and the two coordinated atoms in the chelate ring, were calculated. The results are given in Table 3. The diamine chelate rings in the dien ligand take reasonable conformations,[8] *δ* form for N(2)-C(8)-C(9)-N(4) and *λ* one for N(2)-C(6)-C(7)-N(3). The N-S chelate ring in the L-pen ligand has a similar conformation to that of the *trans(O)*-[Co(*R*,*R*-ebsmc)]+ complex, where *R*,*R*-ebsmc denotes *N*,*N'*-ethylenebis(*S*-methyl-L-cysteinate) which has the same frame-work as the L-pen ligand.[9]

Electronic Absorption and CD Spectra. The electronic absorption and CD spectra of the *trans(N$_1$N)*-[Co(L-pen)(dien)]+ complex are shown in Fig. 4. The sulfur-to-metal charge transfer band of this complex is observed at 34.5×10^3 cm^{-1}, as in the case of the cobalt(III) complexes with thiolato and thioether ligands.[3,9,14] In the first absorption band region, the complex shows an explicit shoulder (*ca.* 16.7×10^3 cm^{-1}) on the lower energy side of the major peak (20.0×10^3 cm^{-1}) and the lower energy component is characteristic of thiolato coordination.[3,15] The absorption spectrum of this complex shows comparatively intense humps in the region from 23×10^3 cm^{-1} to 28×10^3 cm^{-1} and an intense positive CD band ($\Delta\varepsilon$ +3.75 at 25.0×10^3 cm^{-1}) in appearance corresponds to the humps. The absorption and CD spectral behavior in this region are common to those of the *trans(N$_1$O)*- and *trans(N$_1$S)*-[Co(L-pen)(dien)]+ complexes.[4,16] Similar spectral patterns are observed for the [Co(L-pen)(NH$_3$)$_3$]+ complex, which belongs to the *cis(SO)*-[Co(N)$_4$(S)(O)] type. It does not have chirality arising from the skew pair of chelate rings because of the coordination of three ammonia molecules instead of dien.[16] Taking these facts into account, it can be considered that the absorption and CD bands in this region are characteristic of the coordinated thiolato donor atom of the ligand.

Spectrophotometric Determination of Silicic Acid by Flow Injection Analysis

Takushi Yokoyama,* Yukio Hirai, Norimasa Yoza, Toshikazu Tarutani, and Shigeru Ohashi

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 10, 1982)

Flow injection analysis (FIA) was developed for the spectrophotometric determination of silicic acid based on the formation of a yellow molybdosilicic acid (yellow method) and a heteropoly blue complex (blue method). In the yellow method, silicic acid in the concentration range of 2 to 100 ppm (SiO_2) could be determined at a sampling rate of 60 samples/h. The FIA system was modified to determine silicic acid in the presence of orthophosphate. Oxalic acid was used for the decomposition of molybdophosphoric acid. The modified system was employed for the rapid and selective determination of silicic acid in well and river waters. In the blue method, ascorbic acid was used to reduce the yellow molybdosilicic acid to a heteropoly blue complex. Silicic acid in the concentration range of 0.02 to 1.0 ppm (SiO_2) could be determined at a sampling rate of 40 samples/h. The FIA system was also modified to determine silicic acid in the presence of orthophosphate. The reducing agent was introduced after molybdophosphoric acid had been completely decomposed by adding oxalic acid. The modified system was employed for the determination of silicic acid in sea water.

The silicic acid content of natural waters is of particular interest in geochemistry inasmuch as it is related to the weathering of rocks and the formation of clay minerals. Recently, interest in the study of the behavior of silicic acid in natural waters has increased, because silicic acid as well as orthophosphate is one of the major inorganic nutrients for planktons and microorganisms. Since it is necessary to analyze a large number of samples, rapid and automatic method of analysis for silicic acid is increasingly becoming important.

Silicic acid is usually determined by spectrophotometric method based on the formation of a yellow molybdosilicic acid (yellow method). Often, to enhance the sensitivity of the analysis, the molybdosilicic acid is reduced to yield a heteropoly blue complex (blue method).

An air-segmented method has been applied to the determination of silicic acid.[1] The method is satisfactory with respect to reproducibility and sensitivity, but the disadvantages are that the instrument is expensive and that the procedure is somewhat time-consuming. Recently a flow-coulometric method has been developed for the rapid determination of silicic acid.[2] The method is convenient but less sensitive than the conventional spectrophotometric method.

Flow injection analysis (FIA) is a simple and convenient approach to rapid chemical analysis.[3] The present authors have already reported successful applications of FIA to the determination of phosphorus compounds.[4,5] One of the most advantages of FIA is that reaction conditions, *e.g.*, reaction time, reaction temperature, reagent concentration, *etc*, can easily be kept constant with a simple apparatus. The formation of molybdosilicic acid is susceptible to such conditions as described above. Therefore the application of FIA is effective to achieve a rapid and precise analysis for silicic acid.

In a previous paper,[6] we have briefly reported a successful application of FIA to the determination of silicic acid based on the formation of a molybdosilicic acid. The present work was carried out to attain two purposes. One is to determine silicic acid rapidly and precisely in the wide range of concentration. The other is to modify the FIA system for the determination of silicic acid in the presence of orthophosphate. The FIA system was found to be useful for the determination of silicic acid in natural waters such as well, river and sea waters.

Experimental

Samples and Reagents. All reagents used were of analytical reagent grade. Unless otherwise stated deionized distilled water was used. A monosilicic acid stock solution (100 ppm SiO_2) was prepared by dissolving silica gel (Mallinckrodt Chemical Works) in a boiling water. The concentration of this stock solution was standardized spectrophotometrically. Working standard solutions were prepared by diluting the stock solution with water. A molybdenum(VI) reagent was prepared by dissolving 8.83 g of hexaammonium heptamolybdate ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$) in *ca.* 0.9 dm^3 of water. After 7.5 cm^3 of concentrated sulfuric acid had been added, the solution was diluted to 1 dm^3 with water. The reagent was composed of 0.05 mol dm^{-3} Mo^{VI} and 0.135 mol dm^{-3} H_2SO_4. A 0.5 mol dm^{-3} oxalic acid solution was prepared by dissolving oxalic acid ($H_2C_2O_4\cdot 2H_2O$). Orthophosphate solution was prepared by dissolving potassium dihydrogenorthophosphate (KH_2PO_4), which had been dried for 1 h at 110 °C. L-Ascorbic acid solutions (0.02 mol dm^{-3}) containing various amounts of sulfuric acid were prepared under cooling with ice. Artificial sea water as a carrier solution for the analysis of sea water was prepared by dissolving 24.7 g of sodium chloride, 13 g of magnesium chloride ($MgCl_2\cdot 6H_2O$) and 4 g of anhydrous sodium sulfate in water, and then the volume was made up to 1 dm^3. Natural water was filtered just after sampling by membrane filter (0.45 μm pore size) and stored in a 50-cm^3 polyethylene bottle. The determination of silicic acid in natural water samples was carried out within 24 h after sampling.

Apparatus, Manifold, and Procedure. Four kinds of manifolds (systems I—IV) were designed (Fig. 1). Two reciprocating pumps (Kyowa KHU-W-104 (P_1) and Kyowa KHU-W-52 (P_2)) with double plungers were used to introduce carrier solutions into analytical lines. A sample (S) was injected into a carrier stream *via* a loop-valve in-

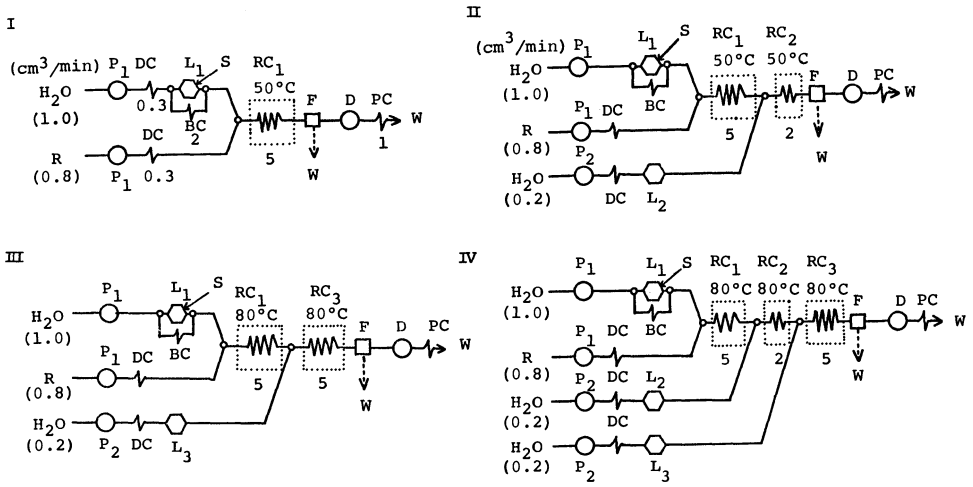

Fig. 1. FIA systems I—IV for the determination of silicic acid based on the yellow method (I and II) and the blue method (III and IV). FIA systems II and IV were designed to determine silicic acid in the presence of orthophosphate. R: molybdenum(VI) reagent, P_1 and P_2: reciprocating pump, DC: damper coil, BC: bypass coil, RC_1, RC_2, and RC_3: reaction coil, PC: back pressure coil, L_1, L_2, and L_3: loop valve injector, F: three way valve, D: detector and W: waste. The numerals under the coils refer to their lengths in meter. The numerals under the pump indicate the flow rate of solutions. The dotted lines show the manifolds immersed in the thermostated silicone oil-bath.

jector (L_1, Seishin VMU-6). The injected sample was then transported through reaction coils (RC_1, RC_2, and RC_3, PTFE 0.5 mm ID). To accelerate chemical reaction the reaction coils were heated in a silicone-oil bath (Thomas-T-201). Color complexes formed in the reaction coils were monitored using a spectrophotometer (D, Hitachi 200—10) with a flow-through cell (8 mm light path, 8 μl volume).

An elastic precoil (DC, Technicon Part No. 065-116-0536-13, 30 cm) was applied to dampen the pressure pulse caused by the reciprocating pumps. A bypass coil (BC, PTFE 0.3 mm i.d., 2 m) was also applied to minimize the injection shock. A three way valve (F, Kyowa KMM-4V) was located just before the detector to observe the variation in absorbance of a sample zone in the flow-through cell (Stopped-flow method). A back pressure coil (PC, PTFE 0.3 mm i.d., 1 m) was attached at the exit of the flow-through detector to eliminate a noise due to gas-bubbling. Both an oxalic acid and an ascorbic acid solutions were introduced *via* loop-valve injectors L_2 and L_3, (Kyowa KMM-4V-2) respectively. The function of these valves was precisely described in a previous paper.[5] This method makes it possible to put in, cut off or exchange a reagent without any reconditioning of a pump.

In FIA system I, a sample was mixed with a molybdenum (VI) reagent (R). A molybdosilicic acid formed in the reaction coil (RC_1) was directly monitored at 400 nm. FIA system II was designed to determine silicic acid in the presence of orthophosphate. The oxalic acid solution was added from another line using the loop-valve injector (L_2) to decompose molybdophosphoric acid formed in the first reaction coil (RC_1). The remaining molybdosilicic acid was monitored at 400 nm. In FIA system III, the ascorbic acid solution was introduced using the loop-valve injector (L_3) to reduce the molybdosilicic acid in the reaction coil (RC_3). The resultant blue complex was monitored at 820 nm. FIA system IV was designed to determine silicic acid in the presence of orthophosphate. After decomposition of molybdophosphoric acid, the remaining molybdosilicic acid was reduced with ascorbic acid to a heteropoly blue complex.

Results and Discussion

Flow Injection Analysis for Silicic Acid Based on the Formation of a Molybdosilicic Acid. Flow rates of carrier solutions through the pump (P_1) and a length of the reaction coil (RC_1) of the FIA system I were designed to determine silicic acid at 60 samples/h. Taking the composition of a molybdosilicic acid (Si:Mo= 1:12) and the flow rate of each carrier solution into account, 0.05 mol dm^{-3} molybdenum(VI) reagent solution was used to determine silicic acid up to 100 ppm (SiO_2). The acid concentration of the molybdenum(VI) reagent was adjusted to 0.135 mol dm^{-3} in H_2SO_4.[7] The temperature of the heating bath was kept at 50 °C to accelerate the chemical reaction. The residence time of a sample in the reaction coil was about 1 min.

Figure 2 shows a normal FIA signal and a stopped-flow signal. The same sample was injected twice. At the top of the second signal, the valve F was switched to hold the sample zone in the flow-through cell.

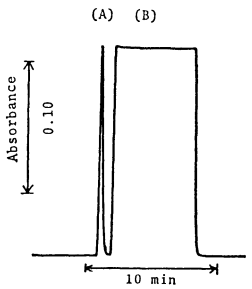

Fig. 2. FIA profile (A) and stopped flow signal (B) for silicic acid obtained by FIA system I.
Sample: 50 ppm (SiO_2), 0.10 cm^3.

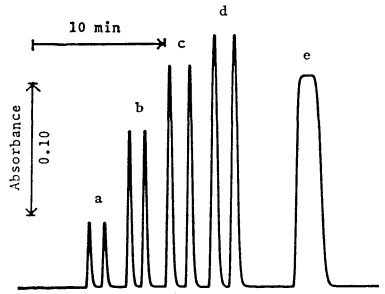

Fig. 3. Effect of the length of sample loop on the FIA signal.
Sample: 10 ppm (SiO_2), a; 0.08, b; 0.50, c; 1.0, d; 1.5, and e; 5.0 m. FIA system I was used.

There was no remarkable change in absorbance. This suggests the completion of the color forming reaction.

Figure 3 shows the effect of the sample volume on the FIA signal. The injection volume of a sample was varied by using the sampling loops (PTFE, 0.5 mm i.d.) with different length. The peak height of the FIA signal increased with lengthening the sampling loop up to 1.5 m and decreased at 5.0 m.[8] Therefore, sampling loops of 0.08 and 1.5 m, corresponding to *ca.* 0.10 and 0.50 cm^3, were used.

To demonstrate the reproducibility, the samples (2, 20, and 100 ppm (SiO_2)) were injected ten times. The precisions (C.V.) were 1.7, 0.2, and 0.07% for silicic acid of 2, 20, and 100 ppm (SiO_2), respectively. The standard sample of silicic acid could be measured in the concentration range of 2 to 100 ppm. The sampling rate was 60 samples/h. The detection limit (S/N=2) was 0.3 ppm.

Orthophosphate reacts with molybdenum(VI) reagent to form a yellow molybdophosphoric acid and the complex interferes with the determination of silicic acid. In order to eliminate the interference, decomposing agents have been employed for the decomposition of molybdophosphoric acid. In Japanese Industrial Standard (JIS) method,[9] oxalic acid is used as the decomposing agent. As it is necessary to add an excessive amount of the decomposing agent compared with that of molybdenum(VI),[10] 0.5 mol dm^{-3} oxalic acid solution was used.

The FIA system II was designed to determine silicic acid in the presence of orthophosphate. Oxalic acid solution was introduced from another line using a loop-valve injector (L_2). As the decomposition of molybdophosphoric acid proceeds rapidly even at room temperature,[10] a short reaction coil (RC_2, 2 m) was applied. The heating bath was kept at 50 °C. The remaining molybdosilicic acid was monitored at 400 nm.

The efficiency of the decomposition effect of oxalic acid was examined. The results are shown in Fig. 4. From the FIA signals (a—c), it is clear that both molybdosilicic acid and molybdophosphoric acid form independently in the absence of oxalic acid. From the FIA signals (d—k), the interference due to orthophosphate up to 100 ppm (PO_4^{3-}) could be eliminated by the addition of oxalic acid. Further increase in the concentration of phosphate caused a decrease in peak height. At 300 and 400 ppm (PO_4^{3-}), the FIA signals became double peak. The decrease in peak height and the appearance of double peak may be caused by the deficiency of molybdenum(VI) to be required for the formation of molybdosilicic acid, because molybdenum(VI) is consumed by the formation of molybdophosphoric acid.

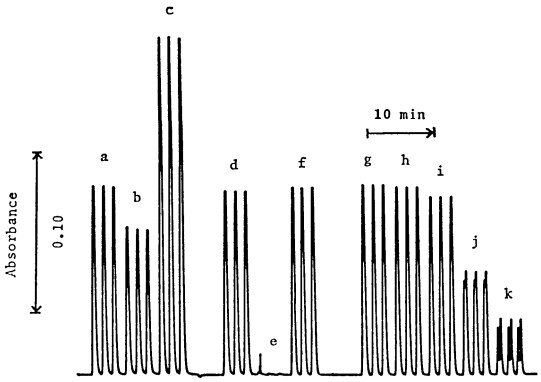

Fig. 4. Detection peaks for silicic acid samples containing various amounts of orthophosphate in the absence (a—c) and presence (d—k) of oxalic acid.
Sample: a; 10 ppm (SiO_2)+0 ppm (PO_4^{3-}), b; 0 ppm (SiO_2)+20 ppm (PO_4^{3-}), c; 10 ppm (SiO_2)+20 ppm (PO_4^{3-}), d; 10 ppm (SiO_2)+0 ppm (PO_4^{3-}), e; 0 ppm (SiO_2)+20 ppm (PO_4^{3-}), f; 10 ppm (SiO_2)+20 ppm (PO_4^{3-}), g; 10 ppm (SiO_2)+50 ppm (PO_4^{3-}), h; 10 ppm (SiO_2)+100 ppm (PO_4^{3-}), i; 10 ppm (SiO_2)+200 ppm (PO_4^{3-}), j; 10 ppm (SiO_2)+300 ppm (PO_4^{3-}), and k; 10 ppm (SiO_2)+400 ppm (PO_4^{3-}), 0.50 cm^3. Each sample was injected in triplicate.

Table 1. Silicic acid concentration in well and river water samples obtained by the FIA and JIS method

Sample	FIA(SiO_2 ppm)	JIS(SiO_2 ppm)
Well water		
(A)	17.8	17.4
(B)	20.0	19.3
(C)	20.9	20.3
River water		
(D)	9.9	9.5
(E)	12.6	12.1
(F)	12.5	12.1
(G)	12.4	12.1
(H)	12.6	12.3
(I)	11.8	11.5
(J)	13.4	13.1
(K)	13.7	13.3
(L)	14.2	14.0

Determination of Silicic Acid in Well and River Waters. The FIA system II was employed for the determination of silicic acid in well and river waters. Routine runs for the determination are illustrated in Fig. 5, together with that for a series of standard silicic acid. The sampling rate was 40 samples/h. The analytical values obtained by FIA are shown in Table 1, together with those obtained by JIS method. Both results coincide satisfactorily with a correlation coefficient of 0.998.

Flow Injection Analysis for Silicic Acid Based on the Formation of a Heteropoly Blue Complex. To get higher sensitivity and avoid the interference due to absorption by foreign compounds at 400 nm, a method was examined for the determination of silicic acid based on the formation of a heteropoly blue complex. Among many reducing agents,[11] ascorbic acid was used to reduce a yellow molybdosilicic acid to a blue compound because of its simple preparation. The reducing agent was composed of 0.02 mol dm^{-3} ascorbic acid and 2 mol dm^{-3} sulfuric acid. The reducing agent was added after the formation of molybdosilicic acid.[11]

In the FIA system III, the ascorbic acid solution was introduced from the another line using a loop-valve injector (L_3). A five meter reaction coil (RC_3) was applied to reduce a molybdosilicic acid to a heteropoly blue complex. Figure 6 shows that FIA signal and stopped-flow signal greatly depended on the temperature of the heating bath. The stopped-flow signal at 60 °C showed a steep increase in absorbance followed by a steady state. The signal was quite different from the signal observed in Fig. 2. There was no remarkable increase in the base line level when the carrier reagent was stopped in the flow-through cell (Fig. 6(IV)). This indicates that the formation of blue isopolymolybdic acid during the stopping period is negligible. Therefore the difference in height between the FIA signal and the top of the stopped flow signal is regarded as an unreduced portion of the molybdosilicic acid. At 80 °C, more than 90% of molybdosilicic acid was reduced. The determination of silicic acid hereafter was carried out at 80 °C.

The standard sample of silicic acid could be measured in the concentration ranges of 0.02 to 0.1 and 0.2 to 1.0 ppm (SiO_2). The samples were injected successively at the sampling rate of 40 samples/h. The detection limit (S/N=2) was 0.01 ppm (SiO_2). The precision (C.V.) was 0.5% for 0.6 ppm silicic acid.

The formation of a heteropoly blue complex of silicon and molybdenum and blue isopolymolybdic acid is susceptible to acid concentration, temperature and addition of decomposing agent of molybdophosphoric acid.[7] The effect of acid concentration on the FIA signal and the base line level was examined by using FIA system IV. The effect was examined under two conditions. Figure 7 shows the effect of the acid con-

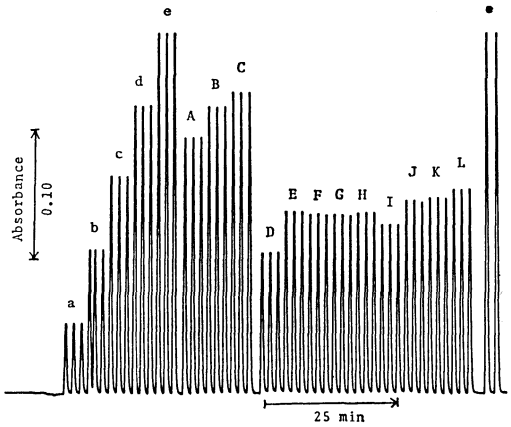

Fig. 5. Determination of silicic acid in well and river waters using FIA system II.
The first fifteen peaks on the left and the last two peaks on the right were obtained by injecting standard samples of silicic acid. Sample: a; 5, b; 10, c; 15, d; 20, and e; 25 ppm (SiO_2), A—C; well waters, D—L; river waters. Sample volume: 0.50 cm^3.

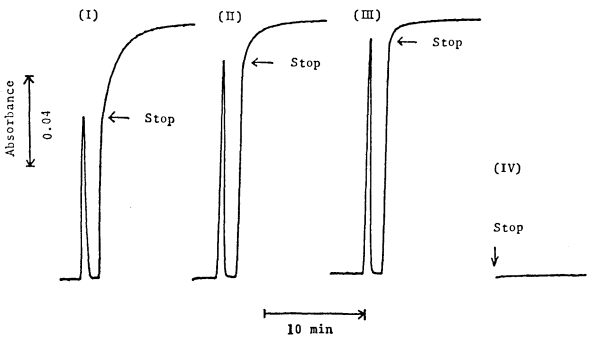

Fig. 6. FIA profiles and stopped flow signals for silicic acid of 1 ppm (SiO_2), 0.50 cm^3.
Temperature of the heating bath: (I); 60 °C, (II); 70 °C, and (III); 80 °C. The signal (IV) shows a stopped flow signal of a base line level at 80 °C. FIA system III was used.

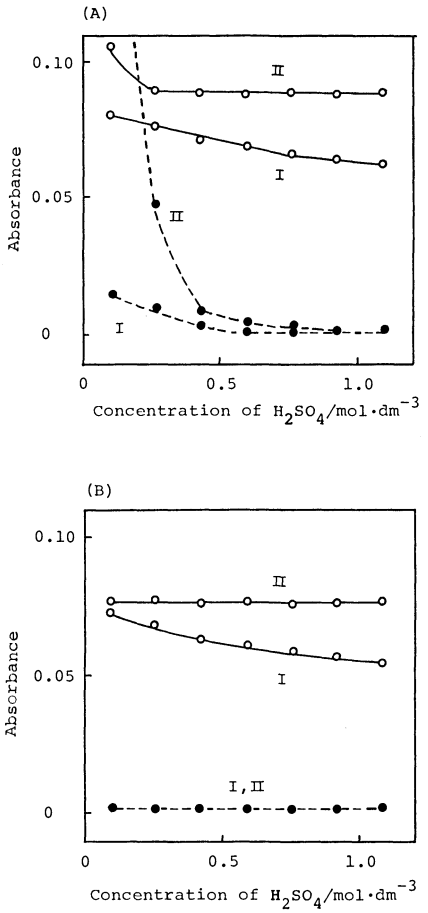

Fig. 7. Effect of acid concentration in the reaction coil (RC_3) and temperature of the heating bath on the FIA peak height and base-line level in the absence (A) and presence (B) of oxalic acid.
FIA system IV was used. ○: Peak height, ●: base line level. I: 50 °C and II: 80 °C. Sample: 1 ppm (SiO_2), 0.50 cm^3.

centration on the FIA signal and the base line in the absence and the presence of oxalic acid, respectively. Oxalic acid and ascorbic acid solutions were introduced with the loop-valve injectors (L_2) and (L_3), respectively. Figure 7(A) shows the results obtained by introducing water in place of oxalic acid solution. The abscissa of Fig. 7 indicates the acid concentration in the reaction coil (RC_3). The acid concentration was controlled by adding various amounts of sulfuric acid to the ascorbic acid solution.

It is clear from Fig. 7(A) that the rate of the formation of both a heteropoly blue complex and blue isopolymolybdic acid increases at higher temperature and at lower acid concentration. Therefore a suitable amount of sulfuric acid must be added to avoid the formation of the blue isopolymolybdic acid in the absence of oxalic acid. It is also necessary to increase the temperature of the heating bath to accelerate the formation of the heteropoly blue complex.

From Fig. 7(B), it is seen that blue isopolymolybdic acid does not form in the presence of oxalic acid. This fact also indicates that oxalic acid reacts with molybdenum(VI). The absorbance of the plateau region of the heteropoly blue complex at 80 °C obtained in the presence of oxalic acid is somewhat lower than that obtained in the absence of oxalic acid, because oxalic acid decomposes a part of molybdosilicic acid at such a high temperature as 80 °C.

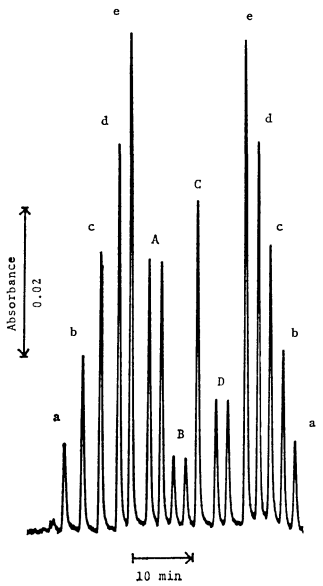

Fig. 8. Determination of silicic acid in sea waters using FIA system IV.
The first five peaks on the left and last five peaks on the right were obtained by injecting standard samples of silicic acid. Sample: a; 0.2, b; 0.4, c; 0.6, d; 0.8, and e; 1.0 ppm (SiO_2), A—D; sea waters, 0.50 cm^3. Each sample was injected in duplicate except C.

It must be noted that there is no need to add sulfuric acid to the ascorbic acid solution, when oxalic acid is used. This fact is favorable for the preparation of ascorbic acid solution, because ascorbic acid is easily oxidized in the presence of sulfuric acid.

Determination of Silicic Acid in Sea Water. The FIA system IV was employed for the determination of silicic acid in sea water. Artificial sea water was introduced as a carrier solution of a sample. Figure 8 shows routine runs for the analysis of sea water. A reducing agent, ascorbic acid solution, was composed of 0.02 mol dm^{-3} L-ascorbic acid and 2 mol dm^{-3} sulfuric acid. The silicic acid concentration of the four samples were (A) 0.57, (B) 0.15, (C) 0.69, and (D) 0.30 ppm (SiO_2), respectively.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56030024 from the Ministry of Education, Science and Culture.

Electron Transfer from Tetrakis(isocyanide)rhodium(I) Monomers, and the Oligomers to Iron(III) and Cobalt(III) Complexes. Enhancement of the Reactivity by the Oligomerization

Shunichi Fukuzumi, Nobuaki Nishizawa, and Toshio Tanaka*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received April 17, 1982)

Electron transfer reactions from tetrakis(isocyanide)rhodium(I) ($[RhL_4]^+$ to iron(III) complexes of the $[Fe(N\text{–}N)_3]^{3+}$ type (N–N=1,10-phenanthroline, 2,2′-bipyridine) proceed through precursor complexes formed between $[RhL_4]^+$ and $[Fe(N\text{–}N)_3]^{3+}$ with 1:1, 1:2, and 2:1 stoichiometry. A similar scheme is suggested for the reaction of bis(isocyanide)bis(triphenylphosphine)rhodium(I) with the same oxidants. The intramolecular electron transfer rate constants k_1 in the 1:1 precursor complexes have been determined in MeCN at 298 K. In accordance with Marcus theory, the log k_1 values are linearly related with the reduction potentials of oxidants with the theoretical slope of 8.5. The $[RhL_4]^+$ cations form oligomers in MeCN; $[RhL_4^+]_n$ (n=2,3), and the equilibrium constants for oligomerization have been determined. For a given oxidant $[Co(bpy)_3]^{3+}$ (bpy= 2,2′-bipyridine), the log k_1 value of $[RhL_4^+]_n$ increases in parallel with the HOMO energy of $[RhL_4^+]_n$; monomer<dimer<trimer.

Considerable interest exists in transition metal complex oligomers from the view point of their potential role in solar energy storage reaction,[1] as well as the understanding of the fundamental nature associated with the metal-metal interaction.[2] The redox properties of such metal complex oligomers, however, have scarcely been known especially in the comparison between the oligomers and the monomer. Thus, there has been no report yet on electron transfer reactions of rhodium(I) complex monomers and the oligomers, although extensive studies have been carried out on the oxidative addition reactions to rhodium(I) complexes, as well as the catalytic reactions.[3,4]

In the present study, we report kinetics of electron transfer reactions of tetrakis(isocyanide)rhodium(I) and the oligomers, $[RhL_4^+]_n$ (n=1—3) with some oxidants, $[Fe(N\text{–}N)_3]^{3+}$ (N–N=2,2′-bipyridine, substituted 1,10-phenanthrolines) and $[Co(bpy)_3]^{3+}$ (bpy=2,2′-bipyridine), as well as the effects of the ligand (L) on the oligomerization of $[RhL_4]^+$. Mechanisms for the electron transfer reactions of $[RhL_4^+]_n$ which forms highly associative precursor complexes with oxidants prior to electron transfer are discussed based on the kinetics. The intramolecular electron transfer rate constants in the precursor complexes have been obtained for both the $[RhL_4]^+$ monomers and the oligomers, and are compared in the context of the Marcus theory.[5]

Results and Discussion

Oligomerization of $[RhL_4]^+$. The $[Rh(PhNC)_4]^+$ cation has been reported to oligomerize in MeCN, yielding the dimer, $[Rh_2(PhNC)_8]^{2+}$, and the trimer, $[Rh_3(PhNC)_{12}]^{3+}$, which involve face to face contact of the $[Rh(PhNC)_4]^+$ units with weak, but direct Rh(I)–Rh(I) bonds.[2e] The formation of oligomers is characterized from the electronic spectra which show absorption bands in longer wavelengths than those due to the monomer.[2e] The electronic transition energies of the monomers, the dimers, and the trimers of a series of $[RhL_4]^+$ were determined as listed in Table 1. The equilibrium constants K_D and K_T for oligomerization defined by Eqs. 1 and 2 were determined by Eqs. 3 and 4, respectively,[2e]

$$2[RhL_4]^+ \overset{K_D}{\rightleftharpoons} [Rh_2L_8]^{2+} \quad (1)$$

$$[Rh_2L_8]^{2+} + [RhL_4]^+ \overset{K_T}{\rightleftharpoons} [Rh_3L_{12}]^{3+} \quad (2)$$

$$[Rh]/A_D^{1/2} = 1/(\varepsilon_D K_D)^{1/2} + 2A_D^{1/2}/\varepsilon_D \quad (3)$$

$$A_T = (\varepsilon_T K_T A_D^{3/2})/(\varepsilon_D^{3/2} K_D^{1/2}), \quad (4)$$

where [Rh] is the total Rh concentration in terms of the monomer, A_D and A_T are the absorbances due to dimers and trimers, respectively, and ε_D and ε_T are the corresponding molar extinction coefficients. According to Eq. 3, there is a linear relation between $[Rh]/A_D^{1/2}$ and $A_D^{1/2}$; the values of ε_D and K_T are obtained from the slope and the intercept, respectively. The K_T value is evaluated from a proportional relation between A_T and $A_D^{3/2}$ in Eq. 4, using the values of ε_D and K_D obtained from Eq. 3 as well as ε_T evaluated from the relation $\varepsilon_T = 1.5\ \varepsilon_D$.[2e] Application of Eqs. 3 and 4 to $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ and $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K is shown in Figs. 1a and 1b, respectively. The K_D and K_T values also are listed in Table 1. Plots of Eqs. 3 and 4 require the presence of a large amount of the oligomers within limited solubilities of $[RhL_4]^+$. Thus, when the K_D and K_T values are small (<2 mol^{-1} dm^3), Eqs. 5 and 6 are

$$A_D = \varepsilon_D K_D [Rh]^2 \quad (5)$$

$$A_T = \varepsilon_T K_D K_T [Rh]^3 \quad (6)$$

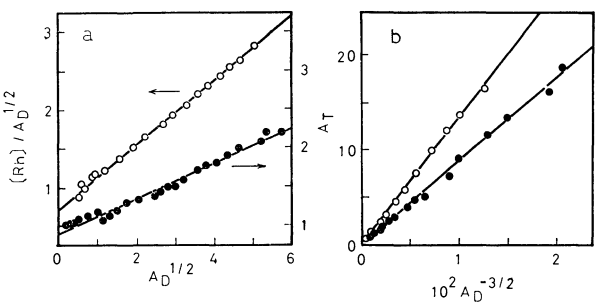

Fig. 1. Plots for the determination of (a) K_D and (b) K_T in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K; ○ $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$, A_D at 564 nm and A_T at 710 nm, ● $[Rh(p\text{-}MeC_6H_4NC)_4]^+$, A_T at 563 nm and A_T at 705 nm. See Eqs. 3 and 4 in text.

used instead of Eqs. 3 and 4, respectively. By using the relations, $\varepsilon_D=2\,\varepsilon_M$ and $\varepsilon_T=3\,\varepsilon_M$,[2e] the K_D or K_T value for $[Rh(PhCH_2NC)_4]^+$ was estimated from the slope in Fig. 2a or 2b. Similarly, the K_D values for $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ (Fig. 2a), $[Rh(t\text{-}BuNC)_4]^+$, and $[Rh(cyclo\text{-}C_6H_{11}NC)_4]^+$ were obtained from the plots of Eq. 5. No appreciable oligomer formation was observed for $[Rh(p\text{-}ClC_6H_4NC)_4]^+$, $[Rh(2,6\text{-}Me_2C_6H_3NC)_4]^+$, $[Rh(p\text{-}MeOC_6H_4NC)_2(PPh_3)_2]^+$, and $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_2(PPh_3)_2]^+$.

For tetrakis(*p*-substituted phenyl isocyanide)rhodium(I), $[Rh(p\text{-}RC_6H_4NC)_4]^+$, the K_D and K_T values increase in the order R=Cl<H<Me<MeO, which is compatible with the donor ability of the para-substituents. In addition, the rhodium(I) complexes with *t*-BuNC and *cyclo*-$C_6H_{11}NC$ as ligands (Nos. 9 and 10), whose donor ability is less than PhNC,[6] oligomerize in less extents than $[Rh(PhNC)_4]^+$. On the other hand, methyl substitution on the 2,6 positions of PhNC (Nos. 5 and 6) causes substantial decrease of the K_D and K_T values compared with the corresponding rhodium(I) complexes without substituents at these positions (Nos. 2 and 3). Such a steric effect on the 2,6 positions is consistent with a staggered configration of the ligands in the crystal structure of dimeric $[Rh(PhNC)_4^+]_2$.[2e] No appreciable oligomerization in MeCN was observed also in the rhodium(I) complexes with bulky triphenylphosphine (Nos. 7 and 8). Thus, the K_D and K_T values seem to be determined by the balance between the electronic and the steric effects of the ligands.

Kinetics and Reaction Scheme for Electron Transfer Reactions between $[RhL_4]^+$ *and* $[Fe(N\text{–}N)_3]^{3+}$. Upon mixing $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ and $[Fe(phen)_3]^{3+}$ in MeCN containing 0.1 mol dm^{-3} *n*-Bu_4NClO_4 at 298 K, an intense absorption band due to the reduced iron(II) species, $[Fe(phen)_3]^{2+}$, appears at 507 nm without delay. The stoichiometry of the reaction has been established as 1:1 by the spectral titration of the iron(II) species using $[Fe(phen)_3]^{2+}$ prepared independently as a reference, as shown in Fig. 3. All the rhodium(I) complexes studied here also were readily oxidized by various iron(III) complexes, $[Fe(N\text{–}N)_3]^{3+}$, as oxidants in MeCN (Eq. 7). The oxidized rhodium-

$$[RhL_4]^+ + [Fe(N\text{–}N)_3]^{3+} \longrightarrow [RhL_4]^{2+} + [Fe(N\text{–}N)_3]^{2+} \quad (7)$$

(II) species has well been regarded as radicals,[7] and dimerizes rapidly as shown in Eq. 8.[8] Thus, electron

$$2[RhL_4]^{2+} \xrightarrow{\text{fast}} [Rh_2L_8]^{4+} \quad (8)$$

transfer from $[RhL_4]^+$ to $[Fe(N\text{-}N)_3]^{3+}$ is irreversible and no back electron transfer may occur.

Rates of the electron transfer reactions between $[RhL_4]^+$ and $[Fe(N\text{-}N)_3]^{3+}$ were followed by monitoring the rise of the absorbance due to $[Fe(N\text{-}N)_3]^{2+}$ in MeCN at 298 K, using a stopped flow spectrophotometer. The ionic strength was maintained constant with n-Bu_4NClO_4 (0.1 mol dm^{-3} in most cases). The reactions of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ and $[Rh(t\text{-}BuNC)_4]^+$ which do not oligomerize appreciably obeyed pseudo-first-order kinetics with excess amounts of either $[Fe(N\text{-}N)_3]^{3+}$ or $[RhL_4]^+$; the kinetic plots were linear over several half-lives. As typical examples, the dependences of the pseudo-first-order rate constants k_{Fe} and k_{Rh} on the concentrations of $[Fe(N\text{-}N)_3]^{3+}$ and $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$, respectively, are shown in Fig. 4. The rate constants k_{Fe} and k_{Rh} are different from each other at the same concentrations of reactants used in a large excess. In additon, k_{Rh} exhibits "saturation kinetics" with increasing the concentration of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$, while k_{Fe} is linear against the concentration of $[Fe(N\text{-}N)_3]^{3+}$. However, the intercepts of k_{Fe} and k_{Rh} on extrapolation to [Fe]=0 and [Rh]=0, respectively, are identical, irrespective of the reactant used in excess and the ionic strength (μ=0.1 and 0.05) (Fig. 4). Such a complicated kinetics is quite different from other electron transfer reactions of transition metal complexes which show simple second-order kinetics (first-order on each reactant).[9] Furthermore, the intercept and the curveture found in Fig. 4 cannot be attributed to the reversibility of Eq. 7 in competition with the reaction in Eq. 8 since the electron transfer reaction proceeds to completion and the pseudo-first-order kinetics holds precisely under the experimental conditions in Fig. 4.

The pseudo-first-order kinetics and the complicated kinetic behavior of the pseudo-first-order rate constants in Fig. 4 may be best interpreted by assuming the following scheme for the electron transfer reaction (Eq. 7) as the rate-determining step,

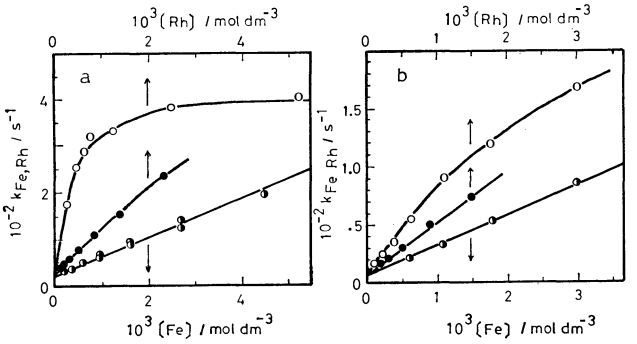

Fig. 4. Kinetics of the oxidation of $[RhL_4]^+$ (L=2,4,6-$Me_3C_6H_2NC$) with $[Fe(N\text{-}N)_3]^{3+}$; the pseudo-first-order rate constant as a function of large excess $[Fe(N\text{-}N)_3]^{3+}$ or $[RhL_4]^+$ in MeCN at 298 K; (a) N-N=phen, (b) N-N=bpy; ○ excess $[RhL_4]^+$ with 0.1 mol dm^{-3} n-Bu_4NClO_4, ● excess $[RhL_4]^+$ with 0.05 mol dm^{-3} n-Bu_4NClO_4, ◑ excess $[Fe(N\text{-}N)_3]^{3+}$ with 0.1 mol dm^{-3} n-Bu_4NClO_4.

$$[RhL_4]^+ + [Fe(N\text{-}N)_3]^{3+} \overset{K_1}{\rightleftharpoons} ([RhL_4]^+[Fe(N\text{-}N)_3]^{3+}) \xrightarrow[\text{e.t.}]{k_1} \quad (9)$$

$$([RhL_4]^+[Fe(N\text{-}N)_3]^{3+}) + [Fe(N\text{-}N)_3]^{3+} \overset{K_2}{\rightleftharpoons} ([RhL_4]^+2[Fe(N\text{-}N)_3]^{3+}) \xrightarrow[\text{e.t.}]{k_2} \quad (10)$$

$$([RhL_4]^+[Fe(N\text{-}N)_3]^{3+}) + [RhL_4]^+ \overset{K_3}{\rightleftharpoons} (2[RhL_4]^+[Fe(N\text{-}N)_3]^{3+}) \xrightarrow[\text{e.t.}]{k_3} \quad (11)$$

Scheme 1.

where e. t. represents the intramolecular electron transfer. Combination of Eq. 9 with Eqs. 10 and 11 gives the kinetic expressions of Eqs. 12 and 13, respectively,

$$k_{Fe} = \frac{k_1K_1[Fe] + k_2K_1K_2[Fe]^2}{1 + K_1[Fe] + K_1K_2[Fe]^2} \quad (12)$$

$$k_{Rh} = \frac{k_1K_1[Rh] + k_3K_1K_3[Rh]^2}{1 + K_1[Rh] + K_1K_3[Rh]^2} \quad (13)$$

for the oxidation of $[RhL_4]^+$ with $[Fe(N\text{-}N)_3]^{3+}$. When $K_1[Fe]$, $K_1[Rh] \gg 1$, Eqs. 12 and 13 are reduced to Eqs. 14 and 15, respectively.

$$k_{Fe} = \frac{k_1 + k_2K_2[Fe]}{1 + K_2[Fe]} \quad (14)$$

$$k_{Rh} = \frac{k_1 + k_3K_3[Rh]}{1 + K_3[Rh]} \quad (15)$$

The dependences of k_{Fe} and k_{Rh} on [Fe] and [Rh] in Fig. 4 are well reproduced by Eqs. 14 and 15, respectively, with the rate and the equilibrium constants listed in Table 2. The k_2, K_2, k_3, and K_3 in Eqs. 14 and 15 will be vanished at the intercepts of k_{Fe} and k_{Rh} (extrapolation to [Fe], [Rh]=0 in Fig. 4), which yield the same intramolecular electron transfer rate constant k_1 in Scheme 1. Such an intramolecular rate constant k_1 should be independent of the ionic strength of the media,[10] in accordance with the results in Fig. 4. On the other hand, the equilibrium constants K_1, K_2, and K_3 depended on the ionic strength of the media. At the ionic strength μ=0.1, the equilibrium constant K_1 was too high to be determined ($K_1[Fe]$, $K_1[Rh] \gg 1$; $K_1 \gg 1 \times 10^4$ mol^{-1} dm^3), and Eqs. 14 and 15 were applied to the results in Fig. 4. When the ionic strength μ was reduced from 0.1 to 0.05, however, the k_{Fe} values decreased to reach zero with decreasing [Fe] in the lower concentrations ($>4.0 \times 10^{-4}$ mol dm^{-3}) in contrast with the results at μ=0.1 in Fig. 4. The K_1 values at μ=0.05 were determined by fitting the data to Eq. 12,[11] and also listed in Table 2. The rate and the equilibrium constants were evaluated also for the reaction of $[Rh(t\text{-}BuNC)_4]^+$ with $[Fe(phen)_3]^{3+}$ (Table 2).

The large equilibrium constants K_1, K_2, and K_3 (Table 2) indicate the exceptionally high affinity of the cationic oxidants towards the cationic reductants in MeCN. Such cation-cation interactions are supported by the salt effects on the equilibrium constants since if the ions are of the same sign, decreasing the ionic strength makes the equilibrium constants de-

TABLE 2. RATE AND EQUILIBRIUM CONSTANTS FOR THE ELECTRON TRANSFER REACTIONS BETWEEN $[RhL_4]^+$ AND $[Fe(N\text{–}N)_3]^{3+}$ IN MeCN AT 298 K[a]

$[RhL_4]^+ + [Fe(N\text{–}N)_3]^{3+}$

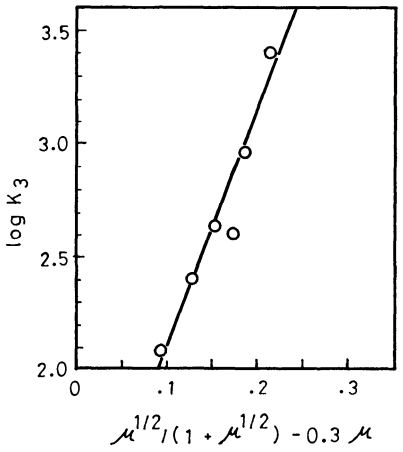

Fig. 5. Salt effect on the equilibrium constant K_3 for the oxidation of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ with $[Fe(phen)_3]^{3+}$; the solid line is drawn with the theoretical slope, $8A = 11$ in Eq. 16, see text.[14]

crease,[12] as observed for K_1 (Table 2). To confirm this quantitatively, the salt effect on K_3 was examined in detail for the reaction of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ with $[Fe(phen)_3]^{3+}$ in MeCN at various ionic strengths adjusted by *n*-Bu_4NClO_4. The theoretical salt effect on K_3 may be given by Eq. 16 when the activity coefficients of ions are evaluated from the Davies equation,[13]

$$\log K_3 = \log K_3^0 + 2z_Az_BA(\mu^{1/2}/(1+\mu^{1/2}) - 0.3\,\mu) \qquad (16)$$

where K_3^0 is the equilibrium constant at $\mu=0$, z_A and z_B are the charges of $([RhL_4]^+[Fe(phen)_3]^{3+})$ and $[RhL_4]^+$, respectively; $z_A=4$, $z_B=1$, and A is the Debye-Hückel coefficient.[14] The experimental salt effect on K_3 shows reasonable agreement with the theoretical slope of Eq. 16 ($2z_Az_BA=11$) as shown in Fig. 5. Thus, Scheme 1 can account for the pseudo-first-order kinetics, the complex dependences of k_{Fe} and k_{Rh} on [Fe] and [Rh], respectively (Fig. 4), and the salt effects, which otherwise would be impossible to be explained together. The high affinity between the cationic oxidants and the cationic reductants (Table 2) is unprecedented,[15] and at present the origin of the interaction is not clear. However, the similar affinity of $[RhL_4]^+$ towards 2,2′-bipyridine (bpy) observed in the ligand substitution reactions of $[RhL_4]^+$ with bpy[16] suggests that the interaction between $[RhL_4]^+$ and $[Fe(N\text{–}N)_3]^{3+}$ could be mediated by the N–N ligand of $[Fe(N\text{–}N)_3]^{3+}$.

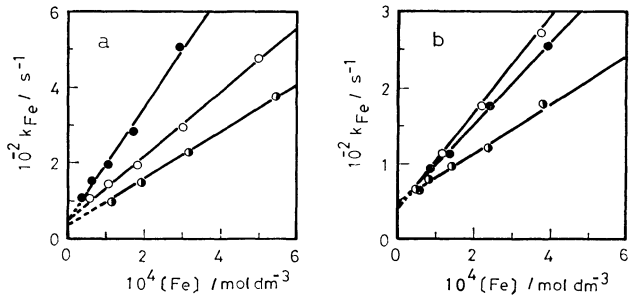

Fig. 6. Plots of the pseudo-first-order rate constant k_{Fe} for the reactions of $[RhL_4]^+$ with (a) large excess $[Fe(phen)_3]^{3+}$ and (b) $[Fe(bpy)_3]^{3+}$ in MeCN containing 0.1 mol dm^{-3} *n*-Bu_4NClO_4 at 298 K; ○ $[Rh(p\text{-}MeC_6H_4NC)_4]^+$, ● $[Rh(PhCH_2NC)_4]^+$, ◑ $[Rh(PhNC)_4]^+$.

Electron Transfer Rate Constants in the $[RhL_4]^+$ Monomer–$[Fe(N\text{–}N)_3]^{3+}$ System. Under the conditions of $K_2[Fe] \ll 1$, Eq. 14 can be reduced to Eq. 17, which predicts a linear relation between k_{Fe} and [Fe]. Plots

$$k_{Fe} = k_1 + k_2K_2[Fe] \qquad (17)$$

of the pseudo-first-order rate constant k_{Fe} against the concentrations of $[Fe(phen)_3]^{3+}$ and $[Fe(bpy)_3]^{3+}$ are illustrated in Figs. 6a and 6b, respectively. The concentrations of the Rh^I complexes used in the reactions were between 3.0×10^{-6} and 3.2×10^{-4} mol dm^{-3}, except for $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$, $[Rh(p\text{-}MeC_6H_4NC)_4]^+$, and $[Rh(PhNC)_4]^+$ whose concentrations were less than 1×10^{-5} mol dm^{-3} in order to avoid the appreciable oligomerization in the higher concentrations. Under such concentrations, only monomeric $[RhL_4]^+$ may be involved in the electron transfer reactions with $[Fe(N\text{–}N)_3]^{3+}$. The electron transfer rate constants of k_1 and k_2K_2 for the $[RhL_4]^+$–$[Fe(N\text{–}N)_3]^{3+}$ system, obtained from the intercept and the slope of the plots of Eq. 17, respectively, are listed in Table 3. The k_3 and K_3 values have not been determined except for the Rh^I complexes in Table 2, because the reactions of the other Rh^I complexes in a large excess ($>1\times10^{-3}$ mol dm^{-3}) were too fast to follow by the stopped flow technique.

It is noteworthy that the k_1 value is rather independent of the ligands except for the sterically hindered 2,4,6-$Me_3C_6H_2NC$, *t*-BuNC, and PPh_3, and that the k_2K_2 value is more or less in parallel with the k_1 value. Such an insensitive dependence of k_1 as well as k_2K_2 on the diversed type ligands agrees with the

a) In MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K.

HOMO energy of the nearly nonbonding d_{z^2} level of the Rh^I complexes which may be insensitive to the difference of ligands.[17]

Kinetic studies were performed also for the oxidation of fixed $[RhL_4]^+$ (L=*t*-BuNC, 2,4,6-$Me_3C_6H_2NC$) with various oxidants; $[Fe(5\text{-}NO_2phen)_3]^{3+}$, $[Fe(5\text{-}Clphen)_3]^{3+}$, $[Fe(phen)_3]^{3+}$, $[Fe(bpy)_3]^{3+}$, $[Fe(4,7\text{-}Ph_2phen)_3]^{3+}$, and $[Co(bpy)_3]^{3+}$. The electron transfer rates were measured as described above, except for the oxidation with $[Co(bpy)_3]^{3+}$ which was followed by the decay of the 440 nm and 459 nm bands of $[Rh(t\text{-}BuNC)_4]^+$ and $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$, respectively ($^1A_{1g}\rightarrow{}^3A_{2u}$ transition), in the presence of excess $[Co(bpy)_3]^{3+}$ (8.9×10^{-4}—1.0×10^{-2} mol dm^{-3}) using a conventional spectrophotometer; the reaction rate was much slower than that with $[Fe(N-N)_3]^{3+}$. The pseudo-first-order rate constant k_{Co} in the presence of excess $[Co(bpy)_3]^{3+}$ also showed a linear relation with the Co concentration. The rate constants k_1 and k_2K_2 determined from the intercept and the slope of the linear plots of k_{Fe} *vs.* [Fe] and k_{Co} *vs.* [Co] are listed in Table 4. The reduction potentials of the oxidants determined by cyclic voltammetry in MeCN also are listed in Table 4 for comparison. There can be seen a trend that the electron transfer rate constants k_1 and k_2K_2 decrease with decreasing the reduction potentials of the oxidants; this is particularly the case in $[Co(bpy)_3]^{3+}$.

Electron Transfer Rate Constants in the $[RhL_4]^+$ Oligomer–$[Co(bpy)_3]^{3+}$ System. As described in the foregoing section, high concentration solutions of $[Rh(PhNC)_4]^+$ ($>1\times10^{-3}$ mol dm^{-3}) exhibit an absorption band attributable to the dimer, $[Rh_2(PhNC)_8]^{2+}$. The rate of reaction of $[Rh(PhNC)_4]^+$ with excess $[Co(bpy)_3]^{3+}$ under such conditions was measured by monitoring the decay of an absorbance due to the dimer at 600 nm, as shown by the open circles in Fig. 7. This decay curve can be expressed by Eq. 18 as plotted by the closed circles (Fig. 7),

$$A_D^{-1/2} = at + b \qquad (18)$$

where a and b are constants as 6.4×10^{-4} s^{-1} and 1.21, respectively. On the other hand, the absorbance A_D is proportional to the square of the total amount of Rh under the experimental conditions stated in Fig. 7; A_D (at 600 nm) $=1.20\times10^5$ $[Rh]^2$. Thus, Eq. 18 may alternatively be formulated as the pseudo-second-order rate law shown in Eq. 19. It was confirmed that the decay of the absorbance due to monomeric $[Rh(PhNC)_4]^+$ at 462 nm with time also followed Eq. 19, yielding the same value of k_{Co}. Moreover, the kinetics of the oxidation of $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ (4.0×10^{-4} mol dm^{-3})[18] with $[Co(bpy)_3]^{3+}$ also followed Eq. 19, which reveals that the oxidation of the Rh^I

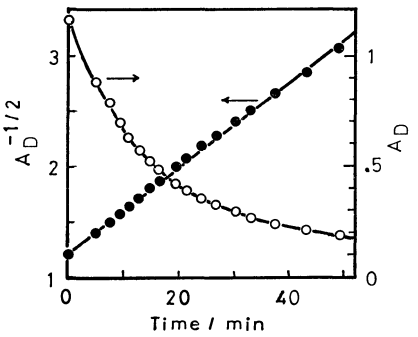

Fig. 7. Decay of the absorbance at 600 nm with time in the reaction of $[Rh_2(PhNC)_8]^{2+}$ (2.5×10^{-3} mol dm^{-3} as $[Rh(PhNC)_4]^+$) with large excess $[Co(bpy)_3]^{3+}$ (2.0×10^{-2} mol dm^{-3}) in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K (○), and the second-order plot as $A_D^{-1/2}$ *vs.* time (●), see text.

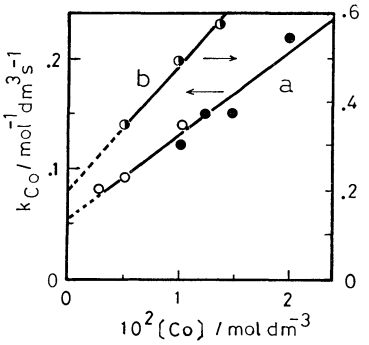

Fig. 8. Dependence of the pseudo-second-order rate constant k_{Co} on the concentration of $[Co(bpy)_3]^{3+}$ for the oxidation of (a) $[Rh(PhNC)_4]^+$ and (b) $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ (4.0×10^{-4} mol dm^{-3}) in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K; ●,◑ determined from the decay of the dimer band at 600 nm, ○ determined from the decay of the monomer band at 459 nm.
The ratio of [Co]/[Rh]=10 for $[Rh(PhNC)_4]^+$.

$$-d[Rh]/dt = k_{Co}[Rh]^2 \quad (19)$$

complexes proceeds through the dimers present in solution.

The pseudo-second-order rate constants, k_{Co}/mol^{-1} dm^3 s^{-1}, obtained for the oxidation of $[Rh(PhNC)_4]^+$ and $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ show linear dependences on the concentration of $[Co(bpy)_3]^{3+}$, as shown in Fig. 8. Thus, the rate constant k_{Co} is written by Eq. 20. The kinetic formulation of Eq. 20 for the dimer oxidation is analogous to that for the monomer oxidation in Eq. 17. Then, the reaction scheme for the oxidation of $[Rh(PhNC)_4]^+$ and $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ with $[Co(bpy)_3]^{3+}$ may be given by combining the scheme for the monomer oxidation (Scheme 1) with the corresponding scheme for the dimer oxidation as follows.

$$k_{Co}/\text{mol}^{-1}\,\text{dm}^3\,\text{s}^{-1} = k_a + k_b[Co] \quad (20)$$

$$[RhL_4]^+ + [RhL_4]^+ \overset{K_D}{\rightleftharpoons} [Rh_2L_8]^{2+} \quad (21)$$

$$[RhL_4]^+ + [Co(bpy)_3]^{3+} \overset{K_{1M}}{\rightleftharpoons} ([RhL_4]^+[Co(bpy)_3]^{3+}) \xrightarrow[\text{e.t.}]{k_{1M}} \quad (22)$$

$$([RhL_4]^+[Co(bpy)_3]^{3+}) + [Co(bpy)_3]^{3+} \overset{K_{2M}}{\rightleftharpoons} ([RhL_4]^+2[Co(bpy)_3]^{3+} \xrightarrow[\text{e.t.}]{k_{2M}} \quad (23)$$

$$[Rh_2L_8]^{2+} + [Co(bpy)_3]^{3+} \overset{K_{1D}}{\rightleftharpoons} ([Rh_2L_8]^{2+}[Co(bpy)_3]^{3+}) \xrightarrow[\text{e.t.}]{k_{1D}} \quad (24)$$

$$([Rh_2L_8]^{2+}[Co(bpy)_3]^{3+}) + [Co(bpy)_3]^{3+} \overset{K_{2D}}{\rightleftharpoons} ([Rh_2L_8]^{2+}2[Co(bpy)_3]^{3+}) \xrightarrow[\text{e.t.}]{k_{2D}} \quad (25)$$

Scheme 2.

The second and the third steps in Scheme 2 are the same as Eqs. 9 and 10 in Scheme 1 for the monomer oxidation, respectively. The observed pseudo-second-order kinetics in excess $[Co(bpy)_3]^{3+}$ shows that the dimer oxidation (Eqs. 24 and 25) is much faster than the corresponding monomer oxidation (Eqs. 22 and 23); $k_{1D}\gg k_{1M}$, $k_{2D}\gg k_{2M}$. According to Scheme 2, the pseudo-second-order rate constant, k_{Co}/mol^{-1} dm^3 s^{-1}, is given by Eq. 26 under the conditions of $[Rh_2L_8]^{2+}\ll[RhL_4]^+$. When the equilibrium constants for the complex formation with $[Co(bpy)_3]^{3+}$ are assumed to be the same between the monomer and the dimer, *i.e.*, $K_{1D}=K_{1M}$ and $K_{2D}=K_{2M}$, Eq. 26 has an equivalent form to Eq. 12 derived from Scheme 1. Then, Eq. 26 is reduced to Eq. 27 which is analogous to Eq. 17 for the oxidation of monomeric $[RhL_4]^+$ with excess $[Fe(N\text{–}N)_3]^{3+}$. The electron transfer rate constants for the dimer, k_{1D} and $k_{2D}K_{2D}$, were thus obtained from the relations $k_a=k_{1D}K_D$ and $k_b=k_{2D}K_{2D}K_D$, respectively, using the k_a and k_b values in Eq. 20 as well as the K_D values (Table 1), and listed in Table 5. In spite of the apparant difference in the reactivity between $[Rh(PhNC)_4]^+$ and $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ as seen in Fig. 8, the rate constants k_{1D} and $k_{2D}K_{2D}$ are almost the same for both dimers. This is analogous result to the oxidation of the corresponding monomers (Table 3).

$$k_{Co}/\text{mol}^{-1}\,\text{dm}^3\,\text{s}^{-1} = \frac{k_{1D}K_DK_{1D}[Co]+k_{2D}K_DK_{1D}K_{2D}[Co]^2}{1+K_{1M}[Co]+K_{1M}K_{2M}[Co]^2} \quad (26)$$

$$k_{Co}/\text{mol}^{-1}\,\text{dm}^3\,\text{s}^{-1} = K_D(k_{1D}+k_{2D}K_{2D}[Co]) \quad (27)$$

Table 5. Electron transfer rate constants for the oxidation of $[RhL_4^+]_n$ (n=2 and 3) with $[Co(bpy)_3]^{3+}$ a)

	k_{1D} / s^{-1}	$k_{2D}K_{2D}$ / mol^{-1} dm^3 s^{-1}
$[Rh_2(PhNC)_8]^{2+}$	1.6×10^{-3}	2.2×10^{-1}
$[Rh_2(p\text{-}MeC_6H_4NC)_8]^{2+}$	1.5×10^{-3}	2.2×10^{-1}
	k_{1T}/s^{-1}	
$[Rh_3(p\text{-}MeOC_6H_4NC)_{12}]^{3+}$	5.4×10^{-1}	—

a) In MeCN with 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K.

The kinetics of the oxidation of $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ with excess $[Co(bpy)_3]^{3+}$ was third-order in the range of the Rh concentration 1.5×10^{-4}—4.8×10^{-4} mol dm^{-3}, as expressed by Eq. 28; the third-order plots were obtained as a linear relation between A_D^{-1} *vs.* time, since $A_D=\varepsilon_D K_D[Rh]^2$. This indicates that

$$-d[Rh]/dt = k_{Co}[Rh]^3 \quad (28)$$

the oxidation occurs through trimeric $[Rh_3(p\text{-}MeOC_6H_4NC)_{12}]^{3+}$, the concentration of which is proportional to $[Rh]^3$. The pseudo-third-order rate constant k_{Co}/mol^{-2} dm^6 s^{-1} was constant irrespective of the concentration of $[Co(bpy)_3]^{3+}$ in the range of 1.4×10^{-3}—3.0×10^{-3} mol dm^{-3}, and thus k_{Co}/mol^{-2} dm^6 s^{-1}=$k_{1T}K_DK_T$. Using the K_D and K_T values in Table 1, the intramolecular electron transfer rate constant of the trimer, k_{1T}, is determined as 5.4×10^{-1} (Table 5).

Comparison of Intramolecular Electron Transfer Rate Constants between the $[RhL_4]^+$ Monomers and the Oligomers. For a particular $[RhL_4]^+$, the logarithm of the intramolecular electron transfer rate constant, $\log k_1$, varies with the reduction potentials of the oxidants (Table 4), as illustrated in Fig. 9a. Although the number of the oxidants used in this study is limited, the slope of the correlation can be expressed by Eq. 29 which is equivalent to the Marcus relation expressed by Eq. 30.[5,19]

$$\log k_1 = 8.5E^0_{red} + \text{Const} \quad (29)$$

$$\Delta G_1^* = 0.5\Delta G^0 + \text{Const} \quad (30)$$

For a given oxidant, $[Co(bpy)_3]^{3+}$, the intramolecular electron transfer rate constant k_1 of $[RhL_4^+]_n$ (n=1—3) increases in the order monomer<dimer<trimer (Tables 4 and 5). This order is in parallel with the HOMO energy level from which electron is removed; monomer<dimer<trimer, as illustrated in Fig. 10. The energy difference between the monomer and the dimer (ΔE_D) as well as the trimer (ΔE_T)

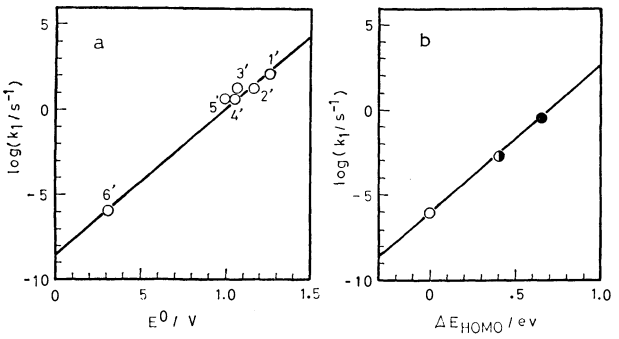

Fig. 9. Marcus plot for the intramolecular electron transfer rate constant k_1 of $[RhL_4^+]_n$ (n=1—3).
(a) Plot of log k_1 for the oxidation of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ *vs.* the reduction potentials of the oxidants, E^0_{red}, numbers refer to the oxidants in Table 4. (b) Plot of log k_1 for the oxidation of $[RhL_4^+]_n$ with $[Co(bpy)_3]^{3+}$ *vs.* the difference in the HOMO energies, ΔE_{HOMO}, between the $[RhL_4]^+$ oligomers and the monomer; ○ $[RhL_4]^+$ (L=2,4,6-$Me_3C_6H_2NC$, *t*-BuNC), ◑ $[RhL_4^+]_2$ (L=PhNC, *p*-MeC_6H_4NC), ● $[RhL_4^+]_3$ (L=*p*-$MeOC_6H_4NC$). The lines are arbitrarily drawn with the Marcus slope of 8.5 to show the agreement,[19] see text.

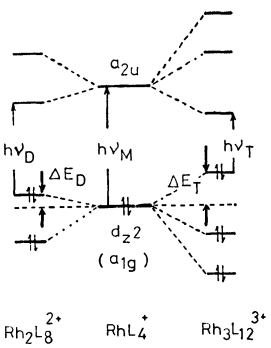

Fig. 10. Energy diagram for the $[RhL_4]^+$ monomer, the dimer, and the trimer.[2e]

is estimated from the electronic transition energies listed in Table 1, using Eq. 31. A plot of $\log k_1$ *vs.*

$$\Delta E_D = (h\nu_M - h\nu_D)/2, \quad \Delta E_T = (h\nu_M - h\nu_T)/2 \quad (31)$$

ΔE_{HOMO} thus obtained shows a linear relation as shown in Fig. 9b, from which the following equation is obtained. Thus, the Marcus slope in Eq. 29 can be

$$\log k_1 = 8.5\Delta E_{HOMO} + \text{Const} \quad (32)$$

applied also to the difference of the reactivity among the $[RhL_4]^+$ monomer, the dimer, and the trimer. The constancy of k_1 for the $[RhL_4]^+$ monomers with different ligands also accords with Eq. 32, since the HOMO energies are constant irrespective of the ligands.[17]

Summary and Conclusions. Square-planar rhodium(I) isocyanide complexes can interact with one another through the d_{z^2} HOMO orbital, yielding the dimer and the trimer. The strength of the rhodium-rhodium interaction which reflects the magnitude of the equilibrium constants for the oligomer formation is determined by the balance between electronic and steric effects of the ligands. Such availability of the interacting HOMO gives a novel feature in the electron transfer reactions. A series of $[RhL_4]^+$ forms strongly associative precursor complexes with oxidants, $[Fe(N\text{-}N)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$, prior to the electron transfer. Since the oxidant or the $[RhL_4]^+$ cation can interact from both sides of the square-planar $[RhL_4]^+$, not only the 1:1 complex but also the 1:2 and the 2:1 complexes are formed between the $[RhL_4]^+$ and the oxidants. The rate constants of the intramolecular electron transfer in the precursor complexes are readily separated from the observed rate constants and largely depend on the energy difference between the HOMO of the $[RhL_4^+]_n$ (n=1—3) and the LUMO of the oxidants represented by the reduction potentials, following the Marcus relation. As such, the rate constants of intramolecular electron transfer of $[RhL_4^+]_n$ increase in the order monomer<dimer<trimer with increasing the HOMO energy.

Experimental

Materials. A series of tetrakis(isocyanide)- and bis(isocyanide)bis(triphenylphosphine)rhodium(I) perchlorates used in this study was prepared as described elsewhere.[20] 2, 2′-Bipyridine (bpy), 1,10-phenanthroline monohydrate

(phen), and substituted 1,10-phenanthroline (5-NO_2phen, 5-Clphen, 4,7-Ph_2phen) were obtained from Wako Pure Chemicals. The $[Fe(N\text{–}N)_3]X_2$ complexes (X=ClO_4 or PF_6; N–N=bpy, phen, 5-NO_2phen, 5-Clphen, and 4,7-Ph_2phen) were obtained according to the literature method.[21] The iron(III) complexes were synthesized as the sulfate by oxidation of the corresponding iron(II) complexes with ceric ammonium sulfate in concentrated sulfic acid. Of those, $[Fe(5\text{-}NO_2phen)_3](ClO_4)_3$ was obtained by the careful addition of 0.1 mol dm^{-3} perchloric acid to the oxidized solution, and the hexafluorophosphate salts, $[Fe(phen)_3](PF_6)_3$ and $[Fe(bpy)_3](PF_6)_3$, and the other perchlorate salts were obtained by the addition of NH_4PF_6 and $NaClO_4$, respectively. The $[Co(bpy)_3](PF_6)_3$ complex was prepared by refluxing a 30% methanol solution containing pentaamminechlorocobalt(III) chloride, $[Co(NH_3)_5Cl]Cl_2$,[22] and 2,2′-bipyridine, followed by the addition of NH_4PF_6 as described elsewhere.[23] Recrystallization was performed from hot water two times. Reagent grade acetonitrile (Wako Pure Chemicals) was purified by the standard procedure,[24] followed by redistillation from diphosphorous pentaoxide.

Oligomer Formation of $[RhL_4]^+$. Electronic absorption spectra were measured with a Union SM-401 spectrophotometer, using a 10 or 1 mm cell placed in a compartment thermostated at 298 K. Absorption maxima observed for the $[RhL_4]^+$ monomers and oligomers as well as their assignment are listed in Table 6. Equilibrium constants for the oligomer formation were determined from the change of absorbances of the $[RhL_4]^+$ oligomers as a function of the total concentration in MeCN (1×10^{-4}—1×10^{-2} mol dm^{-3}) containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K. The oligomer formation of $[Rh(p\text{-}ClC_6H_4NC)_4]^+$ has not been observed in the electronic spectra because of the limited solubility in MeCN ($<2\times10^{-4}$ mol dm^{-3}). There has been found no evidence also for oligomerization of the mixed ligands rhodium(I) complexes, $[RhL_2(PPh_3)_2]^+$ (L=p-$MeOC_6H_4NC$ and 2,4,6-$Me_3C_6H_2NC$), even in nearly saturated solutions.

Electron Transfer Reactions. Acetonitrile solutions of the $[RhL_4]^+$ complexes as well as oxidants ($[Fe(N\text{–}N)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$) were freshly prepared before use. The reactions were carried out at 298 K under the conditions with either the rhodium(I) complex or the oxidant in a large excess. Rates of the reactions between $[RhL_4]^+$ and $[Fe(N\text{–}N)_3]^{3+}$ were measured by monitoring the rise of absorbances due to $[Fe(N\text{–}N)_3]^{2+}$ (λ_{max}: 520 nm for $[Fe(bpy)_3]^{2+}$, 507 nm for $[Fe(phen)_3]^{2+}$, 510 nm for $[Fe(5\text{-}NO_2phen)_3]^{2+}$ and $[Fe(5\text{-}Clphen)_3]^{2+}$, and 530 nm for $[Fe(4,7\text{-}Ph_2phen)_3]^{2+}$),[25] by using a Union RA-103 stopped flow spectrophotometer. The ionic strength of the reaction medium was adjusted to 0.1 with n-Bu_4NClO_4 other than the cases to examine the effect of ionic strengths on the reaction. Rates of the reactions between $[RhL_4]^+$ and $[Co(bpy)_3]^{3+}$ were measured by monitoring the decay of the absorption band ($^1A_{1g}\rightarrow{}^3A_{2u}$) of $[RhL_4]^+$ listed in Table 6 by using a Union SM-401 spectrophotometer.

Cyclic Voltammetry. The standard reduction potentials of $[Fe(N\text{–}N)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ were measured by cyclic voltammetry on a Hokuto Denko Model HA-301 potentiostat/galvanostat. The experiments were carried out in MeCN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 as a supporting electrolyte, using a platinum working electrode and a saturated NaCl calomel reference electrode. The scan rates were varied in the 20—500 mV s^{-1} range. The separation of cathodic and anodic peaks was 62 mV at the scan rate of 20 mV s^{-1} which is very close to the theoretical separation of 59 mV s^{-1} for a reversible one-electron process.[26] Attempts to measure the E^0 values for the $[RhL_4]^{+/2+}$ couple in MeCN by cyclic voltammetry have been unsuccessful; the anodic oxidation of the $[RhL_4]^+$ complexes was irreversible and no cathodic wave on the reverse scan was observed at various sweep rate between 100 and 900 mV s^{-1}.[8]

Spectroscopic Studies of Copper(I) Complexes of 1,8-Di(2-pyridyl)-3,6-dithiaoctane in a Nonaqueous Solvent. The Halide-ion Effect on Their Structure

Susumu KITAGAWA,* Megumu MUNAKATA, and Shoji OKADA

Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka 577

(Received May 4, 1982)

The complexes of 1,8-di(2-pyridyl)-3,6-dithiaoctane(pdto) with CuX(X=Cl and Br) and $[Cu(CH_3CN)_4]ClO_4$ have been synthesized in chloroform, methanol, ethanol, and acetone. Their absorption spectra show an intense metal-to-ligand charge-transfer band at 307 nm: This band is assigned to pyridyl nitrogen←Cu. $[Cu(pdto)]^+$ (**1**) has been prepared from $[Cu(CH_3CN)_4]ClO_4$, its pdto acting as a four-coordinate ligand. CuX reacts with pdto to yield two complexes: One is **1**, and the other is [CuX(pdto)] (**2**). Both complexes are four-coordinate, but in the **2** one of the two pyridyl groups is dissociated. The complex **2** is unstable and is oxidized by oxygen. Neither complex reacts with CO, indicating the tight binding of pdto with Cu(I). The **1** and **2** are equilibrated in solution. The ^1H NMR spectra well demonstrate that **2** is dominant in chloroform and that **1** is the principal form in alcohol, while the **1**/**2** ratio is 3/7. This solvent-dependence is ascribed to the coordination ability and/or polarity of the solvent.

Recent interest in copper proteins has been focused on the copper(I) complexes containing several types of donor atoms. In addition to ligands having N and O donor atoms, copper(I) complexes with ligands containing sulfur have been synthesized and characterized.[1-7] 1,8-Di(2-pyridyl)-3,6-dithiaoctane (pdto), which is a quadridentate N_2S_2-type ligand, gives both copper(I) and copper(II) complexes. The crystal structure of their perchlorate and hexafluorophosphate have been determined by X-ray crystallography.[7] The geometry of this copper(I) complex is tetrahedral, characteristic of usual four-coordinate copper(I) complexes. This suggests that the Cu(I) complex of pdto is four-coordinate, the set of donor atoms being of the N_2S_2-type. However, in the presence of a halide ion(X^-), all the donor atoms of pdto do not necessarily bind the Cu(I) ion in a nonaqueous solvent. We have previously pointed out[8,9] that copper(I) complexes prepared from CuX in a nonaqueous solvent are accompanied by halide ion-bindings, and sometimes their bridging, leading to a binuclear structure. In this sense, both the copper(I) starting material and the solvent used play an important role in the formation of the copper(I) complexes. It is of significance to substantiate the coordination chemistry of CuX–pdto systems in various solvents. The purpose of this work is to elucidate the structure of copper(I) complexes prepared from CuX and pdto, and their equilibria in solution, with the aid of absorption and ^1H NMR spectroscopy.

Experimental

Materials. Reagent-grade copper(I) chloride and bromide were purified according to the literature.[11] All the materials were dried *in vacuo* (75—100 °C). The $[Cu(CH_3CN)_4]ClO_4$ was prepared in the usual way,[12] and recrystallized from ether under nitrogen. The $AgClO_4$ was purchased from Wako LTD., and was used without further purification. 1,8-Di(2-pyridyl)-3,6-dithiaoctane(pdto) was prepared by the methods of Goodwin and Lions.[13]

The acetone, chloroform, methanol, and ethanol were all dried and distilled before use.

Preparation of $[Cu(pdto)]ClO_4$. A 50-cm^3 portion of a 2.5×10^{-5} mol pdto chloroform solution was added to 7.6 mg (2.5×10^{-5} mol) of $[Cu(CH_3CN)_4]ClO_4$ under nitrogen, and this mixture was stirred for 1 h. A colorless solution of $[Cu(pdto)]ClO_4$ was thus formed. This solution was transferred anaerobically into a cuvette (1 cm path length) with a stop cock, and the absorption spectrum was measured by means of a Hitachi 200-10 spectrometer. The complex in the other solvent was prepared in a similar way.

Preparation of [*CuX(pdto)*]. A 50-cm^3 portion of a 2.5×10^{-5} mol pdto chloroform solution was added to 2.5×10^{-5} mol of CuX under nitrogen, and this mixture was stirred for 3 h. In other solvents, the copper complexes were prepared in a similar way. A 10.4 mg (5.0×10^{-5} mol) of $AgClO_4$ was added to the resultant solution. The solution was stirred for 0.5 h and filtered off under nitrogen, and the filtrate was transferred anaerobically into a cuvette for the measurement of the absorption spectra.

Physical Measurements. The ^1H NMR spectra were measured on a JEOL FX200 FT NMR spectrometer. Between 256 and 320 transients were accumulated with the use of a 13-μs pulse (90°). 4 K data points were collected over the band-width of 2500 kHz. The temperature was set at -90 ± 2 °C (acetone-d_6 and methanol-d_4) and -59 ± 1 °C (chloroform-*d*).

The conductances were measured at 25 °C with a Kyoto Elec. Co. Model CM-05, and a cell with two platinum electrodes.

Cyclic voltammetric measurements were made with a Hokuto Model HA104 potentiostat/galvanostat driven by a model HB107A function generator. A Pt wire served as the working electrode, while a Pt coil was used as the counter electrode. A commercial saturated calomel electrode (SCE) was utilized as the reference electrode. Tetrabutylammonium perchlorate (TBAP) was used as the supporting electrolyte.

Results and Discussion

[Cu(pdto)]ClO$_4$. Figure 1(1) shows the absorption spectrum of $[Cu(pdto)]ClO_4$ in the region of 300—500 nm. Only a single band appears at 307 nm when 1 equivalent of pdto is added to $[Cu(CH_3CN)_4]ClO_4$ in $CHCl_3$. The intensities of this band did not increase further upon the addition of an excess of pdto, indicating that pdto has a high

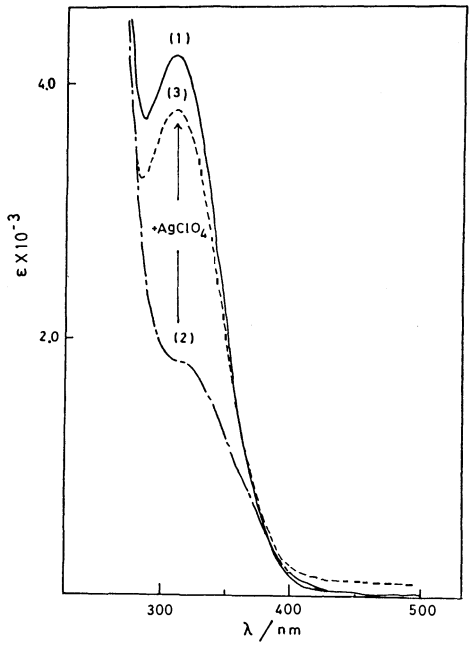

Fig. 1. Absorption spectra of a $CHCl_3$ solution. (1): 5.0×10^{-4} M† of $[Cu(pdto)]ClO_4$, (2): 5.0×10^{-4} M of [CuCl(pdto)], (3): the addition of 1.0×10^{-3} M of $AgClO_4$ to a solution of (2).

affinity for the Cu(I) ion and yields a $[Cu(pdto)]ClO_4$ quantitatively. The pdto itself has no absorption band in this region. The dithioether–Cu(I) complexes, such as $[Cu(2,5\text{-dithiahexane})_2]BF_4$ and $[Cu(3,6\text{-dithiaoctane})_2]BF_4$, have no absorption bands in this region.[2] This leads to the conclusion that there is no charge-transfer band between thioether S and Cu(I) in the region of 300—800 nm.[14] We have elsewhere demonstrated that $[Cu(py)_4]ClO_4$ reveals, at 330 nm an intense band, which is assigned to the metal-to-ligand charge transfer(MLCT) band as py←Cu(I).[9] Consequently, the band at 307 nm of $[Cu(pdto)]ClO_4$ is also ascribed to the MLCT band of py(pdto)←Cu(I).

$[Cu(pdto)]ClO_4$ was also prepared in several solvents, such as methanol, ethanol, and acetone. The values of λ_{max} and ε_{max} are listed in Table 1, together with the molar conductivities (Λ_M) of the solution of $[Cu(pdto)]ClO_4$. In the case of acetone, the MLCT band is covered with the absorption peak of acetone itself. As is shown in Table 1, the λ_{max} value of the MLCT band is unaffected by the solvent used, while the ε_{max} value shows a solvent-dependence which falls within $4.0—4.5\times10^3$ M^{-1} cm^{-1}. A solution of $[Cu(pdto)]ClO_4$ gives molar conductivities of 1.1, 104, 46, and 160 for $CHCl_3$, CH_3OH, C_2H_5OH, and $(CH_3)_2CO$ respectively, which are characteristic of a typical 1:1 electrolyte.[10] This strongly supports the dissociation of the ClO_4^- ion and the coordination of the four donor atoms(N_2S_2) of pdto. Hence, $[Cu(pdto)]ClO_4$ prepared from $[Cu(CH_3CN)_4]ClO_4$ and pdto in the above solvents is a four-coordinate monomer, just as in the solid state.[7]

The ^1H NMR spectra were measured for $[Cu(pdto)]ClO_4$ in several solvents. All the ^1H NMR spectra at room temperature are influenced by the chemical-exchange effect to give unresolved broad signals for each proton of pdto. At a low temperature, the chamical exchange is depressed and the ^1H NMR spectra exhibit well-resolved signals of 2-pyridyl group of pdto, but the methylene protons still show unresolved signals because of collapsing to each other. Figures 2(1) and (4) show the aromatic region of the ^1H NMR spectra in the acetone solution, indicating the unbound and bound 2-pyridyl groups of pdto respectively. The unbound 2-pyridyl group gives four signals which can be readily assigned to 6,4,3,5-H(from downfield to upfield) with the aid of the double-resonance technique. When pdto is coordinated to Cu(I), the 2-pyridyl group signals shift downfield. The protons in the 3 and 5 positions are almost collapsing, but the 3-H signal has a slight bias toward downfield. The assignments of these signals were done with the aid of the double-resonance technique; the signals of 8.73, 8.14, 7.69, and 7.67 ppm are 6, 4, 3, and 5-H respectively. Four similar signals with the same intensity are also observed in the cases of methanol (Fig. 4) and chloroform.

Halide Ion-binding. Absorption Spectra: The pdto also reacts with CuX(X=Cl and Br) in $CHCl_3$, CH_3OH, C_2H_5OH, and $(CH_3)_2CO$ to yield clear solutions. Both methanol and ethanol solutions give the MLCT band at 307 nm with an ε_{max} value of *ca.* 4×10^3 M^{-1} cm^{-1}, which is in good agreement with that of $[Cu(pdto)]ClO_4$. It is worth noting that the MLCT band of the $CHCl_3$ solution has a λ_{max} value of 314 nm and an ε_{max} value of 1.9×10^3 M^{-1} cm^{-1}, both different from those of $[Cu(pdto)]ClO_4$ in $CHCl_3$. The ε_{max} is anomalously small. The large excess of pdto did not increase the absorbance, indicating that the ε_{max} of 1.9×10^3 M^{-1} cm^{-1} is characteristic of [CuCl(pdto)]. The difference in both ε_{max} and λ_{max}

Table 1. Absorption maxima, extinction coefficients of the MLCT band, and molar conductivities of [Cu(pdto)]X and [CuX(pdto)]

† 1 M = 1 mol dm^{-3}.

is associated with the halide ion-binding to Cu(I).

In order to demonstrate the halide ion-binding, we use a comparable amount of $AgClO_4$,[8] which will break down the Cu–Cl bond if it exists. The white precipitate of AgCl appeared rapidly upon the addition of $AgClO_4$ to the solution of CuX and pdto, resulting in a spectrum similar to that of $[Cu(pdto)]ClO_4$ (Fig. 1). This drastic change in the MLCT band would not occur without halide ion-binding to Cu(I). This reaction, thus, follows Eq. 1;

$$[CuX(pdto)] + AgClO_4 \longrightarrow [Cu(pdto)]ClO_4 + AgClO_4 \quad (1)$$

If the precursor complex, [CuX(pdto)], is a four-coordinate, one of the donor atoms(N_2S_2) of pdto should be dissociated; in this sense, a N_2S or NS_2 donor set may be considered. The coordination of two N and one S atoms is unfavorable, because the complex contains a very unstable chelate ring of eight members. The NS_2 is most feasible for explaining the spectral change; the rupture of the Cu–X bond by Ag^+ is followed by the formation of the bonding of Cu–py, and, consequently, the absorbance of the MLCT band increases. The alcohol solution undergoes a minor change in absorbance upon the addition of $AgClO_4$.

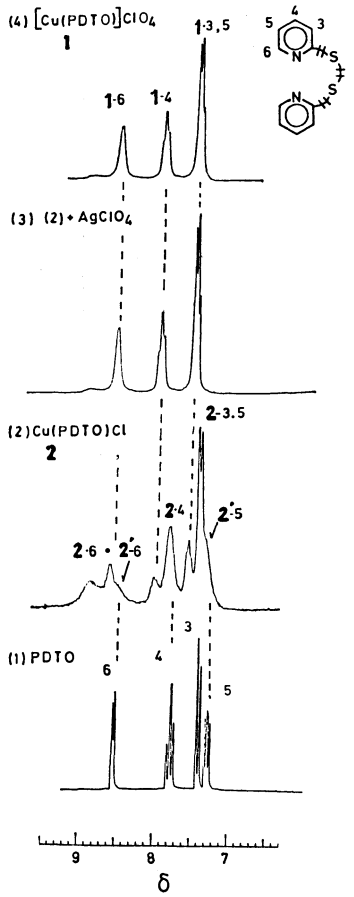

Fig. 2. ^1H NMR spectra at −90 °C of an acetone-d_6 solution.
(1): 5.0×10^{-3} M of pdto, (2): equimolar quantities (5.0×10^{-3} M) of CuCl and pdto, (3): the addition of 1.0×10^{-2} M $AgClO_4$ to a solution of (2), (4): 5.0×10^{-3} M of $[Cu(pdto)]ClO_4$.

Molar Conductivities: The molar conductivities, $\Lambda_M(X)$ (or $\Lambda_M(ClO_4)$), of a solution containing equimolar amounts of CuX and pdto(or $[Cu(CH_3CN)_4]ClO_4$ and pdto) have been measured (Table 1). Table 1 shows that the $\Lambda_M(X)$ of the acetone solution is much smaller than the $\Lambda_M(ClO_4)$, indicative of the presence of halide ion-binding. On the other hand, the alcohol solution also gives a $\Lambda_M(X)$ smaller than the $\Lambda_M(ClO_4)$. This difference is possibly attributable to the difference in the mobilities of ClO_4^- and Cl^- in alcohol. This trend has been found in the systems containing *n*-Bu_4NClO_4 or *n*-Bu_4NCl in *n*-propanol.[15] Otherwise, the difference in Λ_M might arise from the presence of species having a coordinated halide ion, of which minute quantities are demonstrated by the ^1H NMR spectra to be considered below. The $\Lambda_M(ClO_4)$ of the $CHCl_3$ solution is quite small (1.1 Ω^{-1} cm^2 mol^{-1}). Unfortunately, the value $\Lambda_M(X)$ is less than 1 Ω^{-1} cm^2 mol^{-1}, undetectable with our instrument, also implying the presence of a coordinated halide ion.

^1H NMR Spectra: The ^1H NMR spectra were measured in order to elucidate the species in solution. Figure 2(2) shows the ^1H NMR spectra at −90 °C of [CuCl(pdto)] in acetone. This spectrum is quite different from that of $[Cu(pdto)]ClO_4$ (Fig. 2(4)); three types of 2-pyridyl signals were observed. Type-1 signals have the same chemical shifts as those of Fig. 2(4), indicating the formation of [Cu(pdto)]Cl. Type-2 signals are ascribed to coordinated 2-pyridyl of [CuCl(pdto)]. The last Type-2′ corresponds to

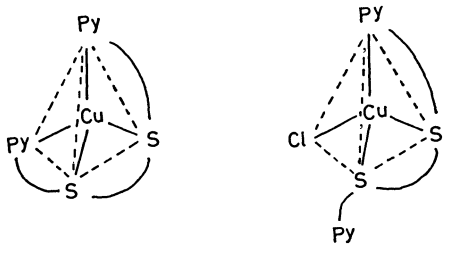

Fig. 3. Proposed structure of $[Cu(pdto)]^+$ (**1**) and [CuX(pdto)] (**2**).

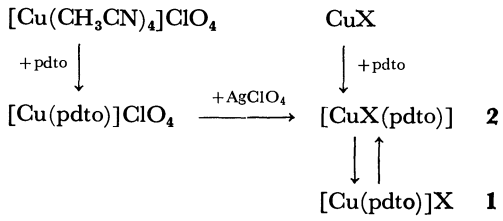
the signals of which shifts are similar to those of a metal-free 2-pyridyl. The computer simulation of the three types of signals gives the ratios of intensities of the Type 1, 2, and 2′ signals; thus, $r_{1/2}=3/7$ and $r_{2/2'}=1$ are obtained. The equal intensities of Type-2 and Type-2′ signals indicate the coordination of pdto as a NS_2 donor set; one 2-pyridyl of pdto is dissociated, as has been discussed in the previous section, and of course, a five-coordinate species is avoided. Upon the addition of $AgClO_4$ as well as in the case of absorption spectra, the Type-2 and Type-2′ signals disappear and the intensity of the Type-1 signals increases. The final spectrum well corresponds to that of $[Cu(pdto)]ClO_4$ (Figs. 2(3) and (4)). These ^1H NMR spectra excellently illustrate the halide ion-binding to Cu(I) and the formation of Cu-2-pyridyl bonding after the removal of the halide ion by Ag^+. We are now in a position to present a structure which best explains the spectral properties obtained here: The proposed structure of [CuX(pdto)] is Structure **2** in Fig. 3, where one 2-pyridyl group of pdto is coordinated to Cu(I), while the other is dissociated. $[Cu(pdto)]^+$ is also presented as Structure **1** in Fig. 3. The ^1H NMR spectrum of a $CDCl_3$ solution exhibits the signals of [CuCl(pdto)], but no signals of [Cu(pdto)]Cl, indicating the formation of [CuCl(pdto)] to a great extent. In this case, $AgClO_4$ also influences this spectrum and provides a spectrum similar to that of $[Cu(pdto)]ClO_4$ in $CDCl_3$. The observed ^1H NMR shifts are listed in Table 2. On the other hand, the ^1H NMR spectrum of CD_3OD solution with CuCl and pdto is just the same as that of $[Cu(pdto)]ClO_4$ (Fig. 4). Hence, CuCl reacts with pdto in alcohols, mostly yielding [Cu(pdto)]Cl. This is also suggested by the same values of λ_{max} and ε_{max} between CuCl and $[Cu(CH_3CN)_4]ClO_4$.

Solution Equilibria: The absorption, ^1H NMR spectra, and molar conductivities characterize the reaction of CuX with pdto, comprising a part of Scheme 1. The equilibrium between Complex **1** and **2** is dependent



Scheme 1.

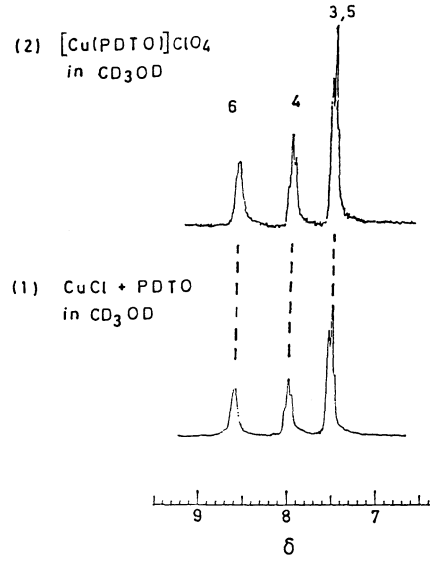


Fig. 4. ^1H NMR spectra at −90 °C of a methanol-d_4 solution.
(1): Equimolar quantities (5.0×10^{-3} M) of CuCl and pdto, (2): 5.0×10^{-3} M of $[Cu(pdto)]ClO_4$.

on the solvent used. Complex **2** dominantly forms in $CHCl_3$, while Complex **1** selectively forms in alcohol. In acetone, Complex **2** is in equilibrium with Complex **1**. The ^1H NMR spectra (Fig. 2) provides a **1**/**2** ratio of 3/7. Chloroform has a lower polarity than acetone, as has been characterized by the dielectric constant, ε. Methanol has the greatest ε value among the four solvents used. The order is 32.7 (methanol) > 24.6(ethanol) > 20.7(acetone) > 4.8(chloroform).[15)] This order is also considered to be that of the coordination ability of the solvents. On this basis, the step of Cu–X bond fission is likely to be significant in the complex formation. In alcohol, its bulk properties and/or its coordination ability allow the Cu–X bond fission to occur readily and promote the coordination of the four donor atoms (N_2S_2) of pdto. On the other hand, in a non-polar solvent such as chloroform, halide ion-binding to Cu(I) appears to be tight: Hence, it is not broken even by the 2-pyridyl of pdto. The similar halide ion-binding has also been found in the acetone solution of CuX and 2,2′-bipyridine(bpy);[8)] a binuclear $[CuX(bpy)]_2$ preferably forms in acetone, while a monomer $[Cu(bpy)_2]^+$ principally forms in alcohol. Consequently, alcohol is available for the breakdown of the Cu–X bond.

It is to be noted in Table 3 that **1**/**2** ratio is smaller in the case of Br^- than in the case of Cl^-. This indicates that Complex **2** prefers Br^- to Cl^-, the Cu–Br bond being stronger than the Cu–Cl bond. This is reasonable, for CuCl itself is rather more unstable

than CuBr upon exposure to air.

The oxidation-reduction potentials of the copper of [CuCl(pdto)] and [Cu(pdto)]ClO_4 in acetone at 25 °C have been measured by means of cyclic voltammetry(CV). [Cu(pdto)]ClO_4 gave a single pair of waves corresponding to the electrode reaction of Cu^I/Cu^{II}, the half-wave potential of which is 0.60 V *vs.* SCE. In the case of an acetone solution containing equimolar quantities of CuCl and pdto, two pairs of waves were observed. The first pair, in the cathodic region, has an $E_{1/2}$ value of 0.60 V *vs.* SCE, indicative of the Cu^I/Cu^{II} reaction of [Cu(pdto)]Cl, while the second, with an $E_{1/2}$ value of 0.49 V, is attributable to the Cu^I/Cu^{II} reaction of [CuCl(pdto)]. Hence, copper(I) states are more stable in [Cu(pdto)]Cl than in [CuCl(pdto)].

Neither [Cu(pdto)]ClO_4 nor [CuCl(pdto)] reacts with CO, as is demonstrated by monitoring the absorption and ^1H NMR spectra. This indicates that pdto in both complexes tightly binds the Cu(I) atom, which prevents the substitution reaction, and that they keep the structure, presumably a tetrahedral environment, around the Cu(I) atom, the rigidity of which inhibits the addition reaction and accompanying conformational change.

[Cu(pdto)]ClO_4 is quite stable against oxygen, while [CuCl(pdto)] is gradually oxidized upon exposure to air. This is accounted for by their redox properties obtained from CV. Hence, pdto stabilizes the copper (I) ion when all four donor atoms of pdto bind the Cu(I) ion.

This work was supported in part by a grant from the Ministry of Education, Science and Culture.

Argon Plasma Treatment of Packing Materials for Gas Chromatography and Comparison with Acid Wash and Dimethyldichlorosilane Treatment of Support

Seiji Oka, Yukio Yamamoto,* and Koichiro Hayashi

The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567

(Received May 6, 1982)

Argon plasma treatment of column packings for gas chromatography was examined with commercially obtained diatomaceous earth coated with several kinds of stationary liquid phases, such as squalane, Apiezon L, dioctyl phthalate, Silicone DC, and polyethylene glycol. It was found that the plasma treatment improves chromatographic properties of all the packings examined except those with polyethylene glycol. The effect of the plasma treatment is attributable to the reduction of support adsorptivity by the formation of an inert coating on the support surface. The plasma treatment of Chromosorb W coated with 5% squalane was compared with dimethyldichlorosilane (DMCS) treatment of the acid-washed (AW) support, the so-called AW-DMCS-treatment of support. Although the AW-DMCS-treatment is superior to the plasma treatment for the reduction of support adsorptivity, a complete elimination of the adsorptivity was attained by the plasma treatment of the packing having the AW-DMCS-treated support.

Preceding papers have illustrated the effect of argon plasma treatment of diatomaceous earth coated with squalane or Apiezon L on gas chromatograms of hydrocarbons.[1,2] By the plasma treatment, the chromatographic resolution was improved and the retention times were decreased. The effect has been attributed to the reduction of support adsorptivity by the formation of an inert coating on the support surface, based on the following results. (1) By the plasma treatment, the tailings of aromatic hydrocarbon peaks were reduced, and their retention times were decreased more than those of saturated aliphatic hydrocarbons. (2) The weight loss of the packing treated which occurred by the extracting the stationary liquid phase decreased with increasing treatment time, indicating the formation of an insoluble component on the support surface. (3) The ESCA spectrum of the support recovered from the treated packing by extracting the liquid phase indicated that the support surface is covered with an organic component. (4) NMR spectrometry showed that the soluble fraction of liquid phase of the treated packing remains unchanged.

The experiments described here were undertaken to enhance the utility of argon plasma treatment for the improvement of chromatographic properties of column packings. The plasma treatment of various kinds of familiar packings was examined. A comparison was made with dimethyldichlorosilane (DMCS) treatment of acid-washed (AW) support, the so-called AW-DMCS-treatment of support, which is usually used to reduce the support adsorptivity.

Experimental

Column packings (60/80 mesh) were obtained from Wako Pure Chemical Industry. The apparatus and experimental details of the plasma treatment were described previously.[2] The gas chromatographic test of the treated packing was also carried out as described previously; the packing was packed into a 1 m×3 mm i.d. stainless steel tube, and the nitrogen flow rate was 30 ml/min. Before its use, the packing was conditioned longer than overnight at a temperature 10 °C below the maximum temperature of the packing.

Results and Discussion

Figure 1 shows the effect of argon plasma treatment of Chromosorb W (non-acid washed (NAW)) coated with 5% squalane (max. temp, 140 °C) on the gas chromatogram of aromatic ketones. The retention times and tailings of the peaks are reduced by the plasma treatment. On the 60 min treated packing, sharp peaks with improved separations are obtained. A similar effect was also observed on the gas chromatogram of aliphatic ketones such as 5-nonanone and 6-undecanone. The results suggest that the plasma treatment enables the packing to be used for the

analysis of ketones as well as hydrocarbons.

Figures 2 and 3 show the gas chromatograms of the aromatic ketones on untreated and treated packings, Chromosorb W (NAW) coated with 5% Silicone DC 200 (max. temp, 200 °C) and Shimalite (NAW) coated with 25% Silicone DC 702 (max. temp, 200 °C), respectively. The decrease in the retention times and the improvement of peak separations by the plasma treatment are also observed with these packings.

Similar results were obtained by the plasma treatment of other kinds of packings: Chromosorb W (NAW) coated with 20% Apiezon L and 10% KOH (max. temp, 180 °C) and Chromosorb W (NAW) coated with 10% dioctyl phthalate (max. temp, 140 °C). The former packing is used for the analysis of amines, and the latter for the analysis of alcohols and esters. Examples of the gas chromatograms on these packings are shown in Figs. 4 and 5, illustrating

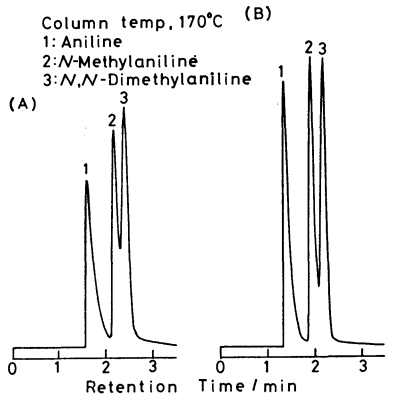

Fig. 4. Gas chromatograms on Chromosorb W (NAW) coated with 20% Apiezon L and 10% KOH: (A) untreated; (B) 10 min plasma treated.

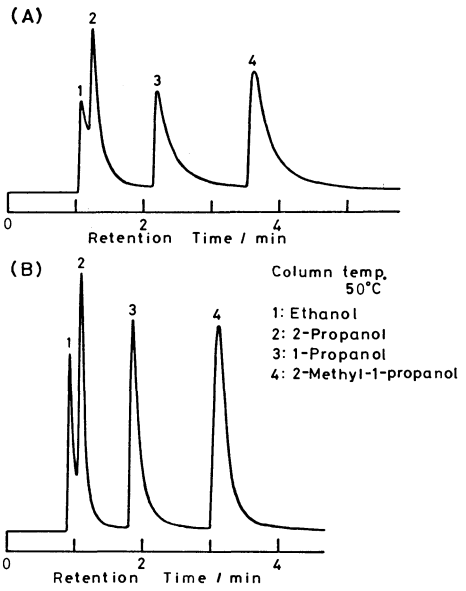

Fig. 5. Gas chromatograms on Chromosorb W (NAW) coated with 10% dioctyl phthalate: (A) untreated; (B) 60 min plasma treated.

the improvement of their chromatographic properties by the plasma treatment.

By the plasma treatment the retention times and tailings of chromatographic peaks were reduced in all the cases of the packings described above, although the treatment times needed for an appreciable effect to occur on the gas chromatograms differ from one another. The prolonged plasma treatment resulted in further decrease in the retention times accompanying a decrease in the peak separations. According to the previous studies,[1,2] it is reasonable to assume that the effect of the plasma treatment of these packings is due to the reduction of support adsorptivity.

The surface of the diatomite supports is covered with reactive silanol groups, which cause tailings of chromatographic peaks,[3] and the AW-DMCS-treated supports are usually used to avoid the adsorption on the support surface. Thus, it is interesting to compare the effect of the plasma treatment of packing with that of the AW-DMCS-treatment of support,

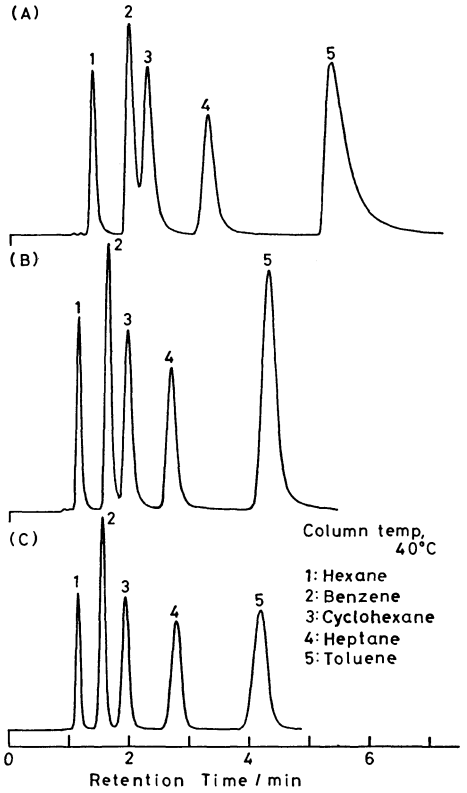

Fig. 6. Gas chromatograms on Chromosorb W coated with 5% squalane: (A) untreated packing, AW support; (B) 30 min plasma treated packing, AW support; (C) untreated packing, AW-DMCS treated support.

Figure 6 illustrates the gas chromatograms of a hydrocarbon mixture on Chromosorb W (NAW) coated with 5% squalane, in order to compare the effect of the plasma treatment of the packing having the AW support with that of the AW-DMCS-treatment. These chromatograms should also be compared with those on the untreated and treated packings having the NAW support, which have previously been shown in Ref. 1 (Fig. 3). A comparison of the figures shows that the chromatograms on the 30 min plasma treated packings having the NAW and AW supports (Fig. 3(b) in Ref. 1 and Fig. 6(B), respectively) are almost identical with that on the untreated packing having the AW-DMCS-treated support (Fig. 6(C)). On these packings, benzene and cyclohexane are well separated and the tailing of the peak of toluene is completely suppressed in contrast to the untreated packings having the NAW and AW supports (Fig. 3(a) in Ref. 1 and Fig. 6(A), respectively). That is to say, the effect of the plasma treatment of the packings having the NAW and AW supports on the gas chromatograms of the hydrocarbon mixture is almost the same as that of the AW-DMCS-treatment of support. It is also shown that, on the untreated packings, the AW support is better for the separation of benzene and cyclohexane than the NAW support (Fig. 6(A) compared with Fig. 3(a) in Ref. 1).

Since polar compounds are sensitive to the support adsorptivity and are expected to give more detailed information about it than the hydrocarbons, the gas

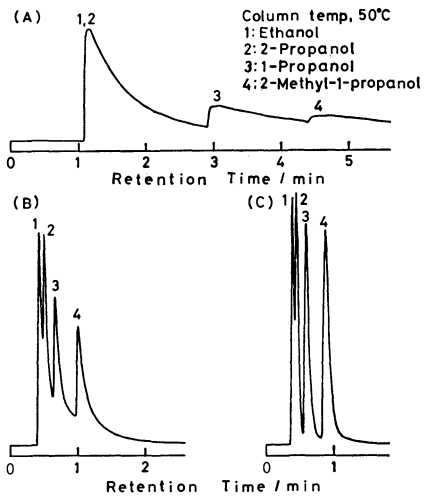

Fig. 7. Gas chromatograms on Chromosorb W coated with 5% squalane: (A) 60 min plasma treated packing, NAW support; (B) untreated packing, AW-DMCS treated support; (C) 30 min plasma treated packing, AW-DMCS treated support.

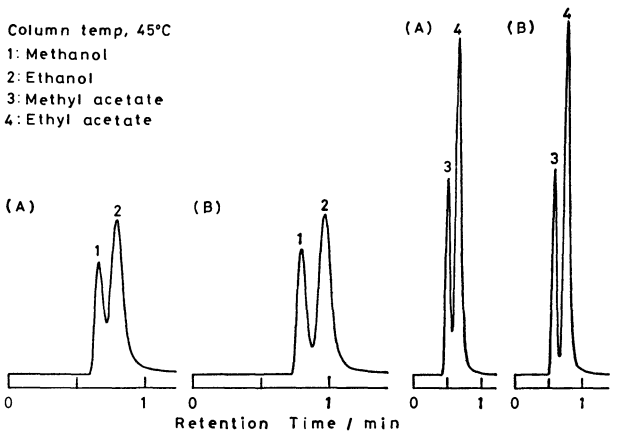

Fig. 8. Gas chromatograms on Chromosorb W (NAW) coated with 10% polyethylene glycol 20M: (A) untreated; (B) 20 min plasma treated.

chromatograms of alcohols on the packings with 5% squalane are compared in Fig. 7. On the 60 min treated packing having the NAW support, the peaks are very broad with extensive tailings. The tailings are appreciably reduced on the untreated packing having the AW-DMCS-treated support, indicating that the AW-DMCS-treatment of support is superior to the plasma treatment of the packing for the reduction of the support adsorptivity. However, a complete suppression of the tailings is attained by the 30 min plasma treatment of the packing having the AW-DMCS treated support, as is shown by Fig. 7(C). Thus, the plasma treatment is useful for the complete suppression of the adsorption on the support surface when used together with the AW-DMCS-treatment of support.

The effect of the plasma treatment of diatomaceous earth coated with polyethylene glycol was different from that of the other packings described above; the plasma treatment tends to increase the retention times

on the packings. Figure 8 shows the gas chromatograms of alcohols and esters on the untreated and treated Chromosorb W (NAW) coated with 10% polyethylene glycol 20 M (max. temp, 200 °C), demonstrating that both the retention times and the peak separations are increased by the plasma treatment. The plasma treatment of Shimalite (base-treated) coated with 25% polyethylene glycol 6000 (max. temp, 200 °C) was also examined, but the observed effect on the gas chromatograms was only a slight increase in the retention times. Such exceptional results can be ascribed to the high polarity of the liquid phase; the adsorption on support surface is not important on the packings with the polar liquid phase. In practice, tailings of the peaks are not observed even on the untreated packings. The increase in the retention times by the plasma treatment is probably due to some modification of the liquid phase.

Mössbauer Emission Spectroscopic Study of Some Spin Crossover Cobalt(II) Complexes

Yonezo MAEDA,* Hiroki OHSHIO, and Yoshimasa TAKASHIMA

Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812

(Received October 8, 1981)

The Mössbauer emission spectra of $[^{57}Co(terpy)_2]X_2$ (X=Cl and ClO_4), $[^{57}Co(snn)_2](ClO_4)_2$, and $[^{57}Co(snnme)_2](ClO_4)_2$ (terpy=2,2′: 6′2″-terpyridine, snn=*N*-(2-pyridylmethylene)-2-(methylthio)aniline, and snnme=*N*-(6-methyl-2-pyridylmethylene)-2-(methylthio)aniline) were examined. These cobalt complexes show thermally induced spin crossover behavior and the temperature dependence of their magnetic moment varies with the counter anion, although the corresponding iron complexes are in a low-spin state. The high-spin iron(II) species ascribed to a metastable form are observed in the emission spectra of $[^{57}Co(terpy)_2](ClO_4)_2\cdot 2H_2O$ and $[^{57}Co(snnme)_2](ClO_4)_2$, and their spectral areas increase with decreasing source temperature. The effective vibrating mass for the iron complex observed in the emission spectra of $[^{57}Co(snnme)_2](ClO_4)_2$ was calculated from the temperature dependence of the isomer shift value, and was used to distinguish whether the iron complex formed by EC-decay of a cobalt-57 atom is stable or metastable.

The Mössbauer emission spectroscopic method provides for studying the after-effects attended by EC-decay of a cobalt-57 atom in a solid state. The chemical after-effects in solids, reflected in the Mössbauer spectra, are categorized as follows: (i) The oxidation state of the iron atom formed in the EC-decay of a cobalt-57 atom in the lattice of the labeled cobalt complexes is different from that of the parent cobalt atom (formation of foreign-charge state). (ii) An iron atom after EC-decay does not have the same spin state as the corresponding iron complexes but the same oxidation state (formation of anomalous spin state). (iii) An iron atom after EC-decay is stabilized in a coordination atmosphere different from that of a cobalt atom because of the radiolysis of the ligands, although it does have the same spin and oxidation state as the corresponding iron complex. These phenomena have been explained by various mechanisms as described below:

Friedt and Danon reported on the behavior of $^{57}CoX_2$ in terms of the lattice energy.[1] Friedt *et al.* reported that iron(III) appearing in the emission spectra of $^{57}CoSO_4\cdot nH_2O$ was due to the radiolysis of hydrated water.[2-4] The role of the radicals resulting from autoradiolysis of ligands due to photoelectrons and X-rays have been extensively examined, and Sano *et al.* concluded that the redox properties of radicals affect the final oxidation state of the daughter atom, and that these effects are due to the radiolytic self-decomposition of the molecular environment of the decaying atoms.[5-8] These mechanisms have been supported by performing an external irradiation experiment using electrons and X-rays.

On the other hand, Nath *et al.* suggested that the multiple charged iron atom after Auger cascade was rapidly neutralized by electron transfer from ligands, and the coulomb repulsion between the iron and ligands resulted in the fragmentation of molecules; the fragmentation was highly dependent on the degree of bonding conjugation in the molecule.[9,10]

The Mössbauer emission spectra of some cobalt complexes with imines or their derivatives were measured by Gütlich *et al.*[11-15] They proposed that the anomalous spin states appearing in these emission spectra had lifetimes of the order of 100—400 ns and were the immediate precursors of the stable states. Several studies were performed from the view point of the spin state of the daughter iron atom.[16-19]

In this study we measured the Mössbauer emission spectra of spin crossover cobalt complexes in order to investigate how the difference in the spin state of a parent cobalt atom affects the lifetime of a metastable state of a daughter iron atom. The effective vibrating mass calculated using the method proposed by Herber[20] was used to distinguish between the metastable and the stable state.

Experimental

The cobalt complexes used in this study were prepared described in the literature. $[Co(terpy)_2]X_2$ (X=Cl and ClO_4),[21] $[Co(snn)_2](ClO_4)_2$,[22] and $[Co(snnme)_2](ClO_4)_2$:[23] terpy; 2,2′: 6′,2″-terpyridine, snn; *N*-(2-pyridylmethylene)-2-(methylthio)aniline, and snnme; *N*-(6-methyl-2-pyridylmethylene-2-(methylthio)aniline. Iron complexes were prepared by methods similar to those of the cobalt complexes. The elemental analysis was performed with unlabeled samples and the values found for carbon, nitrogen, and hydrogen deviated by less than 0.3% from the calculated values. The compounds for the Mössbauer emission spectroscopic measurement were all labeled with 1 mCi of cobalt-57. The magnetic susceptibilities at 297 K and 80 K were measured on polycrystalline samples by the Faraday method. $HgCo(NCS)_4$ was used as the calibration substance. The effective magnetic moment was calculated using the formula $\mu_{eff}=2.84\sqrt{\chi_M T}$, where χ_M is the molar susceptibility after dia-

TABLE 1. EFFECTIVE MAGNETIC MOMENT OF COBALT AND IRON COMPLEXES

Complex	μ_{eff}/BM	
	297 K	80 K
$[Co(terpy)_2]Cl_2\cdot 5H_2O$	2.53	2.10

magnetic corrections. These data are listed in Table 1.

The external irradiation experiments with γ-ray for [Fe(snn)$_2$](ClO$_4$)$_2$ and [Fe(snnme)$_2$](ClO$_4$)$_2\cdot$2H$_2$O were performed as described elsewhere.[24]

Mössbauer spectra were measured with a constant acceleration spectrometer(Austin Science Associate). The data are stored in a 1024 channel analyzer, type 5200 (Inotech, Inc). Temperature was monitored with a calibrated copper *vs.* constantan thermocouple in a variable temperature cryostat, type ASD-4V(Austin Science Associate) and maintained with a temperature controller, type S-8(Austin Science Associate). In the emission spectroscopy, potassium hexacyanoferrate(III) enriched with iron-57 was used as a standard absorber and was maintained at room temperature. A cobalt-57 source of 10 mCi diffused into palladium foil was used for the absorption experiment. All the spectra were fitted by Lorentzian line shapes using the least-square method at the Computer Center, Kyushu University; the velocity scale was normalized with respect to the center of the spectrum of an iron foil at 297 K. The geometry effect on the spectra(dimensions of source and absorber in relation to the distance between them) were taken into consideration in the fitting procedure. The experimental errors for Mössbauer parameters(isomer shift, quadrupole splitting, and full width at half-maximum) are estimated to be about $\pm$0.01 mm s^{-1} or less.

Results and Discussion

Figures 1—4 show the Mössbauer emission spectra recorded for [^{57}Co(terpy)$_2$]Cl$_2\cdot$5H$_2$O, [^{57}Co(terpy)$_2$](ClO$_4$)$_2\cdot$2H$_2$O, [^{57}Co(snn)$_2$](ClO$_4$)$_2$, and [^{57}Co(snnme)$_2$](ClO$_4$)$_2$, respectively. The values for the Mössbauer parameters are listed in Tables 2—4 together with those for the absorption spectra of the analogous iron complexes and those for the corresponding iron-57 doped cobalt complexes. It was found that the iron atoms in the iron complexes and in the matrices of the cobalt complexes were in a low-spin state, while the corresponding cobalt complexes exhibited thermally induced spin crossover behavior.

The emission spectrum of [^{57}Co(terpy)$_2$]Cl$_2\cdot$5H$_2$O recorded at 80 K is very similar to that at 297 K; both spectra are characterized by two quadrupole doublets(A and B) assigned to low-spin iron(II). An additional resonance line C ascribed to low-spin iron (III) is observed at 80 K. The disappearance of the species C at 297 K is due to the decrease of the recoil free fraction of this species. The values of the isomer shift and the quadrupole splitting of A are similar to those for the absorption spectra of the corresponding iron complex. The similarity between their parameters indicates that A is attributable to an iron atom stabilized without undergoing any after-effect, and that the electronic ground state of A, which is formed in the lattice of the paramagnetic cobalt compound by nuclear disintegration, is not influenced by the high-spin character of the surrounding cobalt ions at room temperature. The doublet B is attributable to a species stabilized in a coordination atmosphere different from that of A. This stabilization occurs

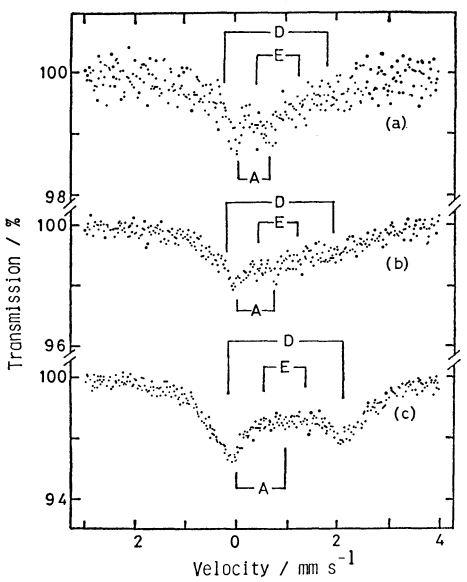

Fig. 4. Mössbauer emission spectra of $[^{57}Co(snnme)_2](ClO_4)_2$ at (a) 297 K, (b) 200 K, and (c) 80 K.

within the lifetimes of iron-57 m (10^{-7} s) through a secondary process after EC-decay. The coordination structure around B is distorted from the original coordination atmosphere by after-effects of nuclear disintegration.

The Mössbauer emission spectrum recorded at 80 K for $[^{57}Co(terpy)_2](ClO_4)_2\cdot 2H_2O$ is quite different from that at 297 K. The spectrum at 297 K is fitted to doublet A and B. However, when the source temperature was lowered, two additional resonance lines, D ascribed to high-spin iron(II) and C to low-spin iron(III) appeared in the emission spectra. These C and D lines are obviously attributable to a new chemical species because their chemical states are different from that of iron-57 doped in the host matrix $[Co(terpy)_2](ClO_4)_2\cdot 2H_2O$ as shown in Fig. 2. The decrease in the recoil free fraction with increasing temperature have resulted in the disappearance of C in the Mössbauer spectra at 297 K; C is a minor absorption peak even at 80 K. There is a possibility that the high-spin species D is in the stable state produced by the radiolytic reaction between the ligands and ClO_4^-. However we ascribe D to a metastable species leading to stable low-spin iron(II) for the following reasons:[15,25] It is assumed that the average ligand field strength experienced by the iron-57 daughter atom on the Mössbauer time scale of *ca.* 10^{-7}—10^{-8} s tends to decrease effectively because of coulomb repulsion between central iron-57 atom and ligands after Auger cascade. The absence of D in other emission spectra is caused by rapid relaxation of energy produced by EC-decay. Berlin and Schmand[26] have concluded that the existence of a metastable state is proved in the emission spectra of $^{57}CoSO_4\cdot 7H_2O$ because the metastable state has a long relaxation time of energy deposited on an iron atom after EC-decay; and they determined the lifetime of high-spin iron (II) species as a function of temperature.

The chemical structure of ligands snn and snnme are the same except for the methyl group located at the 6-position of pyridine. Therefore, the effects of autoradiolysis on both ligands by photoelectron and X-rays emitted following EC-decay are assumed to be similar. However, the methyl group of $[Co(snnme)_2](ClO_4)_2$ causes magnetic behavior different from that of $[Co(snn)_2](ClO_4)_2$.

The Mössbauer emission spectra of $[^{57}Co(snn)_2](ClO_4)_2$ at various temperatures are mainly composed of two kinds of quadrupole doublets A and B, and the ratios of the absorption areas of A and B to the total absorption area are almost the same in the range of the source temperature(80 K—297 K). This indicates that these species are in a stable state. The Mössbauer parameter of A appearing in the emission spectra is in good agreement with that obtained for the Mössbauer absorption spectra of $[^{57}Fe_{0.1}Co_{0.9}$-

	80	0.41	0.80	0.36		
$[Fe(snnme)_2](ClO_4)_2\cdot2H_2O$ irrad.[b]	80	0.45	0.81	0.33		

a) E: high-spin Fe(II). b) Total exposure dose is 5.2×10^8 R.

$(snn)_2](ClO_4)_2$. The high-spin chemical species D appearing in the emission spectrum recorded at 80 K for $[^{57}Co(snn)_2](ClO_4)_2$ disappeared as the source temperature was increased due to the decrease of the recoil free fraction.

The high-spin character of $[Co(snnme)_2](ClO_4)_2$ is enhanced in comparison with $[Co(snn)_2](ClO_4)_2$ as indicated by the effective magnetic moments. The emission spectra of $[^{57}Co(snnme)_2](ClO_4)_2$ at various temperatures are composed of three species (A, D, and E). It is worthy of note that high-spin iron(II) D appearing in the emission spectra of $[^{57}Co(snnme)_2](ClO_4)_2$ can be ascribed to a metastable state, because the ratio of the peak area of D to the total absorption area increases as the source temperature decreases, and this phenomenon is in good accord with that of $[^{57}Co(terpy)_2](ClO_4)_2\cdot2H_2O$. The three emission spectra of $[^{57}Co(snnme)_2](ClO_4)_2$ consist of two kinds of high-spin iron(II) (D and E) and low-spin iron(II) A. The species E ascribed to high-spin iron(II) is in a stable state with the ligands partly decomposed by autoradiolysis. The assumption that E is in a stable state is supported by the temperature independent ratio of the peak area of E to the total absorption area, and by the high value (>57) of the effective vibrating mass(EVM) as described later.

The absence of E in $[^{57}Co(snn)_2](ClO_4)_2$ or of B in $[^{57}Co(snnme)_2](ClO_4)_2$ can account for the fact that snn makes a stronger ligand field around the center atom than snnme; that is, the iron atom after EC-decay in the former complex is still in a low-spin state even if snn is exposed to secondary process following EC-decay because of its strong ligand field. On the other hand, the high-spin species is believed to be produced easily in the latter complex because the slight increase of the bond length between the iron atom and the coordination atom brings about a predominance of high-spin character.

External irradiation experiments with γ-rays were performed for $[Fe(snn)_2](ClO_4)_2$ and $[Fe(snnme)_2]$-

$(ClO_4)_2 \cdot 2H_2O$ and no chemical effect was observed in the irradiated samples.

Next we discuss the difference in the EVM for each chemical species of $[^{57}Co(snnme)_2](ClO_4)_2$, cobalt(II) complexes reported by other authors, and the corresponding iron complexes. The EVM can frequently be estimated from the second order Doppler shift, and is given by

$$M_{eff} = -\frac{3}{2} \times \frac{E_\gamma K}{c^2} \left(\frac{dIS}{dT} \right)^{-1}, \quad (1)$$

where E is the energy of the Mössbauer transition. The calculated data are listed in Table 5. The values of EVM obtained from the Mössbauer emission spectra is less than that from the absorption spectra for the corresponding iron compounds. The values for the metastable species D are smaller than the free-atom value 56.95 amu. On the other hand, it is interesting that the value obtained for E is larger than 56.95 amu. These results can reasonably be accounted for as follows. Equation 1 is based on a harmonic system. It is reasonable to conclude that the iron atom emerging in the emission spectra is in a excited state after EC-decay. Thus the local lattice vibrating behavior is no longer expressed in a harmonic system if anharmonicity remains on the time scale of 10^{-7}—10^{-8} s after EC-decay. It is reasonable to rewrite EVM as follows by considering the anharmonicity of the lattice vibration in order to supplement this model.

$$M_{eff} = -\frac{3}{2} \times \frac{E_\gamma K}{c^2} \left(\frac{dIS}{dT} \right)^{-1} (1 + 2\alpha KT) \quad (2)$$

where α is a positive coefficient derived from Thirring expansion.[27] This equation is useful for evaluating the EVM value for the chemical species in a metastable state. Namely, the value of EVM will exceed 56.95 amu if the second term in the parentheses (Eq. 2) is taken into account. The vibrational motion of the molecular moiety containing a daughter iron atom in a metastable state is disturbed by the "hot process" defined as all those processes occuring after EC-decay. Unfortunately, we cannot estimate the coefficient α because we cannot know the absolute value of EVM for a species in the metastable state. The value for E is calculated to be larger than 56.95 amu from Eq. 1, and this implies that E, rather than D, is in a stable state. The data for the other cobalt complexes listed in Table 5 are also interpreted in a similar manner. In this way, the daughter atoms in a metastable state can be distinguished from those in a stable state by evaluating the EVM value.

a—c) Data for the isomer shifts are quoted from Refs. 14, 12, and 11, respectively. d) Metastable state.

The origin of a metastable state is believed to be as follows in connection with bonding between an iron and a coordination atom.

(i) The bonds between the metal and the ligands are excited by the photoelectrons and X-rays emitted after Auger cascade.

(ii) Auger cascade produces a highly charged iron atom. The coulomb repulsion occurs between the highly-positive charged iron atom and the positively charged ligands; these arise from electron transfer from ligands to an iron atom in order to neutralize the positive charge on the iron atom, and the coulomb repulsion changes the bond length.

At the same time, inter- or intramolecular vibration modes are excited through the secondary process and the energy deposited on a daughter atom is released to this vibrational system. This relaxation time would be dependent on the temperature of the lattice system. The decrease and disappearance of D as the source temperature rises in the emission spectra of $[^{57}Co(terpy)_2](ClO_4)_2 \cdot 2H_2O$ and $[^{57}Co(snnme)_2](ClO_4)_2$, respectively, suggest that the energy deposited by EC-decay is easily transferred to the lattice system as phonons. In these cases the spin-orbit coupling of the iron atoms is presumed to play an important role in the rapid relaxation of the energy to the lattice system.

It is concluded that the stronger the low-spin character of the cobalt complexes and the lower the source temperature, the longer the lifetime of a metastable state. At low temperatures, several parts of the decayed atoms become observable in the metastable state because of the greater lifetime of this state.

Solvent Extraction of Alkali Metal Picrates with Poly- and Bis(benzo-12-crown-4)s

Takumi MAEDA, Keiichi KIMURA,* and Toshiyuki SHONO*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received October 9, 1981)

Solvent extractions of alkali metal picrates were carried out using newly synthesized poly- and bis(crown ether)s containing benzo-12-crown-4 moieties in a water–chloroform system. The extraction equilibrium constants(K_e) and the complexation constants (K_c) in the chloroform phase were determined at 25 °C. The K_e values for the alkali metal cations decreases as follows: $Na^+ > K^+ > Rb^+ \geq Cs^+$ with the poly(benzo-12-crown-4) and K^+, Rb^+, $Cs^+ > Na^+$ with the bis(benzo-12-crown-4). The poly(benzo-12-crown-4) improved the sodium-ion selectivity of the corresponding monocyclic analog because of the easy formation of 2:1 crown ether unit-cation complexes assisted by the cooperative action of two adjacent crown ether units, while the bis(benzo-12-crown-4) did not. A separate extraction experiment was also undertaken in a water–dichloromethane system in order to compare the extractability of these benzo-12-crown-4 derivatives with that of 12-crown-4.

It is known that 12-crown-4 has a relatively small cavity, which seems to be suitable for forming stable complexes with Li^+ or Na^+. However, only a few papers have been published on the solvent extraction of metal cations using 12-crown-4 and its derivatives.[1,2] On the other hand, our previous work concerning the cation-binding ability of benzo-15-crown-5 and benzo-18-crown-6 derivatives has made it clear that poly- and bis(crown ether)s have much greater extractabilities and selectivities than their monocyclic analogs, especially for the cations which form 2:1 crown ether unit-cation complexes with them.[3–6] Some cooperative effects of adjacent crown ether units of the crown ethers were thought to bring about these results. This observation induced us to synthesize poly- and bis(crown ether)s containing benzo-12-crown-4 moieties and then to investigate their binding properties for alkali metal cations.

In this paper, we will consider the solvent extraction of alkali metal picrates with newly synthesized poly- and bis(crown ether)s **2**($n=1$), **3** and their monocyclic analogs **1**($n=1$), **4** in water–chloroform and water–dichloromethane systems.

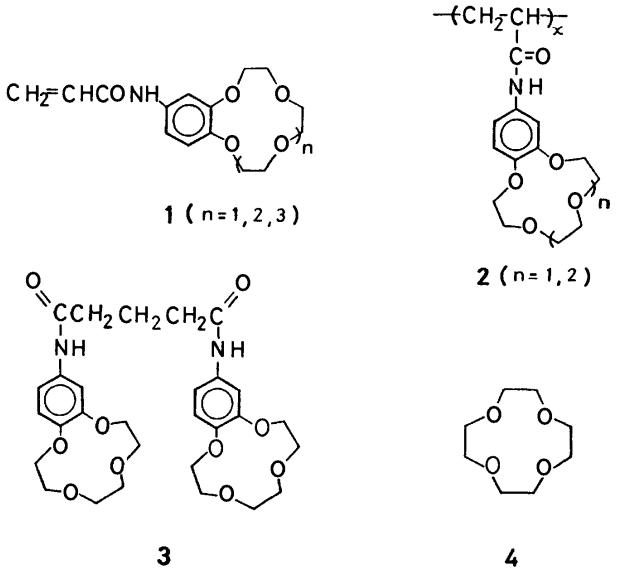

Fig. 1. Crown ether derivatives used in this study.

Experimental

Materials. 12-Crown-4 was obtained from Wako Pure Chemical Industries, Ltd., and used without further purification. Benzo-12-crown-4 was prepared according to Liotta's method.[7] The monocyclic crown ether **1**($n=1$) and poly- and bis(crown ether)s **2**($n=1$) and **3** were derived from benzo-12-crown-4 in the manner described elsewhere.[3] The analytical data of **1**($n=1$) and **3** are as follows: **1**($n=1$): mp 105.0—106.5 °C; M^+ 293. Found: C, 61.18; H, 6.70; N, 4.34%. Calcd for $C_{15}H_{19}O_5N$: C, 61.42; H, 6.53; N, 4.78%. **3**: Mp 170.0—171.0 °C; M^+ 574. Found: C, 60.20; H, 6.85; N, 4.88%. Calcd for $C_{29}H_{38}O_{10}N_2$: C, 60.62 H, 6.67; N, 4.88%. Poly(crown ether) **2**($n=1$) was purified by reprecipitation in chloroform–diethyl ether system. The alkali metal picrates were synthesized according to Fuoss' method.[8] Tetrahydrofuran (THF) was dried over sodium. Chloroform and dichloromethane were purified by distillation just before use.

Optical Spectra. Optical spectral changes in the above crown ether–cation complexes were measured by adding the crown ethers to 2.5×10^{-5} M(1 M = 1 mol dm^{-3}) THF solutions of alkali metal picrates. Measurements were carried out with a Hitachi 340 recording spectrophotometer.

Extraction. Equal volumes (10 ml) of organic and aqueous solutions were shaken in a stoppered flask for 40 min at 25±0.1 °C.

Chloroform was chosen primarily as the organic phase for extraction. However, in order to compare the extractabilities and cation selectivities of the crown ethers **1**, **2** ($n=1$), and **3** with those of **4**, solvent extractions were also carried out with a dichloromethane solution of the crown ethers (1.4×10^{-2} M or 3.5×10^{-3} M for crown ether units) and an aqueous solution of alkali metal hydroxide (1.0×10^{-2} M) and picric acid(7.0×10^{-4} M), because the chloroform solution containing **4** often became turbid.

Extraction equilibrium constants with **1**, **2**($n=1$), and **3** were calculated in a water–chloroform system. In this system, the concentrations of the crown ether in the organic phase were $(1.0—5.0)\times10^{-4}$ M for **2** ($n=1$) and $(1.0—5.0)\times10^{-3}$ M for **1** ($n=1$) and **3**, while that of the alkali metal picrate in the aqueous phase was 1.0×10^{-2} M. After the complete phase separation, a 2-ml portion of acetonitrile was added to 2 ml of the chloroform phase, and the concentration of the picrate was determined spectrophotomerically[$\lambda_{max}=374$ nm, ε: Na^+ 1.86, K^+ 1.87, Rb^+ 1.88, Cs^+ 1.86 ($\times10^4$ M^{-1} cm^{-1})]. The distribution constants of

the picrates in the absence of crown ethers, K_d, have been obtained previously [Na^+ 1.20, K^+ 2.67 Rb^+ 3.66, Cs^+ 6.66 ($\times 10^{-3}$ M^{-1})].[4]

Extraction Equilibrium Constant and Complexation Constant for the Organic Phase. The overall extraction equilibrium may be written as:

$$M^+ + Pi^- + n\text{Cr}^* \rightleftharpoons M(\text{Cr})_n\text{Pi}^*$$

$$K_e = [M(\text{Cr})_n\text{Pi}^*]/[M^+][Pi^-][\text{Cr}^*]^n \quad (1)$$

where M^+, Pi^-, and Cr denote an alkali metal cation, a picrate anion, and a crown ether unit, respectively. The asterisk refers to the species in the organic phase.[9] This equilibrium consists of the following equilibria:[10]

$$M^+ + Pi^- \rightleftharpoons \text{MPi}^*$$

$$K_d = [\text{MPi}^*]/[M^+][Pi^-], \quad (2)$$

$$\text{MPi}^* + n\text{Cr}^* \rightleftharpoons M(\text{Cr})_n\text{Pi}^*$$

$$K_c = [M(\text{Cr})_n\text{Pi}^*]/[\text{MPi}^*][\text{Cr}^*]^n. \quad (3)$$

K_c represents the complexation constant in the organic phase, which can be calculated with Eq. 4;

$$K_c = K_e/K_d. \quad (4)$$

In the same way as has been described in the previous paper, the following relations can be derived;[4,11]

$$D = K_e(M^\circ - A)(Cr^\circ - A), \quad (5)$$

$$D = K_e(M^\circ - A)(Cr^\circ - 2A)^2, \quad (6)$$

$$D = K_e(M^\circ - A)(Cr^\circ - 2A), \quad (7)$$

where D is the distribution ratio of the metal between the two phases. M°, Cr°, and A denote the initial concentrations of metal cations and crown ether units, and the concentrations of the picrates extracted into the organic phase as the counter anions, respectively. Equation 5 is applied when 1:1 crown ether unit-cation complexes are formed. When 2:1 crown ether unit-cation complexes are formed by monomeric crown ethers, Eq. 6 is used. However, in the system of poly- and bis(crown ether)s, which may be thought to form intramolecular 2:1 crown ether unit-cation complexes, Eq. 7 can be applied.

Results and Discussion

Optical Spectra of Alkali Metal Picrates and Their Crown Ether Complexes. Optical spectral changes of alkali metal picrates in THF accompanying an increase in the concentration of crown ether units suggest the stoichiometry of the crown ether unit-cation complexes qualitatively.[6,12] The maxima of the main absorption band, λ_{max}, for alkali metal picrates are found to be at 351 nm (Na^+), 358 nm (K^+), 359 nm (Rb^+), and 361 nm (Cs^+). In their complexes with crown ethers, the increase in the distance between cations and counter anions causes bathochromic shifts of the spectrum. When 1:1 crown ether unit-cation complexes are formed, cations and their counter anions are close to each other, forming tight ion-pairs. In this case, the bathochromic shift is not very large. On the other hand, in 2:1 crown ether unit-cation complexes, cations are forced to separate from their counter anions, which results in the large spectral shift to nearly 380 nm. Figure 2 shows some typical optical spectra for the 1:1 and 2:1 crown ether unit-cation complexes. In the **3**–Na^+ system, the addition of a large excess of crown ethers (the molar ratio of crown ether unit to picrate salt is 100) causes a spectral shift to only 353 nm, which suggests that 1:1 crown ether unit-cation complexes are formed. On the contrary, in the system of **2**(n=1)–Na^+, the absorption maximum shifts to 378 nm, showing the formation of 2:1 crown ether unit-cation complexes. However, a much higher concentration of crown ether units is needed for the pronounced bathochromic shift of the spectrum in the **2**(n=1)–Na^+ system than for that in the system of **2**(n=2)–K^+, which suggests that the complexation constant of the **2**(n=1)–Na^+ complex is quite small. From the results of similar experiments for other systems, the stoichiometry of these complexes was determined to be as follows: for Na^+ through Cs^+, only **2**(n=1) forms 2:1 crown ether unit-cation complexes; **1**(n=1) and **3** form 1:1 complexes.

Extraction Equilibria. Table 1 shows a considerable difference in the extractability for Na^+ between **1**(n=1) and **4**, although they have the same number of oxygen atoms. For the system of **4**, the extractability apparently depends on the relation between the cation size and the cavity size of **4**. For the sys-

	Na^+	K^+	Rb^+	Cs^+
1(n=1)	(0.670)	(1.85)	(2.20)	(2.55)
2(n=1)	7.15	6.67	4.68	4.43
3	(5.03)	(6.19)	(5.76)	(5.44)
1(n=2)	5.26[b]	16.7	9.72	0.708[b]
1(n=3)	6.16[b]	53.2	47.3	46.9

a) [Picrate]=1×10^{-2} M, [crown ether unit]=5×10^{-4} M (5×10^{-3} M in parentheses). b) Taken from Ref. 4.

tem of **1**(n=1), the distribution of picrate itself from the aqueous phase to the dichloromethane phase, the order of which can be expected to be the same as that in chloroform ($Cs^+>Rb^+>K^+>Na^+$, see Experimental), might contribute significantly to the extractability compared to the complexing ability, probably because the benzene ring decreases the basicity of the oxygen atoms adjacent to aromatic carbons,[13] which seems to lower the complexing ability. Poly(crown ether) **2**(n=1) has a much greater extractability for Na^+ than the others. Because of the extremely strong hydration, very little Li^+ was extracted [*e.g.*, <1% for **1**(n=1)], so no further investigation was made with respect to Li^+. Values of distribution ratios, D, are useful for comparing the extractability of the crown ethers for these cations. Since **1**(n=1) and **3** have much smaller extractabilities than **2**(n=1) and **1**(n=2, 3), the concentrations of **1**(n=1) and **3** in extractions were ten times higher than those of **2**(n=1) and **1**(n=2, 3). It should be noted that poly(crown ether) **2**(n=1) has a larger extractability and selectivity for Na^+ than **1**(n=2, 3) does.

The plots of logarithms of both sides in Eqs. 5—7 gave straight lines with a slope of 1, indicating that the stoichiometry of the complexes and the assumptions used for the derivation of these equations are reasonable. Figure 3 shows the plots for the **2**(n=1) systems as the examples. The values of log K_e, which are obtained from the intercepts of the lines, and those of log K_c, which are calculated from Eq. 4, are listed in Tables 3 and 4. There is a close correlation between the D and K_e values. **1**(n=1) and **3** have very small log K_e values for all the cations. The order of log K_e

values for alkali metal ions with **1**(n=1) and **3** are $Cs^+>Rb^+>K^+>Na^+$ and K^+, Rb^+, $Cs^+>Na^+$, respectively. On the other hand, a relatively high selectivity for Na^+ was observed with poly(crown ether) **2**(n=1).

The stoichiometry of the crown ether unit-cation complexes is likely to have a correlation with these results. When we compare the relative size of the cavity of 12-crown-4 and alkali metal cations (cavity radius: 12-crown-4 0.5—0.65 Å[1], ionic radius: Na^+ 0.95 Å, K^+ 1.33 Å, Rb^+ 1.48 Å, Cs^+ 1.69 Å[14]), **1**, **2**(n=1), and **3** may be anticipated to form 2:1 crown ether unit-cation complexes. Nevertheless, the formation of the 2:1 crown ether unit-cation complexes was ob-

served only with **2**(n=1) (see the optical measurement section). For the systems of **1**(n=1) and **3**, the comparison of the values of log K_e and log K_c shows a large difference in the sequence between them, which suggests that the extractability for the cations depends mainly on the value of K_d and not on that of K_c. However, poly(crown ether) **2**(n=1), which may be thought to have a close proximity of adjacent crown ether moieties induced by the rigidity of its comformation, may be able to form 2:1 crown ether unit-cation complexes more easily than **1**(n=1) and **3**. Therefore, the suitable structure of the crown ether to form the 2:1 crown ether unit-cation complex with Na^+ may result in the selective binding of **2**(n=1) for Na^+. Moreover, the large lipophilicity of **2**(n=1) may also be thought to bring about its high extractability for Na^+, which is comparable to that of **1**(n=2,3). In this case, the values of log K_e reflect those of log K_c. That is to say, the extractability of **2**(n=1) for the cations depends mainly on the values of K_c and not on those of K_d, as was observed in our previous work with benzo-15-crown-5 and benzo-18-crown-6 derivatives.[4,5]

In conclusion, the newly synthesized poly(crown ether) **2**(n=1) forms 2:1 crown ether unit-cation complexes with alkali metal cations, and the cooperative effect of two adjacent crown ether units of **2**(n=1) in forming the 2:1 complexes brings about the selectivity and the large extractability for Na^+.

Graphite Furnace Atomic Absorption Spectrometry with a Tantalum Boat for the Determination of Yttrium, Samarium, and Dysprodium in a Mish Metal

Hidehiro DAIDOJI* and Shohei TAMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received January 12, 1982)

The determination of yttrium, samarium, and dysprodium by means of graphite-furnace atomic absorption spectrometry (AAS) was studied by a tantalum boat inserted into a graphite tube atomizer. These elements could not be determined by the use of a commercial graphite tube. In the atomization from a tantalum boat, better analytical sensitivities and negligible memory effects for these rare earths are obtained. The analytical sensitivities of yttrium, samarium, and dysprodium with the tantalum boat were 0.60 ng, 0.86 ng, and 0.17 ng respectively. This method was applied for the determination of yttrium, samarium, and dysprodium in a mish metal. The measurements were performed with slightly acidified solutions (0.01 mol dm^{-3} HCl or HNO_3). The sensitivities and the precisions for these elements decreased with increasing acid concentration. An enhancement in the sensitivities of yttrium and dysprodium upon the addition of a large excess of lanthanum, neodymium, and praseodymium salts were observed. The yttrium, samarium, and dysprodium in a mish metal were determined with both analytical curves of standard solutions containing an excess of lanthanum, cerium, and neodymium ions and of the standard addition. The precisions for this work were in the 3—9.3% range.

Atomic absorption analysis in an electrically heated graphite atomizer has a number of disadvantages. The graphite itself has been improved to overcome these problems. Particularly, a graphite-tube atomizer pyrocoated with a hydrocarbon such as methane has recently been used. Attempts have also been made to use a pre-coated graphite tube with salts of tantalum,[1,2,6] zirconium,[3,4] tungsten,[5] or lanthanum.[3,6] Other attempts have been to use a tantalum or tungsten liner, collar or wire inserted inside the graphite furnace.[7–15] Enhancements in the sensitivity of many elements were obtained with a metal liner, collar, or wire, because metal carbide formation in these causes is impossible. There have been few studies for the determination of rare earths by means of graphite-furnace atomic absorption spectrometry (AAS). Dittrich[16] determined traces of rare earths by means of electrothermal atomization with a carbon rod, a graphite furnace, and a tantalum ribbon. Kuga[17] and Grobenski[18] measured rare earth by the use of a pyrolitic graphite-coated tube. Sastry[6] repoated the determination of rare earth in uranium by the use of a pyrolitic carbon-coated tube pre-coates with lanthanum, tantalum, or yttrium. Moreover, Wahab[14,15] studied the atomization of yttrium using a pyrocoated graphite tube, a carbidized graphite tube, and tantalum or tungsten foil.

In this work, we determined yttrium, samarium, and dysprodium in a mish metal by the use of a laboratory-made tantalum boat inserted inside a graphite tube.

Experimental

Instrumentation. A Nippon Jarrel-Ash atomic absorption spectrophotometer, AA-1E, fitted with a flameless atomizer, FLA 100, A Hamamatsu TV deuterium Arc lamp, and hollow cathode lamps, was used.

Reagents. Stock solutions of 1000 or 2000 μg ml^{-1} of yttrium, samarium, dysprodium, praseodymium, neodymium, and lanthanum were prepared from oxides of these elements dissolved in hydrochloric acid and nitric acid respectively. Stock solutions of 1000 μg ml^{-1} aluminum and iron were prepared from high-purity metals dissolved in hydrochloric acid and nitric acid respectively. A stock solution of 5000 μg ml^{-1} cerium was prepared from cerium nitrate dissolved in distilled water. The acidities of these solutions were 0.1—0.5 mol dm^{-3}. Analytical solutions were prepared from stock solutions by dilution with distilled water. Distilled water was prepared by the distillation of Milli-Q water.

Tantalum Boat. The tantalum boat was made by cutting pure tantalum foil (99.95%) 0.1 mm thick and exerting pressure on it. This boat was then fitted in a commercial graphite tube with an inner diameter of 3.2 mm, as is shown in Fig. 1.

Procedure. A comparison of the situation with and without the tantalum boat was achieved by the injection of volumes (10 μl) of standard solutions and by the subsequent measurement of the peak absorbance. The hollow cathode lamps were used at 14 mA for yttrium, at 10 mA for samarium, and at 12 mA for dysprodium. The argon flow rate through the graphite furnace was 2.0 l min^{-1}.

Results and Discussion

The ashing and atomizing conditions in the use of the tantalum boat for yttrium, dysprodium, and samarium are shown in Figs. 2—4. The dotted lines in each figure show the relationship between the absorbances (as the peak height) and the ashing temperature. The full lines show the relationship between the absorbances and the atomizing temperature. The operating conditions selected from these results are shown in Table 1. When yttrium, samarium, and dysprodium are determined under these operating conditions, the absolute sensitivities are obtained as 0.60 ng for yttrium, 0.86 ng for samarium, and 0.17 ng for dysprodium. These sensitivities are similar to the values in previous reports.[6,13,17,18] The sensitivity of samarium by the use of a commercial graphite tube is obtained as 20 ng. In this determination, a strong memory effect of carbide formation is observed. The determinations of yttrium and dysprodium by the use

of the graphite tube were impossible, because the memory effects by the formation of the refractory carbides of these elements are too great.

Wavelength and Sensitivity. Tables 2—4 show several atom lines of yttrium, dysprodium, and samarium, the relative intensities emitted by the hollow cathode lamps, the *gf* values,[21] and the absorbances of 50 ng of yttrium, 43 ng of dysprodium, and 100 ng of samarium by the use of the tantalum boat. Wahab[13,14] and Manning[19] used 407.7 nm in the determination of yttrium. In this work, the atom line at 410.2 nm shows the highest intensity and the maximum absorption of all the atom lines of yttrium. For dysprodium,

the most sensitive lines are observed at 421.1 nm and 419.4 nm. The sensitivity at 419.4 nm is high in comparison with the results obtained by the use of a nitrous oxide–acetylene flame.[19,20] For samarium, absorbances are obtained at various atom lines.

Effect of Acids and Matrix Elements. The effects of acids for the determined elements are shown in Figs. 5—7. The sensitivities and precisions for these elements decrease with increasing acid concentration. Therefore, the acidity for the determination of these elements is selected as 0.01 mol dm^{-3} HCl for yttrium and dysprodium and as 0.01 mol dm^{-3} HNO_3 for samarium. The effect of acids for samarium differ from those in the previous report using pyrolitic-coated graphite tube.[18]

Graphite-furnace AAS, with the tantalum boat inserted inside the graphite tube, was used for the determination of yttrium, dysprodium, and samarium in a mish metal. The composition of a mish metal con-

sists of 45% cerium, 30% lanthanum, 15% neodymium, 4% praseodymium, and small percentage of iron, aluminum, and silicon. The interferences of these matrix elements with the determinations of yttrium, dysprodium, and samarium are shown in Figs. 8—10. Enhancements in the absorption sensitivity of yttrium are observed with increasing lanthanum, praseodymium, and neodymium concentrations. With increasing samarium concentration, the absorption of yttrium decreases. The sensitivity of dysprodium is

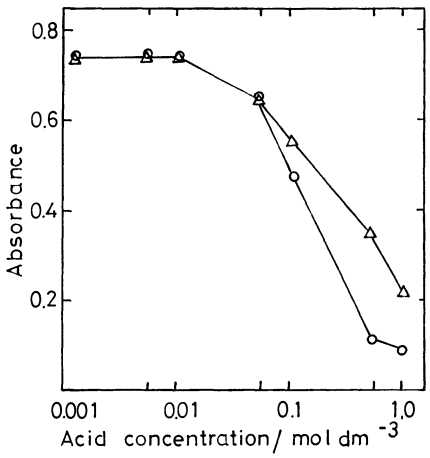

Fig. 5. Effect of acids on absorbance of yttrium of 100 ng.

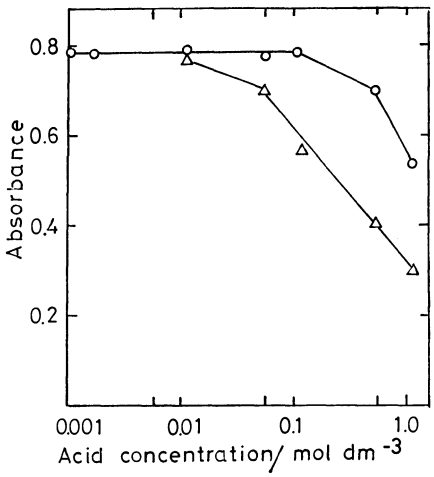

Fig. 6. Effect of acids on absorbance of dysprodium of 43 ng.
○: HCl, △: HNO_3.

enhances by increasing lanthanum, praseodymium, cerium and neodymium concentrations. The effects of other elements are negligible. In the determination of samarium, the effect of iron is important. The existence of 100 μg ml^{-1} of iron causes a remarkable decrease in the absorbance of samarium. However, the effect of iron in this sample is slight, for the concentration of iron in this sample is below 50 μg ml^{-1}. The sensitivity of samarium is slightly decreased by the presence of lanthanum and neodymium. The effects of the other elements on samarium are negligible.

Two samples of about 0.5 g were dissolved in hydrochloric acid and in nitric acid. The sample solution containing hydrochloric acid was used to analyze the yttrium and dysprodium, while the other solution was used to analyze the samarium. The determinations of these elements were done by the following two methods. One method used the analytical curves in the range of 1.0—6.0 μg ml^{-1} of yttrium and in the range of 0.5—3.0 μg ml^{-1} of dysprodium. To these standard solutions of yttrium and dysprodium we added 500 μg ml^{-1} of lanthanum, 600 μg ml^{-1} of cerium,

and 300 μg ml^{-1} of neodymium. To the other solutions containing 1.0—6.0 μg ml^{-1} of samarium, we added 500 μg ml^{-1} of lanthanum, 600 μg ml^{-1} of cerium, and 100 μg ml^{-1} of neodymium. The other method used the analytical curves obtained by standard addition. Both analytical curves for each element gave identical slopes. These results are shown in Table 5. The precision of these determinations was in the range of 3—9.3%. It was found that the concentrations of these elements in a mish metal was 0.70% for yttrium, 0.20% for dysprodium, and 0.82% for

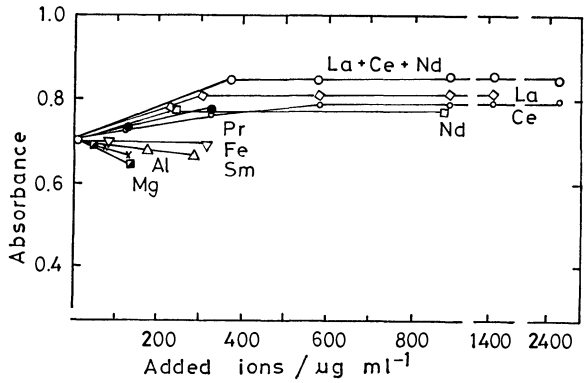

Fig. 9. Effect of matrix elements on absorbance of dysprodium of 4.3 μg ml^{-1}.

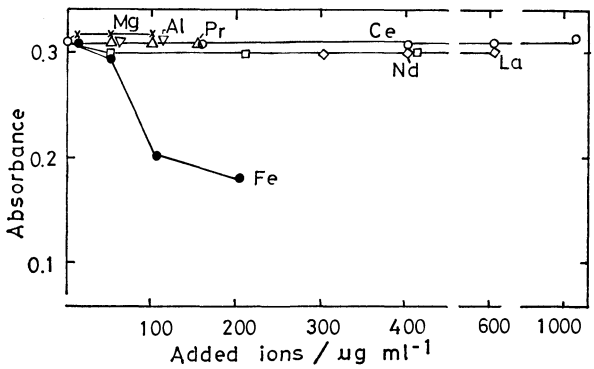

Fig. 10. Effect of matrix elements on absorbance of samarium of 10 μg ml^{-1}.

samarium. It was also estimated by flame AAS; these results are shown in Table 5.

Conclusion

Yttrium, dysprodium, and samarium are determined by the means of graphite-furnace AAS with a tantalum boat inserted inside a graphie tube. In this method, the memory effect of carbide formation is negligible and the analytical sensitivities of these elements suffice for the determination of this sample.

Spectrophotometric and Electrochemical Investigations of [Tetrakis(1-methylpyridinium-4-yl)porphine]iron(III) Ion in Aqueous Solution

Hirondo KURIHARA,* Fumihiro ARIFUKU, Isao ANDO, Minoru SAITA, Rika NISHINO, and Kikujiro UJIMOTO

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma 11, Jonan-ku, Fukuoka 814-01

(Received February 4, 1982)

The equilibria among the species of [tetrakis(1-methylpyridinium-4-yl)porphine]iron(III) ion (Fe(III)-TMPyP) in aqueous solution and the redox reactions of their central metals were investigated by means of spectrophotometric, electrochemical and spectroelectrochemical methods. Two acid-dissociation equilibria involving three monomeric species of Fe(III)-TMPyP were found: one with a pK_a of 5.5 and the other with a pK_a of *ca.* 12. After electrochemical reduction, an equilibrium between two monomeric species of Fe(II)-TMPyP with a pK_a of 11 was observed. In the Fe(III)-TMPyP solution at relatively high concentration, two additional different species, probably dimeric, were found in the pH regions of 5—8 and 9—13, respectively. The consistency of specification of the species with the scheme of redox reactions is discussed.

Since water-soluble metalloporphyrins were synthesized by introducing hydrophilic groups into the meso-positions of porphine rings, they have attracted the increasing interest of many chemists and biochemists as model substances for studies on biological processes.[1] Considerable information that is attractive to chemists has become available: *e.g.* the reaction mechanisms of complex formation,[2,3] the specification of species,[4-8] the substitution of axial ligands[9-12] and the mechanisms of redox reactions.[13,14]

Among water-soluble porphyrins, [tetrakis(1-methyl pyridinium-4-yl)porphine]iron(III) ion (Fe(III)-TMPyP) has often been studied because of its stability and relatively high solubility over a wide pH region. Nevertheless, the specification of species is very complicated and has not yet been clarified completely, owing to simultaneous acid-dissociation and dimerization equilibria depending on pH and/or concentration.

Therefore, this work was undertaken in order to specify the species of Fe(III)-TMPyP in aqueous solution and to clarify the mechanism of electrochemical redox reaction of the central metal of each species. In the course of the work, a paper concerning the same subject was published by Forshey and Kuwana.[15] However, our spectrophotometric, electrochemical and spectroelectrochemical investigations gave results which were significantly different from those reported,[15] especially in the pH region of 5—10. In addition, at pH 11 we newly confirmed monomeric iron(II) and iron(III) species. In this paper, we provide an overall scheme for the acid-dissociation equilibria among the Fe(III)-TMPyP species in aqueous solution at pH 1—13 and for the redox reactions of the species involved.

Experimental

Materials and Sample Solutions. Fe(III)-TMPyP perchlorate was prepared according to the method of Hambright and Fleischer[2] with a slight modification and stored in aqueous solution because of its explosiveness. The concentration of the Fe(III)-TMPyP stock solution was determined spectrophotometrically at 403 nm by the use of a molar absorption coefficient of 1.02×10^5 mol^{-1} dm^3 cm^{-1} at pH 2 and at an ionic strength of 0.1 mol dm^{-3}.[7] All other chemicals of guaranteed reagent grade were used without further purification.

Sample solutions were prepared by diluting the stock solution appropriately with deionized-distilled water. The pH values of the sample solutions were adjusted with sulfuric acid or sodium hydroxide solution and the ionic strength with sodium sulfate solution at 0.1 mol dm^{-3}, except for the highly acidic ($pH\leqslant1$) and basic ($pH\geqslant13$) solutions. In case buffered solutions were required, the following buffers were used: acetate buffer at pH 3—6, phosphate at pH 4.5—7.2, and phosphate-borate at 5.8—9.

Spectrophotometric, Electrochemical, and Spectroelectrochemical Measurements. A Shimadzu UV-300 and a Hitachi 100-30 spectrophotometer were used for the spectrophotometric investigation over a wide pH range. The pH values of the solutions were measured with a TOA HM-5B pH meter.

The cyclic voltammograms of Fe(III)-TMPyP in the same pH region were obtained by means of an NF FG-121B function generator and a Yanaco P8-CV potentiostat equipped with a conventional three-electrode system. A glassy carbon rod (GC-30, Tokai Carbon) plugged into a Teflon tube was used as the working electrode. The carbon surface exposed to a solution was a circle 0.196 cm^2 in area. The electrode surface was polished with diamond lapping paste (6×10^4 meshes) until a mirrorlike finish was obtained. Then it was wiped with a chamois skin dampened with carbon tetrachloride and rinsed with methanol and then with water. A platinum plate ($0.1\times5\times5$ mm^3) and a saturated calomel electrode (SCE) were employed as the counter and reference electrodes, respectively. Prior to both the electrochemical and spectroelectrochemical measurements, the sample solution was deoxygenated by bubbling a high-purity nitrogen gas through the solution for about 15 min, and the measurements were carried out under an atmosphere of nitrogen.

The spectroelectrochemical examination was achieved with an optically transparent thin layer electrode (OTTLE)[16] constructed with a gold minigrid (500 wires per inch, Buckbee Mears) which was sandwiched between two micro-slide glasses. The distance between two plates was controlled with Teflon spacers (*ca.* 0.1 mm thick, Delectrix DF-1200). The assembled OTTLE system had a thickness of an absorbing medium of *ca.* 0.22 mm and a transmittance of *ca.* 53%. While the Soret-band spectra of Fe(III)- and/or Fe(II)-TMPyP were measured with a Hitachi 100-30 spectrophotometer, the potential at the gold minigrid as the working electrode was controlled by a Yanaco P8-DP potentiostat using an SCE both as the counter and as the ref-

erence electrode.

All the measurements were performed at 25 °C.

Results and Discussion

Spectrophotometry. Figure 1 shows the typical UV- and visible spectra of Fe(III)–TMPyP aqueous solutions at various pH values. Since the spectra at pH above 10 changed gradually, they were obtained within 0.5 h after the preparation of each sample solution, except for spectrum e′. Three different species, corresponding to spectra a, c, and e in Fig. 1, were observed in turn with two sets of isosbestic points with increasing pH of the solution.

Insofar as we know, spectrum e at pH above 13 was observed for the first time, although spectra a and c were in fair agreement with those in the literature.[6,8] The e spectrum faded out depending on the time after the preparation of the sample solution and then altered to spectrum e′ after 48 h. This suggests that decomposition and/or transformation of species e to other formes should occur in such a strongly basic solution.

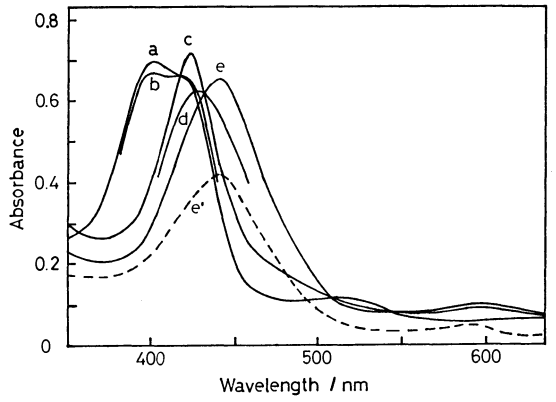

Fig. 1. Absorption spectra of Fe(III)-TMPy Paqueous solution at various pH.
Concentration: 7.06×10^{-6} mol dm^{-3}; pH of solutions: a 1.4, b 4.2, c 7.6, d 11.9, e 13.1, e′ 13.1 after 48 h.

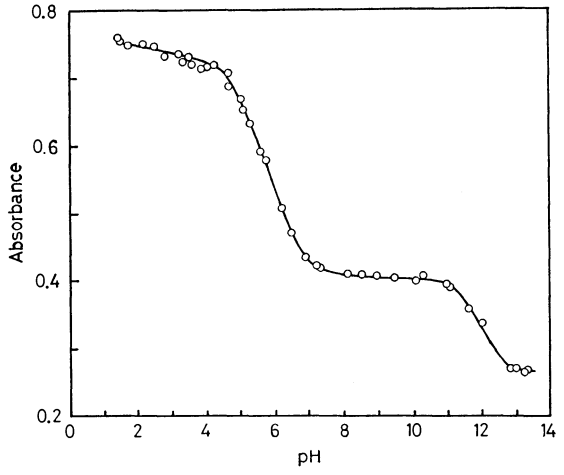

Fig. 2. Spectrophotometric pH titration curve of Fe(III)-TMPyP solution.
Concentration: 7.08×10^{-6} mol dm^{-3}; λ: 403 nm.

In order to examine the equilibria involving the new species e, spectrophotometric pH titrations were performed at the wavelengths of absorption maxima in spectra a, c, and e (403, 424, 440, and 596 nm). In the region of pH above 10, the absorbance at the time immediately after preparation was employed to remove any effect due to the decomposition and/or transformation of the species included. Figure 2 shows the pH titration curve obtained with 7.6×10^{-6} mol dm^{-3} Fe(III)-TMPyP solution at 403 nm. Since the phosphate buffer appreciably depressed the absorbance at pH below 6, the acetate buffer was used in that pH region.

A set of two inflection points was observed in each instance, and their positions were the same irrespective of the wavelength examined. This indicates the existence of two equilibria accompanying proton transfer: the one at pH 4—8 includes species a and c, and the other at pH 11—13 includes species c and e. We also examined the relationship between the absorbance and the concentration of Fe(III)–TMPyP solutions (Beer's law test) over the concentration range of 2.5×10^{-7}—1×10^{-5} and 5×10^{-7}—1×10^{-5} mol dm^{-3} at pH 2 and 13.6, respectively, at the wavelengths of absorption maxima (403 and 440 nm). The absorbance immediately after the preparation of sample solutions was employed at pH 13.6. The excellent proportionality obtained in the Beer's law test gave no evidence for any dimeric species in concentrations lower than 1×10^{-5} mol dm^{-3}. Therefore, at least species a and e should be monomeric, and the former in acidic solution is probably $[Fe(III)\text{–}TMPyP(H_2O)]^{5+}$ as proposed in the literature,[7,15] or diaqua-monomer.

Consequently, the equilibrium between species a and c may be represented by one of the following equations:

$$\text{Monomer} \rightleftharpoons \text{Monomer}' + n\,H^+, \quad (1)$$

$$2\ \text{Monomer} \rightleftharpoons \text{Dimer} + n\,H^+. \quad (2)$$

The number of transferred protons, n, and the equilibrium constant, K_a, were evaluated from the data of the pH titration experiments according to Eqs. 1 and 2 (Table 1). As can be seen in Table 1, the equilibrium in the region of pH 4—8 should include the reaction accompanying one proton transfer between different monomers under the experimental conditions employed, because the n and pK_a values according to Eq. 1 are close to an integer and to the pH value corresponding to the inflection point, respectively.

Table 1. The number of transferred protons (n) and the equilibrium constant (K_a) obtained from pH titration curves

pH	λ / nm	M⇌M′		2M⇌D	
		n	pK_a	n	pK_a
4—8	403	0.9	5.1	1.4	2.9
	424	0.9	5.3	1.2	2.2
	596	1.0	5.9	1.8	5.5
10—14	424	1.0	11.4	1.5	16.6
	440	1.1	13.2	1.6	13.9

M: Monomer, M′: monomer′, D: dimer.

This fact leads to the specification of species c to be $[Fe(III)-TMPyP(H_2O)(OH)]^{4+}$. Similary, species e can also be specified to be $[Fe(III)-TMPyP(OH)_2]^{3+}$ from the values of n and pK_a in Table 1. Only one equilibrium with a pK_a of 5.5 in the region of pH 4—8 is inconsistent with the two equilibria with pK_a values of 4.7 and 6.5 reported by Pasternack *et al.*[7] However, the specification of the three monomeric species is well consistent with the results obtained by the present electrochemical and spectroelectrochemical investigations, as described in the last section.

Electrochemistry. Figure 3 illustrates typical cyclic voltammograms of 1.4×10^{-4} mol dm^{-3} Fe(III)-TMPyP solutions at different pH values obtained at a scan rate of 0.1 V s^{-1}. Peak A accompanied by a corresponding oxidation wave was assigned to the reduction peak of monomeric species. The potential of peak A was independent of the pH of the solution, in acidic solution at pH below 5.5. On the other hand, at pH above 5.5 peak A shifted to become more negative with increasing pH and an additional reduction peak B appeared at a more negative potential than that of peak A with no corresponding oxidation wave. Multicycle or slow (0.01 V s^{-1}) scanning diminished peak B. The number of transferred electrons in the redox reactions was confirmed to be unity from the results of electrochemical and spectroelectrochemical measurements. These phenomena are fundamentally similar to those reported already.[15]

However, we found that in the region of pH 5.5—9 the reduction potential, $(E_p)_R$, of peak A in buffered solutions differs significantly from that in solutions free from the buffer, as shown in Fig. 4. In order to clarify the reason, nonbuffered sample solutions in

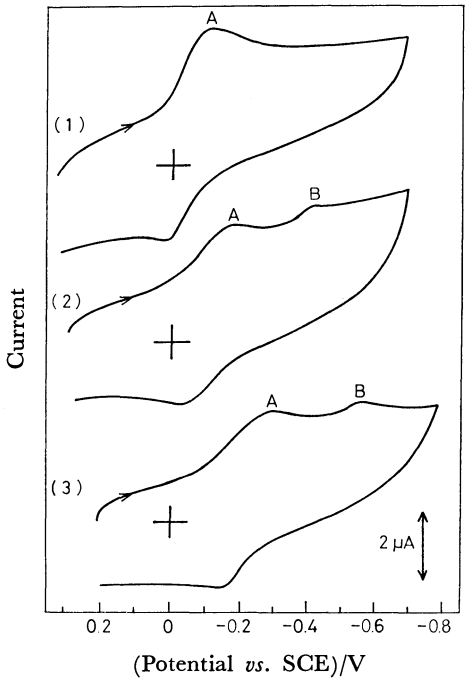

Fig. 3. Cyclic voltammograms of Fe(III)-TMPyP solution.
Concentration: 1.4×10^{-4} mol dm^{-3}; scan rate: 0.1 V s^{-1}; pH: (1) 4.6, (2) 6.5, (3) 9.4.

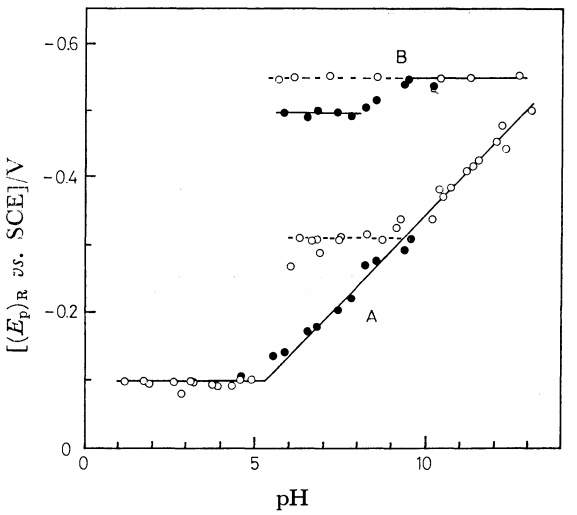

Fig. 4. Plot of $(E_p)_R$ *vs.* pH for Fe(III)-TMPyP solution.
○: In nonbuffered solution, ●: in buffered solution. Others are the same as in Fig. 3. $(E_p)_R$: see text.

the neutral pH region were reduced in an H-shaped cell which was separated into two compartments by a sintered glass. The pH of the solution in the compartment in which the working electrode was immersed increased beyond 9 as the electrolytic reduction progressed, indicating that the reduction of Fe(III)-TMPyP consumes hydrogen ions. This fact suggests that near the surface of the working electrode the pH value of the nonbuffered solutions in the pH range of 5.5—9 varied to higher pH than that of the bulk during the cathodic potential scanning.

As can be seen in Fig. 4, $(E_p)_R$ of peak A shifts by *ca.* −60 mV/pH at pH higher than 5.5, while it is independent of pH below 5.5. This finding indicates that the reduction yielding peak A accompanies only one-electron transfer in the region of pH below 5.5, and both one-electron and one-proton additions in the region of pH above 5.5.

Peak B may be assigned to that arising from the reduction of dimeric species as proposed by Forshey and Kuwana.[15] There is a probability of dimerization, because the electrochemical data were obtained on a concentrated solution, 10^{-4} mol dm^{-3}. In preliminary experiments, the value of the peak-current ratio of B to A increased with increasing the concentration beyond 10^{-5} mol dm^{-3}. The $(E_p)_R$ value of peak B in the buffered solution was appreciably different from that in the nonbuffered solution over the pH range of 5.5—9. This may also be ascribed to the variation in pH due to the reduction which consumes hydrogen ions.

The decomposition and/or transformation of the monomeric species at very high pH, mentioned in the preceding section, was investigated by following the time-course of $I-E$ curves of peak A by means of linear sweep voltammetry. The reduction current of peak A decreased with an increase in time at pH above 11.5. Figure 5 demonstrates a typical example of the time dependence of the $I-E$ curve at pH 12.5. In Fig. 6 is shown the time-dependent variation of

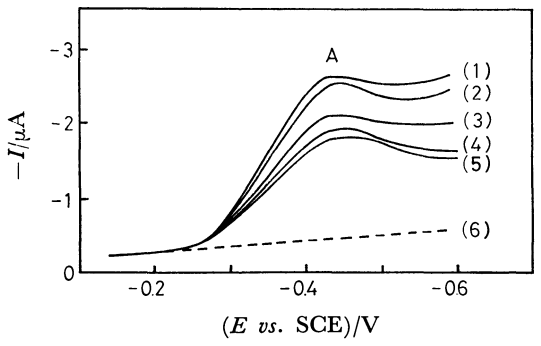

Fig. 5. $I-E$ curves of Fe(III)-TMPyP solution at various time after sample preparation.
Concentration: 1.0×10^{-4} mol dm^{-3}; pH: 12.5; time: (1) 0.5 h, (2) 2 h, (3) 7 h, (4) 24 h, (5) 7 d; (6): base line.

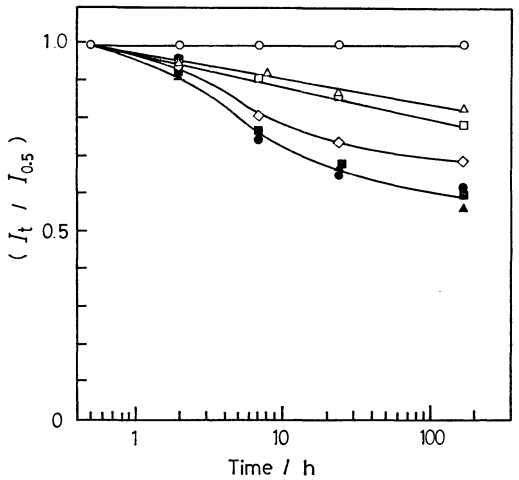

Fig. 6. $(I_t/I_{0.5})$ *vs.* time after sample preparation.
pH: ○ 11.30, △ 11.50, □ 11.80, ◇ 12.15, ● 12.49, ▲ 12.79, ■ 13.25.

$(I_t/I_{0.5})$ values, which are the ratios of the reduction currents of peak A at various times after the sample preparation to that obtained within 0.5 h. The $(I_t/I_{0.5})$ value decreases with increasing time after preparation at different rates depending on the pH of the solution, and finally it seems to approach a limiting value. This phenomenon corresponds well with the fade-out of spectrum e at pH 13.1, suggesting the fact that the monomeric species in highly basic solution transformes gradually into other forms which are inert to both the spectrophotometric and electrochemical detection.

Spectroelectrochemistry. The Soret-band spectra of 1.7×10^{-4} mol dm^{-3} Fe(III)-TMPyP aqueous solutions at various pH values were obtained before and after the electrochemical reduction by the use of an OTTLE. Figure 7 shows the wavelengths of Soret-band maxima, λ_{max}, of both iron(II) and iron(III) species plotted as a function of pH. The spectra before reduction, of course, were identical with those obtained at corresponding pH values in.

Spectrophotometry. The variation in Soret-band spectrum during incremental charge addition at pH below 10.5 was the same as that reported by Forshey

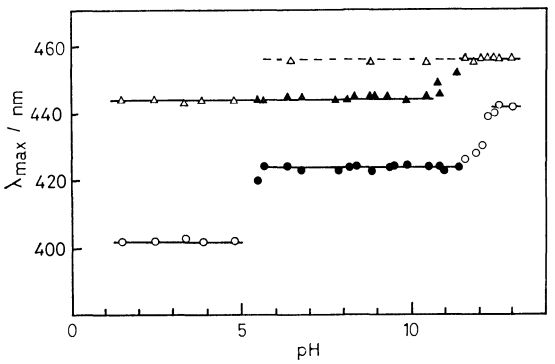

Fig. 7. Wavelength of Soret-band maxima (λ_{max}) *vs.* pH of Fe(III)-TMPyP solution before and after the reduction on OTTLE.
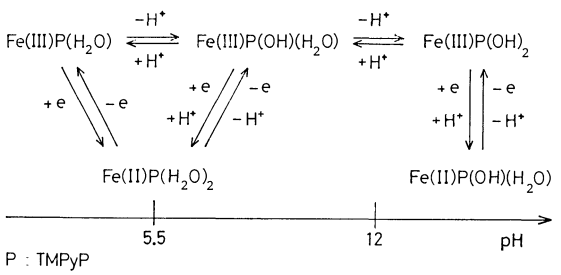
Concentration: 1.7×10^{-4} mol dm^{-3}. ○,●: Before the reduction in non-buffered and buffered solutions; △,▲: after the reduction in nonbuffered and buffered solutions, respectively.

and Kuwana.[15] At pH above 10.5, a new spectrum with an absorption maximum of 456 nm was observed as an iron(II) species. The λ_{max} values of iron(II) species in nonbuffered solutions at pH 6—10.5 were also different from those in buffered solutions, owing to the cause mentioned in *Electrochemistry.*

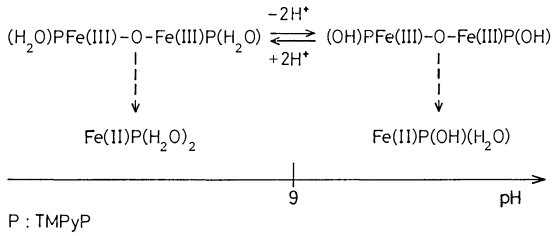
Consequently, three iron(III) species were observed predominantly in respective pH regions before the reduction. After the reduction, however, only two iron(II) species were recognized as the predominants in the regions of pH above and below 11, although Forshey and Kuwana proposed two different iron(II) species at pH values below 11.[15]

Equilibria among Species and Schemes of Their Redox Reactions. The spectrophotometric investigation revealed two acid-dissociation equilibria with pK_a values of 5.5 and 12 in dilute Fe(III)-TMPyP solutions over the pH range of 1—13. The equilibria involve three monomeric species which were specified to be those given in Scheme 1. Each equilibrium undergoes the transfer process of one proton. After the reduction with the OTTLE, an equilibrium with a pK_a of *ca.* 11 was found between two iron(II) species, probably both monomeric, which were also assigned to be those in Scheme 1 according to the results of this work. Cyclic voltammetric examination showed that the reduction of the monomeric species accompanies additions of only one electron at pH below 5.5, and of both one electron and one proton at pH above 5.5. At pH above 11.5, the monomeric species transforms gradually into other forms, inert for the detection methods employed in this study.

Preliminary ESR experiments provided additional information for the specification of the monomeric species. Namely, only a high-spin signal with a g-value of 5.5[4] was observed in acidic solution, and the signal height decreased with increasing pH. At pH values above 11 low-spin signals appeared with g-values of 1.9, 2.1, and 2.5;[4] these signals grew markedly with increasing pH. This phenomenon suggests the successive replacement of the axial ligands from a water molecule to a hydroxide ion, as shown in Scheme 1.



Scheme 1.



Scheme 2.

Two different dimeric species, probably μ-oxo-iron(III) dimer,[7,15] were found over the pH range of 5.5—9 and 9—13 in the electrochemical experiments. The reduction peaks of the dimeric species were not accompanied by any corresponding oxidation wave and diminished by the repetition of a cyclic potential sweep regardless of the pH range. These phenomena probably mean that the reduction of dimer gives iron(II) monomers and the dimerization of iron(III) monomers is a very slow process. These results lead to Scheme 2, which indicates that the reduction of both two iron(III) dimers results in formation of the iron(II) monomers with different combinations of the axial ligands depending on the pH of the solution. The specification of the dimeric species and the investigation of their reduction mechanism are in progress.

The authors wish to thank Messrs. Ikuhiro Tokuda, Ryuji Kikuchi, Hiroshi Kohama, and Toshihiro Takuma for technical collaboration. The present work was partially supported by a grant from the Central Research Institute of Fukuoka University.

The Spectrofluorometric Determination of 9,10-Phenanthrenequinone

Masaki TACHIBANA,* Makoto HAYAKAWA,† and Motohisa FURUSAWA

Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received April 12, 1982)

9,10-Phenanthrenequinone (9,10-PQ) reacts with guanidine in an alkaline medium to form 2-amino-1*H*-phenanthro[9,10-*d*]imidazole. The reaction can be used for the fluorometric determination of 9,10-PQ, since the reaction product is fluorescent in an acidic solution. A dimethyl sulfoxide-methanol mixture is suitable as the solvent. A sample solution was allowed to stand for 15 min at room temperature after the additions of guanidine hydrochloride and sodium methoxide solutions, followed by the addition of hydrochloric acid. After the solution had been allowed to stand for 20 min, the fluorescence intensity of the solution was measured at 403 nm with excitation at 363 nm. The fluorescence intensity was stable for at least 8 h. The determination limit of 9,10-PQ was 50 ng.

For the determination of small amounts of 9,10-phenanthrenequinone (9,10-PQ), spectrophotometric methods[1-2] have been developed. In these methods, however, the determination limit of 9,10-PQ is approximately 1 μg.

In the present paper, a spectrofluorometric determination of 9,10-PQ will be described for the determination of minute amounts of 9,10-PQ. In order to convert 9,10-PQ into a fluorescent substance, the reaction of 9,10-PQ with guanidine[3] is useful. 9,10-PQ forms 2-amino-1*H*-phenanthro[9,10-*d*]imidazole with guanidine in an alkaline medium, and the product is fluorescent in an acidic solution.

Experimental

Reagents. Dimethyl sulfoxide (DMSO) was purified by using active aluminium oxide and a molecular sieve. To 500 g of commercial DMSO, 50 g of active aluminium oxide was added. The mixture was sufficiently shaken and then allowed to stand for several hours. After the DMSO had been separated by decantation, this process was repeated by using the molecular sieve instead of the aluminium oxide. Finally, the molecular sieve was filtered off.

9,10-PQ was purified by zone melting. Guanidine hydrochloride used was of a special-use reagent grade purchased from Tokyo Kasei Kogyo Co., Ltd. Methanol used was of a guaranteed reagent grade. Sodium methoxide was purchased from Kanto Chemicals Co., Inc.

Solutions. The guanidine solution was prepared by dissolving 50 mg of the hydrochloride in 100 ml of DMSO. The sodium methoxide solution was prepared by dissolving 1.00 g of the solid in 100 ml of a mixture of DMSO and methanol (4:1).

Apparatus. All the fluorometric measurements were carried out using a Hitachi 650-10S fluorescence spectrophotometer. A 150-W xenon lamp was used as the exciting source. A 10 mm × 10 mm × 45 mm quartz cell was used.

Procedure. Five milliliters of a sample solution containing less than about 1 μg of 9,10-PQ in a mixture of DMSO and methanol (4:1) was transferred into a 10-ml volumetric flask (amber). Then, 1 ml of the guanidine solution and 1 ml of the sodium methoxide solution were added. After the mixture had been allowed to stand for 15 min at room temperature, it was diluted to 10 ml with a 0.1 M (1 M = 1 mol dm^{-3}) solution of hydrochloric acid dissolved in DMSO. The resultant solution was allowed to stand for 20 min. The 9,10-PQ was determined by measuring the fluorescence intensity of the solution at 403 nm, with excitation at 363 nm. A solution containing 1.00 μg of 9,10-PQ was treated under the same conditions and at the same time; the resultant fluorescence was used as the standard.

Results and Discussion

Fluorescence Spectra. The fluorescence spectra of the reaction product of 9,10-PQ with guanidine are shown in Fig. 1. The excitation spectrum has maxima at 266 nm, 313 nm, and 363 nm. The emission spectrum exhibits a maximum at 403 nm. As the excitation wavelength, 363 nm was selected for the determination in order to minimize the interference of diverse substances. The fluorescence intensity of the reagent blank was negligibly small.

Effects of Sodium Methoxide and Methanol. DMSO was selected as the solvent considering the solubility of polynuclear aromatic compounds including 9,10-PQ. For the reaction of 9,10-PQ with guanidine, it is necessary to alkalify the solution. For this purpose, sodium methoxide was useful. To dissolve sodium methoxide in DMSO, the presence of methanol is necessary. The effect of sodium methoxide on the fluorescence intensity was studied by varying the amounts of sodium methoxide. The fluorescence intensities were almost constant over the range of 8—20 mg of

Standard: fluorescence intensity of anthracene solution (40 ng/ml) in CH_3OH–DMSO (1:4) was taken as 100 div.; 9,10-PQ: 1.00 μg; (1): methanol was added before the reaction; (2): methanol was added after acidifying the solution of the reaction product (0.2 ml of methanol exists during the reaction).

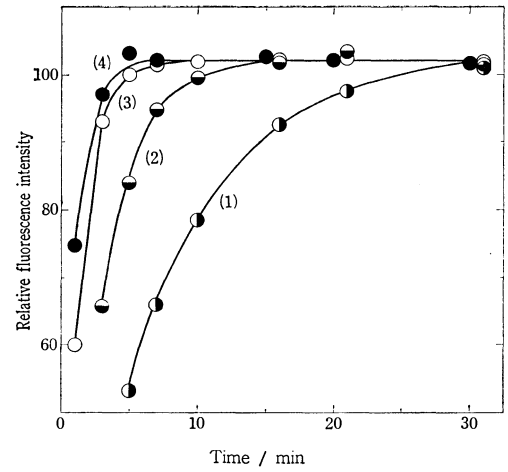

Fig. 3. Effect of reaction time on the fluorescence intensity in the presence of various amounts of guanidine hydrochloride.
Standard: fluorescence intensity of anthracene solution (40 ng/ml) in CH_3OH–DMSO (1:4) was taken as 100 div.; (1): 0.05 mg; (2): 0.15 mg; (3): 0.5 mg; (4): 1.5 mg; temp: 20 °C.

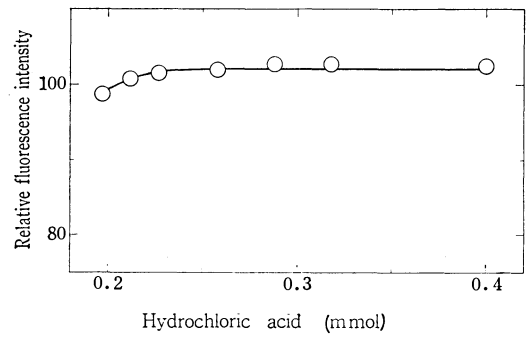

Fig. 4. Effect of the amounts of hydrochloric acid. 9,10-PQ: 1.00 μg; standard: fluorescence intensity of anthracene solution (40 ng/ml) in CH_3OH–DMSO (1:4) was taken as 100 div.

sodium methoxide. It is recommended, therefore, that 10 mg of sodium methoxide is added for the determination.

The reaction of 9,10-PQ with guanidine was carried out in the presence of various amounts of methanol. The fluorescence intensities measured are illustrated in Fig. 2 (1). For comparison, the effect of methanol was also studied in the case in which methanol was added after the solution of the reaction product had been acidified. These experimental results are shown in Fig. 2 (2). Figure 2 indicates that the reaction of 9,10-PQ with guanidine is influenced by the presence of methanol and that the maximum intensity is obtained when 1.2 ml of methanol exists during the reaction. Therefore, a mixture of DMSO and methanol (4:1) is suitable as the solvent for dissolving the sample and sodium methoxide.

Effects of Guanidine and Reaction Time. The hydrochloride of guanidine was used because of its high solubility in DMSO. The sulfate dissolves only slightly in DMSO. The amounts of guanidine and the reaction time are important variables for the determination. The effect of the reaction time on the fluorescence intensity was investigated at 20 °C in the presence of 0.05—1.5 mg of guanidine hydrochloride. The results of these experiments are shown in Fig. 3. Figure 3 indicates that the reaction of 9,10-PQ with guanidine is completed within 10 min at 20 °C when more than 0.5 mg of guanidine hydrochloride has been added. It is recommended, therefore, that the solution is allowed to stand for 15 min at room temperature in the presence of 0.5 mg of guanidine hydrochloride.

Effect of Hydrochloric Acid. The reaction product of 9,10-PQ with guanidine is not fluorescent in an alkaline solution, whereas it is fluorescent in an acidic solution. To acidify the solution, hydrochloric acid dissolved in DMSO was employed. The effect of the amounts of hydrochloric acid on the fluorescence intensity is illustrated in Fig. 4. The amounts of hydrochloric acid were varied from 0.20 to 0.40 mmol, because 0.19 mmol of hydrochloric acid was required to neutralize 10 mg of sodium methoxide. From the results in Fig. 4, the intensities are almost constant over the range from 0.23 to 0.40 mmol. In the determination procedure, about 3 ml of 0.1 M hydrochloric acid was used.

Stability of Fluorescence. In order to investigate the stability of the fluorescence intensity of the reaction product, a solution containing 1.00 μg of 9,10-PQ was operated according to the procedure. The fluorescence intensity was measured by varying the standing time from 2 min to 8 h. The intensity increased for a while after the solution had been acidified. The fluorescence intensity, however, remained highly constant for at least 8 h after 15 min. An amber volumetric flask was used in the procedure to shield it from light in some degree, since the intensity was relatively unstable under scattered sunlight.

Calibration Curve and Reproducibility. A calibration curve was prepared from 9,10-PQ solutions con-

TABLE 1. EFFECTS OF DIVERSE SUBSTANCES

Substances added (μg)		Relative fluorescence intensity[a)]	Difference
None		100.0	
Biphenyl	103	103.3	+0.3

	51	96.6	−3.4

a) The fluorescence intensity of the solution of the reaction product (1.00 μg 9,10-PQ per 10 ml) was taken as 100 div.

taining 0—1.00 μg per 5 ml according to the procedure. As the standard, the solution obtained by operating 1.00 μg of 9,10-PQ was used. The calibration curve thus prepared was linear between the fluorescence intensity and the concentration of 9,10-PQ. The coefficient of variation obtained in 10 measurements was 1.3% at 1.00 μg of 9,10-PQ. In these measurements, an anthracene solution was used as the standard.

Effect of Diverse Substances. The effects of 14 substances on the determination are summarized in Table 1. The determination of 9,10-PQ is not interfered with the presence of 100-fold amounts of biphenyl, naphthalene, acenaphthene, dibenzofuran, dibenzothiophene, and acenaphthenequinone and 20-fold amounts of phenanthrene, 9-fluorenone, and anthraquinone. Fluorene and acridine reduce the fluorescence intensity. Carbazole gives a positive error. Anthracene and fluoranthene give serious interferences

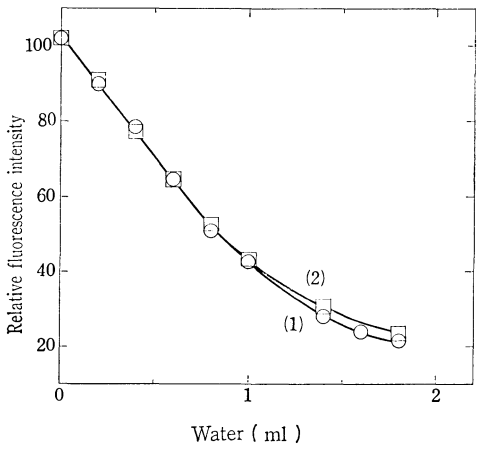

Fig. 5. Effect of water on the fluorescence intensity. 9,10-PQ: 1.00 μg; standard: fluorescence intensity of anthracene solution (40 ng/ml) in CH_3OH–DMSO (1:4) was taken as 100 div.; (1): water was added before the reaction; (2): water was added after acidifying the solution of the reaction product.

because they are fluorescent at the characteristic wavelength of the reaction product of 9,10-PQ.

Effect of Water. The effect of water on the fluorescence intensity was studied by varying the water content in the solvent. The fluorescence intensities measured are shown in Fig. 5 (1). For comparison, the additions of water were performed after the solution of the reaction product had been acidified. As is shown in Fig. 5 (2), these results are identical with that in Fig. 5 (1). Figure 5 indicates that the fluorescence intensity greatly decreases in the presence of water. Therefore, a nonaqueous solvent is desirable for a highly sensitive determination of 9,10-PQ. The identical solvent must be used during the determination to avoid the influence of water, which is contained in the solvent as an impurity.

The authors are indebted to Miss Sumiko Yamada for her technical assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Stereochemistry of the Photochemical Rearrangement of 1-Substituted 1a,7b-Dihydro-1*H*-cyclopropa[*a*]naphthalenes under Sensitized Conditions[1)]

Masahiko KATO,* Hisako KOBAYASHI, Hiroyuki YAMAMOTO,
Koji SETO, Satoru ITO, and Toshio MIWA

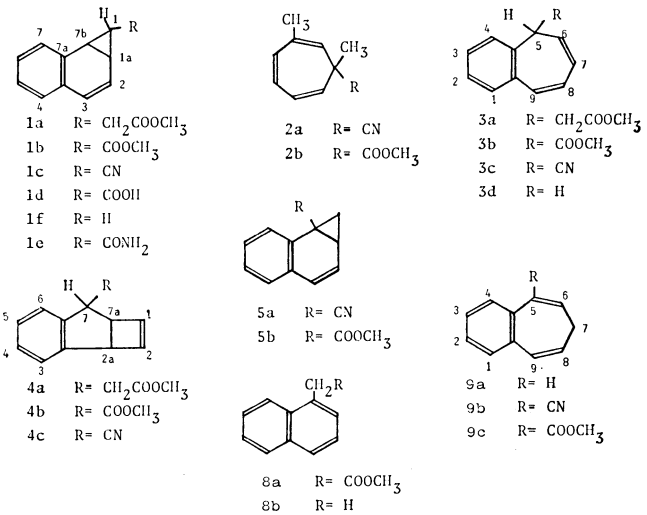
Faculty of Science, Osaka City University, Sugimoto-3, Sumiyoshi-ku, Osaka 558

(Received December 21, 1981)

The photolysis of 1-substituted 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes in the presence of Michler's ketone leads principally to 5-substituted 5*H*-benzocycloheptenes as primary products *via* a stepwise mechanism. The reaction proceeds smoothly with inversion of the migrating carbon if there is no steric hindrance, but it proceeds predominantly with retention if the inversion course is severely suppressed by steric hindrance. The marked difference in the *exo-endo* ratio of the secondary photocyclization products depending on the irradiation conditions was also recognized for 1-methoxycarbonylmethyl derivative.

The stereochemical course of the photochemical Berson-Willcott rearrangements had been reported by us for 1-methoxycarbonylmethyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene (**1a**) under direct irradiation[2)] and by Klärner for 7-cyano- and 7-methoxycarbonyl-2,7-dimethyl-1,3,5-cycloheptatriene (**2**) under sensitized irradiation.[3)] In both cases, the rearrangements proceeded principally by way of inversion at the migrating carbon center. In the former case, in parallel with a result for the 4-*t*-butyl derivative of **1a**,[4)] we suggested a concerted mechanism controlled by the Woodward-Hoffmann rule, while in the latter, Klärner proposed a biradical pathway.

In the course of a photochemical study of 1-*exo*-methoxycarbonyl derivative (**1b**) in the presence of several sensitizers, 5-methoxycarbonyl-5*H*-benzocycloheptene (**3b**)[5)] was obtained as a primary product but 7-methoxycarbonyl-7*H*-benzocycloheptene or the secondary photo-products derived from it were not detected. This and the results by Klärner[3)] suggest that the reaction course and the stereochemistry under such photolytic conditions might be different from the results of direct irradiation. Interest has also been focused on the effect of a substituent on C-1, *i.e.*, electron-attracting or releasing, which would affect the bond strength of the three-membered rings not only in their ground state[6)] but also in the excited states.[6)] In order to clarify these points, we studied the stereochemical course of sensitized reactions of a series of 1-substituted 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalenes (**1**) using their racemic and optically active forms. The substituents chosen were methoxycarbonylmethyl as an electron-releasing group, and methoxycarbonyl and cyano as electron-attracting groups with large and small steric requirement, respectively.



Scheme 1.

*Photochemistry of 1-exo-Methoxycarbonyl Derivative (**1b**). Irradiation in the Presence of Michler's Ketone*: Irradiation of **1b** in benzene with 4,4'-bis(dimethylamino)benzophenone (Michler's ketone) for 2.5 h gave a recovery of material corresponding to 75% of the initial weight of **1b**, from which **1b** (30%), **3b** (30%), and **8a** (10%) were separated. Under these conditions, the cyclization products from **3b** were negligible but prolonged irradiation gave a small amount of an *exo-endo* mixture of 7-methoxycarbonyl-2a,7a-dihydro-7*H*-cyclobut[*a*]-indene (**4b**), which was not detected under direct irradiation.

When we used **1b**-1-d_1 for photolysis, we obtained only **3b**-5-d_1 as new products; this result supports the regiospecific rearrangement at C-1.

In the same experiment, (+)-**1b** ($[\alpha]_D$ +124°) gave **3b** ($[\alpha]_D$ −2.82°) in addition to a recovery of **1b** ($[\alpha]_D$ +114°).

Identification of the Products: **3b** was identical with a sample obtained by alcoholysis of the corresponding nitrile (**3c**) reported previously.[5)] An *exo-endo* mixture of **4b** was separated by VPC. The mass spectra of the two components showed very similar fragmentation patterns except for their relative intensities: peaks at *m/e* 200 (M^+), 174 ($M^+-C_2H_2$), 141 (base peak, $M^+-COOCH_3$), 115 ($M^+-CHCHCOOCH_3$).

The UV spectra of *exo*-**4b** and *endo*-**4b** are very similar and are characteristic of benzocyclopentenes.[7)] The NMR spectra of both compounds could be accounted for by structure **4b** (Aromatic H: aliphatic H: olefinic H: OCH_3=4:3:2:3) and the coupling patterns between the olefinic protons and H_{7b}'s of *exo*- and *endo*-**4b** were quite similar to those of known *exo*- and *endo*-**4a**, respectively.[8,9)]

*Irradiation of Optically Active 1-Methoxycarbonylmethyl Derivative (**1a**)*: Because of its facile double epimerization above room temperature, the *exo*-ester (**1a**), carefully obtained below 3 °C from the known (+)-(1*R*)-**1d**[1)] ($[\alpha]_D$ +147°, >95% optically pure), was irradiated in dichloromethane in the presence of Michler's ketone below 0 °C for 5 min. After chromatographic

separation of the products from the sensitizer, they were identified and estimated to consist of **1a** (53%), **3a** (38%),[2] and **4a** (*endo* (6%)+*exo* (1.5%)).[8] Repeated chromatography on silica gel of the mixture gave **3a** and *endo*-**4a** in optically active forms (**3a**, $[\alpha]_D$ +65° (76% enantiomer excess (e.e.); *endo*-**4a**, $[\alpha]_D$ +81° (76% e.e.)).

In a separate experiment, (+)-(5S)-**3a** ($[\alpha]_D$ +86°, >95% optically pure) was similarly photolyzed in benzene to give a product (30%) consisting of *exo*- and *endo*-**4a** (1:5) which retained their optical activities [*endo*-**4a**, $[\alpha]_D$ −107° (>95% optically pure); *exo*-**4a**, $[\alpha]_D$ +180°]; these determined the (7*S*)-configuration for both (+)-*exo*-**4a** and (−)-*endo*-**4a**.

Therefore, the stereochemistry of the rearrangement of *exo*-**1a** to **3a** under the above conditions is deduced to be 88% retention of the C-1 configuration; this result is opposite to the one for the same rearrangement under direct irradiation.[2,5] When we use (+)-**1a** (*exo*:*endo*=2:1; $[\alpha]_D$ +24.7°) after thermal equilibration as the starting material, we obtain (+)-**3a** in 16% e.e. (58% retention) after 20% conversion. In this case, if a rearrangement starting from *exo*-**1a**, which forms 67% of the starting ester, proceeds with 88% retention as observed above, the calculated percentage of retention originating from *exo*-**1a** will be 59% in the total rearrangement, which is well coincident with the observed value (58%). Therefore, the *endo*-**1a**, composing 33% of the starting material, is supposed to rearrange solely to (−)-**3a** through inversion of the C-1 configuration. The longer irradiation time (72% conversion) using an *exo-endo* mixture of optically active **1a** (2:1) gave *endo*-**4a**, instead of **3a**, as the main product with the same enantiomer excess within the experimental error (19% e.e.; 59% retention).

*Photochemistry of 1-Cyano Derivative (**1c**). Synthesis of (1*R*)-(−)-1-endo-Cyano Derivative (1-endo-**1c**)*: Because of the double epimerization of *exo*-**1a**, *endo*-**1a**, and *endo*-**1b**,[5] we could not make clear the stereochemistry of the photochemical *exo-endo* isomerization for these compounds under the above conditions. In hopes of obtaining a thermally stable and optically active **1c**, we synthesized it from an optically active acid **1d** under mild conditions. Thus, from (+)-**1d** ($[\alpha]_D$ +143°) we obtained (+)-**1c** as colorless crystals ($[\alpha]_D$ +103°, mp 76 °C) by dehydration with trifluoroacetic anhydride[10] *via* the amide,[11] **1e** ($[\alpha]_D$ +201°, mp 261—262 °C). The obtained nitrile **1c** showed a characteristic 1-*endo* proton triplet (J=4.3 Hz) at δ 0.69 ppm. Upon heating this nitrile **1c** at 130 °C for 20 min, an *exo-endo* (2:3) mixture of **1c** was obtained, from which *endo*-**1c** was isolated as colorless crystals, mp 153 °C, $[\alpha]_D$ −579°. In the NMR spectrum, the latter showed a triplet of C-1 proton at δ 2.19 ppm with a *cis* vicinal proton coupling (J=8.3 Hz) characteristic to the cyclopropane ring.[5,12] The UV spectrum was very similar in shape to that of *exo*-**1c**, but the maximum (270 nm (log ε 3.89)) appeared at a shorter wavelength than that of *exo*-**1c** (273 nm (log ε 3.89)). From the absolute configuration of the starting (+)-**1d**, the absolute configuration of (+)-*exo*-**1c** must be (1*R*). Therefore, the configuration of (−)-*endo*-**1c** corresponds to (1*R*), because the latter should be formed *via* a symmetry-allowed double Cope rearrangement from the former.[13,14] The minus sign in *endo*-**1c** is coincident with the existence of an enantiomeric benzonorcaradiene moiety against (1*R*)-(+)-*exo*-**1c**.[15]

*Irradiation of **1c***: Solutions of racemic *exo*- and of *endo*-**1c** in benzene were irradiated for 15 min in the presence of Michler's ketone to give 68% and 88% recovery of the initial amount of the starting material, respectively. The products were *exo*-**1c**, *endo*-**1c**, and 7b-cyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene (**5a**)[16] in 34.9%, 6.2%, and 25.4%, respectively from *exo*-**1c** and 44.8%, 15.7%, and 25.0%, respectively from *endo*-**1c**.

In an independent experiment, we observed that 5-cyano-5*H*-benzocycloheptene (**3c**) rearranged readily to **5a** under the same conditions. Therefore, both isomers of **1c** interconvert with each other and probably rearrange to **5a** *via* **3c**.

In order to test the possibility of trapping **3c**, if it were formed from **1c**, an authentic sample of **3c** was irradiated with Michler's ketone in furan as a solvent instead of benzene; we obtained, in addition to **5a** (25%), a 1:1 adduct (*adduct*-1; 23%) composed of furan and **3c** as expected. In the direct irradiation of **3c** in furan, we obtained two kinds of 1:1 adducts (40%): one was identical with the above *adduct*-1 and the other was an isomer (*adduct*-2).

The Structures of Adduct-1 and -2: The NMR spectra of these two adducts showed quite similar coupling patterns over all the region; therefore, it is reasonable to suppose that they have the same molecular framework. The confirmation of the existence of vicinal couplings by the stepwise decoupling experiment on the NMR signals of the *adduct*-1 revealed a carbon skeleton (**A**) and a 2,3-dihydrofuran moiety (**B**)[17] in *adduct*-1. As the two fragments contain all of the carbons and hydrogens in the molecule, we can obtain the structures **6** and **7** from their spectral analysis. Of **6** and **7**, the latter, in which the proton H_{10} is located in proximity to the oxygen of the furan ring, was chosen for the adduct by considering its NMR spectrum. The *syn* structures, **7a** and **7c**, rather than the *anti*, **7b** and **7d**, were selected because their NMR spectra, taken with a shift reagent, showed an extraordinary lower field shift of H_{10} and the least shifts of H_{12} and H_5 signals. The larger lower field shifts of H_{11} as well as H_{10} signals in *adduct*-1 compared

with those of the same proton signals in *adduct*-2 suggested the structure **7a** for *adduct*-1 and **7c** for *adduct*-2.

*Irradiation of (1*R)-exo-*(+)-**1c** in Furan*: Irradiation of *exo*-(+)-**1c**, $[\alpha]_D$ +103°, in furan in the presence of Michler's ketone was performed as mentioned above. The isolated products were, in addition to *exo*-(+)-**1c** ($[\alpha]_D$ +110°; 56%), *endo*-(+)-**1c** ($[\alpha]_D$ +572°; 19%), **5a** (13%), and *adduct*-1 ($[\alpha]_D$ −0.8°; 12%).

*Photochemistry of **1f**-1,1-*d_2. *Synthesis of **1f**-1,1-*d_2: In all the above-mentioned examples of the sensitized irradiation of 1-substituted **1**, the products detected were only the ones derived from the rearrangement of C-1 toward C-7a. This fact was quite different from the results obtained under direct irradiation. In order to test whether such regioselectivity of rearrangement under sensitized conditions is available in the simplest case, we studied the rearrangement of **1f**-1,1-d_2. Though **1f**-1,1-d_2 was previously prepared from naphthalene with dideuteriocarbene,[18] the yield and deuterium content were unsatisfactory. So we prepared it starting from 1,2-dihydronaphthalene as follows: addition of dibromocarbene, reduction with tributyltin deuteride,[19,20] and NBS bromination followed by dehydrobromination with calcium hydrogen phosphate in DMF.[21] The deuterium content of C-1 of **1f**-1,1-d_2 was estimated to be 97% by H NMR spectrum.

*Irradiation of **1f**-1,1-*d_2: **1f**-1,1-d_2 dissolved in benzene was irradiated with Michler's ketone for 15 min to give a mixture of **1f**-d_2[18] (**C**), 5*H*-benzocycloheptene-d_2 (mainly **3d**-5,5-d_2)[18] (**D**), and 1-(methyl-d_2)naphthalene (**11b**-d_2) in a ratio of 11.2:9.0:1.0; this was estimated by a combination of VPC and NMR measurements. A longer irradiation time did not increase the amount of **3d**, because the latter was found to be transformed back to **1f** under the same conditions in an independent experiment.

The deuterium distribution in compound **C** was studied carefully with use of the FT-NMR spectrum. Thus the integrated area of the signal of the proton bound to C-1a did not change compared with that of the olefinic proton signals (2H). On the other hand, the area due to the proton bound to C-7b decreases, in compensation for the increase of those due to the *exo*- and *endo*-protons on C-1. The results allowed us to estimate that compound **C** contained **1f**-1,1-d_2 and **1f**-1,7b-d_2 in a ratio of 3.2:1.

Similar irradiation of 7*H*-benzocycloheptene (**12a**) gave a mixture of **9a**, **1f**, **3d**, and **8b** in a ratio of 73.5:20:6.5:trace, respectively. From this experiment, it is clear that **9a**-7,7-d_2, if it were formed from **1f**-1,1-d_2 in the above experiment, should partly survive and partly give **1f**-1,1a-d_2 by [1,7]D-shift from C-7 to C-6 and simultaneous bond formation between C-5 and C-7.

The fact that no deuterium incorporation was found in C-1a of compound **C** shows that the rearrangement proceeds through one direction, similar to other cases mentioned above. It is noteworthy that, while 1-methylnaphthalene was identified, neither naphthalene nor 2-methylnaphthalene was detected in the sensitized reaction.

*Formation of the Furan Adducts of **1a** and **1f**.* Irradiation of **1a** and **1f** in furan in the presence of Michler's ketone gave *adduct*-3 and -4, respectively. Their similarities in the proton NMR spectral pattern to those of *adduct*-1, except for the signals due to substituent and/or H_1, determined the structures: **10a** and **10b**, respectively. *Adduct*-3 was obtained in 44% yield from the irradiation of **3a** in furan in the presence of the sensitizer.

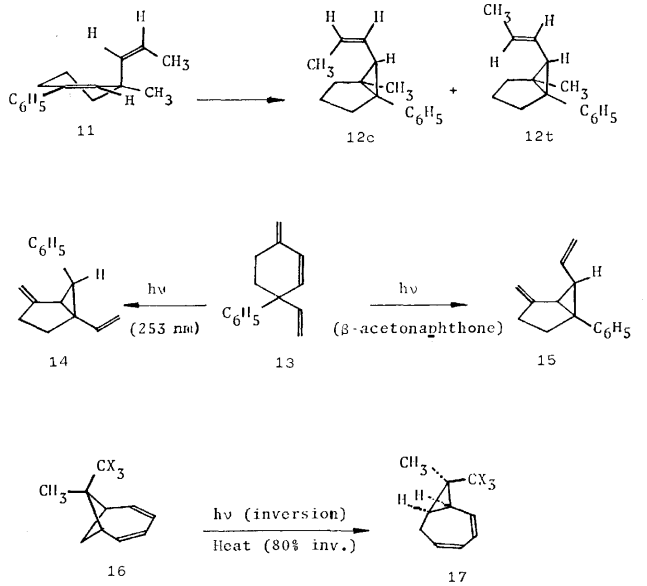
Discussion

The photochemical Berson-Willcott rearrangement of benzonorcaradiene was initially reported by Ciganek on 1,1-dicyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene in 1968.[22] The stereochemical course of the photochemical rearrangement of tropilidenes was studied by Klärner[3] under benzophenone sensitized conditions on 1,3-dimethyl-2,4,6-cycloheptatriene-1-carboxylic ester and nitrile (**2a** and **2b**), which proceed mainly with inversion at the migrating carbon center of their norcaradiene tautomers. They proposed a stepwise mechanism through the biradical intermediates keeping the substituents *exo* in order to relieve the repulsion between π-electrons to predict inversion and partial racemization.

In the above experiment, we found that the stereochemical course of the rearrangement of **1a** under Michler's ketone-sensitized irradiation was quite different in nature from that under direct irradiation. Fukui deduced as follows: "In a triplet-state reaction each bond, which is to be newly formed through the overlapping of AO's of the two parts where the orbital interaction is considered, should be formed so as to result in a structure having two unpaired electrons not in conjugation with each other by virtue of that

bond. Excited singlet-state reactions are not necessarily subject to such a limitation."[23]

There are many examples in which different products are produced under sensitized irradiation from those under the direct type,[24] but little is known concerning the case which gives the same products with different stereochemistry depending on the irradiation conditions. Mariano reported that the di-π-methane rearrangement of **11** gives stereospecifically *cis* product (**12c**) from its excited singlet but mainly *trans* (**12t**) on sensitized irradiation.[25] Swenton described the different behavior of **13** under direct irradiation and under 2-acetonaphthone sensitization.[26] These examples are not similar to our case precisely in the sense of whether the migrating carbon changes the stereochemistry or not. Our results obtained on *exo*-**1a** are unique because of its completely opposite stereochemistry toward **3a** depending on the irradiation conditions. It is noteworthy that the optical purities of the products from direct irradiation are the same within the experimental error and hence stereochemistry is not altered whether we use *exo*-**1a**, obtained below 3 °C from pure (1*R*)-(+)-**1d**, or an thermally equilibrated *exo*-*endo* mixture (2:1) of **1a** obtained from the same acid.[27] This means that, under the direct irradiation, the *exo*-**1a** and *endo*-**1a** follow the same stereochemistry, 80% inversion and 20% retention of the configuration at the migrating center. These facts suggest the presence of different mechanisms for the two modes of irradiation; under direct irradiation, both *exo*- and *endo*-**1a** follow mainly the same symmetry-allowed suprafacial [1,5]sigmatropic shift with inversion at the migrating center, but under sensitized conditions, they follow a stepwise process with either the stereochemistry governed by the principle of the least motion or that of releasing the steric hindrance in the process. Thus, under the sensitized irradiation, the rearrangement of *endo*-**1a** proceeds with inversion at the migrating center in accordance with the principle of least motion[28] with little change in spatial environment, while that of the *exo*-**1a** proceeds mainly with retention at the center, avoiding the steric hindrance caused by the substituent on C-1 and a hydrogen on C-7 in the least motion movement. Borden reported such a least motion pathway for the thermal [1,5]sigmatropic shift of **16**, contrary to the prediction of the Woodward-Hoffmann rule. Direct irradiation of **16** also affords **17** with high stereoselectivity.[29]



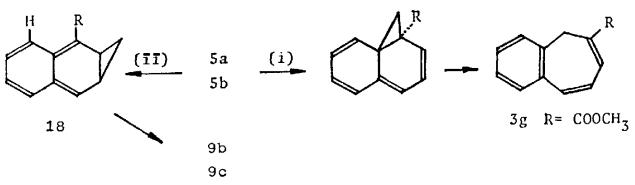
Scheme 5.

The suppression of the reaction by steric repulsion was recognized in the case of a kinetic study on the rearrangement of 3-isopropyl derivative of *exo*-**1a** compared with that of *endo*-**1a** under direct irradiation.[30] Swenton found, in addition to the path ii products, the presence of path i products in the case of direct irradiation of **5b**. He attributed this to the steric hindrance between a peri-hydrogen and the methoxycarbonyl group present in the intermediate (**18**). Such obstruction to path ii is not seen in the case of photolysis of **5a**.[16]

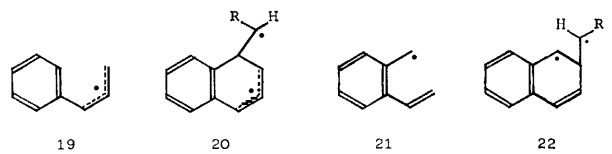
In the study of **1a**, it was difficult to recover *exo*-**1a** without contamination of *endo*-**1a** owing to its thermal instability; even so, the stepwise mechanism under sensitized conditions was supported by the findings that (1*R*)-*exo*-**1c** was recovered from the reaction mixture without racemization and at the same time (1*S*)-*endo*-**1c** was obtained with high optical rotation[31] when (1*R*)-*exo*-**1c** was irradiated in furan. Simple Hückel calculations predict the resonance energy of 1-phenylallyl radical (**19**) composed of a part of **20** to be larger than that of *o*-vinylbenzyl radical (**21**) composed of a part of **22**. Thus the cleavage of a bond C-1 to C-1a in **1** is expected to be easier than that of C-1 to C-7b.[32]

The adduct of (1*R*)-(+)-**1c** to furan was found to be optically inactive. We could not detect any of **9b** in the reaction mixture, so the possibility of racemization of an initially formed optically active **3c** under reaction conditions is rather low. The fact that the absolute configuration of C-7b on *exo*-**1c** is conserved in *endo*-**1c** obtained by the sensitized irradiation shows the existence of diradical intermediates **23c** and **24c**[33,34] during the epimerization. But it is difficult to explain why the *endo*-**1c** rearranges to *exo*-**1c** much faster than the *exo*-**1c** does to *endo*-**1c** in the comparative study.[35]

The occurrence of biradical intermediates **23c** and **24c** clarifies the production of **3c** in an optically in-

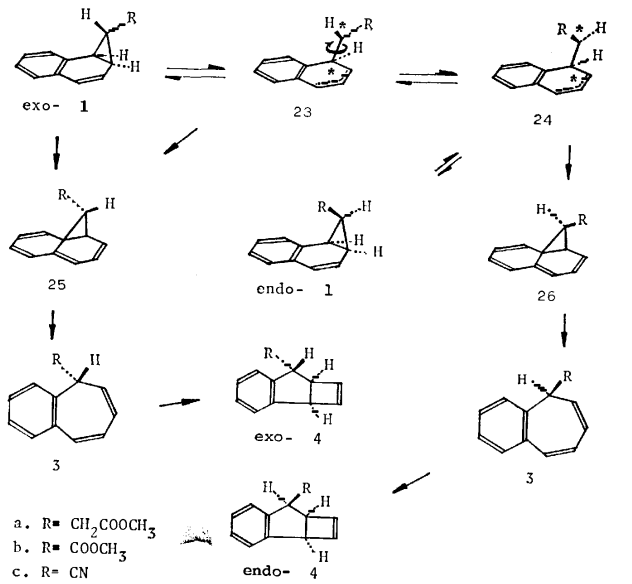


Scheme 6.



$RE(\mathbf{19}) - RE(\mathbf{21}) = -0.09\beta$ (RE=Resonance energy)

Scheme 7.



Scheme 8.

active form.

The stereochemical results of the rearrangement of (+)-**1b** are explained as follows. In this case, as is expected from the fact that **1b** exists solely in its *exo* form and *endo*-**1b**, when it is prepared by photolysis of **3b**,[5] isomerizes readily at room temperature, the steric repulsion between methoxycarbonyl group and π-electrons in the ring **24b** is too large to get close enough to *endo*-**1b**; therefore, the loss of the optical activity of (+)-**1b** is found to be quite small (8%) during irradiation. For the rearrangement to **3b**, the closure of **23b** and **24b** to position C-7a is expected to have the same order of large steric repulsion, because the steric requirement of methoxycarbonyl group is larger than that of cyano group. Therefore, we may obtain **3b** at a rate rather slower than those of **3a** or **3c** and in almost racemic form. However, another explanation for the occurrence of racemic **3b** from (1*R*)-**1b** is possible: that is the racemization of initially formed optically active **3b** under the reaction conditions. This possibility has not been investigated yet.

Next, we must deal with the mechanism of cycloaddition of **1c**, **1a**, and **1f** to furan. Generally, the photochemical [4πs+2πs]-addition is not allowed under the control imposed by the orbital symmetry rule. Two mechanistic alternate pathways may serve to predict the adducts. One is the successive photochemically allowed processes, [2πs+2πs] or [4πs+4πs] cycloaddition, as observed in the photochemical addition of furan to benzene,[36] followed by [1,3]sigmatropic shift to give products. The other is a stepwise biradical or the equivalent process. As the latter cannot explain the regioselectivity of the adduct, the former mechanism assisted by the overlap of the secondary orbitals may satisfactorily predict the selectivity. The stereoselective formation of *exo*-adducts shows that a steric factor is playing an important role as the controlling factor.

Finally, the fact that the *exo-endo* ratio of the cyclization products **4a** formed from **3a** is quite different depending on the irradiation conditions is also interesting. Under direct irradiation, **3a** gives mainly *exo*-**4a** (*exo*:*endo*=95:5) in various solvents, but under sensitized conditions, it gives **4a** in variable ratios of 10:90 to 40:60 (*exo*:*endo*) depending mainly on the reaction temperature. These facts suggest the existence of two different cyclization mechanisms depending on the conditions used. It was reported that, under direct irradiation, such cyclization often proceeds by the concerted disrotatory mode[37] but under the sensitized conditions and/or from easily attained excited triplets, the reaction proceeds with initial *cis-trans* isomerization followed by the thermally allowed conrotatory ring closure.[38,39] It is possible to assume that these two modes of mechanisms might have played a role in the above case, and from each of their favored conformations, they will give the *exo-endo* mixture of **4a** in different ratios following the "accordant rule" discussed by Dauben.[40]

Experimental

General Procedure. UV, IR, H-NMR, and Mass spectra were recorded according to the methods given in the previous paper.[4] C-13 NMR spectra were recorded on a JNM FX-100 spectrometer (25.05 MHz) in $CDCl_3$ and the chemical shifts are expressed in ppm to the middle peak of the solvent-carbon as a standard (δ 77.1 ppm). A Varian Aerograph model 90P was used for the preparative VPC (helium flow rate; 30—40 mL/min) and a Shimazu Gas Chromatograph GC-4BM was used for the analytical purposes (Hydrogen flame ionization detector). The columns used for separation are ϕ 3.2 mm×1.8 m columns charged with: A, 10% Silicone DC QF-1; B, 5% Silicone OV-17; C, 3% Silicone OV-17; D, 5% Silicone SE-30, on Chromosorb WAW.

For irradiation of more than 100 mL volume, a solution charged in a vessel fitted with a quartz cooling jacket was purged with dry nitrogen for 5 min and internally irradiated with an Ushio High Pressure mercury arc (UM-452) through a Pyrex filter. For small scale irradiation (less than 15 mL), unless otherwise described, a solution charged in a drum-shaped Pyrex vessel with a ground glass joint fitted with a three-way cock, was purged with dry nitrogen for 5 min and dipped in ice water in a quartz Dewar bottle with a flat quartz window. The solution was then irradiated externally with an Ushio lamp (USH-500D) through a Toshiba filter (UV-31). After irradiation, the solvent was evaporated under reduced pressure and the residue taken in chloroform was chromatographed on silica gel to remove the sensitizer. The product mixture was then purified by the appropriate method.

Photolysis of ***1b***. A solution of **1b** (233 mg, 1.2 mmol) and Michler's ketone (1.31 g, 4.9 mmol) dissolved in benzene (400 mL) was irradiated for 2.5 h. The usual work-up gave a mixture (175 mg, 75% of the starting material) mainly composed of **1b** and **3b**. They were purified by chromatography on silica gel (5 g) using hexane–ether (95:5 *v/v*) as an eluent. A mixture (139 mg, 60%) composed of **1b** and **3b** (1:1), in addition to **8a** (23 mg, 10%), was separated and each was identified by direct comparison with the authentic samples.[5] For further identification, the mixture in ethyl acetate was hydrogenated over 10% palladium on carbon at room temperature to give two products (1:1): one was identified with known 2,3-dihydro-**1b**[41] and the other was tetrahydro-**3b**. They were separated by VPC

TABLE 2. PRODUCT DISTRIBUTIONS FOR THE PHOTOLYSIS OF **1b** IN THE PRESENCE OF SEVERAL SENSITIZERS

Sensitizer	E_T / kJ mol^{-1}	Products' ratio

Pyrene	201.2	100	0	0	0	0

(column A, 152 °C: *retention time*; 23.1 min, 14.2 min, respectively). **3b** NMR ($CDCl_3$) δ: 3.62 (1H, d, J=5 Hz), 3.74 (3H, s), 5.9—6.2 (2H, m), 6.38—6.6 (2H, m), 6.9—7.4 (4H, m). Mass *m/e* (rel intensity, %): 200 (M^+, 15), 141 (100), 115 (25). Tetrahydro-**3b** NMR (CCl_4) δ: 2.77 (2H, m), 3.67 (3H, s), 3.78 (1H, d,d, J=2.2, 6.4 Hz), 1.48—2.13 (6H, m), 6.84—7.13 (4H, m). UV (CH_3OH) λ_{max}: 256.5 (sh), 264, 272 nm. Mass *m/e* (%): 204 (M^+, 18), 172 (10), 145 (100), 117 (20), 91 (16). Found: C, 76.41; H, 7.87%. Calcd for $C_{13}H_{16}O_2$: C, 76.44, H, 7.90%.

Photolysis of **1b**-1-d_1. A solution of **1b**-1-d_1 (198 mg, 0.99 mmol) and Michler's ketone (1.01 g, 3.8 mmol) dissolved in benzene (400 mL) was irradiated for 3 h at 0—5 °C. After work-up as above, a product mixture (182 mg) was chromatographed on silica gel (6 g, 5% ether–hexane) to give a mixture (151 mg) of **1b**-d_1 and **3b**-d_1 (1.1:1.0). Careful examination of the proton NMR spectrum and comparisons with those of **1b** and **3b** revealed that (1) the area ratio of proton signals for H_1 (δ: 0.74 ppm), H_{1a} (δ: 2.49 ppm, d,d, J=8.2, 4.2 Hz), and H_{7b} (δ: 2.92 ppm, d, J=8.2 Hz) on **1b**-d_1 is equal to 7:100:98, which corresponds to the ratio observed in the starting **1b**-1-d_1 within the experimental error, and that (2) the signal due to H_5 for **3b**-d_1 was very feeble compared with those of olefinic protons (δ: 5.9—6.2 ppm, 2H; δ: 6.38—6.6 ppm, 1H), which fits those for **3b**-5-d_1.

Photolysis of **1b** *in Benzene with Several Sensitizers.* The irradiation was carried out in benzene solution (150 mg, 0.75 mmol/300 mL) in the presence of 4 equiv. mol of sensitizer for 2 h. The yields of the products were assayed by VPC (column A, 162 °C; *exo*-**4b** (*retention time*, 9.6 min), *endo*-**4b** (*r.t.*, 12 min), **1b**+**3b** (*r.t.*, 20.8 min), **8a** (*r.t.*, 24.4 min)) and NMR spectroscopy (Table 2).

Characterization of **4b**: After evaporation of the solvent, the residue taken in methanol was treated with sodium borohydride (4 equiv. mol) to make separation of the products from ketonic sensitizer easier. The usual work-up followed by chromatography (silica gel/10% ether–hexane) gave *exo*- and *endo*-**4b** together with **8a**. They were further purified by preparative VPC (column A, 162 °C) as mentioned above. *exo*-**4b** NMR (CCl_4) δ: 3.65 (3H, s), 3.78—3.95 (2H, m), 4.31—4.40 (1H, m), 6.12 and 6.31 (2H, AB type d, J=2.8 Hz), 7.07—7.38 (4H, m). UV (cyclohexane) λ_{max} (log ε): 255.5 (2.71), 262 (2.89), 268 (3.06), 275 (3.11) nm. IR (liq. film) ν_{max}: 1731, 1486, 1442, 1251, 1178, 772, 747 cm^{-1}. Mass *m/e* (rel intensity, %): 200 (M^+, 12), 185 (11), 174 (7), 141 (100), 115 (10). Found: C, 77.91; H, 6.15%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%. *endo*-**4b** NMR (CCl_4) δ: 3.73 (3H, s), 3.89, 4.04 (AB part of ABX, J_{ab}=10, J_{ax}=3.6 Hz), 4.24 (1H, X part of ABX, J_{ax}=3.6 Hz), 6.04 and 6.38 (2H, AB type, J=2.8 Hz), 7.08—7.36 (4H, m). UV (cyclohexane) λ_{max}: 263, 268, 275.5 nm. Found: C, 77.96; H, 6.12%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%.

*Photolysis of (1R)-***1b**. A solution of (1*R*)-**1b** ($[\alpha]_D^{14}$ +124° (*c* 1.16, CH_3OH); 228 mg, 1.14 mmol), prepared from (1*R*)-**1d** ($[\alpha]_D$ +143°), and Michler's ketone (1.84 g, 6.84 mmol) dissolved in benzene (120 mL) was irradiated under ice-cooling for 2 h. The usual work-up gave a mixture (102 mg, 45%) composed of mainly **3b** and **1b**, in addition to small amounts of *exo*- and *endo*-**4b** and **8a** (VPC, column C, 165 °C). The mixture was separated by medium pressure liquid chromatography (Kieselgel 60, 23 g/5% ether–hexane) into 60 fractions of 5 ml each. Fractions 20—23 contained **3b** (22.7 mg, $[\alpha]_D^{14}$ −2.82° (*c* 1.13, 95% C_2H_5OH)) and fractions 27—30 contained recovered **1b** (23.3 mg, $[\alpha]_D^{15}$ +114° (*c* 1.16, CH_3OH)).

Synthesis of Optically Active **1a**. (1*R*)-**1d** (522 mg, $[\alpha]_D$ +143°, optical purity >95%) was transformed to the corresponding diazo ketone (yellow silky crystals, 578 mg, 98%; ν_{max}: 2120, 1600 cm^{-1}), *via* the acid chloride (solid, 599 mg; $\nu_{C=O}$ 1760 cm^{-1}) by the usual method.[8] The diazo ketone dissolved in anhydrous methanol was irradiated at *ca.* 2 °C until 80% of the theoretical amount of nitrogen had evolved (22 min) and then concentrated below 3 °C under reduced pressure. The residue taken in cold chloroform was chromatographed on silica gel below 5 °C to give an optically active 1-*exo*-(+)-**1a** (300 mg; no contaminants other than **1a**, by TLC).

For the synthesis of *exo-endo* mixture (2:1) of (1*R*)-**1a**, the above photolysate was purified by chromatography on silica gel at room temperature with 10% ether–hexane as an eluent. Then the product (393 mg, 65% of the theoretical amount) was thermally equilibrated by heating it at 95 °C for 5 min ($[\alpha]_D^{31}$ +24.7° (*c* 1.2, CH_3OH)).

Photolysis of exo-endo *Mixture of (1R)-***1a**. A solution of (1*R*)-**1a** ($[\alpha]_D$ +24.7°; 118 mg, 0.55 mmol) and Michler's ketone (888 mg, 3.31 mmol) dissolved in dichloromethane (130 mL) was irradiated under nitrogen below 5 °C for 30 min. After the usual work-up, the product was rechromatographed on silica gel (12 g/benzene) to give an *exo-endo* mixture of **4a** (43.6 mg). VPC separation (column B, 150 °C) of it gave (−)-*endo*-**4a** ($[\alpha]_D^{25.5}$ −28° (*c* 0.35, $CHCl_3$) 19% enantiomer excess) and (+)-*exo*-**4a** ($[\alpha]_D^{23}$ +56° (*c* 0.35, $CHCl_3$)).[8]

Similarly, a solution of (1*R*)-**1a** (228 mg, 1.07 mmol) and Michler's ketone (1.72 g, 6.42 mmol) in benzene (110 mL) was irradiated at 40±1 °C for 5 min. The usual work-up and repeated chromatography gave a mixture (182 mg, 80%), which was estimated to be composed of **1a** (80%) and **3a** (20%), in addition to a minor amount of **4a**. A pure sample (3.5 mg) of **3a** was isolated by medium pressure liquid chromatography (Kieselgel 60, 23 g) and estimated to be 16% enantiomer excess by NMR measurement in the presence of tris[3-(2,2,3,3,4,4,4-heptafluoro-1-hydroxybutylidene)-*d*-camphorato]europium (III).

Photolysis of (1R)-exo-***1a***.* (1*R*)-*exo*-**1a**, obtained above, was photolyzed in dichloromethane (5 min) below 3 °C as described in the case of (1*R*)-**1a** (*exo-endo* mixture) and gave (+)-**3a**[1] ($[\alpha]_D^{18}$ +65° (*c* 0.63, 95% C_2H_5OH); 76% enantiomer excess (chiral NMR shift reagent)) and *endo*-**4a**[1] ($[\alpha]_D^{18}$ −81° (*c* 0.21, $CHCl_3$); 76% enantiomer excess) in addition to a recovery of **1a** ($[\alpha]_D^{23}$ −3.1° (*c* 1.04, CH_3OH).

Synthesis of Optically Active ***3a***. (5*S*)-(+)-**3a** ($[\alpha]_D^{17}$ +86° (*c* 0.88, 95% C_2H_5OH)) was prepared from benzotropylium tetrafluoroborate as described previously.[2]

*Photolysis of (+)-****3a***. A solution of (+)-**3a** (128 mg, 0.60 mmol; $[\alpha]_D$ +86°, 95% optically pure) and Michler's ketone (802 mg, 2.99 mmol) dissolved in benzene (110 mL) was irradiated under nitrogen for 40 min at 40 °C. After the usual work-up, an *exo-endo* mixture (1:4.8; 39 mg) of **4a** was obtained. VPC separation (column B, 150 °C) of the mixture gave (−)-*endo*-**4a** ($[\alpha]_D^{27}$ −107° (*c* 0.38, $CHCl_3$)) and (+)-*exo*-**4a** ($[\alpha]_D^{27}$ +180° (*c* 0.08, $CHCl_3$)).

Synthesis of Optically Active ***1e***. Into the acid chloride, obtained from (1*R*)-(+)-**1d** ($[\alpha]_D$ +143°, optical purity >95%; 1.16 g, 6.24 mmol) and dissolved in anhydrous ether (170 mL), was passed gaseous ammonia at 0 °C for 25 min until the pH of the solution reached 10 against a wet test paper. After stirring for 1 h at room temperature, water (150 mL) was added to the solution. The aqueous solution was separated and extracted three times with dichloromethane and the combined organic layer was washed successively with water and saturated brine, and then dried. The crude amide (1.11 g, 96%) was recrystallized from methanol. **1e** colorless crystals (775 mg, 67%), mp 261—262 °C; $[\alpha]_D^{15}$ +201° (*c* 0.51, dioxane). IR (Nujol mull) ν_{max}: 3420, 3230, 1645, 1605, 775, 735 cm^{-1}. NMR (DMSO-d_6) δ: 0.72 (1H, t, J=4.0 Hz), 2.5 (H_{1a}, m), 2.83 (1H, d,d, J=8.3, 4.0 Hz), 6.2—6.5 (2H, m) 7.0—7.5 (4H, m). Found: C, 77.76; H, 5.99; N, 7.52%. Calcd for $C_{12}H_{11}NO$: C, 77.81; H, 5.99; N, 7.56%.

Synthesis of Optically Active ***1c***. To a solution of the amide ($[\alpha]_D$ +201°; 519 mg, 2.81 mmol) and anhydrous pyridine (445 mg, 5.62 mmol) in anhydrous dioxane (12 mL) was added dropwise a solution of trifluoroacetic anhydride (649 mg, 3.1 mmol) in dioxane (5 mL) in a period of 25 min. After stirring for 3 h at room temperature, chloroform (50 mL) was added to the mixture. The organic layer was then washed successively with water (three times), and with saturated brine and dried. Evaporation of the solvent gave a crude nitrile (487 mg, 100%). Chromatographic separation (silica gel (12 g)/10% ether–hexane), followed by recrystallization from hexane gave **1c** as colorless crystals (280 mg, mp 76.5 °C; $[\alpha]_D^{15}$ +103° (*c* 0.95, CH_3OH)). *exo*-**1c** IR (Nujol mull) ν_{max}: 2225, 770, 730 cm^{-1}. UV (CH_3OH) λ_{max} (log ε): 273 nm (3.89): (cyclohexane) λ_{max}: 273 nm (3.89). H-NMR ($CDCl_3$) δ: 0.69 (1H, t, J=4.3 Hz), 2.69 (1H, d,d,d, J=8.3, 4.3, 4.2 Hz), 3.10 (1H, d,d,d, J=8.3, 4.3, 0.7 Hz), 6.25 (1H, d,d,d, J=9.8, 4.2, 0.7 Hz), 6.39 (1H, d, J=9.8 Hz), 7.0—7.5 (4H, m). C-13 NMR ($CDCl_3$) δ: 130.5 (s), 130.0 (s), 129.0 (d), 128.4 (d), 128.1 (d), 127.7 (d), 126.8 (d), 123.9 (d), 121.5 (s), 28.8 (d, J=168 Hz), 25.7 (d, J=171 Hz), 7.6 (d, J=178 Hz). Found: C, 86.32; H, 5.48; N, 8.36%. Calcd for $C_{12}H_9N$: C, 86.20; H, 5.43; N, 8.38%.

*Thermal Conversion of (+)-*exo-***1c*** to* endo-***1c***. (+)-*exo*-**1c** ($[\alpha]_D^{18}$ +103°; 16.6 mg) dissolved in DMSO-d_6 (0.4 mL) was heated in an NMR tube at 130 °C for 20 min. The mixture (*exo*:*endo*=2:3) was separated by chromatography on silica gel (10 g) and 37 fractions (fr. 1—30; 10% ether–hexane: fr. 31—37; CH_2Cl_2) of 8 mL each were collected. Fractions 6—10 contained 8 mg of (+)-*exo*-**1c**, mp 76.5 °C, $[\alpha]_D^{18}$ +103° (*c* 0.21, CH_3OH), and fraction 35, (−)-*endo*-**1c**, mp 153 °C, $[\alpha]_D^{16}$ −579° (*c* 0.17, CH_3OH). IR (Nujol mull) ν_{max}: 2217 cm^{-1}. UV (CH_3OH) λ_{max} (log ε): 270 nm (3.89): (cyclohexane) λ_{max} 270 nm (3.88). NMR ($CDCl_3$) δ: 2.19 (H_1, t, J=8.3 Hz), 2.63 (H_{1a}, d,t, J=8.3, 5.1 Hz), 3.03 (H_{7b}, t,d, J=8.3, 0.7 Hz), 6.12 (H_2, d,d,d, J=9.7, 5.1, 0.7 Hz), 6.70 (H_3, d, J=9.7 Hz), 7.2—7.4 (4H, m).

*Photolysis of 1-*exo-***1c*** in Benzene.* A solution of *exo*-**1c** (64.5 mg, 0.39 mmol) and Michler's ketone (486 mg, 1.81 mmol) in benzene (40 mL) was irradiated with HPL (100 W) through a Pyrex filter under ice cooling for 15 min. The usual work-up gave a mixture (44.0 mg, 68.2%), which was separated by column chromatography into *endo*-**1c** (4.0 mg, 6.2%) and a mixture (7:5) of *exo*-**1c** and **5a** (39 mg, 60%). The latter was estimated by VPC (column C, 165 °C: *retention time*; **5a**, 3.5 min; **1c** 5.7 min).

Photolysis of endo-***1c*** *in Benzene.* The same experiment as that of *exo*-**1c** was carried out using *endo*-**1c** (63.6 mg, 0.38 mmol). We obtained a mixture of products (55.7 mg, 88%) which was revealed by VPC and NMR spectroscopy to contain *endo*-**1c** (10 mg, 15.7%), *exo*-**1c** (28.5 mg, 44.8%), and **5a** (15.9 mg, 25.0%).

Photolysis of Optically Active exo-***1c*** *in Furan.* A solution of (+)-*exo*-***1c*** ($[\alpha]_D$ +103°, 133 mg, 0.80 mmol) and Michler's ketone (1.28 g, 4.77 mmol) dissolved in furan (110 mL) was irradiated below 5 °C under nitrogen for 15 min. After furan was recovered by distillation, the residue was chromatographed on silica gel (90 g/chloroform) to give an *adduct*-1 (12.1 mg), (−)-*endo*-**1c** (17.2 mg), and **5a** (10.8 mg) in addition to the recovered (+)-*exo*-**1c** (50.9 mg, $[\alpha]_D^{20}$ +110°, mp 74.5 °C). (−)-*endo*-**1c** Colorless needles, mp 153 °C; $[\alpha]_D^{16}$ +572° (*c* 0.8, CH_3OH). NMR ($CDCl_3$) δ: 2.19 (1H, t, J=8.3 Hz), 2.63 (1H, t,d, J=8.3, 5.1 Hz), 3.03 (1H, t,d, J=8.3, 0.7 Hz), 6.12 (1H, d,d,d, J=9.7, 5.1, 0.7 Hz), 6.70 (1H, d, J=9.7 Hz), 7.4—7.21 (4H, m). *Adduct*-1 Colorless needles, mp 107—109 °C; $[\alpha]_D^{15}$ −0.8° (*c* 0.25, $CHCl_3$). IR (Nujol mull) ν_{max}: 2230, 1615, 1140, 1070, 1015 cm^{-1}. NMR ($CDCl_3$) δ: 3.42 (1H, d,d, J=6.8, 2.9 Hz), 3.51 (1H, broad d, J=2.4 Hz), 3.62 (1H, m), 4.43 (1H, t, J=2.3 Hz), 4.56 (1H, d, J=3.2 Hz), 5.00 (1H, d,d, J=11.7, 6.8 Hz), 6.08 (1H, d,d, J=2.9, 2.0 Hz), 6.21 (1H, d, J=7.1 Hz), 6.72 (1H, m), 7.35—6.9 (4H, m). Found: C, 81.66; H, 5.53; N, 5.88%. Calcd for $C_{16}H_{13}NO$: C, 81.68; H, 5.57; N, 5.95%. Mass *m/e* (rel intensity): 235 (M^+, 0.38), 206 (2.73), 168 (46.9), 167 (100). **5a** IR (liq. film) ν_{max}: 3030, 2920, 2235, 1490, 1455, 1215, 1045, 955, 900, 855, 778, 740 cm^{-1}.

Photolysis of ***3c***. A solution of **3c** (58 mg, 0.35 mmol) and Michler's ketone (465 mg, 1.73 mmol) in benzene (13 mL) was irradiated externally for 3 h under ice-cooling to give, in addition to **3c** (7.5 mg, 13%), **5a** (19.5 mg, 34%) after chromatographic separation followed by preparative VPC (column A, 150 °C: *retention time*; **3c**, 10.3 min; **5a**, 11.4 min).

Photolysis of ***3c*** *in Furan.* A solution of **3c** (17 mg, 0.1 mmol) and Michler's ketone (136 mg, 0.81 mmol) dissolved in furan (13 mL) was irradiated externally for 2 h. The solution was concentrated and the residue taken in benzene was chromatographed on silica gel to give 10 mg of material composed of **5a** (52%) and *adduct*-1 (48%) estimated by VPC (column D, 169 °C: *retention time*; **5a**, 2.4 min; *adduct*-1, 9.6 min).

*Synthesis of 1a,2,3,7b-Tetrahydro-1*H*-cyclopropa*[a]*naphthalene-1,1-*d_2. To a stirred solution of 1,2-dihydronaphthalene containing 20% of naphthalene (12 g, 92 mmol) dissolved

in tribromomethane (60 g, 0.24 mol) was added dropwise 50% aq sodium hydroxide (20 mL) in the presence of tetrabutylammonium iodide (0.35 g, 0.95 mmol) under ice-cooling in a period of 10 min. Then the solution was vigorously stirred for 0.5 h. Then it was gradually warmed and stirred for 24 h at 40 °C. After cooling, water was added to the mixture and the aqueous layer was extracted with chloroform. The combined organic layer was washed with water and dried. Separation by chromatography (silica gel/hexane) of the product gave 1,1-dibromo-1a,2,3,7b-tetrahydro-1*H*-cyclopropa[*a*]naphthalene (17.3 g, 63%) as a yellow oil. A mixture of the bromide (5.8 g, 19 mmol), 40% tributyltin deuteride (32 g; contaminated by tributyltin chloride) and a catalytic amount of 2,2′-azobis(2-methylpropionitrile) (60 mg) was stirred at 95±5 °C for 26 h. The mixture was separated by column chromatography (Woelm neutral aluminium oxide, 300 g/hexane) to give 2,3-dihydro-**1f**-1,1-d_2 (2.5 g, 17 mmol, 89%). For analysis, it was purified by preparative VPC (column A, 99 °C; *retention time*, 12 min). Found: C, 90.36; H, 8.44% (H_2O as D_2O). Calcd for $C_{11}H_{14}$: C, 90.35; H, 9.65%: for $C_{11}H_{10}D_2$: C, 90.35; H, 8.27%. NMR (CCl_4) δ: 1.7—2.85 (6H, m), 6.85—7.5 (4H, m).

Synthesis of ***1f***-1,1-d_2. A solution of 2,3-dihydro-**1f**-1,1-d_2 (1.1 g, 7.7 mmol) and *N*-bromosuccinimide (1.4 g, 7.9 mmol) in carbon tetrachloride (70 mL) was refluxed in the presence of 2,2′-azobis-(2-methylpropionitrile) (60 mg) for 2.5 h. The solution was filtered and the filtrate was concentrated to dryness to give a yellow liquid, which was taken in *N*,*N*-dimethylformamide (40 mL). The solution was stirred with calcium hydrogen phosphate (1.38 g, 10.1 mmol) at 80—90 °C for 16 h. After cooling, the solution was diluted with water (100 mL) and extracted with ether. The combined ether solution was washed with water and dried. Evaporation of the solvent in vacuo left a crude product, which was purified by column chromatography (silica gel, 15 g/hexane). **1f**-1,1-d_2 (626 mg, 44%) was obtained as a colorless liquid. For photolysis, it was further purified by preparative VPC (column A, 100 °C; *retention time*, 14 min). NMR (CCl_4) δ: 1.93 (1H, broad; when irradiated on 6.18 ppm it becomes a broad doublet, J=8 Hz), 2.36 (1H, broad d, J=8 Hz), 6.18 (2H, two sharp signals), 6.9—7.35 (4H, m). The proton area ratio of *exo*-H_1 to olefinic 2H is 2:167=1:83.5 (purity 97%).

The same experiments as above were carried out using 1,1-dibromo-1a,2,3,7b-tetrahydro-1*H*-cyclopropa[*a*]naphthalene and tributyltin hydride in place of tributyltin deuteride. We obtained **1f** as a colorless liquid. UV (95% C_2H_5OH) λmax (log ε): 274.5 (3.87), 306 (3.11). H-NMR (CCl_4) δ: −0.3 (1H, d,t, J=3.8, 5 Hz), 1.50 (1H, d,t, J=3.8, 9 Hz), 1.96 (1H, m), 2.40 (1H, d,d,d, J=9, 7, 5 Hz), 6.20 (2H, m), 6.9—7.4 (4H, m). C-13 NMR ($CDCl_3$) δ: 9.45 (t, J_{CH}=164 Hz), 17.7 (d, J_{CH}=165 Hz), 20.6 (d, J_{CH}=163 Hz), 123.6, 125.7, 127.1, 127.7, 128.2, 129.0, 130.7, 135.5.

Photolysis of ***1f***. A solution of **1f** (34 mg, 0.24 mmol) and Michler's ketone (318 mg, 1.9 mmol) dissolved in benzene (130 mL) was irradiated under ice-cooling for 30 min. The usual work-up and VPC separation left a mixture of products (6 mg). Careful examination of the NMR spectrum revealed that the mixture contained mainly 5*H*-benzocycloheptene (**3f**) in addition to a minor amount of **1f**. **3f** NMR (CCl_4) δ: 3.02 (2H, d, J=6.5 Hz), 5.73 (1H, m), 6.03 (1H, m), 6.43 (1H, d,d, J=11, 6 Hz), 7.04 (1H, d, J=11 Hz).

Photolysis of ***1f***-1,1-d_2. A solution of **1f**-1,1-d_2 (23 mg, 0.16 mmol) and Michler's ketone (230 mg, 0.86 mmol) dissolved in benzene (100 mL) was irradiated for 15 min. The NMR spectrum of the isolated mixture (12 mg) was compared with that of the products from **1f**. They were quite similar, but in the former, the signal due to H_5 of **3f** were very weak and that of H_6 appeared as a broad doublet at 5.8 ppm. Further, the signal due to H_1 of **1f** appeared as weak as that of H_5 on **3f**. VPC (column A, 100 °C) of the mixture showed 4 peaks: peak-1 (unknown; *retention time*, 18.4 min; 7.1%), peak-2 (**3f**; 21.6 min; 39.4%), peak-3 (**1f**; 25.6 min; 49.1%), and peak-4 (**8b**-d_2; 33.2 min; 4.4%). In the NMR spectrum of peak-3, the peak area ratio for H_{7b}:H_{1a}:*endo*-H_1:H_2+H_3 is equal to 32:42:5:83. These results define unambiguously that **1f**-d_2 is composed of **1f**-1,1- and 1,7b-d_2 in a ratio of 3.2:1.

Photolysis of ***9a***. A solution of **9a** (33.5 mg, 0.24 mmol) and Michler's ketone (31.9 mg, 1.18 mmol) dissolved in benzene (100 mL) was irradiated for 30 min. The product (9 mg), isolated as above, showed 5 peaks in the VPC (column A, 100 °C) with a area ratio for an unknown, naphthalene, a mixture (1:2) of **3d** and **9a**, **1f**, and **8b** was 1:6:125:96:2, respectively. The NMR spectrum of the mixture also supports these assignments.

Photolysis of ***1a*** *in Furan*. A solution of **1a** (15 mg) and Michler's ketone (80 mg) dissolved in furan (12 mL) was irradiated externally for 3 h. The product was separated as above by chromatography (silica gel 5 g/benzene followed by benzene–ethyl acetate (9:1 v/v)) to give a product mixture (6.5 mg). This was estimated by VPC (column B, 165 °C) to contain the *adduct*-3 (30%).

Photolysis of ***3a*** *in Furan*. A solution of **3a** (40 mg, 0.19 mmol) and Michler's ketone (450 mg, 1.68 mmol) dissolved in furan (75 mL) was irradiated with a medium pressure mercury lamp (500 watts) for 0.5 h in a Pyrex jacket. After separation of the mixture by the usual method, the products were purified by preparative TLC (silica gel/20% ether–hexane) to give *adduct*-3 (23 mg, 43%). *Adduct*-3 IR (liq. film) ν_{max}: 3050, 2925, 1735, 1616, 1250, 1140, 1075, 760, 740, 725 cm^{-1}. UV (95% C_2H_5OH) λ_{max} (ε): 220 (end absorp., 9990), 260 (648), 267 (678), 275 (617) nm. NMR ($CDCl_3$) δ: 2.5—2.9 (2H, m), 3.0—3.56 (3H, m), 3.82 (3H, s), 4.47 (1H, t, J=2.5 Hz), 5.10 (1H, d,d, J=7, 11 Hz), 6.1—6.3 (2H, m), 6.78 (1H, d,d, J=7, 8 Hz), 6.9—7.4 (4H, m). C-13 NMR ($CDCl_3$) δ: 36.7 (d), 38.6 (d), 41.9 (t), 45.6 (d), 49.3 (d), 51.8 (q), 82.5 (d), 101.4 (d), 125.9 (d), 126.6 (d), 128.3 (d), 129.6 (d), 131.0 (d), 138.4 (d), 138.6 (s), 140.8 (s), 146.6 (d), 173.0 (s). Mass *m/e* (rel intensity): 250 (1.78, M^+-OCH_4), 215 (11.3), 214 (64.3, M^+−furan), 155 (14.9), 154 (59.5), 142 (12.5), 141 (100). Found: C, 77.04; H, 6.52%. Calcd for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43%.

Photolysis of ***1f*** *in Furan*. Irradiation of **1f** (94 mg, 0.67 mmol) and Michler's ketone (888 mg, 3.3 mmol) in furan (80 mL) for 45 min gave a product (76 mg) after chromatography (silica gel, 20 g/hexane). VPC separation (column D, 170 °C) of the product gave **1f** (23.5 mg; *retention time*, 1 min) and *adduct*-4 (5.2 mg; *r.t.*, 4.8 min). *Adduct*-4 UV (95% C_2H_5OH) λ_{max} (ε): 220 (end absorp. 8900), 260 (599), 267 (751), 275 (723) nm. IR (liq. film) ν_{max}: 3050, 2925, 1616, 1140, 1075, 1017, 745, 720, 710 cm^{-1}. NMR ($CDCl_3$) δ: 2.83 (*exo*-H_{10}, d,d, J=4, 20 Hz), 2.9—3.15 (H_6, m), 3.3—3.8 (*endo*-H_{10}, H_7, H_1, m), 4.27 (H_5, t, J=2.5 Hz), 5.0 (H_2, d,d, J=6.5, 10.5 Hz), 6.10 (H_{11}, d,d, J=6, 8 Hz), 6.22 (H_4, t, J=2.5 Hz), 6.6 (H_{12}, d,d, J=6, 8 Hz), 6.86—7.2 (4H, m). Mass *m/e* (rel intensity): 210 (M^+, 0.55), 165 (3.1), 142 (100, M^+−furan). Found: C, 86.00; H, 6.78%. Calcd for $C_{15}H_{14}O$: C, 85.68; H, 6.71%.

The authors wish to thank Mr. Jun-Ichi Goda of our University for the elementary analyses and Mr. Tadasu Tahara of the Nitto Kasei Chemical Co. for a generous supply of tributyltin chloride.

27) We confirmed the optical yields for the rearrangement under direct irradiation[8] as follows: **1a** obtained from **1d** ($[\alpha]_D$ +143°) below 5 °C gave *exo*-**4a** ($[\alpha]_D$ −122° (*c* 0.65, $CHCl_3$)) and the thermally equilibrated *exo-endo* mixture (2:1) of **1a** ($[\alpha]_D$ +29° (*c* 0.98, $CHCl_3$)) obtained from the same acid gave *exo*-**4a** ($[\alpha]_D$ −120° (*c* 0.65, $CHCl_3$)). The enantiomer excesses of both *exo*-**4a** were found to be 60% by NMR measurements using tris[3-(2,2,3,3,4,4,4-heptafluoro-1-hydroxybutylidene)-*d*-camphorato]europium-(III) as a chiral shift reagent.

30) M. Kato, M. Tsuji, and T. Miwa, *Bull. Chem. Soc. Jpn.*, **51**, 1450 (1978).

31) The determination of optical purity with chiral NMR shift reagent was unsuccessful but the absolute value of the specific rotation was the same as the one thermally obtained from (1*R*)-*exo*-**1c**.

32) These facts are parallel with the thermal behavior of **1a**. When **1a** was heated above 250 °C for 1.5 h, it gave, in addition to a trace amount of naphthalene, methyl 3-(1-naphthyl)acrylate (29%) and methyl 3-(1-naphthyl)propanoate (53%). The latter was identified by direct comparison with an authentic sample and the former was confirmed by the spectral data (NMR ($CDCl_3$) olefinic protons δ: 8.2 (1H, d, J=16 Hz), 6.2 (1H, d, J=16 Hz): UV λ_{max}: 330 nm. IR ν_{max}: 1710, 1635 cm^{-1}) and by quantitative transformation to the latter under catalytic hydrogenation (H_2 (10% Pd–C, CH_3OH)).

33) N. H. Fischer and H.-N. Lin, *J. Org. Chem.*, **38**, 3073 (1973).

34) M. P. Schneider and R. J. Crawford, *Can. J. Chem.*, **48**, 628 (1970); M. J. Jorgenson, *J. Am. Chem. Soc.*, **91**, 6432 (1969).

35) In a rough approximation, the rotamer relationships about the sp^2–sp^3 bond of **23** or **24** (C_{7b}–C_1) are similar to those of substituted acetaldehydes or 3-substituted propenes.[42] Karabatsos described that, of the two minimum energy-tautomers, **27a** has an advantage over **28a** by 250 cal/mol when two ethyl groups are attached to the α-carbon of acetaldehyde. Further, **27a** increases its stability about 350 cal/mol by the phenyl substitution in place of ethyl group in butanal.[42] Therefore, in 2-phenylbutanal, **27a** might be estimated to be more stable (250—600 cal/mol) than **28a**. Similar trends are seen in the substituted propenes (**27b** and **28b**). In the conformers, **23c** and **24c**, because the substituents are regarded as a phenyl and a vinylmethinyl group (**29** and **30**), the steric requirement is supposed to be of the same order as the one substituted with a phenyl and an ethyl group. If we assume the conformer **23c** related to **29** is more stable and hence more populated than **24c** related to **30** and that there is little difference in steric requirement for reconversion processes of **23c** to *exo*-**1c** and of **24c** to *endo*-**1c**, the rates of ring closure might be governed mainly by the population of **23c** against that of **24c**.

Photochemical Reaction of 4-Hydroxy-diphenylamine with Polychloromethane

Tadao HINOHARA* and Kazuo AMANO

Department of Chemistry, Faculty of Engineering, Toyo University, Kuzirai, Kawagoe, Saitama 350

(Received January 16, 1982)

The main photochemical reaction of 4-hydroxy-diphenylamine (R) in the aerated cyclohexane was photocyclization. In the presence of polychloromethane (Q), however, photooxidation to *N*-phenyl-*p*-benzoquinone monoimine (PBQI) took place instead of the photocyclization. The formation of PBQI was in parallel with the quenching of fluorescence by Q, and it was proposed that both PBQI formation and fluorescence quenching by Q proceed *via* exciplex, $(R^+Q^-)^*$, which is nonfluorescent. The kinetic analysis based on this reaction mechanism gives the fluorescence quenching constant, which is in good agreement with the value obtained directly from the fluorescence quenching study. This agreement strongly supports the validity of the proposed reaction mechanism.

The electron donor and acceptor system involves the electron transfer as the deactivation process of the electronically excited state of the donor or acceptor and forms a resultant pair of radical cation and anion which participates in various types of reactions.[1] The aromatic amine and polychloromethane (Q) system can be regarded as one electron donor–acceptor system. Latowsky and Zelent have made systematic studies on the photochemistry of monophenylamines–Q systems and have pointed out that the primary process may be an electron transfer from the excited amine to Q, however, the final products were not simple enough to allow them to analyze the over-all reaction completely.[2] Diphenylamine and its *N*-substituted derivatives have been known to photocyclize to give carbazoles.[3,4] This photocyclization has been proposed to proceed *via* triplet state.[5] In the presence of Q, however, photolysis of diphenylamines furnishes a variety of products which are quite different from the photocyclization product.[6–9] These new products are considered to arise from the electron transfer from the excited amine to Q. The present authors extended the treatment to 4-substituted diphenylamines because the effect of substituent in the benzene nucleus on the photochemical path ways of diphenylamine has rarely been reported.

In this paper, the identification of the photolysis product from 4-hydroxy-diphenylamine and Q system together with the discussion on the mechanism of the reaction will be presented.

Experimental

Materials. 4-Hydroxy-diphenylamine was obtained commercially and purified by repeated recrystallization. Polychloromethanes and solvents were the spectroscopic grade reagents and were used without further purification.

Light Source and Actinometry. The high pressure mercury lamp was used with an interference filter for 313 nm light source. The intensity of the incident light was measured by the method of potassium trioxalatoferrate(III) actinometer.

Analysis. Measurement of the quantum yield of the reaction was carried out spectroscopically by monitoring the increase in characteristic absorption of the reaction product. The absorption spectra were measured by Hitachi EPS-2-model spectrophotometer and emission spectra were taken with a Hitachi MPE-3-model fluorescence spectrophotometer.

Results and Discussion

The progressive spectral changes of 4-hydroxy-diphenylamine (AH_2) in aerated cyclohexane solution caused by irradiation of 313 nm light in the absence and presence of Q are given in Fig. 1 (a) and Fig. 1 (b), respectively. The spectral changes under the absence of Q are characteristic for the well-known photocyclization. The final spectrum obtained under the presence of Q shown in Fig. 1 (b), however, is quite different from that shown in Fig. 1 (a), and is identical with that of *N*-phenyl-*p*-benzoquinone monoimine (PBQI) reported by Teuber.[10] Further confirmation of the reaction product was carried out as follows: The crude product separated from the irradiated solution was submitted to the alumina chromatography using benzene as a solvent. The red fine crystal was separated from benzene. The melting point of this crystal coincided with that reported for PBQI,[11] and the mixed melting point with the synthesized PBQI showed no depression. Since the irradiation of *p*-aminophenol in the presence of Q gave complicated reaction products other than *p*-benzoqui-

k_Q[a)]	6.0	23.5	79.2
k_Q[b)]	7.3	20	75
$1/(k_0k_1\tau)$	0.91	0.20	0.013
$k_Q/(k_0k_1\tau)$	6.6	4.0	1.0

a) Obtained from the fluorescence quenching experiment. b) Obtained from the reaction kinetics.

none monoimine, the photooxidation by Q giving benzoquinone monoimine-type product is the characteristic reaction for AH_2.

The quantum yield of PBQI formation (Φ_q) in cyclohexane increased with increasing the concentration of Q, as shown in Fig. 2. Polychloromethane acts as a quencher on the fluorescence of AH_2 and the Stern-Volmer plots give a straight line. Values of Φ_q, obtained under the condition where the concentration of Q is 0.01 mol dm^{-3}, and values of the fluorescence quenching constant (k_Q) are listed in Table 1. It may be seen in the Table that the effect of Q on PBQI formation becomes more notable as the fluorescence quenching ability of Q increases. This result suggests that the process of fluorescence quenching by Q leads to the formation of PBQI. To make sure of this assumption, the mechanism of the reaction and fluorescence quenching by Q were studied. The photochemical reaction of aromatic amine with Q has been known to result in the formation of hydrogen chloride (HCl). In the present case, the formation of HCl was confirmed from the increase in the concentration of hydrogen ion under the irradiation of AH_2–Q–ethanol–water system. Similar to the case of aniline derivatives,[2)] the following mechanism may be presented:

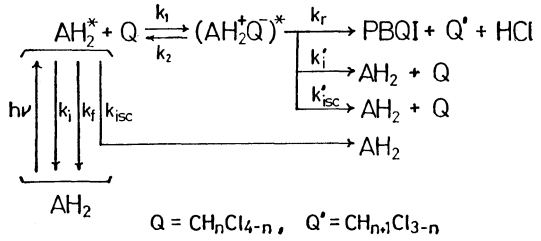
$$AH_2^* + CH_nCl_{4-n} \longrightarrow AH_2^+ + (CH_nCl_{4-n})^-, \quad (1)$$

$$AH_2^+ + (CH_nCl_{4-n})^- \longrightarrow A + CH_{n+1}Cl_{3-n} + HCl, \quad (2)$$

where AH_2^* and A are the excited AH_2 and PBQI, respectively. CH_nCl_{4-n} and $CH_{n+1}Cl_{3-n}$ denote polychloromethane, where $n=0$, 1, 2.

It has been reported that the aromatic amine forms a stable complex with Q in their ground state.[12,13)] On the other hand, Sharpe[14)] reported that the amine forms a complex with Q only in the excited state. The fluorescence spectrum of AH_2 was sensitively affected by the addition of Q, while the absorption spectrum was almost unchanged. The quantum yield (Φ_q) was found to be markedly reduced in liquid paraffin compared with that in cyclohexane, as shown in Fig. 2. These results clearly indicate that the diffusion controlled encounter process is involved in the reaction between the excited amine and Q and the role of the stable complex is not important.

The results described above can be accounted for by the following reaction scheme. Polychloromethane



Reaction scheme.

forms a exciplex, $(AH_2^+Q^-)^*$, *via* the encounter complex with the excited amine. As for the relaxation process of the exciplex, the reaction leading to PBQI (rate constant: k_r), nonradiative relaxation (k_i'), and intersystem crossing (k'_{isc}) are taken into account. The stability of the exciplex depends on the nature of Q. Using the steady state approximation, the following equations are obtained for Φ_q and Φ_f°/Φ_f:

$$\Phi_q = \frac{k_0k_1\tau[Q]}{1+k_Q[Q]}, \quad (3)$$

$$\Phi_f^\circ/\Phi_f = 1 + k_Q[Q], \quad (4)$$

where

$$k_Q = k_1\tau/(1+k_2\tau), \quad \tau = 1/(k_i+k_f+k_{isc}),$$
$$\tau' = 1/(k_i'+k_r+k'_{isc}),$$

and

$$k_0 = k_r\tau'/(1+k_2\tau).$$

Equation 3 is rewritten as follows:

$$\Phi_q^{-1} = k_Q/k_0k_1\tau + (1/k_0k_1\tau)[Q]^{-1}.$$

Then, the reciprocal of the quantum yield is expected to have a linear relation with the reciprocal of the concentration of Q. The experimental results meet with this expectation, and the value of k_Q is obtained from the intercept ($k_Q/k_0k_1\tau$) and slope ($1/k_0k_1\tau$) of the straight line. This value of k_Q can be compared with that obtained directly from the fluorescence quenching and these are summarized in Table 1. The good agreement of the values obtained by reaction kinetic analysis and by the fluorescence quenching experiment strongly supports the validity of the proposed reaction scheme.

A part of this work was carried out at Gunma University. The authors wish to thank Professor Kohji Matsui of Gunma University and Professor Ikuzo Tanaka of Tokyo Institute of Technology for their helpful discussions.

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received January 29, 1982)

Some crosslinked chelating resins were prepared and the catalytic activity of the resin–metal chelates for the oxidation of 2,6-dihydroxyphenylacetic acid(homogentisic acid) and hydroquinone was investigated. The resin–Cu(II), resin–Au(III), and resin–Ag(I) chelates had a high catalytic activity. Especially resin–Cu(II) chelate had the highest catalytic activity for these oxidation reactions, and its activity did not decrease even after repeated use. The chelating resins having hydrazide or polyethylenepolyamine side chains had a high catalytic activity. In order to have a high catalytic activity, the resin–metal chelates must leave coordination places open for the substrate to coordinate to metal in the chelates. In the oxidation of homogentisic acid, the catalytic activity of gel type resin increased with the increase of crosslinking degree in the range from 0.5% to 7.5%. However, the catalytic activity of the macroreticular chelating reins was scarcely affected by the degree of crosslinking. The oxidation reaction of homogentisic acid showed a kinetic behavior of a typical Michaelis-Menten type.

It is known that Cu(II) ion acts as a catalyst for the oxidation of organic substrates by molecular oxygen.[1,2] Pecht and coworkers reported that the binding of Cu(II) to polyhistidine enhanced the catalytic activity of Cu(II) for the oxidation of homogentisic acid and hydroquinone.[3] However, the catalytic activity of crosslinked chelating resin–metal complexes(resin–metal chelates) for the oxidation of the substrate mentioned above have never been investigated. The use of resin–metal chelates as catalysts have apparently the following advantages:

1) The resin–metal chelates can easily be separated by filtration from the products after use.

2) The resin–metal chelates can be used repeatedly many times. Therefore, if the resin–metal chelates have a high catalytic activity for the various reactions, they will be applicable to an industrial use. Many kinds of the chelating resins having thiol group, hydrazino carbonyl group, and polyethylenepolyamine side chain have been prepared in our laboratory. In this report the oxidation of homogentisic acid and hydroquinone catalyzed by resin–metal chelates was investigated.

Experimental

Preparation of Crosslinked Chelating Resins. Seven chelating ion exchange resins were used for this research. Each resin was prepared as follows, and the estimated structures of functional groups in these chelating ion exchange resins with the abbreviated symbols are shown below.

RST: The macroreticular styrene–divinylbenzene (7 mol%) copolymer beads were prepared by suspension polymerization in the presence of 2,2,4-trimethylpentane (100 vol%). The gel type syrene–divinylbenzene copolymer beads were also prepared by suspension polymerization. Abovementioned styrene–divinylbenzene copolymer beads and commercial macroreticular copolymer beads were chloromethylated with chloromethylether at 0—5 °C. The chloromethylated copolymer beads were treated with triethylenetetramine.[4]

RMH: The macroreticular methyl methacrylate–divinylbenzene copolymer beads (RM) were prepared by suspension polymerization in the presence of 2,2,4-trimethylpentane. The copolymer beads were treated with hydrazine hydrate.[5]

RMT: The macroreticular copolymer beads (RM) were treated with triethylenetetramine.[6]

RGT: The macroreticular poly(glycidyl methacrylate) beads (RG) were prepared by suspension polymerization in the presence of 2,2,4-trimethylpentane (50 vol%). The polymer beads were treated with triethylenetetramine.[7]

RGS: The macroreticular polymer beads (RG) were treated with ammonium thiocyanate, and then followed by the reaction with ethanolic potassium hydrogensulfide.[8]

The cationic exchange resin WK-11 and the chelating resin CR-10 were kindly supplied from Mitsubishi Kasei

a) RST-L, -I, -II, and -III were prepared from commercial copolymer beads. b) The former and latter numbers represent the volume percentage of divinylbenzene in the monomer mixture and the volume percentage of 2,2,4-trimethylpentane to the monomer mixture, respectively.

Kogyo Co. Ltd. The resins used in this research were macroreticular chelating resins except the resins described as gel type resin. The characterization of the resins used in this research is shown in Table 1.

Adsorption of Metal Ion on the Chelating Resins. The chelating resin (0.25 g) was weighed accurately and immersed in 50 cm^3 of an aqueous metal solution at room temperature for 96 h. The amount of metal ion adsorbed on the resins was calculated by chelatometric determination of the metal ion concentration in the supernatant.

Measurement of Anionic Exchange Capacity of Resins. The resin (OH type) (0.5 g) was weighed accurately and immersed in 100 cm^3 of a 0.1 mol dm^{-3} HCl–1 mol dm^{-3} KCl aqueous solution at room temperature for 24 h with occasional shaking. The aniohic exchange capacity was determined by titrating the concentration of hydrochloric acid in the supernatant with a 0.1 mol dm^{-3} NaOH solution.

Measurement of the Catalytic Activity. A mixture containing homogentisic acid (or hydroquinone), phosphate buffer solution (pH 7), and resin–metal chelates was placed in a 500 cm^3 three-neck flask and stirred at a revolution rate of 300 rpm at 40 °C (or 50 °C for hydroquinone). The catalytic reactions were carried out under air except the experiments described as under nitrogen. The initial concentrations of homogentisic acid and hydroquinone were controlled to 4×10^{-4} mol dm^{-3}. The rate of their oxidation was measured by the titration with ammonium cerium nitrate or spectrophotometrically at 290 nm.

Results and Discussion

Effect of the Kind of Metal Ion on the Catalytic Activity. The effect of adsorbed metal ions on the catalytic activity was investigated by use of macroreticular chelating resins at 40 °C. The amount of metal added to the reaction system was kept constant (4×10^{-4} g atom). The amounts of the resin–metal chelates added to the reaction system were different in each oxidation reaction, since the amounts of metal ions adsorbed on the resins were different. The oxidation rates of homogentisic acid are shown in Fig. 1, in which the catalytic activity decreased in the following order; RST-Cu(II) > RST-Au(III) > RST-Ag(I) > RST-Hg(II) > RST-Fe(III). RST-Ni(II) and RST-Zn(II) chelates showed scarcely the catalytic activity for the oxidation of homogentisic acid.

In the oxidation of hydroquinone, the catalytic activity decreased in the following order: RST-Au(III) > RST-Ag(I) > RST-Cu(II) > RST-Hg(II).

The RST–metal chelates which showed a high catalytic activity were used repeatedly three times. The results are shown in Fig. 2. The chelates were dried at 50 °C for 12 h after they were once used. Then they were used repeatedly as catalysts. Figure 2 shows that the catalytic activity of RST-Cu(II) chelates did not decrease, even when the chelates were used repeatedly, whereas those of RST-Au(III), RST-Ag(I), and RST-Hg(II) chelates decreased gradually, as the chelates were used repeatedly. Especially, the

extent of the decrease of the catalytic activity of RST–Ag(I) and RST–Hg(II) chelates is larger than that of RST–Au(III) chelate. During the oxidation reaction Ag(I) and Hg(II) were eluted from the chelates into the reaction solution.

Copper(II), gold(III), and mercury(II) in the resin–metal chelates which showed high catalytic activities have the coordination number of 4, while the coordination number of 2 in the reduced states. This change of the coordination number is responsible for the catalytic activity. The fact that Cu(I) forms a stable complex as well as Cu(II) is probably the reason why the catalytic activity of RST–Cu(II) chelate did not decrease, when the chelate was used repeatedly. The reason of a high catalytic activity of the RST–Ag(I) chelate is not clear yet.

Effect of the Mole Ratio of Cu(II) Adsorbed to the Ligand in Resins(Cu(II)/N) on the Catalytic Activity. Figure 3 shows the oxidation rate of homogentisic acid catalyzed by the RST–Cu(II) chelates with various Cu(II)/N ratios. The catalytic activity increased with

an increase in the Cu(II)/N ratios in the resin–metal chelates. These results suggest that, in order to have a high catalytic activity, the resin–metal chelates must leave coordination places open for the substrate to coordinate to the metal. The same results were also observed for RMT–Cu(II) and RGT–Cu(II) chelates. These results agree with those obtained by Sigel,[9] and Hatano *et al.*[10]

Effect of the Kind of Chelating Resins on the Catalytic Activity. The catalytic activity of various resin–Cu(II) chelates for the oxidation of homogentisic acid was investigated. The amounts of Cu(II) added into the reaction system are listed below Fig. 4 which revealed the highest catalytic activity of RMH–Cu(II) chelate. These resin–Cu(II) chelates were used three times. The catalytic activities of RMH–Cu(II), RST–Cu(II), WK-11–Cu(II), and CR-10–Cu(II)chelates scarcely decreased, whereas that of RGS–Cu(II) chelate decreased gradually, as these chelates were

used repeatedly. The decrease of catalytic activity of RGS-Cu(II) chelate is ascribed to the elution of Cu(II) ion from the resin-metal chelate during the oxidation reaction.

Effect of the Degree of Crosslinking of Chelating Resins on the Catalytic Activity. Firstly, the effect of the degree of crosslinking of resins on the oxidation of homogentisic acid was investigated by use of gel type resins with different degrees of crosslinking. Figure 5 shows that the catalytic activity of gel type resin-Cu(II) chelates increased with an increase in the degree of crosslinking in the range from 0.5% to 7.5%, and the catalytic activity decreased gradually, as the resin-Cu(II) chelates were used repeatedly. The anion exchange capacity and the adsorption capacity for Cu(II) ion of these resins are listed in Table 2, which shows that both these capacities decreased with an increase of the crosslinking degree, and the decrease of the adsorption capacity is larger than that of the anion exchange capacity. The adsorption capacity of highly crosslinked resins for metal ions seems to be limited by steric hindrance. From the results mentioned above, the catalytic activity increase with an increase of crosslinking degree of resins is ascribed to the fact that metals in the higher crosslinked resin-metal chelates have a larger number of coordination places for substrate than those in the lower crosslinked resin-metal chelates. Figure 6 shows the oxidation rate of homogentisic acid catalyzed by RMH-Cu(II)

Table 2. Anion exchange capacity of gel type resins and the amount of Cu(II) adsorbed with the resins

chelates with different degrees of crosslinking. In this case, the catalytic activity did not decrease with an increase in the degree of crosslinking, and the catalytic activity did not decrease after repeated use. The decrease of the catalytic activity of gel type resin-Cu(II) chelates is ascribed to the elution of Cu(II) ion from the chelates to the reaction system during the oxidation reaction. The results suggest that the macroreticular chelating resins are suitable as catalysts for the oxidation reaction.

The Effect of the Porosity of Macroreticular Chelating Resins on the Catalytic Activity. The catalytic activity of resin-Cu(II) chelates for the oxidation of homogentisic acid was investigated by use of the macroreticular chelating resin(RMT) with different porosities. The results are shown in Fig. 7. RMT with different porosities were prepared by the amination of macroreticular copolymer beads which were polymerized by varying the amount of 2,2,4-trimethylpentane in the suspension polymerization. The chelating resin prepared by use of 2,2,4-trimethylpentane (50 vol% on monomer) had the specific surface area of 4.6 m^2/g, the pore volume of 0.28 cm^3 and the average pore radius of 775 Å (Table 1), and this resin had the maximum adsorption capacity for Cu(II) ion (Fig. 7). These results suggest that the resin which was prepared under the conditions mentioned above had the most suitable pore structures for the adsorption of Cu(II) ion. The catalytic activity of this resin did not decrease, when the resin was used repeatedly. However, the catalytic activity of all other resins decreased gradually after repeated use. The reason is also ascribed to the elution of Cu(II) adsorbed because of the instability of these resin-Cu(II) chelates. Figure 8 shows the oxidation rate of homogentisic acid catalyzed by RST-Cu(II) chelates. These RST have different porosities, especially, specific surface areas (Table 1). The catalytic activity increased

5	Cu^{2+}	2.67	9.05	265.5

a) In the catalytic reaction by resin–Cu(II) chelates, Cu(II) content in the reaction system was 2×10^{-4} g atom, whereas in the catalytic reaction by Cu^{2+} only, Cu(II) content was 5×10^{-6} g atom.

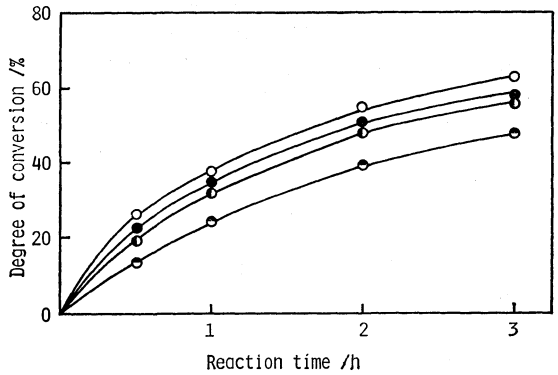

Fig. 8. Effect of the porosity of macroreticular chelating resins on the oxidation of homogentisic acid (II). Cu(II) content: 2×10^{-4} g atom, catalyst: RST–Cu(II) chelate. ○: RST-I, ●: RST-II, ◐: RST-III, ◓: RST-IV.

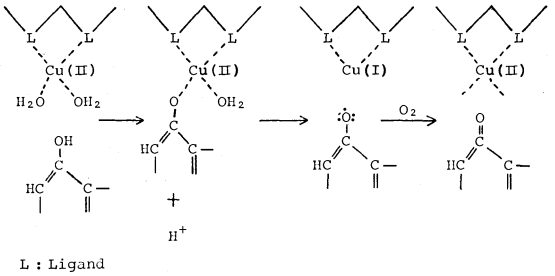
with an increase in the specific surface area of the resins and was little affected by the pore volume and average pore radius.

Kinetic Behavior of the Oxidation of Homogentisic Acid Catalyzed by Resin–Cu(II) Chelates. The catalytic activity of the RST–Cu(II) chelate for the oxidation of homogentisic acid was investigated under nitrogen, but it was not recognized. The result shows that molecular oxygen is necessary for this reaction.

The oxidation rate of homogentisic acid was observed at its various concentrations. The rate is proportional to the concentration of homogentisic acid in the lower concentrations and becomes independent of it in the higher concentrations. This is the kinetic behavior of a typical Michaelis-Menten type, which indicates the presence of a catalyst-substrate complex. These results suggest that the oxidation of homogentisic acid catalyzed by resin–Cu(II) chelates proceeds through the following mechanism which is similar to that of the oxidation of ascorbic acid catalyzed by ascorbic acid oxidase or lactose.

The plots of the reciprocal of the rate *vs.* the reciprocal of the substrate concentration gave straight lines in this oxidation reaction catalyzed by resin–Cu(II) chelates. From the intercept of each line and its slope, the specific rate for the decomposition of the reaction intermediate (k_3) and Michaelis-Menten constant (K_m) can be calculated. The data are listed in Table 3. For comparison, the results observed for Cu(II) ion are also listed in Table 3. The highest V_{max} value was observed for RST–Cu(II) chelate except the value observed for Cu(II) ion only. The lowest K_m value was observed for RMH–Cu(II) chelates. These results suggest that the oxidation rate of homogentisic acid catalyzed by RST–Cu(II) chelate is larger than that catalyzed by other resin–Cu(II) chelates and the affinity of RMH–Cu(II) chelate to the substrate is larger than that of other resin–Cu(II) chelates.



From the results mentioned above, the macroreticular resin–Cu(II) chelates were found to be suitable as catalysts for the oxidation of substrates such as homogentisic acid, hydroquinone, *etc.* and the catalytic activity of the resin–Cu(II) chelates was affected by the porosity of the resins. The macroreticular resin–Cu(II) chelates can be used repeatedly for these catalytic reactions.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 010405 from the Ministry of Education, Science and Culture.

Carbon Black as an Electron-transfer Catalyst. The Two-phase Dehydrogenation of Hydrazo Nitriles by an Aqueous Solution of Potassium Hexacyanoferrate(III), Using Carbon Black as the Catalyst

Norio Tsubokawa,* Naoki Takeda, and Yasuo Sone

Department of Applied Chemistry, Faculty of Engineering, Niigata University, Ikarashi, Niigata, Niigata 950-21

(Received February 5, 1982)

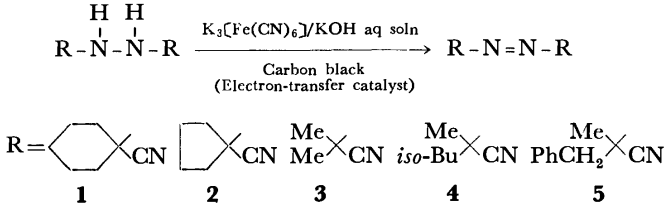
The two-phase(aqueous and organic phase) dehydrogenation of hydrazo nitriles by an aqueous solution of potassium hexacyanoferrate(III), using carbon black as the catalyst, was carried out at 40 °C with shaking. In the presence of carbon black, the two-phase dehydrogenation of hydrazo nitriles was accelerated, and the corresponding azo nitriles were obtained in good yields. The catalytic activity of channel blacks was larger than that of furnace blacks. Moreover, the increasing content of phenolic hydroxyl groups tended to increase the catalytic activity of carbon blacks. It became apparent that phenolic hydroxyl groups on the surface of carbon black act as an electron-transfer catalyst in the two-phase dehydrogenation. The reaction scheme was considered to be as follows. In the aqueous phase, phenolic hydroxyl groups on the surface are oxidized by an aqueous solution of $K_3[Fe(CN)_6]$ to give phenoxyl radicals, and then the carbon black with phenoxyl radicals is transferred into the organic phase, which contains hydrazo nitriles. Subsequently, in the organic phase, the phenoxyl radicals oxidize the hydrazo nitriles to give the corresponding azo nitriles, by which phenolic hydroxyl groups are regenerated. Thus, it was concluded that phenolic hydroxyl groups on the surface are recycled and that carbon black mediates the redox reaction occurring between aqueous and organic phases.

Recently, oxidation-reduction polymers containing 1,4-dihydronicotinamide(NAH), 2,4,5,6(1*H*,3*H*)-pyrimidinetetrone (alloxan), and 1,1'-dialkyl-4,4'-bipyridinium(viologen) moieties have been prepared, and their behavior as polymeric electron carriers has been investigated.[1] For instance, it has been reported that a polymer containing alloxan moieties mediates the redox reaction occurring between aqueous and organic phases (two-phase reaction).[1] Furthermore, it has been proved that the redox reaction between insoluble solids—two polymer beads, one containing NAH moietics and the other containing *p*-benzoquinone, was feasibly mediated by alloxan as an electron-transfer catalyst.[1,2]

On the other hand, using hindered phenols (*e.g.*, 2,4,6-triphenylphenol) as electron-transfer catalysts, the two-phase dehydrogenation of 1,2-disubstituted hydrazines in an organic solvent by means of an aqueous solution of potassium hexacyanoferrate(III) has been reported by Dimroth and Tüncher.[3]

The presence of phenolic hydroxyl groups on the surface of carbon black has been supported in the literature.[4,5] It is well known that phenolic hydroxyl groups are easily oxidized to quinonic oxygen groups or phenoxyl radicals (so-called "quinone radicals").[5,6]

In the present paper, we wish to report that, as well as hindered phenols, phenolic hydroxyl groups on the surface of carbon black act as electron-transfer catalysts in the two-phase dehydrogenation of hydrazo nitriles by means of an aqueous solution of $K_3[Fe(CN)_6]$:



1 **2** **3** **4** **5**

Experimental

Materials and Reagents. The carbon black used was of two types: furnace black and color-channel black. The furnace blacks, Philblack O (BET specific surface area; 79.6 $m^2 g^{-1}$) and Philblack I (116.8 $m^2 g^{-1}$), were dried *in vacuo* after Soxhlet extraction with benzene to remove the resinous substances present on the surface. The color-channel blacks, Carbolac 1 (839.2 $m^2 g^{-1}$), FW 200 (460 $m^2 g^{-1}$), and Neospectra II (906 $m^2 g^{-1}$), were dried *in vacuo* without extraction, because it was known that channel blacks contain no resinous substances.

The hydrazo nitriles (**1**, **2**, **3**, **4**, and **5**) were prepared by the reaction of the corresponding ketones with sodium cyanide and hydrazine sulfate according to the method of Overberger *et al.*[7-9] All of these compounds were identified by means of mp, IR, NMR, and elemental analysis.

The benzene and dichloromethane used as solvents were purified and distilled by a general method.

Guaranteed-reagent-grade $K_3[Fe(CN)_6]$ from the Tokyo Kasei Kogyo Co., Ltd., was used without further purification.

Procedure of Two-phase Dehydrogenation. A typical example was as follows.[10] A solution of 2.0 g (6.0 mmol) of $K_3[Fe(CN)_6]$ in 10.0 cm^3 of aqueous potassium hydroxide (2.0 mol dm^3) was added to a mixture of 0.5 g of carbon black and 0.5 g (2.0 mmol) of **1** in 10.0 cm^3 of benzene. The reaction mixture was then shaken at 40 °C for 6 h. After the reaction, the carbon black was filtered with suction and washed with benzene. The benzene layer was separated from the filtrate, washed with 5 times with water, and dried over sodium sulfate. The solvent was removed under reduced pressure, and the residue was recrystallized from ethanol. The yield of the corresponding azo nitriles was determined by measuring the absorbance of the adsorption maximum at 350 nm (95% ethanol) due to the azo nitriles.

Treatment of Carbon Black with Sodium Tetrahydroborate. The treatment of carbon black with $NaBH_4$ was carried out according to the method of Studebaker.[11] For instance, 2.0 g of carbon black was stirred into 50 cm^3 of an aqueous solution containing 0.2 g of $NaBH_4$ and 0.6 g of sodium

hydroxide under a nitrogen atmosphere. After reacting for 2 h at room temperature, the solution was made acidic with dilute sulfuric acid. The carbon black was subsequently filtered, washed with degassed hot water until the filtrate was neutral, and then dried *in vacuo*.

Treatment of Carbon Black with Hydrogen Peroxide. Into a mixture of 5.0 cm^3 of concentrated sulfuric acid, 50 cm^3 of glacial acetic acid, and 2.0 g of carbon black, 50 cm^3 of H_2O_2 (*ca.* 35%) was stirred drop by drop.[12,13] After the reaction for 24 h at room temperature, the carbon black was filtered, washed with water until the filtrate was neutral, and then dried *in vacuo*.

Treatment of Carbon Black with Benzoyl Peroxide. The treatment of carbon black with benzoyl peroxide (BPO) was carried out according to the method previously reported.[14] Two grams of BPO were added to a mixture of 2.0 g of carbon black and 150 cm^3 of carbon tetrachloride. In order to accelerate the oxidation of the surface of carbon black, oxygen gas was gradually bubbled into the mixture during the reaction. After a reaction for 50 h at 45 °C with stirring, the carbon black was separated by centrifugation at 10^4 rpm for 2 h. Subsequently, it was extracted with carbon tetrachloride, using a Soxhlet apparatus, for 100 h and then dried *in vacuo*.

Treatment of Carbon Black with Diazomethane. The treatment of carbon black with CH_2N_2 was carried out by a method similar to that described by Studebaker *et al.*[15] A typical example was as follows. Two grams of carbon black were stirred into 150 cm^3 of a diethyl ether solution of CH_2N_2 (*ca.* 2 wt%) at 0 °C. After a reaction for 48 h, the carbon black was filtered, washed with an absolute diethyl ether, and then dried *in vacuo*.

Results and Discussion

Two-phase Dehydrogenation of **1** *in the Presence of Carbon Black.* The two-phase dehydrogenation of **1** by an aqueous solution of $K_3[Fe(CN)_6]$ was carried out; the results are shown in Table 1. When the reaction was carried out in the absence of carbon black, 90.5% of the **1** remained unchanged (Run No. 1). Carbon black itself had no ability to dehydrogenate **1** in the absence of $K_3[Fe(CN)_6]$ (Run No. 2). However, in the presence of carbon black, **1** was dehydrogenated to the corresponding azo nitrile, 1,1′-azobis(cyclohexane-1-carbonitrile) in a good yield. Therefore, the results suggest that carbon black has a catalytic activity in the two-phase dehydrogenation of **1**.

Table 1. Two-phase dehydrogenation of **1** in the presence of carbon black

a) A 10 cm^3 portion of benzene was used as the solvent; 40 °C, 6 h. b) Isolated yield after recrystallization: 90%.

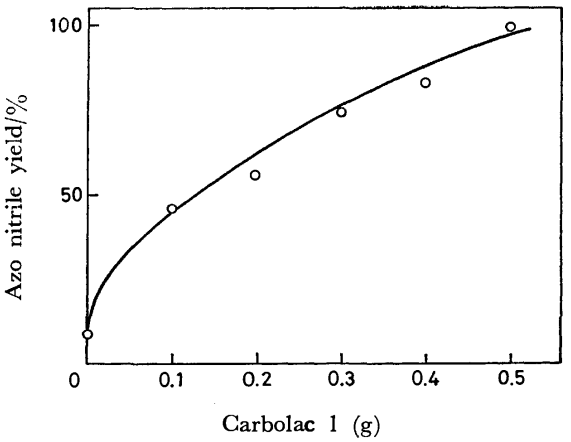

Fig. 1. The effect of the amount of Carbolac 1 on the two-phase dehydrogenation of **1**.
1 2.0 mmol, benzene 10.0 cm^3, $K_3[Fe(CN)_6]$ aq soln 10.0 cm^3; 40 °C, 6 h.

Using 2.0 mmol of **1** and various amounts of Carbolac 1, the effect of the amount of carbon black on the reaction was investigated. The results obtained are shown in Fig. 1. As is shown in Fig. 1, the reaction was accelerated with an increase in the amount of Carbolac 1.

From the above results, it may be concluded that carbon black acts as a catalyst in the two-phase dehydrogenation of **1** by an aqueous solution of $K_3[Fe(CN)_6]$.

Two-phase Dehydrogenation of Hydrazo Nitriles Using Carbolac 1 as a Catalyst. The results of the two-phase dehydrogenation of **2**, **3**, **4**, and **5** are shown in Table 2. It is found that the two-phase dehydrogenation of **2** to the corresponding azo nitrile is catalyzed by Carbolac 1 as well as that of **1**. Although **3**, **4**, and **5** were considerably oxidized to the corresponding azo nitriles by an aqueous solution of $K_3[Fe(CN)_6]$, even in the absence of carbon black, it became apparent that the two-phase dehydrogenation of these hydrazo nitriles was accelerated by Carbolac 1 and that the corresponding azo nitriles were obtained in good yields.

The azo nitriles obtained from the reaction were identified by the measurement of the mp and the IR and NMR spectra; no by-products were observed to be formed.

The preparation of azo nitriles is usually carried out by the oxidation of the corresponding hydrazo nitriles with Br_2 or nitrous acid.[7] In contrast to such oxidation, the two-phase dehydrogenation of hydrazo nitriles by an aqueous solution of $K_3[Fe(CN)_6]$, using carbon black as a catalyst, is a effective and convenient method for the preparation of azo nitriles, which are useful radical-chain initiators.

Ability of Various Kinds of Carbon Black as a Catalyst for the Two-phase Dehydrogenation. Using various kinds of carbon black, the effect of functional groups on the surface of carbon black on the two-phase dehydrogenation of **1** was studied. The results are shown in Table 3. The carbon black used was of two types:

Table 2. Two-phase dehydrogenation of hydrazo nitriles by the use of Carbolac 1 as the catalyst

a) Color-channel black. b) Furnace black.

color-channel black and furnace black. The content of the phenolic hydroxyl groups was determined using 2,2-diphenyl-1-picrylhydrazyl according to the method previously reported by us.[13] The analysis of the quinonic oxygen groups was carried out by the determination of the hydrogen uptake from a $NaBH_4$ solution according to the method of Studebaker.[11] In general, color-channel blacks contain a number of phenolic hydroxyl and quinonic oxygen groups in comparison with furnace blacks.

From the results shown in Table 3, the ability of channel blacks as catalysts for the two-phase dehydrogenation was found to be larger than that of furnace blacks. Moreover, the increasing content of phenolic hydroxyl groups tends to increase the catalytic activity of channel blacks. In addition, Dimroth *et al.* have reported that hindered phenols act as electron-transfer catalysts in the two-phase dehydrogenation of 1,2-disubstituted hydrazines.[3]

Accordingly, it is suggested that phenolic hydroxyl groups on the surface of carbon black play an important role as catalysts in the two-phase dehydrogenation.

Two-phase Dehydrogenation Catalyzed by Various Treated Carbon Blacks. In order to clarify the reaction sites on the surface of carbon black, the two-phase dehydrogenation of **1** catalyzed by carbon black treated with $NaBH_4$, H_2O_2, or BPO was compared with that catalyzed by the untreated one. The results are shown in Table 4.

It has been reported that quinonic oxygen groups on the surface of carbon black are reduced by $NaBH_4$ to give phenolic hydroxyl groups.[11] The content of phenolic hydroxyl groups on the surface of such treated Philblack O is 0.07 mequiv. g^{-1}.

Table 4. Two-phase dehydrogenation of **1** by the use of treated Philblack O as the catalyst (Treated carbon black 1.00 g, **1** 2.0 mmol, benzene 10.0 cm^3, $K_3[Fe(CN)_6]$aq soln 10.0 cm^3; 40°C, 6h.)

Philblack O	$K_3[Fe(CN)_6]$ soln (cm^3)	Azo nitrile yield/%
Untreated	—	0.6
	10	49.6
Treated with $NaBH_4$	—	0.5
	10	63.0
Treated with H_2O_2	—	10.0
	10	100
Treated with BPO	—	25.8
	10	100
Treated with BPO and then $NaBH_4$	—	1.5
	10	99.5

The results shown in Table 4 indicate that the yield of the 1,1′-azobis(cyclohexane-1-carbonitrile) is increased by the use of $NaBH_4$-treated Philblack O as a catalyst. The result suggests that the catalytic activity of carbon black in the two-phase dehydrogenation is responsible for the phenolic hydroxyl groups on the surface.

Furthermore, the catalytic activity of carbon black

in the two-phase dehydrogenation was extremely enhanced by the treatment with H_2O_2 and BPO. It is interesting to note that both H_2O_2- and BPO-treated Philblack O have the ability to oxidize **1** even in the absence of an aqueous solution of $K_3[Fe(CN)_6]$.

It has been confirmed that the pH of an aqueous slurry of furnace black changes from the basic to the acidic side and that the content of phenolic hydroxyl groups is increased by the treatment with H_2O_2.[12,13] The content of phenolic hydroxyl groups of such treated Philblack O is 0.11 mequiv. g^{-1}. Moreover, the surface of carbon black is also oxidized with H_2O_2 to give quinone radicals.

On the other hand, it has previously been reported that quinonic oxygen groups and phenoxyl radicals were easily introduced to the carbon black surface by treatment with BPO in the presence of oxygen.[14,16] In addition, it is well known that the number of unpaired electrons present on the surface of carbon black increases about 10 times when the carbon black is treated with BPO.[17] Therefore, BPO-treated Philblack O has a number of phenoxyl radicals, because it is believed that a large portion of the unpaired electrons on the surface of carbon black exists in quinone-radical forms.[6,14,16]

On the basis of the foregoing facts, it is considered that the high catalytic activity of both H_2O_2- and BPO-treated Philblack O may be due to the phenoxyl radicals formed on the surface of carbon black by the treatment. That is, phenoxyl radicals present on the surface of H_2O_2- and BPO-treated carbon black oxidize the hydrazo nitriles, by which means phenolic hydroxyl groups with the catalytic activity in the two-phase dehydrogenation are newly formed.

To confirm this, the catalytic activity of carbon black treated with BPO and then $NaBH_4$ was investigated. As is shown in Table 4, although BPO–$NaBH_4$-treated carbon black lost the ability to oxidize **1** in the absence of $K_3[Fe(CN)_6]$, the treated carbon black kept a high catalytic activity in the two-phase dehydrogenation. From these results, it is concluded that both phenolic hydroxyl groups and phenoxyl radicals on the surface catalyze the two-phase dehydrogenation.

On the other hand, using CH_2N_2-treated carbon black, the two-phase dehydrogenation of **1** was also studied; the results are shown in Table 5.

It is well known that phenolic hydroxyl groups on the surface are blocked by methylation with CH_2N_2.[14] As is shown in Table 5, the catalytic activity of the carbon black completely disappeared upon the treatment with CH_2N_2. The results also clearly show the role of phenolic hydroxyl groups as a catalyst in the two-phase dehydrogenation.

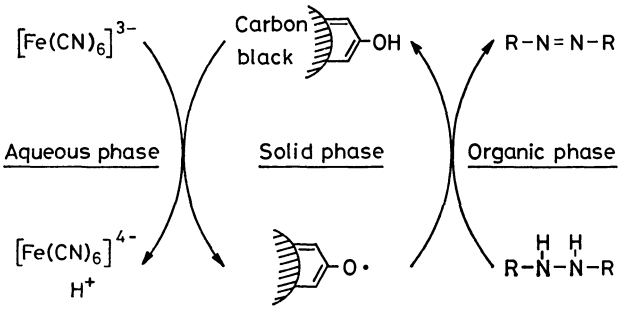
Table 5. Two-phase dehydrogenation of **1** by the use of CH_2N_2-treated carbon black as the catalyst (**1** 2.0 mmol, benzene 10.0 cm^3, $K_3[Fe(CN_6]$aq soln 10.0 cm^3; 40 °C, 6 h.)

Carbon black	(g)	Azo nitrile yield/%
CH_2N_2-treated Philblack O	1.00	0.7 (49.6) [a]
CH_2N_2-treated Carbolac 1	0.50	1.0 (99.0) [a]

a) The values in parentheses indicate the results in the presence of untreated carbon black.

Reaction Scheme of the Two-phase Dehydrogenation Catalyzed by Carbon Black. As has been mentioned above, it becomes apparent that the phenolic hydroxyl groups on the surface play an important role in the two-phase dehydrogenation. On the other hand, it is well known that phenolic hydroxyl groups on the surface are easily oxidized to quinonic oxygen groups or phenoxyl radicals("quinone radicals").[5,6,18] The phenoxyl radical formed on the surface will be stabilized by polycondensed aromatic rings of carbon black[13,16] and will have the ability to oxidize some compounds as well as 2,4,6-trisubstituted phenoxyl radicals.[3]

Therefore, the reaction scheme of the two-phase dehydrogenation using carbon black as a catalyst was considered to be as follows:



In the aqueous phase, the phenolic hydroxyl groups on the surface of carbon black will be oxidized by an aqueous solution of $K_3[Fe(CN)_6]$ to give phenoxyl radicals, and then the phenoxyl radicals will be transferred into the organic phase, where they will abstract hydrogen atoms from the hydrazo nitriles to give the corresponding azo nitriles and phenolic hydroxyl groups regenerated. That is, during the reaction, phenolic hydroxyl groups on the surface of carbon black are recycled and the carbon black mediates the electron transfer(*i.e.*, redox reaction) between aqueous and organic phases. For example, in the case of Run No. 4 in Table 1, the carbon black was recycled *ca.* 45 times.

In conclusion, it is considered that carbon black acts as an electron-transfer catalyst in the two-phase dehydrogenation.

Two-phase Dehydrogenation of 1,2-Disubstituted Hydrazines by an Aqueous Solution of $K_3[Fe(CN)_6]$ Using Carbon Black as a Catalyst. The two-phase dehydrogenation of 1,2-disubstituted hydrazines, such as hydrazobenzene and *N*-phenyl-*N'*-triphenylmethylhydrazine, was also carried out. However, the effect of carbon black as a catalyst could not be confirmed, because these hydrazines were easily dehydrogenated to the corresponding azo compounds by the use of an aqueous solution of $K_3[Fe(CN)_6]$, even in the absence of carbon black.

In addition, the two-phase dehydrogenation of 9,10-dihydroanthracene and 1,2-diphenylethane by an aqueous solution of $K_3[Fe(CN)_6]$, using carbon black as

a catalyst, was investigated at 40—90 °C. The dehydrogenation of these compounds was unsuccessful under these conditions, and the starting material was recovered unchanged.

†*Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received March 2, 1982)

Asymmetric transformation of racemic 2-phenyl- and 2-chloroalkanoic acids *via* oxazolines into the corresponding optically active acids was investigated using (*S*)-phenylalaninol as a chiral auxiliary. The asymmetric transformation was performed by metalation of the oxazolines with butyllithium followed by protonation of the resulting lithiooxazolines. 2-Phenyl- and 2-chloroalkanoic acids were obtained in the optical yields of 29—53% and 45—73%, respectively, by the acidic hydrolysis of the chiral oxazolines thus formed. The mechanism of the asymmetric transformation was discussed.

Asymmetric transformation of racemic compounds into a single optically active form remains a major challenge in organic synthesis.[1] The great majority of work on the transformation has dealt with atropisomers.[2] Recently, optical activation of racemic aldehydes or ketones *via* enamines and of racemic amino acids *via* cobalt complexes has been reported.[3]

Although preparation of optically active alkanoic acids is important,[4] the asymmetric transformation of racemic alkanoic acids into optically active form has not been reported except for amino acids.[3] Therefore, in this study the asymmetric transformation of racemic 2-substituted alkanoic acids was intended, and 2-phenyl- and 2-chloroalkanoic acids were used as examples.[5] Chiral oxazolines, which had been originally used by Meyers *et al.* for the asymmetric synthesis of carbonyl compounds, were applied for the study of this asymmetric transformation.[6]

Oxazolines **2a**—**e** were prepared by alkylation of (4*S*)-(−)-2,4-dibenzyl-2-oxazoline (**1**), and **3a**—**e** were prepared from corresponding imidates and (*S*)-phenylalaninol. After metalation of **2** and **3** with butyllithium, the resulting lithio carbanions were quenched by addition of water (Scheme 1). Subsequent hydrolysis of **2** and **3** gave optically active 2-phenyl- and 2-chloroalkanoic acids respectively. The extent of asymmetric induction in the metallation and protonation process was monitored by examining the optical rotations of the obtained acids or diastereomer ratios of the oxazolines with NMR or GLPC analysis.

*Preparation of (4S)-2-(2-Chloroalkyl)-4-benzyloxazolines **3a—e**.*

3a: Ethyl 2-chloropropionimidate hydrochloride was prepared from 2-chloropropionitrile according to the method described by McElvain and Nelson:[10] mp 90.5—91 °C; IR (Nujol) 1670 cm^{-1} (C=N). Ethyl 2-chloropropionimidate hydrochloride (8.6 g, 0.05 mol) and (*S*)-phenylalaninol (8.3 g, 0.055 mmol) was dissolved in 100 ml of dry dichloromethane and stirred for 10 h at room temperature. The reaction mixture was condensed under reduced pressure, and the residue was purified by chromatography on silica gel, and distilled to give 8.35 g (75% yield from ethyl 2-chloropropionimidate hydrochloride) of **3a**: bp 124—126 °C (200 Pa); $[\alpha]_D^{25}$ −70.7° (*c* 1.04, MeOH); IR (neat) 1662 cm^{-1} (C=N); Found: 223.0771. Calcd for $C_{12}H_{14}NOCl$: M, 223.0765.

3b: 2-Chlorobutyronitrile (10.4 g, 0.1 mol) and ethyl alcohol (5.06 g, 0.11 mol) was dissolved in 10 ml of dry ether, and dry hydrogen chloride gas was saturated. After 1 h at room temperature, the reaction mixture was condensed under reduced pressure, the residue was suspended in 150 ml of dry ether and 25 ml of triethylamine was added. Resulting white precipitate was filtered off and filtrate was concentrated. Distillation of the residue gave ethyl 2-chlorobutyrimidate (10.5 g, 70%); bp 86—88.5 °C (8665 Pa); IR (neat) 1660 cm^{-1} (C=N). Ethyl 2-chlorobutyrimidate (3.0 g, 0.02 mol) and (*S*)-phenylalaninol (3.62 g, 0.024 mol) were dissolved in 40 ml of dry dichloromethane, and to this mixture boron trifluoride etherate (0.284 g, 0.002 mol) and triethylamine (0.202 g, 0.002 mol) were added. The reaction mixture was stirred for 2 d at room temperature, and resulting white precipitate was filtered off, and filtrate was concentrated under reduced pressure. The residue was purified by chromatography on silica gel, and then distilled to give 2.85 g (60%) of **3b**: bp 133—137 °C (200 Pa); $[\alpha]_D^{25}$ −60.2° (*c* 1.01, MeOH); IR (neat) 1662 cm^{-1} (C=N); Found: *m/e* 237.0906. Calcd for $C_{13}H_{16}NOCl$: M, 237.0921.

3c: This material was prepared from ethyl 2-chlorovalerimidate according to the method described for **3b** in 65% yield: bp 136—140 °C (267 Pa); $[\alpha]_D^{25}$ −60.1° (*c* 1.02, MeOH); IR (neat) 1663 cm^{-1}; Found: *m/e* 251.1073. Calcd for $C_{14}H_{18}NOCl$: M, 251.1077.

3d: This material was prepared from ethyl 2-chlorohexanimidate hydrochloride according to the method described for **3a** in 80% yield: bp 143.5—145.5 °C (267 Pa); $[\alpha]_D^{25}$ −57.6° (*c* 1.02, MeOH); IR (neat) 1663 cm^{-1} (C=N); Found: *m/e* 265.1227. Calcd for $C_{15}H_{20}ONCl$: M, 265.1234.

3e: This material was prepared from ethyl 2-chloro-4-methylvalerimidate hydrochloride as described for **3a** in 82% yield; bp 143.5—146 °C (267 Pa); $[\alpha]_D^{25}$ −57.9° (*c* 1.02, MeOH); IR (neat) 1660 cm^{-1} (C=N); Found: *m/e* 265.1215; Calcd for $C_{15}H_{20}ONCl$: M, 265.1234.

*Hydrolysis of **2** before the Asymmetric Transformation.* **2b** (279 mg, 1 mmol) was suspended in 10 ml of 3 M (1 M=1 mol dm^{-3}) sulfuric acid and the suspension was refluxed for 4.5 h. The acidic solution was extracted with ether, and the ethereal solution was extracted with 5% aqueous potassium carbonate. The alkaline solution was acidified (pH 1) with hydrochloric acid, and extracted with ether. The ethereal solution was dried and concentrated, and the residue was distilled (bulb to bulb: 145—155 °C (bath temperature) (200 Pa)) to give 151 mg (92%) of (*S*)-(+)-2-phenylbutyric acid. The 2-phenylalkanoic acids (Table 1) were obtained as described above and the structures of the compounds were identified by their IR, Mass, and ^1H NMR spectra.

*Hydrolysis of **2** after the Asymmetric Transformation.* Under an argon atmosphere, **2b** (279 mg, 1 mmol) in 1 ml of dry tetrahydrofuran was cooled to −78 °C, and 0.86 ml of butyllithium (1.4 M solution) in hexane was added dropwise. The mixture was stirred for 45 min at −78 °C, and then 50% aqueous tetrahydrofuran was added at this temperature. The mixture was allowed to warm to room temperature, and the oxazoline was extracted with ether. This oxazoline was hydrolyzed as described above, and 122 mg (74%) of (*S*)-(−)-2-phenylbutyric acid was obtained. The 2-phenylalkanoic acids (Table 2) were obtained as described above.

*Hydrolysis of **3** before the Asymmetric Transformation.* **3b** (713 mg, 3 mmol) was suspended in 30 ml of 1 M hydrochloric acid and the suspension was kept at 80 °C for 1.5 h under stirring. The acidic solution was treated as described for **2b**, and 300 mg (82%) of (*R*)-(+)-2-chlorobutyric acid was isolated. The 2-chloroalkanoic acids (Table 3) were obtained as described above and the structures of the compounds were identified by their IR, MS, and ^1H NMR spectra.

*Hydrolysis of **3** after the Asymmetric Transformation.* **3b** (713 mg, 3 mmol) was dissolved in 3 ml of dry tetrahydrofuran and the solution was cooled to −78 °C under an argon atmosphere. To the solution, 2.77 ml of butyllithium (1.3 M solution) in hexane was added dropwise, and the mixture was stirred at −78 °C. After 45 min, 3 ml of 25% aqueous tetrahydrofuran was added to the mixture and the oxazoline

a) Optical purities were based upon the highest literature values available (see Table 3). b) The diastereomeric compositions of **3c—e** suggested that the optical purities of the obtained acids were lower than the calculated values. c) The diastereomeric composition was determined by ^1H NMR analysis. d) The diastereomeric composition was determined by GLPC analysis.

was extracted with ether. This oxazoline was hydrolyzed as described above, and 266 mg (72%) of (*R*)-(+)-2-chlorobutyric acid was isolated. The 2-chloroalkanoic acids (Table 4) were obtained as described above.

*Measurement of Diastereomeric Composition of **3** after the Asymmetric Transformation.* **3a** (112 mg, 0.5 mmol) was dissolved in 0.5 ml of dry tetrahydrofuran and the solution was cooled to −78 °C under an argon atmosphere. To the solution 0.5 ml of butyllithium (1.2 M solution) in hexane was added dropwise and the mixture was stirred at −78 °C. After 45 min, 0.5 ml of 25% aqueous tetrahydrofuran was added to the mixture and the oxazoline was extracted with ether. The ethereal solution was dried over Na_2SO_4 and concentrated under reduced pressure. **3b—e** were treated as described above, and the ratios of the diastereomers of **3a** and **3b** were calculated from their ^1H NMR spectra, and those of **3c—e** were estimated by peak area measurement of the GLPC (column: OV-101 0.27 mm × 50 m, temperature 100—240 °C).

*Mutarotation of **3d**.* **3d** (2.66 g, 10 mmol) was treated with 12 mmol of butyllithium in the same manner as described for the asymmetric transformation of **3b**, and then the prepared carbanion was quenched by addition of water. The product was purified with chromatography on silica gel (dichloromethane) to give 2.39 g (90%) of epimerized **3d**: $[\alpha]_D^{25}$ −46.4° (*c* 1.03, MeOH). This epimerized **3d** (1.33 g, 5 mmol) was dissolved in 50 ml of 2 M KOH–MeOH solution, and the solution was kept at 25 °C. An aliquot of the solution was used for the measurement of the mutarotation at 589 nm at 25 °C. Just after the preparation of the alkaline solution, 20 ml of the solution was removed and diluted with 200 ml of water. This solution was saturated

with NaCl, and **3d** was extracted with ether. **3d** was hydrolyzed as described for **3b** to give 156 mg (52%) of (*R*)-(+)-2-chlorohexanoic acid. After 24 h, 20 ml of the alkaline solution was treated as described above to give 161 mg (53%) of (*S*)-(−)-2-chlorohexanoic acid.

The Effect of Temperature in the Asymmetric Transformation of 2b. Under an argon atmosphere, 55.8 mg (0.2 mmol) of **2b** in 0.2 ml of dry tetrahydrofuran was cooled to −78 °C, and 0.17 ml of butyllithium (1.4 M solution) in hexane was added dropwise. Each carbanion solution, thus prepared, was stirred for 45 min at temperatures of 0, −20, −40, −60, and −78 °C. Then, water was added to the solutions at the temperatures, and the solutions were extracted with ether. The ether extracts were washed with brine, dried, and evaporated to give **2b**. The ratios of two diastereomers of **2b** were determined by peak area measurements of methyl peaks of the diastereomers in the ^{1}H NMR spectra.

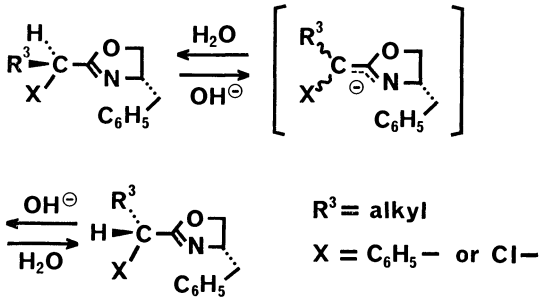
Results and Discussion

Asymmetric Transformation of 2. Hydrolysis of **2a—e** after the asymmetric transformation gave the corresponding acids in the optical yields of 29—53% as shown in Table 2. Because **2a—e** were prepared by alkylation of the chiral oxazoline (**1**), asymmetric induction by this alkylation step was possible. Hydrolysis of **2a—e** before the asymmetric transformation gave the corresponding optically active acids in the optical yields of 2—18% (Table 1). The results shown in Tables 1 and 2 indicate that the asymmetric induction is attributable to the asymmetric transformation, and not to the alkylation step.

Asymmetric Transformation of 3. In preliminary expeiments, racemization of optically active 2-chloroalkanoic acids under the hydrolysis conditions of **2** (3 M sulfuric acid, reflux 4.5 h) was observed. Therefore, weaker acid (1 M hydrochloric acid) and lower heating temperature (80 °C) were employed for the hydrolysis of **3**. **3a—c** were hydrolyzed for 1.5 h, and in the case of **3d** and **3e**, hydrolysis were prolonged to 4.5 and 6 h respectively because of low hydrolysis yields. Hydrolysis of **3** (**3a—c** 1.5 h, **3d** 4.5 h, **3e** 6 h) before the asymmetric transformation gave the corresponding acids in the optical yields of less than 5%.

Hydrolysis of **3** after the asymmetric transformation gave the corresponding acids in the optical yields of 45—73% (Table 4). The results shown in Tables 3 and 4 indicate that the asymmetric induction is definitely due to the transformation. The optical purities of the acids were calculated based upon the highest literature values available, but there was some doubt that the optical purities of the compared data were insufficient from the preparation methods described in the literatures. Therefore, the diastereomeric composition of **3a—e** after the asymmetric transformation was measured by ^{1}H NMR or GLPC. The results are listed also in Table 4. Although the calculated optical purities of **3a** and **3b** correspond to the diastereomeric compositions, the calculated optical purities of **3c—e** disagree with the compositions of **3c—e**. From the diastereomeric compositions of **3c—e**, the enantiomeric purities of **3c—e** are expected to be about 50%. Asymmetric synthesis of 2-chloroalkanoic acids *via* chiral oxazolines was reported by Meyers *et al.*, and in their synthesis, the 2-chloroalkanoic acids corresponding to **3a**, **3b**, and **3d** were prepared in the optical yields of 3—28%.[11] It is noteworthy that in the present transformation, using simple chiral auxiliary (*S*)-phenylalaninol, 2-chloroalkanoic acids can be obtained in fairly good optical purities compared with the Meyers' asymmetric synthesis.

Mutarotation. One possible mechanism of this asymmetric transformation is a base catalyzed epimerization governed by thermodynamic control as illustrated in Scheme 2. To examine whether this asymmetric transformation was governed by the thermodynamic control or not, the mutarotation of **3d** was measured. **3d** was treated with butyllithium followed by addition of water to give epimerized **3d**. This epimerized **3d** was dissolved in an alkaline solution (2 M KOH–MeOH), and optical rotation of **3d** was recorded. If the asymmetric induction had been governed by the thermodynamic control, optical rotation of this epimerized **3d** was not expected to change. However, as shown in Fig. 1 mutarotation of the epi-



Scheme 2.

Table 5. Hydrolysis of **3d** before and after the equilibrium

Mutarotation t/h	$[\alpha]_D^{25}$ (CH_3OH) / 10^4 degree ml g^{-1} dm^{-1}	Optical[a] purity / %	Absolute configuration
0	+7.63 (*c* 5.14)	65.2	*R*
24	−0.87 (*c* 5.07)	7.4	*S*

a) Optical purities were based upon the highest literature values available (See Table 3).

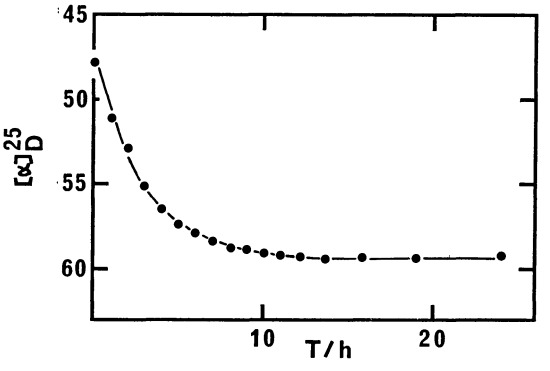


Fig. 1. Mutarotation of **3d** (0.1 M) in 2 M KOH–MeOH at 25 °C.

merized **3d** was observed. The optical rotation did not change after 12 h indicating that the epimerization attained equilibrium under the conditions. Two aliquots of **3d**, which were taken from the alkaline solution at 0 and 24 h, were hydrolyzed to give 2-chlorohexanoic acid. Specific rotations of the acid at 0 and 24 h are shown in Table 5. Under the epimerization conditions, the contribution of asymmetric induction governed by thermodynamic control is revealed to be small in the asymmetric transformation.

Isotopic Labeling Study. When butyllithium solution was added to the solutions of **2** or **3**, the reaction mixture became yellow suggesting the formation of lithio carbanion (**4**). The formation of the carbanion was confirmed by quenching the carbanion using deuterium oxide. After the treatment described above, exo methine proton of the oxazoline ring of **2** and **3** was shown from ^{1}H NMR spectra to be substituted by deuterium. The extent of deuterium incorporation to **2** and **3** was calculated from their mass spectra to be 90—98% and 80—90%, respectively. These results indicate that this asymmetric transformation proceeds through the formation of lithio carbanion (**4**), and subsequent protonation of the carbanion.

Effects of Temperature. The effects of temperature on the asymmetric transformation was examined using **2b**. Lithio carbanion of **2b** was prepared in tetrahydrofuran at −78 °C using butyllithium. Each anion solution, thus prepared, was stirred for 45 min at temperatures of 0, −20, −40, −60, and −78 °C, and then quenched with water. The ratios of two diastereomers of **2b** were determined by ^{1}H NMR spectra. The results are summarized in Table 6. The ratios are not affected by temperature.

Table 6. The effects of temperature on the asymmetric transformation

Temperature °C	Diastereomeric composition
0	72 : 28
−20	71 : 29
−40	72 : 28
−60	70 : 30
−78	71 : 29

Possible Mechanisms of Asymmetric Transformation. On the basis of the results presented above, this asymmetric transformation is assumed to proceed through stereoselective formation of lithio carbanion and protonation to the carbanion. Observation that there are virtually no effects of temperature on the extent of asymmetric induction suggested that both the ratios of the isomeric anions **4a** and **4b**, and stereoselectivity of protonation to the anions are not changed between −78 and 0 °C. According to the chiralities of the obtained 2-substituted alkanoic acids, two mechanisms (A) and (B) are probable to accommodate this asymmetric transformation and they are illustrated in Scheme 3.[12] In mechanism (A) isomeric lithiooxazoline **4a** predominates over **4b** and protonation occurs from the bottom side of the oxazoline ring. As shown in mechanism (B), a reversal of the predominant isomeric anions and a reversal of the direction of protonation gave the same result indicated in the mechanism (A). Although mechanism (A) is supported by lithium–arene π coordination effect,[13] no evidence to exclude mechanism (B) is available at present. To establish the mechanism for this asymmetric transformation further investigation is now in progress.

The Fusion Synthesis of Aryl 1-Thioglycosides

Toshisada SHIMADATE,* Sachiyo CHIBA, Kazuko INOUYE,
Teruhiko IINO, and Yoshiyuki HOSOYAMA
Department of Chemistry, Nihon University, Sakurajosui-3, Setagaya-ku, Tokyo 156
(Received March 10, 1982)

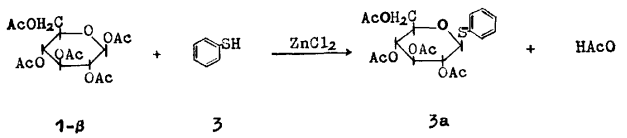
A simple method for the preparation of aryl 1-thioglycosides is described. The reaction of D-glucose pentaacetate or 2-acetamido-2-deoxy-D-glucose tetraacetate with arenethiols in the presence of zinc chloride under fusion conditions formed their 1-thioglycosides in good yields. Some Lewis acids in addition to zinc chloride were studied as catalysts in the reaction.

The Helferich method was applied successfully to the preparation of aryl 1-thioglycosides from sugar acetates with arenethiols.

The method is known as a simple and general procedure for the synthesis of aryl glycosides; it consists of fusing a sugar carboxylate and a phenol in the presence of an acid catalyst. The first extension of the method to the preparation of aryl 1-thioglycosides was attempted by Hurd and Bonner, who obtained phenyl 2,3,4,6-tetra-*O*-acetyl-1-thio-*β*-D-glucopyranoside (**3a**) from 1,2,3,4,6-penta-*O*-acetyl-*β*-D-glucopyranose (**1-β**) and benzenethiol (**3**) with a *p*-toluenesulfonic acid or zinc chloride catalyst.[1] However, the yield of the product (**3a**) was very low. After that, in order to improve the yields, this acid-catalyzed condensation of sugar carboxylates with arenethiols has been performed on a solution using inert solvents; the method is considered to be a modification of the fusion synthesis.[2,3]

In the present work, we studied the condensation of D-glucose pentaacetate or 2-acetamido-2-deoxy-D-glucose tetraacetate with several arenethiols by the Helferich method, under fusion conditions and at much higher temperature than those shown in Hurd and Bonner's report,[1] and found that this simple procedure was superior to any other synthetic methods in the yields of products.

Thus, **1-β** was treated with **3** on fusion in the presence of zinc chloride to prepare a crystalline product which was identified with an authentic **3a**.[2] According to the GLC analysis of the reaction product, a small quantity of the 1-thio-*α*-glycoside (**3a-α**) was contained in **3a**, but it was too small to isolate by a



1-β 3 3a

usual procedure using PLC silica-gel plates.[2] The reaction conditions, yield, and physical and analytical data of **3a** are shown in Table 1.

1,2,3,4,6-Penta-*O*-acetyl-*α*-D-glucopyranose (**1-α**) was also fused with **3** and a zinc chloride catalyst under similar conditions; the same product (**3a**) was thus obtained in a high yield, together with a small quantity of the 1-thio-*α*-glycoside (**3a-α**), which was confirmed by comparing its physical data with those in the literature.[4]

Several arenethiols besides **3** were allowed to react with **1-β** and a zinc chloride catalyst under similar fusion conditions; *p*-chlorobenzenethiol (**4**), *o*-tolylthiol (**5**), *m*-tolylthiol (**6**), *p*-tolylthiol (**7**), *p*-*t*-butylbenzenethiol (**8**), and 2-naphthalenethiol (**9**).

The condensation products of **1-β** with **4**, **5**, **7**, and **9** were identified as *p*-chlorophenyl, *o*-tolyl, *p*-tolyl, and 2-naphthyl 2,3,4,6-tetra-*O*-acetyl-1-thio-*β*-D-glucopyranoside (**4a**, **5a**, **7a**, and **9a**) respectively by comparing their physical data with those of the corresponding 1-thio-*β*-D-glucosides in the literature.[5-7] Also, the reaction products of **1-β** with **6** and **8** were confirmed to be *m*-tolyl and *p*-*t*-butylphenyl 2,3,4,6-tetra-*O*-acetyl-1-thio-*β*-D-glucopyranoside (**6a** and **8a**) respectively on the basis of their physical and analytical data, which are summarized in Table 1.

1,3,4,6-Tetra-*O*-acetyl-2-acetamido-2-deoxy-*α*-D-glucopyranose (**2-α**)[8] and its *β*-anomer (**2-β**)[9,10] were also treated with **3** and the same catalyst on fusion to form an identical product, phenyl 3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-1-thio-*β*-D-glucopyranoside (**3b**),[11] which was confirmed on the basis of its physical and analytical data, in good yields, but the 1-thio-*α*-glycoside was not found among those reaction products.

Similarly, the fusion reactions of **2-α** with the arenethiols, **4**, **5**, **6**, **7**, **8**, and **9**, gave their 1-thioglycosides, which were confirmed to be *p*-chlorophenyl, *o*-tolyl, *m*-tolyl, *p*-tolyl, *p*-*t*-butylphenyl, and 2-naphthyl 3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-1-thio-*β*-D-glucopyranoside (**4b**, **5b**, **6b**, **7b**, **8b**, and **9b**) respectively on the basis of their physical and analytical data, as is summarized in Table 1.

Several Lewis acids in addition to zinc chloride were studied as catalysts in the reactions of **3** with **1-α**, **1-β**, **2-α**, and **2-β** under definite conditions, as is shown in Table 2. Tin(II), tin(IV), and iron(III) chloride are effective as well as zinc chloride, although iron(III) chloride in the reaction with an *α*-acetate (**1-α** or **2-α**) is a little inferior to the others. On the contrary, *p*-toluenesulfonic acid, phosphoryl chloride, and boron trifluoride, which are used often in the Helferich method, did not give good results in the present work.

In the Helferich reaction with simple phenols, the formation of *β*-glycosides was noted when *p*-toluenesulfonic acid, phosphoryl chloride, or tin(IV) chloride was utilized as the catalyst, whereas zinc chloride favored the formation of the *α*-anomers. However, the reaction with arenethiols is always favorable for the formation of 1-thio-*β*-glycosides, regardless of the catalyst.

a) A sugar acetate (**1-β** or **2-α**, 10 mmol), an arenethiol (13 mmol), and $ZnCl_2$ (*ca.* 0.05 g) were used. b) Other signals were commonly observed as follows: on **3a-9a**, δ=1.37 (9H, s, *t*-butyl), 2.00—2.10 (12H, 4×CH_3CO), 2.36 (3H, s, CH_3), 3.76—3.80 (1H, m, H-5), 4.20—4.30 (2H, oct, H-6,6′), 4.76—5.40 (3H, m, H-2, H-3, H-4), 7.00—8.00 (Aromatic H), on **3b-9b**, δ=1.37 (9H, s, *t*-butyl), 1.95—2.05 (12H, 4×CH_3CO), 3.70—3.80 (1H, m, H-5), 3.95—4.20 (3H, m, H-2, H-6,6′), 4.85—5.50 (2H, m, H-3, H-4), 5.85—6.60 (1H, d, NH), 7.00—8.00 (Aromatic H).

Table 2. Reaction of sugar acetates with benzenethiol in the presence of acid catalysts

Sugar acetate[a]	Reaction temp/°C[b]	Compound	Yield/%			
			$ZnCl_2$	$SnCl_2$	$SnCl_4$	$FeCl_3$
1-α	160	**3a**	73	67	50	37
		3a-α	4			
1-β	160	**3a**	80	75	52	61
2-α	175	**3b**	66	61	45	40
2-β	175	**3b**	68	59	47	52

a) A sugar acetate (10 mmol), benzenethiol (13 mmol), and an acid catalyst (*ca.* 0.05 g) were used. b) The reaction time was 60 min.

Experimental

All the melting points are uncorrected. The ^1H NMR spectra were measured with a JMN-4H-100 Spectrometer Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard. The GLC analyses were performed with a JGC-20 KFP model (Japan Electron Optics Laboratory Co., Ltd.). A 2-m analytical column with 30% Silicone GE-SE 30 was used.

*Preparation of Aryl 1-Thioglycosides (**3a**, **4a**, **5a**, **6a**, **7a**, **8a**, **9a**, **3b**, **4b**, **5b**, **6b**, **7b**, **8b**, and **9b**) Listed in Table 1.* A mixture of a sugar acetate (**1-β** or **2-α**; 10 mmol) and an arenethiol (**3**, **4**, **5**, **6**, **7**, **8**, or **9**; 13 mmol) was heated in an oil bath at the temperature shown in the second column in Table 1. After a few minutes, a catalytic amount of freshly fused and powdered zinc chloride (*ca.* 0.05 g) was stirred into the melt. The temperature of the oil bath was kept for the period given in Table 1. Then, the resulting colored melt was cooled and dissolved in ethanol (*ca.* 50 ml). After cooling in a freezer, the crystalline product was collected and recrystallized from ethanol. The yields and physical and analytical data of all the products are summarized in Table 1.

The melting point of **3a** was not depressed upon admixture with an authentic sample.[2] The products, **4a**, **5a**, **7a**, and **9a**, were confirmed by comparing their melting points and specific rotation values with those in the literature.[5-7] The other products, **6a**, **8a**, **3b**, **4b**, **5b**, **6b**, **7b**, **8b**, and **9b**, were confirmed on the basis of their analytical and NMR data, in which the signals of anomeric protons were observed at 4.68—4.94 ppm as a doublet, J=9.5—9.8 Hz, and on the basis of their specific rotation values, which were negative and not very different from each other.

Examination of Lewis Acids (Zinc Chloride, Tin(II) Chloride, Tin(IV) Chloride, and Iron(III) Chloride) in Table 2 as Catalysts. The Lewis acids were utilized as catalysts in the fusion reactions between **3** (13 mmol) and four sugar acetates (**1-α**, **1-β**, **2-α**, and **2-β**; 10 mmol). These reactions were performed under the definite conditions shown in Table 2, according to the procedure described above. Among them, the reaction of **1-α** with **3** in the presence of zinc chloride yielded a small amount of **3a-α** in addition to **3a** in the following manner. After the reaction mixture was fused, the resulting melt was dissolved in ethanol (*ca.* 50 ml), cooled, and filtered to obtain a crude crystalline product. It was recrystallized from ethanol to give **3a** (3.20 g, 73%). The mother liquor, which on GLC (the column was at 200 °C, and the carrier N_2 was 45 ml/min) showed two peaks, one appearing immediately after the other (corresponding to **3a**), was evaporated till *ca.* 20 ml under reduced pressure and then cooled. The colorless needles thus obtained were recrystallized from ethanol to yield **3a-α** (0.20 g, 4%), which, on GLC under the same conditions as above, showed just one peak; mp 90—91 °C, $[\alpha]_D^{20}$ +235° (*c* 0.52, $CHCl_3$), (lit,[4] mp 91—92 °C, $[\alpha]_D^{20}$ +234° (*c* 1, $CHCl_3$)). ^1H NMR ($CDCl_3$), δ=2.00—2.12 (12H, 4×CH_3CO), 4.20 (2H, oct, H-6,6′), 4.60 (1H, m, H-5), 5.02—5.22 (2H, m, H-2, H-4), 5.50 (1H, t, H-3), 5.97 (1H, d, anomeric H, J=5.5 Hz), 7.25—7.60 (5H, aromatic H). Found: C, 54.72; H, 5.30; S, 7.40%. Calcd for $C_{20}H_{24}O_9S$: C, 54.54; H, 5.49; S, 7.28%.

The authors wish to express their thanks to Professor Juji Yoshimura of the Tokyo Institute of Technology and the staff in his laboratory for their kind help in getting some of the NMR spectra.

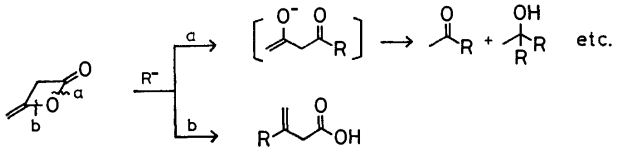
(Received March 23, 1982)

Primary alkyl Grignard reagents react regioselectively with diketene in the presence of cobalt(II) iodide to afford 3-methylenealkanoic acids in good yields. The synthetic utility of this reaction is demonstrated in the syntheses of terpenoids by two methods. Utilizing the isomerization of double bond of 3-methylenealkanoic acids, geranic acid and farnesic acid were obtained in two steps. Another method, the tandem [3,3] sigmatropic rearrangement of the corresponding allylic esters was used for the synthesis of C_{18}-Cecropia juvenile hormone.

Regioselective ring-opening reaction of β-propiolactones with diorganocuprates[1] or with Grignard reagents in the presence of copper(I) salt[2] has been previously shown to be a useful synthetic method of β-substituted propionic acids. This three carbon homologation terminated with a carboxyl group provided a convenient procedure for the syntheses of various natural products.[3,4] Especially, β-methyl-β-propiolactone is a useful building block in the terpene synthesis,[4] *i.e.* geraniol was derived by the introduction of double bond into α,β-position of the ester of 3,7-dimethyl-6-octenoic acid (citronellic acid), which was obtained from β-methyl-β-propiolactone and homoprenyl Grignard reagent, followed by the reduction with $LiAlH_4$.[4a] On the other hand, diketene (**1**) possesses not only the same carbon skeleton but also a carbon-carbon double bond. If the regioselective alkylation at the β-position of **1** is possible in a similar manner as β-methyl-β-propiolactone, it will provide a convenient method for the synthesis of 3-methylenealkanoic acids, and **1** will be employed as a C_4 unit of various terpenes involving double bond(s).

3-Methylenealkanoic acid derivatives have been reported as important precursors or intermediates for synthesis of several terpenoids.[5-8] 3-Methylenealkanoic acids have been synthesized by tedious routes *i.e.* the isomerization of the corresponding crotonic acid derivatives[5,9] the oxidation of homoallylic alcohol derivatives[7a] or the carboxylation of methallyl Grignard reagents.[10]

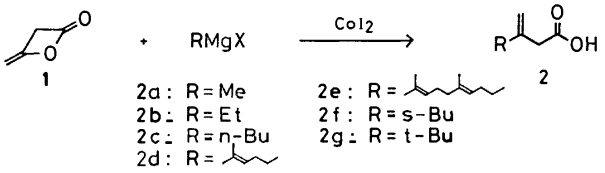
There were the enormous literatures[11] on **1**. Nevertheless, a few reports have been published on the reaction with organometallic reagents leading to a carbon-carbon bond formation.[12] Grignard reagents react with **1** to give carbonyl carbon-oxygen bond cleavage products such as methyl ketones, 1,1-disubstituted ethanol derivatives and dehydroacetic acid in low yields.[12a,b,13] On the other hand, only one example of selective β-carbon-oxygen bond fission of **1** by organometallic reagent has been reported: the reaction



Scheme 1.

of trimethylsilylmethyl Grignard reagent in the presence of nickel(II) chloride as a catalyst to afford 3-trimethylsilyl-3-butenoic acid.[12c] Thus, the catalyzed reaction of **1** with general Grignard reagents, which seems to be more useful, was explored.

The investigations were undertaken by surveying the reaction of **1** with Grignard reagents in the presence of various metal salts (10 mol%). When butylmagnesium bromide was added into a mixture of **1** and various metal halides in ether or THF at −78 °C and stirred for 6 h at the same temperature, the yield of 3-methyleneheptanoic acid (**2c**), produced by β-carbon-oxygen bond fission of **1** was listed in Table 1. Cobalt(II) iodide was found to be the best catalyst.



Scheme 2.

Further, solvent effects were examined in the same conditions as shown in Table 1. 3-Methyleneheptanoic acid (**2c**) was obtained in the best yield of 66% by the use of cobalt(II) iodide in ether. Inverse addition of **1** into a mixture of butylmagnesium bromide and the catalyst decreased the yield (23%). The reaction was influenced by the halide ion of Grignard reagents, and butylmagnesium chloride, bromide, and iodide gave **2c** in 58, 66, and 39% yields, respectively. The results of the reaction of several representative Grignard reagents with **1** were shown in Table 2.

TABLE 1. REACTION OF DIKETENE WITH BUTYLMAGNESIUM BROMIDE IN THE PRESENCE OF METAL SALTS (10 mol%) AT −78 °C, 6 h

MX′	Solvent	Yield %	MX′	Solvent	Yield %
CuI	THF	1	$CoBr_2$	Et_2O	8
NiI_2	Et_2O	2	CoI_2	Et_2O	66
FeI_2	Et_2O	42	CoI_2	THF	56
$Fe(acac)_3$	THF	38	CoI_2	THF-HMPA (12 : 1)	16
$Co(acac)_3$	THF	54	CoI_2	Toluene	28
$CoCl_2$	Et_2O	1	CoI_2	CH_2Cl_2	3

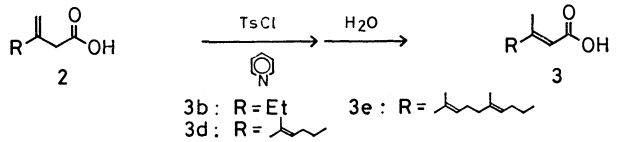
Table 2. Reaction of diketene with Grignard reagents[a)]

	RMgX	Time/h	Product **2**	Yield/%[b)]
a	MeMgBr	3		84
b	EtMgBr	6		65
c	*n*-BuMgBr	6		66
d		6		52
e		6		53[c)]
f	*s*-BuMgCl	6		8
g	*t*-BuMgCl	6		6

a) The reaction was carried out in ether at −78 °C in the presence of CoI_2 (10 mol%). b) Isolated yields by distillation. c) Isolated yield by TLC.

Primary alkyl Grignard reagents gave the corresponding acids **2** in good yields, whereas secondary and tertiary alkyl ones gave the desired acids in only a small amount. Phenyl, vinyl, and allyl Grignard reagents gave only polymeric products without the desired acids.

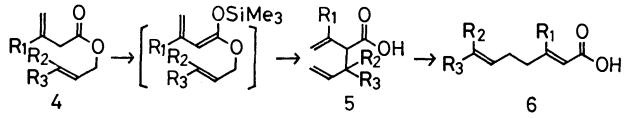
Next, the application to the synthesis of terpenoic carboxylic acids utilizing the ring-opening reaction of **1** followed by some simple transformation of 3-methylenealkanoic acid was attempted. The β,γ-unsaturated acids **2** obtained by the reaction can be isomerized successfully to α,β-unsaturated acids (**3**) by the treatment with *p*-toluenesulfonyl chloride in pyridine at 30 °C for 1 h and then water (Table 3). For example,



Scheme 3.

3,7-dimethyl-2,6-octadienoic acid (geranic acid) (**3d**)[8,14] and 3,7,11-trimethyl-2,6,10-dodecatrienoic acid (farnesic acid) (**3e**) were obtained in good yields by the reaction of **1** with homoprenyl- and homogeranylmagnesium bromide, followed by the isomerization of the double bond of 7-methyl-3-methylene-6-octenoic acid (isogeranic acid) (**2d**) and 7,11-dimethyl-3-methylene-6,10-dodecadienoic acid (isofarnesic acid) (**2e**).

In addition, 3-methylenealkanoic acids can be subjected to further carbon chain homologation by the tandem [3,3] sigmatropic rearrangement of the corresponding allylic ester. For example, 3-methyl-3-butenoic acid (**2a**) produced by the reaction of **1** with methylmagnesium bromide can be used for a building block of a C_5 unit to form a terpene chain. The tandem [3,3] sigmatropic rearrangement of allyl 3-methylenealkanoate is performed as follows. The Claisen rearrangement of trimethylsilylketene acetal,[15] which was obtained by treating the allylic esters (**4**) with lithium *N*-isopropylcyclohexylamide and trimethylsilyl chloride, produced the dienoic acid (**5**), which was subsequently converted into the dienoic acid (**6**) by the Cope rearrangement. For example, the Claisen



Scheme 4.

rearrangement of prenyl 3-methyl-3-butenoate (**4**; R_1, R_2,R_3=Me) *via* trimethylsilylketene acetal in THF at 67 °C for 3 h gave the dienoic acid (**5**; R_1,R_2,R_3=Me), in sequence, geranic acid (**3d**) was obtained in a yield

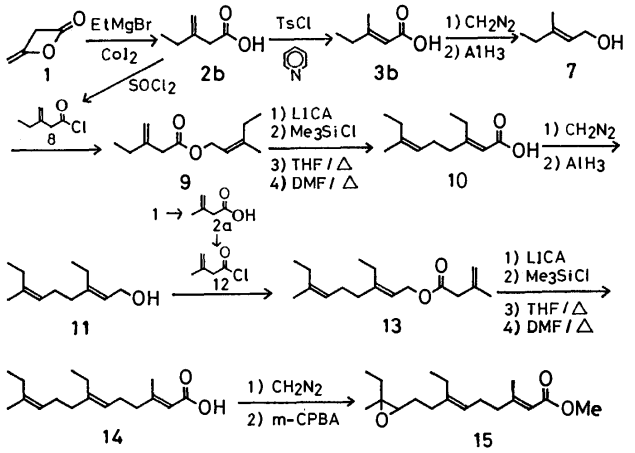
Table 3. Isomerization of 3-methylenealkanoic acid (**2**)

Acid **2**	Product **3**	Yield/%	
	 (**3b**)	80	*E*:*Z*=67:33
	 (**3d**)	95	*E*:*Z*=66:34
 a)	(**3e**)	86	*EE*:*EZ*:*ZE*:*ZZ*=47:17:27:9

a) Homogeranyl bromide (*E*:*Z*=75:25) was used as a starting material.

of 81% (*E*:*Z*=49:51) by the Cope rearrangement of **5** in DMF at 156 °C for 2 h. The tandem [3,3] sigmatropic rearrangement of geranyl 3-methyl-3-butenoate (**4e**; R_1,R_2=Me, R_3=Homoprenyl), afforded farnesic acid (**3e**) in 63% yield (*EE*:*EZ*:*ZE*:*ZZ*=36:13:20:31). It should be noted that the tandem [3,3] sigmatropic rearrangement of allyl 3-methylenealkanoate gave the single product, although analogous rearrangement of allyl 3-alkylcrotonate has been reported to give two isomers by the migration of double bond.[16]

The utility of these reactions was demonstrated in the synthesis of C_{18}-Cecropia juvenile hormone from **1**. Starting material, 3-methylenepentanoic acid **2b** was prepared in 65% yield from **1** and ethylmagnesium bromide. The acid **2b** was isomerized to 3-methyl-2-pentenoic acid (**3b**) by the treatment of **2b** with *p*-toluenesulfonyl chloride in pyridine and then water, and the ratio of the *E* isomer to *Z* isomer for **3b** was 67:33. 3-Methyl-2-penten-1-ol (**7**) was obtained in 81% yield by the esterification of **3b** with diazomethane at 0 °C and the reduction with aluminum hydride at −18 °C. Alcohol **7** was treated with 3-methylenepentanoyl chloride (**8**), prepared in 84% yield from **2b** and thionyl chloride, to afford the allyl ester (**9**) in 87% yield. The tandem [3,3] sigmatropic rearrangement of **9** *via* trimethylsilylketene acetal gave 7-methyl-3-ethyl-2,6-nonadienoic acid (**10**) in 83% yield (*EE*:*EZ*:*ZE*:*ZZ*=21:13:36:30). The acid **10** was esterified with diazomethane and reduced with aluminum hydride to give 7-methyl-3-ethyl-2,6-nonadien-1-ol (**11**) in 81% yield.



Scheme 5.

Allylic ester **13** was obtained in 86% yield from **11** and 3-methyl-3-butenoyl chloride (**12**), prepared from 3-methyl-3-butenoic acid (**2a**). The tandem [3,3] sigmatropic rearrangement of **13** furnished 3,11-dimethyl-7-ethyl-2,6,10-tridecatrienoic acid (**14**) in 61% yield (*EEE*:*EEZ*:*EZE*:*EZZ*:*ZEE*:*ZEZ*:*ZZE*:*ZZZ*=9:7:14:11:17:13:16:13). The acid **14** was esterified with diazomethane and oxidized by the known method[17] with *m*-chloroperbenzoic acid at 0 °C to yield C_{18}-Cecropia juvenile hormone (**15**) in 37% yield, which consists of a mixture of eight geometrical isomers.

Thus, the cobalt-catalyzed ring-opening reaction of diketene with Grignard reagents offered a simple and convenient synthetic method for various 3-methylenealkanoic acids, and the reaction, which is four carbon homologation containing a terpene unit, should be useful for the synthesis of various terpenes.

Experimental

The IR spectra were recorded on a Hitachi EPI-G2 spectrometer. The NMR spectra were taken in a CCl_4 solution with a Varian A-60 spectrometer using TMS as an internal standard. The GLC analyses were performed on a Yanaco G-180 Gas Chromatograph using a ϕ 3 mm×2 m 20% PEG 20 M column, a ϕ 3 mm×2 m 15% Apieson T column, and a ϕ 0.25 mm×50 m FFAP column. The preparative TLC was performed on Wakogel B-5F. All boiling points are uncorrected.

Reaction of Diketene with Grignard Reagents. To a solution of cobalt(II) iodide (2.6 mmol) in ether 54 ml was added diketene (24 mmol) at −78 °C. Then ethereal solution of Grignard reagent (26.4 mmol) was slowly dropped and stirring was continued at −78 °C for the indicated period in Table 2. The reaction was quenched with 6 M (1 M=1 mol dm^{-3}) HCl and extracted with ether. The separated organic layer was extracted with 3 M NaOH. The alkaline solution was acidified with 6 M HCl, and then extracted with ether. The ether extracts were washed with brine and dried ($MgSO_4$). Distillation gave 3-methylenealkanoic acid.

3-Methyl-3-butenoic Acid (2a). The acid **2a** was obtained in 84% yield from diketene (**1**) and methylmagnesium bromide (0.994 M) in ether at −78 °C for 3 h; bp 88 °C/25 mmHg (1 mmHg=133.322 Pa) (lit,[10] 68—70 °C/5 mmHg); IR (neat) 1710 (C=O) and 900 cm^{-1} (>C=CH$_2$); NMR δ=1.81 (3H, s), 3.00 (2H, s), 4.82 (2H, s), and 11.87 (1H, s).

3-Methylenepentanoic Acid (2b). The acid **2b** was obtained in 65% yield from diketene (**1**) and ethylmagnesium bromide (1.02 M) in ether at −78 °C for 6 h; bp 95 °C/13 mmHg; IR (neat) 1700 (C=O) and 890 cm^{-1} (>C=CH$_2$); NMR δ=1.08 (3H, t, J=7 Hz), 2.10 (2H, q, J=7 Hz), 3.20 (2H, s), 4.98 (2H, s), and 11.58 (1H, s). Found: C, 63.22; H, 9.04%. Calcd for $C_6H_{10}O_2$: C, 63.13; H, 8.83%.

3-Methyleneheptanoic Acid (2c). The acid **2c** was obtained in 66% yield from diketene (**1**) and butylmagnesium bromide (0.942 M) in ether at −78 °C for 6 h; bp 102 °C/5 mmHg; IR (neat) 1710 (C=O) and 900 cm^{-1} (>C=CH$_2$); NMR δ=0.95 (3H, t, J=7 Hz), 1.2—1.6 (4H, m), 2.0—2.3 (2H, m), 3.03 (2H, s), 4.95 (2H, s), and 11.45 (1H, s). Found: C, 67.47; H, 9.85%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

7-Methyl-3-methylene-6-octenoic Acid (2d). The acid **2d** was obtained in 52% yield from diketene (**1**) and homoprenylmagnesium bromide (0.685 M) in ether at −78 °C for 6 h; bp 116—117 °C/1.9 mmHg; IR (neat) 1710 (C=O) and 900 cm^{-1} (>C=CH$_2$); NMR δ=1.68 (3H, s), 1.74 (3H, s), 2.15—2.35 (4H, m), 2.90 (2H, s), 4.78 (2H, s), 4.75—5.15 (1H, m), and 11.85 (1H, s). IR and NMR spectra of the corresponding methyl ester were identical with reported ones.[5]

7,11-Dimethyl-3-methylene-6,10-dodecadienoic Acid (2e). The acid **2e** was obtained in 53% yield from diketene (**1**) and homogeranylmagnesium bromide (0.900 M), prepared from homogeranyl bromide (*E*:*Z*=75:25),[18] in ether at −78 °C for 6 h; IR (neat) 1700 (C=O) and 890 cm^{-1} (>C=CH$_2$); NMR δ=1.60 and 1.66 (9H, s), 1.90—2.40 (8H, m), 3.00 (2H, s), 4.88 (2H, s), 4.9—5.3 (2H, m), and 10.44 (1H, s). Found: C, 76.02; H, 10.47%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

4-Methyl-3-methylenehexanoic Acid (2f). The acid **2f** was obtained in 8% yield from diketene (**1**) and *s*-butylmagnesium chloride (0.916 M) in ether at −78 °C for 6 h; bulb to bulb distillation (200 °C/25 mmHg); IR 1710 (C=O) and 900 cm^{-1} (>C=CH_2); NMR δ=0.98 (3H, t, J=7 Hz), 1.05 (3H, d, J=7 Hz), 1.40 (2H, m), 1.8—2.3 (1H, m), 2.98 (2H, s), 4.95 (2H, s), and 10.28 (1H, s). Found: C, 67.56; H, 9.87%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

4,4-Dimethyl-3-methylenepentanoic Acid (2g). The acid **2g** was obtained in 6% yield from diketene (**1**) and *t*-butylmagnesium chloride (0.680 M) in THF at −78 °C for 6 h; bulb to bulb distillation (200 °C/25 mmHg); IR 1700 (C=O) and 900 cm^{-1} (>C=CH_2); NMR δ=1.10 (9H, s), 2.85 (2H, s), 4.77 (2H, s), and 10.44 (1H, s). Found: C, 67.37; H, 9.98%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

General Procedure for the Isomerization of 3-Methylenealkanoic Acid. *p*-Toluenesulfonyl chloride (22 mmol) was added to a solution of 3-methylenealkanoic acid (20 mmol) in pyridine (60 ml), and stirred at 30 °C for 1 h. Then, water (100 mmol) was added into the reaction solution and stirring was continued at 30 °C for 30 min. The reaction mixture was poured upon cold 6 M HCl, and extracted with ether. The separated organic layer was extracted with 3 M sodium hydroxide solution. The alkaline solution was acidified with 6 M HCl, and then extracted with ether. The extracts were washed with brine and dried over anhydrous $MgSO_4$. Concentration gave α,β-unsaturated acid.

3-Methyl-2-pentenoic Acid (3b).[19a] The acid **3b** was obtained in 80% yield from 3-methylenepentanoic acid (**2b**); bp 100—104 °C/12 mmHg; NMR δ=1.08 (3H, t, J=7.5 Hz), 2.08 (d, J=1 Hz, CH_3 of *Z*-**3b**), 2.34 (d, J=1 Hz, CH_3 of *E*-**3b**), 2.44 (q, J=8 Hz, CH_2 of *E*-**3b**), 2.84 (q, J=8 Hz, CH_2 of *Z*-**3b**), 5.78 (1H, t, J=1 Hz), and 12.08 (1H, s); GLC of the methyl ester (*E*:*Z*=67:33), Rt. 9′ 30″ (*Z*), 11′ 40″ (*E*) (FFAP 50 m, 60 °C).

3,7-Dimethyl-2,6-octadienoic Acid (3d).[19b] The acid **3d** was obtained in 95% yield from 7-methyl-3-methylene-6-octenoic acid (**2d**); NMR δ=1.70 (3H, s), 1.75 (3H, s), 2.02 (s, CH_3 of *Z*-**3d**), 2.20 (s, CH_3 of *E*-**3d**), 2.1—2.9 (4H, m), 4.92—5.34 (1H, m), 5.66 (1H, s), and 11.96 (1H, s); GLC of the methyl ester (*E*:*Z*=66:34), Rt. 8′ 00″ (*Z*), 9′ 40″ (*E*) (PEG 20 M, 2 m, 160 °C).

3,7,11-Trimethyl-2,6,10-dodecatrienoic Acid (3e).[19b] The acid **3e** was obtained in 86% yield from 7,11-dimethyl-3-methylene-6,10-decadienoic acid (**2e**); NMR δ=1.62 and 1.68 (9H, s), 2.00—2.16 (11H, m), 4.90—5.30 (2H, m), 5.60—5.80 (1H, m), and 11.10 (1H, s); GLC of the methyl ester (*EE*:*EZ*:*ZE*:*ZZ*=47:17:27:9), 21′ 00″ (*Z*,*Z*), 24′ 00″ (*Z*,*E*), 26′ 00″ (*E*,*Z*), 28′ 40″ (*E*,*E*) (Apieson T 2 m, 200 °C).

General Procedure for the Synthesis of 3-Methylenealkanoyl Chloride. Thionyl chloride (3 equiv.) was added dropwise to 3-methylenealkanoic acid (1 equiv.) and the reaction mixture set aside overnight at room temperature. Distillation gave 3-methylenealkanoyl chloride.

3-Methylenepentanoyl Chloride (8). The acid chloride **8** was obtained in 84% yield from 3-methylenepentanoic acid (**2b**); bp 50 °C/100 mmHg (lit,[20] 110—117 °C); NMR δ=1.04 (3H, t, J=7 Hz), 2.16 (2H, q, J=7 Hz), 3.45 (2H, s), and 4.75—4.90 (2H, m); IR (neat) 1790 (C=O) and 900 cm^{-1} (>C=CH_2).

3-Methyl-3-butenoyl Chloride (12). The acid chloride **12** was obtained in 86% yield from 3-methyl-3-butenoic acid (**2a**); bp 80 °C/100 mmHg; NMR δ=1.80 (3H, s), 3.43 (2H, s), and 4.90 (2H, m); IR (neat) 1800 (C=O) and 900 cm^{-1} (>C=CH_2).

General Procedure for the Esterification of 3-Methylenealkanoic Acid with Allylic Alcohol. A solution of acid chloride (10.5 mmol) in ether (35 ml) was slowly added dropwise to a mixture of alcohol (10 mmol) and pyridine (11 mmol) in ether (33 ml) at −15 °C for 40 min, and stirred for 1.5 h. The reaction was quenched with water and the ethereal solution was washed with water and dried ($MgSO_4$). The crude product was purified by column chromatography on silica gel (hexane:dichloromethane=1:1).

Prenyl 3-Methyl-3-butenoate (4d). The ester **4d** was derived in 73% yield from 3-methyl-3-butenoyl chloride (**12**) and prenol; IR (neat) 1720 (C=O) and 900 cm^{-1} (>C=CH_2); NMR δ=1.72 (3H, s), 1.75 (3H, s), 1.77 (3H, s), 2.92 (2H, s), 4.48 (2H, d, J=7.5 Hz), 4.78 (2H, s), and 5.08—5.46 (1H, m). Found: C, 71.27; H, 9.67%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

Geranyl 3-Methyl-3-butenoate (4e). The ester **4e** was derived in 86% yield from 3-methyl-3-butenoyl chloride (**12**) and geraniol; NMR δ=1.61, 1.66, 1.70, and 1.76 (12H, s), 1.94—2.20 (4H, m), 2.86 (2H, s), 4.34 (2H, d, J=6 Hz), 4.70 (2H, s), and 4.90—5.40 (2H, m); IR (neat) 1720 (C=O) and 890 cm^{-1} (>C=CH_2). Found: C, 76.20; H, 10.53%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

General Procedure of the Tandem [3,3] Sigmatropic Rearrangement of Allyl 3-Methylenealkanoate. A solution of *N*-isopropylcyclohexylamine (16.6 mmol) in THF (101 ml) was cooled to 0 °C and treated with butyllithium in hexane solution (13.5 mmol, 1.5 M) over 3 min. After the mixture was stirred for an additional 10 min, the solution was cooled to −78 °C and the ester (9 mmol) was added over 3 min. Within 5 min after the addition of the ester was complete, Me_3SiCl (16.3 mmol) was added to the reaction solution, and stirred at −78 °C for 5 min. The reaction solution was allowed to warm to 25 °C over 30 min and then refluxed for 2 h. After cooling the reaction mixture, 6 M HCl was added and extracted with ether. The ether extracts were washed with brine and dried ($MgSO_4$). The extracts were concentrated. DMF (30 ml) was added and refluxed for 2 h. To this solution 6 M HCl was added and extracted with ether. The ether extracts were washed with brine and dried ($MgSO_4$). The crude product was purified by distillation, TLC or column chromatography on silica gel.

3,7-Dimethyl-2,6-octadienoic Acid (3d).[19b] The acid **3d** was obtained in 81% yield from prenyl 3-methyl-3-butenoate (**4d**); bp 180 °C/2 mmHg; GLC of the methyl ester (*E*:*Z*=49:51) Rt. 7′ 30″ (*Z*), 9′ 10″ (*E*) (20% PEG 20 M, 2 m, 160 °C).

3,7,11-Trimethyl-2,6,10-dodecatrienoic Acid (3e).[19b] The acid **3e** was obtained in 63% yield from geranyl 3-methyl-3-butenoate (**4e**); TLC, R_f 0.5 (hexane:ether=2:1); GLC of the methyl ester (*EE*:*EZ*:*ZE*:*ZZ*=36:13:20:31) Rt. 21′ 00″ (6*Z*,2*Z*), 24′ 00″ (6*E*,2*Z*), 26′ 00″ (6*Z*,2*E*), and 28′ 40″ (6*E*,2*E*) (Apieson T 2 m, 200 °C).

3-Methyl-2-penten-1-ol (7). A solution of diazomethane in ether was added to a solution of 3-methyl-2-pentanoic acid (**3b**) (10 mmol) in ether (10 ml) at 0 °C. To a solution of the methyl ester in dry ether (30 ml) was slowly added an excess solution of aluminum hydride in ether (0.285 M) at −18 °C, and stirred for 1 h. The reaction was quenched with saturated ammonium chloride, and then extracted with ether and dried ($MgSO_4$). Distillation gave **7** in 81% yield; bp 110 °C/140 mmHg (lit,[21] 79—81 °C/40 mmHg); IR 3300 cm^{-1} (O–H); NMR δ=1.02 (3H, t, J=7 Hz), 1.62 (3H, s), 2.15 (2H, q, J=7 Hz), 3.40 (1H, b), 3.98 (2H, d, J=7 Hz), and 5.46 (1H, t, J=7 Hz).

3-Methyl-2-pentenyl 3-Methylenepentanoate (9). The ester **9** was derived in 87% yield from 3-methylenepentanoyl

chloride (**8**) and 3-methyl-2-penten-1-ol (**7**) according to the general procedure for the esterification as described above; NMR δ=1.04 (6H, t, J=7 Hz), 1.74 (3H, s), 1.85—2.40 (4H, m), 2.92 (2H, s), 4.44 (2H, d, J=7 Hz), 4.76 (2H, s), and 5.24 (1H, t, J=7 Hz). Found: C, 73.21; H, 10.48%. Calcd for $C_{12}H_{20}O_2$: C, 73.27; H, 10.27%.

*3-Ethyl-7-methyl-2,6-nonadienoic Acid (**10**).*[19a] The acid **10** was obtained in 83% yield by the tandem [3,3] sigmatropic rearrangement of 3-methyl-2-pentenyl 3-methylenepentanoate (**9**); column chromatography; TLC, R_f 0.5 (hexane : ether=2:1); GLC of the methyl ester (*EE*:*EZ*:*ZE*:*ZZ*=21:13:36:30), Rt. 38′ 50″ (30%) (2*Z*,6*Z*), 44′ 20″ (36%) (2*Z*,6*E*), 44′ 00″ (13%) (2*E*,6*Z*), and 45′ 50″ (21%) (2*E*, 6*E*) (FFAP 50 m, 120 °C); NMR δ=0.96 (3H, t, J=7 Hz), 1.08 (3H, t, J=7 Hz), 1.60 and 1.66 (3H, s), 1.80—2.80 (8H, m), 4.90—5.20 (1H, m), 5.55 (1H, s), and 11.96 (1H, s).

*3-Ethyl-7-methyl-2,6-nonadien-1-ol (**11**).*[21] The alcohol **11** was obtained in 81% yield from 3-ethyl-7-methyl-2,6-nonadienoic acid (**10**) according to the procedure for the synthesis of **7**; bp 122—123 °C/7.5 mmHg; IR 3300 (OH) and 1660 cm^{-1} (C=C); NMR δ=1.00 (3H, t, J=7 Hz), 1.08 (3H, t, J=7 Hz), 1.46 and 1.54 (3H, s), 2.00—2.30 (8H, m), 2.16 (1H, s), 3.98 (2H, d, J=6 Hz), 4.84—5.20 (1H, m), and 5.25 (1H, t, J=6 Hz). Found: C, 78.88; H, 11.92%. Calcd for $C_{12}H_{22}O$: C, 79.02; H, 12.16%.

*3-Ethyl-7-methyl-2,6-nonadienyl 3-Methyl-3-butenoate (**13**).* The ester **13** was derived in 92% yield from 3-methyl-3-butenoyl chloride (**12**) and 3-ethyl-7-methyl-2,6-nonadien-1-ol (**11**); IR (neat) 1720 (C=O) and 900 cm^{-1} (>C=CH$_2$); NMR δ=0.82—1.23 (6H, m), 1.55 and 1.62 (3H, s), 1.82 (3H, s), 2.88 (2H, s), 4.45 (2H, d, J=7 Hz), 4.74 (2H, s), and 4.85—5.30 (2H, m). Found: C, 77.04; H, 10.52%. Calcd for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67%.

*7-Ethyl-3,11-dimethyl-2,6,10-tridecatrienoic Acid (**14**).*[19a] The acid **14** was obtained in 61% yield by the tandem [3,3] sigmatropic rearrangement of 3-ethyl-7-methyl-2,6-nonadienyl 3-methyl-3-butenoate (**13**); TLC, R_f 0.5 (hexane:ether=2:1), GLC of the methyl ester (*EEE*:*EEZ*:*EZE*:*EZZ*:*ZEE*:*ZEZ*:*ZZE*:*ZZZ*=9:7:14:11:17:13:16:13), Rt. 23′ 20″ (13%) (2*Z*,6*Z*,10*Z*), 24′ 40″ (16%) (2*Z*,6*Z*,10*E*), 26′ 20″ (13%) (2*Z*,6*E*,10*Z*), 27′ 40″ (17%) (2*Z*,6*E*,10*E*), 30′ 20″ (11%) (2*E*,6*Z*,10*Z*), 32′ 10″ (14%) (2*E*,6*Z*,10*E*), 33′ 40″ (7%) (2*E*,6*E*,10*Z*), and 35′ 20″ (9%) (2*E*,6*E*,10*E*) (FFAP 50 m, 150 °C); NMR δ=0.98 (6H, t, J=7 Hz), 1.56 and 1.66 (3H, s), 1.80—2.35 (15H, m), 4.88—5.28 (2H, m), 5.60 (1H, s), and 11.72 (1H).

*Methyl 10-Epoxy-7-ethyl-3,11-dimethyl-2,6-tridecadienoate (**15**).* A solution of diazomethane in ether was added to a solution of acid **14** (1 mmol) in ether at 0 °C. The mixture was concentrated and purified by TLC (hexane:ether=2:1, R_f 0.8). A solution of *m*-chloroperbenzoic acid (318 mg, 0.96 mmol, 52% pure) in dichloromethane (2 ml) was added to a solution of methyl 7-ethyl-3,11-dimethyl-2,6,10-tridecatrienoate (242 mg, 0.87 mmol) in dichloromethane (2 ml) at 0 °C, and then stirred at 0 °C for 24 h. The reaction solution was washed with saturated sodium hydrogencarbonate solution and dried ($MgSO_4$).

Purification by TLC on silica gel (R_f 0.4—0.5, benzene: ethyl acetate=15:1) gave juvenile hormone (**15**) (98.2 mg, 0.33 mmol) in 37% yield from the acid **14**. IR (neat) 1710 (C=O) and 1140 cm^{-1}; NMR δ=0.98 (6H, t, J=7 Hz), 1.16 (3H, s), 1.38—1.80 (4H, m), 1.90 and 2.16 (3H, s), 1.80—2.70 (9H, m), 3.64 (3H, s), 5.00—5.20 (1H, m), and 5.58 (1H, s). IR and NMR spectral data were in agreement with the reported ones.[17,19a]

(Received April 17, 1982)

The conformations of the diastereoisomers of 1-phenylethyl phenyl (**1**), 1-phenylethyl *p*-tolyl (**2**), 1-phenylpropyl phenyl sulfoxides (**3**) were studied by NMR spectroscopy, largely by means of the computer simulation of the lanthanoid-induced shifts. It has been suggested that the rotamer in which the aromatic group (Ar) is

$C_6H_5CH(R)$-SO-Ar **1**: R = CH_3, Ar = C_6H_5; **2**: CH_3, $C_6H_4CH_3(p)$; **3**: C_2H_5, C_6H_5

gauche to the phenyl (Ph) and *anti* to the alkyl (R) group is most populated in the conformational equilibria of (*RS*/*SR*)-**1**, **2**, **3**, and (*RR*/*SS*)-**3**. For (*RR*/*SS*)-**1** and **2**, on the other hand, the most important contributor has been suggested to be the rotamer in which Ar is flanked by Ph and R. The results have been discussed in the light of the presence of attractive interactions between relevant groups.

In relation to our interest in the favored *gauche* interactions of flexible aliphatic systems,[1] the conformations were studied for several compounds which have an aromatic group on each end of the molecules. This paper will deal with the diastereoisomeric pairs of 1-phenylethyl phenyl (**1**), 1-phenylethyl *p*-tolyl (**2**), and 1-phenylpropyl phenyl sulfoxides (**3**). The results allow us to conclude unequivocally that these compounds favor the folded (*gauche* aromatic groups) conformations in solution.

Experimental

Materials. The sulfoxides were prepared by the oxidation of the corresponding sulfides using (dichloroiodo)-benzene and water in pyridine.[2] The reaction was run at the rather high temperature of 50 °C, which enhanced the formation of the minor component in the diastereoisomeric pair. The isomeric sulfoxides were separated by repeated column chromatography on silica gel, with hexane–diethyl ether (4:1) as the eluent. The absolute configurations at the carbon and sulfur centers of optically active **1** and **2** have been rigorously determined.[3,4] The NMR spectra of these sulfoxides allow us to make a configuration assignment for the racemic diastereomers of **1** and **2** studied in this work.

The stereochemical assignment of **3** is based on the similarity in the ^{13}C and ^{17}O chemical-shift patterns (see Table 1) between the 1-phenylethyl and 1-phenylpropyl derivatives: the sulfoxide with the higher mp and the smaller retention volume was assigned the (*RR*/*SS*) configuration.

(*RR*/*SS*)-**3**. Mp 142—143 °C. Found: C, 73.51; H, 6.56; S, 13.48%. Calcd for $C_{15}H_{16}OS$: C, 73.73; H, 6.60; S, 13.12%. (*RS*/*SR*)-**3**. Mp 90—93 °C. Found: C, 73.57; H, 6.61; S, 13.52%.

The ^{17}O-enriched sulfoxides were prepared by treating the sulfides with (dichloroiodo)benzene and ^{17}O-enriched water (10 atom%, Prochem) in dry pyridine, as has been described by Montanari *et al.* for unenriched sulfoxides.[2]

NMR Spectra. The NMR spectra were obtained on a Varian EM-390 spectrometer for ^1H and on a JEOL FX-90Q spectrometer for ^{13}C NMR. The chemical shifts are given in ppm downfield from internal tetramethylsilane.

The ^{17}O NMR spectra of the labelled sulfoxides were measured[5] on a Varian FT-80A spectrometer: *ca.* (1—3)$\times 10^5$ transients were accumulated with a 90° pulse and an acquisition time of 0.03—0.04 s. The chemical shifts were measured as frequency shifts from the synthesizer frequency (8.53200 MHz) and expressed in ppm relative to the oxygen of water, which resonated at 10.78321 MHz when measured in a concentrically placed capillary tube. The chemical shifts are accurate to ±1 ppm. The sample temperature was 60 °C. Under these conditions, the half-band width was in the range of 150—200 Hz.

Lanthanoid-induced Shifts (LIS) Measurements. Weighted $Eu(fod)_3$ was added incrementally to a solution of a known amount of a substrate in $CDCl_3$ (*ca.* 0.2 M), and the chemical shifts were followed in the spectra. The induced shifts of each group of protons were found to be directly proportional to the $Eu(fod)_3$/substrate ratios up to a value of *ca.* 0.2 equiv. mol^{-1}. A least-squares analysis was performed on from four to six experimental points; correlation coefficients of 0.979 or better were thus obtained.

Results

Table 1 lists the ^1H, ^{13}C, and ^{17}O NMR parameters of the sulfoxides, **1**, **2**, and **3**. Table 2 summarizes the lanthanoid-induced shifts on proton resonances.

At first, we carried out a computer simulation of the LIS according to the procedure reported previously.[7] Thus, the position of the lanthanoid shift-reagent (LSR) and the conformation of the molecule (with regard to the central C–S bond) were varied, step by step, in the search for a reasonable fit of the computed LIS's with the observed values [assuming the $(3\cos^2 x_i - 1)\, r_i^{-3}$ proportionality]. For the methyl (ethyl) and aromatic groups, the contribution of the individual protons in a number of conformers was calculated and then averaged. The crystallographic reliability factor (*AF*)[8] was used in order to assess the agreement between the computed LIS's and the observed ones.

Figure 1 plots the *AF* against the O–S–C–C_6H_5 dihedral angle, ϕ, for compounds (*RS*/*SR*)-**1**, **2**, and

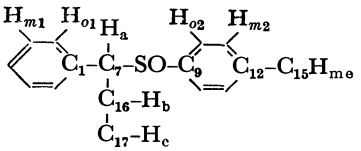
a) $\delta(^{1}H)$ and $\delta(^{13}C)$: Reported in ppm downfield from internal TMS in $CDCl_3$. The chemical shifts of the aromatic protons were determined by the extrapolation of the linear LIS plots to the intercept at the LSR concentration of zero. b) From Ref. 6. The ^{17}O data (ppm downfield from external D_2O in $CDCl_3$) reported previously for (*RS*/*SR*)-**3** (19 ppm) should be corrected to this. c) Data in parentheses are the aromatic solvent-induced shifts (ASIS): $\delta(CDCl_3) - \delta(C_6D_6)$. d) $J_{ab}=11.4$ Hz (*RS*/*SR*), 9.6 Hz (*RR*/*SS*); LIS is smaller for this proton than for the diastereotopic congener. e) $J_{ab}=4.2$ Hz (*RS*/*SR*), 6.0 Hz (*RR*/*SS*). The coupling constants are insensitive to the addition of the LSR.



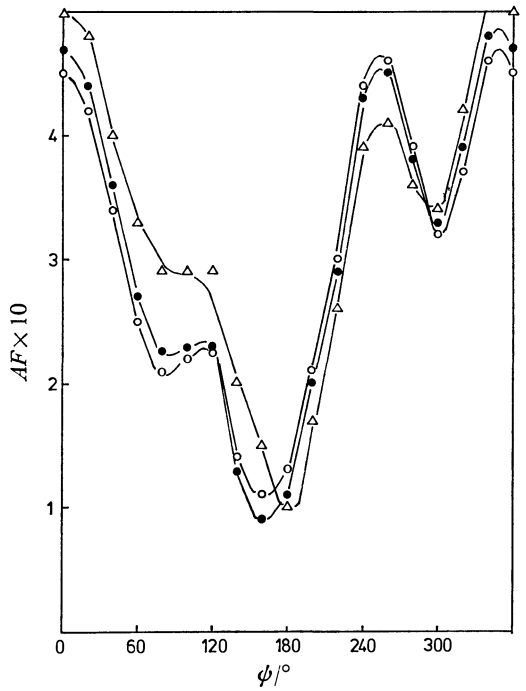


Fig. 1. Plots of *AF* *vs.* the O/Ph dihedral angle (ψ) for sulfoxides with the (*RS*/*SR*) configuration. ○—○: (*RS*/*SR*)-**1**. ●—●: (*RS*/*SR*)-**2**. △—△: (*RS*/*SR*)-**3**.

3; here, the values of R (LSR–O distance), θ (LSR–O–S angle), and A (index for the LSR-distribution)[7] are kept constant at 0.36 nm, 120°, and 0.8 respectively. The monitor nuclei are H_a, H_b, H_{o1}, H_{o2}, and H_{m1} in every case.

A notable feature of these profiles is the appearance of three minima at about the staggered geometries (ψ *ca.* 80°, 160—180°, and 300°) of the molecules. For reasons previously mentioned,[7] we believe that the values of ψ and *AF* at the extrema reflect, though in an indirect manner, the approximate geometries and the relative importance of the plausible rotamers.[9] In view of this, the most populated rotamer is suggested to have the O–S–C–Ph dihedral angle (ψ) *ca.* 160—180° for (*RS*/*SR*)-**1**, **2**, and **3** (**a** rotamer).[10] Note that in the **a** rotamer the aromatic group (Ar) is *gauche* to the phenyl group (Ph) and *anti* to the methyl group (Me). Also interesting is that the profiles suggest the second most stable one to be the **b** rotamer in every case. In this rotamer Ar is flanked by Me and Ph; the concentration of this rotamer appears to decrease in the 1-phenylpropyl derivative (*RS*/*SR*)-**3**.[11]

The profiles for the (*RR*/*SS*)-isomers are given in Fig. 2; in these cases also three minima are found. The most stable geometry is suggested to be the **b** rotamer for (*RR*/*SS*)-**1** and **2** (ψ *ca.* 200°; Ar is flanked by Me and Ph), the second most stable one being the **a** rotamer (ψ *ca.* 300°). The proportion of the **a** *vs.* **b** rotamer for the 1-phenylpropyl derivative (**3**, R=C_2H_5) seems to differ from that observed for **1** and **2** (R=CH_3); the most stable conformation is suggested to be the **a** rotamer for (*RR*/*SS*)-**3**.[11]

Discussion

A remarkable feature of the above results is that the rotamers which have the aromatic groups *gauche*

a) Relative values.

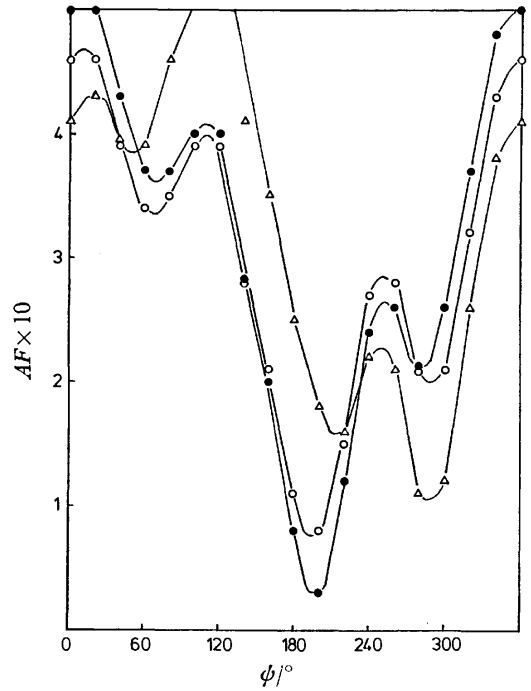

Fig. 2. Plots of *AF vs.* the O/Ph dihedral angle (ψ) for sulfoxides with the (*RR/SS*) configuration. ○—○: (*RR/SS*)-**1**. ●—●: (*RR/SS*)-**2**. △—△: (*RR/SS*)-**3**.

to each other (**a** and **b**) are present predominantly in the conformational equilibria for all of the compounds studied. Evidence was, therefore, sought in the present NMR data to support this suggestion.

^{13}C and ^{17}O γ-Effects. Significant differences are found between the diastereoisomers of **1** and **2** with regard to the chemical shifts of the methyl carbon [C(16)] and the oxygen of the sulfoxide. This can be understood well on the basis of the rotameric equilibria suggested by the LIS method (Fig. 3). In the cases of (*RS/SR*)-isomers, the oxygen is *gauche* to Me in the **a** rotamer, but is *anti* in the **b** rotamer. For the (*RR/SS*)-sulfoxides, on the other hand, O is *gauche* to Me in both of the preferred rotamers. We can, therefore, expect a more profound *γ-gauche* effect to be observed for the (*RR/SS*)-isomers.[7] The data in Table 1 support this. An essentially similar, but somewhat different, trend is observed for the 1-phenylpropyl derivatives[6] (**3**). We will refrain from discussing this problem in more detail, however, until more exact knowledge about the conformational equilibria becomes available.[12]

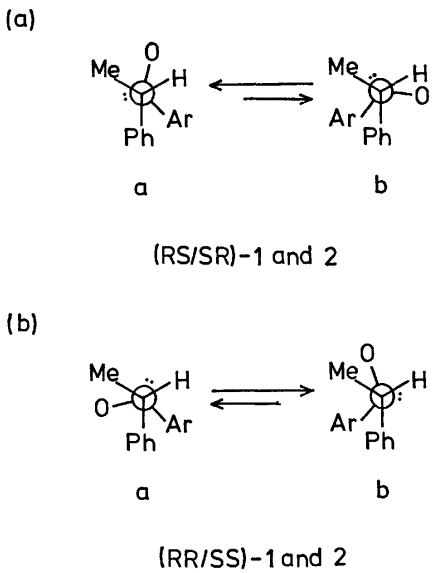

Fig. 3. Conformational equilibria suggested for (a) (*RS/SR*)-**1** and **2**, (b) (*RR/SS*)-**1** and **2**.

Chemical Shifts of the Aromatic Protons. A common aspect of the NMR spectra of **1**—**3** is that the aromatic protons give multiplets which cover a rather wide range of magnetic fields. Figure 4 illustrates this for a representative case of (*RR/SS*)-**2**. In contrast, the aromatic protons of the alkyl analogues (in which Ar is replaced by an alkyl group) gave rise to broad singlets (or narrow multiplets) centered at δ *ca.* 7.25.[7b] In the present cases (Ar=C_6H_5 or $C_6H_4CH_3$), the signals ascribable to the *ortho* protons of the 1-phenylethyl (or 1-phenylpropyl) moiety (H_{o1}), have been shown to resonate at considerably higher magnetic fields [δ 6.97—7.11 for (*RS/SR*), 6.85—7.00 for (*RR/SS*)]; this was shown by extrapolating the linear LIS plots to the intercept at the LSR concentration of zero (see Fig. 5). This is reasonable, since, in the **a** and **b** rotamers, the aromatic groups are close to each other; H_{o1} (and H_{o2}) can be expected to be effectively shielded by the opposing aromatic ring.

Aromatic Solvent-induced Shifts (ASIS). In Fig. 3, the sulfoxide oxygen in (*RS/SR*)-isomers is flanked by H_a in both of the predominant rotamers (**a** and **b**), but in the (*RR/SS*)-sulfoxides O approaches H_a only in the **b** rotamer. The reverse is true for the orientation of Me with respect to the oxygen. According to the theory,[13] the upfield shifts induced

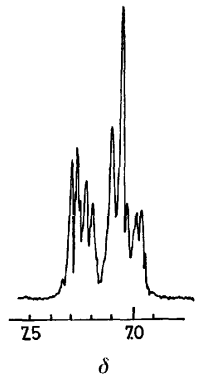

Fig. 4. The aromatic part of the ^{1}H NMR spectrum for (*RR*/*SS*)-**2**.

by benzene (ASIS) are expected to decrease if the relevant nuclei lie close to the negative end of the molecule. The trend observed in ASIS (Table 1) is consistent with the LIS results. Thus, ASIS for the methyl protons (H_b) is larger in (*RS*/*SR*)-**1** and **2** than in the respective (*RR*/*SS*)-isomer. ASIS for H_a, in contrast, is larger in (*RR*/*SS*)-sulfoxides.

Importance of Attractive Ar/Ar Interaction. From the considerations raised above, we conclude that these molecules favor the folded (*gauche* aromatic groups) conformations in solution. The preference of the folded conformation has been demonstrated in 1967 by Dewar for 2-arylethyl *p*-toluenesulfonates ($C_7H_7SO_2OCH_2CH_2Ar$; Ar=1-pyrenyl and 9-phenanthryl)[14] and more extensively by Engberts *et al.*[15] for several sulfonyl compounds, $ArSO_2CH_2Ar$, $ArSO_2CH_2NMeCO_2Ar$, and $(ArSO_2CHPhNH)_2CO$. Their conclusions were drawn mainly on the basis of the X-ray,[15] UV, (appearance of the intramolecular charge-transfer band),[15] and NMR data (upfield shifts of the aromatic protons as compared with those of reference compounds).[14,15] The predominance of the *gauche* rotamers has been argued also for several sulfoxides similar to **1** and **2**[3a,6] and structurally related sulfides.[16] The present findings provide strong support for this and, further, suggest that the favored interaction between aromatic groups is rather general in other kinds of molecules. Also noteworthy in the above results is the importance of the rotamer with the aromatic group (Ar) flanked by Ph and Me (**b** rotamer); in some cases, this becomes the main contributor.

In view of this and other evidence,[17] we conclude that the conformations of these molecules are determined principally by the interaction between aromatic groups, which must be attractive, at least in the framework of the molecules presently studied. Superimposed on this effect is probably the dipole(SO)/quadrupole(Ph) interaction (repulsive, if parallelly oriented).[13,17]

The nature of the attractive Ar/Ar interaction remains open, but we feel it likely that the London dispersion force is mainly responsible, since the phenomenon appears to be rather general for a variety of compounds.[14-19] The CH/π[1,20] (CH_3 *vs.* Ar; C-H_o *vs.* Ar) and quadrupole/quadrupole (Ph *vs.* Ar)[21] interactions may also play some parts in determining the molecular structures of these compounds. In order to obtain insight into this problem, theoretical calculations are currently being made in these laboratories; the results will appear in a future paper.

8) $AF = [\sum_i (LIS_i^{obsd} - LIS_i^{calcd})^2 / \sum_i (LIS_i^{obsd})^2]^{1/2}$. The calculated shifts were normalized to the average experimental LIS in the computational process.[1,7a] The normalization was made to the largest LIS in Ref. 7b.

9) Perturbation to the conformational equilibria by the complex formation has been shown to be unimportant in these cases.[7] This is shown also by the insensitivity of $^3J_{H_aH_b}$ in **3** to the addition of the LSR.

10) In view of the limitation of the present methodology (a number of approximations were introduced in the computational procedure), we do not wish to imply that the values of ϕ at the *AF* minima correspond exactly to the molecular shapes of these compounds. Earlier work on similar subjects, however, has shown that the LIS method gave results which agreed quite well with those obtained by other means, including the X-ray crystallographic work.

See Ref. 7b and Y. Kodama, K. Nishihata, M. Nishio, and Y. Iitaka, *J. Chem. Soc., Perkin Trans. 2*, **1976**, 1490.

11) The results are compatible with our stereochemical intuition.

12) Differences are also found between the diastereomers of **1** and **2** (and **3**) for chemical shifts of H_a, H_b(methyl), C(1), and C(7). These may be conformational effects, but at present we have no clear explanation.

The Dechlorination of Polychlorinated Biphenyls by UV-irradiation. VIII. Reactions of 2,3- and 3,4-Dichlorobiphenyl in a 2-Propanol Solution

Tohru Nishiwaki,* Tsutomu Shinoda, Kinji Anda, and Mitsuhiko Hida†

Organic Division, Tokyo Metropolitan Industrial Technology Center, Nishigaoka, Kita-ku, Tokyo 115

†*Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158*

(Received May 1, 1982)

The photodechlorinations of 2,3-dichlorobiphenyl (2,3-DCB) and 3,4-dichlorobiphenyl (3,4-DCB) in 2-propanol gave 3-chlorobiphenyl and 4-chlorobiphenyl respectively. The quantum yields of monochlorobiphenyl formation were 0.2 for 2,3-DCB and 0.06 for 3,4-DCB, independent of the substrate concentration and the wavelength of the exciting light. On the basis of the results obtained in quenching experiments using *cis*-1,3-pentadiene, it was concluded that 2,3-DCB was photodechlorinated exclusively in the excited singlet state, while 3,4-DCB was photodechlorinated in both excited singlet and triplet states. In the case of 3,4-DCB, the relative contributions of excited singlet and triplet states to the total dechlorination were evaluated as 0.8 and 0.2 respectively. The participation of the excited triplet state in the photodechlorination of 3,4-DCB was ascertained both by quenching reactions with biacetyl as a quencher and by photosensitized dechlorinations with acetone and acetophenone as sensitizers.

In connection with the environmental breakdown of pollutants initiated by sunlight, the photodechlorination of polychlorobiphenyls has attracted the interests of several authors.[1] Safe and Hutzinger[2] found that 2,2′,4,4′,6,6′-hexachlorobiphenyl was photochemically decomposed by the irradiation of 310 nm. Schuetz *et al.*[3] proposed that the excited triplet state was involved in the photodechlorination of six symmetrical tetrachlorobiphenyls, based on the effective quenching for the reaction by 1,3-cyclohexadiene.

Recently Bunce *et al.*[4,5] reported that the excited triplet state plays an important role in the photodechlorination of chlorobiphenyls; he based this conclusion on the following grounds: (1) The xenon assistance of the reaction, and (2) the quenching of the reaction by biacetyl. However, the reactivity of the photodechlorination of polychlorobiphenyls depends on the position of the eliminated chlorine atom and is largely affected by the presence of ortho chlorine atoms.[3,4,6] The same positional dependence of reactivity has also been found in the photodechlorination of polychlorinated benzenes, and it has been clarified that the reaction involves not only an excited triplet state, but also an excited singlet state.[7]

In this paper, the photodechlorinations of 2,3-dichlorobiphenyl (2,3-DCB) and 3,4-dichlorobiphenyl (3,4-DCB) were studied by photoquenching and photosensitization examinations. Also, the reactivities and the multiplicities of the excited state responsible for the reactions were discussed. A reaction mechanism will also be proposed.

Experimental

Materials. The 2,3-DCB and 3,4-DCB were prepared and purified as reported in a previous paper.[6] The *cis*-1,3-pentadiene, biacetyl, acetophenone, and triethylamine were used after distillation. The 2-propanol (Dotite Luminasol for fluorometry; Wako Pure Chemical Co., Ltd., Osaka) and acetone (solvent for pesticide residue analysis; Wako Pure Chemical Co., Ltd., Osaka) were used without further purification.

Apparatus. Irradiation was carried out on a Hitachi MPF-4 spectrofluorometer equipped with a 150-W Xenon lamp and a grating monochrometer (Czerny-Turner mounting). Using the maximum slit width, a monochromatic light was obtained with a wavelength purity of 20 nm; its intensity was about 2×10^{15} photons s^{-1} at 300 nm.

The amount of monochlorobiphenyls produced in the irradiated reaction mixture was determined with a JEOL Model D-100 gas chromatograph-mass spectrometer system which was equipped with a 2 m × 3 mmϕ stainless steel column packed with 10% SE-30 on 80—100 mesh chromosorb A (HMDS). The magnetic field of the mass spectrometer was fixed at *m/e* 188 to detect the molecular-ion peak of monochlorobiphenyls.

GLC analysis was conducted on a JEOL 20-K gas chromatograph with a flame-ionization detector. A glass capillary column, 60 m × 1 mmϕ, with PEG-20M (Chromato Research Co.) was used to separate the 3-chlorobiphenyl from the 4-chlorobiphenyl.

The number of photons absorbed by the reaction mixture was determined by the use of a chemical actinometer of potassium tris(oxalato)ferrate(III). A Union Giken SM-401 spectrophotometer and a Hitachi MPF-4 spectrofluorometer were used for the measurement of the UV absorption spectra and the emission spectra respectively.

Procedures. After the 2-propanol solution (4.5 cm^3) in a quartz reaction cell had been bubbled with purified nitrogen for 5 min, the cell was sealed and irradiated. Irradiation was continued until the concentration of monochlorobiphenyls increased to about 10 μmol dm^{-3} in the irradiated reaction mixture.

Quenching studies were carried out at the excitation of 290 nm to avoid the direct excitation of *cis*-1,3-pentadiene. The incident light was absorbed only by dichlorobiphenyl molecules. The concentrations of 2,3-DCB and 3,4-DCB were 20 mmol dm^{-3} and 1.5 mmol dm^{-3} respectively.

In photosensitizing experiments, the wavelength of the exciting light was selected so that the incident light was absorbed only by sensitizer molecules. The concentrations of the sensitizers were adjusted so that about 90% of the incident light was absorbed. The wavelengths and concentrations employed were as follows: 320 nm and 2.0 mol dm^{-3} for acetone; 340 nm and 40 mmol dm^{-3} for acetophenone, and 366 nm and 20 mmol dm^{-3} for benzophenone. The concentrations of 2,3-DCB and 3,4-DCB were both 1.5 mmol dm^{-3}.

Results and Discussion

The Quantum Yield for Dechlorination. 2,3-DCB and 3,4-DCB gave 3-chlorobiphenyl and 4-chlorobiphenyl respectively upon UV irradiation in 2-propanol, as was reported in our previous paper.[6] A further, detailed examination of the products revealed that the direct irradiation of 3,4-DCB afforded 4-chlorobiphenyl in a 92% yield and 3-chlorobiphenyl in an 8% yield. The quantum yields of monochlorobiphenyl formation are listed in Table 1. These values are comparable to the quantum yields of dechlorination in cyclohexane for six tetrachlorobiphenyls reported by Schuetz *et al.*[3] The chlorine atom at the ortho position of 2,3-DCB was found to have a much higher elimination efficiency than the chlorine atom at the meta position of 3,4-DCB.

Bunce *et al.*[8] reported that the quantum yield of 1-chloronaphthalene rose with an increase in the substrate concentration. Excimer formation was considered to stimulate the photoreduction of 1-chloronaphthalene to naphthalene. On the contrary, the quantum yield of monochlorobenzene photolysis in cyclohexane has been reported to decrease with an increase in the concentration of chlorobenzene.[9] Mori *et al.*[10] found that the photolysis of chlorobenzene in the gas phase depended on the excitation wavelength.

Our examinations, however, showed that no essential change was observed in the reactivities of 2,3-DCB and 3,4-DCB upon changes in the wavelength of irradiation and the substrate concentration (Table 1). Excimer formation is, therefore, not considered to play an important role in the photodechlorination of 2,3-DCB and 3,4-DCB.

The Quenching Experiment Using cis-*1,3-Pentadiene.* As Fig. 1 shows, a good linear Stern-Volmer plot was obtained for 2,3-DCB with a slope of 3.1 dm^3 mol^{-1} and an intercept equal to unity. On the other hand, the Stern-Volmer plot for 3,4-DCB gave a straight line with an intercept different from unity, indicating that two different excited states are involved in the photoreaction. The fluorescences of these dichlorobiphenyls were quenched to an extent similar to their photodechlorinations by *cis*-1,3-pentadiene.[11]

Table 1. Wavelength effect and concentration effect on dechlorination quantum yield in 2-propanol solution

Wavelength nm	Concn mol dm^{-3}	Φ_r[a] 2,3-DCB	Φ_r[a] 3,4-DCB
250	1.5×10^{-2}	0.21	0.063
	1.5×10^{-3}	0.18	0.053
	1.5×10^{-4}	0.22	0.056
290	1.5×10^{-2}	0.18	0.056
	1.5×10^{-3}		0.064
	1.5×10^{-4}		0.064
300	1.5×10^{-2}	0.15	
310	1.5×10^{-2}		0.059

a) Φ_r is the quantum yield of monochlorobiphenyl formation.

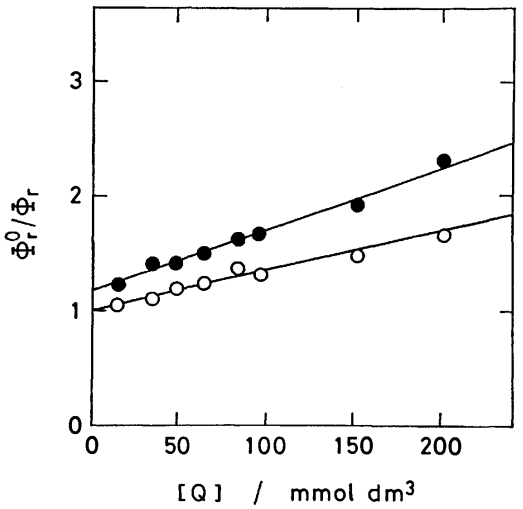

Fig. 1. Stern-Volmer plots for the quenching of dechlorination in 2-propanol solution by *cis*-1,3-pentadiene. ○: 2,3-DCB (20 mmol dm^{-3}), ●: 3,4-DCB (1.5 mmol dm^{-3}).

These results suggest that the dechlorination of 2,3-DCB occurs virtually all from the excited singlet state, while that of 3,4-DCB occurs from both excited singlet and triplet states.

Since the quantum yield for the dechlorination of 2,3-DCB from the excited singlet state is 0.2, its quantum yield for intersystem crossing must be smaller than that of biphenyl, 0.81,[12] in spite of the internal heavy-atom effect of chlorine atoms. Taking into consideration the fact that biphenyl has a planar structure in its excited singlet state, whereas it is twisted in the ground state in solution,[13] the chlorine atom at the 2-position in 2,3-DCB must be very labile in its excited state because of the large steric hindrance. This elimination is presumed to reduce the intersystem crossing efficiency of 2,3-DCB.

In the case of 3,4-DCB, the Stern-Volmer expression can be written by Eq. 1:

$$\frac{\Phi_r^\circ}{\Phi_r} = \frac{(1+k_q^S\tau_S[Q])(1+k_q^T\tau_T[Q])}{1+\{\Phi_r^S/(\Phi_r^S+\Phi_r^T)\}k_q^T\tau_T[Q]}, \quad (1)$$

where Φ_r° and Φ_r designate the quantum yields for the dechlorination of 3,4-DCB measured in the absence and in the presence of a quencher respectively, Φ_r^S and Φ_r^T the quantum yields for the dechlorination of 3,4-DCB from excited singlet and triplet states respectively in the absence of a quencher ($\Phi_r^\circ=\Phi_r^S+\Phi_r^T$), k_q^S and k_q^T the rate constants for quenching excited singlet and triplet states of 3,4-DCB respectively, τ_S and τ_T the lifetimes of excited singlet and triplet states of 3,4-DCB respectively, and [Q] is the concentration of the quencher, Q.

At sufficiently high concentrations of Q, Eq. 1 can be rewritten as Eq. 2:

$$\frac{\Phi_r^\circ}{\Phi_r} \simeq \left(\frac{\Phi_r^S+\Phi_r^T}{\Phi_r^S}\right)k_q^S\tau_S[Q] + \left(\frac{\Phi_r^S+\Phi_r^T}{\Phi_r^S}\right)\left(1-\frac{\Phi_r^Tk_q^S\tau_S}{\Phi_r^Sk_q^T\tau_T}\right). \quad (2)$$

Since τ_T is generally much larger than τ_S, the term of $\Phi_r^Tk_q^S\tau_S/(\Phi_r^Sk_q^T\tau_T)$ can be neglected. Thus, Eq. 2 can be approximated by Eq. 3:

$$\frac{\Phi_r^\circ}{\Phi_r} \approx \left(\frac{\Phi_r^S+\Phi_r^T}{\Phi_r^S}\right)k_q^S\tau_S[Q] + \frac{\Phi_r^S+\Phi_r^T}{\Phi_r^S}. \quad (3)$$

A plot of Φ_r°/Φ_r *versus* [Q] should give a straight line, with an intercept of $(\Phi_r^S+\Phi_r^T)/\Phi_r^S$ and a slope of $(\Phi_r^S+\Phi_r^T)k_q^S\tau_S/\Phi_r^S$.

From the intercept of 1.2 for the straight line of 3,4-DCB (Fig. 1), the contribution of each excited state to the total dechlorination was evaluated to be 0.8 for the excited singlet state and 0.2 for the excited triplet state. From the slope and intercept, the Stern-Volmer constant of 3,4-DCB, $k_q^S\tau_S$, was calculated to be 4.4 $dm^3\ mol^{-1}$, while the value of 3.1 $dm^3\ mol^{-1}$ was obtained for 2,3-DCB.

The Quenching of 3,4-DCB Photodechlorination by Biacetyl. When [Q] is low enough to make $k_q^S\tau_S[Q] \ll 1$,[14] Eq. 1 can be approximated as Eq. 4:

$$\frac{\Phi_r^\circ}{\Phi_r} \approx \frac{1+k_q^T\tau_T[Q]}{1+\{\Phi_r^S/(\Phi_r^S+\Phi_r^T)\}k_q^T\tau_T[Q]}. \quad (4)$$

Equation 4 can be rewritten as Eq. 5:

$$\frac{1}{\Phi_r^\circ/\Phi_r-1} \approx \frac{1+\Phi_r^S/\Phi_r^T}{k_q^T\tau_T[Q]} + \frac{\Phi_r^S}{\Phi_r^T}. \quad (5)$$

A linear plot of the (Φ_r°/Φ_r-1) reciprocal versus the [Q] reciprocal is predicted by Eq. 5, with an intercept of Φ_r^S/Φ_r^T and a slope of $(1+\Phi_r^S/\Phi_r^T)/(k_q^T\tau_T)$. Figure 2 depicts the linear plot in the case of 3,4-DCB. In this experiment, biacetyl was used as a quencher in place of *cis*-1,3-pentadiene in the concentration range of 0.3—2.0 mmol dm^{-3}. The least-squares fits of the plots gave the slope of 1.6×10^{-3} $dm^3\ mol^{-1}$ and the intercept of 2.2. From the value of the intercept, the contribution of each excited state to the total dechlorination was evaluated to be 0.7 for the excited singlet state and 0.3 for the excited triplet state.[15] It should be noted that the excited singlet state plays an important role in the photodechlorination of dichlorobiphenyls, while in the case of other chlorobiphenyls[3-5] the photodechlorination takes place through their excited triplet states.

The double reciprocal linear plots were not affected by the change in the concentrations of 3,4-DCB.[16]

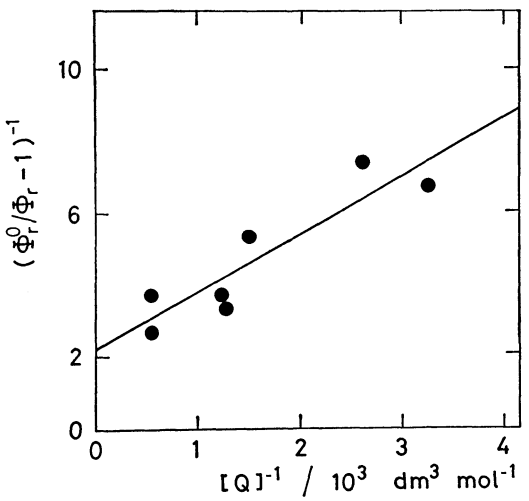

Fig. 2. Modified Stern-Volmer plot for the quenching of 3,4-DCB dechlorination in 2-propanol solution by biacetyl. 3,4-DCB: 1.5 mmol dm^{-3}.

Consequently, the dechlorination of 3,4-DCB from its excited triplet state is considered to be concentration-independent, like the dechlorination from its excited singlet state.

The results of quenching experiments at high concentrations of *cis*-1,3-pentadiene and at low concentrations of biacetyl are summarized in Table 2. A fairly good agreement is observed between them.

Photosensitized Dechlorination. Table 3 summarizes the results of dechlorination photosensitized by several ketones. Since the dechlorination of 2,3-DCB was sensitized by neither acetone nor acetophenone, the excited triplet state of 2,3-DCB was considered to be unreactive toward dechlorination. The dechlorination of 3,4-DCB was not sensitized by benzophenone, while acetone and acetophenone both sensitized the photoreaction of 3,4-DCB to give 3-chlorobiphenyl as the sole product. These photosensitization experiments revealed that the dechlorination of 3,4-DCB takes place from the excited triplet state as well as the excited singlet state, while the dechlorination of 2,3-DCB proceeds exclusively from the excited singlet state. As is shown in Table 3, sensitization by acetophenone was much less efficient than that by acetone. Benzophenone failed to sensitize the dechlorination of 3,4-DCB. The triplet energies of these ketones are as follows;[12] benzophenone, E_T=289 kJ mol^{-1}; acetophenone, E_T = 310 kJ mol^{-1}; acetone, E_T = 330 kJ mol^{-1}. The triplet energy of 3,4-DCB was estimated to be 268 kJ mol^{-1} from its phosphorescence spectrum in a EPA glass at 77 K. Although benzophenone has a higher triplet energy than 3,4-DCB by 21 kJ mol^{-1}, the photosensitized dechlorination of 3,4-DCB by benzophenone was not observed.

Wagner[17] pointed out that the quenching efficiencies of biphenyl for the photoreduction of benzophenone by benzhydrol was unexpectedly inefficient. He explained this finding on the basis of a difference in the

Table 2. Contribution of singlet and triplet states to photodechlorination in 3,4-DCB

Quencher	Relative quantum yield of photodechlorination from	
	Singlet	Triplet
cis-1,3-Pentadiene	0.8	0.2
Biacetyl	0.7	0.3

Table 3. Photosensitized dechlorination by ketones

Compound	Sensitizer	E_T[a] kJ mol^{-1}	Φ_{app}[b]	Excitation wavelength/nm
2,3-DCB	Acetone	330	0	320
	Benzophenone	289	0	366
3,4-DCB	Acetone	330	0.0097	320
	Acetophenone	310	0.0003	340
	Benzophenone	289	0	366

a) E_T is the triplet energy of a sensitizer. b) Φ_{app} is the apparent quantum yield for dechlorination and is given by:

$$\Phi_{app} = \frac{\text{number of monochlorobiphenyl molecules formed}}{\text{number of quanta absorbed by a sensitizer}}.$$

Table 4. Acetone-sensitized photodechlorination of 3,4-DCB in the presence of TEA

[TEA] / mol dm^{-3}	Φ_{app} [a]	N_{rel} [b]	Φ_{app}/N_{rel}
0	0.0097	1.00	0.0097
2×10^{-3}	0.0046	0.93	0.0049
2×10^{-2}	0.0015	0.58	0.0026
2×10^{-1}	0.0007	0.12	0.0058

a) See Table 3. b) N_{rel} is the calculated relative number of excited triplet-state 3,4-DCB molecules formed by energy transfer from excited triplet-state acetone.

geometry of biphenyl between the ground state and the excited triplet state. The most stable conformation of ground-state biphenyl is a twisted one in solution. The dihedral angle between the two phenyl rings is 20—25°. On the other hand, excited triplet-state biphenyl is considered to take a planar conformation. Thus, the energy required to activate twisted ground-state biphenyl into its twisted excited triplet state is greater than the energy liberated by the transition from the planar excited triplet state to the planar ground state. The latter energy is estimated from the phosphorescence spectrum. This is why the intermolecular energy transfer did not take place from excited triplet-state benzophenone to ground-state 3,4-DCB, since the situation described above is also the case for 3,4-DCB.

Ohashi *et al.*[18] reported that the photodechlorination of 4-chlorobiphenyl was greatly enhanced in the presence of triethylamine (TEA) by the formation of an excited charge-transfer complex between excited singlet-state 4-chlorobiphenyl and ground-state TEA. As is shown in Table 4, the apparent quantum yield of the acetone-sensitized dechlorination of 3,4-DCB decreased with an increase in the concentration of TEA.

The following deactivating processes of excited triplet-state acetone can be assumed: (1) Unimolecular decay ($k_q^T \approx 2\times10^5$ s^{-1}),[19a] (2) hydrogen abstraction from 2-propanol (k_H[2-propanol] $\approx 1\times10^7$ s^{-1}),[19b] (3) energy transfer to 3,4-DCB (k_{en}[3,4-DCB] $\approx 7\times10^6$ s^{-1}),[19c] and (4) electron transfer to TEA ($k_{el}\approx 3\times10^8$ dm^3 mol^{-1} s^{-1}).[19b] The relative number, N_{rel}, of excited triplet-state 3,4-DCB molecules formed by energy transfer from excited triplet-state acetone was calculated as a function of the concentration of TEA by assuming the above processes from (1) to (4) (Table 4). By comparing these values with the apparent quantum yields for dechlorination one can see that the efficiency of photosensitized dechlorination, Φ_{app}/N_{rel}, does not increase in the presence of TEA. Furthermore, as has been described in the previous section, the dechlorination of 3,4-DCB from its excited triplet state does not depend on its concentration. Accordingly, electron-transfer processes, such as exciplex and excimer formations, seem unlikely in the dechlorination of triplet-state 3,4-DCB. It may thus be concluded that the homolytic fission of the carbon-chlorine bond takes place in excited triplet-state 3,4-DCB.

From the quantum yield for the dechlorination and the contribution of the excited triplet state to the total dechlorination, the quantum yield for the dechlorination of 3,4-DCB from excited triplet state is evaluated to be 0.02. Since the carbon-chlorine bond-dissociation energies for aromatic chloro compounds are about 356 kJ mol^{-1},[20] the triplet-sensitized photodechlorination of 3,4-DCB by acetone or acetophenone would be endothermic.

The authors wish to express their thanks to Mr. Masao Usui of the Tokyo Metropolitan Industrial Technology Center for his helpful discussions.

(Received May 1, 1982)

The multiplicity of the photo-excited state responsible for the dechlorination reaction of monochlorobiphenyls was determined in 2-propanol. Linear Stern-Volmer plots were obtained by the use of 1,3-cyclohexadiene for the dechlorination reactions of 2- and 3-chlorobiphenyl; the slopes were 35.7 and 11.0 $dm^3\ mol^{-1}$ respectively. Fluorescence emissions were also quenched, and the quenching constants for 2- and 3-chlorobiphenyls were in accord with the respective values of the slope obtained from the Stern-Volmer plot for the reaction. The reaction of 4-chlorobiphenyl was quenched by *cis*-1,3-pentadiene, but was accelerated by 1,3-cyclohexadiene. Photosensitized dechlorinations of monochlorobiphenyls took place with several ketones, such as acetone and acetophenone. These sensitized reactions were, however, very inefficient compared with the reactions in the direct excitations, except in the case of 4-chlorobiphenyl. It was, then, concluded that the dechlorinations of 2- and 3-chlorobiphenyl occurred only from the excited singlet state, while that of 4-chlorobiphenyl took place predominantly from the excited triplet state.

In the preceding paper[1] the authors proposed that the excited singlet state plays an important role in the photodechlorinations of 2,3- and 3,4-dichlorobiphenyls, and that the dechlorinations do not proceed through excimer formation between the excited-state and ground-state chlorobiphenyls, but through simple homolytic fission in their excited states. Contrary to our results, several authors[2,3] have confirmed that the photodechlorinations of chlorobiphenyls take place through the excited triplet state. These results were obtained mainly with respect to highly chlorinated biphenyls, in which the intersystem crossings are enhanced by the internal heavy-atom effect, so that the reaction from the excited triplet state will tend to be emphasized.

In the present paper, the quenching and sensitized studies were applied to the dechlorination of 2-chlorobiphenyl (2-CB), 3-chlorobiphenyl (3-CB), and 4-chlorobiphenyl (4-CB) to make clear the excited state responsible for the reactions of the monochlorinated biphenyls. The reaction mechanism will also be discussed.

Experimental

Materials. The 2-propanol (Dotite Luminasol for fluorometry; Wako Pure Chemical) and acetone (solvent for pesticide residue analysis; Wako Pure Chemical) were used without further purification. The *cis*-1,3-pentadiene and 1,3-cyclohexadiene (Tokyo Kasei; guaranteed grade), and acetophenone (Wako Pure Chemical; guaranteed grade) were used after an ordinary distillation. The benzophenone (Wako Pure Chemical, special grade) was purified by recrystallization from ethanol. The 2-CB, 3-CB, and 4-CB were prepared by a modification of Cadogan's method.[4] The crude CBs were chromatographed several times over a silica-gel column, using hexane as the eluent, and recrystallized from ethanol. The purified CBs were contaminated by a trace of biphenyl; the contents in 2-, 3-, and 4-CB were estimated to be 0.16, 0.15, and 0.0002% respectively.

Irradiation. A solution of CBs, and the quenchers or sensitizers if necessary, was pipetted into a quartz reaction cell (4.5 ml), deaerated by bubbling nitrogen for 5 min, and then sealed. Photolyses were carried out under the following conditions: A) The reaction cell was placed in a water bath kept at 30 °C and then irradiated through an interference filter (Nihon Shinku S50ϕ, 298 nm) with a 250W highpressure mercury lamp (Ushio USH-250). B) The photolyses with a monochromatic light of an adequate purity were carried out with a Hitachi MPF-4 spectrofluorometer equipped with a 150W xenon lamp and a grating monochrometer. The intensity of incident light for reaction cell was about $(1.8—3.4)\times10^{15}$ photons s^{-1} in the wavelength region of 290—370 nm. Actinometry was done by the method of Hatchard and Parker[5] using potassium tris(oxalate)ferrate(III).

Analysis of the Photolyzed Product. The photolyzed samples were analyzed for the formation of biphenyl as follows. GLC analysis was conducted on a JEOL 20-K gas chromatograph with a flame-ionization detector employing a 2 m×3 mmϕ stainless steel column packed with 10% SE-30 on 80—100 mesh Chromosorb A (HMDS). A JEOL Model D-100 mass spectrometer was used to estimate the trace amounts of biphenyl quantitatively; the strength of the magnetic field was fixed at *m/e* 154.

Absorption and Emission Spectra. The absorption spectra of sample solutions were taken on a Union Giken SM-401 spectrophotometer before and after irradiation. The fluorescences of CBs at the ambient temperature and the phosphorescence emissions at 77 K in a EPA glass were examined with a Hitachi MPF-4 spectrofluorometer.

Results and Discussion

Quenching Experiments by Dienes. The photodechlorination reactions of 2-CB and 3-CB were quenched by 1,3-cyclohexadiene in 2-propanol. As is shown in Fig. 1, both Stern-Volmer plots were linear with an intercept equal to unity; the slopes were 35.7 $dm^3\ mol^{-1}$ and 11.0 $dm^3\ mol^{-1}$ for 2-CB and 3-CB respectively. Thus, a single excited state was considered to play an important role in the dechlorinations of both 2-CB and 3-CB. The fluorescences of these chlorobiphenyls were observed in the wavelength region of 300—380 nm. In the presence of 1,3-cyclohexadiene the fluorescences were quenched with the quenching constants of 33.5 $dm^3\ mol^{-1}$ and 11.5 $dm^3\ mol^{-1}$ for 2-, and 3-CB respectively. The respective quench-

ing constant of the dechlorination reactions for 2-, and 3-CB exhibits a good agreement with that of the fluorescence. Assuming a diffusion-control rate for the quenching,[6] the lifetimes were roughly estimated to be 7 and 3 ns for 2- and 3-CB respectively from the Stern-Volmer constants in the dechlorination reactions. The value of 3—7 ns would be reasonable for the lifetime of the excited singlet-state monochlorobiphenyls; this may be compared with that of 4-CB, reported to be 1.2—1.3 ns.[7] The dechlorination reactions of 2-, and 3-CB were concluded to take place through their excited singlet states.

The quenching reaction of 4-CB was more complicated than those of 2-, and 3-CB. A curved Stern-Volmer plot was obtained by using *cis*-1,3-pentadiene, as is shown in Fig. 2. This suggests that both excited singlet and triplet states of 4-CB are responsible for the dechlorination reaction. The slope of the curved Stern-Volmer plot decreased with the increase in the diene concentration, and the plot tend to be asymptotic to a straight line in the high-concentration ranges of diene.

As has been discussed in the preceding paper,[1] at a sufficiently high concentration of diene, the curved Stern-Volmer plot may be approximated in the following form:

$$\frac{\Phi_r^\circ}{\Phi_r} \approx \left(\frac{\Phi_r^S+\Phi_r^T}{\Phi_r^S}\right) k_q^S \tau_S [Q] + \frac{\Phi_r^S+\Phi_r^T}{\Phi_r^S} \qquad (1)$$

where Φ_r° and Φ_r are the quantum yields for the dechlorination of 4-CB measured in the absence and in the presence of a quencher respectively. Φ_r^S and Φ_r^T are the quantum yields for the dechlorination of 4-CB in the excited singlet state and the excited triplet state respectively in the absence of a quencher (namely, $\Phi_r^\circ=\Phi_r^S+\Phi_r^T$). $k_q^S\tau_S$ is the quenching constant of excited singlet-state 4-CB. [Q] denotes the concentration of the quencher, Q.

The ratio of the quantum yields for the dechlorination from the excited singlet and triplet states, Φ_r^T/Φ_r^S, can be determined from the value of the intercept. As may be seen in Fig. 2, the curved plot is not completely asymptotic to a straight line, even in high-concentration ranges of diene, but the intercept can be roughly estimated to be larger than 9. This implies that the contribution of the excited triplet state to the dechlorination of 4-CB is more than 90%. Thus, it was concluded that the dechlorination of 4-CB occurred from both excited singlet and triplet states, but predominantly from the latter state.

Interestingly, the dechlorination of 4-CB was clearly accelerated by adding 1,3-cyclohexadiene, as is shown in Fig. 2. A similar acceleration has been found in the photo-dechlorination reaction of 4-CB with triethylamine;[8] it was interpreted in terms of the formation of a charge-transfer complex between the excited singlet-state 4-CB and triethylamine in the ground state.

It is well known that aromatic hydrocarbons such as methylnaphthalenes in the excited singlet state interact with the ground-state dienes, and that the degree of exciplex formation increases with the decrease in the adiabatic ionization potential (I_p) of diene.[9] The I_p values of 1,3-cyclohexadiene and *cis*-1,3-pentadiene are believed to be 7.88 and 8.42 eV[10] respectively. This implies that 1,3-cyclohexadiene is more reactive than *cis*-1,3-pentadiene in the exciplex formation with 4-CB in the excited singlet state. Thus, 1,3-cyclohexadiene would accelerate the dechlorination of 4-CB *via* exciplex formation. On the other hand, because of the large I_p value, *cis*-1,3-pentadiene is less reactive for the exciplex formation and the charge separation in the exciplex ($CB^{\delta-}\cdots Q^{\delta+}$) would be small, so that dechlorination would not take place in this case.

Photosensitized Dechlorination. Table 1 summarizes the results of sensitizations. It must be noted that the yield shown in Table 1 does not represent the quantum yield for a dechlorination reaction from the excited triplet-state CB, since the efficiency of

Table 1. Apparent quantum yields sensitized with ketones[a-d]

Compound	Acetone	Acetophenone	Benzophenone
2-CB	0.0024		0.00010
3-CB	0.00015		
4-CB	0.0041	0.00015	0.00010

a) Apparent quantum yield = $\frac{\text{formation of biphenyl}}{\text{photons absorbed by ketone}}$. b) The excitations of these ketones were carried out at 320, 320, and 366 nm for acetone, acetophenone, and benzophenone respectively. c) The concentrations of sensitizers were as follows: acetone, 2 mol dm^{-3}; acetophenone, 2×10^{-2} mol dm^{-3}; benzophenone, 2×10^{-2} mol dm^{-3}. d) Measurements were done in duplicate, and the results were averaged.

energy transfer from the excited triplet ketone to the ground-state CB is not evaluated. The efficiency, (Φ_{et}) can be represented by a familiar equation:

$$\Phi_{et} = \frac{k_{et}[CB]}{k_d + k_h[i\text{-PrOH}] + k_{et}[CB]} \Phi_{ic}, \quad (2)$$

where k_{et} is the rate constant of energy transfer from triplet ketone to ground-state CB, k_d is the rate constant of hydrogen abstraction from 2-propanol in triplet ketone, and Φ_{ic} is the quantum yield of the intersystem crossing of ketone.

By the use of the values of the rate constants found in the literature, the efficiency could be tentatively estimated. The k_d, k_h, and Φ_{ic} values of acetone have been reported to be 2.0×10^5 s^{-1}, 1×10^6 dm^3 mol^{-1} s^{-1}, and 1.0[11] respectively. Thus, the efficiency of energy transfer from triplet acetone to CB was estimated to be 0.8, assuming the diffusion-control rate in 2-propanol[12] for k_{et}[CB]. This shows that 80% of the energy absorbed by acetone will be transferred to the ground-state CB. Therefore, the apparent yields obtained by using acetone as a sensitizer will afford the approximate quantum yields for dechlorination reactions from the excited triplet-state CBs. Table 1 makes it clear that the reactions from the excited triplet-state CBs take place. However, the dechlorinations of 2- and 3-CB are very inefficient compared with the quantum yields for dechlorinations obtained by the direct-excitation method, given in Table 2. Thus, the triplet contribution to their dechlorinations is considered to be negligibly small. This finding supports the conclusion obtained in the quenching experiments of 2- and 3-CB by 1,3-cyclohexadiene. The apparent yield of 4-CB sensitized by acetone is larger than that obtained in a direct-excitation method, but both yields are of the same order of magnitude (10^{-3}). Thus, a remarkable dechlorination from the excited triplet state of 4-CB was supported by the results of the sensitization reaction with acetone.

On the other hand, the apparent quantum yields of 4-CB sensitized by acetophenone and benzophenone are much lower than that sensitized by acetone. However, the efficiencies of energy transfer from these triplet ketones to 4-CB are presumed to be 0.7 and 0.6[13] for acetophenone and benzophenone respectively; these values are comparable to 0.8 of acetone.

Table 2. Direct photolysis of CBs in 2-propanol solution[a-c]

Compound	Irradiation time t/min	Formation of Biph c/μmol dm^{-3}	Quantum[d] yield
2-CB	15	118	0.3
3-CB	60	7.4	0.0047
4-CB	120	5.0	0.0016

a) Excitation: 290 nm. b) Strength of incident light: $\approx 1.5 \times 10^{15}$ photons s^{-1}. c) Concentrations of CBs were 5.0 – 5.5 mmol dm^{-3}. d) Value determined from the average of two or more runs.

It must be kept in mind that these efficiencies were calculated on the assumption of a diffusion-control rate for the energy-transfer process. The triplet energy of 4-CB can be roughly estimated to be 269 kJ mol^{-1} from the phosphorescence spectrum. This triplet level is low enough to accept the energy at the diffusion-control rate from triplet benzophenone, which has the lowest triplet energy (298 kJ mol^{-1})[11] among the sensitizers used. However, it has been considered by some authors[1,3,14] that the occurrence of dechlorination in CB requires a higher energy than the triplet energy estimated from the emission spectrum. Therefore, from the results shown in Table 1 one can lead the conclusion that the triplet-energy level of 4-CB responsible for dechlorination lies between the triplet levels of acetone (330 kJ mol^{-1})[11] and acetophenone (310 kJ mol^{-1});[11] the assumption of diffusion control is not satisfied in the case of acetophenone and benzophenone.

Typical carbon-chlorine bond dissociation energies for aromatic compounds are reported to be about 356 kJ mol^{-1}.[15] Therefore, the dechlorination reaction from the excited triplet state of 4-CB would be endothermic. This is confirmed by the low quantum yield shown in Table 2.

Reaction Mechanism. The dechlorinations of 2- and 3-CB occurred from the excited singlet state, while that of 4-CB occurred from the excited triplet state. Biphenyl has a planar structure in the excited singlet state,[16] whereas it is twisted in the ground state in solution. 2-CB will suffer a large steric hindrance in the excited singlet state due to the presence of the chlorine atom at the 2-position, so the chlorine atom in the excited singlet state would be very labile. We have considered that the high reactivity of the chlorine atom at the 2-position is derived from this steric effect.[17] The racemization of 2′-methoxy-6-nitrobiphenyl-2-carboxylic acid is appreciably depressed by introducing the chlorine atom at the 3′-position,[18] this depression was interpreted in terms of the buttressing effect. Thus, the hydrogen atom at the 2-position of 3-CB will be pushed to the opposite direction by the chlorine atom at the 3-position, and the rotation barrier around the carbon-carbon bond between two phenyl rings will increase. This suggests that the same lability of the chlorine atom as that of 2-CB can be expected for the dechlorination from the excited singlet-state 3-CB. However, the reaction of 3-CB should be very inefficient compared with that of 2-CB, since the rotation barrier induced by the but-

tressing effect would be much lower than the barrier induced by the chlorine atom at the 2-position.

On the other hand, the dechlorination of 4-CB occurred predominantly from the excited triplet state. The reaction from the excited singlet state would not be important, since no steric effect is expected in the case of 4-CB.

(Received May 15, 1982)

Several novel neolignans and neosesquilignans represented by heterotropanone and heterotropatrione, respectively, have been isolated from the plant *Heterotropa takaoi* M. and their structures also been elucidated on the basis of their spectral data closely related to that of asatone. From a biogenetic point of view, furthermore, these neolignans and neosesquilignans were chemically correlated to one another.

In the course of our searching for physiologically active substances in nature, we found two novel neolignans, asatone and isoasatone, in the plant *Asarum teitonense* Hayata (Taiton Kan-aoi in Japanese), the decoction of the stems and rhizomes of which has been used in Taiwan as a remedy for neuralgia by the local people.[1] In connection with these two interesting neolignans, we further examined chemical components of the plant *Heterotropa takaoi* M. (Hime Kan-aoi in Japanese) and could isolate several new types of neolignan and neosesquilignan. In this paper, we wish to describe the isolation and structures of these compounds. From a biogenetic point of view, furthermore, chemical correlation among them is also presented.

Isolation of Neolignans and Neosesquilignans. Fresh leaves and roots of the above plant, which were collected at Sanage in Aichi Prefecture in April as well as in December, were disintegrated into large amounts of methanol, and then the methanol extract was partitioned between water and ethyl acetate. The ethyl acetate extract was roughly separated by column chromatography [silica gel (Mallinckrodt, 100 mesh)] using hexane–ethyl acetate (1:1) and then ethyl acetate to give several fractions. Each fraction was further separated by a combination of repeated column chromatography (silica gel, Florisil and/or alumina) and preparative TLC (Kieselgel PF_{254}) using hexane, ethyl acetate, chloroform and/or their mixed solvent to afford heterotropanone, isoheterotropanone, isoasatone A, isoasatone B, heterotropan, heterotropatrione and isoheterotropatrione in 0.00023, 0.00074, 0.0041, 0.0012, 0.00048, 0.00042, and 0.0019% yields, respectively,[2] in addition to asatone as a main product (0.065% yield). All of them are new types of neolignan, of which the last two neolignans are regarded as a new class of neosesquilignan which consists of three C_6–C_3 units.

The Structures of Heterotropanone (1) and Isoheterotropanone (2). Heterotropanone and isoheterotropanone both have the same molecular formula [$C_{24}H_{32}O_7$(*m/e* 432(M^+))] and their spectral data are quite similar to each other, as described in Tables 1 and 2, indicating that these two neolignans must be stereoisomers.

Heterotropanone (**1**), which includes seven oxygen atoms in its molecular formula, has six methoxyl groups (δ 3.28, 3.34, 3.60, 3.82, and 3.84) and one CO group (ν_{max} 1745 cm^{-1}; δ 201.7). The presence of a partial structure [A] including 3,4,5-trimethoxyphenyl group

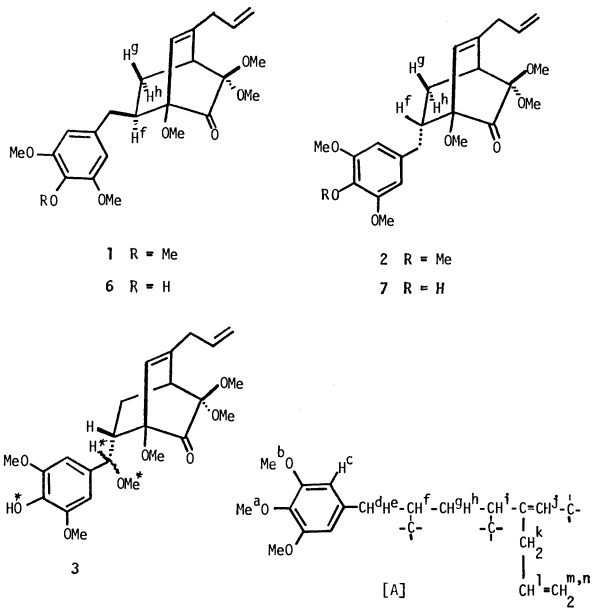

Fig. 1

can be confirmed by analysis of the ^1H NMR spectrum of **1** with aid of double resonance experiments [δ 3.82(H^a), 3.84(H^b), 6.35(H^c), 2.09(H^d),[3] 3.10(H^e), 2.47(H^f), 1.13(H^g), 1.92(H^h), 2.81(H^i), 5.84(H^j), 2.99(H^k), 5.87(H^l), 5.13(H^m), and 5.15(H^n)]. On irradiation at δ 5.84, particularly, the signals assignable to H^i and H^k became triplet and slightly broad singlet, respectively. Furthermore, the signal at δ 5.84 was changed to slightly broad singlet on irradiation at δ 2.81 as well as at δ 2.99.[4] As seen in Table 1, these spectral data are quite similar to those of the oxidation product (**3**), which has been electrochemically synthesized from 4-allyl-2,6-dimethoxyphenol,[5] except for some asterisk-hydrogen atoms in **3**. For example, each δ-value assignable to H^i is in good agreement with one another (δ 2.81 in **1**; δ 2.82 in **2**; δ 2.82 in **3**). Particularly, an exhaustive comparison between **2** and **3** indicates that both compounds adopt the same stereochemistry. Furthermore, the ^{13}C NMR spectra of heterotropanone (**1**) and isoheterotropanone (**2**) indicate that both neolignans with a bicyclic carbon skeleton have the two quaternary carbon atoms (δ 86.1 and 94.2 in **1**; δ 86.5 and 94.7 in **2**), to which three methoxyl groups must be attached, and one CO group (δ 201.7 in **1**; δ 201.0 in **2**) in addition to the carbon atoms included in the partial structure [A]. The close similarity among **1**, **2**, and **3** was further

a) In the cases of **1** and **2**, the signals corresponding to the aromatic ring are not cited. b) In the case of **8**, the signals due to a 1-propenyl group are observed at δ 18.4(q), 128.2(d), and 128.7(d).

explained by their mass spectra, as follows.

The mass spectra of both heterotropanone (**1**) and isoheterotropanone (**2**) have two characteristic peaks at *m/e* 223 and 181, and the corresponding peaks are observed at *m/e* 223 and 197 in **3**. The common fragment ion at *m/e* 223 must be formed by retro-Diels-Alder reaction of **1**, **2**, and **3** on electron impact. Finally, the stereostructures of these two neolignans (**1** and **2**) were elucidated by a comparison of their ^{1}H NMR spectra.

Of the two protons (H^g and H^h) in **1**, the signal at higher magnetic field (δ 1.13) can be assigned to H^g, whose coupling constant with H^f is 5 Hz, indicating that the relationship between H^g and H^f must be in a trans configuration. In the case of **2**, the corresponding one is 10 Hz, indicating that the dihedral angle between H^g and H^f is $\approx 0°$. From the above results, the stereostructures of heterotropanone and isoheterotropanone can be represented by **1** and **2**, respectively.

From a biogenetic point of view, these two neolignans seem to be produced *in vivo* from elemicin and an unstable dienone (**4**). Thus, they were synthesized by means of retro-Diels-Alder reaction of asatone (**5**) generating the desirable dienone (**4**), as follows.[6]

A mixture of asatone (1 equiv.) and 1-allyl-3,4,5-trimethoxybenzene (4 equiv.) in a sealed tube was heated at 175—180 °C for 1.5 h to afford heterotropanone (**1**) and isoheterotropanone (**2**) in 14 and 13% yields, respectively.[7] In addition, 4-allyl-2,6-dimethoxyphenol, demethylheterotropanone (**6**) and demethylisoheterotropanone (**7**) were also obtained in *ca.* 3, 1—2 and 1—2% yields, respectively. These two compounds (**6** and **7**) were readily converted into heterotropanone (**1**) and isoheterotropanone (**2**) in almost quantitative yields, using CH_2N_2 in ether containing methanol. Clearly, the dienone (**4**) as an important intermediate was competitively decomposed into 4-allyl-2,6-dimethoxyphenol, as shown in Scheme 1. Similarly, when heated in mesitylene, instead of 1-allyl-3,4,5-trimethoxybenzene (160—165 °C, 2.5 h), asatone (**5**) was also converted into **6**, **7**, and 4-allyl-2,6-dimethoxyphenol in 19, 18, and 27% yields, respectively.

The Structures of Isoasatone A (8) and Isoasatone B (9). Isoasatone A, which has the same molecular formula ($C_{24}H_{32}O_8$) as that of asatone (**5**),[1] shows the IR and mass spectra (ν_{max} 1745, 1720, and 1640 cm^{-1}; *m/e* 448 and 224) similar to those of asatone, indicating a close similarity of these two neolignans. In fact, on catalytic hydrogenation in ethyl acetate over 10% Pd-C, isoasatone A (**8**) was readily converted into tetrahydroasatone (**10**)[1] in 61% yield. As seen in Tables 2 and 3, however, only one different point is that isoasatone A has one 1-propenyl group (^{1}H NMR δ 1.73, 5.97, and 6.27; ^{13}C NMR δ 18.4, 128.2, and 128.7) instead of one of the two allyl groups in asatone (**5**). Particularly, the partial structure [B] including the 1-propenyl group in **8** was confirmed by the following double resonance experiments. On irradiation at δ 1.73, the olefinic proton signal at δ 6.27 was collapsed to a doublet (J=16 Hz) forming an AB system with the signal at δ 5.97, and the broad doublet at δ 5.66 was changed to a sharp doublet (J=2 Hz). On the other hand, the presence of the remaining allyl group is also confirmed by comparison of the ^{1}H NMR signals assignable to the methylene group (H^a and H^b) between **5** and **8**, as described in Table 3 (δ 2.15 and 2.60—2.95 in **5**; δ 2.34 and 2.76 in **8**). This is also supported by comparison of the δ-values of the allyl groups in the ^{13}C NMR spectra of **1**, **2**, **5** and **8** (see Table 2). Thus, the structure of isoasatone A can be represented by **8**.

Isoasatone B (**9**) with a molecular formula ($C_{24}H_{32}O_9$) has the following spectral data: *m/e* 464(M^+), 240 and 224; ν_{max} 3470, 1750, 1720, and 1640 cm^{-1}. As observed in the cases of asatone (**5**) and isoasatone A (**8**), the retro-Diels-Alder reaction of **9** took place on electron impact, leading to the formation of two fragment ions [**C** and **D**], to which the remarkable peaks at *m/e* 240 and 224 are assignable, respectively, suggesting that this neolignan has the same carbon skeleton as those of **5** and **8**. Finally, the structure of isoasatone B was unambiguously established as **9** on the basis of comparison of the ^{1}H NMR spectra between **8** and **9**, as shown in Table 3. Isoasatone B has a HO-CH_2-CH=CH- grouping (ν_{max} 3470 cm^{-1};

	6.27(1H, dq, J=16, 6 Hz)	6.28(1H, d, J=16 Hz)
5.50—6.20(2H, complex)	6.40(1H, m)	5.92(1H, m)

a) ^{1}H NMR spectrum of **8** was measured in C_6D_6. b) δ($CDCl_3$) 2.34(1H^a, dd, J=14, 7 Hz) and 2.76(1H^b, dd, J=14, 8 Hz). c) Superimposed on MeO signals.

^{1}H NMR δ 2.30, 4.30, 6.09 and 6.28) in the partial structure [**E**], which is also confirmed by the double resonance experiments similar to those of isoasatone A (**8**) having one 1-propenyl group. The other remaining signals in their ^{1}H NMR spectra are quite similar to each other, particularly in the methylene proton signals (H^a and H^b).

*The Structure of Heterotropan (**11**).* Heterotropan with a molecular formula [$C_{24}H_{32}O_6$ (*m/e* 416(M$^+$) and 208)] has a symmetric character in its structure, because only a half of the total number of protons and carbon atoms are found in its ^{1}H and ^{13}C NMR spectra: the former indicates the presence of two secondary methyl groups (δ 1.19), six methoxyl groups (δ 3.30, 3.42, and 3.54) and four methine protons (δ 2.78 and 4.15) in addition to two 1,2,4,5-tetrasubstituted aromatic rings (δ 6.11 and 6.66). This result is also compatible with the ^{13}C NMR spectrum of **11**. Thus, two possible stereostructures (**11** and **12**) were deduced from its ^{1}H NMR spectrum with aid of NOE measurements, as shown in **11**. Finally, the stereostructure of heterotropan was proved to be depicted as **11** by the following chemical evidence: *E*-asarone (**13**) was irradiated in hexane using Pyrex filter at room temperature to afford heterotropan (**11**) as the sole photodimer,[8] in 15% yield.[9]

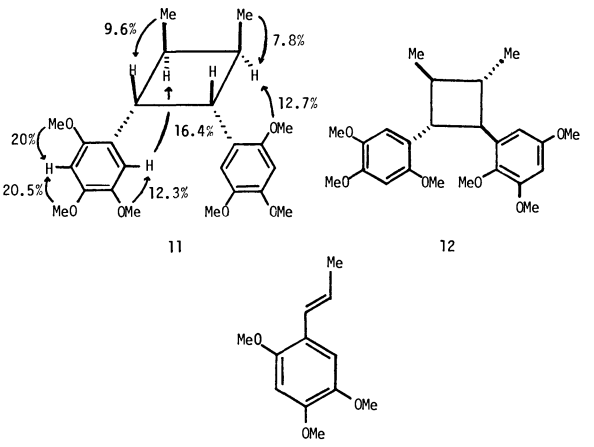

Fig. 3.

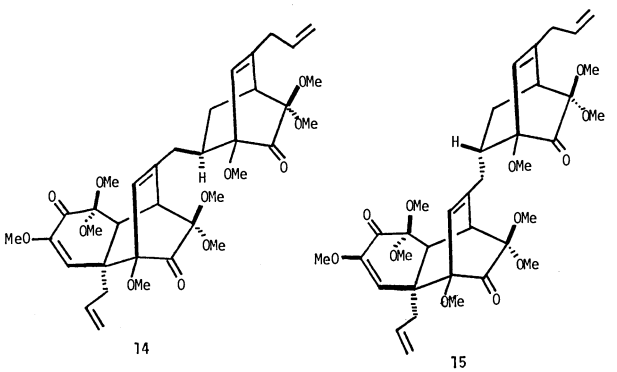

Fig. 4.

*The Structures of Neosesquilignans, Heterotropatrione (**14**) and Isoheterotropatrione (**15**).* Heterotropatrione and isoheterotropatrione both have the same molecular formula ($C_{36}H_{48}O_{12}$), and their IR, ^{1}H NMR, and mass spectra are quite similar to each other, indicating that they are stereoisomers to each other. Particularly, the ^{1}H and ^{13}C NMR spectra of **14** and **15** indicate the presence of nine methoxyl groups and three CO groups as oxygen-containing functional groups. Furthermore, the same partial structure as that of asatone (**5**) in both **14** and **15** was elucidated by comparing their mass and ^{13}C NMR spectra with those of **5**, as follows.

The mass spectra of these two neosesquilignans have a remarkable fragment peak at *m/e* 448, in addition to the molecular ion peak (*m/e* 672). The former must be generated by retro-Diels-Alder reaction of the original molecules on electron impact, as seen in the case of asatone [*m/e* 448(M$^+$) and 224]. As showm

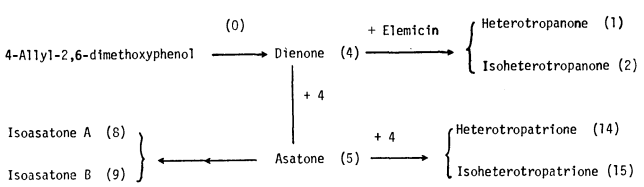
in Table 2, the ^{13}C NMR spectra of **14** and **15** include the signals corresponding to those of asatone (**5**). In addition, the remaining signals show the one to one correspondence to each carbon atom of heterotropanone (**1**) as well as of isoheterotropanone (**2**) except for the aromatic ring of **1** and **2**, suggesting that both **14** and **15** have the bicyclo[2.2.2]octane skeleton similar to that of **1** or **2**, as the partial structure.

Thus, there are two possibilities in a combination of the above two moieties. However, of the two allyl groups in asatone (**5**), the angular one must be present in both **14** and **15**, as judged by their ^{13}C NMR spectra which have the signals (δ 41.1, 117.1, and 134.8 in **14**; δ 41.4, 117.4, and 135.2 in **15**) corresponding to those of the angular allyl group in isoasatone A (**8**) (δ 41.5, 117.3, and 135.0). Finally, the stereostructures of heterotropatrione and isoheterotropatrione were elucidated by comparing their ^1H NMR spectra with those of heterotropanone (**1**) and isoheterotropanone (**2**) in addition to some chemical evidence, as follows.

Heterotropanone (**1**) has the ^1H NMR signals assignable to H^g at δ 1.13 (1H, ddd, J=3, 5, 14 Hz). In the case of heterotropatrione, the corresponding signal was also observed at δ 0.94 (1H, ddd, J=3, 4, 14 Hz). Accordingly, the stereostructure of heterotropatrione can be represented by **14**.[10] The stereostructure of isoheterotropatrione is also depicted as **15**,[10] on the basis of the ^1H NMR signals due to H^g and H^h (δ 1.41—1.92), as seen in the case of isoheterotropanone (**2**) which has the corresponding signal (H^g) at δ 1.52 in addition to the signal (H^h) at δ 1.69. In fact, these results were confirmed by the following chemical evidence.

As seen in the case of asatone (**5**) which has been converted into 4-allyl-2,6-dimethoxyphenol on zinc reduction, when treated with active zinc powder in AcOH (60 °C, 1 h), isoheterotropatrione (**15**) was readily converted into demethylisoheterotropanone (**7**) in 58.4% yield, in addition to 4-allyl-2,6-dimethoxyphenol.

Biogensis of Heterotropanone, Heterotropatrione, and Related Compounds. These novel neolignans and neosesquilignans occurring in the plant *Heterotropa takaoi* M., whose carbon skeleton consists of two or three C_6–C_3 units, are optically inactive and regarded as racemic compounds ($[\alpha]_D^{23}$ ±0°), as described in the cases of asatone (**5**) and isoasatone.[1] From a biogenetic point of view, 4-allyl-2,6-dimethoxyphenol is enzymatically oxidized to the optically inactive dienone (**4**), as an important precursor, from which a number of neolignans and related compounds are produced, as shown in Scheme 2. In fact, heterotropanone (**1**) and isoheterotropanone (**2**) both have been produced on Diels-Alder reaction between **4** and elemicin, as demonstrated in Scheme 1. On the other hand, two molecules of the dienone (**4**) react to each other to yield asatone (**5**),[11] from which both isoasatone A (**8**) and isoasatone B (**9**) may be produced. Presumably, further Diels-Alder reaction between asatone (**5**) and the dienone (**4**) affords both heterotropatrione (**14**) and isoheterotropatrione (**15**).



Scheme 2. Biogenesis of neolignans and neosesquilignans.

Experimental

All the melting points were uncorrected. ^1H and ^{13}C NMR spectra were taken on JEOL JNM-PS 100 (100 MHz) and JNM-FX 100 (25.0 MHz) spectrometers, respectively, using $CDCl_3$ as solvent, unless otherwise stated. Chemical shifts are given in ppm from TMS as an internal standard. Coupling constants are given in Hz (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet). IR spectra were recorded on a JASCO Model IR-S spectrophotometer. Mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating with an ionization energy (70 eV). Preparative TLC were carried out on Kieselgel PF_{254} (E. Merck A. G., Germany), unless otherwise stated.

Isolation of Neolignans and Neosesquilignans. Fresh leaves and roots of the plant *Heterotropa takaoi* M. (6.5 kg), which were collected as Sanage in Aichi Prefecture early in April, were pulverized with a mixer and immersed in MeOH (36 l) at room temperature for 45 d, and then filtered. The filtrates were concentrated under reduced pressure below 35 °C to leave a greenish brown residue (343 g) which was partitioned between water and AcOEt. The AcOEt layer was dried over large amounts of Na_2SO_4 and then concentrated under reduced pressure to leave a greenish brown oil (29.4 g) which was directly chromatographed on silica gel (Mallinckrodt, 100 mesh) (1350 g) and eluted successively with 3, 3.8 and 11.6 l of hexane–AcOEt (2:1) to afford three fractions (I, 4.9 g; II, 0.49 g; III, 2.3 g) after removal of the nonpolar fraction containing hydrocarbons using the same eluent (2.4 l). Further successive elution with 3.8 l of hexane–AcOEt (1:1) and then with AcOEt (1.5 l) gave two fractions (IV, 1.1 g; V, 1.0 g). Each fraction was further separated by a combination of repeated column chromatography and preparative TLC, as follows.

The fraction I was allowed to stand at room temperature to give a greenish brown solid, which was crystallized from hexane and collected by filtration to afford asatone (**5**)[1] (3.6 g). The filtrate was chromatographed on Florisil (150 g) using hexane–AcOEt (3:1) to give an oil, which was directly rechromatographed on silica gel (Mallinckrodt, 100 mesh) (50 g) and eluted with the same mixed solvent to afford asatone (600 mg). Further elution with the same mixed solvent gave an almost colorless viscous liquid of heterotropanone (**1**) (15 mg): $[\alpha]_D^{23}$ ±0°; IR (film) 1745, 1635, 1590, 1510sh., and 1500 cm^{-1}; MS (70 eV), *m/e* 432 (M^+), 404, 389, 372, 223 and 181. Found: *m/e* 432.2125. Calcd for $C_{24}H_{32}O_7$: M, 432.2148.

The fraction II was chromatographed on silica gel (Mallinckrodt, 100 mesh) (25 g) using $CHCl_3$ to give an oil (33 mg) which was purified by preparative TLC using $CHCl_3$ to afford 3,4-dimethoxybenzaldehyde (15 mg) (IR and ^1H NMR spectra). Further elution with the the same solvent also gave an oil (162 mg), which was further subjected to preparative TLC using $CHCl_3$–AcOEt (20:1) to afford asatone (**5**) (47 mg) from the less polar fraction. From the polar fraction, isoheterotropanone (**2**) (43 mg) was obtained as a colorless viscous liquid: $[\alpha]_D^{23}$ ±0°; IR (film) 1750, 1640, 1590, 1510sh., and 1505 cm^{-1}; MS (70 eV),

m/e 432 (M^+), 404, 389, 357, 223, and 181. Found: *m/e* 432.2161. Calcd for $C_{24}H_{32}O_7$: M, 432.2148.

The fraction III was roughly separated into two fractions A and B by column chromatography (Mallinckrodt, 100 mesh) (100 g) using hexane–AcOEt (4:1) and then hexane–AcOEt (2:1), respectively. Furthermore, the fraction A was chromatographed on silica gel (Mallinckrodt, 100 mesh; $CHCl_3$ as eluent) (50 g) and then on Florisil (50 g) using $CHCl_3$ as the same eluent to afford a viscous liquid, which was further chromatographed on alumina (Nakarai Chemicals, 100 mesh) (50 g) using hexane–AcOEt (2:1) to afford a crystalline solid of isoasatone A (**8**) (260 mg) in addition to a crude oil which was further purified by repeating preparative TLC [1) alumina, hexane–$CHCl_3$ (3:1); 2) 10% $AgNO_3$–SiO_2, hexane–AcOEt (1:1)] to afford a colorless viscous liquid of heterotropan (**11**) (31 mg), which was crystallized in a refrigerator. Both neoligans are characterized by their physical data: **8**: mp 122—124 °C (from hexane–ether); $[\alpha]_D^{23}$ ±0°; IR (Nujol) 1745, 1720 and 1640 cm^{-1}; MS (70 eV), *m/e* 448(M^+), 416, 384 and 224. Found: *m/e* 448.2117. Calcd for $C_{24}H_{32}O_8$: M, 448.2097. **11**: $[\alpha]_D^{23}$ ±0°; IR (film) 1610, 1590 and 1510 cm^{-1}; ^1H NMR (C_6D_6) δ=1.19 (6H, d, J=6 Hz),[12] 2.78 (2H, m), 3.30 (6H, s), 3.42 (6H, s), 3.54 (6H, s), 4.15 (2H, d, J=5.5 Hz),[12] 6.11 (2H, s) and 6.66 (2H, s); ^{13}C NMR δ=15.1(q), 34.0(d), 42.5(d), 56.1(q), 56.3(q), 56.7(q), 97.7(d), 112.4(d), 122.1(s), 142.3(s), 147.2(s) and 151.6(s). Found: *m/e* 416.2185. Calcd for $C_{24}H_{32}O_6$: M, 416.2199.

The fraction B was further chromatographed on silica gel (Mallinckrodt, 100 mesh) (100 g) using hexane–AcOEt (2:1) to give an oil (217 mg), which was subjected to repeated preparative TLC using hexane–AcOEt (2:1) and then $CHCl_3$–AcOEt (10:1) to give a viscous liquid which was further purified by preparative TLC (10% $AgNO_3$–SiO_2) using $CHCl_3$–AcOEt (10:1) to afford an almost colorless viscous liquid of heterotropatrione (**14**) (27 mg): $[\alpha]_D^{23}$ ±0°; IR (film) 1750br., 1730sh., and 1645 cm^{-1}; ^1H NMR δ=0.94 (1H, ddd, J=3, 4, 13 Hz), 1.94—2.99 (11H, complex), 3.04 (3H, s), 3.25 (3H, s), 3.27 (3H, s), 3.30 (3H, s), 3.34 (3H, s), 3.39 (3H, s), 3.47 (3H, s), 3.51 (3H, s), 3.57 (3H, s), 4.84—5.22 (4H, complex), 5.32 (1H, s), 5.45 (1H, br.s), 5.59 (1H, br.s) and 5.60—6.10 (2H, complex); MS (70 eV), *m/e* 672 (M^+), 644, 640, 565, 448 and 317. Found: *m/e* 672.3147. Calcd for $C_{36}H_{48}O_{12}$: M, 672.3145.

The fraction IV was chromatographed on silica gel (Mallinckrodt, 100 mesh) (30 g) using $CHCl_3$–AcOEt (10:1) to give a pale yellow oil (217 mg), which was subjected to preparative TLC using $CHCl_3$–AcOEt (10:1) to afford an almost colorless viscous liquid of isoheterotropatrione (**15**) (120 mg): $[\alpha]_D^{23}$ ±0°; IR (film) 1760, 1725 and 1645 cm^{-1}; ^1H NMR δ=1.41—1.92 (2H, complex), 2.0—3.0 (10H, complex), 3.05 (3H, s), 3.28 (3H, s), 3.32 (3H, s), 3.33 (3H, s), 3.37 (3H, s), 3.38 (3H, s), 3.40 (3H, s), 3.47 (3H, s), 3.57 (3H, s), 4.88—5.23 (4H, complex), 5.04 (1H, br.s), 5.38 (1H, s), 5.39—6.07 (2H, complex) and 5.84 (1H, br.s); MS (70 eV), *m/e* 672 (M^+), 644, 640, 565, 448, 418, and 343. Found: *m/e* 672.3149. Calcd for $C_{36}H_{48}O_{12}$: M, 672.3145.

The fraction V was subjected to preparative TLC using AcOEt to give a slightly greenish oil, which was further purified by preparative TLC using benzene–acetone (1:1) to give a crystalline solid of isoasatone B (**9**) (76 mg):[13] mp 129—131 °C (from hexane–ether); $[\alpha]_D^{23}$ ±0°; IR (KBr) 3470, 1750, 1720, and 1640 cm^{-1}; MS (70 eV), *m/e* 464(M^+), 432, 400, 368, 327, 240, and 224. Found: *m/e* 464.2058. Calcd for $C_{24}H_{32}O_9$: M, 464.2046.

Synthesis of Heterotropanone (1) and Isoheterotropanone (2). A solution of asatone (**5**) (44.8 mg) in 1-allyl-3,4,5-trimethoxybenzene (165 mg) in a sealed tube was heated at 175—180 °C for 1.5 h and then cooled to leave a pale brown oil, which was separated by preparative TLC using hexane–AcOEt (1:1) to afford 1-allyl-3,4,5-trimethoxybenzene (121 mg), 4-allyl-2,6-dimethoxyphenol (7.8 mg), heterotropanone (**1**) (12 mg), isoheterotropanone (**2**) (11.6 mg), demethylheterotropanone (**6**) (*ca.* 1 mg) and demethylisoheterotropanone (**7**) (*ca.* 1 mg). The first four products were identified by comparing their TLC [hexane–AcOEt (3:1)] and IR spectra with those of each authentic sample. Demethyl compounds (**6** and **7**) were characterized by their spectral data: **6** as a pale yellow oil: IR (film) 3500br., 1750, 1610, and 1520 cm^{-1}; MS (70 eV), *m/e* 418(M^+), 343, 285, and 167. Found: *m/e* 418.2010. Calcd for $C_{23}H_{30}O_7$: M, 418.1991. **7** as an almost colorless oil; IR (film) 3500 br., 1755, 1615, and 1520 cm^{-1}; MS (70 eV), *m/e* 418 (M^+), 343, 285, and 167. Found: *m/e* 418.2012. Calcd for $C_{23}H_{30}O_7$: M, 418.1991. Furthermore, these two phenols (**6** and **7**) were dissolved in excess CH_2N_2 in ether (20 ml) containing MeOH (5 ml), allowed to stand at room temperature overnight and then concentrated under reduced pressure to leave the corresponding methyl ethers (**1** and **2**) in quantitative yields, respectively [TLC (hexane–AcOEt (3:1) and IR spectra].

Thermal Reaction of Asatone (5). A solution of asatone (39 mg) in mesitylene (1 ml) was gently heated under reflux for 2.5 h, and then concentrated under reduced pressure to leave a pale yellow oil, which was subjected to preparative TLC using hexane–AcOEt (1:1) to afford 4-allyl-2,6-dimethoxyphenol (9.2 mg), demethylheterotropanone (**6**) (7.1 mg) and demethylisoheterotropanone (**7**) (6.0 mg) [TLC (hexane–AcOEt (1:1) and IR spectra].

Catalytic Hydrogenation of Isoasatone A (8). Catalytic hydrogenation of isoasatone (15 mg) in AcOEt (2 ml) was carried out over 10% Pd–C (5 mg) at room temperature overnight. After filtration of the catalyst, the solvent was evaporated under reduced pressure to leave a white crystalline solid, which was purified by preparative TLC using hexane–AcOEt (3:1) to afford white crystals of tetrahydroasatone (**10**) (9.2 mg) (mp and IR spectrum).[1]

Synthesis of Heterotropan (11). A solution of *E*-asarone (40 mg) in hexane (5 ml) was irradiated at room temperature for 10 d, using Pyrex filter [apparatus: Eiko-Sha PIH-100, high pressure Hg lamp (100 W)]. The reaction solution was then evaporated under reduced pressure to leave a pale yiellow oil, which was purified by preparative TLC using hexane–AcOEt (3:1). From the more polar fraction corresponding to that of heterotropan (**11**), a colorless viscous liquid (*ca.* 6 mg) was obtained [TLC (hexane–AcOEt (3:1)) and IR spectrum]. From the less polar fraction, a mixture of *E*- and *Z*-asarones (*ca.* 30 mg) was obtained without further purification.

Zinc Reduction of Isoheterotropatrione (15). A mixture of isoheterotropatrione (115 mg) and activated zinc powder[14] (500 mg) in AcOH (2 ml) was heated at 60 °C, with stirring, for 1 h, and then poured into a lot of water, and then extracted with AcOEt. The extract was successively washed with dil. $NaHCO_3$ aq solution and sat. NaCl aq solution, and then dried over Na_2SO_4. Removal of the solvent under reduced pressure afforded a brown oil (76.7 mg), which was subjected to preparative TLC using $CHCl_3$–AcOEt (10:1). From the less polar fraction, 4-allyl-2,6-dimethoxyphenol (30 mg) was obtained [TLC (hexane–AcOEt (3:1)) and IR spectrum]. From the polar fraction, a colorless viscous liquid (41.8 mg) was obtained, whose TLC (hexane–AcOEt (1:1)) and IR spectrum were completely identical with those of demethylisoheterotropanone (**7**).

The authors wish to thank Dr. Masaaki Toda (Ono Central Research Institute) and Mr. Shinpei Kidokoro (Ohmori Research Institute, Tobishi Pharmaceutical Co. Ltd.) for measurements of high resolution mass spectra. This research has been supported in part by grants from the Ministry of Education, Science and Culture to which greatful acknowledgement is made.

(Received May 25, 1982)

Crystals of 1,2,3,4-tetrachloro-9-(2-oxopropyl)triptycene grown from tetrahydrofuran-hexane were found to contain 1:1 *ap* and ±*sc* rotational isomers about the C_9–C_{Pr} bond by the X-ray diffraction method. The molecular structures had the following features. The acetyl group in the 9-substituent takes an *O*-inside, relative to the triptycene skeleton, conformation in both forms. The benzene rings are deformed by the steric effect to form boats. The 2-oxopropyl groups in both forms were planar within the experimental error but the C_2–C_1 bond in the 2-oxopropyl group was appreciably shorter in the ±*sc* conformation than that in the *ap*. The results are discussed on the ground of steric repulsion and the existence of the interaction between the C=O and the Cl groups which are located only 3.035 Å apart in the ±*sc* form.

A number of 9-substituted triptycenes was synthesized to manifest isolation of stable rotational isomers and to examine the effects of substituents on the rotational barrier.[2,3] Out of these studies, it has emerged that triptycenes which carry a *t*-alkyl group in the 9-position exhibited high enough barriers to rotation to isolate the rotamers at room temperature, whereas those carrying an *s*-alkyl group in the 9-position possess barriers to rotation which are borderline values for isolation of rotamers at room temperature.

Triptycenes carrying a primary 9-substituent exhibit still lower barriers than 9-*s*-alkyltriptycenes and the internal rotation in 9-(primary alkyl)triptycenes is frozen only on the NMR time scale at low temperatures which are easily accessible. Although the internal rotation is fast in these compounds, the population ratios of the rotamers concerned afford interesting information. Since the peri-substituent in the 1-position of the triptycene skeleton is very closely located to the second atom of the 9-substituent, if a proper rotational form is taken, a weak interaction, which is not otherwise detected, can be detected as a change in populations of rotamers due to the highly congested state.

We found that unusually facile cyclization occurs, if a cationoid is formed in the second atom of the 9-substituent, between the cationoid center and the 1-methoxyl group in 9-substituted 1,4-dimethoxytriptycenes.[4] 9-(2-Acyloxyethyl)-1,4-dimethoxytriptycenes show higher ±*sc*/*ap* values when the acyl group becomes more electronegative to indicate that an interaction exists between the acyloxymethyl and the 1-methoxyl groups.[5] 9-Substituted triptycenes carrying a carbonyl group in the 2-position of the 9-substituent showed high ±*sc*/*ap* values, if there is an electron-donating substituent in the 1-position of triptycene, to suggest that there is an attractive interaction between the carbonyl and the 1-substituent.[6] All of these results imply that the triptycene system is a good model to find a weak, often hidden interaction by either a reaction or population distribution.

During the course of investigation on *n*-donor-carbonyl interaction, we encountered a queer phenomenon. Apparently a formyl group is less electron accepting than an acetyl group. This is contrary to the common sense of organic chemistry because aldehydes are usually more reactive than ketones toward nucleophiles. We suspected that the origin of this anomaly might be the presence of different conformations in aldehydes from those of ketones. Since a hydrogen is much smaller than an oxygen atom in a formyl group, an oxygen-inside conformation relative to the triptycene skeleton is of prohibitively high energy in the case of 9-(2-oxoethyl)triptycenes, while such a conformation will be favored in the case of 9-(2-oxopropyl)triptycenes because an oxygen atom is smaller than a methyl group. Unfortunately, strongly interacting formyl compounds did not give crystals suitable for X-ray analysis. However, 1,4-dimethyl-9-(2-oxoethyl)triptycene gave good crystals and its *ap* form was shown by X-ray crystallography to exist as an oxygen-outside conformation.[6b]

1,2,3,4-Tetrachloro-9-(2-oxopropyl)triptycene, which was known to exist as ±*sc* conformations solely in solution,[6] was found to give good crystals in which both ±*sc* and *ap* conformations are contained. Thus fortunately we can now compare the molecular structures of ±*sc* and *ap* forms of this compound. This paper reports the outcome of the investigation and discusses the implications of the results.

Experimental

Crystals of 1,2,3,4-tetrachloro-9-(2-oxopropyl)triptycene was grown from a tetrahydrofuran-hexane solution. A crystal with dimensions $0.45\times0.44\times0.37$ mm^3 was mounted on a Rigaku automated four-circle diffractometer and the intensity data were collected using Mo $K\alpha$ radiation monochromated by a graphite plate. The θ-2θ scan technique was employed to collect the intensities with $|F_o|\geq3\sigma|F_o|$ in the range $2\theta\leq57°$. A total of 6067 reflections were used for analysis.

The crystal data are as follows: $C_{23}H_{14}Cl_4O$, F.W.=448.18, monoclinic, space group $P2_1/a$, $a=30.812(2)$ Å, $b=8.304(1)$ Å, $c=15.103(1)$ Å, $\beta=97.19(1)°$, $Z=8$, $D_x=1.55$ g cm^{-3}, μ(Mo $K\alpha$)$=6.29$ cm^{-1}.

The structure was solved by the direct method. Isotropic temperature factors were used for hydrogen atoms and anisotropic temperature factors were employed for others. All these positional and thermal parameters were refined by the least-squares method including the anomalous scattering corrections for chlorine, oxygen, and carbon atoms. The atomic scattering factors were taken from a literature.[7] The final R value was 0.048.

TABLE 1. ATOMIC POSISIONAL PARAMETERS ($\times 10^4$) WITH ESTIMATED STANDARD DEVIATIONS IN PARENTHESES AND ANISOTROPIC TEMPERATURE FACTORS ($\times 10^4$)[a)]

a) The form of the anisotropic temperature factor is: $T=\exp(-B_{11}h^2-B_{22}k^2-B_{33}l^2-2B_{12}hk-2B_{13}hl-2B_{23}kl)$.

Results and Discussion

The nonhydrogen atomic positional parameters are tabulated in Table 1. In the crystalline state, two molecules, *ap* and +(or −)*sc*, coexist in an asymmetric unit, as shown in Fig. 1. The coexistence of *ap* and ±*sc* conformations enables us to compare the structural features and to discuss the implications of the structures which were not possible in other triptycenes.

We point out first that the acetyl groups in both conformations take the *O*-inside conformation, as are seen in Fig. 1. Thus the difference in conformations about the carbonyl moieties in the formyl and the acetyl compounds is now verified. The Coulombic attraction between the acetyl group and the peri-chloro must be playing some role in stabilizing the ±*sc* form

of 1,2,3,4-tetrachloro-9-(2-oxopropyl)triptycene, in contrast to the Coulombic repulsion between the formyl and the peri-chloro groups in 1,2,3,4-tetrachloro-9-(2-oxoethyl)triptycene that should destabilize the $\pm sc$ form.

The intramolecular strain seems to be distributed widely over the molecules. This can be pointed out from bond lengths and bond angles (Table 2), atomic shifts from the least-squares planes of the carbon atoms in the aromatic groups (Table 3), and dihedral angles concerned (Table 4). Numberings of atoms and designations of rings are shown in Fig. 2.

There are some common features of structures in both ap and $\pm sc$ forms. The bond lengths of C_9–C_{17} are very large 1.578 Å in ap and 1.564 Å in $\pm sc$, although these distances are not so long as that in 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene.[8] Other bonds

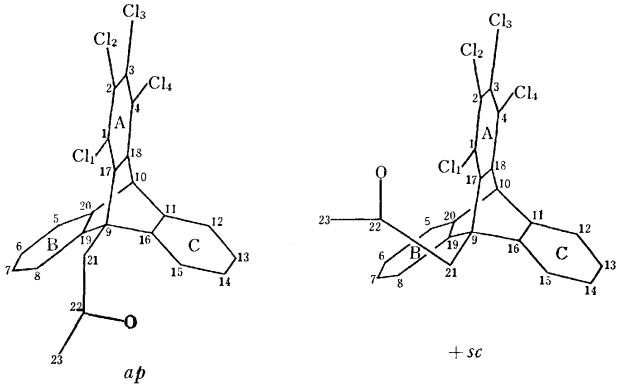

Fig. 2. Numberings of atoms and designations of rings in ap- and $\pm sc$-1,2,3,4-tetrachloro-9-(2-oxopropyl)-triptycene.

connecting the C_9 with the aromatic rings are also longer than the normal C_{sp^2}–C_{sp^3} bond and this point is apparent if one compares those with bonds connecting C_{10} with aromatic rings. The bond angles C_1–C_{17}–C_9 are extraordinarily large, reflecting the relief of steric strain by the deformation. The C_9–C_{21} bond lengths are shorter than normal C_{sp^3}–C_{sp^3} bonds: this is attributed to the increased s-character of the orbital concerned of C_9 because of the lengthening of other bonds involving C_9. The apex angle of the pyramid formed by C_9 with C_{16}, C_{17}, and C_{19} is smaller than that formed by C_{10} with C_{11}, C_{18}, and C_{20}, indicating that the steric repulsion between Cl_1 and the 9-substituent is relieved by this modification as well. The similar structural features were also found in 1,4-dimethyl-9-(2-oxoethyl)triptycene.[6b]

The Cl_1–C_1 and C_9–C_{21} bonds are tilted against each other, as were the cases in 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene.[8] The bond angle deformation is much greater for the angle C_{17}–C_9–C_{21} than that for Cl_1–C_1–C_{17} because of the large force constant for the deformation of Cl–C_{sp^2}–C_{sp^2} and buttressing effect of the Cl_2 and others. The small apex angle of C_9 pyramid may also contribute to enlarging the angle C_{17}–C_9–C_{21}. Rather small difference in bond angles C_{17}–C_9–C_{21} between the ap and the $\pm sc$ forms may be taken as supportive in assuming that the ground state energies of the ap and the sc forms are nearly the same as far as the interaction between the 9-substituent and the flanking benzene rings are concerned. Relatively long C–Cl distances in both forms (average 1.728 Å) may be due to the repulsive force among chlorine atoms.

The least squares planes of aromatic rings were cal-

culated from the positional parameters of carbon atoms comprising the rings. Dihedral angles made by two aromatic rings listed in Table 4 clearly demonstrate that the dihedral angles made by two benzene rings which flank the acetyl group are much larger than others in both *ap* and $\pm sc$ forms. This will mean that the carbonyl oxygen which extends into the gap between the two benzene rings interacts strongly with the aromatic rings.

Alternatively, the aromatic rings exhibit interesting features. Although less significant in another, the benzene rings flanking the acetyl group are distorted significantly. C_1 and C_8 in rings A and B which are close to the acetyl group are significantly displaced from what is expected from a molecular model to avoid repulsive interactions in the $\pm sc$ form. Similarly C_8 in the B ring and C_{15} in the C ring of the *ap* form show significant displacement. Examining the structures of these benzene rings, we notice that the carbon atoms para to each other are displaced from the least squares plane, which is made by other four carbons, to the same direction to form boats. They are C_3 and C_{17} in A, C_6 and C_{19} in B and C_{11} and C_{14} in C of the *ap* form, whereas C_3 and C_{17} in A, C_5 and C_8 in B and C_{11} and C_{14} in C of the $\pm sc$ isomer form also the bow and the stern of a boat. This makes a sharp contrast to the fact that triptycene itself possesses planar benzene rings within 0.01 Å.[9] There are a few examples of the boat form of twisted benzenes in the literature[10] and theoretical verification for the boat benzene was given.[11] However, the earlier works treat relatively small shifts from the mean plane and/or contain large ambiguities in atomic coordinates. Since the shift from the plane observed in this study is large and the standard deviations of the positional parameters perpendicular to the plane are small (*ca.* 0.003 Å) for carbon atoms, the results serve as unambiguous evidence for the stability of the boat form of benzene.

In contrast to the benzene rings, the 2-oxopropyl groups make perfect planes (Table 3), which nearly include the C_9–C_{10} axis. However, the planes of the 2-oxopropyl groups were not coplanar with the mean plane of the benzene ring which is *ap* to the group: the 2-oxopropyl group does not bisect the dihedral angle made by flanking benzene rings but are close to one of the two aromatic rings. The deviation from the anti-benzene planes are 6.9° (closer to ring B than to ring C) and 12.6° (closer to ring B than to ring A) for *ap* and $\pm sc$ forms respectively. It is reasonable to be so in the $\pm sc$ form because the steric repulsion between the ring A and the 2-oxopropyl group will be severe (for attractive interactions *vide infra*). The reason for the asymmetric structure of the *ap* form is not understood at the moment.

The structural features discussed so far are rather common for both conformations of 1,2,3,4-tetrachloro-9-(2-oxopropyl)triptycene but there are some structural features which are different when we go from the *ap* conformation to the $\pm sc$. Bond lengths and bond angles, which show differences more than 3σ and 7σ, respectively, are listed in Table 5. The large bond angles of C_{17}–C_9–C_{19} for the $\pm sc$ form relative to the *ap* and the same trend of C_{16}–C_9–C_{19} for the *ap* form relative to the $\pm sc$ can be attributed to the steric effect of the 2-oxopropyl group, as were seen in the dihedral angles made by two aromatic rings. The large bond angle of C_{18}–C_{10}–C_{20} in the $\pm sc$ form, though smaller than 7σ, relative to the *ap* may have the same origin because the bond angle C_{11}–C_{10}–C_{20} is also larger in the *ap* form than in the $\pm sc$.

Table 5. Structural parameters which differ by over the estimated errors on going from the $\pm sc$ to the *ap* isomers[a,b]

Bond length	l/Å	Bond angle	ϕ/°
C_9–C_{17}	−0.014(4)	C_{16}–C_9–C_{19}	−2.6(2)
C_{21}–C_{22}	−0.036(5)	C_{17}–C_9–C_{19}	3.8(2)
		C_{17}–C_9–C_{21}	1.7(2)
		C_9–C_{21}–C_{22}	2.2(3)

a) The difference is shown in the form: parameter(sc) − parameter(ap). b) Those listed here show differences of $\Delta r \geq 3\sigma(r)$ and $\Delta\theta \geq 7\sigma(\theta)$.

The differences in other bond lengths and bond angles deserve further comment on the ground of the postulated Cl···C=O interaction.[5] We propose that the 2-oxopropyl group and its vicinity assume the structure of the *ap* conformation if there is no interaction which affects the structure. The *ap* form possesses the following features. The C_9–C_{17} bond is abnormally long for normal C_{sp^2}–C_{sp^3} bonds. This must be attributed to the steric effect of the 9-substituent. Another point of interest is the C_{21}–C_{22} bond: it is unusually long as a C_{sp^2}–C_{sp^3} bond. This together with the fact that the bond angle C_9–C_{21}–C_{22} is larger than the normal tetrahedral angle suggests that, to relieve the steric strain caused by the carbonyl oxygen and the flanking benzene rings, the 2-oxopropyl group is deformed.

Comparing the bond lengths of the $\pm sc$ and *ap* forms, one notices that the unusuality observed in the *ap* form is corrected to some extent: the C_9–C_{17} bond length and the C_{21}–C_{22} bond length become closer to the normal values in the $\pm sc$ form than in the *ap* form. However, the bond angles C_{17}–C_9–C_{21} and C_9–C_{21}–C_{22} are larger in the $\pm sc$ form than in the *ap* form. We wish to attribute the structural change to the relative positions of the 1-chloro and the carbonyl groups in space which are required for the Cl···C=O interaction, as suggested by Dunitz and his coworkers.[12] If the bonds are longer, the geometry is not favorable for the Cl···C=O interaction. Therefore the bonds must shrink from the values observed in the *ap* form in order to realize the interaction in the $\pm sc$ form. However, if the shrinkage occurred without change in bond angles, the steric repulsion between the carbonyl oxygen and the aromatic rings would be too great. Thus the molecule shrinks in the $\pm sc$ form at the expense of widening the bond angles for which energy required is small.

One might argue that if there is a Cl···C=O interaction, the nonplanarity of the 2-oxopropyl group should be observed as are the cases in N···C=O interactions.[12,13] However, we believe that the carbonyl

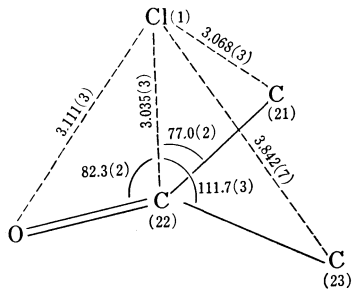

Fig. 3. Atomic distances and angles showing relative positions in space of the Cl_1 and the 2-oxopropyl group.

group in this case is under special conditions. As are depicted in Fig. 3, the Cl_1 atom located over the 2-oxopropyl group is over the C=O bond, closer to the carbon of the carbonyl group than the oxygen, to make $Cl_1\cdots C_{22}$–O angle of 82.3° and is closer to the C_{21} atom than the C_{23}. Under the optimum conditions of N···C=O interaction, the nitrogen is on the bisecting plane of the C–C(O)–C angle and N···C=O angle is close to 109°.[12] The reason for the unfavorable arrangement in space of the Cl_1 and the 2-oxopropyl group is of course the geometrical requirements, bond angles and bond lengths. Thus we have to admit that, although the Cl_1 and the carbonyl carbon are located closely, the relative arrangement of the two groups is far from the optimum one. Therefore, the Cl···C=O interaction we observe in this compound may not be very strong. There is another possible reason why we do not observe the pyramidality of the 2-oxopropyl group. That is the steric reason. If it were to take a pyramidal structure, the repulsion between the atoms within the 2-oxopropyl group and the benzene ring B in the $\pm sc$ conformation would become formidable.

There is a piece of evidence, however, that there is an attractive interaction of a Cl···C=O type from the X-ray diffraction results. That is the bond lengths of the C=O. The C_{22}–O bond in the $\pm sc$ form is longer than that in the *ap* by 0.009 Å, although the difference is not listed in Table 5 because this is within 3σ. But it is tempting to consider that the C=O bond in the $\pm sc$ form is lengthened by the Cl···C=O interaction.

We conclude from both the population ratio in solution and the structural features observed by X-ray diffraction that there exists a Cl···C=O interaction in 1,2,3,4-tetrachloro-9-(2-oxopropyl)triptycene, if it is the $\pm sc$ form. The main driving force for the interaction is the charge transfer between the Cl_1 and the carbonyl carbon which are placed in proximity (3.035 Å), although their relative geometry is far from the optimum for the interaction. This interaction is strong enough to deform the 2-oxopropyl group in the $\pm sc$ conformation from that in the *ap* as discussed above. The C=O bond is lengthened by the Cl···C=O interaction in the $\pm sc$ form from that in the *ap*.

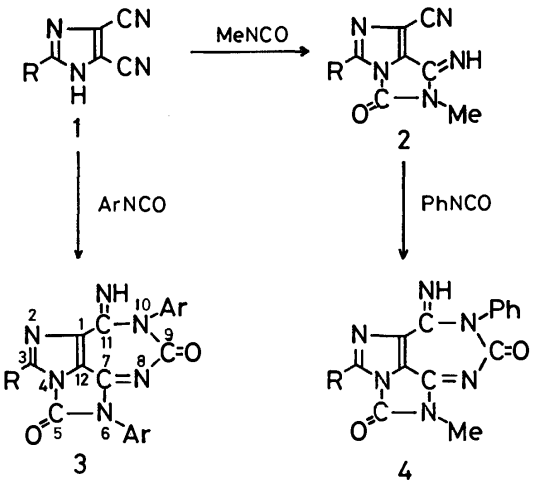
(Received June 1, 1982)

The reactions of 4,5-dicyanoimidazoles with methyl isocyanate gave 7-cyano-1-imino-2-methyl-2,3-dihydro-1*H*-imidazo[3,4-*c*]imidazol-3-ones (**2**), while the similar reactions with phenyl isocyanate resulted in the formation of the tricyclic imidazoles, 11-imino-6,10-diphenyl-2,4,6,8,10-pentaazatricyclo[5.4.1.$0^{4,12}$]dodeca-1(12),2,7-triene-5,9-diones (**3**) and the same type of the tricyclic imidazoles **4** were obtained by carbamoylation of **2** with phenyl isocyanate. The reactions of **2**, **3**, and **4** with amines were further investigated.

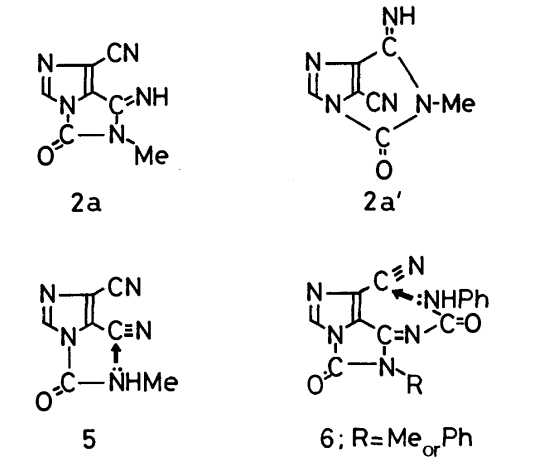
It is well known that imidazole itself reacts with isocyanates under mild conditions to form 1-(substituted carbamoyl)-1*H*-imidazoles,[1-3] which can be rearranged to 2-(substituted carbamoyl)-1*H*-imidazoles at a high temperature and that such 4,5-disubstituted imidazoles as 4,5-diarylimidazoles yield 2-(substituted carbamoyl)-1*H*-imidazoles by the reactions with aryl isocyanates under rather drastic conditions.[4-6] These interesting results of carbamoylation and rearrangement prompted us to apply such reactions to 4,5-dicyanoimidazoles to search some new imidazole derivatives.[7] In the present paper, we wish to report on the reactions of 4,5-dicyanoimidazoles with isocyanates which afford the novel condensed tricyclic imidazoles *via* ready intramolecular cyclization of the assumed intermediates, 4,5-dicyano-1-(substituted carbamoyl)-1*H*-imidazole followed by further cyclization of thus formed bicyclic imidazoles with another isocyanate.



Scheme 1.

Results and Discussion

The reaction of 4,5-dicyanoimidazole (**1a**) with methyl isocyanate was carried out in chloroform at room temperature for 24 h in the presence of 2-methyl-1,4-diazabicyclo[2.2.2]octane (Me-DABCO)[8] and a catalytic amount of dibutyltin dilaurate (DBTDL).[9] Me-DABCO was added not only to dissolve **1a** completely but to accelerate the reaction. The resulting precipitate was collected and recrystallized from chloroform to give the white plates which were assigned to 7-cyano-1-imino-2-methyl-2,3-dihydro-1*H*-imidazo-[3,4-*c*]imidazol-3-one (**2a**) on the basis of its spectral data and elemental analysis. The elemental analysis and the integration in ^{1}H NMR spectrum suggest an 1:1 adduct between **1a** and methyl isocyanate, while the IR spectrum shows bands at 3300(NH), 2220(C≡N), 1780(C=O), and 1670 cm^{-1}(C=N). In particular, band due to carbon-oxygen at 1780 cm^{-1}, which is much higher than that (about 1730 cm^{-1}) in the usual 1-(alkylcarbamoyl)-1*H*-imidazole,[5] strongly supports the five-membered ring structure **2a**.[10] Moreover, the strongly deshielded singlet peak of methyl protons (δ 3.20) in ^{1}H NMR is consistent with this structure.[11] Although the alternative structure **2a'** derived by the participation of 4-cyano group can be anticipated, it is denied from the steric consideration in constructing the model.



The similar reactions of 2-methyl (**1b**) and 2-ethyl analogues (**1c**) gave the corresponding bicyclic imidazoles **2b** and **2c** (Scheme 1). These results are summerized in Table 1.

On the other hand, the reactions with aryl isocyanates gave the quite different products. The reaction of **1a** with phenyl isocyanate at room temperature in the presence of Me-DABCO and DBTDL gave the tricyclic imidazole, 11-imino-6,10-diphenyl-2,4,6,8,10-pentaazatricyclo[5.4.1.$0^{4,12}$]dodeca-1(12),2,7-triene-5,9-dione (**3a**), in 62% yield. Its structure was determined by an elemental analysis and spectroscopic properties. The elemental analysis, the MS spectrum (*m/e*; 356, M$^+$), and the integration in ^{1}H NMR spectrum indicate an adduct between **1a** and two

a) Isolated yields after recrystallization, being based on isocyanates. b) Yield obtained by running the reaction in nitrobenzene without catalyst.

equiv. of phenyl isocyanate. The IR spectrum shows bands at 3270(NH), 1780(C=O), 1685(C=N), and 1640 cm^{-1}(C=O and C=N),[12] no absorption due to the C≡N group being observed. These data support the structure **3a**.

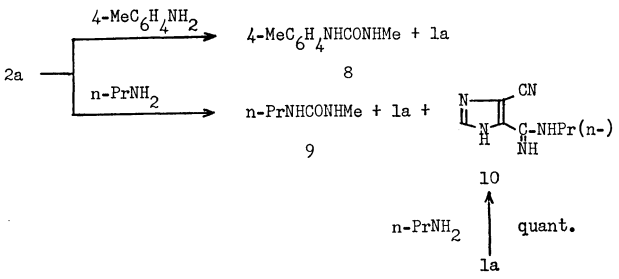
Reaction of **1a** with 1-naphthyl isocyanate and of **1b** and **1c** with phenyl isocyanate gave also the corresponding tricyclic imidazoles **3a′**, **3b**, and **3c** (Scheme 1, Table 2).

Under more drastic conditions of refluxing in nitrobenzene for 2.5 h, the reaction of **1a** with phenyl isocyanate was carried out and only the tricyclic imidazole **3a** was obtained. The formation of 4,5-dicyano-2-(phenylcarbamoyl)-1*H*-imidazole expected through rearrangement[4] couldn't be observed at all.

Though the bicyclic imidazole **2a** didn't undergo the further reaction with another molecule of methyl isocyanate, it reacted with phenyl isocyanate to give the similar tricyclic imidazole, 11-imino-6-methyl-10-phenyl-2,4,6,8,10-pentaazatricyclo[5.4.1.0^{4,12}]dodeca-1(12),2,7-triene-5,9-dione (**4a**), of which structure was also identified on the basis of its elemental analysis and spectral data. The bicyclic imidazoles **2b** and **2c** gave the similar results which were summerized in Table 2.

The formation of **2**, **3**, and **4** can be explained in terms of the intramolecular cyclization of the presumed intermediates **5** and **6**. The bicyclic imidazole **2** may be led *via* the attack of the carbamoyl nitrogen of **5** at the carbon of 5-cyano group causing proton transfer. In the case of methyl isocyanate the reaction terminates at this step, whereas in the case of more reactive phenyl isocyanate, it may further proceed *via* addition of another molecule of isocyanate followed by the cyclization with 4-cyano group to give **3** and **4**.

Next the reactivity of **2**, **3**, and **4** toward amines was investigated. 4-Methylaniline reacted with **3a** giving *N*-(4-methylphenyl)-*N′*-phenylurea (**7**) and with **4a** to yield urea **7** along with a small amount of *N*-(4-methylphenyl)-*N′*-methylurea (**8**). These results seem to suggest that amine initially attacks the carbonyl group of the diazepine ring and then that of imidazolidine ring. The reaction of **2a** with 4-methylaniline was then carried out, affording urea **8** and **1a** in 42 and 35% yields, respectively, whereas the



Scheme 2.

similar reaction with a more nucleophilic amine, propylamine, gave not only *N*-methyl-*N'*-propylurea (**9**) (41%) and a trace amount of **1a** but also 4-cyano-5-(N^1-propylamidino)-1*H*-imidazole (**10**) in 26% yield (Scheme 2). From the fact that **1a** reacted with propylamine to give the imidazole **10** quantitatively, it is supposed that **10** was obtained by the reaction of propylamine with the initially formed **1a**.

Experimental

All melting points are uncorrected. IR spectra were recorded on a JASCO IRA-1 spectrometer. ^{1}H NMR spectra were measured with a JEOL JNM-PMX 60 spectrometer using tetramethylsilane (TMS) as an internal standard, the chemical shifts being given in δ ppm downfield from TMS. MS spectra were recorded on a Finnigan 3300E GC-MS spectrometer operating at 120 eV.

Dicyanoimidazoles **1a**—**c** were prepared by routes reported in the previous paper.[13] Elemental analyses and $\nu_{C=O \text{ and } C=N}$ in IR (KBr) for **2**, **3**, and **4** are summerized in Tables 1 and 2.

Reaction of 1a with Methyl Isocyanate. A solution of 4.8 g (40 mmol) of **1a**, 5 drops of DBTDL, 4 ml of Me-DABCO, and 2.3 g (40 mmol) of methyl isocyanate in 60 ml of anhydrous chloroform was stirred at room temperature for 24 h. The precipitated white solid was collected and recrystallized from chloroform to give the white plates **2a** (4.2 g, 60%), mp, 166—169 °C. ^{1}H NMR (DMSO-d_6–$CDCl_3$) δ 3.20 (s, 3, N-CH_3), 8.35 (s, 1, imidazole 2H), and 9.90 (s, 1, NH). IR (KBr) 2220 (C≡N) and 3300 cm^{-1} (NH).

Similarly **2b** was obtained in 64% yield, mp, 156—159 °C (recrystallized from chloroform–carbon tetrachloride). ^{1}H NMR (DMSO-d_6–$CDCl_3$) δ 2.70 (s, 3, CH_3), 3.20 (s, 3, N-CH_3), and 9.40 (s, 1, NH). IR (KBr) 2220 (C≡N) and 3295 cm^{-1} (NH).

Reaction of 1c with Methyl Isocyanate. Methyl isocyanate (1.1 g, 20 mmol) was added to a solution of 2.9 g (20 mmol) of **1c**, 5 drops of DBTDL, and 2 drops of Me-DABCO in 30 ml of anhydrous chloroform. After the reaction mixture was stirred at room temperature for 24 h, the solvent was distilled out under reduced pressure to give the residual oil. The oil was placed on the column (silica gel) and eluted with chloroform to give the crude white solid **2c**. The solid was recrystallized from carbon tetrachloride to afford the white plates **2c** (1.8 g, 44%), mp, 119—122 °C. ^{1}H NMR ($CDCl_3$) δ 1.40 (t, 3, CH_3), 3.05 (q, 2, CH_2), 3.30 (s, 3, N-CH_3), and 8.75 (s, 1, NH). IR (KBr) 2220 (C≡N) and 3295 cm^{-1} (NH).

Reaction of 1a with Phenyl Isocyanate. (A): Five drops of DBTDL and 4 ml of Me-DABCO was added to a suspension of 4.8 g (40 mmol) of **1a** in 60 ml of anhydrous chloroform under stirring. Me-DABCO (4 ml) thoroughly dissolved **1a**. Phenyl isocyanate (4.8 g, 40 mmol) was then added to the solution. After the mixture was stirred at room temperature for 24 h, a precipitate formed was filtered out and the filterate was evaporated under reduced pressure. The residual yellow solid and a precipitate were combined, washed with ethyl acetate to remove the excess **1a**, and recrystallized from acetonitrile to yield the yellow needles **3a** (4.4 g, 62% based on phenyl isocyanate), mp, 214—215 °C (decomp). MS (*m/e*) 356 (M^+). ^{1}H NMR (DMSO-d_6) δ 6.95—7.75 (m, 10, aromatic-H), 8.85 (s, 1, imidazole 2H), and 10.05 (s, 1, NH). IR (KBr) 3270 cm^{-1} (NH).

(B): Phenyl isocyanate (3.6 g, 30 mmol) was added to a suspension of 2.4 g (20 mmol) of **1a** in 30 ml of nitrobenzene. The mixture was refluxed for 2.5 h, cooled, and a precipitate formed was collected. The precipitate was washed with carbon tetrachloride and a small amount of ethanol to remove the excess **1a** and recrystallized from acetonitrile to give the yellow needles **3a** (2.0 g, 37% based on phenyl isocyanate), mp, 214—215 °C (decomp).

Similarly **3a'** and **3b** were obtained in 23 and 30% yields, respectively, by following method *(A)*. **3a'**: mp, 182—184 °C (decomp). ^{1}H NMR (DMSO-d_6) δ 7.35—8.25 (m, 14, aromatic-H), 8.90 (s, 1, imidazole 2H), and 9.95 (s, 1, NH). IR (KBr) 3200 cm^{-1} (NH). **3b**: mp, 203—203.5 °C (decomp). ^{1}H NMR (DMSO-d_6) δ 2.65 (s, 3, CH_3), 6.85—7.65 (m, 10, aromatic-H), and 9.90 (s, 1, NH). IR (KBr) 3360 cm^{-1} (NH).

Reaction of 1c with Phenyl Isocyanate. A solution of 2.9 g (20 mmol) of **1c**, 6 drops of DBTDL, 2 ml of Me-DABCO, and 2.4 g (20 mmol) of phenyl isocyanate in 40 ml of anhydrous chloroform was stirred at room temperature for 17 h. The solvent was evaporated under reduced pressure and the residual oil was washed with hexane and benzene to give the crude yellow solid. The solid was recrystallized from acetonitrile to afford the yellow needles **3c** (1.4 g, 36% based on phenyl isocyanate), mp, 183.5—184 °C (decomp). ^{1}H NMR (DMSO-d_6–$CDCl_3$) δ 1.30 (t, 3, CH_3), 2.90 (q, 2, CH_2), 6.90—7.60 (m, 10, aromatic-H), and 8.85 (s, 1, NH). IR (KBr) 3220 cm^{-1} (NH).

Reaction of 2a with Phenyl Isocyanate. Phenyl isocyanate (1.2 g, 10 mmol) was added to a suspension of 1.8 g (10 mmol) of **2a**, 5 drops of DBTDL, and 2 ml of Me-DABCO in 30 ml of anhydrous chloroform. The reaction mixture was stirred at room temperature and **2a** completely dissolved after 1 h. After the solution was stirred for 23 h, the yellow solid precipitated. The solid was collected, washed with chloroform, and recrystallized from acetonitrile to give the yellow needles **4a** (0.7 g, 24%), mp, 199—201 °C. MS (*m/e*) 294 (M^+) and 175 (M^+−PhNCO). ^{1}H NMR (DMSO-d_6) δ 3.20 (s, 3, N-CH_3), 6.95—7.70 (m, 5, aromatic-H), 8.65 (s, 1, imidazole 2H), and 10.10 (s, 1, NH). IR (KBr) 3280 cm^{-1} (NH).

Similarly **4b** and **4c** were obtained in 33 and 29% yields, respectively. **4b**: mp, 223—224 °C (decomp). ^{1}H NMR (DMSO-d_6) δ 2.60 (s, 3, CH_3), 3.20 (s, 3, N-CH_3), 7.00—7.80 (m, 5, aromatic-H), and 10.20 (s, 1, NH). IR (KBr) 3360 cm^{-1} (NH). **4c**: mp 209—210 °C (decomp). ^{1}H NMR (DMSO-d_6) δ 1.30 (t, 3, CH_3), 2.95 (q, 2, CH_2), 3.20 (s, 3, N-CH_3), 7.00—7.80 (m, 5, aromatic-H), and 10.25 (s, 1, NH). IR (KBr) 3380 cm^{-1} (NH).

Reaction of 3a with 4-Methylaniline. A suspension of 0.7 g (2 mmol) of **3a** and 0.6 g (6 mmol) of 4-methylaniline in 30 ml of anhydrous chloroform was refluxed for 65 h and after cooled, the formed solid was collected (0.4 g), mp, 219—220 °C (lit,[14] 218 °C). This was identified to be urea **7** by its IR spectrum. The filtrate was evaporated under reduced pressure to leave the residual solid. Its IR and ^{1}H NMR spectra showed it to be the mixture of urea **7** and the starting material.

Reaction of 4a with 4-Methylaniline. A suspension of 0.8 g (3 mmol) of **4a** and 0.6 g (6 mmol) of 4-methylaniline in 80 ml of anhydrous chloroform was refluxed for 96 h until **4a** thoroughly disappeared. After cooled, the formed solid was separated, 0.3 g, mp, 219—220 °C. This was identified to be urea **7** by its IR spectrum. The filtrate was evaporated under reduced pressure to give the residual solid. The solid was placed on the column (silica gel) and eluted with chloroform to give 0.38 g of urea **7** and 0.08 g of urea **8**, mp, 175—177 °C (lit,[15] 178 °C).

Reaction of ***2a*** *with 4-Methylaniline.* A solution of 0.97 g (5.5 mmol) of **2a** and 1.18 g (10 mmol) of 4-methylaniline in 50 ml of anhydrous chloroform was refluxed for 24 h. The solvent was evaporated under reduced pressure to leave the residual solid. The solid was placed on the column (silica gel) and eluted with chloroform to give the mixture of 4-methylaniline and urea **8**. The mixture was washed with hexane and toluene to yield 0.76 g (42%) of urea **8**, mp, 175—177 °C. In addition, the residual solid was eluted with ethanol to give the crude **1a**. This crude **1a** was recrystallized from water to afford the pure **1a** (0.46 g, 35%).

Reaction of ***2a*** *with Propylamine.* A solution of 1.75 g (10 mmol) of **2a** and 1.18 g (20 mmol) of propylamine in 30 ml of anhydrous chloroform was refluxed for 24 h. After cooled, the formed solid was collected and recrystallized from chloroform–acetonitrile to give 0.92 g of the pure amidine **10** (26%), white needles, mp, 142—144 °C. IR (KBr) 3220 (NH), 2220 (C≡N), and 1610 cm^{-1} (C=N). ^1H NMR ($CDCl_3$–DMSO-d_6) δ 1.00 (t, 3, CH_3), 1.60 (q of t, 2, CH_2), 2.85 (t, 2, N-CH_2), 7.25 (br.s, 3, 3NH), and 7.40 (s, 1, imidazole 2H). Found: C, 53.82; H, 5.87%. Calcd: C, 54.22; H, 6.26%.

The filtrate was evaporated under reduced pressure to leave the residual solid. By column chromatography (silica gel, chloroform) of the residue, 0.96 g of urea **9** was isolated (41%), mp 63.5—64.5 °C (lit,[15] 67—68 °C). The structure was identified by its IR spectrum.

Reaction of ***1a*** *with propylamine.* A solution of 1.18 g (10 mmol) of **1a** and 0.59 g (10 mmol) of propylamine in 40 ml of anhydrous chloroform was refluxed for 1 h and then stirred at room temperature for 24 h. The formed solid was collected and recrystallized from chloroform–acetonitrile to give 1.7 g of the pure amidine **10** (96%), mp 142—144 °C.

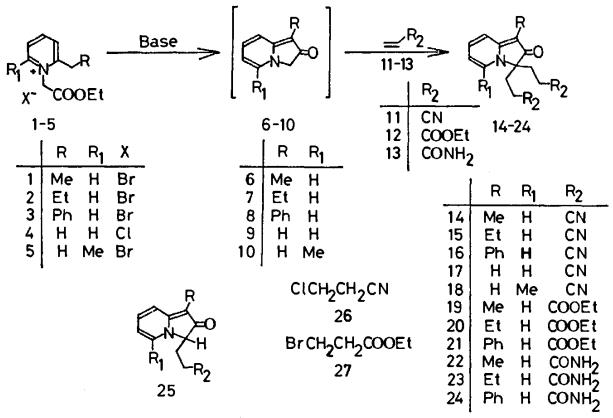
(Received June 1, 1982)

Michael additions of some 2(3*H*)-indolizinone derivatives to α,β-unsaturated nitriles, esters, and an amide gave the corresponding double Michael adducts, 3,3-disubstituted 2(3*H*)-indolizinones, in moderate to high yields, and those to methyl vinyl ketone afforded further condensed products, spiro[cyclohexane-1,3′(2′*H*)-indolizin]-2′-ones, instead of the expected 1:2 adducts. On the other hand, the reactions of the indolizinones with activated ethylenes having an appropriate leaving group at the β-position or with an acetylenic ester formed unstable 1:1 Michael adducts, which were converted to stable 2-acyloxy- or 2-alkoxy-3-vinylindolizine derivatives by the treatment with some acylating or alkylating agents in comparatively good yields.

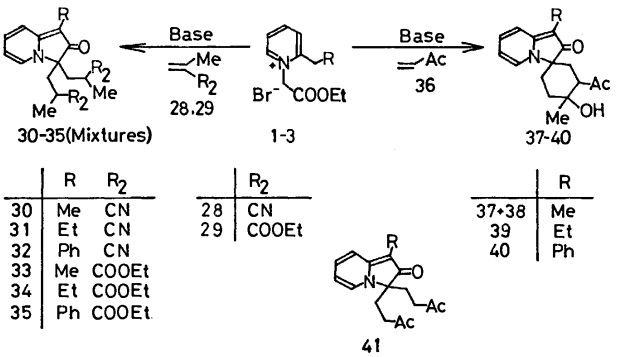
In our continuing investigation of the synthetic utilization of nitrogen-bridged heterocycles, we recently reported a facile preparative method of 2(3*H*)-indolizinone derivatives and their reactions with some alkylating and acylating agents.[1] The reactions of the indolizinones with these reagents are very useful for the preparations of simple 2-acyloxy- or 2-alkoxyindolizines and 3,3-dialkyl-2(3*H*)-indolizinones but not so for that of functionalized ones. Similarly, direct 3-vinylation of indolizines with activated ethoxymethylene compounds such as ethyl (ethoxymethylene)cyanoacetate and (ethoxymethylene)malononitrile was recently found by Masumura *et al.*[2] and by us,[3] but the application was largely restricted by the availability and thermal stability of the starting indolizines. In this paper we wish to report the one-pot and versatile syntheses of polyfunctionalized indolizine and indolizinone derivatives by way of Michael additions to 3-unsubstituted 2(3*H*)-indolizinones generated *in situ* from pyridinium salts.

Results and Discussion

Reactions of 2(3H)-Indolizinones with α,β-Unsaturated Nitriles, Esters, an Amide, and a Ketone. Since the high reactivity of the 3-methylene group in 2(3*H*)-indolizinone derivatives was proven well by the *C*-alkylation with various alkyl halides,[1] we focused next our attention on the functionalization of these indolizinones by taking advantage of their reactivity, especially the high nucleophilicity at the 3-position. As a model reaction for this purpose, Michael addition was examined under some alkaline conditions and proved to proceed successfully. For example, the reactions of 2(3*H*)-indolizinones **6**—**10**, generated *in situ* by the alkali treatment of the corresponding 1-(ethoxycarbonylmethyl)-2-methylpyridinium salts **1**—**5**, with excess acrylonitrile **11** gave yellow crystalline compounds, 3,3-bis(2-cyanoethyl)-2(3*H*)-indolizinone derivatives **14**—**18**, respectively, in various yields (0—95%) depending upon conditions used (See Table 1). Similarly, the reactions of **6**—**8** with excess ethyl acrylate **12**, and acrylamide **13** afforded the corresponding 1:2 adducts, 3,3-bis(2-ethoxycarbonylethyl)-**19**—**21** and 3,3-bis(2-carbamoylethyl)-2(3*H*)-indolizinones **22**—**24**, as products isolable each other. The products **14**, **16**, **19**, and **21** were the same with those



Scheme 1.



Scheme 2.

prepared by the reactions of **1** and **3** with 3-chloropropionitrile **26** and ethyl 3-bromopropionate **27** in the presence of alkali, respectively.[1] No 1:1 adduct such as **25**, however, could be detected in these reactions and even when equimolar amounts of olefins **11**—**13** were used.

On the other hand, the Michael additions of **6**—**8** to methacrylonitrile **28** and ethyl methacrylate **29** formed the mixtures **30**—**35** of each two stereoisomeric 1:2 adducts, respectively, which, though attempted separations were unsuccessful, were determined by the TLC and by the spectral inspection (See below). Interestingly, the reactions of **6**—**8** with methyl vinyl ketone **36** did not give the expected adduct **41** or a Robinson annelation product,[4] but afforded further condensed compounds, spiro[cyclohexane-1,3′(2′*H*)-indolizin]-2′-ones **37** and **38**, **39**, and **40** (Scheme 2).

Table 1. Some data of 3,3-disubstituted 2(3*H*)-indolizinones

Compd No.	Reactants		Yield/%[a]			Mp θ_m/°C	$\tilde{\nu}$/cm^{-1}(KBr)			Formula	Calcd(%)			Found(%)

a) Method A, Method B, and Method C. b) Ref. 1. c) High soluble substance. d) 3490 cm^{-1}(OH). e) Low soluble substance. f) 3170 cm^{-1}(OH). g) 3250 cm^{-1}(OH). h) 3500 cm^{-1}(OH).

In the above reactions of **6**—**10** with **11**—**13**, **28**, **29**, and **36** the method C using ethanolic sodium ethoxide as a base was found better than the method A (aq potassium hydroxide as a base) and B (anhydrous potassium carbonate) from the viewpoint of the yields of the corresponding products and the reaction time (See Table 1 and Experimental).

Structural elucidations of these double Michael adducts **14**—**24** and **30**—**35** and spiro compounds **37**—**40** were accomplished mainly by the physical and spectral means and in part by considering unequivocal syntheses of **14**, **16**, **19**, and **21**. In particular, the elementary analyses of all products were in good accord with the proposed compositions and the IR spectra showed without exceptions a largely shifted 2-keto absorption band characteristic of 2(3*H*)-indolizinone derivatives in the range of 1578—1611 cm^{-1}.[1,5] In addition, the saturated cyano bands (near 2240 cm^{-1}) in **14**—**18** and **30**—**32** or the saturated ester carbonyl bands (near 1730 cm^{-1}) in **19**—**21** and **33**—**35** also supported these structures. On the other hand, the IR spectra of **37**—**40** exhibited the carbonyl bands at comparatively low region (near 1690 cm^{-1}) and the hydroxyl absorption bands at 3170—3500 cm^{-1}, which suggested the presence of a hydrogen bonding between them. In the NMR spectra of these compounds **14**—**21**, **30**—**35**, and **37**—**40** the chemical shifts and the signal patterns (Table 2) due to the protons of the 2(3*H*)-indolizinone moiety were very similar to each others and also with those of authentic 3,3-dialkyl-2(3*H*)-indolizinone derivatives.[1] In addition, the fact that compounds **30**—**35** were mixtures of two stereoisomers (not *dl*-pair) was also indicated by the NMR spectral inspection: especially, the NMR spectra of **30**, **31**, and **33** showed clearly the proton signals due to the 1-methyl or 2-ethyl group of the minor product, together with the proton signals of the major compounds.[6] On the other hand, the NMR spectra of **37**—**40** were apparently different from those of initially expected 1:2 Michael adducts such as **41**. For example, the spectrum of **37** exhibited signals at δ 1.33 (3H, s), 2.28 (3H, s), 1.4—2.7 (6H, m), 4.11 (1H, q, J=12.0 and 4.0 Hz), and 4.03 (1H, s, disappeared with deuterium oxide) attributable to a methyl attached to an sp^3 carbon, only one acetyl, three methylenes, a methine, and a hydroxyl group, respectively, together with the signals due to the 2(3*H*)-indolizinone moiety. The NMR spectra of **39** and **40** were the almost same as that of **37**, while that of **38** was slightly different from them (Table 3). Apparently, the presences of the methyl group attached to an sp^3 carbon and the hydroxyl group showed that compounds **37**—**40** were formed by the condensation between the two 3-oxobutyl groups in primary 1:2 adduct **41**. Judging from above physical and spectral data, products **14**—**24** and **30**—**35** were concluded

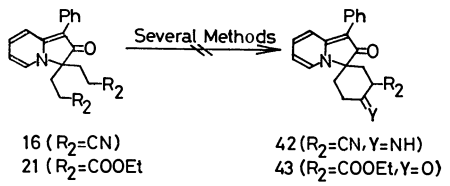
a) The coupling constants were as follows: $J_{5,6}=J_{6,7}=7.0$ Hz, $J_{7,8}=9.0$ Hz, $J_{6,8}=1.5$ Hz, and $J_{CH_2CHAc}=12.0$ and 4.0 Hz. b) Substance with high solubility. c) Substance with low solubility. d) Overlapped with the methylene protons. e) Overlapped with the phenyl protons.

to be double Michael adducts of olefins **11**—**13**, **28**, and **29** to 2(3*H*)-indolizinones **6**—**10**, and **37**—**40** to be further condensed spiro[cyclohexane-1,3′(2′*H*)-indolizin]-2′-one derivatives. The stereochemistry of **30**—**35** and **37**—**40** were still uncertain, however.

The smooth formation of 3-spiroindolizinones **37**—**40**, perhaps *via* aldol reaction of the 1 : 2 adducts such as **41**, prompted us to investigate the possibility of similar cyclizations of other adducts. However, many attempts to obtain the corresponding spiro compounds



Scheme 3.

such as **42** and **43** from a nitrile **16** and an ester **21** were unsuccessful.[7]

Reactions of ***6*****—****10** *with Activated Ethylenes Possessing an Appropriate Leaving Group and an Acetylenic Ester.* In the *C*-alkylation and the Michael addition of 2(3*H*)-indolizinones such as **6**—**10**, the exclusive formation of the corresponding 3,3-disubstituted derivatives was always observed. However, in the reactions of **6** and **8**—**10** with active ethoxymethylene compounds, only 2*H*-pyrano[2,3-*b*]indolizin-2-one derivatives (formed *via* primary 1:1 Michael adducts between them) were isolated, though the yields were low.[1] The primary adducts could be detected with ease, by means of TLC, from the reaction mixtures at early stage of the addition of the ethoxymethylene compounds; however, they were very sensitive to air and a column chromatographic operation and thus they could not be isolated in pure form. In order to confirm the intermediacy of the labile adducts such as **45** and/or **46** shown in Scheme 4 and to find the method for the functionalization of these 2(3*H*)-indolizinones, their conversions to more stable derivatives, especially the replacements of the active proton at the 3-position in **45** and/or the hydroxyl proton in **46** with some acylating and alkylating agents, were attempted.

The reactions were performed stepwise as follows: 1) The treatment of pyridinium salt with two molar amounts of ethanolic sodium ethoxide (or methanolic sodium methoxide), 2) the addition of an equimolar amount of a vinylating agent, and 3) the addition of excess acylating or alkylating agent. For example, the reactions of salts **1**—**5**, ethyl (ethoxymethylene)-cyanoacetate **44**, and acetic anhydride **47** in the presence of alkali afforded yellow crystalline products, 2-acetoxy-3-vinylindolizine derivatives **52**—**56**, in 47—96% yields. Similar reactions in which benzoyl chloride **48**, dimethyl sulfate **49**, and ethyl bromoacetate **51** instead of **47** were used as an acylating or an alkylating agent gave the corresponding 2-benzoyloxy-**57**—**61**, 2-methoxy- **62**—**66**, and 2-(ethoxycarbonylmethoxy)-3-vinylindolizines **67**—**71**, respectively, as yellow or red crystals. The same 2-methoxy compounds **62** and **64** were also obtained by the reactions of **6** and **8** with **44** and methyl iodide **50**, but the yields were low (17 and 27%).

In order to establish the scope and limitation of this reaction, the uses of other ethoxymethylenes, a ketene dithioacetal, and an acetylenic ester as vinylating agents were investigated. For example, the

treatment of **6**—**10** or **6** and **8** with (ethoxymethylene)-malononitrile **72**, diethyl (ethoxymethylene)malonate **73**, and (ethoxymethylene)acetylacetone **74**, followed by the acetylation with acetic anhydride **47** gave the corresponding 2-acetoxy-3-vinylindolizine derivatives **75**—**83** in 32—91% yields (Scheme 5), while those of **6** and **8** with [bis(methylthio)methylene]malononitrile **84** and dimethyl acetylenedicarboxylate (DMAD) **87** afforded products **85**, **86**, **88**, and **89** in 75, 62, 70, and 60% yields, respectively (Scheme 6).

Structural assignments of these 2-(R_4-oxy)-3-vinylindolizine derivatives **52**—**71**, **75**—**83**, **85**, **86**, **88**, and **89** were achieved by their elementary analyses, spectral inspection, and partly on the basis of unequivocal syntheses. In particular, all of their elementary analyses were in good accord with the proposed compositions, and the IR spectra showed an α,β-unsaturated cyano band(s) at near 2200 cm^{-1} (**52**—**71**, **75**—**79**, **85**, and **86**) and/or an α,β-unsaturated carbonyl band(s) at 1653—1729 cm^{-1} (**52**—**71**, **80**—**83**, **88**, and **89**) attributable to the vinyl group introduced in these reactions (Table 4), but not the 2-keto carbonyl band at near 1600 cm^{-1} as seen in those of 2(3*H*)-indolizinones. The chemical shifts of the protons and alkyl protons on the indolizine ring in the NMR spectra of these products were much closer to those of aromatic indolizines rather than nonaromatic 2(3*H*)-indolizinones (Table 5). Furthermore, the chemical shifts (near δ 4.00) of the methyl protons in **62**—**66** and those (near δ 4.80) of the methylene protons in **67**—

71 derived from the alkylating agents **49**—**51** showed definitely that both groups were attached on an oxygen atom but not on the other atoms. Independent syntheses of 2-methoxy-3-vinylindolizines **62**—**64**, that is to say, the direct 3-vinylation of 2-methoxyindolizines **90**—**92** with **44** in the presence of alkali supported these proposed structures (Scheme 7). On the other hand, the configuration of the 3-vinyl moiety in **52**—**71** were concluded to be *trans* by the comparisons of the chemical shifts (δ 8.23—8.43) of the vinyl protons with those of similar 1-[8] and 3-vinylindolizines[2] and 3-vinylpyrazolo[1,5-*a*]pyridines,[9] but that in **88** and **89** were assigned tentatively to be *cis* by similar comparison of the vinyl proton signals at δ 6.18 and 6.30 with those at δ 6.48 and 6.80 in dimethyl maleate and dimethyl fumarate, respectively.

Reaction Mechanisms. Possible mechanisms for these reactions are summarized concisely in Scheme 8. Path a leading to compounds **14**—**24**, **30**—**35**, and **37**—**40** is the double Michael addition of electron-poor olefins **11**—**13**, **28**, **29**, and **36** to 3-unsubstituted 2(3*H*)-indolizinones **6**—**10** in the presence of alkali, and, in part, followed by the Aldol reaction of the primary 1:2 adducts such as **41**, and Path b leading to 2-(R_4-oxy)-3-vinylindolizines **52**—**71**, **75**—**83**, **85**, **86**, **88**, and **89** is the single Michael addition of vinylating agents **44**, **72**—**74**, **84**, and **87** to **6**—**10** and the elimination of one molecule of ethanol from **93**, followed by keto–enol isomerization and finally by the *O*-acylation or the *O*-alkylation of the resulting 3-vinyl-2-indolizinol **95**. Recently, the isolation of 2-indolizinol such as **95** in the reaction of 2,6-dimethylpyridinium salt **5** with a ketene dithioacetal was reported by Kobayashi *et al.*[10] The reason for the different behavior between the 1:1 and 1:2 Michael additions in these reactions was still uncertain, but the steric effect of the incoming olefins and the influence of the conjugation of the 3-vinyl group may be con-

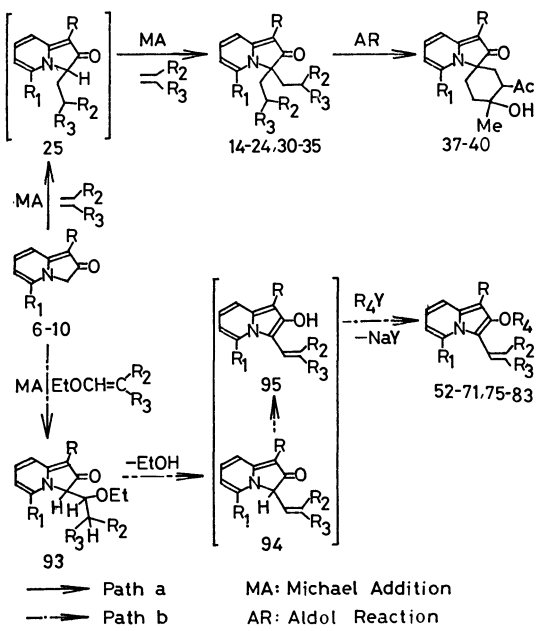

Scheme 8.

sidered.

Since effective functionalization of indolizine nucleus, except the synthesis of cyclazine[11] and the route *via* 2-allylidene-1,2-dihydropyridine,[8] are scarcely found, our present reactions using the Michael additions of 3-unsubstituted 2(3*H*)-indolizinones may provide useful routes for the preparations of condensed indolizine series owing to the simplicity of the procedure and of easy availability of starting materials.

Experimental

Melting points were measured with a Yanagimoto MP-S3 micromelting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 elemental analyzer. The NMR spectra were determined with a Varian EM360A spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 infrared spectrophotometer.

Reactions of 2(3H)-Indolizinones ***6—10*** *with α,β-Unsaturated Nitriles, Esters, an Amide, and a Ketone. Method A*: To an ethanolic solution (60 ml) of 1-(ethoxycarbonylmethyl)-2-methylpyridinium salts (**1—5**, 5 mmol) and α,β-unsaturated compound (**11—13**, **28**, **29**, and **36**, 20 mmol) was added dropwise aqueous potassium hydroxide (5.5 mmol in 1 ml of water) with stirring at room temperature. After the addition the reaction mixture was stirred at the same temperature for about 2 h until the 2(3*H*)-indolizinone (**6—10**) formed *in situ* was disappeared (detected by TLC) and then filtered to remove insoluble substances. The filtrate was concentrated under reduced pressure, and the residue was separated by column chromatography (alumina) using ether and then chloroform as eluents. Recrystallization from chloroform–hexane gave yellow or orange crystals.

Method B: In similar procedure with Method A, anhydrous potassium carbonate (10 g) as a base was employed and the reactions required more prolonged times (12—24 h) than those in Method A.

Method C: As in Method B, ethanolic sodium ethoxide (5 mmol in 5 ml of ethanol) as a base was used and the reactions required the shortest times (1—2 h) among those in the three methods. On the other hand, the reactions of **6—8** with acrylamide **13** were carried out successfully at 60—70 °C for 1 h, since they were very slow at room temperature.

In the reactions of **6—8** with methacrylonitrile **28** and ethyl methacrylate **29**, the fact that these products **30—35** were mixtures of two stereoisomers (the individual isomers must be *dl*-pair or meso) was indicated by the TLC and also by the NMR spectra. However, our attempts to separate them were unsuccessful. In the reactions of **7** and **8** with methyl vinyl ketone **36** the low soluble products such as **37** could not be obtained. These results and spectral data are summarized in Tables 1—3.

Reactions of ***6*** *and* ***8*** *with 3-Chloropropionitrile* ***26*** *and Ethyl 3-Bromopropionate* ***27***. *General Method*: A mixture of pyridinium salt (**1** or **3**, 5 mmol) and halide (**26** or **27**, 20 mmol) was treated with ethanolic sodium ethoxide (10 mmol in 10 ml of ethanol) in ethanol (60 ml) with stirring at room temperature for 2 h. The resulting brown solution was filtered, and the filtrate was then concentrated at reduced pressure. The same work-ups of the residues as shown in Method A gave yellow crystalline compounds **14**, **16**, **19**, and **21** in 57, 76, 67, and 89% yields, respectively. These compounds **14**, **16**, **19**, and **21** coincided with those prepared above and also with authentic samples[1] in all respects.

Reactions of ***6—10*** *with Activated Ethylenes Possessing an Appropriate Leaving Group and an Acetylenic Ester. General Method*: Pyridinium salt (**1—5**, 3 mmol) dissolved completely in ethanol (50 ml) was heated with an ethanolic sodium ethoxide (6 mmol in 6 ml of ethanol) at 60—70 °C for 2—3 min and then an equimolar amount of vinylating agent (**44**, **72—74**, **84**, or **87**, 3 mmol) was added at once to the reaction mixture. After 1—2 min excess acylating or alkylating agent (**47—51**, 2 ml) was added and the resulting solution

was allowed to react for additional 30 min at the same temperature. The reaction mixture was filtered to remove insoluble inorganic substances and the filtrate was concentrated at reduced pressure. The residue was separated by column chromatography (alumina) using ether and then chloroform as eluents. Recrystallizations from ethanol or chloroform–hexane gave yellow (**52**—**56**, **62**—**71**, **75**—**83**, **88**, and **89**) or red needles (**57**—**61**, **85**, and **86**).

On the other hand, the reactions of **1** and **3** with dimethyl acetylenedicarboxylate **87** were performed in the presence of sodium methoxide as a base in methanol. These results and some data are summarized in Tables 4 and 5.

Reactions of 2-Methoxyindolizines ***90***—***92*** *with Ethoxymethylene Compound* ***44***. *General Method*: A mixture of 2-methoxyindolizine (**90**—**92**, 1 mmol) and ethyl (ethoxymethylene)-cyanoacetate **44** (1 mmol) was heated under reflux in the presence of potassium carbonate (5 g) in chloroform (50 ml) for 3 d. The reaction mixture was filtered and the filtrate was concentrated at reduced pressure. The same work-ups of the residues as indicated in the syntheses of 3-vinylindolizines gave the corresponding 2-methoxy-3-vinylindolizine derivatives **62**—**64** in 81, 89, and 24% yields, respectively. These products **62**—**64** were in accord with those synthesized by the reactions of **6**—**8** with **44** and **49** or **50** in all respects.

Intramolecular Stacking Association of Three Dinucleoside Monophosphates Containing Naturally-occurring 1-Methyladenosine Residue(s): m^1ApA, Apm^{1}A, and m^1Apm^{1}A[1)]

Yasuhiro Takeuchi, Ichiro Tazawa, and Yasuo Inoue*

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

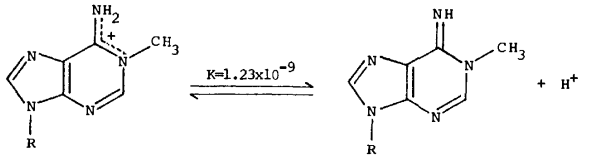
(Received June 18, 1982)

Three modified dinucleoside monophosphates containing naturally-occurring 1-methyladenosine residue, m^1ApA, Apm^{1}A, and m^1Apm^{1}A, were prepared. Intramolecular stacking association properties of these dimers were studied quantitatively using two independent methods. Thermal denaturation and acid-base titration experiments reached to the same conclusion that both $m^1\overset{+}{A}pA$ and Apm$^1\overset{+}{A}$ were less stacked than ApA. Acid-base titration experiment also showed that the three modified dimers, in their neutral forms, were stacked to almost the same extent as ApA. These results indicate the N-1 methylation of an adenine base does not enhance stacking interaction of dimers, in sharp contrast to the N^6 methylation of the same base. UV hypochromicity and CD measurements were also made for the three dimers, and the results were found to be consistent with those of the stacking quotient determination.

As a part of studies on the intramolecular stacking interaction of modified base-containing dinucleoside monophosphates,[2–7)] dimers containing 1-methyladenosine (m^1A) were studied in order to see the effect of a methyl substitution at a ring nitrogen atom of an adenine base on stacking association. In view of a wide occurrence of m^1A residue in eukaryotic tRNA molecules,[8)] it is of interest to study the effect of this residue on the stacking properties and compare it with that of other methylated base residues.

It is well established that a variety of methylated dinucleoside monophosphates exhibit stronger stacking tendency as compared to the unmethylated corresponding parent dimers. For example results from our laboratory and those from others have revealed that N^6 methylation of an adenine base enhances stacking interaction in dimers, as did so for m^6Apm^{6}A,[6)] m_2^6Apm$_2^6$A,[7,9)] m^6ApU,[9,10)] and m_2^6ApU.[9,10)] Little is known, however, about the effect of a m^1A residue on stacking of dimers. Danyluk *et al.* first reported that $m^1\overset{+}{A}pU$ and Upm$^1\overset{+}{A}$ were less stacked than unmethylated ApU and UpA, respectively, as studied by ^{1}H NMR spectroscopy.[11)] Their results are noteworthy in view of the general stacking-enhancing properties of a methyl substituent and the fact that the $m^7\overset{+}{G}$ residue is known to exert such an effect as observed in our previous work for $m^7\overset{+}{G}pU$[3)] and $m^7\overset{+}{G}pG$.[4)]

We have undertaken a detailed study on the effect of m^1A residue on the stacking properties of dimers using three dinucleoside monophosphates, m^1ApA, Apm^{1}A, and m^1Apm^{1}A. Using two independent methods, thermal denaturation and acid-base titration experiments, the stacking quotients were estimated for these three dimers and compared with those for the parent molecule, ApA. Because m^1A exists in the protonated form (Fig. 1) in neutral aqueous solutions (basic pK of m^1A is 8.76, see Table 2), the stacking properties of the monoprotonated dimers were studied together with those of the neutral forms. Optical properties (UV and CD spectra) of the three dimers were also studied, and results were compared with those of the stacking quotients determined.



($m^1\overset{+}{A}$) (m^1A)

Fig. 1. Acid-base equilibrium in 1-methyladenosine,

Experimental

Materials. m^1Apm^{1}A, m^1ApA, and Apm^{1}A: To ApAp (3′) (9 μmol), dissolved in 5 ml of 0.1 M NaOAc buffer (pH 5.0, 1 M = 1 mol dm^{-3}) was added 100 μl of dimethyl sulfate and the solution was kept under stirring for 3 h at room temperature. During the reaction the solution was maintained at pH 3—5 by gradual addition of 1 M NaOH solution. Figure 2 shows chromatographic separation of the products with a Dowex 1X2 anion exchanger (1.3 cm × 50 cm) which afforded three modified dinucleotides and unreacted ApAp(3′). m^1Apm^{1}Ap(3′), m^1ApAp(3′), and Apm^{1}Ap(3′)

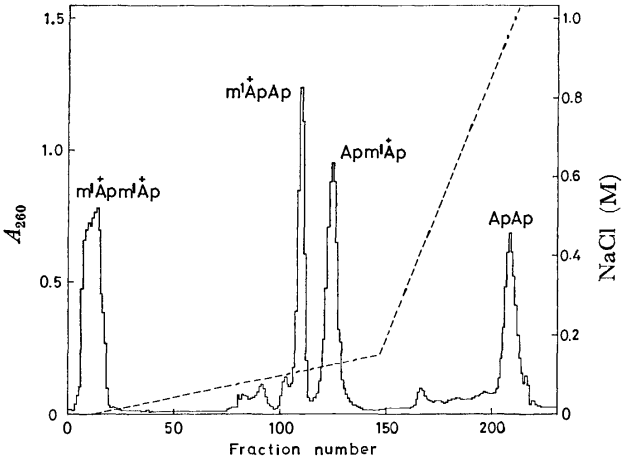

Fig. 2. Chromatogram of a partially methylated ApAp (3′) on a column of Dowex 1X2 (1.3 cm × 50 cm) with linear gradients of NaCl in 5 mM NaOAc (pH 5.0) as indicated. Fraction volume was 10 ml.

thus obtained were treated with *E. coli* alkaline phosphatase (Boehringer, Mannheim) at 39 °C and pH 7 for 4 h to give m¹Apm¹A, m¹ApA, and Apm¹A, respectively. The dimers were susceptible to degradation by ribonuclease T_2 and gave a mixture of the corresponding nucleoside 3′-phosphate and nucleoside. Desalting of the dimer preparations was effected by gel filtration using Sephadex G-10.

m¹A, m¹Ap-OCH₃, and CH₃O-pm¹A: A, Ap-OCH_3,[12] and CH_3O-pA[13] were treated with dimethyl sulfate in a manner similar to that described for ApAp(3′).

Methods. Thermal Denaturation of m¹ÅpA and Apm¹Å: In the present work, methods and calculations followed closely those described previously.[5,14] 3,3-Dimethylglutarate buffer (10 mM; pH 5.5) was used. The dimer concentrations were about 5×10^{-5} mol/l. For each dimer solution, 6 repeated denaturation cycles were performed in the temperature range 0—70 °C, and changes of the difference in absorbance (dimer *vs.* constituent monomers) at 262 nm with temperature were recorded using a recording millivolt meter (Watanabe Sokki MC642).

p*K Determinations of Nucleosides, Nucleoside Methyl Phosphates, and Dinucleoside Monophosphates*: All ionization constants were determined spectrophotometrically at 25 °C and ionic strength 0.1, by the method described previously.[15]

Optical Measurements: UV spectra were recorded with a Hitachi 124 recording spectrophotometer. CD spectra were taken with a JASCO J40 spectropolarimeter with a 1-cm quartz cell at 25 °C and ionic strength 0.1 (We thank Dr. T. Oshima, Mitsubishi-Kasei Institute of Life Sciences, for making the apparatus available to us). Spectra of the neutral dimers were not measured directly because of the lability of m¹A residues in high pH region ($t_{1/2}$ for Dimroth rearrangement of m¹A is about 5 h at pH 11 and 25°). Instead, spectra at several different pH values (as indicated in caption for Fig. 3) were measured and employed to compute the spectra of the neutral species with the knowledge of pK values of the dimers (Table 2).

Results and Discussion

Thermal Denaturation Experiments to Obtain Intramolecular Stacking Equilibrium Quotient, s_1, of m¹ÅpA and Apm¹Å. The thermal denaturation experiments were performed at pH 5.5 to obtain the stacking quotients for the monoprotonated form in which the dimers existed under the physiological conditions (see Table 2). Both dimers showed hyperchromism at 262 nm on heating their solutions. The thermal denaturation profiles were analyzed based on the two-state equilibrium model shown below for a specific case of m¹ÅpA.

$$(m^1\mathring{A}pA)_{unstacked} \overset{s_1}{\rightleftharpoons} (m^1\mathring{A}pA)_{stacked}$$

Here the equilibrium quotient, s_1, for the reversible association of an unstacked conformer, $(m^1\mathring{A}pA)_{unstacked}$, to give the stacked conformer, $(m^1\mathring{A}pA)_{stacked}$, is defined as

$$s_1 = \frac{[(m^1\mathring{A}pA)_{stacked}]}{[(m^1\mathring{A}pA)_{unstacked}]}$$

The stacking quotient, s_1, at a given temperature and thermodynamic functions, ΔH° and ΔS°, were then calculated according to Eq. 1 with the assumption that the parameters, ε_u, ε_s, ΔH°, and ΔS° are all temperature-independent.

$$\ln s_{1i} = \ln \frac{\varepsilon_u-\varepsilon_i}{\varepsilon_i-\varepsilon_s} = -\frac{\Delta H^\circ}{RT_i} + \frac{\Delta S^\circ}{R} \qquad (1)$$

where ε_i, ε_s, and ε_u are the observed molar absorption coefficients at the ith of n temperature readings, and those for the extreme stacked and unstacked conformers, respectively. In this case, the parameters ε_u, ε_s, ΔH°, and ΔS° were found by an iterative nonlinear least-squares approximation on a HITAC M-200H computer at the Computer Center of the University of Tokyo. The formalism and further details are available in Ref. 18

Table 1. Thermodynamic parameters and intramolecular stacking equilibrium quotients (s_1 or s_0)[a] of m¹ÅpA, Apm¹Å, and ApA[b] (25°, I=0.1)

Dimer	ΔH° (σ)[c] / kJ mol^{-1}	ΔS° (σ)[c] / J mol^{-1} deg^{-1}	s_1 or s_0(σ)[c]
m¹ÅpA	−18.5 (0.5)	−64.9 (1.4)	0.70 (0.02)
Apm¹Å	−23.0 (0.5)	−81.0 (1.6)	0.62 (0.02)
ApA	−21.1 (0.3)	−70.1 (0.9)	1.10 (0.01)

a) s_1 for m¹ÅpA and Apm¹Å (at pH 5.5). s_0 for ApA (at pH 7.0). s_1 and s_0 standing for the stacking quotients for monoprotonated and neutral speceis, respectively. b) Taken from our previous paper.[7] c) The standard deviations (σ) were computed from the root mean square (rms) values between experimental and calculated melting profiles as described in a previous paper.[18]

Table 1 lists the values of ΔH°, ΔS°, and stacking equilibrium quotient thus determined at 25 °C for m¹ÅpA and Apm¹Å, together with those for ApA (at pH 7.0)[7] for comparison. From s values in Table 1 it is concluded that m¹ÅpA and Apm¹Å are stacked to a similar extent, and considerably less stacked than the parent molecule, ApA. The same stacking-diminishing effect by m¹Å has been observed by Danyluk *et al.*[13] in m¹ÅpU and Upm¹Å. The present conclusion is rather surprising because the methyl group, when introduced to a nitrogen atom, has almost invariably been found stacking-enhancing in dimers.[3,4,6,7,9,10] To substantiate the above conclusion the acid-base titration experiments were performed.

Acid-base Titration Experiments to Obtain Stacking Equilibrium Quotients, s_1 and s_0 of m¹ApA, Apm¹A, and m¹Apm¹A. We have developed a procedure that can give an estimate of stacking equilibrium quotients of homodimers for both neutral and monoprotonated (or monoionized) species from their ionization constants and those of constituent monomers.[5,6,15,16] We now extend the method to heterodimers (XpY) in which X and Y are both acids or bases. For a diacidic base one can write the following schemes.

$$(\overset{+}{X}pY)_{u+s} \overset{K_2}{\rightleftharpoons} (XpY)^+_{u+s} \overset{K_1}{\rightleftharpoons} (XpY)_{u+s}$$

$$\begin{array}{ccccc} (\overset{+}{\mathrm{X}}\mathrm{p}\overset{+}{\mathrm{Y}})_s & \overset{K_{s2}}{\rightleftharpoons} & (\mathrm{XpY})_s^+ & \overset{K_{s1}}{\rightleftharpoons} & (\mathrm{XpY})_s \\ \updownarrow s_2 & & \updownarrow s_1 & & \updownarrow s_0 \\ (\overset{+}{\mathrm{X}}\mathrm{p}\overset{+}{\mathrm{Y}})_u & \overset{K_{u2}}{\rightleftharpoons} & (\mathrm{XpY})_u^+ & \overset{K_{u1}}{\rightleftharpoons} & (\mathrm{XpY})_u \end{array}$$

where subscripts, u and s, denote unstacked and stacked conformations, respectively, and u+s denotes composite of unstacked and stacked conformations. From these schemes the following equations can be derived which relate ionization constants of a dimer to its stacking equilibrium quotients at various stages of protonation.

$$\mathrm{p}K_2 = \mathrm{p}K_{u2} - \log(1+s_1)/(1+s_2) \quad (2)$$

$$\mathrm{p}K_1 = \mathrm{p}K_{u1} - \log(1+s_0)/(1+s_1) \quad (3)$$

Since s_2 is considered to be very small because of the electrostatic repulsion between two positively charged bases,[15,17,18] Eq. 2 can be simplified to

$$\mathrm{p}K_2 = \mathrm{p}K_{u2} - \log(1+s_1) \quad (4)$$

K_{u1} and K_{u2} are the intrinsic ionization constants for the unstacked residues which must be estimated in some way to solve Eqs. 3 and 4 for s_1 and s_0. For homodimers (X=Y), K_{u1} and K_{u2} have been approximated in the following way using ionization constants of the constituent monomers.[15]

$$K_{u1} = \frac{1}{2}K_0, \quad K_{u2} = 2K_0 \quad (5)$$

$$\mathrm{p}K_0 = \frac{1}{4}[\mathrm{p}K_{3'\text{-nucleotide}} + \mathrm{p}K_{5'\text{-nucleotide}} + 2\mathrm{p}K_{\text{nucleoside}}] \quad (6)$$

For heterodimers in which X and Y have similar basicity, estimation of the intrinsic K's is a complicated matter. However, if they differ markedly in their basicity (say, $|\mathrm{p}K_X - \mathrm{p}K_Y| > 4$), the intrinsic K's can be approximated in the same way as those of homodimers. That is, if $\mathrm{p}K_X > \mathrm{p}K_Y$, it follows that $[(\overset{+}{\mathrm{X}}\mathrm{pY})_u] \gg [(\mathrm{X}\overset{+}{\mathrm{p}}\mathrm{Y})_u]$. Consequently, K_{u1} and K_{u2} are regarded as the intrinsic K's of X and Y residues, respectively, which can be approximated by K_0 in Eq. 6 for X and Y, respectively.

In the present study, because of the large difference in basicity of m^{1}A and A residues in the dimers, values of s_1 and s_0 were obtained by acid-base titration of the dimers and the corresponding constituent monomers. The $\mathrm{p}K_1$ and $\mathrm{p}K_2$ values of m^{1}ApA, Apm^{1}A, and m^{1}Apm^{1}A determined by spectrophotometric titration are given in Table 2 together with the basic pK values of the constituent monomers [The latter values were used to estimate $\mathrm{p}K_{u1}$ and $\mathrm{p}K_{u2}$ values in Table 2]. For comparison, relevant values for ApA[7] are also included in the table.

Values of s_1 and s_0 for three dimers were calculated from the pK values in Table 2 using Eqs. 3 and 4, and listed in Table 3 together with those for ApA. From the numerical data in Table 3 we can draw the following conclusion:

(1) s_1 values of m$^1\overset{+}{\mathrm{A}}$pA (0.87) and Apm$^1\overset{+}{\mathrm{A}}$ (1.11) are similar to each other and they are smaller than s_0 of ApA (1.51). This result substantiates a conclusion reached from the thermal denaturation experiments, and shows that N-1 methylation of an adenine residue decreases the extent of intramolecular stacking interaction.

(2) s_1 values of m$^1\overset{+}{\mathrm{A}}$pA (0.87) and Apm$^1\overset{+}{\mathrm{A}}$ (1.11) are not significantly different from that of (ApA)$^{\pm}$ (1.14). This suggests that the presence of the methyl group itself does not influence the stacking interaction in these monoprotonated dimers.

(3) All four dimers have similar s_0 values. This suggests that in neutral form introduction of a methyl group neither enhances nor diminishes the extent of the stacking interaction of ApA.

Optical Studies of m^{1}ApA, Apm^{1}A, and m^{1}Apm^{1}A. UV absorption and hypochromicity data of the four dimers are shown in Table 4. In agreement with the conclusion from the stacking quotient measurements hypochromicity data indicate the stacking in m$^1\overset{+}{\mathrm{A}}$pA and Apm$^1\overset{+}{\mathrm{A}}$ being a little bit weaker than in ApA. The value for m$^1\overset{+}{\mathrm{A}}pm^1\overset{+}{\mathrm{A}}$ was found to be negligibly small, and this is also in line with the previous assumption of $s_2=0$.

The CD spectra of m$^1\overset{+}{\mathrm{A}}pA, Apm^1\overset{+}{\mathrm{A}}$, and their un-

TABLE 2. IONIZATION CONSTANTS (AS pK) OF m^{1}ApA, Apm^{1}A, m^{1}Apm^{1}A, ApA, AND THE CONSTITUENT NUCLEOSIDES, NUCLEOSIDE MONOPHOSPHATES, AND NUCLEOSIDE METHYL PHOSPHATES (25°, I=0.1), AND CALCULATED INTRINSIC pK's[a,b]

Dimer	pK_1	pK_2	pK_{u1}	pK_{u2}
m^{1}ApA	8.66 (0.02)	3.41 (0.03)	8.80 (0.01)	3.68 (0.01)
Apm^{1}A	8.73 (0.01)	3.36 (0.02)	8.80 (0.01)	3.68 (0.01)
m^{1}Apm^{1}A	8.91 (0.03)	8.29 (0.04)	9.10 (0.01)	8.50 (0.01)
ApA[c]	3.91 (0.03)	3.05 (0.07)	3.98 (0.01)	3.38 (0.01)

Monomer	pK	Monomer	pK
m^{1}A[d]	8.76 (0.01)	A[c]	3.61 (0.02)
m^{1}Ap-OCH$_3$[d]	8.79 (0.02)	Ap[c]	3.66 (0.01)
CH$_3$O-pm^{1}A[d]	8.90 (0.01)	pA[c]	3.85 (0.02)

a) Standard deviations of experimental values are shown in parentheses. b) For homodimers $\mathrm{p}K_{u1}$ and $\mathrm{p}K_{u2}$ were calculated by Eqs. 5 and 6. For heterodimers Eq. 6 was used, K_0 representing either K_{u1} or K_{u2}. c) Revised values from those given in our previous paper.[19] d) Methyl esters of 3'- and 5'-nucleotides were used to avoid an influence of an additional negative charge on the phosphate group in pH region near the pK values.

TABLE 3. ESTIMATED STACKING EQUILIBRIUM QUOTIENTS FROM THE DATA BASED ON TITRATION STUDIES (25°, I=0.1)[a]

Dimer	s_1	s_0
m^{1}ApA	0.87±0.15	1.62±0.23
Apm^{1}A	1.11±0.17	1.48±0.21
m^{1}Apm^{1}A	0.63±0.13	1.56±0.28
ApA[b]	1.14±0.35	1.51±0.43

a) The probable errors given for s_1 and s_0 values are based on errors in $\mathrm{p}K_{u1}$, $\mathrm{p}K_{u2}$, $\mathrm{p}K_1$, and $\mathrm{p}K_2$. b) Revised values from those given in our previous paper.[19]

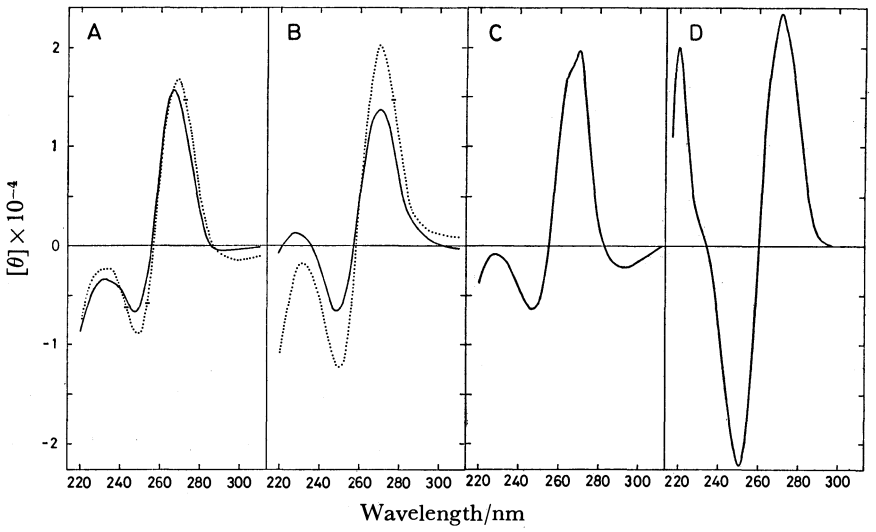

Fig. 3. Difference CD spectra of m¹ApA, Apm¹A, m¹Apm¹A, and ApA (25 °C, I=0.1). Spectra of the constituent monomers have been subtracted from those of dimers. Ellipticity is expressed per mole of monomer residues.
(A) ——, $m^1\overset{+}{A}pA$ at pH 6.0; ----, m¹ApA calculated from spectra at pH 6.0 and 8.9; (B) ——, $Apm^1\overset{+}{A}$ at pH 6.0; ----, Apm¹A calculated from spectra at pH 6.0 and 9.1; (C) m¹Apm¹A calculated from spectra at pH 5.0, 8.1, 9.2, and 10.1; (D) ApA at pH 7.0.

Table 4. UV spectral and hypochromicity data of dimers (25°, I=0.1)

Dimer	pH	λ_{max} / nm	H[a] / %
$m^1\overset{+}{A}pA$	5.5	258	10
$Apm^1\overset{+}{A}$	5.5	258	10
$m^1\overset{+}{A}pm^1\overset{+}{A}$	5.5	258	1
ApA	7.0	258	12

a) Hypochromicity is measured at the λ_{max} of monomers.

protonated species at 25° are shown in Figs. 3A and 3B together with that of ApA for comparison (Fig. 3D). Cation formation of m¹ApA produces only minor changes in the CD spectrum (Fig. 3A) while deprotonation of $Apm^1\overset{+}{A}$ considerably enhances the intensity of the CD spectrum (Fig. 3B). Another feature of interest in the CD spectra shown in Fig. 3 is that the CD spectrum of $m^1\overset{+}{A}pA$ is almost quantitatively similar to that of $Apm^1\overset{+}{A}$ and the intensities of the CD spectra for this pair of sequence isomers are considerably smaller than that for ApA. These observations may be taken as *prima facie* evidence for weaker base-base stacking interactions in $m^1\overset{+}{A}pA$ and $Apm^1\overset{+}{A}$ than ApA. Thus the correlation with the stacking quotient data listed in Tables 1 and 3 is striking. It should be noted on comparing the vastly different CD spectra[4] of a pair of sequence isomers $m^7\overset{+}{G}pG$ and $Gpm^7\overset{+}{G}$ that m¹A-containing dimers differ considerably from other methylated dimers in the molecular conformations.

Concerning the stacking association of m¹Apm¹A, titrations gave an s_0 value of 1.56 at 25 °C. Although acid-base titrations are seen to overestimate the stacking quotient s_0,[5,14] the value for m¹Apm¹A is by no means greater than that for the parent unmethylated ApA. Supporting evidence for this comes from the comparison of the CD spectrum extracted for m¹Apm¹A (Fig. 3C) and that of ApA (Fig. 3D). The presently observed effect for m¹A is thus in contrast to the general pattern of the stacking-enhancing effect of methyl substitution as previously observed in methyl-substituted dinucleoside monophosphates.[3,4,6,7,9,10]

In consequence, m¹A-containing dinucleoside monophosphates stack intramolecularly less extensively than the corresponding parent unmethylated dimers, and differ from other methyl-substituted dimers in the stacking equilibrium ratios. Such differences can be accounted empirically for by the fact that m¹A possesses an amidine structure with a quasi-ortho-quinonoid form unfavoring the stacking-enhancing effect of the methyl group. Incidentally, the CD spectrum of m¹Apm¹A is quite similar in shape to that of IpI[19,20] which has the quasi-ortho-quinonoid amide structure.

Finally, it should be noted that the methylation of N^6 position of an adenine base increased stacking interaction in dimers.[6,7,9,10] Considering the wide existence of these methylated adenine residues in nucleic acid molecules (m¹A in tRNA;[8] m^6A in tRNA[8] and mRNA;[21] $m_2{}^6A$ in rRNA[22]), it is of interest to note that a methyl group can exert various effects on the stacking of dimers depending on the site of its introduction. Thus, the present study has shown that methylation of a nucleic acid base is one of effective means for the fine controll of a nucleic acid conformation.

References

1) Abbreviations:—A dimer means a dinucleoside monophosphate. XpY represents a dimer having a 3′-5′ phosphodiester bond, X-3′-p-5′-Y. "p" to the left of a nucleoside symbol indicates a 5′-phosphate, and to the right indicates a 3′-phosphate. CH_3O- and $-OCH_3$ attached to "p" mean the phosphate is esterified by a methyl group. "+" on a nucleoside symbol indicates the nucleoside has a positive charge. Nucleoside symbols used for modified bases are the following: m^1A, 1-methyladenosine; m^6A, N^6-methyladenosine; m_2^6A, N^6,N^6-dimethyladenosine; m^7G, 7-methylguanosine; I, inosine.

Studies on Salt Hydrate for Latent Heat Storage. I. Crystal Nucleation of Sodium Acetate Trihydrate Catalyzed by Tetrasodium Pyrophosphate Decahydrate

Takahiro WADA* and Ryoichi YAMAMOTO

Material Research Laboratory, Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka 571

(Received April 2, 1982)

The effect of tetrasodium pyrophosphate decahydrate ($Na_4P_2O_7 \cdot 10H_2O$) as a nucleation catalyst for sodium acetate trihydrate ($CH_3CO_2Na \cdot 3H_2O$) is shown. The supercooled melt of 10 g of $CH_3CO_2Na \cdot 3H_2O$ recrystallized at about 5 degrees below the melting point only when 0.1 g of $Na_4P_2O_7 \cdot 10H_2O$ was added to it. More than a thousand cycles of alternate heating and cooling through the melting point were carried out in this work. Some observations on nucleation are given and the results are discussed on the basis of crystallographic data.

Sodium acetate trihydrate ($CH_3CO_2Na \cdot 3H_2O$) has received attention recently because of its large latent heat of fusion (about 264 J/g) which makes it attractive as a latent heat storage material.[1] But once this material melts, it tends to supercool even if it is cooled considerably below the melting point (58.4 °C).[2] One approach to this problem is to add a suitable nucleation catalyst to supercooled $CH_3CO_2Na \cdot 3H_2O$ melt. This nucleation catalyst needs to be hardly soluble in $CH_3CO_2Na \cdot 3H_2O$ melt so as to not lower the melting point nor diminish the heat of fusion.[3] However, such a nucleation catalyst has not been found yet.[4,5] In this study, tetrasodium pyrophosphate decahydrate ($Na_4P_2O_7 \cdot 10H_2O$) was found to act as a nucleation catalyst for $CH_3CO_2Na \cdot 3H_2O$ which hardly lowers the melting point at all and does not diminish the heat of fusion.

We present the results of two different kinds of thermal analysis of $CH_3CO_2Na \cdot 3H_2O$ in the presence of $Na_4P_2O_7 \cdot 10H_2O$. One is a heating and cooling cycle of about 30 g samples in a sealed glass vessel, and the other is differential scanning calorimetry of about 15 mg samples. The reason why it acts as a nucleation catalyst for $CH_3CO_2Na \cdot 3H_2O$ is discussed crystallographically and compared to the well known case of borax ($Na_2B_4O_7 \cdot 10H_2O$) for Glawber's Salt ($Na_2SO_4 \cdot 10H_2O$).[3,6]

Experimental

Materials. $CH_3CO_2Na \cdot 3H_2O$, $Na_4P_2O_7 \cdot 10H_2O$, and $Na_2H_2P_2O_7$ were obtained commercially and $Na_4P_2O_7$ was obtained by heating $Na_4P_2O_7 \cdot 10H_2O$ in an oven at 150—200 °C for 5 h. $Na_4P_2O_7 \cdot 10H_2O$ was used for experiments after it was ground to a powder and passed through a 100 mesh seive.

Heating and Cooling Cycles of About 30 g Samples in a Sealed Glass Vessel. Weighed quantities of $CH_3CO_2Na \cdot 3H_2O$ and $Na_4P_2O_7 \cdot 10H_2O$ were placed in a glass vessel and the sample was covered with liquid paraffin to prevent water evaporation. The temperature of the sample was measured with a thermocouple, whose junction was placed near $Na_4P_2O_7 \cdot 10H_2O$ precipitates because it was expected that recrystallization of $CH_3CO_2Na \cdot 3H_2O$ would start on the surface of $Na_4P_2O_7 \cdot 10H_2O$ crystals. The glass vessel was sealed and put into a water bath. The sample was consecutively heated and cooled at the rate of 0.4 °C/min between 35 °C and 70 °C, and maintained for 30 min each at 35 °C and then 70 °C. In this manner, the melting point t_m and the temperature at which supercooling was broken t_i were measured and supercooling $\Delta t_i (= t_m - t_i)$ was determined in each cycle.

Differential Scanning Calorimetry. Differential scanning calorimetry (DSC) was performed using SSC 560S DSC (Dainiseikosha Co. Ltd.). Weighed quantities of samples were placed in a 15 μl silver crucible and the surface of the sample was covered with one drop of liquid paraffin to prevent water evaporation. The sample was subjected to linearly programmed consecutive heating and cooling in a manner similar to the above. Melting points t_m″s were obtained from the sample temperature curve at times corresponding to endothermal peaks and the temperatures at which supercooling was broken t_i″s were obtained from the sample temperature curves at times corresponding to the onset of exothermal peaks. From these temperatures, supercooling $\Delta t_i' (= t_m' - t_i')$ was calculated. This DSC system was calibrated using ice (t_m: 0.0 °C), sodium sulfate decahydrate (t_m: 32.4 °C) and sodium acetate trihydrate (t_m: 58.4 °C) as a standard.

Results

The heating and cooling curve for a sample consisting of 30 g of $CH_3CO_2Na \cdot 3H_2O$ and 0.3 g of $Na_4P_2O_7 \cdot 10H_2O$ is shown is Fig. 1. The curve shows that the melting point of this sample is 58.4 °C which is the same as that of $CH_3CO_2Na \cdot 3H_2O$ alone. The supercooling of the sample is broken at 53.1 °C and suddenly the temperature of the sample rises to freezing point, 58.4 °C. After this temperature is maintained for about 12 min, the temperature of sample drops.

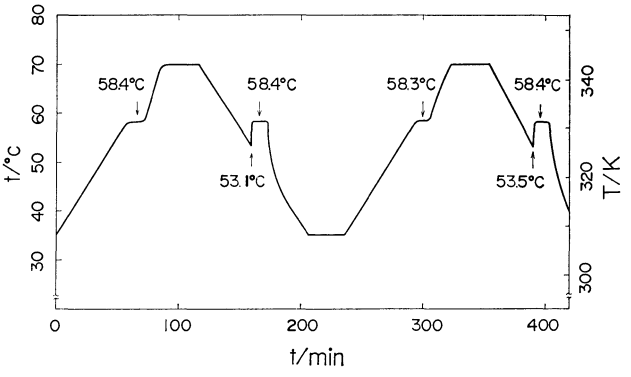

Fig. 1. Heating and cooling curve for a sample consisting of 30 g of $CH_3CO_2Na \cdot 3H_2O$ and 0.3 g of $Na_4P_2O_7 \cdot 10H_2O$.

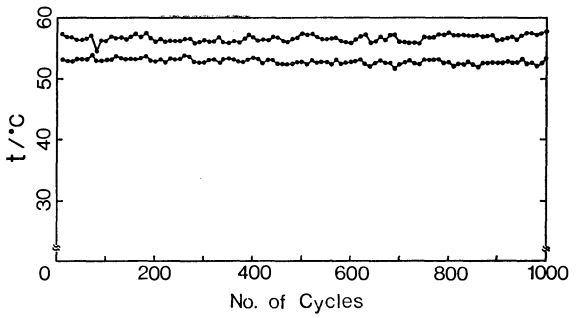

Fig. 2. Changes in melting point t_m and the temperature at which supercooling is broken t_i with cycling.
●: t_m, ○: t_i.

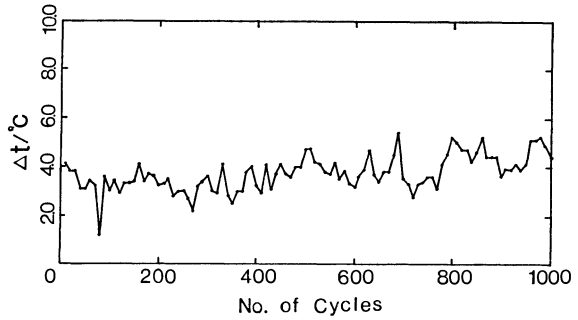

Fig. 3. Changes in supercooling Δt_i with cycling.

In this case, supercooling Δt_i is 5.3 °C.

The melting points t_m's and the temperatures at which supercooling is broken t_i's are plotted in Fig. 2, with temperature as ordinate and number of cycles as abscissa. As shown in Fig. 2, t_i and t_m are almost constantly 53 °C and 58.4 °C respectively. The slight scatter of t_m falls within measuring error. The supercooling Δt_i points are plotted in Fig. 3, using the result of Fig. 2. These Δt_i's are below 6 °C over all the cycles. It was also found that $Na_4P_2O_7 \cdot 10H_2O$ works continuously as a nucleation catalyst for 1000 cycles. On the other hand, when $Na_4P_2O_7 \cdot 10H_2O$ powder was not added to $CH_3CO_2Na \cdot 3H_2O$ melt, supercooling was not broken down to about 35 °C. These experimental results show that $Na_4P_2O_7 \cdot 10H_2O$ serves as a very effective nucleation catalyst for $CH_3CO_2Na \cdot 3H_2O$ whose melting point is scarcely lowered.

A DSC curve of a sample consisting of 14.0 mg of $CH_3CO_2Na \cdot 3H_2O$ and 1.7 mg of $Na_4P_2O_7 \cdot 10H_2O$ is illustrated in Fig. 4. The difference between the temperature of the first endothermal peak and that of the second is probably caused by measuring error. The melting points t_m"s and the temperatures at which supercooling is broken t_i"s which are determined by 50 continuous heating and cooling cycles are shown in Fig. 5. The supercooling in this case Δt_i"s ($=t_m' - t_i'$) are calculated by using the results of Fig. 5 and are plotted in Fig. 6. From Fig. 5, it is found that t_i' varies very widely and irregularly with number of cycles and their average is about 45 °C. Thus $\Delta t_i'$ also varies very widely and their average is 13 °C. It is evident that $\Delta t_i'$ is much larger than Δt_i. Moreover, the heat of fusion per 1 g of $CH_3CO_2Na \cdot 3H_2O$ which was obtained by this DSC measurement is 262

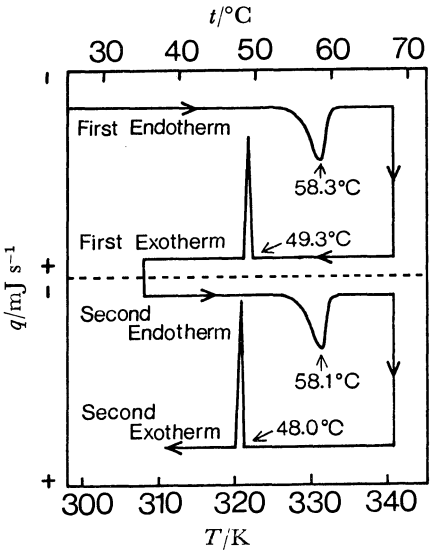

Fig. 4. DSC curve of a sample consisting of 14.0 mg of $CH_3CO_2Na \cdot 3H_2O$ and 1.7 mg of $Na_4P_2O_7 \cdot 10H_2O$.

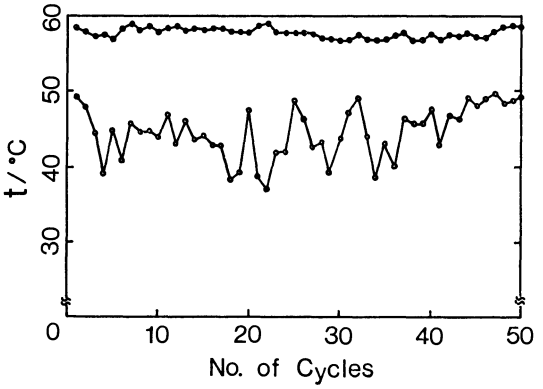

Fig. 5. Changes in melting point t_m' and the temperature at which undercooling is broken t_i' with cycling.
●: t_m', ○: t_i'.

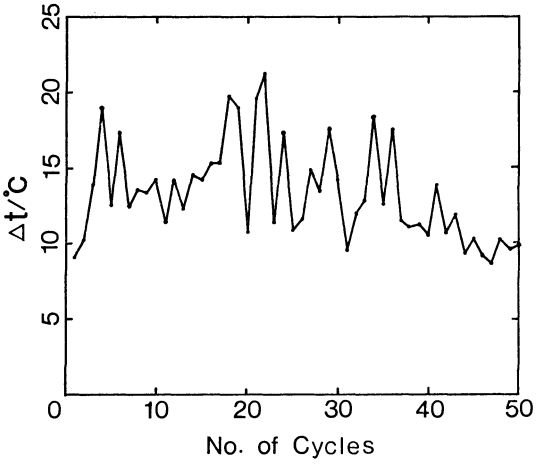

Fig. 6. Changes in undercooling $\Delta t_i'$ with cycling.

J/g, which is good agreement with that of $CH_3CO_2Na \cdot 3H_2O$ alone within measuring error. It is understandable that addition of $Na_4P_2O_7 \cdot 10H_2O$ to $CH_3CO_2Na \cdot 3H_2O$ scarcely decreases its heat of fusion.

The solubilities of $Na_4P_2O \cdot 10H_2O$ in $CH_3CO_2Na \cdot$

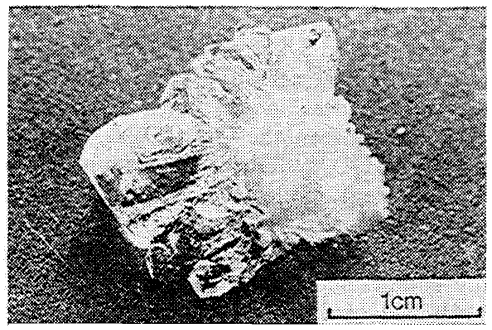

Fig. 7. Photograph of $CH_3CO_2Na \cdot 3H_2O$ crystals grown around a mass of $Na_4P_2O_7 \cdot 10H_2O$ polycrystal.

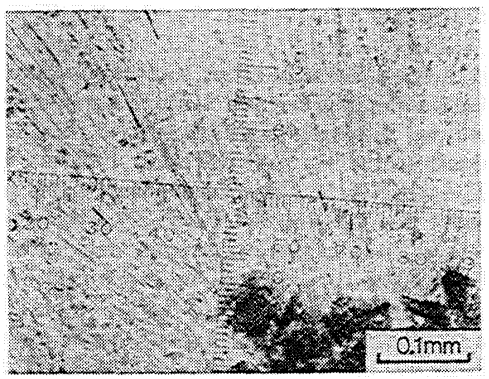

Fig. 8. Micro-photograph of $CH_3CO_2Na \cdot 3H_2O$ grown around $Na_4P_2O_7 \cdot 10H_2O$ particles.

$3H_2O$ melt at 60 °C and 75 °C were both about 0.1 percent by weight. Because of its slight solubility, it is supposed that both the melting point and the heat of fusion of $CH_3CO_2Na \cdot 3H_2O$ are hardly influenced by adding $Na_4P_2O_7 \cdot 10H_2O$. This is in good agreement with the results obtained by these thermal analyses.

Figure 7 shows $CH_3CO_2Na \cdot 3H_2O$ crystals grown around a mass of $Na_4P_2O_7 \cdot 10H_2O$ polycrystal. The white part indicates a mass of $Na_4P_2O_7 \cdot 10H_2O$ and transparent crystals around it are $CH_3CO_2Na \cdot 3H_2O$. Figure 8 is a micro-photograph of $CH_3CO_2Na \cdot 3H_2O$ crystals grown around $Na_4P_2O_7 \cdot 10H_2O$ particles. It is observed that $CH_3CO_2Na \cdot 3H_2O$ needles are radially grown from $Na_4P_2O_7 \cdot 10H_2O$ particles. It is suggested that $CH_3CO_2Na \cdot 3H_2O$ crystallized as needle since it began to recrystallize at a temperature significantly below the melting point. This large supercooling, we suppose, results from the small sample quantities of this experiment. This is consistent with the result obtained by DSC of about 15 mg sample.

Discussion

Table 1 shows the crystallographic data of $Na_2B_4O_7 \cdot 10H_2O$ and that of $Na_2SO_4 \cdot 10H_2O$,[7] and Table 2 shows the crystallographic data of $Na_4P_2O_7 \cdot 10H_2O$[8] and that of $CH_3CO_2Na \cdot 3H_2O$.[9] As shown in Table 1, the crystallographic data of $Na_2B_4O_7 \cdot 10H_2O$ and that of $Na_2SO_4 \cdot 10H_2O$ are quite similar except for a space group. Moreover, these two compounds have remarkably similar chains which are formed by sharing the two edges of $Na(H_2O)_6$ octahedra. These crystallographic similarities have been pointed out to be the cause of the nucleation catalysis.[7]

	Z	4	4

Table 2. Crystallographic data for sodium acetate trihydrate and tetrasodium pyrophosphate decahydrate

		$CH_3CO_2Na \cdot 3H_2O$	$Na_4P_2O_7 \cdot 10H_2O$
Crystal system		Monoclinic	Monoclinic
Space group		C2/c	C2/c
Unit-cell parameter	a/Å	12.353	17.01±0.02
	b/Å	10.466	6.96±0.01
	c/Å	10.401	14.85±0.02
	β/°	111.69	112.0±0.2
	V/Å^3	1249.5	1630
	Z	8	4

On the other hand, both $Na_4P_2O_7 \cdot 10H_2O$ and $CH_3CO_2Na \cdot 3H_2O$ are monoclinic and have the same space group C2/c, however their lattice constants a, b, and c are greatly different. In the crystal structure of $CH_3CO_2Na \cdot 3H_2O$, Na ion has distorted octahedral coordination with six oxygen atoms which consist of one acetate oxygen and five water molecules. Adjacent octahedra share an edge and form a continuous chain along the z axis.[9,10] However, the crystal structure of $Na_4P_2O_7 \cdot 10H_2O$ contains two types of sodium atoms lying within octahedra, which are made up of six water molecules in the one case, and four water molecules and two oxygen atoms of a pyrophosphate group in the other case. The $Na(H_2O)_6$ octahedra share edges and corners with each other so as to build up sheets of linked octahedra. The other octahedron containing a pyrophosphate group shares two edges with the $Na(H_2O)_6$ octahedra so as to link to the sheets of $Na(H_2O)_6$ octahedra.[8,11] Thus it is deduced that the structures of $CH_3CO_2Na \cdot 3H_2O$ and $Na_4P_2O_7 \cdot 10H_2O$ do not have highly similar chains or sheets of water molecules-coordinate Na ions, whereas $Na_2SO_4 \cdot 10H_2O$ and $Na_2B_4O_7 \cdot 10H_2O$ have remarkably similar chains.

The lattice spacings on low index planes of $CH_3CO_2Na \cdot 3H_2O$ and $Na_4P_2O_7 \cdot 10H_2O$ which can be calculated from the lattice constants shown in Table 2 are listed in Table 3. In this table, the lattice spacings on planes of $Na_4P_2O_7 \cdot 10H_2O$ which agree with those of $CH_3CO_2Na \cdot 3H_2O$ within 1%, are written in the same row of those of $CH_3CO_2Na \cdot 3H_2O$. It can be seen that there are many planes of $CH_3CO_2Na \cdot 3H_2O$ whose lattice spacing is close to that of $Na_4P_2O_7 \cdot 10H_2O$.

(10$\bar{2}$)	5.193	5.218	(210)
(210)	5.032	5.073	(11$\bar{2}$)

For example, *d*(11$\bar{1}$) of $CH_3CO_2Na\cdot3H_2O$ agrees very closely with *d*(010) of $Na_4P_2O_7\cdot10H_2O$. Consequently, the reason why $Na_4P_2O_7\cdot10H_2O$ serves as an effective nucleation catalyst for $CH_3CO_2Na\cdot3H_2O$ is considered to be their close resemblance in lattice spacing on certain low index planes.

The extent of supercooling of $Na_2SO_4\cdot10H_2O$ containing $Na_2B_4O_7\cdot10H_2O$ is known to be 1—2 °C in the experiment using test tube[3] and 7 °C in DSC.[12] On the other hand, the extent of supercooling of $CH_3CO_2Na\cdot3H_2O$ containing $Na_4P_2O_7\cdot10H_2O$ is found to be about 5 °C in the experiment using sealed glass vessel and at an average of 13 °C in DSC. In each case, the extent of supercooling of $CH_3CO_2Na\cdot3H_2O$ containing $Na_4P_2O_7\cdot10H_2O$ is larger than that of $Na_2SO_4\cdot10H_2O$ containing $Na_2B_4O_7\cdot10H_2O$. As indicated before, $Na_2SO_4\cdot10H_2O$ and $Na_2B_4O_7\cdot10H_2O$ have analogous unit cells and remarkably similar chains which are formed by sharing two edges of $Na(H_2O)_6$ octahedra each other, whereas $CH_3CO_2Na\cdot3H_2O$ and $Na_4P_2O_7\cdot10H_2O$ only resemble each other in lattice spacing on certain low index planes. The difference of supercooling between the $CH_3CO_2Na\cdot3H_2O$ system and $Na_2SO_4\cdot10H_2O$ system is considered to be due to such a different modes of resemblance in crystal structure.

It was pointed out that there was difference between the supercooling of $Na_2SO_4\cdot10H_2O$ containing $Na_2B_4O_7\cdot10H_2O$ obtained by the heating and cooling cycles using sealed test tube and that obtained by using DSC.[13] The cause of this difference of supercooling extent for the $CH_3CO_2Na\cdot3H_2O$ system is not more clearly understood than for the $Na_2SO_4\cdot10H_2O$ system.

In addition, both anhydrous sodium pyrophosphate ($Na_4P_2O_7$) and sodium hydrogenpyrophosphates such as disodium dihydrogenpyrophosphate ($Na_2H_2P_2O_7$) were found to act as a nucleation catalyst as well as $Na_4P_2O_7\cdot10H_2O$. This effect comes from the fact that a part of $Na_4P_2O_7$ and $Na_2H_2P_2O_7$ become $Na_4P_2O_7\cdot10H_2O$ in $CH_3CO_2Na\cdot3H_2O$ melt. The presence of $Na_4P_2O_7\cdot10H_2O$ both in the mixture of 30 g of $CH_3CO_2Na\cdot3H_2O$ melt and 1 g $Na_4P_2O_7$ and in the mixture of 30 g of $CH_3CO_2Na\cdot3H_2O$ melt and 1 g of $Na_2H_2P_2O_7$ was confirmed by X-ray diffraction.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his many helpful discussions and to Dr. Eiichi Hirota and Dr. Masanari Mikoda for their continuous encouragement. They are also grateful to Dr. Yoshihiro Matsuo for his discussions throughout this work, to Mr. Masahiro Nishikawa for his photography, and to Mr. Koji Matsunaga and Miss Fumiko Kimura for their thermal analyses.

A Comparative Study of the Kinetics and Mechanism of Reactions between Copper(I) Iodide and Mercury(II) Halides in Solid State

Mirza Aijaz Beg* and Afaq Ahmad

Department of Chemistry, The Aligarh Muslim University, Aligarh-202001, India

(Received September 3, 1981)

Kinetics and mechanisms of reactions of HgI_2, HgBrI, or $HgBr_2$ with CuI were studied in the solid state. Mercury(II) halides react *via* vapor phase, and reactions proceed through counter diffusion of Cu^+ and Hg^{2+}. X-Ray and chemical analyses indicate that powdered CuI gives Cu_2HgI_4 when mixed with HgI_2 and a mixture of Cu_2HgI_4 and CuBr when mixed with HgBrI. CuI and $HgBr_2$ react differently in different molar ratios. In a 1:2 molar ratio mixture of CuI and $HgBr_2$, a new product $CuHgBr_3$ and HgBrI are obtained. Data for lateral diffusion best fit the equation $X^n=kt$ where X is the thickness of product layer at time t, and n and k are const. Formation of solid solutions among reactant and product phases is also noted.

AgI reacts with HgI_2[1] in solid state yielding highly conducting Ag_2HgI_4. Its reactions with $HgBr_2$ or $HgCl_2$ are complex and altogether different.[2,3] Formation of Cu_2HgI_4 from HgI_2 and CuI in solid state is long known,[4] but no effort seems to have been made to understand the mechanism of the interaction of CuI with Mercury(II) halides in solid state.

This paper presents a study on Kinetics and mechanisms of the reaction of CuI with HgI_2, HgBrI, or $HgBr_2$ in solid state. It was observed that while the first halide is involved in a simple addition reaction, the last two are involved in multi-step reactions. But in each of these, Cu_2HgI_4 and HgI_2 were formed as intermediates. Mixtures of different molar ratios gave rise to different products, including $CuHgBr_3$ which does not seem to have been reported so far either in solid or in solution. Formation of solid solutions among the products were also noted.

Experimental

Materials. $HgBr_2$ and HgI_2 (E. Merck) were used without further purification. Copper(I) halides, being photosensitive, were prepared fresh for each set of experiments. CuI was prepared according to Berthemot[5] and Guichard.[6] Its X-Ray diffraction patterns showed it to be single phase. CuI was stored in a dark bottle, and experiments were carried out in dark.

Cu_2HgI_4 was prepared by precipitation from solution containing stoichiometric amounts of CuI and HgI_2.[7] Mercury bromideiodide was prepared by Oppenheim's method.[8] X-Ray diffraction patterns showed them to be β-Cu_2HgI_4,[9] and HgBrI.[10]

Rate Measurements. Kinetics of reactions were studied by placing Mercury(II) halides over CuI (each above 300 mesh size) in a vertically held Pyrex glass tube about 0.5 cm in diameter as reported earlier.[11] Each experiment was run in triplicate and the average values were used to calculate rate constants (the readability of the microscope was 0.001 cm and the average deviation of measured values ranged between $\pm$0.00038 cm) as reported in Tables 1—3.

Soon after the placement of Mercury(II) halide (HgBrI, HgI_2, or $HgBr_2$) over CuI in the reaction tube, a dark brown boundary was formed at the interface and this grew with time on the CuI side. A light yellow layer appeared between HgBrI and a brown dark product layer in the case of HgBrI, and a yellow layer between $HgBr_2$ and brown product layer in the case of $HgBr_2$. On cooling to room temperature, the dark brown product turned scarlet red (Cu_2HgI_4 is dark brown above 70 °C and scarlet below this temperature).[12]

Table 1. Dependence of parameters of equation $X^n=kt$ on temperature for CuI-HgI_2 reaction

T/°C[a]	k/cm h^{-1}	n
70	1.42×10^{-4}	2.48
82	3.70×10^{-4}	
93	1.25×10^{-3}	
103	3.54×10^{-3}	
112	5.55×10^{-3}	

a) Accurate within $\pm$0.5 °C.

Table 2. Dependence of parameters of equation $X^n=kt$ on temperature for CuI-HgBrI reaction

T/°C[a]	k/cm h^{-1}	n
64	1.06×10^{-6}	2.53
75	2.56×10^{-6}	
87	7.08×10^{-6}	
95	14.96×10^{-6}	
104	39.81×10^{-6}	

a) Accurate within $\pm$0.5 °C.

Table 3. Dependence of parameters of equation $X^n=kt$ on temperature for CuI-$HgBr_2$ reaction

T/°C[a]	k/cm h^{-1}	n
75	1.13×10^{-6}	2.22
85	7.58×10^{-6}	
98	2.18×10^{-5}	
108	6.60×10^{-5}	
118	8.31×10^{-5}	
128	9.33×10^{-5}	
140	10.50×10^{-5}	

a) Accurate within $\pm$0.5 °C.

Later, when the reactants were placed in a tube with some air gap, the product layers were formed, but with a much slower rate, which decreased with increase in the length of the air gap. This clearly indicates that these reactions proceed *via* surface migration of Mercury(II) halides.

Analysis of the Product Layers. Sufficient amounts of different product layers of reactions CuI-HgI_2(A), CuI-HgBrI(B), and CuI-$HgBr_2$(C) were separately collected carefully by breaking the reaction tubes. Cu^+, Hg^{2+}, and I^- in the case of reaction A, and Cu^+ and Br^- and Cu^+, Hg^{2+}

Table 4. Compounds present in different molar mixtures of CuI and HgI_2

Molar ratio CuI : HgI_2	Compounds present in mixture heated to 120 °C and then cooled to 30 °C
3 : 1	Cu_2HgI_4, CuI
2 : 1	Cu_2HgI_4
1 : 1	Cu_2HgI_4, HgI_2

and I^- in layers of reaction B and C, respectively, were detected by spot tests.[13] X-Ray diffraction analyses showed them to be Cu_2HgI_4, CuBr, and Cu_2HgI_4, respectively.

X-Ray Studies. The reactants (each above 300 mesh) were mixed thoroughly in an agate mortar in different molar ratios. One part of each mixture was heated in an air thermostat at (120±0.5) °C, and another part was maintained at 30 °C. Mixtures were analysed after 48 h using a Norelco Geiger counter X-Ray diffractometer by Cu $K\alpha$ radiations with a Ni filter, applying 32 kV at 12 mA. The compounds thus identified are given in Tables 4—6.

Thermal amd Conductance Measurements. CuI and Mercury(II) halides (HgI_2, HgBrI, or $HgBr_2$) in different molar ratios ranging from 4:1 to 1:2 were weighed separately and mixed thoroughly in a Dewar flask calorimeter. The rise in temperature was noted against time. The electrical conductance of the same molar-ratio mixtures were measured with a current ratio I. C. bridge:[14] as reported elsewhere.[2,3]

Results and Discussion

X-Ray diffraction analyses (Tables 4—6) reveal that while CuI reacts with HgI_2 or HgBrI in 2:1 or 3:1 molar ratios, respectively, it reacts differently with different molar mixtures of $HgBr_2$.

CuI-HgI_2 Reaction. X-Ray analysis (Table 6) of the products obtained with different molar mixtures of CuI and HgI_2 showed that only Cu_2HgI_4 is formed:

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4. \quad (1a)$$

Thermal and conductance curves are also indicative of only a single step reaction.

CuI-HgBrI Reaction. A 3:1 molar mixture of CuI and HgBrI, maintained at 120 °C for about 48 h after mixing, showed presence of only Cu_2HgI_4 and CuBr:

$$3CuI + HgBrI \longrightarrow Cu_2HgI_4 + CuBr. \quad (1)$$

Thermal (Fig. 1) as well as conductance (Fig. 2) measurements made with different molar mixtures of CuI and HgBrI provide no evidence for any additional step in reaction (1). However, the presence of HgI_2 in the mixture maintained at 30 °C but the absence in the one kept at a higher temperature (Table 5) suggests that the reaction goes through formation of HgI_2, which is rapidly consumed by CuI giving the addition product Cu_2HgI_4. The reaction sequence, therefore, may be written as:

$$CuI + HgBrI \longrightarrow HgI_2 + CuBr, \quad (i)$$

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4, \quad (ii)$$

$$3CuI + HgBrI \longrightarrow Cu_2HgI_4 + CuBr.$$

The failure of thermal and conductance measurements to provide evidence for the substep (ii) (Fig. 5(i)) is because it is faster than step (i).[1] However, it is not

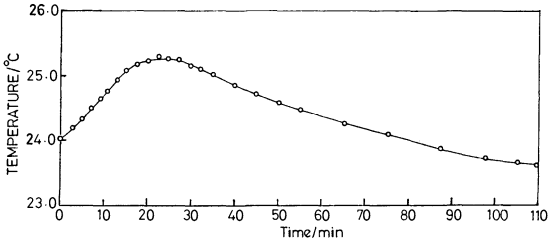

Fig. 1. Temperature rise as a function of time for CuI–HgBrI reaction in 3:1 molar mixture.

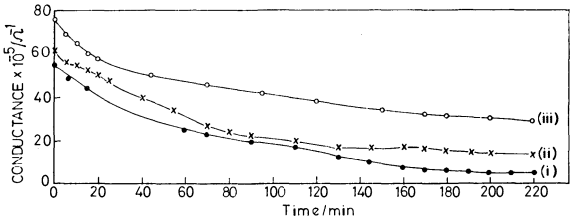

Fig. 2. Change in conductance as a function of time for CuI–HgBrI reaction, molar ratios (i) 3:1, (ii) 2:1, and (iii) 1:2.

Table 5. Compounds present in different molar mixtures of CuI and HgBrI

3 : 1	Cu_2HgI_4, CuBr, HgI_2	Cu_2HgI_4, CuBr
1 : 2	Cu_2HgI_4, CuBr, $HgBr_2$ and HgI_2	Cu_2HgI_4, CuBr and HgBrI

Table 6. Compounds identified in different molar mixtures of CuI and HgBr

Molar ratio CuI : $HgBr_2$	Compounds present at 30 °C	Compounds present in mixture heated to 120 °C and then cooled to 30 °C
4 : 1	Cu_2HgI_4, CuBr, HgI_2	Cu_2HgI_4, CuBr
3 : 1	Cu_2HgI_4, CuBr, HgBrI and HgI_2	Cu_2HgI_4, CuBr, HgBrI
2 : 1	Cu_2HgI_4, CuBr, HgBrI and HgI_2	Cu_2HgI_4, CuBr, HgBrI
1 : 1	Cu_2HgI_4, CuBr, HgBrI	CuBr, HgBrI
1 : 2	Cu_2HgI_4, CuBr, HgBrI and $HgBr_2$	HgBrI and $CuHgBr_3$

so fast as to remove HgI_2, otherwise the latter could not have been detected in the mixture. Reaction (i) is slow because the ionic radii of Cu^+ and Hg^{2+} are very close to each other.

With all other molar mixtures, namely 4:1, 2:1, and 1:2 of CuI and HgBrI, the reaction sequence follows the same pattern and the excess of either reactant remained in the mixtures unreacted.

CuI-$HgBr_2$ Reaction. While HgBrI reacts with CuI in the molar ratio 1:3, $HgBr_2$ seems to do so primarily in 4:1 molar ratio:

$$4CuI + HgBr_2 \longrightarrow Cu_2HgI_4 + 2CuBr. \quad (2)$$

Thermal (Fig. 3) as well as conductance (Fig. 4) measurements show the reaction to be a simple one-step process. The presence of HgI_2 in the 4:1 molar mixture of CuI and $HgBr_2$, kept at room temperature for about 24 h, and its absence in the mixture maintained at 120 °C suggests that this reaction proceeds *via* the formation of HgI_2, much in the same way as CuI-HgBrI reaction does:

$$2CuI + HgBr_2 \longrightarrow 2CuBr + HgI_2. \quad (iii)$$

However, the absence of HgI_2 in the mixture kept at 120 °C raises two possibilities, First, HgI_2 may react with $HgBr_2$ to give HgBrI, which is stable and is known to be formed in the solid state[10] at high temperatures:

$$HgI_2 + HgBr_2 \longrightarrow 2HgBrI. \quad (iv)$$

Second, HgI_2 may also react with CuI present in the reaction mixture to give Cu_2HgI_4:[4]

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4. \quad (v)$$

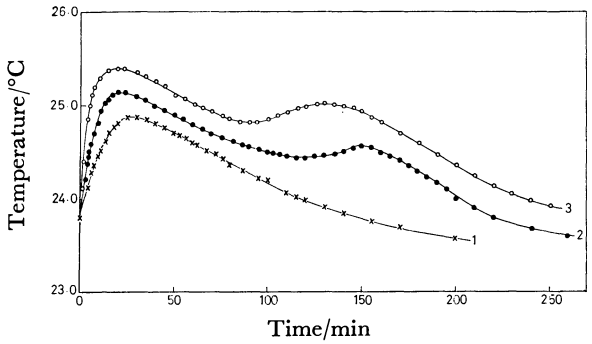

Fig. 3. Temperature rise as a function of time for the reaction between CuI and $HgBr_2$ molar ratios (1) 4:1, (2) 2:1, and (3) 1:2.

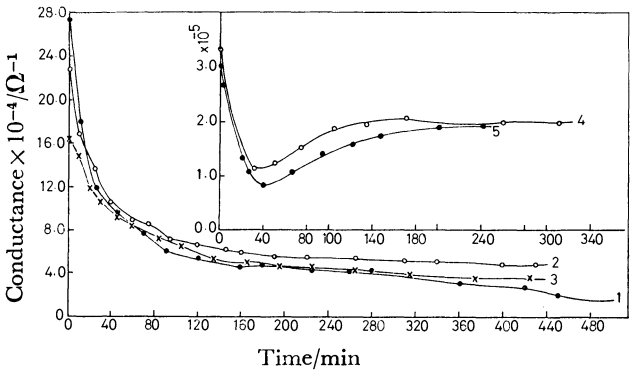

Fig. 4. Conductivity change as a function of time for the reaction between CuI and $HgBr_2$ at 30 °C. Molar ratios of CuI:$HgBr_2$ are (1) 4:1, (2) 3:1, (3) 2:1, (4) 1:1, and (5) 1:2.

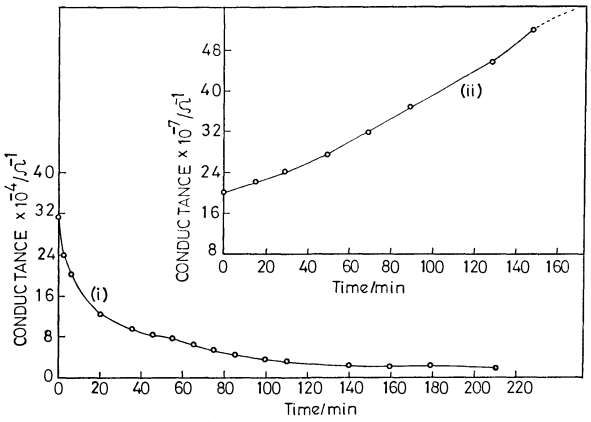

Fig. 5. Change in conductance as a function of time for reactions (i) $2CuI + HgI_2$ and (ii) $HgI_2 + HgBr_2$.

From the conductance curve for the 4:1 molar mixture of CuI and $HgBr_2$ (Fig. 4), it is evident that most of the reaction is over in about only 25 min, whereas conductance measurements (Fig. 5) made with a 1:1 molar mixture of HgI_2 and $HgBr_2$ clearly show that this reaction continues to proceed uniformly even after 3 h. CuI-HgI_2 reaction is, however, quite fast as is evident from Fig. 5(i). Furthermore, the sudden decrease in the conductance curve for the 4:1 molar mixture (Fig. 4) conforms to the change in the conductance curve obtained for reaction (v) and not to reaction (iv). Moreover, the former is already known[10] to be slow at room temperature whereas the latter is fast.[4] Therefore, HgI_2 produced in reaction (iii) reacts mostly with CuI giving Cu_2HgI_4 and to a little extent, if at all, with $HgBr_2$ yielding HgBrI. Hence, the overall reaction may be described as:

$$2CuI + HgBr_2 \longrightarrow 2CuBr + HgI_2,$$
$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4,$$
$$4CuI + HgBr_2 \longrightarrow 2CuBr + Cu_2HgI_4,$$

and

$$2CuI + HgBr_2 \longrightarrow 2CuBr + HgI_2,$$
$$HgBr_2 + HgI_2 \longrightarrow 2HgBrI,$$
$$6CuI + 2HgBrI \longrightarrow 2CuBr + 2Cu_2HgI_4,$$
$$8CuI + 2HgBr_2 \longrightarrow 4CuBr + 2Cu_2HgI_4.$$

The compounds identified in the 3:1 molar mixture of CuI and $HgBr_2$ maintained at 120 °C were HgBrI, CuBr, and Cu_2HgI_4. At 120 °C, the reaction seems to proceed according to

$$9CuI + 3HgBr_2 \longrightarrow 2Cu_2HgI_4 + HgBrI + 5CuBr. \quad (3)$$

The presence of HgI_2 in this molar mixture (Table 5) at 30 °C shows that this reaction also proceeds through initial formation of HgI_2 which thereafter gives rise to Cu_2HgI_4. The presence of HgBrI may create an impression that this could be formed in the initial stage of reaction (iv), but this is not actually the case as already discussed. Excess $HgBr_2$ combines with Cu_2HgI_4 formed in the reaction giving HgBrI

and CuBr. The complete reaction sequence may thus be as follows:

$$6CuI + 3HgBr_2 \longrightarrow 6CuBr + 3HgI_2, \quad (3a)$$

$$6CuI + 3HgI_2 \longrightarrow 3Cu_2HgI_4, \quad (3b)$$

$$Cu_2HgI_4 + 3HgBr_2 \longrightarrow 2CuBr + 4HgBrI, \quad (3c)$$

$$6CuI + 2HgBrI \longrightarrow 2Cu_2HgI_4 + 2CuBr, \quad (3d)$$

$$18CuI + 6HgBr_2 \longrightarrow 4CuHgI_4 + 2HgBrI + 10CuBr.$$

Indeed, when Cu_2HgI_4 and $HgBr_2$ were mixed in 1:3 molar ratio it was found, after keeping it for about 24 h at 120 °C, (by X-Ray diffraction analysis) that it was completely changed into HgBrI and CuBr. Reaction (3d) has already been discussed rearlier. It is perhaps due to the very slow occurrence of Reactions (3c) and (3d) at room temperature that no inflection in the conductance curve (Fig. 4) shows up.

The 1:1 and 1:2 molar mixtures heated to 120 °C showed only the presence of CuBr and HgBrI and of CuBr and $CuHgBr_3$, respectively (Table 6):

$$CuI + HgBr_2 \longrightarrow CuBr + HgBrI, \quad (4)$$

$$CuI + 2HgBr_2 \longrightarrow CuHgBr_3 + HgBrI. \quad (5)$$

It appears as if in the 1:1 mixture, simple exchange took place, which indeed is not the case. When the reactants were mixed at room temperature, they formed a scarlet product turning gradually yellow. The scarlet product turned brown above 70 °C, which incidentally shows that the intermediate could be Cu_2HgI_4. This is also supported by thermal and conductance measurements (Figs. 3 and 4). X-Ray patterns taken about an hour after mixing the two in unimolecular ratio did indicate the presence of Cu_2HgI_4 and HgI_2, which shows that this reaction, too, takes place *via* HgI_2 as the others do.

$$2CuI + HgBr_2 \longrightarrow 2CuBr + HgI_2, \quad (4a)$$

$$2CuI + HgI_2 \longrightarrow Cu_2HgI_4, \quad (4b)$$

$$Cu_2HgI_4 + 3HgBr_2 \longrightarrow 4HgBrI + 2CuBr, \quad (4c)$$

$$4CuI + 4HgBr_2 \longrightarrow 4HgBrI + 4CuBr.$$

The initial fall in the conductance curve (Fig. 4) is due to conversion of highly conducting CuI into Cu_2HgI_4, and the rise thereafter refers to formation of HgBrI.

The reaction sequence for the 1:2 molar mixture is the same as that for 1:1. But, unlike 1:1 reaction, CuBr was not found in the end product (Table 6) in this case. This is because CuBr formed during the reaction is consumed up by $HgBr_2$ giving the addition product $CuHgBr_3$. $CuHgBr_3$ does not seem to have been reported so far either in solid or in solution. $KHgBr_3$ is, however, known in nonaqueous media.[15] Later $CuHgBr_3$ was prepared by heating a unimolar mixture of CuBr and $HgBr_2$ (each above 300 mesh) at 70 °C for about five days. The reflectance spectra (Fig. 6) for the 1:2 molar mixture showed that the product formed is different from the one obtained in the 1:1 molar mixture. The product thus obtained is yellow. The X-ray analysis and indexing of $CuHgBr_3$ are given in Table 7.

Mechanism of Lateral Diffusion. In the initial stage, at the reaction zone, the mercury(II) halide vapor surrounds each CuI grain and reacts through counter diffusion of Cu^+ and Hg^{2+} with simultaneous separation of CuBr and Cu_2HgI_4.

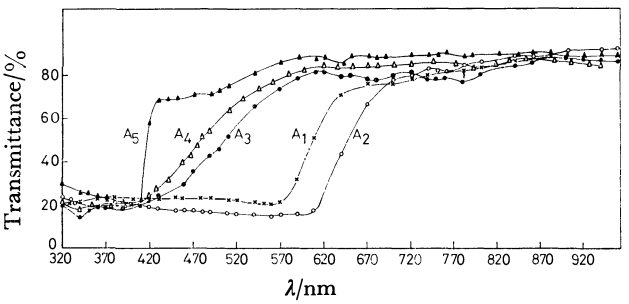

Fig. 6. Reflectance spectra for the CuI+$HgBr_2$ reaction (i) A_2, 4:1 (ii) A_1, 3:1 (iii) A_3, 2:1 (iv) A_4, 1:2 and (v) A_5, 1:2.

Table 7. X-Ray diffraction patterns of $CuHgBr_3$ taken by Norelco, (Philips 1010) diffractometer using Cu $K\alpha$ radiation and Ni-filter

d/Å	I/I_0	$h\,k\,l$	a_0[a]
5.9986	40	111	10.3899
3.8522	25	220	10.9240
3.1015	45	222	10.7439
2.4918	25	411	10.5718
2.2787	100	332	10.6881
2.1245	62	500, 430	10.6225
2.0336	25	511, 333	10.5669
1.9786	12	520, 432	10.6551
1.7614	14	610	10.7142
1.6851	7	620	10.6575
1.6143	5	622	10.7081
1.5367	25	444	10.6467

a) $a_0 = 10.6575$ Å.

Reactions on the two sides of the product layer proceed as follows:

$$HgX_2 + Cu^+ \longrightarrow 2CuX + Hg^{2+}, \quad (9)$$

$$4CuI + Hg^{2+} \longrightarrow Cu_2HgI_4 + 2Cu^+. \quad (10)$$

As the reaction proceeds, the thickness of the product layers increase and the rate decreases. The increase in thickness slows down the diffusion, and reaction rates thus fall gradually.

The kinetic data best fit the equation

$$X^n = kt,$$

where X is the total thickness of the product layers at time t and k and n are constants. k is related to the diffusion coefficient and follows the Arrhenius equation. The reactions proceed by movement of ions of one kind only, in such a way that the cations move through the product layers in opposite directions and react at phase boundaries with further formation of product layers. The continuous flow of cations from one into the other reactant through the product layer is responsible for the reaction. This is similar to the reaction of AgI and HgI_2 to form Ag_2HgI_4.[1]

Activation energies calculated by computer for CuI-HgI_2, CuI-HgBrI, and CuI-$HgBr_2$ reactions are, 97.75

± 2.74, 91.74 ± 2.55, and 82.787 ± 6.829 kJ mol^{-1}. respectively. These activation energies suggest that the reactions are diffusion controlled.

X-Ray analysis of the reaction mixture showed a change in *d*-values of the components which indicates formation of solid solutions in the systems CuBr–CuI, Cu_2HgI_4–CuBr, and HgBrI–Cu_2HgI_4. No attempt was, however, made to study the solutions in detail.

The authors wish to express thanks to the Head, Department of Chemistry for providing research facilities, to K. Rama Rao, R. R. L., Hyderabad for the help in X-ray measurements, and to Dr. M. Rahman, Department of Electrical Engineering for the help in the studies of conductivity measurements. One of us (A. A.) is grateful to C. S. I. R., New Delhi for the financial assistance.

(Received October 1, 1981)

Infrared spectra of *N*-acetylthiourea (ATU) and its *N,N,N'*-trideuterated compound have been examined in the range 4000—50 cm^{-1}. A complete vibrational assignment with a normal coordinate treatment based on a Urey-Bradley type intramolecular potential function supplemented with valence force function for the out of plane and torsional modes is proposed and the feature of the thioureido vibrations explained. A molecular orbital study by the CNDO/2 method of ATU and its oxygen analog is undertaken and the results are analyzed for a comparative study of the molecular electronic structure and conformation.

Thiourea is a compound of considerable importance for the study of spectroscopic, structural and ligational properties. Many sulfur-nitrogen compounds containing $-NHCSNH_2-$ skeleton have been shown to possess carcinostatic and antiviral activities.[1] In this regard the vibrational spectra of thiourea and its various *N*-alkyl derivatives have received detailed attention.[2–10] In this context, it was of interest to study the spectral and structural features of *N*-acetylthiourea (ATU). ATU is isoelectronic with monothiobiuret and is the sulfur analog of *N*-acetylurea (AU), for both of which detailed vibrational spectroscopic studies have been reported very recently.[11,12] We have now examined the infrared spectra of ATU and its *N,N,N'*-trideuterated species and propose an assignment of all the fundamentals. A complete normal coordinate analysis has been carried out for ATU-d_0 and ATU-d_3 employing an intramolecular potential field of the Urey-Bradley type supplemented with valence force functions for the out of plane modes.

Another interesting problem concerning ATU is the identification of the minimum energy conformation. Four planar conformations may be conceived for ATU (Fig. 1). For this purpose, the all valence self consistent field molecular orbital method by the CNDO/2 procedure is employed. The computed bond orders and electron populations are employed to discuss the electronic structure. The calculations have been performed on both ATU and AU to note the electronic effects of the amide/thioamide grouping.

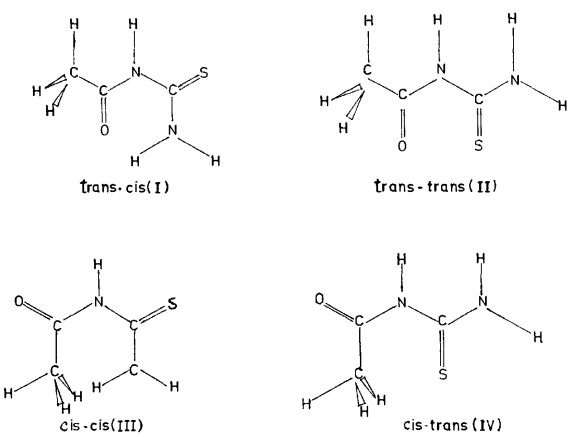

Fig. 1. Planar conformations of ATU.

Experimental

N-Acetylthiourea (Aldrich Chemical) was recrystallized from ethanol. The *N,N,N'*-trideuterated compound was obtained by exchange reaction with heavy water. The infrared spectra (both polycrystalline and solution) were recorded using Perkin-Elmer Model 580 spectrophotometer (4000—200 cm^{-1}) employing KBr pellet and Nujol mull techniques. Far infrared spectra (250—50 cm^{-1}) were recorded on Polytec FIR30 Fourier transform spectrometer as polyethylene pellets. The observed frequencies were calibrated with the usual standards.

Theoretical Treatment

The calculations were done on a DEC 1090 computer system using programs written in FORTRAN IV.

Normal Coordinate Analysis. The observed frequencies of ATU and its *N,N,N'*-trideuterated derivative were used in the calculations cast in terms of the GF matrix formulation.[13] The molecular structure adopted is shown in Fig. 2. This was based on the results of the CNDO/2 calculations and the preliminary X-ray structure determination.[14]

In the C_s point group model, the 33 fundamentals of ATU are classified amongst the symmetry species as 22A′ (In-plane), and 11A″ (out of plane) modes. The structural parameters were transferred from AU[12] and the C–S distance was taken to be 1.72 Å as in thioacetamide.[15] The internal valence coordinates and the local symmetry coordinates adopted were similar to those employed for AU.[12] A simple Urey-Bradley force field supplemented with valence force function for the out of plane deformation and torsional coordinates was employed. The initial values of the intramolecular force constants were transferred from thioacetamide[16–18] (TA), *N*-methylthioacetamide[16] (NMTA), and *N*-methylacetamide[16,19] (NMA), for

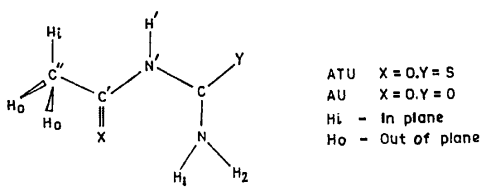

Fig. 2. Molecular structure and numbering scheme.

** Contribution No, 577,

which previously developed reliable potential constants are available. Only a small number of force constants required modification within a narrow range in the iteration process to obtain a desired agreement between the observed and calculated frequencies for ATU-d_0 and ATU-d_3. The programs employed were similar to the normal coordinate package of Schachtschneider.[20]

Molecular Orbital Studies. The calculations were made using the self consistent field CNDO/2 method. A full basis set of orbitals were explicitly considered including the 3d orbitals of sulfur. The geometrical parameters used were the same as those employed for the normal coordinate treatments. The total molecular energy was calculated, for the four more likely planar conformations of AU and ATU assuming the bond lengths and interbond angles to remain the same during the internal rotations. The standard program of Pople and Beveridge was employed.[21]

Results and Discussion

Table 2 gives the values of the final force constants. The values of the force constants appear reasonable and are similar to those of the initial ones indicating the good transferability property of the Urey-Bradley force constants as observed in other amide[16] and thioamide[16,18] derivatives. The force constant values compare well with the appropriate ones of AU.[12]

Spectral Interpretations. The observed spectra are shown in Fig. 3. In Table 1, the observed frequencies are compared with the calculated frequencies for ATU-d_0 and -d_3, wherein calculated potential energy distributions (PED), omitting for simplicity those less than 15%, are shown. A brief discussion of the features of thioureido vibrations of ATU will now be given.

The characteristic bands of interest are due to C=S and C–N stretching vibrations and NH inplane bending corresponding to thioamide I, III, and II bands respectively. The results of the coordinate analysis indicate a delocalized C=S mode contributing chiefly to the 820 cm^{-1} band akin to the 808 cm^{-1} band of thiosemicarbazide[22,23] and in contrast to a localized C=S stretching mode of *N*-methylthiourea at 778 cm^{-1}. Thus the C=S stretching frequency of ATU is higher than that in thiourea[2] and sym. *N,N'*-dimethylthiourea[8,9] assigned near 730 cm^{-1}. In monothiobiuret,[11] which is isoelectronic with ATU, the C=S stretching is assigned at 825 cm^{-1}. The C=S stretching frequency is lowered to 735 cm^{-1} in the *N*-deuterated derivative, the shift is comparable to that in *N*-methylthiourea -d_0 and -d_3.

The high and low C–N stretching frequencies (amide III bands) corresponding to the asymmetric and symmetric modes are assignable at 1525 and 1420 cm^{-1} which compare reasonably with those of *N*-methylthiourea[5] (NMTU) at 1565 and 1500 cm^{-1} and of sym·*N,N'*-dimethylthiourea[8,9] (DMTU) at 1560 and 1355 cm^{-1}. The differences are attributable to the different nature of the coupling of the vibrations involved.

The thioamide II band of the $-CSNH_2$ group due to NH_2 bending is observed at 1590 cm^{-1} which is lower than the 1642 cm^{-1} band of *N*-methylthiourea

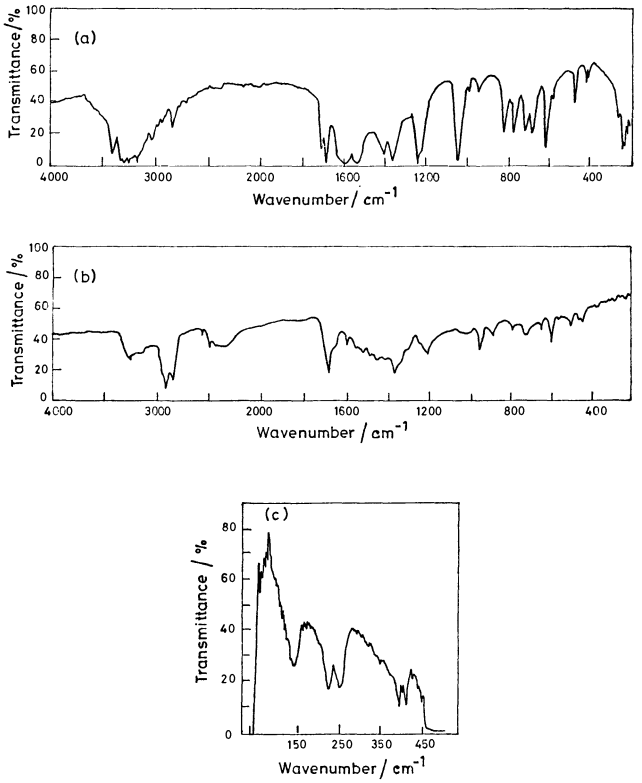

Fig. 3. Spectra of ATU.
a): ATU-d_0, b): ATU-d_3, c): far IR of ATU.

(NMTU). The thioamide II of –CSNH-grouping contributes to two bands at 1525 and 1315 cm^{-1}. The analogous NH bending frequencies are found in the region 1350 to 1400 cm^{-1} in NMTU,[5] DMTU[8,9] and thiosemicarbazide.[22,23] The thioamide VI band due to in-plane C=S bending occurs at 475 cm^{-1} as in thioacetamide.[16,18] In contrast, *N*-methylthiourea exhibits a more delocalized C=S bending mode. The assignments of other frequencies are compatible with the general features of *N*-methylthiourea[5] sym. *N,N'*-dimethylthiourea[8,9] and monothiobiuret[11] and are not discussed here further for brevity.

The intense band at 1680 cm^{-1} of ATU corresponds to the carbonyl stretching mode. The related band in the spectrum of AU occurs at 1670 cm^{-1}.

Molecular Conformation. The calculated total energies (Table 3) reveal that the most stable conformation accessible for ATU is the trans-cis (Fig. 1) concordant with the preliminary X-ray structure data in the solid state.[14] The next stable conformation is trans-trans which lies only some 5.02 kcal mol^{-1} above the lowest energy conformation. The calculations indicate the same trend for AU. The results rule out the accessibility of cis-cis structure and interestingly reveal that only a small activation energy is required for the conversion of cis-trans to the trans-trans form. This energy difference however should not be regarded as significant within the framework of this method. Moreover, the preference for one or the other form can also be affected by such factors as solvent and solid state interactions which are obviously not taken into consideration in the calculations. The implication is that the trans-cis structure is stabilized over

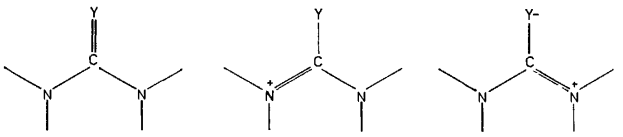
a) The fundamentals of ATU-d_3 have been arranged so as to give as far as possible approximately matching potential energy distributions (PED) stated for ATU-d_0. b) ν: Stretching, δ: bending, γ: rocking, π: out of plane bending, ω: waggingg, τ: torsion, a: asymmetric, and s: symmetric. X:H in ATU-d_0. X:D in ATU-d_3.

the other structures in the solid state. Factors such as steric effects, dipole-dipole interaction, hydrogen bonding and crystal packing determine the conformation of ATU. The large dipole-dipole interaction between the C=O and C=S dipoles is minimized in the trans-cis rotamer, so also the steric hindrance. Examination of the molecular model of ATU showed that this structure is very favourable for strong S···HN intermolecular and O···HN intramolecular hydrogen bonds. The more polarizable nature of the thiocarbonyl sulfur leads to stronger S···HN intermolecular hydrogen bonding between ATU molecules. Isoelectronic monothiobiuret[11] and other related molecules[12,24–26] are shown to possess a similar type of trans-cis structure.

Electronic Structure. Molecular orbital calculations of charge distributions have given an insight into the electronic structures of molecules and the effects



(a) (b) (c)

Fig. 4. Resonance structures.

of substituents.[27] In Table 4, the σ and π electron densities and the net electron populations have been shown for AU and ATU. While the electron densities quoted for a single molecule may not be a good guide, comparisons between related molecules by the same procedure of calculation may be more reliable. On comparing ATU with AU, we find significantly less electron populations for the atoms of the thioureido group excepting for the amide Y (O/S) atom,

for which the reverse is true. This indicates increased delocalization in the thioureido group as is to be expected, suggesting an increased contribution from resonance structures (b) and (c) to the description of bonding of ATU over that in AU shown in Fig. 4. This result is shown clearly in the values of the π bond orders. Table 4 demonstrates that in ATU, there is a significant decrease in the C–S(Y) bond order with consequent increase in the C–N (and C–N′) bond orders compared to those of AU. The C=O bond is also strengthened slightly in ATU relative to AU. From the low C–C π bond orders, it is evident that it hardly contributes to the conjugation of AU or ATU, while C′–N′ acquires slight π bond character. The acetyl carbonyl stretching frequency is observed at a higher wave number in ATU (1680 cm^{-1}) compared to AU in accord with the π bond order values. NH_2 and NH stretching frequencies of ATU should occur at lower wave numbers than those of AU because of increasing positive charge on nitrogen in ATU compared to AU (Table 4). But (Table 1), these frequencies are observed at higher frequencies than those in AU.[12] This demonstrates clearly, possible intermolecular (S···HN) and intramolecular (O···HN) hydrogen bonding between ATU molecules. More information can be obtained on this on the basis of detailed crystal structure analysis.[14]

Electron Transfer Reactions between V(IV) and I(V) Catalyzed by Os(VIII) or Ru(III). A Kinetic Study

Patapati Subbu RADHAKRISHNAMURTI,* Chelli JANARDHANA, and Gopal Krishna MOHANTY

Department of Chemistry, Berhampur University, Berhampur 760007, Orissa, India

(Received November 17, 1981)

Oxidation of V(IV) by iodate, catalyzed by Os(VIII) or Ru(III) in aq perchloric acid medium, was carried out. The order with respect to oxidant is zero in both the Os(VIII)- and Ru(III)-catalyzed reactions. A unit-order dependence on V(IV) is observed in the case of Os(VIII)-catalyzed reaction and a fractional dependence on V(IV) is noticed in the case of Ru(III)-catalyzed reaction. Both Os(VIII)- and Ru(III)-catalyzed reactions exhibit an inverse unit dependence on acidity. Insensitivity to change in the dielectric constant of medium is observed in both the systems. Effects of salt and ionic strength were studied. A plausible mechanism consistent with the experimental results is postulated, rate laws being derived from the proposed mechanism. The stoichiometry of the reaction has proved to be the same for both the systems.

Oxidation of V(IV) by Cr(VI),[1] Mn(III),[2] or Br(V)[3] has been studied previously. Fuller and Ottaway[4] investigated kinetics of oxidation of V(IV) by IO_3^- with a ratio of oxidant:reductant not less than 25 and found a second-order dependence on IO_3^- and a first-order dependence on V(IV). In the present investigation under a reverse condition of substrate [V(IV)]/oxidant $[IO_3^-]>20$, there was no reaction even after keeping the system overnight at the temperature studied. Thus the facile oxidation of V(IV) with Os(VIII) or Ru(III) and with IO_3^- as a co-oxidant has been systematically investigated. To our knowledge this is the first systematic kinetic report on Os(VIII)- or Ru(III)-catalyzed oxidations of V(IV) by iodate.

Experimental

All the reagents used were of AR grade: BDH(AR) $VOSO_4$ and BDH(AR) KIO_3; 70% BDH(AR) $HClO_4$ and $RuCl_3$ and OsO_4 solutions were diluted before use.

The kinetics of reaction was followed by determining the unreacted iodate iodometrically will standardized sodium thiosulfate and starch iodide indicator end point. No solvent decomposition occurred. $Na_2S_2O_3$ reacts with OsO_4 but not with $RuCl_3$. The error involved in the determination is not more than 6% at the highest concentration of Os(VIII) (15.7×10^{-5} M) (1 M=1 mol dm^{-3}). In the majority of experiments the error is not more than 2%; however, in the computation this error level was taken into account. All rate constants were reproducible within ±3% error.

Stoichiometry. The overall stoichiometry for both the Os(VIII)- and Ru(III)-catalyzed oxidations of V(IV) by IO_3^- was found to be 1:6.

Discussion

Oxidation of V(IV) by I(V) Catalyzed by Os(VIII). Oxidation of V(IV) by iodate catalyzed by Os(VIII) was carried out in aq perchloric acid aq acetic acid–perchloric acid media.

Effect of Varying $[IO_3^-]$ on Reaction Rate. The Os(VIII)-catalyzed IO_3^- oxidation of V(IV) was studied under a pseudo-first-order condition with excess [V(IV)] over $[IO_3^-]$. The disappearance of $[IO_3^-]$ conformed to no first-order pattern as seen from the nonlinearity of plots of log $[IO_3^-]_t$ *vs.* time. On the other hand, plots of X *vs.* time are fairly linear at least up to double the half-life, indicating a zero-order dependence with respect to the oxidant. Zero-order rate constants are computed from slopes (x/t) of such linear plots. Moreover, k_0 values computed for various initial concentrations of IO_3^- are almost identical, confirming the zero-order dependence with respect to the oxidant (Table 1) in the concentration range studied. Such zero-order dependence on oxidant has been observed in various reactions catalyzed by transition metal ions.

1.0	4.26	1.0	15.73	8.77

Effect of Varying [V(IV)] on Reaction Rate. Increasing the concentration of V(IV) increases the rate of reaction; rate constants at different concentrations of V(IV) are given in Table 1. The plot of $\log k_o$ *vs.* log[V(IV)] is linear with slope unity, indicating a first-order dependence with respect to substrate.

Effect of Varying [Os(VIII)] on Reaction Rate. Increasing the concentration of Os(VIII) increases the reaction rate; rate constants at different concentrations of Os(VIII) are given in Table 1. The plot of log k_o *vs.* log[Os(VIII)] is linear with slope unity, indicating a first-order dependence with respect to Os(VIII).

Effect of Varying [$HClO_4$] on Reaction Rate. The influence of acid on reaction rate was studied with a view to identifying species which participate in the reaction. Increase in the concentration of perchloric acid decreases the rate of oxidation (Table 1). The plot of $\log k_o$ *vs.* log[H^+] is linear with a negative slope of unity. Thus the dependence on acid is inverse unity. This inverse dependence on acidity deserves a comment. VO^{2+} on hydrolysis forms $VOOH^+$ *via* the equilibrium

$$VO^{2+} + H_2O \overset{K_h}{\rightleftharpoons} VOOH^+ + H^+.$$

Active species of substrate participating in the reaction is $VOOH^+$, hence the inverse dependence on acidity. It is reported[5] that V(IV) in aq acid medium ([H^+]= 0.002—3 M) hydrolyses to $VOOH^+$ with an approximate K_h value of 10^{-6}.

Effect of Varying Concentration of Acetic Acid. These reactions are found to be insensitive to change in dielectric constant of the medium. Increase in the percentage of acetic acid has no effect on the reaction rate. Rate constants at different percent of acetic acid are given in Table 2. Such insensitivity to change in dielectric constant of the medium has been observed also in Ag^+-catalyzed oxidation of α-hydroxy acids by peroxydisulphate.[6]

Effect of Varying Ionic Strength of the Medium. Change in ionic strength of the medium by varying the concentration of sodium perchlorate has no effect on the reaction rate. Rate constants at different concentrations of sodium perchlorate are given in Table 3. This clearly indicates that the reactions are of ion dipolar type.

Effect of Temperature on Reaction Rate. Reactions were conducted at different temperatures in the range from 50 to 70 °C and respective rate constants are given in Table 4. The plot of $\log k_o$ *vs.* $1/T$ is linear. From the slope of the plot of $\log k_o$ *vs.* $1/T$ respective Arrhenius parameters were computed and listed in Table 4. These activation parameters are of correct magnitude.

Oxidation of V(IV) by I(V) Catalyzed by Ru(III). As a continuing study, oxidation of V(IV) by Ru(III)-catalyzed iodate was carried out for comparison, salient features observed in the investigation are as follows:

i) The order with respect to oxidant is zero which is similar to the case of Os(VIII)-catalyzed reactions (Table 5).

ii) Increase in the concentration of V(IV) increases the rate of oxidation, rate constants at different concentrations of [V(IV)] being given in Table 5. The plot of $\log k_o$ *vs.* log[V(IV)] is linear with a slope less than unity, indicating a fractional dependence on substrate. This differs from the previous observation made in the case of Os(VIII)-catalyzed oxidations.

iii) The dependence on Ru(III) is unity which is analogous to that observed in the case of Os(VIII)-catalyzed reactions (Table 5).

iv) To confirm the dependence on acidity with no attendant ionic strength effect, the dependence on [H^+] at constant ionic strength was determined. The plot of $\log k_o$ *vs.* log[H^+] is linear with a slope of −0.5, which shows a fractional dependence on [H^+] (Table 8) and the plot of $\log k_o$ *vs.* log[$NaClO_4$] is linear with a slope of −0.5 (Table 7).

v) The apparent dependence on acid is inverse unity, which results from additive effects of ionic strength and acid both being inverse. It may be pointed out that in OsO_4-catalyzed reaction there

is no influence of ionic strength on the reaction as is clear from Table 5.

vi) Solvent influence is similar to what is found in Os(VIII)-catalyzed reaction (Table 6).

vii) Species of Ru(III): It is well known that Ru^{+3} mainly exists as $[Ru(H_2O)_6]^{3+}$ in acid medium.[7]

viii) The study was carried out at different temperatures in the range 30—40 °C. Rate constants are listed in Table 9. The plot of $\log k_0$ *vs.* $1/T$ is linear. From the slope of the above plot Arrhenius parameters were computed as listed in Table 9. These values are similar to those obtained in the case of Os(VIII)-catalyzed reactions.

From the above findings it can be concluded that the catalytic ability of Ru(III) is in general greater than that of Os(VIII) in the present experimental conditions.

Mechanism of Oxidation. Os(VIII)-catalyzed Oxidation: The kinetic features observed in the Os(VIII)-catalyzed oxidation of V(IV) by iodate indicate that $VOOH^+$ is the active species. The zero-order dependence on oxidant clearly shows nonparticipation of oxidant in the rate-determining step. The mechanism of oxidation can be envisaged through a hydrolytic equilibrium between VO^{2+} and $VOOH^+$ followed by reaction between $VOOH^+$ and OsO_4 as the rate-determining step to give V(V) and Os(VII).

The Os(VII) formed oxidizes in the subsequent fast step another V(IV) entity to give Os(VI) and V(V). The generated Os(VI) is oxidized in the subsequent fast step by IO_3^- to Os(VIII), thus giving rise to the zero-order dependence with respect to oxidant. The detailed steps are represented in Scheme 1:

$$VO^{2+} + H_2O \overset{K_h}{\rightleftharpoons} VOOH^+ + H^+, \quad (1)$$

$$VOOH^+ + OsO_4 \underset{k_1}{\overset{\text{slow}}{\longrightarrow}} VO_2^+ + OsO_3(OH),$$

$$OsO_3OH + VOOH^+ \overset{\text{fast}}{\longrightarrow} OsO_3 + VO_2^+ + H_2O,$$

$$3OsO_3 + IO_3^- \overset{\text{fast}}{\longrightarrow} 3OsO_4 + I^-.$$

Scheme 1.

Rate Law. From Equilibrium 1,

$$K_h = \frac{[VOOH^+][H]^+}{[VO^{2+}]} \text{ or } [VO^{2+}] = \frac{[VOOH^+][H^+]}{K_h},$$

$$[VO^{2+}]_T = VO^{2+} + VOOH^+ = \frac{[VOOH^+]\{H^+ + K_h\}}{K_h}$$

$$\text{or } [VOOH^+] = \frac{[VO^{2+}]_T K_h}{(H^+ + K_h)},$$

$$\text{Rate} = -\frac{d[IO_3^-]}{dt} = k_1[VOOH^+][OsO_4] = \frac{k_1 L_h [VO^{2+}]_T [OsO_4]}{(H^+ + K_h)}.$$

K_h is of the order of 10^{-6} and can be neglected in comparison to $[H^+]$, hence the rate law is reduced to

$$-\frac{d[IO_3^-]}{dt} = \frac{k_1 K_h [VO^{2+}]_T [OsO_4]}{H^+}.$$

Ru(III)-catalyzed Oxidation. The observations noticed in the case of Ru(III)-catalyzed oxidation are analogous to those in the case of Os(VIII)-catalysed reaction, except that the dependence on substrate is fractional. The inverse dependence on acidity indicates that the active species $VOOH^+$ takes part in the reaction. The mechanism of oxidation can be postulated as a formation of an intermediate between $VOOH^+$ and $[Ru(H_2O)_6]^{3+}$ in an equilibrium step. Decomposition of the intermediate takes place in a rate-determining step with one-electron transfer between Ru(III) and V(IV) to give Ru(II) and V(V) in an innersphere mechanism without disturbing the octahedral nature of ruthenium. The Ru(II) formed then reacts with another V(IV) entity in a fast step to give Ru(I) and V(V). The Ru(I) formed is subsequently oxidized by iodate in a fast step to Ru(III), thus giving rise to the zero-order dependence with respect to oxidant. The existence of Ru(II) as an aqua ion $[Ru(H_2O)_6]^{2+}$ has been well documented and the existence of Ru(I) in complexes is well known.[8] Hence the valence states of Ru(II) and Ru(I) as intermediates have been postulated in this mechanism. Various steps involved in the reaction are represented in Scheme 2:

$$VO^{2+} + H_2O \overset{K_h}{\rightleftharpoons} VOOH^+ + H^+, \quad (1)$$

$$[Ru(H_2O)_6]^{3+} + VOOH^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Ru(H_2O)_6{}^{3+}\cdots VOOH^+], \quad \text{(Complex)}$$

$$[Ru(H_2O)_6{}^{3+}\cdots VOOH^+] \underset{\text{slow}}{\overset{k_2}{\longrightarrow}} VO_2^+ + [Ru(H_2O)_6]^{2+} + H^+, \quad \text{(Complex)}$$

$$[Ru(H_2O)_6]^{2+} + VOOH^+ \overset{\text{fast}}{\longrightarrow} [Ru(H_2O)_6]^+ + VO_2^+ + H^+,$$

$$3[Ru(H_2O)_6]^+ + IO_3^- + 6H^+ \overset{\text{fast}}{\longrightarrow} 3[Ru(H_2O)_6]^{3+} + 3H_2O + I^-.$$

Scheme 2.

Rate Law. From Equilibrium 1,

$$K_h = \frac{[VOOH^+][H^+]}{[VO^{2+}]} \text{ or } [VO^{2+}] = \frac{[VOOH^+][H^+]}{K_h},$$

$$[VO^{2+}]_T = VO^{2+} + VOOH^+ = \frac{[VOOH^+]\{H^+ + K_h\}}{K_h}$$

$$\text{or } [VOOH^+] = \frac{[VO^{2+}]_T K_h}{(H^+ + K_h)},$$

$$\text{Complex} = \frac{k_1[Ru(III)][VOOH^+]}{(k_{-1} + k_2)},$$

$$[Ru(III)]_T = [Ru(III)] + [\text{Complex}] = Ru(III)\left\{1 + \frac{k_1[VOOH^+]}{(k_{-1} + k_2)}\right\},$$

$$[Ru(III)] = \frac{(k_{-1} + k_2)[Ru(III)]_T}{(k_{-1} + k_2) + k_1[VOOH^+]}.$$

$$\text{or } [Ru(III)] = \frac{(k_{-1} + k_2)(H^+ + K_h)[Ru(III)]_T}{(k_{-1} + k_2)(H^+ + K_h) + k_1 K_h [VO^{2+}]_T}.$$

$$\text{So, Complex} = \frac{k_1 K_h [VO^{2+}]_T [Ru(III)]_T}{(k_{-1} + k_2)(H^+ + K_h) + k_1 K_h [VO^{2+}]_T}$$

$$\text{or} = \frac{k_1 K_h [VO^{2+}]_T [Ru(III)]_T}{H^+ + K_h + k_1 K_h [VO^{2+}]_T}$$

$$\left(\text{where } K_1 = \frac{k_1}{k_{-1} + k_2}\right),$$

$$\text{Rate} = -\frac{d[IO_3^-]}{dt} = k_2[\text{Complex}] = \frac{k_2 K_1 K_h [VO^{2+}]_T [Ru(III)]_T}{H^+ + K_h + K_1 K_h [VO^{2+}]_T}.$$

This expression is capable of explaining all the observed facts.

Some Observations on the Structural Aspects of *o*-Hydroxythiobenzamide and Its Complexes with Pt(II), Pt(IV), and Au(III)

Karunamay BANERJEE* and Shyamal RAYCHAUDHURY

Department of Pure Chemistry, University College of Science and Technology, Calcutta 700009, India

(Received September 22, 1981)

^{1}H NMR, electronic spectra, electrical conductivity studies in solution and IR study in solid phase have been done on *o*-hydroxythiobenzamide and its complexes with Pt(II), Pt(IV), and Au(III). The results indicate presence of the thioamide-thioimidic acid equilibrium in *o*-hydroxythiobenzamide, the thioamide form in the Pt(II) and Pt(IV) complexes, the thioimidate form in the Au(III) complex and free phenolic OH group in the Pt(IV) and Au(III) complexes.

o-Hydroxythiobenzamide received attention as a complexing agent for quantitative estimation of Pt(IV)[1] and Au(III)[2] ions. The previous workers[1,2] predicted the possible formulas of the complexes as $[Pt^{IV}L_2L'_2]Cl_2$, $[Pt^{II}L'_2]$, and $H[Au^{III}L'_3Cl]$ (where L= *o*-hydroxythiobenzamide and L'=*o*-hydroxythiobenzamide anion), but the structural form of L' and structure of the complexes have not been clearly revealed. The object of the present investigation is to elucidate the ionic forms of the ligand, and nature of bonding present in the above complexes on the basis of ^{1}H NMR, electronic spectra, electrical conductivity studies in solution and IR study in solid phase. In the course of our investigation it has been observed that *o*-hydroxythiobenzamide remains in thioamide-thioimidic acid (*o*-$HOC_6H_4CSNH_2 \rightleftharpoons$ *o*-$HOC_6H_4C(SH):NH$) equilibrium in solution and may lose phenolic OH and/or thiomidic acid proton to satisfy primary valency of the metal ions in complex formation. The probable structures of the metal complexes have been suggested on the basis of the present study as $[Pt^{II}(o\text{-}OC_6H_4CSNH_2)_2]$, $[Pt^{IV}(o\text{-}OC_6H_4CSNH_2)_2(o\text{-}HOC_6H_4CSNH_2)_2]Cl_2$, and $H[Au^{III}(o\text{-}HOC_6H_4CS:NH)_3Cl]$.

Experimental

The complexes were prepared by the methods given in literature.[1,2] The electrical conductivity data of the compounds at 25 °C in methanol were obtained by using Phillips PR 9500 conductivity bridge. The UV and visible absorption spectra of the compounds in solution were recorded at room temperature on Varian Techtron 634 spectrometer. IR shectra were obtained in KBr pellets on Beckmann IR 20 spectrometer. ^{1}H NMR spectra of the compounds in deuterated solvents were obtained on Varian NMR spectrometer EM-390; 90 MHz at 20 °C using tetramethylsilane as the internal reference.

Results and Discussion

NMR, IR, and Electrical Conductivity Studies. o-*Hydroxythiobenzamide*: ^{1}H NMR spectra in Fig. 1 indicate that *o*-hydroxythiobenzamide exists in thioamide form in $CDCl_3$ solution, and thioimidate form in DMSO-d_6 solution. $CDCl_3$ solution of *o*-hydroxythiobenzamide exhibits peaks due to the H-bonded phenolic OH at 11.9 δ, NH_2 and ring protons at 6.9—7.7 δ. ^{1}H NMR spectra of the *o*-hydroxythiobenzamide solution in DMSO-d_6 reveal a broad doublet at (9.6 δ, 9.8 δ). This doublet indicates the magnetic non-equivalence of NH_2 protons due to the restricted rotation about C–N bond in the polar form $\left(\text{S}\rangle\text{C–N}\langle\text{H} \rightleftharpoons \text{S}^-\rangle\text{C}=\overset{+}{\text{N}}\langle\text{H}\right)$ of *o*-hydroxythiobenzamide. The appearence of this doublet in the downfield region can be accounted for by the greater deshielding of protons attached with positive nitrogen in the polar form. A coalesced signal of two protons appears at 13.1 δ due to resonances of thioimidic SH and =NH groups. Analogous observation was reported in the molecular complex of dimethylamine and acetylacetone.[3] The ^{1}H NMR signal of H-bonded phenolic OH is seen at 11.75 δ in DMSO-d_6 solution of *o*-hydroxythiobenzamide. Except the ring protons, all other signals of *o*-hydroxythiobenzamide in DMSO-d_6 disappear on deuteration.

The IR spectral data of *o*-hydroxythiobenzamide in

A=*o*-$HOC_6H_4CSNH_2$; B=$H[Au^{III}(o\text{-}HOC_6H_4CS{:}NH)_3Cl]$; C=$[Pt^{II}(o\text{-}OC_6H_4CSNH_2)_2]$; D=$[Pt^{IV}(o\text{-}OC_6H_4CSNH_2)_2$-$(o\text{-}HOC_6H_4CSNH_2)_2]Cl_2$; s=strong; w=weak; br=broad; m=medium; M=Pt or Au.

KBr pellets are shown in Table 1. The stretching vibrations of OH and NH_2 appear in the 2750—3400 cm^{-1} region. The absence of SH band around 2550 cm^{-1} in the free ligand excludes the possible existence of thioimidic acid form in the solid state. All other band assignments according to Jensen *et al.*[4] are shown in Table 1.

Previous works[5] on the electrical conductivity in methanol indicate that molar conductance values in the 80—115 Ω^{-1} cm^2 mol^{-1} range are due to formation of the 1:1 electrolyte. The conductivity data in Table 2 indicate nonelectrolyte nature of *o*-hydroxythiobenzamide in methanol. Therefore low-field ^{1}H-NMR signal for phenolic OH, lower frequency IR band for ν_{OH} and nonelectrolyte behaviour of *o*-hydroxythiobenzamide suggest that its OH group is H-bonded in solution as well as in solid state.

[Pt^{II}(o-$OC_6H_4CSNH_2)_2$]. ^{1}H NMR spectra of the Pt(II) complex solution in DMSO-d_6 (Fig. 1) indicate the presence of broad doublet due to NH_2 protons at (9.5 δ, 10.4 δ) and the absence of phenolic OH proton signal. The IR data of Pt(II) complex in KBr pellets (Table 1) show slight lowering of ν_{NH_2} and absence of ν_{OH} at 2750 cm^{-1} in comparison to free ligand. It is known[4] that OH deformation band at 1385 cm^{-1} disappears on deuteration for the free ligand and also for the Ni(II) complex. We have also observed that the 1385 cm^{-1} band is absent in the Pt(II) complex. Therefore absence of phenolic OH signal in ^{1}H NMR spectra and absence of δ_{OH} band at 1385 cm^{-1} in IR spectra indicate Pt–O bonding in the Pt(II) complex. The antisymmetric vibration of the N–C=S group in *o*-hydroxythiobenzamide occuring at 1473 cm^{-1} and its subsequent shifting to higher frequency due to increased double bond character of N–C in N–C=S grouping in case of its Ni(II) complex[4] is at par with our observation in the Pt(II) complex. In the case of *o*-hydroxythiobenzamide the stretching vibration due to C=S appears at 742 cm^{-1}, but this band is shifted to 690 cm^{-1} in the Pt(II) complex due to metal-sulfur bonding. In the far IR region the bands at 480 cm^{-1} and 381 cm^{-1} are probably due to Pt–S and Pt–O bonding.

The electrical conductivity data in Table 2 indicate the nonelectrolyte behaviour of the Pt(II) complex in methanol.

Therefore in the square planar arrangement two *o*-hydroxythiobenzamide molecules are bonded through S and O with Pt^{2+} ion in Pt(II) complex.

[Pt^{IV}(o-$OC_6H_4CSNH_2)_2$(o-$HOC_6H_4CSNH_2)_2$]Cl_2. The ^{1}H NMR spectra of the Pt(IV) complex solution in DMSO-d_6 (Fig. 1) exhibit a broad band at (9.7 δ, 10.8 δ) for the NH_2 protons and a single proton peak at 11.8 δ for the H-bonded phenolic OH. IR spectral bands of the Pt(IV) and Pt(II) complexes in KBr pellets are alike except the case where the band due to H-bonded OH stretching of the free ligand at 2750 cm^{-1} is shifted to 2900 cm^{-1}, and OH deformation band at 1385 cm^{-1} does not disappear for the Pt(IV) complex. Therefore ^{1}H NMR signal at 11.8 δ and IR band at 1385 cm^{-1} indicate the existence of free phenolic OH in the Pt(IV) complex. The $\nu_{C=S}$ band of the free ligand appearing at 742 cm^{-1} and its subsequent shifting to 690 cm^{-1} in the Pt(IV) complex

Table 2. Electrical conductivity in methanol at 25 °C

Compound	Concentration mol dm^{-3}	Molar conductance Ω^{-1} cm^2
o-$HOC_6H_4CSNH_2$	2.2×10^{-3}	3.77
$[Pt^{II}(o\text{-}OC_6H_4CSNH_2)_2]$	1.2×10^{-3}	8.24
$[Pt^{IV}(o\text{-}OC_6H_4CSNH_2)_2(o\text{-}HOC_6H_4CSNH_2)_2]Cl_2$	1.2×10^{-3}	99.63
$H[Au^{III}(o\text{-}HOC_6H_4CS:NH)_3Cl]$	0.6×10^{-3}	91.02
$H[Au^{III}(o\text{-}HOC_6H_4CS:NH)_3Cl]$ + Excess o-$HOC_6H_4CSNH_2$	0.6×10^{-3}	114.00

suggests Pt–S bonding. In far IR region, like the Pt(II) complex the appearance of two bands at 380 cm^{-1} and 480 cm^{-1} indicate Pt–O and Pt–S bonding in the Pt(IV) complex. The electrical conductivity data in Table 2 show that the Pt(IV) complex behaves as 1:1 electrolyte in methanol. The lower conductivity of the Pt(IV) complex may be due to ionic association in low dielectric medium where one of the axially S bonded o-hydroxythiobenzamide molecule is replaced by chloride ion to form $[Pt^{IV}(o\text{-}OC_6H_4CSNH_2)_2(o\text{-}HOC_6H_4CSNH_2)Cl]Cl$ and free o-$HOC_6H_4CSNH_2$.

Therefore, IR, ^{1}H NMR, and electrical conductivity studies indicate that Pt^{4+} ion is in octahedral environment where two o-hydroxythiobenzamide molecules are bonded through S and O, and the rest two are coordinated axially only through S leaving free OH.

$H[Au^{III}(o\text{-}HOC_6H_4CS:NH)_3Cl]$. The ^{1}H NMR spectra of the Au(III) complex solution in DMSO-d_6 (Fig. 1) exhibit a broad peak of single proton at 10 δ due to deprotonated thioamide group. Like the Pt-(IV) complex a single proton signal due to H-bonded phenolic OH at 11.9 δ is also found in the Au(III) complex. The IR spectral data of the gold complex in KBr pellets (Table 1) show fewer number of bands for NH_2 stretching vibrations. The stretching vibration due to H-bonded OH of the free ligand at 2750 cm^{-1} is displaced to 2900 cm^{-1}. It is also seen that one of the split band of o-hydroxythiobenzamide at 1600 cm^{-1} is absent in the Au(III) complex. The OH deformation band at 1385 cm^{-1} does not disappear and a band due to C=S stretching appears at lower frequency (698 cm^{-1}) due to gold-sulfur bonding. In the far IR region the gold complex exhibits bands at 490 cm^{-1} and 310 cm^{-1} probably due to ν_{Au-S} and ν_{Au-Cl}; other features of IR spectral bands of the gold complex are similar to the platinum complexes. Therefore, the ^{1}H NMR and IR studies of the gold complex indicate its complexation through thioimidate anion leaving phenolic OH groups free.

The electrical conductivity data in Table 2 indicate that the gold complex behaves as 1:1 electrolyte in methanol. The amperometric study of the gold complex[6] and elemental analysis[2] indicate that the metal-ligand ratio is 1:3. Our chemical tests show that in the gold complex Cl is in the inner sphere which also includes bonded imidate anion and free OH groups. These facts suggest that the square planar arrangement exists in the gold complex. Lower pH of methanolic solution of the gold complex as compared to methanol indicates the presence of H^+ in the outer sphere of the complex. Tarantelli *et al.*[7] have shown that electrical conductivity of $[Pd^{II}L_4]^{2+}$ (where L= $(C_6H_5NH)_2CS$) in methanol or acetone increases on adding excess ligand. Similar increase in conductivity is observed on adding excess o-hydroxythiobenzamide to the methanolic solution of the gold complex. This behaviour may be due to displacement of Cl from the inner sphere of the gold complex by a neutral ligand molecule to form neutral species $[Au^{III}(o\text{-}HOC_6H_4CS:NH)_3(o\text{-}HOC_6H_4CSNH_2)]$ and free HCl. By the mole ratio method the earlier workers[2] have shown that the metal-ligand ratio is 1:4 in the gold complex and at first sight it is apparently misleading as it does not fit their elemental analysis data of 1:3. In the presence of excess reagent a reaction like $[ML_3Cl]^-H^+ \xrightarrow{L} ML_4+HCl$ may have occured in the solution during the mole-ratio method of studying metal-ligand ratio.

Electronic Spectra. o-*Hydroxythiobenzamide*: Electronic spectra of thiocarbonyl derivatives[8–10] show a low intensity and long wavelength band due to the $n\rightarrow\pi^*$ transition. In the case of o-hydroxythiobenzamide interaction of nitrogen lone pair electrons with the C=S unit makes the $n\rightarrow\pi^*$ transition easy. Therefore the low intensity ($\varepsilon<100$) band at 20400 cm^{-1} of o-hydroxythiobenzamide in different solvent media is the $n\rightarrow\pi^*$ transition. Figure 2 shows that this 20400 cm^{-1} band is quenched in neutral and acidic aqueous media, whereas the band is pronounced in DMSO and alkaline aqueous media. Methanolic solution of o-hydroxythiobenzamide also exhibits a very weak intensity $n\rightarrow\pi^*$ transition at $\approx$20000 cm^{-1}.

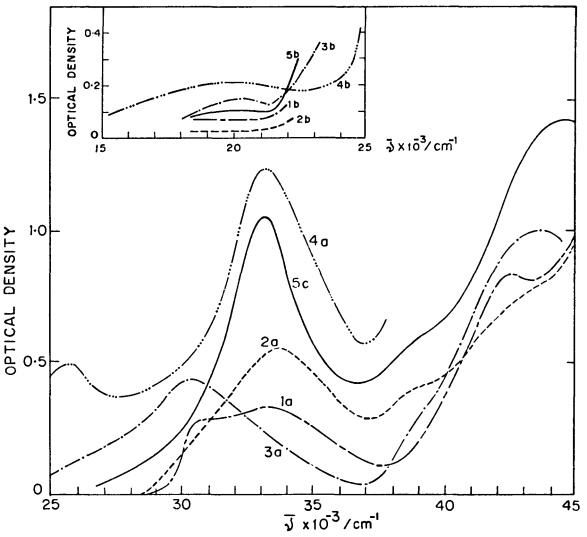

Fig. 2. Absorption spectra of o-hydroxythiobenzamide in 1(a,b) water; 2(a,b) 0.1 M HCl; 3(a,b) 0.1 M NaOH; 4(a,b) DMSO; 5(c,b) Methanol.
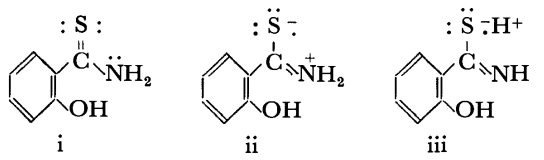
a=10^{-4}, b=10^{-3}, c=2.2×10^{-4} mol dm^{-3}.

In case of thiocarbonyl compounds it has been reported[8-10] that the intense bands immediately preceding n→π* are due to the π→π* rather than the n→σ* transition. Again two different π→π* transitions should also be expected due to conjugation of C=S and C=N groups with the aromatic ring in *o*-hydroxythiobenzamide as found in methyl *N*,*N*-dimethyldithiocarbamate[11] and 5-amino-2-mercaptothiazoles.[12] Therefore two bands at ≈33000 cm^{-1} and 30500 cm^{-1} in aqueous solution of *o*-hydroxythiobenzamide (Fig. 2, 1a) indicate π→π* transitions. Therefore in neutral aqueous medium the existence of both i and ii or iii forms are expected. DMSO solution of *o*-hydroxythiobenzamide also exhibits two π→π* transitions (Fig. 2, 4a) of which the lower frequency one is red-shifted to 26000 cm^{-1} due to high proton binding capacity of DMSO favouring the existence of structure iii. In alkaline medium (Fig. 2, 3a) red shifting of the two (apparently nonresolvable) π→π* bands may be due to deprotonation of SH and OH groups in structure iii. In acidic aqueous medium (Fig. 2, 2a) only 33000 cm^{-1} band is present probably due to protonation of NH_2 group in structure i.



i ii iii

Very intense bands at ≈44000—44500 cm^{-1} is found in methanolic and aqueous alkaline solutions of *o*-hydroxythiobenzamide, and intensity of this band is decreased in acidic medium. Therefore the ≈44500 cm^{-1} band may be due to the n→σ* transition in the ligand molecule. The shoulders at 39000 cm^{-1} may be due to phenolic chromophore as its intensity is decreased in alkaline medium.

Pt(II), Pt(IV), and Au(III) Complexes. The phenolic chromophore band at 39000 cm^{-1} of *o*-hydroxythiobenzamide is red-shifted in the Pt complexes indicating Pt–O bonding, whereas the gold complex does not show such shift. The intensity of the n→π* band (20000 cm^{-1}) of *o*-hydroxythiobenzamide increases significantly on complexation (Fig. 3) and this band shifts to higher frequency in the sequence Au(III)< Pt(IV)<Pt(II) complexes indicating L→M charge transfer.[13,14] The d-d transitions are obscured by the intense charge transfer band. Electronic spectra of the complexes show that the positions of the bands appearing above 20000 cm^{-1} agree more or less with those of the free ligand with enhanced intensities. Hence these bands may be regarded as intraligand transitions with intensities modified on complexation.

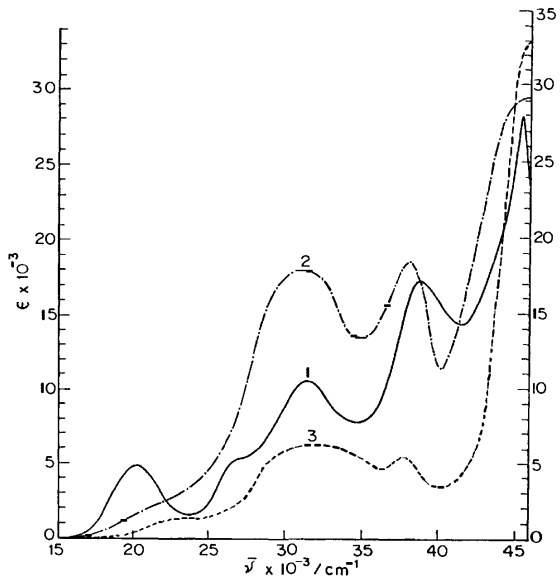


Fig. 3. Absorption spectra.
1: $H[Au^{III}(o\text{-}HOC_6H_4CS{:}NH)_3Cl]$, 2: $[Pt^{IV}(o\text{-}OC_6H_4CSNH_2)_2(o\text{-}HOC_6H_4CSNH_2)_2]Cl_2$, 3: $[Pt^{II}(o\text{-}OC_6H_4CSNH_2)_2]$ in methanol.

Conclusion

From the above studies it is clear that *o*-hydroxythiobenzamide exists in the thioamide-thioimidic acid equilibrium in solution. Metal-sulfur and metal-oxygen bondings are observed in the platinum complexes, whereas the gold complex shows only metal-sulfur bonding. Amide C=S coordinates with Pt(II) and Pt(IV) and the thioimidate anion is bonded with Au(III). The existence of free phenolic OH in the Pt(IV) and Au(III) complexes has been established decidedly by ^1H NMR, IR, and electronic spectral studies. Recent studies also indicate the presence of free phenolic OH group in the Pd(II) complex of salicylaldehyde 2-picoloylhydrazone[15] and rare earth complexes of *o*-hydroxybenzhydroxamic acid.[16]

Thanks are due to Dr. S. K. Bose, Dr. S. N. Bhattacharyya and Dr. M. P. Roy for their encouragement throughout the work and also to UGC, India for financial assistance to one of the authors (K. B.).

(Received October 21, 1981)

The activation volume at normal pressure (ΔV^*) and the reaction volume (ΔV) are obtained for five aquation reactions of the Co(III) complex ion. The results are [given as the complex ion, ΔV^*/cm^3 mol^{-1} (t/°C), ΔV/cm^3 mol^{-1} (t/°C)]: *trans*-$[Co(en)_2NO_2Cl]^+$, 0.1 (15), −10.4 (15); *cis*-$[Co(en)_2NO_2Cl]^+$, 0.9 (30), −9.3 (25); *cis*-$[Co(bpy)_2NO_2Cl]^+$, 2.9 (30), −9.1 (25); *cis*-$[Co(bpy)_2NO_2Br]^+$, 11.3 (30), −6.7 (25); *cis*-$[Co(phen)_2NO_2Br]^+$, 3.3 (35), −12.5 (30). These magnitudes of ΔV^* are interpreted as resulting from the counterbalance of the volume increase attributable to the dissociation of the leaving ligand and the volume decrease due to the partial incorporation of one water molecule in the activated complex.

In this decade, the reaction velocities of the complex ion have been investigated extensively under high pressure.[1-3] Activation volumes have been obtained and the magnitude of ΔV^* has been discussed in relation to the reaction mechanism. The general treatment is that ΔV^* is divided into two contributions: $\Delta V^* = \Delta V^*_{int} + \Delta V^*_{solv}$, where ΔV^*_{int} and ΔV^*_{solv} are the intrinsic and the solvational components of the activation volume respectively. Stranks has made a fundamental assumption that the intrinsic volume of a five-coordinate intermediate in the limiting dissociative mechanism is the same as that of the six-coordinate precursor.[4] Some authors have interpreted the magnitude of ΔV^* according to this postulation.[1] However, the derivation of his postulation seems to have no rational foundation.[4] The present author considers that the relation between the magnitude of ΔV^* and the mechanism should be induced from an examination of the volume profiles (ΔV^* and ΔV) for a series of related reactions.

It has been known for some time that, in a series of *trans*- and *cis*-$[Co(en)_2ACl]^{n+}$, the aquation velocity is rapid for $A=NH_2^-$, moderate for $A=N_3^-$, Cl^-, NO_2^-, and slow for $A=NH_3$.[5] Ingold *et al.* have interpreted this in relation to the electron-donating or the electron-withdrawing power of the A ligand.[5] Langford and Gray have given a slightly different interpretation of this problem and have indicated that, at least, the mechanism for $A=NH_2^-$ differs from those for $A=N_3^-$, Cl^- or NO_2^-.[6] The present author considers that the influence of the A ligand on the aquation mechanism might possibly be reflected in the volume profile.

In this work, ΔV^* and ΔV are obtained for five aquation reactions, where the complex ions have the electron-withdrawing nonlabile NO_2^- ligand in common:

$$trans\text{-}[Co(en)_2NO_2Cl]^+ + H_2O \longrightarrow trans\text{-}[Co(en)_2NO_2H_2O]^{2+} + Cl^- \quad (1)^{7,8}$$

$$cis\text{-}[Co(en)_2NO_2Cl]^+ + H_2O \longrightarrow cis\text{-}[Co(en)_2NO_2H_2O]^{2+} + Cl^- \quad (2)^{7,8}$$

$$cis\text{-}[Co(bpy)_2NO_2Cl]^+ + H_2O \longrightarrow cis\text{-}[Co(bpy)_2NO_2H_2O]^{2+} + Cl^- \quad (3)^{9}$$

$$cis\text{-}[Co(bpy)_2NO_2Br]^+ + H_2O \longrightarrow cis\text{-}[Co(bpy)_2NO_2H_2O]^{2+} + Br^- \quad (4)^{9}$$

$$cis\text{-}[Co(phen)_2NO_2Br]^+ + H_2O \longrightarrow cis\text{-}[Co(phen)_2NO_2H_2O]^{2+} + Br^- \quad (5)^{10}$$

The volume profiles are compared with those of other Co(III) aquation reactions, and the magnitudes of ΔV^* are discussed on this basis. The acid dissociation constant (K_a) is obtained for the *cis*-$[Co(en)_2NH_3H_2O]^{3+}$ at four temperatures. The $\Delta H°$ and $\Delta S°$ are calculated for this equilibrium:

$$cis\text{-}[Co(en)_2NH_3H_2O]^{3+} + OH^- = [Co(en)_2NH_3OH]^{2+} + H_2O. \quad (i)$$

This equilibrium is treated as a model for the preequilibrium of the base-hydrolysis of the Co(III) complex ion.

Experimental

Material. The following complexes were obtained by the published methods: *trans*-$[Co(en)_2NO_2Cl]NO_3$ (**1**),[11] *cis*-$[Co(en)_2NO_2Cl]Cl$ (**2**),[11] *cis*-$[Co(bpy)_2NO_2Cl]Cl\cdot 2H_2O$ (**3**),[12] *cis*-$[Co(bpy)_2NO_2Br]Br$ (**4**),[12] *cis*-$[Co(phen)_2NO_2Br]Br\cdot 2H_2O$ (**5**),[10] and *cis*-$[Co(en)_2NH_3H_2O]Br_3\cdot H_2O$ (**6**).[13] The Co(III) complex with the *bis* bpy or the *bis* phen ligands has the *cis*-configuration.[14] The *cis*-configuration of **6** was identified spectrophotometrically.[15] The results of the elemental analysis (C, H, N) for Complexes **1**—**6** were in good agreement with the theoretically expected values.[16]

Kinetic Measurement. The aquation velocity was followed *in situ* in a thermostatted (±0.1 °C) Hawley and Chase-type high-pressure optical cell with a pair of sapphire windows.[17] This cell was fitted to a Nihon Bunko, model UVIDEC 505, double-beam spectrophotometer. The path length of the sample solution was 1.3 cm. The reference was air. The pressure of the sample solution was measured by means of a Nagano Keiki Bourdon gauge calibrated to a Nagano Keiki-type IP3-178 dead-weight-pressure gauge tester. Each reaction was followed at a certain wavelength to *ca.* 90% completion. The first-order rate constants were obtained from Guggenheim plots of the optical densities.

Dilatometry. A globular glass vessel (39.2 cm^3) fitted with an upright capillary tube (15 cm long) was used as a dilatometer. A capillary tube with an internal diameter of 0.0404 cm was used for the runs of Reactions 2 and 3. Another capillary tube with an internal diameter of 0.0202 cm was used for the runs of Reactions 1, 4, and 5. Distilled water was boiled for several minutes. It was then degassed overnight and was used to dissolve the complex. A weighed quantity of the complex was dissolved in water (45 cm^3) at the reaction temperature. The solution was poured into the dilatometer,

which had been immersed beforehand in a thermostat controlled at the reaction temperature. The capillary tube was then joined, and the overflowing solution was wiped off at the top of the capillary tube. The height (h_t) of the meniscus was followed by the use of a cathetometer. The dilatometer was covered by a piece of aluminium foil to avoid the influence of light. The thermostat temperature was observed by a Beckmann thermometer graduated to 0.001 °C. The maximum variation in the temperature during the dilatometric run was within 0.001 °C in the runs of Reactions 1—4, while it was undetectably small (*ca.* within 0.0002 °C) in the runs of Reaction 5.

Results

Kinetic Results. The rate constants in Table 1 were obtained for the respective complex ion in an aqueous solution without added electrolyte and acid. For the reaction of *trans*-$[Co(en)_2NO_2Cl]^+$, the contribution of the base-hydrolysis can be estimated to be $k_b[OH^-]=8\times10^{-8}$ s^{-1} at 15 °C and $[OH^-]=10^{-7}$ M (1 M=1 mol dm^{-3}), where k_b is the 2nd-order rate constant of the base-hydrolysis.[7,18] For the reaction of *cis*-$[Co(en)_2NO_2Cl]^+$, $k_b[OH^-]$ can be estimated to be 2×10^{-7} s^{-1} at 30 °C and $[OH^-]=10^{-7}$ M.[7,18] These magnitudes of $k_b[OH^-]$ are small enough compared to the corresponding aquation velocities, and the contribution of the base-hydrolysis can be neglected. The contribution of the base-hydrolysis is also neglected for the reactions of *cis*-$[Co(bpy)_2NO_2Cl]^+$, *cis*-$[Co(bpy)_2NO_2Br]^+$, and *cis*-$[Co(phen)_2NO_2Br]^+$, since these complexes have no acidic proton. It can be noticed that the rate constants of Reactions 1—5 remain unchanged or decrease slightly under high pressures. The average k values at each pressure are fitted by the least-squares method to the quadratic formula: $\ln(k/k_0)=aP+bP^2$, where k_0 is the rate constant at normal pressure. The activation volumes at normal pressure are calculated by means of $\Delta V^{\ddagger}=-RT(\mathrm{d}\ln k/\mathrm{d}P)=-RTa$ (Table 2).

Dilatometric Result. Reaction 1 was followed at 15 °C in a 3.4 mM solution of **1** from 26 to 99% completion; Reaction 2, at 25 °C in a 10.9 mM solution of **2** from 14 to 98% completion; Reaction 3, at 25 °C in an 8.5 mM solution of **3** from 31 to 82% completion, and Reaction 4, at 25 °C in a 5.0 mM solution of **4** from 36 to 71% completion. For Reactions 1—4, ΔV is obtained from the intercept at $t=0$ of the ln (h_t-h_∞) *vs.* t plot, where the h_∞ value is calculated from the h_t's (Table 2). The solubility of **5** in water is limited (*ca.* 1.8 mM at 30 °C). Three independent runs were performed where Reaction 5 was followed at 30 °C in a 1.2 mM solution of **5** from 43 to 61%, from 47 to 68%, and from 39 to 61% completion. For Reaction 5, ΔV is calculated from the ratios of Δh_t to $\Delta\xi$, where ξ is the degree of reaction (Table 2). The values of ξ are estimated from the rate constant (2.08×10^{-4} s^{-1} at 30 °C) obtained spectrophotometrically at 404 nm. The average error in ΔV for Reaction 5 is ±1.3 cm^3 mol^{-1}. In Reactions 1—4, the rate constants obtained dilatometrically are in good agreement with those in the literature.[7-9]

pK_a *of* cis-$[Co(en)_2NH_3H_2O]^{3+}$. Complex **6** was dissolved in boiled water; no other electrolyte was added. The solution (5 mM, 25 cm^3) was titrated with a 0.1 M KOH, while nitrogen gas free from oxygen or carbon dioxide was slowly bubbled into the solution.[19] The values of pK_a were [given as t/°C, pK_a]: 2, 6.30±0.07; 10, 6.10±0.07; 20, 5.83±0.07; 40, 5.39±0.07. This temperature dependence can be described by: $\ln K_a=-4800/T+2.91$, from which $\Delta H^\circ=39.9$ kJ mol^{-1} and $\Delta S^\circ=24.2$ J K^{-1} mol^{-1} are calculated for the equilibrium: *cis*-$[Co(en)_2NH_3H_2O]^{3+}=[Co(en)_2NH_3OH]^{2+}+H^+$. Thus, $\Delta H^\circ=-15.9$ kJ mol^{-1} and $\Delta S^\circ=104.9$ J K^{-1} mol^{-1} are obtained for Equilibrium i.[20]

Discussion

In Table 2, the volume profiles obtained in this work are summarized, along with those for other aquation reactions of the Co(III) complexes, where the leaving

ligand is a univalent anion:

trans-$[Co(dtcd)N_3Cl]^+ + H_2O \longrightarrow [Co(dtcd)N_3H_2O]^{2+} + Cl^-$ (6)[21]

trans-$[Co(dtcd)N_3Br]^+ + H_2O \longrightarrow [Co(dtcd)N_3H_2O]^{2+} + Br^-$ (7)[21]

cis-$[Co(en)_2Cl_2]^+ + H_2O \longrightarrow [Co(en)_2ClH_2O]^{2+} + Cl^-$ (8)[3]

trans-$[Co(en)_2Cl_2]^+ + H_2O \longrightarrow [Co(en)_2ClH_2O]^{2+} + Cl^-$ (9)[3]

$[Co(NH_3)_5Cl]^{2+} + H_2O \longrightarrow [Co(NH_3)_5H_2O]^{3+} + Cl^-$ (10)[22,23]

$[Co(NH_3)_5Br]^{2+} + H_2O \longrightarrow [Co(NH_3)_5H_2O]^{3+} + Br^-$ (11)[22,23]

$[Co(NH_3)_5NO_3]^{2+} + H_2O \longrightarrow [Co(NH_3)_5H_2O]^{3+} + NO_3^-$ (12)[22,23]

$[Co(NH_3)_4(NH_2)Cl]^+ + H_2O \longrightarrow [Co(NH_3)_5OH]^{2+} + Cl^-$ (13)[23,25]

$[Co(NH_3)_4(NH_2)Br]^+ + H_2O \longrightarrow [Co(NH_3)_5OH]^{2+} + Br^-$. (14)[23,26]

The volume profiles of Reactions 13 and 14 are calculated from those of the corresponding base-hydrolysis reactions. The S_N1 CB mechanism is now widely established for the base-hydrolysis reaction of $[Co(NH_3)_5X]^{2+}$ (X^-=Cl^-, Br^-).[27-30] In this mechanism, the reaction proceeds in two steps:

$[Co(NH_3)_5X]^{2+} + OH^- = [Co(NH_3)_4(NH_2)X]^+ + H_2O$ (ii)

$[Co(NH_3)_4(NH_2)X]^+ + H_2O \longrightarrow [Co(NH_3)_5OH]^{2+} + X^-$. (iii)

The volume profile ($\Delta V_b^{\ddagger}$ and ΔV_b) of the base-hydrolysis is then, written as; $\Delta V_b^{\ddagger}=\Delta V_{pre}+\Delta V_{cb}^{\ddagger}$, and $\Delta V_b=\Delta V_{pre}+\Delta V_{cb}$, where ΔV_{pre} is the volume change of the preequilibrium ii and where $\Delta V_{cb}^{\ddagger}$ and ΔV_{cb} are the activation volume and the reaction volume respectively of the succeeding aquation Reaction iii of the conjugate-base complex ion $[Co(NH_3)_4(NH_2)X]^+$.[25] The magnitude of ΔV_{pre} is not known. Volume changes are known for four analogous neutralization equilibria of a metal complex ion:[31]

$[Co(NH_3)_5H_2O]^{3+} + OH^- = [Co(NH_3)_5OH]^{2+} + H_2O$

ΔV = 20.6 cm^3 mol^{-1} at 30 °C,

$[Cr(H_2O)_6]^{3+} + OH^- = [Cr(H_2O)_5OH]^{2+} + H_2O$

ΔV = 18.3 cm^3 mol^{-1} at 25 °C,

$[Fe(H_2O)_6]^{3+} + OH^- = [Fe(H_2O)_5OH]^{2+} + H_2O$

ΔV = 20.9 cm^3 mol^{-1}

$[Co(edda)(Hame)]^+ + OH^- = [Co(edda)(ame)]^0 + H_2O$

ΔV = 16.9 cm^3 mol^{-1} at 25 °C.

Then, an average of 19.9 cm^3 mol^{-1} is obtained for the neutralization of a tervalent complex ion. Thus, ΔV= 18.4 cm^3 mol^{-1} (average between 19.9 and 16.9 cm^3 mol^{-1}) is appropriate for the neutralization of the 2+ complex ion. By assuming that ΔV_{pre}=18.4 cm^3 mol^{-1}, $\Delta V_{cb}^{\ddagger}$ and ΔV_{cb} are calculated from $\Delta V_b^{\ddagger}$=33.4 cm^3 mol^{-1} [25] and ΔV_b=9.0 cm^3 mol^{-1} [23] for X^-=Cl^-, and from $\Delta V_b^{\ddagger}$=32 cm^3 mol^{-1} [26] and ΔV_b=9.8 cm^3 mol^{-1} [23] for X^-=Br^-. Burris and Laidler reported $\Delta V_b^{\ddagger}$=8.5 cm^3 mol^{-1} for X^-=Br^-;[32] however, this magnitude is mistaken.[26] The present author and others have previously obtained $\Delta V_b^{\ddagger}$=37 cm^3 mol^{-1} for X^-=Br^- at 21 °C in 10 mM NH_3–1 mM NH_4ClO_4 (I=1.75 mM).[33]

It can be noticed that the magnitudes of ΔV of Reactions 1—5 and 10—14 are close to each other. When the leaving ligand is Cl^-, they are especially close to one another and have a magnitude of -10.0 ± 1.6 cm^3 mol^{-1}, irrespective of the nonlabile ligands in the complex. When the leaving ligand is Br^-, the ΔV's lie in a relatively small range, from −6.7 to −12.5 cm^3 mol^{-1}. In contrast, the magnitudes of $\Delta V^{\ddagger}$ are distrib-

uted over a wide range, from 15 to -10 cm^3 mol^{-1}. This result accords with the expectation that the mechanism is not common throughout Reactions 1—14.[5,6] If the mechanism was the same, the constitutions of their transition states, and hence the magnitudes of ΔV^*, should be similar to each other. The latter might be anticipated, since the magnitude of ΔV, the volume change for a certain substitution, depends only slightly on the nature of the nonlabile ligand.

From various pieces of evidence and the arguments given in previous reports,[25,27-30] Reactions 13 and 14 can be considered to proceed by means of a limiting dissociative or D mechanism. The transition state is constituted of a five-coordinate intermediate and the leaving ligand, and the ΔV^* is the volume change of the reaction:

$$[Co(NH_3)_4(NH_2)X]^+ \longrightarrow [Co(NH_3)_4(NH_2)]^{2+} + X^-, \quad \text{(iv)}$$

where $X^- = Cl^-$ and Br^-.

In the volume profiles of Reactions 10—12, it is clear that the ΔV^* is close to the corresponding ΔV. Then, the constitution of the transition state of Reactions 10—12 should be similar to that of the final state. In the transition state, one water molecule should have already been incorporated into the coordination sphere; it is from this fact that the remarkably smaller magnitudes of ΔV^* of Reactions 10—12 than those of Reactions 13 and 14 must result. The transition state of Reactions 10—12 is an ion pair between the product, $[Co(NH_3)_5H_2O]^{3+}$, and the leaving ligand. Only the separation of this ion pair is necessary to complete the reaction; this explains the experimentally obtained volume decrease $\Delta V^* - \Delta V \simeq 1$ cm^3 mol^{-1} for Reactions 10—12. This interpretation of the transition state of Reactions 10—12 is virtually similar to that given by Jones *et al.*.[22] They have indicated that the transition state of Reactions 10—12 is an ion pair with a momentarily enhanced solvational sphere. The transition state has been denoted as: $\{Co(NH_3)_5^{3+}, X^-, yH_2O\}$, where X^- remains in the first solvation sphere of the complex and where y is large enough to permit the full solvation of both $Co(NH_3)_5^{3+}$ and X^-. They have also estimated the excess number of water molecules in the first solvation sphere over the average at the moment of the transition state as 4, 4, and 2 for $X^- = Cl^-$, Br^-, and NO_3^- respectively. They have explained that the transition state occurs when a wide excursion of a Co–X vibration coincides with the transient excess solvation caused by the fluctuation of the water molecules in the first solvation sphere. In practice, one can not discriminate this solvation-enhanced ion pair from an ordinary ion pair between the product and the leaving ligand, $\{[Co(NH_3)_5H_2O]^{3+}, X^-\}$. The latter is preferable because of its simplicity.

For Reactions 1—9, the magnitudes of ΔV^* are intermediate between those for Reactions 13 and 14 and those for Reactions 10—12. Then, in Reactions 1—9, the transition state is composed of an ion pair between the leaving ligand and the unstable five-coordinate intermediate, $[Co(AA)_2Y\cdots OH_2]^{2+}$, where AA=en, bpy, phen, (dtcd)/2; $Y^- = NO_2^-$, N_3^-, Cl^-. The water molecule is half-way between the vacant coordination site and the first solvation sphere. Thus, the mechanism is a dissociative interchange or I_d for Reactions 1—12.

The essential point of the D or I_d mechanism is that the transition state occurs with the widest excursion of the Co–X bond vibration. However, every widest excursion does not give rise to the transition state. A factor which contributes to the emergence of the transition state is the simultaneous intrusion of one water molecule from the solvation into the coordination sphere. When the initial complex contains the strongly electron-donating NH_2^- ligand, the complex will be unstable, according to Ingold *et al.*, and only a slight intrusion will be enough.[5,6] When the initial complex contains a moderately electron-donating N_3^- or Cl^- ligand, or a moderately electron-withdrawing NO_2^- ligand, the complex will be moderately stable and some further intrusion will be needed. When the initial complex does not contain any ligand with electron-donating or -withdrawing power, the complex will be stable and only a sufficient intrusion of a water molecule will give rise to the transition state.

The widest excursion of the leaving ligand will cause a volume increase (ΔV_d) and the intrusion of a water molecule will accompany a volume decrease ($\alpha\Delta V_{inc}$), where ΔV_{inc} is the volume change for the full incorporation of one water molecule into the five-coordinate intermediate and where α is the degree of the intrusion. According to this model, ΔV^* is expressed as $\Delta V^* = \Delta V_d + \alpha\Delta V_{inc}$. By assuming $\alpha=0$ for Reactions 13 and 14, ΔV_d and ΔV_{inc} can be estimated from the experimentally obtained volume profiles: $\Delta V_d = \Delta V^* = 13$—$15$ cm^3 mol^{-1} and $\Delta V_{inc} = \Delta V - \Delta V^* = -22$—$-25$ cm^3 mol^{-1}. These magnitudes of ΔV_d and ΔV_{inc} give $\Delta V^* = -12$—-7 cm^3 mol^{-1} for $\alpha=1$, which is in agreement with the magnitude of ΔV^* experimentally obtained for Reactions 10—12. In a previous report, the intrinsic and the solvational components of ΔV_d and the content of ΔV_{inc} have been considered.[25] The absolute value of the solvational component of ΔV_{inc} can be expected formally to be small, since the incorporation of a solvent molecule is not accompanied by a change in the ionic valence. In Reactions 1—9, α takes a value between 0 and 1. The completion of the intrusion of the water molecule and the separation of the ion pair are necessary to complete the reaction, which explains the experimentally obtained volume decrease, $\Delta V^* - \Delta V = 18$—$10$ cm^3 mol^{-1}, for Reactions 1—5.

In Reactions 1—5, the *trans*- and *cis*-configuration is retained during the reaction.[7,14] This fact can be interpreted as indicating that, in their transition state, the entering water molecule has already occupied its position to some extent, in accordance with the explanation given above.

For Reaction 1, ΔV^* is obtained at three temperatures. The values of ΔH^* and ΔS^* are calculated at each pressure [given as P/kg cm^{-2}, ΔH^*/kJ mol^{-1}, ΔS^*/J K^{-1} mol^{-1}]: 1, 91.8, 7.1; 400, 91.4, 5.2; 800, 90.6, 3.3; 1200, 94.1, 13.9; 1600, 89.7, -1.6; 2000, 91.4, 5.2. The value of $(\partial\Delta S^*/\partial P)_T$ at normal pressure and 15 °C can

be calculated from the ΔS^*'s at 1, 400, and 800 kg cm^{-2} as -0.05 cm^3 K^{-1} mol^{-1}. On the other hand, $(\partial \Delta V^*/\partial T)_P$ at normal pressure is obtained as 0.06 cm^3 K^{-1} mol^{-1} (Table 2). Thus, the thermodynamic relation $(\partial \Delta S^*/\partial P)_T = -(\partial \Delta V^*/\partial T)_P$ is satisfied; this is consistent with the postulation of the equilibrium between the initial and transition states.[2,3] For Reaction 1, $\Delta V^* = 0.9$ cm^3 mol^{-1} can be obtained at 30 °C by extrapolation. The coincidence of ΔV^* at 30 °C of Reactions 1 and 2 is rather surprising in view of the different initial configurations of the two isomers. Langford has pointed out that the bond distances between the nonlabile ligands and the metal ion might contract during the activation process.[35] However, if the Co–N bond distances of the two en ligands changed considerably in the activation process, some differences in the magnitude of ΔV^* might be expected, since these two isomers have different initial configurations, and so different solvational spheres. For Reactions 1 and 2, the activation energies are also equal (86.7 kJ mol^{-1}), while the activation entropies differ only slightly (Table 2).[8] Thus, the low reaction velocity of the *cis*-$[Co(en)_2NO_2Cl]^+$ is due to the rare chance of the intrusion of a water molecule attributable to the existence of the NO_2^- ligand in a position *cis* to the attacking water molecule.

The existence of a parallel correlation between ΔS^* and ΔV^* has sometimes been indicated.[36] Recently, Palmer and Kelm have examined this relation for 35 coordination reactions and pointed out that the parallelism is only of a qualitative nature.[3] Lawrance and Suvachittanont have indicated that the parallelism does not hold for Reactions 6 and 7.[21] From the present results (Table 2), it is clear that the parallelism is not satisfied for Reactions 3—5, either. The entropy change (ΔS_{pre}) for the preequilibrium ii of the base-hydrolysis can not be known. It is assumed, therefore, that ΔS_{pre} is approximately equal to the $\Delta S°$ of the analogous Equilibrium i. Then the activation entropies (ΔS^*_{cb}) of Reactions 13 and 14 are calculated by the use of $\Delta S^*_{cb} = \Delta S^*_b - \Delta S_{pre}$, where the activation entropies of the base-hydrolysis (ΔS^*_b) are 140 and 187 J K^{-1} mol^{-1} for $[Co(NH_3)_5Cl]^{2+}$ and $[Co(NH_3)_5Br]^{2+}$ respectively.[24] For Reactions 10—14, the parallelism seems to be roughly satisfied. On the other hand, it is surprising that rather a reverse relation seems to hold for Reactions 1—9: ΔV^* is large when ΔS^* is small. It is difficult at present to give any reasonable explanation of this.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 464195 from the Ministry of Education, Science and Culture. The high-pressure optical cell was constructed with the financial support of the Japan Society for the Promotion of Science.

(Received January 16, 1982)

Tin(IV) thiocarbamates of the types $SnX_{4-n}(SOCNR_2)_n$, n-$BuSnCl_{3-n}(SOCNEt_2)_n$, and $R'_2Sn(SOCNEt_2)_n$ (where X=Cl, Br, I; R=Me, Et; R'=n-Bu, n-Pr; n=1—4) were synthesized and characterized by elemental analysis and by molar conductance, molecular weight, and IR and NMR measurements.

The chemistry of metal complexes of thiocarbamate, particularly in association with main group metals, has not thoroughly been investigated in contrast to corresponding dithiocarbamates, only a few reports being made on silicon(IV),[1,2] thallium(I),[3] and some organotin(IV)[4,5] species. The replacement of sulfur by oxygen and the resulting decrease in the chelate bite bring about a remarkable change in the stereochemistry of metal complexes.[6—8] In view of this, we have initiated a detailed and systematic study of metal complexes of thiocarbamate and are reporting here some findings on tin(IV) derivatives.

Experimental

General. All manipulations were carried out under anhydrous conditions in nitrogen atmosphere. Solvents were dried by standard techniques. The sodium and dialkylammonium salts of thiocarbamic acid[9] and tin(IV) halide[10—12] were synthesized by literature procedures. n-$BuSnCl_3$ (93 °C/10 mmHg) (1 mmHg=133.322 Pa), n-Bu_2SnCl_2 (142 °C/11.0 mmHg), and n-Pr_2SnCl_2 (50 °C/1.0 mmHg) were distilled before use. The metal, sulfur, and halogen were estimated gravimetrically. Nitrogen was estimated by Kjeldahl's method. Conductance was measured on a conductivity bridge (Model No. L-370873 from Cambridge Instrument Co., England) at 10^{-3} M (1 M=1 mol dm^{-3}) concentration. Molecular weights of soluble compounds were determined cryoscopically in benzene. Infrared spectra were recorded on a Perkin-Elmer 621 instrument as Nujol mull in the range 4000—200 cm^{-1} and in solution in the range 4000—650 cm^{-1}. NMR spectral studies were carried out on a Varian A-60 spectrometer using tetramethylsilane as the internal standard.

Preparation of Trihalo(thiocarbamato)tin(IV) and Dihalobis(thiocarbamato)tin(IV) Complexes (Table 1). Into a suspension of sodium salt of thiocarbamate in dichloromethane, the stoichiometric amount of tin(IV) halide was added dropwise, and the reaction mixture was allowed to reflux for 12—14 h. The mixture was filtered to remove the separated sodium halide and the volatile materials were removed under reduced pressure. The products were crystallized from acetonitrile/hexane (1:8) and dried at 0.1 mmHg and *ca.* 50 °C for *ca.* 6 h.

Preparation of Chlorotris(diethylthiocarbamato)tin(IV) and Tetrakis(diethylthiocarbamato)tin(IV) Complexes (Table 1). Into a benzene solution of diethylammonium salt of diethylthiocarbamate, the stoichiometric amount of tin(IV) chloride was added dropwise with continuous stirring. The stirring was continued for *ca.* 10 h. The separated diethylammonium chloride was removed by filtration and the volatile materials were removed under reduced pressure. The products were crystallized from benzene/hexane (1:5) and dried at 0.1 mmHg and *ca.* 30 °C for *ca.* 10 h.

Preparation of Butyldichloro(thiocarbamato)tin(IV), Butylchlorobis(thiocarbamato)tin(IV), and Diorganobis(thiocarbamato)tin(IV) Complexes (Table 1). Into an acetone solution of diethylammonium salt of thiocarbamate, the stoichiometric amount of organotin(IV) chloride was added dropwise with continuous stirring. The stirring was continued for *ca.* 6 h. The separated diethylammonium chloride was removed by filtration and the volatile materials were removed under reduced pressure. Viscous liquids thus obtained were dried at 0.1 mmHg and *ca.* 30 °C for *ca.* 6 h.

Preparation of $SnCl_3(C_5H_5N)(SOCNMe_2)$ and $SnX_2(C_5H_5N)(SOCNEt_2)_2$ (X=Cl, I) (Table 1). Into an acetonitrile solution of $SnX_2(SOCNEt_2)_2$ and $SnCl_3(SOCNMe_2)$, an excess of pyridine was added with stirring. The reaction mixture was stirred for *ca.* 6 h and the volatile materials were removed *in vacuo*. The solid products were finally dried at 0.1 mmHg and *ca.* 60 °C for *ca.* 10 h.

Results and Discussion

Thiocarbamatotin(IV), $SnX_{4-n}(SOCNR_2)_n$, and organotin(IV) thiocarbamates, n-$BuSnCl_{3-n}(SOCNEt_2)_n$ and $R'_2Sn(SOCNEt_2)_2$, were synthesized according to the following schemes:

$$SnX_4 + \begin{cases} n'(Et_2NCOS^-\overset{+}{N}H_2Et_2) \longrightarrow \\ \qquad SnX_{4-n'}(SOCNEt_2)_{n'} + n'Et_2NH_2X, \\ n(R_2NCOSNa) \longrightarrow \\ \qquad SnX_{4-n}(SOCNR_2)_n + nNaX, \end{cases}$$

$$R'_2SnCl_2 + 2(Et_2NCOS^-\overset{+}{N}H_2Et_2) \longrightarrow R'_2Sn(SOCNEt_2)_2 + 2Et_2NH_2Cl,$$

$$BuSnCl_3 + n(Et_2NCOS^-\overset{+}{N}H_2Et_2) \longrightarrow BuSnCl_{3-n}(SOCNEt_2)_n + nEt_2NH_2Cl.$$

(X=Cl, Br, I; R=Me, Et; R'=n-Bu, n-Pr; n=1,2; n'=3,4.)

Thiocarbamatotin(IV) derivatives are crystalline solids, insoluble in common organic solvents except acetonitrile, whereas tris and tetrakis derivatives are soluble. Organotin(IV) complexes are viscous liquids, miscible with common organic solvents.

The infrared spectra of all these complexes are dominated by a broad intense band, sometimes split, due to coupled C⋯N and C⋯O stretching vibrations around 1550—70 cm^{-1}, indicating invariably bidentate behavior of the ligand.[4,6,7,13] Medium to strong bands in the regions 560—80 and 380—90 cm^{-1} may be assigned to νSn–O and νSn–S, respectively.[14—16]

Dihalo, dialkyl (molecular weight shows them to be monomeric), and butylchlorobis complexes appear to involve an octahedral geometry. $SnCl_2(SOCNEt_2)_2$ should have a *cis*-structure in the solid state as indi

cated by the two absorptions at 327 and 315 cm^{-1} due to antisymmetric and symmetric νSn–Cl, respectively.[17] This is further evidenced by ^{1}H NMR spectra (Table 2) of the soluble bis complexes, $SnX_2(SOCNEt_2)_2$, which show two overlapping quartets and triplets perhaps arising from their *cis*-structures and magnetic nonequivalence of the ethyl protons at ambient temperature due to the partial double bond character in C–N providing a restricted rotation.[4,9,13] The complex n-$BuSnCl_2(SOCNEt_2)$ is monomeric and nonionic in dichloromethane involving 5-coordinated tin atom.

Interestingly, in the IR spectra (in solution and in the solid state) of $SnCl(SOCNEt_2)_3$ and $Sn(SOCNEt_2)_4$ (found to be monomeric), an additional broad intense band appears at 1595—1605 cm^{-1} due to the coupled νC=N and νC=O, indicating also the presence of thiocarbamato moiety bonded to the tin atom through sulfur only.[18–20] This is strongly substantiated by the nature of the ^{1}H NMR spectrum of $Sn(SOCNEt_2)_4$ at ambient temperature which shows two sets of broad peaks of equal intensity, one due to the methylene protons of the two chelating diethylthiocarbamate moiety centered at δ=3.47 (comparable to the values obtained for our other derivatives) and the other at δ=3.00 (evidently separated by 0.47 in δ) owing to the other two ligands having only sulfur atoms bonded to the metal. The methyl protons appear as a complex mixture of triplets. It is evident that the tetrakis complex is octahedral like tetrakis derivatives of dithiocarbamate[21] $Sn(S_2CNEt_2)_4$ and dithiocarbonates[22] $Sn(S_2COEt)_4$. Efforts are being

made to get variable temperature ^{1}H NMR data for establishing the stereochemistry as well as to carry out a single crystal X-ray analysis for determining the full structure.

The conducting behavior of the tin(IV) halothiocarbamates in donor as well as in solvents of high dielectric constant suggests notable deviation from the behavior of the dithiocarbamate analogues in solutions, indicating a poor coordinating ability of the thiocarbamato moiety as ligand towards tin(IV). Dichlorobis(diethyldithiocarbamato)tin(IV) reported earlier[21] has been found to be essentially nonconducting (molar conductance: 3.92 Ω cm^2 mol^{-1}) in acetonitrile, whereas the trihalo- and dihalotin(IV) thiocarbamates exhibit a substantial molar conductance in acetonitrile in the order Cl>Br>I (Table 1) consistent with the general trend.[23] Substitution of the halide by butyl group also decreases the conductance since it lowers down the electrophilicity of the central tin atom. The data suggest the presence of the following solvolytic equilibrium[24] in acetonitrile:

$$SnX_{4-n}(SOCNR_2)_n \overset{MeCN}{\rightleftharpoons} [SnX_{4-(n+1)}(MeCN)(SOCNR_2)_n]^+X^-.$$

In donor solvents like pyridine (with lower dielectric constant), the equilibrium is more towards the right as evidenced by the comparatively much higher value of conductance, for example, of $SnI_2(SOCNEt_2)_2$ in pyridine (50 Ω cm^2 mol^{-1}) than in acetonitrile (8 Ω cm^{-2} mol^{-1}). The spurious conductance due to cationic species with a molecule of the solvent in the coordination sphere is substantiated by the isolation and characterization of pyridine complexes of the types $[SnCl_2(C_5H_5N)(SOCNMe_2)]^+Cl^-$ and $[SnX(C_5H_5N)(SOCNEt_2)_2]^+ X^-$ (X=Cl, I), which give characteristic bands at 690, 753, 1034, 1059, and 1600 cm^{-1} in the IR spectra due to coordinated pyridine.[25]

The authors are grateful to CSIR, New Delhi for a Junior Research Fellowship (VKG) and a Post-doctoral Fellowship (RKK) and to Nitto Kasei for their generous help in supplying us with organotin(IV) chlorides as a gift.

Photochemical Charging of a Silver Electrode Fixed at a Titanium Dioxide Surface

Hiroshi HADA,* Yoshiro YONEZAWA, and Yasuhito MOMOKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received March 4, 1982)

Synopsis. A regenerative half cell presented here: TiO_2(Ag)–Ag^+ can be photochemically charged by irradiation of the TiO_2 surface with sunlight. Electrical energy is extracted from it by connection through the load with a suitable half cell which has a more positive electrode potential than Ag–Ag^+.

The quantum yield of the photoreduction of silver ion (Ag^+) at the surface of both TiO_2 and ZnO by means of 365 nm light is more than 0.1 under suitable conditions.[1] We are interested in an application of the deposited silver at a semiconductor surface to anodic material of galvanic cells. In this paper, we have tried to use a TiO_2(Ag) electrode as a silver metal electrode. If we construct a half cell:TiO_2(Ag)–Ag^+ and combine it with another half cell:Pt–X^+/X couple, in which the standard electrode potential of the X^+/X couple is more positive than Ag^+/Ag, we can indeed withdraw electrical energy from such a cell. Zaromb *et al.* have previously described a cyclic photogalvanic silver halide cell from an analogous viewpoint.[2] Hodes *et al.* have investigated the photoelectrochemical storage cell by making use of CdSe.[3]

TiO_2 powder labelled TITONE R-310 made by Sakai Kagaku Co., Ltd., Osaka was molded and sintered at 1300 °C in air for 2 h, to obtain a plate of TiO_2 sinter, *ca.* 2 mm in thickness and 1 cm^2 in surface area. The electrical resistance of the sinter was higher than 1 MΩ in the dark. An indium layer was then evaporated on one face of the sinter and a copper wire was soldered to it. The TiO_2 sinter thus treated was immersed in a 0.1 M† $AgNO_3$ solution and irradiated by sunlight for 30 min. As a result, silver was deposited on the surface of the TiO_2. Since the electrical resistance between the deposited silver on the surface and the copper wire was only a few ohms, it was confirmed that the silver on the surface is in direct contact with the indium layer. After the TiO_2 sinter was washed with distilled water, a copper wire was inserted into a glass tube and the indium layer and TiO_2 surface were covered with an epoxy resin except for the face which is to be exposed to an electrolyte solution (*ca.* 0.77 cm^2). The TiO_2(Ag) electrode thus formed (Fig. 1) was immersed in the electrolyte solution containing 0.1 M $AgNO_3$ plus 1 M KNO_3.

The electrode potential of a TiO_2(Ag)–Ag^+ half cell was +0.60 V *versus* saturated KCl–Ag/AgCl electrode. It is in accord with a known value for a Ag–Ag^+ half cell. In order to withdraw electrical energy from such a half cell, we have combined it with another half cell:Pt–Ce^{4+}/Ce^{3+} through a salt bridge containing KNO_3 (Fig. 1). The electrolyte solution of the latter cell comprised 0.05 M $Ce_2(SO_4)_3$, 0.05 M $Ce(SO_4)_2$ and 1 M KNO_3. Current-voltage characteristics of the test cell assembled in this manner: TiO_2(Ag), Ag^+||Ce^{4+}/Ce^{3+}, Pt were examined at 25 °C in the dark. The discharge current was measured by the voltage across a resistance box with a switch closed, which was recorded on a recorder EPR-100A (Toa Electronics Co., Ltd.,). A similar measurement of the reference cell having a silver metal electrode (*ca.* 6 cm^2 in surface area) was carried out for comparison. The relation between the discharge current and the output voltage is given in Fig. 2. The open-circuit voltage and the

† 1 M=1 mol dm^{-3}.

short-circuit current were 0.64 V and 0.9 mA for the test cell and 0.64 V and 0.95 mA for the reference cell, respectively. Although the observed open-circuit voltage was somewhat less than the difference of the standard electrode potentials of Ag^+/Ag (0.80 V *vs.* NHE) and Ce^{4+}/Ce^{3+} (1.61 V) couples, current-voltage characteristics of these two cells were practically equal. Thus, we may state that the TiO_2(Ag) electrode possesses similar electrochemical properties to a silver metal electrode.

Discharge of the test cell was continued through a 30Ω load resistance. It is observed, as indicated in Fig. 3, the discharge current was decreased with the discharge time, but a current of about 0.3 mA was obtained after 15 min. The current-voltage characteristics of the cell at this stage were somewhat degenerated as seen in Fig. 2. The electrical resistance between the TiO_2 surface and the copper wire amounted to *ca.* 500Ω. We then opened the switch and placed the TiO_2(Ag)–Ag^+ half cell under sunlight for 30 min. The electrical resistance decreased again to a few ohms. The characteristics of the recharged cell are given in Figs. 2 and 3. As is indicated, the efficiency in the photochemical charging of the TiO_2(Ag)–Ag^+ half cell is very high. Cycles of photochemical charging and discharge were repeated more than ten times. It is found that the characteristics of the cell are similar to those of the first discharge and the efficiency of recharging is not lowered by such cycles. As we are interested only in an application of deposited silver, we have paid little attention to the regeneration of the Pt-Ce^{4+}/Ce^{3+} half cell in this work.

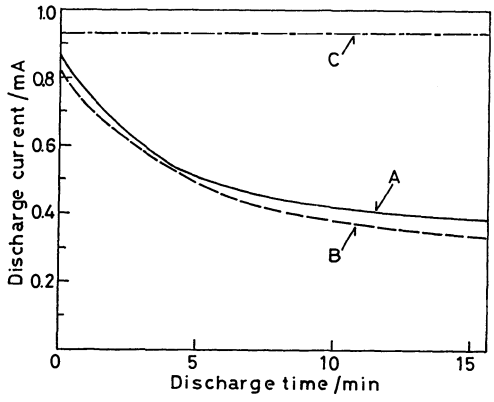

Fig. 3. Relation between discharge current and discharge time.
A: After first charging, B: after second charging, C: reference cell.

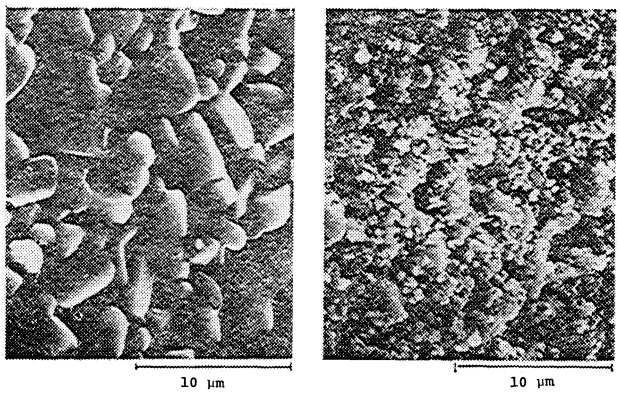

Fig. 4. Scanning electron micrographs of TiO_2 surface before (A) and after (B) charging.

It seems that the lower electrical resistance of the TiO_2(Ag) electrode after charging implies a whole electrode surface covered with deposited silver. Observation of the electrode surface with a scanning electron microscope JSM-T20S (Nippon Denshi Co., Ltd.,) confirms this (Fig. 4). According to a procedure reported previously,[1] the amount of photoreduced silver at the TiO_2 surface in the TiO_2(Ag)–Ag^+ half cell was determined for varying the irradiation time with 365 nm light from a 500 W Xenon lamp. The number of photons incident on the TiO_2 surface was 3×10^{13} cm^{-2} s^{-1}. The quantum yield of the silver deposition (amount of photoreduced silver/number of incident photon) was *ca.* 0.9. Thus the conversion efficiency of the 365 nm light to the reduced silver is very high. It would seem that silver deposited at the surface restricts the penetration of the incident light into the TiO_2 layer and causes a decrease of the rate of silver deposition. Indeed, such a filter effect may ultimately restrict the amount of silver deposition, which determines the maximum amount of silver storage per electrode surface. However, we have observed elsewhere that deposited silver does not influence the rate of silver deposition even when it increases to a considerable extent.[1]

Another important aspect of this cell is that at the time of photochemical charging, the metal deposition is carried out without transporting the charge carriers (electrons and holes) into the TiO_2 bulk. Therefore, we can make use of various semiconductors provided only that they can reduce metal ions under illumination of sunlight. Moreover, at the time of discharge, the current flows from the deposited metal directly to the lead wire without passing through the semiconductor bulk and therefore, its bulk resistance does not affect the internal resistance of the cell. Provided we can establish successful electrochemical properties and photochemical charging, as well as relatively large quantum yield of silver deposition, the TiO_2(Ag)–Ag^+ half cell may be useful in the field of solar energy conversion.

This work was carried out with financial support Grant-in-Aid No. 311607 from the Ministry of Education, Science and Culture.

The CNDO/S-CI Calculations of the Singlet nπ* and ππ* Levels of Quinones

Akira KUBOYAMA,* Yoshikuni KOZIMA,† and JUNZO MAEDA

National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305

† *The Tokyo Metropolitan Industrial Technology Center, Kita-ku, Tokyo 115*

(Received March 6, 1982)

Synopsis. The calculations proved to reproduce well the observed S_1 nπ* levels of quinones, the numbers of the singly excited configurations contained in CI being twice those of the basis AO's. The calculations taking 0.500 as the κ value reproduce well the observed singlet ππ* levels also. The unknown S_1 nπ* levels of some quinones were predicted on the basis of the calculated results.

As for the CNDO/S-CI[1] calculations of the singlet electronic-energy levels of quinones, only a few works[2] on *p*-quinones have been reported. In this work, the lowest-energy singlet $n_{\pm}\pi^*$[3] levels of principal *o*- and *p*-quinones have been studied with the aid of the CNDO/S-CI calculations. In the calculations, two κ values,[4] 0.585 (the formal one) and 0.500, were used. The 0.500 value was chosen to reproduce the observed energy difference between the $n_{\pm}\pi^*$ levels of *p*-benzoquinone, as will be shown later. In this work, the calculations using the two κ values are called as Cals. A and B respectively. The geometries of the quinones used in the calculations were the same as those used in the previous works,[5] except for that of *o*-benzoquinone, where the C–H bond length was taken as 1.084 Å. In *o*-benzoquinone[6] and acenaphthenequinone,[7] those values determined by X-ray-crystal analysis were used. Those of 2,6-naphthoquinone and diphenoquinone, and that of 5,14:7,12-pentacenediquinone, were determined on the basis of those of *p*-benzoquinone and 9,10-anthraquinone respectively.

In Fig. 1, n in the abscissa denotes the ratio of the number of the lowest singly excited configurations included in the calculations (Cal. A) to that of the basis AO's in the MO's. As may be seen in Fig. 1, in *p*-benzoquinone the lowest $n_+\pi^*$ levels is higher than the lowest $n_-\pi^*$ level, and the energy separation (ΔE) between them is of the order of 0.1 eV, while in *o*-benzoquinone the $n_-\pi^*$ level is higher than the $n_+\pi^*$ level and the ΔE is of the order of 1 eV, as in α-diketones.[8] In both quinones, the $n_{\pm}\pi^*$ levels become lower with the increase in n, but, broadly speaking,

settle at the point (n=2). Similar results were obtained in other *o*- and *p*-quinones. Results similar to the above were also obtained in Cal. B. Therefore, only the calculated values in the (n=2) case are used below.

In Table 1, the S_1–S_0 transitions are all found to be allowed transitions (out-of-plane) except for those of the three D_{2h}-type *p*-quinones, such as *p*-benzoquinone. It is also found that the S_1 level of each quinone is a little higher in Cal. A than in Cal. B, except for that of *o*-benzoquinone, and that in both Cals. A and B it is generally in good agreement with the observed one. The observed values are those of the longest-wavelength peaks or shoulders[9] of the S–S $n\pi^*$ absorption spectra in saturated hydrocarbon solutions.

As for ΔE, in Table 1 it is smaller in Cal. B than in Cal. A in each quinone except for 2,6-naphthoquinone. In *p*-benzoquinone, the observed values (0.032[10]—0.0004[11] eV (crystal) and 0.007 eV(gas)[12]) are close to that in Cal. B. As the observed energy separations between the triplet $n_{\pm}\pi^*$ levels of 9,10-anthraquinone[13] are not far from those of *p*-benzoquinone, the ΔE of 9,10-anthraquinone may be expected to be not far from that of *p*-benzoquinone. It is noticeable that the ΔE of 9,10-anthraquinone in Cal. B is considerably larger than that of *p*-benzoquinone. It is, however, uncertain at this stage whether or not this difference is significant.[14] In consideration of the large ΔE values of the *o*-quinones in Table 1, the S–S $n\pi^*$ absorption spectra of *o*-quinones may be concluded to consist of the $n_+\pi^*$ absorption spectra alone, as in α-diketones.[8]

Table 2. Calculated low-energy singlet $\pi\pi^*$ levels of quinones

	A_1	4.377	3.799	3.9
	B_2	4.477	3.949	3.7
	B_2	5.197	4.681	4.8
	A_1	5.458	4.887	

a) The forbidden levels have been omitted.

The low-energy $\pi\pi^*$ levels of the principal *o*- and *p*-quinones[5] obtained by Cal. B are found to be in good agreement with the observed ones in saturated hydrocarbon solutions, as may be seen in Table 2. The $n\pi^*$ S–S absorption spectra of 2,6-naphthoquinone and diphenoquinone have never been reported. In these quinones, as the lowest-singlet $\pi\pi^*$ levels are higher by 0.92 and 0.50 eV than the S_1 $n_-\pi^*$ levels respectively in Cal. B, the S_1 state may be predicted to be the $n_-\pi^*$ state. In addition, the S_1–S_4 states of 5,14:7,12-pentacenediquinone are all the $n\pi^*$ states (the B_{3u}, B_{1g}, A_u, and B_{3g} states respectively) in both Cals. A and B, where the ΔE's between S_1 and S_4 levels obtained by Cals. A and B are 0.320 and 0.195 eV respectively.

The Photoreduction of Viologen Dyes with Palladium *meso*-Tetraphenylporphyrintrisulfonate

Ichiro OKURA,* Shigetoshi AONO, Makoto TAKEUCHI, and Shin KUSUNOKI
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received April 1, 1982)

Synopsis. Pd-$TPPS_3$ was found to be an effective photosensitizer for the photoreduction of viologen dyes, such as methyl, ethyl, propyl, butyl, and heptyl viologens. The order of the reduction rate was as follows: Ethyl>Butyl>Methyl>Propyl>Heptyl. The respective complex formation was observed between Pd-$TPPS_3$ and viologen dyes, and electron transfer from photoexcited Pd-$TPPS_3$ to viologen dye was discussed.

Various attempts have been made to develop suitable redox systems for the photochemical utilization of solar energy. Recent works have shown that three-component systems containing a photosensitizer, an electron donor, and an electron acceptor can be used to evolve hydrogen from water when a suitable catalyst is present.[1] The metallo porphyrins employed almost exclusively in these studies as photosensitizers are zinc porphyrins.[2] It is desirable to explore other, suitable photosensitizers. In this study, palladium *meso*-tetraphenylporphyrintrisulfonate (Pd-$TPPS_3$) was found to be an effective photosensitizer for the photoreduction of viologen dyes; the reason for its effect was discussed.

Experimental

The methyl viologen and heptyl viologen were purchased from the Tokyo Kasei Kogyo Co. and the Aldrich Chemical Co. respectively, while the other chemicals, obtained from the Wako Pure Chemical Co., were of the highest available purity. The ethyl, propyl, and butyl viologens were synthesized according to the literature.[3] Pd-$TPPS_3$ was synthesized by refluxing *meso*-tetraphenylporphyrintrisulfonic acid and equimolar palladium acetate in methanol for 1 h.

The sample solution, which consisted of Pd-$TPPS_3$, viologen dye and 2-mercaptoethanol (RSH) in a Tris-HCl buffer (pH 7.0), was deaerated by repeated freeze-pump-thaw cycles. A typical experiment was performed as follows under anaerobic conditions. To 1.20×10^{-8} mol of Pd-$TPPS_3$ and 8.25×10^{-7} mol of viologen dye, 6.41×10^{-4} mol of RSH was added. The volume of the mixture was adjusted to 6.5 ml with a 0.02 M Tris-HCl buffer (pH 7.0). In the photolysis with continuous irradiation, the sample in a Pyrex cell with a magnetic stirrer was irradiated with light from a 150-W tungsten lamp (from a slide projector). Light of wavelength less than 390 nm was cut off by means of a Toshiba L-39 filter.

Results and Discussion

When an aqueous solution containing Pd-$TPPS_3$, methyl viologen, and RSH was irradiated, the growth of the cation radical of methyl viologen, which has characteristic absorption bands at 395 and 605 nm, was observed. The concentration of the reduced form of methyl viologen (MV^+) increased rapidly at the beginning of the reaction and then reached a constant value. When irradiation ceased, the concentration of MV^+ gradually decreased until it reached zero. MV^+ was reformed by re-irradiating the system, and the MV^+ formation rate was almost the same as the initial rate, for MV^+ returns to its original (oxidized) form in the absence of light. When other viologens, such as ethyl, propyl, butyl and heptyl viologens, were used instead of methyl viologen, the respective cation-radical formation was established by the irradiation. The order of the reduction rate was as follows:

Ethyl (2.40×10^{-5} M) > Butyl (1.8×10^{-5} M) > Methyl (1.56×10^{-5} M) $\simeq$ Propyl (1.55×10^{-5} M) > Heptyl ($\simeq$0 M).

The figures in the parentheses indicate the concentration of cation radicals formed by a 40-min irradiation. As the reduced forms of these viologens have redox potentials high enough for the decomposition of water, they may be useful as electron carriers to evolve hydrogen from water. In practice, hydrogen evolution by the reduction of water has been confirmed by the addition of hydrogenase as a catalyst to the reduced viologen dye formed by the reduction with $Na_2S_2O_4$.

Pd-$TPPS_3$ was a very active photosensitizer such one which was equal to Zn-$TPPS_3$ and far better than popular photosensitizers as ruthenium complexes. The photoreduction rate of methyl viologen with Pd-$TPPS_3$ was 12 times as large as that with palladium tetraphenylporphyrin (Pd-TPP), though it contains the same metal in the porphyrin ring. The difference in these activities may depend on the relative hardness of a complex formation between porphyrin and vi-

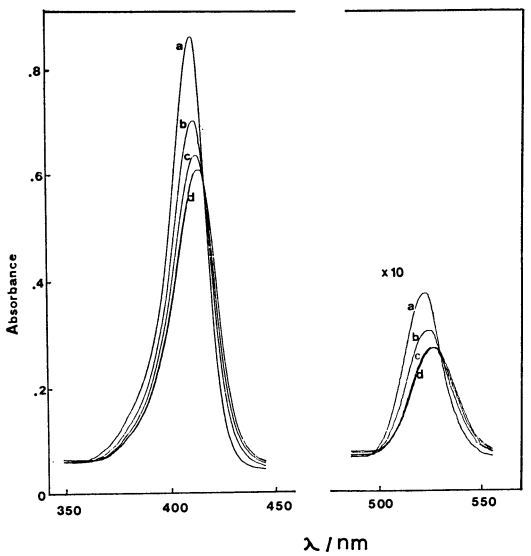

Fig. 1. Spectrum change of Pd-$TPPS_3$ by the addition of methyl viologen.
Sample solution contains 6.85×10^{-6} M of Pd-$TPPS_3$ and methyl viologen (a: 0 M; b: 2.03×10^{-5} M; c: 1.01×10^{-4} M; d: 5.07×10^{-4} M).

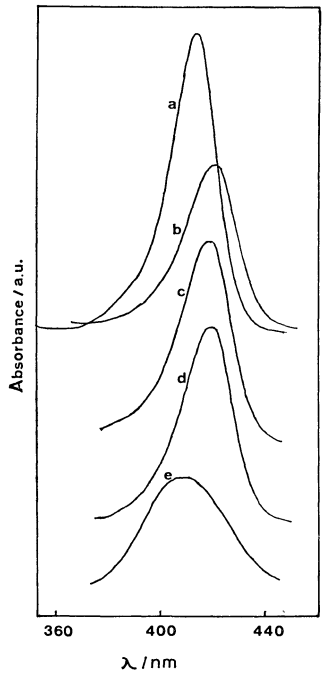

Fig. 2. Spectrum change of Pd–$TPPS_3$ by the addition of viologens.
a: Pd–$TPPS_3$, b: Pd–$TPPS_3$+ethyl viologen, c: Pd–$TPPS_3$+propyl viologen, d: Pd–$TPPS_3$+butyl viologen, e: Pd–$TPPS_3$+heptyl viologen.

ologen dye. Though a complex formation between Pd–$TPPS_3$ and viologens was observed as follows, no complex was formed in the case of Pd–TPP. When Pd–$TPPS_3$ was mixed with methyl viologen, the characteristic absorption bands at 409 and 521 nm of Pd–$TPPS_3$ decreased with the increase in the methyl viologen concentration, and a new spectrum appeared which has characteristic absorption bands at 414 and 527 nm through isosbestic points at 361, 417, 498, and 530 nm (Fig. 1). When other viologen dyes were used, the respective complex formation was observed, as is shown in Fig. 2. In the case of copper uroporphyrin, complex formation with methyl viologen was observed by Shelnutt.[4] The red shift in the Soret band of the complex is usually associated with a decrease in π-electron density in the porphyrin ring. The π-density in the ring follows this order: heptyl>methyl>propyl>butyl>ethyl. The lower the π-density of the ring, the larger the photoreduction rate of viologens, except for methyl viologen. The finding that the porphyrin ring acts as a donor in the ground state of the complex may show that photoinduced electron transfer from Pd–$TPPS_3$ to viologen dyes is apt to occur. Thus, viologens may be easily photoreduced. In the case of Pd–TPP, electron transfer from the photoexcited Pd–TPP to viologens may not proceed easily; a low reduction rate of methyl viologen is observed as a result.

Recently Matsuo *et al.*[5] prepared viologen-linked photosensitizers and found that electron was easily transferred from the photosensitizer to viologen dye and any undesirable back reaction was suppressed. In the cases of these Pd–$TPPS_3$–viologen complexes, easy electron transfer may also be found as a result of a similar effect.

We wish to express our appreciation to Professor Tominaga Keii and Professor Yoshio Ono for their stimulating and helpful discussions.

Thermal *cis-trans* Isomerization of $(CH)_x$ and $(CD)_x$

Masashi TANAKA,*,† Hajime YASUDA, and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

† *Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received April 10, 1982)

Synopsis. Thermal *cis-trans* isomerization of poly(acetylene), $(CH)_x$, and poly(acetylene-d_2), $(CD)_x$, is investigated by visible spectroscopy over the temperature range 90—150 °C. The reaction does not obey simple kinetics. The initial time activation energy for the *cis-trans* isomerization is 11 kcal/mol for $(CH)_x$ and 16 kcal/mol for $(CD)_x$.

In recent years, various properties have been reported for poly(acetylene) since the discovery that it can increase the conductivity by many orders of magnitude up to metallic levels when doped with electron donors or acceptors.[1] For example, the electrical conductivity after strong doping is always smaller for *trans*-$(CH)_x$ than for *cis*-$(CH)_x$ and the doping may induce the *cis-trans* isomerization of $(CH)_x$ films. Furthermore, many studies have focused on the magnetic properties of the neutral soliton defects which appear in *trans*-$(CH)_x$ upon isomerization.[2] Accordingly, detailed studies about the isomerization are necessary to determine the physics and chemistry of poly(acetylene). In the present paper, we show the optical study on the thermal *cis-trans* isomerization mechanism of pure $(CH)_x$ and $(CD)_x$.

The thin $(CH)_x$ and $(CD)_x$ films polymerized at −78 °C show the reddish cupuric color and the film becomes blue on heating it in vacuo. This color change was explained by the analysis of IR vibrational spectra to be due to the *cis-trans* isomerization of $(CH)_x$ and $(CD)_x$.[3,4] Figure 1 describes the visible absorption spectral change of the thin $(CD)_x$ film during the course of heat treatment in vacuo. *cis*-Rich $(CD)_x$ has two vibronic peaks at 17300 and 18500 cm^{-1} and the second peak (18500 cm^{-1}) is the most intense. On heating, the broad band in the region of 15000 cm^{-1} becomes more intense and the 18500 cm^{-1} peak of *cis*-$(CD)_x$ becomes weaker. Finally, the 15000 cm^{-1} band of *trans*-$(CD)_x$ has the same absorption intensity as that of the 18000 cm^{-1} band of *cis*-$(CD)_x$ before heating. Furthermore, it should be noted that an isosbestic point is observed at 17000 cm^{-1}. The same phenomenon can be observed for the $(CH)_x$ film, too.[5]

Then, the rate equation of the *cis-trans* isomerization is given as follows,

$$C_{cis}(t) + C_{trans}(t) = C \tag{1}$$

and

$$-\frac{dC_{cis}(t)}{dt} = k\,C_{cis}(t). \tag{2}$$

Here, $C_{cis}(t)$ and $C_{trans}(t)$ are the concentration of *cis*- and *trans*-forms at time t and C is the total concentration.

The integration gives

$$C_{cis}(t) = C - C_{trans}(t) = C_{cis}(0)\exp(-kt). \tag{3}$$

On the other hand, the observed optical density at time t, $OD(t)$, can be expressed by using the molar extinction coefficients ε_{cis} and ε_{trans} of *cis*- and *trans*-polymers and the thickness, d, of the film,

$$OD(t) = d\,\varepsilon_{cis}C_{cis}(t) + d\,\varepsilon_{trans}C_{trans}(t). \tag{4}$$

Then, Eqs. 3 and 4 lead to

$$OD(\infty) - OD(t) = d\,C_{cis}(0)\{\varepsilon_{trans} - \varepsilon_{cis}\}\exp(-kt), \tag{5}$$

where $OD(\infty) = d\,\varepsilon_{trans}\,C$ is the observed optical density at infinite time. The ratio of Eq. 5 for time t and initial time and the logarithm of the result give

$$\ln\left|\frac{OD(\infty) - OD(t)}{OD(\infty) - OD(0)}\right| = -kt, \tag{6}$$

where $OD(0)$ is the observed optical density at initial time.

Figure 2 shows kinetic plots for the thermal *cis-trans* isomerization at 16000 cm^{-1} by using Eq. 6. The plot does not give the straight line as is pointed out by Ito, *et al.*[4] That is, the rate of isomerization becomes slow and the slope of the plot becomes small as the reaction proceeds. This means that the activation energy increases with increasing *trans*-

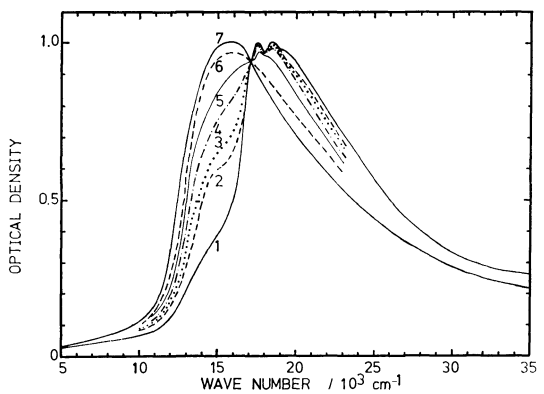

Fig. 1. The visible absorption spectral change due to the *cis-trans* isomerization of the thin $(CD)_x$ film at 140 °C after heating for 1) 0 min, 2) 0.5 min, 3) 1 min, 4) 2 min, 5) 3 min, 6) 5 min, and 7) 20 min.

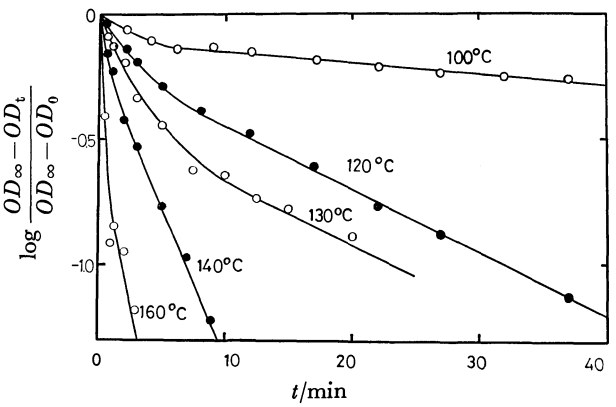

Fig. 2. Kinetic plots for the thermal *cis-trans* isomerization of $(CD)_x$ at 16000 cm^{-1}.

contents.

Arrhenius plots are shown in Fig. 3 and the activation energies at initial time are estimated to be 11 kcal/mol for $(CH)_x$ and 16 kcal/mol for $(CD)_x$. In contrast to Ito, Shirakawa and Ikeda's data (17 kcal/mol for 88% *cis*-rich $(CH)_x$),[4] our value of 11 kcal/mol for $(CH)_x$ corresponds to that of more than 90% *cis*-rich polymer. Furthermore, the larger activation energies for $(CD)_x$ than for $(CH)_x$ may be due to the mass difference between the hydrogen and deuterium atoms. That is, the out of plane C–H or C–D vibration plays an important part of the isomerization process and the difference between the zero point energies of C–H and C–D vibration may be considered to contribute to the difference between the activation energies for $(CH)_x$ and $(CD)_x$. This conclusion supports Ikeda's explanation for the difference between the *cis* and *trans* content ratio for the $(CH)_x$ and $(CD)_x$ polymers.[6]

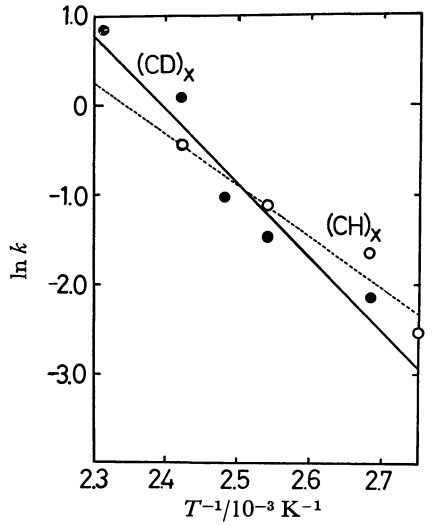

Fig. 3. Arrhenius plot for the thermal *cis-trans* isomerization of $(CH)_x$ and $(CD)_x$.

Mechanochemical Reactions at High Pressures. IV. Transformation of Lead Monoxide

Yasuhiro OKURI and Yoshiaki OGO*

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, 3-3-138, Sugimoto, Sumiyoshi-ku, Osaka 558

(Received Feburary 25, 1982)

Synopsis. The mechanochemical phase transformation of lead monoxide has been studied by the X-ray diffraction method. It is established that the transformation of lead monoxide proceeds by a stress-induced martensitic mechanism.

Lead monoxide exists in two familiar forms: litharge (L, a red tetragonal form) and massicot (M, a yellow orthorhombic form). Most of the studies of phase transformations in PbO have involved milling, comminution, and abrasion. High pressure studies have not been carried out except for an experiment to determine the equilibrium pressure-temperature relation for the L⇌M reaction by White *et al.*[1] These authors reported that L could be converted into M either by raising the temperature above 540 °C or the pressure above 6000 atm, although the reaction was slow at low temperature. Furthermore, they suggested that purely hydrostatic pressure causes the L→M transformation, whereas bond breakage at low pressure gives the M→L transformation.

In the present work, we investigated the L⇌M transformation at room temperature under high pressure with simultaneous shear deformation.

Experimental

The experimental high pressure apparatus combined with simultaneous shear deformation (HP+SSD) consists of Bridgman's type anvils. Details of the apparatus and procedure have been described previously.[2] All experiments were carried out up to 20 kbar (1 kbar=10^8 Pa) at room temperature. In these experiments, the reactions proceeded at a constant shearing velocity of 2.51 rad h^{-1} (2.4° min^{-1}).

As specimens of lead monoxide, the litharge starting material was kindly supplied from Dai Nippon Toryo Co. Ltd. and the massicot was the commercial reagent. The specimens were sieved to 100 mesh and molded in 12-mm diameter pellets. The sample tablet was placed in the HP+SSD apparatus, and the experiment was carried out at the desired pressure. The volume fraction increment of L(or M), after M(or L) was sheared under high pressure, was determined by X-ray diffraction analysis. The lines chosen for comparison were, for M, $2\theta=37.82°$ for the (020) plane and a relative intensity of 20, and for L, $2\theta=35.74°$ for the (002) plane and a relative intensity of 18.[3] According to Lins' report,[4] the relation between the volume fraction of massicot, C_M, and that of litharge, C_L is given by:

$$C_M/C_L = 2(I_M/I_L),$$

where I_M and I_L are the intensity of a chosen diffraction line for M and L, respectively.

Results and Discussion

Figures 1 and 2 show the relations between the static pressure and the shear stress for M and L, respectively. In Fig. 1, the curve exhibits a characteristic change at about 2 kbar, which corresponds to the M→L phase-transition. In Fig. 2, the characteristic variation at about 2 kbar and a slight variation at about 5 kbar were observed. These facts suggest that a large transition energy is required for L in comparison with M→L transformation because M is more stable than L at high pressures. Therefore, the energy required for L→M transformation will be accumulated over the range from 2 to 5 kbar of static pressure. This consideration is supported by the conversion curve of L as shown in Fig. 3. Consequently, the apparent transformation pressure of lead monoxide exsists in the vicinity of 2 kbar, and is smaller than the 5.6 kbar, obtained by extrapolation of the pressure-temperature phase diagram.[1] In conclusion, the forced shear deformation is responsible for the decrease in the transition pressure of lead monoxide.

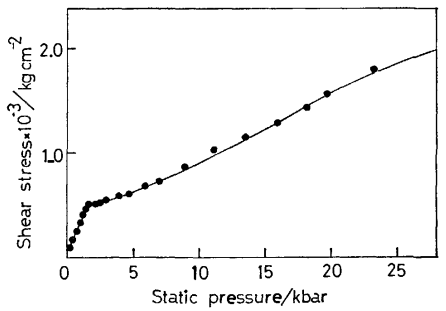

Fig. 1. Relation between the static pressure and the shear stress for massicot.

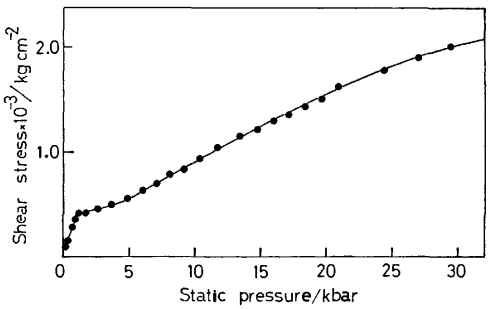

Fig. 2. Relation between the static pressure and the shear stress for litharge.

The effects of the static pressure on the conversion and the shearing degree for L→M, and M→L transformations are shown in Figs. 3 and 4, respectively. As shown in Fig. 3, the L→M transformation curves possess the following features:

(1) At 5 kbar, L was not converted into M in most experiments. These results are correlated with those in Fig. 2.

(2) The percent of M formed did not decrease

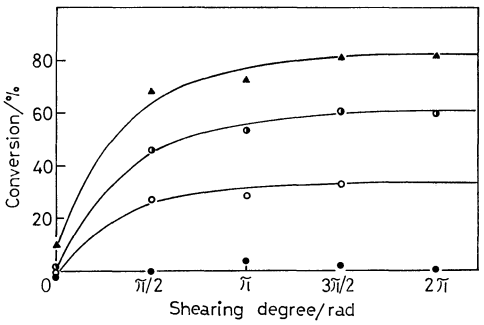

Fig. 3. Relation between conversion and the shearing degree at various static pressures for the litharge to massicot transformation.
● 5 kbar; ○ 10 kbar; ◑ 15 kbar; ▲ 20 kbar.

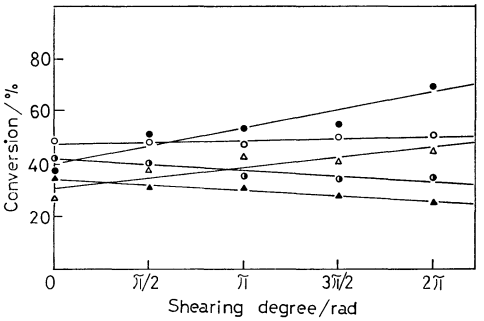

Fig. 4. Relation between conversion and the shearing degree at various static pressures for the massicot to litharge transformation.
△ 2 kbar; ● 5 kbar; ○ 10 kbar; ◑ 15 kbar; ▲ 20 kbar.

with the shearing degree, as was found for the M→L transformation in Fig. 4, but it tended to approach an equilibrium value similar to the value in the literature.[5] Judging from Fig. 3, L will be completely converted into M at about 30 kbar static pressure under our experimental conditions.

(3) The higher the static pressure, the more the transformation proceeds.

(4) The curves all have a parabolic shape.

The M→L transformation in Fig. 4 is characterized as follows:

(1) All relations are linear.

(2) At all static pressures, M is considerably transformed to L even without the forced shear deformation. It can be assumed that the energy required for the M→L transformation is less than that for the L→M transformation because L has a lower potential energy than M.[6]

(3) The conversion of M→L becomes small with the increase the static pressure as a general tendency. Furthermore, the conversion tends to decrease as the shearing proceeds at 15 and 20 kbar static pressure. This fact suggest a transformation back to M. Thus, it can be assumed that the transformation of M to L is an equilibrium reaction, if the transformation can be called the reaction. Judging from Fig. 4, the equilibrium shifts to M with increasing pressure. This consideration agrees with the Le Chatelier principle since M is a high-pressure modification.

The following two mechanisms can be proposed for the transformation of lead monoxide. The one is a nucleation and growth mechanism and the other is a stress-induced martensitic type transformation. When the experimental results fit Avrami equation, the transformation must proceed by a nucleation and growth mechanism.[5] Our experimental data did not fit the Avrami plot, therefore, the transformation of lead monoxide is a martensitic type transformation induced by the strong shear force. This conclusion is consistent with the result for M→L transformation during comminution.[4]

We also carried out some experiments on the transformation of calcium carbonate. The phase diagram of $CaCO_3$ has been studied since Bridgman's work in 1939, but regardless of many studies it is still not completely determined. Burns and Bredig[8] have found calite to be transformed to aragonite by grinding at room temperature, and estimated the pressure necessary for the transformation of calcite to arragonite at 4600 kg cm^{-2}. Ahrens and Katz[9] reported that the transformation of calcite occurs at pressures above 5 kbar. However, our X-ray examination revealed that calcite was not transformed into aragonite under 2π rad shearing at 15 kbar static pressure.

The authors thank Dr. K. Ohashi of Osaka City University for X-ray measurements, and Dai Nippon Toryo Co. Ltd. for a supply of litharge.

(Received October 16, 1981)

Synopsis. The enthalpy(ΔH_r°) and entropy(ΔS_r°) changes for the mixed dimer formation reaction, $Na_2Cl_2+K_2Cl_2=2NaKCl_2$, have been measured by mass-spectrometry in the temperature range of 793 to 1083 K. $\Delta H_r^\circ=-1.67$ kJ mol^{-1} and $\Delta S_r^\circ=5.69$ J K^{-1} mol^{-1} were obtained. These very small values were referred both to the mainly ionic-bonding structure in the related dimers and to preserving the isobonding through the reaction.

Hastie[1] has recently summarized the empirically based rules for complex halide formation. From these it is derived that isobonding mixed-dimer reactions such as $(AX)_2+(BX)_2=2ABX_2$, where A and B are different alkali metals and X is a halogen, should occur with very little enthalpy and entropy changes. However, in practice, the enthalpy changes have ranged from about 0 to approximately −340 kJ/2 mol-complex due to the excess stability associated with the mixed dimer formation.[1]

The following reaction:

$$Na_2Cl_2(g)+K_2Cl_2(g)=2NaKCl_2(g)\,, \qquad (1)$$

was chosen in this study to examine the energetic situation in the mixed dimer formation reaction because of its simplicity in chemical bondings.

Experimental

A series of mass-spectrometric experiments was carried out on the solid solutions of NaCl and KCl with different compositions ranging from 10 to 90 mol% NaCl. A method of detection and identification of species was described in detail elsewhere.[2,3] Approximately 50 mg of the mixed salt was placed in a Knudsen-cell made of pure alumina.

The ions of Na_2Cl^+, K_2Cl^+, and $NaKCl^+$ were determined as the parent ions produced from Na_2Cl_2, K_2Cl_2, and $NaKCl_2$ molecular vapors, respectively.[2] The equilibrium partial pressure of i-th vapor, p_i, is given by $p_i=C_iTI(i^+)$ where $I(i^+)$ is the parent ion intensity, T is the absolute temperature and C_i is a constant involving the ionization cross section(σ_i), the isotopic ratio(γ_i), the collection efficiency (S_i) in the first step of an electron multiplier, and the potential difference (ΔE_i) between an ionizing- and appearance-potentials of i-th ion, and an apparatus constant(k): $C_i=k(\sigma_i\gamma_iS_i\Delta E_i)^{-1}$ for the i-th ion.

The equilibrium constant, K_p, for Eq. 1 can be written as:

$$K_p=\frac{[p(NaKCl_2)]^2}{p(Na_2Cl_2)p(K_2Cl_2)}=\frac{C[I(NaKCl^+)]^2}{I(Na_2Cl^+)I(K_2Cl^+)}, \qquad (2)$$

where,

$$C=\frac{[C(NaKCl_2)]^2}{C(Na_2Cl_2)C(K_2Cl_2)}$$

$$=\frac{\sigma(Na_2Cl_2)\sigma(K_2Cl_2)}{[\sigma(NaKCl_2)]^2}\times\frac{\gamma(^{23}Na_2{}^{35}Cl_2)\gamma(^{39}K_2{}^{35}Cl_2)}{[\gamma(^{23}Na^{39}K^{35}Cl_2)]^2}\times\frac{S(Na_2Cl^+)S(K_2Cl^+)}{[S(NaKCl^+)]^2}\times\frac{\Delta E(Na_2Cl^+)\Delta E(K_2Cl^+)}{[\Delta E(NaKCl^+)]^2}\,. \qquad (3)$$

Assuming that S-values are almost identical for Na_2Cl^+, K_2Cl^+, and $NaKCl^+$ ions and using our previous data[2] for σ and ΔE, $C=1.06$ was obtained.

Vapor equilibrium in the Knudsen cell was ensured by our previous mass-spectrometric measurements of activities of the NaCl–KCl system[2,4] carried out by taking advantage of the ion intensity of Na_2Cl^+, K_2Cl^+, and $NaKCl^+$ which came from Na_2Cl_2, K_2Cl_2, and $NaKCl_2$ molecules: the activity coefficient determined from the ion current ratios of $I(Na_2Cl^+)/I(K_2Cl^+)$ was in close agreement with that obtained from the ratios of $I(NaKCl^+)/I(K_2Cl^+)$. This shows attainment of equilibria between gas phases in Eq. 1.

Results and Discussion

Figure 1 shows the temperature dependence of K_p calculated from Eq. 2 using the mass-spectrometrically observed data. Some K_p data reported by Milne and Klein[5] are also presented in the figure. The least squares treatment gave:

$$\log K_p=0.5945(\pm0.936)+\frac{175.1(\pm101.7)}{T}\,. \qquad (4)$$

Therefore, the Gibbs energy for the mixed dimer reaction (Eq. 1) is calculated as follows:

$$\Delta G_r^\circ=-RT\ln K_p=-3352(\pm1947)-11.38(\pm1.79)T \quad [\text{J/2 mol-complex}]\,. \qquad (5)$$

Thus, from the relation of $\Delta G_r^\circ=\Delta H_r^\circ-T\Delta S_r^\circ$, the

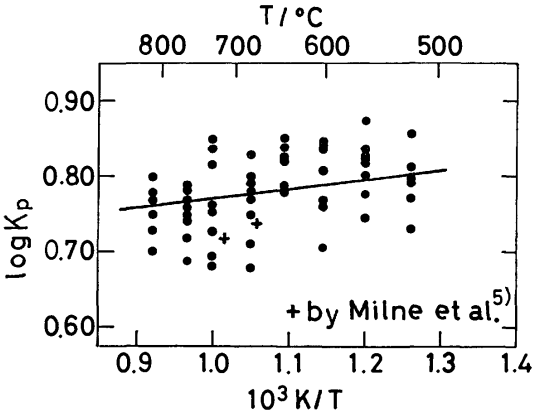

Fig. 1. Temperature-dependence of equilibrium constant, K_p, obtained mass-spectrometrically for the reaction: $Na_2Cl_2(g)+K_2Cl_2(g)=2NaKCl_2(g)$.

enthalpy and entropy changes at the central temperature in the experimental temperature range were:

$$\Delta H^{\circ}_{r,940\,K} = -1.67\pm0.97 \ [kJ\ mol^{-1}], \quad (6)$$

$$\Delta S^{\circ}_{r,940\,K} = 5.69\pm0.90 \ [J\ K^{-1}\ mol^{-1}]. \quad (7)$$

The formation energy of $NaKCl_2(g)$, ΔU, in the following gaseous reaction:

$$\frac{1}{2}\begin{bmatrix} Na^+\text{-}Cl^- \\ | \quad | \\ Cl^-\text{-}Na^+ \end{bmatrix} + \frac{1}{2}\begin{bmatrix} K^+\text{-}Cl^- \\ | \quad | \\ Cl^-\text{-}K^+ \end{bmatrix} = \begin{bmatrix} Na^+\text{-}Cl^- \\ | \quad | \\ Cl^-\text{-}K^+ \end{bmatrix} + \Delta U, \quad (8)$$

was calculated from the equation:

$$\Delta U = U_{NaKCl_2} - \frac{1}{2}(U_{Na_2Cl_2} + U_{K_2Cl_2}), \quad (9)$$

where U denotes the potential energy of each ionic dimer compared to the completely separated ions. The values of $U_{Na_2Cl_2}$ and $U_{K_2Cl_2}$ were given to be -1266 and -1119 kJ mol^{-1} respectively by Milne and Cubicciotti.[6] They also provided the following equation for U_{NaKCl_2}:

$$U_{NaKCl_2} = \left(-\frac{2}{a}-\frac{2}{b}+\frac{1}{c}+\frac{1}{d}+\frac{153.3}{a^{8.6}}+\frac{401.3}{b^{8.6}} + \frac{22.86}{c^{8.6}}+\frac{439.4}{d^{8.6}}\right)\times 1389 \ [kJ\ mol^{-1}], \quad (10)$$

by assuming pure ionic-bonding in all dimers and a diamond-shaped structure for $NaKCl_2$, as shown in Fig. 2, and by employing a model suggested by Pauling.[7] Numerical analyses for Eq. 10 gave a set of the geometrical parameters: $a=2.49$, $b=2.85$, $c=3.70$, and $d=3.83$ Å which resulted in the minimum energy of the $NaKCl_2$ mixed dimer; $U^{MIN}_{NaKCl_2}=-1195$ kJ mol^{-1}. Consequently, we obtained $\Delta U \simeq -2.5$ kJ mol^{-1} from Eq. 9.

On the other hand, a combination of Eq. 6 with the heats of formation[8] for Na^+, K^+, Cl^+, Na_2Cl_2, and K_2Cl_2, leads to $\Delta H^{\circ}_{f,940K}=-1248$ kJ mol^{-1} for the heat of formation of the mixed dimer $NaKCl_2$ from separation Na^+, K^+, and Cl^- ions. If the heat capacities of the dimer molecules are the same, the values of ΔU and $U^{MIN}_{NaKCl_2}$ may be compared directly with those of the $\Delta H^{\circ}_{r,940K}$ and $\Delta H^{\circ}_{f,940K}$ mentioned above. The direct comparison gave good agreement which strongly suggests that each bond in the dimer molecules of Na_2Cl_2, K_2Cl_2, and $NaKCl_2$ is almost ionic and that the mixing of Na^+, and K^+ ions in the mixed dimer $NaKCl_2$ contributes to a lesser extent to the enhancement of bond strength.

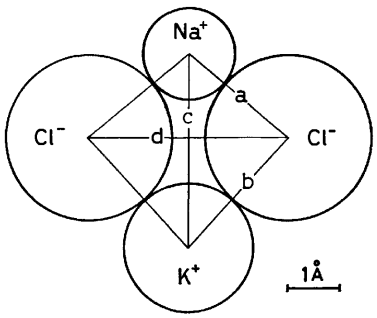

Fig. 2. Schematic representation for a structure of $NaKCl_2$ molecule.

Table 1. Calculated entropy values for gaseous dimers, Na_2Cl_2, K_2Cl_2, and $NaKCl_2$, at 940 K

Dimers	S_{trans} / kJ K mol^{-1}	S_{rot} / kJ K mol^{-1}	S_{vib} / kJ K mol^{-1}
Na_2Cl_2	191.989	119.997	102.462
K_2Cl_2	195.025	128.440	126.194
$NaKCl_2$	193	128	116.7[a]

a) Estimated from the equation: $S_{vib,NaKCl_2}=\Delta S^{\circ}_{r,940\,K}+(S_{total,Na_2Cl_2}+S_{total,K_2Cl_2})/(S_{trans,NaKCl_2}+S_{rot,NaKCl_2})$.

Table 1 shows the translational, ratational, and vibrational entropies for the $NaKCl_2$ molecule at 940 K calculated on the basis of the statistical thermodynamics[9] using the molecular weight, the vapor pressure, the product of the moment of inertia ($I_AI_BI_C=1.224\times10^{-38}$ kg^3 m^6) and the $\Delta S^{\circ}_{r,940K}$, along with those for Na_2Cl_2 and K_2Cl_2 dimers calculated using the required data from the JANAF Tables.[8] It can be seen from the table that the entropy change in the isobonding mixed-dimer reaction, Eq. 1, is very small and that this small entropy change is brought about mainly by the change in the rotational entropy.

Thanks are due to Mr. Kitoshi Ozawa of Tokyo National Technical College for performing the calculations of ionic potentials.

Kinetics of Structural Rearrangement Accompanying the Substitution Reaction on Complex [Co(terpy)(hmpa)$_3$]$^{2+}$(terpy=2,2′ : 6′,2″-Terpyridine) in Hexamethylphosphoric Triamide

Yuriko Abe* and Goro Wada

Department of Chemistry, Nara Women's University, Nara 630

(Received February 1, 1982)

Synopsis. The reaction of structural rearrangement accompanying the substitution of hexamethylphosphoric triamide (HMPA) for 2,2′:6′,2″-terpyridine (terpy) from octahedral [Co(terpy)(hmpa)$_3$]$^{2+}$ to tetrahedral [Co(hmpa)$_4$]$^{2+}$ proceeds through a five-coordinated intermediate in HMPA. The following values for the first-order rate constant at 25 °C, ΔH_d^*, and ΔS_d^* were obtained: $k_d=3.55\times10^{-5}$ s^{-1}, $\Delta H_d^*=105.4$ kJ mol^{-1}, and $\Delta S_d^*=+15.9$ J K^{-1} mol^{-1}.

There are few kinetic data for reactions involving structural interconversions.[1-5] This is probably due to the high reaction rates except for the cases which can be measured by tempertaure jump or NMR, and to the severe thermodynamic requirements of their investigation.

In this report, we studied spectrophotometrically the kinetics of structural rearrangement reactions accompanying HMPA substitution for terpy from octahedral [Co(terpy)(hmpa)$_3$]$^{2+}$ to tetrahedral [Co(hmpa)$_4$]$^{2+}$ in HMPA, for the purpose of clarifying the rearrangement mechanism and the effect of the bulkiness of HMPA on its mechanism. The reaction rate was successfully measured by a conventional technique, since terdentate ligands generally undergo ligand exchange more slowly than unidentate ones.

Experimental

Materials. [Co(hmpa)$_4$](ClO$_4$)$_2$ and [Cu(hmpa)$_4$](ClO$_4$)$_2$ were prepared by methods described in the literature.[6,7] Terpy was used without further purification. The purification of HMPA was carried out as previously described.[8,9]

Rate Measurements. The complex [Co(terpy)(hmpa)$_3$]$^{2+}$ was prepared from appropriate amounts of [Co(hmpa)$_4$]$^{2+}$ and terpy in HMPA in advance and the reaction was initiated by mixing a solution of [Co(terpy)(hmpa)$_3$]$^{2+}$ with a solution of [[Cu(hmpa)$_4$]$^{2+}$] in a large excess over [[Co(terpy)(hmpa)$_3$]$^{2+}$] in HMPA. Cu(II) was used in order to remove the free terpy by its rapid complexation.[10] The reaction rate was followed by observing the increase in the absorbance at 580 nm by use of a Shimadzu Spectrophotometer Model UV-200S with a thermostated cell compartment. The measured absorbances were not corrected because the absorbance due to Cu(II) was approximately constant during the course of the reaction. The ionic strength was adjusted at 0.1 mol dm^{-3} with sodium perchlorate.

Results and Discussion

Rate Constants and Activation Parameters. The reaction obeys the following rate equation (1) under the conditions of [Cu(II)] of a large excess over [Co(II)]$=8\times10^{-4}$ mol dm^{-3},

$$\ln[(A_\infty-A_t)/(A_\infty-A_o)] = -k_{obsd}t, \quad (1)$$

where A_o, A_t, and A_∞ are the absorbances at times 0, t, and infinite at 580 nm, respectively. As shown in Fig. 1, the values of k_{obsd} were found to be linearly dependent upon the Cu(II) concentration. In the similar reactions (such as those of M(II)-terpy complexes (M(II)=Mn(II), Fe(II), Co(II), Ni(II), Zn(II), or Cd(II)) in H_2O,[10] and of Mn(II)-terpy in methanol,[11]) no dependence of the rate constant upon either [Hg(II)] or [Cu(II)] has been observed, where Hg(II) or Cu(II) only acts to scavenge the free terpy. Therefore, this result in HMPA is particularly interesting. The correlation of k_{obsd} with [Cu(II)] in HMPA can be empirically expressed by the following equation;

$$k_{obsd} = k_d + k_a[Cu(II)], \quad (2)$$

in which k_d is a first-order rate constant with respect to [Co(II)] and k_a is a second-order rate constant with respect to [Co(II)] and [Cu(II)]. By plotting $\ln k_d$ or $\ln k_a$ *vs.* $1/T$, ΔH^* and ΔS^* were obtained as follows: $\Delta H_d^*=105.4$ kJ mol^{-1} and $\Delta S_d^*=+15.9$ J K^{-1} mol^{-1} for the k_d path, and $\Delta H_a^*=72.3$ kJ mol^{-1} and $\Delta S_a^*=-54.0$ J K^{-1} mol^{-1} for the k_a path, respectively.

Reaction Mechanism. The reaction with the first-order rate constant k_d corresponds to the following equation:

$$\underset{\text{octahedral}}{[Co(terpy)(hmpa)_3]^{2+}} + hmpa \longrightarrow \underset{\text{tetrahedral}}{[Co(hmpa)_4]^{2+}} + terpy. \quad (3)$$

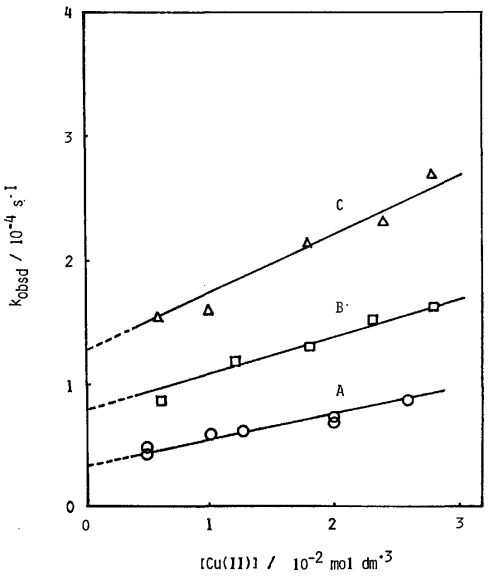

Fig. 1. The dependence of k_{obsd} on the Cu(II) concentrations at 25 °C (A), 30 °C (B), and 35 °C (C).

Two possible reaction mechanisms may be considered for the substitution for terpy on $[Co(terpy)(hmpa)_3]^{2+}$. One is a dissociative mechanism, in which one of the three cobalt-nitrogen bonds is first broken and the reaction goes through a five-coordinated intermediate. The other is an associative mechanism, in which Co(II) first reacts with an HMPA molecule, resulting in a seven-coordinated intermediate or an outer-sphere associated complex. Since the coordination number of Co(II) is reduced from six to four, the former mechanism seems to be more probable. The fact that ΔS_d^* value is positive supports the dissociative mechanism which is represented as follows,

$$[(hmpa)_3Co\text{–}N\langle_{N}^{N}\rangle]^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [(hmpa)_3Co\text{–}N\langle_{N}^{N}\rangle]^{2+} \xrightarrow{k_2} . \quad (4)$$

Thus, k_d can be expressed as $k_1k_2/(k_{-1}+k_2)$.

The [Cu(II)] dependence in HMPA is similar to the case of the [Hg(II)] dependence of the reactions of Ni(II)-bidentate substituted pyridines in dimethyl sulfoxide.[12] Buck and Moore suggested that the reaction of the [Hg(II)] dependence proceeds by the attack of Hg(II) on a nitrogen atom whose bond with Ni(II) has been ruptured.[12] Therefore, it seems that the [Cu(II)] dependence in HMPA is also due to the reaction between the five-coordinated intermediate of Co(II) and Cu(II).

Comparison between Reactions in HMPA and in H_2O. When the equilibrium constant between the tetrahedral⇄octahedral configurations is expressed by $K_1=[[Co(terpy)(hmpa)_3]^{2+}]/[[Co(hmpa)_4]^{2+}][terpy]$, the reaction with the rate constant k_d corresponds to the backward reaction of the equilibrium. In the present study, the values of k_d obtained and the activation parameters in HMPA are as follows: $k_d=3.55\times10^{-5}$ s^{-1} at 25 °C, $\Delta H_d^*=105.4$ kJ mol^{-1}, and $\Delta S_d^*=+15.9$ J K^{-1} mol^{-1}, and the value of K_1 has been obtained as $K_1=7.4\times10^4$ dm^3 mol^{-1}.[9] In H_2O, where $[Co(H_2O)_6]^{2+}$ and $[Co(terpy)(H_2O)_3]^{2+}$ are both octahedral, those values are $k_d=1\times10^{-4}$ s^{-1} at 25 °C,[13] $\Delta H_d^*=82.0$ kJ mol^{-1},[13] $\Delta S_d^*=-1.7$ J K^{-1} mol^{-1},[13] and $K_1=2.5\times10^8$ dm^3 mol^{-1}.[14] Although the value of K_1 in HMPA differs considerably from that in H_2O, the values of k_d and the activation parameters in HMPA resemble those in H_2O.

Since the chelation by terpy in HMPA liberates only one molecule of HMPA in contrast with the liberation of as many as three water molecules in the case of water, the entropy effect would lead to the smaller K_1 in HMPA than in H_2O. Moreover, the coordinating HMPA molecules in $[Co(terpy)(hmpa)_3]^{2+}$ are closely packed. Accordingly, the complex is so unstable, due to its molecular bulkiness, that the equilibrium would be also unfavored, resulting in the smaller K_1 in HMPA than in H_2O. Although the reaction in HMPA is accompanied by a structural rearrangement, the similarity of k_d and the activation parameters in both media support the idea that the reaction proceeds by the same dissociative mechanism, independently of whether the solvent is HMPA or H_2O.

Reference Materials for the Pyrolysis Gas-chromatographic Determination of Ammonia, Nitrogen, Nitrogen Monoxide, Carbon Monoxide, and Carbon Dioxide

Kikuo Miyokawa,* Naoki Abe, and Isao Masuda

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01

(Received March 23, 1982)

Synopsis. Four compounds are proposed as the reference materials to calibrate the pyrolysis gas chromatograph in the determination of inorganic gases: $[Co(NH_3)_5Cl]Cl_2$ for NH_3, $[Co(NH_3)_5NO_2]Cl_2$ for N_2, $[Co(NH_3)_5NO]Cl_2$ for NO, and PbC_2O_4 for both CO and CO_2. On pyrolyses, the gas evolution of these compounds were stoichiometric, and the peak area corresponded fairly well to the weight of the compound. Under the condition employed, 7.3—138 μmol of NH_3, 2.2—67 μmol of N_2, 2.0—61 μmol of NO, 0.84—26 μmol of CO, and 2.5—76 μmol of CO_2 were analyzed by using 0.5—15 mg of the compounds.

Pyrolysis gas chromatography (PGC) has been developed as a technique for the structural characterization of organic polymers.[1] In our previous papers,[2] the PGC technique was successfully employed for the quantitative determination of the gaseous products, N_2 and N_2O, evolved upon the pyrolyses of the series of Co(III)-ammine and Mo- or W-nitrosyl complexes. In practical use, however, it was not quite advantageous to calibrate the PGC instrument with standard gas, since, by the method using a gas syringe, hardly any standard gas was injected exactly into a furnace heated at a high temperature wherein a sample was pyrolyzed. Therefore, it seemed desirable to calibrate the instrument under conditions identical to those for the pyrolysis of sample. The PGC technique can be expected to be more useful if the PGC instrument can be easily calibrated with such reference compounds as evolve the desired gas stoichiometrically upon the pyrolysis.

In the present article, four inorganic compounds have been recommended as useful references for the calibration of the PGC instrument for the determination of NH_3, N_2, NO, CO, and CO_2.

Experimental

Materials. The compounds, $[Co(NH_3)_5Cl]Cl_2$,[3] $[Co(NH_3)_5NO_2]Cl_2$,[4] $[Co(NH_3)_5NO]Cl_2$,[5] and PbC_2O_4,[6] were prepared by the published manner and were purified by repeated recrystallizations.

Measurements. The PGC measurements were carried out by the use of a YANACO G 80 TCD gas-chromatographic instrument equipped with a YANACO GP 1018 pyrolysis pippeter, following the manual. An 0.5—15.0 mg aliquot of the compounds was transferred into a platinum crucible (16 mm^3), and then the crucible was inserted into the pyrolysis pipetter, whose furnace had been kept at the desired temperature. The compound was pyrolyzed instantly in helium gas, and the gaseous products were subsequently swept by the helium-gas carrier into the GC separation column. The peak area was recorded on an integrator. The PGC conditions are tabulated in Table 1.

Results and Discussion

The four compounds considered here can be easily obtained and stored in a pure and stable form. The purities of the cobalt complexes were examined by means of cobalt, ammonia, and chloride analyses, and that of lead oxalate, by lead analysis. The thermal-decomposition processes of these compounds have already been established to follow Eqs. 1—4;[2,6,7] they have also been confirmed, as is shown in Table 2.

$$6[Co(NH_3)_5Cl]Cl_2 \longrightarrow 22NH_3 + N_2 + 6NH_4Cl + 6CoCl_2$$

$$6[Co(NH_3)_5NO_2]Cl_2 \longrightarrow 7N_2 + 22NH_3 + 12H_2O + 6CoCl_2$$

$$[Co(NH_3)_5NO]Cl_2 \longrightarrow NO + 5NH_3 + CoCl_2$$

$$2PbC_2O_4 \longrightarrow CO + 3CO_2 + Pb_2O$$

The relation between the amount of gas, μmol, calculated from Eqs. 1—4 and the peak-area counts, recorded on the integrator is shown in Fig. 1. The correlation curves in Fig. 1 indicate that the amount of gas detected corresponded linearly to the weight of the compound provided for the pyrolysis. In the pyrolysis temperature range given in Table 1, the cor-

Table 1. PGC conditions

Gas	Reference material	Temperature range for pyrolysis/°C	Column Packing	Column length/m	Column temp/°C	TCD temp/°C	Retention[e] time/s
NH_3	$[Co(NH_3)_5Cl]Cl_2$	320—500	Porapak N[a]	1.5[c]	160	170	58—67
N_2	$[Co(NH_3)_5NO_2]Cl_2$	410—500	Molecular[b] Sieve 5A	3.0[d]	60	110	22—27
NO	$[Co(NH_3)_5NO]Cl_2$	180—500	Molecular[b] Sieve 5A	1.5[c]	80	110	63—70
CO	PbC_2O_4	410—500	Silica gel[b]	3.0	80	110	38—41

Column: stainless steel; 3 mm i.d. a) 50—80 mesh. b) 60—80 mesh. c) In order to reduce lingering tailing, a short column was preferred. d) In order to separate N_2 completely from adsorbed NH_3 a long column was preferred. e) The flow rate of the He-gas carrier was 25 cm^3/min.

Table 2. Analytical confirmation of decomposition products

Reference material	$CoCl_2$		NH_4Cl	NH_3[d]	Pb[b]	CO_2[e]
	Co[b]	Cl[c]	Cl[c]			
$[Co(NH_3)_5Cl]Cl_2$	23.57 (23.52)	28.73 (28.35)	13.93 (14.18)	24.96 (24.89)		
$[Co(NH_3)_5NO_2]Cl_2$	22.18 (22.58)	26.24 (27.21)		23.73 (23.89)		
$[Co(NH_3)_5NO]Cl_2$	24.25 (24.05)	28.79 (28.99)		23.54 (24.71)		
PbC_2O_4					69.87 (70.19)	22.30 (22.36)

a) Calculated values are given in parentheses. b) Determined by EDTA titration. c) Determined by the Volhard method. d) Determined by trapping the gas into a standard 0.05 M H_2SO_4 solution and then titrating the excess acid with a standard 0.1 M NaOH solution. e) Determined by trapping the gas into a standard 0.1 M NaOH solution and then titrating the excess alkali with a standard 0.05 M H_2SO_4 solution (1M=1 mol/dm³).

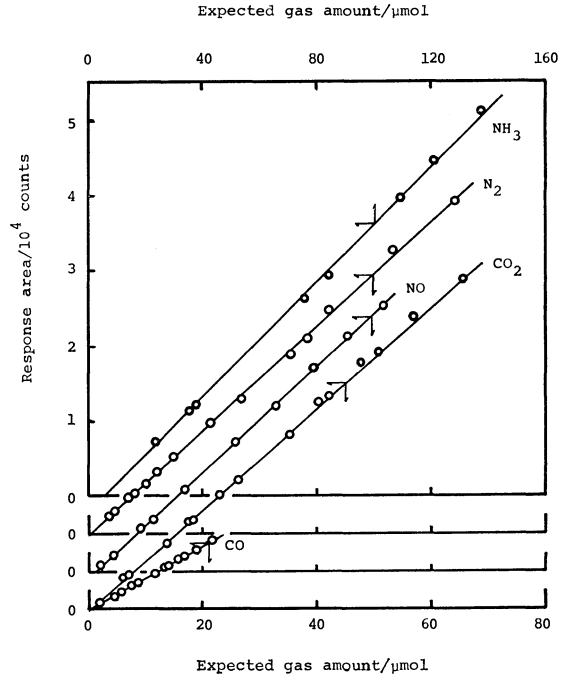

Fig. 1. Calibration curves.

relations fell on a straight line. Under the conditions employed, the weights of the compound provided for the pyrolysis were restricted within the range from 0.5 to 15 mg. Hence, the amount of gas detected corresponds to 7.3—138 μmol for ammonia, 2.2—67 μmol for nitrogen, 2.0—61 μmol for nitrogen monoxide, 0.84—26 μmol for carbon monoxide, and 2.5—76 μmol for carbon dioxide. In the correlation curves for NH_3, N_2, NO, CO, and CO_2 in Fig. 1, extraplotation gives a negative vertical intercept; this may be caused by the chromatographic tailing of these gases, which has often been observed in their GC peaks.[8] The calibration constants and precision are shown in Table 3.

Table 3. Calibration constants and precision; $F=aA-b$

Gas	a	b
NH_3	383 (±3)	2386 (±340)

Determination of Titanium(IV) Using *o*-Hydroxyhydroquinonephthalein and Tween 20

Itsuo Mori,* Yoshikazu Fujita, and Kimiko Sakaguchi
Osaka College of Pharmacy, 2-10-65, Kawai, Matsubara, Osaka 580
(Received May 13, 1982)

Synopsis. A new, simple and sensitive spectrophotometric method for the determination of titanium(IV) was studied using *o*-hydroxyhydroquinonephthalein(Qn.Ph.) and Tween 20. The analytical species of interest have an absorption maximum at 595 nm and obeyed Beer's law over the range 0.3—2.4 μg of titanium(IV) in final 10 ml solution. This method was highly sensitive in comparison with Sandell sensitivity of 0.00025 μg/cm² for titanium(IV) at an absorbance of 0.001 at 595 nm against water and the molecular extinction coefficient of the Qn.Ph.–titanium (IV) complex was 1.91×10^5 l mol^{-1} cm^{-1}.

Various spectrophotometric methods for titanium-(IV), such as tiron,[1] diantipyrylmethane(DAM),[2,3] *N*-benzoy-*N*-phenylhydroxylamine(NBNPA),[4] and trioctylphosphine oxide[5] methods, have been reported. However, most of these methods are not selective, simple, rapid and sensitive.

On the other hand, we have already reported the simple and sensitive spectrophotometries for the determination of various metal ions using *o*-hydroxyhydroquinonephthalein(Qn.Ph.).[6-8]

In this paper, fundamental conditions for the color reaction between Qn.Ph. and titanium(IV) in the presence of various surfactants, and spectrophotometry of titanium(IV) were studied.

Experimental

Apparatus. The absorbance was measured with a Shimadzu Model 202 and 240 recording spectrophotometers using matched 1.0-cm quartz cells. For pH measurements a Toa Dempa Model HM-5 pH meter was used.

Reagents. A 1.0×10^{-3} M (1 M=1 mol dm^{-3}) Qn.Ph. methanol solution was prepared according to the previous report.[6] A stock solution of titanium(IV) was prepared by dissolving of 167 mg titanium dioxide in 10 ml of 97% sulfuric acid, and diluted to 100 ml with water. The working solution was made by suitable dilution of this stock solution as required. A 5% Tween 20 soultion was prepared by dissolving the respective compound in water. All other reagents used were of analytical grade.

Standard Procedure. A solution containing 0.3—2.4 μg of titanium(IV) was placed in a 10-ml measuring flask, 1.0 ml of 5% Tween 20 solution, and 0.5 ml of 1.0×10^{-3} M Qn.Ph. solution were added. The pH of the solution was adjusted to pH 4.7 with 0.2 M sodium acetate–acetic acid buffer (Walpole buffer) solution.

Then the solution was diluted to 10 ml with water, mixed well, kept at 60 °C for 60 min, and cooled for 5 min in water. The absorbance of the Qn.Ph.–titanium(IV) solution was measured at 595 nm against water. The concentration of titanium(IV) was determined using the calibration graph.

Results and Discussion

Absorption Spectra. Figure 1 shows the absorption spectra of the Qn.Ph.–titanium(IV) complex solution and Qn.Ph. solution in the presence of Tween 20 or hexadecyltrimethylammonium chloride (HTAC) as dispersion agent, respectively. It is evident that the Qn.Ph.–titanium(IV) complex exhibits a considerable bathochromic shift in the presence of nonionic surfactant such as Tween 20, and that the complex shows maximum absorption at 595 nm against water.

Effect of pH. The aqueous solution was adjusted to various pH values with Walpole buffer solution. The maximum and constant absorbance was obtained in the pH range from 4.4 to 4.9. Subsequent measurements were carried out at pH 4.7.

Effect of Various Dispersion Agents and Stability of the Complex. The color reaction rate between Qn.Ph. and titanium(IV) was slow in the absence of surfactants. On the other hand, in the presence of nonionic surfactants such as Tween 20 this color reaction was completed in about 45 min by heating at 60 °C, and the reaction was stable with highest sensitivity. In the presence of nonionic surfactants such as poly(vinyl alcohol), poly(*N*-vinylpyrrolidone), Triton X-100 or

$C_2O_4^{2-}$	Sodium	88.0	0.470
$C_2H_2(OH)_2(COO^-)_2$	Acid	2961.4	0.478
$C_3H_4(OH)(COO^-)_2$	Acid	1891.0	0.478
Triethanolamine	—	1491.9	0.470

Ti(IV) taken: 1.2 μg; Qn.Ph.: 5.0×10^{-5} M; Tween 20: 1.0 ml of 5.0% Tween 20 solution; pH: 4.7; Reference: Water.

gelatin this color reaction increased rapidly and then decreased. The maximum and constant absorbance could be obtained over the range of 0.75 to 3.0 ml of 5% Tween 20 solution. The absorbance of the Qn. Ph.–titanium(IV) complex solution was constant and stable at least for 90 min at room temperature.

Calibration Curve. The calibration curve for the determination of titanium(IV) was prepared according to the standard procedure. Beer's law was hold in the concentration of 0.3—2.4 μg of titanium(IV) in final 10 ml. The molar absorptivity of the complex was estimated to be 1.91×10^5 l mol^{-1} cm^{-1} at 595 nm. The Sandell sensitivity was 0.00025 μg/cm^2 titanium(IV).

The precision was estimated for 1.8 μg/10 ml of titanium(IV), and the relative standard deviation was 0.46% for 8 determinations.

Effect of Foreign Ions. Interferences by various foreign ions for the determination of titanium(IV) were examined. The tolerance limit was taken as the amounts required to cause ±2% error in the absorbance. Iron(III), copper(II), aluminum(III), thorium-(IV), molybdenum(VI), vanadium(V), tin(IV), lead-(II), cyanide, sulfide, *etc.* caused a decrease in the absorbance at 595 nm. The interference of copper(II) could be overcome by addition of sodium thiosulfate solution, and that of iron(III) by addition of L-ascorbic acid solution as masking agents, respectively.

Composition of the Complex. The stoichiometry of the Qn.Ph.–titanium(IV) complex was evaluted by the continuous variation and the molar ratio methods. The results were estimated to be a defined 1:2 ratio

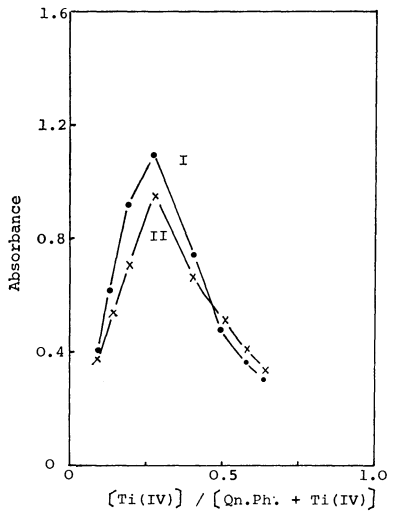

Fig. 2. Continuous variation method.
[Ti(IV)+Qn.Ph.]=2.5×10^{-5} M, Tween 20: 1.0 ml of 5% Tween 20 solution, pH: 4.7, reference: water, curve I: absorbance at 595 nm, curve II: absorbance at 580 nm.

of titanium(IV) to Qn.Ph.

Conclusion. The color reaction between Qn.Ph. and titanium(IV) complex was studied in the absence or presence of nonionic surfactancts such as Tween 20. And then, a simple and sensitive procedure for the determination of titanium(IV) using Qn.Ph. and Tween 20 was studied. The calibration curve was linear over 0.3—2.4 μg of titanium(IV) concentration. The molecular extinction coefficient of the Qn.Ph.–titanium(IV) complex was 1.91×10^5 l mol^{-1} cm^{-1}. It's sensitivity of this method was about ten times greater than DAM method,[2,3] and two fold greater than NBNPA method.[4] Therefore, this method is recommendable for the determination of microgram amounts of titanium(IV) in pigments and metallic luster agents.

Presented at the 102nd Annual Meeting of Pharmaceutical Society of Japan in Osaka, April 1982.

Geometrical Isomerization of μ-Peroxo-bis[diethylenetriamine-(*R*)-propylenediaminecobalt(III)] Ions *via* Labile Cobalt(II) Species

Yoichi SASAKI,* Masahiko TACHIBANA, and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received May 24, 1982)

Synopsis. The title complex ion undergoes slow geometrical isomerization. A mechanism involving labile cobalt(II) species which is in equilibrium with the title ion, is suggested.

Cobalt(II) complexes of various amine ligands uptake dioxygen to give μ-peroxo-dicobalt(III) complexes in basic solutions.[1,2] Such a dioxygen uptake is often reversible; *i.e.* the μ-peroxo complex is in equilibrium with the cobalt(II) complexes and O_2, the equilibrium being in great favor of the μ-peroxo complexes. Unusually rapid ligand substitution reactions of such binuclear cobalt(III) complexes are interpreted by the existence of such equilibria.[2]

Peroxo bridged dicobalt(III) compelexes containing multidentate amine ligands can give many geometrical isomers with respect to the arrangement of chelate rings. Geometrical isomerization of such complexes would not be accompanied by a significant change in their electronic absorption spectra, but can be followed by circular dichroism (CD) spectra by use of an optically active ligand such as (*R*)-propylenediamine (*R*-pn). The CD spectrum of $[(dien)(R\text{-pn})Co^{III}(\mu\text{-}O_2^{(2-)})Co^{III}(R\text{-pn})(dien)]^{4+}$ (dien=diethylenetriamine), indeed changes slowly owing to geometrical isomerization.[3] This work is aimed at clarifying the mechanism of geometrical isomerization of this complex in relation to the deoxygenation equilibrium.

Experimental

Materials. *μ-Peroxo-bis[diethylenetriamine-(R)-propylenediamine-cobalt(III)] Perchlorate, [(dien)(R-pn)Co^{III}(μ-$O_2^{(2-)}$)Co^{III}(R-pn)(dien)](ClO$_4$)$_4$*: Two samples of the complex were obtained by modifying the previously reported method.[3] An aqueous solution (40 cm^3) of cobalt(II) nitrate hexahydrate (5.8 g) containing diethylenetriamine (2.1 g), (*R*)-propylenediamine dihydrochloride (2.9 g), and sodium hydroxide (1.6 g) was aerated at 0 °C, while aqueous solution of sodium perchlorate (20 g in *ca.* 30 cm^3) was slowly added. Brown hygroscopic precipitate was filtered off after 1 h, and dried *in vacuo* (sample A). The sample A was dissolved in a minimum amount of hot water (70 °C), cooled slowly (5—10 °C per hour) to room temperature and stored in a refrigerator overnight. The dark brown needles were filtered off and dried *in vacuo* (sample B). Found: C, 18.79; H, 5.03; N, 15.27%. Calcd for $C_{14}H_{46}N_{10}O_{18}Co_2Cl_4$: C, 18.64; H, 5.14; N, 15.52%.

Other Materials: Propylenediamine was resolved by Dwyer's method.[4] Special grade reagents of diethylenetriamine, ethylenediamine, and disodium dihydrogen ethylenediaminetetraacetate dihydrate, were used as received.

Measurements. Electronic absorption and circular dichroism spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40A automatic recording spectropolarimeter, respectively. The latter and a Hitachi 124 spectrophotometer with a Hitachi recorder QPD-34 were used for the kinetic measurements.

Results and Discussion

The Change in CD Spectra. Samples A and B gave almost identical absorption, but quite different CD spectra immediately after dissolution in water (Figs. 1 (a) and (b)). Their CD spectra changed slowly with time without any clear isosbestic point, and became almost identical with each other after 3 d at 15 °C (Fig. 1 (c)). No appreciable change in absorption spectra was accompanied. The plots of CD strengths at 510, 447, and 395 nm against time failed to give simple first-order decay curves (exemplified by Fig. 2 (d)). More than three geometrical isomers seem to be responsible for the CD change. Three

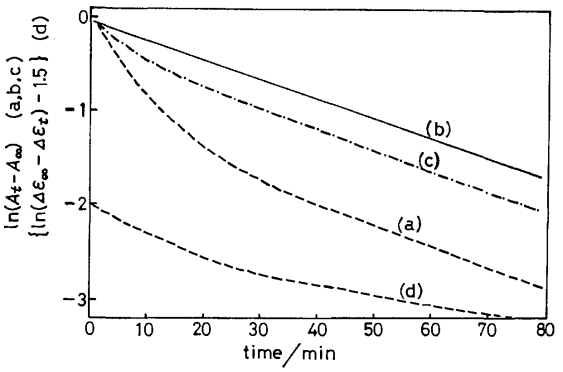

Fig. 2. First-order plots for the decrease in absorbance at 303 nm of $[(dien)(R\text{-pn})Co^{III}(\mu\text{-}O_2^{(2-)})Co^{III}(R\text{-pn})(dien)]^{4+}$ on addition of Na_2H_2edta to (a) fresh solution of sample A (----), (b) fresh solution of sample B (——), and (c) these solutions after 3 d (—·—·—), and (d) first-order plot for the change in CD strength at 447 nm of the fresh solution of sample A (——).

solutions represented by the three different CD curves in Fig. 1 should have different compositions of geometrical isomers.

Deoxygenation Kinetics. The deoxygenation can be followed by adding EDTA[5] to basic solutions of μ-peroxo complexes, EDTA scavenging cobalt(II) species to prevent reformation of μ-peroxo complexes.[2] Figure 2 shows the first-order plots of decrease in absorbance at 303 nm (common peak position of geometrical isomers of $[(dien)(R\text{-pn})Co^{III}(\mu\text{-}O_2^{(2-)})Co^{III}(R\text{-pn})(dien)]^{4+}$) at 40 °C on addition of Na_2H_2edta to basic solutions of the complex in various isomer compositions (pH, *ca.* 8). Two conclusions can be deduced from the plots: (i) Comparison of cruve (a) for the deoxygenation of sample A with curve (d) for the change in CD strength of the same solution, clearly indicates that the deoxygenation occurs much more rapidly than geometrical isomerization. (ii) The deoxygenation rate constants are significantly different among geometrical isomers, since solutions with different isomer compositions give significantly different first-order plots.

The fresh solution of sample B gave a good straight line with the first-order rate constant, 3.5×10^{-4} s^{-1} (40.0 °C, I=0.1 M (NaCl) (1 M=1 mol dm^{-3})), indicating that B is composed of only one geometrical isomer.[6] Fresh solution of sample A and aged solutions of both samples (3 d at 15 °C) gave curved plots, which can be analyzed as representing parallel deoxygenations of more than two geometrical isomers.[7] The last parts of these plots are linear with identical slopes to that of the fresh solution of sample B. The same isomer as that in sample B should be responsible at this stage. Namely the isomer in sample B decomposes at the smallest rate among the isomers. The contents of this isomer were estimated from the plots to be *ca.* 35 and 65% for the fresh and aged solutions of sample A, respectively. The initial rapid decomposition of the fresh solution of sample A gave a rate constant, 2.4×10^{-3} s^{-1}, about one order of magnitude greater than that of sample B.

Ligand Substitution Reaction. When sample B was dissolved in water ([B]=0.0006 M) containing 0.029 M ethylenediamine (en) (pH, 7.9 (ammonia buffer), I=0.05 M (NaCl)), the CD spectrum gradually disappeared without appreciable change in absorption spectrum. The first-order plot of the decrease in CD strength at 447 nm gave a straight line. The slope (3.3×10^{-4} s^{-1} at 39.8 °C) is almost identical with that for its deoxygenation under similar conditions. Thus en should replace the coordinated R-pn through rate-determining deoxygenation process. The formation of $[(en)(dien)Co^{III}(\mu\text{-}O_2^{(2-)})Co^{III}(dien)(en)]^{4+}$ from $[Co^{II}(dien)(en)(H_2O)]^{2+}$ and O_2, as well as the ligand substitution at cobalt(II) state, should be rapid.

Mechanism of the Geometrical Isomerization. The deoxygenation occurs much more rapidly than the CD change in the solution of sample A. Thus, the geometrical isomerization can take place at labile cobalt(II) state which is in equilibrium with the μ-peroxo complex. Such a view is supported by the complete replacement of en for the coordinated R-pn with rate-determining deoxygenation.

Rate of the formation of μ-peroxo complexes from cobalt(II) complexes and O_2 are similar to one another (second-order rate constants, 10^5—10^6 M^{-1} s^{-1} at 25 °C) for even those with different ligands such as $[Co^{II}(NH_3)_5(H_2O)]^{2+}$ and $[Co^{II}(tetren)(H_2O)]^{2+}$ (tetren= tetraethylenepentamine).[8] Thus the formation rates of the μ-peroxo complexes would not be significantly different among the geometrical isomers of $[Co^{II}(dien)(R\text{-pn})(H_2O)]^{2+}$. The initial product of the μ-peroxo complex, sample A, can be a mixture of various isomers. The small CD strength may result from the cancellation of CD spectra of various isomers. The deoxygenation rates are, on the other hand, significantly different among geometrical isomers (Fig. 2). Such a difference would result in the geometrical isomerization in the solution of sample A. Isomers with small deoxygenation rates should accumulate gradually to give thermally equilibrated isomer distribution, of which the deoxygenation pattern is represented by the curve (c) in Fig. 1.

The present results show that the deoxygenation rather than the formation rate is important in determining the stability of μ-peroxo complexes.

Studies on Some Azine Complexes of Lanthanum(III) and Samarium(III)

Satya Prakash MITAL, Ranvir V. SINGH, and Jagdish Prasad TANDON*

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received August 18, 1981)

Synopsis. Pentacoordinated lanthanum(III) and samarium(III) complexes of salicylaldehydeazine and 2-hydroxy-1-naphthaldehydeazine have been synthesized and characterized by elemental analysis, molecular weight determinations, conductance, and magnetic measurements as well as infrared, ultraviolet spectral, and X-ray powder diffraction studies. Their pyrolytic behaviour has also been discussed.

Although, the azine complexes of d-block elements have been extensively studied,[1,2] similar investigations on f-block elements appear to be limited.[3] In view of this, it was considered worthwhile to study the chelating behaviour of azines towards lanthanum(III) and samarium(III) and the results are presented in this paper.

Experimental

All the chemicals used were of analytical grade. Adequate precautions were taken to exclude moisture throughout the experimental work. The triisopropoxylanthanum(III) or -samarium(III)[4] and azines[1,3] were prepared by the literature methods.

The analytical methods and the techniques of physical measurements are the same as reported in our previous communications.[5,6]

Synthesis of Azine Complexes of Lanthanum(III) or Samarium(III): The mixture of triisopropoxylanthanum(III) or -samarium(III) with the stoichiometric amount of azine was heated under reflux for about 8—24 h in benzene medium. The liberated 2-propanol was fractionated azeotropically and then estimated to ascertain the progress of the reaction. On its completion, the excess of the solvent was stripped off under reduced pressure and the residue washed several times with hexane. Finally, the resulting products were dried under vacuum at 50—60 °C/0.5 mmHg† for ≈3 h.

The azinatolanthanum(III) or samarium(III) *t*-butoxides were prepared by refluxing the benzene solution of freshly prepared azinatolanthanum(III) or -samarium(III) isopropoxide with an excess of *t*-butyl alcohol for ≈30 h with continuous removal of benzene-2-propanol azeotrope. After completion of the reaction, the products were isolated by removing the solvent under reduced pressure and subsequent drying.

The analytical data and characteristics of the resulting compounds are recorded in Table 1.

Results and Discussion

These complexes have been synthesized as shown by the following equations:

$$(OC_3H_7^i)_3Ln + azH_2 \longrightarrow (OC_3H_7^i)Ln(az) + 2i\text{-}C_3H_7OH$$

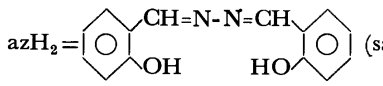
$$2(OC_3H_7^i)_3Ln + 3azH_2 \longrightarrow Ln_2(az)_3 + 6i\text{-}C_3H_7OH$$

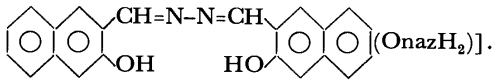
$$(OC_3H_7^i)_3Ln + 2azH_2 \longrightarrow Ln(az)(azH) + 3i\text{-}C_3H_7OH$$

$$(OC_3H_7^i)Ln(az) + t\text{-}C_4H_9OH \longrightarrow \underset{\text{(in excess)}}{} (OC_4H_9^t)Ln(az) + i\text{-}C_3H_7OH$$

† 1 mmHg≈133.322 Pa.

[where Ln=La(III) or Sm(III);





The resulting complexes, $(OC_3H_7^i)Ln$(saz or Onaz), Ln_2(saz or Onaz)$_3$, Ln(saz or Onaz) (sazH or OnazH), and $(OC_4H_9^t)Ln$(saz or Onaz) are yellow to reddish brown coloured, nonvolatile solids and decompose without melting when heated above 200 °C. These are insoluble or sparingly soluble in common organic solvents but soluble in DMF or DMSO and in which these behave as nonelectrolytes ($\mu<20\ \Omega^{-1}\ mol^{-1}\ cm^2$). The alkoxy derivatives, (OR)Ln(az) [where R=Pr^i or Bu^t] are highly moisture sensitive. The azinatolanthanum(III) or -samarium(III) isopropoxides are dimeric, where as the rest of the derivatives are monomeric in nature.

The broad absorption band in the region, 3400—3050 cm^{-1}, due to the hydrogen bonded OH or NH group in the IR spectra of azines disappears in $(OC_3H_7^i$ or $OC_4H_9^t)Ln(az)$ and $Ln_2(az)_3$ complexes indicating the deprotonation of the phenolic protons. However, the characteristic band of νOH/νNH is observed at almost the same position in the spectra of Ln(az)(azH) complexes indicating thereby that at least one hydroxyl group of the two ligand moieties does not take part in coordination.

On the other hand, a strong band at 1610±10 cm^{-1} in the spectra of ligands due to the azomethine (>C=N–)groups splits at 1605±5 and 1580±5 cm^{-1} in the spectra of lanthanum(III) and samarium(III) complexes indicating two different environments around both the azomethine groups of the ligand moiety in the complexes and which is probably due to the coordination of only one unsaturated nitrogen of the ligand to the lanthanoid atom.

The medium to weak intensity bands at 650±10 and 375±10 cm^{-1} in the spectra of azinatolanthanoid complexes may be tentatively assigned to the ring deformation coupled with ν Ln–O and C–H out of plane deformation[7] and ν Ln–N respectively.[8,9]

A bathochromic shift in the transitions of >C=N– chromophore at ≈350 and 425 nm [335 and 415 nm in 2-hydroxy-1-naphthaldehydeazine] in the ultraviolet spectra of lanthanoid complexes probably indicates the formation of Ln–N bond.

The magnetic susceptibilities of these complexes measured at room temperature (35±1 °C) show that the azinatolanthanum(III) complexes are diamagnetic (X_g values-0.34 to -0.92×10^{-6} c.g.s.), whereas the azinatosamarium(III) complexes are paramagnetic (μ eff$_{exp}$=1.25—1.57 BM) in nature.

a) D. P.: Decomposition temperature.

Attempts to grow crystals of suitable size for X-ray crystal diffraction studies remained unsuccessful. However, the X-ray powder diffraction patterns have been recorded and these indicate that the compounds $(OC_3H_7^i)$Sm(saz), $Sm_2(saz)_3$, and Sm(saz)(sazH) belong to the orthorhombic symmetry having the molecular unit cell parameters a,b,c (in Å) and Z as 12.64, 16.37, 14.71, and 4; 12.61, 15.63, 30.46, and 4; 6.70, 15.24, 18.28, and 2, respectively.

The comparative thermal stability of the complexes, $(OC_3H_7^i)$Sm(saz), $Sm_2(saz)_3$, and Sm(saz)(sazH) on the basis of IPDT values (549.2, 537.0, and 507.4, respectively) has been evaluated from the pyrolytic curves plotted in the percentage residual weight against the temperature. The activation energy E_A (K· Cal) and order of reaction $n[E_A, n$: 5.72, 1; 4.35, 1; 4.12, 1, respectively] have also been determined with the help of Freeman and Carroll's method.[10] The following order of thermal stability of the complexes has been noted:

$(OC_3H_7^i)$Sm(saz)>$Sm_2(saz)_3$>Sm(saz)(sazH).

The authors are thankful to the University Grants Commission, New Delhi for the financial support to one of us (S.P.M.).

The Favorskii-type Rearrangement of 3-Bromo-β-ionone with Sodium Ethoxide

Masato NANASAWA* and Hiroyoshi KAMOGAWA

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received August 21, 1981)

Synopsis. The reaction of 3-bromo-β-ionone with sodium ethoxide afforded ethyl 4-(2,6,6-trimethyl-2-cyclohexenylidene)butyrate by a Favorskii-type rearrangement, accompanied by double-bond migration, while with sodium phenoxide or diethyl amine, substitution products were primarily obtained.

In the course of studies of the nucleophilic substitution of 3-bromo-β-ionone (**1**) with the sodiomalonic ester, we have found that the major product thus obtained was an ester with a loss of ketone carbonyl. The preparation of esters from α-halo ketones by the action of bases is known as the Favorskii rearrangement,[1] but there have been no reports on the rearrangement of halo ketones having the halogen atom separated from the carbonyl group by conjugated double bonds. For examining this new type of Favorskii rearrangement in more detail, we conducted the reaction of **1** with several kinds of bases and discussed the reaction mechanism.

The reaction of **1** with sodium ethoxide gave a straight chain ester and 3-ethoxy-β-ionone in the ratio of *ca.* 10:1 (Table 1, Exptl No. 1). The same ester was also obtained when **1** was subjected to the usual conditions of malonic-ester synthesis in ethanol (No. 4), while the reactions with diethyl sodiomalonate in tetrahydrofuran (No. 3), phenoxide (No. 5), or diethyl amine (No. 6) in ethanol gave only substitution products. The UV and ^{1}H-NMR spectra of the ester indicated that the double bond conjugated to the carbonyl group no longer exists; the IR spectrum also indicated the disappearance of the *trans*-double bond, and other analytical results identified the structure of the ester (**8**).

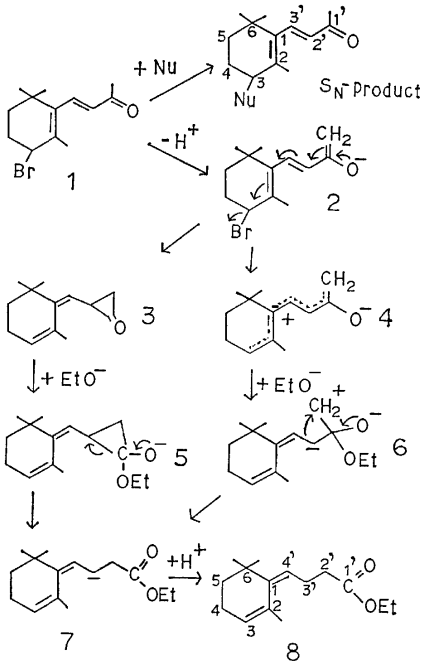
The initial step of the Favorskii rearrangement of α-halo ketones with bases was considered to be a proton abstraction; the resulting enolate anion induces the production of a cyclopropanone or a zwitterion to form a commonly α-branched ester.[2] This suggests that the enolate anion (**2**) might undergo the ejection of bromine with concerted or subsequent double-bond migration by an internal S_N2'-type displacement.[3] The opening of the cyclopropanone ring (**3**) or rearrangement of the zwitterion (**4**) by the attack of the ethoxide ions should give a more stable carbanion. The carbanion in **7** is more stable than the α-branched methylide intermediate because of the resonance stabilization with conjugated double bonds as well as its secondary character, thereby leading to ethyl 4-(2,6,6-trimethyl-2-cyclohexenylidene)butyrate (**8**) as the principal product.

The rate of nucleophilic substitution might be slow at the 3-position of the ring with a boat conformation due to the steric hindrance by the 2,6,6-trimethyl groups, whereas the rearrangement by the removal of enolic hydrogen is facilitated by the presence of the conjugated double bonds at the α-position. Thus, sodium ethoxide in even a minor amount may remove the enolic hydrogen to give the rearrangement intermediate in spite of the unfavorable equilibrium between sodium ethoxide and diethyl sodiomalonate in ethanol; the resulting intermediate (**3** or **4**) might be very unstable and might react easily with excess ethanol as the solvent to form the ethyl ester. The acidity of the enol-tautomer in **1** might not be so large as those of acyclic α-halo ketones[4] and α-haloarylalkyl ketones;[5] therefore, the formation of the enolate anion did not occur with weak bases, but substitution products were primarily formed.

Table 1. The reaction of 3-bromo-β-ionone with nucleophiles

Exptl No.	Nucleophile[a]	Solvent	Reaction product: Rearrangement	Reaction product: Substitution
1	EtONa	EtOH	81%	8%
2	EtONa[b]	EtOH	72	16
3	$NaCH(COOEt)_2$	THF	0	82
4	$NaCH(COOEt)_2$	EtOH	52	32[c]
5	PhONa	EtOH	0	87
6	Et_2NH	EtOH	0	88

a) Two equivalents for 3-bromo-β-ionone. b) Equimolar amount. c) Substitution product with diethyl sodiomalonate.



Scheme 1.

Experimental

The infrared, ultraviolet, ^{1}H-NMR, ^{13}C-NMR, and mass spectra were obtained using Hitachi 215, Hitachi 200-10, JEOL-PMX 60, JEOL-FX 90Q, and Hitachi RMU-6MG spectrometers respectively. Elemental analyses were conducted using a Perkin Elmer 250 instrument.

3-Bromo-β-ionone(**1**) was prepared with β-ionone and *N*-bromosuccinimide in carbon tetrachloride.[6] Since the brominated compound was presumed to be unstable, the crude product after the filtration of succinimide was used for the next process without purification.[7] ^{1}H-NMR(CCl_4): δ= 1.08(s, 6-Me_2), 1.62(m, 5-H_2), 1.85(s, 2-Me), 2.13(d, J= 6 Hz, 4-H_2), 2.20(s, 1'-Me), 4.61(br s, 3-H), 6.05(d, J= 16 Hz, 2'-H), 7.15(d, J=17 Hz, 3'-H).

*Ethyl 4-(2,6,6-Trimethyl-2-cyclohexenylidene)butyrate (**8**)*: A solution of **1** (4.2 g, 15.6 mmol) in carbon tetrachloride (8 ml) was added to freshly prepared ethanolic sodium ethoxide (31.2 mmol in 40 ml) at room temperature. The mixture was stirred overnight and then poured into water (100 ml). The product was extracted with ether and the organic layer was washed with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to give an orange oil. It was chromatographed over a silica-gel column (Wako C-300) with ether in hexane (2% v/v) to give **8** in an 81% yield based on **1**. Bp 110—112 °C/0.7 mmHg. UV_{max} ($CHCl_3$): 242 nm. IR($CHCl_3$): 1725 cm^{-1} (ester). ^{1}H-NMR($CDCl_3$): δ=1.01 (s, 6H, 6-Me_2), 1.33 (t, J=8 Hz, ester-CH_3), 1.2—1.6 (m, 5-H_2), 1.9—2.1 (m, 4-H_2), 2.03 (s, 2-Me)), 2.2—2.6 (m, 4H, 2'-H_2, 3'-H_2), 4.21 (q, 2H, J=7 Hz, ester-CH_2), 5.25 (t, 1H, J=5 Hz), 5.55 (t, 1H). ^{13}C-NMR($CDCl_3$): δ=14.1(ester-CH_3), 23.6 (2-Me), 24.4 (3'), 27.5 (6-Me_2), 27.9 (6), 35.3(4), 35.4(2'), 37.0(5), 60.0 (ester-CH_2), 120.4(3), 127.9(4'), 131.6(2), 145.2(1), 172.9 (1'). MS, *m/e*(rel intensity): 236 (M^+, 18.7), 88 (100). Found: C, 75.62; H, 10.20%. Calcd for $C_{15}H_{24}O_2$: C, 76.21; H, 10.24%.

*Malonic Ester Synthesis Applied to **1** in Ethanol*: Diethyl sodiomalonate was prepared with diethyl malonate (37.4 mmol) and sodium ethoxide (31.2 mmol) in ethanol (50 ml) at 55 °C for 30 min. The reaction conditions were similar to those used for **8**. The reaction product was chromatographed over a silica-gel column with ether in hexane (2%) to give **8** in a 52% yield, subsequent elution with ether in hexane (50%) gave 3-[bis(ethoxycarbonyl)methyl]-β-ionone in a 32% yield. UV_{max}($CHCl_3$): 291 nm. IR ($CHCl_3$): 1725(ester), 1660(ketone), 970(CH:CH) cm^{-1}. ^{1}H-NMR($CDCl_3$): δ=1.05 (s, 6H, 6-Me_2), 1.28 (t, 6H, J=7 Hz, ester-CH_3), 1.7—2.0 (m, 4,5-H_2, 3-H), 1.74(s, 2-Me), 2.2(s, 3H, 1'-Me), 3.78(d, 1H, J=5 Hz, 3-CH), 4.23(q, 4H, J=7 Hz, ester-CH_2), 6.10(d, 1H, J=17 Hz, 2'-H), 7.31(d, 1H, J=17 Hz, 3'-H). ^{13}C-NMR($CDCl_3$): δ=13.9 (ester-CH_3), 19.8(4), 21.7(2-Me), 26.9(1'-Me), 27.9, 28.8(6-Me_2), 34.3(6), 37.0(3), 41.4(5), 53.7(3-CH), 60.9, 61.1(ester-CH_2), 131.9(2), 133.0(3'), 139.6(1), 143.2(2'), 168.0, 168.8(ester C=O), 197.9(1'). MS, *m/e*: 350(M^+, 3), 55(100). Found: C, 69.00; H, 8.75%. Calcd for $C_{20}H_{30}O_5$: C, 68.54; H, 8.62%.

Nucleophilic Substitution with Sodium Phenoxide: A mixture of **1** (15.6 mmol) and sodium phenoxide (32 mmol) in ethanol (30 ml) was stirred overnight at room temperature and then poured into a cold 5% aqueous sodium hydroxide solution. The reaction product was extracted with ether, and the organic layer was washed with a 2% aqueous sodium hydroxide solution and water, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. Subsequent silica gel chromatography afforded 3-phenoxy-β-ionone (hexane–ether, 9:1) in an 87% yield. UV_{max}($CHCl_3$): 285, 275^{sh} nm. IR($CHCl_3$): 1660(ketone), 995(phenoxy), 970(CH:CH) cm^{-1}. ^{1}H-NMR($CDCl_3$): δ=4.48(t, 1H, 3-H), 6.17(d, 1H, J= 17 Hz, 2'-H), 6.9—7.7(m, 6H, phenyl, 3'-H). ^{13}C-NMR ($CDCl_3$): δ=18.8(4), 24.1(2-Me), 27.1, 27.4(6-Me_2), 28.8 (1'-Me), 34.5(5), 34.6(6), 75.7(3), 116, 121.0, 129.5(*o*-, *p*-, and *m*-phenyl carbon), 131.3(2), 133.2(3'), 140.9(1), 142.3 (2'), 158.5 (3-O-C), 198.0(1'). MS, *m/e*: 284(M^+, 2.9), 191(100). Found: C, 79.87; H, 8.56%. Calcd for $C_{19}H_{24}O_2$: C, 80.24; H, 8.50%.

(Received November 9, 1981)

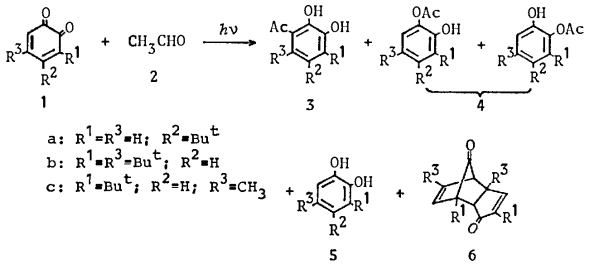
Synopsis. The irradiation of several alkyl-substituted *o*-benzoquinones in the presence of acetaldehyde gave the corresponding acetylcatechol and catechol monoacetates *via* the attack of the acetyl radical on the ground-state quinone molecule. In the reaction of 3,5-di-*t*-butyl- and 3-*t*-butyl-5-methyl-*o*-benzoquinones, the dimer of alkyl-substituted cyclopentadienone, generated by the photodecarbonylation of the quinones, was also obtained.

There have been reported only a few examples of photochemical reactions between *o*-benzoquinone and aldehyde.[1] For example, tetrachloro- and tetrabromo-*o*-benzoquinones usually give the tetrahalocatechol monoesters in a reaction with acetaldehyde and benzaldehyde.[1] In these quinones, the reactive quinonoid bonds are completely replaced with halogen atoms. We ourselves reported recently that 3-acetyl-1,2-naphthalenediol was formed, together with a mixture of 1,2-naphthalenediol monoacetates, in the photochemical reaction of 1,2-naphthoquinone with acetaldehyde.[2] It was, therefore, of interest to examine the possibility of introducing an acetyl group into the quinonoid nucleus of *o*-benzoquinone. In this paper we wish to report the product analyses and reaction courses of the photochemical reactions of mono- and dialkyl-substituted *o*-benzoquinones with acetaldehyde.

The irradiation of a benzene solution of 4-*t*-butyl-*o*-benzoquinone (**1a**) in the presence of a large excess of acetaldehyde (**2**) gave acetylcatechol (**3a**) (20%) and an isomeric mixture of catechol monoacetates (**4a**) (20%). The structures of the products were confirmed by their spectral data and elemental analyses.

The photo-induced reaction of 3,5-di-*t*-butyl-*o*-benzoquinone (**1b**) with **2** produced **3b**, **4b**, **5b**, and the dimer (**6b**) of 2,4-di-*t*-butylcyclopentadienone (CPD) in 6, 36, 22, and 4.5% yields respectively. 3-*t*-Butyl-5-methyl-o-benzoquinone (**1c**) similarly reacted with **2** to give **3c** (12%), **4c** (14%), and **6c** (1%), but no **5c** could be isolated (Scheme 1).

Recently, CPD was obtained from the UV irradiation of **1b**, and it dimerized at room temperature to give **6b** in the mode of Diels-Alder reaction.[3] Actually, two dimers, **6b** and **6c**, were obtained, in yields of 50 and 43% respectively, from the photolysis of a benzene solution of **1b** and **1c** in the absence of **2**; carbon monoxide was also evolved.



Scheme 1.

Thus, the irradiation of mono- and dialkyl-substituted *o*-benzoquinones in **2** gives acetylcatechols, together with catechol monoacetates, although a little photodecarbonylation occurs when **1b** and **1c** are irradiated in the aldehyde.

As for the mechanism of the formation of acetylcatechol and catechol monoacetates, two possibilities have been considered. One is an "in-cage" mechanism, *i.e.*, a process involving the combination of the radical pair consisting of *o*-benzosemiquinone and acetyl radicals in the solvent cage formed by the abstraction of formyl hydrogen from **2** by the excited quinone. The photo-CIDNP technique provides invaluable information for investigating such a radical-pair process.[2] Since, however, no ^{1}H-CIDNP signals could be observed in the reaction of **1a** with **2**, such an "in-cage" mechanism can be excluded.

An alternative mechanism is an "out-of-cage" one, *i.e.*, a process involving the addition of the free acetyl radical which escaped from the solvent cage to ground-state quinone.[2] In order to clarify the possibility, the addition reaction of the free acetyl radical to **1a** in the ground state was undertaken. The treatment of a benzene solution of **1a** and **2** with di-*t*-butyl diperoxyoxalate (DTBP)[4] in the dark allowed us to generate the necessary reacting conditions. When the decomposition of DTBP was carried out at 38 °C in a benzene solution of **1a** and **2**, **3a** and **4a**, which were the same products as those obtained from the photochemical reaction, were isolated in yields of 26 and 7% respectively; a diacetylated product (**7**) was also isolated in a yield of 6% (Scheme 2).

A benzene solution of **3a** and **2** was treated with DTBP to give **7** in a 25% yield. A similar treatment of **4a**, however, led to an almost quantitative recovery

of the starting material. These results suggest that **7** may arise *via* **3a**. In addition, the photo-induced Fries rearrangement of **4a** to **3a** is unlikely under the irradiation conditions in this work, since **4a** does not absorb in the visible region. These results strongly supported the "out-of-cage" process for the mechanism of the present photo-induced reductive acetylation (Scheme 3).

Experimental

The IR, ^{1}H-NMR, and ^{13}C-NMR spectra were recorded on a Hitachi 215 spectrometer, a JEOL MH-100 spectrometer (internal TMS standard), and JEOL FX-100 FT NMR spectrometer respectively. Microanalysis was carried out on a Yanaco MT-2 CHN corder. The yields are based on the quinone used.

Materials. 4-*t*-Butyl- and 3,5-di-*t*-butyl-o-benzoquinones(**1a** and **1b**) were prepared by the oxidation of the corresponding catechols with silver oxide; **1a**: mp 66—68 °C (lit,[5] 68 °C). **1b**: mp 113—114 °C(lit,[3] 114—115 °C). 3-*t*-Butyl-5-methyl-*o*-benzoquinone(**1c**) was prepared by the oxidation of 2-*t*-butyl-4-methylphenol with Fremy's salt; **1c**, IR(KBr): $\nu_{C=O}$ 1660 cm^{-1}, mp 68—70 °C. DTBP was prepared according to the method described in the literature.[4]

General Procedures. A benzene solution (60 ml) of *o*-benzoquinone (2 mmol) and an excess of **2**(10 ml) was irradiated (>400 nm; Toshiba glass filter: VY-42) with a light from a 300W high-pressure Hg arc lamp through a 5 cm-thick layer of cold water (5 °C). When the *o*-benzoquinone had mostly disappeared, the solvent was removed *in vacuo*; then, the resulting oil was chromatographed by means of preparative TLC and eluted with benzene. The products thus obtained were purified by recrystallization from appropriate solvents or by TLC. The melting points, spectroscopic properties, and analytical data of the reductive acetylation products are given in Tables 1 and 2.

Photolyses of 1b and 1c. A pyrex test tube was charged with **1b** (1 mmol) or **1c** (1 mmol) and benzene (20 ml). The solution was then irradiated for 2 days. The volumes of carbon monoxide evolved during the photolyses of **1b** and **1c** were 11.7 and 10.5 ml respectively. After the removal of the benzene under reduced pressure, the resulting oil was chromatographed by means of TLC to give **6b**(50%) and **6c**(43%) respectively. **6b**: needles from ethanol; mp 153—154 °C(lit,[3] 152.5—153 °C). **6c**: needles from ethanol; mp 110—111 °C. IR(KBr) 1780(C=O) and 1696(C=O) cm^{-1}. ^{1}H-NMR(CCl_4): δ=1.10(s, 9H), 1.34(s, 3H), 1.72 (d, J=2.0 Hz, 3H), 2.28(s, 1H), 2.43(s, 1H), 5.58(q, J=2.0 Hz, 1H), and 6.66(s, 1H). ^{13}C-NMR($CDCl_3$): δ=204.9 (s), 200.6(s), 158.5(s), 155.1(d), 139.8(s), 125.8(d), 67.3(s), 61.1(d), 53.9(d), 44.8(s), 32.0(s), 31.0(s), 28.3(q), 27.1(q), 21.5(q), and 18.3(q). Found: C, 79.79; H, 9.44%. Calcd for $C_{20}H_{28}O_2$: C, 79.96; H, 9.39%. The dimers, **6b** and **6c**, were also obtained, in yields of 4.5 and 1% respectively, from the photochemical reactions of **1b** and **1c** with **2** (see Scheme 1).

a) Solvent: chloroform-*d*.

Reaction Involving DTBP. *(a)*: A benzene solution of **1a** (1.5 mmol), **2** (4 ml), and DTBP (1.5 ml) was kept in the dark at 38 °C for 7 h. The resulting yellow solution was concentrated *in vacuo*, and then the residual oil was chromatographed on TLC to give **3a**(26%), **4a**(7%), and **7**(6%). **7**: pale yellow oil. IR(CCl_4): 3530(OH), 1775 (ester C=O), and 1645(C=O) cm^{-1}. ^{1}H-NMR(CCl_4): δ= 1.33(s, 9H), 2.25(s, 3H), 2.60(s, 3H), 7.19(d, J=2.0 Hz, 1H), 7.50(d, J=2.0 Hz, 1H), and 12.6(s, 1H). Found: C, 67.00: H, 7.38%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

(b): A benzene solution of **3a** (0.073 mmol), DTBP (0.074 mmol), and **2**(1 ml) was kept in the dark at 38 °C for 1 h. The subsequent separation of the products by TLC gave **7**(25%) and recovered **3a**.

(c): A benzene solution(10 ml) of **4a**(0.25 mmol), DTBP (0.25 mmol), and **2**(12 mmol) was kept in the dark at 38 °C for 3 h; **4a** was recovered almost quantitatively.

Photolysis of *o*-(*N*-Alkylacylamino)benzophenones

Tadashi HASEGAWA,* Satomi KOSAKU, Junko UENO, and Shōshichi OGUCHI
Department of Chemistry, Tokyo Gakugei University, Nukuikitamachi, Koganei, Tokyo 184
(Received March 15, 1982)

Synopsis. The photochemical reactions of *o*-(*N*-alkylacylamino)benzophenones have been studied. Photochemical behavior of the (acylamino)benzophenones was dependent on the solvent polarity. The (acylamino)benzophenones underwent photodeacylation in polar solvents and photodealkylation in nonpolar solvents.

Hydrogen abstraction by benzophenone and its derivatives is one of the most extensively studied primary photochemical processes. It is now well established that the n,π^* triplet state of the benzophenones undergo hydrogen abstraction and that the π,π^* states are generally inert toward the primary photochemical process.[1] We previously reported photocyclization of *o*-(dialkylamino)benzophenones to indoles *via* intramolecular δ-hydrogen abstraction by the excited carbonyl oxygen.[2] We report here that *o*-(*N*-alkylacylamino)benzophenones undergo unusual photoreactions depending on the solvent polarity.

	R	R′	Solvent	**2**(%)	**3**(%)

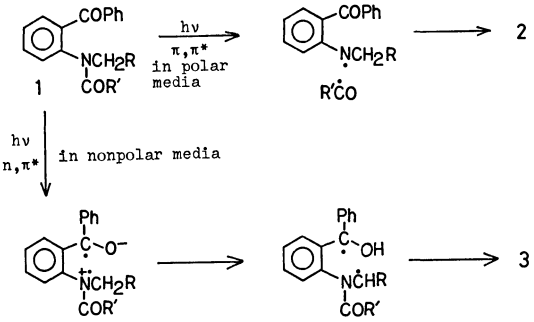
b :	Ph	Ph	MeOH	70	—
			C_6H_6	5	28
c :	H	Me	MeOH	88	—
d :	Ph	Me	MeOH	89	—
			C_6H_6	—	Trace

A methanol solution of *o*-(*N*-methylbenzoylamino)-benzophenone (**1a**) was irradiated under nitrogen with a 450 W high-pressure mercury lamp through a Pyrex filter. After removal of the solvent, the residue was chromatographed on silica gel to yield *o*-(methylamino)-benzophenone (**2a**) and benzoic acid in 57 and 38% yield, respectively. Similarly, irradiation of the (acylamino)benzophenone **1b—d** under the same conditions gave the corresponding (alkylamino)benzophenone **2**. A trace of *o*-aminobenzophenone (**4**) was also obtained in the cases of photolyses of **1b** and **1d**.[3] No indoles, which were expected to form *via* δ-hydrogen abstraction by the excited carbonyl group, and no methyl esters were detected in all cases. The isolation of benzoic acid in the photolysis of **1a** and the absence of methyl esters suggest that the deacylation proceeds *via* homolytic cleavage of CO–N bond. Photodeacylation is well known in the photochemistry of imides.[4] The (acylamino)benzophenone **1** is considered to be the aromatic vinylog of imides.



The quantum yield for production of **2c** from **1c** in methanol was taken as 0.05. The quantum yield was dependent on the solvent polarity. Polar solvents appreciably enhance the quantum efficiency with which the acylamino ketone **1c** undergoes photodeacylation in solution. (Fig. 1) The acylamino ketone **1c** in hexane showed an ultraviolet-absorption peak at 334 nm (ε 140) attributable to the n,π^* transition. This peak underwent blue shift in ethanol and was discerned at 330 nm as a shoulder. These results indicate that the relative disposition of the n,π^* and the π,π^* states of the ketone **1c** is reversed in polar media compared to that in nonpolar media and that photodeacylation occurs from the π,π^* excited state of the acylamino ketone **1c**.

In the case of photolysis of **1b** in benzene *o*-(benzoylamino)benzophenone (**3b**, 28%) was obtained as the main photoproduct, together with **2b** (5%) and a trace of **4**. Similarly, irradiation of *N*-benzylamide **1d** under the same conditions gave a trace of dealkylated photoproduct **3d**. On the other hand, no dealkylated photoproducts could be detected in the cases of *N*-methylamide **1a** and **1c** in benzene. Gold suggested that the Type II cyclization predominated over the Type II elimination in photochemistry of acylamino ketones;[5] however, no indoles could be detected in photolysis of **1** in benzene. The dealkylation

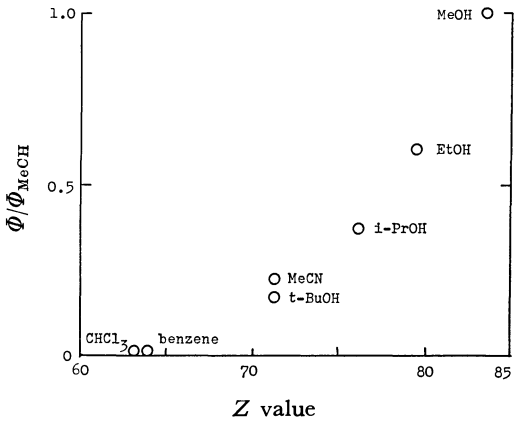


Fig. 1. Relative quantum yields for production of **2c**[a] as a function of solvent polarity (*Z* value[b]).
a) The (acylamino)benzophenone **1c** was irradiated at 313 nm. Production of **2c** was measured by UV spectroscopy. b) [E. M. Kosower, *J. Am. Chem. Soc. Soc.*, **80**, 3253 (1958).

product **3b** formed in benzene could not be detected in the photolysis of **1b** in methanol. We have already reported that a smilar photochemical dealkylation occurred in *o*-(dialkylamino)benzophenones.[2] Production of acylamino ketone **3** can be explained in terms of photodealkylation via intramolecular δ-hydrogen abstraction by the excited carbonyl group. A similar photochemical dealkylation of *o*-methoxybenzophenone via intramolecular δ-hydrogen abstraction by the carbonyl group has been reported by Leary and Oliver.[6] The solvent effect described above also suggests that dealkylation takes place from the n,π^* state of the acylamino ketone **1**.

Quenching of the photodealkylation of the acylamino ketone **1b** by 0.1 M 1,3-pentadiene (E_T=57 kcal)[7] was not observed. The photodealkylation may be considered to proceed from the n,π^* singlet state of the (acylamino)benzophenone **1b**. However, it is quite improbable that δ-hydrogen abstraction from the n,π^* singlet state can compete with intersystem crossing because the rate of intersystem crossing of benzophenone is very rapid (*ca.* 10^{11} s^{-1}).[1] Therefore, the photodealkylation seems to be reasonably explained in terms of the charge-transfer mechanism from the n,π^* state. The charge-transfer interaction is considered to contribute in the excited state of aminobenzophenone,[8] and the interaction between amide nitrogen and carbonyl oxygen was reported in photochemistry of β-oxo amides.[9]

Experimental

Chemicals. The (acylamino)benzophenones **1a—d** were prepared by the usual methods from (alkylamino)-benzophenone, and benzoyl chloride or acetic anhydride.[10]

General Procedure for Photolysis of (Acylamino)benzophenone 1. An (acylamino)benzophenone **1** (500 mg) in solvent (70 ml) was irradiated under nitrogen with a 450 W high-pressure mercury lamp (Ushio Elect. Co.) through a Pyrex filter. After removal of the solvent, the residue was chromatographed on silica gel. Elution with a mixture of benzene–ethyl acetate gave an amino ketone **2** and/or an acylamino ketone **3**. The structure of **2** and **3** were determined by direct comparison with authentic samples.[10]

Quantun Yield Determinations. The degassed solution of (acylamino)benzophenone **1** was irradiated on a merry-go-round apparatus using a 100 W high-pressure mercury lamp (Taika Elect. Co.) and a potassium chromate filter solution to isolate 313 nm irradiation. Production of **2** was measured by a Hitachi EPS-033 UV spectroscopy. Valerophenone was used as a chemical actinometer.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56740205 from the Ministry of Education, Science and Culture.

A Synthetic Route to (±)-Tetrahydroanhydroaucubigenone

Hiroshi KIMURA, Heitaro OBARA,* and Sei TAKAHASHI

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

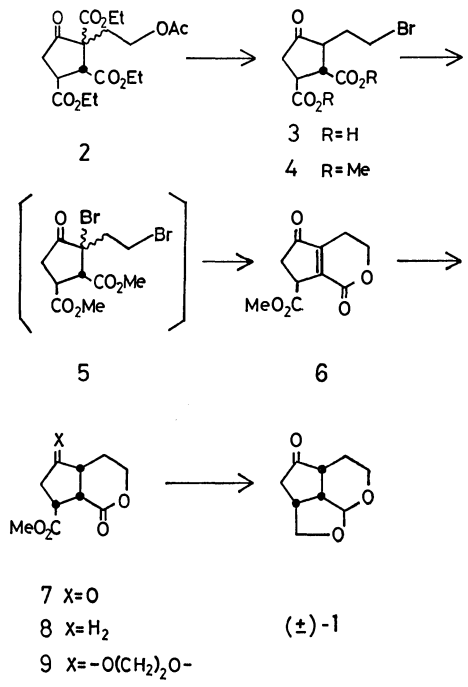
(Received March 23, 1982)

Synopsis. (±)-Tetrahydroanhydroaucubigenone was synthesized by partial reduction, followed by acid hydrolysis, of (4a*RS*,7*RS*,7a*SR*)-7-(methoxycarbonyl)octahydrocyclopenta[*c*]pyran-1,5-dione ethylene acetal, which was prepared from 2,3,4-tris(ethoxycarbonyl)cyclopentanone through 7 steps.

Tetrahydroanhydroaucubigenone (**1**),[1] a unique tricyclic acetal ketone, has been known to be one of the key compounds for the determination of aucubin.[2] Recently, we have succeeded in the synthesis of the racemate of **1** by photo-irradiation of 6-[2-(nitrosooxy)ethyl]-3-oxabicyclo[3.3.0]octan-7-one.[3] In this paper, we wish to describe an alternative synthetic route to (±)-**1**, as shown in the following scheme.

2-(2-Acetoxyethyl)-2,3,4-tris(ethoxycarbonyl)cyclopentanone (**2**) was obtained with a small amount of an *O*-alkylated compound by the alkylation of the sodio derivative of 2,3,4-tris(ethoxycarbonyl)cyclopentanone[4] with 2-iodoethyl acetate in 36% yield. Hydrolysis and decarboxylation of **2** by heating with 47% hydrobromic acid gave *c*-3-(2-bromoethyl)-4-oxo-*r*-1, *t*-2-cyclopentanedicarboxylic acid (**3**), which was further esterified with diazomethane to give dimethyl ester **4**. Bromination of **4** with copper(II) bromide in tetrahydrofuran gave dibromide **5**, which was immediately heated with calcium carbonate in *N*,*N*-dimethylformamide to afford unsaturated lactone **6** in 26% yield.

Hydrogenation of **6** with hydrogen and 5% palladium charcoal in ethanol gave (4a*RS*,7*RS*,7a*SR*)-7-(methoxycarbonyl)octahydrocyclopenta[*c*]pyran-1,5-dione (**7**), mp 125—126 °C, as colorless needles. (4a*RS*,7*RS*,7a*SR*)-7-(Methoxycarbonyl)octahydrocyclopenta[*c*]pyran-1-one (**8**),[5] mp 72—73 °C, was also obtained with **7** in this reaction in 36% yield.



The ethylene acetal (**9**) of **7** was partially reduced with lithium aluminum hydride in tetrahydrofuran at 0—5 °C and the resulting reduction product was warmed with 20% sulfuric acid to give (±)-tetrahydroanhydroaucubigenone, mp 56—57 °C, in 15% yield. This compound was identical in all respects with (±)-**1**, which was previously synthesized by photo-irradiation of 6-[2-(nitrosooxy)ethyl]-3-oxabicyclo[3.3.0]octan-7-one.[3]

Experimental

All the boiling and melting points are uncorrected.

2-(2-Acetoxyethyl)-2,3,4-tris(ethoxycarbonyl)cyclopentanone (2). To a suspension of metallic sodium (2.3 g) in 150 ml of dry toluene was added dropwise 2,3,4-tris(ethoxycarbonyl)cyclopentanone[4] (30 g) with efficient stirring. The stirred mixture was heated on a water bath until all the sodium was consumed. Then 2-iodoethyl acetate (32 g) was added under cooling with ice water, and the mixture was left overnight at room temperature and then refluxed for 18 h. After cooling, the mixture was poured into 10% aqueous acetic acid (50 ml) and the toluene layer was separated, washed with aqueous $NaHCO_3$ solution and water, dried over Na_2SO_4, and freed from toluene to give a viscous liquid. Distillation of the residue under reduced pressure afforded **2** (14 g, 36%) containing a small amount of an *O*-alkylated by-product. Bp 153—155 °C/0.3 mmHg (1 mmHg=133.322 Pa), MS *m/e* 386 (M^+); IR (neat) 1730 cm^{-1} (br. C=O). Additional absorption bands at 1635 and 1685 cm^{-1} can be attributed to the *O*-alkylated by-product. Found: C, 55.86; H, 6.92%. Calcd for $C_{18}H_{26}O_9$: C, 55.95; H, 6.78%.

Dimethyl c-3-(2-Bromoethyl)-4-oxo-r-1,t-2-cyclopentanedicarboxylate (4). A mixture of **2** (5.0 g) and 47% hydrobromic acid (100 ml) was gently refluxed for 2 h. The reaction mixture was evaporated *in vacuo* and the resulting crude bromo keto acid (2.7 g, 75%) was methylated with diazomethane in the usual manner. The resulting crude dimethyl ester was chromatographed on a column of silica gel using benzene–ethyl acetate (4:1) as an eluent to give **4** as a colorless oil (46%). MS *m/e* 306, 308 (M^+). Found: C, 43.37; H, 4.75%. Calcd for $C_{11}H_{15}O_5Br$: C, 43.02; H, 4.92%. *c*-3-(2-Bromoethyl)-4-oxo-*r*-1,*t*-2-cyclopentanedicarboxylic acid (**3**), mp 164—165 °C (from acetic acid), was obtained pure from the above crude bromo keto acid by silica gel column chromatography using toluene–ethyl acetate–acetic acid (25:25:4) as an eluent. Found: C, 38.79; H, 4.04%. Calcd for $C_9H_{11}O_5Br$: C, 38.73; H, 3.97%.

7-(Methoxycarbonyl)-1,3,4,5,6-hexahydrocyclopenta[c]pyran-1,5-dione (6). To a solution of **4** (4.0 g) in tetrahydrofuran (50 ml) was added copper(II) bromide (6.5 g), and the mixture was refluxed with vigorous stirring for 4 h. Then the reaction mixture was filtered and the filtrate was evaporated *in vacuo* to give crude dibromo keto ester (**5**) as an oil, which was immediately used in the next reaction without purification. To a mixture of the above dibromo keto ester in *N*,*N*-dimethylformamide (4 ml) was added calcium

carbonate (1.43 g), and the mixture was heated at 90—100 °C with stirring for 4 h. The reaction mixture was then poured into ice water and the aqueous mixture was extracted several times with ethyl acetate. The ethyl acetate was removed from the extracts *in vacuo* to give a brown oil (3.5 g). The column chromatography on silica gel using benzene–ethyl acetate (5:1) as an eluent gave 2-(2-bromoethyl)-3,4-bis(methoxycarbonyl)-2-cyclopentenone (0.55 g, 14%) as the first eluate. MS *m/e* 304, 306 (M^+), IR (neat) 1725 (br. C=O) and 1640 cm^{-1} (C=C). Found: C, 43.60; H, 4.60%. Calcd for $C_{11}H_{13}O_5Br$: C, 43.30; H, 4.29%. From the second eluate, the target unsaturated lactone **6** (0.72 g, 26%) was obtained. MS *m/e* 210 (M^+), IR (neat) 1740, 1720 (C=O), 1655 cm^{-1} (C=C). Found: C, 56.56; H, 4.85%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

*(4a*RS,7RS,*7a*SR*)-7-(Methoxycarbonyl) octahydrocyclopenta*[c]*-pyran-1,5-dione (**7**).* The unsaturated lactone 6 (0.7 g) was hydrogenated in ethanol (20 ml) using hydrogen and 5% palladium charcoal (0.5 g) as a catalyst at room temperature and atmospheric pressure. After filtration of the reaction mixture, the filtrate was evaporated *in vacuo* and the residue was chromatographed on silica gel using benzene–ethyl acetate (5:2) as an eluent. From the first eluate, (4a*RS*,7*RS*,7a*SR*)-7-(methoxycarbonyl) octahydrocyclopenta-[*c*]pyran-1-one (**8**) (240 mg, 36%) was obtained. Mp 72—73 °C, MS *m/e* 198 (M^+), IR (KBr) 1720 and 1730 cm^{-1} (br. C=O). The physical and spectral data were identical with those of an authentic sample.[5] From the second eluate, **7** (100 mg, 16%) was obtained as colorless needles. Mp 125—126 °C (from benzene), MS *m/e* 212 (M^+), IR (KBr) 1740 and 1723 cm^{-1} (C=O). Found: C, 56.69; H, 5.81%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.70%.

*(±)-Tetrahydroanhydroaucubigenone ((±)-**1**).* A mixture of **7** (80 mg), ethylene glycol (37 mg), and *p*-toluenesulfonic acid (10 mg) in dry toluene (5 ml) was refluxed for 5 h, during which time most of water was removed by azeotropic distillation at atmospheric pressure. After removal of the solvent *in vacuo*, the residue was worked up in the usual manner to give ethylene acetal **9** (98%), MS *m/e* 256 (M^+).

To a solution of **9** (50 mg) in dry tetrahydrofuran (5 ml) was added lithium aluminum hydride in small portions at 0—5 °C until disappearance of a spot of **9** has been confirmed on TLC. Into a reaction mixture was then added 20% sulfuric acid under cooling with ice water until the solution become slightly acidic. The tetrahydrofuran layer was separated by decantation and heated at 50 °C for 20 min. The tetrahydrofuran was removed *in vacuo* and the residue was dissolved in ethyl acetate, and the ethyl acetate solution was washed with aqueous $NaHCO_3$ solution and water, dried over Na_2SO_4, and freed from ethyl acetate to give a viscous oil. The resulting oil was chromatographed on silica gel using benzene–ethyl acetate (5:1) as an eluent to give crude (±)-**1**. Recrystallization from benzene–petroleum ether afforded colorless needles (10 mg, 30%). mp 56—57 °C. The IR and MS spectra of this compound was completely identical with those of an authentic sample of (±)-**1**.[3]

One (H. K) of the authors is grateful to Professor Naomichi Takahashi of Yamagata University for his encouragement. We also thank Mr. Kazuaki Sato for the microanalyses.

The Revised Structure of Furcation, a Component of Leaves of *Viburnum furcatum* Blume

Tsunao HASE* and Tetsuo IWAGAWA

Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890

(Received April 26, 1982)

Synopsis. The structure of furcatin, which was proposed to be *p*-vinylphenyl 6-*O*-apiosyl-(1→6)-*β*-D-glucoside, was revised to *p*-allylphenyl 6-*O*-[3-*C*-(hydroxymethyl)-*β*-D-erythrofuranosyl]-(1→6)-*β*-D-glucopyranoside by spectral and chemical results.

The structure of furcatin was reported to be phenolic glycoside (**1**) isolated as a source of bitterness from *Viburnum furcatum* Blume.[1] Its aglycone was determined as *p*-vinylphenol based on the fact that the methylated aglycone could be oxidized with permanganate, Beckmann mixture, and ozone to give *p*-methoxybenzoic acid, *p*-methoxybenzaldehyde, and formaldehyde, respectively.

However, purified furcatin was not bitter. Spectral and chemical results show that the structure should be revised to *p*-allylphenyl glycoside (**2**).

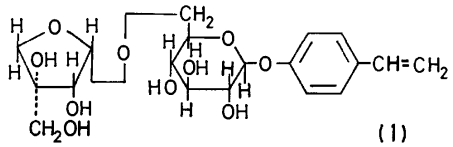
2, colorless needles, mp 160.5—161.5 °C, $[\alpha]_D^{20}$ −103.5; these were identical with results from an authentic sample previously isolated by Hattori and Imaseki. It has a molecular formula $C_{20}H_{28}O_{10}$ and the spectral data showed the presence of a *p*-substituted allylbenzene ring [$\nu_{C=C}$ 1640, 1610, 1590, 1510, 995, 960, 910, and 825 cm^{-1}; λ_{max} 213, 222, 273, and 279 nm; δ 3.27 (2H, d), 4.99 (1H, bd), 5.02 (1H, bd), 6.00 (1H, m), 7.25, and 7.51 (2H each, A_2B_2)].

Acetylation of **2** with acetic anhydride and pyridine gave an amorphous powder (**3**), $C_{32}H_{40}O_{16}$, whose NMR spectrum showed the signals for six acetyl groups δ 2.00—2.07 (3H×6). Treatment of **2** with 2 M (1 M=1 mol dm^{-3}) sulfuric acid afforded an aglycone (**4**) and two sugars which were identified as D-glucose and D-apiose by paper chromatography. The spectra of the aglycone **4** were identical with those of an authentic sample of *p*-allylphenol.[2]

2 was methylated with sodium hydride, dimethyl sulfoxide, and methyl iodide, giving hexamethyl ether (**5**) [*m/z* 512 (M^+); δ 1.83 (3H, d, J=6 Hz) and 3.34—3.62 (3H×6, s)], which seemed to suffer an allylic rearrangement during methylation. Upon hydrolysis with hydrochloric acid, **5** yielded *p*-(1-propenyl)phenol, 2,3,4-tri-*O*-methyl-D-glucose, and 2,3,3′-tri-*O*-methyl-D-apiose. The methylated D-apiose was identified by direct comparison with an authentic sample obtained from heptamethylapiin.[3] Therefore, the structure of apiose in **2** should be 3-*C*-(hydroxymethyl)-D-erythrofuranose.

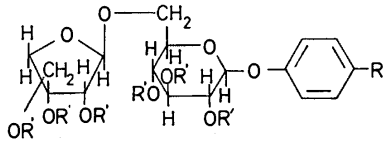
A *β*-glucosidic linkage in **2** was inferred from the anomeric proton signal at δ 5.50 (1H, m, $W_{1/2}$=10 Hz) in the NMR spectrum of **2**. Upon partial hydrolysis with ion exchange resin, **2** gave a glucoside which was determined to be *p*-allylphenyl *β*-D-glucoside (**6**); its negative molecular rotation was consistent with the existence of a *β*-glucosidic linking in **2**.

A *β*-glycosidic linkage of D-apiose to D-glucose was deduced by applying Klyne's rule. The difference of the molecular rotation between **2** (−441°) and **6** (−180°) was −261°, suggesting that the anomeric configuration of D-apiose in **2** is *β*.[3]

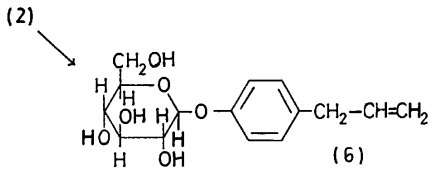


(1)

Configuration shown by dotted lines has not been elucidated.[1]



(2) R: CH_2–CH=CH_2, R′: H
(3) R: CH_2–CH=CH_2, R′: CH_3CO
(5) R: CH=CH–CH_3, R′: CH_3



(6)

The above data show that the structure of furcatin **2** is *p*-allylphenyl 6-*O*-[3-*C*-(hydroxymethyl)-*β*-D-erythrofuranosyl]-(1→6)-*β*-D-glucopyranoside.

Only two *p*-allylphenol diglycosides, rutinoside[4] and 4-*O*-*α*-L-arabinofuranosyl-(1→4)-*β*-D-glucopyranoside[5] have so far been isolated; furcatin is the third example.

Experimental

The plants were collected in the northern highlands of Kagoshima prefecture. All the melting points were uncorrected. IR and UV spectra were taken on a Shimadzu IR-27 and a Shimadzu UV-210A spectrophotometers, respectively. ^{1}H-NMR spectra were obtained on a JEOL MH-100 spectrometer; the chemical shifts are given in *δ*-values with respect to TMS as the internal standard. Mass spectra were taken on a JEOL D-300 mass spectrometer. The optical rotations were measured on a Nihonbunko J-20 recording spectropolarimeter.

Isolation. The fresh leaves of *V. furcatum* Blume (480 g) were extracted with methanol (4 l×2). The extracts were evaporated to dryness *in vacuo* to give a residue (75 g), which was dissolved in water and extracted with ether and then ethyl acetate.

The ethyl acetate extract (8 g) was subjected to chromatography on a silica-gel column with methanol–chloroform (1:9 v/v) and recrystallized from ethyl acetate saturated with water to give furcatin **2**, needles, (500 mg), mp 160—

161.5 °C, $[\alpha]_D^{20}$ −103.5 (*c*, 0.575, MeOH); λ_{max}^{MeOH} nm (*ε*): 213 (9900), 222 (11000), 273 (1300), and 279 (990); ν_{max}^{Nujol} cm^{-1}: 3350, 1640, 1610, 1590, 1510, 995, 910, and 825; ^1H NMR (pyridine-d_5): *δ* 3.27 (2H, d, *J*=7 Hz, $C\underline{H}_2$–C=C), 4.99 (1H, bd, *J*=12 Hz, H\C=C(H)/H), 5.02 (1H, bd, *J*=15 Hz, H\C=C(H)/H), 5.50 (1H, m, $W_{1/2}$=10 Hz), 5.75 (1H, d, *J*=2 Hz), 6.00 (1H, m, $-CH_2-C\underline{H}=CH_2$), 7.25, and 7.51 (2H each, A_2B_2, *J*=9 Hz, aromatic H). Found: C, 55.64; H, 6.62%. Calcd for $C_{20}H_{28}O_{10}\cdot\frac{1}{4}H_2O$: C, 55.48; H, 6.64%.

Acetylation of **2**. **2** (100 mg) was treated with pyridine–acetic anhydride (1:1 2 ml) at room temperature. The product was chromatographed on a silica-gel column with methanol–chloroform (1:99 v/v) to give an amorphous hexaacetate **3** (100 mg); ν_{max}^{Nujol} cm^{-1} (no OH absorption) 1750, 1640, 1590, 910, and 830; ^1H NMR ($CDCl_3$): 2.0—2.07 (3H×6, s, $COC\underline{H}_3$), 3.31 (2H, d, *J*=6 Hz, $-C\underline{H}_2-CH=C$), 6.86 and 7.06 (2H each, A_2B_2, *J*=8 Hz, aromatic H); MS *m/z* 620 (M^+-60). Found: C, 56.48; H, 6.03%. Calcd for $C_{32}H_{40}O_{16}$: C, 56.46; H, 5.92%.

Hydrolysis of **2** *with Sulfuric Acid*. **2** (100 mg) was dissolved in 2 M sulfuric acid (2 ml) and the solution was stirred at 80 °C for 1 h. The reaction mixture was diluted with water, extracted with ether, washed with water and dried over Na_2SO_4. The solvent was evaporated to give an oily aglycone **4** (25 mg), ν_{max}^{film} cm^{-1}: 3300, 1640, 1610, 1600, 1510, 995, 915, and 820; ^1H NMR ($CDCl_3$): 3.33 (2H, d, *J*=6 Hz, $-C\underline{H}_2-CH=C$), 4.83—5.12 (2H, bd, $-CH=C\underline{H}_2$), 5.67—6.36 (1H, m, $-CH_2-C\underline{H}=CH_2$), 6.80, and 7.14 (2H each, A_2B_2, *J*=9 Hz). These data were identical with those of an authentic *p*-allylphenol.[2] The aqueous solution was neutralized with an excess of barium carbonate, then the precipitate was filtered off and the filtrate was evaporated to dryness *in vacuo*. The paper chromatography of the product showed the presence of D-apiose and D-glucose [solvent system, AcOEt:pyridine:H_2O:AcOH=5:5:3:1].

Methylation of **2**. A solution of sodium hydride (250 mg) in dimethyl sulfoxide (5 ml) was stirred at 70 °C for 1 h under an atmosphere of nitrogen. After cooling to room temperature, a solution of **2** (100 mg) in dimethyl sulfoxide (2 ml) was added to the solution. After the mixture was stirred for 1 h, methyl iodide (1 ml) was added to it. The reaction mixture was stirred for 4 more hours, then poured into ice water and extracted with chloroform. The extract was washed with water and dried over Na_2SO_4 and the solvent was evaporated to give a crude product which was chromatographed on silica gel with methanol–chloroform (1:99 v/v) to give an oily permethylate **5** (100 mg), ν_{max}^{film} cm^{-1}: (no OH absorption) 1610, 1580, 1510, 990, 960, 840, and 790; ^1H NMR ($CDCl_3$): 1.83 (3H, d, *J*=6 Hz, $-C=C(H)-C\underline{H}_3$), 3.34, 3.46, 3.52, 3.62 (total 3H×6, s, $OC\underline{H}_3$), 6.92, and 7.20 (each 2H, A_2B_2, *J*=9 Hz, aromatic proton); MS *m/z* 512 (M^+).

Hydrolysis of Permethylate **5**. To a solution of permethylate **5** (186 mg) in a mixture of dioxane (1 ml) and methanol (1 ml), was added 2 M hydrochloric acid (1 ml) and the solution was stirred at 110 °C for 2 h. The reaction mixture was diluted with water, extracted with ether, washed with water and brine, and dried over Na_2SO_4. The solvent was evaporated to give an oily residue, which was chromatographed on silica gel with chloroform to give an oily aglycone (14 mg) which was identical with an authentic *p*-propenylphenol.[6] The aqueous solution was treated with amberlite IR-45 and evaporated to dryness *in vacuo*. The crude product was subjected to column chromatography on silica gel with methanol–chloroform (3:97 v/v) to give a tri-*O*-methyl-D-apiose (25 mg), $[\alpha]_D^{20}$ −5 (*c*, 0.650, MeOH), and a tri-*O*-methyl-D-glucose (27 mg). These methylated sugars were identical with authentic 2,3,3′-tri-*O*-methyl-D-apiose and 2,3,4-tri-*O*-methyl-D-glucose, respectively. An authentic 2,3,3′-tri-*O*-methyl-D-apiose, $[\alpha]_D^{20}$ −1.7 (*c*, 2.3, MeOH), was obtained from apiin which was isolated from parsley, according to the methods in the literature.[3]

Partial Hydrolysis of **2**. 100 mg of **2** was dissolved in water (3 ml) and 1 g of acidic ion exchange resin Amberlite IR-120 was added to it; this mixture was stirred at 65 °C for 1 h. After filtration, the solvent was evaporated to dryness, then the residue (84 mg) was subjected to column chromatography on silica gel with methanol–chloroform (1:9 v/v) and recrystallized from water to give a phenolic glucoside **6** (31 mg), mp 148—149 °C, $[\alpha]_D^{20}$ −61.8 (*c*, 0.275, MeOH), ^1H NMR (acetone-d_6): 3.40 (2H, d, *J*=7 Hz), 5.04 (1H, d, *J*=7 Hz, glucose H-1), 5.10 (1H, bd, *J*=12 Hz), 5.14 (1H, bd, *J*=20 Hz), 5.68—6.24 (1H, m), 7.14, and 7.26 (2H each, A_2B_2, *J*=8 Hz); MS *m/z* (rel int): 296 (M^+, 0.6), 134 ($C_3H_5-C_6H_4-OH$, 100). These data coincided with those of *p*-allylphenyl *β*-D-glucoside in the literature.[7]

The authors are grateful to Professor Hidemasa Imaseki, Nagoya University, for kindly providing authentic samples of furcatin, and to Professor Koichi Koshimizu, Kyoto University, for kindly supplying the IR and ^1H NMR spectra of authentic *p*-allylphenol. They also would like to thank Dr. Shizuo Sako, Kagoshima University, for his aid in the collection and identification of the plants.

Stereoselective Synthesis of Mixed Acetal Glycosides by Reaction of Tri-*O*-acetyl-*N*-(2,4-dinitrophenyl)-α-D-glucosaminyl Bromide with Alcohol in Acetone[1]

Shinkiti Koto,* Shigeru Inada, Tomoko Narita, Naohiko Morishima, and Shonosuke Zen

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received January 14, 1982)

Synopsis. Some mixed acetal glycosides were stereoselectively synthesized by the reaction of 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl bromide with alcohols in acetone containing $Hg(CN)_2$, $HgBr_2$, and tetrabutylammonium bromide at room temperature. When *t*-butyl alcohol was used, a novel enol glycoside of acetone was formed.

3,4,6-Tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranosyl bromide (**1**)[2] has been a useful reagent for synthesizing various α-D-glucosaminides.[3] This report presents our findings that a homogeneous reaction of **1** with methanol (MeOH) in acetone (Me_2CO) in the presence of $Hg(CN)_2$, $HgBr_2$, and tetrabutylammonium bromide (*n*-Bu_4NBr) at room temperature gave a novel acetal glycoside (**2**) (Eq. 1) in a 54% yield (Table 1, Run 2).[4] The reaction was highly stereoselective and gave no methyl glycosides (**3a** and **3b**). The use of solvents such as 1,2-dichloroethane (Run 9) and nitromethane (Run 10) as well as an excess of MeOH (Run 11) caused the

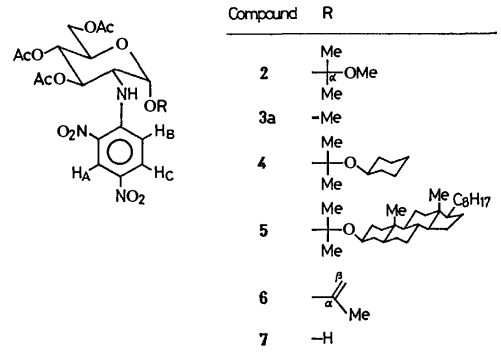
9[c]	0.5	0.5	1.0	35[f]	21
10[d]	0.5	0.5	1.0	60[f]	8
11[e]	0.5	0.5	1.0	53	19

a) Reactions were conducted in 0.1 mmol scale for 6 h at room temperature. b) Yields were determined by measuring ^1H NMR (60 MHz) of product mixtures (see Experimental). c) Me_2CO (66 μl, 9.0 equiv.) and $(CH_2Cl)_2$ (0.46 ml) were used. d) Me_2CO (66 μl, 9.0 equiv.) and $MeNO_2$ (0.46 ml) was used. e) Excess MeOH (12 μl, 3.0 equiv.) was used. f) A very small peak of the β-anomer of **2** was observed at δ 3.01.



formation of **3a** and **3b**. The use of the ternary mixture was essential for the acetalization without forming **3a** and **3b** (Runs 5—8); the optimal proportion of $Hg(CN)_2$, $HgBr_2$, and *n*-Bu_4NBr to **1** found is 0.5:0.5:1.0 (Runs 1—4).

Incidentally, 1-methoxy-1-methylethyl group, known as a labile protecting group of hydroxyl group,[5] was readily removed from **2** by a mild acid hydrolysis without the removal of the acetyl groups and survived through the *O*-deacetylation and the *N*-dedinitrophenylation in basic media.

2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl bromide does not undergo such acetalization reaction. For **1**, Me_2CO is the sole ketone which gives the acetal glycoside in an acceptable yield, aldehydes such as propional are also unsuitable. Cyclohexanol and 5α-cholestan-3β-ol gave the respective acetal glycosides (**4** and **5**). However, *t*-butyl alcohol did not afford such a type of glycoside but isopropenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside (**6**), a novel enol glycoside,[6] was formed.

Experimental

The instruments used were identical with those described earlier.[7] Solid compounds, **1**,[2] $Hg(CN)_2$ (Wako), $HgBr_2$ (Wako), *n*-Bu_4NBr (Tokyo Kasei), and 5α-cholestan-3β-ol (Tokyo Kasei), were stored *in vacuo* over P_2O_5 before use. The physical and analytical data for the acetals are in Table 2.

*1-Methoxyl-1-methylethyl 3,4,6-Tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside (**2**).* MeOH (40 μl, 1.0 mmol) and Me_2CO (5.3 ml) were successively added to a mixture of **1** (534 mg, 1.0 mmol), $Hg(CN)_2$ (126 mg, 1.0 mmol), $HgBr_2$ (180 mg, 1.0 mmol), and *n*-Bu_4NBr (322 mg, 1.0 mmol). After stirring for 24 h at room temperature and adding water (1.0 ml), the mixture was evaporated at 30 °C under diminished pressure and chromatographed on silica gel (Kanto Kagaku) using a mixture of benzene and butanone (10:1). The faster-moving band afforded **2** (310.5 mg, 57%); δ_H ($CDCl_3$, Me_4Si): 1.50 (s, 6H, CMe), 1.80 (s, 3H, OAc),

Table 2. Yields[a] and physical data of acetals

Compd	Yield %	Mp(recrystallized from[b]) θ_m/°C		$[\alpha]_D^{20}$/° (c, Me_2CO)	Mol formula	Found(Calcd)(%) C	H	N

a) Reaction time was 6 h. b) C: Chloroform, E: ethyl acetate, H: hexane, I: diisopropyl ether.

2.06 (s, 3H, OAc), 2.10 (s, 3H, OAc), 3.19 (s, 3H, OMe), 7.07 (d, 1H, J_{BC}=10 Hz, H_B), 8.27 (q, 1H, H_C), 8.72 (d, 1H, J=10 Hz, NH), 9.10 (d, 1H, J_{AB}=3.5 Hz, H_A); δ_C ($CDCl_3$, Me_4Si)[8] 20.6 (3C, OAc), 24.6, 26.3, 50.0 (OMe), 55.3 (C-2), 62.1 (C-6), 67.9, 68.4, 72.9, 90.1 (C-1), 103.3 (C-α), 114.5, 124.3, 130.0, 131.0, 136.7, 147.5, 169.6, 169.9, 170.7. The slower-moving band gave 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranose (**7**) (170.5 mg, 38%), which was identified with the sample prepared by the authentic route.[2]

Heating **2** (52.6 mg, 0.097 mmol) in aq acetic acid (80%, 0.5 ml) at 70 °C for 40 min furnished **7** (42.5 mg, 93%).

*1-Methoxy-1-methylethyl 2-Deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside (**8**).* The treatment of **2** (200 mg, 0.37 mmol) with ammoniacal methanol (38 g, 21%) at room temperature overnight gave **8** (*ca.* 150 mg, quant.); mp 160—162 °C, $[\alpha]_D^{20}$ +4.5° (c 1.0, Me_2CO); δ_H ($(CD_3)_2CO$, Me_4Si) 1.43 (s, 3H, CMe), 1.48 (s, 3H, CMe), 3.16 (s, 3H, OMe), 5.40 (d, 1H, $J_{1,2}$=3.5 Hz, H-1), 7.53 (d, 1H, J_{BC}=10 Hz, H_B), 8.25 (q, 1H, H_C), 8.97 (d, 1H, J_{AB}=2.5 Hz); δ_C ($(CD_3)_2CO$, Me_4Si) 24.9, 26.7, 49.8 (OMe), 57.8 (C-2), 62.4 (C-6), 71.5, 73.4, 75.1, 91.2 (C-1), 102.8 (C-α), 117.2, 124.1, 130.2, 130.9, 136.5, 149.7. Found: C, 45.79; H, 5.44; N, 10.04%. Calcd for $C_{16}H_{23}N_3O_9$: C, 46.04; H, 5.55; N, 10.07%.

*1-Methoxy-1-methylethyl 2-Amino-2-deoxy-α-D-glucopyranoside (**9**).* The treatment of **8** (91.8 mg, 0.22 mmol) with Dowex 1×2 (1 ml) in aq Me_2CO (67%, 5 ml) for 6 h at room temperature afforded **9** (41.1 g, 74%); mp 189—191 °C (decomp), $[\alpha]_D^{20}$ +139° (c 0.3, H_2O); δ_H (D_2O, Me_4Si (ext.)) 1.90 (s, 6H, CMe), 3.16 (dd, 1H, J=3.9 and 9.6 Hz, H-2), 3.76 (s, 3H, OMe) 5.64 (d, 1H, J=3.9 Hz H-1); δ_C (D_2O, Me_4Si (ext.)) 25.2, 26.2, 50.7 (OMe), 56.5 (C-2), 62.0 (C-6), 71.2 (C-4), 73.6 (C-5), 75.2 (C-3), 93.8 (C-1), 103.9 (C-α). Found: C, 47.65; H, 8.52; N, 5.55%. Calcd for $C_{10}H_{21}NO_6$: C, 47.80; H, 8.42; N, 5.57%.

Procedure for the Acetalization to Obtain the Data for Table 1. A round-bottomed flask containing weighed solid compounds (**1** and, optionally, $Hg(CN)_2$, $HgBr_2$ and n-Bu_4NBr) was kept *in vacuo* over P_2O_5 for 30 min. Anhydrous solvent (when necessary), Me_2CO, and MeOH were successively injected into this vessel, stoppered with a rubber-cap. The reaction was stirred and quenched by adding water (1 drop). After evaporation at 30 °C, the mixture was chromatographed as above. Fractions containing **2**, **3a**, and **3b** were combined to give a glass whose ^1H NMR spectrum usually showed three singlets of methoxyl groups of **2**, **3a**, and **3b** at δ 3.20, 3.55, and 3.50 in $CDCl_3$ with Me_4Si (Table 1).

Attempted Acetalization Using t-Butyl Alcohol. Me_2CO (1.0 ml) was injected into a rubber-stoppered flask containing *t*-BuOH (15.2 mg, 0.2 mmol), **1** (106.8 mg, 0.2 mmol), $Hg(CN)_2$ (25.2 mg, 0.1 mmol), $HgBr_2$ (36.0 mg, 0.1 mmol), and n-Bu_4NBr (64.4 mg, 0.2 mmol). After having been stirred for 6 h at room temperature, the mixture was evaporated and chromatographed as above. The faster-moving major band gave isopropenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside (**6**) (37.1 mg, 36%); mp 199—202 °C, $[\alpha]_D^{20}$ −8.6° (c 1.3, Me_2CO); δ_H ($CDCl_3$, Me_4Si) 1.77 (s, 3H, OAc), 1.90 (s, 3H, CMe), 1.97 (s, 3H, OAc), 2.03 (s, 3H, OAc), 7.10 (d, 1H, J_{BC}=9 Hz, H_B), 8.20 (q, 1H, H_C), 8.80 (d, 1H, J=12 Hz, NH), 9.07 (d, 1H, J_{AB}=3 Hz, H_A); δ_C ($CDCl_3$, Me_4Si) 20.2 (CMe), 20.6 (3C, Ac), 55.1 (C-2), 61.5 (C-6), 67.9, 68.3, 73.0, 88.7 (C-β), 94.7 (C-1), 114.4, 124.3, 130.0, 131.3, 136.9, 147.6, 157.1 (C-α) 169.7 (2C, Ac), 170.7 (Ac). Found: C, 48.94; H, 4.84; N, 8.41%. Calcd. for $C_{21}H_{25}N_3O_{12}$: C, 49.32; H, 4.93; H, 8.22%.

Compound **6** (45.7 mg, 0.09 mmol) was treated with dil. sodium methoxide in methanol (0.15%, 2 ml) at room temperature overnight. After NH_4Cl had been added, the mixture was evaporated and chromatographed to give propenyl 2-deoxy-2-(2,4-dinitroanilino)-α-D-glucopyranoside (**10**) (35 mg, 94%); mp 161—165 °C, $[\alpha]_D^{20}$ −1.0° (c 1.4, Me_2CO); δ_H ($(CD_3)_2CO$, Me_4Si) 1.95 (s, 3H, CMe), 5.48 (d, 1H, $J_{1,2}$=3.5 Hz, H-1), 7.57 (d, 1H, J_{BC}=9 Hz, H_B), 8.23 (q, 1H, H_C), 8.95 (d, 1H, J_{AB}=3 Hz, H_A); δ_C ($(CD_3)_2CO$, Me_4Si)[6] 20.4 (CMe), 58.1 (C-2), 62.0 (C-6), 71.0, 74.4, 75.6, 88.3 (C-β), 96.6 (C-1), 117.3, 124.4, 130.5, 131.5, 131.6, 137.2, 150.1, 158.4 (C-α). Found: N, 10.42%. Calcd for $C_{15}H_{19}N_3O_9$: N, 10.90%.

A Through-process for the Preparation of Methyl Per-*O*-acetyl 1-Thio-glycosides from Aldoses

Shinkiti Koto,* Toyosaku Yoshida, Kazuhiro Takenaka, and Shonosuke Zen

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received May 4, 1982)

Synopsis. D-Glucose, D-galactose, D-mannose, D-xylose, L-arabinose, L-fucose, L-rhamnose, maltose, cellobiose, lactose, D-glucosamine, D-galactosamine, and D-mannosamine were converted into the corresponding methyl per-*O*-acetyl 1-thioglycopyranosides by way of a three-step (acetobromination, methylthioation, and acetylation) through-process in a single vessel.

The alkyl thio group is useful for protecting the anomeric center of carbohydrate in the sequential glycoside synthesis.[1] Continuing our methodologic study of oligosaccharide synthesis,[1a,2] a handy procedure for introducing the methylthio group at the anomeric center of a given saccharide was developed.

D-Glucose was smoothly acetobrominated through reaction with acetyl bromide (AcBr) in acetic acid (AcOH). The use of the AcOH solvent prevents any occasional sudden evolution of HBr such as occurs in the direct use of AcBr for the acetobromination of free sugar. The reaction was so clean that the evaporation of excess AcBr and AcOH gave 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide ready for immediate use. The subsequent conversion to the methylthio compound was conveniently carried out by a reaction with commercially available aq sodium methanethiolate (MeSNa) in acetone. Because of the concurrent de-*O*-acetylation during mercaptolysis, a reacetylation process was required. The chromatography of the reaction mixture afforded methyl 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranoside (**1**) in a ≈60% yield. The whole process from D-glucose to **1** could be done in a single vessel.

G = 
Using this through-process, D-galactose, D-mannose, D-xylose, L-arabinose, L-fucose, and L-rhamnose were readily converted into the corresponding acetates of methyl 1-thioglycopyranosides. In the cases of the 6-deoxy sugars, however, a careful control of the temperature for the evaporation of excess AcBr was essential.

Disaccharides, maltose, cellobiose, and lactose, were also suitable; their inter-glycoside linkage was not cleaved at all during acetobromination.

In the case of D-glucosamine, the acetobromination took a much longer time[3] compared to those described above. Nevertheless, methyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio-β-D-glucopyranoside (**11**) was obtained in a ≈50% yield. Other amino sugars, D-galctosamine, and D-mannosamine were derived into the thioglycoside derivatives.

Thus, the through-process presented is so simple and economical that its rather low yields do not make it disadvantageous in comparison with the previously known methods for preparing methyl 1-thioglycoside.[4]

Experimental

General. See the preceeding report.[5]

General Procedure for Obtaining the Data in Table 1. Cooled AcOH (0.5 ml) was added into a suspention of aldose (with or without water of crystallization) or glycosamine hydrochloride (1.0 mmol) in AcBr (1.0 ml) under stirring at 0 °C. The mixture was then stirred at room temperature for 2 h (but for 3 d for amino sugar). The excess reagents were then evaporated off at 25—35 °C, followed by evaporation with toluene. Cold aq MeSNa (Tokyo Kasei, 15%, 2.0 ml) was added into a solution of the acetobromo sugar thus obtained in acetone (3.5 ml) under stirring at 0 °C; in the case of aminosugar, the amount of aq MeSNa was doubled. The mixture was then stirred for 18 h at room temperature. Evaporation at 45—55 °C gave a solid material which was heated in Ac_2O (3.0 ml) containing NaOAc (0.1 g) under stirring at 100 °C. Evaporation on a boiling-water bath and subsequent chromatography on silica gel using the toluene–2-butanone system (gradient) gave totally acetylated methyl 1-thioglycopyranoside.

An Example of Large-scale Preparation. D-Mannose (10 g, 0.056 mol) was added at once into well-cooled AcBr (56 ml) under good stirring at 0 °C. Soon after this, cold AcOH (28 ml) was added to the suspension. During the next 10 min, all the sugar dissolved, with a fairly violent evolution of HBr. After the evolution had been set aside, the ice-bath was removed and the solution was stirred for 1.5 h at the ambient temperature. The excess reagents were evaporated under reduced pressure at 23—35 °C and then co-evaporated with toluene three times. The heavy syrup thus obtained was evacuated for 0.5 h and dissolved in cold Me_2CO (80 ml). Cold aq NaSMe (15%, 86 ml) was then added to the stirred solution at 0 °C. After the ice bath had been removed, the mixture was vigorously stirred at the ambient temperature for 18 h. After the evaporation of volatile ma-

terials at 45—55 °C, the residue thus obtained was stirred in Ac_2O (168 ml) containing AcONa (5.8 g) at 100 °C for 2 h. Evaporation on a boiling water bath and subsequent chromatography gave **3** (8.4 g, 40%).

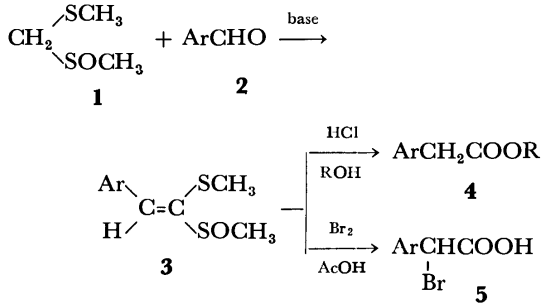
Stereospecific Reductive Desulfinylation of 1-Aryl-2-(methylsulfinyl)-2-(methylthio)ethenes with Grignard Reagents[1)]

Katsuyuki OGURA,*[2)] Kazutaka ARAI,[2)] and Gen-ichi TSUCHIHASHI*[2)]
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received May 6, 1982)

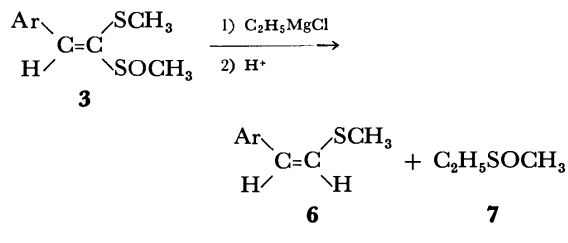
Synopsis. (*E*)-1-Aryl-2-(methylsulfinyl)-2-(methylthio)ethene, obtained by the Knoevenagel-type condensation of methyl (methylthio)methyl sulfoxide with the corresponding aromatic aldehyde, was found to react with ethylmagnesium chloride to give (*Z*)-1-aryl-2-(methylthio)ethene predominantly. Since the reaction of (*Z*)-1-(methylsulfinyl)-1-(methylthio)-2-phenylethene afforded (*E*)-1-(methylthio)-2-phenylethene, the present reaction appeared to be stereospecific.

In the previous papers,[3,4)] methyl (methylthio)methyl sulfoxide (**1**) was reported to react with an aromatic aldehyde (**2**) in the presence of a base to give the (*E*)-1-aryl-2-(methylsulfinyl)-2-(methylthio)ethene (**3**), which appeared to be one of the most important precursors for synthesizing arylacetic acid derivatives. For example, the reaction of **3** with hydrogen chloride in an alcohol (ROH) yields the arylacetic ester (**4**) and treatment of **3** with bromine in acetic acid produces the α-bromoarylacetic acid (**5**).



We further examined the reaction of **3** with Grignard reagents, where many types of the reactions could be expected to take place: (i) Attack on the sulfur atom of the sulfinyl group, bringing about the replacement reaction, analogous to the reaction of aryl chloromethyl sulfoxide (Eq. 1);[5)] (ii) reduction of the sulfinyl group with concomitant alkylation of the sulfinyl methyl group as observed in the reaction of dimethyl sulfoxide (Eq. 2);[6)] (iii) Michael-type addition to the α,β-unsaturated sulfoxide moiety;[7)] and (iv) proton transfer to form a carbanion on the methyl adjacent to the sulfinyl group. In this note, we report that a Grignard

reagent causes reductive desulfinylation of **3** to give a (*Z*)-1-aryl-2-(methylthio)ethene (**6**) stereospecifically.



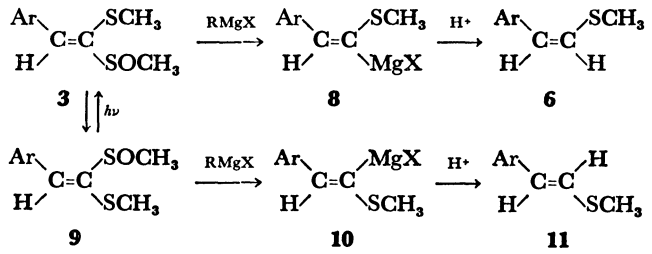
Results and Discussion

To a solution of (*E*)-1-(*p*-chlorophenyl)-2-(methylsulfinyl)-2-(methylthio)ethene (**3**; Ar=*p*-ClC_6H_4), which was obtained by the reaction of **1** with *p*-chlorobenzaldehyde in the presence of a base in tetrahydrofuran (THF),[3)] was added a THF solution of ethylmagnesium chloride (1.5 mol equiv.) under argon atmosphere and cooling with ice–water, and the resulting mixture was stirred at room temperature for 1 h. The color of the mixture changed from pale yellow to orange and then to yellow. Addition of water, followed by the usual work-up, gave 1-(*p*-chlorophenyl)-2-(methylthio)ethene and ethyl methyl sulfoxide (**7**) in yields of 79% and 37%, respectively. The structure of the former was given by an elemental analysis and an NMR spectrum, which showed that this product consisted mainly of the (*Z*)-isomer (**6**; Ar=*p*-ClC_6H_4) together with a small amount (*ca.* 5%) of its (*E*)-isomer. The (*Z*)- and (*E*)-isomers were assigned from the coupling constants (J=11 and 15 Hz, respectively) between the olefinic protons.

In a similar manner, (*Z*)-1-aryl-2-(methylthio)ethenes [**6**; Ar=C_6H_5, *p*-$CH_3C_6H_4$, and *p*-$(CH_3)_2NC_6H_4$] were obtained on treatment of the corresponding (*E*)-1-aryl-2-(methylsulfinyl)-2-(methylthio)ethenes with ethylmagnesium chloride in yields of 82%, 60%, and 41%, respectively. In every case, formation of a small amount of (*E*)-isomer was observed, but the ratio of the (*Z*)- and (*E*)-isomers remained always more than nine. The use of methylmagnesium iodide gave the similar result; The reaction with **3** (Ar=C_6H_5) afforded **6** (Ar=C_6H_5) in 57% yield.

The observation that the thermodynamically less stable (*Z*)-isomer (**6**) was always obtained as the major product in the reaction of **3** with a Grignard reagent suggests stereospecific nature of the reaction. Thus, we studied the reaction of ethylmagnesium chloride with a mixture consisting of **3** (Ar=C_6H_5) and its (*Z*)-isomer (**9**; Ar=C_6H_5). When a 35:65 mixture of **3** (Ar=C_6H_5) and **9** (Ar=C_6H_5), which was obtained by irradiation of **3** (Ar=C_6H_5) with a low-pressure mercury arc lamp,[3)] was subjected to the reaction with ethylmagnesium chloride, the ratio of the (*E*)- and (*Z*)-isomers (**6** and **11**; Ar=C_6H_5) of 1-(methylthio)-2-phenylethene was 29:71. In a similar manner, a 25:75 mixture of **3** (Ar=C_6H_5) and **9** (Ar=C_6H_5) gave a mixture of the corresponding **6** and **11** in the ratio of 21:79. Hence, the present reaction proved to be stereospecific.

The reaction of **3** or **9** with a Grignard reagent may be accounted for by the mechanism involving the attack of a Grignard reagent (RMgX) on the sulfur atom of the sulfinyl group of **3** or **9**, followed by elimination of alkyl methyl sulfoxide ($RSOCH_3$)[8)]



to form a 2-aryl-1-(methylthio)ethenylmagnesium halide (**8** or **10**, respectively) which was finally converted into **6** or **11** by the abstraction of a proton in a retention manner.[9,10]

Experimental

The Reaction of **3** *(Ar=*p*-ClC_6H_4) with Ethylmagnesium Chloride. A Typical Procedure*: To a solution containing 1.18 g (4.8 mmol) of **3** (Ar=*p*-ClC_6H_4) in 6.0 ml of THF, was added 3.5 ml of 2 M solution (1.5 mol equiv.) of ethylmagnesium chloride in THF under argon atmosphere and cooling with an ice-water bath. After removal of the bath, the reaction mixture was stirred for 1 h at room temperature and then water (0.5 ml) was added at 0—5 °C. After addition of diethyl ether (30 ml) and anhydrous sodium sulfate, the resulting mixture was stirred mechanically. The organic layer was separated by decantation and the residue was washed twice with 20 ml of diethyl ether. These ethereal solutions were combined and dried over anhydrous magnesium sulfate, and the solvent was evaporated *in vacuo*. The residual oil was column-chromatographed on silica gel using dichloromethane as an eluent to give 698 mg (79% yield) of **6** (Ar=*p*-ClC_6H_4) as a slightly yellow oil, which was further purified by a short-path distillation [bath temperature: 103—105 °C/0.05 Torr (1 Torr=133.322 Pa)]: IR (neat) 1597, 1590, 1490, 1402, 1089, 1010, 847, 828, and 525 cm^{-1}; NMR ($CDCl_3$) δ 2.35 (3H, s), 6.16 (1H, d, J=11 Hz), 6.30 (1H, d, J=11 Hz), 7.26 (2H, d, J=7 Hz), and 7.33 (2H, d, J=7 Hz).

Found: C, 58.32; H, 4.82%. Calcd for C_9H_9ClS: C, 58.53; H, 4.92%.

Ethyl methyl sulfoxide (**7**) was obtained by washing the residue of the decantation with methanol. Evaporation of the washings gave 162 mg (37% yield) of **7** as a colorless oil, which was identified by a comparison of its IR and NMR spectra with those of the authentic sample prepared by oxidation of ethyl methyl sufide.

The reaction of **3** [Ar=C_6H_5, *p*-$CH_3C_6H_4$, or *p*-$(CH_3)_2NC_6H_4$] with ethylmagnesium chloride under the same conditions afforded **6** [Ar=C_6H_5, *p*-$CH_3C_6H_4$, or *p*-$(CH_3)_2NC_6H_4$] in 82%, 60%, or 41% yield, respectively, as an isomeric mixture consisting mainly of (*Z*)-isomer.

6 (Ar=C_6H_5) purified by a short-path distillation [bath temperature: 130—140 °C/17 Torr (lit,[11] 100—113 °C/3—4 Torr)]: IR (neat) 1600, 1499, 1449, 846, 778, 735, 689, and 530 cm^{-1}; NMR ($CDCl_3$) δ 2.36 (3H, s), 6.19 (1H, d, J=11 Hz), 6.43 (1H, d, J=11 Hz), and 7.1—7.6 (5H, m).

6 (Ar=*p*-$CH_3C_6H_4$) purified by a short-path distillation (bath temperature: 105—115 °C/0.12 Torr): IR (neat) 1598, 1515, 824, 687, and 530 cm^{-1}; NMR ($CDCl_3$) δ 2.29 (3H, s), 2.34 (3H, s), 6.07 (1H, d, J=11 Hz), 6.33 (1H, d, J=11 Hz), 7.11 (2H, d, J=8 Hz), and 7.31 (2H, d, J=8 Hz). Found: C, 72.79; H, 7.15%. Calcd for $C_{10}H_{12}S$: 73.13; 7.36%.

6 (Ar=*p*-$(CH_3)_2NC_6H_4$): mp 63.5—64.5 °C (from methanol); IR (nujol) 1615, 1368, 815, 670, and 530 cm^{-1}; NMR ($CDCl_3$) δ 2.33 (3H, s), 2.91 (6H, s), 5.88 (1H, d, J=10.5 Hz), 6.31 (1H, d, J=10.5 Hz), 6.67 (2H, d, J=8.5 Hz), and 7.34 (2H, d, J=8.5 Hz). Found: C, 68.31; H, 7.78; N, 7.09%. Calcd for $C_{11}H_{15}NS$: C, 68.35; H, 7.82; N, 7.25%.

Reaction of Arenediazonium Salts with Nitriles in the Presence of Sodium Carboxylates. A Convenient Synthesis of Unsymmetrical *N*-Aryl Acyclic Imides

Kiyoshi KIKUKAWA,* Kiyoshi KONO, Fumio WADA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 8, 1982)

Synopsis. Reactions of arenediazonium tetrafluoroborates (ArN_2BF_4), acetonitrile and sodium carboxylates (RCOONa) gave *N*-acyl acetanilides ($ArN(COR)COCH_3$) in moderate to good yields (Ar=Ph, 2-MeC_6H_4, 3-MeC_6H_4, 4-MeC_6H_4, 2,6-$(Me)_2C_6H_3$; R=Et, *i*-Pr, *t*-Bu, Ph). Acrylonitrile and benzonitrile could be used in the reaction instead of acetonitrile.

Acetonitrile has been used as a favorable solvent in the palladium-catalyzed reactions of arenediazonium salts (ArN_2X).[1] However, in the presence of sodium acetate, a base frequently used in the palladium-catalyzed reactions, some ArN_2X rapidly decomposed in acetonitrile to give intractable tarry materials. In the course of the studies to clarify this side reaction, the interesting reaction of ArN_2BF_4 with sodium carboxylates (RCOONa) and nitriles (R'CN) to produce unsymmetrical *N*-aryl acyclic imides is observed.

Results and Discussion

Addition of ArN_2BF_4 to a suspension of RCOONa in CH_3CN at 60—80 °C caused immediate gas evolution, giving unsymmetrical *N*-aryl acyclic imides (*N*-acyl acetanilides (Eq. 1)). Typical results are summarized in Table 1. Various sodium carboxylates could be used effectively and gave the corresponding *N*-aryl imides. Formation of any symmetrical imides could not be observed under the present reaction conditions. It is noticeable that better yields are obtained in the reactants with bulky groups, such as pivalate, 2-methyl- or 2,6-dimethylbenzenediazonium salt.

$$ArN_2BF_4 + RCOONa + CH_3CN \longrightarrow Ar\text{-}N(COR)COCH_3 + N_2 \quad (1)$$

Table 1. Preparation of *N*-aryl acyclic imides (*N*-acyl acetamides) by the reaction of ArN_2BF_4 with RCOONa in acetonitrile (Eq. 1)[a]

a) Reactions were carried out by the addition of of ArN_2BF_4 to a suspension of RCOONa in CH_3CN at 60—80 °C. b) Based on ArN_2BF_4.

Acrylonitrile and benzonitrile also reacted with ArN_2BF_4 and RCOONa to give the *N*-aryl imides and/or *N*-aryl amides (Eqs. 2 and 3). *N*-Arylpropionamides could not be observed under the present conditions.

$$ArN_2BF_4 + CH_2{=}CHCN + EtCOONa \longrightarrow ArN(COEt)COCH{=}CH_2 + ArNHCOCH{=}CH_2 \quad (2)$$

Ar=Ph:	0%	72%
2,6-$(Me)_2C_6H_3$:	49	0

$$ArN_2BF_4 + PhCN + EtCOONa \longrightarrow ArN(COEt)COPh + ArNHCOPh \quad (3)$$

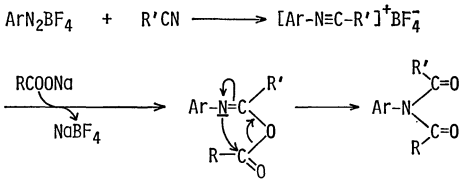
Ar=Ph:	6%	2%
2,6-$(Me)_2C_6H_3$:	25	39

In contrast to the PhN_2BF_4 or $(Me)_nC_6H_{5-n}N_2BF_4$, ArN_2BF_4 bearing electron-withdrawing groups, such as as 4-$NO_2C_6H_4N_2BF_4$ or 4-$BrC_6H_4N_2BF_4$, gave ArH (*ca.* 20%) along with tarry materials under the present conditions. Sodium acetate is used as a base in the Gomberg-Bachmann reaction of an ArN_2X bearing electron-withdrawing group to produce an aryl radical intermediate.[2] Thus, the formation of the ArH is reasonably understood by the pathway *via* aryl radical shown in Eq. 4.

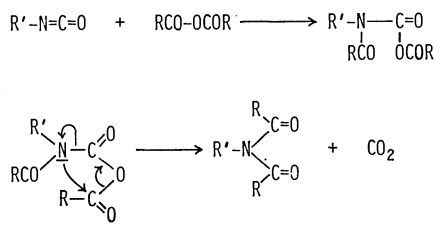
$$ArN_2BF_4 + RCOONa \longrightarrow ArN_2OCOR \longrightarrow Ar\cdot + N_2 + RCOO\cdot \xrightarrow{CH_3CN} ArH \quad (4)$$

Reaction of $(Me)_nC_6H_{5-n}N_2BF_4$ with nitriles has been known to give *N*-aryl nitrilium tetrafluoroborates, $[Ar\text{-}N{\equiv}C\text{-}R]^+BF_4^-$.[3] Since the present reaction favorably proceeds with $(Me)_nC_6H_{5-n}N_2BF_4$, the *N*-aryl nitrilium salt might be an intermediate. Thus, the following scheme could explain the formation of *N*-aryl acyclic imides (Scheme 1). The similar pathway has been proposed for the reaction of isocyanate and acid anhydride to form an acyclic imides (Scheme 2).[4]

Unsymmetrical (mixed) imides are conventionally obtained through acylation of amides with acid anhydrides or acid chlorides.[4,5] But sometimes symmetri-



Scheme 1.



Scheme 2.

cal imides were obtained because the reaction required drastic conditions.

The present reaction provides a convenient route to unsymmetrical *N*-acyl imides, especially *N*-acyl acetanilides.

Experimental

Materials. Sodium carboxylates were used as received or obtained by neutralization of the corresponding acids. Nitriles were distilled before use. Arenediazonium tetrafluoroborates were prepared by the ordinary method[6] and stored at −20 °C.

General Procedure. To a suspension of RCOONa (40 mmol) in a R'CN (40 ml) held at 60—80 °C was added an ArN_2BF_4 (20 mmol) slowly. The addition of ArN_2BF_4 caused exothermic reaction with gas evolution. After the addition, the mixture was stirred for 0.5 h at 60—80 °C. After removal of solids ($NaBF_4$ and excess RCOONa), excess R'CN was evaporated (or distilled) off under reduced pressure. The residue was extracted with hot (≈50 °C) hexane. After evaporation of hexane, the residue was distilled or recrystallized from benzene (or hexane–ether) to give *N*-aryl imides. The extraction with hexane served to seperate the imides from amides, since the latter remained as insoluble solid. The structure of the imides was confirmed by IR, NMR, and elemental analysis. The C=O stretching of the imides was observed near 1700 cm^{-1} and was easily distinguishable from that of amides appeared near 1650 cm^{-1}.

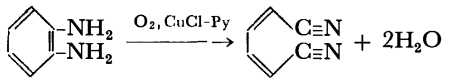
CuCl-catalyzed Oxidative Coupling Reaction of Secondary Amines with Molecular Oxygen in Pyridine

Tsunesuke KAJIMOTO,* Hidetaka TAKAHASHI, and Jiro TSUJI†
Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248

(Received June 9, 1982)

Synopsis. Oxidation of diphenylamine with molecular oxygen in the presence of CuCl in pyridine at room temperature to give tetraphenylhydrazine in a high yield was achieved by selecting suitable reaction conditions. *N*-methylaniline was also oxidized to give *N,N'*-dimethyl-*N,N'*-diphenylhydrazine.

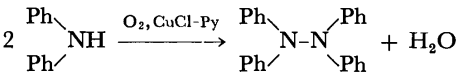
In a previous paper we reported a unique oxidation of *o*-phenylenediamine with molecular oxygen in the presence of CuCl in pyridine at room temperature to give *cis,cis*-muconononitrile.[1] The most important



factor in this reaction is the ratio of *o*-phenylenediamine to CuCl in the reaction medium and the ratio should be kept less than 0.5 (mol/mol) to obtain the nitrile in a high yield. A suitable procedure for this is the dropwise addition of a solution of the diamine in pyridine to a solution of CuCl. In this paper a successful application of this catalyst system to the oxidation of secondary amines to tetrasubstituted hydrazines is reported.

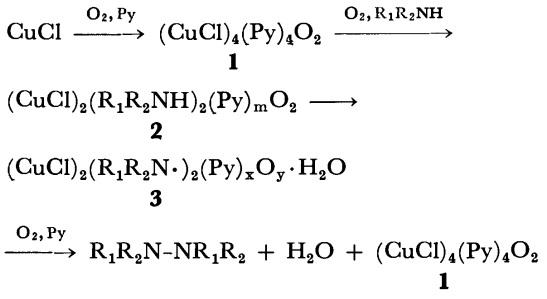
Results and Discussion

Copper(I) chloride is slightly soluble in pyridine under an inert atmosphere at room temperature, but a mixture of CuCl and pyridine absorbs oxygen with stirring under oxygen atmosphere to give a deep green solution. One mol of oxygen is absorbed per four atoms of copper. From this solution an oxygen complex was precipitated by addition of diethyl ether and its elemental analysis supported a composition of $(CuCl)_4(C_5H_5N)_4O_2$.[1] When a pyridine solution of diphenylamine (0.5 molar equiv. to CuCl) was added slowly to a pyridine solution of CuCl pretreated with oxygen, further absorption of oxygen was observed showing that the oxidation took place. The amount of oxygen absorbed during the oxidation was 0.6 molar equivalent to diphenylamine added, and after usual work-up tetraphenylhydrazine was obtaine in 83% yield.



N-methylaniline was also oxidized to give *N,N'*-dimethyl-*N,N'*-diphenylhydrazine in 52%. From other secondary amines such as di-2-naphthylamine and *N*-ethylaniline the corresponding hydradines were not obtained in high yields though similar absorption of oxygen was observed.

A probable reaction mechanism is shown as follows.



Coupling of amino radicals in the coordination sphere of complex **3** gives the hydrazine. When the concentration of the secondary amine in the reaction medium is so high to substitute more pyridines coordinated in the complex **2**, the amino radical may attack another secondary amine coordinated to give by-products such as oligomer and polymer of the amine. The low yield of hydrazine from di-2-naphthylamine may be attributed to the instability of di-2-naphthylamino radical.[2]

The unique oxidation method with CuCl in pyridine is thus useful for the oxidative coupling reaction of secondary amines to give tetrasubstituted hydrazine as well as other oxidation methods with PbO_2 or $KMnO_4$.[3]

Experimental

Melting points are uncorrected. Infrared spectra were recorded on a Shimadzu Model IR-27 infrared spectrophotometer, and nuclear magnetic resonance spectra on a Varian HA-100 (100 MHz) and a Varian A-60 (60 MHz) using tetramethylsilane as an internal standard in $CDCl_3$. All metal salts and secondary amines were obtained commercially.

General Procedure of Oxidation. Copper(I) chloride and pyridine were added in a glass flask immersed in a water bath under argon atmosphere with vigorous stirring and then the atmosphere was replaced with oxygen. After the absorption of oxygen ceased, the secondary amine in pyridine was added slowly with further absorption of oxygen. The amount of oxygen absorbed was measured with a gas buret. Pyridine was distilled off under reduced pressure after the reaction, and the residue was extracted with ether to give a crude product which was subjected to column chromatographic purification.

Tetraphenylhydrazine. Diphenylamine (1.69 g) in 10 ml of pyridine was treated with CuCl(1.98 g) in 50 ml of pyridine and the crude product was chromatographed on an alumina column with benzene–petroleum ether (1:1) to give tetraphenylhydrazine (1.4 g, 83%), mp 146.5 °C (lit,[3] mp 144.5 °C). The IR spectrum was identical with that of an authentic sample. Found: C, 86.03; H, 5.27; N, 8.11%. Calcd for $C_{24}H_{20}N_2$: C, 85.68; H, 5.99; N, 8.33%.

N,N'-*Dimethyl*-N,N'-*diphenylhydrazine.* *N*-Methylaniline (1.07 g) in 10 ml of pyridine was treated with CuCl (1.98 g) in 50 ml of pyridine and distillation of the crude product gave *N,N'*-dimethyl-*N,N'*-diphenylhydrazine (0.6 g,

† Present address: Department of Chemical Engineering, Faculty of Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152.

52%), bp 160 °C/4 mmHg. The IR spectrum was identical with that of an authentic sample. ^{1}H NMR ($CDCl_3$): δ= 2.90(6H, s), 6.5—7.5 (10H, m). Found: C, 79.15; H, 7.56; N, 13.35%. Calcd for $C_{14}H_{16}N_2$: C, 79.21; H, 7.60; N, 13.20%.

Aminolysis of Activated Esters Formed by Reaction of Carboxylate Salts with Strained Phosphonates and Phosphinates

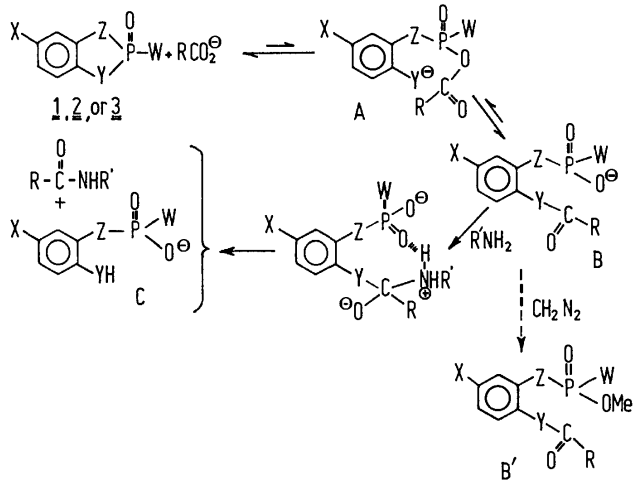
Francine ACHER and Michel WAKSELMAN*
C.E.R.C.O.A.-C.N.R.S. 2 à 8, rue Henry Dunant 94320 THIAIS, France

(Received March 8, 1982)

Synopsis. Nucleophilic attack of a carboxylate salt on a five-membered phosphonic or phosphinic ester followed by an intramolecular acyl transfer reaction gives a substituted aryl ester. Due to the intramolecular base catalysis of a neighbouring P=O group the bimolecular aminolysis of this ester is a fast process.

The study of the reactions of carboxylate salts with strained five-membered phosphonates or phosphinates and the aminolysis of the resulting aryl esters was undertaken for two purposes: on the one hand to serve as a model of the first steps in a scheme for peptide synthesis by means of the "prior amine capture" principle;[1] on the other hand, to compare the reactivities of tetracoordinated alicyclic,[2] cyclic phosphorus (this study) and sulfur[3] esters, all of which also lead to peptides but by different means (bimolecular aminolysis).

Five-membered cyclic phosphonate and phosphinate esters **1**, **2**, and **3** were prepared (*vide infra*). The probable mechanism of their reaction with a carboxylate anion is shown on the scheme. Relief of the strain facilitates the formation of a pentacoordinated intermediate (not shown) which in turn yields a mixed anhydride A. Then an intramolecular acyl transfer reaction gives a substituted aryl ester B. The aminolysis of B can be assisted by the neighbouring phosphoryl group.



Scheme 1.

Experimental

Phosphonothioate **1b** was prepared by adding a mixture of 3,4-toluenedithiol and triethylamine (2 equiv.) to a cooled solution of phenylphosphonic dichloride in benzene. Mp 98 °C; 65% yield; δ ^{31}P: 58.4 ($CDCl_3$); *m/e*: 278 (100) 156 (32) 154 (37.5).

The phosphinates **4a** and **4b** and the phosphonate **5** were obtained by the addition of a solution of 2-hydroxy-5-nitrobenzyl bromide (5 mmol) in 5 ml of dry acetone to a solution of a diethyl phosphonite or trimethyl phosphite (5 mmol) in 1 ml of acetone under dry nitrogen. After 15 min the precipitate was collected.

4a: Mp (decomp) 173 °C; 65% yield. δ($CDCl_3$) 8.0 (m, 2H, ArH), 6.90 (d, J=10, 1H, ArH), 4.05 (m, 2H, $POCH_2$), 3.25 (m, 2H, PCH_2), 1.45 (m, 6H, PCH_3+ $POCH_2CH_3$), *m/e*: 260 (14), 259 (46), 213 (100).

4b: Mp (decomp) 186 °C; 88% yield. δ($CDCl_3$) 8.1—7.5 (m, 7H, ArH), 6.95 (d, J=10, 1H, ArH), 4.0 (m, 2H, $POCH_2$), 3.40 (m, 2H, PCH_2), 1.30 (t, 3H, $POCH_2CH_3$), *m/e*: 322 (16), 321 (63), 275 (23), 229 (15).

5: Mp 162 °C; 90% yield. δ($CDCl_3$) 10.1 (1H, OH), 7.90 (m, 2H, ArH), 6.80 (d, J=10, 1H, ArH), 3.70 (d, J=11, 6H, $POCH_3$), 3.20 (d, J=22, 2H, PCH_2). Found: C, 41.34; H, 4.62%. Calcd for $C_{19}H_{12}NO_6P$: C, 41.39; H, 4.63%. Cyclization occurs by heating to 190 °C under 0.2 mmHg (1 mmHg≈133.322 Pa).

2b: $Bp_{0.5}$ 250 °C (8); 75% yield. δ($CDCl_3$) 8.10 (m, 2H, ArH), 7.05 (d, J=10, 1H, ArH), 3.90 (d, J=10, 3H, $POCH_3$), 3.25 (d, J=16, 2H, PCH_2), *m/e*: 229 (100), 215 (32).

3a: $Bp_{0.5}$ 220 °C (8); 85% yield. δ($CDCl_3$) 7.0 (m, 4H, ArH), 3.15 (m, 2H, PCH_2), 1.80 (d, J=13, 3H, PCH_3), δ ^{31}P: 70.4, *m/e*: 169 (22), 168 (100), 153 (100).

3b: Mp 173 °C; 80% yield. δ($CDCl_3$) 8.05 (m, 2H, ArH), 7.0 (d, J=11, 1H, ArH), 3.25 (m, 2H, PCH_2), 1.85 (d, J=15, 3H, PCH_3), *m/e*: 213 (100), 198 (14), 183 (13), 167 (65).

3c: Mp 175 °C; 90% yield. δ($CDCl_3$) 8.2—7.5 (m, 7H, ArH), 7.10 (d, J=10, 1H, ArH), 3.50 (m, 2H, PCH_2), *m/e*: 275 (69), 229 (33), 158 (100), 141 (19). **B'** (X=NO_2, Y=O, W=Me, Z=CH_2) was obtained after methylation by preparative thin layer chromatography (SiO_2; MeOH–EtOAc: 25—75) in 15% yield. δ($CDCl_3$) 8.30 (m, 2H, ArH) 7.40 (d, 1H, ArH) 3.75 (d, J=11, 3H, $POCH_3$) 3.30 (d, J=19, 2H, PCH_2) 2.40 (s, 3H, $COCH_3$) 1.50 (d, J=14, 3H, PCH_3), IR(CH_2Cl_2): 1770 cm^{-1}, *m/e*: 273 (9), 245 (100), 213 (50).

Some acids C have been characterized.

From ***3a***: C(X=H, Y=O, W=CH_3, Z=CH_2), mp 124 °C. δ(CD_3COCD_3) 9.5 (s, 2H, OH), 6.85 (m, 4H, ArH), 3.25 (d, J=18, 2H, PCH_2), 1.4 (d, J=13, 3H, PCH_3), *m/e*: 186 (46), 168 (91), 153 (63), δ ^{31}P: 53.8.

From ***3b***: C(X=NO_2, Y=O, W=CH_3, Z=CH_2), mp 215—217 °C. δ(CD_3COCD_3) 8.0 (m, 2H, ArH), 6.85 (d, J=10, 1H, ArH), 3.20 (d, J=18, 2H, PCH_2), 1.40 (d, J=13, 3H, PCH_3), *m/e*: 231 (35), 213 (>100), 198 (25), 183 (14), 167 (100).

From ***3c***: C(X=NO_2, Y=O, W=C_6H_5, Z=CH_2), mp 220 °C. δ(CD_3COCD_3) 8.0—7.5 (m, 7H, ArH), 6.75 (d, J=10, 1H, ArH), 3.40 (d, J=13, 2H, PCH_2), *m/e*: 293 (5.6), 275 (100), 245 (15), 229 (56).

Results and Discussion

We were unable to isolate the *o*-phenylene phenylphosphonate **1a** using the described method,[4] even when the rather unexpected aqueous treatments were omitted. A hygroscopic compound was formed following the preparation procedure[5] for a di-*t*-butyl de-

rivative.[6] However, a thioanalog **1b** was obtained from 3,4-toluenedithiol.

Cyclic phosphonate **2a** was prepared from saligenol and a phosphite.[7] The use of diethyl methylphosphonite instead of trimethyl phosphite led to a cyclic phosphinate **3a**.

The reaction of 2-hydroxy-5-nitrobenzyl bromide with diethyl methylphosphonite rapidly gave **4a** which in turn produced **3b** by vacuum heating. Under the same conditions **4b** and **3c** were obtained from diethyl phenylphosphonite. By an analogous Arbuzov reaction and cyclization, **5** and **2b** were formed from trimethyl phosphite.

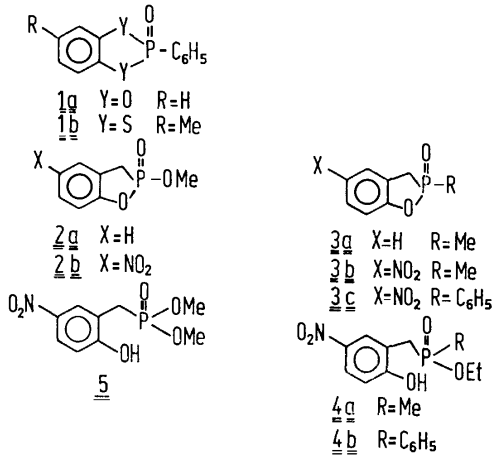


Fig. 1.

1b slowly reacts (2 h) with a mixture of acetic acid (1 mmol) and triethylamine (1 mmol) in 1 ml of $CHCl_3$ to give thioester **B** (Y=Z=S, X=Me, W=C_6H_5; $\nu_{C=O}$ 1700 cm^{-1}). The reaction of triethyl or tetrabutylammonium acetate with the unsubstituted phosphonate or phosphinate **2a** and **3a** leading to esters **B** (Y=O, Z=CH_2, X=H, W=Me, or OMe; $\nu_{C=O}$ 1760 cm^{-1} (CH_2Cl_2)), occurs by heating the substances to 40 °C in CH_2Cl_2. The activated nitro derivatives **2b**, **3b**, and **3c** react at room temperature in 2 h, giving **B** (X=NO_2; $\nu_{C=O}$ 1765 cm^{-1}) in about 80% yield.

In one case, the methylated derivative **B'** (X=NO_2, Y=O, W=Me, Z=CH_2) was isolated by treating **B** with diazomethane and HBF_4.

We did not observe an IR frequency in relationship with mixed anhydride **A**, which did not accumulate in the reaction.

In each case, the rate of aminolysis of **B** is much faster than that of the corresponding unsubstituted aryl ester or thioester. *E.g.*, the reaction of 1 mmol of **B** (Y=O, Z=CH_2, W=CH_3, X=NO_2) with 1 equiv. of benzylamine in 3 ml of CH_2Cl_2 yielding *N*-benzylacetamide (mp 61 °C) is complete in less than five minutes at 20 °C. Under the same conditions the reaction with *p*-nitrophenyl acetate takes about 90 min.

We believe that the observed increase in the reaction rate is mainly due to an anchimeric assistance by the neighbouring P=O group.[9] With this hypothesis, aminolysis of **B** (X=NO_2) is doubly accelerated, first, by the electronwithdrawing effect of the nitro substituent and second, by intramolecular general base catalysis.

Addition of the highly reactive cyclic phosphinate **3b** or **3c** to an equimolar mixture of acetic acid, triethylamine, and benzylamine in CH_2Cl_2 gives *N*-benzylacetamide with a 67% yield.[10] However, the main drawback in using cyclic phosphonic or phosphinic ester as coupling reagents is their sensitivity to moisture.[11]

We have recently shown that the analogous 5-nitrotoluene-α, 2-sultone is stable and yields peptides by a similar mechanism (Scheme 1: SO_2 instead of $\overset{O}{\overset{\|}{P}}$–W[3]).

In conclusion the hygroscopic cyclic phosphonates and phosphinates are not better reagents for coupling than the very efficient alicyclic phosphonates[2] and sultone.[3] Nevertheless the formation of ester **B** corroborates the mechanism of the first steps in the previous method of peptide synthesis.[1]

We thank Dr P. Savignac for his help in the preparation of the diethyl methylphosphonite.

6) In the same reaction, under different experimental conditions, tris(*o*-phenylene)phosphate has been isolated. (T. Koizumi, Y. Watanabe, Y. Yoshida, and E. Yoshii, *Tetrahedron Lett.*, **1974**, 1075).

7) B. E. Ivanov and H. B. Ageeva, *Izv. Akad. Nauk SSSR Ser. Khim.*, **1967**, 226; A. B. Ageeva and B. E. Ivanov, *ibid.*, **1967**, 1494; W. Vogt, *Phosphorus and Sulfur*, **5**, 123 (1978).

8) Temperature of the oven of a Büchi GKR (Bulb to bulb) apparatus.

9) The slightly basic ϕ_3PO is an efficient catalyst of the aminolysis of *p*-nitrophenyl acetate in chlorobenzene. Acceptance of the ammonium proton probably facilitates the decomposition of the tetrahedral intermediate (C. W. Su and J. W. Watson, *J. Am. Chem. Soc.*, **96**, 1854 (1974)). General base catalysis by a neighbouring anion is probably excluded because the aminolysis of the methyl ester of **B** is fast too.

10) We have not observed the formation of a phosphinic amide by the competitive aminolysis of **3b**. Base-catalyzed hydrolysis by contaminant water (M. Mulliez and M. Wakselman, *Phosphorus and Sulfur*, **8**, 41 (1980)) occurs by mixing **3b** or **3c** with a primary amine.

11) However the *o*-hydroxybenzylphosphinic acids may be cyclized by simply vacuum heating them to their melting.

An Effective Process for Treatment of Malodor in Exhaust Gas by Hypochlorite

Kenzo ABE* and Wataru MACHIDA†

Fuso Co., Ltd., Honmura-cho, Shinjuku-ku, Tokyo 162

† *College of Industrial Technology, Nihon University, Izumi-cho, Narashino 275*

(Received January 12, 1982)

Synopsis. Pilot-plant studies were carried out to find out the optimum conditions for hypochlorite-oxidation treatment of malodorous multi-components in exhaust gas from night soil treatment plants. A two-step process was proved to be the most effective: a part of malodorous components are absorbed and oxidized in the first packed-tower into which a pH 7 aqueous solution of sodium hypochlorite slowly introduced and then unreacted components are oxidized in the second tower with a pH 11 solution.

There have been known several methods for treatment of malodor in exhaust gas from night soil or sewage treatment plants, such as adsorption by activated carbon,[1] catalytic oxidation,[2] and wet scrubbing systems using absorptive solutions with oxidizing agents and/or alkaline solution, and water.[3]

The authors have described in the earlier papers[4-8] the wet scrubbing systems using packed towers through which hypochlorite or hydrogen peroxide solutions were allowed to pass and have clarified the relationship between oxidation conditions of malodorous sulfide components and the decrease of COD (chemical oxygen demand) of effluent water. We have defined the conditions (pH of absorptive solution, it's NaOCl concentration, superficial gas velocity, *etc.*) for absorptive oxidation of hydrogen sulfide[4,5] and coexistent malodorous components in exhaust gas such as ammonia, trimethylamine, methanethiol, dimethyl sulfide, dimethyl disulfide, trace acetaldehyde and styrene.[6-8] In the above studies, the effectiveness of scrubbing systems was assessed in terms of the overall mass transfer coefficient $K_G a$.[9]

In this paper, the optimum conditions for effective NaOCl oxidation of mixed systems of malodorous multi-components are investigated with actual exhaust gas, using a pilot-plant.

Experimental

Equipment. Polyvinyl chloride towers of diameter 100 cm, packed with Takiron Trical P 175 packings, were used for absorptive oxidation.

Chemical Analysis. Carbon dioxide and chlorine were determined by the detector tube method and the orthotolidine method, respectively. Hydrogen sulfide, methanethiol, dimethyl sulfide, dimethyl disulfide, trimethylamine, styrene and acetaldehyde were determined by the gas chromatography,[10,11] and ammonia was determined by the spectrophotometry.[10]

Procedure. Sample gas was introduced into the packed tower from the bottom by a blower and the absorptive solution was sprayed onto the packings at the top of the tower, so as to make gas and solution contact in countercurrent fashion. The gas was sampled at the inlet and outlet of the tower and analyzed.

Results and Discussion

Figure 1, prepared by rearranging the data in the earlier papers,[4,6-8] shows the relationship between the pH values of NaOCl solutions and the $K_G a$ values of malodorous gas components under the conditions that they are oxidized separately with 1.2×10^{-2} mol/l NaOCl solution at the superficial gas velocity of 1.7 m/s and the liquid/gas ratio of 2 l/m^3. As shown there, the $K_G a$ values for NH_3, $(CH_3)_3N$, CH_3SCH_3, CH_3SSCH_3, CH_3CHO, and $C_6H_5CH{=}CH_2$ are the largest, respectively at pH 6, while those for CH_3SH and H_2S are the largest at pH 11, respectively. Since the removal rate rises with the increase of the $K_G a$ value, it can be estimated that the most effective oxidation would result at pH 6 and 11 for an actual exhaust gas which contains those components in a mixed state. Then, an experimental study to verify the estimation was carried out with actual mixed systems of those components in exhaust gas from a night soil treatment plant, which contains H_2S, CH_3SH, CH_3SCH_3, CH_3SSCH_3, NH_3, $(CH_3)_3N$, $C_6H_5CH{=}CH_2$, CH_3CHO in 39, 0.05, 1.74, 0.0089, 18.6, 0.32, <0.01, <0.05 ppm, respectively, using two packed towers (60 cm and 180 cm height) arranged in parallel. The exhaust gas was

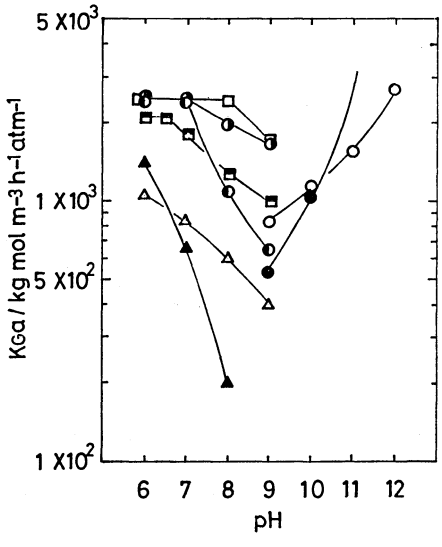

Fig. 1. Effect of pH on K_G a of malodorous components.
Superficial gas velocity: 1.7 m/s, liquid/gas ratio: 2 l/m^3, NaOCl: 1.2×10^{-2} mol/l, packed height: 60 cm (180 cm for H_2S), tower diameter: 8 cm (40 cm for H_2S), □: NH_3 (10 ppm), ■: $(CH_3)_3N$ (5 ppm), ○: CH_3SH (5 ppm), ◑: CH_3SCH_3 (5 ppm), ●: H_2S (60 ppm), ◐: CH_3SSCH_3 (5 ppm), △: CH_3CHO (1 ppm), ▲: $C_6H_5CH{=}CH_2$ (1 ppm).

oxidized both with pH 6 NaOCl solution (in the 60 cm tower) and with the pH 11 solution, separately in parallel. The NaOCl concentration, superficial gas velocity and liquid/gas ratio were set to be the same as described above. The $K_G a$ values of NH_3, $(CH_3)_3N$, and CH_3SCH_3 were determined to be 2550, 2100, 2600 (kg mol/m^3 h atm), respectively, when oxidized with pH 6 solution and that of H_2S to be 2500 with pH 11 solution. These values almost agree with those in the earlier papers[4,6,7] (determined for each component, separately). Therefore, the estimation was verified and the pH values, 6 and 11 were proved to be effective for oxidation of actual malodorous gas in mixed multi-component systems. However, since so much chlorine releases (about 10 ppm) from the absorptive solution at pH 6 that the NaOCl concentration can't be controlled, it is preferable for the actual operation to set the pH at 7 and 11, respectively; at this pH chlorine release can be suppressed to less than 3 ppm.

Next, to make the oxidation process more effective, a two-step oxidation was planned to be tried using two packed towers arranged in series, whereby malodorous components are oxidized in the first tower with pH 7 NaOCl solution and next in the second with the pH 11 solution. Then, another experimental study was carried out with exhaust gas from a night soil treatment plant, which contains H_2S, CH_3SH, CH_3SCH_3, CH_3SSCH_3, NH_3, $(CH_3)_3N$, $C_6H_5CH{=}CH_2$, CH_3CHO in 40, 0.08, 1.97, 0.024, 18.8, 0.024, <0.01, <0.05 ppm, respectively. The gas was introduced into the first tower (60 cm height), where part of H_2S and the other components except CH_3SH were absorbed and oxidized, next into the second (180 cm height), where the remaining H_2S and CH_3SH were oxidized. The NaOCl concentration, superficial gas velocity and liquid/gas ratio were set to be the same as described above. In the effluent gas from the second tower, 0.002 ppm of H_2S and 0.05 ppm of NH_3 were detected and the other malodorous components were reduced to the concentrations below their determinable limit. The treated gas was almost odorless. Therefore, it can be concluded that malodor is removed almost completely by the two-step process under the conditions described above. In the practical operation, however, it is preferable to set the pH around at 10 rather than 11 in the second tower, in the case where much CO_2 gas (1500—3000 ppm) coexists, as in the case of aeration tanks or sludge storage tanks in sewage treatment plants, in order to prevent troubles of carbonate-scaling.

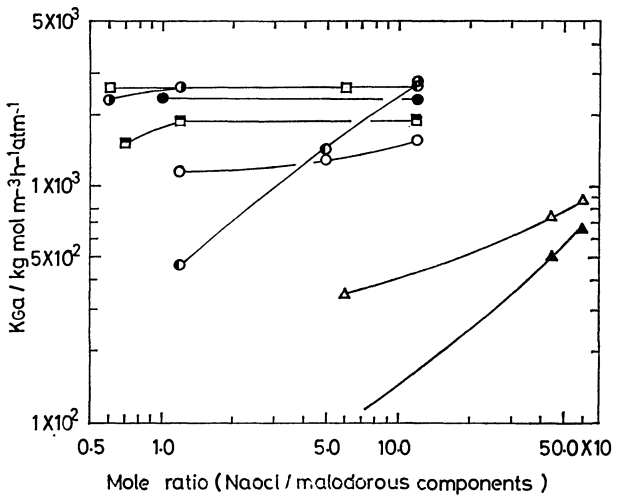

Fig. 2. Effect of mole ratio on $K_G a$ of malodorous components.
Superficial gas velocity: 1.7 m/s, liquid/gas ratio: 2 l/m^3, packed height: 60 cm (180 cm for H_2S), tower diameter: 8 cm (40 cm for H_2S), pH 11 for H_2S and CH_3SH, pH 7 for the others, □: NH_3 (5—10 ppm), ▣: $(CH_3)_3N$ (1—5 ppm), ○: CH_3SH (5 ppm), ◑: CH_3SCH_3 (5 ppm), ●: H_2S (10—100 ppm), ◐: CH_3SSCH_3 (5 ppm), △: CH_3CHO (0.1—1.0 ppm), ▲: $C_6H_5CH{=}CH_2$ (0.1—1.0 ppm).

Figure 2, prepared by rearranging the data in the earlier papers,[4,6-8] shows the relationship between the NaOCl concentration and $K_G a$. Malodorous components are classified roughly into two groups: namely, one to be oxidized almost completely at the mole ratio (hypochlorite/malodorous components) of 12 (or larger) and another to be oxidized at the ratio of larger than 120. CH_3SH, CH_3SSCH_3, CH_3CHO, and $C_6H_5CH{=}CH_2$ belong to the latter. But their contents in actual exhaust gas are negligible small (less than 5 ppm), compared with H_2S, NH_3, $(CH_3)_3N$, and CH_3SCH_3 in the former group. Accordingly, it is adequate that the NaOCl concentration was determined to be 1.2×10^{-2} mol/l on the basis of the mole ratio 12.

This process is applicable to the treatment of malodorous exhaust gas from sewage treatment plants and kraft pulp mills.

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received April 3, 1982)

Synopsis. The wet oxidation of various organic compounds was carried out in the presence of the Co-Bi (5:1) complex oxide catalyst. The catalyst was especially effective for the oxidation of all refractory lower carboxylic acids, which are intermediates in the wet oxidation of many organic compounds.

Wet oxidation, carried out in air under a high pressure and at an elevated temperature, is particularly effective for the purification of wastewaters which are resistant to biological treatment,[1] and the recovery of mechanical energy is possible when the process is applied to a highly contaminated wastewater.[2] The severe operating conditions, however, limit the application of this process, and so the development of various catalysts has been attempted in order to mitigate the reaction conditions.[3-6] Although homogeneous copper salts are highly active,[7] heterogeneous catalysts are recommended in actual waste-water treatment. The available data on active heterogeneous catalysts, however, seem to be meagre.[8]

Previously, it was found that cobalt–bismuth complex oxide with a molar ratio of Co to Bi of 5 was remarkably active in the wet oxidation of acetic acid.[9] In this work, the activity of this catalyst in the wet oxidation of various water-soluble organic compounds was investigated.

Experimental

Reagent. Commercial polyethylene glycol with a molecular weight of 4000 (PEG-4000) and other commercial reagents were used without further purification.

Preparation of the Catalyst. Co-Bi complex oxide with a molar ratio of Co to Bi of 5 (Co/Bi[5/1]) was prepared as follows. Corresponding amounts of cobalt(II) nitrate and bismuth(III) nitrate (total amount: *ca.* 30 g) were dissolved in 100 ml of concentrated nitric acid, and the solution was poured into 500 ml of 3 mol/dm^3 sodium hydroxide. The resultant precipitate was washed with water until no nitrogen component was detected by means of a total-nitrogen analyzer. After drying at 100 °C, the precipitate was calcined at 350 °C for 2 h in air. On the basis of the weight change of the catalyst, the Bi was regarded as BiO(OH), and the Co, as Co_3O_4. The catalyst had a BET surface area of 64 m^2/g and a particle size smaller than 200 mesh.

Procedure. The catalyst, deionized water, nitrogen (3.8 MPa), and oxygen (1.0 MPa) were charged into a 270 cm^3 autoclave equipped with a sample injector and a valve for sampling. After the autoclave had been heated to a prescribed temperature by means of an electric furnace, a known amount of the reactant was injected through an injector under pressure. At appropriate time intervals, an aliquot of the solution was then withdrawn and submitted to analysis. Unless otherwise stated, the pH of the solution was not adjusted.

The oxidation of ammonia was carried out in the same way (Reaction conditions: $[NH_3]=1200$ ppm, $[Co+Bi]=2.0\times10^{-2}$ mol/dm^3, $P(O_2)=1.0$ MPa, $P(N_2)=3.0$ MPa, temp=270 °C, pH=11.0). In this case the determination of total nitrogen (TN) in the solution was carried out when the autoclave was cooled down to room temperature after the reaction for 1 h, because analysis during the reaction at a high temperature (270 °C) might be inaccurate due to the escape of ammonia into the vapor phase.

The total organic carbon (TOC) and TN were determined by means of a Sumitomo GCT-12N TOC-TN analyzer.

Results and Discussion

Table 1 shows the results of the wet oxidation of various organic compounds. R_{cat} and $R_{no\ cat}$ show the initial rates of TOC-decrease in the presence and in the absence of Co/Bi[5/1] respectively. The ratio of the initial rates, $R_{cat}/R_{no\ cat}$, indicates the effect of the catalyst under the present reaction conditions. From the values of $R_{cat}/R_{no\ cat}$, it is shown that Co/Bi[5/1] was effective for the wet oxidation of various compounds. In the cases of the oxidation of 1,2-propanediol and acetonitrile, the induction periods were observed, and the effect of the catalyst was not shown by $R_{cat}/R_{no\ cat}$. However, the percentage decrease in TOC after 20 min shows that the both reactions were accelerated in the presence of the catalyst (Runs 24 and 25). Co/Bi[5/1] was also effective for the oxidation of refractory pyridine, although the effect was not so large. The oxidation of some compounds, such as phenol, glutamic acid, and urea, proceeded so rapidly, even in the absence of Co/Bi[5/1], that the effect of the catalyst could not be evaluated (Runs 15—17 and 27). The effect of the catalyst might be seen by carrying out the reaction at lower temperature. However, as can be seen from the temperature-dependence of the oxidation of acetic acid (Runs 2—5), the effect of the catalyst was less remarkable at lower temperatures. The oxidation of oxalic acid at low temperatures (140 and 112 °C) was not accelerated by Co/Bi[5/1] (Runs 10 and 11). Thus, the appropriate temperature, depending upon

the kind of compound to be oxidized, is necessary for the catalyst to exert its activity.

In order to see the property of the catalyst more clearly, the values of $R_{cat}/R_{no\ cat}$ were plotted against $R_{no\ cat}$ in the oxidation of various compounds at 248 °C (Fig. 1). It is clear that the catalyst is especially effective for the oxidation of carboxylic acid; the more refractory the carboxylic acid is, the more effective the catalyst is. However, for compounds other than carboxylic acid, the effect of the catalyst is not so remarkable. Previously, it was deduced that the catalytic action of Co/Bi[5/1] was due to two of its properties; one was the presence of basic sites, induced by Bi, where acetic acid was adsorbed by an acid–base interaction in the first step of the reaction, and the other was its redox property which induced the decomposition of the adsorbed acetic acid.[9] From the results shown in Fig. 1, it is clear that the catalyst exhibited the former property more strongly; the acid-base interaction played an important role in the oxidation of all carboxylic acids. The catalyst was quite effective for the oxidation of acetamide. As acetamide is readily hydrolyzed to produce acetic acid under the present reaction conditions,[10] the catalyst is apparently highly active in the oxidation of acetamide.

Many organic compounds undergoing wet oxidation gradually degrade to low-molecular-weight compounds and, finally, to highly refractory lower carboxylic acids.[11] As Co/Bi[5/1] is remarkably active for the oxidation of all refractory lower carboxylic acids, it is quite useful as a catalyst for the wet oxidation of wastewater.

The contamination of wastewater by ammonia is a serious environmental problem; however, few active catalysts for the wet oxidation of ammonia have been reported.[12] The catalytic activity of Co/Bi[5/1] in the wet oxidation of ammonia was investigated, the reaction conditions being shown in the Experimental section. The percentage decrease in TN in the solution was 46.0%, compared with 20.5% in the absence of Co/Bi[5/1], showing that the catalyst was also effective in the wet oxidation of ammonia.

The Crystal and Molecular Structure of Staurosporine, a New Alkaloid from a *Streptomyces* Strain

Akio Furusaki,* Nobuhiro Hashiba, Takeshi Matsumoto, Atsushi Hirano,†
Yuzuru Iwai,† and Satoshi Ōmura†

Department of Chemistry, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060
†The Kitasato Institute and Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received January 7, 1982)

The molecular sturcture of staurosporine, an alkaloid from a *Streptomyces* strain, has been determined by means of an X-ray crystallographic analysis of its methanol solvate ($C_{28}H_{26}N_4O_3 \cdot CH_3OH$). The crystals are monoclinic, with four formula units in a unit cell with dimensions of $a=23.487(6)$, $b=7.636(3)$, $c=15.638(4)$ Å, and $\beta=116.71(5)°$; the space group is C2. 2532 unique intensity data were collected on a four-circle diffractometer with LiF-monochromated Cu *Kα* radiation. The structure was solved by the Monte Carlo direct method, using the 20 strongest reflections as the starting set; the 72nd random phase set led to the correct solution. The *R* value reached 0.047 by block-diagonal least-squares refinements. Staurosporine has been found to contain a unique dimeric indole structure. Because of the steric hindrance, the indolo[2,3-*a*]carbazole aromatic system in the molecule is slightly bent; the two terminal benzene rings make an angle of 7.5° with each other.

Staurosporine (**1**), formerly referred to as AM-2282, is an alkaloid isolated from *Streptomyces staurosporeus* Awaya, Takahashi, and Ōmura, nov. sp., and shows strong hypotensive activity as well as antimicrobial activity against fungi and yeast.[1] Since **1** exhibits characteristic ultraviolet absorption at 292 nm, it was compared with other known antibiotics (*e.g.*, oxamicetin[2] and pyridomycin[3,4]) which absorb in a region near 292 nm. However, **1** could not be structurally correlated to these known compounds. Therefore, we have tried to determine the molecular structure of **1** by means of X-ray analysis of its methanol solvate. The results have already been reported in a preliminary form.[5] The present paper will describe the details of the structure determination and molecular geometry of this novel alkaloid, **1**.

Experimental

Pale-yellow plate-like crystals, mp 270 °C (decomp), were obtained from a methanol solution of **1**. A single crystal with dimensions of about $0.5 \times 0.5 \times 0.2$ mm^3 was used for the X-ray measurement. The crystal data are summarized in Table 1. The unit-cell dimensions and reflection intensities were measured on a Rigaku four-circle diffractometer with LiF-monochromated Cu *Kα* radiation ($\lambda=1.5418$ Å). The θ-2θ continuous-scan technique was applied at a 2θ scan rate of 1° min^{-1}; the background was measured for 30—60 s at each end of the scan range. Three standard reflections, measured at intervals of every 29 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 140°, 2532 independent structure factors above the $\sigma(F)$ level were selected for the structure determination.

Structure Determination

The structure was elucidated by the Monte Carlo direct method,[6] using the 20 reflections with the greatest $|E|$ values as the starting set. In order to extend each of the tentative-phase sets derived from random numbers, 12 cycles of the tangent procedure were carried out using 487 $|E|$ values above 1.30. The 72nd phase set which showed a low R_K value of 0.274 ($R_k=\sum||E_o|-k|E_c||/\sum|E_o|$) and a nonzero q value of 0.400 ($q=1-\sum_h|E_h|(|\sum_k E_kE_{h-k}|/\sum_k|E_kE_{h-k}|)/\sum_h|E_h|$)[7] led to the correct solution; an *E*-map based on 458 phases afforded 33 of the 37 independent non-hydrogen atoms. The remaining four atoms were located in a difference Fourier map. After several cycles of the least-squares refinement using the carbon atomic scattering factors for all the non-hydrogen atoms, the nitrogen and oxygen atoms were assigned by taking account of the values of isotropic temperature factors as well as the interatomic distances. The structure thus obtained was refined by the block-diagonal least-squares method with anisotropic thermal parameters. After 25 hydrogen atoms had been located in a second difference Fourier map, further least-squares refinements were performed including the hydrogen atoms with isotropic temperature factors. The weighting scheme used was as follows:

$$w = 1/\{\sigma(F)^2 \exp(c_1X^2+c_2Y^2+c_3XY+c_4X+c_5Y)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The c_1, c_2, c_3, c_4, and c_5 coefficients were evaluated from the $(\Delta F)^2$ distribution: $c_1=-0.552\times10^{-3}$, $c_2=39.5$, $c_3=0.0541$, $c_4=0.0528$, and $c_5=-44.7$. In this manner, the *R* value reached 0.047. The final atomic parameters are listed in Table 2.[8]

The calculations were done on a FACOM 230-75 computer at the Hokkaido University Computing Center, using our own programs. The atomic scattering

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

factors were taken from the International Tables.[9]

Results and Discussion

Molecular Structure. The molecular skeleton of **1** obtained is illustrated in Fig. 1, while the bond distances and angles are given in Table 3. From these results, it is concluded that **1** has the **1a** structure containing a unique dimeric indole skeleton.

As Fig. 2 shows, the aromatic system composed of the A-, B-, C-, D-, and E-rings is slightly bent; the terminal A- and E-rings deviate from the mean plane of the central C-ring onto the side of the N(31)H–C(32)H_3 methylamino group, and make an angle of 7.5° with each other. Of the C–C bond distances in the aromatic system, the C(17)–C(21), C(1)–C(2), and C(13)–C(14)

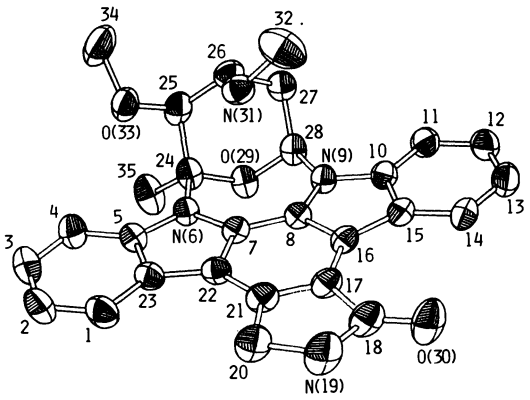

Fig. 1. A perspective view of the staurosporine molecule, showing the crystallographic numbering. Each non-hydrogen atom is represented as a thermal ellipsoid enclosing a 50% probability. The symbol C for carbon atoms is omitted.

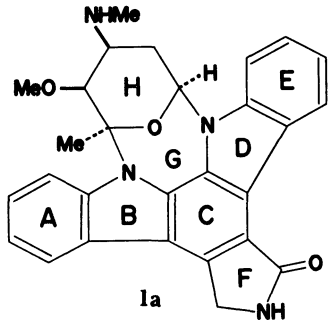

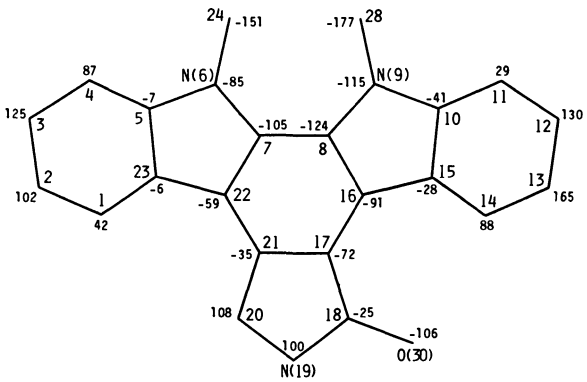

Fig. 2. The deviations ($d\times 10^3$/Å) of the atoms from the mean plane of the A–B–C–D–E aromatic system.
This mean plane is represented by the following equation: $0.1522X+0.9328Y+0.3266Z-3.200=0$, where X, Y, and Z are rectangular coordinates measured in Å units along the a*, b, and c axes respectively.

distances are appreciably shorter than the others. These bond shortenings may be explained on the basis of the π-bond-order distribution in the carbazole molecule[10] as follows: when each of the A–B–C and C–D–E ring

TABLE 3. THE BOND DISTANCES (l/Å) AND ANGLES (ϕ/°), WITH THEIR STANDARD DEVIATIONS
The e.s.d.'s given in parentheses refer to the last decimal position.

systems is taken as the carbazole skeleton, all the above short bonds correspond to the carbazole C_3–C_4 or C_5–C_6 bond having the greatest π-bond order; especially the shortest C(17)–C(21) bond corresponds exactly to such bonds in both A–B–C and C–D–E carbazole skeletons. In order to estimate the π-bond orders in **1**, we performed a Hückel MO calculation on the indolo[2,3-*a*]carbazole (**2**) molecule, assuming the C_{2v} symmetry. The results given in Table 4 show a good correlation between the calculated π-bond orders and the observed C–C bond distances; as has been expected, the C(17)–C(21) bond

TABLE 4. THE π-BOND ORDERS IN INDOLO[2,3-*a*]CARBAZOLE

Bond[a]	π-Bond order[b]	Distance[c] l/Å
C_1–C_2	0.691	1.381

O(29)–C(24)–C(25)–C(26)	−45.5

has the greatest π-bond order, and the C(1)–C(2) and C(13)–C(14) bonds have the next greatest.

The γ-lactam F-ring is almost planar, and lies approximately in the mean plane of the A–B–C–D–E aromatic system. In *cis*-peptides[11] as well as in *trans*-peptides,[12] usually the N–C=O bond angle is larger than the C_α–C=O angle, but the relation is reversed in the present amide (125.2 and 128.3°). This bond-angle deformation may result from the steric hindrance between the O(30) atom and the C(14)H(14) grouping: O(30)···C(14), 3.192(4); O(30)···H(14), 2.47(4) Å. In this connection, the C(16)–C(17)–C(18) bond angle is also found to be larger than the C(20)–C(21)–C(22) angle by 2.2°. Further, the O(30) atom and the C(14)-H(14) group become more distant from each other by deviating slightly from the mean plane of the aromatic system to the opposite sides (see Fig. 2).

The torsion angles for the G- and H-rings are given in Table 5. The seven-membered G-ring has an envelope-like conformation, while the six-membered H-ring takes a flattened chair conformation. All the N(6), N(9), and N(31) atoms are axially placed on the same side of the H-ring. As the result, the N(31) atom approaches the planar N(6)–C(7)–C(8)–N(9) segment very closely: C(7), 3.087(4); C(8), 3.089(4) Å. This close contact results in a slight deviation of the C(24) and C(28) atoms from the N(6)–C(7)–C(8)–N(9) plane. Since the three N–C bonds at each of the N(6) and N(9) atoms are found to be coplanar, this deviation must arise from pure twistings about the N(6)–C(7) and N(9)–C(8) bonds. These twistings can be expanded into the bending deformation of the indolo[2,3-*a*]-carbazole moiety. Thus, the bending of the aromatic system can be regarded as due mainly to the severe steric hindrance between the methylamino group and the aromatic system.

As will be seen from the C(27)–C(26)–N(31)–C(32) and C(25)–C(26)–N(31)–H(31) torsion angles of 70.2 and −56° respectively, the N(31) atom directs its lone pair approximately toward the C(8) atom, and donates its H(31) proton to the O(33) methoxyl oxygen atom, possibly forming a weak hydrogen bond of the five-membered-ring type: N(31)···O(33), 2.814(4); H(31)···O(33), 2.41(6) Å; H(31)···O(33)–C(25), 79(1); H(31)···O(33)–C(34), 96(1)°. The C(34) methoxyl carbon atom is *trans* to the C(24) atom; this corresponds exactly to the most stable of the three staggered conformations about the C(25)–O(33) bond. The O(33) and C(35) atoms are very close to the A-ring: O(33)···C(4), 3.088(4); O(33)···C(5), 3.059(4); C(35)···C(4), 3.108(4) Å. These steric repulsions may explain the following facts: (1) the N(6)–C(24) and C(24)–C(25) bond distances are longer than the N(9)–C(28) and C(27)–C(28) distances by 0.031 and 0.028 Å respectively; (2) the O(29)–C(24)–C(35) bond angle (103.1°) is considerably smaller than the tetrahedral angle; (3) the C(4)–C(5)–N(6) and C(5)–N(6)–C(24) bond angles are larger than the N(9)–C(10)–C(11) and C(10)–N(9)–C(28) angles by 2.6 and 2.8° respectively.

Crystal Structure. The molecular arrangement viewed along the b axis is drawn in Fig. 3. The methanol

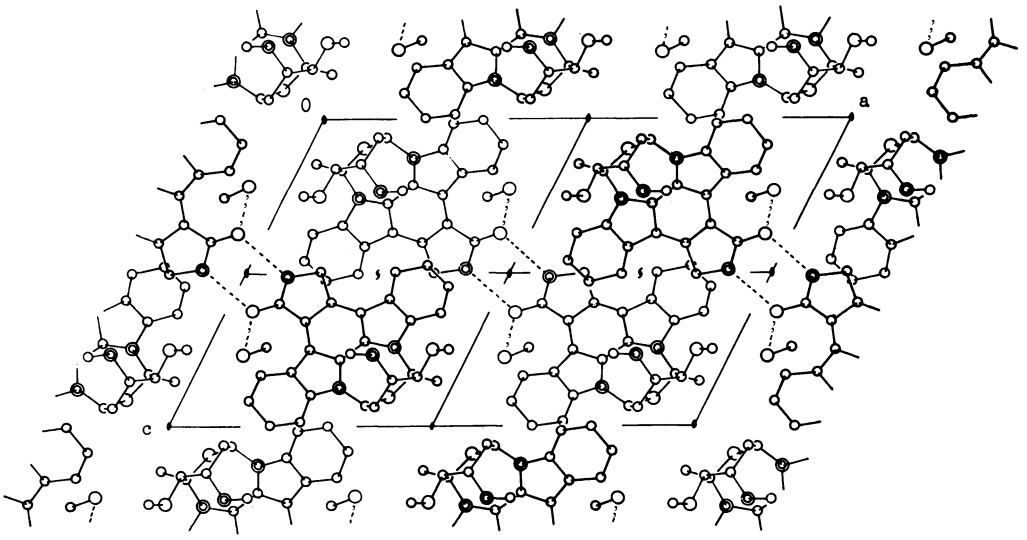

Fig. 3. The crystal structure viewed along the b axis. The samll single circles represent carbon atoms, the large single circles oxygen atoms, and the double circles nitrogen atoms.

molecule is attached to the staurosporine molecule by the O(M)–H···O(30) hydrogen bond with the O···O distance of 2.98(1) Å. The staurosporine molecules related by the two-fold rotation axis are connected by a pair of intermolecular hydrogen bonds, N(19)–H···O(30′) and N(19′)–H···O(30), forming a hydrogen-bonded dimer; the N···O distances are 2.979(3) Å. The N(19), O(30), N(19′), and O(30′) atoms deviate tetrahedrally from the planar arrangement; their deviations from the mean plane are 0.211 Å. These hydrogen-bonded dimers are further held together mainly by the van der Waals interactions. It is interesting to note that the two H-rings, placed approximately perpendicular to the (010) plane, face each other about the two-fold rotation axis.

Formation of Intramolecular Hydrogen Bond in Hydroxy-substituted Nitroxide Radicals as Evidenced by Electron Spin Resonance

Yashige KOTAKE* and Keiji KUWATA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received March 8, 1982)

The nature of the intramolecular hydrogen bond in hydroxysubstituted nitroxide radicals was examined. The hydroxysubstituted radical was produced by the spin trapping reaction of hydroxyalkyl radicals with α-phenyl-*N*-*t*-butylnitrone. The magnitude of the hyperfine splitting caused by β-hydrogen of the radical is strongly dependent on the composition of the solvent, which is attributed to the formation of the intramolecular hydrogen bond. The equilibrium constant of the intramolecular hydrogen bond in an aprotic solvent was determined by observing the magnitude of the hyperfine splitting of β-hydrogen as a function of the amount of added methanol. Based on the temperature dependence of the equilibrium constant, the standard entropy and the standard enthalpy of the formation of the hydrogen-bonded chelate ring was estimated. The same method of analysis was applied to the system of diastereomeric nitroxide and the difference of the internal energy of the chelate ring in the isomers was detected. Moreover, the difference was utilized to separate the ESR spectra of the diastereomers.

Hydrogen bonding in free radicals in solution has been extensively studied by the magnetic resonance technique. In some cases the thermodynamic constants of the formation of the hydrogen bond have been determined, based on the equilibrium study.[1-6] Concerning the intramolecular hydrogen bond, hydroxy-substituted semiquinone radicals exhibit an ESR linewidth alternation caused by the formation of the intramolecular hydrogen bond.[7,8] The linewidth alternation was also detected in hydroxy-substituted nitroxide radicals due to the formation of the chelate ring.[9,10] These studies have confirmed the formation of the intramolecular hydrogen bond, however, experimental difficulties prevent an equilibrium study.

The main difficulty in determining the equilibrium nature of the intramolecular hydrogen bond is to find a sensitive index which establishes the equilibrium state. Also there is characteristic difficulty in studying the hydrogen bond by a magnetic resonance technique: the rate of formation and breakage of the hydrogen bond is very large compared with the time scale of magnetic resonance so that the observed spectrum is that of an equilibrium mean.[11]

Recently it was pointed out that the hydroxy-substituted nitroxide radicals produced by a spin trapping technique have hyperfine splitting (hfs) of the β-hydrogens which is very sensitive to the solvent.[12] Typically, the hfs of β-H decreases forty per cent on changing from an aprotic to a protic solvent. The formation of a chelate ring by the intramolecular hydrogen bond is responsible for the change of the hfs of β-H. The quantitative treatment of the equilibrium is now possible by observing the dependence of the magnitude of the hfs of β-H on the amount of added hydrogen donor such as methanol. Using this technique the standard entropy and the standard enthalpy for the formation of the chelate ring can be estimated by the temperature dependence of the equilibrium constant.

It should be pointed out that IR and NMR studies of the OH···O hydrogen bond were more concerned with the strength of the hydrogen bond than with the structure of the chelate ring.[11] In the present system the magnitude of the β-H hfs provides information about the ring conformation while the *g*-values and N-hfs gives details of the OH···O bond.

The strain energy of the chelate ring is expected to be different for different diastereomers. Therefore the difference of the standard enthalpy of the formation of the chelate ring is utilized for the spectroscopic separation of the diastereomeric radical mixture. Hfs of β-H of diastereomers of hydroxy-substituted nitroxide radicals show different temperature dependence in the presence of proton donors. As a result the ESR spectra of diastereomeric systems showed better resolution at low temperature in toluene in the presence of methanol.

Experimental

Hydroxy-substituted nitroxide radicals were produced by the abstraction of a hydrogen atom from alcohols by photo-excited benzophenone (BP) followed by spin trapping with phenyl-*N*-*t*-butyl nitrone (PBN). The reaction scheme for the formation of the radical is as follows:[13,14]

$$RCH_2OH \xrightarrow{BP^*} \dot{R}CHOH$$

$$\dot{R}CHOH + \phi\text{-}CH{=}N(\rightarrow O)\text{-}t\text{-}Bu \longrightarrow \phi\text{-}CH(R)\text{-}N(\rightarrow O\cdot)\text{-}t\text{-}Bu \quad (1)$$

The details of the experimental procedure has been described elsewhere.[12] After the formation of nitroxides the parent alcohol was removed completely by vacuum distillation and a known amount of toluene and methanol was introduced under vacuum.

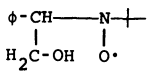
Materials. Benzophenone was recrystallized from petroleum benzine. PBN was purified by sublimation. Toluene was dehydrated by refluxing it with sodium metal and was stored over Na/K alloy under vacuum. Carbon tetrachloride was distilled and stored over calcium chloride. Alcohols were dehydrated by adding calcium hydride and were stored over molecular sieves 4A under vacuum.

The ESR spectrometer employed was operated at the X-band. The temperature of the sample was controlled by a flow of chilled nitrogen. The accuracy of the measurement of the hfs was ±0.005 mT.[12]

Results and Discussion

The magnitude of the β-H hfs of the ESR spectra of

hydroxymethyl adduct (**1**) is increased considerably by



1

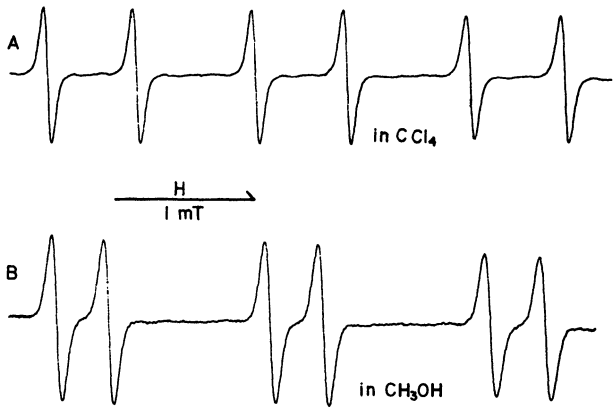


Fig. 1. ESR spectra of hydroxymethyl adduct of PBN(I) in carbon tetrachloride (A) and in methanol (B) at room temperature.

Table 1. *g*-Values and hfs of nitroxide radicals

Radical	Solvent	*g*-Value	A_N/mT	$A_{\beta\text{-H}}$/mT
Hydroxymethyl	toluene	2.0058	1.50	0.66
adduct	methanol	2.0058	1.51	0.36
Di-*t*-butyl	toluene	2.0061	1.53	—
nitroxide[15]	methanol	2.0058	1.62	—

change from a protic to an aprotic solvent as shown in Fig. 1. The solvent effect on the *g*-values and N-hfs of nitroxide radicals has been extensively studied by ESR spectroscopy.[3,15] In general, when the solvent changes from protic to aprotic the *g*-value increases but the N-hfs becomes smaller. The hfs and *g*-values of radical **1** and di-*t*-butyl nitroxide in methanol and toluene are listed in Table 1 for comparison. In contrast to the large solvent effect on the magnitude of the hfs of β-H, the effect is small for the hfs of the N^{14} nucleous and the *g*-value. This fact shows that the solvent did not change the environment of the nitroxide group but changes the steric conformation of the radical. In a protic solvent the hydrogen bond between the solvent and the nitroxide group in the radical is dominant but in an aprotic solvent the hydroxyl group of the radical acts as a hydrogen donor. Thus the intramolecular hydrogen bond in this system effects only the change of steric conformation, *i.e.* the change of the hfs of β-H.

Determination of the Equilibrium Constant for the Formation of Intramolecular Hydrogen Bond. In a pure aprotic solvent observed ESR parameters of radical **1** are the equilibrium mean of the open form radical and intramolecularly hydrogen-bonded radical. Because of the difficulty in deciding the ESR parameters of the independent form, it is impossible to determine the equilibrium constant for the formation and breakage

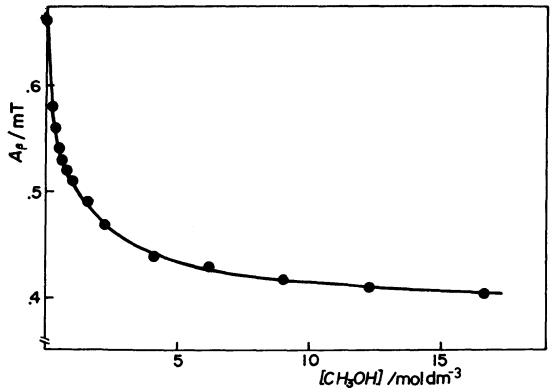

Fig. 2. Variation of β-hydrogen hfs of radical (I) as the function of the amount of methanol in carbon tetrachloride.

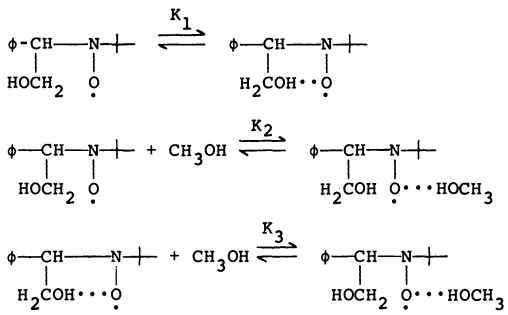
of the intramolecular hydrogen bond.

When methanol was added to the aprotic solvent solution of radical **1**, the hfs of β-H decreases with the increasing amount of methanol. Figure 2 shows the dependence of the magnitude of the β-H hfs on the amount of methanol in CCl_4. Marked decrease of the hfs was observed on the addition of the small amount of methanol.

There are three different equilibria in this system in the presence of methanol as follows. When R_O expresses



the open form radical and R_I and R_H denotes the radicals with an intramolecular hydrogen bond and with an intermolecular hydrogen bond, respectively, then

$$K_1 = [R_I]/[R_O] \quad (5)$$

$$K_2 = [R_H]/[R_O][CH_3OH] \quad (6)$$

$$K_3 = [R_H]/[R_I][CH_3OH], \quad (7)$$

K_1, K_2, and K_3 are not independent and have the relation $K_1 = K_2/K_3$. Observed hfs of β-H is expressed as

$$\bar{A} = P(R_O)A(R_O) + P(R_I)A(R_I) + P(R_H)A(R_H), \quad (8)$$

where P denotes the fraction of each radical and A denotes the hfs of each radical. By a simple calculation

$$\bar{A} = \{1 + K_1 + [R_H]K_1/[R_I]\}^{-1}\{A(R_O) + K_1A(R_I) + [R_H]K_1/[R_I]\}. \quad (9)$$

Based on the experimental fact that N-hfs and *g*-value of radical **1** in a pure aprotic solvent coincide with those in methanol as shown in Table 1, K_1 can be assumed to be very large. Equation 9 then becomes[16–18]

$$\bar{A} = \{1+[R_H]/[R_I]\}^{-1}\{A(R_I) + [R_H]/[R_I]\}. \quad (10)$$

Rewriting Eq. 10 one obtains[18]

$$1/(A(R_I) - \bar{A}) = (1/K_3)[CH_3OH]^{-1}(A(R_I) - A(R_H)) + 1/(A(R_I) - A(R_H)). \quad (11)$$

If the initial concentration of methanol is sufficiently higher than the radical concentration, the plot of $1/(A(R_I)-\bar{A})$ against the reciprocal concentration of methanol gives K_3 and $A(R_H)$. In this plot one can employ the hfs of the β-H in pure aprotic solvent as $A(R_I)=0.66\pm0.01$ mT.

The dotted line in Fig. 3 shows the plot based on Eq. 11 of the hfs shown in Fig. 2. At high concentrations of methanol the points deviate from the linear dependence. This is attributed to the formation of a hydrogen-bonded complex where two or more methanol molecules are present. The resulting equilibrium constant K_3 from Fig. 3 is 2.0 mol^{-1} dm^3 and $A(R_H)$ is 0.43 mT.

Standard Enthalpy and Standard Entropy of the Formation of Hydrogen-bonded Chelate Ring. The temperature dependence of the equilibrium constant K_3 can give the standard enthalpy difference $\Delta H°$ and standard entropy difference $\Delta S°$ for Eq. 4. Carbon tetrachloride solutions

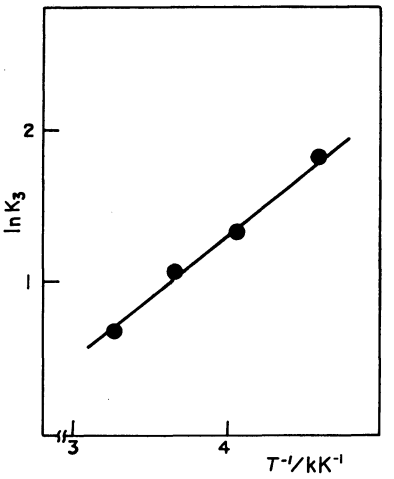

Fig. 4. Van't-Hoff plots for equilibrium contants K_3 derived from Fig. 3.

freeze at a comparatively higher temperature so that toluene was chosen as the solvent for the study of temperature dependence. Before applying Eq. 11 at various temperatures it is confirmed that $A(R_I)$ in pure toluene did not show temperature dependence. The solid lines in Fig. 3 show the plot based on Eq. 11 at various temperatures in toluene. The plot shows that K_3 increases with the lowering of the temperature. K_3's derived from Fig. 3 are listed in Table 2. The slope and the intercept of Van't-Hoff plot (Fig. 4) gives $\Delta H° = -7.4\pm0.5$ kJ mol^{-1} and $\Delta S° = -19\pm2$ J mol^{-1} K^{-1}.

If one assumes that the standard ethalpies for the formation of hydrogen bonds on both sides of Eq. 4 are equal, $\Delta H°$ given above is that for the formation of the chelate ring. This assumption is justified by the fact that the g-value and N-hfs did not change on the addition of methanol. Since the g-value and N-hfs reflect the electronic structure around nitroxide function, the strength of the hydrogen bond of the radicals in Eq. 4 are the same.

The absolute value of $\Delta H°$ is interpreted to be the increment of the energy of interaction among substituents and that of energy of strain caused by the formation of the ring structure.

Intramolecular Hydrogen Bonds in Diastereomeric Nitroxides. When ethanol is used instead of methanol in the reaction (1) a nitroxide radical bearing two asymmetric carbons is produced. The formation of an intramolecular hydrogen bond in the diastereomer gives the cis-trans isomer as shown in Fig. 5.[12] The ESR spectra of the 1-hydroxyethyl adduct in toluene is shown in Fig. 6A. The regular distortion of each line indicates the presence of the diastereomer. The hfs constants of each isomer have been determined by spectrum simulation.

From the discussion in the former section it was concluded that the $\Delta H°$ of Eq. 4 is the enthalpy of the chelate ring formation. The isomers shown in Fig. 5 have different $\Delta H°$ because of the difference of the repulsion of the substituents mainly between the phenyl and methyl groups. It causes a difference of the temperature dependence of K_3. Figures 6B—6D show the temperature dependence of the ESR spectra of the

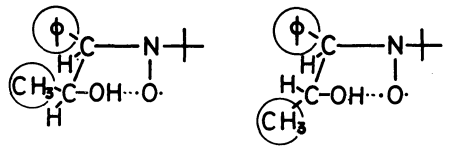

Fig. 5. Cis-trans isomer of 1-hydroxyethyl adduct produced by chelate ring formation.

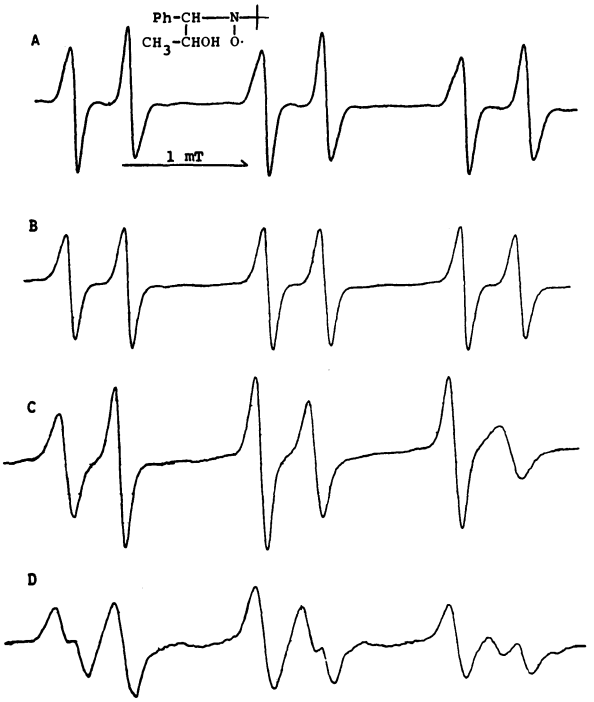

Fig. 6. ESR spectra of 1-hydroxyethyl adduct in toluene at room temperature (A), in toluene with 5 mol dm^{-3} methanol at 297 K(B), at 257 K(C), and at 208 K(D).

hydroxyethyl adduct in toluene containing 5 mol dm^{-3} methanol. At room temperature the resolution of the isomer is even poorer on the addition of methanol than in pure toluene, however, at 308 K the isomer clearly shows the difference in the hfs of the β-H. This experimental fact is explained by the difference of $\Delta H°$ for each isomer resulting in the difference of the temperature dependence of K_3 and also that of the hfs. The assignment of the ESR spectra to each isomer is now possible. The radical with the larger temperature dependence is the cis isomer and that with the smaller temperature dependence is the trans isomer. This assignment is in good accord with the assignment based on the small g-value difference of the isomer.[12]

A quantitative treatment of the difference of $\Delta H°$ for the isomers is possible for the 1-hydroxybutyl adduct of PBN. In this case the resolution is the best in pure toluene solution and the magnitude of the β-H hfs for each isomer is determined by spectrum simulation.[12] By the addition of methanol the resolution is diminished. The hfs constants of each isomer at various temperature were determined by spectrum simulation for each toluene solution of the radical containing a known amount of methanol. The same treatment as for the hydroxymethyl adduct using Eq. 11 gives the Van't-Hoff plot for each isomer. The resulting $\Delta H°$ is -10.2 ± 3.8 kJ mol^{-1} for the radical with smaller β-H hfs (cis isomer) and the radical with larger β-H hfs (trans isomer) has -6.2 ± 2.2 kJ mol^{-1} as $\Delta H°$. The difference of $\Delta H°$ for the isomer is comparable in magnitude with the difference of the heat of formation of the cis-trans isomer in substituted cycloalkanes.[19]

††*The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received March 18, 1982)

The electronic absorption spectra of radical ions produced by γ-ray irradiation of (*E*)-stilbene and related compounds in frozen matrices were measured. On illumination and on controlled warming, the spectra of the radical ions of sterically uncrowded stilbenes and diphenylacetylene remained almost unchanged, while those of the radical ions of sterically crowded stilbenes changed noticeably. Examination of the spectra and of their changes led to the following conclusions: (a) The relaxed geometry of the radical ions of sterically uncrowded stilbenes is planar or nearly planar; (b) in the unrelaxed geometries of the radical ions of (*E*)-α,β-dialkylstilbenes the torsion angles of the Ph–C bonds are nearly as large as in the parent molecules, and on relaxation these angles become smaller and the torsion angle of the central ethylenic bond deviates from 0° to a considerable extent; (c) for the radical ions of *ortho*-substituted (*E*)-stilbenes the geometrical change on relaxation is comparatively small.

Geometries of molecular ions generated from unsaturated molecules by addition or removal of one or two electrons are not always similar to those of the parent molecules. The question of how the molecular geometry changes with the ionization is a subject of interest.

Previously we studied the geometry of neutral molecules of stilbenes[1–6] and of their dianions[7] by means of electronic absorption spectroscopy. The present paper reports the results of a similar investigation of the geometry of radical ions (anion and cation radicals) of (*E*)-stilbene and related compounds, on which no reliable information is available.

In a previous paper,[8] we reported that the electronic absorption spectrum of the tetraphenylethylene (TPE) anion radical in frozen 2-methyltetrahydrofuran (MTHF) changed markedly on controlled warming, and attributed the spectral change to the geomerical change of this sterically crowed anion radical. In the present study, it is examined whether such a phenomenon occurs for radical ions of sterically crowded stilbene derivatives.

The compounds treated here and their abbreviations (in parentheses) are as follows: (*E*)-stilbene (ES), (*E*)-α-methylstilbene (EαMS), (*E*)-α,β-dimethylstilbene (EαβDMS), (*E*)-4,4′-dimethylstilbene (E44′DMS), (*E*)-2,4,6-trimethylstilbene (ETMS), (*E*)-2,2′,4,4′,6,6′-hexamethylstilbene (EHMS), (*E*)-α,β-diethylstilbene (Eαβ-DES), (*E*)-4-phenylstilbene (E4PS), (*E*)-4,4′-diphenylstilbene (E44′DPS), and diphenylacetylene (DPA).

Experimental

Spectra of Radical Ions Produced by γ-Ray Irradiation of Frozen Solutions at 77 K. Radical ions of ES and related compounds were produced by γ-ray irradiation in deaerated solutions frozen at 77 K in liquid nitrogen, and their electronic absorption spectra were measured. For the anion radicals MTHF was used as the solvent, whereas for the cation radicals *s*-butyl chloride (BC) or a Freon Mixture (FM: an equivolume mixture of trichlorofluoromethane and 1,2-dibromo-1,1,2,2-tetrafluoroethane) was employed. The experimental details are described in a previous paper.[8] Both the anion and the cation radicals exhibit two major bands in the visible region. The band at the longer wavelength is designated as A, and that at the shorter wavelength as B.

After recording the spectra of γ-ray irradiated samples, they were illuminated with light of the wavelengths corresponding to and longer than band A for 5—10 min (illumination A). Then, the samples were successively illuminated with light of the wavelengths corresponding to and longer than band B for 5—10 min (illumination B).

To see the effect of limited warming, the γ-ray irradiated sample was taken out of the liquid nitrogen for a limited time, and then refrozen at 77 K. The warming period was successively increased (for example, 20, 24, 28 s for anion radicals; 10, 12, 14 s for cation radicals).

The spectra of the cation radicals of E4PS and E44′DPS were less accurate because of the low solubility of these compounds in BC and in FM.

Spectra of Anion Radicals Produced by Alkali-metal Reduction. The spectra of the anion radicals produced by reduction of ES, EαMS, E44′DMS, ETMS, and EHMS with alkali metals (sodium, potassium, and cesium) in deaerated 1,2-dimethoxyethane (DMS) were also measured for the comparison with those obtained by γ-ray irradiation. The experimental procedure was described previously.[7]

Reliable spectra of the anion radicals of EαβDMS and EαβDES could not be obtained by the alkali-metal reduction even in the presence of a large excess of the parent molecules at low temperature,[8] being masked by the absorption due to the corresponding dianions. This is due to the fact that the equilibrium constant (K_{dispr}) of the disproportionation of the anion radical associated with the counterion to a pair of the neutral molecule and the dianion associated with two counterions is much greater for these sterically crowded stilbenes than for sterically uncrowded or less crowded stilbenes.[7] Even the K_{dispr} value for EαMS was reported to be much greater than that for ES.[9] It is evident that the K_{dispr} values for EαβDMS and EαβDES are much more greater than that for EαMS.

Molecular Orbital Calculation

To characterize the absorption bands and to get the

** Present address: Department of International Culture, Aichi Gakusen Women's Junior College, Toyoda, Aichi 473.

relation between the bands and the geometry of the radical ions, we carried out a semiempirical SCF-MO-CI calculation for the π electronic state of the radical ions by the method developed by Longuet-Higgins and Pople.[13] The details of the calculation procedure are essentially the same as those employed in previous work.[8,14] The same assumptions on the geometry as those in Part I of this series[7] were made.

The carbon skeleton of the (*E*)-stilbene π system and the numbering of the carbon atoms are illustrated in Fig. 1. Torsion angles β-α-1-6 and α-β-1′-6′ are denoted by $\theta_{\alpha 1}$ and $\theta_{\beta 1'}$, respectively. Angle $\theta_{\alpha\beta}$ is defined as 180° minus torsion angle 1-α-β-1′. For the planar *E* form angles $\theta_{\alpha 1}$, $\theta_{\beta 1'}$, and $\theta_{\alpha\beta}$ are 0°.

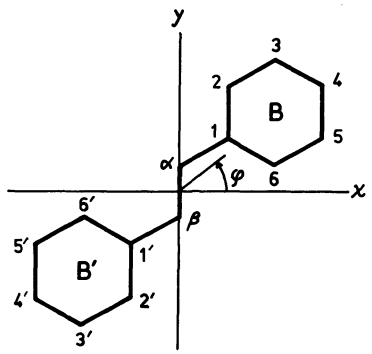

Fig. 1. The carbon skeleton of (*E*)-stilbene.

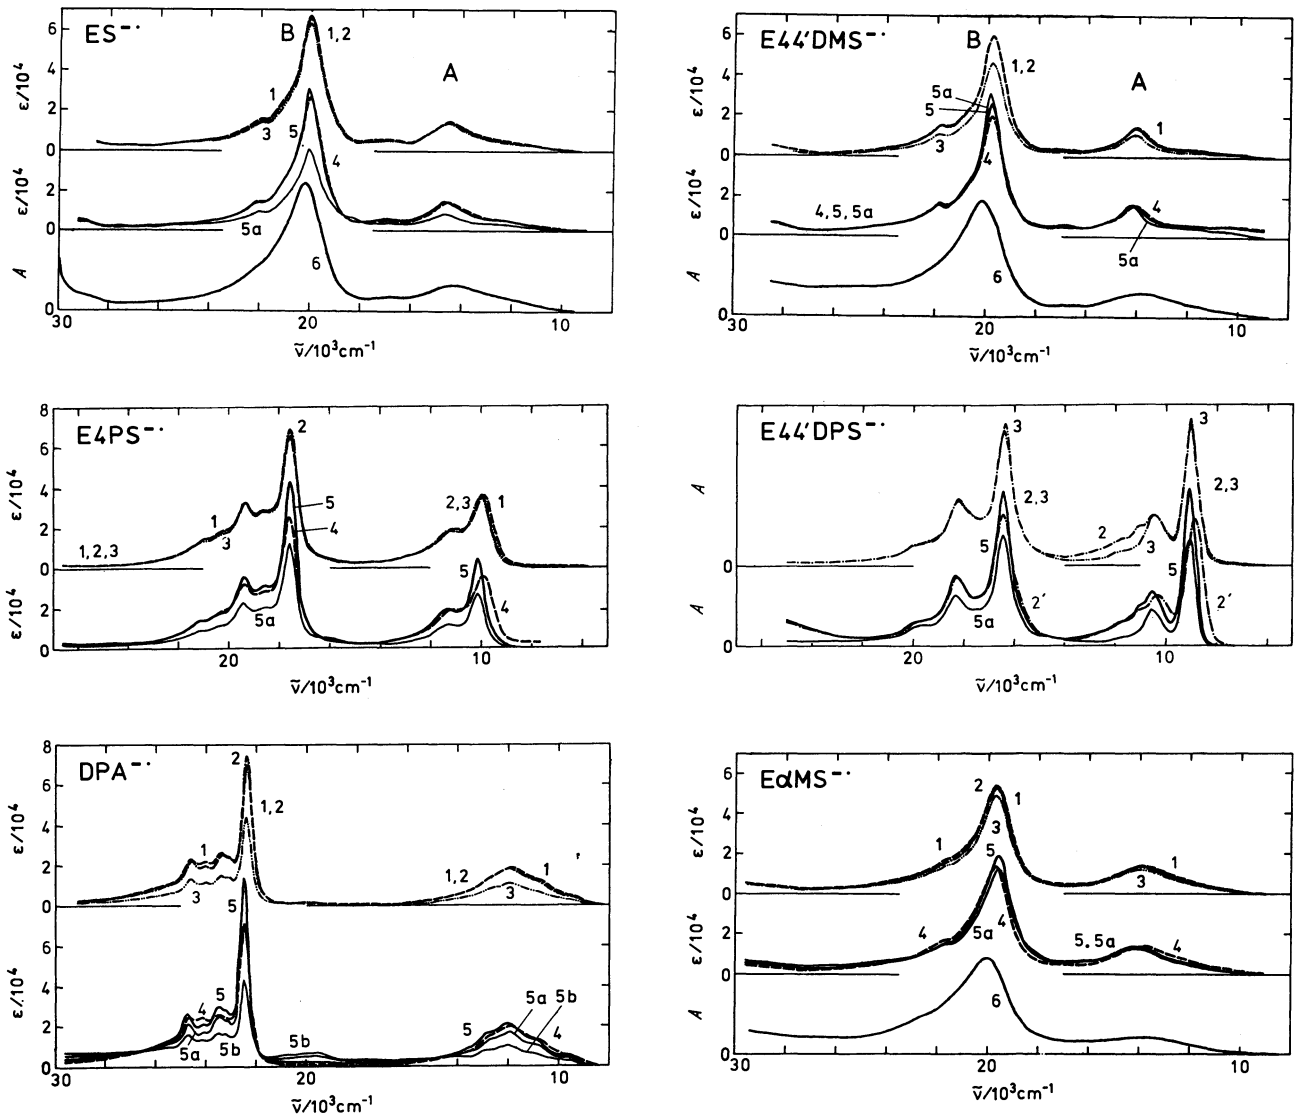
Results and Discussion

Designation of Spectra and of Geometries. Representative spectra of the radical ions measured after various treatments are shown in Figs. 2 and 3, and relevant data are listed in Tables 1 and 2. Although most of the spectral changes are relatively small, they are reproducible with a precision of a few percent. The molar absorption coefficient (ε) was evaluated in the same manner as described in Ref. 8. The values for the spectra of anion radicals are reliable, but those for the spectra of cation radicals are uncertain.[15]

As seen in the figures, the radical ions exhibit two major bands, A and B, in the visible region. For band A, for example, the wavelength (λ) and molar absorption coefficient at the maximum and the oscillator strength (f) are denoted by λ_A, ε_A, and f_A, respectively.



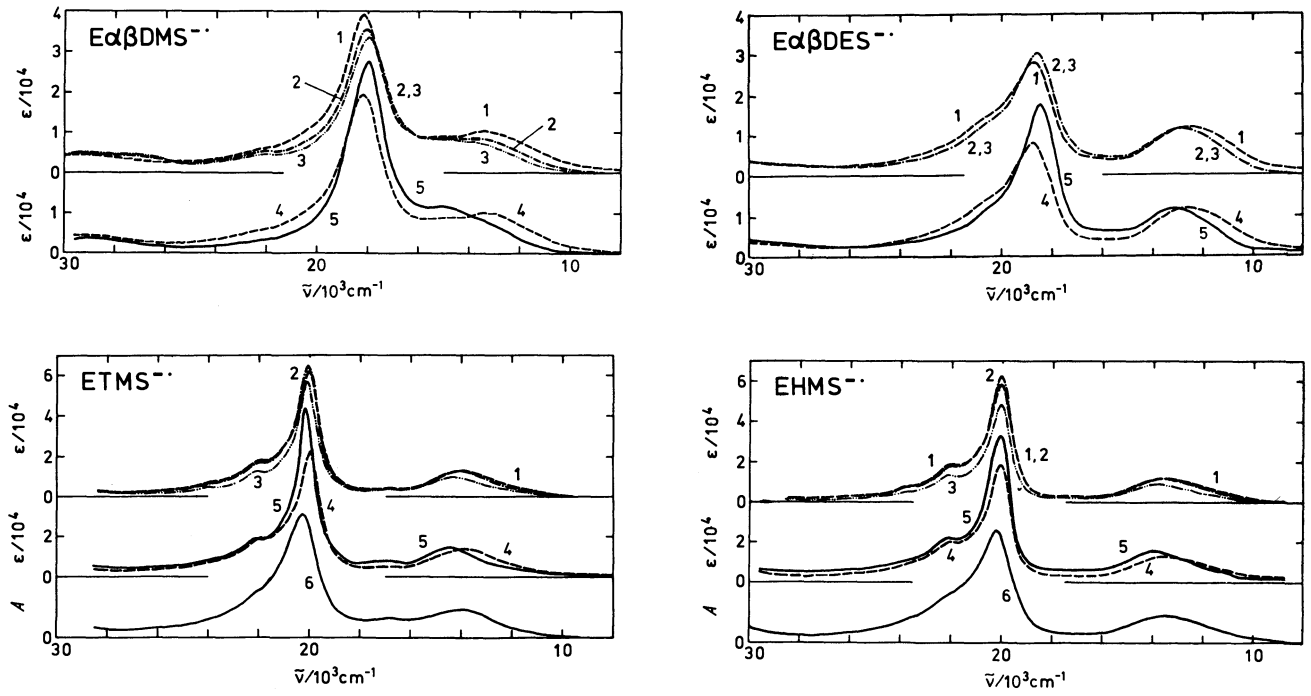


Fig. 2. Electronic absorption spectra of anion radicals. Curves 1 and 4 (------): spectra observed immediately after γ-ray irradiation of frozen solution, designated F in the text. Curve 2 (·–·–·): spectra observed after illumination of the sample for curve 1 with light of wavelengths corresponding to band A, designated PA in the text. Curve 3 (···): spectra observed after illumination of the sample for curve 2 with light of wavelengths corresponding to and longer than band B, designated PB in the text. Curve 5 (——): spectra observed after controlled warming of the sample for curve 4, designated W in the text. Curves 5a, 5b, 5c, ··· (——): spectra observed after additional controlled warming for successively increasing time. The solvent is 2-methyltetrahydrofuran (MTHF) for all the above spectra. Curve 6 (——): spectra of anion radicals produced by alkali-metal reduction in fluid dimethoxyethane (DME), designated M in the text.

For the sake of convenience, spectra of a radical ion measured after different treatments are designated as follows:[8] The spectrum of a radical ion immediately after its production by γ-ray irradiation in a frozen matrix is designated as F (*frozen*), that after illumination as P (*photobleached*), that after controlled warming as W (*warmed*), and that of an anion radical produced by alkali-metal reduction in a fluid DME solution as M (*metal*). Sometimes, spectrum P after illumination A is referred to as spectrum PA, and that after illumination B as spectrum PB. If necessary, the solvent is denoted in parentheses: For example, spectrum F of a cation radical in solution in BC is referred to as spectrum F(BC).

The same designations are also used to specify the geometries of the radical ion after the respective treatments. In addition, the geometry of the parent neutral molecule is designated as N (*neutral*), and the geometry that the radical ion takes in a fluid solution as R (*relaxed*). According to a conclusion in Ref. 8, geometry W is considered to be almost equal to geometry R.

Assignment of Absorption Bands. The results of the MO calculation for the stilbene anion radical in the planar *E* form belonging to point group C_{2h} are shown in Table 3, which includes all the electronic transitions having a transition energy (ΔE) smaller than 4.5 eV. By comparison between the observed spectra and the results of the calculation, bands A and B are ascribed to transitions 3 and 5, respectively. The very weak band appearing between bands A and B in the spectra of ES⁻·, E44′DMS⁻·, ETMS⁻·, and EHMS⁻· is ascribed to transition 4, which is forbidden in the planar *E* form but is weakly allowed in nonplanar geometries in which $\theta_{\alpha\beta}$ is not 0°.

As seen in Table 3, transitions 3, 4, and 5 can be well approximated as the one-electron excitations from ϕ_{-1} to ϕ_{-4}, from ϕ_{-1} to ϕ_{-5}, and from ϕ_{+1} to ϕ_{-1}, respectively. Accordingly, bands A and B of the stilbene anion radical correspond to the longest-wavelength intense band of the stilbene dianion[7] and that of the stilbene molecule,[1,2,6,16] respectively.

The results of the MO calculation for the stilbene cation radical are quite similar to those for the anion radical, because of the pairing properties of π orbitals of the alternant hydrocarbon. Similarly to the case of the anion radical, bands A and B are ascribed to transitions 3 and 5, respectively, and the very weak band appearing between bands A and B in the spectra of ES⁺· and some other cation radicals is ascribed to transition 4. Transitions 3, 4, and 5 in the cation radical can be well approximated as the one-electron excitations from ϕ_{+4} to ϕ_{+1}, from ϕ_{+5} to ϕ_{+1}, and from ϕ_{+1} to ϕ_{-1}, respectively.

The orbitals involved in the approximate one-electron expressions of transitions 3, 4, and 5 in the radical ions can be roughly approximated as follows:

$$\psi_{\pm 1} \approx a\phi_{\pm 1}(\mathrm{B}) \mp b\phi_{\pm 1}(\mathrm{E}) \pm a\phi_{\pm 1}(\mathrm{B}')$$
$$\psi_{\pm 4} \approx a\phi_{\pm 1}(\mathrm{B}) \pm b\phi_{\mp 1}(\mathrm{E}) \mp a\phi_{\pm 1}(\mathrm{B}')$$
$$\psi_{\pm 5} \approx b\phi_{\pm 1}(\mathrm{B}) \pm a\phi_{\pm 1}(\mathrm{E}) \pm b\phi_{\pm 1}(B')$$

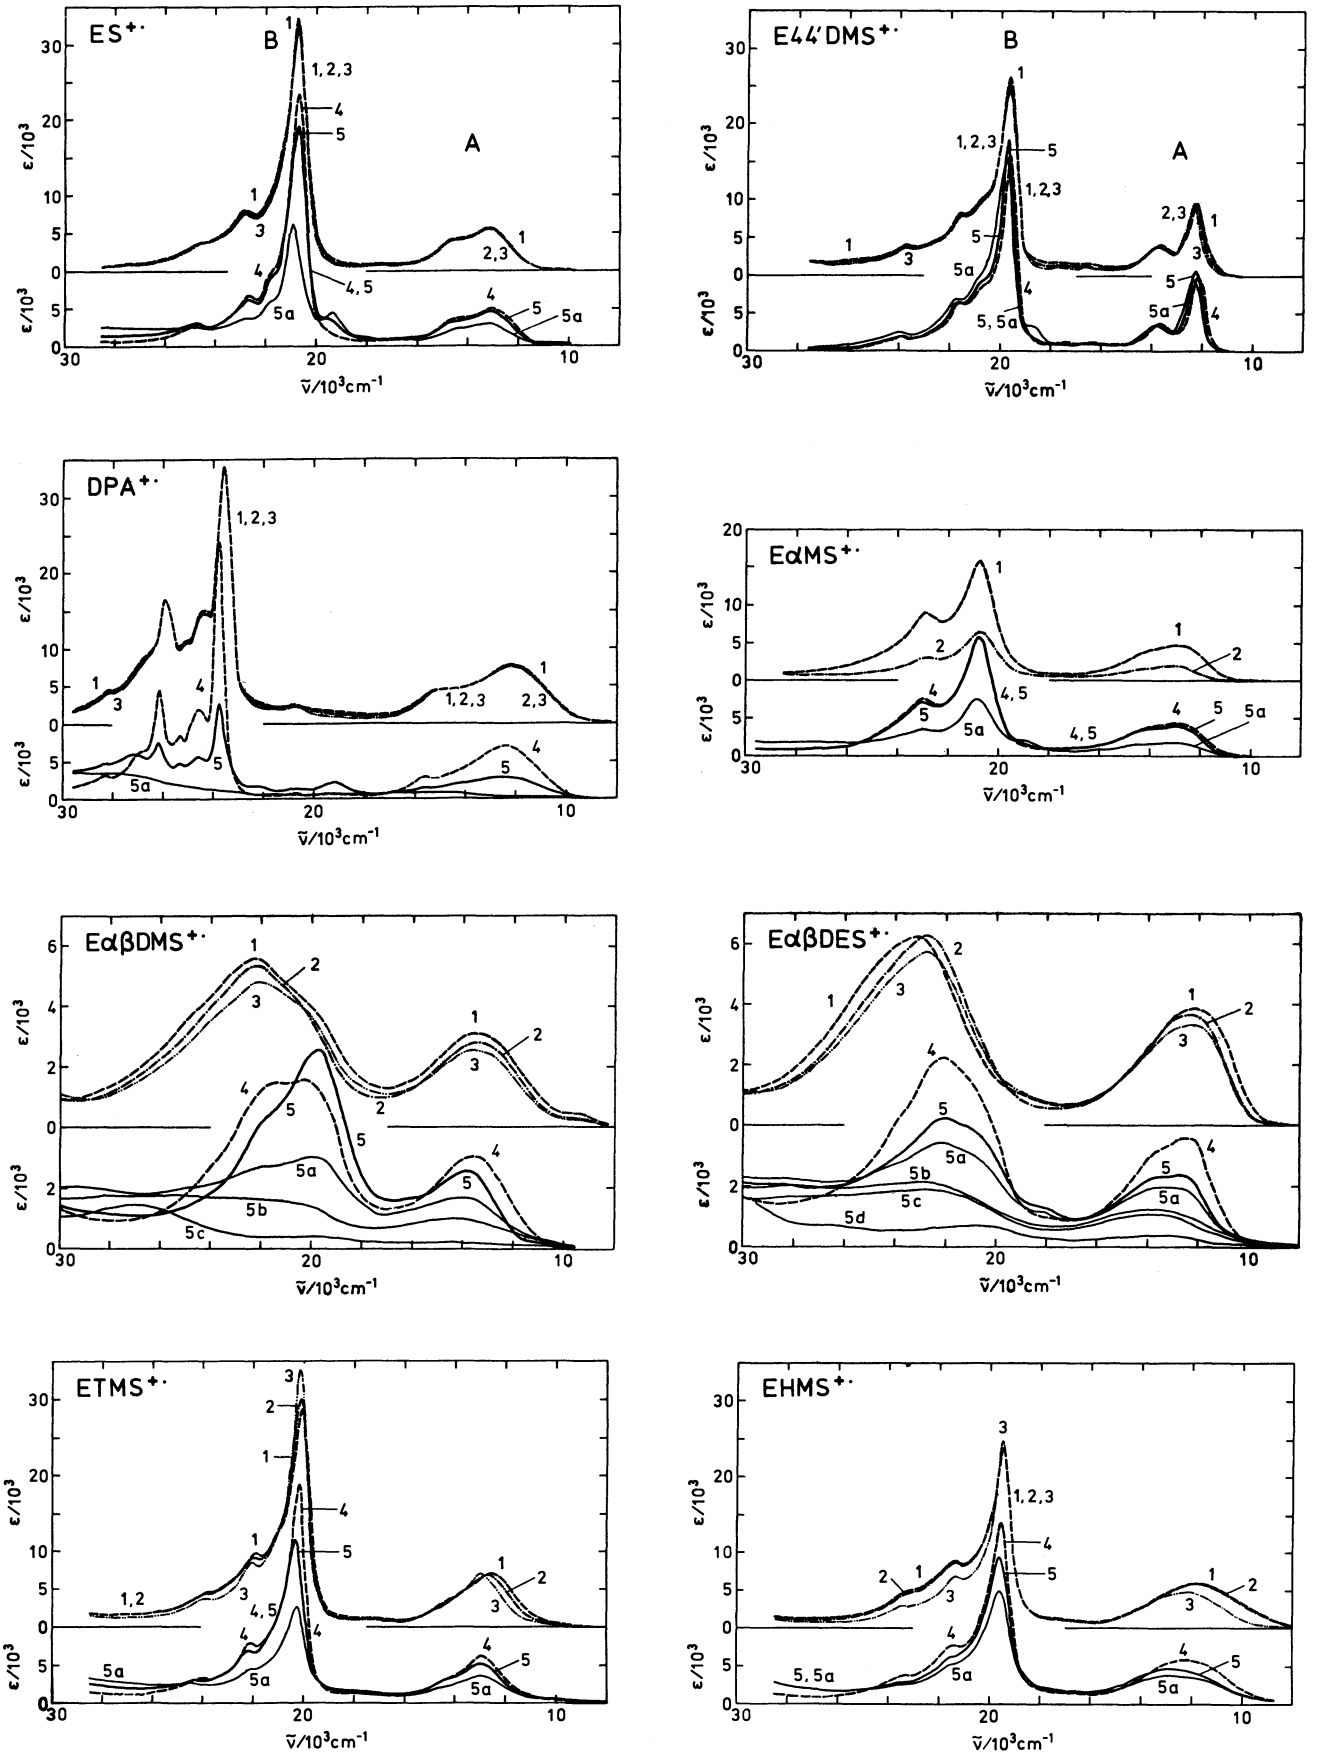

Fig. 3. Electronic absorption spectra of cation radicals. See Caption for Fig. 2. The solvent is *s*-butyl chloride (BC) for spectra 1, 2, and 3, and is a Freon Mixture (FM) for the other spectra.

a) The solvent is DME for spectra M and is MTHF for all the other spectra. For spectra M, the counterion is indicated in parentheses. b) Values tentatively determined by equating the value of ε_B of spectrum M to that of spectrum F. c) Values of the absorbance. d) Values tentatively determined on some assumptions.

In these expressions, a and b represent coefficients bearing the relation $a>b>0$; $\phi_{+1}(E)$ and $\phi_{-1}(E)$ represent the bonding and the antibonding π orbital of the central ethylenic bond, respectively [$\phi_{\pm1}(E)=2^{-1/2}(\chi_\alpha\pm\chi_\beta)$]; $\phi_{+1}(B)$ and $\phi_{-1}(B)$, for example, represent the following π orbitals of benzene ring B (see Fig. 1):

$$\phi_{\pm1}(B) = 12^{-1/2}(2\chi_1 \pm \chi_2-\chi_3 \pm 2\chi_4-\chi_5 \pm \chi_6).$$

With respect to the α-β bond, the orbitals belonging to symmetry species a_u, ϕ_{+5}, ϕ_{+1}, and ϕ_{-4}, are bonding, and the orbitals belonging to symmetry species b_g, ϕ_{+4}, ϕ_{-1}, and ϕ_{-5}, are antibonding; with respect to the α-1 and the β-1′ bond, ϕ_{+5}, ϕ_{+4}, and ϕ_{-1} are bonding, and ϕ_{+1}, ϕ_{-4}, and ϕ_{-5} are antibonding.

Expected Effects of Geometrical Changes on the Electronic Transitions. In Table 4 are listed the calculated values of the energies and oscillator strengths of transitions 3, 4, and 5 and of the ratio between the oscillator strengths of transitions 3 and 5 (f_3/f_5) for the stilbene anion radical in the planar E geometry. Table 4 also lists the calculated values of the changes in these quantities associated with the changes from the planar E geometry to geometries in which $|\theta_{\alpha1}|$, $|\theta_{\beta1'}|$, or $|\theta_{\alpha\beta}|$ is 30°. The corresponding values for the cation radical are almost coincident with the values for the anion radical.

The changes in the properties of the transitions of the anion radical associated with the geometrical changes seen in Table 4 and the corresponding ones of the cation radical should represent the effect of the geometrical changes on the absorption bands: It is expected, for example, that an increase in $|\theta_{\alpha1}|$ and $|\theta_{\beta1'}|$ will exert a large bathochromic and a very small hyperchromic effect on band A and a comparatively large hypsochromic and a large hypochromic effect on band B, and will bring about a large increase in ratio f_A/f_B, and that an increase in $|\theta_{\alpha\beta}|$ will exert a large hypsochromic and a small hypochromic effect on band A and a large bathochromic and a small hypochromic effect on band B, and will bring about a small decrease in f_A/f_B.

Comparison between Spectra of Anion and Cation Radicals. With a few exceptions, the maxima of bands A and B of each anion radical are located at shorter and at longer wavelength, respectively, than are those of the corresponding cation radical, and, without exception, the separation between the maxima of the two bands of each anion radical is considerably smaller than that of the corresponding cation radical.

Because of the pairing properties of π orbitals, the spectra of both radical ions should closely resemble

a) The values for the nonplanar geometries are values relative to the values for the planar geometry.

are aprotic and should have nearly equal values of the static dielectric constant at 77 K,[15] the marked shifts of the bands of the cation radicals as compared with those of the corresponding anion radicals cannot be attributed to the difference in the general solvent effect. The shifts might be a manifestation of the difference in the effect of σ electrons in both the radical ions, as suggested previously,[15] or a manifestation of the difference in the geometry. For example, if the length of the α-β bond is shorter in cation radicals than in the corresponding anion radicals, the directions of the shifts can be well explained.

Electronic Bathochromic Effect of Alkyl Substituents. Before proceeding to discuss the relation between the spectra and the geometry, we must examine the electronic bathochromic effect of alkyl substituents.

Both bands A and B of the E44'DMS radical ions are located at longer wavelengths than are the corresponding bands of the ES radical ions. In Table 5, the magnitudes of bathochromic shift of bands A and B of the ES radical ions caused by substitution of two methyl groups at the *para* positions are compared with those of the corresponding bands of the ES molecule[4] and of the ES dianion.[7] As seen in the table, the magnitude of the bathochromic shift of band A or its corresponding band increases in the order dianion< anion radical<cation radical, and that of band B or its corresponding band increases in the order anion radical<molecule<cation radical.

Table 5. Bathochromic shift of bands of ES by substitution of two methyl groups into the *para* positions

Species	$\tilde{\nu}_B$[a] / cm^{-1}	$\Delta\tilde{\nu}_B$[b] / cm^{-1}	$\tilde{\nu}_A$[a] / cm^{-1}	$\Delta\tilde{\nu}_A$[b] / cm^{-1}
Dianion[c]	—	—	19881	235
Anion radical[d]	20028	210	14486	372
Molecule[e]	34002	812	—	—
Cation radical[f]	20743	1108	13175	920

a) Wave number at the band maximum of ES. b) Difference between the wave number at the band maximum of ES and that of E44'DMS. c) Data on the spectra of the potassium salts in DME.[7] d) Data on spectra F(MTHF) (Curves 4 in Fig. 2). e) Data on the spectra of solutons in heptane.[2,4] f) Data on spectra F(BC) (Curves 1 in Fig. 3).

As mentioned already, band A of the cation radicals can be ascribed to the one-electron excitation from ψ_{+4} to ψ_{+1}, and that of the anion radical as well as the longest-wavelength intense band of the dianion to the one-electron excitation from ψ_{-1} to ψ_{-4}; bands B of the radical ions and the longest-wavelength intense band of the molecule can be ascribed to the one-electron excitation from ψ_{+1} to ψ_{-1}.

The magnitude of the energy lift of a π molecular orbital caused by alkyl substitution depends on the orbital energy and on the absolute magnitude of the atomic orbital coefficient at the substitution position in the molecular orbital: The lower the orbital energy, and the larger the absolute value of the atomic orbital coefficient, the larger will be the magnitude of the lift of the orbital energy.

Table 6 shows the energies (E) and atomic orbital coefficients (C_i) of the π molecular orbitals relevant to bands A and B and their corresponding bands calculated by the SCF-MO method for the planar E geometry. The sequence of the magnitude of the bathochromic shift by 4-methyl substitution expected from the data in this table agrees with the above-mentioned observed sequence both for band A (and its corresponding band) and for band B (and its corresponding band). From the data in this table, it is also expected that the electronic bathochromic effect of alkyl substitution at the *ortho* positions or at positions α and β on bands A and B may be smaller in the case of cation radicals and larger in the case of anion radicals than that of alkyl substitution at the *para* positions.

Classification of Compounds. The compounds treated in the present work are classified into three groups: group I (sterically uncrowded compounds: ES, E44'DMS, E4PS, E44'DPS, and DPA), group II (α-alkylated derivatives of ES: EαMS, E$\alpha\beta$DMS, and E$\alpha\beta$DES), and group III (*ortho*-methylated derivatives of ES: ETMS and EHMS). The following discussion is made on the basis of this classification.

Group I. ES and E44'DMS: Spectra F of the radical ions of ES and E44'DMS exhibit characteristic vibrational fine structure, and remain almost unchanged on illumination and on controlled warming, except for the diminution in intensity on prolonged warming. This fact indicates that geometries P, W, and R of these radical ions are quite similar to geometries F, which in turn must be similar to the most probable geometries of

Table 6. Energy and AO coefficients of π SCF-MO's of ES having the planar geometry

Species	MO	E/eV	$\lvert C_\alpha\rvert$	$\lvert C_2\rvert$	$\lvert C_4\rvert$	$\lvert C_6\rvert$
Dianion	ψ_{-4}	+5.8695	0.2286	0.0239	0.3834	0.1484

the parent molecules in the rigid solutions.

It is established by X-ray analysis that the ES molecule assumes a planar or nearly planar geometry in the crystalline state,[17] and it is inferred that the most probable geometry of the ES molecule in fluid solutions is also planar or nearly planar,[1,2,18] although, according to an electron diffraction study,[19] the most probable geometry of the ES molecule in the gas phase is a nonplanar propeller-like geometry with C_2 symmetry in which $\theta_{\alpha 1}$ and $\theta_{\beta 1'}$ are about 30° and $\theta_{\alpha\beta}$ is about 0°. In addition, nearly all the theoretical calculations conclude that the ES molecule should be essentially planar.[20,21]

Accordingly, geometries F, P, W, and R of the radical ions of ES as well as E44'DMS are concluded to be planar or nearly planar. This conclusion is consistent with the facts found by Chang and Johnson that the same anion radical having the *E* geometry is obtained by reduction of the *Z* or the *E* isomer of stilbene with potassium in DME[22] and that the ESR spectrum of the anion radical at −60 °C shows the presence of two nonequivalent sets of *ortho* protons and of two nonequivalent sets of *meta* protons, implying that the rotation around the C–Ph bonds is frozen on the ESR time scale.[23,24]

In Part I of this series,[7] we concluded that the preferred geometry of the ES dianion resulting from the reduction of ES with alkali metals in DME was planar or nearly planar, although on the geometry of the ES dianion various conflicts exist.[25] We conclude here that all the preferred geometries of the molecule, radical ions, and dianion of ES in solid states or in fluid solutions are planar or nearly planar. This conclusion seems reasonable, since the steric strain in the planar geometry of ES must be very small and hence there must be no driving force for this system to assume a largely twisted geometry.

Spectra M: Spectra M of $ES^{-\cdot}$ and $E44'DMS^{-\cdot}$ are similar, on the whole, to spectra F, P, and W of the same anion radicals. However, a closer examination reveals that the former are much broader than the latter, and that bands A and B in the former are at longer and at shorter wavelength, respectively, than are the corresponding bands in the latter. The same tendencies are also observed for spectra of $E\alpha MS^{-\cdot}$, $ETMS^{-\cdot}$, and $EHMS^{-\cdot}$. As the counterion becomes larger in the series Na^+, K^+, and Cs^+, the maximum of band B shifts slightly to shorter wavelengths, while the maximum of band A shifts rather irregularly (*cf.* Table 7).

Table 7. Data on spectra M of anion radicals

Spectrum	$ES^{-\cdot}$		$E44'DMS^{-\cdot}$		$EHMS^{-\cdot}$	
	λ_B/nm	λ_A/nm	λ_B/nm	λ_A/nm	λ_B/nm	λ_A/nm
M(Na^+)	495	700	499	745	494	745
M(K^+)	494	701	496	725	494	740
M(Cs^+)	493	702	495	715	489	735
F[a]	499.3	690.3	504.6	708.5	498.0	730.6
W[a]	498.4	682.1	502.6	700.0	498.0	717.1

a) Data on spectra F and W are listed for comparison.

The value of K_{dispr} of $ES^{-\cdot}$ in various ethereal solvents increases as the size of the counterion decreases.[10] From this fact, it is inferred that $ES^{-\cdot}$ as well as ES^{2-} forms a contact pair with the counterion.[29] According to the results of our MO calculation, the charge density in $ES^{-\cdot}$ is the largest at positions α and β. It seems most probable that in the contact ion pair the counterion is located near the central ethylenic bond of $ES^{-\cdot}$, as in the contact ion aggregate of ES^{2-} with two counterions.[7] The calculation results also show that the charge density at positions α and β decreases greatly on transition 3 and slightly on transition 5 (*cf.* Table 6). Therefore, it is expected that the counterion exerts a great hypsochromic effect on band A and a slight hypsochromic effect on band B and that the effects decrease as the size of the counterion increases. Agreement between the expectations and the observations is not good. The difference in the position of bands between spectra M and spectra W (as well as F and P) may be partly attributed to a possible difference between geometries M and W (as well as F and P), besides of the effect of the counterion. If $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are slightly larger in geometry M than in geometry W, or if the length of the α-β bond is slightly shorter in geometry M than in geometry W, the direction of the shifts of bands A and B in spectra M as compared with spectra W can be explained.

The values of λ_B and ε_B of $ES^{-\cdot}$ (counterion: Na^+) in hexamethylphosphoric triamide (HMPT) were reported to be 500 nm and 6.0×10^4, respectively.[30] In this solvent the anion radical is considered to exist as free ions, not paired with the counterion. This λ_B value is nearly equal to the values for spectra F, P, and W. On the other hand, the values of λ_B and ε_B of $ES^{-\cdot}$ (counterion: Na^+) in THF were reported to be 494 nm and 5.5×10^4, respectively, or 495 nm and 5.23×10^4, respectively.[27] These λ_B values coincide with the value for spectrum M of $ES^{-\cdot}$ with the same counterion in DME.

E4PS and E44'DPS: $E4PS^{-\cdot}$ and $E44'DPS^{-\cdot}$ also show spectra characteristic of sterically uncrowded radical ions: Spectrum F of $E4PS^{-\cdot}$ and spectrum PA of $E44'DPS^{-\cdot}$ exhibit well-resolved vibrational structure, and remain almost unchanged on illumination, although on controlled warming band A is intensified and is shifted to shorter wavelengths and band B is intensified. Such a spectral change occurs to a smaller extent on illumination, and also occurs in spectra of $ES^{-\cdot}$ and $E44'DMS^{-\cdot}$ to a much smaller extent on controlled warming. Such a spectral change perhaps indicates that $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ and possibly the dihedral angles between two benzene rings in the biphenyl groups deviate from 0° to some extents in geometries F and become smaller in geometries W.

DPA: Spectra F of the radical ions of DPA also exhibit well-resolved vibrational structure and remain almost unchanged on illumination and on controlled warming.

It is known that the molecule of this compound is planar in the crystalline state, belonging to point group D_{2h},[31] and the most preferred geometry of the molecule in solutions is probably also planar in view of its electron-

ic absorption spectrum.[18,32] It is inferred from the similarity of the spectra that geometries F, P, W, and R of the radical ions of this compound are quite similar to one another and are planar similarly to the preferred geometry of the parent molecule.

Bands A and B of the radical ions of DPA are located at longer and at shorter wavelength, respectively, than are the corresponding bands of the radical ions of ES. This is attributed to the fact that the α-β bond in DPA (an acetylenic bond) is shorter than that in ES (an ethylenic bond). Since the α-β bond is bonding in ϕ_{+1} and ϕ_{-4} and antibonding in ϕ_{+4} and ϕ_{-1}, the intensification of the π-π interaction across the α-β bond resulting from the shortening of the bond must lower the energies of the former orbitals and raise the energies of the latter orbitals, and consequently must decrease the energy of transition 3 and increase the energy of transition 5.

Group II. EαMS, EαβDMS, and EαβDES: In contrast with the sterically uncrowded radical ions belonging to group I, the radical ions of EαMS, EαβDMS, and EαβDES exhibit broad spctra,[33] and their spectra F change markedly on illumination and on controlled warming.

The stilbene π system in these compounds cannot be planar owing to the steric interferences of the alkyl substituents with the phenyl groups, and the steric interferences are relieved mainly by rotation of the phenyl groups out of the plane of the central ethylenic bond. According to an electronic absorption spectroscopic study,[1,3,6] $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ in molecules in solutions increase in the order ES (*ca.* 0°)$<$EαMS (average of $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$)$\ll$EαβDMS$<$EαβDES.

Cation Radicals: In spectra F(BC) of cation radicals, λ_B/nm decreases and f_A/f_B increases in the order $ES^{+\cdot}$, $E\alpha MS^{+\cdot}$, $E\alpha\beta DMS^{+\cdot}$, $E\alpha\beta DES^{+\cdot}$, and λ_A/nm increases in almost the same order. If the effect of the geometrical change outweighs the electronic effect of the alkyl substituents, the observed sequences indicate that in geometries F(BC) $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ES^{+\cdot}<E\alpha MS^{+\cdot}$(average)$\ll E\alpha\beta DMS^{+\cdot}<E\alpha\beta DES^{+\cdot}$. This probably means that geometries F(BC) of these cation radicals are similar to geometries N.

On illumination of the BC solution of $E\alpha\beta DMS^{+\cdot}$ as well as that of $E\alpha\beta DES^{+\cdot}$, λ_B/nm increases, λ_A/nm decreases, and f_A/f_B decreases. These spectral changes indicate that, in going from geometry F(BC) to geometry P(BC), $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ decrease and/or $|\theta_{\alpha\beta}|$ increases.

Spectrum F(FM) of $E\alpha\beta DMS^{+\cdot}$ probably indicates the coexistence of the cation radicals having an almost frozen or only slightly relaxed geometry similar to geometry F(BC) or P(BC) and of the cation radicals having a partially relaxed geometry, suggesting that the FM glass at 77 K is softer than the BC glass at the same temperature, as pointed out already.[8,15] On controlled warming, the geometries are converted to geometry W(FM), which is considered to be an almost completely relaxed geometry. In spectrum W(FM), λ_B/nm is much larger, λ_A/nm is appreciably smaller, and f_A/f_B is much smaller than in spectrum F(BC). This indicates that in geometry R of $E\alpha\beta DMS^{+\cdot}$ $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are much smaller and/or $|\theta_{\alpha\beta}|$ is much larger than in geometry F(BC) and hence than in geometry N. The extent of relaxation of the various geometries of this cation radical may be expressed as follows: N$\leqslant$F(BC)$<$P(BC)$\ll$F(FM)$\ll$W(FM)$\approx$R.

From a similar analysis of the spectra of $E\alpha\beta DES^{+\cdot}$, it is inferred that geometry F(FM) of this cation radical is already almost completely relaxed, and that $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are appreciably smaller and/or $|\theta_{\alpha\beta}|$ is appreciably larger in geometry R than in geometry F(BC) and hence than in geometry N. The extent of relaxation of the various geometries of this cation radical may be expressed as follows: N$\leqslant$F(BC)$<$P(BC)$<$F(FM)$\leqslant$W(FM)$\approx$R. The magnitude of the geometrical change on relaxation seems to be smaller in $E\alpha\beta DES^{+\cdot}$ than in $E\alpha\beta DMS^{+\cdot}$.

In spectra W(FM), λ_A/nm increases in the order $E\alpha\beta DMS^{+\cdot}\ll ES^{+\cdot}<E\alpha MS^{+\cdot}\ll E\alpha\beta DES^{+\cdot}$, and λ_B/nm decreases in the same order, that is, in the order $E\alpha\beta DMS^{+\cdot}\gg ES^{+\cdot}>E\alpha MS^{+\cdot}\gg E\alpha\beta DES^{+\cdot}$. If in geometries W(FM) the stericin terferences were relieved only by deviation of $\theta_{\alpha 1}$ and $\theta_{\beta 1'}$ from 0° and $\theta_{\alpha\beta}$ were maintained at approximately 0° as in geometries N, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ in geometries W(FM) would increase in the order $ES^{+\cdot}<E\alpha MS^{+\cdot}$(average)$\ll E\alpha\beta DMS^{+\cdot}<E\alpha\beta DES^{+\cdot}$, and consequently λ_A/nm and λ_B/nm in spectra W(FM) would increase and decrease, respectively, in the same order, as is almost the case in spectra F(BC). It should be noted that the observed λ_A/nm and λ_B/nm values of $E\alpha\beta DMS^{+\cdot}$ are extraordinarily small and large, respectively. This cannot be attributed to the electronic effect of the methyl substituents, and can be explained only by assuming that in geometry W(FM) of this cation radical $|\theta_{\alpha\beta}|$ is appreciably large. Thus, the observed sequences of band position are taken as an indication of the deviation of $\theta_{\alpha\beta}$ from 0° in geometry W(FM) and hence in geometry R of $E\alpha\beta DMS^{+\cdot}$.

It is unlikely that $|\theta_{\alpha\beta}|$ in geometry W(FM) of $E\alpha\beta DES^{+\cdot}$ is smaller than that of $E\alpha\beta DMS^{+\cdot}$. On the other hand, the former may not be much larger than the latter: If it were, the observed sequences of band position in spectra W(FM) would be reversed. The observed sequences seem to indicate that, in geometries W(FM) and R, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ of $E\alpha\beta DES^{+\cdot}$ are much larger than those of $E\alpha\beta DMS^{+\cdot}$, while $|\theta_{\alpha\beta}|$ of the former is not appreciably different from that of the latter. That is to say, on relaxation, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ decrease to a larger extent in $E\alpha\beta DMS^{+\cdot}$ than in $E\alpha\beta DES^{+\cdot}$, while $\theta_{\alpha\beta}$ deviates from 0° to a similar extent in both the cation radicals.

Thus, it is concluded that, in geometries R, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ES^{+\cdot}$ (*ca.* 0°)$<E\alpha MS^{+\cdot}$(average)$\ll E\alpha\beta DMS^{+\cdot}\ll E\alpha\beta DES^{+\cdot}$, and $|\theta_{\alpha\beta}|$ increases in the order $ES^{+\cdot}$(*ca.* 0°)$<E\alpha MS^{+\cdot}\ll E\alpha\beta DMS^{+\cdot}\approx E\alpha\beta DES^{+\cdot}$.

The steric interference between the α-alkyl (β-alkyl) and the β-phenyl (α-phenyl) group in (*E*)-α,β-dialkylstilbenes can be relieved by increase in $|\theta_{\alpha\beta}|$ as well as by increase in $|\theta_{\beta 1'}|$ ($|\theta_{\alpha 1}|$), while the interference between the α-alkyl (β-alkyl) and the α-phenyl (β-phenyl) group can be relieved only by increase in $|\theta_{\alpha 1}|$ ($|\theta_{\beta 1'}|$). Therefore, the above conclusion suggests that in geometry R of $E\alpha\beta DES^{+\cdot}$ the methyl group in

the α-ethyl (β-ethyl) group avoids facing the β-phenyl (α-phenyl) group and interferes mainly with the α-phenyl (β-phenyl) group.

Anion Radicals: In spectra F of anion radicals, λ_A/nm and f_A/f_B increase in the order $ES^{-\cdot} \ll E\alpha MS^{-\cdot} \ll E\alpha\beta DMS^{-\cdot} \ll E\alpha\beta DES^{-\cdot}$, and λ_B/nm increases in the order $ES^{-\cdot} < E\alpha MS^{-\cdot} \ll E\alpha\beta DES^{-\cdot} \ll E\alpha\beta DMS^{-\cdot}$. If it were not for the electronic bathochromic effect of the alkyl substituents, perhaps the sequence of λ_B/nm of $ES^{-\cdot}$ and $E\alpha MS^{-\cdot}$ might be reversed, but the other sequences of band position would not be altered. It should be noted that the λ_B/nm value of $E\alpha\beta DMS^{-\cdot}$ is larger than that of $E\alpha\beta DES^{-\cdot}$, and that these values are larger than the λ_B/nm values of $ES^{-\cdot}$ and $E\alpha MS^{-\cdot}$.

On illumination and on controlled warming, in spectra of $E\alpha MS^{-\cdot}$, $E\alpha\beta DMS^{-\cdot}$, and $E\alpha\beta DES^{-\cdot}$, λ_A/nm and f_A/f_B decrease, and λ_B/nm increases. Especially, the decrease in λ_A/nm of $E\alpha\beta DMS^{-\cdot}$ on controlled warming is notable. In addition, f_B or ε_B of $E\alpha\beta DMS^{-\cdot}$ and that of $E\alpha\beta DES^{-\cdot}$ increase prominently on controlled warming. In spectra W, λ_A/nm increases in the order $E\alpha\beta DMS^{-\cdot} \ll ES^{-\cdot} \ll E\alpha MS^{-\cdot} \ll E\alpha\beta DES^{-\cdot}$, f_A/f_B increases in the order $E\alpha MS^{-\cdot} < E\alpha\beta DMS^{-\cdot} < ES^{-\cdot} \ll E\alpha\beta DES^{-}$, and the sequence of λ_B/nm is the same as that in spectra F. The sequence of λ_A/nm is the same as and that of f_A/f_B is similar to the corresponding sequences in spectra W(FM) of cation radicals.

From these facts the following conclusions are drawn: (1) In going from geometries N of EαMS, EαβDMS, and EαβDES to geometries R of the corresponding anion radicals, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ decrease and $|\theta_{\alpha\beta}|$ increases; (2) in geometries R, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ES^{-\cdot}$ (*ca.* 0°) $< E\alpha MS^{-\cdot}$ (average) $\ll E\alpha\beta DMS^{-\cdot} \ll E\alpha\beta DES^{-\cdot}$, and $|\theta_{\alpha\beta}|$ increases in the order $ES^{-\cdot}$ (*ca.* 0°) $< E\alpha MS^{-\cdot} \ll E\alpha\beta DMS^{-\cdot} \approx E\alpha\beta DES^{-\cdot}$, that is, geometries R of these anion radicals are at least qualitatively similar to geometries R of the corresponding cation radicals; (3) geometries F of these anion radicals in MTHF glasses are already partially relaxed before illumination and controlled warming; (4) the extent of relaxation of the various geometries of the α-alkylated (*E*)-stilbene anion radicals in MTHF may be expressed as follows: $N \ll F < P \ll W \approx R$.

General Discussion on Group II: As concluded above, in geometries R of the radical ions of the α-alkylated (*E*)-stilbenes $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are smaller and $|\theta_{\alpha\beta}|$ is larger than in geometries N. In Part I of this series,[7] a qualitatively similar conclusion was drawn for the geometries of the dianions of these compounds.

Fischer *et al.*[21] stated as follows: Sterically unhindered stilbenes, that is, (*E*)-stilbenes not substituted at the *ortho* and the α and β positions, have a planar geometry both in the ground state (state S_0) and in the first excited singlet state (state S_1); sterically hindered stilbenes, *e.g.*, (*Z*)-stilbenes and α,β-disubstituted (*E*)-stilbenes, are strongly twisted about the α-1 and the β-1′ bond in state S_0, while in state S_1 the major twist is about the α-β bond. Thus, according to the results of their calculation by the CFF-SCF-PI-CI method described by Warshel and Karplus,[36] in going from state S_0 to state S_1, in EαβDMS $\theta_{\alpha 1}$ and $\theta_{\beta 1'}$ decrease from 47° to 13° and $\theta_{\alpha\beta}$ increases from 6° to 49°, while in ES all the torsion angles are 0° in both the states.

State S_1 as well as the first excited triplet state (state T_1) of these compounds can be well approximated by the electron configuration arising from state S_0 by promotion of an electron from ϕ_{+1} to ϕ_{-1}.[37] Therefore, because of the pairing properties of π orbitals in even alternant hydrocarbons, in the one-electron approximation the π-bond order of each bond of the dianion as well as the dication both in state S_0 and that of the neutral molecule in state S_1 as well as T_1 should be equal to each other. Accordingly, it is reasonable that the most probable geometry of the dianion in state S_0 is similar to that of the neutral molecule in state S_1.

In the stilbene molecule in state S_0, the π-bond order of the α-1 as well as the β-1′ bond is much smaller than that of the α-β bond. In the molecule in state S_1 and in the dianion in state S_0, the sequence of the π-bond orders is reversed, and consequently the overcrowding in sterically hindered derivatives is relieved in a different way than in the molecule in state S_0, resulting in a different geometry.

The bonding character of the radical ions in the ground state (state D_0) is intermediate between those of the molecule and of the diions both in state S_0. Therefore, the relaxed geometry of the radical ions of a sterically crowded stilbene derivative in state D_0 is probably intermediate between those of the parent molecule and of the corresponding diions both in state S_0.

The values of π-bond order calculated by the SCF-MO-CI method are shown in Table 8. From these values it is expected that in geometries R of sterically crowded stilbene molecules and ions $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ decrease and $|\theta_{\alpha\beta}|$ increases in the following order: the molecule in state S_0, the radical ions in state D_0, the molecule in state T_1, the molecule in state S_1, the diions in state S_0.

Group III. ETMS and EHMS: The spectra of the radical ions of ETMS and EHMS are similar to those of the radical ions of ES, exhibiting characteristic vibrational structure. In contrast to spectra F of the radical ions of ES, however, those of the radical ions of ETMS and EHMS change distinctly on illumination and on controlled warming. Especially, λ_A/nm and f_A/f_B decrease, although the magnitude of the spectral changes is considerably smaller than in the case of the radical ions of EαβDMS and EαβDES. In addition, f_B and ε_B of the anion radicals of ETMS and EHMS increase prominently on controlled warming. The spectra of these anion radicals in MTHF glass at 77 K are similar on the whole to spectra M of the same anion radicals. Thus, with respect to the spectral behavior,

Table 8. The π-bond orders of the planar (*E*)-stilbene molecule and molecular ions calculated by SCF-MO method

Bond	$ES(S_0)$[a]	$ES^{-\cdot}(D_0)$ $ES^{+\cdot}(D_0)$	$ES(T_1)$[b]	$ES(S_1)$[b]	$ES^{2-}(S_0)$[a] $ES^{2+}(S_0)$
α-1;β-1′	0.341	0.448	0.508	0.563	0.711
α-β	0.886	0.705	0.664	0.543	0.448

a) Ref. 7. b) Ref. 37.

group III is intermediate between groups I and II.

Analysis of the spectra of the radical ions of ETMS and EHMS leads to the following conclusions on geometries of these radical ions.

(1) Geometries F are similar to geometries N. In geometries F, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ES^{\pm\cdot}$ (*ca.* 0°)$\ll$$ETMS^{\pm\cdot}$ (average of $|\theta_{\alpha 1}|$ and $|\theta_{\beta' 1}|$)$<$ $EHMS^{\pm\cdot}$, as in geometries N.

(2) On controlled warming and on illumination, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ decrease and $|\theta_{\alpha\beta}|$ increases.

(3) The extent of the geometrical relaxation may be expressed as follows: for the cation radicals, N$<$ F(BC)$<$P(BC)$\approx$F(FM)$\leqslant$W(FM)$\approx$R; for the anion radicals, N$<$F$<$P$<$W$\approx$R.

(4) The geometrical changes on the relaxation are comparatively small. Especially, the values of $|\theta_{\alpha\beta}|$ in geometries R are probably much smaller than those in geometries R of the radical ions of E$\alpha\beta$DMS and E$\alpha\beta$DES.

Conclusion 4 above is rather surprising, because in the case of neutral molecules both the steric interference caused by the *ortho* substitution in EHMS and that caused by the α and β substitution in E$\alpha\beta$DMS are relieved by rotation to comparable degrees about the α-1 and the β-1′ bond.[3,4] However, this conclusion is consistent with the following facts.

(i) As found in Part I of this series,[7] as positions α and β of the ES dianion are increasingly substituted with alkyl groups, the longest-wavelength intense band shifts rapidly to shorter wavelengths, which indicates that $|\theta_{\alpha\beta}|$ increases rapidly; on the other hand, as the *ortho* positions are increasingly substituted with methyl groups, the band shifts slowly to shorter wavelengths, indicating that $|\theta_{\alpha\beta}|$ increases slowly. From these facts, it was inferred that the values of $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ in the EHMS dianion, for example, were larger than those in the E$\alpha\beta$DMS dianion, and that the value of $|\theta_{\alpha\beta}|$ in the former was smaller than that in the latter.

(ii) ETMS and EHMS as well as ES can readily be converted into the corresponding anion radicals by alkali-metal reduction,[7] but it is difficult to reduce them to the dianions, indicating that the values of K_{dispr} are small for these compounds.[9] On the other hand, as mentioned already, E$\alpha\beta$DMS and E$\alpha\beta$DES[7] as well as TPE[8] are readily reduced to the dianions with alkali metals, which indicates that the values of K_{dispr} are probably large for these sterically crowded compounds. These facts suggest that the geometries of the molecule, anion radical, and dianion are not much different from one another in the case of ETMS and EHMS as well as ES, while those are markedly different in the case of E$\alpha\beta$DMS, E$\alpha\beta$DES, and TPE.

(iii) According to a study by Fischer *et al.*,[21] the observed "Stokes shift"[38] ($\Delta\lambda$) of stilbenes parallels the increase ($\Delta\theta_{\alpha\beta}$) in the calculated equilibrium value of $\theta_{\alpha\beta}$ on the excitation from state S_0 to state S_1. For sterically uncrowded stilbenes, both $\Delta\lambda$ and $\Delta\theta_{\alpha\beta}$ are small: For ES, $\Delta\lambda$ is *ca.* 0 nm, $\theta_{\alpha\beta}$ is 0° in both the states, and $\Delta\theta_{\alpha\beta}$ is 0°. On the other hand, for sterically crowded stilbenes such as (*Z*)-stilbene, E$\alpha\beta$DMS, and its *Z* isomer, both $\Delta\lambda$ and $\Delta\theta_{\alpha\beta}$ are large: For E$\alpha\beta$DMS, for example, $\Delta\lambda$ is 67 nm, and $\theta_{\alpha\beta}$ increases from 6° to 49° on the excitation, that is, $\Delta\theta_{\alpha\beta}$ is 43°. For EHMS $\Delta\lambda$ is as small as 4 nm. This fact suggests that the change in $\theta_{\alpha\beta}$ of this compound on the excitation is very small.

These facts are interpreted as follows. Since in the stilbene molecule in state S_0 the π-bond order of the α-β bond is large and those of the α-1 and the β-1′ bond are small, the steric interference in sterically crowded stilbenes is relieved almost exclusively by rotation about the α-1 and the β-1′ bond. In the radical ions in state D_0, the neutral molecule in state S_1, and the diions in state S_0, the π-bond order of the α-β bond decreases, and those of the α-1 and the β-1′ bond increase (*cf.* Table 8). Therefore, the possibility arises that the steric interference in sterically crowded stilbenes is relieved by rotation about the α-β bond as well as by rotation about the α-1 and the β-1′ bond. The steric interference caused by the *ortho* substitution may be smaller than that caused by the α and β substitution. In addition, while a major part of the steric interference caused by the α and β substitution may effectively be relieved by rotation about the α-β bond, the steric interference caused by the *ortho* substitution cannot be relieved by rotation about the α-β bond so effectively as is that caused by the α and β substitution, and must be relieved mainly by rotation about the α-1 and the β-1′ bond, as in the neutral molecules in state S_0.

25) An X-ray study by Walczak and Stucky of crystals of salts of ES^{2-} with Li^+ complexed with amines revealed that the ES^{2-} moiety in the salts had a planar geometry.[26] Jachimowicz *et al.* inferred that ES^{2-}, if associated with its counterions, had a planar or nearly planar geometry, and that, if not associated with the counterions, it had a fully twisted geometry.[12] On the other hand, Garst *et al.*[11] and Wang *et al.*[27] proposed a nonplanar geometry twisted by 90° around the central ethylenic bond for ES^{2-}. A basis for the proposition by Garst *et al.* is an anticipation of a direct correspondence between the geometry of the dianion in its ground state and that of the molecule in its lowest excited triplet state, which was assumed to be a 90° twisted one. However, this correspondence may not necessarily hold good. In addition, according to a study by Benson and Williams of the photochemical *Z-E* isomerization of stilbene in its triplet state, the 90° twisted geometry is at a maximum in the potential energy profile for the triplet state.[28] All the phenomena interpreted in terms of the twisted geometry of ES^{2-} by Garst *et al.*,[11] by Wang *et al.*,[27] and by Jachimowicz *et al.*[12] seem also to be interpretable in terms of an approximately planar geometry of ES^{2-}. We believe that ES^{2-} has a planar or approximately planar geometry, whether it is associated with the counterions or not.

33) Quantity f/ε_{max} may be taken as a measure of broadness of a band. The values of $10^4 f_B/\varepsilon_B$ for the radical ions of the α,β-dialkylstilbenes ($E\alpha\beta DMS^{+\cdot}$, 0.30; $E\alpha\beta DES^{+\cdot}$, 0.27; $E\alpha\beta DMS^{-\cdot}$, 0.14; $E\alpha\beta DES^{-\cdot}$, 0.16) are much larger than those for the radical ions of the compounds belonging to group I or group III (0.08—0.10). The large broadness of the band may be taken as reflecting the large deviation of the geometry from planarity.[34,35]

38) Fischer *et al.*[21] defined the "Stokes shift" ($\Delta\lambda$) as the wavelength difference between the longwave "onset" of the longest-wavelength intense absorption band and the shortwave "onset" of the fluorescence band, and defined the "onset" as the wavelength at which the absorbance or the emission was 1% of its peak value. The values of $\Delta\lambda$ were obtained from absorption and fluorescence spectra both measured at −180 to −190 °C using an equivolume mixture of methylcyclohexane and 3-methylpentane as the solvent. The Stokes shift is ordinarily defined as the difference in wavelength or in wave number between the most intense maximum of the absorption band and that of the fluorescence band. The Stokes shift so defined, $\Delta\lambda_{max}$ (or $\Delta\tilde{\nu}_{max}$), is evaluated from the data by Fischer *et al.* as follows: 42 nm (3.85×10^3 cm^{-1}) for ES, 180 nm (16.74×10^3 cm^{-1}) for $E\alpha\beta DMS$, and 85 nm (8.42×10^3 cm^{-1}) for EHMS.

Kinetic studies of the amylose–iodine complex formation for the amylose of degree of the polymerization (DP) of 32 were made using the temperature-jump method. The reciprocal relaxation time increases with increase of the concentration of iodine and decreases with that of amylose. Based on these results, the reaction, $H_0+3\,I_3^- \rightleftharpoons H_3$ was proposed as a plausible mechanism for the relaxation phenomenon, where H_0 denotes the free helical segment of amylose and H_3 the helical segment containing three I_3^-. The relaxation phenomena were observed for the amyloses of DP 42, 57, and 76, and analyzed by the same mechanism as that proposed in the case of DP 32. The rate constants for the forward and the backward reactions (k_f and k_b) were determined: the k_f value increases with DP of amylose and the k_b value decreases. Examination of the relaxation time and the relaxation amplitude suggested that the relaxation phenomenon is not based on the whole process of the amylose–iodine complex formation but on the H_3 complex formation reaction which was shown to be the nucleation process.

Amylose–iodine complexes show the well-known specific blue color which is widely utilized for the detection of starch and iodine: a number of static studies have been made on the characteristics of the complex.[1–5] On the other hand, few kinetic studies of the amylose–iodine complex formation have been carried out and plausible mechanisms have been proposed.[6–9] Thompson and Hamori[6] revealed that the complex formation begins with the very rapid formation of H_3 followed by the slow rate-determining reaction of H_4 formation and that successive uptake of iodine molecule by H_4 is very fast. Hiromi *et al.*[7] studied the reaction with use of the amyloses of various degree of the polymerization (DP) and observed two processes: one is the very fast formation of H_n†† (n=2—4) and the other is the subsequent slow rearrangement of H_n. Grätzel *et al.*[8] investigated the reaction by the pulseradiolysis with a mechanism proposed by Thompson and Hamori[6] and obtained the rate constants of H_6 and H_7 complex formation reactions, but the rapid H_3 complex formation process was not studied.

Although the nucleation process is significant as a source of the propagation process, and its existence has been supported by the above investigations, it is still not completely elucidated kinetically. One of the reasons it remains open is the difficulty of measuring the nucleation process independently of the propagation process; the other is the rapidity of the nucleation process. Taking these into account we used, in the present study, the amylose of low DP which has the advantage of lacking the propagation process because of its short helical part[10–13] and low facility for binding iodine.[14] Considering that the nucleation process is very fast and the amylose–iodine complex formation equilibrium is perturbed effectively with temperature, the temperature-jump method is an appropriate technique for the present investigation. The persent study was undertaken to clarify the nucleation process by the temperature-jump method using amylose of low DP.

†† H_n: The helical segment containing nI_3^-.

Experimental

Materials. Amyloses of various DP were prepared as described in a previous paper.[14] Iodine and potassium iodide were of guaranteed reagent and were used without further purification. Freshly prepared amylose solution is used for each measurement.

Measurements. Kinetic measurements were carried out by the temperature-jump method with optical detection in the range of 350—550 nm. Since the addition of electrolytes to the sample solution is required for the Joule-heating temperature-jump method, 50 mmol dm^{-3} of KI was added. The concentration of iodine was determined by amperometric titration as shown in the previous paper.[14] All of the experiments were performed at 22 °C.

Results and Discussion

For the solution of amylose of DP 32 with iodine, the relaxation phenomenon was observed at 530 nm and 350 nm, *i.e.*, the maximum wavelengths of the amylose–iodine complex and that of free I_3^-, respectively: in the actual experiments, the relaxation spectra were recorded at 530 nm, because of the larger relaxation amplitude. Representative relaxation curves are shown in Figs. 1a and 1b. The absorbance change observed in Fig. 1a indicates the decrease of the complex, while that in Fig. 1b indicates the increase of I_3^-. Both curves were characterized as single relaxation phenomena and the relaxation times were coincident. These results indicate that the temperature-jump decomposes the complex and produces free I_3^- at the same time, and suggests that the present relaxation phenomenon is due to the amylose-iodine complex formation.[15]

The kinetic experiments were carried out by changing the concentration of iodine while keeping the concentration of amylose constant, or *vice versa*. The plots of the reciprocal relaxation time (τ^{-1}) *vs.* the total concentration of I_3^- [16] and that of amylose are shown in Figs. 2 and 3, respectively. As shown in these figures, the value of τ^{-1} increases with increase of the concentration of iodine but decreases with that of amylose.

Combining the above results together with the static

information, the following reaction was proposed as a plausible mechanism for the present relaxation phenomenon:

$$H_0 + nI_3^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} H_n, \qquad (1)$$

where H_0 denotes the free helical segment of amylose. The relaxation equation for the above reaction is given as

$$\tau^{-1} = k_f(\bar{C}_I^n + n^2\bar{C}_I^{n-1}\bar{C}_{H_0}) + k_b, \qquad (2)$$

where k_f and k_b are the forward and the backward rate constants, respectively, $\bar{C}_I$ is the concentration of free iodine and $\bar{C}_{H_0}$ is the concentration of free helical segment of amylose.[19] An increase of Σ[amylose] increases $\bar{C}_{H_0}$ but decreases $\bar{C}_I$ due to the shift of the equilibrium (1) to the right under the constant initial concentration of iodine. Since $\bar{C}_I$ contributes to τ^{-1} by the n and $(n-1)$ powers in Eq. 2, the variation of $\bar{C}_I$ predominantly effects τ^{-1}. Therefore, the experimental results in Figs. 2 and 3 seem to be well described by Reaction 1. The plots of τ^{-1} *vs.* the concentration term in Eq. 2 with various n values are shown in Fig. 4. As shown in the figure, the plot with $n \leqq 2$ gives a negative intercept and in the cases of $n \geqq 4$, it does not give a straight line. Only the plot with $n=3$ gives a best straight line, *i.e.*, Reaction 1 is shown to be

$$H_0 + 3I_3^- \underset{k_b}{\overset{K_f}{\rightleftharpoons}} H_3. \quad (3)$$

Reaction 3 is considered to be composed of the following three elementary reactions:

$$H_0 + I_3^- \overset{K_1}{\rightleftharpoons} H_1, \quad (4)$$

$$H_1 + I_3^- \overset{K_2}{\rightleftharpoons} H_2, \quad (5)$$

$$H_2 + I_3^- \underset{k_{-3}}{\overset{K_3\ k_3}{\rightleftharpoons}} H_3, \quad (6)$$

Assuming that the concentrations of H_1 and H_2 are very low and Reaction 6 is the rate-determining step of Reaction 3, the relaxation time for Reaction 3 is given by

$$\tau^{-1} = K_1K_2k_3(\bar{C}_I^3 + 9\bar{C}_I^2\bar{C}_{H_0}) + k_{-3}. \quad (7)$$

In comparison to Eq. 2 with $n=3$, $K_1K_2k_3$ corresponds to k_f, and k_{-3} to k_b. From the slope and intercept of the straight line of the plot with $n=3$ in Fig. 4, we can evaluate the values of k_f and k_b to be $(7.7\pm0.2)\times10^{16}$ (mol dm^{-3})$^{-3}$ s^{-1} and $(8.4\pm0.9)\times10^3$ s^{-1}, respectively, and the equilibrium constant K was obtained to be $(9.2\pm0.8)\times10^{12}$ (mol dm^{-3})$^{-3}$ from the ratio of k_f and k_b.

The equilibrium constant is also obtained amperometrically by the following equation:

$$K = [H_3]/[H_0][I_3^-]^3 = \bar{C}_B/(3\Sigma\bar{C}_H - \bar{C}_B)(\bar{C}_I)^3, \quad (8)$$

where $\bar{C}_B$ denotes the concentration of the bound iodine and $\Sigma\bar{C}_H$ is the total concentration of the helical segment of amylose. Introducing the same assumptions as those used in the derivation of Eq. 7, *i.e.*, $[H_1]=[H_2]\simeq0$ and H_3 is the only species of the complex, the value of K was determined to be $(1.3\pm0.6)\times10^{13}$ (mol dm^{-3})$^{-3}$, which is in good agreement with the above value.

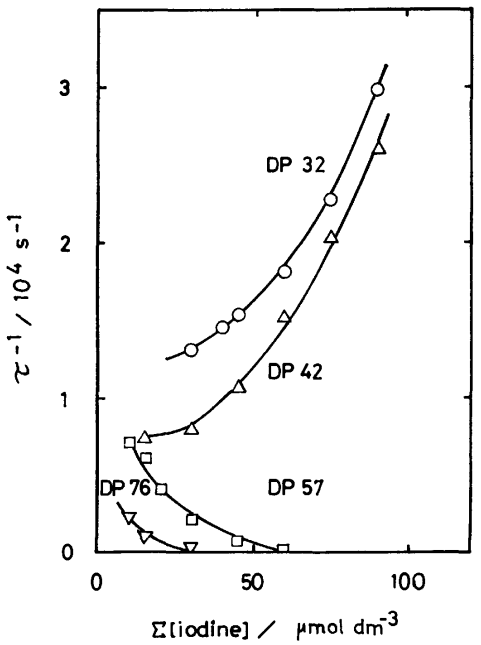

Fig. 5. Iodine concentration dependences of the reciprocal relaxation time for the amyloses of various DP and iodine system.
Σ[amylose]$=5\times10^{-4}$ mol dm^{-3}.

The same experiments as those described above were performed for the amyloses of DP 42, 57, and 76 and the effect of DP of amylose was investigated. The iodine concentration dependences of τ^{-1} for amyloses of various DP are shown in Fig. 5, where the positive and negative dependences were observed below DP 42 and above DP 57, respectively. In the case of lower DP amyloses, the binding of iodine is so weak that the added iodine increases the concentration term of Eq. 7 and induces the increase of τ^{-1} value. On the other hand, in the case of higher DP amyloses, most of the added iodine binds to the amylose and makes a negative contribution to the increase of the concentration term of Eq. 7. Consequently, the apparently opposing behavior of the concentration dependences of τ^{-1} can be well understood.

It is well known that the amylose–iodine complex becomes longer with increase of the DP of the amylose. In the case of these higher DP amyloses, the value of n for the final species of the complex (H_n) will exceed 3, *e.g.*, $n=4$ or more.[10-14] Therefore, if we are observing the whole process of the amylose–iodine complex formation in the present temperature-jump experiment

the value of n should be 4 or more in the case of higher DP amyloses. For all amyloses of various DP, however, only the plot with $n=3$ gave a good straight line with positive slope and the positive intercept as shown in Fig. 6. These results suggest that only Reaction 3 is responsible for the present relaxation and the reactions having order higher than 3 are not observed in these experiments. The values of k_f and k_b for the amyloses of various DP were obtained from each straight line in Fig. 6; they are summarized in Table 1 along with the value of K. With increasing DP of the amylose, the k_f value increases but the k_b value decreases.

The relaxation amplitude was found to be greatly affected by the DP of the amylose as shown in Fig. 7; the relaxation amplitude decreases steeply with increase of the DP of the amylose. This behavior of the relaxation amplitude is well understood by considering the shift of the equilibrium of Reaction 3 to the right[20] with DP of amylose, as indicated by the increase of K in Table 1. Another reason for the decrease of the relaxation amplitude will be in the decrease of the concentration of H_3 due to the propagation of H_3 to H_n ($n\geqq4$) in the case of higher DP amyloses.

The results on the relaxation time and the relaxation amplitude suggest that the relaxation phenomenon is not based on the whole process of the amylose–iodine complex formation but on the H_3 complex formation reaction. This consideration implies that the H_3 complex is relatively unstable and is easily perturbed by temperature but the higher order complex, *e.g.*, H_4, very stable and not perturbed. These are consistent with the explanation proposed by Thompson and Hamori[6] where the existence of a stable nuclei, H_4, is postulated for the high DP amylose.

Hiromi *et al.*[7] have proposed the following mechanism for the amylose–iodine complex formation:

$$H + nI_3^- \overset{\text{fast}}{\rightleftharpoons} \text{complex } \mathbf{1} \overset{\text{slow}}{\rightleftharpoons} \text{complex } \mathbf{2}.$$

The slow reaction with a time constant of 1—200 ms was investigated in detail but the fast reaction was just noted. Its existence in the time region is less than 1 ms. The existence of the process where three iodines bind to amylose has been suggested by other investigators.[6,8] The relaxation phenomenon observed in the present study was in the time region of less than 1 ms and ascribed to the reaction $H_0+3\,I_3^-\rightleftharpoons H_3$: these results were in complete agreement with the features predicted for the nucleation process. Finally, the fact that three iodines bind successively to the helical segment of amylose is indicative of the cooperative binding, which is compatible with the result we obtained by amperometric titration.[14]

Appendix

$$\text{For a reaction } H_0 + nI_3^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} H_n, \tag{A-1}$$

the rate equation is given by

$$\begin{aligned} -\frac{d}{dt}C_{H_0} &= k_f C_{H_0} C_I^n - k_b C_{H_n} \\ &= k_f(\bar{C}_{H_0}+\Delta C_{H_0})(\bar{C}_I+\Delta C_I)^n \\ &\quad - k_b(\bar{C}_{H_n}+\Delta C_{H_n}), \end{aligned} \tag{A-2}$$

where a bar over the concentration symbols indicates the equilibrium value and Δ indicates the small deviation from equilibrium. The stoichiometry gives the following relation,

$$\Delta C_{H_0} = \frac{1}{n}\Delta C_I = -\Delta C_{H_n} \tag{A-3}$$

At an equilibrium state,

$$K = \frac{k_f}{k_b} = \frac{\bar{C}_{H_n}}{\bar{C}_{H_0}\bar{C}_I^n}. \tag{A-4}$$

Neglecting the quadratic term in Eq. A-2, the rate equation is developed as follows,

$$\begin{aligned} -\frac{d}{dt}C_{H_0} &= -\frac{d}{dt}C_{H_0}(\equiv\tau^{-1}\Delta C_{H_0}) \\ &= k_f\{\Delta C_{H_0}\bar{C}_I^n + n\Delta C_I\bar{C}_I^{n-1}\bar{C}_{H_0}\} - k_b\Delta C_{H_0} \\ &= \{k_f(\bar{C}_I^n+n^2\bar{C}_I^{n-1}\bar{C}_{H_0}) + k_b\}\Delta C_{H_0}, \end{aligned} \tag{A-5}$$

then the reciprocal relaxation time τ^{-1} is given by,

$$\tau^{-1} = k_f(\bar{C}_I^n + n^2\bar{C}_I^{n-1}\bar{C}_{H_0}) + k_b. \tag{A-6}$$

Liquid Crystal Formation in Binary Systems. VII.[1] Liquid Crystals Induced in *N*-[4-(Dimethylamino)benzylidene]-4-alkoxyaniline-4,4′-Dinitrobiphenyl and Related Systems

Minoru Fukui and Yoshio Matsunaga*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received March 23, 1982)

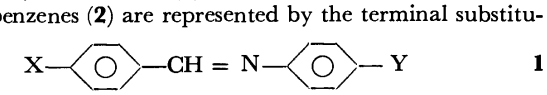
By the addition of 4,4′-dinitrobiphenyl to nonmesogenic 4-(dimethylamino)-4-alkoxy derivatives of *N*-benzylideneaniline, smectic liquid crystals could be induced. This dinitro compound induces liquid crystals more pronouncedly than *N*-(4-nitrobenzylidene)-4-nitroaniline and 4,4′-dinitroazoxybenzene do when the alkoxyl group in the donor molecule is methoxyl or ethoxyl, while it induces less pronouncedly when the alkoxyl group is propoxyl. 4,4′-Dicyanobiphenyl gives a metastable nematic liquid crystal when it is mixed with *N*-[4-(dimethylamino)-benzylidene]-4-propoxyaniline and a metastable smectic liquid crystal with *N*-(4-propoxybenzylidene)-4-(dimethylamino)aniline. Moreover, liquid crystals are formed in the binary systems of *N,N,N′,N′*-tetramethylbenzidine with 4-nitro-4-alkoxy derivatives of *N*-benzylideneaniline. They are metastable but cover rather wide composition ranges. The examination of the layer spacing of the smectic A phase revealed that the induced phase is a monolayer liquid crystal.

In one of our earlier papers,[2] the induction of liquid crystals in binary mixtures of *N*-(4-nitrobenzylidene)-4-nitroaniline or 4,4′-dinitroazoxybenzene with 4-(dimethylamino)-4-alkoxy derivatives of *N*-benzylideneaniline was reported. The interaction of the electron donor-acceptor type was supposed to contribute to the achievement of the ordered arrangement of the molecules required for the mesophases. The maximum temperatures of the smectic liquid crystal-isotropic liquid (S–I) transition in these systems vary over only eight degrees according to the dinitro compound employed. The absence of a large difference in the maximum temperature by the change in the central double bond linkage might be an indication that the central linkage does not play a dominant role in the induction of the mesophases. To develope this subject somewhat farther, the examination of the systems of 4,4′-dinitrobiphenyl with the same *N*-benzylideneanilines seemed to be worthwhile.

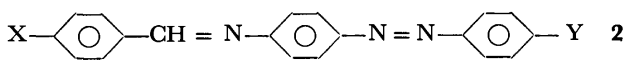
As liquid crystals could be observed in several mixtures of *N*-[4-(dialkylamino)benzylidene]-4-(dialkylamino)-aniline or 4,4′-bis(dialkylamino)azoxybenzene with 4-nitro-4-alkoxy derivatives of *N*-benzylideneaniline, the phase diagram approach was applied also to the systems consisting of *N,N,N′,N′*-tetramethylbenzidine and the same Schiff bases.

Experimental

Materials. The preparation of the Schiff bases was described in our previous papers,[3,4] In this text, *N*-(4-X-benzylidene)-4-Y-anilines (**1**) and 4-(4-X-benzylideneamino)-4′-Y-azobenzenes (**2**) are represented by the terminal substitu-



1



2

ents in parentheses or brackets, (X, Y) or [X, Y] respectively. The alkoxyl groups employed are methoxyl (MeO), ethoxyl (EtO), and propoxyl (PrO). 4,4′-Dinitrobiphenyl (DNBP) was prepared by nitration of biphenyl and recrystallized from acetone.[5] 4,4′-Dicyanobiphenyl (DCNBP) was synthesized starting from benzidine by the procedure reported by Ferriss and Turner.[6] *N,N,N′,N′*-Tetramethylbenzidine (TMB) Aldrich Chemical Co., was purified by recrystallization from a mixture of ethanol and toluene.

Measurements. The calorimetric and microscopic studies were carried out as described in Part IV of this series.[4] X-Ray diffraction by liquid crystalline phases was examined with the aid of a temperature-regulated sample holder described in a paper from this laboratory.[7]

Results and Discussion

4,4′-Dinitrobiphenyl (DNBP) as an Electron Acceptor. As is shown in Fig. 1a, the phase diagram of the binary system with (Me_2N, MeO) exhibits a metastable smectic phase of the A type in the composition range from 11 to 25 mol% of DNBP. The maximum lies a little bit below the eutectic temperature of 132 °C. By the exchange of the position of the terminal substituents on the donor compound (see Fig. 1b), the composition range becomes markedly narrower but the maximum temperature is shifted slightly above the eutectic temperature (135 °C).

When DNBP is added to (Me_2N, EtO), both smectic and nematic liquid crystals are observable (see Fig. 1c). The former phase appears in the range from 17 to 33 mol% of DNBP. The maximum temperature of the S–I transition curve coincides with the eutectic temperature of 138 °C. The stabilization of the smectic liquid crystal formed by mixing (EtO, Me_2N) and DNBP is more significant, the maximum being at about 164 °C and 37 mol%. Nevertheless, the induced mesophase is entirely below the freezing point curve on the DNBP-rich side. The N–I transition lines in these figures were drawn by connecting the observed point and the latent N–I transition temperature estimated in our earlier work.[3]

The smectic phase induced in mixtures with (Me_2N, PrO) is stable in a small area defined by the following points: the intersection between the horizontal S–I transition line in the coexistence of the solid donor compound and the freezing point curve of the donor compound located at 117 °C and 16 mol%, the eutectic point at 115 °C and 22 mol%, and the intersection between the other horizontal S–I transition line and the

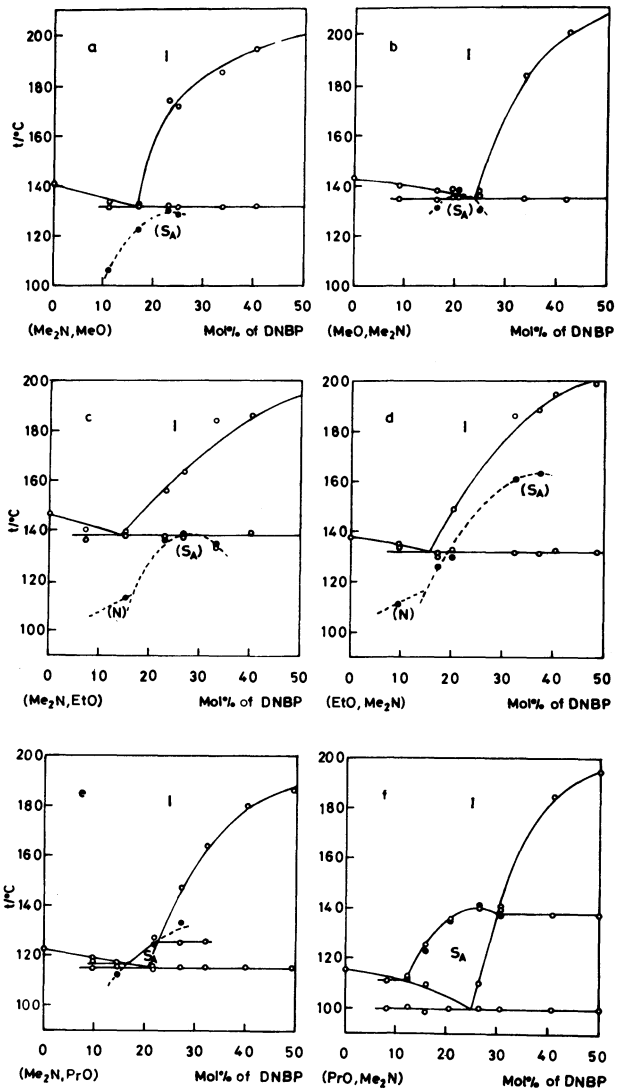


Fig. 1. Phase diagrams of the systems of DNBP with (a) (Me_2N, MeO), (b) (MeO, Me_2N), (c) (Me_2N, EtO), (d) (EtO, Me_2N), (e) (Me_2N, PrO), and (f) (PrO, Me_2N). The open and shaded circles are transitions observed in the processes of heating and cooling respectively.

freezing point curve on the DNBP-rich side at 125 °C and 23 mol%. The mesophase produced by mixing with (PrO, Me_2N) is more significantly stabilized (see Fig. 1f). The S–I transition curve meets the freezing point curve of the donor compound at 111 °C and 12 mol%, passes through the maximum at 140 °C and 26 mol%, and then meets the other freezing point curve at 138 °C and 30 mol%.

The maximum transition temperatures observed in the above-mentioned six systems are compared with

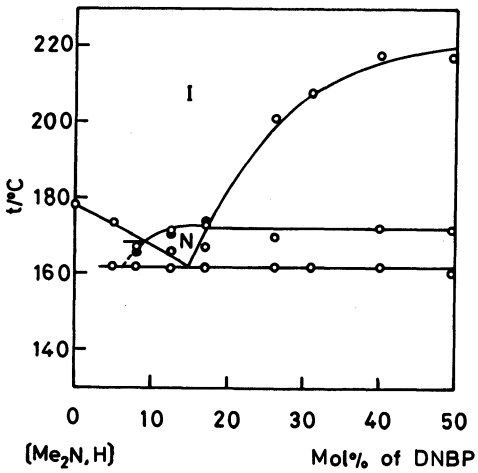

Fig. 2. Phase diagram of the [Me_2N, H]–DNBP system. As to the open and shaded circles, see the caption of Fig. 1.

those of the systems containing (NO_2, NO_2) or 4,4′-dinitroazoxybenzene (DNAO) in Table 1. When the methoxy derivatives are employed as electron donors, smectic liquid crystals can be observed only with DNBP. The mesophases induced with DNBP are more thermally stabilized than those induced with the other two acceptors when the donors are the ethoxy derivatives. On the other hand, the smectic liquid crystal in the (Me_2N, PrO)–DNBP is least stable and the liquid crystal in the (PrO, Me_2N)–DNBP is of intermediate stability. Thus, the absence of a central double bond linkage favors the induction of mesophase with the methoxy and ethoxy derivatives of *N*-benzylideneaniline but not with the propoxy derivatives. If the donor molecule is much larger than the acceptor molecule, there might be some combinations where the charge-transfer interaction is too weak to induce a smectic phase but still enough to induce a less-ordered nematic phase. Such a condition seems to be achieved by the addition of DNBP to the dimethylamino derivative of *N*-(benzylidene)-4-aminoazobenzene [Me_2N, H]. As is shown in Fig. 2, a stable nematic liquid crystal is observable in this system. The nematic liquid crystal-isotropic liquid (N–I) transition curve meets the freezing point curve of the donor compound at 168 °C and 9 mol% of DNBP, and the other freezing point curve at 172 °C and 17.5 mol%. The maximum lies at 174 °C and 15.5 mol%. The donor [Et_2N, EtO] is nematogenic by itself. When this compound is mixed with DNBP, the N–I transition curve is found to be convex upwards, in agreement with the induction observed in Fig. 2. In addition, one can see a metastable smectic phase of the A type induced in the composition

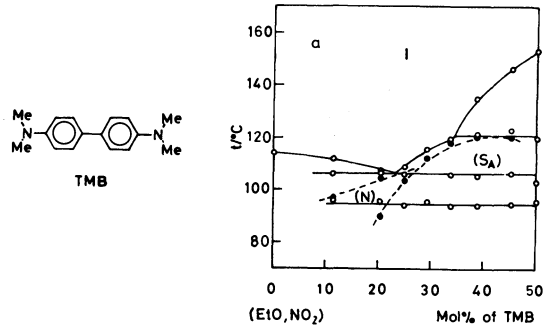

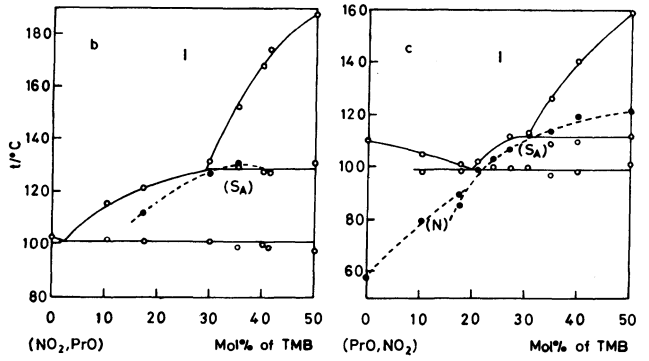

Fig. 4. Phase diagrams of the systems of TMB with (a) (EtO, NO_2), (b) (NO_2, PrO), and (c) (PrO, NO_2). As to the open and shaded circles, see the caption of Fig. 1.

range from 9 to 31 mol% of DNBP, the maximum being located at 136 °C and 23 mol%. This temperature is lower by 23 °C than the eutectic point. The induced metastable smectic phase is also noted in the system with nematogenic [Me_2N, EtO].

As described in one of our earlier papers, the present observations may imply that DNBP is potentially smectogenic.[3] It may be interesting to add that 4,4'''-dinitro-*p*-quaterphenyl has been reported by Vorländer to be a mesogenic substance.[8]

4,4'-Dicyanobiphenyl (DCNBP) as an Electron Acceptor. The electron acceptor strength of DCNBP is less than that of DNBP; therefore, the induced mesophase could be found only in the systems with (Me_2N, PrO) and (PrO, Me_2N). The mesophase in the former system is nematic and its appearance is limited to a narrow composition range (see Fig. 3a). A metastable smectic liquid crystal is present in the latter system. The monotropic S–I transition curve covers the range from 14 to 20 mol%, passing near the eutectic point located at 105 °C and 16.5 mol% (see Fig. 3b).

N,N,N',N'-*Tetramethylbenzidine (TMB) as an Electron Donor.* Smectic liquid crystals are induced in the systems with (MeO, NO_2), (EtO, NO_2), (NO_2, PrO), and (PrO, NO_2). The mesophase produced by mixing with the first acceptor is so unstable that the phase diagram approach failed to locate the existence region. Consequently, only the other diagrams can be presented here. In Figs. 4a and c, nematic liquid crystals are also observable. Thus, TMB is more efficient in the induction of mesophases than (Me_2N, Me_2N) and 4,4'-bis-(dimethylamino)azoxybenzene (BDMAAO), which can induce smectic liquid crystals only in the systems with (NO_2, PrO).[2]

The metastable nematic mesophase in the system with (EtO, NO_2) is stabilized up to 110 °C at about 28 mol% of TMB. The N–I transition curve passes near the eutectic point located at 106 °C and 23 mol%. The smectic mesophase is detectable in the composition range from 20 to 45 mol%. The maximum lies at 121 °C around 40 mol%. The horizontal line at 121 °C starting from the peritectic point at 34.5 mol% indicates the formation of a solid complex. at 50 mol% or higher. The other line at 94 °C may be due to a solid-solid transition of the complex.

The diagram of the (NO_2, PrO)–TMB system exhibits a metastable smectic phase in the composition range from 17 to 42 mol% of TMB. The maximum is located slightly above the peritectic temperature of 129 °C. It may be noted that the smectic liquid crystal is the most stabilized in this combination among those shown in Fig. 4. This finding is consistent with the previous results that smectic mesophases are induced only when (Me_2N, Me_2N) and BDMAAO are mixed with this Schiff base.[2] In the (PrO, NO_2)–TMB system, the whole examined range is covered by metastable nematic or smectic phase. The intersection between the I–N and I–S transition curves occurs at about 90 °C and 19 mol% of TMB. The latter curve reaches 121 °C at 50 mol%.

No liquid crystal is formed when TMB is replaced by *N,N,N',N'*-tetraethylbenzidine in any of these binary systems.

The addition of TMB to [NO_2, H] resulted in the formation of a congruently melting solid complex at 33 mol% of TMB and the induction of a smectic A phase in the range from 42 to 50 mol%, the temperature at the latter composition being 152 °C. The acceptor itself is nematogenic. As the I–N transition lowers linearly with the mol% of TMB and is observable up to 45 mol%, there is no thermal stabilization of this phase by TMB. No new mesophase appears when TMB is added to nematogenic [NO_2, EtO].

The maximum of the I–S transition curve lies between 20 and 50 mol% of DNBP or TMB. The exact composition is supposed to depend upon the extent of the formation of the 2 : 1 complex in addition to the 1 : 1

complex and/or upon the difference in the latent I–S transition temperature between the component compounds.

As the smectic layers consist of molecular complexes, the thickness is dependent on how the donor and acceptor molecules are stacked and could be larger than the average length of the component molecules. In order to check this possibility, the interlayer spacing in the stable smectic phase of the A type induced in the (PrO, Me_2N)–DNBP mixture at 19.7% was measured. The observed spacing of 1.80 nm is in good agreement with the weighted mean molecular length of 1.87 nm. The latter was estimated assuming 1.97 nm for the donor molecule and 1.46 nm for the DNBP molecule; these values were calculated by employing the bond lengths and the van der Waals radii compiled by Kitaigorodskii.[9] Thus, it seems quite certain that the mesophase induced in this particular mixture is a monolayer liquid crystal. In connection with this measurement, the smectic phases of the A and B types induced in mixtures of [PrO, H]–[NO_2, H], [Et_2N, H]–[NO_2, H], and [PrO, EtO]–[NO_2, EtO] were similarly examined. In all the cases, the monolayer model accounts for the observed thickness.

The present work was partly supported by a Grant-in-Aid for Scientific Research No. 543001 from the Ministry of Education, Science and Culture.

Conformational Characteristics of Poly(vinylnaphthalene)s from Energy Contour Map

Kazuhiko SEKI* and Yoshio IMAMURA
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 15, 1982)

In poly(1-vinylnaphthalene)(P1VN) and poly(2-vinylnaphthalene)(P2VN), conformational energies of meso and racemic dyads were computed as functions of skeletal bond and side group rotations (0°(*o*) or 180°(π)). The calculation was carried out according to the truncation procedure proposed by D.Y.Yoon. The backbones in P1VN and P2VN were limited to just two rotational states, trans (t) and gauche (g) conformation. The steric interactions involving the bulky naphthyl group precluded $\bar{g}$ conformation; a similar situation occurs in polystyrene. Numerical results suggested these conclusions: the excimer forming site conformations for P1VN were meso : tt($\pi\pi$) and racemic : tt($\pi\pi$) states, and for P2VN were meso : tt($\pi\pi$), tt(oo), tt($o\pi$), and tt(πo) states. These conformations could also be correlated to the dual emissions observed in P1VN and P2VN.

In a previous paper,[1] we pointed out the differences in some solution properties between poly(1-vinylnaphthalene) (P1VN) and poly(2-vinylnaphthalene) (P2VN), and also the resemblance of the latter to polystyrene in solution. We discussed the conformation of pendant groups in P1VN and P2VN. In another paper,[2] we treated the steric effect on ^{13}C NMR chemical shifts in poly(vinylnaphthalene)s (PVN), taking into account the Rotational Isomeric State (RIS) of the pendant group; this was based on discussions in the preceding paper.[1] In PVN, the ring current effect by naphthyl groups was rather small and there was not much difference between P1VN and P2VN. The different spectral patterns in ^{13}C NMR spectra of the aliphatic carbon region were attributed to the difference of the degree of the steric compression shift induced by the steric interaction between the methine hydrogen and the atoms in the naphthyl group.

Among recent discussions on the conformation of PVN, one of the most interesting problems is the studies on the excimer fluorescence of PVN in solutions.[3] Hirayama[4] proposed the "$n=3$ rule" for the intramolecular excimer formation and indicated that an excimer was an electronically excited molecular complex formed between two aromatic chromophores in a coplanar sandwich arrangement. For a P2VN chain which satisfies the $n=3$ rule, Frank *et al.*[5] studied the geometrical arrangement of two chromophores in an excimer state in detail: the conformations of the possible excimer forming site were found to be tt for the isotactic and t$\bar{g}$ or $\bar{g}$t for the syndiotactic chain. He concluded that the ground state (preferred conformation) was tg or gt for isotactic chain, and tt for syndiotactic chain. These results have been predicted by a simple statistical model with RIS approximation. However, in the conformational analysis of PVN in terms of rotations around the skeletal bonds, a more attractive procedure is the preparation of conformational maps developed by Flory *et al.*[6-10] The detailed discussion should be based on the average energy $\langle E \rangle_s$ for each rotational state s of skeletal bonds derived from the conformational maps. The purpose of this paper is to discuss the RIS for skeletal bonds in P1VN and P2VN chains, which are closely related to the ground site and excimer forming site conformation.

Calculation

Recently, Sundararajan reported the conformational maps in terms of skeletal bond rotations ϕ_i and ϕ_{i+1}, for the meso and the racemic dyads of poly(*N*-vinylcarbazole) (PVCz).[11] In PVCz chain, the skeletal bond angle θ (at the methylene carbon atom: αC–CH$_2$–αC) in the minimum energy position in the tt state of the meso and the racemic dyads was larger than that in the other conformations. Since PVN chains have bulky side groups like those of the PVCz chain, the energy maps are computed by varying the bond angles θ from 114° to 126° in steps of 2° at each (ϕ_i, ϕ_{i+1}) grid point. RIS of side groups in PVN are also taken into account in conformational maps.

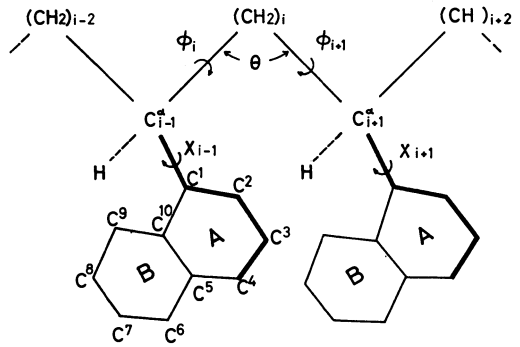

Fig. 1. Portion of the isotactic P1VN chain in the all-trans ($\pi\pi$) conformation. In the P2VN chain, the α-carbon is bonded to the C(2) atom in the naphthyl group.

TABLE 1. GEOMETRICAL PARAMETERS

Bond length	l/Å	Bond angle	ϕ/°
C–C	1.53	$\angle CC^{\alpha}$–C	112
		$\angle C^{\alpha}$–CC^{α}	Variable
C^{α}–C^{ar}	1.51	$\angle CC^{\alpha}$–C^{ar}	112
C–H	1.10	$\angle CC^{\alpha}H$	107
C^{ar}–H	1.10	$\angle C^{\alpha}CH=\angle HCH$	110
C^1–C^2	1.36	$\angle C^1C^2C^3$	121
C^2–C^3	1.42	$\angle C^1C^{10}C^9$	122
C^1–C^{10}	1.43	$\angle C^1C^{10}C^5$	119
C^{10}–C^5	1.41	$\angle C^2C^1C^{10}$	120

Figure 1 shows that the meso : tt state of PIVN chain is occupied by π-conformation. According to the convention of Flory *et al.*,[10] the torsional angles ϕ_i and ϕ_{i+1} for meso *dl* dyads (see Fig. 1) are measured in the right- and left-handed senses, respectively. For the racemic *dd* dyad, ϕ_i and ϕ_{i+1} are measured in the right-handed sense. The bond lengths and bond angles for PVN are given in Table 1.[10] The conformational parameters for naphthyl group were taken from studies on the crystal structure of naphthalene.[12]

In previously calculated results of steric energies for pentamer models,[1] the optimized rotational angles of 1- and 2-naphthyl rings did not exceed $\pm 4.5°$ away from the position where the ring was perpendicular to the plane made by the adjoining backbone bonds. Accordingly, the rotational angles X (see Fig. 1) of the naphthyl groups are fixed at 0° (*o*-conformation) or 180° (π-conformation).

The nonbonded van der Waals energy among all atoms was computed using the Lennard-Jones 6—12 potential function:

$$E_{vdw} = a_{i,j}/(r_{i,j})^{12} - c_{i,j}/(r_{i,j})^6, \quad (1)$$

where radii, polarizabilities and effective numbers of electrons for C_{sp2}, C_{sp3}, and H were taken from Flory *et al.*[10] Torsional energies for ϕ_i and ϕ_{i+1} were calculated using the intrinsic three-fold torsional function:[7]

$$E_{tor} = (V/2)(1+\cos 3\phi), \quad (2)$$

where ϕ is the dihedral angle and V is a barrier of 2.8 kcal mol^{-1}.† The deformation energy for the bond angle θ was treated in the harmonic approximation:[9]

$$E_{bend} = (K_\theta/2)(\theta-\theta_0)^2, \quad (3)$$

where θ_0 was assigned as tetrahedral, and K_θ is the bending constant of 0.044 kcal mol^{-1} deg^{-2}.†† Energies used for construction of the contours were computed at intervals of 5° in ϕ_i and ϕ_{i+1}. These functions were appropriate to reproduce the unperturbed dimensions of PVCz and polystyrene.[10,11]

Results and Discussion

The conformational energies for the meso and the racemic dyads of PIVN chain occupied by π-conformation, using $\theta=114°$, are shown in Figs. 2 and 3 as functions of the skeletal bond rotational angles ϕ_i and ϕ_{i+1}, respectively. Contours are shown at the energies quoted in kcal mol^{-1} relative to the minimum for the meso : tg (10,105°) or gt (105,10°) state. The tt states for the meso and the racemic dyads did not appear in the energy map until θ went beyond 116°. This feature of the energy surface is a consequence of the planar geometry of the 1-naphthyl groups which are occupied by π-conformation. The B ring (see Fig. 1) overlaps with another B ring at the distance of 2.60 Å, in the racemic : tt state. The steric repulsion between B rings, which are spatially crowded by neighboring atoms, can not relieved by small increases in ϕ_i and ϕ_{i+1}. On the other hand, in the case of meso : tt state, each 1-naphthyl ring is parallel to the neighboring ones, and

† 1 kcal mol^{-1}=4.184 kJ mol^{-1}.
†† 1 kcal mol^{-1} deg^{-2}=4.184 kJ mol^{-1} deg^{-2}.

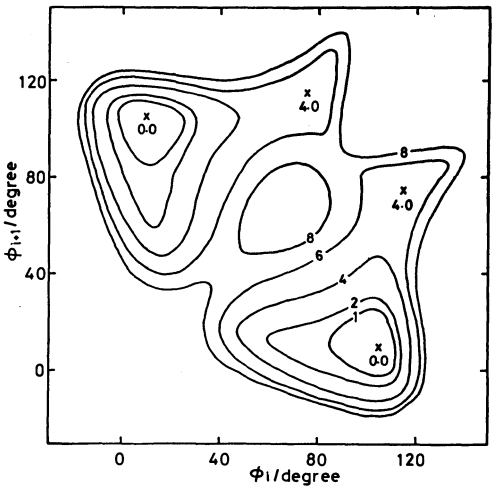

Fig. 2. Conformational energy contours for a meso dyad of PIVN calculated as functions of skeletal bond rotations ϕ_i, ϕ_{i+1}. Naphthyl group rotations fixed at X= 180° (π-conformation). A value of $\theta=114°$ is used. Locations of minima are denoted by × and the energy contours are labeled in kcal mol^{-1} relative to the energy minium of the moso; tg conformation.

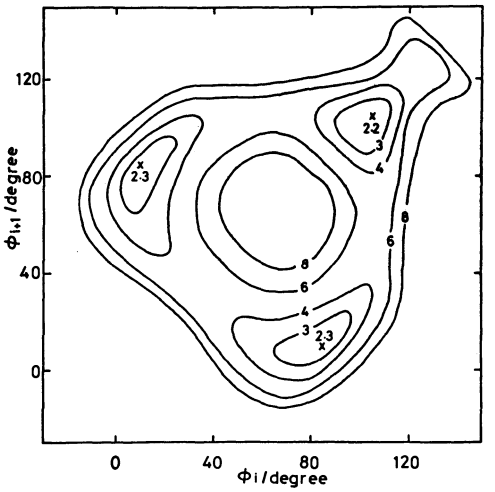

Fig. 3. Conformational energy contours for a racemic dyad of PIVN. A values of X=180° and θ=114° are used.

directed in the same direction; the distance between neighboring planes is estimated to be 2.60—2.75 Å. This steric repulsion between neighboring planes can not be avoided by small increases in ϕ_i and ϕ_{i+1}, as in the racemic : tt state.

Figures 4 and 5 show the conformational energy maps for the meso and the racemic dyads of PIVN chain occupied by π-conformation, using $\theta=120°$. The energies of the minima in Figs. 4 and 5 are expressed relative to the energy of the tt state of the racemic dyad. Six minima appear in Fig. 4 and four minima in Fig. 5. These minima are identified as tt, tg or gg. The $\bar{g}$ conformation is precluded, due to the interaction resulting from the planarity of the 1-naphthyl group.

In meso dyad, the minima at 80,120° or 120,80° in

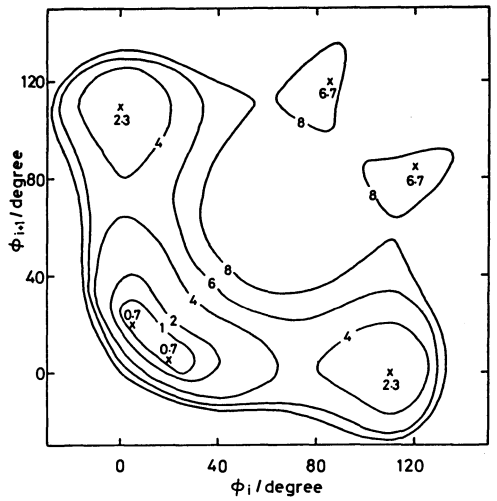

Fig. 4. Conformational energy contours for a meso dyad of PlVN, using $X=180°$ and $\theta=120°$. The energy contours are labeled in kcal mol^{-1} relative to the energy minimum of the racemic; tt ($\pi\pi$) at $\theta=120°$.

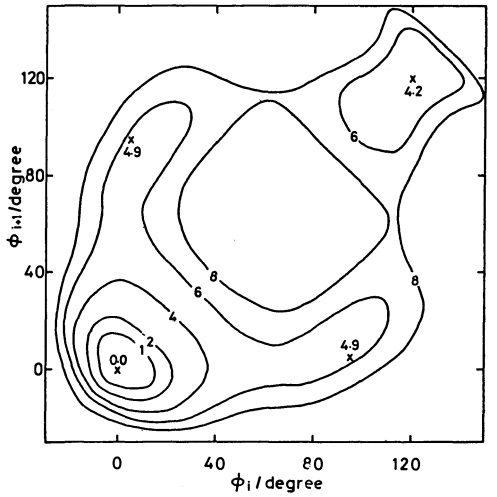

Fig. 5. Conformational energy contours for a racemic dyad of PlVN, using $X=180°$ and $\theta=120°$.

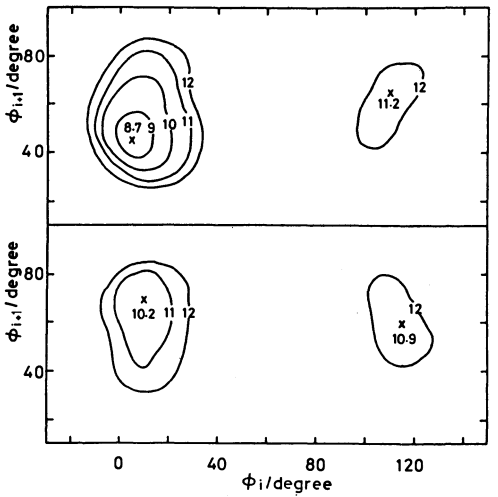

Fig. 6. Energy contours maps for (a) meso and (b) racemic dyads of PlVN, using $X_{i-1}=180°$, $X_{i+1}=0°$ (o-conformation) and $\theta=114°$. The energy contours were labeled in kcal mol^{-1} relative to the energy minimum of the meso; tg at $\theta=114°$ (see Fig. 2).

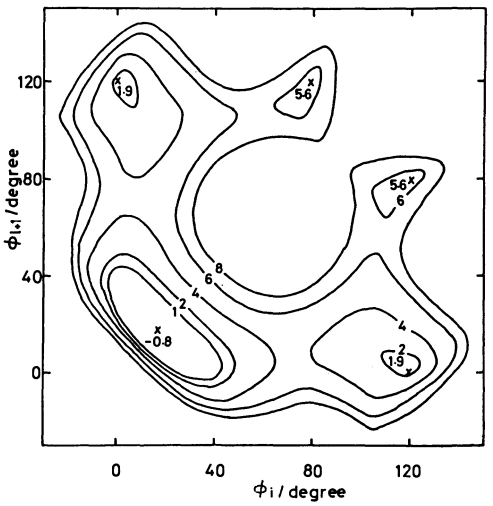

Fig. 7. Conformational energy contours for the meso dyad of P2VN($\pi\pi$), using $\theta=114°$. The energy contours are labeled in kcal mol^{-1} relative to the energy minimum of the racemic; tt($\pi\pi$) at $\theta=114°$.

Fig. 4 are isolated completely from the other minima. All minima are surrounded by the contour with 9 kcal mol^{-1}. In the energy maps of polystyrene chain, conformational energy contours of 5 kcal mol^{-1} are sufficient to surround all minima. The tt conformation is separated into two minima with a low energy barrier (<0.2 kcal mol^{-1}) between them. The distances between 1-naphthyl rings for $\phi_i,\phi_{i+1}=0,0°$ are 2.73—3.37 Å. The steric repulsion in this case was more relaxed than that for $\theta=114°$. Futhermore, ϕ_i,ϕ_{i+1} will displace somewhat from the perfect staggering (0,0°), and the energy then falls rapidly.

In racemic dyad, all minima could be surrounded by a contour with a larger value (about 8 kcal mol^{-1}). The minima for racemic : tt state appeared at smaller values of θ (about 116°) than those for the meso : tt state (about 118°). As described above, the neighboring 1-naphthyl ring in racemic : tt state was placed so as to approach to a part of 1-naphthyl ring (B ring), while 1-naphthyl ring in meso : tt state was placed in close proximity to the adjoining 1-naphthyl ring. The steric repulsion between neighboring 1-naphthyl rings in the racemic : tt state is smaller than that in the meso : tt state, and can be avoided by a small increase in θ.

Figures 6a and b show the energy contour maps for the meso(πo) and the racemic(πo) dyads, respectively. The energy contours are labeled in kcal mol^{-1} relative to the energy minimum of the meso tg (10,105°) at $\theta=114°$. The numbers of minima in Fig. 6 are less than that of PlVN occupied by π-conformation. Two minima for the meso and the racemic dyads are located at 5,45° and 110,65°, and at 10,70° and 115,60°, respectively. These minima values, as a function of ϕ_i and ϕ_{i+1}, have the lowest values at $\theta=114°$ over the range from 110° to 126°. However, these values are much higher than that of PlVN ($\pi\pi$). The o-conformation imposes steric overlap between the hydrogen at C(9) in

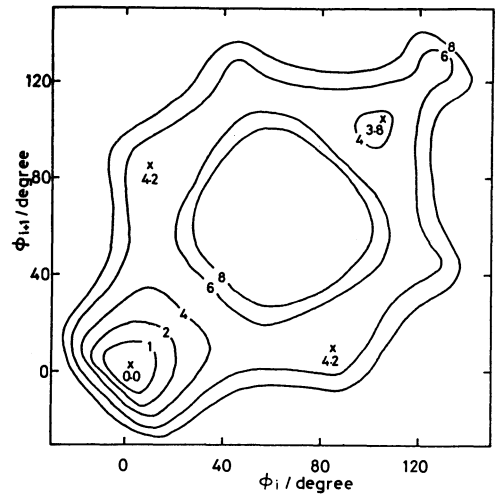

Fig. 8. Conformational energy contours for racemic dyad of P2VN($\pi\pi$), using $\theta=114°$.

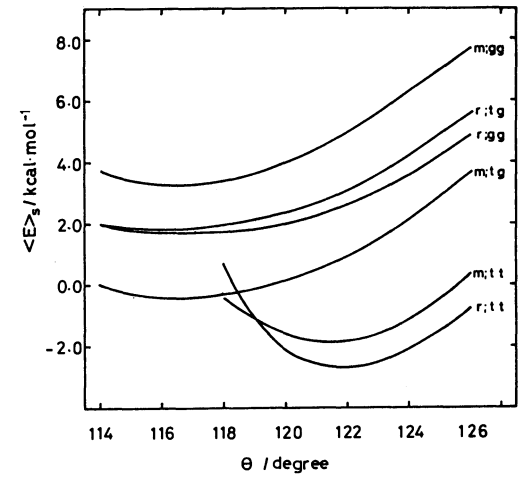

Fig. 9. The average energy $\langle E\rangle$ for PlVN were plotted as a function of the bond angle θ. All values were evaluated relative to the meso; tg($\pi\pi$) at $\theta=114°$.

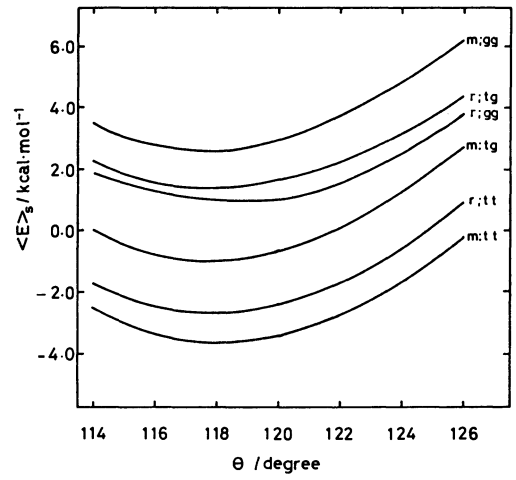

Fig. 10. The average energy $\langle E\rangle$ for P2VN. All values were evaluated relative to the meso; tg($\pi\pi$) at $\theta=114°$.

a rotating 1-naphthyl ring and one of the methylene or α-carbons which belong to adjacent monomer unit, as reported in our previous paper.[1] Neither of the minima calculated here are assigned to RIS of skeletal bonds (t, g, and $\bar{g}$). The energy contour maps, in which all the RIS of side groups are in o-conformation, are not recorded in this paper, but the minimum values were remarkably large (=20 kcal mol^{-1}).

Figures 7 and 8 show the conformational energy contours for the meso and the racemic dyads of P2VN ($\pi\pi$), using $\theta=114°$. The energy surfaces in Figs. 7 and 8 were little influenced by the RIS of the side groups, and closely resembled that of polystyrene, except for the values of minima. For meso dyad, the distance between 2-naphthyl rings was 2.60—2.77 Å for $\phi_i,\phi_{i+1}=0,0°$. This distance is nearly equal to that of PlVN, but the minima of tt states for the meso have appeared over a range of $\theta(114°—120°)$. In PlVN chain, the steric interactions produced by the carbon and the hydrogen atoms in B ring are responsible for the larger conformational energy. On the other hand, in P2VN chain, the atoms in B ring are far apart from the backbone atoms (*e.g.*, αC or CH_2), and rapidly become detached from adjacent naphthyl rings if a small increase in ϕ_i and ϕ_{i+1} occurs. As reported in the previous paper,[1] there were no appreciable nonbonded interactions between the carbon atoms or hydrogen atoms bonded to carbon atoms in B ring of 2-naphthyl group and the main chain (or the neighboring side group). In racemic : tt, the B ring did not approach to the adjacent B ring, in contrast to that in PlVN chain.

The average energy $\langle E\rangle$, the partition function Z, and the average rotation angles $\langle\phi_i\rangle$, $\langle\phi_{i+1}\rangle$ were evaluated for each state with the use of energies calculated at intervals of 5° in ϕ_i and ϕ_{i+1}. These are given by

$$Z_s = \Sigma_i\Sigma_{i+1}\exp(-E_k/RT) \quad (4)$$

$$\langle E\rangle_s = Z_s^{-1}\Sigma_i\Sigma_{i+1}E_k\exp(-E_k/RT) \quad (5)$$

$$\langle\phi_j\rangle_s = Z_s^{-1}\Sigma_i\Sigma_{i+1}\phi_j\exp(-E_k/RT), \quad (6)$$

where the subscript k refers to each conformation (ϕ_i, ϕ_{i+1}) and j=i or i+1. The average energies $\langle E\rangle$ for PlVN and P2VN are plotted as functions of θ in Figs. 9 and 10, respectively. All values of $\langle E\rangle$ were evaluated relative to each meso : tg($\pi\pi$) state. Calculations were carried out for a temperature of 300 °K. The $\langle E\rangle$ for PlVN, except tt states, remained unaltered in the range of $\theta(114°—120°)$ and these curves showed precipitous rises of $\langle E\rangle$ beyond $\theta=120°$. The $\langle E\rangle$ of tt states had the lowest values at $\theta=122°$, as described above. In P2VN chain, all values had the lowest values at $\theta=118°$, and have the same curvature. The curves of polystyrene showed a similar tendency.

The lowest values appearing in Figs. 9 and 10 are assigned to the average energy of each RIS of skeletal bonds. The average energies $\langle E\rangle$ derived from Figs. 9 and 10, together with the averaged rotation angles $\langle\phi_i\rangle$, $\langle\phi_{i+1}\rangle$ are given in Table 2. The values of $\langle E\rangle$ were evaluated relative to that of the racemic : tt conformation. The meso : tt conformation in PVN and polystyrene had a lower energy. However, the rotational barrier of the aromatic group was much higher than

a) All values are evaluated relative to each racemic : tt ($\pi\pi$) state, in kcal mol^{-1} units. b) These values were calculated by Yoon *et al.* (Ref. 10).

that of the aromatic group in meso : tg conformation. This leads to a decrease of entropy in the planar conformation. Thus, at normal temperature, the meso : tt conformation seems to be unfavoured due to its larger free energy.

This problem can be resolved by a truncation procedure devised by Yoon *et al.*[6,10,11] This was followed so as to allow for the conformational dependence of solvent interaction. Beyond a certain distance, which is sufficient to permit the entry of the solvent molecules, the reduced interaction between aromatic groups will be replaced by the interaction between aromatic group and solvent, and the energy of the system levels off at this distance. Thus, the calculated energy remains constant at the value for $r=\sigma$ for all distances greater than a suitably chosen values of σ. The average energies $\langle E\rangle$, using $\sigma=5.0$ Å and 3.9 Å are given in Table 3, together with the $\langle E\rangle$ values for polystyrene calculated by Yoon.

In P2VN and PS chain, it is clear that racemic : tt conformation corresponds to the ground state (preferred conformation). The relationship of $\langle E\rangle_{tt}<\langle E\rangle_{gg}<\langle E\rangle_{tg}$ is found to hold, regardless of the value of σ chosen. The racemic : $t\bar{g}$ and $\bar{g}t$ conformations correspond to the excimer forming sites.[5] These conformations are unstable ones and have a energy of 7 kcal mol^{-1} higher than the lowest energy (tt state), since the conformations include the interaction between the aromatic groups. These results suggest that the statistical weights relating to $t\bar{g}$ and $\bar{g}t$ states are extremely small at normal temperature. Use of a truncation procedure shows that the conformational energy of meso : tt state is larger than that of meso : tg state, and that at $\sigma=$ 3.9 Å meso : tt conformation becomes the most unfavourable one in the meso dyad. Accordingly, the meso : tg conformation corresponds to the ground state, and the tt conformation corresponds to an excimer forming site, which is electronically stabilized under excimer formation.

In P1VN chain, the relative stability of each RIS in meso dyad is similar to those of P2VN and polystyrene, regardless of the value of σ chosen. Evidently, the meso : tg conformation corresponds to the ground state, and the conformational stability of it is higher than that of polystyrene and P2VN in meso dyad. On the other hand, the relative stability of each RIS in racemic dyad is strongly dependent on the value of σ : $\langle E\rangle_{gg}<\langle E\rangle_{tg}<\langle E\rangle_{tt}$ at $\sigma=3.9$ Å. The racemic : tt conformation is not necessarily the most stable one. The racemic: gg and tt conformations correspond to the ground state at $\sigma=3.9$ Å and $\sigma\geqq5.0$ Å, respectively. The racemic : $t\bar{g}$ and $\bar{g}t$ conformations are less favored states than tt, tg, and gg states; this is also found in P2VN and in polystyrene.

In PVN chain, the dual emission in excimer region was observed in solution. Gupta *et al.*[13] concluded that the two types of singlet excimers characterized by emission spectra of P1VN may consist of parallel and antiparallel conformations of pairs of 1-naphthyl groups. From the emission spectra of P2VN and its model compound (*meso*-1,1′-di-2-naphthyldiethylether) in solution, Schryver *et al.*[14] pointed out that the observation of a dual decay could be due to the relative orientation in the ground state of the naphthyl groups prior to excimer formation. The dual emission may be correlated with the RIS for side groups in PVN chain.

In P2VN chain, the dual emission in the excimer region may be correlated with two types of excimers site conformation differing in RIS for side group or site conformation differing in RIS for skeletal chain. Concerning the latter, meso : $\bar{g}\bar{g}$, meso : tt and racemic: $t\bar{g}(\bar{g}t)$ can be formed in a parallel sandwich arrangement

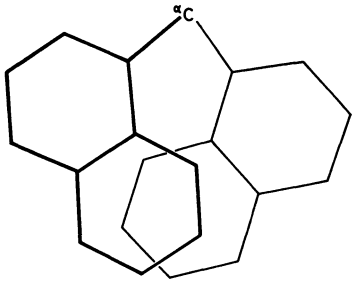

Fig. 11. A segment of a racemic; tt($\pi\pi$) of P1VN chain. 1-naphthyl groups are parallel to the space. The hydrogens and methylene carbons are omitted.

of aromatic groups. However, the formations of the excimers consisting of those skeletal conformations, except meso : tt state, seem less likely, on the basis of our calculated results. The RIS of skeletal chain with respect to the excimer formation is occupied by the meso : tt conformation, and few racemic : t$\bar{g}$($\bar{g}$t) conformations occur. Since 2-naphthyl groups in P2VN chain are occupied by both π- and o-conformations,[1] there are $\pi\pi$, oo, πo, and $o\pi$ conformations for RIS of side groups in meso : tt state. The structure of $\pi\pi$ and oo-conformation are made up by the total superposition of 2-naphthyl groups, while 2-naphthyl groups in πo and $o\pi$ conformation are placed so as to approach near a part of 2-naphthyl group (A ring). It can be concluded that the dual emission observed in atactic P2VN chain should be attributed to the RIS of 2-naphthyl group in meso : tt state. The excimer forming site conformations are $\pi\pi$ and oo conformations; other conformations are πo and $o\pi$ ones.

Since 1-naphthyl groups in P1VN chain were limited to a preferred state (π-conformation),[1] tt($\pi\pi$) conformation in meso dyad is the only conformation which forms the excimer. Other conformations are not detected in meso dyad. However, the racemic : tt($\pi\pi$) conformation can be formed in a sandwich arrangement of 1-naphthyl groups, whether that conformation is preferred or not. Figure 11 shows the relaxed molecular model of racemic: tt($\pi\pi$) state obtained by the force field method. This model structure fits with that used in the present paper. The racemic : tt conformation comes to be the excimer forming site conformation by deforming the bond angle of $C_{aromatic}$–αC–$H_{methine}$(about 7°). Accordingly, it is concluded that the dual emission in atactic P1VN chain should be attributed to the meso : tt($\pi\pi$) and racemic: tt($\pi\pi$) states. The meso : tt($\pi\pi$) and racemic : tt($\pi\pi$) states correspond to the parallel and antiparallel configurations proposed by Gupta,[13] respectively.

The averaged rotation angles $\langle\phi_i\rangle$, $\langle\phi_{i+1}\rangle$ in Table 2 are independent of the values of σ chosen. The averaged rotational angles for the meso : tg in P1VN chain largely deviate from the perfect staggered conformation (0,120°). The values suggest that an isotactic P1VN chain forms a 4_1 helix. This conclusion is approximately consistent with the X-ray data on isotactic P1VN reported by Natta.[15] Table 2 also shows that an isotactic P2VN chain forms a 3_1 helix.

The Macromolecular Ion Flotation of Fe^{3+}, Cu^{2+}, and Ni^{2+} by the Use of Charcoal and Cationic Surfactant

Tsunetaka Sasaki,* Kōji Mochizuki, and Satoshi Ishiwata
Department of Chemistry, Faculty of Science, Tokai University, 1117 Kitakaname, Hiratsuka 259-12
(Received April 23, 1982)

The macromolecular ion flotation of Fe^{3+}, Cu^{2+}, and Ni^{2+} ions by the combined use of charcoal and hexadecyltrimethylammonium chloride (HTAC) was studied. The flotation of powdered active charcoal itself was first studied; a 100% floatability was obtained for the flotation of 2500 ppm charcoal by the addition of 6 ppm of polyacrylamide and 550 ppm of HTAC in the pH range from 4 to 13. For the studies of the flotation of Fe^{3+}, Cu^{2+}, and Ni^{2+} ions, diagrams of the floatability of the respective ions *vs.* the composition of charcoal and HTAC, and the floatability of the respective ions *vs.* the pH at a constant composition of charcoal and HTAC, were constructed. A nearly 100% floatability was obtained for Fe^{3+}, Cu^{2+}, and Ni^{2+} ions at pH values larger than 4.5, 9.5, and 11 respectively. This order is the same as that of the solubility products of $Fe(OH)_3$, $Cu(OH)_2$, and $Ni(OH)_2$. It was confirmed that Fe^{3+} ions are adsorbed as hydroxides on charcoal; they are subsequently floated over the whole range of pH values combined with charcoal, while the Cu^{2+} and Ni^{2+} ions are adsorbed as simple ions on charcoal and floated in the lower pH region. They are adsorbed as hydroxide on charcoal and floated in a higher pH region.

In preceding papers, we have reported the applicability of macromolecular ion flotation to the flotation of inorganic and organic anions and cations.[1,2] There, macromolecular ions, namely, macroscopic or colloidal particles possessing an ion-exchange capacity and organic or inorganic polymer ions, together with ionic surfactants with an electric charge the opposite of that of macromolecular ions, were used.

To date, ion flotation using charcoal and surfactant has not been reported, although flotations of charcoal by surfactants have been reported.[3,4] Considering the remarkable adsorbing power of charcoal for various organic and inorganic ions, effective ion flotation by the use of charcoal can be expected.

In this case, powdered active charcoal is preferable, since this offers both a very large and readily accessible area for the substance to be floated. However, the powdered charcoal has the difficulty of not being easily floated.[4] In the present paper, this difficulty could be overcome by the addition of a small amount of polyacrylamide.

In the present paper, charcoal was used as the macromolecular ion in our series of studies.[1] Fe^{3+}, Cu^{2+}, and Ni^{2+} ions were floated by HTAC.

Experimental

Materials. The charcoal was the product of Wako Pure Chemicals, labelled "Chemical Activated." HTAC was the product of Wako Pure Chemicals of a chemically pure grade. The polyacrylamide DCLE MA-3000H (PAA) was the product of Mitsubishi Chemical Industries, the mean degree of polymerization being 1×10^5. The $FeCl_3$, $CuSO_4$, and $NiSO_4$ were commercial products of a guaranteed grade.

Measurement. For the flotation measurement, 20 cm^3 of a solution containing the ions to be floated, charcoal, HTAC, and HCl or NaOH if necessary for controlling the pH was introduced into a stoppered test tube 16 mm in inner diameter and 290 mm in length, equipped with a stopcock at the bottom. The test tube was shaken 20 times by hand. After the test tube had been kept standing for 10 min to complete the flotation, the concentrations of Fe^{3+}, Cu^{2+}, and Ni^{2+} ions in the underlying solution were measured and the floatability percentage, F, was calculated by means of the following equation:

$$F = (1 - C_f/C_i) \times 100\ \%,$$

where C_i and C_f denote the concentrations of the ions to be floated in the solution before and after the flotation respectively.

The concentrations of the Fe^{3+}, Cu^{2+}, and Ni^{2+} ions were measured with a Hitachi Atomic Absorption Spectrometer 508 at wave lengths of 248.3, 324.7, and 232 nm respectively.[2] The pH was controlled if necessary by the addition of HCl or, NaOH.

The measurement was carried out at a room temperature, about 25°C.

Results and Discussion

Floatability of Charcoal. First, we studied the floatability of charcoal. The floatability of charcoal *vs.* the concentration of the PAA relation was studied at constant concentrations of 2500 ppm of charcoal and 550 ppm of HTAC at pH 4.0. The floatability increased from zero at zero ppm of PAA to 100% at 4.5 ppm of PAA, beyond which it remained constant. Therefore, we fixed the concentration of PAA at 6 ppm and examined the relation between the concentration of HTAC and the floatability of charcoal at pH 6. The solid line of Fig. 1 shows the result. It can be confirmed

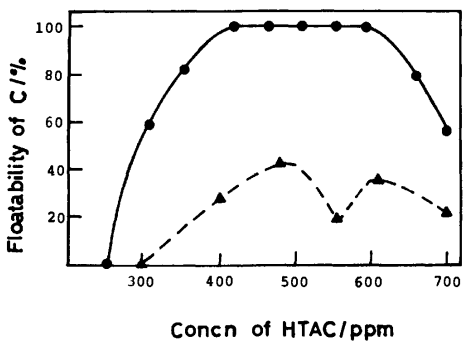

Fig. 1. Floatability of C *vs.* concn of HTAC.
pH: 6.0, solid line: C; 2500 ppm, PAA; 6 ppm, broken line: C; 2500 ppm, PAA; 0 ppm.

that a flat maximum of a nearly 100% floatability could be obtained in the concentration region from 400 to 600 ppm HTAC. In the same figure, the charcoal–HTAC system without the addition of PAA is shown by a broken line. The effectiveness of the addition of PAA is evident for charcoal flotation.

We further measured the floatability of charcoal *vs.* the pH relation at constant concentrations of 2500 ppm of charcoal, 6 ppm of PAA, and 550 ppm of HTAC, as shown in Fig. 2. A broad maximum of a nearly 100% floatability of charcoal was obtained in the pH region from 4 to 13. The system without PAA is shown by a broken line in Fig. 2. We can see a similar floating effect of the addition of PAA.

Floatability of Fe^{3+}, Cu^{2+}, and Ni^{2+} vs. Composition of PAA and HTAC. Macromolecular ion flotations of Fe^{3+}, Cu^{2+}, and Ni^{2+} were carried out with the addition of 2500 ppm of charcoal, 6 ppm of PAA, and varying compositions and total amounts of charcoal and HTAC. Figure 3 shows the floatabilities of the Fe^{3+}, Cu^{2+}, and Ni^{2+} ions as a function of the total weight concentration of C†+HTAC and the weight fraction of C/(C+HTAC) at pH 10.8, 10.0, and 11.1 respectively. The concentration of Fe^{3+}, Cu^{2+}, and Ni^{2+} were kept constant at 1.65×10^{-4}, 1.83×10^{-4}, and 1.69×10^{-4} mol dm^{-3} respectively. The areas inside the curves indicate the optimum composition regions of floatability larger than 95%. The upper parts of these optimum regions form a vertical shape, while the lower parts bend towards 100% HTAC.

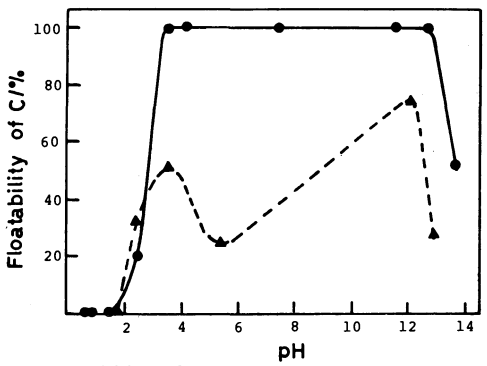

Fig. 2. Floatability of C *vs.* pH.
Solid line: C; 2500 ppm, PAA; 6 ppm, HTAC; 550 ppm, broken line: C; 2500 ppm, PAA; 0 ppm, HTAC; 550 ppm.

Floatabilities of Fe^{3+}, Cu^{2+}, and Ni^{2+} vs. pH. The relations between floatabilities of Fe^{3+}, Cu^{2+}, and Ni^{2+} ions and pH were also measured; they are shown in Fig. 4. The experimental conditions are listed as a caption in the figure. In this figure, both the system with and that without the addition of charcoal are shown. In Fig. 4(a), showing the flotation of Fe^{3+} ions, the floatability sharply rose from zero to nearly 100% at pH 4, beyond which it remained constant up to pH 11. The effect of the addition of charcoal is evident from a comparison of this curve with the curve of the broken line without the addition of charcoal. In Fig. 4(b), showing the flotation of Cu^{2+}, the floatability gradually rose from zero at a pH of about 3 and attained nearly 100% beyond pH 9.4. The effect of the addition of charcoal is evident from a comparison of the curves of the solid and broken lines. In Fig. 4(c), showing the flotation of Ni^{2+}, the floatability rose gradually from zero at pH 3 and attained nearly 100% beyond a pH of about 11. The effect of the addition of charcoal can still be observed from a comparison of the solid and broken lines.

The values of the pH's at which $Fe(OH)_3$, $Cu(OH)_2$, and $Ni(OH)_2$ begin to form are calculated from each solubility product to be 2.2, 6.2, and 7.0 respectively. Considering these values, it is likely that Fe^{3+} ions are adsorbed as hydroxide on charcoal and that they are subsequently floated, while in the case of Cu^{2+} and Ni^{2+}, each ion is adsorbed on charcoal and floated in the low-pH region. In the high-pH region, however, the latter two hydroxides are considered to be adsorbed on charcoal and floated. The pH's beyond which the floatability remains at its maximum value for these ions

are found to be:

$$Fe^{3+} < Cu^{2+} < Ni^{2+},$$

which is in the same order as that of the solubility product. A sharp rise in the floatabilities of these ions in the system without the addition of charcoal observed at a high pH may be explained by the sufficiently large hydroxide particle formed at a high pH being entangled in the foam.

(Received April 27, 1982)

The absolute rate constants of the addition of H and D atoms to propylene-d_0 and -d_6 have been measured by means of the pulse radiolysis-resonance absorption technique over the temperature range of 200—500 K. The rate constants obtained were well expressed by these Arrhenius equations: $k(H+C_3H_6)=(3.00\pm0.38)\exp[-(1612\pm66)/RT]$, $k(H+C_3D_6)=(2.55\pm0.57)\exp[-(1509\pm128)/RT]$, $k(D+C_3H_6)=(1.99\pm0.05)\exp[-(1550\pm15)/RT]$, and $k(D+C_3D_6)=(2.20\pm0.27)\exp[-(1587\pm67)/RT]$ in units of 10^{-11} cm^3 molecule^{-1} s^{-1}. The unit of activation energy is cal mol^{-1}. Practically no isotope effects attributable to the difference between C_3H_6 and C_3D_6 could be observed. This is similar to the kinetic isotope effects previously observed in the rate constants of the addition of H and D atoms to isotopic ethylenes. The theoretical rate constants of the above reactions have been calculated by the conventional activated complex theory using the potential energy surface drawn by the *ab initio* method; however, no agreement with regard to the isotope effects could be obtained between experiment and theory because of the difference between C_3H_6 and C_3D_6. This also is similar to the isotope effects found in the $H+C_2H_4\rightarrow C_2H_5$ reaction.

In previous papers,[1,2] we reported the absolute rate constants of the addition of H and D atoms to C_2H_4, C_2H_3D, C_2D_4, C_2H_2, and C_2D_2 obtained by the pulse radiolysis-resonance absorption technique over the temperature range of 200—500 K, and discussed the kinetic isotope effects on the basis of the activated complex theory, since the potential energy surfaces obtained by the *ab initio* calculations were available for both reactions, $H+C_2H_4\rightarrow C_2H_5$[3] and $H+C_2H_2\rightarrow C_2H_3$.[4] Experimentally, no differences among three isotopic ethylenes, C_2H_4, C_2H_3D, and C_2D_4, as well as between two acetylenes, C_2H_2 and C_2D_2 could be found in the rate constants of the H- and D-atom-addition reactions, while, theoretically, these differences clearly appeared, mainly because of the zero-point energy differences between the reactants and the activated complexes.

It is well known that the present status of the *ab initio* calculations is not reliable enough to discuss the absolute value of the barrier height for a reaction involving polyatomic molecules. Therefore, we parametrized the barrier heights so as to fit the theoretical rate constants for the $H+C_2H_4\rightarrow C_2H_5$ and $H+C_2H_2\rightarrow C_2H_3$ reactions at room temperature to the experiment, and then investigated the isotope effects; however, no agreement could be obtained between experiment and theory.

The present paper is a simple extension of the previous one. Experimentally, however, more accurate measurements of the reactant pressure and the temperature were required because the rate constant of the $H+C_3H_6\rightarrow C_3H_7$ reaction was larger than that of $H+C_2H_4\rightarrow C_2H_5$. In the theoretical calculation, about twice as much time was consumed.

Experimental and Calculational Procedures

The experimental procedure was the same as that described previously.[2] Hydrogen or deuterium gas (≈500 Torr; 1 Torr≈133.322 Pa) containing a small amount of propylene (0.01—0.1 Torr) was pulse-irradiated with high-energy electrons from Febetron 706 (Hewlett Packard Co.), and the decay of the concentration of H or D atoms was observed by the use of Lyman-α's. From this first-order decay curve, the rate constant was estimated.

The propylene used was purchased from the Takachiho Shoji Co. The propylene-d_6 was the product of Merck, Sharp, and Dohme, Canada, Ltd., the nominal purity being 99%; this purity was confirmed gaschromatographically.

The *ab initio* calculation method used is the same as that used for drawing the potential energy surface for the $H+C_2H_4\rightarrow C_2H_5$ reaction.[3] The details of the calculated results will be published elsewhere; in the present paper, only the data necessary for the estimation of the rate constants are presented.

Results

Table 1 summarizes the rate constants obtained. Four to five different pressures of propylenes were used to measure the rate constants at each temperature. The fluctuation of the temperature (±2 °C) in each measurement was corrected in the same manner as that previously described in detail.[2] In Fig. 1, all the rate constants obtained are plotted in the form of Arrhenius plots. The Arrhenius parameters thus determined are summarized

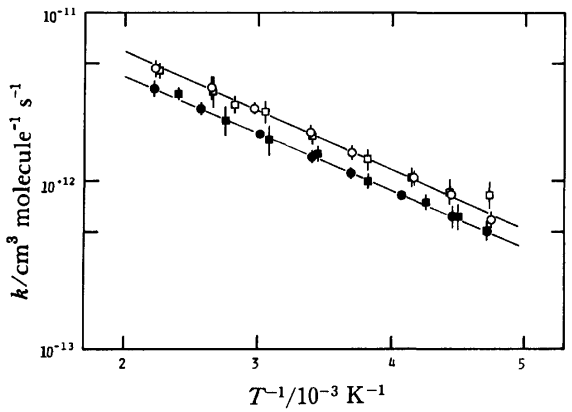

Fig. 1. The Arrhenius plots for the reactions: (○), $H+C_3H_6$; (□), $H+C_3D_6$; (●), $D+C_3H_6$; (■), $D+C_3D_6$.

	212	5.18±0.75

Table 2. Arrhenius parameters obtained A/10^{-11} cm^3 molecule^{-1} s^{-1} and E/cal mol^{-1}; uncertainties are 2σ.

	H-atom addition		D-atom addition	
	A	E	A	E
C_3H_6	3.00±0.38	1612± 66	1.99±0.05	1550±15
C_3D_6	2.55±0.57	1509±128	2.20±0.27	1587±67

in Table 2. The uncertainties are 2σ. The method of calculating these uncertainties has been described previously.[2] It is noticeable that no kinetic isotope effects due to the difference between C_3H_6 and C_3D_6 could be observed.

Figure 2 shows the structures of propylene and the activated complex calculated by the *ab initio* unrestricted Hartree-Fock method with the 4-31 split-basis set. These geometries were fully optimized with the energy-gradient method. The force-constant matrices for propylene and the activated complex were then constructed by the numerical differentiation of the energy gradients.

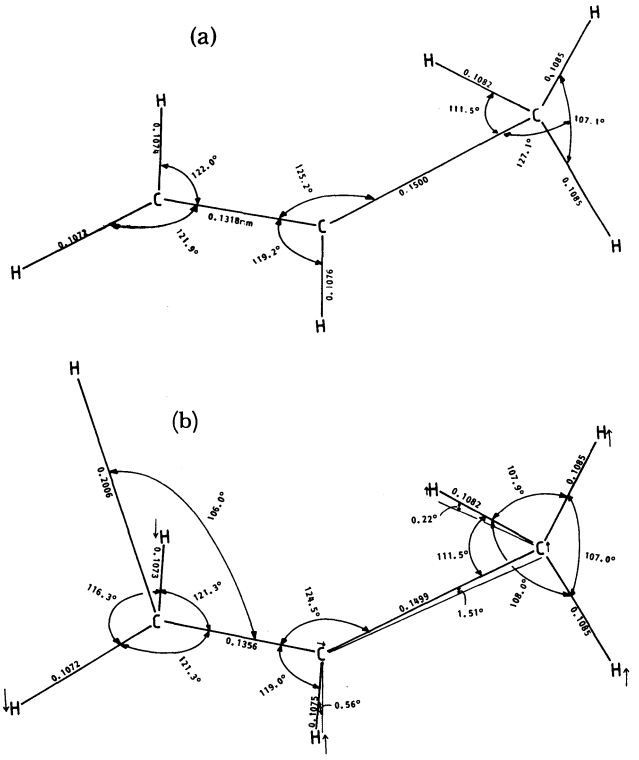

Fig. 2. The Geometries of C_3H_6 (a) and the activated complex for the reaction, $H+C_3H_6$, (b). Arrows indicate the direction of the displacement of the equilibrium position from the reactant.

Table 3 summarizes the resultant normal-mode frequencies, moments of inertia, and zero-point energies. Although the calculated normal-mode frequencies for propylene did not agree exactly with those experimentally obtained,[5] we did not ascertain the correction factor since the discrepancy between experiment and calculation was not systematic and prevented us for estimating a simple correction factor.

The barrier height calculated for the $H+CH_3CH=-CH_2 \rightarrow CH_3CH-CH_3$ reaction was 2.41 kcal/mol (1 kcal=4.184 kJ), a value which was obviously too high compared with the experimentally obtained activation energies. Therefore, we had to parametrize this value in the calculations of the rate constants, as will be shown later. It is well known that hydrogen atoms mainly add to the double bond of propylene at the terminal carbon atom.[6] The *ab initio* calculation is consistent with this observation: the barrier height for $H+CH_3CH=CH_2 \rightarrow CH_3CH_2CH_2$ addition reaction was calculated to be 4.24 kcal/mol.

Discussion

Propylene is known to be more reactive than ethylene to hydrogen atoms at room temperature.[7] The present experiments clearly showed that this difference comes from the activation energies. The Arrhenius equation for the $H+C_2H_4 \rightarrow C_2H_5$ reaction previously obtained is $k_{exp}=(4.70\pm0.49)\times10^{-11}\exp[-(2178\pm58)/RT]$ cm^3 molecule^{-1} s^{-1}.[2] Since the pre-exponential factor for the reaction of propylene is about 2/3 of that for the

reaction of ethylene, if the Arrhenius equations can be extrapolated to higher temperatures, the rate constants of these two reactions will coincide with each other at around 360 °C.

According to the conventional activated complex theory, the rate constant of the $H+C_3H_6 \rightarrow C_3H_7$ reaction is expressed as follows:

$$\kappa = \kappa L^\dagger \frac{kT}{h} \frac{F^\dagger}{F_H F_P} \frac{f_{rot}^\dagger}{f_{rot}} \frac{f_{vib}^\dagger}{f_{vib}} \exp(-V/RT). \quad (1)$$

Here, κ is the transmission coefficient, which may be calculated by Wigner's approximation:

$$\kappa = 1 + (1/24)(h|\nu_i|/kT)^2. \quad (2)$$

The values of ν_i are listed in Table 3. $L^\dagger$ is the path degeneracy. F_H, F_P, and $F^\dagger$ are the translational partition functions for hydrogen atoms, propylene molecules, and an activated complex respectively. f_{rot} and $f_{rot}^\dagger$ are the rotational partition functions without a symmetry number. f_{vib} and $f_{vib}^\dagger$ are the vibrational partition functions including the contribution of zero-point energies. V is the barrier height.

Since the calculated barrier height was too high, we adjusted this value so as to fit the theoretical rate constant of the $H+C_3H_6 \rightarrow C_3H_7$ reaction at room temperature to the experimental result. The adjusted barrier height was 1.63 kcal/mol. This value is common to three other reactions also; $D+C_3H_6$, $H+C_3D_6$, and $D+C_3D_6$.

Figure 3 compares the rate constants thus calculated

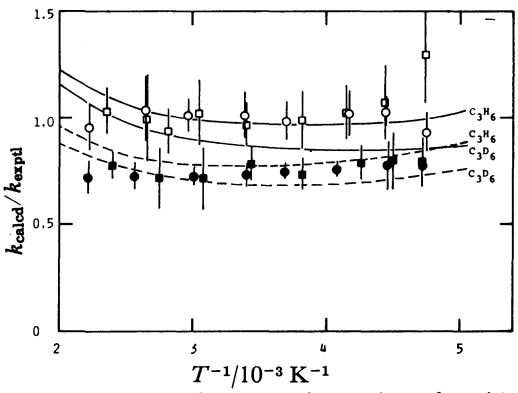

Fig. 3. Comparison of the experimental results with the theoretical calculations. For symbols, see the caption of Fig. 1. The experimentally obtained rate constant for the reaction, $H+C_3H_6$, $k_{exptl}=3.00\times10^{-11}$ exp $(-1612/RT)$ cm^3 molecule^{-1} s^{-1}, is taken as the standard. Solid lines are for the H-atom reactions and dashed lines for the D-atom reactions.

with those obtained in the present experiments. Here, the experimentally obtained Arrhenius equation for the $H+C_3H_6 \rightarrow C_3H_7$ reaction, $k_{exptl}=3.00\times10^{-11}$ exp $(-1612/RT)$ cm^3 molecule^{-1} s^{-1}, is taken as the standard. Obviously the agreement between experiment and theory is poor for the isotope effects because of the difference between C_3H_6 and C_3D_6, while the isotope

effects due to the difference between H and D atoms are well explained. This is exactly the same as was found previously in the reactions of H and D atoms with isotopic ethylenes.[1,2]

At present, we have no proper interpretations for this disagreement. One possible reason might be fundamental assumption on which the activated complex theory is based. In the formulation of the activated complex theory, the equilibrium between a reactant and the activated complex is postulated; however, in such exothermic fast reactions as $H+C_3H_6 \rightarrow C_3H_7$, some normal modes of vibration in the activated complex might not be able to reach the equilibrium before the reaction system crosses over the saddle point. Consequently, some normal modes of vibration in the reactant remain as they are and cannot contribute to the change of the state density, *i.e.*, to the rate constant. It is well known that the kinetic isotope effect results from the difference in zero-point energy between reactant and activated complex. The critical energy defined by the following equation is a crucial factor in determining the isotope effects:

$$E_0 = V + \Delta E_{\text{vib}},$$

$$\Delta E_{\text{vib}} = \frac{1}{2}\sum h\nu^{\dagger} - \frac{1}{2}\sum h\nu.$$

Here, $\nu^{\dagger}$ and ν are the normal-mode frequencies in the activated complex and the reactant. If ΔE_{vib} is reduced by the reasoning above stated, the isotope effects in the rate constants will also be reduced. A rigorous formulation of this will be the subject of our further investigations.

Cyclic Orbital Interaction and Orbital Phase in Acyclic Conjugation

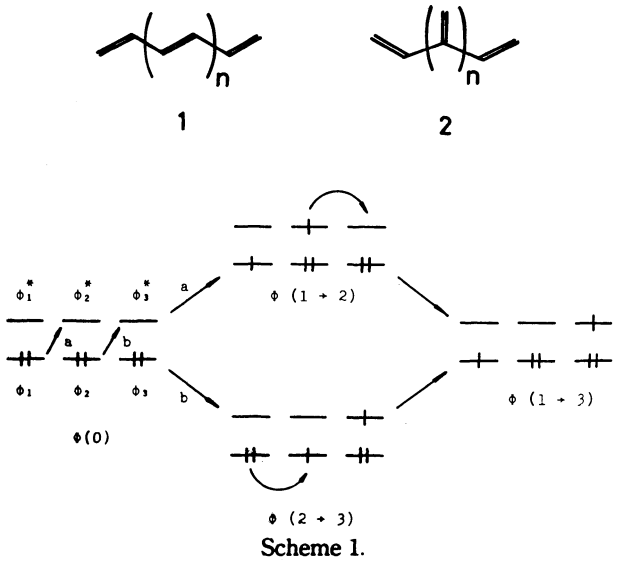
Satoshi INAGAKI,* Hirofumi KAWATA, and Yoshio HIRABAYASHI
Department of Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received May 7, 1982)

The orbital phase continuity-discontinuity property is shown to control electron delocalization and polarization even in open chain conjugated molecules. Its chemical consequences are discussed.

The π electron delocalization has been one of the central subjects in organic chemistry. There are well-established rules for monocyclic conjugation. The $4n+2$ π electron aromaticity rule[1] is related to the static state of the ground-state molecules at their equilibrium geometries. The stereoselection rule[2-4] is the counterpart for the dynamic process or for the transition state of chemical reactions. Both rules were founded on the identical basis, *i.e.*, the continuity-discontinuity of orbital phase of many composite systems.[5-8] The phase control has been believed to be characteristic of nothing but *cyclic* conjugated molecules. In this paper the orbital phase will be shown to be more fundamental, and to play a significant role in determining electron delocalization even in *acyclic* conjugated molecules.

Theoretical

Delocalization. We are concerned with two types of acyclic conjugation of ethylenic π bonds. In the head-to-tail polyenes (**1**), a π bond interacts at one end (head) with a second bond and at the other end (tail) with a third bond. In the head-to-head polyenes (**2**), a π bond interacts at an end (head) with two neighboring bonds. There is no primary difference between **1** and **2** in the electron delocalization between the adjacent units, which is considered as that in butadiene. The indirect delocalization between two bonds mediated by another should make a characteristic distinction between **1** and **2**. There are two paths for the end-to-end electron delocalization in the triene unit, as is illustrated in Scheme 1.[9]



Scheme 1.

An electron in the bonding orbital, ϕ_1, of a terminal bond transfers to the antibonding orbital, ϕ_2^*, of the middle and then to ϕ_3^* of the other terminus (path a). By the other path an electron hole in ϕ_2 resulting from the electron shift from ϕ_2 to ϕ_3^* is supplied with an electron by ϕ_1 (path b). The coefficients, $C_a(1\rightarrow3)$ and $C_b(1\rightarrow3)$, of the $1\rightarrow3$ transferred configuration, $\Phi(1\rightarrow3)$, contributed through the paths, a and b, are given by the perturbation theory, respectively:

$$C_a(1\rightarrow3) = \frac{\langle\Phi(0)|H'|\Phi(1\rightarrow2)\rangle\langle\Phi(1\rightarrow2)|H'|\Phi(1\rightarrow3)\rangle}{[E(1\rightarrow2) - E(0)][E(1\rightarrow3) - E(0)]}$$

$$C_b(1\rightarrow3) = \frac{\langle\Phi(0)|H'|\Phi(2\rightarrow3)\rangle\langle\Phi(2\rightarrow3)|H'|\Phi(1\rightarrow3)\rangle}{[E(2\rightarrow3) - E(0)][E(1\rightarrow3) - E(0)]}.$$

When the Hückel approximation is employed, we obtain the following equations:

$$C_a(1\rightarrow3) = C_b(1\rightarrow3), \textit{ i.e., } C(1\rightarrow3) = 2C_a(1\rightarrow3)$$

for the head-to-tail triene, and

$$C_a(1\rightarrow3) = -C_b(1\rightarrow3), \textit{ i.e., } C(1\rightarrow3) = 0$$

for the head-to-head triene. The $1\rightarrow3$ delocalization is amplified in the head-to-tail polyenes while cancelled out in the head-to-head polyenes.

The clear-cut difference in the indirect delocalization between the head-to-head and head-to-tail polyenes is ascribed to the cyclic orbital interaction in the acyclic conjugation. The configuration interactions between $\Phi(0)$ and $\Phi(1\rightarrow2)$ and between $\Phi(1\rightarrow2)$ and $\Phi(1\rightarrow3)$ in C_a contain the orbital interactions between ϕ_1 and ϕ_2^* and between ϕ_2^* and ϕ_3^*, respectively. The ϕ_1-ϕ_2^*-ϕ_3^* orbital interaction is involved in the delocalization *via* path a. The corresponding configuration interactions between $\Phi(0)$ and $\Phi(2\rightarrow3)$ and between $\Phi(2\rightarrow3)$ and $\Phi(1\rightarrow3)$ in C_b contain the orbital interactions between ϕ_2 and ϕ_3^* and between ϕ_1 and ϕ_2, respectively. The ϕ_1-ϕ_2-ϕ_3^* orbital interaction is involved in the delocalization *via* path b. These orbital interactions share the ϕ_1 and ϕ_3^* orbitals at either end to form a cyclic orbital interaction like $\overline{\phi_1\text{-}\phi_2\text{-}\phi_3\text{-}\phi_2^*}$. As a result, the extent of the indirect delocalization, *i.e.*, the magnitude of the coefficient of the $1\rightarrow3$ electron transferred configuration is dependent on the orbital phase property.

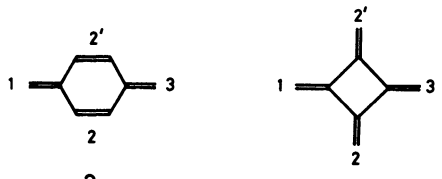
For further understanding of the cyclic property of the orbital interactions involved in the acyclic conjugation, it is preferable to suppose "hypothetical" cyclic systems, **3** and **4**, which have a bonding orbital, ϕ_2, only on the bond 2 and antibonding orbital, ϕ_2^*, only on the bond 2′. There are analogous pathways for the $1\rightarrow3$ delocalization. An electron in ϕ_1 transfers to ϕ_2^* of the bond 2′ and then to ϕ_3^* (path c). An electron hole resulting from the electron shift from ϕ_2 of the bond 2 to ϕ_3^* is supplied with an electron by ϕ_1

(path d). The formula for the coefficients of the indirectly transferred configurations contributed from the paths, c and d,

$$C_c(1 \rightarrow 3) = \frac{\langle \Phi(0)|H'|\Phi(1 \rightarrow 2')\rangle\langle \Phi(1 \rightarrow 2')|H'|\Phi(1 \rightarrow 3)\rangle}{[E(1 \rightarrow 2') - E(0)][E(1 \rightarrow 3) - E(0)]}$$

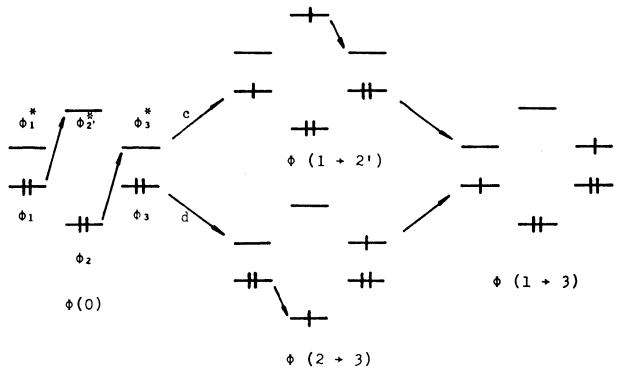
$$C_d(1 \rightarrow 3) = \frac{\langle \Phi(0)|H'|\Phi(2 \rightarrow 3)\rangle\langle \Phi(2 \rightarrow 3)|H'|\Phi(1 \rightarrow 3)\rangle}{[E(2 \rightarrow 3) - E(0)][E(1 \rightarrow 3) - E(0)]}$$

are equivalent to C_a and C_b, respectively. In this sense, the acyclic systems, **1** and **2**, have the same features as the cyclic systems, **3** and **4**, with respect to the 1→3 delocalization.



3

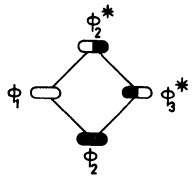
4



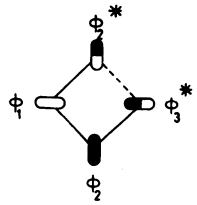
Scheme 2.

The 1→3 delocalization in **3** and **4** is a mode of cyclic delocalization, where the bonds, 1 and 2, are donors, the bonds, 2′ and 3, being acceptors. The donors are on one side of the conjugation chain while the acceptors are on the other side. The D-A alternation occurs only twice along the conjugation. Such conjugation is classified into the continuous conjugation.[6] The delocalization is then subject to the orbital phase continuity-discontinuity property. The orbital phase requirements for many-system interaction are as follows:[5,6] (1) The electron-donating orbitals out of phase, (2) the electron-accepting orbitals in phase, and (3) the donating and accepting orbitals in phase. The requirements are satisfied in **3** (see **5**), but not in **4** (see **6**).[10] The cyclic delocalization is allowed in **3**, but forbidden in **4**. The mathematical equivalence of the 1→3 delocalization in **1** and **2** to the modes of cyclic delocalization in **3** and **4** means that the open-chain conjugated systems share a characteristic with the corresponding cyclic conjugated systems. *Even acyclic conjugation contains cyclic orbital interaction. The delocalizability in acyclic conjugation is also under the influence of the orbital phase property.*

Polarization. Only one-electron transferred configurations were taken into consideration in the preceding



5



6

section. In general, locally-excited configurations contribute to the electronic structures of interacting systems. Let us study two interacting ethylenic double bonds in butadiene. There are two pathways for electron promotion in a double bond, as is illustrated in Scheme 3.[11] An electron in ϕ_1 transfers to ϕ_2^* ande thn back to ϕ_1^* (path e). Otherwise, an electron hole in ϕ_2 resulting from electron shift to ϕ_1^* is supplied with an electron by ϕ_1 (path f). The coefficients of the locally-excited 1→1 configuration, obtained in the same way,

$$C_e(1 \rightarrow 1) = \frac{\langle \Phi(0)|H'|\Phi(1 \rightarrow 2)\rangle\langle \Phi(1 \rightarrow 2)|H'|\Phi(1 \rightarrow 1)\rangle}{[E(1 \rightarrow 2) - E(0)][E(1 \rightarrow 1) - E(0)]}$$

$$C_f(1 \rightarrow 1) = \frac{\langle \Phi(0)|H'|\Phi(2 \rightarrow 1)\rangle\langle \Phi(2 \rightarrow 1)|H'|\Phi(1 \rightarrow 1)\rangle}{[E(2 \rightarrow 1) - E(0)][E(1 \rightarrow 1) - E(0)]}$$

have an identical magnitude and the opposite signs:

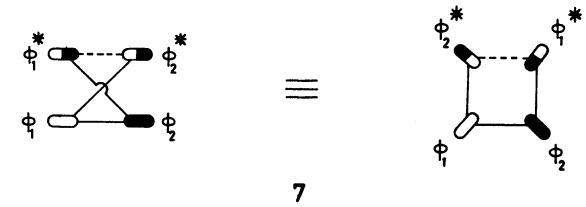
$$C_e(1 \rightarrow 1) = -C_f(1 \rightarrow 1).$$

Then

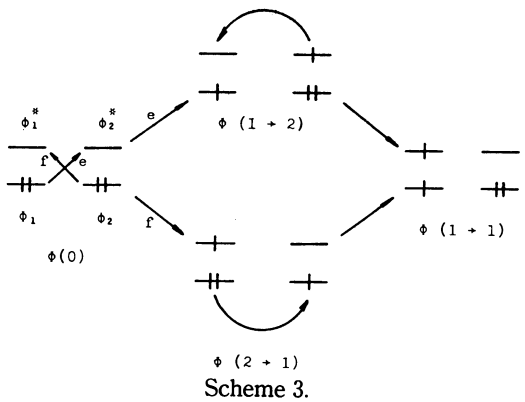
$$C(1 \rightarrow 1) = 0.$$

The polarization is depressed completely. The result is understood in terms of the cyclic orbital interaction (**7**). The polarization is also controlled by the continuity-discontinuity of orbital phase. The forbidden polarization justifies the neglect of the locally-excited configurations in the preceding arguments about the delocalization in polyenes.

Polarization Effects on Delocalization. The absence of the local excitation in polyenes comes from the

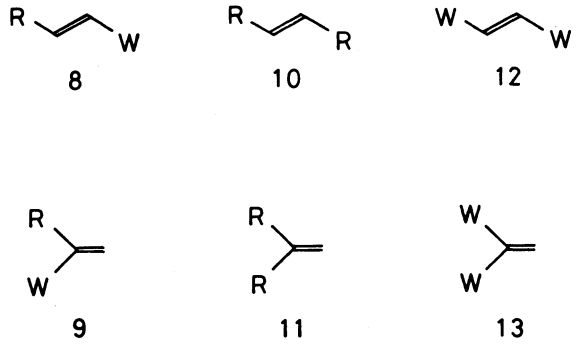


7



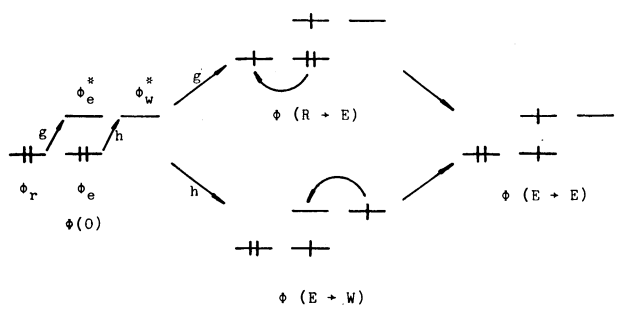
Scheme 3.

peculiar feature of the interaction between the equivalent systems at the equivalent sites like Y–X···X–Y (see C_e and C_f). An ethylenic π bond is usually polarized by the interactions with substituents or attacking reagents. Here, the effects of polarization on delocalization will be examined in terms of orbital phase, using the simple models, *i.e.*, disubstituted ethylenes, **8**—**13**. Electron-releasing (R) and withdrawing (W) substituents are represented by the doubly occupied bonding orbital of ethylene (E) and the vacant anti-bonding orbital, respectively. This model allows the substituted double bond to polarize by eliminating one of the pathways involving the opposite phase mixing of locally-excited configurations.

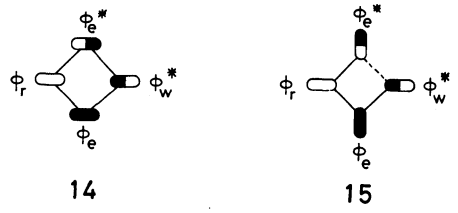


Electron delocalization primarily occurs from R to E and from E to W in R,W-substituted ethylenes, **8** and **9**. The present question is reduced to whether the mixing of the locally-excited configuration, $\Phi(E\rightarrow E)$, can enhance the delocalization or not. There are two pathways for electron promotion in E (Scheme 4). The electron hole in ϕ_r resulting from electron shift $\phi_r\rightarrow\phi_e^*$ is supplied with an electron by ϕ_e (path g). The electron is transferred from ϕ_e to ϕ_w^* and then back to ϕ_e^* (path h). The corresponding cyclic orbital interactions are **14** for **8** and **15** for **9**. The polarization is allowed in the *vic*-R,W-disubstituted ethylene **8** but not in the geminal isomer **9**. The allowed polarization enhances the delocalization due to the interactions of the locally-excited configuration $\Phi(E\rightarrow E)$ with the transferred configurations, $\Phi(R\rightarrow E)$ and $\Phi(E\rightarrow W)$.

The R→W delocalization in the vicinal isomer corresponds to the 1→3 delocalization in the head-to-tail triene. The cyclic orbital interaction is favored by the orbital phase (**5**). The delocalization is then promoted by the distant delocalization as well. On the other hand, the R→W delocalization in the geminal isomer



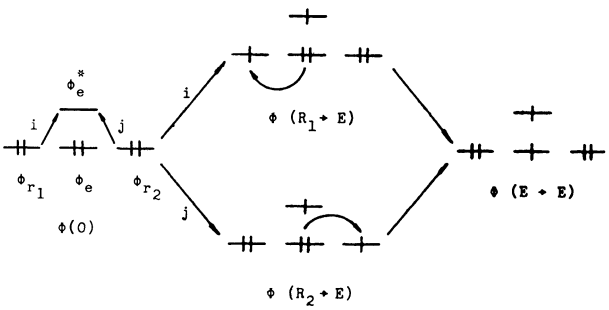
Scheme 4.



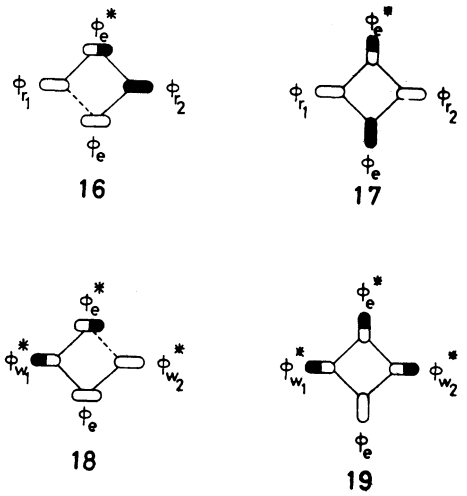
corresponds to the forbidden 1→3 delocalization in the head-to-head triene (**6**). The delocalization is never enhanced by the R→W delocalization. It is noteworthy that the cyclic orbital interactions, **14** and **15**, for the polarization of the double bond are common to those (**5** and **6**) for the distant R→W delocalization in the R,W-ethylenes. The cyclic orbital interactions have the dual meaning in this sense.

The mechanism of polarization in the R,R-disubstituted ethylenes, **10** and **11**, is illustrated in Scheme 5. An electron in ϕ_{r_1} (ϕ_{r_2}) is transferred to ϕ_2^* by the path i (path j). The resulting electron hole in ϕ_{r_1} (ϕ_{r_2}) is supplied with an electron by ϕ_e. The cyclic orbital interaction meets the phase continuity requirements in the *gem*-R,R-ethylene **11** (see **17**) while not in the vicinal isomer **10** (see **16**). A similar argument is applicable to the polarization in the W,W-ethylenes, **12** and **13**. The cyclic orbital interactions are shown in **18** for **12** and in **19** for **13**.

The geminal substituents of the same donor-acceptor property and the vicinal ones of the opposite donor-acceptor property enhance electron delocalization through the polarization. The latter substitution pattern



Scheme 5.



also promotes the delocalization by the distant R→W delocalization. The other models do not meet the orbital phase continuity requirements. As a result the delocalizability is predicted to increase in the order of *vic*-R,R (**10**), *vic*-W,W (**12**), *gem*-R,W (**9**)<*gem*-R,R (**11**), *gem*-W,W (**13**)<*vic*-R,W (**8**).

Calculation

We carried out calculation by a linear combination of electron configurations at the Hückel level (HMO–LCEC)[12] to examine the preceding theoretical conclusions in a numerical manner. The zero-configuration, $\Phi(0)$, the one-electron locally-excited configuration, $\Phi(n\rightarrow n)$, and the one-electron transferred configuration, $\Phi(n_1\rightarrow n_2)$, are involved in the calculation. Figure 1 shows the range of the coefficient ratios, $|C(n_1\rightarrow n_2)/C(0)|$, (see Appendix) of triene through nonaene as the function of the distance ($\Delta n=|n_1-n_2|$) between the double bonds where an electron transfers. The magnitude of the coefficient ratio reasonably decreases with the distance. There is no significant difference in the adjacent delocalization ($\Delta n=1$) between the head-to-head and head-to-tail polyenes. Most outstanding is the coefficient ratio of the distantly transferred configurations in the head-to-head polyenes; $|C(\Delta n)/C(0)|=0$ for $\Delta n\geqq 2$.[13] This is also the case with the locally-excited configurations in both types of polyenes; $C(n\rightarrow n)/C(0)=0$. These results confirm the theoretical prediction. The delocalization is "localized" between the neighboring double bonds in the head-to-head polyenes whereas farther delocalization can take place in the head-to-tail polyenes.

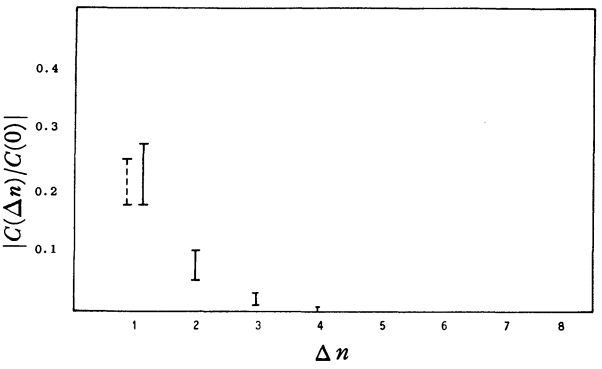


Fig. 1. The coefficient ratio ($C(\Delta n)/C(0)$) of the $n_1\rightarrow n_2$ transferred configurations to the zero-configuration for **1** (I) and **2** (I), where $\Delta n=n_1-n_2$.

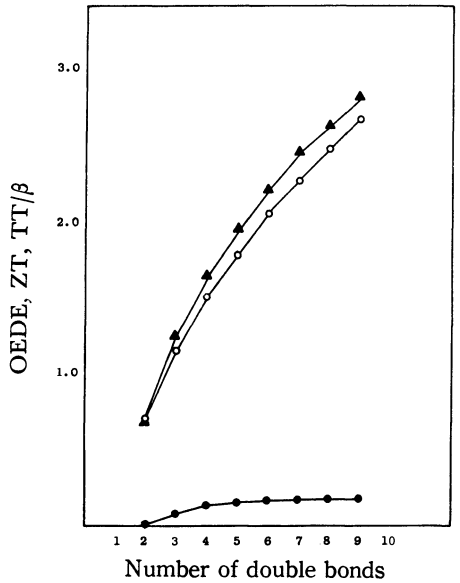

Fig. 2. The one-electron delocalization energies of **1** (▲) and **2** (○), the ZT energies of **1** (○) and **2** (○), and the TT energies of **1** (●) and **2** (zero).

We also calculated one-electron delocalization energy (OEDE),[14] which was recently proposed[8] to be a measure of electron delocalization. The head-to-tail polyenes have greater OEDE than the corresponding head-to-head polyenes (Fig. 2),[15] as is expected. The OEDE is composed of the ZT and TT energies.[8] The ZT energy is due to the interaction between $\Phi(0)$ and $\Phi(n_1\rightarrow n_2)$ or the donor-acceptor interaction between of neighboring bonds. The TT energy is due to the interactions between $\Phi(n_1\rightarrow n_2)$'s, and can be used as a measure of the distant delocalization. The ZT energies of both types of polyenes are found to be identical and equal to be the OEDE of the head-to-head polyenes. The TT energy is appreciable for the head-to-tail polyenes and zero for the head-to-head polyenes. As a result, the difference in OEDE or in electron delocalizability is attributed to the difference in the TT energy or in the distant delocalization. These numerical results argue for the prediction that the 1→3 delocalization is forbidden in the head-to-head polyenes while not in the head-to-tail polyenes.

The OEDE was calculated for the model compounds, **8**—**13**. The results are consistent with the prediction. The OEDE of the least delocalizing group including **9**, **10**, and **12** is 0.707β. The intermediately delocalizing **11** and **13** have 0.801β OEDE. The most delocalizing **8** has 0.905β. The OEDE increment from the first to the second group results from the contribution of polarization. Without polarization, the OEDE of both groups is identical (0.707β). The difference between the latter two groups is attributed to the allowed R→W electron delocalization in **8**. Without the transferred configuration, the OEDE is reduced to that of the second group (0.801β).

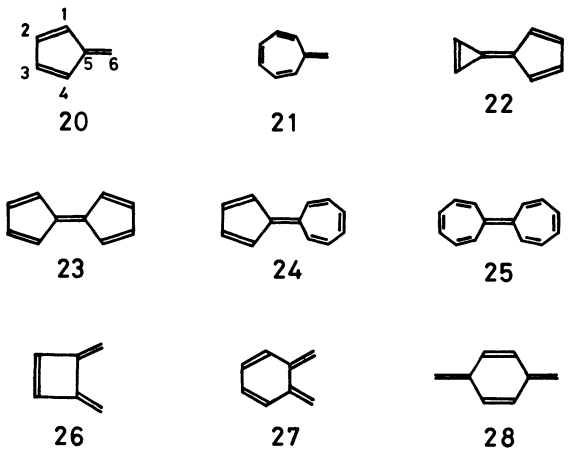
Discussion

The chemistry of the head-to-head polyenes has been advanced much less than that of the head-to-tail polyenes, presumably due to their instability inferred from the present theory. There are many works on the head-to-tail polyenes. A high polymer of the head-to-tail polyenes, *i.e.*, "polyacetylene," was synthesized more than two decade ago,[16] still attracting attention of chemists because of electrical conductivity of the doped material.[17] Polyacetylene was reported to contain 200—300 ethylenic double bonds.[18] In contrast, there are only a few reports[19] about the head-to-head polyenes limited to their low homologs or up to tetraenes. The present situation is similar for polycarbonyl com-

pounds, an analogous series of the head-to-head polyenes. Only a small number of reports on triones and tetraones are available.[20] No higher homologs were found in the literature.

Independent theoretical calculations make up for the insufficiency of the experimental results. Hess and Schaad[21] obtained the π-single-bond energy, E^{π}_{c-c}, of **1** and **2** from the Hückel molecular orbital calculation on the Dewar's assumption[22] that the bond energy is additive: $E^{\pi}_{c-c}=0.628\beta$ for **1** and 0.396β for **2**. The π-single-bond energy corresponds primarily to the electron delocalization between the double bonds. The conspicuous difference is consistent with our prediction. Del Re[23] calculated the interaction energies between the component systems in some π conjugated molecules. The interaction energy was found to be greater for the head-to-tail coupling than for the head-to-head coupling. Aihara[24] obtained the HMO energy of the unit structure, C=C–C, in cyclic head-to-tail (annulene) and head-to-head (radialene) polyenes, and showed E_u(annulene)$>E_u$(radialene). Kollmar[25] calculated the resonance energies of 1,3,5-hexatriene (**1**; $n=1$) and 3-methylene-1,4-pentadiene (**2**; $n=1$) as the energy difference between the ab initio SCF energy and the energy expectation value with respect to a model wavefunction in which the SCF π orbitals were replaced by appropriate nonresonating localized π MO's (reference state). The "vertical" and "normalized" resonance energies of the head-to-head triene are smaller by 2.3 and 0.3 kcal/mol than those of the head-to-tail triene.

The orbital phase control over the delocalization in acyclic conjugated molecules provides us with an unprecedented insight into a general aspect of cyclic conjugation. Cross-conjugation is an element in the cyclic conjugated hydrocarbons with exocyclic double bonds. The orbital phase discontinuity prohibited electrons from delocalizing from a π bond to another across the exocyclic π bond. The feature clearly distinguishes this class of molecules from cyclic head-to-tail polyenes where the acyclic delocalization is ideally favored by the orbital phase continuity. The orbital phase discontinuity in acyclic delocalization is a key to understanding the extreme instability of cyclic conjugated hydrocarbons with the exocyclic bonds such as fulvene (**20**),[26] heptafulvene (**21**),[26k,27] calicene (**22**),[28]



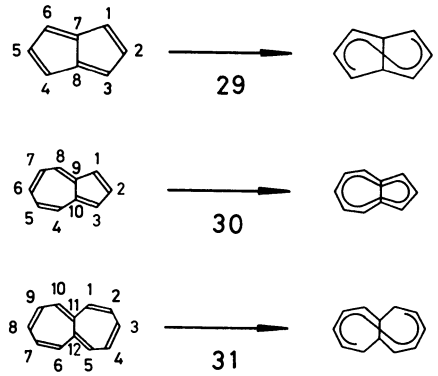
fulvalene (**23**),[29] sesquifulvalene (**24**),[26k,27e,27f,30] heptafulvalene (**25**),[29a,31] 3,4-dimethylenecyclobutene (**26**),[32] 5,6-dimethylene-1,3-cyclohexadiene (**27**),[33] and 3,6-dimethylene-1,4-cyclohexadiene (**28**),[34] irrespective of the number of electrons.

Appreciable stability is gained only when appropriate substituents are attached to the exocyclic bonds. There are usually both cyclically delocalizing and localizing modes of orbital interactions in a π conjugated molecules with exocyclic bonds.[6] The substituents make a delocalizing mode predominate over the localizing modes through the enhanced donor-acceptor power, on one hand. The orbital phase discontinuity for the delocalization across the exocyclic bond is partly due to the identical magnitude of the delocalization through the antibonding orbital of the exocyclic bond (path a) and through the bonding orbital (path b). The substituents prefer a path to the other, and relax the orbital phase discontinuity, on the other hand.

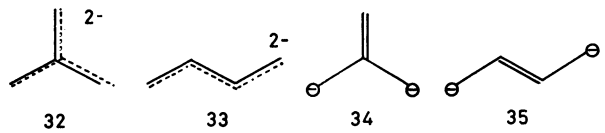
Some theoretical and experimental results argue for the peculiarity of the cross-conjugation in the molecules. Let us see the bond lengths or the bond orders in fulvene. There are two sorts of single bonds, *i.e.*, C_1–C_5 and C_2–C_3 bonds. The C_1–C_5 single bond is an element of the acyclic conjugations, *i.e.*, the head-to-tail C_4=C_3–C_2=C_1–C_5=C_6 and the head-to-head C_2=C_1–C_5(=C_6)–C_4=C_3. On the other hand, the C_2–C_3 bond belongs to the head-to-tail chains, *i.e.*, C_1=C_2–C_3=C_4–C_5=C_6 and C_4=C_3–C_2=C_1–C_5=C_6. Consequently, the delocalization is expected to be low in C_2=C_1···C_5=C_6 relative to that in C_1=C_2···C_3=C_4. In fact, the bond order[35,36] is smaller between C_1 and C_5 of the head-to-head junction than between C_2 and C_3 of the head-to-tail one. Some molecular orbital calculations[22a,37,38] predicted consistent bond lenghts. The bonds of the head-to-head conjugation are longer than those of the head-to-tail conjugation. This is confirmed by the electron diffraction study of the 6,6-dimethyl derivative.[39] A similar argument is applicable to and confirmed by the theoretical calculations and/or the experiments for **21**,[22a,35–37,40] **22**,[41] **23**,[22a,35–37,40b] **24**,[22a,36,37] **25**,[22a,35–37] **26**,[38,39,41,42] and **27**.[35,41]

The tendency to avoid the cross-conjugation is also recognized in pentalene (**29**),[43] azulene (**30**),[44] heptalene (**31**).[45] There are two possible ways to reduce the cross-conjugation effects by adjusting the bond distances; *i.e.*, by stretching the fused bond (C_7–C_8 in **29**, C_9–C_{10} in **30**, C_{11}–C_{12} in **31**) and the peripheral bonds (C_1–C_7, C_4–C_8 in **29**, C_1–C_9, C_4–C_{10} in **30**, C_1–C_{11}, C_6–C_{12} in **31**). The fused bond elongation provides the molecules with a quality of the peripheral monocyclic head-to-tail conjugation. With the lengthened peripheral bonds, the molecules acquire a property of acyclic head-to-tail polyenes. Azulene prefers monocyclic conjugation because of 10 π electrons. According to the experimental data,[46] the peripheral bond alternation is small. The deviation of the bond distances fall in the range of 0.03 Å. The fused bond is much longer by 0.07 Å than the longest peripheral bond. The similar theoretical results[37,40b] are available. On the other hand, pentalene and heptalene should choose acyclic conjugation because of 4n π electrons on the

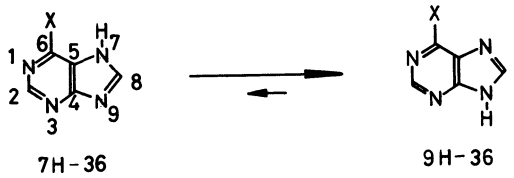
periphery. Some calculations[37,40b,47] suggest that the peripheral cross-conjugated bond in pentalene is the weakest, the fused bond being stronger, while the single bonds between the endocyclic double bonds are much stronger than both. The shortening of the fused bond is interpreted as the geometrical deformation to gain the stabilization due to acyclic head-to-tail conjugation.



Acyclic Aromaticity. The degree of electron delocalization in trimethylenemethane (**32**) and butadiene (**33**) dianions was shown in a preliminary communication[48] to be determined by the orbital phase properties. Trimethylenemethane dianion is considered to be a π-conjugated molecule where two anion centers interact with an end of the double bond (see **34**). Butadiene dianion has the identical subsystems which, however, lie in the different relative positions (see **35**). The orbital phase aspects of the dianions are the same as those of the R,R-substituted ethylene models. Trimethylenemethane dianion corresponds to *gem*-R,R (**11**) while butadiene dianion corresponds to *vic*-R,R (**10**). The cyclic orbital interaction is favored by the orbital phase continuity in trimethylenemethane dianion (see **17** for **11**), but not in butadiene dianion (see **16** for **10**). This is consistent with the suggestion of "Y-aromaticity,"[49] with the experimental observation of the relative thermodynamical stabilities of the anions,[50] and with the heat of formation of the related species calculated by Schleyer *et al.*[51]



Tautomerim in Purines. A significant polarization effect is found in the protropic tauromerism of biological important bases, purine (**36a**; X=H) and adenine (**36b**; X=NH_2).[52] There is no difference in the Kekulé structures of the pyrimidine and imidazole rings between the 7H- and 9H-tautomers. The way of fusion of the heterocyclic rings distinguishes one from the other. The preceding theoretical result has shown that electrons delocalize to the greatest degree when R- and W-substituents are attached to the vicinal carbons of the C=C double bond. In both tautomers, the bond in the pyrimidine ring, vicinal to the electron-donating amino nitrogen in the imidazole ring, is identical, *i.e.*, the imino double bonds. However, the electron accepting power of the C=N moiety is different between C and N. The AO coefficient in the LUMO is larger at C than at N. The imino group is linked at the nitrogen, N_3, in the 7H-tautomer and at the carbon, C_6, in the 9H-tautomer. As a result the donor-acceptor disposition favors electron delocalization in the 9H-tautomer.



The calculation supports the prediction. The OEDE is by 0.021β greater for 9H-**36a** than for 7H-**36a**. In order to examine the origin of the difference, we carried out the calculations without the locally-excited configuration of each bond. The OEDE of the 9H-tautomer significantly decreases to be close to the almost unchanged OEDE of 7H-**36a**, when the polarization of the fused C_4=C_5 bond is excluded. The polarization effect of the other bond was found to be of negligible importance. Another series of calculations confirmed this conclusion. The OEDE difference between 7H- and 9H-**36a** is small ($\approx 0.005\beta$) when only transferred configurations are involved. With the inclusion of the fused bond polarization function, the difference increases up to 0.021β. The polarization of the other bonds makes no considerable change in OEDE. As a result, the relative stability of the purine tautomers is attributed to electron delocalization assisted by the polarization at the fused C_4=C_5 bond, or to the orbital phase continuity-discontinuity in the acyclic conjugation. A similar result of calculation were obtained for the tautomerism of adenine, *i.e.*, 6-aminopurine (**36b**).

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture. The calculations were carried out by the HITAC-M200H computer, Institute for Molecular Science and the FACOM M-200 computer, Nagoya University Computer Center. The authors thank Prof. P. von R. Schleyer of Universität Erlangen-Nürnberg for private communication in prior to publication of the results (Ref. 51).

Appendix

The wavefunction, Ψ^M, of any electronic state of molecule, M, can be expanded[53] in terms of electron configurations including electron transferred and locally-excited configurations:

$$\Psi^M = C_0^M \Phi_0^M + \sum_K C_K^M \Phi_K^M,$$

where the zero-configuration, $\Phi(0)$ is the wavefunction of the reference state involving neither electron promotion nor shift. The magnitude of the configuration coefficients provides us with the information on the detail of electronic structure. A question comes to our minds when we compare the corresponding parts of electronic structure in different molecules. The number of configurations involved increases with the size of molecules or with the number of subsystems. Then the

magnitude of coefficients relatively decreases because of the normalization even if the chemical situation is equivalent. The coefficient ratio C_K/C_0 was, though intuitively, recommended as a preferable measure rather than C_K itself.[7] We present a rigorous meaning of the coefficient ratio.

Suppose an arbitrary molecule, R, as a reference, the wavefunction, Ψ^R, being expanded similarly:

$$\Psi^R = C_0^R \Phi_0^R + \sum_L C_L^R \Phi_L^R.$$

The wavefunction, Ψ^{RM}, of the combined system of R and M, where R and M do not interact with each other at all, is then as follows:

$$\begin{aligned}\Psi^{RM} &= \Psi^R \Psi^M \\ &= C_0^{RM} \Phi_0^R \Phi_0^M + \sum_K C_K^{RM} \Phi_0^R \Phi_K^M + \sum_L C_L^{RM} \Phi_L^R \Phi_0^M \\ &\quad + \sum_{K,L} C_{K,L}^{RM} \Phi_L^R \Phi_K^M,\end{aligned}$$

where

$$\begin{aligned}C_0^{RM} &= C_0^R C_0^M \\ C_K^{RM} &= C_0^R C_K^M \\ C_L^{RM} &= C_L^R C_0^M \\ C_{K,L}^{RM} &= C_L^R C_K^M.\end{aligned}$$

The configuration coefficients of the reference molecule in RM, C_L^{RM}, is dependent on the molecule, M. The coefficient, C_L^{RM}, should be invariable and equal to C_L^R when we study the electronic structure through comparing the configuration coefficients between different molecules. Dividing C_L^{RM} by C_0^M transforms the wavefuction as required:

$$C_L^{RM}/C_0^M = C_L^R.$$

The transformation leads to

$$C_K^{RM}/C_0^M = C_0^R(C_K^M/C_0^M).$$

The coefficient of the reference, C_0^R, can be taken to be a constant, *i.e.*, unity for the present purpose. It follows that C_K^M/C_0^M is a good measure for comparing different molecules.

9) The mechanism of electron delocalization among many systems in such a form as described in the text has been proposed and successfully applied to various chemical problems;[5-8] see also: J. P. Malrieu, "Localization and Delocalization in Quantum Chemistry," ed by O. Chalvet *et al.*, D. Reidel Publishing Company, Dordrecht-Holland (1975), Vol. 1, p. 335.

10) In the illustrations of the orbital phase relation throughout the paper, the solid and dashed lines denote the orbital pairs between which the phase requirements are satisfied and dissatisfied, respectively. In general, there are an odd number of the orbital pairs dissatisfying the requirements, in the discontinuous orbital phase systems, while an even number of them in the continuous ones. The number can be reduced to one or zero, respectively. The continuity-discontinuity of the orbital phase is a property of a whole molecule but not of specific parts of molecule. However, it is preferable to place the discontinuity between the HOMO's or between the LUMO's in the illustrations if possible since the HOMO–LUMO interaction is more primary.

11) Our attention is confined to the mixing-in of the locally-excited configurations through orbital overlapping though there are the other origins of polarization, *e.g.*, electrostatic interaction.

12) a) The method[8] is a simple extension of the "Molecules in Molecule" approach[b,c] in the sense that the interaction is considered to occur among many systems; b) H. C. Longuet-Higgins and J. N. Murrell, *Proc. Phys. Soc.*, **A68**, 601 (1955); c) J. N. Murrell, *ibid.*, **A68**, 969 (1955).

13) According to the HMO–ECAMSI calculation,[7] $C(\Delta n$: odd) has non-zero (negligibly small) value, possibly because the other configurations than are involved in the HMO–LCEC calculations are contained implicitly.

14) The total energy of the HMO–LCEC calculation[8,12a] is decomposed into three terms:

$$E = \sum_M C_M^2 H_{MM} + 2\sum_{M\neq 0} C_0 C_M H_{OM} + 2\sum_{M<N} C_M C_N H_{MN}.$$

The OEDE is defined as a measure of the delocalization to be the sum of the energies of the interactions between $\Phi(0)$ and $\Phi(n_1 \to n_2)$ (the second terms denoted by the ZT energy) and those between $\Phi(n_1 \to n_2)$'s (the third terms denoted by the TT energy). The energy of the interaction between $\Phi(n \to n)$ and $\Phi(n_1 \to n_2)$ is here contained in the latter terms.

15) This is also the case with the normal HMO total energy.

Thermal Decomposition of Calcium Sulfate Dihydrate under Self-generated Atmosphere

Kimio Isa* and Hiroki Okuno

Department of Chemistry, Faculty of Education, Fukui University, Bunkyo 3-9-1, Fukui 910

(Received April 1, 1982)

Dehydration of calcium sulfate dihydrate was studied by means of simultaneous TG-DTG-DTA under various sealed atmospheres corresponding to three systems open, completely sealed, and quasi-sealed. Two dehydration steps could be detected under self-generated atmospheres by using 12.3, 18.7, 30.0, and 250 μm tungsten wires. This new method enables us to identify intermediates more easily than any other techniques hitherto adopted. Endothermic DTA peaks appeared earlier, at 129 and 133 °C, than the point of decreasing TG. This technique, resembling the quasi-isothermal and -isobaric thermogravimetry (Q-TG), is superior to Q-TG in that it requires smaller amounts of sample.

By the self-generated atmosphere[1] is meant an atmosphere which is composed of gaseous decomposition products of a reaction and which is in intimate contact with the sample with the aid a sample holder employed. In the case of thermal decompositions producing gases, the equilibrium will be attained for the partial pressure of the gases. It was reported[2] that a thermal decomposition of ammoniumh eptamolybdate(6−) tetrahydrate ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, AHM) producing both H_2O and NH_3 was studied by means of simultaneous TG-DTG-DTA from room temperature to 500 °C under static air atmosphere and flow conditions of various gases. This system was also subjected to Q-derivatography (quasi-isothermal and -isobaric thermogravimetry) and home-built quasi-sealed thermogravimetry.[3] The first step of the thermal decomposition of AHM was considered to be associated with two reaction schemes,[4-6] one Funaki's scheme and the other Ma's. Our results proposed a new reaction scheme, and disclosed a new intermediate stage. However, it was difficult to get rid of intermediates out of the apparatus and also more difficult to identify the intermediate because of the uncertainty of element analysis. Until then we had been able to clarify the existence of anhydrous after dehydration and the new intermediate had been confirmed by means of high-temperature oscillating X-ray diffraction with a rotating anode-type large-capacity generator.[7] In the case of thermal decomposition of AHM, our conclusion was that both H_2O and NH_3 are capable of desorbing simultaneously after dehydration. As to the self-generated atmospheres of H_2O and NH_3, the thermal decomposition mechanism was affected by that changeable condition.

Next, we selected calcium sulfate dihydrate ($CaSO_4\cdot 2H_2O$) as a model substance since it produces only H_2O in its thermal decomposition from room temperature to 400 °C which may be followed by TG-DTG-DTA and quasi-sealed TG.

There are various dynamical techniques for thermal analysis which are powerful for studying the thermal decomposition. Instruments have become capable of auto-operation, thus improving both the accuracy and precision of measurements as well as reducing both investigator's time and patience. Advantages of these methods are that extremely small amounts of sample may be required, that operator's time may considerably be saved, and that reaction rate may be determined very easily. But information furnished from various apparatus are different from one another. In order to eliminate the above disadvantages, we will discuss the applicability of the quasi-sealed TG under the condition of self-generated atmosphere.

Experimental

Materials. Calcium sulfate dihydrate of Wako Co. or Nakarai Co. (GR quality) was used in the form of powder. The sample amounts used were from 0.0023 mmol (0.40 mg) to 0.10 mmol (18 mg) and the reference material used for DTA was α-Al_2O_3.

Apparatus. A modified Thermoflex 8002 (Rigaku Denki Co.) was used for simultaneous TG-DTG-DTA measurements. The range of temperature covered was usually from room temperature to 360 °C and the sample was heated, in most cases, at the rate of 1 °C/min (the mean heating rate 1.005 °C/min).

Quasi-sealing. Aluminium small pan and cover (Rigaku Denki Co.) were sealed completely by the sample sealer for liquid materials (Rigaku Denki Co.) (Fig. 1). For the purpose of quasi-sealing, both aluminium pan and the cover and thin tungsten wire (12.3, 18.7, 30.0, 250, or 250 μmϕ × 2) were sealed in the same way as illustrated (Fig. 1(a)) and this sealed pan had a small leak along the thin wire. In the case of completely sealed pan, the critical explosion pressure had been determined to be above 3 atm.[8]

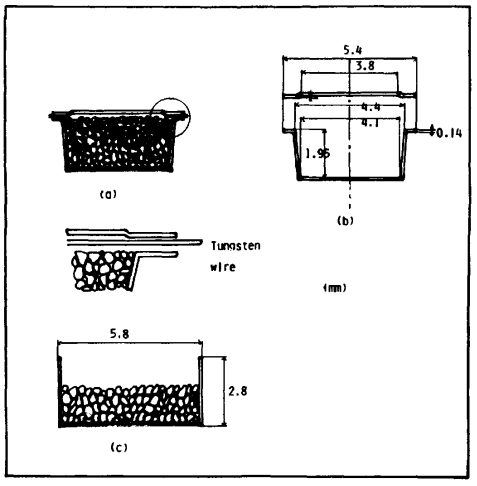

Fig. 1. a) Schematic diagram of a sample cell, aluminum cell. b) Dimension of sample cell. c) Schematic diagram of a sample cell, platinum cell.

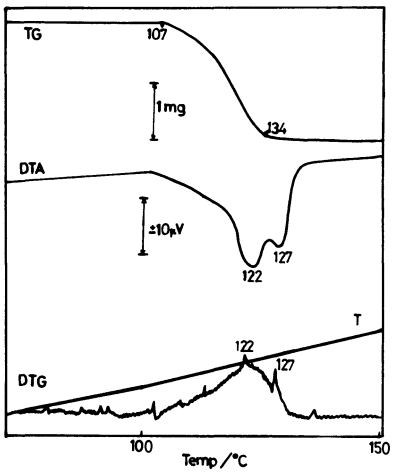

Fig. 2. TG-DTG-DTA of calcium sulfate dihydrate under open system. Sample amount is 0.067 mmol. Reference material is α-Al_2O_3. Cell is platinum. Heating rate is 1 °C/min.

Results and Discussion

Open System. With platinum cells (Fig. 1(c)), sample weights were changed from 0.0289 mmol (4.98 mg) to 0.090 mmol (15.56 mg) and simultaneous TG-DTG-DTA measurements were run. The range of TG used was usually 10 mg, and the ranges of DTA used were both ± 100 and ± 20 μV (the upper side corresponds to exothermic reaction). Typical results for 0.067 mmol of $CaSO_4 \cdot 2H_2O$ are shown in Fig. 2. The results of TG indicates two different types of descent tendencies and the result of DTG also indicates two peaks but they cannot be seperated from each other completely. If we want to analyse the thermal decomposition by the Freeman-Carroll[9] or Coats-Redfern method,[10] we must discuss these methods.

The endothermic peak of DTA owing to dehydration begins at 102 °C, and the descends of TG and DTG curves begin at 107 and 102 °C, respectively. For the simultaneous technique, the same temperature of 102 °C indicates the coincidence of the thermal and thermogravimetric behaviours of dehydration. But this temperature is not easy to be regarded as the decomposition temperature because the temperature would change if we change some experimental conditions, *e.g.*, the sample amount, heating rate, sensitivity of TG, DTG, and DTA, and signal-to-noise ratio. The DTA peak is divided into two peaks at 122 and 130 °C, and the reaction steps may be considered to be composed of two. With the method described in a previous report[11] it was difficult to seperate reaction steps into two.

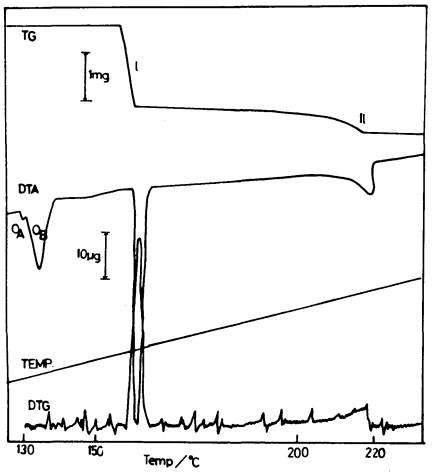

Fig. 3. TG-DTG-DTA of calcium sulfate dihydrate under completely sealed system. Sample amount is 0.0670 mmol. Reference material is α-Al_2O_3. Cell is aluminum. Heating rate is 1 °C/min.

Completely Sealed System. According to the suggestion of Miyazaki,[11] in order to obtain TG-DTA curves in an atmosphere containing much water vapor, TG-DTG-DTA measurements on samples of 0.0136, 0.0293, and 0.0670 mmol were run in the completely sealed system. The results of TG-DTG-DTA for the open system is apparently different from that for the completely sealed system. Figure 3 shows results of the sample of 0.0670 mmol. Concerning the TG results, the first step of TG seems to be a rapid decreasing reaction which corresponds to the dehydration of $\frac{3}{2}H_2O$ to produce $CaSO_4 \cdot \frac{1}{2}H_2O$, from a calculation of weight losses. Concerning the results of DTA, both endothermic peaks of the first and second steps to be at 162 and 219 °C, respectively. At lower temperatures than these, endothermic peaks without decreasing TG appear to be around 129 and 133 °C. These are named the O_A and O_B steps. Such behaviour is observed in 15 cases of sample weights ranging from 0.0030 to 0.0714 mmol. Almost the same temperature is registered for each group of O_A and O_B steps.

Reaction scheme for the TG descent may be considered as follows:

$$CaSO_4 \cdot 2H_2O \longrightarrow CaSO_4 \cdot \frac{1}{2}H_2O + \frac{3}{2}H_2O, \quad \text{(I)}$$

hemihydrate (15.70% loss)

$$CaSO_4 \cdot \frac{1}{2}H_2O \longrightarrow CaSO_4 + \frac{1}{2}H_2O. \quad \text{(II)}$$

nonhydrate (5.23% loss)

The rapid descent of the first step of TG is considered to be in the following sequence. Desorption of H_2O owing to hydration at the O_A and O_B steps and after these steps continue gradually, and the equilibrium vapor pressure is increased greatly by a rise in temperature, until the aluminum pan is caused to explode above the critical pressure. Considering the change in weight of H_2O, 1.812 mg, and the capacity of the sealed cell, 0.029 cm^3, the water vapour pressure is as high as about 6 atm at 159 °C.[9] Then H_2O of 0.0049 mmol is liberated and equilibrated. Over the critical pressure for the aluminium pan, the sealed pan is opened under the vapor pressure of H_2O and the vapor is allowed to escape from the sealed pan through the leak. The equilibrium of Reaction I is disturbed, the self-generated atmosphere is removed from the pan, and the unreacted water of Reaction I begins to be liberated rapidly. The rapid descent for the first decomposition step is caused in such a way that the response rate is

slower than the reaction rate or both rates were fast so that the equilibrium is disturbed and the unreacted substance is changed under a superheated condition. We must consider the situation more carefully. However, the temperature of 159 °C is higher than the end temperature of the second reaction illustrated in Fig. 2 (static condition), but it is important that the second reaction is not yet allowed to begin. A summary of the results of TG, DTG, DTA suggests a mechanism for the hydration which is considerably different from that of the first reaction. The results of TG were analyzed by the Coats-Redfern method, the reaction order, n, being determined as follows:

1) In the case of sample weight 15.08 mg and diameter of tungsten wire 12.3 μm:
I step: 2.0 order reaction.
II step: 1.0 order reaction.

2) In the case of sample weight 10.00 mg and diameter of tungsten wire 30.0 μm:
I step: 2.5 order reaction.
II step: 1.0 order reaction.

According to published results,[11] the first reaction step has been considered to be dehydration of structural water and the second reaction step to be dehydration of mobile water. But this water may come out at relatively high temperatures and the temperature ranges for the two dehydrations are about 60 °C. Until now we couldn't ewplain this behaviour by means of the sealed method or on account of property of mobile water. Moreover, in order to compare the decompositions of $CaSO_4 \cdot \frac{1}{2}H_2O$ and $CaSO_4 \cdot 2H_2O$ by means of the completely sealed TG, measurements were made by TG-DTG-DTA. The same results were obtained except the behavior of the water previously adsorbed (Fig. 4). The second steps of both $CaSO_4 \cdot \frac{1}{2}H_2O$ and $CaSO_4 \cdot 2H_2O$ were almost the same. For this reason the product of the first step of decomposition of $CaSO_4 \cdot 2H_2O$ may be considered to be $CaSO_4 \cdot \frac{1}{2}H_2O$.

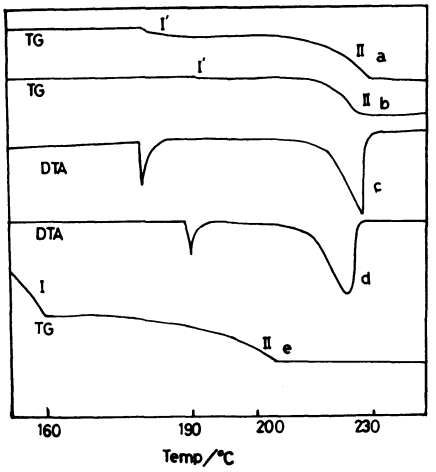

Fig. 4. TG-DTA of $CaSO_4 \cdot \frac{1}{2}H_2O$ under completely sealed method.
a): TG, sample amount is 18.73 mg ($CaSO_4 \cdot \frac{1}{2}H_2O$),
b): TG, sample amount is 15.38 mg ($CaSO_4 \cdot \frac{1}{2}H_2O$),
c): DTA, sample amount is 18.73 mg ($CaSO_4 \cdot \frac{1}{2}H_2O$),
d): DTA, sample amount is 15.38 mg ($CaSO_4 \cdot \frac{1}{2}H_2O$),
e): TG, sample amount is 11.57 mg ($CaSO_4 \cdot 2H_2O$).

With respect to these O_A and O_B peaks, Table 1 and Fig. 5 show figures and behaviour of O_A and O_B, when the amount was changed from 0.00302 to 0.0714 mmol. Peak temperatures are consistent with each other within the experimental error. The difference in temperature of the O_A and O_B peaks is about 4 °C on the average, in dependent of sample amount. Two possible explanations are applicable to these results: one is that there are two binding states of water which may be seperated from each other in the process of dehydration; the other is that in the case of complete sealing, a part of H_2O is caused to come out in an endothermic reaction. Moreover, when the system temperature is increased

Table 1. Peak temperatures of DTA of O_A step (T_{O_A}) and O_B step (T_{O_B}) under completely sealed system

Heating rate, 2 °C/min. Chart speed, 0.5 cm/min. X-Ray source, Cu *Kα* 120 mA, 50 kV.

several degrees, the decomposition process is resumed and the amount of the water coming out from the sample is increased. If the sample amount is made to decrease, the O_A peak of DTA becomes broader and the effect of diffusion in the sealed cell comes to play an important role. In addition, the descent for the second step of TG is caused slowly in raising temperature and it is better to consider that the leak is in operation.

Quasi-sealed Method. A TG-DTG-DTA curve was recorded for the quasi-sealed system and is shown in Fig. 6, which induces the results for both the open and completely sealed systems for comparison; a selection has been made so that all the sample weights may fall in the range 11.54—12.60 mg. As the radius of tungsten wire is increased, results become similar to those of the open system. Onset temperatures of reaction are 111, 113, and 114 °C in the case of open system, two pieces of 250 μm tungsten wire, and a piece of 250 μm tungsten wire, respectively. But the turning point of TG presents itself more clearly and the peaks of DTA can be seperated more easily. The results of both the 30 and 18.7 μm tungsten wires indicate that the decreasing temperatures are 125 and 127 °C and appear with more enhanced separation. These results are what we have expected. In the case of quasi-sealed system, dehydration first occurs after some inner pressure of water vapor had been reached, making a TG decreasing recognizable. If we want to get the stable state of $CaSO_4 \cdot \frac{1}{2}H_2O$, we must use a tungsten wire 30 μm or less in radius.

A precise measurement of high-temperature oscillating X-ray diffraction of calcium sulfate dihydrate was done at a heating rate of 2 °C/min. The result could identify the stable $CaSO_4 \cdot \frac{1}{2}H_2O$ (Fig. 7).

In connection with the above-mentioned experimental results, the following conclusions may be drawn:

(1) According to the experimental results of Miyazaki,[11] it is difficult to separate the first and the second steps of $CaSO_4 \cdot 2H_2O$ decomposition. However, he succeeded only in first making non-hydrate $CaSO_4$ followed by making $CaSO_4 \cdot \frac{1}{2}H_2O$ under the saturated vapor pressure of water. But in our cases, we could easily seperate two steps under a quasi-sealed condition using 12.3, 18.7, and 30.0 μm tungsten wires.

(2) This method enables one to seperate dehydrations of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ and $CaSO_4 \cdot 2H_2O$, *etc.*, so that we can easily get intermediates. The advantage of this method is that it requires smaller amounts of sample than the Q-TG method. By smaller amounts of sample it is meant that there are narrower ranges of temperature distribution and that there may be many applications available to other fields, for example, biochemistry.

(3) In the process of dynamic heating, the temperature distribution caused by endo- and exothermic behaviour is relatively small so that the quasi-equilibrium condition may be established easily.

(4) With the completely sealed system, two types of reactions, O_A and O_B occur without decreasing TG. But this phenomenon cannot be explained in terms of different stages of binding or influence of the self-generated condition.

Simple inorganic salts containing water have been studied by means of simultaneous TG-DTG-DTA. Since it seemed most important to investigate first self-generated atmospheres, we planned to study those in the vacuum condition as well as in the gas-flowing condition; thus in the present report, we have studied the self-generated atmosphere.

This study will be applied to various dehydration systems, especially those for which it is said to be difficult to remove intermediates. Now we are planning to apply this method to various decompositions involving gases such as CO_2, H_2S, and NH_3. We are also planning to invent a micro-quasi-isothermal and -isobaric thermogravimetry.

The authors wish to thank (the late) Professor Hajime Ishimura for encouraging us in our early work, and Mr. Masahiro Nogawa and Ms. Yayoi Yamada for conducting measurements in the last stage of experiment. The X-ray generator used belongs to the Research Institute for Material Science and Engineering, Fukui University.

Studies on Mixed Chelates. XIII. Formation and Electronic Spectra of 5-Coordinated Mixed Copper(II) Chelates Containing *N*-Alkylated Ethylenediamine, Acetylacetonate, and Halide Anions[1)]

Yutaka FUKUDA, Hiroko KIMURA, and Kozo SONE*

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received January 16, 1982)

The visible absorption spectra of three new mixed chelates of copper(II), Cu(acac)(tmen)X (acac=acetylacetonate ion, tmen=*N,N,N',N'*-tetramethylethylenediamine, and X^-=Cl^-, Br^-, or I^-) were studied in various organic solvents. The $\tilde{\nu}_{max}$ values of their d-d bands depend strongly on the nature of the solvent, similarly to the pseudohalide complexes reported in the preceding paper.[1)] These data show the existence of the equilibrium:

$$[Cu(acac)(tmen)X] \rightleftharpoons [Cu(acac)(tmen)]^+ + X^-$$
(5-coordinated) (4-coordinated, with axial solvation)

in such solutions, which is shifted to the right hand side with increase of the solvent polarity and with decrease of the coordination ability of the X^- anion, *i.e.*, in the order $Cl^- \rightarrow Br^- \rightarrow I^-$.

We have prepared several mixed copper(II) chelates containing N-alkylated ethylenediamine(diam) and the β-diketonate ion (β-dik), Cu(β-dik)(diam)X, where X^- is an anion such as ClO_4^-, NO_3^-, or pseudohalide ions.[1,2)] They are all soluble in various organic solvents, and the visible absorption spectra of such solutions reveal the existence of different kinds of solvent effects on their structures in solution. Such effects originate in the donor property and polarity of the solvent used, and the coordinating power of the anion X^-. In continuation of these studies, we have prepared the corresponding halide complexes, Cu(acac)(tmen)X, in which X^-=Cl^-, Br^- or I^-, and studied their visible absorption spectra in organic solvents. The results obtained and their probable explanations will be presented in this paper.

Experimental

Preparation of the New Complexes. An excess of an aqueous solution of potassium halide (KCl, KBr, or KI, *ca.* 20 mmol in 30 cm^3 of H_2O) was added to a solution of [Cu(acac)(tmen)]ClO_4[2)] in water–ethanol (10 mmol in 20 cm^3), and the mixture was stirred for several hours. It was then filtered and concentrated under reduced pressure below room temperature until the complex formed as a crystalline powder. The crude bluish green crystals were recrystallized from 1,2-dichloroethane($ClCH_2CH_2Cl$=DCE). The Cl- and Br-complexes{Cu(acac)(tmen)X; X=Cl or Br} are stable at room temperature, but the crystals of the I-complex gradually decompose on standing, changing from bluish green to brown by the redox reaction between Cu(II) and I^-. Therefore, in the physical measurements a freshly prepared sample must be used and must be kept in a refrigerator when not in use.

Physical Measurements. The electronic spectra of the solutions (visible region) were measured with a Hitachi 340 Recording Spectrophotometer at room temperature (20—25 °C), in 10 cm quartz cells. The reflectance spectra of the solid samples were measured with the same instrument with a reflectance attachment, using $BaSO_4$ as the reference. Infrared spectra (400—5000 cm^{-1}) were measured as Nujol mulls with a JASCO IR-A3 Grating Spectrophotometer. Magnetic susceptibility measurements were performed with a Shimadzu Tortion Magnetometer MB-100. Electric conductivities of the solutions were measured with a conductivity outfit AOC-10 (Denki-kagaku Keiki Co. Ltd.) at 25±0.2 °C.

Results and Discussion

Properties of the Solid Complexes. Table 1 summarizes the analytical data and magnetic moments of the three new complexes. All show normal magnetic moments for monomeric Cu(II) complexes, but their colors (bluish green with different shades) are notably different from that of the perchlorate, [Cu(acac)(tmen)]ClO_4 (reddish violet), as are their visible reflectance spectra (see later).

Electronic Spectra of the Complexes in Various Solvents. These complexes are all readily soluble in various organic solvents, but here again the visible absorption spectra observed in such solvents are remarkably different from those of the perchlorate in the same solvents. For example, the spectra of the Cl-complex, [Cu(acac)(tmen)Cl], in four solvents are given in Fig. 1. The observed values of $\tilde{\nu}_{max}$ and ε_{max} for all these complexes are summarized in Table 2, and the shifts of $\tilde{\nu}_{max}$ of each one in various organic solvents are shown in Fig. 2, in comparison with the data of the perchlorate and the NCO-complex reported previously as the

TABLE 1. ELEMENTARY ANALYSES AND MAGNETIC MOMENTS OF THE COMPLEXES OBTAINED

Cu(acac)(tmen)Cl	41.99(42.03)	7.44(7.38)	8.91(8.91)	1.85
Cu(acac)(tmen)Br	37.00(36.83)	6.54(6.46)	7.84(7.81)	1.84
Cu(acac)(tmen)I[b)]	31.58(32.56)	5.51(5.71)	6.22(6.90)	1.74

a) Calculated values are in parentheses. b) The somewhat poorer agreements may be due to partial decomposition which occurred during handling prior to analysis. *Cf.* Experimental.

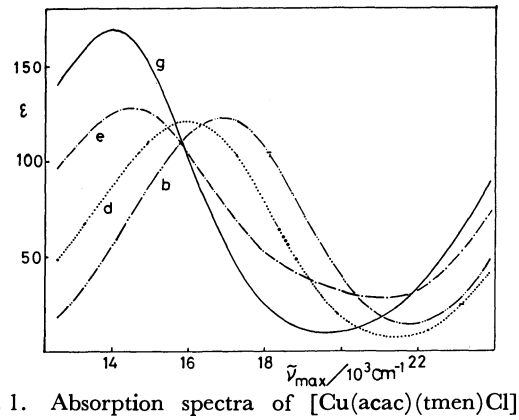

Fig. 1. Absorption spectra of [Cu(acac)(tmen)Cl] in various organic solvents. As to the symbols on the curves, *cf.* Fig. 2.

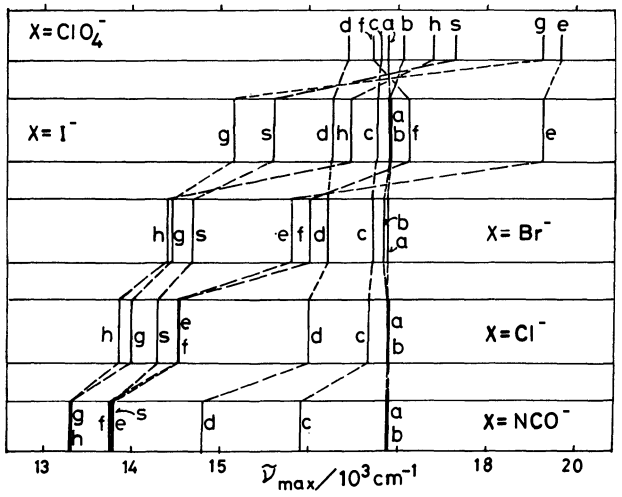

Fig. 2. Diagrammatic representation of the $\tilde{\nu}_{max}$ of the complexes shown in Table 2, and those of [Cu(acac)-(tmen)]ClO_4 and [Cu(acac)(tmen)NCO]† reported previously.[1] The symbols (a) to (h) correspond to the following solvents: a=H_2O, b=MeOH, c=EtOH, d=DMSO, e=NM, f=CH_3CN, g=DCE, and h=acetone. The value of the solid reflectance spectrum is shown by s.

reference.[1],†

It was shown that the $\tilde{\nu}_{max}$ value of the perchlorate shifts to the red with the increase of the donor number of the solvent.[2,3] However, the data in Fig. 2 clearly show that the values of the halide complexes shift to the red with the decrease of solvent polarity, *i.e.*, in apparently opposite direction as compared with the perchlorate. When X^- is Cl^- or Br^-, the order of $\tilde{\nu}_{max}$ in various solvents is expressed as:

$$H_2O \geqq MeOH > EtOH > DMSO > CH_3CN \geqq NM > DCE \geqq \text{acetone.} \quad \text{(i)}\,\dagger\dagger$$

† In Fig. 2 of the preceding paper (Ref. 1), the symbols III and IV mean the N_3- and NCO-complex, respectively (the reverse given there was a mistake; *cf.* the data in Table 3 of the same paper).

†† The abbreviations of the solvent names used are as follows: NM:CH_3NO_2, DCE:$ClCH_2CH_2Cl$, DMSO:$(CH_3)_2SO$ (see also in Table 2).

TABLE 2. $\tilde{\nu}_{max}$ AND ε_{max} VALUES OF [Cu(acac)-(tmen)X] IN SOLID STATE AND IN VARIOUS SOLVENTS AT *ca.* 20 °C[a-c]

	X=Cl	X=Br	X=I
Solid[d]	14.3	14.8	15.6
H_2O	16.89(101)	16.89(101)	16.89(97)
CH_3OH(MeOH)	16.89(123)	16.84(108)	16.92(106)
C_2H_5OH(EtOH)	16.67(133)	16.72(130)	16.75(111)
$(CH_3)_2SO$(DMSO)	16.00(121)	16.21(129)	16.26(113)
$(CH_3)_2NCHO$(DMF)	14.71(114)	16.21(112)	16.50(100)
CH_3NO_2(NM)	14.53(128)	15.82(103)	18.48(96)
CH_3CN	14.53(132)	16.08(112)	17.27(100)
$C_2H_4Cl_2$(DCE)	14.03(169)	14.45(173)	15.15(135)
$(CH_3)_2CO$	13.83(153)	14.39(154)	16.47(94)

a)$\tilde{\nu}_{max}$ in 10^3 cm^{-1}, ε_{max} in parentheses. b) Concentrations: *ca.* 5×10^{-3} M (1 M=1 mol/dm^3). c) It can be noted that there is a remarkable increase in ε_{max} when most of the complex is in the 5-coordinated state (*cf.* the values for the Cl- and Br-complexes in DCE and acetone, and for the I-complex in DCE). Such an increase in band intensity is often observed when a 5-coordinated Cu(II) complex is formed in solution. d) Solid reflectance spectral peaks are broad.

These results are similar to those observed for pseudohalide complexes[1] (compare the data of Cl- and NCO-complexes in Fig. 2, for example), and indicate that the same type of equilibrium as that observed in the solutions of the pseudohalide complexes is established. The equilibrium of the dissociation and formation of the 5-coordinated complex species as shown in Eq. 1:

$$\underset{\text{(5-coordinated)}}{[Cu(acac)(tmen)X]} \rightleftharpoons \underset{\text{(4-coordinated, with axial solvation)}}{[Cu(acac)(tmen)]^+} + X^- \quad (1)$$

is shifted to the right hand side with increase of solvent polarity; this is generally expressed in terms of their E_T or Z values.[3]

Like the pseudohalide complexes, the spectra in DCE and acetone, which are the most non-polar solvents used ($E_T \simeq 42$), can be ascribed to the 5-coordinated complexes, [Cu(acac)(tmen)X]; the fact that these complexes are practically non-electrolytes in DCE supports this view (see below). On the other hand, the spectra in H_2O and MeOH, which are the most polar solvents used (E_T=55—63), are nearly the same as those of the perchlorate in these solvents, and are ascribed to the 4-coordinated ionic complexes [Cu(acac)-(tmen)]$^+$ with axial solvation.

The spectra in other solvents with intermediate polarity correspond to equilibrium mixtures containing these two complex species. In EtOH and DMSO, the spectra are similar to those of the perchlorate, but their $\tilde{\nu}_{max}$ are shifted toward the red, indicating the coexistence of small amounts of [Cu(acac)(tmen)X]. The shift is larger in CH_3CN, and still larger in NM. These results show that the extent of formation of [Cu(acac)-(tmen)X] increases in the order of EtOH<DMSO<CH_3CN<NM. It is thus concluded that the solvent series (i) is essencially the order of the shift of the equilibrium (1) to the right hand side, just as in the case of the pseudohalide complexes.

Table 3. Acceptor numbers(AN) of the solvents used

Solvent	AN
H_2O	54.8
MeOH	41.3
EtOH	37.1
DMSO	19.3
DMF	16.0
CH_3CN	19.3
NM	20.5
DCE	—
Acetone	12.5

It is also interesting to note that the series (i) can also be taken as the order of the acceptor numbers (AN) of Gutmann (*cf.* Table 3) of the solvents,[3] which is the measure of their ability to combine with the negatively charged particles or negative ends of dipoles. This is natural, since a solvent with a high AN will be able to pull out the X^- ions from the coordination sphere of [Cu(acac)(tmen)X] more easily than that of a lower AN.††† A practical reason for our preference for the E_T scale is that the value of DCE, in which the contrast between the spectrum of the perchlorate and those of the halide and pseudohalide complexes is largest, is lacking in Gutmann's table.

Comparison of the data for Cl- and Br-complexes reveals further that, in every solvent (with the exception of H_2O and MeOH) the band of the Cl-complex is shifted more to the red than that of the Br-complex, and in solvents of lower polarity (DCE, acetone, CH_3CN, and NM), the $\tilde{\nu}_{max}$ of the Cl-complex tend to flock together around *ca.* 14×10^3 cm^{-1}. These facts indicate that Cl^- is more strongly bound with $[Cu(acac)(tmen)]^+$ than Br^- in any solvent, except in H_2O and MeOH where no such combination occurs.

The data for the I-complex, on the other hand, show more complexity. The $\tilde{\nu}_{max}$ values in DCE, DMSO, H_2O, and alcohols can be expected by comparison with the Cl- and Br-complexes, but those in acetone and NM (especially the latter) are nearer to the values of the perchlorate in the same solvents, and the value in CH_3CN is even higher than that of the perchlorate. Although the meaning of these $\tilde{\nu}_{max}$ is still not fully understood, it is thus clear that appreciable formation of the 5-coordinated complex occurs only in DCE (and to a much less extent in acetone). In most other solvents, the $\tilde{\nu}_{max}$ values are closer to those of the perchlorate, showing that most of the I^- ions merely dissociate in such solvents. Therefore, the I-complex may be taken as an intermediate between the Br-complex and the perchlorate complex in its behavior.

Electric Conductivities of the Complexes. Conductometric measurements were carried out on some of these solutions to gain information on the equilibrium (1). Some data are shown in Table 4. They show that, in DMSO, all the three complexes are 1 : 1 electrolytes. In NM, however, only the I-complex is a 1 : 1 electrolyte, and partial ionization takes place with other complexes, the degree of which increases from the Cl-complex to the Br-complex. In DCE, the same tendency is observed much more apparently.

Table 4. Molar conductivities (Λ_M) of the complexes (Ω^{-1} cm^2 mol^{-1}, at 25.0 °C)[a] and approximate degrees of dissociation (%, in parentheses)[b]

Complex	DCE	NM	DMSO
Cu(acac)(tmen)Cl	0.6(3)	43.7(51)	32.6(93)
Cu(acac)(tmen)Br	1.2(6)	70.5(83)	36.1(100)
Cu(acac)(tmen)I	6.6(33)	83.6(98)	35.4(100)

a) Concentration: *ca.* 1×10^{-3} M. b) Calculated on the assumption that the Λ_M values of a typical 1:1 electrolyte in these three solvents are 20, 85, and 35 Ω^{-1} cm^2 mol^{-1}, respectively (see Ref. 4).

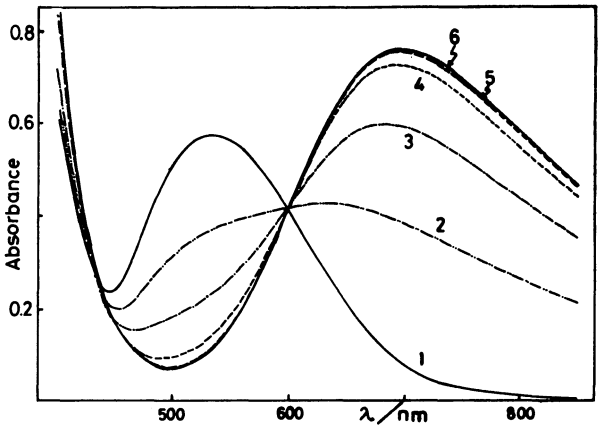

Fig. 3. The effect of Cl^- ions on the spectrum of $[Cu(acac)(tmen)]^+$ in NM (concentration: 5.01×10^{-3} M). The curve 1 is that of $[Cu(acac)(tmen)]ClO_4$, and 2 to 6 correspond to solutions in which the $[Cu(acac)(tmen)]^+$: Cl^- ratios are 1 : 0.5, 1 : 1, 1 : 2, 1 : 3, and 1 : 4, respectively.

These data are compatible with the expectation from the spectral data. They can be summarized by stating that the degree of ionization of [Cu(acac)(tmen)X] increases, in every case, in the order of DCE<NM< DMSO and Cl^-<Br^-<I^-.

Solution Equilibria of the Complexes in NM. Comparison with the Pseudohalide Complexes: More spectral measurements on the systems of $[Cu(acac)(tmen)]ClO_4+Et_4NX$ (X=Cl or Br) in NM were made by varying the molar ratio $[Cu(acac)(tmen)]^+/X^-$ continuously. Figure 3 shows some of the curves obtained. Analysis of these data provides an estimation of the equilibrium constants K of these systems.[5] The same K's could also be estimated from the data in Table 4, by comparing the obtained Λ_M (molar conductivity) values with the mean values of common 1 : 1 electrolytes in the solvents used.[4] The K values obtained in both ways are shown in Table 5. The good agreement may be fortuitous, but it can be seen from these data (and the values of the NCS-complex estimated with the data in the preceding paper)[1] that the coordination abilities

††† An apparent exception is that NM tends to come after CH_3CN and DMSO in the present series; here, however, the AN are nearly the same, and the large difference in their DN may be acting to upset the order.

Table 5. Values of the equilibrium constant, K, of Eq. 1 in NM, estimated from spectra (K^a) and conductometric data (K^b)

Complex	K^a	K^b
Cu(acac)(tmen)Cl	0.46×10^{-3}	0.35×10^{-3}
Cu(acac)(tmen)Br	1.52×10^{-3}	1.69×10^{-3}
Cu(acac)(tmen)NCS[a)]	0.67×10^{-3}	0.74×10^{-3}

a) These values were estimated from the data in Ref. 1.

of the ions studied increase in the order of $Cl^- > NCS^- > Br^-$ in NM.

It is desirable to make similar measurements on all the other systems, *i.e.*, in every solvent and with every halide or pseudohalide ion, but it is not always practicable owing to experimental difficulties, *e.g.*, unfavorable solubility. Comparison of Fig. 2 with the corresponding figure in the preceding work,[1] however, indicates that the coordination abilities of the halide and pseudohalide ions in organic solvents toward $[Cu(acac)(tmen)]^+$ can be arranged, approximately, in the following order:

$$I^- < Br^- \approx NCS^- < Cl^- \approx N_3^- < NCO^-.$$

This sequence may be of some interests, since it is often stated that pseudohalide ions are stronger ligands than halide ions,[6] and the spectrochemical series also states that the ligand field caused by NCS^- is much stronger than those of the halide ions. The "spectrochemical series for axial ligands" found by Addison *et al.*[7] also indicates the same trend. In the present case, however, the two series Cl^-–Br^-–I^- and NCS^-–N_3^-–NCO^- run nearly parallel (or intermixed together), although I^- is probably the weakest, and NCO^- the strongest ligand among all these ions. More studies on related complexes will be necessary for the proper understanding of this sequence.

Structures of the Complexes in Solid State. The fact that the $\tilde{\nu}_{max}$ values of the solid Cl- and Br-complexes (*cf.* Table 2 and Fig. 2) are similar to those of their DCE solutions indicates the 5-coordinated structure of these complexes in solid state. Even for the I-complex, the $\tilde{\nu}_{max}$ is near that in DCE, suggesting the same structure.

However, the bands of the solids are all rather broad, and the possibility of other structures (*e.g.*, a 6-coordinated one in which X^- ions are bound weakly above and below the chelate plane as the bridging ligand) cannot be ruled out with certainty. At any rate, there is a strong axial influence of X^-, and the structures of the complexes in these solids are far from square planar.

It is now clear that these three complexes and the three pseudohalide complexes reported previously provide an interesting group of mixed chelates of Cu(II), with which one can observe the competition of anions and solvent molecules for the axial coordination sites by means of their visible absorption spectra.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 0554182 from the Ministry of Education, Science and Culture.

Preparation and Structure of μ-Oxalato-bis{μ-oxo-μ-sulfido-bis-[(oxalato)oxomolybdate(V)]} Complex, $K_6[\{Mo_2O_3S(ox)_2\}_2(ox)]\cdot 10H_2O$

(Received February 1, 1982)

The μ-oxo-μ-sulfido-(oxalato)molybdate(V) complex has been prepared and characterized by X-ray analysis. The potassium salt crystallizes in monoclinic system, space group C2/c, with cell dimensions $a=13.640(3)$, $b=20.296(3)$, $c=15.213(4)$ Å, $\beta=106.42(2)°$, and $Z=4$. The structure was solved by the heavy-atom technique and refined by the block-diagonal least-squares method to $R=0.048$ for 3552 independent reflections. The complex anion is tetrameric, two dimeric $Mo_2O_3S(ox)_2$ moieties being bridged by one oxalato ligand. Both the molybdenum atoms in the dimer are bridged by one sulfur and one oxygen atoms. Each molybdenum atom has distorted octahedral environment; two oxygen atoms of a bidentate oxalato ligand, bridging sulfur and oxygen atoms in the equatorial plane, a terminal oxygen and one of the bridging quadridentate oxalato ligand oxygens. The complex can be denoted as $K_6[\{Mo_2O_3S(ox)_2\}_2(ox)]\cdot 10H_2O$ and has an approximate C_{2h} symmetry, with a crystallographic center of symmetry. The Mo–O (quadridentate bridging oxalato) bonds (2.304(4), 2.302(4) Å) are evidently longer than the Mo–O (bidentate oxalato) bonds (2.112(4), 2.102(4), 2.093(4), 2.120(4) Å). The influence of the bridging oxalato ligand on the geometry of Mo_2O_3S core will be discussed.

The presence of sulfur in several molybdenum containing enzymes led us to the chemistry of μ-sulfur molybdenum compounds.[1]

The chemistry of di-μ-oxo and di-μ-sulfido molybdenum(V) compounds has been widely developed;[1] however, the reports of μ-oxo-μ-sulfido molybdenum(V) compounds are yet relatively rare.[2,3] Cotton and Morehouse[4] reported the structure of di-μ-oxo oxalato complex of $[Mo_2O_4(ox)_2(H_2O)_2]^{2-}$, and that of the di-μ-sulfido oxalato complex of $[Mo_2O_2S_2(ox)_2(H_2O)_2]^{2-}$ was determined by McDonald.[5]

Now we report here the preparation and X-ray structure of the potassium salt of μ-oxalato-(*O*,*O*′,*O*″,*O*‴)-bis{μ-oxo-μ-sulfido-bis[(oxalato)oxomolybdate(V)]}.

Experimental

Preparation of a Solution of μ-Oxo-μ-sulfido-bis[triaquaoxomolybdenum(V)], $[Mo_2O_3S(H_2O)_6]^{2+}$. The aqua complex was prepared by dissolving the corresponding cysteinato complex, $Na_2[Mo_2O_3S(cys)_2]\cdot 5H_2O$[2] in 1 M (1 M=1 mol dm^{-3}) perchloric acid followed by the Sephadex G-10 column separation, which gave three bands. The first and third effluents were proved to involve $[Mo_2O_4(H_2O)_6]^{2+}$ and $[Mo_2O_2S_2(H_2O)_6]^{2+}$, respectively, as evidenced by the UV and visible spectroscopy.

The second effluent was further purified by the use of cation exchange resin Dowex 50W-X2, on which the complex was sorbed and washed with 0.1 M $HClO_4$ and eluted with 2 M $HClO_4$. The analysis of the effluent (Mo: S=2.03: 1) suggests that this is $[Mo_2O_3S(H_2O)_6]^{2+}$.[6a]

Preparation of Potassium μ-oxalato-(O, O′, O″, O‴)-bis{μ-oxo-{μ-sulfido-bis[(oxalato)oxomolybdate(V)]} Decahydrate, $K_6[\{Mo_2O_3S(ox)_2\}_2(ox)]\cdot 10H_2O$. The preparative method of the sample is similar to that of the di-μ-sulfido-bis[aqua(oxalato)-oxomolybdate(V)];[6a] the addition of oxalic acid ($H_2ox/Mo=1.2$) to *e.g.* 250 ml of the $Mo_2O_3S^{2+}$ aqua dimer solution (0.0264 M in 1 M $HClO_4$)[6b] and neutralization to pH *ca.* 3 by the addition of *ca.* 10 M KOH solution. The solution was cooled, filtered, and rotary-evaporated to the volume of *ca.* 70 ml. After one gram of KCl was added, the solution was cooled for some time in an ice bath and then filtered. The filtrate was made turbid by the addition of ethanol and kept in a refrigerator overnight. The resulting orange crystals were filtered and washed successively with ethanol and diethyl ether. Yield 2.6 g. Found: C, 8.67; H, 1.20%. Calcd for $C_{10}H_{20}K_6Mo_4O_{36}S_2$: C, 8.56; H, 1.44%.

Data Collection. The crystal employed for data collection was approximately $0.20\times 0.15\times 0.15$ mm in dimension with well defined faces. Crystal data: $C_{10}H_{20}K_6Mo_4O_{36}S_2$, $M=1398.72$, monoclinic, $a=13.640(3)$, $b=20.296(3)$, $c=15.213(4)$ Å, $\beta=106.42(2)°$, $V=4039.8$ Å^3, $D_m=2.29$ g cm^{-3}, $Z=4$, $D_c=2.30$ g cm^{-3}, space group C2/c, λ(Mo *Kα*)=0.7107 Å, and μ(Mo *Kα*)=20.1 cm^{-1}. Intensity data ($2\theta\leqslant 55°$) were collected on a Phillips 1100 four-circle diffractometer using graphite-monochromatized Mo *Kα* radiation with ω-scan technique. The scan range was 1.20°, and the scan speed, 0.033° s^{-1}; the background was counted for half of the scan time at each end of the scan. The three standard reflections 600, 080, and 008, monitored every 360 min showed no appreciable decay. A total of 4793 reflections were collected, of which 3552 with $F_o^2\geqslant 3\sigma(F_o^2)$ were used for the structure analysis. No correction was made for absorption.

Structure Determination and Refinement. The two molybdenum atoms were located from a Patterson synthesis and the remaining non-hydrogen atom positions were obtained from successive difference-Fourier calculations. The electron density of one potassium ion indicated disorder. It was possible, however, to resolve the ion into two with an ocucpancy factor of 0.5 (*K*(1) and K(2)). The block-diagonal least-squares refinement with anisotropic temperature factors for all non-hydrogen atoms gave $R=0.048$ and $R'=[\sum w\Delta F^2/\sum wF_o^2]^{1/2}=0.060$. The function minimized was $\sum w(F_o-F_c)^2$, where $w=\sigma^{-2}$ (F_o) was used. All the parameter shifts were less than 0.3 σ except for O(1) (0.8 σ) and O(4) (0.4 σ). A final difference Fourier map revealed no peaks greater than 0.9 e Å^{-3}. The positions of hydrogen atoms of water of crystallization could not be found unequivocally. The atomic scattering factors, with correction for anomalous dispersion of Mo^0, K^{+1}, and S were taken from Ref. 7. The F_o-F_c table and the anisotropic thermal parameters are preserved by the Chemical Society of Japan (Document No 8251). Most of the computation were carried out by the Melcom Cosmo 700 III computer at Okayama University of Science. The programs used included a local version of the UNICS.[8]

Results and Discussion

Peak positions of UV-visible spectra of $[Mo_2O_3S(H_2O)_6]^{2+}$ and $[\{Mo_2O_3S(ox)_2\}_2(ox)]^{6-}$ are as follows: $[Mo_2O_3S(H_2O)_6]^{2+}$ (per dimer),[9] 220_{sh}(ε=5600), 278 (3950), 314(3250), 450_{sh}(57) nm; $[\{Mo_2O_3S(ox)_2\}_2(ox)]^{6-}$ (per tetramer), 280(ε=13600), 320_{sh}(10400), 470_{sh}(220) nm. Addition of cysteine or $Na_2H_2edta\cdot 2H_2O$ to the $[Mo_2O_3S(H_2O)_6]^{2+}$ solution and neutralization to pH *ca.* 6 gave $[Mo_2O_3S(cys)_2]^{2-}$ and $[Mo_2O_3S(edta)]^{2-}$, respectively, and this can confirm the existence of μ-oxo-μ-sulfido molybdenum(V) dimer. The $[Mo_2O_3S(H_2O)_6]^{2+}$ aqua dimer is not so stable as the $[Mo_2O_2S_2(H_2O)_6]^{2+}$ is; the solution of the former gives yellow precipitates in a week even in a refrigerator.

It is interesting that the order of elution from Sephadex G-10 column depends on the number of the sulfur atoms in the bridge, possibly being due to difference in molecular size which will give three bands in the separation column (see Experimental).

The atomic coordinates, and bond lengths and bond angles are listed in Tables 1 and 2, respectively.

The complex anion contains two $Mo_2O_3S(ox)_2$ moieties bridged by an oxalato ligand as shown in Fig. 1. The midpoint of C–C bond of the bridging oxalato ligand lies on the crystallographic center of symmetry at (−1/4, 1/4, 0) and the complex anion has an approximate mirror plane which passes through six atoms, *viz*, two μ-S's, two μ-O's, and two carbon atoms of the bridging oxalato ligand; thus the tetramer has an approximate C_{2h} symmetry.

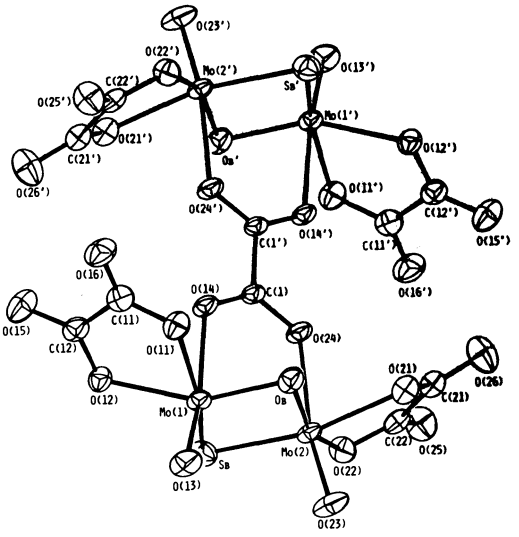

Fig. 1. Molecular structure of $[\{MO_2O_3S(ox)_2\}_2(ox)]^{6-}$ showing 50% probability ellipsoids of thermal vibration. The primed atoms are centrosymmetric of the unprimed ones.

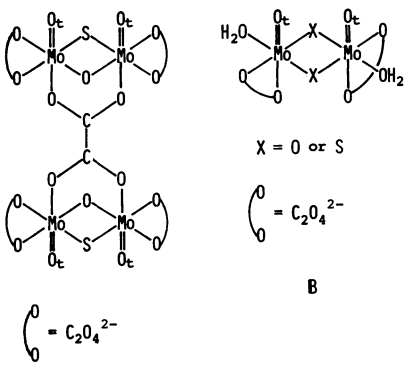
The mode of ligation of the oxalato ligand in this complex (**A**) is different from those of the di-μ-oxo and di-μ-sulfido oxalato complex anions (**B**), but rather similar to that of the di-μ-oxo malonato complex, $K_6[\{Mo_2O_4(mal)_2\}_2(ox)]\cdot 4H_2O$ (**C**), where two types of malonato ligands are existent; one is bidentate and the other is quadridentate.[10] The reason why the oxalato ligand has such a coordination mode in the



A B C

μ-oxo-μ-sulfido complex is not clear at present; the use of less amount of oxalic acid ($H_2ox/Mo=1.0$, see Experimental) also gives the same type of complex, though the yield is low.

Each molybdenum atom in the tetramer has distorted octahedral environment, disregarding any Mo–Mo bonding included in the coordination sphere: two oxygen atoms of a bidentate oxalato ligand and bridging sulfur and oxygen atoms in the equatorial plane, a terminal oxygen and one of the bridging quadridentate oxalato ligand oxygens. In the $Mo_2O_3S(ox)_2$ moiety, two terminal oxygen atoms are *cis* to each other.

The present Mo–Mo bond distance 2.667(1) Å is close to those of $[Mo_2O_3S(p_rdtc)_2]$ (2.673(3) Å)[11] and $[Mo_2O_3S(pdta)]^{2-}$ (2.656(1) Å)[12] and also to the mean value (2.681 Å) of the di-μ-oxo and di-μ-sulfido oxalato complexes.

While no trans influence due to the multiply-bonded terminal oxo ligand was observed for both the di-μ-oxo and di-μ-sulfido exalato complexes, evident lengthening of the Mo–O bond trans to the terminal oxo ligand is observed as seen in Table 3. It seems that, if one oxalato ligand occupies both the trans and cis positions to the multiply-bonded terminal oxygen as in **B**, no trans influence is observed, whereas, in case the trans and cis positions are occupied by the two respective oxalato ligands as in **A**, trans influence can be found.

The angle O_t–Mo–O (trans to O_t, 170.8(2) and 170.3(2)°) and the dihedral angle (168.5°) defined by O_B, Mo(1), S_B and O_B, Mo(2), S_B planes are considerably larger than those of di-μ-oxo and di-μ-sulfido oxalato complexes (Table 3). These enlargement may be caused by the coordination of the bridging oxalato anion as a quadridentate ligand.[10] This fact indicates that the present way of occupation of the sixth coordination position trans to O_t will give a remarkable influence to the coordination geometry, the existence of trans influence of O_t being overcome.

There is slight trans influence of the bridging sulfur; bond lengths of Mo–O (trans to μ-S) are 2.112(4) and 2.120(4) Å, and those of Mo–O (trans to μ-O) are 2.102(4) and 2.093(4) Å.

(D) Plane through SB, OB, O(21), and O(22):
Mo(2) −0.387, SB 0.005, OB −0.005, O(21) 0.006, O(22) −0.006
Equation of planes (Orthogonalized coordinates)
(A) $0.8937x-0.4481y-0.0226z+1.4469=0$
(B) $-0.8711x-0.4774y-0.1152z+3\ 3196=0$
(C) $0.9839x-0.1785y-0\ 0023z+0\ 8313=0$
(D) $-0\ 9808x-0\ 1881y-0\ 0514z+1\ 0281=0$

O(22), C(21), and C(22) are coplanar, the largest deviation from the plane being 0.075 Å. The molybdenum atoms are displaced (0.371 and 0.387 Å) toward terminal oxygens from the basal planes (Table 4).

The potassium ions are coordinated by four to seven oxygen atoms within the range of 2.7—2.9 Å. All water oxygens (from O(1) through O(4)) except O(5) coordinate to potassium ions, and O(5) is close to O(1) (2.992(16) Å). An additional contact is observed between O(1) and O(22) (2.924(14) Å) indicating formation of a hydrogen bond (Table 2).

We are grateful to Dr. H. Kimura for the arrangement of the program UNICS, and to Dr. K. Matsumoto for his help in the data collection.

Catalytic Activity of Planar Copper(II) Complexes for the Chemiluminescence of Luminol

Naoyasu Oishi, Masataka Takeuchi, Yuzo Nishida,* and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
(Received March 25, 1982)

Some planar binuclear copper(II) complexes showed high catalytic activity for the chemiluminescence of luminol in the presence of hydrogen peroxide compared with those of mononuclear planar copper(II) complexes. The formation of singlet O_2 in the reaction mixture of a binuclear copper(II) complex and hydrogen peroxide was assumed to play a key role in the catalytic function of the binuclear copper(II) complexes for the luminol chemiluminescence.

Since the discovery of the chemiluminescence of luminol by Albrecht,[1] many chemists have been interested in the light producing step. White *et al.*[2,3] have established the stoichiometry of the overall reactions as well as the identity of the emitting species. According to them, 3-aminophthalate is the light emitter in protic and approtic solvents.[2-5]

It is well known that hemin catalyzes the chemiluminescence of luminol very effectively in the presence of hydrogen peroxide. It was also shown that some metal complexes cause the luminol chemiluminescence though much less effectively compared with hemin.[6,7] Ojima[7] investigated the catalytic activity of copper(II) complexes for the luminol chemiluminescence, and found that some di-μ-hydroxo binuclear copper(II) complexes show high catalytic activities for the luminol chemiluminescence; howerver, he did not investigate further the function of the binuclear copper(II) complexes for the reaction.

We already showed that some planar binuclear copper(II) complexes, *e.g.*, $[Cu_2(pia)_2]$ and $[Cu_2(et\text{-}2\text{-}3)_2]^{2+}$, *etc.* (for the abbreviations of the complexes, see Fig. 1) show remarkably high reactivities in the redox reactions with ascorbic acid, catechol, *etc.*, compared with the reactivities of planar mononuclear copper(II) complexes.[8-11] More recently we[12] also found that some planar binuclear copper(II) complexes exhibit high catalytic activity for the decomposition of hydrogen peroxide ("catalase-like" function) compared with that of the planar mononuclear copper(II) complexes. These results suggest that the "catalase-like" function of the binuclear copper(II) complexes may be closely related to the specific function of the binuclear copper(II) complexes for the chemiluminescence of luminol observed by Ojima, because these experiments on the luminol chemiluminescence are usually done in the presence of hydrogen peroxide. In order to confirm the above view, in this study, we have investigated the catalytic activity of various planar copper(II) complexes for the luminol chemiluminescence.

Experimental

Materials. Copper(II) complexes cited in Fig. 1 were prepared according to the literature methods. (C),[13] (D),[14] (E),[15] (F),[16] (G),[17] (H),[18] (I),[8] and (J).[19] Luminol (Tokyo Kasei Co.) and hydrogen peroxide (Nakarai's Guaranteed Reagent, 30%) were obtained commercially.

Measurements of Chemiluminescence Intensity. The aqueous solution containing luminol (1.4×10^{-4} mol dm^{-3}), NaOH (2.8×10^{-4} mol dm^{-3}) and H_2O_2 (1.4×10^{-3} mol dm^{-3}) and the dmf solution of copper(II) complexes ($[Cu^{2+}]=2\times10^{-4}$ mol dm^{-3}) were kept standing for 1 d at 18 °C prior to the reaction. The apparatus for the measurement is shown in Fig. 2. The solution of copper(II) complex (0.5 cm^3) was mixed with the luminol solution (30 cm^3) in vessel A by injection from the syringe, and the emitted light was collected on the photomultiplier (RCA 1P28) through the lens, and recorded with a Servocorder type SR651 (Watanabe Instrument Corp.). The temperature of the room was kept at 18 °C throughout the experiments.

Results and Discussion

Some examples of the time course of luminol chemiluminescence using copper(II) complexes as catalyst are shown in Fig. 3. Planar mononuclear copper(II) complexes, such as [Cu(salen)], [Cu(J-en)], and [Cu(m-cr)]$^{2+}$ showed practically no catalytic activity for the luminol chemiluminescence. In contrast to this, planar binuclear copper(II) complexes, *e.g.*, [Cu_2(pia)$_2$], [Cu_2(et-2-3)$_2$]$^{2+}$, and [Cu_2(pc-1,3)$_2$], exhibited remarkable catalytic activities, whereas binuclear copper(II) complexes, [Cu_2(me-ox)]$^{2+}$ and [Cu_2(sal-m-phen)$_2$] showed no catalytic activity.

The luminol chemiluminescence occurs only when luminol, NaOH, H_2O_2, and a copper(II) complex are mixed in a solution, where NaOH seems to be necessary for the formation of the dianion of luminol. In Table 1 the catalytic activities of various copper(II) complexes

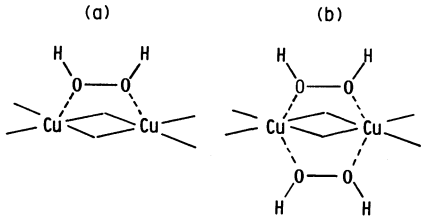

Fig. 4. The assumed intermediate complex between a binuclear copper(II) complex and H_2O_2.

[Cu_2(dpl)$_2$]$^{2+}$	$t_{1/2}\approx 10$ min[d]	50
[Cu_2(pc-1,3)$_2$]	$t_{1/2}<0.2$ min	290
[Cu_2(me-ox)]$^{2+}$	a)	a)
[Cu_2(sal-m-phen)$_2$]	a)	a)

a) Practically zero. b) $t_{1/2}$ denotes the half-life time of H_2O_2 in the reaction mixture of a copper(II) complex and ten times excess of H_2O_2 in methanol at 25°C. c) This denotes the highest value of chemiluminescence intensity (*cf.* Fig. 3). d) In water.

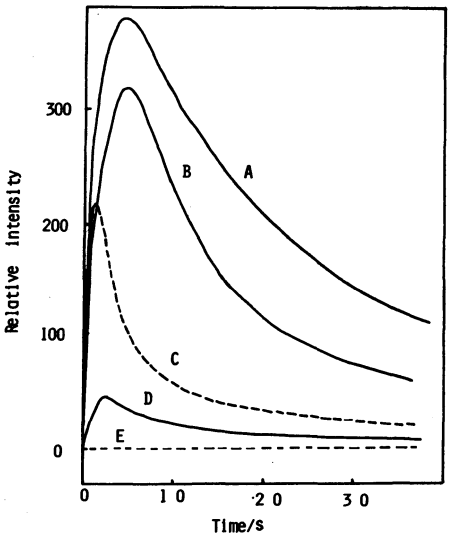

Fig. 3. Chemiluminescence intensity as a function of time. A: [Cu_2(salpa)$_2$]$^{2+}$, B: [Cu_2(et-2-3)$_2$]$^{2+}$, C: [Cu_2(pia)$_2$], D: [Cu_2(dpl)$_2$]$^{2+}$, E: [Cu(salen)].

for the decomposition of hydrogen peroxide[12] and for the luminol chemiluminescence are shown. It is obvious from the data that the catalytic functions of copper(II) complexes for the decomposition of hydrogen peroxide and for the luminol chemiluminescence are paralell (at least qualitatively) with each other. These facts suggest that the decomposed product of H_2O_2 in the reaction mixture plays a key role in the luminol chemiluminescence.

The decomposition reaction is essentially a redox-disproportionation reaction between two H_2O_2 molecules *e.g.*,

$$2H_2O_2 \longrightarrow 2H_2O + O_2.$$

However, the rate of the reaction is very slow in the absence of catalysis. In the preliminary report,[12] we discussed the catalytic function of binuclear copper(II) complexes for the decomposition of hydrogen peroxide, and assumed that the first step is the formation of a H_2O_2 complex as depicted in Fig. 4-a and the second step is the approaching of another H_2O_2 molecule to the vacant site of the H_2O_2-binuclear complex, forming the intermediate complex as shown in Fig. 4-b; the third step is the two-electron transfer from one H_2O_2 molecule to another through the copper atoms, resulting in a formation of O_2 and $2H_2O$. In the cases of [Cu_2(me-ox)]$^{2+}$ and [Cu_2(sal-m-phen)$_2$], the formation of the intermediate complex is impossible because of the long Cu–Cu distance.[8,12] This may explain the very low catalytic activity of these complexes for the decomposition of hydrogen peroxide.

In the intermediate complex as shown in Fig. 4-a or 4-b, a H_2O_2 molecule bidentately coordinates to the two copper(II) ions with its nonbonding filled 2p orbitals. When two electrons are transfered from the peroxide to the two copper(II) ions, a single electron is left in each oxygen 2p orbital which was used for the coordination. These orbitals will immediately form a π bond pairing the electron spins, because the two Cu–O

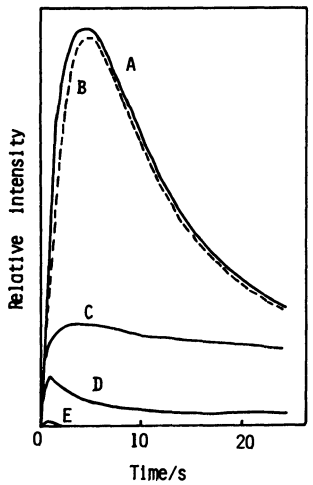

Fig. 5. Chemiluminescence intensity in the $[Cu_2(et\text{-}2\text{-}3)_2]^{2+}$ system in the presence of DABCO (R=[DABCO]/[Luminol]). A: R=0, B: R=100, C: R=1000, D: R=2500, E: R=10000.

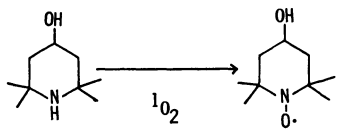
bonds should be nearly paralell to each other due to the steric requirement of the Cu_2–O_2 bonding system. Thus, the H_2O_2 molecule will become a singlet dioxygen molecule losing two protons. Accordingly, it seems that singlet dioxygen molecule (denoted as $^1O_2$ hereafter) plays a key role in the catalytic function of the binuclear copper(II) complexes for the luminol chemiluminescence.

It is well known that $^1O_2$ reacts with luminol to induce chemiluminescence. Thus, we have measured the luminol chemiluminescence in the NaClO–H_2O_2 system, because the NaClO–H_2O_2 system is one of the simplest ways to generate $^1O_2$ in the laboratory.[20] The luminol chemiluminescence was observed in the NaClO–H_2O_2 system, as expected. When a large excess of 1,4-diazabicyclo[2.2.2]octane (DABCO, one of the scavenger[21] of $^1O_2$) was added to this system, the intensity of chemiluminescence was greatly quenched. This fact indicates that the luminol chemiluminescence in the NaClO–H_2O_2 system is caused by the generation of $^1O_2$ in this system.[22] In Fig. 5, the time courses of luminol chemiluminescence in the presence of $[Cu_2(et\text{-}2\text{-}3)_2]^{2+}$ and DABCO are shown. These clearly indicate that the intensities of luminol chemiluminescence by $[Cu_2(et\text{-}2\text{-}3)_2]^{2+}$ are greatly depressed by the presence of DABCO, similarly to the case of the NaClO–H_2O_2 system. Such a quenching effect by DABCO was also observed for all the luminol chemiluminescence catalyzed by the binuclear copper(II) complexes examined in this study.

It is well known that 2,2,6,6-tetramethyl-4-piperidinol reacts with $^1O_2$ to yield the nitroxide radical, as shown below.[23] We could observe the ESR signal due to the nitroxide radical in the reaction mixture of a binuclear copper(II) complex (*e.g.*, $[Cu_2(pia)_2]$), H_2O_2 and 2,2,6,6-tetramethyl-4-piperidinol. Thus, we may conclude that the $^1O_2$ produced by the simultaneous two-electron transfer from H_2O_2 to two copper(II) ions plays a key role in the catalytic function of the binuclear copper(II) complexes for the luminol chemiluminescence.



The present authors wish to express their sincere thanks to Prof. R. Shimada (Kyushu University) for his kind advices in setting up the apparatus for the measurements of chemiluminescence intensity.

Metal Complexes of Peptides. III. The Preparation and Properties of Diammine(oligopeptidato)cobalt(III) Complexes

Hiroshi KAWAGUCHI,* Mari ISHII, Tomoharu AMA, and Takaji YASUI
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
(Received March 26, 1982)

Complexes of the [Co(tripeptidato)$(NH_3)_2$] and NH_4[Co(tetrapeptidato)$(NH_3)_2$] types (tripeptidato and tetrapeptidato denote the tri- and tetraanions of the coordinating peptides respectively) have been prepared and characterized by means of their electronic, ^{1}H NMR, and circular dichroism (CD) spectral data. In the NH_4-[Co(tetrapeptidato)$(NH_3)_2$] complex, the peptide coordinates to cobalt(III) as a quadridentate ligand through the nitrogens of an amino and three amide groups. The additivity of the vicinal CD spectra has been found to hold for the complexes of a series of tripeptides containing L-alanine and/or glycine residue. These tri- and tetrapeptidato complexes in water easily undergo aquation reaction, releasing the ammonia molecule.

A number of oligopeptide complexes of metals, such as Cu(II, III), Ni(II, III), and Pd(II), have been reported in which the peptides coordinate as quadridentate chelates.[1–16] Although the preparations of the cobalt(III) complexes with tri- or tetrapeptides have been reported in the literature,[17–22] there have been only two reports of the cobalt(III) complexes with a peptide coordinated as a quadridentate chelate.[21,22] Manyak *et al.* reported on the [Co(gly–gly–gly)$(NH_3)_2$] and Na[Co(gly–gly–gly)(gly)] complexes (gly–gly–gly denotes the trianion of glycylglycylglycine), in which the three chlate rings of the peptide were noncoplanar.[21] As X-ray structural studies have shown that the peptide group retains its rigid planar structure upon coordination,[23–27] the structure postulated by Manyak *et al.* is thought to be very unlikely. The complex [Co(gly–gly–gly)$(NH_3)_2$] described by them was rose in color and so different from the present complex (brown in color) with the same chemical formula. Evans *et al.* have prepared diammine(tripeptidato)cobalt(III) complexes in which the peptides coordinate as a coplanar quadridentate chelate and discussed in detail the effects of chelation on the ^{13}C and ^{1}H NMR resonances of peptides.[22]

Our recent works concerning dipeptidato complexes have shown that the [Co(*N*-methyliminodiacetato)-(dipeptidato)]$^-$ type of complex exhibits novel spectral behavior in the d-d transition region,[28] and that the absolute configurations of bis(dipeptidato)cobaltate(III) complexes can be determined on the basis of their CD patterns in the range of 40000 to 50000 cm^{-1}.[29] In the present paper, we wish to report the preparation and spectroscopic properties of the cobalt(III) complexes with a series of tri- and tetrapeptides in which the peptides coordinate as quadridentate chelates.

Experimental

Ligands. Glycylglycylglycine (H_3gly–gly–gly) was synthesized according to the literature.[30a]

L-Alanyl-L-alanyl-L-alanine (H_3L-ala–L-ala–L-ala) was prepared by a combination of conventional techniques, starting with *N*-benzyloxycarbonyl-L-alanine (Z-L-ala)[30b] and L-alanine ethyl ester hydrochloride (L-ala–OEt·HCl).[30c] Dicyclohexylcarbodiimide (DCC) coupling was used to form a dipeptide derivative from these precursors.[30d] The dipeptide ethyl ester was formed by the reaction of Z-L-ala–L-ala–OEt with HBr–acetic acid (25%). It was then coupled with another equivalent of Z-L-ala, again using DCC. The tripeptide hydrobromide was formed by the reaction of Z-L-ala–L-ala–L-ala–OEt with an aqueous NaOH solution and then with HBr–acetic acid. The free peptide was obtained by the action of aqueous NH_3 on the tripeptide hydrobromide and was then recrystallized from the EtOH–water system.

Other tripeptides, L-alanyl-L-alanylglycine (H_3L-ala–L-ala–gly), L-alanylglycyl-L-alanine (H_3L-ala–gly–L-ala), glycyl-L-(alanyl-L-alanine (H_3gly–L-ala–L-ala), L-alanylglycylglycine (H_3L-ala–gly–gly), glycyl-L-alanylglycine (H_3gly–L-ala–gly), glycylglycyl-L-alanine (H_3gly–gly–L-ala), β-alanylglycylglycine (H_3β-ala–gly–gly), glycyl-β-alanylglycine (H_3gly–β-ala–gly), and glycylglycyl-β-alanine (H_3gly–gly–β-ala), were also prepared by the same procedure as that used for H_3L-ala–L-ala–L-ala.

The same DCC coupling method was used for the syntheses of tetrapeptides. In the case of glycyl-L-alanylglycylglycine (H_4gly–L-ala–gly–gly), the tetrapeptide derivative, Z–gly–L-ala–gly–gly–OEt, was prepared by the action of Z–gly with L-ala–gly–gly–OEt, but for the other tetrapeptides, L-alanylglycylglycylglycine (H_4L-ala–gly–gly–gly), glycylglycyl-L-alanylglycine (H_4gly–gly–L-ala–gly), glycylglycylglycyl-L-alanine (H_4gly–gly–gly–L-ala), β-alanylglycylglycylglycine (H_4β-ala–gly–gly–gly), glycyl-β-alanylglycylglycine (H_4gly–β-ala–gly–gly), glycylglycyl-β-alanylglycine (H_4gly–gly–β-ala–gly), and glycylglycylglycyl-β-alanine (H_4gly–gly–gly–β-ala), the corresponding peptide derivatives were prepared by coupling Z-dipeptide with dipeptide–OEt.

Preparations of Complexes. [*Co(tripeptidato)(NH$_3$)$_2$*]·x*H$_2$O*: This type of complex was prepared by two different methods.

(1): A solution of tripeptide (5 mmol) in aqueous 1 M† NaOH (5 cm^3) was added to a DMSO solution (50 cm^3) containing[Co$(NH_3)_5(H_2O)](ClO_4)_3\cdot H_2O$[31] (2.48 g, 5 mmol); the mixed solution was heated at *ca.* 50 °C with constant stirring. Ammonia was evolved, and after *ca.* 1 h brown precipitates started to separated out. After additional heating for a few hours, the reaction mixture was allowed to stand in a refrigerator overnight. The brown precipitates obtained by filtration were dissolved again in a minimum amount of water, and then the aqueous solution was chromatographed on a Sephadex G-10 column (3.5 cm × 80 cm), with water as the eluant, giving three bands. The first (red-brown) and third (pink) descended bands were rejected. The desired complex was isolated as crystalline powder from the eluate of the second band on the addition of a large amount of acetone; it was then dried over $CaCl_2$. The diammine(tripeptidato)cobalt(III) complexes with the following peptides: H_3gly–gly–gly, H_3L-

ala–gly–gly, H_3gly–L-ala–gly, H_3gly–gly–L-ala, $H_3\beta$-ala–gly–gly, H_3gly–β-ala–gly, and H_3gly–gly–β-ala, were prepared by this method.

(2): In the present paper, a series of diammine(tripeptidato)cobalt(III) complexes were also prepared by modifying the method described in the literature.[22]

Tripeptide (3.4 mmol) was dissolved in 10 cm^3 of water, and the solution was adjusted to pH 9.0—9.5 with a 28% NH_3 solution. A fresh peroxo-dimer, $[(NH_3)_5CoO_2Co(NH_3)_5](NO_3)_4\cdot 2H_2O$, was added to the above peptide solution chilled in an ice bath with constant stirring. After stirring for *ca.* 2 h, the solution was allowed tostand in a refrigerator for one day. The resulting solution was filtered, and the red-brown filtrate was chromatographed on a Sephadex G-10 column (3.5 cm × 80 cm). The adsorbed band was separated into brown (main) and pink (a little) bands by elution with water. To the eluate from the brown band was added a large amount of acetone. The desired complex was then deposited by allowing the solution to stand overnight at room temperature; it was filtered, washed with acetone, and then dried over $CaCl_2$. This preparative method was used for all of the [Co(tripeptidato)$(NH_3)_2$] complexes presented here.

NH_4[Co(tetrapeptidato)$(NH_3)_2]\cdot xH_2O$: The preparation of this type of complex was carried out by the same method as (2) described above, except for the addition of a small amount of aqueous NH_3 (28%) prior to adding acetone. As the reaction of tetrapeptide with a peroxo-dimer was slower than that of tripeptide, the reaction solution was allowed to stand for two day in a refrigerator. Standing for more than two days gave a larger amount of another red-brown by-product (probably an aqua complex), which was eluted faster than the desired complex on a Sephadex G-10 column. The gly–gly–L-ala–gly, gly–gly–β-ala–gly, and gly–gly–gly–β-ala complexes were rechromatographed on a Bio-Gel P2 column (3.5 cm × 30 cm), with water as an eluant to ensure the purity. Despite such a procedure, these complexes separated out as syrup products for which the analytical data were unsatisfactory.

The analytical data for the [Co(tripeptidato)$(NH_3)_2$] and NH_4[Co(tetrapeptidato)$(NH_3)_2$] complexes are listed in Table 1.

Measurements. The absorption and CD spectra were measured by means of a Hitachi 557-type spectrophotometer and a JASCO J-22 spectropolarimeter respectively. The proton NMR were recorded on a JEOL MH-100 spectrometer, with DSS as the internal reference.

Results and Discussion

Although the reaction of tripeptide with an equimolar quantity of pentaammineaquacobalt(III) complex in DMSO yielded the desired product, the same reaction in water gave unsatisfactory results; many bands appeared when the reactant solution was chromatographed on a Sephadex G-10 column. As the [Co(tripeptidato)$(NH_3)_2$] type of complex is more labile in water than other ammine complexes such as [Co(dipeptidato)$(NH_3)_3]^+$, presumably the complicated consecutive reactions must occur in water. On the other hand, the [Co(tripeptidato)$(NH_3)_2$] complex is only slightly soluble in DMSO, being protected from the consecutive reactions. With H_3gly–gly–gly, H_3L-ala–gly–gly, H_3gly–L-ala–gly, H_3gly–gly–L-ala, $H_3\beta$-ala–gly–gly, H_3gly–β-ala–gly, and H_3gly–gly–β-ala, the preparative method in DMSO (Method (1)) was applied; however, the yields of the complexes depended on the sort of peptides: in the cases of the gly–gly–L-ala and gly–gly–β-ala complexes, the yields were below half of that for the gly–gly–gly complex. The application of this method to the preparation of the NH_4[Co(tetrapeptidato)$(NH_3)_2$] type of complex was unsuccessful.

The preparative method using the peroxo-dimer (Method (2)) gave constantly high yields of the desired products for all the tripeptides used here. When the reactant solution was chromatographed on a Sephadex G-10 column, two completely separated bands were usually observed, but in some cases, *e.g.*, in the [Co(gly–gly–β-ala)$(NH_2)_2$] complex, another red-brown band, which is presumably an aqua complex, was eluted earlier than the desired band. As the [Co(tripeptidato)$(NH_3)_2$] type of complex is relatively labile in water, as will be described below, rechromatography to ensure purity causes an aquation reaction and brings about a low yield, even though aqueous ammonia was used as an

AB: AB pattern resonance, s: singlet, d: doublet, q: quartet, br: slightly broad. a) Observed as a triplet-like broad peak.

eluant. The major disadvantage of this method is that the yield of the desired complex significantly depends on the purity of the peroxo-dimer used as a starting material.

The reaction of the peroxo-dimer with H_4gly-gly-gly-gly afforded a high yield of the desired complex, NH_4[Co(gly-gly-gly-gly)$(NH_3)_2$], as needle crystals. The same reactions with H_4gly-L-ala-gly-gly, H_4gly-gly-gly-L-ala, $H_4\beta$-ala-gly-gly-gly, and H_4gly-β-ala-gly-gly also produced considerable quantities of the desired complexes, which were liable to separate out as syrup products upon the addition of acetone to the eluates from Sephadex G-10 columns. Fortunately, we could isolate these complexes as crystalline products by allowing the acetonic suspensions to stand at room temperature for several days. In the cases of H_4L-ala-gly-gly-gly, H_4gly-gly-L-ala-gly, H_4gly-gly-β-ala-gly, and H_4gly-gly-gly-β-ala, the reaction of these peptides with the peroxo-dimer gave a large amount of by-products. The precipitation of the diammine(tetrapeptidato)cobaltate(III) complex by adding acetone under weak acidic conditions (pH 3—4) gave the protonated complex, H[Co(tetrapeptidato)$(NH_3)_2$]·$x H_2O$.

^{1}H NMR. Evans *et al.* prepared seven kinds of the [Co(tripeptidato)$(NH_3)_2$] type of complexes in which the peptides coordinate through the terminal NH_2, two amide N, and terminal CO_2^- groups and reported ^{1}H and ^{13}C NMR data in D_2O for the complexes.[22] Figure 1 shows a comparison among the ^{1}H NMR spectra of [Co(gly-gly-gly)$(NH_3)_2$], [Co(L-ala-gly-gly)$(NH_3)_2$], [Co(gly-L-ala-gly)$(NH_3)_2$], and [Co(gly-gly-L-ala)$(NH_3)_2$] complexes in slightly basic D_2O. The spectrum of [Co(gly-gly-gly)$(NH_3)_2$] shows three singlet peaks due to three CH_2 groups at 3.72, 3.93, and 4.18 ppm, suggesting that the chelate rings of the peptide are coplanar. The singlet peaks at 3.88 and 4.11 ppm in the L-ala-gly-gly complex correspond to those at 3.93 and 4.18 ppm respectively in the gly-gly-gly complex. Therefore, these peaks can be assigned to either the C-terminal or central CH_2 of the tripeptide ligand. Similar relationships are also found between the gly-gly-gly complex and the gly-L-ala-gly or gly-gly-L-ala complex (Fig. 1 and Table 2). These results indicate that the N- and C-terminal CH_2 of the tripeptide

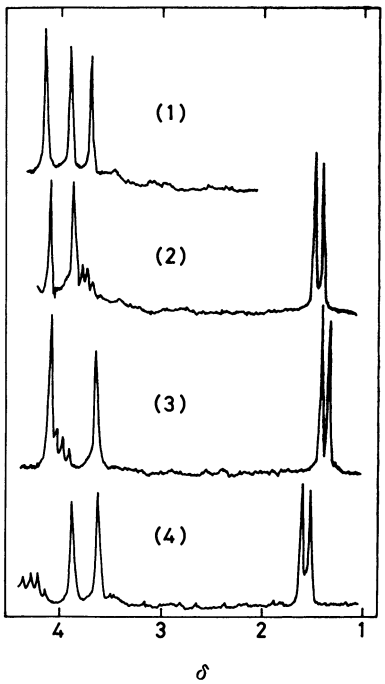

Fig. 1. The ^{1}H NMR spectra of [Co(gly-gly-gly)$(NH_3)_2$] (1), [Co(L-ala-gly-gly)$(NH_3)_2$] (2), [Co(gly-L-ala-gly)$(NH_3)_2$] (3), and [Co(gly-gly-L-ala)$(NH_3)_2$] (4) in slightly basic D_2O.

ligand resonate at the highest and lowest magnetic fields respectively; thus we are able to assign each peak. The same relationship is also realized for the complexes of the tripeptides containing the glycine and/or β-alanine residue (Table 2). Each spectrum of the β-ala–gly–gly, gly–β-ala–gly, and gly–gly–β-ala complexes exhibited two broad triplet-like peaks due to the $-CH_2-CH_2-$ group. The same pattern of the signals has been observed in the complexes of dipeptides containing the β-alanine residue.[28,29] An examination of the molecular models indicates that the tripeptides containing the β-alanine residue can coordinate to cobalt(III) in a noncoplanar configuration (*cis*-α); however, the possibility of the noncoplanar form can be rejected on the basis of the fact that the signals due to the CH_2 groups of glycine residues are singlets in these complexes. For the complexes of the tripeptides containing two or three L-alanine residues, the methine signals can be assigned on the basis of a comparison of the chemical shifts; in these complexes, the N- and C-terminal >CH– of the peptide ligands resonate at the highest and lowest magnetic fields respectively. The regular trend in chemical shifts is also observed for the CH_3 signals of the tripeptidato complexes containing the L-alanine residue, making it possible to assign those signals: the signals at 1.36—1.40, 1.45—1.47, and 1.55—1.58 ppm are assigned to central, N-terminal, and C-terminal CH_3 respectively. The ^1H NMR data of the [Co(tripeptidato)$(NH_3)_2$] complexes are also listed in Table 2.

In the present study, the [Co(gly–L-ala–L-ala)$(NH_3)_2$] complex is the only example in which the CH_2 protons are inequivalent at 100 MHz. The CH_2 signal of the L-ala–gly–L-ala complex is also a slightly broad singlet at 100 MHz, indicating a tendency toward splitting.

Absorption Spectra. Figure 2 shows the absorption spectra of the [Co(gly–gly–gly)$(NH_3)_2$] and [Co(gly–β-ala–gly)$(NH_3)_2$] complexes. The former complex

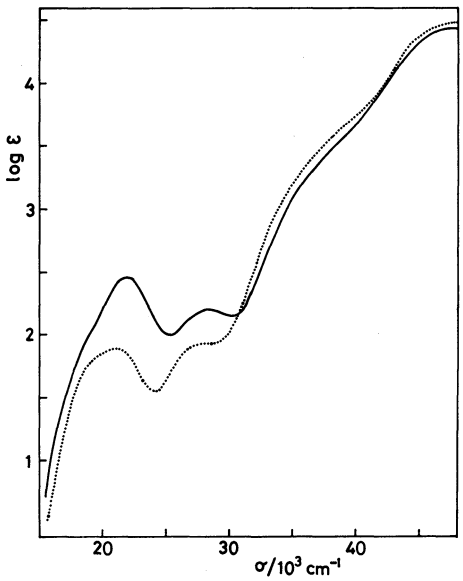

Fig. 2. The absorption spectra of [Co(gly–gly–gly)$(NH_3)_2$] (——) and [Co(gly–β-ala–gly)$(NH_3)_2$] (------) in water.

exhibits the characteristic spectrum for the complex containing chelated peptide: the first band at 21880 cm^{-1} has an enhanced intensity (ε=292 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$) in contrast with the second band. The ratio of the absorption coefficients for the first and second bands ($\varepsilon_1/\varepsilon_{11}$) of [Co(gly–gly–gly)$(NH_3)_2$] (2.14) is higher than that for [Co(gly–gly)$(NH_3)_3]^+$ (1.8),[32] but lower than that for [Co(gly–gly)$_2]^-$ (3.98).[29] A split component in the first band region for the [Co(gly–gly–gly)$(NH_3)_2$] complex is observed as a shoulder band at *ca.* 18200 cm^{-1}. The absorption spectra of other diammine(tripeptidato)cobalt(III) complexes, where the tripeptides are composed of only α-amino acid residues, are

a) sh: Shoulder.

quite similar to that of the [Co(gly–gly–gly)$(NH_3)_2$]; the spectral data are listed in Table 3. The [Co(β-ala–gly–gly)$(NH_3)_2$] and [Co(gly–gly–β-ala)$(NH_3)_2$] complexes also showed spectral patterns almost identical with that of the gly–gly–gly complex, indicating that the spectra are little affected by the exchanges of the CH_2 group with the $-CH_2-CH_2-$ group in the N- and C-terminal fragments of tripeptides (Table 3). As is shown in Fig. 2, however, the [Co(gly-β–ala–gly)-$(NH_3)_2$] complex shows remarkably different absorption behavior in the d-d transition region, compared with that of other [Co(tripeptidato)$(NH_3)_2$] complexes: The first band is broad (showing splitting) and has a relatively weak intensity ($\varepsilon=77$ dm^3 mol^{-1} cm^{-1}).

In our previous works,[28,29] we reported that the complexes with dipeptides containing the N-terminal β-alanine residue were different in the spectral behavior of the d-d transition from the complexes with dipeptides containing the N-terminal α-amino acid residue. In the present case, the gly–β-ala–gly complex differs from the other tripeptidato complexes in spectral behavior. Such a difference in spectral behavior may arise from the differences in electronic delocalization around the peptide backbone and in the ring strain of the chelated peptide. The electronic delocalization and the ring strain must be affected by the position of the β-alanine residue in the peptide chain, even though simple molecular models provide no obvious reasons for this.

The first band maxima of the complexes with tripeptides containing the β-alanine residue shift to the lower-energy side compared with that of the gly–gly–gly complex. Such a blue shift is contrary to the red shifts observed for the copper(II) complexes of di- and tripeptides containing the β-alanine residue[33,34] and also for the cobalt(III) complexes of dipeptides containing the β-alanine residue.[29]

CD Spectra. In the case of the tetragonal coordination of tripeptides containing only α-amino acid residues to cobalt(III), the chelate rings of the peptide ligand are expected to take a coplanar form, ruling out any configurational and conformational contributions to optical activity. Therefore, the sole source of optical activity in the d-d transition region is the vicinal effect due to the asymmetric carbons.[35] As is shown in Fig. 3, the [Co(tripeptidato)$(NH_3)_2$] complexes exhibit two major negative CD bands associated with two d-d transitions in the visible region, while additional very weak positive CD components are observed at 22370 and 26210 cm^{-1} for the L-ala–gly–gly and gly–gly–L-ala complexes respectively. The numerical CD data in the d-d transition region are summarized in Table 3.

For the [Co(gly–L-ala–gly)$(NH_3)_2$] and [Co(gly–gly–L-ala)$(NH_3)_2$] complexes, the magnitudes of $\Delta\varepsilon_{ext}$ in the first band region are nearly comparable to each other, but more than twice that for the [Co(L-ala–gly–gly)$(NH_3)_2$] complex. This result is consistent with those for [Co(*N*-methyliminodiacetato)(dipeptidato)]$^-$ complexes, in which the CD contribution from the C-terminal active source is larger than that from the N-terminal one.[28] The tripeptidato complexes containing two or three asymmetric carbons show enhanced negative CD bands associated with the first d-d bands

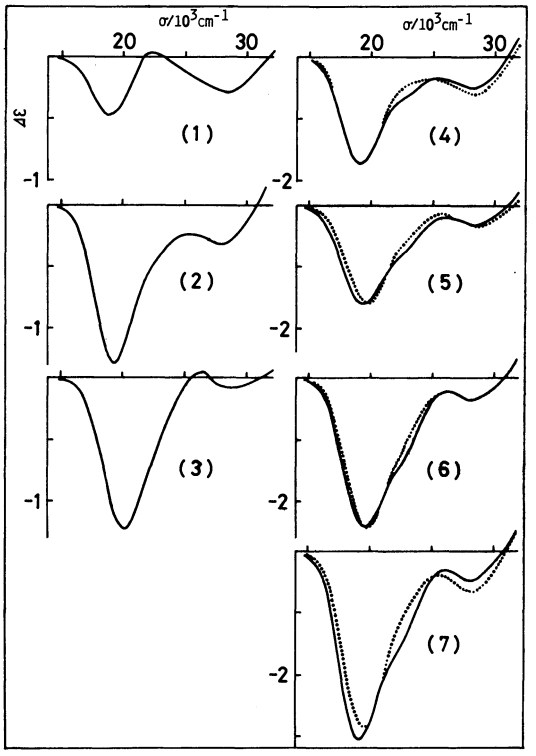

Fig. 3. The CD spectra of the type [Co(tripeptidato)-$(NH_3)_2$] in water (——). The dotted lines represent the CD curves calculated from the CD data of two (or three) tripeptidato complexes containing only one asymmetric carbon.
Tripeptidato: (1) L-ala–gly–gly, (2) gly–L-ala–gly, (3) gly–gly–L-ala, (4) L-ala–L-ala–gly, (5) L-ala–gly–L-ala, (6) gly–L-ala–L-ala, (7) L-ala–L-ala–L-ala.

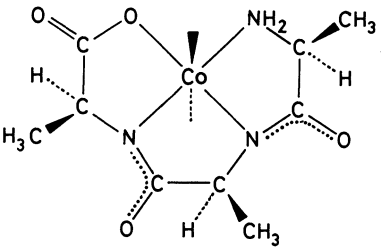

Fig. 4. The structure of [Co(L-ala–L-ala–L-ala)$(NH_3)_2$] drawn from the direction of the NH_3–Co–NH_3 axis.

(Fig. 3 and Table 3).

The dotted lines in Fig. 3 represent the CD curves calculated from the CD data of two (or three) tripeptidato complexes containing only one asymmetric carbon; *e.g.*, in the case of the L-ala–L-ala–gly complex, the dotted line represents the sum of the two CD curves observed for the L-ala–gly–gly and gly–L-ala–gly complexes. In each case, the good coincidence obtained between the observed (solid line) and calculated (dotted line) CD curves demonstrates the additivity of the vicinal contribution. Such direct comparison may be valid for the present series of complexes, because the spectral behaviors of these complexes are quite similar to each other in the d-d transition region.

Figure 4 shows the structure of the [Co(L-ala–L-ala–L-ala)$(NH_3)_2$] complex drawn from the direction of the

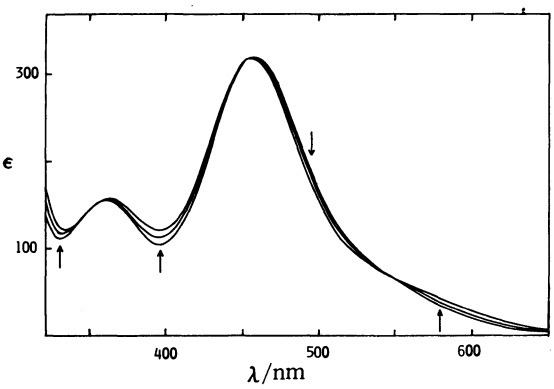

Fig. 5. Change of absorption spectrum with time for [Co(gly-gly-L-ala)$(NH_3)_2$] in water at 30.1 °C. The curves show the spectra measured at 1, 21, and 61 min, respectively.

NH_3–Co–NH_3 axis, in which two NH_3 are omitted and in which all methyl groups of the side chain are above the chelate plane. The octant rule has been proposed to account for the results of the CD signs in the visible absorption region of transition metal complexes;[36] however, the octant rule can not account for the additivity of the CD spectra of the tripeptidato complexes. Whenever the nodal surfaces are drawn, the octant rule predicts that the gly–L-ala–gly complex should exhibit signs opposite to those of the L-ala–gly–gly and gly–gly–L-ala complexes. The same situation has also been realized in the Cu(II) and Ni(II) complexes. The double octant rule has been proposed to account for the CD signs of those complexes in the d-d transition region.[2] The double octant rule is actually valid in the diammine(tripeptidato)cobalt(III) complexes.

Chemical Properties. The absorption and CD spectra of the diammine(tripeptidato)cobalt(III) complexes in an aqueous solution changed with the lapse of time. Figure 5 shows the time-course of the absorption curve for the gly–gly–L-ala complex in water at 30.1 °C. Over an initial period of *ca.* 1 h, the isosbestic points were observed, but not from that time on, indicating that the next reaction occurred. The same situation was also realized for other tripeptidato complexes: The changes in spectra for the complexes of tripeptides containing glycine and/or L-alanine residues, especially the L-ala–L-ala–L-ala and L-ala–L-ala–gly complexes, were fast; however, those for the tripeptidato complexes containing the β-alanine residue were slow and almost negligible over a period of one hour after dissolving. The spectral changes were accelerated in the acidic and basic aqueous solutions (even in an NH_3 aqueous solution); however, in the 1 M NH_4Cl aqueous solution with its pH of the solution adjusted at 7 with NH_3, the spectral change was not observable for *ca.* 2 h. For the complex of tripeptide containing the L-alanine residue, the CD spectral change was the same as the absorption spectral change. These results suggest that the following reaction occurs initially:

$$[\text{Co(tripeptidato)}(NH_3)_2] + H_2O \longrightarrow [\text{Co(tripeptidato)}(NH_3)(H_2O)] + NH_3.$$

Tetrapeptidato Complexes. On the basis of the examination of molecular models and the fact that the ^1H NMR spectrum of the [Co(gly–gly–gly–gly)$(NH_3)_2$]$^-$ complex in a weak alkaline D_2O shows four singlet peaks due to four CH_2 groups of the gly–gly–gly–gly ligand at 3.52, 3.72, 3.86, and 3.90 ppm, it can be concluded that the most probable structure of [Co(gly–gly–gly–gly)$(NH_3)_2$]$^-$ is the *trans*(NH_3) form, in which the tetraglycine coordinates to cobalt(III) as a tetragonal quadridentate chelate. The other tetrapeptidato complexes prepared in this study also showed singlet peaks due to the CH_2 of the glycine-rings, indicating the same structure as that of the gly–gly–gly–gly complex.

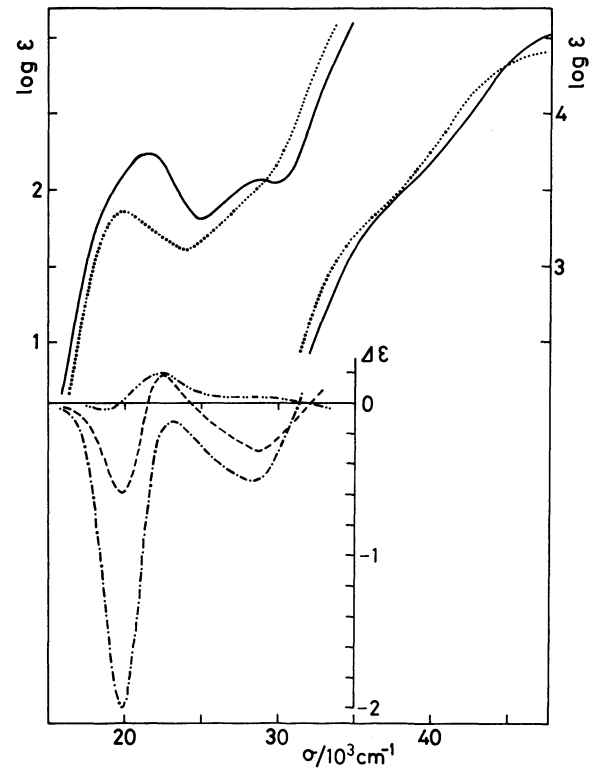

Fig. 6. The absorption spectra of [Co(gly–gly–gly–gly)$(NH_3)_2$]$^-$ (——) and [Co(gly–β-ala–gly–gly)$(NH_3)_2$]$^-$ (……) in water, and the CD spectra of [Co(L-ala–gly–gly–gly)$(NH_3)_2$]$^-$ (------), [Co(gly–L-ala–gly–gly)$(NH_3)_2$]$^-$ (·—·—·), and [Co(gly–gly–gly–L-ala)$(NH_3)_2$]$^-$ (–···–···) in water.

As is shown in Fig. 6 and Table 3, the absorption spectrum of the diammine(tetraglycinato)cobaltate(III) complex exhibits the first and second bands at 21550 and 28820 cm^{-1} respectively. The first band has an enhanced intensity (ε=175 $dm^3\,mol^{-1}\,cm^{-1}$), following a tendency toward splitting (shoulder band at *ca.* 19000 cm^{-1}). This spectral behavior is similar to that of the diammine(tripeptidato)cobalt(III) complex and supports the assertion that the tetraglycinato complex has the *trans*(NH_3) structure. The absorption spectra of the other tetrapeptidato complexes are similar to that of the tetraglycinato complex. The only exception is the gly–β-ala–gly–gly complex, which shows a lower intensity of the first band (ε=72 $dm^3\,mol^{-1}\,cm^{-1}$), just as in the gly–β-ala–gly complex (Table 3 and Fig. 6).

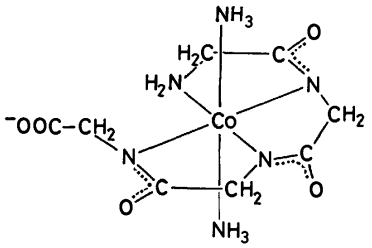

Fig. 7. The structure of $[Co(gly\text{-}gly\text{-}gly\text{-}gly)(NH_3)_2]^-$.

The CD spectra of the $[Co(L\text{-}ala\text{-}gly\text{-}gly\text{-}gly)(NH_3)_2]^-$ and $[Co(gly\text{-}L\text{-}ala\text{-}gly\text{-}gly)(NH_3)_2]^-$ complexes in the d-d transition region are similar in pattern to those of the $[Co(L\text{-}ala\text{-}gly\text{-}gly)(NH_3)_2]$ and $[Co(gly\text{-}L\text{-}ala\text{-}gly)(NH_3)_2]$ complexes respectively; however, the $[Co(gly\text{-}gly\text{-}gly\text{-}L\text{-}ala)(NH_3)_2]^-$ complex shows a remarkably different CD behavior in the d-d transition region compared with those of the L-ala-gly-gly-gly, gly-L-ala-gly-gly, and also tripeptidato complexes (Fig. 6 and Table 3). The $[Co(gly\text{-}gly\text{-}L\text{-}ala\text{-}gly)(NH_3)_2]^-$ complex, which was not isolated in the pure state, showed two negative signs of CD associated with the first and second bands. These results indicate that the tetrapeptides coordinate to cobalt(III) as quadridentate chelates through the terminal NH_2 and three amide N groups, as is shown in Fig. 7.

The diammine(tetrapeptidato)cobaltate(III) complexes also show the absorption and CD spectral changes in water with the same order of time-course as those of diammine(tripeptidato)cobalt(III) complexes; these changes are ascribed to an aquation reaction.

UV Photoelectron Spectroscopic Investigation and the DV-Xα MO Calculation of Tetrakis(2-methyl-2-propanethiolato)molybdenum(IV)

Masao TAKAHASHI,* Iwao WATANABE, Shigero IKEDA, Masato KAMATA,† and Sei OTSUKA†
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
†*Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560*
(Received April 15, 1982)

Helium(I) ultraviolet photoelectron spectrum is reported for the compound Mo(*t*-BuS)$_4$. The observed spectrum is interpreted by means of DV-Xα MO calculations on the model compounds Mo(SH)$_4$ and Mo(SMe)$_4$. The UV photoelectron spectrum of Mo(*t*-BuS)$_4$ exhibits a low ionization potential band (*IP*=6.43 eV) which corresponds to ionization of mainly Mo4d$_{z^2}$ electron of A_1 representation. This molecular orbital has also bonding character between Mo4d and S3d.

Currently thiolatomolybdenum complexes due to their possible implication in redox-active molybdoenzymes are receiving considerable attention. The homoleptic tetrakis(thiolato)molybdenum(IV) compound and products derived therefrom were reported recently.[1,2] The electronic structures of molybdenum compounds have been investigated by use of X-ray and UV photoelectron spectroscopy (XPS and UPS).[3,4] The UPS is especially useful for the study of the valence orbitals in a molecule.

Recently the discrete-variational(DV)-Xα method has been shown to be useful for evaluating electron binding energies and studying electronic structures, and applied for the interpretation of photoelectron spectroscopic data of various materials.[5,6]

The Mo(*t*-BuS)$_4$ compound exhibits outstanding reactivity toward various reagents. In this paper we report the study on its electronic structure by using UPS and by performing the DV-Xα MO calculation.

Experimental

Materials. The compound, Mo(*t*-BuS)$_4$, was prepared and purified as described elsewhere.[1] This compound is sensitive to air and moisture and sublimes at 343 K (0.13 Pa). It was preserved under a nitrogen atmosphere until UPS measurements. The compounds, 2-methyl-2-propanethiol, di-*t*-butyl disulfide and 2-methyl-1-propene, were obtained commercially.

UPS Measurements. The He(I) photoelectron spectrometer used was constructed by one of the authors (I.W.). The spectrometer was controlled by a mini-computer so that the effect of energy drift of the spectrometer during the measurement was completely compensated by a real-time energy calibration technique.

The sample, Mo(*t*-BuS)$_4$, seemed to be liable to decomposition on heating, so UV photoelectron spectra for its expected decomposition products, *i.e.*, 2-methyl-2-propanethiol, 2-methyl-1-propene, and di-*t*-butyl disulfide, were also measured, and they were found to be identical with the spectra reported[7-9] (a, b, and c in Fig. 2 respectively). When the sample, Mo(*t*-BuS)$_4$, was heated to 340 K in a glass tube at the distance of 30 cm from the ionization chamber with an electric heater to obtain a sufficient vapor pressure for the measurement, the observed spectrum was that for the mixture of the above mentioned decomposition products. Therefore the ionization chamber as shown in Fig. 1 was necessary. On the wall of the ionization chamber two metal-film resistors (C in Fig. 1) and a calibrated thermistor (B) were fixed with aluminum tapes. An alternating current supplied to the

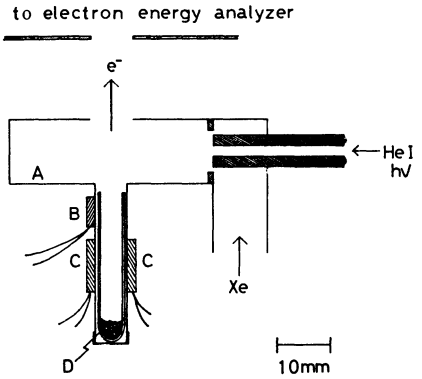

Fig. 1. Schematic drawing of ionization chamber. A) ionization chamber made of 0.2 mm thick copper sheet, B) thermistor, C) metal-film resistors, D) solid samples in a glass tube.

resistors heated the ionization chamber, the temperature of which was measured by the thermistor. The magnetic field produced by the a.c. current caused neither peak shift nor peak broadening.

It was necessary to keep the temperature of the ionization chamber as low as possible in order to minimize the sample decomposition. The measurements were performed at 331± 2 K, *i.e.*, about 10 K lower than the temperature at which the sublimation of Mo(*t*-BuS)$_4$ was noticeable. Because of the low vapor pressure at that temperature, the spectral data were accumulated for 2 d to get a satisfactory spectrum.

The ionization energy scale was calibrated with xenon used as an internal standard (*IP*=12.130 eV). Spectral resolution defined by the full width at half-maximum (FWHM) of the $^2P_{3/2}$ xenon peak was less than 30 meV. All ionization energies were read at the maximum of each peak as vertical ionization potential.

Computations. The DV-Xα method used was described in detail elsewhere.[10,11] Molecular orbital energies were calculated by employing models of Mo(SH)$_4$ and Mo(SMe)$_4$ for Mo(*t*-BuS)$_4$, and that of Mo(NH$_2$)$_4$ for Mo(NMe$_2$)$_4$. Each model has D_{2d} symmetry. Numerically generated atomic basis functions (1s-5p for Mo, 1s-3d for S, 1s-2p for C and N, and 1s for H) were used to expand the molecular orbitals. The bond distances and angles used for the calculations were taken from the results of X-ray crystallography for Mo(*t*-BuS)$_4$[1] and Mo(NMe$_2$)$_4$,[12] except that S–H, C–H, and N–H bond distances were taken to be 0.1336, 0.1090, and 0.1022 nm respectively. In the compound, Mo(*t*-BuS)$_4$, the MoS$_4$ skeleton has nearly perfect D_{2d} symmetry, while in Mo(NMe$_2$)$_4$, having exact D_{2d} symmetry as a whole, the MoN$_4$ moiety has almost perfect T_d symmetry. Thus we have chosen the

models of Mo(SH)$_4$ or Mo(SMe)$_4$ and Mo(NH$_2$)$_4$ with D_{2d} symmetry in calculations for Mo(*t*-BuS)$_4$ and Mo(NMe$_2$)$_4$ respectively, assuming that the effect of such distortion is negligible.

Results and Discussion

The UV photoelectron spectrum of Mo(*t*-BuS)$_4$ is shown in Fig. 2. There are at least four bands in Fig. 2. The first ionization band (*IP*=6.43 eV) is assigned an ionization of metal orbital because of its very low IP. The second band (*IP*=7.70 eV) is so sharp that it could be interpreted to correspond to the ionization of a non-bonding orbital. Over the very broad fourth band (*IP*= 9—10 eV), there are two peaks of 9.03 eV and 9.06 eV which are in perfect agreement with the peaks in the photoelectron spectrum of 2-methyl-2-propanethiol. Therefore the peaks are most possibly assigned to the ionization of sulfur lone pair MOs of one of the decomposition products of Mo(*t*-BuS)$_4$. We presume that the peaks of 9.03 eV and 9.4 eV consist of the ionizations of 2-methyl-2-propanethiol and 2-methyl-1-propene (the spectra inserted in Fig. 2) respectively. Hence the spectral intensity due to the ionizations of those decomposition products should account for more than 70% of all the spectral intensity in the area of 9.0—9.8 eV, and in the area above 9.8 eV less than 35%. Furthermore there stand three peaks at 9.61 eV, 10.26 eV, and 11.57 eV, corresponding to the ionizations of xenon $^2P_{3/2}$ by HeIγ (23.74 eV) and HeIβ (23.09 eV), and $^2P_{1/2}$ by HeIβ, respectively.

Table 1. VERTICAL IONIZATION POTENTIALS FOR Mo(*t*-BuS)$_4$ AND CALCULATED ORBITAL ENERGIES FOR Mo(SH)$_4$ AND Mo(SMe)$_4$ (IN eV)

Observed IP Mo(*t*-BuS)$_4$	Orbital energies	
	Mo(SH)$_4$	Mo(SMe)$_4$
6.43	−3.26($13a_1$)	−3.04($16a_1$)
7.70	−4.33($2a_2$)	−3.86($3a_2$)
8.5	−4.77(13e)	−4.10(17e)
—	−5.45(12e)	−5.10(16e)

The vertical ionization potentials and computed orbital energies for Mo(SH)$_4$, and Mo(SMe)$_4$ are listed in Table 1. The molecular orbital energies are related to the vertical ionization potentials through Koopmans' theorem. The gross-orbital populations of filled and empty orbitals were calculated for Mo(SMe)$_4$ (Table 2). The calculation on Mo(SH)$_4$ gave similar results to those for Mo(SMe)$_4$ with respect to the bonding character between Mo and S. The first band (*IP*=6.43 eV) corresponds to the ionization of $16a_1$ molecular orbital which consists mainly of metal $4d_{z^2}$ orbital and partly of S3d and C2p orbitals. This orbital is of weakly bonding character between Mo4d-S3d and of antibonding between Mo4d-S3p_z and Mo4d-S3s. Further this orbital has additional weak d-p bonding character for the ligand S–C bond.

The next two bands (*IP*=7.70 and 8.5 eV) are

Table 2. MOLECULAR ORBITAL COMPONENTS CALCULATED FOR Mo(SMe)$_4$ (IN %)

Level[a]	Orbital energy/eV	Mo				S		
		$4d_{z^2}$	$4d_{x^2-y^2}$	$4d_{xy}$	$4d_{xz/yz}$	3d	3p	3s
$5b_1$	−1.14	—	54	—	—	5	40	0
$16a_1$[b]	−3.04	56	—	—	—	13	8	5
$3a_2$	−3.86	—	—	—	—	0	93	0
17e	−4.10	—	—	—	0	0	96	0
16e	−5.10	—	—	—	17	1	66	6
$15a_1$	−5.29	9	—	—	—	1	69	2
$4b_1$	−5.51	—	37	—	—	4	55	0
$14b_2$	−5.57	—	—	35	—	2	56	2

a) Any contribution of other orbitals to the levels listed here is negligible except that $16a_1$ contains 15% contribution of C2p, and $15a_1$ contains 12% of Mo5s. b) This MO is the HOMO in Mo(SMe)$_4$.

assigned to the ionization of the molecular orbitals of $3a_2$ and 17e levels, respectively. The $3a_2$ level consists of only sulfur 3p lone pair MOs. The sharpness of the second band (IP=7.70 eV) supports this interpretation. The orbital of the 17e level consists of sulfur 3p lone pair MOs, too, and corresponds to the third band (IP=8.5 eV), which is slightly broader. The breadth of this band may be ascribed to be due to the Jahn-Teller effect. It is probable that the fourth band (IP>9 eV) contains the ionizations both of Mo(*t*-BuS)$_4$ and of decomposition products.

The complex, Mo(NMe$_2$)$_4$ or Mo(NEt$_2$)$_4$, is the only complex to our knowledge, which is analogous to Mo(*t*-BuS)$_4$ with respect to the molecular symmetry and the valence type of Mo, and for which UV photoelectron spectrum is known. Their spectra together with the Fenske-Hall type MO calculation on the model compound, Mo(NH$_2$)$_4$, have been reported by Chisholm *et al.*[12,13] In order to get an insight into the electronic structure of these complexes, the DV-Xα MO calculation was performed on the amidomolybdenum complex Mo(NH$_2$)$_4$ in addition to the thiolatomolybdenum complex. The result from the calculation on Mo(NH$_2$)$_4$ is consistent with that obtained by Chisholm *et al.*

The calculations on Mo(NH$_2$)$_4$ and Mo(SMe)$_4$ predict that the bond-overlap populations of Mo–N and Mo–S are 0.248 and 2.648, and that the net charge on Mo central atoms are +2.15 and +0.80, respectively. Therefore, it could be stated that the Mo–N bond is ionic in character but that the Mo–S bond is covalent if compared each other. The calculations also predict that the HOMO of the amidomolybdenum complex consists almost entirely of Mo4d$_{x^2-y^2}$ (88%), while that of the thiolatomolybdenum complex ($16a_1$) delocalizes slightly as shown in Table 2. The contents of this theoretical calculation appear to be inconsistent with the experimental fact that the half-width of the first band, corresponding to the ionization of the HOMO, in the spectrum of Mo(NMe$_2$)$_4$ is estimated to be about twice as large as that of Mo(*t*-BuS)$_4$ by comparing the published spectrum and the one in Fig. 2.

The difficulty to understand the contradiction has arisen in the same way on the studies of some metal-halide complexes.[14] For example, the photoionization of TlBr[15] gives a broad peak due to the ejection of the electron localized on Br *i.e.*, the "non-bonding" or "lone-pair electron," together with a sharp peak due to the ejection of the electron delocalized over the two atoms, *i.e.*, the "bonding electron" according to a molecular orbital model. The phenomenon was simply understood by taking account of the roles of localized and delocalized electrons in an ionic-bond. In the ionic-bond the electron on Br$^-$ acts as a bonding electron, so its ionization causes a broad peak. The present case of amidomolybdenum and thiolatomolybdenum complexes could be understood in quite the same manner. Thus the electron in HOMO of amidomolybdenum plays a role as an anti-bonding electron with respect to the ionic Mo–N bond more strongly than the corresponding electron in thiolatomolybdenum does as a bonding electron with respect to the covalent Mo–S bond. Therefore, the spectra exhibit the broader first band for the amidomolybdenum complex than for the thiolatomolybdenum complex.

The authors wish to thank Professor Hirohiko Adachi and Mr. Hirohide Nakamatsu for the computer program of the DV-Xα calculation. The numerical calculations were carried out using ACOS NEAC 900 at the Computation Center, Osaka University, and ACOS NEAC 700 at the Crystallographic Research Center Institute for Protein Research, Osaka University. This work was supported by Toray Science and Technology Grants 72-1302.

An Analysis of the Chemical Compositions of Groundwaters Utilizing a Leaching Technique. An Application to the Rokko Mountains and Their Surroundings

Yuzo Tamari,* Yukiharu Inoue, Haruo Tsuji, and Yuzuru Kusaka
Department of Chemistry, Faculty of Science, Konan University, Higashinada-ku, Kobe 658
(Received April 19, 1982)

The chemical composition of groundwaters from granitic alluvial plains is different from that from the clayey "Kobe-group" strata surrounding the Rokko mountains. The former groundwaters are dominantly rich in Ca and HCO_3, while the latter are rich in Na and HCO_3. In order to investigate the difference in the groundwater compositions, a chemical leaching technique was applied to samples of soils, well-sediments, and rocks collected from the Rokko mountains and their surroundings. Three leaching solutions used were as follows. CO_2-saturated water to investigate the effect of chemical weathering; a 0.1 M† HNO_3 solution to remove hydroxide, sulfide, and colloidal matters; and a 1 M CH_3COONH_4 solution to leach exchangeable ions from the samples. In the leaching, leachable amounts of Na, K, Ca, and Mg as the major species and Fe and Mn as the minor species in groundwaters were determined. From the results of leaching and adsorption experiments for cations, and from a comparison of the analytical values of the cations in groundwaters with the data of the leaching experiments on the key diagram, the association of the chemical species dissolved in groundwaters with the geological characters was analysed.

The Rokko mountains are located north of Osaka Bay, behind the port of Kobe. The mountains essentially consist of granitic rocks characterized by biotite, and they are covered with granitic detritus called "Masatsuchi." The detritus forms alluvial plains and terrace deposits in the southern part of the Rokko mountains, and the detrital layers form a well aquifer because of the poorly coagulating layers. In the northern or northwestern side of the mountains, the Neogene strata (*ca.* 15 million years old), called argillaceous "Kobe group" strata, which are composed of such detritus as silt mudstone, sandstone, and conglomerates and of volcaniclastic materials containing large amounts of tuff, are widely distributed.[1]

It has been generally recognized that the chemical species dissolved in groundwaters are mainly Na^+, Ca^{2+}, Mg^{2+}, K^+, HCO_3^-, Cl^-, SO_4^{2-}, and soluble SiO_2, and that these species make up more than 95% of the total dissolved solids.[2] The chemical compositions of groundwaters in the Rokko mountains and their surroundings have been studied, and the concentrations of major and trace species have been reported by some of the present authors.[3,4] Table 1 shows some of the analytical results in their reports. This table shows that the groundwaters from the alluvial plains are dominantly rich in Ca and HCO_3, whereas the groundwaters from the Kobe-group area are rich in Na and HCO_3. The difference in the chemical compositions of groundwaters in these two areas is explained by the following reactions of major chemical species: the chemical actions controling the dissolution of the major species are weathering by CO_2 for granitiform soils in the alluvial plains, while the cation-exchange reactions by clay minerals are dominant in the Kobe-group area. In order to analyse the difference in the chemical compositions of groundwaters between the alluvial plains and the Kobe-group area, and in order to elucidate the association of geological strata with the chemical compositions, a chemical leaching technique was applied in this work.

Chemical leaching techniques are generally utilized

Table 1. Mean chemical compositions of groundwaters

to separate different minerals, such as ferro-manganese and carbonate, or trace elements adsorbed on minerals to solutions by means of chemical reactions.[5-7)] This technique is also used for the state analysis of Se in sediments.[8)] In this work, a chemical leaching method was applied to powdered samples of rocks, soils, and well-sediments collected from Mt. Rokko and its surroundings, using leaching solutions of 0.1 M HNO_3, 1 M CH_3COONH_4, and CO_2-saturated water. From the results of 1) the X-ray diffraction patterns of the samples, 2) leaching experiments in which amounts of Na, K, Ca, Mg, Fe, and Mn removed from the samples by the leaching solutions were determined, 3) adsorption experiments using commercially available clay minerals and the samples, and 4) the analysis of key diagrams on which the leaching and analytical results of groundwaters had been plotted, it has been concluded that the chemical composition of each groundwater from the alluvial plains and the Kobe-group area depends on their geological strata, and that the leaching method is significant in analysing the influence of the geological strata on the chemical species dissolved in groundwaters.

Experimental

Samples, Reagents, and Apparatus. The sampling descriptions of the well-sediments, rocks, soils, and clay minerals used for these experiments are given in Table 2. The sediment samples were collected from the bottom to a depth of about 5 cm in relatively shallow wells, using a mud-sampler (Rigo Co., Ltd., model No. 2007).

The solutions of 0.1 M HCl, 0.1 M HNO_3, and 0.1 M CH_3COOH were prepared by diluting each reagent of an analytical-reagent grade with distilled water. The pH 7 solution of 1 M CH_3COONH_4 was also prepared by dissolving 77.09 g of CH_3COONH_4 with water to a 1000 ml volume and by adjusting the pH to 7.0 with a small quantities of CH_3COOH and NH_4OH solutions.

The following pieces of apparatus were employed; a flame photometer (Hiranuma-sangyo Co., Ltd., model FPF-2A), a spectrophotometer (Hitachi, Ltd., model 100-10), an atomic absorption spectrophotometer (Hitachi, Ltd., model 207), an X-ray diffractometer (Rigaku-denki Co., Ltd., model MJ-200-DH), and a washer-bath with irradiation by ultrasonic waves (Shimada Physical and Chemical Industrial Instruments Co., Ltd., model CF-16-2B, 200 W 28 kHz, and Branson Instruments Co., Ltd., model Bransonic 12,80 W 60 Hz).

Preparation of Samples. Wet sediment samples collected from wells were centrifuged, and the solid parts of the samples were dried for 5 h at 110 °C. After cooling, the samples were crushed in an agate mill and then powdered so as to pass through a 100-mesh-size sieve. Finely powdered dry samples were prepared by quartering them four times after the samples had been mixed in an agate mill for 10 min. Samples of rocks and clay minerals were also prepared in the same manner. In this sample preparation, about 95% of the homogeneities for trace elements in sediment samples and more than *ca.* 90% of the homogeneities for major constituents in artificial samples were estimated.[9,10)]

Leaching Solutions. The solutions used for the chemical leaching experiments were as follows. 1) CO_2-saturated water to investigate the effect of chemical species being dissolved in groundwaters by chemical weathering by CO_2; 2) a 1 M CH_3COONH_4 solution to remove the exchangeable ions sorbed by clay minerals; 3) a 0.1 M HCl solution to leach the metal sulfides and hydroxides and loosely adsorbed metal ions that were originally present in overlying water as fine-grained suspended phases;[6)] and 4) 0.1 M HNO_3 and 0.1 M CH_3COOH solutions to compare the effects of the leaching.

Recommended Leaching Procedure. Figure 1 shows the recommended procedure for the leaching method as established from the experimental results of investigating the effect of the reaction temperatures of leaching solutions, the effect of the intensity of ultrasonic waves irradiated during the leaching, and the effect of the irradiation time of ultrasonic waves on the leachable amounts of Na, K, Ca, Mg, Fe, and Mn.

One gram of a powdered sample was placed in a stoppered centrifugal tube (Vol. 50 ml), and a 25-ml portion of a leaching solution was added to the tube. The tube was set in a water-bath filled with hot water (40 °C) and irradiated by ultrasonic waves with an electric current of 3 A and for an irradiation time of 20 min. The tube was centrifuged for 10 min at 2500 rpm; then the supernatant solution was filtered (filter pore-size: 0.45 μ) and transferred to a 50-ml measuring flask (Fraction No. 1). A 25-ml portion of the same fresh leaching solution was added to the residue in the tube; the mixture was irradiated for 20 min and then centriguged. The solutions from Fractions No. 2 to No. 5 were prepared in the same way.

In the leaching with CO_2-saturated water, CO_2 gas was introduced into a mixture of 1 g of the sample and 25 ml of H_2O in a centrifugal tube under the same reaction conditions as are shown in Fig. 1.

Procedure of Adsorption Experiments. A solid-residue sample, after treatment by the leaching procedure with the 1 M CH_3COONH_4 solution, was used for the experiments. The sample was washed with water and then centrifuged.

JB-1[a)]	2.08	1.19	6.63	4.66	6.30	1200

a) Certified values.[11)]

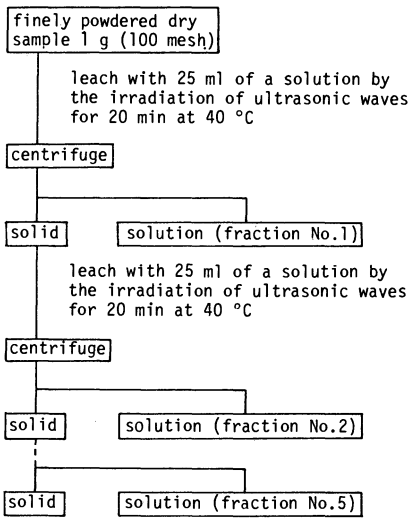

Fig. 1. The flow diagram of the leaching procedure.

After washing with water twice, a 25-ml portion of the solution adjusted to pH 7 and containing definite amounts of the chloride of each Na, K, Ca, and Mg was added to the sample. The mixture was irradiated by ultrasonic waves for 100 min (20 min × 5) at 40 °C. Then, after the centrifugation, the amounts of Na, K, Ca, and Mg in the supernatant liquid were determined.

Determination of Elements. To each solution from Fractions No. 1 to No. 5, 1 ml of a 10% La solution and 1 ml of a 5 M HNO_3 solution were added, and the mixture was diluted with water to 50 ml. In the solution, the Na and K were determined by flame photometry, and the Ca, Mg, Fe, and Mn, by atomic-absorption spectrophotometry.

For the determination of the Na, K, Ca, Mg, Fe, and Mn content of the samples given in Table 2, the samples were wet-ashed by general HF–$HClO_4$–HNO_3 treatments; these elements were then determined by the analytical procedure described above.

Results and Discussion

Analytical Data of Samples. Table 3 lists the Na, K, Ca, Mg, Fe, and Mn content of the samples. As shown in this table, the content of each element in the Mt. Rokko granite sample is fairly close to that of one reported by Kasama.[1)] However, it is difficult to find the geological differences between samples from the chemical compositions shown in this table.

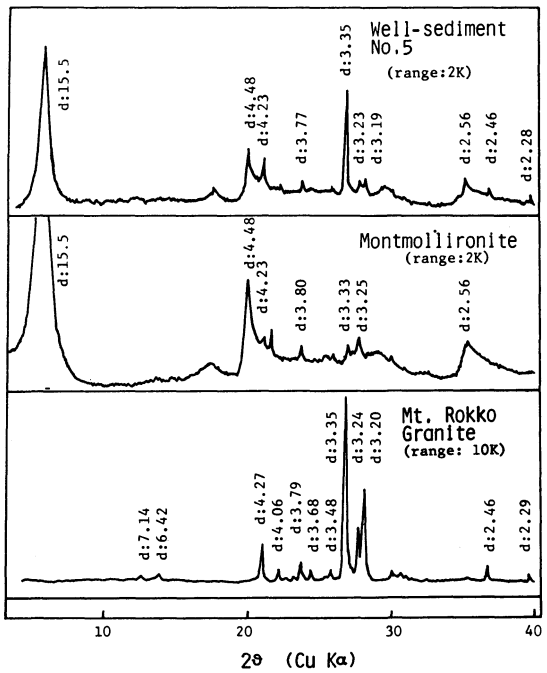

Fig. 2. X-Ray diffraction spectra of samples.

Figure 2 shows some typical X-ray diffraction patterns of the samples. The diffraction patterns of the soil No. 1 and the well-sediment No. 1 from the alluvial plains were identical with that of the Mt. Rokko granite, in which peaks corresponding to quartz (d: 4.26, 3.35, 2.46, 2.24, and 2.13) were found. In the well-sediments No. 2—No. 5 from the Kobe-group area, the peaks of montmollironite and quartz were detected.

Reproducibility of the Leaching Method. Table 4 shows the reproducibility of the leaching method, repeated four times by the recommended procedure given in Fig. 1. In this experiment, the soil No. 1 and a 0.1 M HNO_3 solution were used as the sample and the leaching solution respectively. For each element, in the sum of five fractions, a coefficient of variation of 0.99—4.5%, which was approximately within the limits of analytical error, was obtained.

Effect of Leaching Solutions. Table 5 gives the experimental results of the leaching with different solutions from the samples. It may be found from the table that the amounts of each of six elements leached

	0.1 M CH_3COOH	513	969	1410	564	4904	29.4
	1 M CH_3COONH_4	580	1565	2750	455	ND	42.7

Values: μg amounts of an element leached in the sum of 5 fractions from 1 g of a sample.

with the 0.1 M HCl solution was nearly equal to that leached with the 0.1 M HNO_3 solution, but was larger than that leached with the 0.1 M CH_3COOH and 1 M CH_3COONH_4 solutions. In the leaching with the CO_2-saturated water, the dissolved amounts of the elements tended to agree with that of the 0.1 M HCl or 0.1 M HNO_3 solution from the soil No. 1 and not with that from the well-sediment No. 2. This difference between the two samples probably depends on the characteristics of their samples, *i.e.*, the fact that montmollironite was contained in the well-sediment No.2, while quartz was found in the soil No. 1.

Leaching of Elements from Samples. Table 6 lists the amounts of elements leached from different samples. From the table, the following characteristics of the leaching could be recognized.

In the alluvial soil No. 1, the considerably large amount of Ca was more easily dissolved with the CO_2-saturated water than in the Kobe-group samples. In the well-sediments from the Kobe-group strata, the percentages of Na and K leached with the CH_3COONH_4 solution were remarkably higher than that from the alluvial samples, and the amounts of Na, K, Ca, and Mg leached by the HNO_3 solution were almost equal to that by the CH_3COONH_4 solution. Similar results of the leaching were found in the clay minerals, montmollironite and kaolinite. This similarity is considered to be due to the presence of montmollironite in all the Kobe-group samples.

Adsorption of Cations on Samples. Adsorption experiments were carried out in order to investigate the chemical state of the elements in these samples;

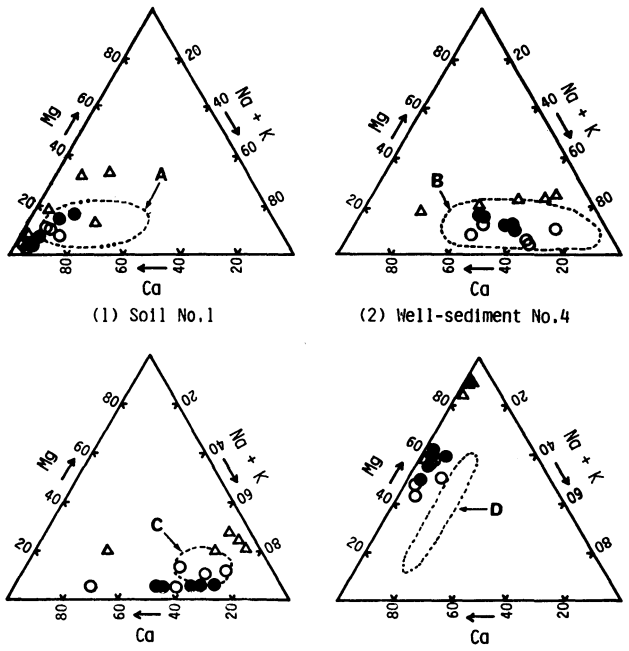

Fig. 3. Key diagram of relative percentages of milligram equivalents.
●: Leaching by CO_2-saturated water, ○: 1 M CH_3COONH_4 leaching, △: 0.1 M HNO_3 leaching, A: 34 Groundwaters from the alluvial plains, B: 38 Groundwaters from the Kobe-group strata, C: 7 Stream waters from topmost Mt. Rokko, D: 8 groundwaters from the worldwide 8 basaltic regions.

the soil No. 1 from the alluvial plains, the well-sediment No. 2 from the Kobe-group strata, and the clay minerals. Table 7 shows the results of the experiments. In this table, the amounts of elements leached from the original sample (see Table 6) are also listed.

In the montmollironite and bentonite, the amounts of divalent Ca adsorbed was higher than that of monovalent Na and K. The adsorptive behavior of the cations was observed also in the soil No. 1 and the well-sediment No. 2. However, from the fact that the ratio of the amounts adsorbed to those leached is 0.08 for Ca in the soil, it can be seen that scarcely no exchangeable Ca existed in the soil from the alluvial plains. In contrast, from the relatively high ratio of 0.5 for Ca in the well-sediment No. 2, it seems that much Ca was present as exchangeable ions in the sediment from the Kobe-group strata.

Association of the Chemical Species Dissolved in Groundwaters with Their Surrounding Geology. Figure 3 gives the key diagram of the relative percentages of milligram equivalents for Na+K, Ca, and Mg leached from the four samples. In Fig. 3-(1) for the soil No. 1, it is indicated that the plots of cations leached from the soil agree almost entirely with the A area, the plots of the 34 shallow groundwaters from the alluvial plains (see Table 1). A similar agreement is also found in the well-sediment No. 1 from the same alluvium.

In Fig. 3-(2) for the well-sediment No. 4 from the Kobe-group strata, the plots of leached cations, especially with the CH_3COONH_4 solution or the CO_2-saturated water, overlap well with the analytical results of the 38 shallow groundwaters (B) from the Kobe-group strata.[3,4] This agreement is also found in the well-sediment No. 3 from the same strata.

The leaching data of the Mt. Rokko granite, plotted in Fig. 3-(3), are somewhat scattered, but those with the CO_2-saturated water tend to overlap with the results of the 7 stream waters located at the top of Mt. Rokko (C).[12] From this tendency, it can be pointed out that the chemical composition of stream waters is determined by the leaching of constituents in the granitic rocks by chemical weathering with CO_2.

In Fig. 3-(4) for JB-1, it is shown that the plots of cations leached with the CO_2-saturated water or the CH_3COONH_4 solution fall close to the analytical data of the 8 groundwaters in the 8 basaltic regions worldwide (D).[13]

In conclusion, it can be analysed that the chemical compositions of groundwaters are considerably influenced by the geological strata through which the groundwaters pass, and that they can be estimated by utilizing the proposed leaching experiments for the solid samples around the groundwater area. In the leaching, the CO_2-saturated water is effective for investigating the influence of rocks on groundwaters, whereas the 1 M CH_3COONH_4 solution is useful for the samples containing clay minerals.

The Mechanism of the Hydrolysis of Polyphosphates. VI.[1] The Effect of Cations on the Hydrolysis of *cyclo*-Tri- and *cyclo*-Tetraphosphates

Makoto WATANABE

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai, Aichi 487

(Received April 30, 1982)

The effect of cations on the rate of the hydrolysis of *cyclo*-tri- and *cyclo*-tetraphosphates was studied by adding metal chlorides to aqueous solutions of the ring phosphates. The concentrations of the phosphates and metal chlorides were 0.025 mol dm^{-3} and 0.1 mol dm^{-3} respectively. Alkali-metal cations retarded the hydrolysis of both the *cyclo*-phosphates in acidic media and accelerated it in basic media. The following sequence of efficiency resulted:

$$Li^+ > Na^+ > K^+.$$

Magnesium, calcium, and nickel(II) cations retarded the hydrolysis of the *cyclo*-phosphates in the pH range of 1.0—2.0 or 1.0—2.7, while they accelerated it in the pH regions higher than 2.7 or 3.5. A copper(II) ion retarded the hydrolysis at pH 1.0, and accelerated it in the pH ranges higher than 2.0. An aluminium ion highly accelerated the hydrolysis of both the ring phosphates at pH 1.0 and 2.0.

Though many papers concerning the hydrolysis of polyphosphates have been reported, there have been few reports about the effect of metal cations on the hydrolysis. Thilo and Wieker studied the catalytic efficiencies of cations on the hydrolysis of high polyphosphates at pH 8 and obtained the following sequence of efficiency:

$$Al^{3+} > Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+} > H^+ > Li^+ > Na^+ > K^+.$$[2-4]

Osterheld recently presented a review on the hydrolysis of condensed phosphates.[5] The present author has reported the reaction mechanism of the hydrolysis of chain and small-ring polyphosphates from the point of view of the interaction between a water molecule and a polyphosphate ion by using aqueous organic solvents.[6-9] In a previous paper,[1] the effect of metal cations on the hydrolysis of di- and triphosphates was reported. This paper describes the effect of metal cations on the hydrolysis of *cyclo*-tri- and *cyclo*-tetraphosphates.

Experimental

Materials and Procedure. All the materials other than sodium *cyclo*-tri- and *cyclo*-tetraphosphates were commercial grade. Sodium *cyclo*-tri- and *cyclo*-tetraphosphates were produced by the method described in Refs. 10 and 11. The initial concentration of sodium *cyclo*-tri- and *cyclo*-tetraphosphates was 0.025 mol dm^{-3}. This concentration is suitable for analysis. *cyclo*-Tri- and *cyclo*-tetraphosphate solutions free from sodium ions were prepared by passing the sodium *cyclo*-phosphate solutions mentioned above through cation-exchange resin in the H^+ form. The *cyclo*-phosphate solutions without sodium ions were used to study the effect of alkali-metal cations on the rate of the hydrolysis of the *cyclo*-phosphates in both acidic and basic media. These *cyclo*-phosphate solutions could not be used to investigate the effect of alkaline-earth, aluminium and some transition-metal cations over a wide pH range of the solution, because precipitates were formed. So the sodium *cyclo*-phosphate solutions were used to test the effect of these cations on the rate of the hydrolysis of the *cyclo*-phosphates. Metal chloride was added to the phosphate solutions to make it 0.1 mol dm^{-3}. The metal chlorides used were LiCl, NaCl, KCl, $MgCl_2$, $CaCl_2$, $AlCl_3$, $NiCl_2$, and $CuCl_2$. The pH's of the *cyclo*-phosphate solutions containing one of the cations mentioned above were controlled with hydrochloric acid and/or aqueous tetramethylammonium hydroxide by using a Hitachi-Horiba pH meter, F-7, at a given reaction temperature. The pH of the solution was periodically measured and if it was in need of adjustment, enough tetramethylammonium hydroxide or hydrochloric acid was added to bring it back to the proper pH. The pH adjustment was made within ±0.1 pH unit of the required value. At measured intervals of time, about a 1-cm^3 portion of the *cyclo*-phosphate solution was withdrawn. About 50 mg of disodium dihydrogen ethylenediaminetetraacetate dihydrate (EDTA) was added to the phosphate solution containing a metal cation, and then the pH of the solution was adjusted to 7—9 with aqueous ammonia or hydrochloric acid and 8 mm^3 of the solution was spotted on Toyo No. 51A filter paper (2 by 50 cm) for the separation of the phosphates in the solution. When the *cyclo*-phosphate solution did not contain any metal ion, the pH of the withdrawn 1-cm^3 portion of the phosphate solution was adjusted to about 7 with aqueous ammonia or hydrochloric acid. The separation of the phosphate species in the solution was made by spotting 8 mm^3 of the solution on the filter paper mentioned above. The separation and determination of the phosphates in the sample solution were carried out by the method described in previous papers.[6,8,9] When some precipitate was formed during the hydrolytic processes of the *cyclo*-phosphates, no further treatment was made.

Results and Discussion

The Effect of Cations. The rate of the hydrolysis of *cyclo*-tri- and *cyclo*-tetraphosphates obeyed first-order kinetics with respect to the concentration of the respective *cyclo*-phosphates under all the conditions studied. The hydrolysis of sodium *cyclo*-tri- and *cyclo*-tetraphosphates is an acid- and base-catalyzed reaction.[8,9] As Tables 1 and 2 show, the hydrolysis of *cyclo*-tri- and *cyclo*-tetraphosphates in an aqueous solution containing alkali-metal cations or in a solution free from metal cations gave the result mentioned above. The rate of the hydrolysis of the *cyclo*-phosphates in a solution containing Mg^{2+}, Ca^{2+}, or Ni^{2+} decreased with an increase in the pH of the solution from 1.0 to 2.7 or 3.5, while the rate of the hydrolysis of *cyclo*-triphosphate containing Mg^{2+} and of *cyclo*-tetraphosphate containing

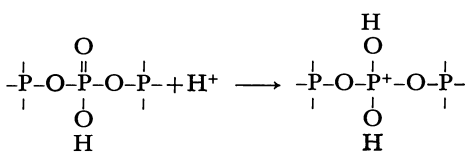
Ni^{2+} increased with an increase in the pH of the solution from 3.5 to 5.0. The rate of the hydrolysis of the *cyclo*-phosphates in a solution containing Cu^{2+} decreased as the pH of the solution changed from 1.0 to 2.0. On the other hand, the rate increased as the pH of the solution increased from 2.0 to 2.7 and 3.5. In the case of the hydrolysis of the ring phosphates in a solution containing Al^{3+}, the rate of the hydrolysis of the *cyclo*-phosphates increased with an increase in the pH of the solution from 1.0 to 2.0. For the hydrolysis of the short-chain polyphosphates, these cations used here all retarded the rate of the hydrolysis of the polyphosphates in acidic media and alkali-metal ions accelerated the rate in basic media. This tendency is the same as that of the hydrolysis of the ring phosphates in a solution containing alkali-metal ions. Magnesium, calcium, and nickel ions retarded the rate of the hydrolysis of the *cyclo*-phosphates in the pH region of 1.0—2.0 or 1.0—2.7, while they seemed to accelerate the rate in the pH regions higher than 2.7 or 3.5. The rate was retarded by Cu^{2+} at pH 1.0, while it was accelerated at a pH region higher than 2.0. An aluminium ion extremely accelerated the rate of the hydrolysis of the *cyclo*-phosphates at pH 1.0 and 2.0. The acceleration of the rate of the hydrolysis by metal cations was not observed for the hydrolysis of di- and triphosphates in acidic media.

Reaction Mechanism. The activation parameters for the hydrolysis of *cyclo*-tri- and *cyclo*-tetraphosphates were calculated by means of an Arrhenius plot and are listed in Tables 3 and 4 respectively. In the case of the hydrolysis of both the *cyclo*-phosphates in a solution containing an alkali-metal ion or in a solution free from a metal ion, the activation energy increased with an increase in the pH of the solution. The activation energy also seemed to increase by addition of an alkali-metal ion into the phosphate solution. In previous papers,[6-9] the author proposed the following hydrolysis mechanism for chain and small-ring phosphates and concluded that Reaction 2 is the rate-determining step:



(1)

Table 3. Activation parameters of the hydrolysis of *cyclo*-triphosphate

Phosphate	Added cation	pH	Activation energy/kJ mol^{-1}	log (frequency factor/min^{-1})

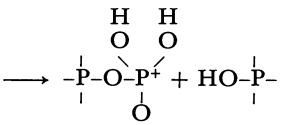
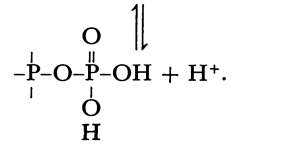
(2)



(3)



(4)

As mentioned above, the effect of alkali-metal ions on the kinetics parameters and the order of the efficiency of alkali-metal ions for the hydrolysis of both the ring phosphates was the same as that of the hydrolysis of di- and triphosphates. So the same reaction mechanism described in a previous paper[1] may be applicable for the hydrolysis of the *cyclo*-phosphates, and the retardation of the hydrolysis rate by alkali-metal ions in acidic

Table 4. Activation parameters of the hydrolysis of *cyclo*-tetraphosphate

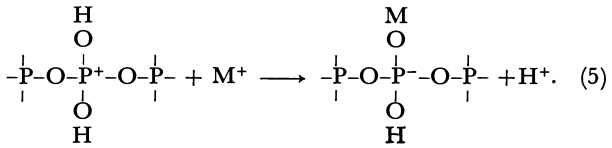
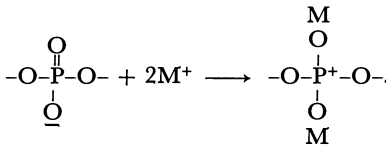
media could be attributable to the exchange of a hydrogen ion with a catalytically less effective alkali-metal ion as follows:



(5)

The acceleration of the rate by alkali-metal ions in basic media could be explained by the formation of the complex as follows:



(6)

As Tables 3 and 4 show, this acceleration is exclusively dependent on the entropy term. The retardaction of the rate of the hydrolysis of *cyclo*-tri- and *cyclo*-tetraphosphates by Mg^{2+}, Ca^{2+}, Ni^{2+}, and Cu^{2+} in highly acidic media depended exclusively upon the entropy term. So, when the exchange of a hydrogen ion with a catalytically less effective Mg^{2+} ion takes place according to Reaction 5, it could be concluded that there is a difference between the structures of the complexes of an alkali-metal ion and of an Mg^{2+}, Ca^{2+}, Ni^{2+}, or Cu^{2+} ion. The acceleration of the hydrolysis of the *cyclo*-phosphates by Cu^{2+} and Al^{3+} in acidic media depended

upon the energy and/or the entropy term. Since Reaction 2 is the rate-determining step of the hydrolysis of polyphosphates, Cu^{2+} and Al^{3+} may affect Reactions 1 and 2. The exchange of a hydrogen ion with Cu^{2+} or Al^{3+} may occur according to Reaction 5 and the cations are considered to be catalytically more effective than a hydrogen ion for the hydrolysis of the small-ring phosphates.

Thermal Cis-to-Trans Isomerization of $[CoX_2en_2]X$ (X=Cl, Br)

Ryokichi Tsuchiya,* Akira Uehara, and Yoshinori Muramatsu
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received April 30, 1982)

By measuring calorimetrically the heats of reaction of solid *cis*- and *trans*-$[CoX_2en_2]X$ (X=Cl, Br) with alkaline sodium sulfide solution, the heats of isomerization were obtained as -11.4 kJ mol^{-1} for *cis*-$[CoCl_2en_2]Cl(s)$=*trans*-$[CoCl_2en_2]Cl(s)$ and -6.4 kJ mol^{-1} for *cis*-$[CoBr_2en_2]Br(s)$=*trans*-$[CoBr_2en_2]Br(s)$. Assuming the entropy changes from cis- to trans-form, ΔS, to be -0.0116 kJ mol^{-1} K^{-1} at 25 °C statistically, the free energy changes were calculated as $\Delta G°=-8.0$ kJ mol^{-1} and -3.0 kJ mol^{-1} for the isomerization of *cis*-$[CoCl_2en_2]Cl$ and *cis*-$[CoBr_2en_2]Br$ respectively. From these thermodynamic data, cis-to-trans isomerization was expected to occur in $[CoX_2en_2]X$ (X=Cl or Br), which was verified experimentally by thin-layer chromatography and the spectral measurement.

The cis-to-trans isomerization of $[M^{III}X_2(AA)_2]X$-type chromium complexes in a solid phase has extensively been investigated, where X is a chloride or a bromide ion and AA is a diamine.[1-5] However, the isomerization of the corresponding cobalt(III) complexes has never been studied so widely, because they are often apt to undergo reduction of the metal ion upon heating in a solid phase. The samples of the cobalt(III) complexes so far studied are: Trans-to-cis isomerization for $[CoCl_2(NH_3)_4]IO_3\cdot 2H_2O$,[6] $[CoCl_2pn_2](H_5O_2)Cl_2$,[7] and $[CoBr_2pn_2](H_5O_2)Br_2$;[8] cis,trans(Cl,Cl)-to-cis,cis isomerization for $[CoCl_2(NH_3)_2en]ClO_4$[9] and $[CoCl_2(NH_3)_2en]Br\cdot H_2O$.[10] On the other hand, for $[CoCl_2en_2](H_5O_2)Cl_2$ and $[CoBr_2en_2](H_5O_2)B_2$, neither trans-to-cis nor cis-to-trans isomerization has been found in a solid phase.

The present study was undertaken 1) to find whether or not the isomerization can occur in a solid phase from the viewpoint of enthalpy or free energy changes and, if it does occur, 2) to verify it experimentally.

Experimental

Preparation of Complexes. *trans*-$[CoCl_2en_2]Cl$,[11] *cis*-$[CoCl_2en_2]Cl$,[12] *trans*-$[CoBr_2en_2]Br$,[13] and *cis*-$[CoBr_2en_2]Br$[14] were prepared by the known methods and identified by the elemental analysis and the electronic spectral measurements.

Calorimetric Measurements. The enthalpy changes in the reaction of the trans and cis complexes in the powder state with an alkaline solution of sodium sulfide were measured with a Tokyo-Riko twin isoperibol calorimeter TIC-2S at 25 °C. In each run, the diamine complexes employed were accurately weighed in the range of order of 2×10^{-4} mol and the reacting solution used was 100 cm^3 of 2×10^{-2} mol dm^{-3} of Na_2S in 1 mol dm^{-3} NaOH solution.

Derivatography. The differential thermal analysis (DTA) of the cis complexes was measured with a Derivatograph Typ-OD-102.

Thin Layer Chromatography (TLC). The TLC was employed to distinguish the cis and trans complexes and to confirm the occurrence of isomerization. The TLC plates used were those of silica gel 60F-254 made by Merck Ltd. The developer used was a mixture of *n*-BuOH: H_2O: AcOH= 7:2:1.

Electronic Spectra. Electronic spectra of the complexes were recorded on a JASCO Uvidec 550 spectrophotometer.

Results and Discussion

Enthalpy and Free Energy Changes in the Isomerization. The enthalpy changes for the reaction of *cis*- and *trans*-dichloribis(ethylenediamine)cobalt(III) chloride and dibromobis(ethylenediamine)cobalt(III) bromide with sodium sulfide solution were measured as below.

$$cis\text{-}[CoCl_2en_2]Cl(s) + {}^3/_2S^{2-}(aq) = {}^1/_2Co_2S_3(s) + 3Cl^-(aq) + 2en(aq) \qquad \Delta H = -71.9\ \text{kJ mol}^{-1} \quad (1)$$

$$trans\text{-}[CoCl_2en_2]Cl(s) + {}^3/_2S^{2-}(aq) = {}^1/_2Co_2S_3(s) + 3Cl^-(aq) + 2en(aq) \qquad \Delta H = -60.5\ \text{kJ mol}^{-1} \quad (2)$$

$$cis\text{-}[CoBr_2en_2]Br(s) + {}^3/_2S^{2-}(aq) = {}^1/_2Co_2S_3(s) + 3Br^-(aq) + 2en(aq) \qquad \Delta H = -46.9\ \text{kJ mol}^{-1} \quad (3)$$

$$trans\text{-}[CoBr_2en_2]Br(s) + {}^3/_2S^{2-}(aq) = {}^1/_2Co_2S_3(s) + 3Br^-(aq) + 2en(aq) \qquad \Delta H = -40.5\ \text{kJ mol}^{-1} \quad (4)$$

By combining Eq. 1 with 2, and Eq. 3 with 4, the enthalpy changes of the isomerization for the dichloro- and dibromo-complexes are obtained as follows:

$$cis\text{-}[CoCl_2en_2]Cl(s) = trans\text{-}[CoCl_2en_2]Cl(s) \qquad \Delta H = -11.4\ \text{kJ mol}^{-1}$$

$$cis\text{-}[CoBr_2en_2]Br(s) = trans\text{-}[CoBr_2en_2]Br(s) \qquad \Delta H = -6.4\ \text{kJ mol}^{-1}$$

Statistically, the probability of the formation of the cis complex is 4, whereas that of the trans complex is just one, and thereby the entropy of the cis complex is larger than that of the trans one by the value

$$\Delta S = R\ln 4 = 11.5\ \text{J mol}^{-1}\text{K}^{-1}.$$

The entropy change of cis-to-trans isomerization is, therefore, $\Delta S=-11.5$ J mol^{-1}K^{-1}, and the free energy changes are calculated as:

$$cis\text{-}[CoCl_2en_2]Cl(s) = trans\text{-}[CoCl_2en_2]Cl(s) \qquad \Delta G° = -8.0\ \text{kJ mol}^{-1}$$

$$cis\text{-}[CoBr_2en_2]Br(s) = trans\text{-}[CoBr_2en_2]Br(s) \qquad \Delta G° = -3.0\ \text{kJ mol}^{-1}.$$

On the basis of the above data of enthalpy and free

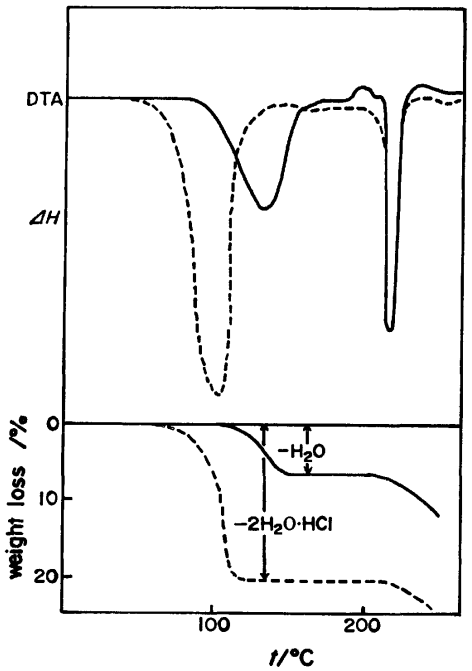

Fig. 1. Derivatograms of *cis*-$[CoCl_2en_2]Cl \cdot H_2O$ (——) and *trans*-$[CoCl_2en_2](H_5O_2)Cl_2$ (------).

Table 1. The results of TLC

Materials	R_f values
Thermal products from	0.56 (blue) 0.24 (green)
cis-$[CoCl_2en_2]Cl$	0.15 (blue) 0.04(brown)
trans-$[CoCl_2en_2]Cl$	0.24 (green)
cis-$[CoCl_2en_2]Cl$	0.17 (violet)
$CoCl_2 \cdot 6H_2O$	0.57 (blue) 0.26 (blue)
	0.10 (blue)
Thermal product from	
cis-$[CoBr_2en_2]Br$	0.36
trans-$[CoBr_2en_2]Br$	0.35
cis-$[CoBr_2en_2]Br$	0.30

energy changes, the cis-to-trans isomerization is expected to take place both in $[CoCl_2en_2]Cl$(s) and $[CoBr_2en_2]$-Br(s), although neither cis-to-trans nor trans-to-cis isomerization has been found for these complexes in a solid phase.

Derivatogtaphy. Figure 1 shows the derivatograms of *cis*-$[CoCl_2en_2]Cl \cdot H_2O$ and *trans*-$[CoCl_2en_2](H_5O_2)$-Cl_2. In the latter, neither endo- nor exothermic peak appears, except for the endothermic peaks due to the dehydration plus dehydrochlorination and the decomposition or melting. On the other hand, in the former, in addition to the endothermic peaks due to the dehydration and the decomposition or melting, a small exothermic peak is displayed at *ca.* 200 °C immediately before the decomposition or melting of the complex. In the isothermal heating of *cis*-$[CoCl_2en_2]Cl$ and *cis*-$[CoBr_2$-$en_2]Br$, the color change from violet to green was observed at 215 °C and 210 °C, respectively. Therefore, the appearance of an exothermic peak in the derivatogram of *cis*-$[CoCl_2en_2]Cl$ suggests the occurrence of isomerization to the corresponding trans-form.

TLC. In order to identify the components of

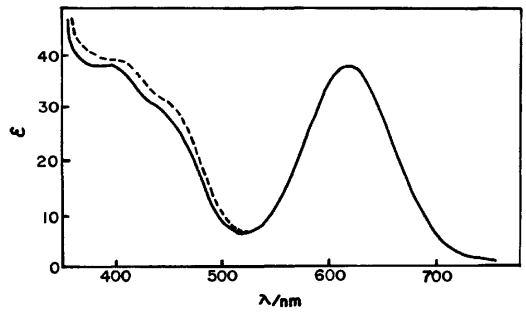

Fig. 2. Electronic spectra of *trans*-$[CoCl_2en_2]Cl$ (——) and of the third fraction of thermal products from *cis*-$[CoCl_2en_2]Cl$ (------).

thermal products of *cis*-$[CoCl_2en_2]Cl$ and *cis*-$[CoBr_2$-$en_2]Br$, the products were examined by means of TLC. The results of TLC are listed in Table 1. In the dichloro complex, four spots were clearly developed. The R_f value of 0.24 of the green spot is identical with that (0.24) of *trans*-$[CoCl_2en_2]Cl$ freshly prepared, and the value is obviously distinguished from those of the other spots due to the original cis complex and others. The thermal product obtained from *cis*-$[CoBr_2en_2]Br$ gave the R_f value of 0.36, which is also very close to that (0.35) of *trans*-$[CoBr_2en_2]Br$ freshly prepared.

Spectral Measurements. In order to confirm the formation of *trans*-$[CoX_2en_2]X$ from the thermal reaction of the corresponding cis complexes, the thermal product was separated by means of column chromatography. The thermal product of the cis-dichloro complex was separated into four fractions on a column of the cation exchange resin (SP Sephadex C-25, H^+ form). The third fraction was green and eluted with 0.1 mol dm^{-3} HCl methanolic solution. The green product of the cis-dibromo complex was separated on a column of cellulose and eluted with methanol as rapidly as possible because the trans-dibromo complex is readily isomerizes to the original cis-form during elution. The electronic spectrum of the green compound thus obtained from *cis*-$[CoCl_2en_2]Cl$ is shown in Fig. 2. It is almost identical with that of *trans*-$[CoCl_2en_2]Cl$ freshly prepared. The same result is obtained for the dibromo complex.

The results of the above experiments support that both *cis*-$[CoCl_2en_2]Cl$ and *cis*-$[CoBr_2en_2]Br$ isomerize to the corresponding trans-form in a solid phase as expected from the thermodynamic consideration.

Kinetic Studies of Solvent Extraction of Metal Complexes. VIII. Rate of Complex Formation and Solvent Extraction of Iron(III) in Aqueous Perchlorate Solutions with 1,1,1-Trifluoro-2,4-pentanedione

Tatsuya SEKINE* and Kazuho INABA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 4, 1982)

The rate of the extraction of iron(III) in aqueous 4 mol dm^{-3} sodium perchlorate solutions with 1,1,1-trifluoro-2,4-pentanedione (Htfa) into carbon tetrachloride was measured, and the rate constants for the controlling reactions in the aqueous phase:

$$Fe^{3+} + Htfa \longrightarrow Fe(tfa)^{2+} + H^+ \text{ and } Fe(OH)^{2+} + Htfa \longrightarrow Fe(tfa)^{2+} + H_2O,$$

were calculated. These constants were also determined from spectrophotometric measurements of the aqueous solutions in the absence of the organic phase. The two series of rate constants obtained by the independent experiments agreed well. It was pointed out that equilibrium constants among the complexes in the aqueous and organic phases are indispensable in order to make a precise discussion of the solvent extraction of metal ions when aqueous-complex formation controls the whole process.

In this series, the rate of the solvent extraction of beryllium(II),[1] iron(III),[2,3] and gallium(III)[4] with β-diketones into nonpolar solvents was measured, and it was concluded that the formation of metal complexes took place in the aqueous phase first, and then the uncharged one among them was extracted into the organic phase. Thus, the whole process in these extractions was controlled by the formation of the first complex in the aqueous phase. In these previous studies, the effects of mass transport and interfacial reactions were neglected because the experiments were carried out at such an agitation speed that no increase in the rate was found on its further increase. This type of extraction mechanism seems to be very common among the extractions done under similar experimental conditions.[5] In the present study, the rate of the solvent extraction of iron(III) in aqueous 4 mol dm^{-3} perchlorate solutions with 1,1,1-trifluoro-2,4-pentanedione (trifluoroacetylacetone, Htfa) into carbon tetrachloride was determined at 298 K. At the same time, the rate of the complex formation of iron(III) with this ligand in these aqueous solutions was determined in separate experiments in the absence of the organic phase by a spectrophotometric method. From the results of these two series of experiments, two kinds of reaction routes were found for the complex formation; the two sets of rate constants, one of them obtained from the spectrophotometric data, and the other calculated from the extraction data, agreed well each other.

Experimental

The rate was always determined at 298 K. The aqueous solutions were constant ionic media, 4 mol dm^{-3} (H, Na)ClO_4. The hydrogen-ion concentration of the sample solutions was measured potentiometrically. By measuring a series of standard solutions, the acid concentrations of which had been determined by titration with a standard sodium hydroxide solution, a calibration curve of the emf *vs.* the hydrogen-ion concentration was prepared. The hydrogen-ion concentration in the sample solutions was calculated from the potentiometric data by using this curve. Thus the stoichiometric units are used in this study. The experiments by the spectrophotometric method was made with Htfa in a large excess to iron(III). The spectrophotometric experiments were made in a manner similar to that described previously except that the absorptions at 450 nm were measured at certain time intervals after the metal ion and the ligand solutions had been mixed.[6] The experiments of the solvent extraction were made in a manner similar to that previously described.[2,3,6] A carbon tetrachloride solution containing Htfa and a perchlorate solution containing iron(III) perchlorate at 5×10^{-4} mol dm^{-3} were agitated so vigorously that no increase in the rate was found on a further increase in the agitation speed. The amount of iron(III) extracted after a certain time interval was determined by an atomic-absorption method.

Statistical

Any chemical species in the organic phase will be denoted by the subscript "org" and those in the aqueous phase, by the lack of any subscript. The initial concentration will be denoted by the subscript "init."

The acid-dissociation and two-phase distribution constants of the ligand and the stability constant of the "*n*-th" complex are defined as:

$$K_a = [H^+][tfa^-][Htfa]^{-1} \quad (1)$$

$$K_d = [Htfa]_{org}[Htfa]^{-1} \quad (2)$$

$$\beta_n = [Fe(tfa)_n^{3-n}][Fe^{3+}]^{-1}[tfa^-]^{-n}. \quad (3)$$

As will be seen later, the two-phase distribution constant of the uncharged complex is necessary to correlate the rate constants for the solvent extraction and for the complex formation. It is defined as:

$$K_{dm} = [Fe(tfa)_3]_{org}[Fe(tfa)_3]^{-1}. \quad (4)$$

When the rate of the complex formation of Fe^{3+} in aqueous solutions is first-order with respect to Fe^{3+}, and when several reaction routes are present, it can generally be written as:

$$V = -d[Fe^{3+}]/dt = \sum K_{CF(a,b\cdots)}[Fe^{3+}][Htfa]^a[H^+]^b\cdots, \quad (5)$$

where a,b··· are certain integers. From Eq. 5, the following equation is obtained when a certain component, for example, H^+, is changed, but the others are

kept constant:

$$-\log[Fe^{3+}] = q_{H^+} \times t + \log[Fe^{3+}]_{init} \quad (6)$$

$$q_{H^+} = \sum K^*_{CF(a,b\cdots)} \times C_{Htfa}{}^a \times [H^+]^b \cdots, \quad (7)$$

where $K^*_{CF(a,b\cdots)} = K_{CF(a,b\cdots)}/\ln(10)$ and where C_{Htfa} is the concentration of Htfa kept at a certain value. Similar equations may be written with respect to the other components.

Treatment of Optical Absorption Data. When the rate of complex formation is first-order with respect to Fe^{3+}, and when an equilibrium is established for all practical purposes among the complexes, the following treatments of the optical-absorption data are possible.

When the absorption due to the Fe^{3+} species is negligible, the over-all absorbance experimentally measured can be written as:[6]

$$\varepsilon_T = (\varepsilon_1[Fe(tfa)^{2+}] + \varepsilon_2[Fe(tfa)_2{}^+] + \varepsilon_3[Fe(tfa)_3])([Fe(tfa)^{2+}] + [Fe(tfa)_2{}^+] + [Fe(tfa)_3])^{-1}$$
$$= (\varepsilon_1\beta_1[tfa^-] + \varepsilon_2\beta_2[tfa^-]^2 + \varepsilon_3\beta_3[tfa^-]^3)(\beta_1[tfa^-] + \beta_2[tfa^-]^2 + \beta_3[tfa^-]^3)^{-1}, \quad (8)$$

where ε_n is the molar absorption coefficient of the "n-th" complex. The value of ε_T can be calculated from ε_n and β_n for a certain $[tfa^-]$, and by using this parameter and the absorbance experimentally measured, the total amount of complexes or the decrease in $[Fe^{3+}]$ by the complex formation can be obtained as:

$$E/\varepsilon_T = [Fe(tfa)^{2+}] + [Fe(tfa)_2{}^+] + [Fe(tfa)_3]$$
$$= [Fe^{3+}]_{init} - [Fe^{3+}]. \quad (9)$$

By introducing $[Fe^{3+}]$ into Eq. 6, the value of q_{H^+} (or q with respect to the other components) under certain conditions can be obtained, and from the slope of the plot of log q *versus* the logarithmic concentration of the component, the dependences, a, b$\cdots$, can be obtained.

Treatment of Solvent-extraction Data. When several roues are present in the solvent extraction of Fe^{3+} in the aqueous phase with Htfa, the rate may be written in a way similar to Eqs. 5 to 7:

$$V = -d[Fe(III)]/dt$$
$$= \sum K_{SE(a,b\cdots)}[Fe(III)][Htfa]^a[H^+]^b\cdots. \quad (10)$$

Here, the total concentration of iron(III) species in the aqueous phase is considered instead of the Fe^{3+} concentration in Eq. 5. For example, with respect to H^+, the following equation can be written:

$$-\log[Fe(III)] = q_{H^+} \times t + \log[Fe(III)]_{init} \quad (11)$$

$$q_{H^+} = \sum K^*_{SE(a,b)} \times C_{Htfa}{}^a \times [H^+]^b\cdots. \quad (12)$$

Results

Rate of Change in Optical Absorption. The absorption in the range from 400 to 600 nm of aqueous perchlorate solutions containing Fe^{3+} and Htfa was only slight at first but it gradually increased until a maximum absorption was observed at about 450 nm. The absorbance at this wavelength was measured at certain time intervals. Figure 1 gives an example of such results. In order to treat these absorption data, it was assumed that the formation of the first complex, $Fe(tfa)^{2+}$, from Fe^{3+} was the controlling step and that the formation of the higher complexes proceeded much more rapidly than this, in other words, the three complexes, $Fe(tfa)^{2+}$, $Fe(tfa)_2{}^+$, and $Fe(tfa)_3$, were in an equilibrium with each other. From the absorbance and the concentra-

$K_d = 10^{0.39}$	
$K_e^{a)} = 10^{-1.96}$	
$\beta_1 = 10^{7.7}$	$\varepsilon_1 = 170$
$\beta_2 = 10^{14.4}$	$\varepsilon_2 = 1050$
$\beta_3 = 10^{19.8}$	$\varepsilon_3 = 2560$
$K_{dm} = 10^{4.2}$	
$K_h^{b)} = 10^{-3.1}$	

a) $K_e = [Htfa]_{enol}[Htfa]^{-1}_{keto}$. b) $K_h = [Fe(OH)^{2+}][H^+][Fe^{3+}]^{-1}$ (in 3 mol dm^{-3} (H, Na)ClO_4 Ref. 9).

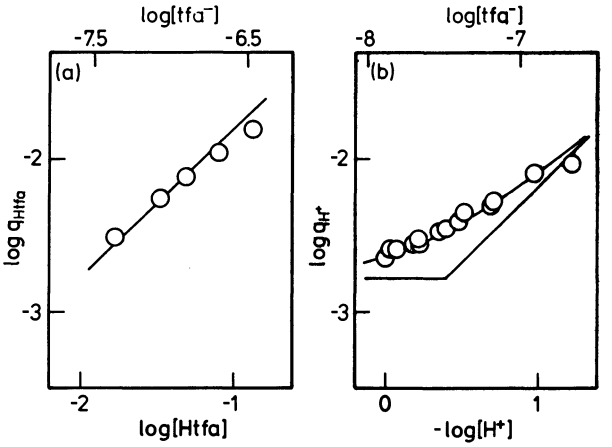

Fig. 2. Dependence of the rate of complex formation of iron(III): (a) on the Htfa concentration when [H+] is 1.0×10^{-1} mol dm^{-3} and (b) on the hydrogen-ion concentration when [Htfa] is 5.0×10^{-2} mol dm^{-3}.
The straight line in (a) and the curve in (b) are calculated by introducing the constants in Table 2 into Eq. 13. The two lines in (b) are the asymptotes for the curve.

tions of Htfa and hydrogen ions, the total amount of complexes formed, that is, the decrease in the Fe^{3+} concentration, was calculated on the basis of Eq. 8 by introducing the molar-absorption coefficients and stability constants in Table 1, which had been determined in a previous study.[6] From this calculated decrease in the Fe^{3+} concentration, the parameters, q, were obtained. Figure 2 gives the dependence of q on the Htfa and hydrogen-ion concentrations. As may be seen, the rate was first-order with respect to Htfa. However, the dependence of the rate on the hydrogen ions approached to zero-order in the higher acidity range, while it approached to inverse-first-order in the lower acidity range. From these data, the rate of complex formation was concluded to be given by:

$$V = K_{CF(1,0)}[Fe^{3+}][Htfa] + K_{CF(1,-1)}[Fe^{3+}][Htfa][H^+]^{-1}$$
$$= K_{CF(1,0)}[Fe^{3+}][Htfa](1 + K_{CF(1,-1)}/K_{CF(1,0)}[H^+]^{-1}). \quad (13)$$

The values of $K_{CF(1,0)}$ and $K_{CF(1,-1)}/K_{CF(1,0)}$ were determined graphically. The plot in Fig. 2(b) was fitted with a standard curve:

$$y = \log(1 + w) : x = \log w \quad (14)$$

and the values were obtained from the parameters of the fitted curve (*cf.* pp. 85 to 96 in Ref. 7). The rate constants obtained are listed in Table 2.

Table 2. Summary of rate constants

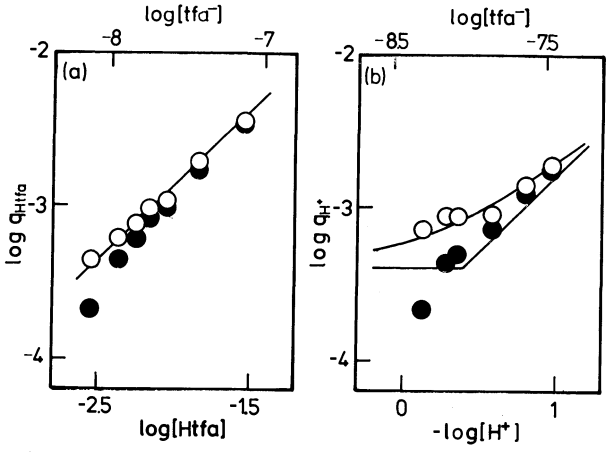

Fig. 3. Dependence of the rate of extraction of iron(III) (closed circles) and the rate of complex formation calculated from the extraction data using Eq. 21 and the constants in Table 1 (open circles): (a) on [Htfa] when $[H^+]$ is 1.0×10^{-1} mol dm^{-3} and (b) on $[H^+]$ when [Htfa] is 1.4×10^{-2} mol dm^{-3}.
The straight line in (a) and the curve in (b) are calculated by introducing the constants in Table 2 into Eq. 13. The two lines in (b) are the asymptotes for the curve.

Rate of Solvent Extraction. The amount of iron(III) extracted into the organic phase was measured as a function of the time; the parameters given by Eqs. 11 and 12 were also calculated as has been described previously.[1-4,7] The closed-circle in Fig. 3 give the dependence of the rate on the Htfa and hydrogen-ion concentrations in the aqueous phase. The rates are apparently first-order and inverse-first-order with respect to [Htfa] and $[H^+]$ respectively. From these data, the rate was concluded to be given (*cf.* Eqs. 10 and 11) by:

$$V = K_{SE(1,-1)}[Fe(III)][Htfa][H^+]^{-1}. \quad (15)$$

The rate constant for the solvent extraction, $K_{SE(1,-1)}$, was obtained from the data in Fig. 3 (*cf.* Table 2).

Discussion

In aqueous solutions, β-diketones are mainly in the keto hydrate form.[8] However, the complex formation in the aqueous phase should take place between hydrated metal ions and the β-diketone in the enol form. The controlling step for a reaction route whose rate is dependent only on the Htfa concentration in Eq. 13 should be:

$$Fe^{3+} + Htfa \longrightarrow Fe(tfa)^{2+} + H^+. \quad (16)$$

However, that for the reaction which is first-order with respect to Htfa and inverse-first-order with respect to hydrogen ions can be both:

$$Fe^{3+} + tfa^- \longrightarrow Fe(tfa)^{2+} \quad (17)$$
$$Fe(OH)^{2+} + Htfa \longrightarrow Fe(tfa)^{2+} + H_2O. \quad (18)$$

Since the reaction in Eq. 18 explains the rate of complex formation of Fe^{3+} with several β-diketones more reasonably,[3] this will also be adopted in the present study. The rate constant assuming the reaction in Eqs. 16 and 18 with the enol form of Htfa is calculated using the hydrolysis constant of Fe^{3+} given in Table 1.[9] (This was given for the equilibrium in 3 mol dm^{-3} $NaClO_4$ media, but the difference of the value in 4 mol dm^{-3} $NaClO_4$ media in the present study should not be large.) Using the constant for the keto-enol equilibrium of Htfa in aqueous solutions in Table 1,[8] the rate constant for the following reactions can be calculated:

$$Fe^{3+} + Htfa_{(enol)} \longrightarrow Fe(tfa)^{2+} + H^+$$
$$K_{CF(1,0)enol} = K_{CF(1,0)} \times (K_e + 1)K_e^{-1} \quad (19)$$
$$Fe(OH)^{2+} + Htfa_{(enol)} \longrightarrow Fe(tfa)^{2+} + H_2O$$
$$K_{CF(1,-1)enol} = K_{CF(1,-1)} \times K_h^{-1}(K_e+1)K_e^{-1}. \quad (20)$$

The calculated values are listed in Table 3.

The kinetics of the complex formation of iron(III) has been studied with several ligands. These data with β-diketones and 4-isopropyltropolone are summarized in Table 3.[10-14] The rate constants with other types of ligands are also in nearly the same order (10^0 to 10^2 for the type of reaction in Eq. 16 and 10^2 to 10^5 for the type of reaction in Eq. 18. For example, Refs. 15 to 29 and also those cited in Ref. 15).

The rate of extraction is determined from the amount of extracted iron(III) and is treated by Eq. 15. This was first-order with respect to the total aqueous concentration of iron(III). When the whole extraction is controlled by the formation of the first complex in the

TABLE 3. RATE CONSTANTS FOR FORMATION OF IRON(III) COMPLEXES IN AQUEOUS PERCHLORATE IONIC MEDIA AT 298 K

Ligand (HL)	$Fe^{3+}+HL$ ($mol^{-1}\ dm^3\ s^{-1}$)	$Fe(OH)^{2+}+HL$ ($mol^{-1}\ dm^3\ s^{-1}$)	Ionic strength / mol dm^{-3}	Ref.
Acetylacetone[a)]	$10^{0.7}$	$10^{3.6}$	1.0	10
2-Thenoyltrifluoroacetone	$10^{-0.3}$	$10^{2.6}$	1.0	11
2-Thenoyltrifluoroacetone	$10^{0.1}$	$10^{3.1}$	1.0	12
4-Isopropyltropolone	$10^{1.4}$	$10^{3.7}$	1.0	13
Trifluoroacetylacetone	$10^{0.9}$	$10^{3.6}$	4.0	b)
Triouoroacetylacetone	$10^{0.8}$	$10^{3.5}$	4.0	c)

a) Another study was also made of the rate of the complex formation of Fe^{3+} and acetylacetone by assuming a somewhat different mechanism.[14)] b) Spectrophotometric method in the present work. c) Solvent-extraction method in the present work.

aqueous phase, and when, consequently, the three aqueous complexes and the tris complex in the organic phase are in an equilibrium to each other, the decrease in the Fe^{3+} concentration should give the rate of this controlling reaction. The $[Fe^{3+}]$ concentration can be written as:

$$[Fe^{3+}] = [Fe(III)]_{init} - ([Fe(tfa)^{2+}] + [Fe(tfa)_2^+] + [Fe(tfa)_3] + [Fe(tfa)_3]_{org})$$
$$= [Fe(III)]_{init} - ((\beta_1\beta_3^{-1}[tfa^-]^{-2} + \beta_2\beta_3^{-1}[tfa^-]^{-1} + 1) \times K_{dm}^{-1} + 1) \times [Fe(tfa)_3]_{org}. \quad (21)$$

Thus, if the rate constant for the formation of the first complex in the aqueous phase is calculated from the extraction data, the decrease in the Fe^{3+} concentration, which can be obtained from the $Fe(tfa)_3$ concentration in the organic phase means of Eq. 21, should be employed instead of the decrease in the total aqueous iron(III) concentration. The open symbols in Fig. 3 were calculated in this way. As may be seen, the open symbols in Fig. 3 should correspond with the plot in Fig. 2, and by treating these data in a similar manner, the rate constants for the complex formation listed in Table 2 were obtained; they agreed well with those obtained from the spectrophotometric data. The rate constants for the complex formation with the enol form of Htfa in Eqs. 19 and 20 can also be obtained from the rate constant for the extraction. These values are also listed in Table 3.

Figure 3 shows that when no consideration is given to the reaction given by Eq. 21, no final conclusion as to the reaction mechanism of the solvent extraction in such systems can be drawn. Moreover, in general, it is not possible to determine the dependence of the rate of extraction on the extractant and the hydrogen ion; in other words, it is not always possible to know the controlling reaction only from a plot such as given by Eq. 10. In this series, we have often observed that the slope of such a plot as Fig. 3 deviates from that to be expected from the assumed controlling reaction; the above is presumably the reason for such deviations. This kind of deviation should be great when the proportion of the extracted complex to the total amount of the complexes produced after the controlling step is small. From Eq. 21, it may be seen that such a deviation occurs when the concentration of the ligand ($[tfa^-]$ in the present study) is low and/or when K_{dm} is low. Figure 4 gives the calculated percentage distributions of the complexes in the two phases when their volumes

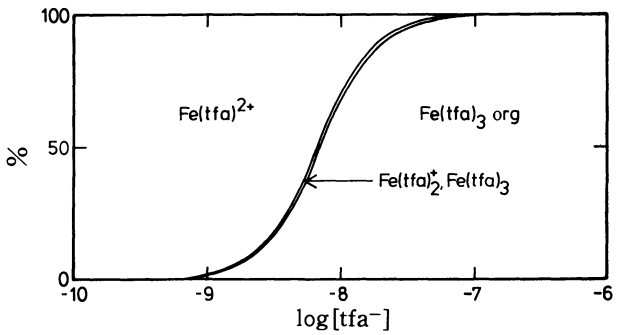

Fig. 4. Percentage distribution of complexes as a function of the ligand concentration when the volumes of the two phases are the same. The percentage gives the ratio of the concentration of each complex to the total concentration of the complexes, $([Fe(tfa)^{2+}]+[Fe(tfa)_2^+]+[Fe(tfa)_3]+[Fe(tfa)_3]_{org})$.

are the same. As may be seen, in the region where $[tfa^-]>10^{-7}$ mol dm^{-3} the molar ratio of the extracted complex to the total amount of the aqueous complexes is very high, and thus the deviation should be negligible. As may be seen from Fig. 3, a deviation occured in our experiments, and since $[tfa^-]$ in these experiments was lower than 10^{-7} mol dm^{-3}, this deviation can be explained reasonably by Fig. 4 and Eq. 21. In some kinetic studies of the extraction of iron(III) with chelating reagents, it was possible to conclude only from the extraction data, that the mechanism was that given by Eq. 16, making no consideration of such an effect.[2,30)] It was also possible in another study to conclude, though no consideration of the equilibrium was made, that the formation of the first complex controlled the complex formation of iron(III) in aqueous solutions with 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione, Htta, and also the solvent extraction of the metal ion.[11)] This was possible because the experiments were made under conditions where the ligand concentration was high and/or the K_{dm} in Eq. 4 was large.

From the good agreement of the rate constant for the formation of the iron(III) complex in the aqueous phase determined from the spectrophotometric and solvent-extraction data, it may finally be concluded that the extraction mechanism proposed above is reasonable and that the reaction on the interface is negligible.

The authors are very grateful to Dr. Yū Komatsu of the National Institute for Researches in Inorganic

Materials, Ibaraki, for his valuable discussions in connection with this work.

An Alternative Display of Potentiostatic Measurements. II. Electrochemical Determination of Outer-sphere Association Constants of Several Substitution-inert Complexes with Sulfate Ions

Akifumi YAMADA,* Yoshikiyo KATO,† Yasuo NAKABAYASHI,†† and Nobuyuki TANAKA†

Department of Materials Science and Technology, Technological University of Nagaoka, Kamitomioka, Nagaoka 949-54

†*Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980*

(Received June 14, 1982)

A modified technique for the potentiostatic method has been applied to the study on the outer-sphere association of some substitution-inert complex cations with sulfate ions. The association constants were determined from the change in limiting time as function of the concentration of sulfate ions at ionic strength 0.2 and 25 °C: 29±3 for $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, 23±2 for $[Co(en)_3]^{3+}$–SO_4^{2-}, 34±3 for $[Co(H_2O)(NH_3)_5]^{3+}$–SO_4^{2-}, 18±2 for $[Cr(NH_3)_6]^{3+}$–SO_4^{2-}, 21±2 for $[Cr(en)_3]^{3+}$–SO_4^{2-}, 19±2 for $[Cr(H_2O)(NH_3)_5]^{3+}$–SO_4^{2-}, 13±2 for $[Cr(urea)_6]^{3+}$–SO_4^{2-}. The ratios of the diffusion coefficient of the univalent ion pairs to that of tervalent substitution-inert complex cations were also obtained. From these ratios, the diffusion coefficients of the univalent ion pairs were calculated; these were found to be close to those of univalent complex ions with similar structures.

The potentiostatic method has been recognized as the principal tool for the investigation of electrode kinetics. Previous studies[1,2] have demonstrated an alternative mode of potentiostatic measurement, which analyzes the relationship between the potential and the time required to reach a constant sampling current in the potentiostatic measurement.[1] The instrumental design of an automatic recording of potential-time curves of this mode was described in the first paper of this series.[3] The chief advantage of this mode is that the limiting time at diffusion-controlled potential is directly proportional to the diffusion coefficient,[1] whereas, in the normal potentiostatic method, the limiting current is proportional to the square root of diffusion coefficients. Thus, the modified potentiostatic method is convenient for detection of the diffusion coefficient in a series of measurements.

It has been reported that the polarographic diffusion current and the chronopotentiometric transition time for some tervalent cations, such as $[Cr(NH_3)_6]^{3+}$,[4] $[Cr(en)_3]^{3+}$,[5] $[Cu(urea)_6]^{3+}$,[6] $[Co(NH_3)_6]^{3+}$,[7] and $[Co(en)_3]^{3+}$,[8] decrease upon the addition of sulfate ions. This decrease is attributed mainly to the effect of outer-sphere association of the tervalent cations and the sulfate ions; the diffusion coefficient of the sulfate ion decreases upon the formation of ion pairs. The decrease in the polarographic diffusion current[9,10] and in the chronopotentiometric transition time[11] was used for the determination of the association constant.

In this paper, a method for the determination of association constants with the aid of the modified potentiostatic method is presented and applied to the ion pairs: $[Cr(urea)_6]^{3+}$–SO_4^{2-}, $[Cr(H_2O)(NH_3)_5]^{3+}$–SO_4^{2-}, $[Cr(NH_3)_6]^{3+}$–SO_4^{2-}, $[Cr(en)_3]^{3+}$–SO_4^{2-}, $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, $[Co(en)_3]^{3+}$–SO_4^{2-}, and $[Co(H_2O)(NH_3)_5]^{3+}$–SO_4^{2-}.

Experimental

The complexes, $[Cr(urea)_6](ClO_4)_3$,[12] $[Cr(NH_3)_6](ClO_4)_3$,[13] $[Cr(H_2O)(NH_3)_5](ClO_4)_3$,[13] $[Cr(en)_3](ClO_4)_3$,[14] $[Co(NH_3)_6](ClO_4)_3$,[15] and $[Co(en)_3](ClO_4)_3$[16] were prepared according to the literature and converted to perchlorate salt. All other chemicals used were of guranteed reagent-grade. Redistilled water was used to prepared the solutions of desired concentrations. Polyethylene glycol dodecyl ether (LEO: mean molecular weight, 862) was used as the maximum suppressor.

Modified potentiostatic measurements were carried out by means of the modified pulse polarograph described in a previous paper.[3] A digital multimeter (Takeda Riken TR-6355) and a universal counter (Takeda Riken TR-5104G) were used; the potential and the time were thus measured precisely. A three-electrode cell equipped with a saturated calomel electrode (Yanagimoto MR-P2-05-1) and a platinum wire electrode were employed. The DME with a flow rate of 1.17 mg s^{-1} and a drop time of 2.0 s in 0.5 M (1 M=1 mol dm^{-3}) of NaCl was used. Electrolytic solutions were deaerated by bubbling purified nitrogen gas through the solution for 20 min. Measurements were made at 25 °C in solutions of ionic strength of 0.2 containing appropriate amounts of maximum suppressors. Ionic strength was adjusted with NaCl (for chromium(III) complexes) or with $NaNO_3$ (for cobalt(III) complexes).

Results and Discussion

From the modified potentiostatic measurements, the association constant can be determined in the following way. Consider the association reaction

$$M^{3+} + Z^{2-} \rightleftharpoons M^{3+}Z^{2-}, \quad (1)$$

where M^{3+} represents a complex cation, Z^{2-}, a sulfate anion and $M^{3+}Z^{2-}$, an ion pair. Since the dissociation and the association of ion pairs are very rapid, the apparent diffusion coefficient (D) is given by[17,18]

$$D = \frac{D_M + Kc_Z D_{MZ}}{1 + Kc_Z}, \quad (2)$$

where c_Z means the concentration of Z^{2-}, D_M, and D_{MZ} are the diffusion coefficient of M^{3+} and $M^{3+}Z^{2-}$, respectively, and K is the association constant of $M^{3+}Z^{2-}$ given by

$$K = c_{MZ}/c_M c_Z. \quad (3)$$

†† Present address: Department of Chemistry, Faculty of Science, Kobe University, Kobe 657.

Here c_M and c_{MZ} are the concentration of M^{3+} and $M^{3+}Z^{2-}$, respectively.

The observed limiting time (t) of the modified potentiostatic method in the presence of ion pairs can be expressed as follows:[1,2]

$$\sqrt{t} = nFc^\circ\sqrt{D}/\sqrt{\pi}I, \quad (4)$$

where c° is the bulk concentration of the electroactive species; n, the number of electrons; F, the Faraday constant; and I, the constant sampling current in the modified potentiostatic method. From Eqs. 2 and 4, one can deduce the following relation:

$$\left(\frac{c_M}{c}\right)^2\left(\frac{t}{t_M}\right) = \frac{1+Kc_Z\xi}{1+Kc_Z} \quad (5)$$

with

$$\sqrt{t_M} = nFc_M^\circ\sqrt{D_M}/\sqrt{\pi} \text{ and } \xi = D_{Mx}/D_M, \quad (6)$$

where t_M is the limiting time which is obtained when the bulk concentration of M^{3+} is c_M° and no ion pair is formed. The left-hand side of Eq. 5 is obtained experimentally, and plotted as a function of c_Z; a hyperbola is obtained, from which the association constant can be calculated.

Equation 5 can be transformed to

$$\frac{c_Z}{1-\left(\frac{c_M^\circ}{c^\circ}\right)^2\left(\frac{t}{t_M}\right)} = \frac{1+Kc_Z}{K(1-\xi)}. \quad (7)$$

Equation 7 indicates that the plot of $c_Z/[1-(c_M^\circ/c^\circ)^2\times(t/t_M)]$ *versus* c_Z will give a straight line and the association constant K can be determined from the ratio of its slope to its intercept. The ratio (ξ) of the diffusion coefficient of ion pairs $M^{3+}Z^{2-}$ to that of complex cation M^{3+} can then be obtained from the intercept.

The measurements for the determination of association constants were carried out in the solutions containing 0.01 M acetate buffer, since it was reported that the reduction waves of chromium(III) and cobalt(III) complexes used are not well-defined in neutral solutions, but are well-defined in acidic solutions.[4,5,19,20] An amount of 2—4 μM LEO was added to the solution to prevent the streaming effect.[5,21]

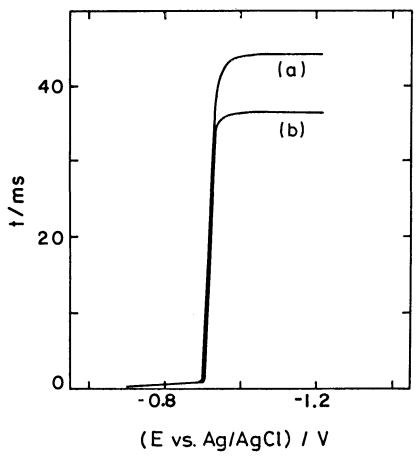

Fig. 1. An example of potential-time curves for the modified potentiostatic method with 0.5 mM $[Cr(NH_3)_6](ClO_4)_3$ obtained in (a) 0.195 M NaCl and (b) 0.065 M Na_2SO_4 containing 5 mM acetate buffer and 2 μM LEO at 25 °C. The measurements were made at 6.0 μA of sampling current.

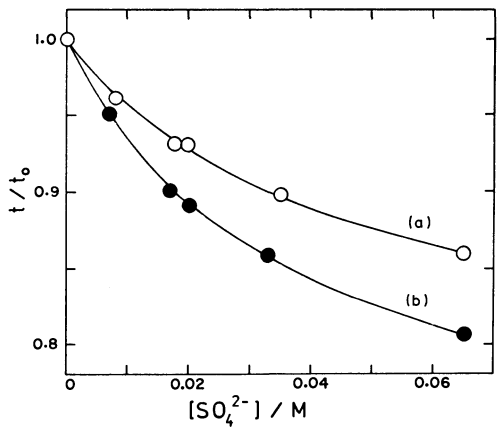

Fig. 2. Variation of the limiting time for the reduction of (a) $[Co(en)_3]^{3+}$ and (b) $[Co(NH_3)_6]^{3+}$ with the change in the concentration of sulfate ions, observed in the solutions containing 5 mM acetate buffer+(a) 4 μM LEO or (b) 2 μM LEO.

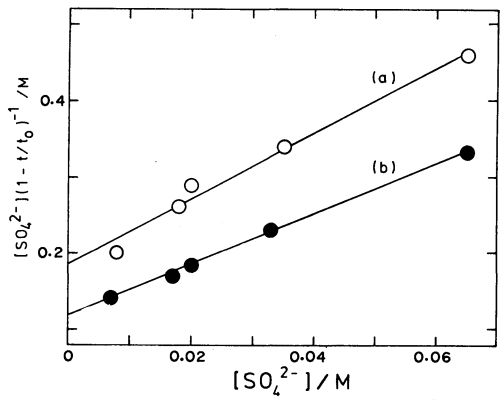

Fig. 3. Relation between the value of the left-hand side of Eq. 7 and sulfate concentration.
(a): $[Co(en)_3]^{3+}$, (b): $[Co(NH_3)_6]^{3+}$.

Figure 1 shows a typical example of a potential-time curve of the modified potentiostatic method for $[Cr(NH_3)_6]^{3+}$ ions which was obtained in solution with and without sulfate ions. The time was measured at a sampling current of 6 μA. It can be seen from Fig. 1 that the limiting time by means of the modified potentiostatic method decreased due to the presence of sodium sulfate. An example of the change in limiting time with the increase in the concentration of sodium sulfate is shown in Fig. 2 for $[Co(NH_3)_6]^{3+}$–SO_4^{2-} and $[Co(en)_3]^{3+}$–SO_4^{2-}. The value of t_0 was obtained with the solution of the bulk concentration $c_M^\circ(c_M^\circ=c^\circ)$ containing no sodium sulfate. A linear plot of Eq. 7 for $[Co(NH_3)_6]^{3+}$–SO_4^{2-} and $[Co(en)_3]^{3+}$–SO_4^{2-} is also given in Fig. 3.

The association constant (K) and the ratio of the diffusion coefficient (ξ) were calculated by the method of least squares. The results are given in Table 1. Comparison of the association constants of chromium(III) complexes with those of cobalt(III) ones having the

same ligands showed that the association constants of the chromium(III) complexes studied were smaller than those of the corresponding cobalt(III) ones.

The association constants of hexaamminecobalt(III) and tris(ethylenediamine)cobalt(III) with sulfate ion have been reported by several researchers.[22] The logarithmic constants of $[Co(NH_3)_6]^{3+}$–SO_4^{2-} at infinite dilution range between 2.89 and 3.71 and those of $[Co(en)_3]^{3+}$–SO_4^{2-} range between 2.72 and 3.45. Corrected for the effect of activity coefficient,[23] the logarithmic association constant at infinite dilution obtained from the present result becomes 3.19 for $[Co(NH_3)_6]^{3+}$–SO_4^{2-} and 2.88 for $[Co(en)_3]^{3+}$–SO_4^{2-}. The values obtained in this study are in good agreement with those in the literature, and with that expected from Bjerrum's theory[24] of ion association due to coulombic interaction between tervalent and bivalent ions of opposite charge at the distance of closest approach, 5—6 Å. Similarly, the values of $[Cr(NH_3)_6]^{3+}$–SO_4^{2-} obtained in this study also agree well with those obtained by other electrochemical methods.[2]

The association constant and the ratio of diffusion coefficients for ion pairs $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, $[Co(en)_3]^{3+}$–SO_4^{2-}, $[Cr(NH_3)_6]^{3+}$–SO_4^{2-} and $[Cr(en)_3]^{3+}$–SO_4^{2-} are compared with those obtained by chronopotentiometry.[22] They are given in Table 2, though the ionic strength in the measurements is different. The association constants of the present work ($\mu=0.2$) were approximately one third of those at $\mu=0.1$, whereas the ratios of diffusion coefficients were not so different for the two ionic strengths.

The association constants of $[Co(H_2O)(NH_3)_5]^{3+}$–SO_4^{2-}, $[Cr(H_2O)(NH_3)_5]^{3+}$–SO_4^{2-} and $[Cr(urea)_6]^{3+}$–SO_4^{2-} have not been reported, but the constant obtained in this study seems appropriate compared with the values for the ion pairs $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, $[Co(en)_3]^{3+}$–SO_4^{2-}, $[Cr(NH_3)_6]^{3+}$–SO_4^{2-} and $[Cr(en)_3]^{3+}$–SO_4^{2-}. Though detailed comparison of the constant with that of $[Cr(NH_3)_6]^{3+}$–SO_4^{2-} is limited, it may be said that $[Cr(urea)_6]^{3+}$–SO_4^{2-} is slightly less stable than $[Cr(NH_3)_6]^{3+}$–SO_4^{2-}.

The diffusion coefficients of ion pairs were calculated by using the diffusion coefficient of tervalent cation and the ratio of the diffusion coefficients, ξ, obtained in this study. They are compared with the diffusion coefficients of ion pairs given in the literature and with those of other univalent complex ions, which are given in Table 3.

Although such a comparison is limited because of insufficient accuracy in the measurement, it may be concluded that the diffusion coefficients of univalent ion pairs differ little from those of univalent complex ions.

In the derivation of Eq. 7, only the association of one cation and one anion was taken into consideration. With the precision of the present experiment it is difficult to determine the ion-pair formation involving more than one sulfate ion. The formation of such species is negligibly small compared with the ion pairs such as $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, $[Cr(NH_3)_6]^{3+}$–SO_4^{2-}, *etc.*, if the association is assumed to depend mainly on the coulombic interaction between ions.

Studies of Hydrous Tin(IV) Oxide Ion-exchangers. I. A Method for Synthesis and Some Properties

Yasushi INOUE* and Hiromichi YAMAZAKI
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received December 21, 1981)

A comprehensive study of the preparation of hydrous tin(IV) oxide ion-exchangers was made by using eight systems: (1)$Na_2[Sn(OH)_6]$–H_2SO_4, (2)$Na_2[Sn(OH)_6]$–H_2SO_4(boiling), (3)$Na_2[Sn(OH)_6]$–HCl, (4)$Na_2[Sn(OH)_6]$–CH_3COOH, (5)$SnCl_4$–NaOH, (6)$SnCl_4$–NH_3aq, (7)$SnCl_4$–NH_3aq(boiling), and (8)$SnCl_4$–pyrohydrolysis. From a detailed examination of the dependency of the yield, the ion-exchange behavior toward Na^+ and Cl^- ions, the composition, and some other properties on the conditions for precipitation, it was found that the ion-exchange characteristics are similar among materials produced from the systems from (1) through (7) if we neglect some aging effect of boiling, while the difficulty of synthesis differs according to the systems. The materials obtained from the (8) system, however, showed titration curves different from those for the exchanges obtained from the other systems and had less cation-exchange capacity for Na^+ by 20 per cent. From these results, it is concluded that the simplicity of the synthetic procedures in the most important criterion for choosing the best conditions for preparing the exchanger.

Many hydrous oxides for use as ion-exchange materials have been investigated because of their unique characteristics of selectivity and the simplicity of preparation. They have, however, the serious disadvantage of giving inconsistent results to different investigators. This may be due to irreproducibility of the synthesis. Nevertheless, many authors do not describe the details of the investigations concerning synthesis. To promote further investigation of this group of ion-exchange materials, it is indispensable to reexamine the synthetic conditions for establishing reproducible methods. With this point in mind, one of the present authors previously successfully studied hydrous titanium(IV) oxide in establishing a satisfactory method of synthesis.[1] Several studies have been carried out on hydrous tin(IV) oxide[3–9] since the work of Kraus *et al.*, who first reported the amphoteric ion-exchange property of this material.[2] In this case, also, different compositions and ion-exchange properties were reported by each investigator. This induced us to undertake a thorough study of the synthesis of hydrous tin(IV) oxide.

This paper will describe the results of one investigation to establish the best conditions for the synthesis by varying such factors as the starting materials, the methods of hydrolysis, the pH values of precipitation, and the concentrations of the hydrolyzing reagents, as well as aging.

Experimental

Reagents and Apparatus. $Na_2[Sn(OH)_6]$ was purified by recrystallization.[10] The other chemicals were of the highest purity grade and were used without further purification. The pH values were measured with a Toa Dempa model HM-5BS pH meter. The atomic absorption measurements were made with a Nippon Jarrell-Ash model AA-782 atomic-absorption and a flame-emission spectrophotometer, while the other absorption measurements were carried out with a Hitachi model 124 double-beam spectrophotometer.

Synthesis of Hydrous Tin(IV) Oxide. The synthetic systems adopted in the present investigation are shown schematically in Fig. 1. In the systems from (1) through (3), hydrous tin(IV) oxide was precipitated by hydrolyzing a $Na_2[Sn(OH)_6]$ solution by the addition of different acids,

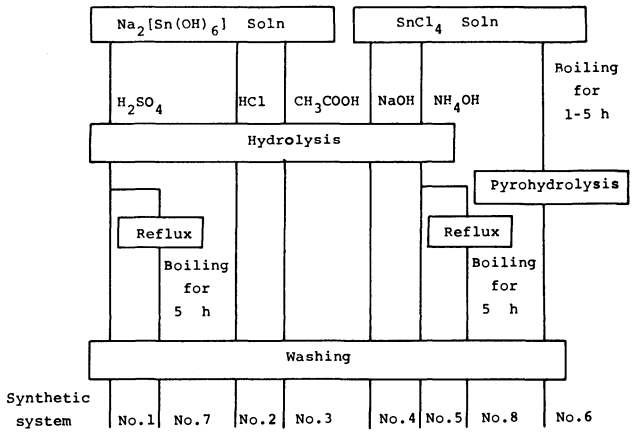

Fig. 1. Method of synthesis.

while in the (4) and (5) systems, the precipitate was made by hydrolyzing $SnCl_4$ solution by the addition of alkaline solutions. In some cases the slurries thus obtained were refluxed for five hours; the methods of precipitation of the (7) and (8) systems are similar to those of the (1) and (5) systems respectively. In the (6) system, the oxide was precipitated by the pyrohydrolysis of the $SnCl_4$ solution.

After precipitation had been completed, the precipitate was washed and dried by the following procedure unless otherwise noted. After being separated from the mother liquor by a combination of decantation and filtration through Toyo No. 1 filter paper under suction, the precipitate was uniformly dispersed into distilled water and filtered again after being completely sedimentated. This procedure was repeated until no impurity was detected in the filtrate. Then the precipitate was sufficiently air-dried at room temperature. The resulting product was then immersed in distilled water to break it down into fine particles, which were subsequently dried again at room temperature. At this stage the yield was calculated. Particles were then ground in a porcelain mortar and sieved to obtain the required particle sizes.

Conditioning. The exchanger of a desired particle size (100—200 mesh) was washed with water to remove any adherent powder. The slurry was poured into a glass tube, 10 mm in inside diameter and 15 cm high, with glass-wool plugging for column support. Then, 0.1 M (1 M=1 mol dm^{-3}) HCl was passed through the column until the pH of the

effluent approached that of the influent at a flow rate of about 1 cm^3 min^{-1}. Then the column was washed with water until the effluent showed a constant pH value (about 5). The exchanger in H^+ form thus prepared was air-dried and stored in a desiccator containing a saturated NH_4Cl solution (relative humidity, 79% at 25 °C).

Specific Ion-exchange Capacity and Titration Curves. A quarter gram of the exchanger in H^+ form was immersed in 30 cm^3 of various solutions, prepared by the desired combination of 0.1 M NaCl, and 0.1 M NaOH or 0.1 M HCl, for 4 d at room temperature with intermittent shaking. This was followed by pH measurements and by the determination of the sodium or chloride ions. The chloride concentrations were determined by the Fajans' method after the solution had been neutralized. The sodium ions were converted to pure sodium chloride and indirectly determined by titrating the chloride ions. The amount of the ions taken up by the exchanger was evaluated from the difference between the initial and final concentrations of the respective ions present in the solution. The amount of the exchanger dissolved was also evaluated from the amount of tin dissolved in the supernatant solution spectrophotometrically by the phenylfluorone method.[11] The limit of detection was 0.05 wt% of the exchanger used.

Total Analysis of the Exchanger. *Na^+ and SO_4^{2-}*: A half gram of the exchanger was dissolved in hydrobromic acid containing 10% bromine. The Na^+ concentration in this solution was determined atomic absorption-spectrophotometrically, while the absence of SO_4^{2-} ions was checked by adding a $BaCl_2$ solution. The limit of detection was 0.01 wt% for Na^+ and 0.005 wt% for SO_4^{2-}.

Cl^-: A sample of 0.5 g was dissolved by heating with 100 cm^3 of 9 M H_2SO_4 in a 500-cm^3 distilling flask, and the HCl evolving therefrom, carried by steam, was absorbed in a slightly alkaline solution and then determined spectrophotometrically, using mercury(II) thiocyanate and ammonium iron(III) sulfate as coloring reagents. The limit of detection was 0.02 wt%.

Water: A sample of 0.25 g was ignited at 850 °C, and the water content was calculated from the weight loss. The validity of the procedure had been confirmed thermogravimetrically.

Density: The density of the exchangers were measured in the usual manner using a 25-cm^3 pycnometer.

Results and Discussion

Precipitation Behavior in Various Synthetic Systems. It is required for practical purposes that a large amount of pure hydrous tin(IV) oxide can be prepared readily in a high yield; especially, the precipitation conditions should be such that the precipitate can be easily washed without peptization. For this reason, the yield evaluated from only the solubility loss is impractical; the yield should include all losses resulting from the whole synthetic processes. With this in view, we examined the relation between the yield and the conditions of precipitation for the synthetic systems shown in Fig. 1.

In this experiment, the solution of tin and a solution of acid or base of a suitable concentration were mixed together to make a total volume of 50 cm^3. The precipitate thus formed was then treated by the method described in the Experimental section. The yield was measured on the basis of the recovery of tin. Figure 2 shows the results for the (2) system. In this figure, the concentrations of tin and hydrochloric acid in the mixed solution were taken as the abscissa and the ordinate respectively. The area of the figure was distinguished into four regions based on the overall yield.

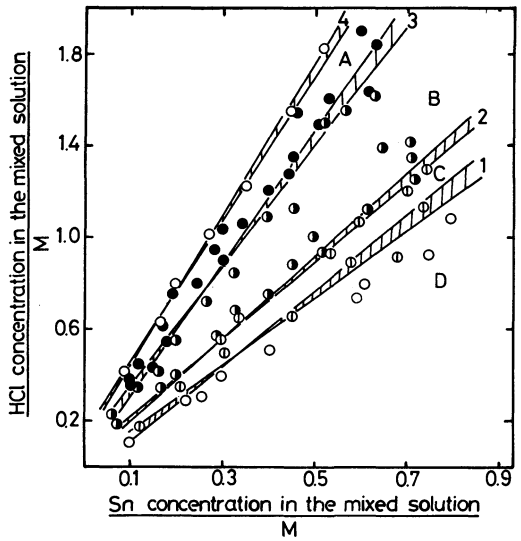

Fig. 2. Dependence of the yield of hydrous tin(IV) oxide on the conditions for precipitation (system (2)). Yield; ○: zero, ◔: <0.2, ◑: <0.6, ●: >0.8. Molar ratio ([HCl]/[Sn^{4+}]); 1: 1.5—1.7, 2: 1.7—1.8, 3: 2.7—3.0, 4: 3.3—3.4. For A, B, C, and D, see text.

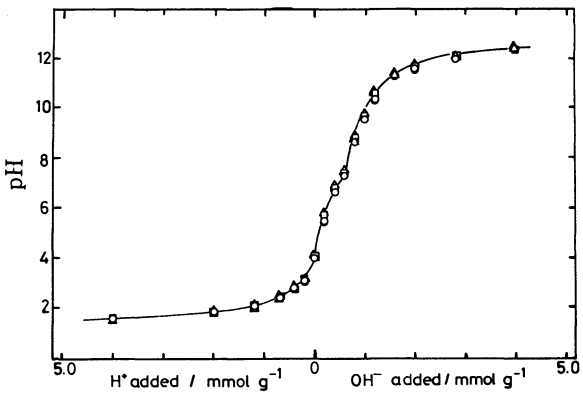

Fig. 3. Titration curves.
○: System (1) (pH=3.8), ●: system (2) (pH=3.8), □: system (3) (pH=4.6), △: system (4) (pH=3.5), ▲: system (5) (pH=3.5), ( ) shows the pH value at precipitation.

Region A: The precipitate could be washed without peptization until no impurity was detected in the filtrate, and the yield exceeded 80%. Thus, this is the optimum region.

Region B: The precipitate peptized during washing, and the yield was 20—80%.

Region C: The precipitate peptized at an early stage of washing, and the yield fell below 20%.

Region D: No precipitate was formed at all. Figures similar to Fig. 2 were made for every synthetic system; the results are summarized in Table 1. The appraisal of the synthetic system is made by a comparison of the area of Region A, because the experimental conditions can be more easily set up for a system having the larger

Table 1. Summary of the precipitation behavior

area of this region. Table 1 reveals that the (1) and (5) systems have A regions relatively large compared with other systems. The (1) system, however, has a defect in that it must be washed nearly three times as much as other systems before any impurities are removed. This makes the whole procedure unduly long. On the other hand, the area of Region A is small in the (2) and (4) systems due to the peptization of the precipitate; in the latter system, the concentration of tin is limited to the rather low value of 0.3 M since the peptization increases its prominence with an increase in the concentration. In the (6) system, Region A is found only in a concentration less than 0.1 M. Region A does not exist in the (3) system.

Ion-exchange Properties. The titration curves for the exchangers prepared from the systems from (1) through (5) are shown in Fig. 3. This indicates that no variations in the titration curves are observed between different systems and that the exchangers have at least two dissociable hydrogen atoms, since the inflection points exist in the curves at pH 7.5—8.0. Figure 4 shows the uptake curves for sodium ions as a function of the pH. These curves correspond to those in Fig. 3 except in the extremely high pH region, where the specific ion-exchange capacity decreases with the pH. This observation is attributable to the dissolution of a part of the exchanger, which was verified by analyzing the amount of tin dissolved in the supernatant solution; about 8 wt% of the exchanger was dissolved at pH 12.3. Figure 4 also shows that the exchanger possesses the maximum cation-exchange capacity of 1.17—1.25 mmol Na^+/g.

The anion-exchange property is not clearly observed in the titration curves. The uptake curves for chloride ions (Fig. 5), however, do indicate anion exchanges

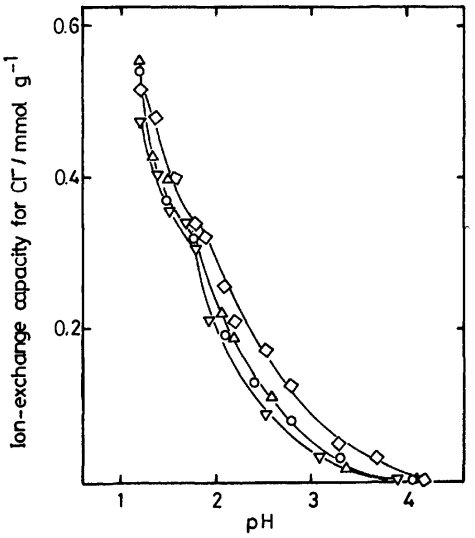

Fig. 5. Uptake curves of various exchangers for Cl^- ions. ○: System (1) ([Sn]=0.28 M, pH=3.8), △: system (5) ([Sn]=0.23 M, pH=3.1), ▽: system (8) ([Sn]=0.26 M, pH=3.1), ◇: system (6) ([Sn]=0.048 M, pH=1.2), ( ) shows the conditions for precipitation.

which occurs in two steps, an inflection point being at about 0.3 mmol Cl^-/g. The anion-exchange capacity is 0.56—0.60 mmol Cl^-/g at pH 1.2.

Sharygin[7] and Jaffrezic-Renault[8,9] reported the multiple cation-exchange behavior. They observed a maximum cation-exchange capacity similar to ours, but two inflection points in the titration curves showing three cation-exchange stages. On the other hand, anion-exchange capacity, 0.3—0.7 mmol/g, for the chloride ion in the vicinity of pH 1 was reported, but the multiple steps were not observed for anion exchange.[2,3,5,9] The reason for the contradiction between the published data and the present results is not clear, but it may be the difference in the details of the experimental procedure. In any event, this material is an amphoteric ion-exchanger possessing at least two weakly dissociable ion-exchange sites. The isoelectric point exists close to pH 4, as can be seen from Figs. 4 and 5. Hereafter, we will concentrate our discussion mainly on the cation-exchange properties because of the large ion-exchange capacity and the convenience of experimentation. For convenience, the cation exchange in the pH region lower than the inflection point will be referred as the first stage, and that in the higher pH region, as the second stage.

The uptake curves of the exchangers prepared from the (7) and (8) systems are shown in Fig. 4, which indicates that the boiling does not affect the first stage, but diminishes the ion-exchange capacity of the second stage by a total amount of 0.15 mmol/g. These findings suggest that the weak dissociable exchange sites are liable to be destroyed by aging. In these exchangers, the degree of the decrease in the ion-exchange capacity in the highly alkaline region becomes small, probably because of the stabilization of the exchanger against alkaline solutions; actually, all kinds of exchangers were dissolved only as much as 2 wt% at pH 12.5. It is, therefore, considered that the stabilization by aging is accompanied by the degradation of some of the weakly acidic sites. It is concluded that the hydrolysis by neutralization, with the exception of the decrease in the cation-exchange capacity by aging, leads to the exchangers having essentially the same ion-exchange characteristics regardless of the systems employed. The (1) and (5) systems being thus found to be most promising on account of the ease with which the precipitating conditions can be set up, efforts were then concentrated on elecidating the relation between the synthetic conditions (the effect of pH and the concentration of tin) and exchange properties with these systems in detail.

a) pH at precipitation. b) Washed.

The effect of the pH at precipitation was examined for the (1) and (5) systems. For the (1) system, this effect was not observed to any appreciable extent on the titration-and uptake curves. The effect of the pH was, however, observed for the (5) system. The experiments carried out to examine this effect are presented in Table 2. The uptake curves are shown in Fig. 6, which reveals nearly the same curves for all the exchangers precipitated at pH values lower than 2.6. For those precipitated at a pH higher than 2.6, however, the ion-exchange capacity increases with the pH at the precipitation. Table 2 also shows the interesting fact that the water content of the exchanger increases with the pH at the precipitation. In order to examine the aging effect of washing, the uptake curves of the (5) system were compared for samples with or without washing. It is revealed from this comparison that the washing results in a slight lowering of the ion-exchange capacity in the region of high pH values. As is shown in Table 2, the water content also decreases by washing.

The effect of the concentration of tin in the mixed solution was then studied at the conditions shown in Table 3. The concentration of tin did not appreciably affect the titration curves, but it did influence the

physical properties; the exchangers precipitated from the solution of a high concentration of tin (0.53 M), possess no glassy luster and a low density (3.06±0.06 g/cm^3), in contrast with those precipitated from the dilute solution of tin, which have densities of 3.26—3.31 (g/cm^3) and a large, glassy grain. Table 3 shows an example of the size distribution of the exchanger before grinding in a porcelain mortar. It is evident from this table that the distribution of particle size extends to a smaller range with materials obtained from a tin solution of a higher concentration. Similar results were obtained for other systems. Thus, the concentration of tin at the precipitation affects the physical properties, but not the ion exchange.

Figure 7 shows the uptake curves of the exchangers prepared by hydrolyzing a 4.8×10^{-2} M $SnCl_4$ solution by boiling for one or five hours with refluxing (the (6) system). The ion-exchange capacities of these materials are smaller than those of others by 0.05—0.1 mmol/g at the first stage and 0.2—0.3 mmol/g at the second stage. Hence, the numbers of exchange sites of this exchanger are small throughout the pH range examined as compared with those precipitated by neutralization. As the drop of the ion-exchange capacity at pH values higher than 11 is slight, the stability against an alkaline solution appears to be improved to some extent. Actually, the amount of the exchanger dissolved in the solution with a pH of 12.8 was only 1 wt%. The smaller ion-exchange capacity at the first stage in addition to the second suggests the formation of an exchanger with distinctive characteristics.

Stability in Air. Inoue and Yamazaki reported that the hydrous titanium(IV) oxide in the H^+ form lost its cation-exchange capacity appreciably during storage in air.[12] As the exchanger in the present study is the same type of compound as hydrous titanium(IV) oxide and is subjected to some aging effect by boiling with the mother solution, the ion-exchange capacity is expected to decrease during storage. Figure 8 shows the results for the materials prepared from the (1) system, which was stored over a saturated NH_4Cl solution. The ion-exchange capacity decreased by 0.1—0.2 mmol/g in the second stage 15 months after the prepara-

tion. This aging effect is similar to that by boiling, but it is not as abrupt as in hydrous titanium(IV) oxide. The result is compatible with Fuller's observation that the capacity for Cu(II) decreased by 0.18 mmol/g after 200 d of preparation.[5]

Composition and Other Properties. The purity, water content, density, and acidity (the equilibrium pH of the supernatant solution when the exchangers are immersed in 0.1 M NaCl) were measured. The results are summarized in Table 4, along with the ion-exchange capacity for Na^+ ions at pH 11. The amount of impurities was below or near the limit of detection.

As to the water content, a variety of papers have been published. According to Donaldson and Fuller, 17% of the water was contained in the exchanger prepared by a method similar to that used in our (1) system.[5] Sautereau *et al.* reported that the composition of α-stannic acid, prepared by a method similar to that used in (5) system, was $SnO_2\cdot1.78H_2O$.[13] Durand and Masdupuy obtained an exchanger whose composition was $H_2[Sn(OH)_6]$ by adding aqueous ammonia to a solution of $SnCl_4$ to make pH 5—6.[14] Abe and Ito obtained the composition of $SnO_2\cdot1.8H_2O$ for α-stannic acid.[3] Mikhail *et al.* obtained an exchanger whose composition was $SnO_2\cdot1.66H_2O$.[15] Goodman and Gregg prepared hydrous tin(IV) oxide with the composition of $SnO_2\cdot1.0$—$1.3H_2O$ by hydrolyzing tin(IV) ethoxide and by drying the precipitate at 25 °C.[16] Weiser and Milligan regarded the stannic acid as a hydration product of tin(IV) oxide rather than of tin(IV) hydroxide.[17] Based on this view, it is considered that the water content of the exchanger changes continuously with aging. Thiessen and Koerner reported a variety of compositions for hydrous tin(IV) oxide, that is, $2SnO_2\cdot5H_2O$, $SnO_2\cdot2H_2O$, $4SnO_2\cdot7H_2O$, and $SnO_2\cdot H_2O$.[18] As has been pointed out above, there exist discrepancies in water content between the results reported by different authors, even when the exchangers were prepared by substantially the same method. The reason for this may be the difference in the details of the conditions for precipitating and drying the precipitate. When we look over Table 4, we find the compositions of the exchangers in the vicinity of $SnO_2\cdot2H_2O$, although the exchangers prepared by neutralizing $Na_2[Sn(OH)_6]$ by acids contained a little more water. Furthermore, the exchangers containing a larger amount of water tend to have higher ion-exchange capacities.

From the values of acidity listed in Table 4, it can be deduced that the exchange sites of the first stage are more basic for the exchanger prepared by pyrohydrolysis than for that aged by boiling.

The density (3.23—3.40 g cm^{-3}) was nearly the same, irrespective of the method of precipitation, although the exchangers precipitated from the concentrated solution of tin had small densities and the densification occurred by heating. The fact that the water content decreases with the density suggests the extrusion of water by the densification.

Recommended Procedure. Since the ion-exchange behavior is not so much affected by the conditions of preparation, the simplicity and the rapidity of the procedure are a matter of utmost concern in choosing the best conditions for the preparation. Thus, the (1) and (5) systems are most appropriate. If we compare these two systems, the first is inferior to the second in that washing is very lengthy, while superior in that the starting materials are less expensive. The selection, therefore, should be made based on the judgment of which is more significant, the time or the cost spent in preparing the material.

Kinetics of the Ligand Substitution Reactions of Tetrahedral Complexes $[Co(NN)(hmpa)_2]^{2+}$ (NN = 2,2′-Bipyridine, 4,4′-Dimethyl-2,2′-bipyridine, or 1,10-Phenanthroline) in Hexamethylphosphoric Triamide, Nitrobenzene, Acetone, 1,2-Dichloroethane, and Nitromethane

Yuriko ABE* and Goro WADA
Department of Chemistry, Nara Women's University, Nara 630
(Received December 25, 1981)

The substitution reaction rates of hexamethylphosphoric triamide (HMPA) for NN (NN=2,2′-bipyridine (bpy), 4,4′-dimethyl-2,2′-bipyridine (dmbpy), or 1,10-phenanthroline (phen)) on tetrahedral complexes $[Co(NN)(hmpa)_2]^{2+}$ were determined spectrophotometrically in pure HMPA or in nitrobenzene, acetone, 1,2-dichloroethane, and nitromethane at various concentrations of HMPA, for the purpose of clarifying the reaction mechanism and the effect of the bulkiness of HMPA. The ligand substitution reaction on bpy and dmbpy complexes proceeds simply *via* a dissociative mechanism in nitrobenzene. In inert solvents other than nitrobenzene, it proceeds in parallel *via* two simultaneous paths of both dissociative and associative mechanisms. In the case of the phen complex, the reaction proceeds only by a dissociative mechanism in pure HMPA and in all the inert solvents used. The activation enthalpies and the activation entropies of the dissociative mechanism of bpy and dmbpy complexes were (80—90) kJ mol^{-1} and approximately zero J K^{-1} mol^{-1}, respectively, in all the solvents used. Those for the phen complex were (86—101) kJ mol^{-1} and (−16—+36) J K^{-1} mol^{-1}, respectively, while those of the associative mechanism for bpy and dmbpy complexes in all the solvents used except nitrobenzene were (50—65) kJ mol^{-1} and large negative values, respectively. Whether the substitution proceeds by the dissociative mechanism or by the associative one, both the steric and the solvent effects appear seriously, because HMPA is a bulky ligand and had a large dipole moment.

There are few accumulated kinetic data for reactions involving ligand substitution in tetrahedral complexes,[1] although those in octahedral ones[2] have been profoundly investigated. This is probably due to their fast reaction rates in the former complexes caused by the small crystal field stabilization. The measurements were made by NMR,[3–5] temperature jump,[6] *etc.*, and the thermodynamic requirements have severely restricted their studies.

We recently reported that hexamethylphosphoric triamide (HMPA) has a tendency to form complexes of a tetrahedral configuration.[7,8] In this paper, we measured spectrophotometrically the substitution reaction rates of HMPA for NN (NN=2,2′-bipyridine (bpy), 4,4′-dimethyl-2,2′-bipyridine (dmbpy), or 1,10-phenanthroline (phen)) on the tetrahedral complexes $[Co(NN)(hmpa)_2]^{2+}$ in pure HMPA and in nitrobenzene, acetone, 1,2-dichloroethane, and nitromethane at various concentrations of HMPA for the purpose of clarifying the reaction mechanism and the effect of the bulkiness of HMPA on the mechanism. The reaction rates were successfully measured by the conventional technique because, in general, bidentate ligands are exchanged more slowly than unidentate ones. The flexibilities of ligand molecules vary among bpy, dmbpy, and phen. Therefore, when one of those ligands is exchanged with HMPA which is more bulky than the original ligand, the reaction mechanism is strongly affected by the nature of the original ligands. When the reaction proceeds by an associative mechanism, the solvent effect may be stronger than for a dissociative mechanism.

Experimental

Materials. $[Co(hmpa)_4](ClO_4)_2$ and $[Cu(hmpa)_4](ClO_4)_2$ were prepared by methods described in the literature.[9,10] The recrystallizations of $NaClO_4$ and bpy were carried out by procedures we have described previously.[7] Anhydrous phen and dmbpy were used without further purification. The purifications of HMPA and nitromethane were carried out according to our previous description. Nitrobenzene and 1,2-dichloroethane were dried over calcium chloride and molecular sieves 4A, and then distilled under reduced pressure and at atmospheric pressure, respectively. Acetone was dried over calcium sulfate and molecular sieves 4A, and then distilled at atmospheric pressure.

Rate Measurements. The complex $[Co(NN)(hmpa)_2]^{2+}$ was prepared by mixing appropriate amounts of $[Co(hmpa)_4]^{2+}$ and bpy, dmbpy, or phen in HMPA or in one of the inert solvents in advance. The reaction was then initiated by mixing a solution of $[Co(NN)(hmpa)_2]^{2+}$ with a solution of $[Cu(hmpa)_4]^{2+}$ at a concentration in excess of the concentration of $[Co(NN)(hmpa)_2]^{2+}$ in a given solvent. The NN liberated by substitution was removed from the reaction system by its rapid complexation with $[Cu(hmpa)_4]^{2+}$. The reaction rate was followed by observing the increase in the absorbance at 580 nm using a Shimadzu Model UV-200S Spectrophotomer with a thermostated cell compartment. The ionic strength was adjusted at 0.06 mol dm^{-3} with sodium perchlorate or tetraethylammonium perchlorate.

Results and Discussion

Absorption Spectra of $[Co(dmbpy)(hmpa)_2]^{2+}$ and $[Co(phen)(hmpa)_2]^{2+}$ in HMPA and in Inert Solvents. As shown in Fig. 1, the absorption spectra of both $[Co(dmbpy)(hmpa)_2]^{2+}$ in HMPA and $[Co(phen)(hmpa)_2]^{2+}$ in acetone are quite similar to that of $[Co(bpy)(hmpa)_2]^{2+}$ in HMPA, which is already reported to be tetrahedral.[8] Therefore, $[Co(dmbpy)(hmpa)_2]^{2+}$ and $[Co(phen)(hmpa)_2]^{2+}$ in the respective solvents are deduced to be also tetrahedral. In other solvents, the same results were obtained.

Rate Constants of the Substitution Reaction. In any of the solvents used, the reaction obeys Eq. 1 under the

condition of $[Cu(II)]$ of a large excess over $[Co(II)] = 8\times10^{-4}$ mol dm^{-3},

$$\ln(A_\infty - A_t)/(A_\infty - A_0) = -k_{obsd}t, \quad (1)$$

where A_0, A_t, and A_∞ are the absorbances at 580 nm at times 0, t, and infinity, respectively, and k_{obsd} is the observed first-order rate constant. An example of the linear relationship based on Eq. 1 is shown in Fig. 2. The measured absorbances need not be corrected because the disappearing $[Cu(hmpa)_4]^{2+}$ and the produced Cu(II)–NN complex exhibit an isosbestic point at 580 nm. In all the solvents used, k_{obsd} was independent of $[Cu(II)]$; the experimental results in the case of the bpy complex in HMPA are given in

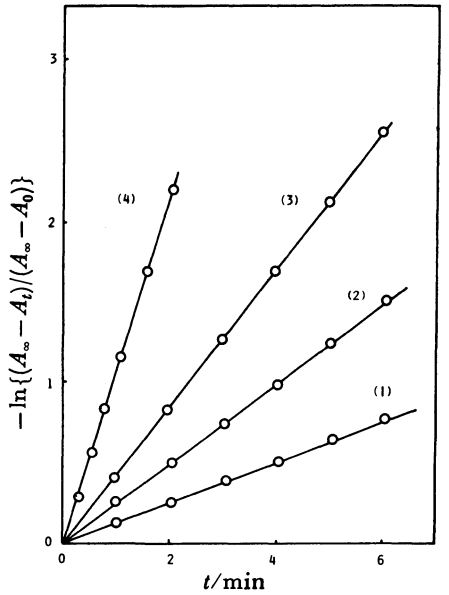

Fig. 2. Plots of $-\ln(A_\infty - A_t)/(A_\infty - A_0)$ *vs.* t at $[Co(II)] = 8\times10^{-4}$ mol dm^{-3} and $[Cu(II)] = 1.0\times10^{-2}$ mol dm^{-3} for the dmbpy complex in HMPA. Temperatures are (1) 15°C, (2) 20°C, (3) 25°C, and (4) 30 °C.

Table 1. Essentially similar data were also obtained in the other solvents. Since the liberated NN reacts rapidly with $[Cu(hmpa)_4]^{2+}$, the following Reaction 2 and the rate equation 3 are deduced.

$$[Co(NN)(hmpa)_2]^{2+} + 2hmpa \xrightarrow{k_{obsd}} [Co(hmpa)_4]^{2+} + NN, \quad (2)$$

$$-\frac{d[[Co(NN)(hmpa)_2]^{2+}]}{dt} = k_{obsd}[[Co(NN)(hmpa)_2]^{2+}]. \quad (3)$$

Dependence of k_{obsd} on the HMPA Concentration and Reaction Mechanism. The dependence of k_{obsd} on the HMPA concentration in the inert solvents can be classified into the following three types as shown in Figs. 3—5.

Type 1): As is shown in Fig. 3, k_{obsd} at first increases with increase in HMPA concentration and then reaches a constant value above a certain concentration of HMPA; this trend is also seen for the bpy and dmbpy complexes in nitrobenzene and for the phen complex in acetone, nitrobenzene, and nitromethane.

Type 2): The value of k_{obsd} is independent of the HMPA concentration in the case of the phen complex in 1,2-dichloroethane as shown in Fig. 4.

Type 3): The correlation of k_{obsd} with the concentration of HMPA can be empirically expressed by the sum of two terms; the zeroth and the first order with respect to the HMPA concentrations.

$$k_{obsd} = k_d + k_a[hmpa] \quad (4)$$

This is seen in the cases for the bpy and dmbpy complexes in acetone, 1,2-dichloroethane, and nitromethane; the examples for the bpy complex are shown in Fig. 5.

Judging from the above features of the reaction, two mechanisms may be considered for the substitution reaction of NN with $[Co(NN)(hmpa)_2]^{2+}$. One is a

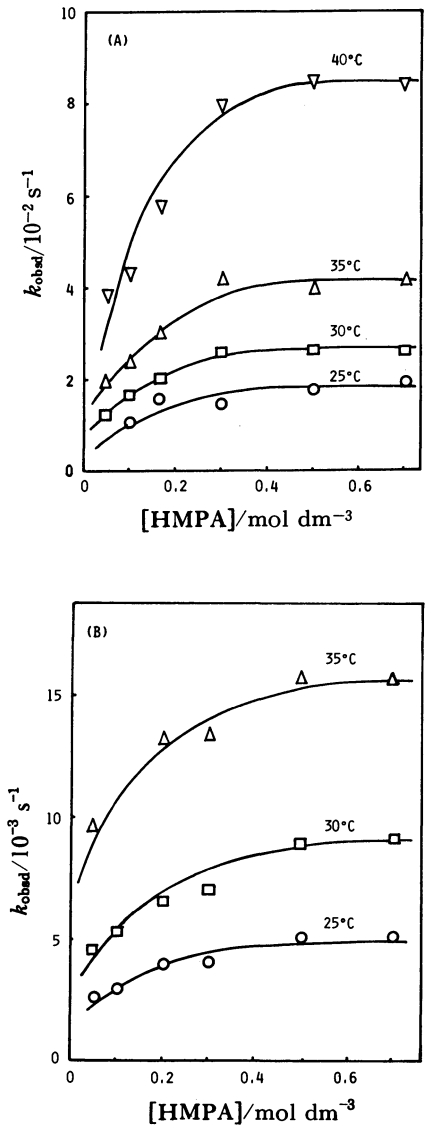

Fig. 3. The dependence of k_{obsd} on the HMPA concentration for the bpy (A) and dmbpy (B) complexes in nitrobenzene at 25 °C (○), 30 °C (□), 35 °C (△), and 40 °C (▽).

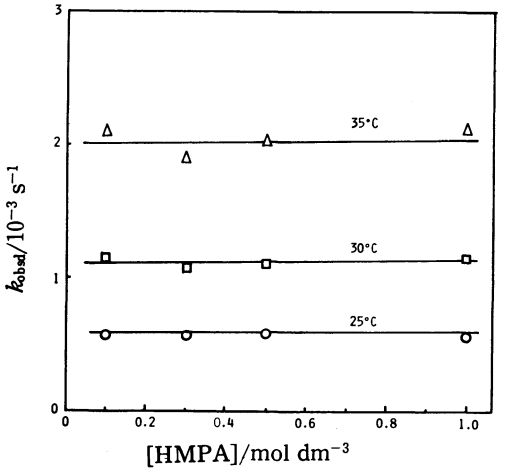

Fig. 4. The dependence of k_{obsd} on the HMPA concentration for the phen complex in 1,2-dichloroethane at 25 °C (○), 30 °C (□), and 35 °C (△).

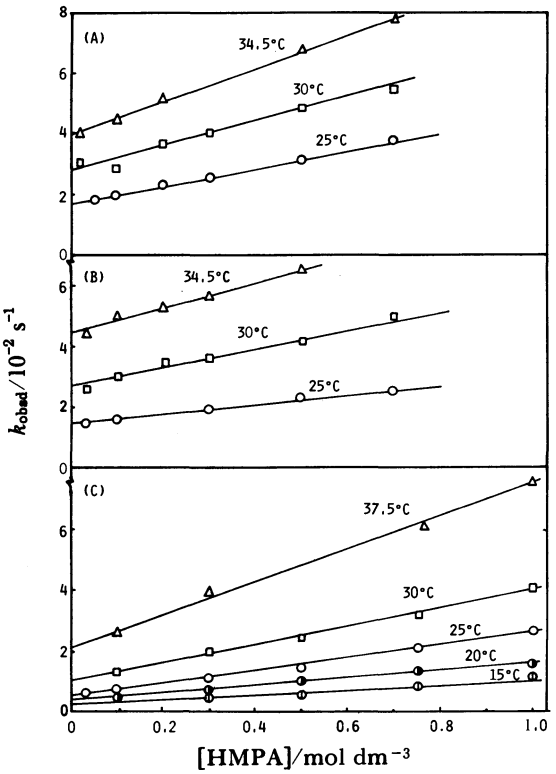

Fig. 5. The dependence of k_{obsd} on the HMPA concentration for the bpy complex in acetone (A), 1,2-dichloroethane (B), and nitromethane (C) at 15 °C (◐), 20 °C (◑), 25 °C (○), 30 °C (□), and 34.5 °C or 37.5 °C (△).

dissociative mechanism, in which one of the two cobalt-nitrogen bonds is first broken, followed by the reaction of the three-coordinated intermediate with an HMPA. The other is an associative mechanism, in which Co(II) first reacts with an HMPA, resulting in a five-coordinated intermediate.

The following reaction scheme may be valid when the substitution reaction proceeds by the dissociative mechanism.

$$[(hmpa)_2Co(\overset{\frown}{N\ N})]^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [(hmpa)_2Co\text{-}\overset{\frown}{N\ N}]^{2+} \quad (5)$$

$$[(hmpa)_2Co\text{-}\overset{\frown}{N\ N}]^{2+} + hmpa \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [(hmpa)_3Co\text{-}\overset{\frown}{N\ N}]^{2+} \quad (6)$$

$$[(hmpa)_3Co\text{-}\overset{\frown}{N\ N}]^{2+} + hmpa \xrightarrow{k_3} [(hmpa)_4Co]^{2+} + NN \quad (7)$$

Application of the steady-state method to the unstable intermediates, $[(hmpa)_2Co\text{-}\widehat{NN}]^{2+}$ and $[(hmpa)_3Co\text{-}\widehat{NN}]^{2+}$, leads to Eq. 8.

$$k_{obsd} = \frac{k_1k_2k_3[hmpa]^2}{k_{-1}k_{-2} + k_{-1}k_3[hmpa] + k_2k_3[hmpa]^2} \quad (8)$$

By rearranging Eq. 8, the following equation is derived;

$$\frac{1}{k_{obsd}} = \frac{1}{k_1} + \frac{k_{-1}}{k_1k_2}\frac{1}{[hmpa]} + \frac{k_{-1}k_{-2}}{k_1k_2k_3}\frac{1}{[hmpa]^2}. \quad (9)$$

On the other hand, for the associative mechanism, Reactions 10—12 are considered.

Table 2. Rate constants at 25 °C, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ of the dissociative mechanism and the associative mechanism for bpy, dmbpy, and phen complexes in HMPA, nitrobenzene, acetone, 1,2-dichloroethane, and nitromethane

$$[(\text{hmpa})_2\text{Co}(\overset{N}{\underset{N}{\frown}})]^{2+} + \text{hmpa} \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} [(\text{hmpa})_3\text{Co}(\overset{N}{\underset{N}{\frown}})]^{2+} \quad (10)$$

$$[(\text{hmpa})_3\text{Co}(\overset{N}{\underset{N}{\frown}})]^{2+} \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} [(\text{hmpa})_3\text{Co-}\overset{\frown}{\text{N N}}]^{2+} \quad (11)$$

$$[(\text{hmpa})_3\text{Co-}\overset{\frown}{\text{N N}}]^{2+} + \text{hmpa} \xrightarrow{k_6} [(\text{hmpa})_4\text{Co}]^{2+} + \text{NN} \quad (12)$$

Again, by use of the steady-state method for $[(\text{hmpa})_3\text{Co}(\overset{N}{\underset{N}{\frown}})]^{2+}$ and $[(\text{hmpa})_3\text{Co-}\overset{\frown}{\text{NN}}]^{2+}$, k_{obsd} is expressed by the following equation 13.

$$k_{obsd} = \frac{k_4k_5k_6[\text{hmpa}]^2}{k_{-4}k_{-5}+(k_{-4}+k_5)k_6[\text{hmpa}]} \quad (13)$$

By rearranging Eq. 13, Eq. 14 holds;

$$\frac{1}{k_{obsd}} = \frac{k_{-4}+k_5}{k_4k_5}\frac{1}{[\text{hmpa}]} + \frac{k_{-4}k_{-5}}{k_4k_5k_6}\frac{1}{[\text{hmpa}]^2}. \quad (14)$$

If the plots of $1/k_{obsd}$ *vs.* $1/[\text{hmpa}]$ are linear without passing the origin, the reaction may proceed by the dissociative mechanism with the third term on the right-hand side in Eq. 9 negligibly small. Examples are seen in the case of the dmbpy complex in nitrobenzene and the phen complex in acetone of the Type 1 as shown in Fig. 6. Essentially similar data are obtained in other solvents. Therefore, the reaction of Type 1 proceeds by the dissociative mechanism. Accordingly, k_1 and k_{-1}/k_2 can be obtained, respectively, from the intercept and slope of the straight line. These results are summarized, respectively, in Tables 2 and 3.

In the case of Type 2, plotting $1/k_{obsd}$ *vs.* $1/[\text{hmpa}]$ will give a straight line parallel to the abscissa, and therefore this type of the reaction can be deduced to proceed through the dissociative mechanism with k_{-1}/k_2 nearly equal to zero. Thus, k_{obsd} becomes nearly equal to k_1, suggesting that Reaction 5 is the rate-determining step in the dissociative mechanism.

If either the first and the third terms on the right-hand side in Eq. 9 in the dissociative mechanism or the second term on the right-hand side in Eq. 14 in the associative mechanism can be neglected, k_{obsd} will become equal to $(k_1k_2/k_{-1})[\text{hmpa}]$ for the dissociative path or equal to $\{k_4k_5/(k_{-4}+k_5)\}[\text{hmpa}]$ for the associative path, respectively. In the case of Type 3, however, the plots of k_{obsd} *vs.* [hmpa] actually show linearities without passing through the origin as expressed by Eq. 4 (as shown in Fig. 5). Accordingly the reaction can not be simply explanined by either of the two above assumptions. When the reaction of Type 3 is assumed to proceed by both the dissociative and associative mechanisms simultaneously, Eq. 4 can be well explained. The first-order rate constant k_d corresponds to the rate constant k_1 which is independent of the HMPA concentrations as the Type 2. Necessarily, the term of the [HMPA] dependence in Eq. 4 is due to the associative mechanism, where the second term on the right-hand side in Eq. 14 is negligibly small. Therefore, the total rate constant k_{obsd} is given by the sum of the following two terms;

$$k_{obsd} = k_1 + \frac{k_4k_5}{k_{-4}+k_5}[\text{hmpa}] \quad (15)$$

k_d and k_a in Eq. 4 corresponding to k_1 and $k_4k_5/(k_{-4}+k_5)$.

Table 3. The values of k_{-1}/k_2 for bpy, dmbpy, and phen complexes in nitrobenzene, acetone, and nitromethane at 25 °C, 30 °C, and 35 °C

phen	Nitrobenzene	0.048	0.081	0.116
	Acetone	0.047	0.052	0.055
	Nitromethane	0.101	0.125	0.096

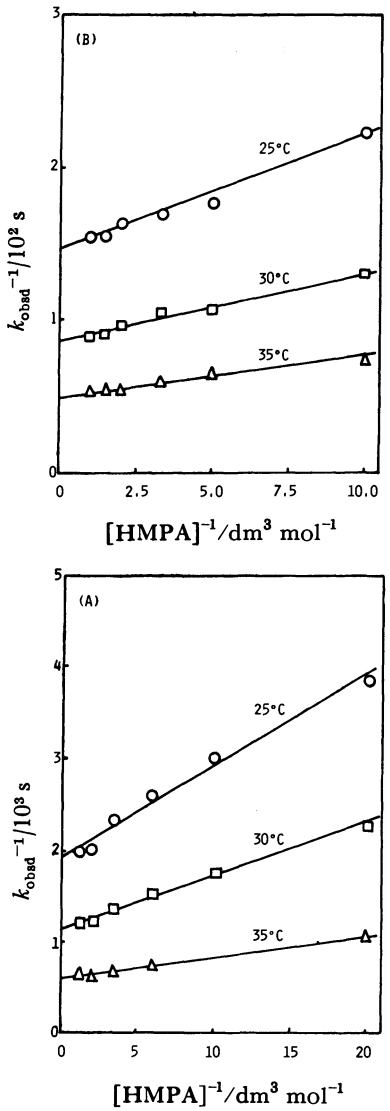

Fig. 6. Plots of k_{obsd}^{-1} *vs.* $[hmpa]^{-1}$ for the dmbpy complex in nitrobenzene (A) and for the phen complex in acetone (B) at 25 °C (○), 30 °C (□), and 35 °C (△).

The values of k_d and k_a in the inert solvents at 25 °C are summarized in Table 2.

Temperature Dependence of k_{obsd} and Activation Parameters. The rates of the substitution reactions were measured at various temperatures, and the values of sets of (ΔH_1^* and ΔS_1^*) and (ΔH_a^* and ΔS_a^*) were obtained by plotting ln k_1 or ln k_a *vs.* $1/T$; these values are summarized in Table 2. In the associative mechanism, the values for ΔH_a^* and ΔS_a^* are only the apparent ones because the apparent rate constant k_a is composed of rate constants of the elementary processes.

General Discussion. Table 2 gives a survey of the two schemes of the reaction through the single path of the dissociative mechanism and the simultaneous paths of the dissociative and associative mechanisms.

Dissociative Mechanism: Some features are found in the values of k_1, ΔH_1^*, and ΔS_1^* for the dissociative mechanism in Table 2; k_1 values are nearly in the ranges $(1.3—1.5)\times10^{-2}\ s^{-1}$ for bpy complex and $(4.5—5.6)\times10^{-3}\ s^{-1}$ for dmbpy complex, respectively, in nitrobenzene, acetone, and 1,2-dichloroethane, and ΔH_1^* and ΔS_1^* values are 80—90 kJ mol^{-1} and approximately zero J K^{-1} mol^{-1} for both bpy and dmbpy complexes in all the solvents used. The constancy of these values would indicate that the inert solvents exhibit little influence on the cleavage of cobalt-nitrogen bonds, and moreover, the fact that ΔS_1^* values are not largely negative would support the occurrence of the three-coordinated intermediates in the course of the dissociative mechanism.

In HMPA, the mechanism of the substitution reaction is difficult to be analyzed because of the existence of the large excess of solvent HMPA. In the case of the dmbpy complex in HMPA, however, since the observed values, $k_{obsd}=6.64\times10^{-3}\ s^{-1}$ at 25 °C, $\Delta H^*=89.2$ kJ mol^{-1} and $\Delta S^*=+11.7$ J K^{-1} mol^{-1}, are very close to those in inert solvents where the reactions proceed by the dissociative mechanism, the reaction of the dmbpy complex in HMPA may proceed also by the dissociative mechanism.

For the phen complex, the values, $k_{obsd}=(6—9)\times10^{-4}\ s^{-1}$ at 25 °C, $\Delta H^*=(86—101)$ kJ mol^{-1}, and $\Delta S^*=(-16—+36)$ J K^{-1} mol^{-1}, are roughly constant, irrespective of the media used. Therefore, it can be concluded that the reaction in all the inert solvents used, as well as in HMPA, proceeds simply by the dissociative mechanism for the same reason as in the case of the dissociative mechanism for the bpy and dmbpy complexes.

If the reactions of Type 1 were hypothesized not to proceed by the dissociative mechanism but by a mechanism involving the formation of an outer-sphere associated complex between Co(II) and HMPA in the solvents used;

$$[Co(NN)(hmpa)_2]^{2+} + hmpa \overset{K_o}{\rightleftharpoons} [Co(NN)(hmpa)_2]^{2+}\cdot hmpa \quad (16)$$

$$[Co(NN)(hmpa)_2]^{2+}\cdot hmpa \xrightarrow{k_i} \text{products}, \quad (17)$$

the rate constant, k_{obsd}, would be expressed by the following equation:

$$k_{obsd} = \frac{k_i K_o[hmpa]}{1+K_o[hmpa]}. \quad (18)$$

Then Eq. 18 is rearranged to give

$$\frac{1}{k_{obsd}} = \frac{1}{k_i} + \frac{1}{k_i K_o}\frac{1}{[hmpa]}. \quad (19)$$

Therefore, k_i and K_o of the outer-sphere association mechanism might apparently correspond to k_1 and k_2/k_{-1} in Eq. 9 of the dissociative mechanism, respectively. If the reaction proceeds truly by the outer-sphere association mechanism, the values of K_o (the reciprocals of k_{-1}/k_2 in Table 3) could be shown to be about 8—31 $dm^3\ mol^{-1}$. The values of K_o for the systems between $[Ni(H_2O)_6]^{2+}$ and HF, NH_3, or C_5H_5N in H_2O have been reported to be 0.15 $dm^3\ mol^{-1}$,[2,11] which is far smaller than 8—31 $dm^3\ mol^{-1}$ for the system between Co(II) and HMPA. Moreover, the ΔS_i^* value is supposed to be negative in process 17 for the associated complex between Co(II) and HMPA. However, the actually observed values of ΔS_i^* are approximately zero against the above supposition. Thus, the reaction of Type 1 is believed more probably to proceed through

the dissociative mechanism than through the outer-sphere association one.

Associative Mechanism: As have been shown in Table 2, the substitution reactions for the bpy and dmbpy complexes in acetone, 1,2-dichloroethane, and nitromethane proceed not only by the dissociative mechanism but also by the associative mechanism simultaneously, the k_a values being in the order: acetone>nitromethane >1,2-dichloroethane for the bpy complex and acetone> 1,2-dichloroethane>nitromethane for the dmbpy complex. In nitrobenzene, on the other hand, the substitution does not occur by the associative mechanism in either complex. The values of $\Delta H_a^* = (50—65)$ kJ mol^{-1} for the associative mechanism are smaller than those about 80—90 kJ mol^{-1} for the dissociative mechanism, and the largely negative values of ΔS_a^* are compared with those of ΔS_1^* of approximately zero as shown in Table 2. This is reasonable for the associative mechanism with largely negative values of ΔS_a^* on account of the occurrence of the five-coordinated intermediates.

In the case of the bpy complex in HMPA, $k_{obsd} = 3.4 \times 10^{-2}$ s^{-1} is larger than k_1 of the dissociative mechanism in inert solvents, and the apparent value of ΔS^*, however, was found to be strongly negative. Therefore, the reaction occurs not only by the dissociative mechanism but also by the associative one. The values of the rate constants at various temperatures, ΔH^*, and ΔS^* for both mechanisms in HMPA were thus obtained from Eq. 4 by using [HMPA]=5.8 mol dm^{-3} and the averaged k_1 values in inert solvents, as shown in Table 2.

Steric Effect: In general, the associative mechanism has been accepted as the mechanism of substitution reactions of tetrahedral complexes.[3] However when a bulky ligand such as HMPA is exchanged, both the associative and dissociative mechanisms are known to occur simultaneously.[5] In the present investigation, the substitution reactions of bpy and dmbpy complexes have been found to proceed only by the dissociative mechanism in nitrobenzene, and by both mechanisms in parallel in inert solvents other than nitrobenzene. On the other hand, in the case of the phen complex, the reaction proceeds only by the dissociative mechanism in all the inert solvents used as well as in HMPA. It seems that this difference may be caused by the difference of the bond flexibility between two pyridine rings in bpy or dmbpy and phen. Since the carbon-carbon bond connecting two pyridine rings in bpy or dmbpy is allowed to rotate fairly freely, the degree of molecular flexibility is large. However, the carbon-carbon bond between two pyridine rings in phen is fixed, and therefore the molecular flexibility of phen should be small. Because the reaction of the associative mechanism proceeds *via* a five-coordinated intermediate which may be much sterically strained due to the bulkiness of HMPA molecules, the two pyridine rings may not become coplanar. Therefore, it is considered that the complexes of bpy and dmbpy with large flexibility are favorable for the associative mechanism. However in the case of the phen complex, the reaction occurs wholly *via* the dissociative mechanism which goes through a three-coordinated intermediate, first cleaving one of the two cobalt-nitrogen bonds to avoid the rigidity of the phen molecule.

Solvent Effect: The fact that the bpy and dmbpy complexes in nitrobenzene undergo ligand exchange only through the dissociative mechanism can not be accounted for simply by the steric hindrance between Co(II) and the bulky HMPA. Fujiwara and his coworkers reported[12] that an associated complex is formed between HMPA and nitrobenzene, both of which have large dipole moments, thus interacting strongly with each other in nonpolar solvents. Therefore, the bpy and dmbpy complexes as well as the phen complex are restricted from undergoing ligand exchange through the associative mechanism but simply allowed to go through the dissociative mechanism, with a three-coordinated intermediate in nitrobenzene. On the basis of the extent of the interaction between HMPA and solvent molecules, the sequence of k_a for the associative mechanism can also be explained. The rate constants, k_a, fall into the sequences: acetone>nitromethane> 1,2-dichloroethane$\gg$nitrobenzene for the bpy complex, and acetone>1,2-dichloroethane>nitromethane$\gg$nitrobenzene for the dmbpy complex; these are almost in the reverse order of the values of their dipole moments, except for 1,2-dichloroethane with a small dielectric constant: acetone (2.9)<nitromethane (3.46)<nitrobenzene (4.21).

Conclusion. It can be concluded that the substitution reaction of bpy and dmbpy complexes proceeds only by the dissociative mechanism in nitrobenzene, and simultaneously by the dissociative and the associative mechanisms in parallel in inert solvents other than nitrobenzene. On the other hand, for the phen complex, the reaction proceeds simply by the dissociative mechanism in pure HMPA and in all the inert solvents used. Whether the substitution reaction proceeds by the dissociative mechanism or by the associative one, both the steric effect and the solvent effect seem to be important since HMPA is a bulky ligand and has a large dipole moment.

Chemical Effects Due to the (γ, n) Reaction and Isomeric Transition Studied by a Vacuum Sublimation Technique

Tsutomu SEKINE,† Masanobu SAKANOUE, Takashi NAKAMURA, and Kenji YOSHIHARA*,†
Department of Chemistry, Faculty of Science, Kanazawa University 1-1, Marunouchi, Kanazawa 920
†*Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980*
(Received March 25, 1982)

Chemical effects of the $^{59}Co(\gamma,n)^{58m,g}Co$ reaction and of the isomeric transition of ^{58m}Co in $Co(acac)_3$, $Co(acac)_2$, and $Co(acac)_2\cdot 2H_2O$ were studied by using a vacuum sublimation technique. In the isomeric transition, highly enriched $^{58g}Co(acac)_2$ was separated from $^{58m}Co(acac)_3$. By the (γ,n) reaction, about a half of the radioactive nuclides produced were found in the form of $Co(acac)_2$ after irradiation of $Co(acac)_3$. The present results were compared with those obtained by other authors.

A vacuum sublimation method has been successfully applied to hot atom chemical study and enrichment of radioactive isotopes in our laboratory.[1-3] It was found that this method was an effective radiochemical separation method for the following reasons. It can separate chemical species of tracer scale in dry environment immediately after irradiation. If the volatile metal organic complex of suitable stability is chosen for the study, sublimation can be made at a moderate temperature under which ordinary inorganic compounds can not sublime. It is well known that β-diketones, such as 2,4-pentanedione (acetylacetone, Hacac), 2,2,6,6-tetramethyl-3,5-heptanedione (dipivaloylmethane, Hdpm or Hthd), form volatile complexes with many metallic elements, and these complexes are available as irradiation targets for hot atom chemical studies.

For neutron-irradiated $Co(acac)_3$, it was found previously that highly enriched $^{60}Co(acac)_2$ was separated from the target by sublimation in an evacuated tube with a temperature gradient.[2] However, detailed studies of chemical effects due to the (γ, n) reaction have not yet been carried out, except for the few papers mentioned below. In order to obtain high specific activity of ^{58}Co, Hoffman tried a hot atom chemical enrichment by using ion exchange separation.[4] Nath studied the change of the retention value of $Co(acac)_3$ in the (n, 2n) reaction.[5] Shoji *et al.* investigated the hot atom chemistry of the tetraphenylporphyrin complex of cobalt due to ^{58m}Co decay, and they found a retention value higher than 75%.[6] Lazzarini and Lazzarini reported the survival probabilities for several cobalt complexes in isomeric transition of ^{58m}Co.[7]

In order to study the hot atom chemistry of the (γ, n) reaction of cobalt, the accumulative effects of the (γ, n) reaction and the isomeric transition of ^{58m}Co must be evaluated. In the present study, these effects were separately analysed. Chemical effects of the (γ, n) reaction and of the isomeric transition of ^{58m}Co were investigated by applying a sublimation method which is specifically useful to separate $Co(acac)_2$ from $Co(acac)_3$.

Experimental

Sample Preparation. Two kind of cobalt complexes, tris-(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) and diaquabis-(2,4-pentanedionato)cobalt(II) ($Co(acac)_2\cdot 2H_2O$), were synthesized from $CoCl_2\cdot 6H_2O$ and acetylacetone (both were commercially obtained from the Wako Pure Chemical Co. Ltd., Guaranteed) by the previously reported methods.[8,9] The tracer of ^{60}Co was spiked in the synthesis to enable us to estimate the processes of radiation and thermal decomposition. Each complex was purified twice by sublimation.

The sample of $Co(acac)_2\cdot 2H_2O$ transfers to $Co(acac)_2$ in the vacuum sublimation, while the former is obtained by allowing $Co(acac)_2$ to stand in the atmosphere for one day after the sublimation. As for $Co(acac)_2$, which is strongly hydroscopic, the sample was sealed in a plastic package as soon as possible after breaking the vacuum of the sublimation tube so that hydration could be avoided. The chemical form of $Co(acac)_2$ was examined by X-ray diffraction in order to evaluate the effectiveness of sealing. By this examination, it was found that most of the $Co(acac)_2$ remained unchanged for a few days. Therefore, $Co(acac)_2$ used for the target was prepared just before the irradiation with γ-rays.

Irradiation. Irradiation with bremsstrahlung (maximum energy: 60 MeV) was carried out by an electron linear accelerator of the Laboratory of Nuclear Science, Tohoku University. A platinum converter was used to obtain bremsstrahlung from electrons; unconverted electrons were removed by a sweep magnet, and the targets were cooled by Dry Ice during an irradiation period of about seven hours.

Radioactivity Measurement. Radioactivity was measured with a 4K γ-ray spectrometer equipped with a Ge(Li) detector of 80 cm^3. Determenation of ^{58g}Co can be made by measuring its γ-ray of 810 keV. Owing to the very low energy of this γ-ray and to its large internal conversion coefficient ($\approx$2000), ^{58m}Co was determined indirectly from the growth curve of ^{58g}Co, which allowed analysis of ^{58m}Co decay.

Sublimation System. The sublimation system used in this experiment is shown in Fig. 1. Though the electric furnace (Type 1) in the figure was designed to have little temperature gradient inside, a steep temperature gradient outside the furnace was effective to separate $Co(acac)_3$ from $Co(acac)_2$, which was more volatile than the former complex. This type of furnace was found useful in purification of the cobalt complexes. Another electric furnace (Type 2) used in this study has a temperature gradient inside; it can effectively

separate various volatile chelate compounds.[3] The temperature for sublimation was set at 170 °C. Beyond this temperature $Co(acac)_3$ would be decomposed to $Co(acac)_2$ in a considerably higher rate and, on the other hand, below this temperature a much longer time would be needed to sublime the sample completely. At 170 °C, sublimation started at about five minutes after inserting the sample tube under the vacuum of about 0.13 Pa. Almost complete sublimation finished after about fifteen minutes.

Results and Discussion

Isomeric Transition Effect of ^{58m}Co Decay. One of the difficulties in investigating the isomeric transition effects due to ^{58m}Co decay is to prepare the complexes labeled with ^{58m}Co and to purify them in a very short time. However, we have solved this problem by sublimatographic separation of the irradiated cobalt complexes using an electric furnace of Type 1. This procedure can be performed easily. Examination of chemical properties by alumina column chromatography using chloroform as a solvent, or by thin layer chromatography using benzene-ether (50/50) guaranteed the chemical identity and purity of each complex.[10]

The complex $Co(acac)_3$ labeled with ^{58m}Co was stored in a small glass tube under Dry Ice cooling. Its portions were taken as samples for sublimation from time to time. Concentrated hydrochloric acid was added to three different fractions separated by sublimation, and their radioactivity was measured at appropriate time intervals. As an example, the results of radioactivity measurements are shown in Fig. 2. Only the radioactivity of the $Co(acac)_3$ fraction increased. Whereas the radioactivities for the residue and the $Co(acac)_2$ fractions showed no change with time. Almost all the radioactivity of ^{60}Co which was spiked before irradiation was detected in the $Co(acac)_3$ fraction. From these results, ^{58g}Co radioactivities detected in the residue and also in the $Co(acac)_2$ fraction could be ascribed to the decay product of ^{58m}Co during the storage. Calculation of the retention value can be done as schematically shown in Fig. 3. When the m/g ratio of ^{58m}Co to ^{58g}Co at $t=0$ is expressed as A_{m0}/A_{g0}, the total radioactivity of

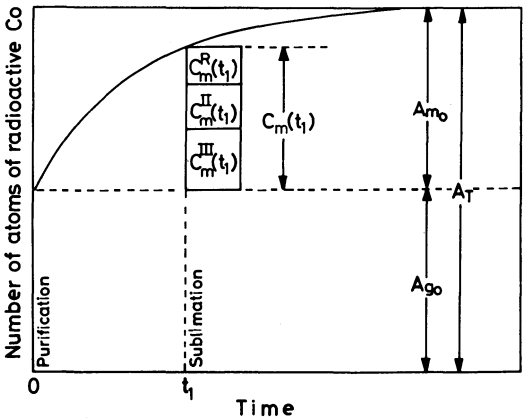

Fig. 3. Relationship between the number of atoms and time in the study of ^{58m}Co decay effect.

^{58}Co after a cooling time which is long enough to allow ^{58m}Co to decay out is $A_T(=A_{m0}+A_{g0})$. And the disintegrating amount of ^{58m}Co from $t=0$ to $t=t_1(C_m(t_1))$ can be calculated from the same growth curve.

$$C_m(t_1) = A_{m0}(1-e^{-\lambda_m t_1}) = A_T(1-f)(1-e^{-\lambda_m t_1}), \quad (1)$$

where $f=A_{g0}/A_T$. Then the retention value (R) is obtained by the following equation:

$$R(\%) = \frac{C_m^{III}(t_1)}{C_m(t_1)} \times 100 = \left\{1 - \frac{C_m^R(t_1)+C_m^{II}(t_1)}{A_T(1-f)(1-e^{-\lambda_m t_1})}\right\} \times 100, \quad (2)$$

where $C_m^{III}(t_1)$, $C_m^{II}(t_1)$, and $C_m^R(t_1)$ are radioactivities of the decayed components in $Co(acac)_3$ and $Co(acac)_2$ and of the residue at $t=t_1$, respectively. The retention values obtained from these analyses are plotted against storage times in Fig. 4. This result shows that some annealing effect during storage can not be avoided even under Dry Ice cooling; a constant value of about 60% was obtained after ten days. The increase in the retention value with storage time was balanced by the decrease in the yield of $^{58g}Co(acac)_2$. In a study of ^{58m}Co decay effects by using a wet separation method, Lazzarini

and Lazzarini reported 47.9% of the daughter nuclides remained in the chemical form of the parent, and 47.2% were found in the Co^{2+} ion fraction.[7] The $Co(acac)_3$ retention in our experiments is slightly below 40% at an earlier stage and then gradually increases up to 60%. It is very interesting to see that there is an agreement between our values and Lazzarini's, although they gave the percentage of Co^{2+} instead of the $Co(acac)_2$ reported in our experiments. These facts show that annealing during sublimation in the present study *per se* does not contribute much to the overall results. The presence of $Co(acac)_2$ in a large amount is a rather striking finding, and this was made possible by the application of sublimatographic procedures in this study. However, the detailed mechanism of formation of $Co(acac)_2$ is not so simple.

Though the increase of the retention values with storage time is not yet explained very clearly, some possibilities can be considered. One is a charge transfer reaction between Co^{2+} and surrounding molecules, which Kalliat and Nath suggested.[11] Another explanation is the existence of a reaction which proceeds with very low activation energy even under Dry Ice temperature, although this would be unusual. The last explanation, which seems to be more plausible than the earlier ones, is an electrostatic interaction between recoils and their partners or surrounding matrices. This does not require much thermal agitation. This type of interaction is found in some cases involving positively charged species after nuclear decay and negatively charged oxygen impurities; detailed features of this mechanism will appear in forthcoming papers.[12]

The most significant result in this experiment is that a considerable amount of ^{58g}Co was found as the chemical form of $Co(acac)_2$. This fraction seems to correspond to the fraction analysed by Lazzarini and Lazzarini as the fraction of Co^{2+} ion which corresponds to the "complete fragmentation" in the decay event. It is known that radioactive atoms produced by nuclear reactions form a considerable amount of ligand-deficient species.[13] Tominaga and Saito pointed out the possibility of the presence of ligand-deficient complexes of the types $Co(acac)_{3-n}^{n+}$.[14] If $n=1$ is assumed, $Co(acac)_2$ and $Co(acac)_2^+$ are present in the solid: the former is observed in our experiment and the latter may be sensitive to annealing reactions. Therefore, it is considered that $^{58g}Co(acac)_2$ separated by sublimation has its own chemical form and/or charge state in solids just before separation.

The yield of the residue was almost constantly 3—4%. Although the chemical components of the residue are not clear, the residual amount of ^{58g}Co radioactivity agreed with that which Lazzarini and Lazzarini denoted as partial fragmentation.

A similar experiment was carried out for the $Co(acac)_2$ complex. Highly enriched $^{58g}Co(acac)_3$ was not obtained; the retention value as $Co(acac)_2$ was 99% and did not vary with storage time. Almost all the ^{60}Co radioactivity was found in the parent complex, and 1% of ^{58g}Co remained in the residue; this result seems to show the extent of decomposition induced by the isomeric transition.

The Chemical Effect by the (γ, n) Reaction. The sublimatographic results obtained by using the electric furnace (Type 2) with temperature gradient are shown in Fig. 5. The dotted line in Fig. 5(a) for $Co(acac)_3$ shows the distribution of ^{60}Co radioactivity obtained by the sublimation before irradiation. Thermal decomposi-

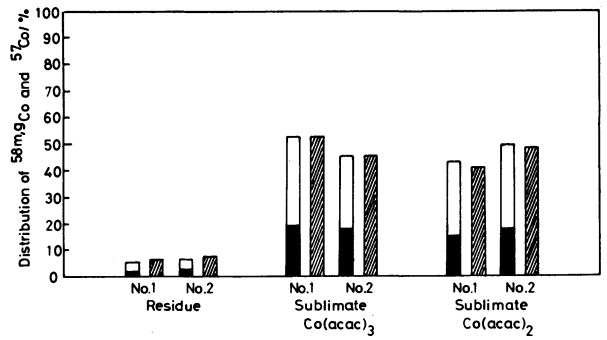

Fig. 6. Distribution of ^{58m,g}Co and ^{57}Co in each fraction. ^{58g}Co: closed area, ^{58m}Co: open area, ^{57}Co: shaded area. Nos. 1 and No. 2 denote experimental number.

tion of $Co(acac)_3$ is almost negligible under these conditions. In the case of sublimation after irradiation, about 4% of total ^{60}Co radioactivity was observed (shaded area) in the form of $Co(acac)_2$. The radioactivity of ^{58}Co was measured after long period during which almost all ^{58m}Co decayed out. A half of ^{58}Co radioactivity was found in the $Co(acac)_2$ fraction.

Figure 6 shows the distribution of ^{58}Co in each fraction separated by sublimation made immediately after the irradiation. This is compared to the distribution of ^{57}Co produced simultaneously by the $(\gamma, 2n)$ reaction. This result shows that the radioactivity of ^{58}Co almost equally distributed in the $Co(acac)_3$ and $Co(acac)_2$ fractions; the same tendency appears for the distribution of ^{57}Co.

The ^{58m}Co/^{58g}Co ratio in each fraction was obtained by the growth curve of each fraction, and is shown in Fig. 7. The residue showed the smallest value, while the $Co(acac)_3$ fraction showed the largest value. This pattern was found to be sufficiently reproducible. Each fraction was considered to consist of three components at the end of irradiation; ^{58g}Co and ^{58m}Co produced directly by (γ, n) reaction (A_g, A_m), and a part of ^{58g}Co produced by the decay from ^{58m}Co during the irradiation ($A_{m\to g}$). A_g, A_m, and $A_{m\to g}$ are represented as follows:

$$A_g = N\phi\sigma_g(1-e^{-\lambda_g t}) \quad (3)$$

$$A_m = N\phi\sigma_m(1-e^{-\lambda_m t}) \quad (4)$$

$$A_{m\to g} = N\phi\sigma_m\left\{(1-e^{-\lambda_g t}) - \frac{\lambda_g}{\lambda_g-\lambda_m}(e^{-\lambda_m t}-e^{-\lambda_g t})\right\}, \quad (5)$$

where ϕ is flux of γ-rays, N is the amount of cobalt atoms in the target, t is irradiation time, λ_g and λ_m are the decay constants of ^{58g}Co and ^{58m}Co, respectively, σ_g and σ_m are the independent reaction cross sections of (γ, n) reactions to produce ^{58g}Co and ^{58m}Co, respectively. $A_{m\to g}$ can be obtained from the Eqs. 3 and 5

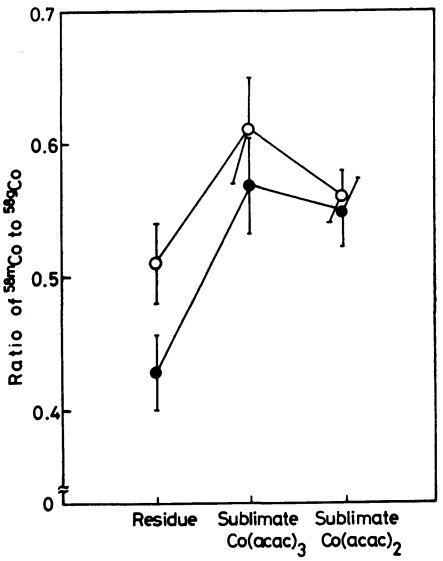

Fig. 7. Ratio of ^{58m}Co to ^{58g}Co in each fraction. ○: Experiment No. 1, ●: Experiment No. 2.

and A_T, which is the total amount of radioactivity of ^{58}Co after long cooling when all the ^{58m}Co atoms have decayed out.

$$A_T = N\phi(\sigma_m+\sigma_g)(1-e^{-\lambda_g t}) \quad (6)$$

From Eqs. 3, 5, and 6,

$$\frac{\sigma_m}{\sigma_g} = \frac{(1-e^{-\lambda_g t})\{A_T-(A_{m\to g}+A_g)\}}{(1-e^{-\lambda_g t})(A_{m\to g}+A_g)-\left\{(1-e^{-\lambda_g t})-\frac{\lambda_g}{\lambda_g-\lambda_m}(e^{-\lambda_m t}-e^{-\lambda_g t})\right\}A_T} \quad (7)$$

Since the ratio of σ_m/σ_g is determined experimentally to be 1.16 ± 0.06, the percent ratio of $A_{m\to g}$ to A_T is given by the equation:

$$\frac{A_{m\to g}}{A_T}\times 100 = \frac{\sigma_m/\sigma_g\left\{(1-e^{-\lambda_g t})-\frac{\lambda_g}{\lambda_g-\lambda_m}(e^{-\lambda_m t}-e^{-\lambda_g t})\right\}}{(\sigma_m/\sigma_g+1)(1-e^{-\lambda_g t})}\times 100 \quad (8)$$

In this case, a value of 11.84 ± 0.75% was obtained for the percent ratio of $A_{m\to g}$ to the total activity A_T. By sublimation each component can be separated into the residue, the $Co(acac)_3$ fraction, and the $Co(acac)_2$ fraction. The proportion of distribution of A_g and $A_{m\to g}$ in each fraction can not be determined directly in this experiment, but the latter can be estimated by assuming that the proportions of initial distribution of A_g in each fraction are equal to that of A_m. This assumption is reasonable, judging from the relationship of the recoil energy-percentage of product found by Yoshihara and Kudo,[15] because similar recoil energies (beyond 1 keV)

TABLE 1. RETENTION VALUE AND ^{58m}Co/^{58g}Co RATIO FOR IRRADIATED $Co(acac)_2$ AND $Co(acac)_2\cdot 2H_2O$ OBTAINED BY SUBLIMATION SEPARATION

		^{58}Co (%)	^{57}Co (%)	^{60}Co (%)	m/g ratio[a)]
$Co(acac)_2$	Sublimate	98.2±0.4	98.0±1.0	98.7±0.1	0.52±0.10
	Residue	1.8±0.1	2.0±0.1	1.3±0.1	0.45±0.07
$Co(acac)_2\cdot 2H_2O$	Subl mate	97.2±0.4	97.3±0.7	97.4±2.0	0.58±0.07
	Residue	2.8±0.1	2.7±0.1	2.6±0.1	0.50±0.06

a) It means a ratio of ^{58m}Co to ^{58g}Co.

of both nuclides will give the same plateau value of the product percentage. This relationship is further justified by the equal product distribution of the (γ, n) and $(\gamma, 2n)$ reactions described before. The distribution of $A_{m\to g}$ in each fraction was calculated to be $9.8\pm1.2\%$ in the residue, $41.9\pm9.8\%$ in the $Co(acac)_3$ fraction, and $48.3\pm6.3\%$ in the $Co(acac)_2$ fraction. The contribution to the residue for $A_{m\to g}$ was larger by about 4.4% than that for A_m. Therefore, it is considered that the two kinds of effects by (γ, n) reaction and isomeric transition have superimposed additively.

A similar study was made for the irradiation of $Co(acac)_2$ and $Co(acac)_2\cdot 2H_2O$, and the results are shown in Table 1. The retention value in $Co(acac)_2\cdot 2H_2O$ was slightly smaller than that in $Co(acac)_2$. This tendency is the same as reported by Yoshihara *et al.* in the case of the (γ, γ') reaction in In·hedta complexes with and without crystalline water.[16] This difference may be attributed to the decrease of back reaction probability by obstruction in the presence of water molecules.

The m/g ratio in the sublimate and the residue did not show the same value as those in the case of $Co(acac)_3$. It is suggested that ^{58g}Co produced by the decay of ^{58m}Co tends to form more nonvolatile species than that produced directly by nuclear reaction.

The authors thank Dr. Masuo Yagi of Tohoku University for his cooperation in performing the irradiation with the electron linear accelerator.

(Received March 29, 1982)

In order to clarify the effect of the coexistent elements on the determination of the atomic ratio between C, H, O, and N by the pyrolytic sulfurization gas chromatography (PSGC), compounds containing 25 kinds of elements were investigated. Only 7 of these interfered the determination of the atomic ratio. Several organophosphorus, lithium-, and boron-containing compounds were also analyzed. The results obtained by the present work are summarized in the periodic table together with those from previous work.

In order to establish a new organic elemental analysis method by which several elements can be simultaneously determined, the authors have developed pyrolytic sulfurization gas chromatography (PSGC) based on a combustion technique in sulfur vapor instead of the conventional one in an oxygen atmosphere.[1] According to PSGC, the simultaneous determination of the atomic ratio between C, H, O, and N in a sample can be achieved with a usual organic compound,[2] a metal organic chelate compound,[3] a polymer,[4] and an organic halogen compound.[5]

In the field of elemental analysis, research concerning metal organic chelate compounds has not been carried out so much because of the fact that metallic elements show a strong affinity for oxygen and are apt to form oxides and carbonates. However, PSGC method is characterized by conversion of the metal in a compound into sulfide by means of a sulfur combustion technique and by simultaneously determining the atomic ratio between C, H, O, and N in a sample without using a special procedure such as addition of reducing agent. In the previous work,[3] this PSGC method was applied to the analysis of compounds containing 24 elements: Na, K, Mg, Ca, Sr, Ba, La, Ti, U, Cr, Mo, W, Mn, Fe, Co, Ni, Pd, Cu, Ag, Zn, Cd, Hg, Al, and P. But many elements still remain unsolved, so the present study has been carried out with the objective of estimating the atomic ratio between C, H, O, and N in compounds containing 25 metallic elements other than the previously reported ones: Li, Rb, Cs, Be, Ce, Pr, Eu, Th, Zr, Hf, V, Nb, Rh, Pt, Au, B, Ga, In, Tl, Si, Pb, As, Sb, Bi, and Se. Several organophosphorus compounds were also analyzed. The results obtained by the present work are summarized in the periodic table together with those obtained by the previous study. The PSGC method can be successfully applied to the analysis of the compounds containing 39 elements, but not to those containing 10 kinds of elements.

Experimental

Apparatus and Reagents. The reagents and apparatus used were the same as those reported.[2] The peak areas of the gas chromatogram were read out by the use of a Shimadzu digital integrator E1A. A definite amount of metal oxide was taken with a Shimadzu microbalance MDP-5.

Procedure. The preparation and reaction conditions of sample as well as the conditions of gas chromatographic analysis are similar to those reported.

Samples. The following samples were prepared by the methods found in the literature for their gravimetric analyses: bis(2-methyl-8-quinolinolato)beryllium(II), $Be(C_{10}H_8ON)_2$;[6] tetrakis(mandelato)zirconium(IV), $Zr(C_8H_8O_3)_4$;[7] tetrakis(mandelato)hafnium(IV), $Hf(C_8H_8O_3)_4$;[8] tetrakis(8-quinolinolato)hafnium(IV), $Hf(C_9H_6ON)_4$;[9] trioxotetrakis(8-quinolinolato)divanadium(V), $V_2O_3(C_9H_6ON)_4$;[9] oxotris(8-quinolinolato)niobium(V), $NbO(C_9H_6ON)_3$;[10] tris(8-quinolinolato)bismuth(III), $Bi(C_9H_6ON)_3$;[9] tris(8-quinolinolato)antimony(III), $Sb(C_9H_6ON)_3$;[11] tris(thionalidato)antimony(III), $Sb(C_{12}H_{10}ONS)_3$;[12] bis(thionalidato)mercury(II), $Hg(C_{12}H_{10}ONS)_2$;[12] tetrakis(8-quinolinolato)thorium(IV), $Th(C_9H_6ON)_4$;[13] triethanolammonium tetraphenylborate, $(HOH_2CH_2C)_3NHB(C_6H_5)_4$;[14] dibutylammonium tetraphenylborate, $(n\text{-}C_4H_9)_2NH_2B(C_6H_5)_4$;[14] benzylammonium tetraphenylborate, $C_6H_5NH_3B(C_6H_5)_4$;[14] 8-quinolinol-quinolinolium tetraphenylborate, $(C_9H_7ON)_2HB(C_6H_5)_4$;[15] gold(I) 2-mercaptoacetate, $AuSO_2H_3C_2$;[16] (2,2',4,4',6,6'-hexanitrodiphenylaminato)potassium, $KN[C_6H_2(NO_2)_3]_2$;[17] (2,2',4,4',6,6'-hexanitrodiphenylaminato)rubidium, $RbN[C_6H_2(NO_2)_3]_2$;[17] (2,2',4,4',6,6'-hexanitrodiphenylaminato)cesium, $CsN[C_6H_2(NO_2)_3]_2$;[17] tris(2,4-pentanedionato)rhodium(III), $[Rh(C_5H_7O_2)_3]$; bis(*N,N'*-disalicylideneethylenediaminato)cerium(IV), $[Ce(C_{16}H_{14}O_2N_2)_2]$, and bis(2,4-pentanedionato)platinum(II), $[Pt(C_5H_7O_2)_2]$ were prepared by the method found in the literature.[18] Lithium butanoate, lithium hexanoate, lithium octanoate, and lithium decanoate were obtained by allowing lithium hydoxide to react with the corresponding acid and by recrystallizing them repeatedly until the range of the melting point of each sample decreased to less than 1 °C. The other reagents were commercial products and were purified in a way similar to that used for the lithium salts. The composition and purity of the samples were confirmed by the CH and/or CHN analysis carried out in the Elemental Analysis Center of the Pharmaceutical Department of Kyoto University (Table 1). *p*-Aminophenylarsonic acid for elemental analysis, octaphenylcyclotetrasiloxane for atomic absorption spectroscopy, and tris(2,2,6,6-tetramethyl-3,5-heptanedionato)europium(III) and tris(2,2,6,6-tetramethyl-3,5-heptanedionato)praseodymium(III) for NMR spectroscopy were of reagent grade and were used without further purification. The metal oxides were of analytical grade and treated at 950 °C before use.

Results and Discussion

Reactivity of Metal Oxide. The reactivity between metal oxide and sulfur was investigated prior to the analysis of metal organic chelate compound. The reactivity of metal oxide is expressed in terms of α,

which refers to the mole ratio of sulfur dioxide (SO_2) from the metal oxide against that from a reference substance, silver nitrate. The reactivity of metal oxide, α, is estimated approximately by the equation adopted in the previous paper (Table 2).[3] As can be seen from Table 2, the oxides of beryllium(II), thorium(IV), zirconium(IV), hafnium(IV), niobium(V), tantalum-(V), silicon(IV), and boron(III) are barely converted into the sulfides under the experimental conditions, while arsenic(III) and bismuth(III) oxide react quantitatively with sulfur.

Analysis of Various Organic Chelate Compounds. Various metal organic chelate compounds were analyzed (Table 3). The compounds containing four elements of the lanthanoids, La, Ce, Pr, and Eu gave fairly good results. Lanthanoids, especially light rare earths, resemble each other very closely in chemical properties, so it can be expected that PSGC is applicable to the compounds containing three light rare earth elements other than the investigated ones. Selenium was expected to form carbon diselenide and hydrogen selenide under the experimental conditions and to give an error in C and H values. Selenium did not, however, interfere with the determination of the atomic ratio and satisfactory results were obtained with (8-quinolineselenolato)-cadmium(II). Almost all the complexes gave satisfactory

results, but the complexes of Be, Th, Zr, Hf, V, B, and Si gave a negative error in the oxygen value. As can be seen from Table 2, the oxides of these seven elements were highly stable and were scarecely converted into their sulfides. Therefore, the oxygen atom in their complex salts is expected to remain more or less in the residues and this is consistent with the results shown in Table 3. Negative errors in both the oxygen and nitrogen values were obtained in several ammonium tetraphenylborates. Boron nitride was subjected to pyrolytic sulfurization under the experimental conditions, but no evolution of nitrogen was observed. From the above mentioned fact, the negative error in nitrogen values of ammonium tetraphenylborates seems to be ascribed to the formation of boron nitride.

Analysis could not be carried out for lithium acetate, CH_3COOLi, since the reaction tube containing lithium acetate, in which the atomic ratio of carbon to oxygen (C/O) is 1.0, exploded by itself during the course of sulfurization. With the objective of clarifying this phenomena, a series of lithium salts were investigated. Oxygen-rich compounds such as lithium lactate ($C_3H_5O_3Li$, C/O=1.0) and lithium citrate tetrahydrate ($C_6H_5O_7Li_3 \cdot 4H_2O$, C/O=0.55) could not be analyzed since the reaction tube exploded by itself similarly to the way it did in lithium acetate. Relatively oxygen-poor compounds such as lithium butanoate (C_3H_7COOLi, C/O=2.0), lithium hexanoate ($C_5H_{11}COOLi$, C/O=3.0), lithium octanoate ($C_7H_{15}COOLi$, C/O=4.0), and lithium decanoate ($C_9H_{19}COOLi$, C/O=5.0) could be subjected to sulfurization without any explosion. The satisfactory results are obtained when value of C/O exceeds 2.0. The above explosion seems to be ascribed to some lithium silicate, $xLi_2O\,ySiO_2$, which is formed by the reaction between SiO_2 and Li_2O.

Analysis of Organophosphorus Compounds. It was reported in the previous paper that carbon-rich compounds such as dioctadecyl hydrogenphosphate [$(n\text{-}C_{18}H_{37}O)_2HPO_2$, C/O=9.0] gave satisfactory results while carbon-poor compounds such as diguanidium hydrogenphosphate [$(CH_5N_3)_2H_3PO_4$, C/O=0.5] produced a low oxygen value. In order to clarify the difference between these two cases, further study was carried out on a series of organic phosphates in which the oxidation number of phosphorus is +5, that is, piperazinium dihydrogenphosphate monohydrate ($C_4C_{10}N_2 \cdot H_3PO_4 \cdot H_2O$, C/O=0.8), benzoguanamine phosphate ($C_9H_9N_5 \cdot H_3PO_4$, C/O=2.5), benzidine phosphate ($C_{12}H_{12}N_2 \cdot H_3PO_4$, C/O=3.0), and triphenyl phosphate [$(C_6H_5O)_3PO$, C/O=4.5]. As can be seen from Table 4, the present method gives satisfactory results when the value of C/O exceeds 4.5 but does not satisfactory results in C/O less than 3.0.

Interferences. As can be seen from the above-mentioned results, PSGC was applicable to various metal organic chelate compounds, and the atomic ratio between C, H, O, and N in a sample could be determined simultaneously. Some metals in their compounds took up the oxygen in a sample to form their oxides during pyrolytic sulfurization, and this brought about the most serious problems in the analyses of the compounds containing these metals. However, if one takes into account the difficulties in analysis of oxygen in a metal organic chelate compound by the conventional methods, the utility of PSGC in analysis of metal organic chelate compound is obvious even though the applicable elements are restricted.

On the basis of the results obtained with regard to the formation of oxides, the effect of the coexistent elements on the determination of the atomic ratio is summarized on the periodic table (Fig. 1). The amount of oxygen

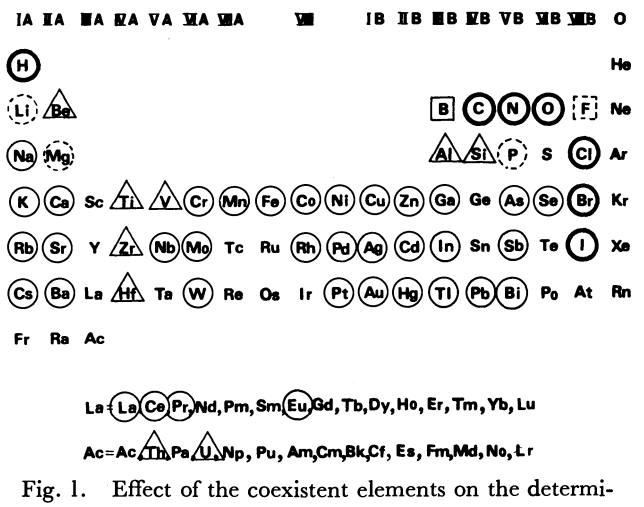

Fig. 1. Effect of the coexistent elements on the determination of the atomic ratio.
○: Harmless, △: form oxide and harmful, □: form both oxide and nitride and harmul, □: react with reaction tube also harmful, ○: can be determined simultaneously.

in an organic compound containing an oxygen atom and one of the following 39 kinds of elements can be satisfactorily estimated by PSGC : (Li), Na, K, Rb, Cs, (Mg), Ca, Sr, Ba, Nb, Cr, Mo, W, Mn, Fe, Co, Rh, Ni, Pd, Pt, Cu, Ag, Au, Zn, Cd, Hg, Ga, In, Tl, Pb, (P), As, Sb, Bi, Se, La, Ce, Pr, and Eu. Since there is close resemblance in chemical properties between the elements of lanthanoids, more particularly between ones of light rare earths, it can be expected that PSGC is applicable to the compounds containing three other lanthanoids, *i.e.*, Nd, Pm, and Sm, and the number of applicable elements would rise to 42. Both magnesium- and lithium-containing samples gave satisfactory results only if the number of carbon atoms exceeds that of oxygen atoms in a sample. Organic phosphates gave satisfactory results when the value of C/O exceeded 4.5, but the quantitative details of other types of organophosphorus compounds is not still clear. The compound containing oxygen atoms and one of the following 10 elements, however, gave a low oxygen value: Be, Ti, Zr, Hf, Th, U, V, B, Al, and Si. Boron-containing compounds show a negative error in both oxygen and nitrogen values.

This study was supported by a Grant-in-Aid for the Special Research project on "Trace Characterization" gived by the Ministry of Education, Science and Culture.

(Received May 18, 1982)

The X-ray structure of the CoO_8 unit in cobalt garnet, a new synthetic silicate of the composition $Co_3Al_2Si_3O_{12}$, is presented. The unit can be taken as a deformed cube, but its central Co^{II} is more regularly 8-coordinated than that in $[Co(NO_3)_4]^{2-}$ studied formerly by Bergman and Cotton.[5] The electronic spectrum and magnetic moment of cobalt garnet are discussed in comparison with those of two other silicates containing CoO_4 units.

Minerals are metallic complexes in nature, and their studies have played important roles in the development of crystal field theory.[1] Synthetic silicates are also of much interest from the standpoint of coordination chemistry.

This paper deals with the structure and some related properties of cobalt garnet, a new and interesting example of such synthetic silicates.

Experimental

Figure 1 and Table 1 were obtained using the data of Ohashi *et al.*[2] which are not explicity given in their original paper. Spectral measurements were made with a Hitachi Recording Spectrophotometer 323, using an electro-polished Al mirror as the standard. Magnetic measurements were made with a Shimadzu MB-2H Magnetic Balance, using Mohr's salt as the standard.

Results and Discussion

The structure of cobalt garnet, $Co_3Al_2Si_3O_{12}$, was recently analyzed by Ohashi *et al.*[2] This silicate was synthesized by the hydrothermal reaction of CoO, Al_2O_3 and SiO_2 at 900 °C and 50 kbar (1 bar=10^5 Pa), which took 3 h in a belt-type. high pressure reaction vessel.[3] It has a structure which is common to natural garnets, *i.e.*, a three-dimensional network composed of tetrahedral SiO_4, octahedral AlO_6, and 8-coordinated $M^{II}O_8$ units.[4] Thus, in terms of coordination chemistry, it is a new example of 8-coordinated cobalt(II) complexes, of which only a limited number seems to be known at present.

A well-known example of such complexes is $[Co(NO_3)_4]^{2-}$, studied formerly by Bergman and Cotton.[5] In this complex, cobalt(II) is at the center of a dodecahedron of eight oxygen atoms, formed by the chelation of four nitrate ions around it. Two different sets of Co–O bonds exist, *i.e.*, one set of four bonds which are 2.03—2.11 Å long, and the other set of four bonds which are much longer (2.36—2.54 Å; 1 Å=10^{-1} nm). The dodecahedron can therefore be taken as a superposition of two deformed tetrahedra, one inside and the other outside, around the central cobalt(II).

The CoO_8 unit in cobalt garnet is, on the other hand, quite different in shape. Here the eight oxygen atoms around the central cobalt(II) form a severely deformed cube, as can be seen from the data in Fig. 1 and Table 1. Among the Co–O bonds, four are 2.21 Å long, and the other four are slightly longer (2.33 Å). The bonds of each set lie on a deformed plane ($O^AO^BO^CO^D$ and $O^EO^FO^GO^H$ in Fig. 1, respectively). The cobalt(II) in cobalt garnet is, therefore, much more "regularly" 8-coordinated than that in $[Co(NO_3)_4]^{2-}$.

To see the influence of such a structure on the electronic state of Co^{II}, the electronic spectrum and magnetic susceptibility of cobalt garnet were studied. The data on $Ca_2CoSi_2O_7$ and $Sr_2CoSi_2O_7$ with melilite structure,[6] containing tetrahedral CoO_4 units, were also obtained for the sake of comparison. These two compounds were

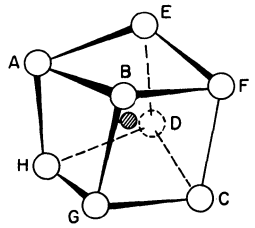

Fig. 1. Sketch of the CoO_8 unit in cobalt garnet. Each oxygen is bound tetrahedrally to two Co^{II}, each at the center of this type of CoO_8 unit, and also to a Si^{IV} and an Al^{III}, forming tetrahedral SiO_4 and octahedral AlO_6 units, respectively, around them.

Table 1. Bond lengths and angles of the polyhedron shown in Fig. 1.

Bond length	l/Å		
$Co-O^A=Co-O^B=Co-O^C=Co-O^D$	2.332(2)		
$Co-O^E=Co-O^F=Co-O^G=Co-O^H$	2.211(2)		
Bond angle	**ϕ/°**	**Bond angle**	**ϕ/°**
$\angle O^ACoO^B=\angle O^CCoO^D$	72.06	$\angle O^ACoO^E=\angle O^DCoO^H$	70.97
$\angle O^BCoO^C=\angle O^ACoO^D$	110.35	$\angle O^ACoO^G=\angle O^DCoO^F$	93.42
$\angle O^ACoO^C=\angle O^BCoO^D$	163.81	$\angle O^CCoO^G=\angle O^BCoO^F$	73.02
$\angle O^ECoO^F=\angle O^GCoO^H$	68.88	$\angle O^BCoO^H=\angle O^CCoO^E$	123.94
$\angle O^ECoO^H=\angle O^FCoO^G$	114.49		
$\angle O^ECoO^G=\angle O^FCoO^H$	161.05		

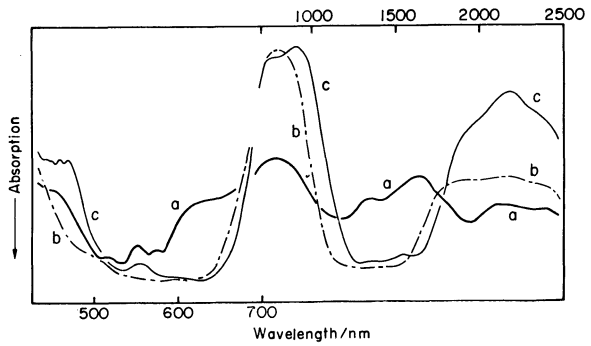

Fig. 2. Powder reflection spectra of cobalt garnet (a) and $Ca_2CoSi_2O_7$ (b) and $Sr_2CoSi_2O_7$ (c) with melilite structure.

synthesized by solid state reaction at 1 atm. The structure refinement of $Ca_2CoSi_2O_7$ has been carried out by Kimata.[7]

Figure 2 shows the reflection spectra of these three silicates. As a whole, there is a general resemblance between the spectrum of cobalt garnet and those of the other two, which, on the other hand, show the broad and split bands of tetrahedral Co^{II} ($\tilde{\nu}_3$ and $\tilde{\nu}_2$, or $^4A_2 \rightarrow {}^4T_1$ (P) and$\rightarrow {}^4T_1$(F)) at around 600 and 1300 nm, just like the spectrum of lusakite cited by Burns.[1] This resemblance is what one can expect, since the splitting of the d-orbitals in a quasi-cubic CoO_8 unit will be essentially similar to that in a tetrahedral CoO_4 unit.

One can now imagine that the ligand field strength (l.f.s.) in cobalt garnet will be nearly twice as large as in the two CoO_4 type silicates. In fact, the above-mentioned bands are shifted somewhat toward blue in cobalt garnet; moreover, a new set of bands appear at *ca.* 2000—2500 nm, which may correspond to the weak shoulders and humps observed on the curves of the CoO_4-type silicates at the same wavelength region, and may be due to the transition $\tilde{\nu}_1$, or $^4A_2 \rightarrow {}^4T_2$, which is sometimes observed in the infrared spectra of tetrahedral Co^{II} complexes. Nevertheless, all these spectral shifts are seemingly rather small, and one can even suppose that the l.f.s. of cobalt garnet and the other two silicates are quite comparable,[††] although the broadness and complicated splittings of the bands hinder reliable comparison of the ligand field parameters.

The reason for the relatively weak l.f.s. in cobalt garnet may be in part found in the distortion of the cubic field, but it must be noted that the Co–O bond in it is much longer than the sum of the effective ionic radii of Co^{2+} (0.58 Å when 4-coordinated, as in melilite, and high-spin) and O^{2-} (1.38 Å when 4-coordinated, as in melilite and cobalt garnet).[8] In the case of Co-melilite, the Co–O bond length (1.926 Å) was slightly shorter than the corresponding sum (1.96 Å).[7]

†† This can be seen, for example, by comparing the data of Fig. 1 with those of Cotton *et al.* on the spectra of CoX_4^{2-} (X=Cl, Br, or I). The latter shows that the change from $CoCl_4^{2-}$ to $CoBr_4^{2-}$, where the l. f. s. (Dq) changes only less than 10%, causes quite remarkable shifts of $\tilde{\nu}_2$ and $\tilde{\nu}_3$.[9]

Table 2. μ_{eff} and θ values of the three silicates

Silicate	μ_{eff}/BM	θ/K
Cobalt garnet	4.57	−12
$Ca_2CoSi_2O_7$	4.17	−24
$Sr_2CoSi_2O_7$	4.13	−20

An apparent expansion of a metallic ion in going from 4- to 8-coordination was already reported to occur in many cases by Shannon,[8] who assigned an effective ionic radius of 0.90 Å to 8-coordinated Co^{II}, making use of the data of Bergman and Cotton.[5] Interestingly, this is in good agreement with the radius of Co^{2+} in cobalt garnet (0.89 Å), obtained by taking the mean of the two Co–O lengths in it and subtracting the radius of O^{2-} from it. Such an expansion, which should be due to the interligand repulsion and/or the attraction of O^{2-} ions toward the cations which are outside of the CoO_8 unit, will certainly enlarge the "box" of O atoms to accomodate Co^{II}, and diminish the l.f.s. acting on it considerably.[†††]

At any rate, therefore, it seems that the effect of the high coordination number in cobalt garnet is largely cancelled by this expansion, causing only relatively small changes in its spectral pattern in comparison with the two CoO_4-type silicates studied.[11]

The magnetic susceptibilities of the three silicates obey Curie-Weiss law down to liquid N_2 temperature, and the values of μ_{eff} and θ obtained from them are shown in Table 2. They are thus all high-spin d^7 complexes with no apparent magnetic anomaly.

††† On the other hand, comparison of the spectra of the two CoO_4-type silicates indicates that the change from Ca to Sr lowers the values of $\tilde{\nu}_2$ and $\tilde{\nu}_3$, or weakens the l. f. s. around the Co^{2+} ions. This may be due to the expansion of the unit cell (the values of a(Å), c(Å), and V(Å^3) are: 7.844(1), 5.027(1), and 309.33(10) for $Ca_2CoSi_2O_7$, and 8.027(1), 5.161(1), and 332.55(9) for $Sr_2CoSi_2O_7$, respectively[10]), which will lead to the elongation of the Co–O bonds, and the decrease of the l. f. s.

Conformational Studies of Bis(cyclic tetrapeptide), *S,S'*-Bis[cyclo-(Gly-L-hemiCys-Sar-L-Pro)]. A Proposed Castanet-type Structure in a Dimethyl Sulfoxide Solution

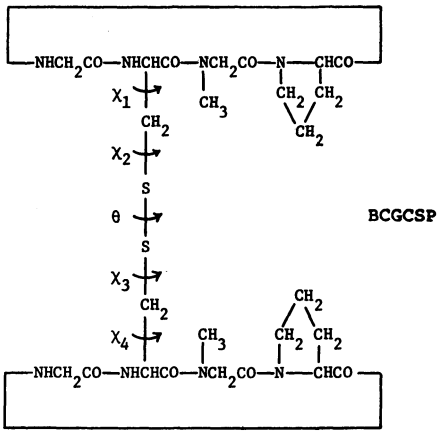
Toshimi SHIMIZU,* Yoshio TANAKA, and Keishiro TSUDA
Research Institute for Polymers and Textiles, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received February 1, 1982)

A bis(cyclic tetrapeptide), *S,S'*-bis[cyclo(Gly-L-hemiCys-Sar-L-Pro)] (BCGCSP), was prepared by coupling two homodetic cyclotetrapeptide. The conformations of BCGCSP in solutions were investigated by means of NMR, Raman, and CD spectroscopy. The ^{1}H-NMR data in dimethyl-d_6 sulfoxide (Me_2SO-d_6) demonstrated that the two cyclic skeletons of BCGCSP take the same conformations as that of an authentic cyclic tetrapeptide, cyclo-[Gly-L-Cys(Bzl(OMe))-Sar-L-Pro] (CGCSP). The ^{1}H-NMR spectrum of CGCSP contains three sets of resonances, corresponding to three different molecular conformations. From the Raman lines of BCGCSP at 529 cm^{-1} and 683 cm^{-1} in Me_2SO-d_6, it is deduced that the two HC_α–$C_\beta S$ dihedral angles are 180°(trans), while one of the SS–$C_\beta C_\alpha$ dihedral angles is 20—30° and the other is either near 90° or near 180°. In addition, the values of two Raman lines predict that the $C_\beta S$–SC_β dihedral angle is in the range of near 90°. Such a conformation around the $C_\beta S$–SC_β bond is also reasonable in the light of the presence of a CD transition (CS–SC) at $\lambda > 250$ nm in water. By combining the above data, the CPK molecular model of BCGCSP was constructed. An inspection of the model reveals that this bis(cyclic tetrapeptide) is likely to adopt a "castanet-type" structure in Me_2SO-d_6. At the same time the individual cyclic skeleton is considered to take three different ring conformations in equilibrium.

Synthetic cyclic peptides are useful model compounds for elucidating the conformational features (for example, β-turns, γ-turns, and transannular hydrogen bonds) which are recognized as important in protein structure.[1,2] They are also ideal candidates for a new class of carrier molecules which have the capability of ion-binding and ion-transporting through a biological membrane,[3-5] for it is artificially possible to synthesize cyclic peptides, which are molecularly designed to be furnished with the structural characteristics of naturally occurring peptidic substances.[6] Some of the cyclic tetrapeptides have been investigated as to their solution conformations, in connection with their residual properties.[7] However, our cation-binding study of cyclotetrapeptide, cyclo(L-Pro–Sar)$_2$ demonstrated that an efficient ion-dipole interaction was unlikely to take place for lack of conformational flexibility.[8] This result also implied that cyclic peptide comprised of a relatively small number of amino acid residues (4—5) tends to form 2 : 1 (peptide=2, cation=1) complexes with some metal cations.

Thus, a bis(cyclic tetrapeptide), *S,S'*-bis[cyclo(Gly–L-hemiCys–Sar–L-Pro)], in which two homodetic cyclotetrapeptides are joined by a covalent bond, was designed and synthesized. The methodology for such a synthesis of a bis(cyclic peptide) was established by Schwyzer *et al.*[9] and Murakami *et al.*[10] Schwyzer *et al.* synthesized a *S,S'*-bis[cyclo(Gly–L-hemiCys–Gly–Gly–L-Pro)] and proposed a possible model of a cation pump by this peptide, which is driven by the oxidoreduction process. Murakami *et al.* synthesized a *S,S'*-bis-[cyclo(Gly–L-hemiCys–Gly–L-His–L-Cap–L-Und)] and found that this peptide enhanced the hydrolysis of *p*-nitrophenyl carboxylates bearing a long alkyl chain. The conformational study of the bis(cyclic tetrapeptide) described herein provided spectroscopic evidence that this peptide takes a "castanet-type" structure in Me_2SO-d_6. This structure is requisite for all available carbonyl oxygens to bind to a cation cooperatively. During the present study, our attention was focused on the restriction of the total molecular conformation by the $C_\alpha C_\beta SSC_\beta C_\alpha$ group.



BCGCSP

As has been mentioned above, BCGCSP is a useful model compound containing an SS linkage for elucidating conformational features in naturally occurring peptides. However, the very poor solubility of this peptide restricted the use of a variety of solvents. Therefore, dimethyl sulfoxide was chosen as the solvent for the NMR and Raman studies, and water was utilized for the CD study.

Results and Discussion

Conformations of Individual Cyclic Peptide Skeletons of the Bis(cyclic tetrapeptide) in Solution. The 360 MHz ^{1}H-NMR spectrum of *S,S'*-bis[cyclo(Gly–L-hemiCys–Sar–L-Pro)] (BCGCSP) in Me_2SO-d_6 is shown in Fig. 1. More or less resolved signals for each proton in BCGCSP are seen, particularly in the region of 0—6 ppm. At the same time, at least six amide NH proton signals are positioned at 6.8—8.8 ppm. At first, the characterization of the amide NH protons was inferred from variable-temperature ^{1}H-NMR studies. The temperature effect

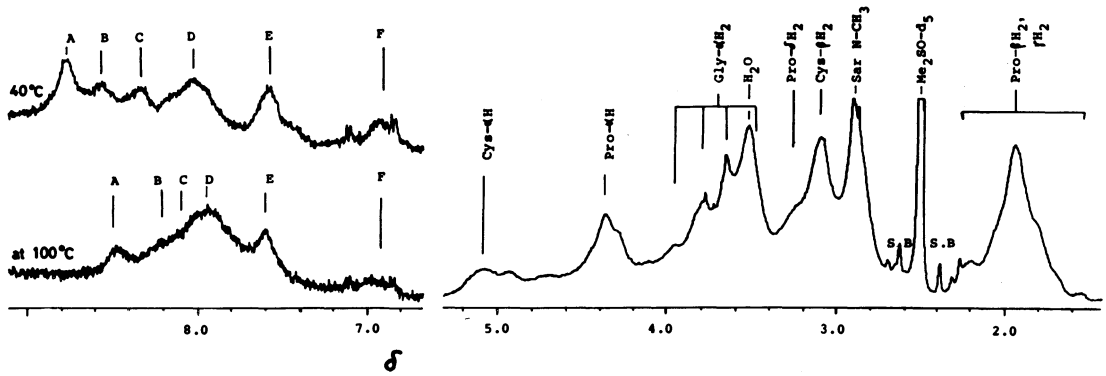


Fig. 1. ^{1}H-NMR spectrum (360 MHz) of BCGCSP in Me_2SO-d_6 at 100 °C and (upper left) at 40 °C. Concentration: 10 g dm^{-3}, S.B.: spinning sideband.

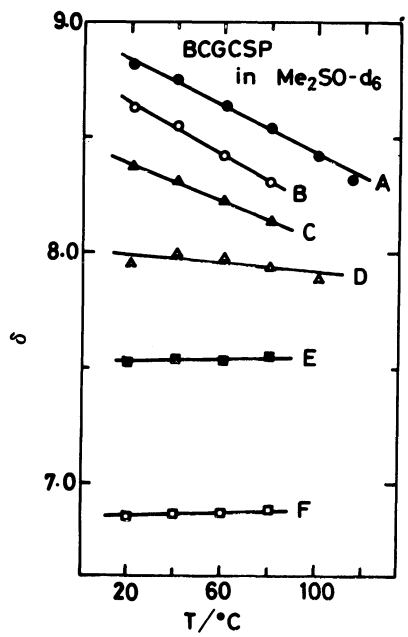

Fig. 2. Temperature dependence of the Gly and Cys amide proton chemical shifts of BCGCSP in Me_2SO-d_6

on the chemical shift of NH signals in Me_2SO-d_6 is shown in Fig. 2. Three NH resonance signals (A, B, and C) move upfield as the temperature increases [$|d\delta(dT)^{-1}|>0.004$ ppm deg^{-1}], while the other three resonances (D, E, and F) are almost independent of the temperature [$|d\delta(dT)^{-1}|<0.001$ ppm deg^{-1}]. These remarkable differences in temperature dependence are attributed to the accessibility of the amide NH proton to a solvent [an internal NH proton (buried or hydrogen-bonded) or an external one (exposed to the solvent)]. According to the usual criteria of accessibility determined from temperature dependence, the three NH protons (A, B, and C) must be exposed to the solvent, while the other three NH protons (D, E, and F) must be shielded from the solvent. A comparison of the ^{1}H-NMR spectrum of the authentic monocyclic tetrapeptide with that of the bis(cyclic tetrapeptide) will now give helpful information for the assignment of the NH proton signals of BCGCSP. The 360 MHz ^{1}H-NMR spectrum of the authentic cyclic tetrapeptide, cyclo[Gly–L-Cys(Bzl(OMe))–Sar–L-Pro] (CGCSP), in Me_2SO-d_6 is shown in Fig. 3. Assignments of signals for each proton were made by spin-decoupling. The NMR parameters of the NH proton resonances of BCGCSP and CGCSP

a) Chemical shift, δ, coupling constant, J/Hz. The coupling constants, J, are to within ±0.5 Hz. b) Signals for the protons of the *p*-methoxybenzyl group were omitted.

in Me_2SO-d_6 are summarized in Table 1. Each of the chemical shifts and each of the temperature coefficients of the three NH resonances (A, B, and C) of BCGCSP indicate good similarities to those of the three NH resonances (G, H, and I) of CGCSP. As to the parameters of the remaining three proton resonances (D, E, and F), they also closely resemble those of three resonances (J, K, and L) of CGCSP. This finding supports the idea that three resonances (A, B, and C) are to be assigned to the glycyl NH protons, and the other resonances (D, E, and F), to the cystyl NH ones. It also leads us to the conclusion that the two homodetic cyclic peptide skeletons of BCGCSP take the same structure as that of monocyclic peptide, despite the fact that two cyclic peptides are joined by a bridge containing the S–S bond. Therefore, it seems plausible that the two cyclic skeletons exist in the same conformational state. These conclusions imply that three pairs of the glycyl and cystyl NH proton (A and E, B and D, and C and F) are to be ascribed to the three coexisting structures of BCGCSP in equilibrium. It is of great interest that the conformational properties of the cyclic skeleton of this bis(peptide) are essentially determined by the ring conformation of the individual cyclic tetrapeptide.

Our discussion will, therefore, be concentrated on multiple-ring conformations of CGCSP in Me_2SO-d_6. The ^{1}H-NMR spectrum of CGCSP contains three sets of resonances for each proton. The chemical shifts for the three sets of signals and corresponding coupling constants are summarized in Table 2. All the coupling constants were experimentally obtained. The computer-simulated spectrum using these spectral parameters was in good agreement with the observed one. The N–CH_3 protons of the sarcosyl residue in CGCSP give rise to three signals, at 2.81, 2.79, and 2.78 ppm, with the relative intensity of 3 : 1 : 1 (*cf.* Fig. 4(8)). This, together with the occurrence of the three NH proton signals of each glycyl and cysteinyl residue, means that

M **m** **n**

Fig. 6. Three different conformations (**M**, **m**, and **n**) of CGCSP proposed on ground of the NMR data in Me_2SO-d_6.

CGCSP has three conformational states. When benzene-d_6 (C_6D_6) was added to a chloroform-d_1 ($CDCl_3$) solution of CGCSP, all the N–CH_3 proton signals represented two different tendencies of upfield shifts. Figure 4(1) shows the 360 MHz ^{1}H-NMR spectrum of CGCSP in $CDCl_3$. The addition of C_6D_6 produced large upfield shifts for the signal at 3.18(●), 3.09(■), and 3.04(○), and small upfield shifts for the remaining signals at 3.06(□), 3.02(△), and 2.86 ppm (▲). Taking into account this phenomenon, N–CH_3 protons anti to the carbonyl oxygen of its peptide bond (*i.e.*, the trans Cys–Sar peptide unit) can be differentiated from that in the cis peptide bond. That is, this differentiation technique is based upon the large benzene-induced upfield shift of the resonance ascribable to the N–CH_3 protons involved in the trans peptide bond.[11] It is thus concluded that the signals at 3.18(●), 3.09(■), and 3.04 ppm (○) are attributable to the N–CH_3 protons involved in the trans Cys–Sar peptide bond, while the other signals, at 3.06(□), 3.02(△), and 2.86 ppm (▲), are attributable to the N–CH_3 protons on the cis Cys–Sar bond in $CDCl_3$. The interaction of CGCSP with C_6D_6 in $CDCl_3$ will be discussed in detail in the following paper.[12] Figure 4(2)—4(8) indicates the ^{1}H-NMR spectral change in CGCSP in the sarcosyl N–CH_3 region when Me_2SO-d_6 was added to the $CDCl_3$ solution. It can be seen that three signals in $CDCl_3$, at 3.18(●), 3.09(■), and 2.86 ppm (▲), disappear gradually as the proportion of Me_2SO-d_6 increases. Finally, this solvent-titration study showed that the two N–CH_3 signals at 2.81 and 2.78 ppm in Me_2SO-d_6 are ascribable to the N–CH_3 protons on the cis Cys–Sar peptide bond (Fig. 4(8)). In addition, one remaining signal, at 2.79 ppm, can be attributed to the N–CH_3 protons on the trans Cys–Sar bond in Me_2SO-d_6. From the relative area underneath the N–CH_3 proton signals, it is also clear that a predominant conformer, **M**, has a cis Cys–Sar peptide bond, while two remaining minor conformers, **m** and **n**, contain a trans and a cis Cys–Sar peptide bonds respectively.

The chemical shifts of the Pro C_β and Pro C_γ carbon are often applicable in establishing the cis-trans isomeric state of the X–Pro peptide bond (X=any amino acid residue). The 90 MHz ^{13}C-NMR spectrum of CGCSP in Me_2SO-d_6 is shown in Fig. 5. From the literature information[13] about the differentiation of the trans X–Pro peptide bond from the cis X–Pro bond, it can be determined that the Pro C_β resonance at 33.7 ppm and the Pro C_γ resonance at 24.0 ppm are typical of the cis Sar–Pro peptide bond. Another Pro C_β resonance at 30.7 ppm and the Pro C_β resonance at 26.5 ppm can also be attributed to the trans Sar–Pro bond. As judged from the relative intensities of the Pro C_β and C_γ resonances, one-third of the populations of Sar–Pro peptide bonds seem to have the trans form. If one considers the cis-trans isomerism about the Cys–Sar and the Sar–Pro peptide bond, three of the four different conformations can be attributed to CGCSP, thus explaining all the situations mentioned above. At first, the glycyl and cysteinyl ϕ angles are calculated from the observed vicinal coupling constants, $J_{NH-C_\alpha H}$, using a Ramanchandran-type relationship (Table 1).[14] Taking these conformational parameters into account, three different CPK model of CGCSP can then be

constructed. Schematic representations of the proposed backbones for CGCSP in Me_2SO-d_6 are shown in Fig. 6. These three types of conformations indicate four characteristic features. First, the conformers, **M**, **m**, and **n**, contain cis-cis, trans-cis, and cis-trans peptide bond sequences of the Cys–Sar–Pro units respectively. Second, the conformation about the prolyl C_α–CO single bond is trans'(Pro $\psi=120°$)[15] in all three species. Third, a transannular hydrogen bond between the Cys amide NH proton and the Pro C=O oxygen would be possible. This satisfies the hydrogen-bonding requirement evidenced by the solvent shielding of the Cys NH proton. The molecular model indicates that the hydrogen bond is nonlinear, having a short C=O··· HN distance. In this respect, the rate of exchange of the amide NH protons in a mixed solvent of Me_2SO-d_6 and 10%-D_2O has been studied. The Gly amide NH proton in **M** was totally exchanged in less than 250 min at 30°C, while the NH proton of cystein in **M** remained unexchanged after 400 min. In **m**, the exchange of the glycyl NH proton was completed in less than 90 min, whereas the exchange of the cysteinyl NH proton took more than 150 min. These results provide strong evidence that the cysteinyl NH proton in at least two conformers (**M** and **m**) is involved in the formation of a transannular hydrogen bond. Fourth, similar species appear to arise in the conformation of CGCSP in acetonitrile-d_3 (CD_3CN), as will be discussed in the following paper.[12]

Conformations of a Side-chain Bridge Containing a Disulfide S–S Bond in Me_2SO-d_6. The Raman spectrum of BCGCSP in Me_2SO-d_6 is shown in Fig. 7. Two Raman lines are observed at 529 cm^{-1} due to a S–S stretching vibration and at 683 cm^{-1} due to a C–S stretching vibration, plus a line at 616 cm^{-1} derived from the solvent. The correlations of the S–S stretching frequencies, ν(S–S), with the conformational properties of the $C_\alpha C_\beta SSC_\beta C_\alpha$ fragment have so far been investigated on organic disulfides. Wart and Scheraga have studied the Raman spectra of a number of primary disulfides which are structurally related to cystine.[16] They proposed a correlation between ν(S–S) and the conformation about the C_β–S bonds in the $C_\alpha C_\beta SS_\beta C_\alpha$ fragment. According to their assumption, the observed value of ν(S–S) of 529 cm^{-1} can be ascribed to the conformation in which one SS-$C_\beta C_\alpha$ dihedral angle(χ_2) is 20—30° (neither cis nor gauche) and the other(χ_3) is 90° (neither gauche nor skew) or 180° (trans). In addition, the assignment of the C–S stretching modes was proposed by Sugeta *et al.*[17] It leads us to the conclusion that the value of ν(C–S) of 683 cm^{-1} is responsible for the conformation in which two HC_α–$C_\beta S$ dihedral angles (χ_1 and χ_4) are 180° (trans). As to the conformations about the S–S bond, compounds containing an unstrained $C_\alpha C_\beta SSC_\beta C_\alpha$ fragment generally have similar conformations (*i.e.*, $C_\beta S$–SC_β dihedral angles near $\pm 90°$). It will, then, be valid to say that the stereochemistry of the $C_\beta S$–SC_β group in BCGCSP has a restricted range of dihedral angles near $\pm 90°$ in Me_2SO-d_6. This assumption is consistent with the results of the study of Wart and Scheraga.[16] They suggested that the observation of values of ν(S–S) higher than about 510 cm^{-1} would imply the presence of unstrained S–S bonds (*i.e.*, the dihedral angle retains its minimum energy value of $\pm 90°$).

Chirality of Disulfide S–S Bond in Water. Next, our discussion will be focused on the chirality of the disulfide bridge between two homodetic cyclic tetrapeptides. For the dimethyl sulfoxide solution, the circular dichroism (CD) spectrum was too complicated to analyze because of the presence of solvent absorption. Some information about the chirality was obtained, however, from the CD spectrum in water. The CD spectrum of BCGCSP is shown in Fig. 8: it has a small negative band ($[\theta]=-11$ deg cm^2 $dmol^{-1}$) at 295 nm, a positive band ($[\theta]=+1400$) at 253 nm, a large negative band ($[\theta]=-17700$) at 226 nm, and a positive band ($[\theta]=+4700$) at 208 nm. Taking into consideration the fact that BCGCSP does not contain any aromatic side chains, the 295 nm band and the 253 nm band can certainly be assigned to the disulfide chromophore. Moreover, the remaining two bands, at 226 nm and at 208 nm, are attributable to the amide-bond transition. The correlations between the chirality of the S–S bond and the

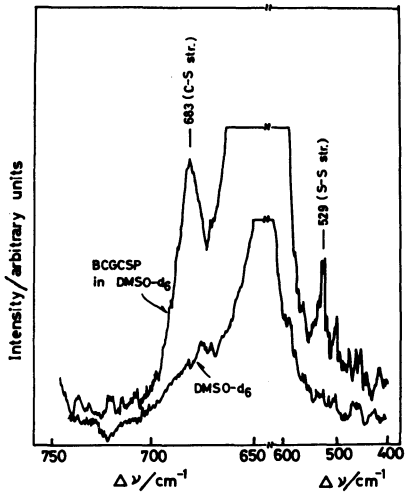

Fig. 7. Raman spectra of BCGCSP in Me_2SO-d_6 at room temperature.

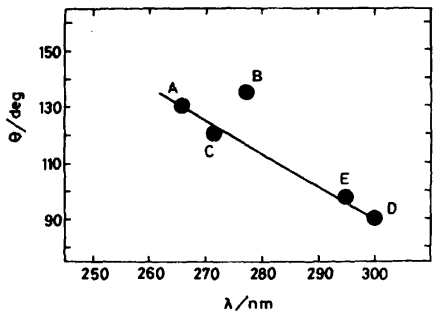

Fig. 9. Dependence of disulfide angle θ, to λ_{min} for various cyclic peptides containing S–S bond.
θ: The value which was estimated by CD spectra and/or measured on the molecular model. λ_{min}: Longer wavelength which affords a negative cotton effect and is attributed to the lowest energy transition. A: *S,S'*-Bis[cyclo(L-hemiCys–L-Pro)] in ethanol,[23] B: malformin-A in hexafluoro-1-propanol,[22] C: [2,7-L-Cystine]-gramicidin S in ethanol,[19] D: *S,S'*-bis[cyclo(Gly–L-hemiCys–Gly–Gly–L-Pro)] in 2,2,2-trifluoroethanol,[9] E: *S,S'*-bis[cyclo(Gly–L-hemiCys–Sar–L-Pro)] in H_2O.

sign of the two Cotton effects in the $250<\lambda<300$ nm and $230<\lambda<250$ nm regions were provided by the work of Carmack and Neubert.[18] According to it, a right-handed helical sence (*P*-chirality) is related to a positive Cotton effect at $\lambda>250$ nm and a negative one at $230<\lambda<250$ nm in the range of dihedral angles of $0°<\theta<90°$ [*vice versa* for a left-handed helical sense (*M*-chirality)]. The investigation of [2,7-L-Cystine]-gramicidin S provided an experimental finding concerning the chirality of the disulfide S–S bond.[19] It completed the evidence for the validity of the theoretical predictions formulated by Bergson[20] and by Linderberg and Michl.[21] If the 295 nm band of this bis(cyclic peptide) corresponds to the long-wavelength transition[20] of the disulfide S–S bond, the quadrant rule for a negative Cotton effect predicts a dihedral angle of either $90°<\theta<180°$ (*P*-chirality) or $-90°<\theta<0°$ (*M*-chirality). The S–S dihedral angles, θ, of compounds containing a cystine moiety previously reported are: (1) malformin-A[22] ($\theta=130$—$140°$, $[\theta]_{276-278}=-5500$ deg cm^2 dmol^{-1}), (2) [2,7-L-Cystine]-gramicidin S[19] ($\theta=120°$, $[\theta]_{271.5}=-7500$ in the difference spectrum between [2,7-L-Cystine]-gramicidin S and [2,7-S-acetamidomethyl-L-cysteine]-gramicidin S), and (3) *S,S'*-Bis[cyclo(Gly–L-hemiCys–Gly–Gly–L-Pro)][9] ($\theta=90°$). From these results, it can be seen that the lowest energy transition in the disulfide S–S chromophore occurs at the longer wavelength, as the S–S dihedral angle, θ, is reduced from 140° to 90° (Fig. 9). However, in the case of $\theta=90°$, the inherent optical activity could not be observed to determine whether the conformation around the S–S bond takes a *P*-chirality or not.[19] Actually, the CD spectrum of a bis(cyclic pentapeptide) shows no Cotton effect centered near 300 nm.[9] These findings substantiate a *P*-chirality with $\theta>90°$ for the S–S bond of BCGCSP. If we adopt the conclusion that the dihedral angle, θ, is 90°—100°, the observation of the negative Cotton effect at 295 nm agrees well with the rules of Linderberg and Michl[21] for the inherent optical

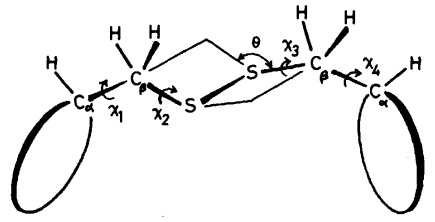

Fig. 10. Schematic representation of $C_\alpha C_\beta SSC_\beta C_\alpha$ moiety in BCGCSP.

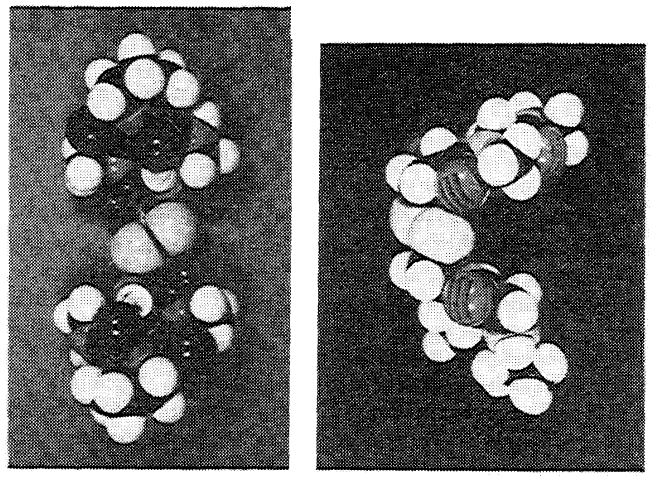

Fig. 11. Photograph of CPK model of proposed a "castanet-type" conformation of BCGCSP in solution. Individual ring conformation of BCGCSP represents that of species **M**, tentatively.

activity of the disulfide chromophore. A *P*-chirality with $\theta=90°$—$100°$ is also in better agreement with the linear correlation in Fig. 9 between the S–S dihedral angles and the corresponding transition wavelength. The 220—250 nm band could not be used to estimate the chirality of the disulfide bond, for it may contain contributions from perturbation by the peptide bond $n\rightarrow\pi^*$ transitions. On the other hand, the CD spectrum of monocyclic tetrapeptide, CGCSP, in water–methanol (9 : 1, by volume) ($[\theta]_{217}=-4700$ deg cm^2 dmol^{-1}) is remarkably different from that of BCGCSP. In the $n\rightarrow\pi^*$ transition region of amide bonds, the total contributions by the four amide-bond chromophores to the CD spectrum will be equal between CGCSP and BCGCSP. Therefore, the CD differences may originate from the perturbations between the amide chromophores of the two homodetic peptide rings in BCGCSP. In other words, the side-chain group of $C_\alpha C_\beta SSC_\beta C_\alpha$ in water is assumed to have such a conformation that they make one peptide ring approach to another one (Fig. 10).

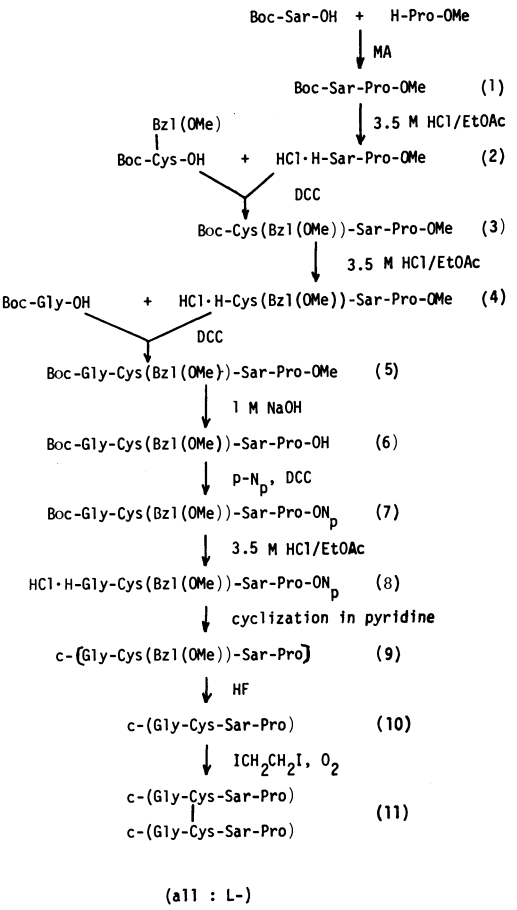
Molecular Conformation of BCGCSP in Me_2SO-d_6. The above assumption regarding the $C_\alpha C_\beta SSC_\beta C_\alpha$ structure in water seems to be reasonable in explaining the Raman spectrum in Me_2SO-d_6. The *P*-chirality of the S–S bond in BCGCSP will probably be retained even in Me_2SO-d_6, judging from the polarity of water and Me_2SO-d_6. Thus, a CPK model of the bis(cyclic tetra-

peptide) could be constructed so that the $C_\alpha^{\chi_1}—C_\beta^{\chi_2}—S^{\theta}—S^{\chi_3}—C_\beta^{\chi_4}—C_\alpha$ group was in the $\chi_1(180°)$-$\chi_2(20°—30°)$-$\theta(90°)$-$\chi_3(180°)$-$\chi_4(180°)$ conformation. At that time, the ring-part conformation of **M** was tentatively assumed to have the conformation of the constituent cyclic tetrapeptide. An inspection of the CPK model reveals that BCGCSP is likely to adopt a "castanet-type" structure, as is shown in Fig. 11. It should be noted that the two planes of the cyclic peptide rings are not essentially positioned in parallel fashion. Therefore, the proposed molecular conformation in the case is different from the specifically folded conformation proposed for *S,S'*-Bis-[cyclo(L-Cys–L-Pro)] in water.[24] The above considerations lead us to the conclusion that BCGCSP must have a "castanet-type" conformation in Me_2SO-d_6 as a whole of the molecule. At the same time, the individual cyclic peptide rings occur in the three interconverting species. This also led us to an interest in binding studies of this bis(cyclic peptide) to a metal ion. A detailed account on the cation-selectivity profiles of this peptide will be presented elsewhere.

Experimental

*S,S'-Bis[cyclo(Gly–L-hemiCys–Sar–L-Pro)](BCGCSP)(**11**).* This was synthesized according to Scheme 1. Cyclo[Gly–L-Cys(Bzl(OMe))–Sar–L-Pro](CGCSP)(**9**) was synthesized *via* the cyclization of the corresponding linear tetrapeptide glycyl-[*S*-(*p*-methoxybenzyl)-L-cystyl]sarcosyl-L-prolyl-*p*-nitrophenyl ester hydrochloride (HCl·H–Gly–L-Cys(Bzl(OMe))–Sar–L-Pro–ON_p) (**8**) in a dilute solution of pyridine. Cyclo(Gly–L-Cys–Sar–L-Pro) (**10**) was afforded by the treatment of CGCSP (**9**) with anhydrous hydrogen fluoride (HF). The final product, BCGCSP (**11**), was obtained from **10** by bubbling with oxygen in the presence of 1,2-diiodoethane as the oxidizing agent.[25] The intermediate peptide fragments and the resulting peptide were purified thoroughly by gel filtration and/or crystallization where possible. The identity and purity of the peptides were checked by a combination of thin-layer chromatography (TLC), nuclear magnetic resonance (NMR), and infrared spectroscopy (IR). We used the I solvent system (chloroform : methanol : acetic acid=95 : 5 : 1 by volume), and the II solvent system (chloroform : methanol =5 : 1, by volume) for the TLC. The synthetic procedures are described in detail below.

*N-(t-Butoxycarbonyl)sarcosyl-L-proline Methyl Ester (**1**).* A solution of Boc–Sar–OH (13.27 g, 70 mmol) in chloroform (50 ml) was cooled to −20 °C and then treated with *N*-methylmorpholine (7.71 ml, 70 mmol) and isobutyl chloroformate (9.19 ml, 70 mmol) to prepare the mixed anhydride. After 3 min, a solution of HCl·H-L-Pro–OMe (11.62 g, 70 mmol) in chloroform (20 ml), were added to the reaction mixture, which was then stirred at −15 °C for 1 h. It was subsequently allowed to warm to room temperature slowly with continuous stirring. After 24 h, the reaction mixture was diluted with chloroform (30 ml) and then extracted successively with 100 ml of water (2 times), 4% sodium hydrogencarbonate (2 times), and a saturated sodium chloride aqueous solution (2 times). The chloroform layer was separated and dried over anhydrous sodium sulfate overnight. After the removal of the sodium sulfate by filtration, the chloroform was evaporated to yield the linear dipeptide as a pale yellow syrup. Crystallization attempts were unsuccessful. The material was used for the following reaction without further purification,



Scheme 1. Synthetic route of BCGCSP. Abbreviations: Boc; *t*-butoxycarbonyl, Sar; *N*-methylglycine, -OMe; methyl ester, DCHA; dicyclohexylamine, MA; mixed anhydride method, -Bzl(OMe); methoxybenzyl, 3.5 M HCl/EtOAc, 3.5 M anhydrous hydrogen chloride in ethyl acetate, DCC; dicyclohexylcarbodiimide, *p*-N_p; *p*-nitrophenol, -ON_p, *p*-nitrophenyl ester.

since it was judged to be the desired product on the basis of TLC: yield, 21.02 g (100%); $R_f^I=0.41$, $R_f^{II}=0.77$.

*Sarcosyl-L-proline Methyl Ester Hydrochloride (**2**).* 3.5 M HCl in ethyl acetate (600 ml) was added to Boc–Sar–L-Pro–OMe (1) (21.02 g, 70 mmol). The reaction mixture was then allowed to stand at room temperature for 1 h. The subsequent removal of the solvent by evaporation left a pale yellow syrup. Trituration with ether yielded a white solid. Recrystallization from methanol–ethyl acetate–ether gave HCl·H–Sar–L-Pro–OMe (**2**) as a white solid: yield, 13.92 g (84%); mp 167—168 °C; $R_f^I=0.03$, $R_f^{II}=0.21$. Found: C, 45.64; H, 7.23; N, 11.81%. Calcd for $C_9H_{17}O_3N_2Cl$: C, 45.67; H, 7.24; N, 11.83%.

*N-(t-Butoxycarbonyl)[S-(p-methoxybenzyl)-L-cysteinyl]sarcosyl-L-proline Methyl Ester (**3**).* Dicyclohexylcarbodiimide (DCC) (1.95 g, 9.45 mmol) in chloroform (10 ml) was stirred into a solution of dicyclohexylammonium salt of Boc–L-Cys(Bzl(OMe))–OH (Boc–L-Cys(Bzl(OMe))–OH·DCHA, 4.94 g, 9.45 mmol) and HCl·H–Sar–L-Pro–OMe (**2**) (2.24 g, 9.45 mmol) in chloroform (60 ml) at −10 °C. The reaction mixture was stirred for 5 h at −5 °C and then overnight at room temperature. After the removal of *N,N'*-dicyclohexylurea, the filtrate was evaporated and the residue was diluted with ethyl acetate (100 ml). The precipitate was filtered off, and the filtrate was successively washed with 100

ml of 10% citric acid (2 times), 4% sodium hydrogencarbonate (3 times), and water (2 times). The organic layer was dried over anhydrous sodium sulfate and concentrated to leave a colorless syrup, which was then triturated with hexane. An attempted recrystallization from ether–hexane was unsuccessful. The Boc-tripeptide (**3**) was obtained as a white semisolid: yield 4.16 g (84%(; $R_f^{\mathrm{I}}=0.44$, $R_f^{\mathrm{II}}=0.80$; $[\alpha]_D^{25}=-75.9°$ ($c=1.19$). Found: C, 57.41; H, 7.17; N, 7.96%. Calcd for $C_{25}H_{37}O_7N_3S$: C, 57.34; H, 7.12; N, 8.02%.

[S-(p-*Methoxybenzyl*)-L-*cysteinyl*]*sarcosyl*-L-*proline Methyl Ester Hydrochloride* (*4*). This tripeptide hydrochloride was prepared by the removal of the Boc group of tripeptide Boc–L-Cys(Bzl(OMe))–Sar–L-Pro–OMe (**3**) (4.00 g, 7.64 mmol), as has been described above for HCl·H–Sar–L-Pro–OMe (**2**). Recrystallization from ethanol–ether gave a white solid: yield 3.51 g (100%); mp 83—84 °C; $R_f^{\mathrm{I}}=0.03$, $R_f^{\mathrm{II}}=0.54$. Found: C, 52.18; H, 6.64; N, 9.11%. Calcd for $C_{20}H_{30}O_5N_5SCl$: C, 52.22; H, 6.57; N, 9.13%.

N-(t-*Butoxycarbonyl*)*glycyl*-[S-(p-*methoxybenzyl*)-L-*cysteinyl*]-*sarcosyl*-L-*proline* (*6*). Boc–Gly–OH·DCHA (2.56 g, 7.17 mmol) was coupled with HCl·H–L-Cys(Bzl(OMe))–Sar–L-Pro–OMe (**4**) (3.30 g, 7.17 mmol), using DCC (1.48 g, 7.17 mmol) in chloroform (100 ml) in the same manner as that used for the preparation of Boc–L-Cys(Bzl(OMe))–Sar–L-Pro–OMe (**3**). Recrystallization from ether–hexane gave Boc–Gly–L-Cys(Bzl(OMe))–Sar–L-Pro–OMe (**5**) as a pale yellow semisolid: yield 3.04 g (73%); mp 49—50 °C; $R_f^{\mathrm{I}}=0.27$, $R_f^{\mathrm{II}}=0.76$; $[\alpha]_D^{25}=-84.8°$ ($c=1.00$).

Boc–Gly–L-Cys(Bzl(OMe))–Sar–L-Pro–OMe (**5**) (3.00 g, 5.17 mmol) in methanol (25 ml) was treated with 1 M NaOH (10.33 ml, 10.33 mmol). After 1.5 h, the methanol was evaporated and the residual solution was diluted with water (25 ml). The aqueous solution was washed with ether (30 ml) and acidified with 10% citric acid under cooling. The resulting precipitate was extracted with ethyl acetate (100 ml), and the organic layer was dried over anhydrous sodium sulfate. After the removal of the sodium sulfate, the solvent was evaporated to leave a colorless foam, which was solidified by the addition of petroleum ether. The product was recrystallized from ethyl acetate–petroleum ether: yield, 2.93 g (89%). mp 82—84 °C; $R_f^{\mathrm{I}}=0.06$, $R_f^{\mathrm{II}}=0.17$. Found: C, 54.66; H, 6.80; N, 9.31%. Calcd for $C_{26}H_{38}O_8N_4S\cdot 0.5H_2O$: C, 54.25; H, 6.83; N, 9.73%.

N-(t-*Butoxycarbonyl*)*glycyl*-[S-(p-*methoxybenzyl*)-L-*cysteinyl*]-*sarcosyl*-L-*proline* p-*Nitrophenyl Ester* (*7*). Into a solution of Boc–Gly–L-Cys(Bzl(OMe))–Sar–L-Pro–OH (**6**) (1.60 g, 2.82 mmol) and *p*-nitrophenol (0.43 g, 3.10 mmol, pulverized previously) in chloroform (15 ml), we stirred a solution of DCC (0.64 g, 3.10 mmol) in chloroform (3 ml) at −5 °C. Stirring was continued at 0 °C overnight. Monitoring the reaction mixture by TLC showed a small amount of the unreacted starting material, so that 0.078 g more of *p*-nitrophenol and 0.058 g of DCC were added after 20 h. Additional stirring was continued at 5 °C for 5 h. The solution was then filtered to remove the precipitated urea, treated with 3 drops of acetic acid, and stirred for 1 h. The solution was subsequently filtered again to ensure the complete removal of the additional amount of urea. The evaporation of the solvent left a pale brown foam, which was triturated with ether–hexane and dried *in vacuo*. The Boc-tetrapeptide *p*-nitrophenyl ester (**7**) was obtained as an off-white solid: yield 1.80 g (92.8%); mp 59—60 °C; $R_f^{\mathrm{I}}=0.07$, $R_f^{\mathrm{II}}=0.76$; $[\alpha]_D^{25}=-78.7°$ ($c=1.00$). Found: C, 56.18; H, 5.98; N, 9.92%. Calcd for $C_{32}H_{41}O_{10}N_5S$: C, 55.88; H, 6.01; N, 10.18%.

Cyclo[*glycyl*-[S-(p-*methoxybenzyl*)-L-*cysteinyl*]*sarcosyl*-L-*prolyl*] (*9*). A solution of HCl·H–Gly–L-Cys(Bzl(OMe))–Sar–L-Pro–ON_p (**8**) (1.61 g, 2.58 mmol) (prepared by the treatment of Boc–Gly–L-Cys(Bzl(OMe))–Sar–L-Pro–ON_p (**7**) with 3.5 M HCl in ethyl acetate at 0 °C for 50 min, trituration with ether, and drying *in vacuo*) in *N,N*-dimethylformamide (DMF) 10 ml) (distilled over calcium hydride just before use), containing a few drops of glacial acetic acid, was added drop by drop and over a period of 5 h to a stirred spectral-grade pyridine (860 ml) at 60 °C. The stirring of the reaction mixture was continued at 30 °C overnight and then allowed to proceed for 3 h at 60 °C. The complete evaporation of pyridine and DMF under reduced pressure left an oily brown residue which was subsequently taken up by water–methanol (1 : 3 by volume) (20 ml). The insoluble material was filtered off, and the filtrate was eluted through columns (1.7× 17 cm) packed with ion-exchange resin of IR-120B (H^+-type) and IRA-400 (OH^--type) successively. The columns were washed with the same solvent until the color of the eluate disappeared. The combined effluent (*ca.* 300 ml) was concentrated to yield a pale yellow syrup. Trituration with ether gave an off-white solid. The crude product (100 mg) was dissolved in a minimum amount of methanol and chromatographed on a Sephadex LH-20 column (2.7×85 cm), using methanol as the eluate. A total of 7 ml×60 fractions were collected. The single components (Nos. 40—46 tubes) were collected, and the solvent was evaporated. The residual syrup was triturated with ether. Recrystallization from methanol–water–ether gave a white solid of cyclo[Gly–L-Cys(Bzl(OMe))–Sar–L-Pro] (**9**); yield 90 mg; ninhydrin test, negative; IR (KBr disk); 3450 (NH str.), 2950 (CH str.), 1650 cm^{-1} (C=O str,); mp 142—143 °C; $R_f^{\mathrm{I}}=0$, $R_f^{\mathrm{II}}=0.47$; $[\alpha]^{25}=-79.2°$ ($c=0.59$). Found: *m/e*=448. Calcd for $C_{21}H_{28}O_5N_4S$: M= 448. Found: C, 55.17; H, 6.12; N, 12.12%. Calcd for $C_{21}H_{28}O_5N_4S\cdot 0.5H_2O$: C, 55.13; H, 6.39; N, 12.25%.

S,S′-*Bis*[*cyclo*(*glycyl*-L-*hemicystyl*-*sarcosyl*-L-*prolyl*) (*11*). Cyclo[Gly–L-Cys(Bzl(OMe))–Sar–L-Pro] (**9**) (90 mg, 0.2 mmol) was placed in an HF-reaction reservoir vessel together with anisole (0.3 ml). Anhydrous HF was added the reservoir vessel using an HF-reaction apparatus, after which the mixture was allowed to react at 0 °C for 1 h while being stirred. The excess HF was removed under reduced pressure at 0 °C, and the residue was dried under reduced pressure for 6 h at room temperature. Subsequent crystallization from methanol–ether gave an off-white solid as cyclo(Gly–L-Cys–Sar–L-Pro) (**10**). The material was immediately used in the next step without further purification. 1,2-diiodoethane (0.042 g, 0.15 mmol) (crystallized from ethanol just before use) and triethylamine (0.056 ml, 0.4 mmol) were stirred into a solution of cyclo(Gly–L-Cys–Sar–L-Pro) (**10**) in methanol (15 ml) under hydrogen.[23] The reaction mixture was then stirred at room temperature overnight. Monitoring the reaction mixture by a nitroprusside test showed it still positive, so an additional amount of 1,2-diiodoethane (0.020 g) was added, after which air was bubbled through the reaction mixture for 6 h. The methanol-insoluble white powdery material was separated on standing overnight: it was then filtered off and thoroughly washed with methanol. The product was found to be insoluble in most organic solvents, such as acetone, chloroform, and ethanol. Recrystallization from water–methanol gave an off-white solid of bis(cyclic tetrapeptide) (**11**): yield 25 mg (38%); ninhydrin test, negative; nitroprusside test, negative; IR (KBr disc) 3450 (NH str.), 2920 (CH str.), 1640 cm^{-1} (C=O str.); mp 280—285 °C (decomp.); $R_f^{\mathrm{I}}=0$, $R_f^{\mathrm{II}}=0.11$. Found: C, 44.26; H, 5.75; N, 15.61%. Calcd for $C_{26}H_{38}O_8N_8S_2\cdot 3H_2O$: C, 44.06; H, 6.26; N, 15.81%.

Procedures. All the melting points were measured on a Yanagimoto Melting-point Apparatus and were not corrected. The optical rotations were measured with a Perkin-Elmer 241 polarimeter. The IR spectra were taken on a

Shimadzu spectrometer, model IR-430.

The ^{1}H-NMR spectra obtained at 360.06 MHz on a NICOLET NT-360 spectrometer with the NIC 1180 Computer Data System, operating in the Fourier transform mode with quadrature detection. The chemical shifts are reported in parts per million (ppm) downfield from internal tetramethylsilane (TMS). The ^{13}C-NMR data were recorded on either a NICOLET NT-360 or a Varian CFT-20 spectrometer at 90.54 MHz or 20.12 MHz respectively, in the Fourier transform mode with proton-noise decoupling. Chemical shifts are given in ppm relative to the internal TMS. The Raman spectra of the bis(peptide) in the liquid state were measured with a JEOL Raman 400D spectromer equipped with an argon-ion laser.

The circular dichroism (CD) spectra were recorded on a JASCO J-40A automatic recording spectropolarimeter equipped with a J-DPY data processor at 25 °C. Generally measurements were carried out in quartz cells with a 0.1-cm path length over 250 nm to 200 nm and a 1-cm path length over 350 nm to 250 nm. Data are represented as molar ellipticities. Spectrophotometric-grade methanol and water were used as solvents.

The authors wish to express their thanks to Dr. Yukio Imanishi of Kyoto University for his valuable suggestions and discussions. We also would like to thank Dr. Shoei Fujishige of our Institute for his useful comments.

Multiple Conformations and Conformational Change in the Acetonitrile of Cation-binding Cyclic Tetrapeptide, Cyclo[Gly-L-Cys(Bzl(OMe))-Sar-L-Pro]

Toshimi SHIMIZU,* Yoshio TANAKA, and Keishiro TSUDA
Research Institute for Polymers and Textiles, Yatabe-Higashi, Tsukuba, Ibaraki 305
(Received February 1, 1982)

The conformations of the cyclic tetrapeptide, cyclo[Gly-L-Cys(Bzl(OMe))-Sar-L-Pro] (CGCSP), in solution, were studied by means of ^{1}H-, ^{13}C-nuclear magnetic resonance (NMR), and circular dichroism (CD). The CGCSP equilibrates among three conformers, **M**, **m**, and **n**, in acetonitrile, providing three sets of resonances for each proton in the ^{1}H-NMR spectrum. An inspection of a CPK model indicated that the three structures were sterically allowed to occur by the *cis-trans* isomerism around the Cys–Sar and Sar–Pro peptide bond. The temperature dependence of the amide proton resonances in ^{1}H-NMR suggested that one γ-turn (1←3 hydrogen bond from the Cys to the Pro) is present in the two conformers, **M** and **m**. Thus, the three conformations in acetonitrile were deduced from all of the spectral data. This cyclic tetrapeptide is capable of binding a monovalent cation, Li^+, and divalent cations, Mg^{2+}, Ca^{2+}, and Ba^{2+}. Its CD titration curves demonstrated that at least three types of complexes with Ca^{2+} and Ba^{2+} were formed. In contrast, Li^+ and Mg^{2+} were shown to form the 1 : 1 complex with this peptide. The NMR data suggest that the conformational change of the cyclic backbone takes place by changing the geometry of the peptide bonds around the Cys–Sar–Pro sequence on the addition of a metal cation.

In the preceding paper,[1] the conformation of bis-(cyclic tetrapeptide), *S,S'*-Bis[cyclo(Gly–L-hemiCys–Sar–L-Pro)], in solution was investigated using such spectroscopic studies as ^{1}H-NMR, ^{13}C-NMR, Raman, and CD. The proposed conformation in dimethyl-d_6 sulfoxide, which takes a "castanet-type" structure, attracted our attention to the potential activity of this bis(peptide) as an ionophore.

In the present report, the conformations and ion-binding capabilities of the homodetic cyclic tetrapeptide, cyclo[Gly–L-Cys(Bzl(OMe))–Sar–L-Pro], in solution, are described on the basis of the results from ^{1}H-NMR, ^{13}C-NMR, and CD measurements. The small cyclic peptides consisting of 4—5 amino acid units have somewhat rigid backbones of the ring. Therefore, a conformational change is unlikely to take place in these small cyclic peptides on the addition of metal cation to the solution. Actually, the ^{13}C-NMR spectrum of a cyclic tetrapeptide, cyclo(Sar–L-Pro–Sar–L-Pro), in acetonitrile afforded a single resonance for each carbon resulting from one conformer. This conformation is retained even on the addition of the magnesium cation.[2] Recent investigations of naturally occurring cyclic tetrapeptide have revealed the importance of the cyclic structure in the evolution of its biological activity.[3,4] The present study describes an investigation of the conformational change on binding to a metal cation by the cyclic tetrapeptide. This is closely connected with biological events by means of some small cyclic molecules in the membrane transport.[5]

Experimental

Synthesis. The synthesis of cyclo[Gly–L-Cys(Bzl(OMe))–Sar–L-Pro] (CGCSP) has been described in the previous paper.[1]

Procedures. The ^{1}H-NMR spectra were recorded at 360.06 MHz on a NICOLET NT-360 spectrometer with a NIC 1180 Computer Data System, operating in the Fourier transform mode. The ^{13}C-NMR spectra were obtained at 20.12 MHz on a Varian CFT-20 spectrometer, in the Fourier transform mode with proton noise decoupling. All the chemical shifts are given in ppm relative to the internal tetramethylsilane.

The circular dichroism (CD) spectra were recorded using a 0.1-cm path length quartz cell on a JASCO J-40A automatic recording spectropolarimeter equipped with a J-DPY data processor at 25 °C. The data were represented as molar ellipticities. The concentrations of the resulting peptide solutions containing salt were 10^{-3}—10^{-4} mol dm^{-3}. Spectrophotometric-grade acetonitrile was used as the solvent. Analytical reagent-grade perchlorates were used as the metal salts.

Results

Backbone of Cyclic Peptide. ^{1}H-NMR. The ^{1}H-NMR spectrum at 360 MHz of CGCSP in acetonitrile-d_3 is presented in Fig. 1. The assignments were confirmed by the spin-decoupling method and by comparisons with the precursor linear tetrapeptides. It may be seen that the spectrum contains three sets of ABMX-spin systems for the cysteinyl residue and three sets of the ABX systems for the glycyl residue. This finding demonstrates that three species (**M**, **m**, and **n**), each having well-defined, highly populated conformational states, exist on the NMR time scale. From the relative intensities of the Cys and the Gly amide proton signals, the populations of **M**, **m**, and **n** are estimated to be 50, 30, and 20% respectively. The chemical shifts for the three sets of signals and related coupling constants are summarized in Table 1. All the coupling constants were experimentally obtained and optimized by computer simulations. In order to determine the accessibility of each amide NH proton to the solvent, the temperature dependences of the Gly and the Cys NH resonances in **M**, **m**, and **n** (a total of six NH resonances) were measured. The results are shown in Fig. 2. The temperature coefficients of the three cysteinyl amide NH signals, A, B, and F, are zero or small ($d\delta(dT)^{-1}$=0.00(A), 0.00(B), and 2.33 ppm deg^{-1} (F)). In contrast, those of the remaining three glycyl amide NH resonances, C, D, and E, are larger than those of the A, B, and F signals

a) Chemical shift, δ, coupling constant, J/Hz. The coupling constants, J, are to within $\pm$0.5 Hz. b) Signals for the protons of the *p*-methoxybenzyl group were omitted.

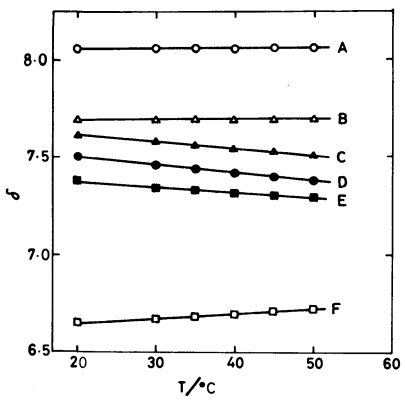

Fig. 2. Temperature dependence of the Gly and Cys amide proton chemical shifts of CGCSP in CD_3CN.

($d\delta(dT)^{-1}=-3.97$(C), -4.00(D), and -3.00 ppm deg^{-1} (E)). According to the usual criteria of accessibility determined from the temperature dependence of the NH's, the Cys NH proton in **M** and **m** is probably buried in the molecule or is hydrogen-bonded. The Gly NH proton is assumed to be exposed to the solvent in all three species.

Next, two resonances for the Sar N–CH_3 protons occur at 2.85 ppm and 2.89 ppm, with the relative intensity of 4 : 1 in acetonitrile-d_3. Solvent-titration experiments were performed in an attempt to distinguish the Sar N–CH_3 resonances derived from a trans Cys–Sar peptide bond from that derived from a cis Cys–Sar bond. First, the ^{1}H-NMR spectra of the cyclic tetrapeptide in a chloroform-*d* solution were examined, while benzene-d_6 was added to bring the total up to 30% (by

Upfield shifts for N–CH_3 signals of CGCSP as a function of the volume fraction of C_6D_6 in $CDCl_3$–C_6D_6 solvent mixtures (left) and the shift of N–CH_3 signals as a function of the volume fraction of CD_3CN in $CDCl_3$–CD_3CN solvent mixtures (right). —●—: a, —■—: b, —□—: c, —○—: d, —△—: e, —▲—: f.

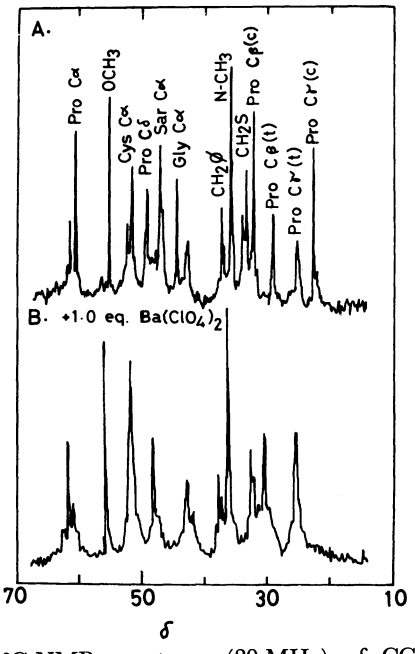

Fig. 4. ^{13}C-NMR spectrum (20 MHz) of CGCSP in CD_3CN. The peptide concentration was 0.12 mol dm^{-3}. The spectra are (A) free peptide and (B) barium perchlorate added to a concentration of 0.12 mol dm^{-3} (molar ratio of peptide: salt, 1: 1).

volume). The addition of benzene gave rise to neither any significant change in the vicinal coupling constants of the Gly or the Cys residue nor that of the intensity of six Sar N–CH_3 resonances. At the same time, the chemical shifts of N–CH_3 signals changed monotonically with the increase in the volume fraction of benzene. These observations, therefore, established that no conformational changes in CGCSP were induced by benzene. The addition of benzene to chloroform induces six N–CH_3 signals to move upfield. The profiles of the upfield shifts for the N–CH_3 signals are shown in Fig. 3 as a function of the volume fraction of benzene-d_6. The a, b, and d signals have larger benzene-induced upfield shifts than those of the c, e, and f signals. These two different tendencies of upfield shifts for N–CH_3 signals are considered to reflect the different local geometries of the Sar N–CH_3 group and the Cys carbonyl group, namely, a cis Cys–Sar peptide bond or a trans Cys–Sar bond. Therefore, an established method based on the benzene-induced shift concerning the assignment of the N–CH_3 signal of cyclo(Sar)$_4$[6] or cyclo(L-Pro–Sar–Gly)$_2$[7] is applicable in this case. Thus, the a, b, and d resonances in a chloroform solution are assigned to the N–CH_3 protons involved in the trans Cys–Sar peptide bond, while the remaining resonances, c, e, and f, are attributable to those involved in the cis Cys–Sar bond.

Second, the ^1H-NMR spectra of the cyclic tetrapeptide were examined in a chloroform-*d*–acetonitrile-d_3 mixed solvent system. In Fig. 3, the chemical shifts of the Sar N–CH_3 signals are plotted as a function of the acetonitrile fraction in a volume. Two signals, a and b, move lowfield, while the f signal reveals an upfield shift, as the concentration of acetonitrile increases. At the same time, the three signals were accompanied by a decrease in the intensity. Finally, in the 1 : 1 mixture of a chloroform–acetonitrile solvent system by volume, these three signals, a, b, and f, almost disappeared. On the other hand, the c signal, associated with the cis Cys–Sar peptide bond, shifts upfield with an increase in the intensity. At the same time, the d signal, attributed to the trans Cys–Sar bond, and the e signal, attributed to the cis Cys–Sar bond, weakened in intensity with the upfield shifts. On the basis of these observations, it is confirmed that the signal at 2.89 ppm in acetonitrile contains two N–CH_3 resonances involved in the cis and trans Cys–Sar peptide bonds, while the resonance at 2.85 ppm is associated with the cis Cys–Sar peptide bond. From the relative intensity of the Gly and the Cys NH proton resonances, it is assumed that the conformers, **M**, **m**, and **n**, contain cis, trans, and cis Cys–Sar peptide bonds respectively.

^{13}C-NMR. The upfield regions of the ^{13}C-NMR spectrum at 20 MHz of CGCSP in acetonitrile-d_3 are shown in Fig. 4A. The assignments of the resonances were confirmed by examining ^1H-coupled and selectively ^1H-decoupled spectra and by comparisons with the spectra of related compounds. Further conformational features of **M**, **m**, and **n** other than those from ^1H-NMR observations can not be inferred from this ^{13}C-NMR spectrum. However, rotational isomers around the Sar–Pro peptide bond can be discriminated by the resulting separate chemical shifts of the Pro C_β and Pro C_γ carbons.[8] The two chemical shifts of the signal at 32.8 ppm for the Pro C_β and at 23.1 ppm for the Pro C_γ are indicative of the presence of the cis Sar–Pro bond. Moreover, the other two signals, at 29.6 ppm for the Pro C_β and at 25.6 ppm for the Pro C_γ, are within the region associated with the trans Sar–Pro bond. The

TABLE 2. SIDE-CHAIN CONFORMATIONS OF THE CYSTEIN RESIDUE IN CGCSP IN CD_3CN

Species	Proportion[a]/%		
	F	U_I (or U_{II})	U_{II} (or U_I)
M	21.7	39.7	38.6
m	20.0	40.8	39.2
n	30.1	30.7	39.2

a) Calculated from observed J_{AM} and J_{BM} using the following relationship; $U_I=[J_{AM}(\text{or } J_{BM})-J_g]/(J_t-J_g)$, $U_{II}=[J_{BM}(\text{or } J_{AM})-J_g]/(J_t-J_g)$, $F=1-(U_I+U_{II})$ where $J_t=13.56$, $J_g=2.60$ Hz.

relative intensity of the two Pro C_β and two Pro C_γ resonances show clearly the presence of 70—80% of the cis Sar–Pro peptide bond and that of 20—30% of the trans Sar–Pro bond.

Side Chain of Cyclic Peptide. ^1H-NMR. It is assumed that the orientation of the cysteinyl side chain from C_β carbon on (C_β–S–Bzl(OMe)) occurs in an extended chain with a lower potential energy. Therefore, the conformation of the side-chain group C_α–C_β–S–Bzl(OMe), is essentially determined by the rotation about the C_α–C_β bond of the cysteinyl residue. This implies that the side-chain group exists in the three energetically stable rotational isomers (Fig. 5). One is

the folded conformation (F), while the others are unfolded ones (U_I and U_{II}), which rapidly interconvert on the NMR time scale. From the Pachler equation[9] using the vicinal coupling constants, J_{AM} and J_{BM}, in Table 1, the ratio of the presence of the three rotamers was evaluated; it is shown in Table 2. A folded conformation (F) in which the aromatic ring of the side chain is positioned over the cyclic backbone of peptide, is more favored in **n** than in **M** and **m**.

Ion Binding. Circular Dichroism (CD): A solution of CGCSP in acetonitrile was titrated with alkali ions (Li^+ and Na^+) and alkaline earth ions (Mg^{2+}, Ca^{2+}, and Ba^{2+}) while the circular dichroism (CD) spectra were examined. The extrema of the CD spectrum of free cyclotetrapeptide in different solvents and that of complexed peptide with various cations in acetonitrile are summarized in Table 3. The CD spectrum of the free cyclic peptide shows a negative band at 212 nm in acetonitrile (Fig. 6). Common features are observed for the CD spectra of the free peptide in water–methanol (9 : 1, by volume) and in methanol. This finding suggests that there are no significant differences among the conformations of the peptide backbone in these solvents. Upon the addition of metal ions to the solution of the cyclic peptide in acetonitrile, remarkable changes take place, particularly when the divalent cations are added. In the case of Ba^{2+} addition (Fig. 6), the minimum observed for the free peptide increases until the molar ratio of peptide to salt is 2 : 1 stoichiometry ("peptide-sandwich type"). After that, the curves display no drastic change upon the addition of salt until the molar ratio is *ca.* 10. This second step of complexing corresponds to the formation of a 1 : 1 complex (cyclopeptide–Ba^{2+}). At a high salt concentration above this point, the CD spectrum shows a decrease in the minimum which appeared in the presence of 10 equiv. of Ba^{2+}. This finding suggests the appearance of the third complex of Ba^{2+}–cyclopep-

tide–Ba^{2+} with 1 : 2 stoichiometry ("metal cation-sandwich type"). Titration curves were, therefore, depicted in Fig. 7 for the several divalent cations (Ba^{2+}, Ca^{2+}, and Mg^{2+}) and the monovalent cation (Li^+ and Na^+). Then, $\Delta[\theta]$ at 210 nm was plotted against the molar ratio of peptide to the metal cation, where $\Delta[\theta]$ indicates the difference between the molar ellipticity, $[\theta]$, of a peptide plus an ion and that of a free peptide. The curve obtained for Ca^{2+} clearly indicates at least three inflections. This finding demonstrates that at least three types of complexing occurred with the variation of the salt-to-peptide molar ratio. On the other hand, judging from the monotonous increment of $\Delta[\theta]$, only one type of complex with 1 : 1 stoichiometry is assumed to be formed when Li^+ or Mg^{2+} is added.

Equilibrium constants for the first complexed species with several cations were calculated from the CD titration data. For the "peptide-sandwich type" complexes with Ca^{2+} and Ba^{2+}, the following equilibrium constants were defined in terms of the concentrations;

$$K_{1/2} = [P_2C][P]^{-2}[C]^{-1}.$$

For 1 : 1 complexes in the presence of Li^+, Na^+, and Mg^{2+}, K_1 is defined as:

$$K_1 = [PC][P]^{-1}[C]^{-1},$$

where P_2C denotes a sandwich complex; PC, a 1 : 1 complex; P, a peptide, and C, cation. The degree of complexation was determined from the molar ellipticity at a certain wavelength and at a certain salt concentration, on the assumption that the value of ellipticity is the sum of that for free cyclic peptide and that for the complexed peptide present. The calculation of the equilibrium constants were based on the principle reported by Deber *et al.*[10] The results are shown in Table 4. One characteristic feature of the cation-binding properties of this peptide is that it binds divalent cations in preference to monovalent cations. The constant for the formation of a 1 : 1 complex with Mg^{2+} is about 10^3—10^5 fold those of Li^+ or Na^+.

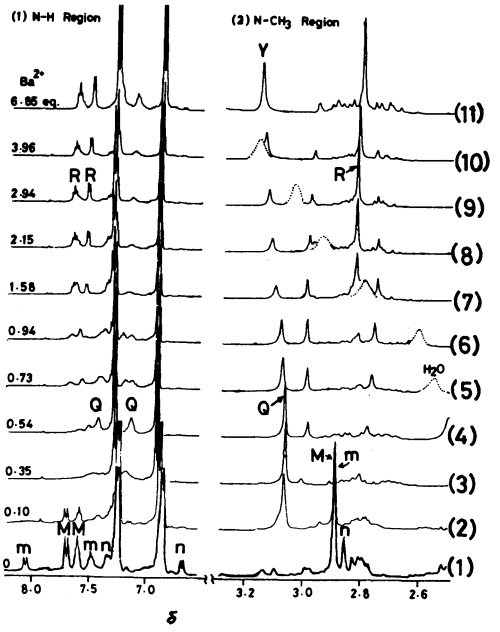

Fig. 8. ^{1}H-NMR spectra of NH and N–CH_3 regions of CGCSP in CD_3CN as $Ba(ClO_4)_2$ is added.
Molar ratio of $Ba(ClO_4)_2$ to CGCSP: (1) 0, (2) 0.10, (3) 0.35, (4) 0.54, (5) 0.73, (6) 0.94, (7) 1.58, (8) 2.15, (9) 2.94, (10) 3.96, (11) 6.85.

^{1}H-NMR and ^{13}C-NMR. In order to elucidate the conformational properties of the cyclic tetrapeptide on complexing with a metal cation, the amide proton and the N–CH_3 proton regions of ^{1}H-NMR were examined in acetonitrile-d_3, titrating with $Ba(ClO_4)_2$. The results are presented in Fig. 8. At least three different types of complex formations can be deduced from the coalescence phenomena of the NH and N–CH_3 proton signals. That is, when $Ba(ClO_4)_2$ was added to the solution, a new signal of N–CH_3 resonance appeared at 3.07 ppm in addition to the signal already present. The signal became pronounced until 0.5 equiv. of salt has been added. The resulting single major resonance at 3.07 ppm for N–CH_3 protons and the two resonances at 7.15 and 7.44 ppm for NH protons are associated with the first complexed species, **Q**. The second complexed species, **R**, which is deduced from the major signal at 2.83 ppm for N–CH_3 protons and the signal at 7.67 and 7.54 ppm for NH protons, appears on the addition of *ca.* 3 equiv. of salt. In the presence of an additional, larger amount of salt, a new resonance, different from that of the second species, appears and grows. This third species, **Y**, is characterized by the signal at 3.18 ppm for N–CH_3 protons. The above results of titration experiments using CD and ^{1}H-NMR leads us to the conclusion that at least three types of complex formations between the cyclotetrapeptide and Ba^{2+} occur in the range of salt concentration of 0—6.85 equiv.

The step-by-step addition of $Ba(ClO_4)_2$ to CGCSP in acetonitrile-d_3 yields ^{13}C-NMR spectra which suggest a convergence to a single conformer. With the increase in the salt concentration, the Pro C_β and the Pro C_γ resonances positioned at the chemical shifts typical of the cis Sar–Pro peptide bond diminished in intensity. The ^{13}C-NMR spectrum in Fig. 4B when 1.0 equiv. of Ba^{2+} is added provides a single resonance for each carbon present in cyclic tetrapeptide. The chemical shifts of the Pro C_β and Pro C_γ resonances (30.5 ppm and 25.4 ppm) are indicative of the presence of the trans Sar–Pro peptide bond (>90%).

Discussion

Free Peptide. If one considers the cis-trans rotational isomers around the Cys^{a}—Sar and Sar^{b}—Pro peptide bond, four distinct conformers are possible; (a-cis, b-cis), (a-cis, b-trans), (a-trans, b-cis), and (a-trans, b-trans). From the results of ^{1}H-NMR, it is deduced that **M** and **n** contain the cis Cys–Sar peptide bond (a-cis). Therefore, the (a-cis, b-cis) and (a-cis, b-trans) sequence of the Cys^{a}—Sar^{b}—Pro peptide linkages must certainly be found in **M** and **n**. If one considers the peptide bond sequence of the Cys–Sar–Pro bond in **m** as (a-trans, b-trans), this is inconsistent with the result from the ^{13}C-NMR data, for it reveals that the cis Sar–Pro peptide bond is superior to the trans bond in population. These considerations enable us to deduce that **m** takes a skeletal conformation containing the (a-trans, b-cis) Cys^{a}—Sar^{b}—Pro peptide linkages. Moreover, the predominance of the cis Cys–Sar bond over the trans bond suggests that the skeletal conformation of the predominant species **M** contains the (a-cis, b-cis) sequence of the Cys–Sar–Pro linkages. The remaining species, **n**, is considered to take a conformation which contains the (a-cis, b-trans) sequence. From a Ramachandran relationship[11] using the vicinal coupling constants (J_{AX}, J_{BX}, and J_{MX}) in Table 1, the conformational angles of the Cys and the Gly residues are calculated:

	M	**m**	**n**
Cys ϕ/°	−120	−120	−139
Gly ϕ/°	128	103	130

Utilizing these conformational parameters, the CPK model construction to be seen in Fig. 9 is sterically allowed. It should be noted that the Cys NH proton is nonlinearly hydrogen-bonded to the Pro C=O oxygen. This finding is supported by the independence of the Cys NH resonance of the temperature. By the same manner as has been described above, **m** is assumed to have one intramolecularly hydrogen-bonded (Pro C=O···Cys NH). This hydrogen bond has the same features as that in **M**. The conformational properties of the several synthetic cyclic tetrapeptide have been studied by the measurement of NMR[12] and by X-ray analysis.[13,14] However, most of these peptides have the simple ^{1}H-NMR spectrum of one conformer in solution. On the contrary, it is surprising that the NMR studies of the present peptide revealed the coexistence of three species with potentially permitted conformational states. This result is closely related to the conformational properties of peptide linkage. Since typical values of an energy barrier to rotation about the peptide bond are within 20 ± 1 kcal mol^{-1},[15] the presence of cis and trans N-substituted peptide bonds can generate different cyclic conformations. In addition, the rotational cis-trans isomerism about two N-substituted peptide bonds in CGCSP is slow on the NMR time scale. Thus, it permits us to observe separate resonances for each proton of the different cyclic conformers. This cis-trans isomerism can often be observed about X-imino acid (X; any amino acids) peptide bonds in cyclic hexa-[2,16] or cyclic octapeptide.[2,17] The above results indicate that, even in a cyclic tetrapeptide, the implantation of some N-substituted amino acids in the peptide yields significant multiple conformations. It should also be noted that these three conformational species are almost entirely consistent with those present in dimethyl-d_6 sulfoxide, as reported in the preceding paper.[1]

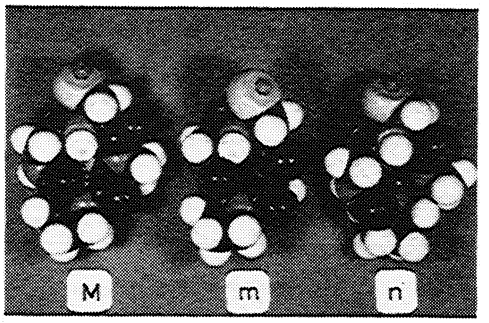

Fig. 9. Photograph of CPK model of proposed three conformations of free CGCSP in CD_3CN. Note the non-linear γ-turn hydrogen bond from the Cys to the Pro in **M** and **m**.

Ion Binding. Since chiroptical properties, such as CD and ORD, depend uniquely upon the molecular geometry, the CD spectral change observed for CGCSP on the addition of salt reflects the change in skeletal conformation. That is, it can be said that this peptide changes its conformation depending on the size and charge of the cation, upon complexation. This conformational change is accompanied by the rotational isomerism about N-substituted peptide bonds. The ^{1}H- and ^{13}C-NMR spectral changes of CGCSP in Fig. 4 and Fig. 8, resulting from the addition of salt, give us some information about the cis-trans isomerism of the two N-substituted peptide bonds (Cys–Sar and Sar–Pro bonds). The chemical shifts of N–CH_3 proton resonances usually serve to differentiate the trans peptide bond containing the sarcosyl N atom from the cis bond. It has been reported that a resonance for N–CH_3 protons whose geometry is anti to carbonyl oxygen occurred in a lower field region than a resonance for N–CH_3 protons which are involved in the cis peptide bond.[18,19] This, together with the results from ^{13}C-NMR, leads us to the confirmation that the first 2 : 1 complex (**Q**) contains trans Cys–Sar and trans Sar–Pro bonds, namely, all trans peptide bonds. This all-trans species, **Q**, is distinct from the three different ones, **M**, **m**, and **n**,

which are initially present in free peptide. An inspection of the CPK model indicates that the conformation can be allowed in which three carbonyl groups direct to the same side, preferentially for ion binding. The binding sites in **Q** appear to be the Sar C=O, the Cys C=O, and the C=O of Gly. Therefore, the intramolecular hydrogen bond can not be found. Actually, when a 1.0 equiv. of salt is added to peptide, the diminution of the negative $n\rightarrow\pi^*$ CD transition band and the downfield shift of the Pro C_β resonance about 0.9 ppm can be observed. This finding strongly supports the disruption[20] of the 1←3 hydrogen bond of γ-turn present in the free cyclic peptide. The second species, **R**, is characterized by the peptide linkages containing the cis Cys–Sar and trans Sar–Pro peptide bond. Judging from the large difference of CD pattern and the difference of the chemical shift for the Gly and Cys NH protons, **R** is likely to be different in backbone conformation from **n**, particularly in Pro ϕ angle. An inspection of the CPK model for **R** reveals that the Cys, Sar, and Pro carbonyls are oriented favorably for binding to a metal cation. The ^{1}H-NMR spectrum of CGCSP on the addition of 6.85 equiv. of salt demonstrates that the third species, **Y**, starts to spring up in addition to **R**. This **Y** is considered to contain the trans Cys–Sar and trans Sar–Pro peptide bonds. This cation-sandwich species, **Y**, appears to be the same as **Q**, judging from the similarities in the chemical shifts of the NH and N–CH_3 signals of the peptide. However, one can not exclude an alternate species which has a different conformation from that of **Q**, for there is only one available carbonyl group in **Y**, which should form a secondary binding site in a cation-sandwich complex. In order to account for the above observations in NMR and CD studies, the following scheme for the Ba^{2+} binding by CGCSP may be proposed;

$$\mathbf{M}_{\text{cis-cis}} \rightleftarrows \mathbf{m}_{\text{trans-cis}} \rightleftarrows \mathbf{n}_{\text{cis-trans}}$$

$$K_{1/2} \downarrow +Ba^{2+}$$

$$\mathbf{Q}_{\text{trans-trans}}\ Ba^{2+}\mathbf{Q}_{\text{trans-trans}}\ \text{(2: 1 complex)}$$

$$K_1 \downarrow +Ba^{2+}$$

$$\mathbf{R}_{\text{cis-trans}}\ Ba^{2+}\ \text{(1 : 1 comprex)}$$

$$\downarrow +Ba^{2+}$$

$$\mathbf{R}_{\text{cis-trans}}Ba^{2+} \rightleftarrows Ba^{2+}\mathbf{Y}_{\text{trans-trans}}Ba^{2+},$$

(1 : 1 complex) (1 : 2 complex)

where the subscript of each species denotes the peptide bond sequence a—b of Cys—Sar—Pro.

Previous studies have established the conformational fitting of cyclic penta-[20] and cyclic hexapeptide[21] on binding with alkali and alkaline earth cations. In these bindings, from two to four carbonyl groups in peptide were essential for coordination to occur. The present study of CGCSP provides the first evidence for conformational fitting on ion binding by a homodetic cyclic tetrapeptide. These facts demonstrate that even a cyclic tetrapeptide can have a potential for binding if two or three carbonyls favoring the cation interaction are available to form a coordination site. In conclusion, it is reasonable to think that conformational flexibility resulting from the cis-trans isomersim around the two N-substituted peptide bonds is responsible for the conformational fitting of CGCSP to a cation.

The authors are grateful to Dr. Yukio Imanishi of Kyoto University for his valuable suggestions and discussions. We are also grateful to Dr. Shoei Fujishige of our Institute for his useful comments.

Syntheses of Saccharin and Cyclamate Derivatives Bearing Polymerizable Vinyl Group

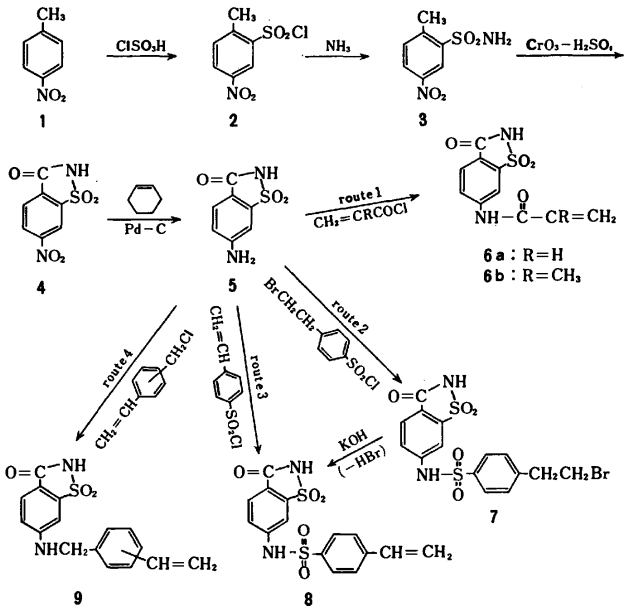
Hiroyoshi KAMOGAWA,* Shuji YAMAMOTO, and Masato NANASAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu, Yamanashi 400
(Received March 18, 1982)

Vinyl monomers containing saccharin or cyclamate residues were synthesized. 6-Acrylamido-, 6-methacrylamido-, 6-(4-styrenesulfonamido)-, and 6-(vinylbenzylamino)saccharins were synthesized from 6-aminosaccharin. *N*-[2-(4-Styrenesulfonamido)cyclohexyl] and *N*-[2-(vinylbenzylamino)cyclohexyl]sulfamic acids were synthesized starting with 1,2-cyclohexanediamine *via* sodium *N*-(2-aminocyclohexyl)sulfamate. All monomers thus synthesized were found to polymerize or copolymerize with *N*-vinyl-2-pyrrolidone to afford vinyl polymers with pendant saccharin and cyclamate units.

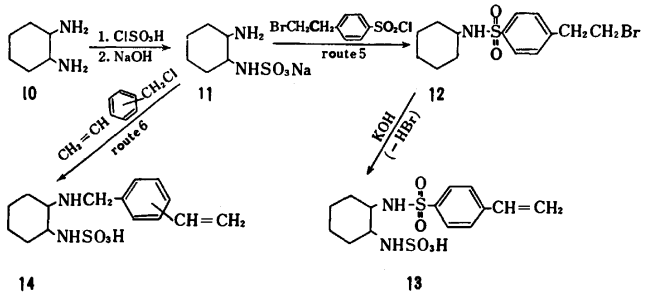
In our previous studies, we have prepared food colorant monomers[1] and food preservative and antioxidant monomers and their polymers,[2,3] which are considered to have a potentiality as nondigestive and nonabsorbable food additives.

In this paper, we wish to report syntheses of vinyl monomers containing saccharin and cyclamate residues, which are intended to provide nondigestive sweeteners in their final polymer forms.

Saccharin monomers (**6a**, **6b**, **8**, **9**) were synthesized *via* the key intermediate 6-aminosaccharin (**5**) as follows:



Cyclamate vinyl monomers (**13**, **14**) were synthesized *via* sodium *N*-(2-aminocyclohexyl)sulfamate (**11**) in the following manners:



All monomers synthesized were homopolymerized or copolymerized with *N*-vinyl-2-pyrrolidone (VP) to afford respective pendant polymers.

Results and Discussion

Owing to the deactivating effect of *p*-nitro group on 3 and 5 positions of *p*-nitrotoluene (**1**), 2-methyl-5-nitrobenzenesulfonamide (**3**) was isolated as the sole product (^{1}H NMR) by the chlorosulfonation of **1** and subsequent reaction with ammonia. Chromium trioxide oxidation in sulfuric acid was adopted for the conversion of **3** to 6-nitrosaccharin (**4**), since permanganate oxidation as in the case of commercial production of saccharin gave no satisfactory results (very low yields). For the reduction of the nitro group of **4** to afford 6-aminosaccharin (**5**) the amphoteric character of **5** hindered the use of conventional methods such as the $SnCl_2$–HCl one. The combination of cyclohexene as hydrogen donor with Pd–C as catalyst[4] allowed a smooth progress of reduction and easy purification of the product **5** by reprecipitation. 6-Acrylamido- and 6-methacrylamidosaccharins (**6a** and **6b**) were synthesized by the reactions of **5** with acryloyl chloride and methacryloyl chloride in aqueous mixtures, respectively (route 1). Alternatively, **6a** was synthesized from **4** by the reduction with aqueous sodium dithionite and subsequent addition of acryloyl chloride to the reaction mixture without isolating **5**, although yield was low (*ca.* 13%). The sulfonamide group which is more resistant to hydrolysis was introduced by the reaction of **5** with 4-(2-bromoethyl)benzenesulfonyl chloride (route 2). The presence of acidic hydrogen (s, 1H) at δ 11.5 in NMR identified structure **7**. The dehydrobromination of **7** by a conventional procedure gave a vinyl monomer **8**. Monomer **8** was also prepared from **5** in a single step by the use of *p*-vinylbenzenesulfonyl chloride (route 3). The reaction of **5** with vinylbenzylchloride (*m*/*p*=60/40) provided another vinyl monomer 6-(vinylbenzylamino)saccharin (**9**, a *m*-*p* mixture) (route 4). Single absorption peak (NH) at 3380 cm^{-1} in IR (KBr) identified structure **9**. Both column and thin-layer chromatographic separations of meta from para isomer failed due largely to the unfavorable solubility characteristic of **9**.

In the cyclamate series, 1,2-cyclohexanediamine (**10**) was converted to sodium *N*-(2-aminocyclohexyl)sulfamate (**11**), which was subjected to the same reaction procedures as those in the saccharin series using 4-(2-

Table 1. Polymerization behavior of the synthesized monomers

No.	Monomer	VP/Monomer (mol/mol)	Polymer		
			Conversion %	VP/Monomer[a] (mol/mol)	$[\eta]$ dl g^{-1}
1	**6a**	0	85	0	0.34
2	**6a**	8.99	35	13.9	0.78
3	**6b**	0	56	0	0.18
4	**6b**	10.03	28	5.00	0.18
5	**8**	0	82	0	0.13
6	**8**	8.92	13	0.61	0.07
7	**9**	0	68	0	Insol in DMF
8	**9**	13.24	38	0.045	Insol in DMF
9	**13**	0	72	0	Insol in DMF
10	**13**	8.96	44	1.87	Insol in DMF
11	**14**	9.04	34[b]	13.3	0.39[c]

a) Determined by CHN-analyses. b) A solution of **14** (0.21 g), VP (0.68 g), potassium persulfate (0.009 g), and sodium hydroxide (0.033g) in water (3 ml) was polymerized. c) Value in water.

bromoethyl)benzenesulfonyl chloride and vinylbenzyl chloride to afford *N*-[2-[4-(2-bromoethyl)benzenesulfonamido]cyclohexyl]sulfamic acid (**12**) and *N*-[2-(vinylbenzylamino)cyclohexyl]sulfamic acid (**14**), respectively (routes 5 and 6). Compound **12** was converted to the corresponding vinyl monomer **13** by alkaline dehydrobromination. Relatively low yields observed in steps **12**→**13** and **11**→**14** (35% and 29%) are considered to be caused by the fact that fairly large amounts of the sulfamic acids produced remained in solutions without being isolated. All attempts to separate para and meta isomers of **14** failed too.

Some of the novel monomers synthesized here are slightly colored, presumably due to the presence of traces of unremovable impurities. However, results of IR, NMR, MS, and elemental analyses indicate that they are essentially pure.

As indicated in Table 1, all monomers were found to polymerize in either *N*,*N*-dimethylformamide (DMF) or aqueous alkali (No. 11 in Table 1) with radical initiators. Some homopolymers and copolymers with *N*-vinyl-2-pyrrolidone (VP) (Nos. 7—10) were insoluble in DMF. These monomers (**9**, **13**), however, can make alkali-soluble copolymers by selecting suitable monomer ratios, as exemplified in the case of monomer **14** (No. 11). It is interesting to note that both saccharin and cyclamate monomers with the sulfonamide linkage (**8** and **13**) provide remarkably low values of VP/monomer ratio in copolymer as compared with those in the corresponding monomers (Nos. 6 and 10). This is also the case with monomer **9** having the benzylamino linkage (No. 8). In the latter two cases (monomers **9** and **13**), however, the polymerizations were heterogeneous, so that exact estimation of monomer reactivity may be difficult.

All copolymers of saccharin and cyclamate monomers with VP synthesized here can be made water-soluble, when suitable monomer ratios are selected and the resulting copolymers are neutralized with aqueous alkali. Although the taste of these copolymers has not exactly been estimated at this stage, copolymers of this kind, as they are or when suitably modified, might conform to the requirements mentioned above.

Experimental

IR, ^{1}H NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively. Elemental analyses were conducted using a Perkin-Elmer 250 instrument.

2-Methyl-5-nitrobenzenesulfonamide (3). A solution of *p*-nitrotoluene (6.9 g, 50 mmol) in chlorosulfuric acid (17.5 g, 150 mmol) was kept at 60—70 °C for 24 h with exclusion of moisture. The reaction mixture was poured onto ice and extracted with ether (200 ml). The organic layer was washed with aqueous sodium chloride, treated with concd aqueous ammonia (50 ml), and stirred by the application of heat to evaporate ether completely (about 2 h). The mixture was then filtered and crude product was recrystallized from water to afford yellow needles (mp 183—185 °C) in 45% yield. Found: C, 38.73; H, 3.58; N, 13.10%. Calcd for $C_7H_8N_2SO_4$: C, 38.89; H, 3.73; N, 12.96%. IR (KBr) 3420, 3300 (NH_2), 1600 (Ar), 1540 (NH), 1350 (NO_2), 1330, 1310 (SO_2), 1160, and 1120 (SO_2) cm^{-1}. NMR ($CDCl_3$–DMSO-d_6) δ=2.8 (s, 3H, Me), 7.4—7.8 (d, 3H, NH_2+ArH), 8.3 (d, 1H, ArH), and 8.8 (s, 1H, ArH). MS (*m/e*) 216 (M^+, 8) and 135 (100).

6-Nitrosaccharin (4). To a solution of chromium trioxide (9.0 g, 900 mmol) in water (66.7 ml) concd sulfuric acid (83.5 ml) was added gradually. To the resulting solution was added **3** (4.32 g, 20 mmol) and the mixture was stirred at room temperature for 24 h. Crude product was obtained by filtration of the reaction mixture with a glass filter followed by thorough washing with water. Purification by dissolution in 10% aqueous sodium hydrogencarbonate, filtration, and reprecipitation of the filtrate with 5% aqueous hydrochloric acid provided a white powder (mp 205—207 °C) in 56% yield. Found: C, 36.54; H, 1.89; N, 12.12%. Calcd for $C_7H_4N_2SO_5$: C, 36.85; H, 1.78; N, 12.28%. IR (KBr) 3150 (NH), 1730 (C=O), 1660 (Ar), 1530 (NO_2), 1340 (SO_2, NO_2), 1170, and 1120 (SO_2) cm^{-1}. NMR ($CDCl_3$–DMSO-d_6) δ= 8.1—9.0 (m, 3H, ArH), 10.1 (s, 1H, NH). MS (*m/e*) 228 (M^+, 100).

6-Aminosaccharin (5). To a solution of **4** (11.4 g, 50 mmol) and cyclohexene (25.4 ml, 250 mmol) in ethanol (100 ml), 5% Pd-C (53.0 g) was added with cooling. The black mixture was refluxed for 2 h with stirring and filtered several times until the filtrate became clear. The filtrate was then evaporated to dryness to afford a crude product, which was purified by dissolution in 2 M hydrochloric acid (1 M=1 mol dm^{-3}) and subsequent precipitation into aqueous sodium

hydrogencarbonate to provide a slightly yellow powder (mp 264—265 °C) in 63% yield. Found: C, 42.46; H, 3.22; N, 13.98%. Calcd for $C_7H_6N_2SO_3$: C, 42.42; H, 3.05; N, 14.13%. IR (KBr) 3380, 3320 (NH), 1720 (C=O), 1610 (Ar), 1315, 1170, and 1120 (SO_2) cm^{-1}. NMR (DMSO-d_6) δ= 6.5—7.8 [m, 3H (Ar)+3H (NH)]. MS (*m/e*) 198 (M^+, 54) and 63 (100).

*6-(Acrylamido)saccharin (**6a**).* *(a) From 6-Aminosaccharin (**5**):* To a solution of **5** (1.98 g, 10 mmol), sodium hydrogencarbonate (1.8 g), and a small amount of hydroquinone in water (50 ml), acryloyl chloride (2.72 g, 30 mmol) was added dropwise with ice cooling followed by stirring at room temperature for 30 min. The reaction mixture was then poured into cold 2 M hydrochloric acid to effect precipitation. The precipitate was filtered and recrystallized from methanol to afford a slightly yellow powder (mp>290 °C) in 73% yield. Found: C, 47.62; H, 3.28; N, 11.09%. Calcd for $C_{10}H_8N_2SO_4$: C, 47.62; H, 3.20; N, 11.11%. IR (KBr) 1735 (C=O), 1695 (amide I), 1600 (Ar), 1530 (amide II), 1320, 1180, 1150 (SO_2), 980, and 900 (CH_2=CH–) cm^{-1}. NMR (DMSO-d_6) δ=5.8—6.0 (m, 1H, –C<u>H</u>=CH_2), 6.3—6.5 (t, 2H, –CH=C<u>H</u>$_2$), 7.9 (s, 2H, ArH), 8.5 (s, 1H, ArH), 9.7 (s, 1H, amide NH), and 10.9 (s, 1H, =NH). MS (*m/e*) 252 (M^+, 20) and 55 (100).

*(b) From 6-Nitrosaccharin (**4**):* To a solution of sodium dithionite (3.5 g, 22 mmol) in water (5 ml), **4** (1 g, 4 mmol) was added and the mixture stirred at room temperature for 30 min. A small amount of sodium hydrogencarbonate was added to give a clear solution, which was cooled in an ice-water bath followed by addition of a small amount of hydroquinone. Acryloyl chloride (1.2 g, 13 mmol) was then added dropwise to the solution and the mixture was stirred for 30 min under ice cooling. Acidification of the solution with 5% hydrochloric acid provided a crude product, which was purified by dissolution in 10% aqueous sodium carbonate and subsequent precipitation into 5% hydrochloric acid to afford a slightly green powder (**6a**) in 13% yield. Elemental analyses, IR, NMR, and MS identified the same structure as that prepared in *(a)*.

*6-(Methacrylamido)saccharin (**6b**).* The same reaction procedure as that for **6a** was applied to **5** (2.0 g, 10 mmol) and methacryloyl chloride (3.1 g, 30 mmol) to afford a slightly yellow powder (mp 215—217 °C) in 71% yield. Found: C, 49.92; H, 3.90; N, 10.01%. Calcd for $C_{11}H_{10}N_2SO_4$: C, 50.25; H, 3.89; N, 9.85%. IR (KBr) 1760 (C=O), 1710 (amide I), 1590 (Ar), 1540 (amide II), 1340, 1190, 1130 (SO_2), and 930 (CH_2=CCH_3–) cm^{-1}. NMR (DMSO-d_6) δ=2.1 (s, 3H, Me), 5.7 (s, 1H, =CH_2), 6.0 (s, 1H, =CH_2), 8.0—8.8 (m, 3H, ArH), 8.6 (s, 1H, NH), and 10.6 (s, 1H, NH). MS (*m/e*) 266 (M^+, 5) and 69 (100).

*6-[4-(2-Bromoethyl)benzenesulfonamido]saccharin (**7**).* To a solution of **5** (2.0 g, 10 mmol), a small amount of hydroquinone and sodium hydroxide (0.96 g) in water (30 ml) was added with stirring a solution in acetonitrile (25 ml) of 4-(2-bromoethyl)benzenesulfonyl chloride (5.7 g, 20 m mol),prepared from (2-bromoethyl)benzene and chlorosulfuric acid according to a known method.[5] The mixture was stirred at room temperature for 12 h and poured into cold 2 M hydrochloric acid to afford a precipitate, which was filtered and recrystallized from methanol–water to afford a slightly pink powder (mp 168—171 °C) in 27% yield. Found: C, 40.51; H, 3.05; N, 6.25%, Calcd for $C_{15}H_{13}N_2S_2BrO_5$: C, 40.46; H, 2.94; N, 6.29%. IR (KBr) 3240 (NH), 2920, 2850 (CH_2), 1730 (C=O), 1325, and 1160 (SO_2) cm^{-1}. NMR (DMSO-d_6+$CDCl_3$) δ=3.1—3.4 (t, 2H, CH_2), 3.7—3.9 (t, 2H, CH_2), 6.3 (s, 1H, NH), 7.5—8.2 (m, 7H, ArH), and 11.5 (s, 1H, NH). MS (*m/e*) 216 and 197.

*6-(4-Styrenesulfonamido)saccharin (**8**).* *(a)* Via *Route 2*: A solution of **7** (2.0 g, 4.5 mmol), potassium hydroxide (0.6 g, 11 mmol), and a small amount of hydroquinone in methanol (30 ml) was refluxed for 1 h with stirring. The reaction mixture was poured into cold 2 M hydrochloric acid. The precipitate thus produced was filtered and recrystallized from methanol–water to afford a slightly pink powder (mp 144—147 °C) in 80% yield. Found: C, 49.56; H, 3.12; N, 7.50%. Calcd for $C_{15}H_{12}N_2S_2O_5$: C, 49.44; H, 3.32; N, 7.69%. IR (KBr) 1730 (C=O), 1320, 1160 (SO_2), 985, and 910 (vinyl) cm^{-1}. NMR (DMSO-d_6+$CDCl_3$) δ=5.2—6.2 (q, 2H, CH_2=), 6.3 (s, 1H, NH), 6.5—7.3 (m, 1H, =CH–), 7.5—8.1 (m, 7H, ArH), and 11.6 (s, 1H, NH).

(b) Via *Route 3*: A solution of **5** (2.0 g, 10 mmol), *p*-vinyl benzenesulfonyl chloride (4.1 g, 20 mmol),[6] triethylamine (1.5 g), and hydroquinone (0.1 g) in DMF (50 ml) was stirred at room temperature for 12 h and poured into cold 2 M hydrochloric acid. The resulting precipitate was collected by filtration and washed with ether. Recrystallization from methanol–water provided a white powder (mp 148—149 °C) in 14% yield. Found: C, 49.19; H, 3.43; N, 7.47%. IR and NMR spectra were essentially identical with those of the product in *(a)*.

*6-(Vinylbenzylamino)saccharin (**9**).* A solution of **5** (1.0 g, 5 mmol), triethylamine (0.7 ml, 5 mmol), vinylbenzyl chloride (Seibi Chem. Co., *m/p*=60/40; 2.3 g, 15 mmol), and hydroquinone (0.1 g) in DMF (30 ml) was stirred at 90 °C for 7 h. The reaction mixture was poured into ice-cold 2 M hydrochloric acid. The resulting precipitate was filtered and recrystallized from methanol–water to afford a white powder (mp 155—158 °C) in 32% yield. Found: C, 61.33; H, 4.48; N, 8.70%. Calcd for $C_{16}H_{12}N_2SO_3$: C, 61.13; H, 4.49; N, 8.91%. IR (KBr) 3380 (NH), 2945, 2845 (CH_2), 1720 (C=O), 1600 (Ar), 1330, 1300, 1175, 1140 (SO_2), 995, and 915 (vinyl) cm^{-1}. NMR (DMSO-d_6+$CDCl_3$) δ=4.9 (s, 2H, CH_2), 5.3—6.1 (q, 2H, CH_2=), 6.7—8.0 (m, 10H, =CH–+ ArH+NH). MS (*m/e*) 314 (M^+, 4) and 250 (100).

*Sodium N-(2-Aminocyclohexyl)sulfamate (**11**).* To a solution of 1,2-cyclohexanediamine (**10**; 25 g, 220 mmol) in anhydrous chloroform (110 ml) cooled below 0 °C, chlorosulfuric acid (8.43 g, 72 mmol) was added dropwise with stirring. It required about 2 h. The mixture was further stirred for 30 min below 0 °C and poured into 6% aqueous sodium hydroxide (100 ml). The aqueous layer was separated, extracted with ether to remove the ether-soluble part, and free-zedried to afford a crude product, which was extracted with hot 90% ethanol to afford a white powder upon cooling in 53% yield. Found: C, 33.31; H, 6.23; N, 12.62%. Calcd for $C_6H_{13}N_2SO_3Na$: C, 33.33; H, 6.06; N, 12.96%. IR (KBr) 2940, 2860 (CH_2, CH), 1610 (NH), and 1200 (SO_2) cm^{-1}. NMR (D_2O) δ=1.0—3.0 (m, 11H, CH_2, CH+NH+NH_2).

*N-[2-[4-(2-Bromoethyl)benzenesulfonamido]cyclohexyl]sulfamic Acid (**12**).* A mixture of **11** (1.0 g, 4.6 mmol), 4-(2-bromoethyl) benzenesulfonyl chloride (1.57 g, 5.6 mmol), sodium hydroxide (0.22 g), and acetonitrile–water (1 : 2 v/v; 30 ml) was stirred at room temperature for 12 h. The reaction mixture was then poured into cold 2 M hydrochloric acid and let stand overnight to afford a white precipitate, which was filtered, washed with ether, dissolved in aqueous sodium hydroxide, and reprecipitated with hydrochloric acid to afford white crystals (mp 184—187 °C) in 74% yield. Found: C, 37.89; H, 4.82; N, 6.50%. Calcd for $C_{14}H_{21}N_2S_2BrO_5$: C, 38.09; H, 4.80; N, 6.35%. IR (KBr) 3290 (NH), 2960, 2950, 2870 (CH, CH_2), 1595 (Ar), 1330, 1315, 1300, 1165, and 1155 (SO_2) cm^{-1}. NMR (DMSO-d_6) δ=0.8—1.9 (b, 8H, 4CH_2), 1.9—3.3 (b, 3H, 2CH+NH), 2.8—3.4 (t, 2H, CH_2), 3.5—4.0 (t, 2H, CH_2), 5.3 (s, 1H, NH), and 7.5—8.3 (q, 5H, ArH+SO_3H).

N-[*2-(4-Styrenesulfonamido)cyclohexyl*]*sulfamic Acid* (**13**). A mixture of **12** (1.5 g, 3.4 mmol), potassium hydroxide (0.42 g, 7.6 mmol), and hydroquinone (0.1 g) in 90% ethanol (30 ml) was stirred at 80 °C for 1 h. The resulting solution was poured into ice-cold 2 M hydrochloric acid to afford a precipitate, which was filtered, dissolved in aqueous sodium hydroxide, and reprecipitated with hydrochloric acid to afford a slightly pink powder (mp 148—149 °C) in 35% yield. Found: C, 46.54; H, 5.68; N, 7.86%. Calcd for $C_{14}H_{20}N_2S_2O_5$: C, 46.65; H 5.59; N, 7.77%. IR (KBr) 2935, 2865 (CH_2, CH), 1600 (Ar), 1320, 1160 (SO_2), 990, and 930 (vinyl) cm^{-1}. NMR ($CDCl_3$+DMSO-d_6) δ=0.8—1.9 (b, 8H, $4CH_2$), 2.0—3.5 (m, 3H, 2CH+NH), 5.5 (d, 1H, CH_2=), 6.0 (d, 1H, CH_2=), 6.8 (q, 1H, =CH-), 7.5—8.1 (q, 5H, ArH+NH), and 8.5 (s, 1H, $-SO_3H$).

N-[*2-(Vinylbenzylamino)cyclohexyl*]*sulfamic Acid* (**14**). To a solution of **11** (2.0 g, 9.3 mmol), triethylamine (1.1 g, 11 mmol), and hydroquinone (0.2 g) in 90% ethanol (30 ml), vinylbenzyl chloride (*m*/*p*=60/40; 1.41 g, 9.3 mmol) was added dropwise and the mixture stirred at 65 °C for 2 h. The reaction mixture was poured into cold 2 M hydrochloric acid. Upon standing overnight, the resulting precipitate was filtered and purified by dissolution in aqueous sodium hydroxide and subsequent reprecipitation into cold aqueous hydrochloric acid. A slightly colored powder of mp 255—257 °C was obtained in 29% yield. Found: C, 58.26; H, 7.06; N, 8.83%. Calcd for $C_{15}H_{21}N_2SO_3H$: C, 58.04; H, 7.14; N, 9.02%. IR (KBr) 3350 (NH), 2945, 2865 (CH_2, CH), 1630 (NH), 1600 (Ar), 1280, 1170 (SO_2), 985, and 925 (vinyl) cm^{-1}. NMR (CF_3COOH) δ=1.0—2.7 (b, 10H, CH_2, CH), 3.2—3.8 (b, 1H, NH), 4.1—4.8 (b, 3H, CH_2NH), 5.5 (d, 1H, CH_2=), 6.0 (d, 1H, CH_2=), 6.9 (q, 1H, =CH-), 7.0—8.0 (m, 4H, ArH), and 10.5 (s, 1H, $-SO_3H$).

Polymerization of Monomers. In a typical example, a solution of monomer **6a** (1.5 g) and α,α'-azobisisobutyronitrile (AIBN; 0.015 g) in DMF (3.5 g) was put into a glass ampoule, which was evacuated, filled with nitrogen, and sealed in a conventional manner. Polymerization was carried out at 70 °C for 72 h. The content of the ampoule was then poured into aqueous sodium carbonate and dialyzed through a cellulose tubing (Visking) against water for 3 d. The dialyzed mixture was filtered and the filtrate was freeze-dried.

In the copolymerization with VP, the composition was adjusted so as to afford 30% total monomer concentration and 1% AIBN/total monomers. The results thus obtained are given in Table 1.

All homopolymers and copolymers synthesized indicated IR absorptions at 2930 and 2860 cm^{-1} characteristic of the vinyl polymer backbone together with those of the pendant saccharin and cyclamate units.

Intrinsic Viscosity. Intrinsic viscosities [η] of the synthesized polymers were measured in DMF solutions at 20 °C by means of an Ostwald-type viscometer, unless otherwise noted.

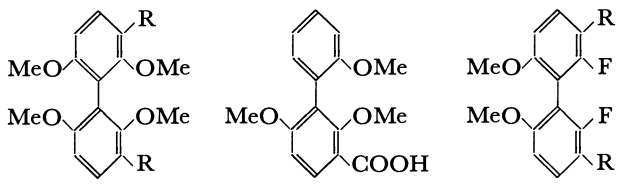
Optical Resolution of 2,2′,6,6′-Tetrafluorobiphenyl-3,3′-dicarboxylic Acid

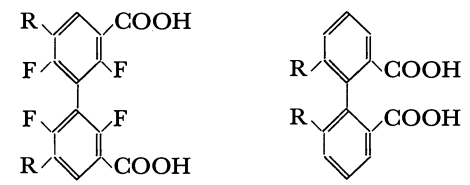
Noriko HASAKA, Masayoshi OKIGAWA, Isao KOUNO, and Nobusuke KAWANO*
Faculty of Pharmaceutical Sciences, Nagasaki University, Bunkyomachi, Nagasaki 852
(Received April 16, 1982)

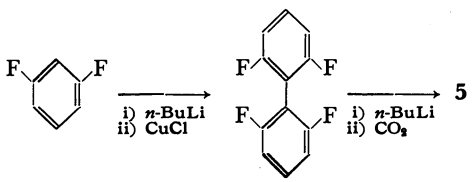
Optically active (−)- and (+)-2,2′,6,6′-tetrafluorobiphenyl-3,3′-dicarboxylic acids were obtained through brucine salts. The half-life times for racemization of their dimethyl esters were estimated at various temperatures and the activation energy was calculated to be 25.6 kcal/mol.

Recently, the optical resolution of 2,2′,6,6′-tetramethoxybiphenyl compounds (**1** and **2**), 2,2′,6-trimethoxybiphenyl-3-carboxylic acid (**3**), and 2,2′-difluoro-6,6′-dimethoxybiphenyl-3-carboxylic acid (**4**) were reported.[1] These results disclosed the erroneous findings reported by Adams and co-wokers[2] and stimulated us to attempt the optical resolution of 2,2′,6,6′-tetrafluorobiphenyl-3,3′-dicarboxylic acid (**5**), although Adams and co-workers reported[3] that 2,2′,6,6′-tetrafluoro-5,5′-dichlorobiphenyl-3,3′-dicarboxylic acid (**6**) was nonresolvable. The activation energy for racemization of the compound **5** should be less than that of the compounds, **1** and **4** because of the smaller van der Waals radius of fluorine atom than that of oxygen.

Racemic **5** was obtained from *m*-difluorobenzene by a synthetic route shown in Scheme 1 although another route was formerly reported.[4] The optical resolution of **5** was achieved through brucine salts. Fortunately, two kinds of brucine salts were obtained in the course of the resolution. The first salt, mp 151—156 °C, gave (−)-acid, mp 243—245°C, $[\alpha]_D^{24}$ −35.9° (ethanol) and the second salt, mp 169—179 °C, gave (+)-acid, mp 241—244 °C, $[\alpha]_D^{24}$ +36.2° (ethanol). Their dimethyl esters were also optically active and showed $[\alpha]_D^{24}$ −33.5° (dioxane) and +34.0° (dioxane), respectively. In the preceding paper[1] the optical purities of active esters were estimated from ^{1}H NMR spectra taken with use of a chiral NMR-shift reagent (CSR), tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium-(III).[5] However, the racemic ester of **5** showed only one set of signals even in the presence of a large amount of the same CSR. Therefore, NMR-shift reagents were not useful for the estimation of the optical purities of the active esters of **5**.







Scheme 1. Synthetic route of **5**.

Racemization experiments were performed with use of both the (−)- and (+)-dimethyl esters and the results obtained are shown in Tables 1 and 2. The activation energy for racemization of these active esters was first determined graphically; 25.9 kcal/mol from the (−)-ester (Table 1) and 25.7 kcal/mol from the (+)-ester (Table 2). Calculations by the least squares method at 95% confidence limit gave 25.4±1.0 kcal/mol from the (−)-ester and 25.8±0.8 kcal/mol from the (+)-ester. The mean of these values is 25.6 kcal/mol, and this value is 13.8 kcal/mol less than the activation energy of the optically active ester of **4** (39.4 kcal/mol in a 2-phenylethanol solution),[1] corresponding to the structural difference between **4** and **5**, fluorine atoms instead of methoxyl groups at 6- and 6′-positions.

A similar structural difference can be seen in two compounds, 2,2′-difluorobiphenyl-6,6′-dicarboxylic acid (**7**) and 2,2′-dimethoxybiphenyl-6,6′-dicarboxylic acid (**8**), reported by Adams and co-workers.[6] Racemization

Table 1. Racemization data[a] of (−)-dimethyl ester of **5**

Temp/°C	Time/min	α_{546}^{20}/°	log *k*	Half-life time/min
73.9±0.2	360	−0.0495	−4.611	469.5
79.6±0.1	240	−0.045	−4.363	267.0
88.7±0.2	90.75	−0.047	−3.957	104.8
97.1±0.1	60	−0.035	−3.614	47.5

a) A solution of 30.0 mg of (−)-ester in 10.0 ml of dioxane was used. Initial rotation: α_{546}^{20} −0.084° (*l*= 10.00 cm).

Table 2. Racemization data[a] of (+)-dimethyl ester of **5**

Temp/°C	Time/min	α_{546}^{20}/°	log *k*	Half-life time/min
75.3±0.1	300	+0.082	−4.551	411.0
80.9±0.1	180	+0.078	−4.288	224.3
89.0±0.1	90	+0.073	−3.938	100.3
96.9±0.1	60	+0.056	−3.608	46.9

a) A solution of 41.0 mg of (+)-ester in 10.0 ml of dioxane was used. Initial rotation: α_{546}^{20}+0.136°(*l*=10.00 cm).

data of these compounds observed by them are as follows: The complete racemization time of **7** was about 2 h in boiling ethanol or 10 min in boiling acetic anhydride, whereas the half-life period of **8** was 78 min in boiling glacial acetic acid or about 60 h in boiling ethanol. Afterwards, the racemization of **8** was extensively studied in various solvents and the $\Delta H^{\ddagger}$ in dioxane has been reported[7] as 25.15±0.07 kcal/mol. This value of **8** should be larger than that of **7**. However, the energy difference between **7** and **8** is only a few kcal/mol at most. This is much less than the former difference of 13.8 kcal/mol between **4** and **5**. The reasons considered are as follows: a) The electronic effects of carboxyl groups in **4** and **5**, b) the use of a different solvent (2-phenylethanol) in the case of **4**, and c) in **4** and **5**, racemization requires the passage of MeO (**4**) and F (**5**) groups past F groups, whereas in **7** and **8**, F (**7**) and MeO (**8**) groups must pass COOH groups.

In order to investigate the molecular chirality of **4** without buttressing effects ^{1}H NMR spectra of 2,2′-difluoro-6,6′-dimethoxybiphenyl (**9**) were taken with use[8,9] of the CSR. When two molar ratio of the CSR was added, two methyl signals were observed with a chemical shift difference of 2.5 Hz, indicating that **9** is chiral at room temperature on the NMR time scale. This observation means that F and MeO groups at *ortho*-position of biphenyl compounds are large enough to restrict the rotation without buttressing effects. The lower limit of the rotational barrier of **9** may be estimated to be about 16 kcal/mol from the Eyring equation.[10] Adams' method[11] of predicting the resolvability of chiral biphenyls should be partly revised since there have been some reports[12] concerning the effective van der Waals radii of these atoms and groups.

Experimental

All melting points are uncorrected. Optical rotations were measured with a Nihon-Bunko (JASCO) DIP-181 polarimeter. UV and IR spectra were recorded with a Hitachi 323 recording spectrometer and a JASCO IRA-2 grating infrared spectrophotometer respectively. ^{1}H NMR spectra were recorded with a JEOL PS-100 instrument using TMS as internal reference. Mass spectra were obtained from a JEOL JMS-01SG double-focus instrument.

2,2′,6,6′-Tetrafluorobiphenyl. *m*-Difluorobenzene (2.0 g) was dissolved in anhydrous tetrahydrofuran (THF, 50 ml) and kept at −70 °C in a Dry Ice and methanol mixture. To the cooled and stirred solution was added dropwise 15% butyllithium hexane solution (12.5 ml) during 15 min. Stirring was continued for a further 3 h period at the same temperature and then anhydrous $CuCl_2$ (2.9 g) was added. After the mixture was stirred for 2 h the temperature slowly rose to room temperature during 1 h. Stirring was continued for 5 h at room temperature. The reaction mixture was acidified with diluted hydrochloric acid and extracted with diethyl ether. The ether solution was washed with water, dried over $MgSO_4$, and evaporated. The reaction product was purified by column chromatography (silica gel and hexane) to give a product (1.03 g), mp 47.5—48.5 °C from hexane–ether (reported[13] mp 47.5—48.5 °C), UV_{max} (EtOH) 230 (log ε 4.16) and 265 nm (3.24); IR (KBr) 1615, 1459, 1265, 1234, 1004 (C–F), and 990 cm^{-1}; MS *m/z* 226 (M$^+$).

2,2′,6,6′-Tetrafluoro-3,3′-bis(methoxycarbonyl)biphenyl. 2,2′,6,6′-Tetrafluorobiphenyl (2.5 g) was dissolved in anhydrous THF (70 ml) and kept at −70 °C. To the cooled and stirred solution was added dropwise 15% *n*-BuLi hexane solution (12.0 ml) during 15 min. Stirring was continued for further 6 h at the same temperature and dried CO_2 was introduced to the cooled solution for 2 h. During that time the temperature of the reaction mixture was gradually raised to room temperature. The mixture was acidified with diluted hydrochloric acid and extracted with diethyl ether. The ether solution was washed with water, dried over $MgSO_4$, and evaporated. The reaction products obtained were methylated with diazomethane and purified by column chromatography (silica gel and hexane and then hexane–chloroform) to give colorless needles from hexane–diethyl ether (0.7 g, 18.5% yield), mp 136.5—137.5 °C (reported[4] mp 136—137 °C); UV_{max} (EtOH) 218 (log ε 4.60) and 277 nm (3.45); IR (KBr) 1722 (C=O), 1267, 1216, 1131, and 1007 cm^{-1}; MS *m/z* 342 (M$^+$), 311 (M-OCH$_3$, base peak), 252, 224; ^{1}H NMR ($CDCl_3$) δ 3.96 (6H, s, Me), 7.11 (2H, br. t, J=8.1 Hz), 7.90—8.25 (2H, m).

2,2′,6,6′-Tetrafluorobiphenyl-3,3′-dicarboxylic Acid (5). The above diester (0.70 g) was hydrolyzed with 8% NaOH solution (20 ml) at 90 °C for 2 h to give colorless acid and recrystallized from diluted ethanol, mp above 295 °C (reported[4] mp 306.5—307.5 °C), (0.61 g, 95% yield); UV_{max} (EtOH) 215 (log ε 4.57) and 274 nm (3.55); IR (KBr) 3433, 2980, 2590, 1710 (C=O), 1607, 1261 (COOH), 1039, and 1010 cm^{-1}; MS *m/z* 314 (M$^+$), 297, 269, and 224.

(−)-2,2′,6,6′-Tetrafluorobiphenyl-3,3′-dicarboxylic Acid. Racemic **5** (157 mg, 0.5 mmol) and brucine dihydrate (430 mg, 1.0 mmol) were dissolved in hot ethanol (5 ml) and left to stand overnight. Brucine salt obtained was recrystallized two times from ethanol to afford colorless crystals (35 mg), mp 151—156 °C, which were decomposed with 10% hydrochloric acid and extracted with ether. The ether solution was washed with water, dried over $MgSO_4$, evaporated, and crystallized from ethanol to give optically active acid (8 mg), mp 243—245 °C, $[\alpha]_D^{24}$ −35.9° and $[\alpha]_{546}^{24}$ −40.9° (0.32%, EtOH).

(−)-2,2′,6,6′-Tetrafluoro-3,3′-bis(methoxycarbonyl)biphenyl. The above (−)-acid (25.8 mg) was methylated with diazomethane to give an optically active ester (27.5 mg), mp 55—58 °C, $[\alpha]_D^{24}$ −33.5° and $[\alpha]_{546}^{24}$ −40.4° (0.49%, dioxane); UV_{max} (EtOH) 218 (log ε 4.58) and 277 nm (3.43); IR, MS, and ^{1}H NMR the same with those of racemic dimethyl ester.

(+)-2,2′,6,6′-Tetrafluorobiphenyl-3,3′-dicarboxylic Acid. The filtrate separated from the first brucine salt was evaporated to about 3.5 ml and left to stand overnight to give the second salt, which was recrystallized two times from ethanol to afford colorless crystals (98 mg), mp 173—179 °C. The salt was decomposed and the optically active acid obtained was crystallized from ethanol to give colorless crystals (24 mg), mp 241—244 °C, $[\alpha]_D^{24}$ +36.2° and $[\alpha]_{546}^{24}$ +41.2° (1.2%, EtOH).

(+)-2,2′,6,6′-Tetrafluoro-3,3′-bis(methoxycarbonyl)biphenyl. The above (+)-acid (38 mg) was methylated with diazomethane to give a dimethyl ester (41 mg), mp 56—59 °C, $[\alpha]_D^{24}$ +34.0° and $[\alpha]_{546}^{24}$ +40.6° (1.1%, dioxane); UV_{max} (EtOH) 218 (log ε 4.57) and 277 nm (3.42); IR, MS, and ^{1}H NMR the same with those of racemic dimethyl ester.

The authors are grateful to Professor K. Mislow, Princeton University, for his valuable advices and encouragements and Miss H. Kammura and Y. Kawabata for their technical assistance.

Synthesis of A and B Rings Analog of Coleon B

Takashi MATSUMOTO,* Koji IYO, and Shigekazu MIUCHI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 19, 1982)

Catalytic hydrogenation of 19-norabieta-4(18),8,11,13-tetraen-3α-ol over Raney Ni and subsequent dehydration afforded 18-norabieta-2,8,11,13-tetraene, which was converted into 3α-bromo-18-norabieta-8,11,13-trien-2-one (**8**) *via* a bromohydrin. Acetalization of **8** with 1,2-ethanediol in the presence of *p*-toluenesulfonic acid afforded a mixture of 3α-bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-triene (**10**) and its 3β-bromo isomer (**11**) in a ratio of *ca.* 2 : 3. Oxidation of **10** and **11** with chromium trioxide in acetic acid gave the corresponding ketones **12** and **13**. The ketone **13** was then converted into a diosphenol derivative, 3β-bromo-2,2-ethylenedioxy-6-hydroxy-18-norabieta-5,8,11,13-tetraen-7-one (**14**), by treatment with oxygen in the presence of potassium *t*-butoxide. Hydrolysis of **14** with dilute hydrochloric acid followed by dehydrobromination afforded the desired analog, 6-hydroxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione. A related A/B ring oxygenated compound, 19-norabieta-3,5,8,11,13-pentaene-2,7-dione was also synthesized from **12** and **13** *via* the corresponding 6α-bromo derivatives.

Coleon B (**1**) is a rare tricyclic norditerpene phenol isolated from *Coleus iguiarius* Schweinf. (Labiatae) by Eugster *et al.*[1] To establish the synthetic route of this highly-oxygenated norditerpene, we investigated the oxidation of rings A/B of dehydroabietic acid (**2**); the introduction of oxygen functions at the C-11, C-12, and C-14 positions in ring C has already been achieved in our laboratory.[2] This paper will describe the synthesis of A and B rings analog (**3**) of coleon B, starting from 19-norabieta-4(18),8,11,13-tetraen-3α-ol (**4**) which was prepared from **2** by the known procedure.[3–5]

4

Catalytic hydrogenation of **4** in ethanol over Raney Ni at room temperature afforded 18-norabieta-8,11,13-trien-3α-ol (**5**),[6,7] which was dehydrated with phosphoryl chloride in refluxing pyridine to give 18-norabieta-2,8,11,13-tetraene (**6**) in 65.3% yield from **4**. The ^{1}H NMR spectrum of **6** showed doublet signals at δ 1.05 due to the C-4 methyl group and at δ 5.66 due to the two vinylic protons. The tetraene **6** was treated with *N*-bromosuccinimide in dimethyl sulfoxide containing a small quantity of water at 20—25 °C under a stream of nitrogen to give a bromohydrin (**7**) which, without purification, was used in the next reaction. The structure of **7** as indicated was predicted by a well-documented mechanistic pathway[8] and was substantiated spectroscopically. In the ^{1}H NMR spectrum of **7**, the downfield shift of the signal (δ 1.36) due to the methyl group at the C-10 position relative to the corresponding signal (δ 1.20) for **6** suggested a 1,3-diaxial-*cis*-relationship between the methyl goup and the new hydroxyl group. Consequently, the structure of **7** was assigned to be 3α-bromo-18-norabieta-8,11,13-trien-2β-ol. Oxidation of the crude **7** in acetone with Jones reagent at 0 °C afforded 3α-bromo-18-norabieta-8,11,13-trien-2-one (**8**) in 69.1% yield from **6**. This bromo ketone **8** was easily dehydrobrominated by heating at 120—125 °C with lithium carbonate and lithium bromide in *N*,*N*-dimethylformamide under a stream of nitrogen; an α,β-unsaturated ketone, 19-norabieta-3,8,11,13-tetraen-2-one (**9**), was obtained. The structure of **9** was supported by its IR (1654, 1622 cm^{-1}) and ^{1}H NMR (δ 1.99, C_4–CH_3; 5.86, C_3–H) spectra. From the formation of **9**, the position of the bromine atom in **7** and **8** was conclusively assigned to be the C-3 position. To protect the carbonyl group as ethylene acetal, the ketone **8** was refluxed with 1,2-ethanediol and *p*-toluenesulfonic acid in benzene to give two epimeric acetals in 81.1%yield, **10** and **11**, in a ratio of *ca.* 2 : 3. Hydrolysis of **10** with dilute hydrochloric acid in refluxing acetic acid afforded the original ketone **8**, which was also obtained by the same hydrolysis of **11**. The ^{1}H NMR spectrum of **10** showed a multiplet signal at δ *ca.* 3.8—4.3 due to the ethylenedioxy group at the C-2 position, while that of **11** showed the corresponding signal at δ 3.98 as a broad singlet with half-height width of 6 Hz. These spectral data suggested[9] the presence of an axial bromine atom in **10** and an equatorial one in **11**. Thus, the structures of **10** and **11** were determined respectively to be 3α-bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-triene and 3β-bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-triene. The acetals **10** and **11** were then oxidized with chromium trioxide in acetic acid to give the corresponding 7-oxo compounds, **12** and **13** in yields of 52.6 and 52.2% respectively. Treatment of **13** in *t*-butyl alcohol with oxygen in the presence of potassium *t*-butoxide afforded a diosphenol derivative, 3β-bromo-2,2-ethylenedioxy-6-hydroxy-18-norabieta-5,8,11,13-tetraen-7-one (**14**), in 61.0% yield. The IR spectrum of **14** showed bands at 3432, 1663, 1638, and 1608 cm^{-1} corresponding to a diosphenol moiety. The compound **14** was hydrolyzed with dilute hydrochloric acid in refluxing acetic acid and the resulting

ketone (**15**), without purification, was treated at 120—125 °C with lithium carbonate and lithium bromide in *N,N*-dimethylformamide under a stream of nitrogen to give the desired 6-hydroxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione (**3**) together with a small amount of 6-hydroxy-18-norabieta-5,8,11,13-tetraene-2,7-dione (**16**). Acetylation of **3** and **16** with acetic anhydride in pyridine afforded the corresponding monoacetates, **17** and **18**. These acetates were easily hydrolyzed with dilute hydrochloric acid in refluxing ethanol to give the original diones, **3** and **16**.

Subsequently, the synthesis of 19-norabieta-3,5,8,11,-13-pentaene-2,7-dione (**19**) was carried out as follows. The ketone **13** was brominated with pyridinium tribromide in dichloromethane at room temperature to give 3β,6α-dibromo-2,2-ethylenedioxy-18-norabieta-8,11,13-trien-7-one (**20**) in 76.5% yield. The stereochemistry of the C-6 position in **20** was supported by its ^{1}H NMR spectrum, which showed a doublet signal due to the C-6 proton at δ 4.84 with coupling constant of 13 Hz, suggesting the presence of an axial β proton. Hydrolysis of **20** with dilute hydrochloric acid in refluxing acetic acid afforded the corresponding 2,7-dioxo compound which, without purification, was converted into **19** in 93.0% yield by treatment with lithium carbonate and lithium bromide in *N,N*-dimethylformamide at 120—125 °C. Similarly, the ketone **12** was also converted into **19** *via* the corresponding 6α-bromo compound (**21**).

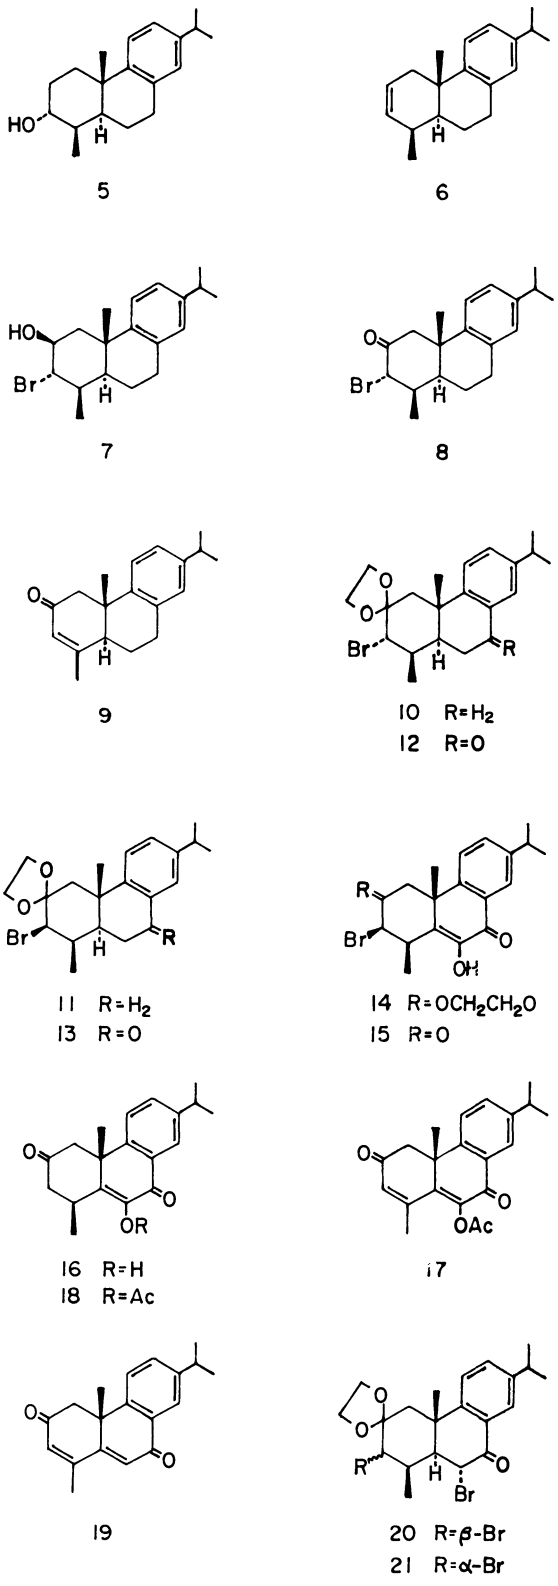
Experimental

All melting points are uncorrected. The IR and optical rotations were measured in chloroform, and the ^{1}H NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, m: multiplet. The column chromatography was performed using Merck silica gel.

18-Norabieta-8,11,13-trien-3α-ol (5). A solution of **4**[3-5] (418 mg) in ethanol (10 ml) was hydrogenated at room temperature for *ca.* 3 h in an atmosphere of hydrogen using Raney Ni (W-7) prepared from nickel-aluminium alloy (50%: 1.078 g). After the usual work-up, the crude product was recrystallized from hexane to give **5**[6,7] as colorless crystals (305 mg: 72.3%), mp 117—121 °C. Further crystallization gave an analytical sample; mp 122—123 °C; $[\alpha]_D$ +76.0°; IR: 3616, 3412 cm^{-1}; ^{1}H NMR: 0.92 (3H, d, J=7.5 Hz, C_4-CH_3), 1.11 (3H, s, C_{10}-CH_3), 1.22 (6H, d, J=7 Hz, -CH(C$\underline{H}_3$)$_2$), 1.93 (1H, s, -OH), 3.68 (1H, bs, $W_{1/2}$=5.5 Hz, C_3-H), 6.65—7.15 (3H, m, aromatic protons). Found: C, 83.83; H, 10.60%. Calcd for $C_{19}H_{28}O$: C, 83.77; H, 10.36%.

18-Norabieta-2,8,11,13-tetraene (6). A mixture of **5** (504 mg), phosphoryl chloride (0.9 ml), and pyridine (4.0 ml) was refluxed for 1 h, cooled, and then poured into ice-dilute hydrochloric acid. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (30 g), using hexane as the eluent, to give **6** (425 mg: 90.3%) as an oil; $[\alpha]_D$ +291°; ^{1}H NMR: 1.05 (3H, d, J=7.5 Hz, C_4-CH_3), 1.20 (3H, s, C_{10}-CH_3), 1.22 (6H, d, J=7 Hz, -CH(C$\underline{H}_3$)$_2$), 5.66 (2H, d, J=3 Hz, C_2-H and C_3-H), 6.70—7.20 (3H, m, aromatic protons). Found: C, 89.91; H, 10.58%. Calcd for $C_{19}H_{26}$: C, 89.70; H, 10.30%.

3α-Bromo-18-norabieta-8,11,13-trien-2-one (8). A solution of **6** (425 mg) in dimethyl sulfoxide (7.0 ml) containing a small quantity of water (0.1 ml) was stirred with *N*-bromosuccinimide (620 mg) at 20—25 °C for 1 h under a stream of nitrogen. The stirred mixture was cooled in an ice-water bath and aqueous sodium hydrogencarbonate was added.



The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude 3α-bromo-18-norabieta-8,11,13-trien-2β-ol (**7**) (596 mg) as an oil; IR: 3570, 3370 cm^{-1}; ^1H NMR: 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.29 (3H, d, J=7.5 Hz, C_4-CH_3), 1.36 (3H, s, $C_{10}-CH_3$).

The crude **7** (596 mg) in acetone (7.0 ml) was oxidized with Jones reagent [2.5 M (1 M=1 mol dm^{-3}): 1.2 ml] at 0 °C for 5 min. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (35 g), using hexane–benzene (1 : 1) as the eluent, to give **8** (403 mg: 69.1%) as an oil which responded positively to the Beilstein halogen test; $[\alpha]_D$ +185°; IR: 1707 cm^{-1}; ^1H NMR: 1.16 (3H, d, J=7.5 Hz, C_4-CH_3), 1.17 (3H, s, $C_{10}-CH_3$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 4.06 (1H, bs, C_3–H), 6.83 (1H, bs) and 6.97 (2H, s) (aromatic protons). Found: C, 65.03; H, 7.33%. Calcd for $C_{19}H_{25}OBr$: C, 65.33; H, 7.23%.

*19-Norabieta-3,8,11,13-tetraen-2-one (**9**).* A mixture of **8** (44 mg), lithium carbonate (30 mg), and lithium bromide (38 mg) in *N,N*-dimethylformamide (2.0 ml) was stirred at 120—125 °C for 3 h in a stream of nitrogen. The reaction mixture was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (10 g), using ether–benzene (3 : 97) as the eluent, to give **9** (32 mg; 92.3%) as an oil; $[\alpha]_D$ +121°; IR: 1654, 1622 cm^{-1}; ^1H NMR: 1.12 (3H, s, $C_{10}-CH_3$), 1.23 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.99 (3H, bs, C_4-CH_3), 5.86 (1H, bs, C_3–H), 6.70—7.20 (3H, m, aromatic protons). Found: C, 84.72; H, 9.30%. Calcd for $C_{19}H_{24}O$: C, 85.02; H, 9.01%.

*Acetalization of the Bromo Ketone **8**.* A mixture of **8** (833 mg), 1,2-ethanediol (3.0 ml), *p*-toluenesulfonic acid (784 mg), and dry benzene (20 ml) was refluxed for 10 h with a water separator containing 4 Å molecular sieves. The mixture was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (30 g), using hexane–benzene (65 : 35) as the eluent, to give 3α-bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-triene (**10**) (311 mg: 33.1%). It was recrystallized from ether–methanol, mp 114.5—115.5 °C, $[\alpha]_D$ +8.7°; ^1H NMR: 1.20 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.26 (3H, d, J=7.5 Hz, C_4-CH_3), 1.31 (3H, s, $C_{10}-CH_3$), 1.70 and 2.48 (each 1H and d, J=14 Hz, C_1-H_2), 3.80—4.50 (5H, m, $-OCH_2CH_2O-$ and C_3–H), 6.74 (1H, s) and 6.91 (2H, bs) (aromatic protons). Found: C, 64.23; H, 7.32%. Calcd for $C_{21}H_{29}O_2Br$: C, 64.12; H, 7.45%.

Further elution with the same solvent gave 3β-bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-triene (**11**) (451 mg: 48.0%) as an oil; $[\alpha]_D$ +108°; ^1H NMR: 1.22 (9H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$ and C_4-CH_3), 1.30 (3H, s, $C_{10}-CH_3$), 3.98 (4H, bs, $-OCH_2CH_2O-$), 4.09 (1H, d, J=3 Hz, C_3–H), 6.77 (1H, s), and 6.93 (2H, bs) (aromatic protons). Found: C, 64.40; H, 7.47%. Calcd for $C_{21}H_{29}O_2Br$: C, 64.12; H, 7.45%.

*Hydrolysis of the Acetals **10** and **11**.* *a)*: A mixture of **10** (190 mg) and dilute hydrochloric acid (10%: 0.7 ml) in acetic acid (6.0 ml) was refluxed for 1 h, concentrated *in vacuo*, diluted with water, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using hexane–benzene (1 : 1) as the eluent, to give an oil (129 mg: 76.3%), whose IR and ^1H NMR spectra were identical with those of **8**.

b): A mixture of **11** (70 mg) and dilute hydrochloric acid (10%: 0.4 ml) in acetic acid (2.0 ml) was refluxed for 1 h. After the same work-up as described in *a*), the crude product was chromatographed on silica gel (10 g), using hexane–benzene (6 : 4) as the eluent, to give an oil (41 mg: 66.5%), whose IR and ^1H NMR spectra were identical with those of **8**.

*3α-Bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-trien-7-one (**12**).* A stirred solution of **10** (625 mg) in acetic acid (7.0 ml) was oxidized with chromium trioxide (614 mg) at room temperature for 2.5 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (40 g), using ether–benzene (1 : 99) as the eluent, to give **12** (340 mg: 52.6%). It was recrystallized from methanol; mp 136.5—139 °C; $[\alpha]_D$ −16.5°; IR: 1676, 1607 cm^{-1}; ^1H NMR: 1.25 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.33 (3H, d, J=7.5 Hz, C_4-CH_3), 1.41 (3H, s, $C_{10}-CH_3$), 3.85—4.50 (5H, m, $-OCH_2CH_2O-$ and C_3–H), 7.09 (1H, d, J=8 Hz, C_{11}–H), 7.29 (1H, dd, J=2 and 8 Hz, C_{12}–H), 7.78 (1H, d, J=2 Hz, C_{14}–H). Found: C, 61.97; H, 6.70%. Calcd for $C_{21}H_{27}O_3Br$: C, 61.92; H, 6.69%.

*3β-Bromo-2,2-ethylenedioxy-18-norabieta-8,11,13-trien-7-one (**13**).* A stirred solution of **11** (2.542 g) in acetic acid (14 ml) was oxidized with chromium trioxide (2.525 g) as described for the preparation of **12**. The crude product was chromatographed on silica gel (100 g), using ether–benzene (1 : 99) as the eluent, to give **13** (1.374 g: 52.2%). It was recrystallized from methanol; mp 141—142 °C; $[\alpha]_D$ +65.2°; IR: 1673, 1608 cm^{-1}; ^1H NMR: 1.27 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.30 (3H, d, J=7.5 Hz, C_4-CH_3), 1.39 (3H, s, $C_{10}-CH_3$), 3.90—4.20 (5H, m, $-OCH_2CH_2O-$ and C_3–H), 7.14 (1H, d, J=8 Hz, C_{11}–H), 7.34 (1H, dd, J=2 and 8 Hz, C_{12}–H), 7.81 (1H, d, J=2 Hz, C_{14}–H). Found: C, 61.63; H, 6.44%. Calcd for $C_{21}H_{27}O_3Br$: C, 61.92; H, 6.69%.

*3β-Bromo-2,2-ethylenedioxy-6-hydroxy-18-norabieta-5,8,11,13-tetraen-7-one (**14**).* A stream of oxygen was bubbled in a stirred solution of **13** (1.226 g) and potassium *t*-butoxide (3.80 g) in *t*-butyl alcohol (25 ml) at 35 °C for 35 min. The mixture was diluted with water and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (30 g), using benzene as the eluent, to give **14** (772 mg: 61.0%). It was recrystallized from methanol; mp 180—181 °C; $[\alpha]_D$ +17.2°; IR: 3432, 1663, 1638, 1608 cm^{-1}; ^1H NMR: 1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.51 (3H, d, J=7.5 Hz, C_4-CH_3), 1.61 (3H, s, $C_{10}-CH_3$), 2.37 (2H, s, C_1-H_2), 3.40—4.40 (5H, m, $-OCH_2CH_2O-$ and C_3–H), 6.67 (1H, s, –OH), 7.31 (2H, bs, C_{11}–H and C_{12}–H), 7.95 (1H, bs, C_{14}–H). Found: C, 59.98; H, 6.18%. Calcd for $C_{21}H_{25}O_4Br$: C, 60.01; H, 6.01%.

*3β-Bromo-6-hydroxy-18-norabieta-5,8,11,13-tetraene-2,7-dione (**15**).* A mixture of **14** (684 mg) and dilute hydrochloric acid (10%: 2.5 ml) in acetic acid (15 ml) was refluxed for 70 min, concentrated *in vacuo*, diluted with water, and then extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude **15** (670 mg) which, without purification, was used in the next reaction.

*Dehydrobromination of the 2,7-Dione **15**.* A mixture of the crude **15** (670 mg), lithium carbonate (380 mg), and lithium bromide (450 mg) in *N,N*-dimethylformamide (8.0 ml) was stirred at 120—125 °C for 3 h in a stream of nitrogen. After the same work-up as described for the preparation of **9**, the

crude product was purified by column chromatography on silica gel (40 g), using ether–benzene (0.5 : 99.5) as the eluent, to give 6-hydroxy-18-norabieta-5,8,11,13-tetraene-2,7-dione (**16**) (63 mg). It was recrystallized from ether–hexane; mp 95—96.5 °C; $[\alpha]_D$ +18.8°; IR: 3428, 1708, 1661, 1638, 1608 cm^{-1}; ^1H NMR: 1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.43 (3H, d, J=7.5 Hz, C_4-CH_3), 1.59 (3H, s, $C_{10}-CH_3$), 6.87 (1H, s, -OH), 7.40 (2H, d, J=2 Hz, C_{11}–H and C_{12}–H), 7.98 (1H, bs, C_{14}–H). Found: C, 76.72; H, 7.65%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

Subsequent elution gave a mixture of **16** and 6-hydroxy-19-norabieta-3,5,8,11,13-pentaene-2,7-dione (**3**) (188 mg), whose purification is described later.

Further elution gave **3** (83 mg); $[\alpha]_D$ −215°; IR: 3365, 1664, 1646, 1611 cm^{-1}; ^1H NMR: 1.33 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.54 (3H, s, $C_{10}-CH_3$), 2.32 and 2.99 (each 1H and d, J=15 Hz, C_1-H_2), 2.49 (3H, d, J=2 Hz, C_4-CH_3), 5.98 (1H, bs, C_3–H), 7.48 (2H, d, J=2 Hz, C_{11}–H and C_{12}–H), 7.63 (1H, s, -OH), 8.02 (1H, bs, C_{14}–H). Found: C, 76.72; H, 6.97%. Calcd for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80%.

The above mixture of **16** and **3** (188 mg) was acetylated with acetic anhydride (1.0 ml) and pyridine (2.0 ml) at 80—85 °C for 1 h. After the usual work-up, the crude product was chromatographed on silica gel (15 g), using ether–benzene (2 : 98) as the eluent, to give 6-acetoxy-19-norabieta-3,5,8,-11,13-pentane-2,7-dione (**17**) (139 mg); $[\alpha]_D$ −95.9°; IR: 1771, 1662, 1613 cm^{-1}; ^1H NMR: 1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.61 (3H, s, $C_{10}-CH_3$), 2.34 (6H, s, C_4-CH_3 and $-OCOCH_3$), 6.05 (1H, bs, C_3–H), 7.41 (2H, d, J=2 Hz, C_{11}–H and C_{12}–H), 7.96 (1H, bs, C_{14}–H). Found: C, 74.23; H, 6.60%. Calcd for $C_{21}H_{22}O_4$: C, 74.53; H, 6.55%.

Further elution with ether–benzene (7 : 93) gave 6-acetoxy-18-norabieta-5,8,11,13-tetraene-2,7-dione (**18**) (34 mg): IR: 1766, 1715, 1663, 1612 cm^{-1}; ^1H NMR: 1.29 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.35 (3H, d, J=7.5 Hz, C_4-CH_3), 1.63 (3H, s, $C_{10}-CH_3$), 2.32 (3H, s, $-OCOCH_3$), 7.37 (2H, bs, C_{11}–H and C_{12}–H), 7.93 (1H, bs, C_{14}–H).

*Hydrolysis of the Acetates **17** and **18**.* *a)*: A mixture of **17** (143 mg) and dilute hydrochloric acid (10%: 2.0 ml) in ethanol (7.0 ml) was refluxed for 2.5 h, concentrated *in vacuo*, diluted with water, and then extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (12 g), using ether–benzene (3 : 97) as the eluent, to give an oil (114 mg), whose IR and ^1H NMR spectra were identical with those of **3**.

b): A mixture of **18** (33 mg) and dilute hydrochloric acid (10%: 1.0 ml) in ethanol (5.0 ml) was refluxed for 1.5 h. After the same work-up as described in *a*), the crude product was purified by column chromatography on silica gel (5.0 g), using ether–benzene (2 : 98) as the eluent, to give **16** (23 mg), whose IR and ^1H NMR spectra were identical with those of the authentic sample.

*3β,6α-Dibromo-2,2-ethylenedioxy-18-norabieta-8,11,13-trien-7-one (**20**).* A mixture of **13** (611 mg) and pyridinium tribromide (80%: 1190 mg) in dichloromethane (14 ml) was stirred at room temperature for 160 min. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate, dilute hydrochloric acid, and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (60 g), using benzene as the eluent, to give **20** (558 mg: 76.5%) as an oil; $[\alpha]_D$ +84.8°; IR: 1687, 1607 cm^{-1}; ^1H NMR: 1.27 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.36 (3H, d, J=7.5 Hz, C_4-CH_3), 1.39 (3H, s, $C_{10}-CH_3$), 2.10 (1H, bd, J=14 Hz) and 2.62 (1H, d, J=14 Hz) (C_1-H_2), 3.90—4.30 (5H, m, $-OCH_2CH_2O-$ and C_3–H), 4.84 (1H, d, J=13 Hz, C_6–H), 7.14 (1H, d, J=8 Hz, C_{11}–H), 7.35 (1H, dd, J=2 and 8 Hz, C_{12}–H), 7.80 (1H, d, J=2 Hz, C_{14}–H). Found: C, 51.78; H, 5.55%. Calcd for $C_{21}H_{26}O_3Br_2$: C, 51.87; H, 5.61%.

*3α,6α-Dibromo-2,2-ethylenedioxy-18-norabieta-8,11,13-trien-7-one (**21**).* A mixture of **12** (262 mg) and pyridinium tribromide (80%: 410 mg) in dichloromethane (6.0 ml) was stirred at room temperature for 160 min. After the same work-up as described for the preparation of **20**, the crude product was chromatographed on silica gel (30 g), using benzene as the eluent, to give **21** (222 mg: 70.9%) as a solid; $[\alpha]_D$ +30.7°; IR: 1685, 1608 cm^{-1}; ^1H NMR ($CDCl_3$): 1.27 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.40 (3H, d, J=7.5 Hz, C_4-CH_3), 1.43 (3H, s, $C_{10}-CH_3$), 1.98 and 2.60 (each 1H and d, J=14 Hz, C_1-H_2), 3.95—4.55 (5H, m, $-OCH_2CH_2O-$ and C_3–H), 5.02 (1H, d, J=13 Hz, C_6–H), 7.17 (1H, d, J=8 Hz, C_{11}–H), 7.44 (1H, dd, J=2 and 8 Hz, C_{12}–H), 7.90 (1H, d, J=2 Hz, C_{14}–H).

*19-Norabieta-3,5,8,11,13-pentaene-2,7-dione (**19**).* *a)*: A mixture of **20** (486 mg) and dilute hydrochloric acid (10%: 1.2 ml) in acetic acid (8.0 ml) was refluxed for 1 h, concentrated *in vacuo*, diluted with water, and then extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude 2,7-dioxo compound (395 mg) which, without purification ,was used in the next reaction.

A mixture of the crude 2,7-dioxo compound (395 mg), lithium carbonate (391 mg), and lithium bromide (480 mg) in *N,N*-dimethylformamide (6.5 ml) was stirred at 120—125 °C for 3 h in a stream of nitrogen. After the same work-up as described for the preparation of **9**, the crude product was purified by column chromatography on silica gel (15 g), using ether–benzene (3 : 97) as the eluent, to give **19** (261 mg: 93.0%) as an oil; $[\alpha]_D$ −51.2°; IR: 1668, 1650, 1608 cm^{-1}; ^1H NMR: 1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.51 (3H, s, $C_{10}-CH_3$), 2.29 (3H, d, J=2 Hz, C_4-CH_3), 6.13 (1H, bs, C_3–H), 6.63 (1H, s, C_6–H), 7.43 (2H, d, J=2 Hz, C_{11}–H and C_{12}–H), 7.94 (1H, bs, C_{14}–H). Found: C, 81.09; H, 7.32%. Calcd for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

b): A mixture of **21** (209 mg) and dilute hydrochloric acid (10%: 0.6 ml) in acetic acid (4.0 ml) was refluxed for 1 h, concentrated *in vacuo*, diluted with water, and then extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*.

The crude 2,7-dioxo compound (179 mg), without purification, was stirred at 120—125 °C for 3 h with lithium carbonate (180 mg), lithium bromide (220 mg), and *N,N*-dimethylformamide (3.0 ml) in a stream of nitrogen. The reaction mixture was treated as described for the preparation of **9** and then purified by column chromatography on silica gel (15 g), using ether–benzene (2 : 98) as the eluent. The IR and ^1H NMR spectra of the product (96 mg: 79.8%) were identical with those of **19**.

The authors are grateful to Arakawa Chemical Co. Ltd. for a generous gift of rosin. This work was partially supported by Grant-in-Aid for Scientific Research No. 56540324 from the Ministry of Education, Science and Culture.

Synthesis of 11,14-Diacetoxy-13-(acetoxymethyl)podocarpa-8,11,13-triene. Correction of Proposed Structure for Premnolal

Takashi MATSUMOTO,* Sachihiko IMAI,* and Shuhei YUKI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 24, 1982)

Oxidation of 11-acetoxyabieta-8,11,13-triene, derived from methyl 11-methoxyabieta-8,11,13-trien-18-oate, with chromium trioxide afforded 11,15-diacetoxyabieta-8,11,13-trien-7-one and 11-acetoxy-13-acetylpodocarpa-8,11,13-trien-7-one (**11**) in a ratio of *ca.* 2 : 1. The acetyl compound **11** was converted into a quinone, 13-(hydroxymethyl)podocarpa-8,12-diene-11,14-dione (**18**), by a series of reactions : iodoform reaction, esterification, acetylation, sodium borohydride reduction, dehydration, catalytic hydrogenation, lithium aluminium hydride reduction, and oxidation with Fremy's salt. Reductive acetylation of **18** produced 11,14-diacetoxy-13-(acetoxymethyl)-podocarpa-8,11,13-triene (**2**). The ^{1}H NMR spectrum of **2** was different from that of 15-acetoxypremnol diacetate which was prepared from natural premnolal. Based on this fact a corrected structure of premnolal is proposed.

Premnolal, a new aromatic bisnorditerpene, has recently been isolated from the root bark of *Premna latifolia* Roxb. (Verbenaceae) by Rao *et al.*[1] On the basis of chemical and spectroscopic studies, they deduced the structure of premnolal to be 11,14-dihydroxypodocarpa-8,11,13-triene-13-carbaldehyde (**1**). This structure is unique among the naturally-occurring tricyclic diterpenes, in that it contains a formyl group at C-13 and two hydroxyl goups at C-11 and C-14. To confirm the validity of their proposed structure, we now attempted the synthesis of **1** or its derivatives. This paper will describe the synthesis of the proposed 15-acetoxypremnol diacetate, 11,14-diacetoxy-13-(acetoxymethyl)-podocarpa-8,11,13-triene (**2**), and present a revised structure of natural premnolal.

In the present study, methyl 11-methoxyabieta-8,11,13-trien-18-oate (**3**)[2] prepared from methyl (+)-13β-abiet-8-en-18-oate (**4**)[3] in our laboratory, was chosen as the starting material. Reduction of **3** with lithium aluminium hydride in refluxing ether afforded 11-methoxyabieta-8,11,13-trien-18-ol (**5**)[4,5] which, without purification, was oxidized at room temperature with pyridinium chlorochromate in dichloromethane to give 11-methoxyabieta-8,11,13-trien-18-al (**6**). The crude aldehyde **6** was immediately treated with 80% hydrazine hydrate in diethylene glycol at 125—140 °C and then with sodium hydroxide at 195—200 °C. Separation of the reaction mixture by column chromatography on silica gel yielded 11-methoxyabieta-8,11,13-triene (**7**)[4] and abieta-8,11,13-trien-11-ol (**8**) in a ratio of *ca.* 3 : 1. The methoxy compound **7** was easily demethylated at room temperature with boron tribromide in dichloromethane to give **8**, which was converted into the corresponding acetate (**9**) with acetic anhydride in pyridine. Oxidation of **9** with chromium trioxide in a mixture of acetic anhydride and acetic acid afforded two ketones, **10** and **11**, in yields of 48% and 23% respectively. The IR spectrum of **10** showed bands at 1768, 1735, and 1685 cm^{-1}, while that of **11** at 1768 and 1690 cm^{-1}. The ^{1}H NMR spectrum of **10** showed singlet signals at δ 1.74 (6H) due to two methyls, at δ 1.98 (3H) and 2.26 (3H) due to two acetoxyls, and two doublet signals at δ 6.98 (1H, J=2 Hz) and 7.84 (1H, J=2 Hz) assigned to two aromatic protons. On the other hand, the ^{1}H NMR spectrum of **11** showed an acetoxyl at δ 2.29 (3H, s), an acetyl at δ 2.57 (3H, s), and two aromatic protons at δ 7.57 (1H, d, J=2 Hz) and 8.35 (1H, d, J=2 Hz). From these spectral data, the structures of **10** and **11** were assigned respectively to be 11,15-diacetoxyabieta-8,11,13-trien-7-one and 11-acetoxy-13-acetylpodocarpa-8,11,13-trien-7-one.

Hydrolysis of **10** with sodium hydrogencarbonate in refluxing aqueous acetone afforded the known 11,15-dihydroxyabieta-8,11,13-trien-7-one (**12**) which was prepared by Kawazu *et al.*[6] from the natural fish-killing component, callicarpone (**13**).

The ketone **11** was then converted into 11-acetoxy-13-(methoxycarbonyl)podocarpa-8,11,13-trien-7-one (**14**) by a series of reactions: iodoform reaction, esterification with diazomethane, and acetylation. The IR spectrum of **14** showed carbonyl absorptions at 1768, 1728, and 1690 cm^{-1}. Reduction of **14** with sodium borohydride in methanol, followed by dehydration with *p*-toluenesulfonic acid in refluxing benzene afforded 13-(methoxycarbonyl)podocarpa-6,8,11,13-tetraen-11-ol (**15**), whose ^{1}H NMR spectrum showed C-5, C-6, and C-7 protons at δ 2.20 (t, J=3 Hz), 6.03 (dd, J=10 and 3 Hz), and 6.48 (dd, J=10 and 3 Hz) respectively. The tetraene **15** was submitted to catalytic hydrogenation over Pd–C in ethanol and the resulting 13-(methoxycarbonyl)-podocarpa-8,11,13-trien-11-ol (**16**) was reduced with lithium aluminium hydride in refluxing ether to give

15

13-(hydroxymethyl)podocarpa-8,11,13-trien-11-ol (**17**). Introduction of oxygen function at C-14 was successfully achieved by oxidation of **17** in aqueous methanol with Fremy's salt in the presence of sodium dihydrogenphosphate and a *p*-quinone compound, 13-(hydroxymethyl)-podocarpa-8,12-diene-11,14-dione (**18**), was obtained. The ^1H NMR spectrum of **18** showed a broad singlet signal at δ 4.37 (2H) due to the hydroxymethyl group at C-13 and a triplet signal at δ 6.49 (1H, J=1.5 Hz) due to a vinylic proton at C-12. Reductive acetylation of **18** with zinc in acetic anhydride and pyridine afforded a triacetate **2**, whose ^1H NMR spectrum showed three acetoxyls at δ 1.98 (3H) and 2.24 (6H), a methylene of acetoxymethyl group at δ 4.87, and an aromatic proton at δ 6.78. Oxidation of **2** with chromium trioxide in acetic acid gave 11,14-diacetoxy-13-(acetoxymethyl)-

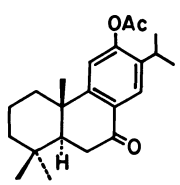
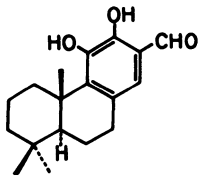
19



20

podocarpa-8,11,13-trien-7-one (**19**), whose IR spectrum showed bands at 1763, 1745, and 1685 cm^{-1}. The presence of an aromatic proton at C-12 in **19** was supported by its chemical shift (δ 7.09) in the ^1H NMR spectrum; if the aromatic proton is located at C-14, the chemical shift might be expected to be δ *ca.* 8, like that (δ 7.94) of 12-acetoxyabieta-8,11,13-trien-7-one (**20**).[7]



21

Thus, the structure of **2** was conclusively assigned to be 11,14-diacetoxy-13-(acetoxymethyl)podocarpa-8,11,13-triene. Since the ^1H NMR spectrum of the synthetic **2** was different from that of 15-acetoxypremnol diacetate which was prepared from natural premnolal, all of the proposed structures[1] for premnolal and its derivatives should be revised. From the present study together with consideration of the published spectral data, we now propose the correct structure of premnolal to be 11,12-dihydroxypodocarpa-8,11,13-triene-13-carbaldehyde (**21**).

Experimental

All melting points are uncorrected. The IR and optical rotations were measured in chloroform, and the ^1H NMR spectra in carbon tetrachloride at 90 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet, dm: doublet of multiplet. The column chromatography was performed using Merck silica gel.

Abieta-8,11,13-trien-11-ol (8). *a)*: A solution of methyl 11-methoxyabieta-8,11,13-trien-18-oate (**3**)[2] (6.26 g) in dry ether (70 ml) was added dropwise to a stirred suspension of lithium aluminium hydride (1.38 g) in dry ether (120 ml). The mixture was refluxed for 4 h, cooled, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give 11-methoxyabieta-8,11,13-trien-18-ol (**5**)[4,5] (5.81 g) which, without purification, was used in the next reaction. IR: 3630, 3440 cm^{-1}; ^1H NMR (60 MHz): 0.81 (3H, s, C_4–CH_3), 1.21 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.27 (3H, s, C_{10}–CH_3), 2.16 (1H, s, –OH), 3.22 (2H, ABq, J_{AB}=11 Hz, δ_{AB}=20 Hz), 3.75 (3H, s, –OCH_3), 6.30 (2H, s, C_{12}–H and C_{14}–H).

A solution of the crude **5** (5.81 g) in dichloromethane (46 ml) was added to a stirred suspension of pyridinium chlorochromate (5.96 g) in dichloromethane (70 ml) at room temperature. The mixture was stirred for 105 min, diluted with ether, and then decanted from a tarry residue, which was washed with ether. The combined organic solution was washed with brine, passed through a short alumina column, and evaporated *in vacuo* to give the crude 11-methoxyabieta-8,11,13-trien-18-al (**6**) (5.20 g); IR: 2700, 1724 cm^{-1}; ^1H NMR (60 MHz): 1.12 (3H, s, C_4–CH_3), 1.19 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.29 (3H, s, C_{10}–CH_3), 3.77 (3H, s, –OCH_3),

6.42 (2H, s, C_{12}–H and C_{14}–H), 9.18 (1H, s, -CHO).

A stirred mixture of the crude **6** (5.20 g) and 80% hydrazine hydrate (24.9 ml) in diethylene glycol (156 ml) was heated at 125—140 °C for 2 h, and then powdered sodium hydroxide (33.1 g) was added. The mixture was stirred at 195—200 °C for 3 h, cooled, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product (4.75 g) was chromatographed on silica gel (500 g), using hexane–benzene (99 : 1) as the eluent, to give 11-methoxyabieta-8,11,-13-triene (**7**)[4] (3.40 g: 62%) as an oil; $[\alpha]_D$ +125° (*c* 1.32); ^{1}H NMR: 0.92 and 0.94 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.19 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.24 (3H, s, C_{10}–CH_3), 3.01 (1H, dm, J=13 Hz, $C_{1\beta}$–H), 3.74 (3H, s, $-OCH_3$), 6.36 (2H, s, C_{12}–H and C_{14}–H). Found: C, 84.19; H, 10.93%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

Further elution with hexane–benzene (2 : 3) gave abieta-8,11,13-trien-11-ol (**8**) (1.04 g: 20%) as a solid; $[\alpha]_D$ +94° (*c* 1.56); IR: 3595, 3340 cm^{-1}; ^{1}H NMR: 0.91 and 0.93 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.14 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.27 (3H, s, C_{10}–CH_3), 3.04 (1H, dm, J=13 Hz, $C_{1\beta}$–H), 4.38 (1H, s, -OH), 6.05 (1H, bd, J=2 Hz, C_{12}–H), 6.35 (1H, bd, J=2 Hz, C_{14}–H). Found: C, 84.02; H, 10.69%. Calcd for $C_{20}H_{30}O$: C, 83.86; H, 10.56%.

b): A solution of boron tribromide (0.38 ml) in dichloromethane (1.5 ml) was added to a stirred solution of **7** (300 mg) in dichloromethane (3.0 ml) over a period of 5 min with cooling in an ice-bath. The mixture was stirred at the same temperature for 10 min and at room temperature for 2 h, poured into ice–water, and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (30 g), using hexane–benzene (3 : 2) as the eluent, to give an oil (257 mg: 90%), whose IR and ^{1}H NMR spectra were identical with those of **8**.

11-Acetoxyabieta-8,11,13-triene (9). A solution of **8** (257 mg) and acetic anhydride (1.4 ml) in pyridine (1.4 ml) was allowed to stand overnight at room temperature. After the usual work-up, the crude product was recrystallized from methanol to give **9** (149 mg: 51%); mp 98.5—99.5 °C; $[\alpha]_D$ +94° (*c* 1.68); IR: 1748 cm^{-1}; ^{1}H NMR (60 MHz): 0.96 (6H, bs, $-\dot{C}(CH_3)_2$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.23 (3H, s, C_{10}–CH_3), 2.22 (3H, s, $-OCOCH_3$), 6.45 (1H, bs, C_{12}–H), 6.66 (1H, bs, C_{14}–H). Found: C, 80.64; H, 10.08%. Calcd for $C_{22}H_{32}O_2$: C, 80.44; H, 9.83%. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (15 g), using hexane–benzene (7 : 3) as the eluent, to give additional **9** (128 mg: 43%).

*Oxidation of the Acetate **9** with Chromium Trioxide.* Chromium trioxide (500 mg) was added portionwise at 0—5 °C to a stirred solution of **9** (328 mg) in acetic anhydride (2.3 ml) and acetic acid (3.3 ml). The mixture was further stirred at 0—5 °C for 1 h and at room temperature for 1 h. After the successive addition of aqueous sodium acetate (10%: 2.0 ml), methanol (1.5 ml), and brine (50 ml), the mixture was extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (40 g), using ether–benzene (1 : 99) as the eluent, to give 11,15-diacetoxyabieta-8,11,13-trien-7-one (**10**) (153 mg: 38%). This was recrystallized from methanol; mp 135—136 °C; $[\alpha]_D$ +45° (*c* 3.11); IR: 1768, 1735, 1685 cm^{-1}; ^{1}H NMR: 0.99 (6H, bs, $-\dot{C}(CH_3)_2$), 1.34 (3H, s, C_{10}–CH_3), 1.74 (6H, bs, $-C(C\underline{H}_3)_2OCOCH_3$), 1.98 (3H, s, C_{15}–$OCOCH_3$), 2.26 (3H, s, C_{11}–$OCOCH_3$), 6.98 (1H, d, J=2 Hz, C_{12}–H), 7.84 (1H, d, J=2 Hz, C_{14}–H). Found: C, 71.92; H, 8.15%. Calcd for $C_{24}H_{32}O_5$: C, 71.97; H, 8.05%.

Further elution with the same solvent gave a mixture (148 mg) of **10** and 11-acetoxy-13-acetylopodocarpa-8,11,13-trien-7-one (**11**). This mixture was rechromatographed on silica gel (15 g), using ether–hexane (1 : 4) as the eluent, to give additional **10** (37 mg: 9%) and **11** (79 mg: 23%). The acetyl compound **11** was recrystallized from methanol; mp 111—112 °C; $[\alpha]_D$ +67° (*c* 0.925); IR: 1768, 1690, 1607 cm^{-1}; ^{1}H NMR: 1.01 (6H, s, $-\dot{C}(CH_3)_2$), 1.35 (3H, s, C_{10}–CH_3), 2.29 (3H, s, $-OCOCH_3$), 2.57 (3H, s, $-COCH_3$), 7.57 (1H, d, J=2 Hz, C_{12}–H), 8.35 (1H, d, J=2 Hz, C_{14}–H). Found: C, 73.95; H, 7.74%. Calcd for $C_{21}H_{26}O_4$: C, 73.66; H, 7.66%.

11,15-Dihydroxyabieta-8,11,13-trien-7-one (12). A mixture of **10** (220 mg) in hot aqueous acetone (50%: 44 ml) and sodium hydrogencarbonate (460 mg) was refluxed for 2 h. The mixture was diluted with brine and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was recrystallized from chloroform to give **12** (74 mg: 43%); mp 220—222 °C; MS (*m/e*): 316 (M^+); $[\alpha]_D$ +45° (*c* 0.245, MeOH) (lit,[6] mp 220—222 °C, $[\alpha]_D^{25}$ +44° (MeOH)); ^{1}H NMR (acetone-d_6): 0.97 and 1.01 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.43 (3H, s, C_{10}–CH_3), 1.48 (6H, s, $-C(C\underline{H}_3)_2OH$), 3.41 (1H, dm, J=13 Hz, $C_{1\beta}$–H), 3.91 (1H, s, C_{15}–OH), 7.28 (1H, d, J=2 Hz, C_{12}–H), 7.62 (1H, d, J=2 Hz, C_{14}–H), 8.40 (1H, s, C_{11}–OH). ^{1}H NMR (pyridine-d_5): 0.88 and 0.93 (each 3H and s, $-\dot{C}(CH_3)_2$), 1.58 (3H, s, C_{10}–CH_3), 1.71 (6H, s, $-C(C\underline{H}_3)_2OH$), 3.79 (1H, dm, J=12 Hz, $C_{1\beta}$–H), 7.90 (1H, d, J=2 Hz, C_{12}–H), 8.30 (1H, d, J=2 Hz, C_{14}–H). Found: C, 75.89; H, 8.91%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (15 g), using ether–benzene (1 : 3) as the eluent, to give additional **12** (49 mg: 28%).

11-Acetoxy-13-(methoxycarbonyl)podocarpa-8,11,13-trien-7-one (14). A mixture of **11** (638 mg), iodine (710 mg), and pyridine (12 ml) was refluxed for 3 h. The mixture was allowed to stand overnight at room temperature, diluted with water, and extracted with chloroform. The chloroform extract was washed successively with dilute hydrochloric acid, aqueous sodium thiosulfate, and brine. After drying over sodium sulfate, the solution was evaporated *in vacuo*. The residual oil in ethanol (15 ml) was refluxed for 3 h with aqueous sodium hydroxide (10%: 8.2 ml), cooled, acidified with dilute hydrochloric acid, and extracted with chloroform. The chloroform extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude acid. This crude acid was immediately methylated with diazomethane in ether and the resulting methyl ester was acetylated with acetic anhydride (3.0 ml) in pyridine (3.0 ml) at room temperature overnight. After the usual work-up, the crude product was chromatographed on silica gel (70 g), using ether–benzene (2 : 98) as the eluent, to give **14** (299 mg: 45%); $[\alpha]_D$ +55° (*c* 0.725); IR: 1768, 1728, 1690 cm^{-1}; ^{1}H NMR: 1.01 (6H, s, $-\dot{C}(CH_3)_2$), 1.36 (3H, s, C_{10}–CH_3), 2.30 (3H, s, $-OCOCH_3$), 3.89 (3H, s, $-CO_2CH_3$), 7.62 (1H, d, J=2 Hz, C_{12}–H), 8.45 (1H, d, J=2 Hz, C_{14}–H). Found: C, 70.65; H, 7.40%. Calcd for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31%.

13-(Methoxycarbonyl)podocarpa-6,8,11,13-tetraen-11-ol (15). A mixture of **14** (152 mg) and sodium borohydride (24 mg) in methanol (4.0 ml) was stirred at 0—5 °C for 1 h and at room temperature for 2 h. After the addition of acetone, the mixture was evaporated *in vacuo*. The residue was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium

sulfate, and evaporated *in vacuo* to give the corresponding alcohol.

A mixture of the above crude alcohol and *p*-toluenesulfonic acid (3.0 mg) in benzene (15 ml) was refluxed for 1 h, cooled, and then diluted with ether. The ether solution was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (15 g), using ether–benzene (1 : 99) as the eluent, to give **15** (116 mg: 90%). This was recrystallized from hexane; mp 147.5—149 °C; $[\alpha]_D$ −73° (*c* 1.11); IR: 3590, 3430, 1705 cm^{-1}; ^1H NMR ($CDCl_3$): 0.98 and 1.03 (each 3H and s, $-C(CH_3)_2$), 1.13 (3H, s, C_{10}–CH_3), 2.20 (1H, t, J=3 Hz, $C_{5\alpha}$–H), 3.00 (1H, m, $C_{1\beta}$–H), 3.89 (3H, s, $-CO_2CH_3$), 6.03 (1H, dd, J=10 and 3 Hz, C_6–H), 6.17 (1H, s, C_{11}–OH), 6.48 (1H, dd, J=10 and 3 Hz, C_7–H), 7.27 (1H, d, J=2 Hz, C_{12}–H), 7.43 (1H, d, J=2 Hz, C_{14}–H). Found: C, 75.98; H, 8.18%. Calcd for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05%.

*13-(Methoxycarbonyl)podocarpa-8,11,13-trien-11-ol (**16**).* A mixture of **15** (169 mg) and 5% Pd–C (80 mg) in ethanol (5.0 ml) was submitted to catalytic hydrogenation with 1 atm hydrogen pressure at room temperature for *ca.* 2 h. After the usual work-up, the crude product was recrystallized from hexane to give **16** (118 mg: 69%); mp 180—181 °C; $[\alpha]_D$ +73° (*c* 1.56); IR: 3600, 3410, 1708 cm^{-1}; ^1H NMR ($CDCl_3$): 0.94 and 0.97 (each 3H and s, $-C(CH_3)_2$), 1.34 (3H, s, C_{10}–CH_3), 2.88 (2H, m, C_7–H_2), 3.18 (1H, dm, J=13 Hz, $C_{1\beta}$–H), 3.89 (3H, s, $-CO_2CH_3$), 5.97 (1H, bs, C_{11}–OH), 7.31 (2H, bs, C_{12}–H and C_{14}–H). Found: C, 75.54; H, 8.70%. Calcd for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67%. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (5.0 g), using ether–benzene (2 : 98) as the eluent, to give additional **16** (33 mg: 19%).

*13-(Hydroxymethyl)podocarpa-8,11,13-trien-11-ol (**17**).* A mixture of **16** (149 mg) and lithium aluminium hydride (38 mg) in dry ether (10 ml) was refluxed for 2 h. The mixture was cooled, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was recrystallized from chloroform–hexane to give **17** (97 mg: 72%); mp 153—154 °C; $[\alpha]_D$ +77° (*c* 0.830); IR: 3600, 3330 cm^{-1}; ^1H NMR ($CDCl_3$): 0.94 and 0.96 (each 3H and s, $-C(CH_3)_3$), 1.32 (3H, s, C_{10}–CH_3), 2.18 (1H, bs, $-CH_2O\underline{H}$), 2.82 (2H, m, C_7–H_2), 3.13 (1H, dm, J=13 Hz, $C_{1\beta}$–H), 4.50 (2H, bs, $-C\underline{H}_2OH$), 5.73 (1H, bs, C_{11}–OH), 6.52 and 6.56 (each 1H and bs, C_{12}–H and C_{14}–H). Found: C, 79.00; H, 9.77%. Calcd for $C_{18}H_{26}O_2$: C, 78.79; H, 9.55%. The mother liquor of recrystallization was evaporated *in vacuo* and the residue was chromatographed on silica gel (5.0 g), using ether–benzene (1 : 1) as the eluent, to give additional **17** (33 mg: 24%).

*13-(Hydroxymethyl)podocarpa-8,12-diene-11,14-dione (**18**).* A solution of aqueous sodium dihydrogenphosphate [0.17 M (1 M=1 mol dm^{-3}): 4.0 ml] and Fremy's salt (150 mg) in water (8.0 ml) was added at 45 °C to a stirred solution of **17** (30 mg) in methanol (9.0 ml) over a period of 13 min. After being stirred at this temperature for 45 min, additional methanol (3.0 ml) and a solution of aqueous sodium dihydrogenphosphate (0.17 M: 4.0 ml) and Fremy's salt (150 mg) in water (8.0 ml) were added. The mixture was stirred at 45 °C for 45 more min, cooled, diluted with water, and extracted with chloroform. The chloroform extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (5.0 g), using ether–benzene (8 : 92) as the eluent, to give **18** (23 mg: 72%) as an oil; $[\alpha]_D$ −88° (*c* 1.01); IR: 3360, 1645 cm^{-1}; ^1H NMR: 0.92 and 0.94 (each 3H and s, $-C(CH_3)_2$), 1.26 (3H, s, C_{10}–CH_3), 4.37 (2H, bs, $-C\underline{H}_2OH$), 6.49 (1H, t, J=1.15 Hz, C_{12}–H). Found: C, 74.93; H, 8.39%. Calcd for $C_{18}H_{24}O_3$: C, 74.97; H, 8.39%.

*11,14-Diacetoxy-13-(acetoxymethyl)podocarpa-8,11,13-triene (**2**).* A mixture of **18** (47 mg), zinc (53 mg), acetic anhydride (0.5 ml), and pyridine (0.5 ml) was stirred at 0—5 °C for 10 min and then at room temperature for 1 h. The reaction mixture was filtered and the filtrate was diluted with ether. The ether solution was washed successively with aqueous sodium hydrogencarbonate, dilute hydrochloric acid, and brine. After drying over sodium sulfate, the ether solution was evaporated *in vacuo* to give an oil, whose IR spectrum showed a hydroxyl absorption band at 3330 cm^{-1}. The crude oil was immediately acetylated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) at *ca.* 95 °C for 10 min. After the usual work-up, the crude product was chromatographed on silica gel (5.0 g), using ether–benzene (5 : 95) as the eluent, to give **2** (60 mg: 88%) as an oil; MS (*m/e*): 416 (M^+); $[\alpha]_D$ +61° (*c* 0.785); IR: 1765, 1745 cm^{-1}; ^1H NMR: 0.92 and 0.96 (each 3H and s, $-C(CH_3)_2$), 1.26 (3H, s, C_{10}–CH_3), 1.98 (3H, s, $-CH_2OCOC\underline{H}_3$), 2.24 (6H, s, C_{11}–$OCOCH_3$ and C_{14}–$OCOCH_3$), 2.60 (3H, m, $C_{1\beta}$–H and C_7–H_2), 4.87 (2H, bs, $-CH_2OAc$), 6.78 (1H, bs, C_{12}–H). ^1H NMR spectrum for natural 15-acetoxypremnol diacetate:[1] 0.90, 0.93, and 1.18 (each 3H and s, 3–CCH_3), 1.92, 2.13, and 2.16 (each 3H and s, 3–$OCOCH_3$), 2.45 (1H, dm, $C_{1\beta}$–H), 2.85 (2H, m, C_7–H_2), 4.86 (2H, s, $-C\underline{H}_2OAc$), 6.91 (1H, s, an aromatic proton). The ^1H NMR spectrum of **2** was not identical with that of natural 15-acetoxypremnol diacetate.

*11,14-Diacetoxy-13-(acetoxymethyl)podocarpa-8,11,13-trien-7-one (**19**).* A solution of chromium trioxide (35 mg) in acetic acid (0.16 ml) and water (0.04 ml) was added dropwise to a stirred solution of **2** (48 mg) in acetic acid (0.72 ml) at room temperature over a period of 3 min. The mixture was stirred at the same temperature for 15 h, poured into brine, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (5.0 g), using ether–benzene (5 : 95) as the eluent, to give the starting **2** (23 mg: 47%). Further elution with the same solvent afforded **19** (17 mg: 34%) as an oil; $[\alpha]_D$ +72° (*c* 0.615); IR: 1763, 1745, 1685 cm^{-1}; ^1H NMR: 0.98 (6H, s, $-C(CH_3)_2$), 1.31 (3H, s, C_{10}–CH_3), 1.99 (3H, s, $-CH_2OCOC\underline{H}_3$), 2.26 (6H, s, C_{11}–$OCOCH_3$ and C_{14}–$OCOCH_3$), 4.95 (2H, bs, $-C\underline{H}_2$-OAc), 7.09 (1H, s, C_{12}–H). Found: C, 66.95; H, 7.20%. Calcd for $C_{24}H_{30}O_7$: C, 66.96; H, 7.02%.

The authors are grateful to Professor Ch. B. Rao for kindly supplying the spectral data of natural products.

(Received May 4, 1982)

Three potential biosynthetic intermediates for aminocyclitol antibiotics, neosamine C-CDP, -UDP, and -ADP, have been synthesized from D-glucosamine by chemical means. 2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl phosphate, derived from the corresponding glycosyl bromide, was condensed with three nucleosides (CMP, UMP and AMP) by a known procedure. The configurations of the neosamine C nucleoside diphosphates have been confirmed by ^{13}C NMR spectra.

In the last decade, the biosynthesis of aminocyclitol antibiotics (neomycin, gentamicin, spectinomycin, streptomycin, and related compounds) has been investigated actively in several laboratories.[1] Of the subunits of the antibiotics, the amino sugars and aminocyclitols are constructed from rather simple sugars (usually, D-glucosamine and D-glucose) as primary metabolites. These results were obtained largely by incorporation experiments involving both radioisotope-labeled and stable isotope-labeled sugars. However, the reactions involved in bond-formation between the amino sugars and the aminocyclitols are far less understood. Thus, while it is well known that D-glucosamine is incorporated into neomycin, there are two possible pathways for this incorporation (Scheme 1). In one pathway neosamine C (2,6-diamino-2,6-dideoxy-D-glucose) is converted to a nucleoside diphosphate and attached directly to deoxystreptamine to give neamine. In the second pathway D-glucosamine is converted to a nucleoside diphosphate, then attached to deoxystreptamine to give paromamine, which is subsequently aminated at C-6″ to give neamine, In both cases, an amino sugar serves as a glycosyl donor from its nucleoside diphosphate for transfer to the aminocyclitol moiety.

A large number of sugar nucleoside diphosphates have been identified in nature[2] (in higher plants, microorganisms, *etc.*) and many of the naturally occurring sugar nucleoside diphosphates are thought to be glycosyl donors in the formation of oligo- and polysaccharides in living systems.[3] A number of naturally occurring sugar nucleoside diphosphates possess *N*-acetyl-D-glucosamine as the amino sugar[4] and nucleoside diphosphates of *N*-acetylglucosamine have been synthesized not only for biosynthetic research, but also for the elucidation of the reactivity of sugar phosphate esters. For example, Jeanloz *et al.*,[5] recently synthesized uridine 5′-(2-acetamido-2-deoxy-α-D-mannopyranosyluronic acid di-

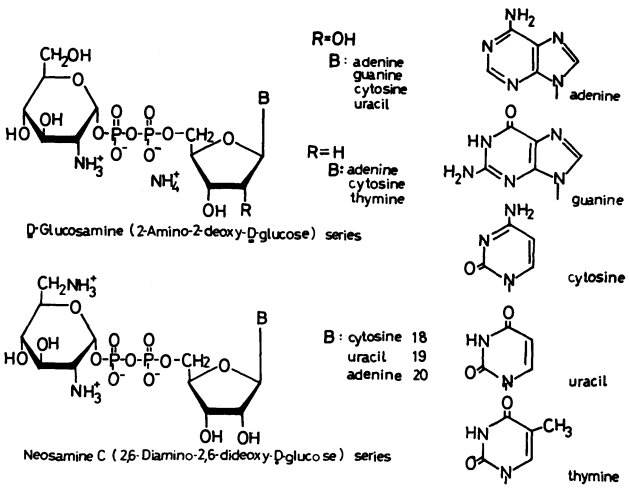

Fig. 1.

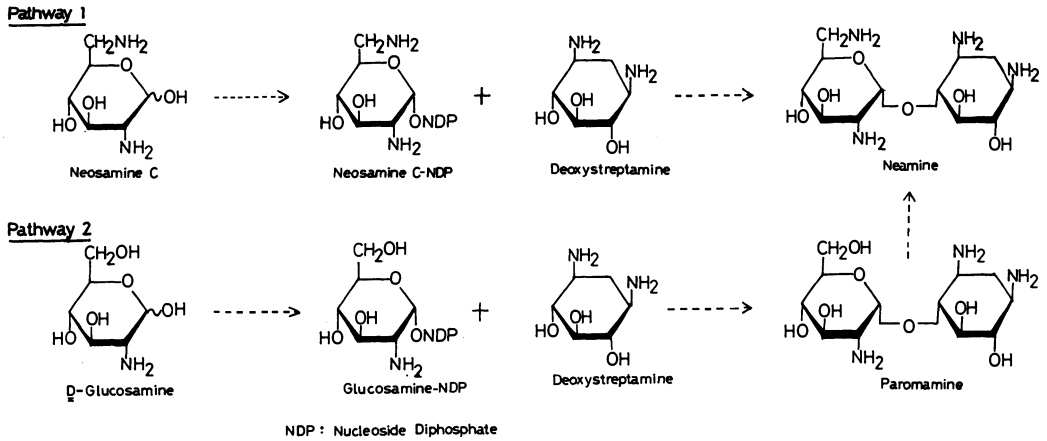


Scheme 1.

phosphate), which is considered to be a glycosyl donor to lipids in *Micrococcus lysodeikticus*. To our best knowledge, however, only one report[6] has appeared on chemical (rather than enzymatic) synthesis of a nucleoside diphosphate containing free D-glucosamine (or other free amino sugar) as the sugar moiety.

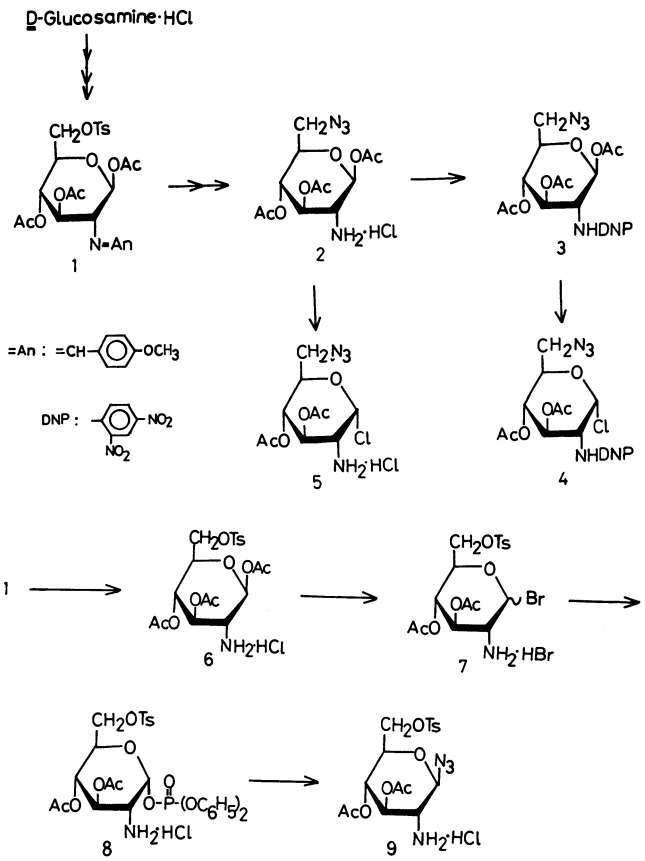
In order to investigate the second possibility, we recently synthesized[7] seven nucleoside diphosphates of glucosamine, namely, dTDP-, UDP-, CDP-, ADP-, GDP-, dCDP-, and dADP-glucosamines (Fig. 1) by chemical means and used the same procedure to synthesize several nucleoside diphosphates of D-[1-^3H]-glucosamine from the labeled D-glucosamine.

In the present communication, we describe the synthesis of three neosamine C nucleoside diphosphates, namely, cytidine-, uridine-, and adenosine-5′-(2,6-diamino-2,6-dideoxy-α-D-glucopyranosyl diphosphates, **18**—**20**, respectively, compounds which can be employed in examining the first biosynthetic pathway of Scheme 1, *i.e.*, that neosamine is transferred directly to deoxystreptamine.

Initially, we examined the stability of a protected D-glucosaminyl phosphate (diphenyl 3,4,6-tri-*O*-acetyl-α-D-glucosaminyl phosphate hydrobromide) prepared previously by us[7] in basic media: (1) In pyridine at room temperature for 3 h, (2) in *N*,*N*-dimethylformamide containing sodium azide at 120 °C for 30 min, (3) in ammonia-saturated methanol at 5 °C for 23 h, and (4) in methanol containing aqueous sodium hydrogencarbonate at room temperature for 70 min. Under all conditions, phosphate bond cleavage (C–O–P) was observed, so a route to neosamine C nucleoside diphosphates involving introduction of an amino group (or its equivalent) at C-6 of the glucosaminyl phosphate was abandoned.

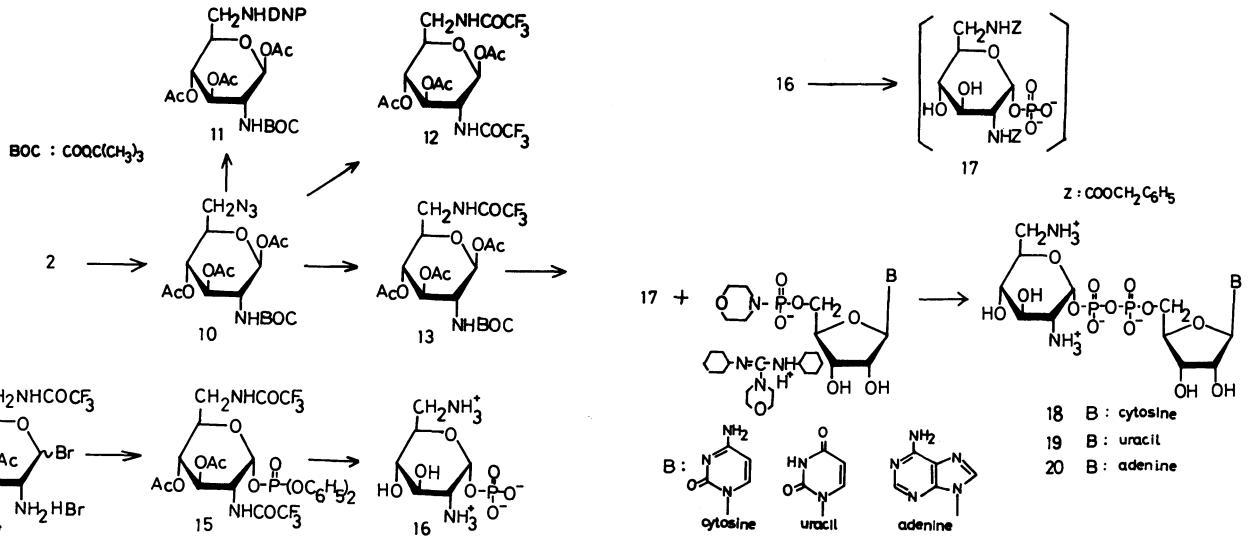
Next, introduction of an amino group at C-6 of D-glucosamine prior to formation of the sugar phosphate ester was investigated. D-Glucosamine hydrochloride was converted to the *N*,*O*-protected 6-*O*-tosylate (**1**) by a known procedure,[8] then to the known 6-azido derivative (**2**).[9] In order to introduce a phosphate ester and an α-linkage at the anomeric center, protection of the 2-amino group with a non-participating functionality is essential. For this purpose, **2** was converted to its *N*-(2,4-dinitrophenyl) derivative (**3**), then to the corresponding α-glucosaminyl chloride (**4**) by a known procedure.[9] In addition, **2** was converted to the glycosyl chloride (**5**) possessing a free amino group at C-2. Both of the α-glucosaminyl chlorides, **4** and **5**, were treated with diphenyl hydrogenphosphate in dry benzene in the presence of triethylamine (the same procedure employed for phosphorylation of D-glucosaminyl bromide).[7] At room temperature no phosphate was introduced in either case. At elevated temperature (45 to 80 °C for 4 to 5 h) a complex mixture was formed, as shown by TLC, and the mixture was not further investigated.

In the next attempted synthesis, a 6-*O*-tosylate possessing a free amino group at C-2 (**6**) was prepared by acid treatment of **1** and converted to the glycosyl bromide (**7**) (of undetermined anomeric cofiguration), since in general, glycosyl bromides are more reactive



than the corresponding chlorides. Treatment of **7** with diphenyl hydrogenphosphate at room temperature for 18 h gave the desired α-linked phosphate (**8**) in 35% yield. The α-linkage was confirmed by the ^1H NMR spectrum (showing a triplet at δ 6.22, $J_{1,2}=J_{1,P}=4.5$ Hz, for H-1). It has been reported that ^1H-^{31}P coupling in an R_2CH–O–P system is 5 to 7 Hz.[10] Substitution of the 6-*O*-tosyl group by the azido group was tried (sodium azide in acetonitrile at 55 °C for 3 h). The predominant product, isolated as crystals was the glycosyl azide (**9**) instead of the expected 6-azido derivative. Disappearance of the phenoxy protons and presence of the tosylate protons were observed in the ^1H NMR spectrum of **9**. Furthermore, an azido group absorption (2090 cm^{-1}) appeared in the IR spectrum of **9** and elemental analyses also supported the glycosyl azide structure. Thus, introduction of the amino group at C-6 prior to phosphate formation, appears indispensible.

In the successful synthesis the free amino group in **2** was temporarily protected with a *t*-butoxycarbonyl group to afford **10**. The azido group of **10** was hydrogenated and the amino group formed was treated with 2,4-dinitrofluorobenzene to afford **11**. Compound **10** was also converted to **12** and **13** by hydrogenolysis, followed by trifluoroacetylation. When trifluoroacetylation of the 6-amino group was carried out in dichloromethane, cleavage of the 2-*N*-*t*-butoxycarbonyl group occurred, so that subsequent 2,6-di-*N*-trifluoroacetylation affored **12** as the sole product in low yield (39%); the structure was confirmed by its ^1H NMR and IR spectra. On the other hand, when *N*-trifluoroacetylation



in dichloromethane was carried out in the presence of pyridine, only 6-*N*-acetylation was observed and **13** was isolated in 72% yield from **10**. Compound **13** was then converted in quantitative yield to the glycosyl bromide (**14**) by treatment of hydrobromic acid in acetic acid at room temperature for 16 h. During this strong acid treatment removal of the *N*-*t*-butoxycarbonyl group occurred simultaneously. Because of its low solubility in several organic solvents, the configuration of the anomeric center of **14** could not be determined.

Without further purification, **14** was treated with diphenyl hydrogenphosphate (1 molar equivalent) in dry benzene in the presence of triethylamine at room temperature for 1 h. The glycosyl phosphate formed (TLC: R_f 0.48, $PhCH_3$: EtOH=5 : 1) was quite unstable on silicic acid, so purification at this stage was avoided and the free amino on C-2 was immediately protected with a trifluoroacetyl group to afford **15** in 86% yield form **14**. Since the yield during formation of glycosyl phosphates is, in general, moderate or low, the yield of **15** is remarkable. An α-configuration in **15** was confirmed by its ^1H NMR spectrum (H-1, δ 5.95, doublet of doublets, $J_{1,2}$=4 Hz, $J_{1,P}$=6 Hz).

Deprotection of **15** was achieved by hydrogenolysis (removing the phenyl group on the phosphate), followed by saponification. 2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl phosphate (**16**) was purified by ion exchange and its structure was confirmed by ^1H and ^{13}C NMR spectra. In the ^1H NMR spectrum of **16** a doublet of doublets (H-1, δ 5.66, $J_{1,2}$=3.2 Hz, $J_{1,P}$=7.2 Hz) revealed the existence of an α-glycosyl phosphate. The ^{13}C NMR spectrum of **16** resembled the spectrum of α-D-glucosaminyl phosphate,[7] except for the chemical shift of C-6 (at δ 41.4 for **16** and at δ 61.1 for the glucosaminyl phosphate), indicative of the replacement of a hydroxyl group by an amino group. The coupling constants between the phosphorus nucleus and C-1 and C-2 were approximately equal to those of the glucosaminyl phosphate ($J_{C,P}$=4.3 Hz for C-1, and $J_{C,P}$=8.5 Hz for C-2 in **16**; 4.9 Hz and 7.8 Hz, respectively, in the glucosaminyl phosphate). At this stage, we had in hand the desired neosamine C phosphate **16** in moderate overall yield from D-glucosamine, and the remaining problem to synthesis of the final amino sugar nucleoside diphosphate was the condensation of **16** with the nucleoside 5′-monophosphates. Several examples[11] are known of the condensation reaction and we intended to use a procedure slightly modified from that of Khorana and Moffatt[12] employing nucleoside 5′-phosphoromorpholidate as phosphate donors. However, **16** has an extremely low solubility in organic solvents for the condensation (including *N*,*N*-dimethylformamide, dimethyl sulfoxide, and hexamethylphosphoric triamide), even at elevated temperature. To convert **16** to a more soluble derivative, the 2- and 6-amino groups of **16** were converted to their benzyloxycarbonyl derivatives. The bis(*N*-benzyloxycarbonyl) derivative (**17**), without isolation, was dissolved in dry pyridine and condensed with nucleoside (cytidine, uridine, and adenosine) 5′-phosphoromorpholidate (as their *N*,*N*′-dicyclohexyl-4-morpholinecarboxamidine salts). The mixtures were stirred at room temperature for 5 to 12 d. After catalytic hydrogenolysis to remove the *N*-benzyloxycarbonyl groups, the reaction mixtures were purified on Dowex 1×8 (formate) column. The desired three neosamine C NDP's (**18**—**20**) were eluted with dilute formic acid, and their structures were established by ^1H and ^{13}C NMR spectra. Though the yields were unsatisfactory (20% for neosamine C-CDP, (**18**); 34% for neosamine C-UDP, (**19**); and 33% for neosamine C-ADP, (**20**)), **18**—**20** were predominant products in the reaction mixtures. All of the carbons in **18**—**20** were assigned in their ^{13}C NMR spectra from the chemical shifts of nucleoside 5′-monophosphates[13] and those of **16**. Four doublets are observed in the sugar skeleton carbon region, and those are attributed to C-4 ($J_{C,P}$>8 Hz) and C-5 ($J_{C,P}$<6 Hz) on D-ribose, and C-1 ($J_{C,P}\approx$5 Hz) and C-2 ($J_{C,P}$>8 Hz) on neosamine C. These patterns are typical for sugar nucleoside diphosphates. The three neosamine C NDP's were also characterized by their fast atom bombardment (FAB) mass spectra, which in each case gave the expected M+H peak in the positive ion mode: *m*/*z* 564 for neosamine C-CDP, 565 for -UDP, and 588 for -ADP.

In spite of rather low yields in the final condensation reaction, the synthesis developed in this communication is applicable for a general synthesis of free amino sugar nucleoside diphosphates.

Experimental

Melting points were determined with a Büchi apparatus (Model 510) and are uncorrected. Solutions were evaporated under diminished pressure at a bath temperature below 40 °C. Specific rotations were measured in a 1-dm tube with a JEOL DIP-4 polarimeter. TLC was performed on glass plates coated with Wako Gel B-5 F, and compounds were detected by UV light and by spraying with sulfuric acid followed by heating. Cellulose TLC was performed on plastic sheets coated withc ellulose (Eastman Chromatogram Sheet, 13254); 0.2% ninhydrin–pyridine solution was used for visualization of amino sugars. IR spectra were recorded with a Hitachi Model-225 spectrometer. ^{1}H NMR (90 MHz) spectra were recorded with a Varian EM-390 spectrometer. ^{1}H NMR (100 MHz) and ^{13}C NMR (25 MHz) spectra were recorded with a Varian XL-100 spectrometer. Chemical shifts for $CDCl_3$ solutions are reported from internal tetramethylsilane, and chemical shifts for D_2O solutions are reported from internal DSS. Mass spectra were taken on a Varian MAT-731 mass spectrometer, using Xenon as the reagent gas. The FAB gun was an Ion Tech FAB gun, attached to either an Ion Tech or Spellman high voltage power supply. Elemental analyses were performed by Mr. Saburo Nakada of this university, to whom our thanks are due.

*1,3,4-Tri-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-6-*O*-tosyl-β-*D*-glucopyranose (**1**).* This compound was prepared from 2-deoxy-2-(*p*-methoxybenzylideneamino)-D-glucose by the method of Morel;[8] mp 198—199 °C, $[\alpha]_D^{22}$ +98.2° (*c* 2.0, $CHCl_3$) [lit,[8] mp 203—204 °C, $[\alpha]_D^{20}$ +99.3° (*c* 2, $CHCl_3$)].

*1,3,4-Tri-*O*-acetyl-2-amino-6-azido-2,6-dideoxy-β-*D*-glucopyranose Hydrochloride (**2**).* Compound **1** was converted to the 6-azide, then hydrolyzed to prepare the title compound by the known method;[9] mp 149 °C (decomp), $[\alpha]_{23}^{D}$ +53.1° (*c* 1, H_2O) [lit,[9] mp 147—154 °C (decomp), $[\alpha]_D^{25}$ +55.8° (*c* 1, H_2O)].

*1,3,4-Tri-*O*-acetyl-6-azido-2,6-deoxy-2-(2,4-dinitroanilino)-β-*D*-glucopyranose (**3**).* This compound was prepared from **2** by the known method;[9] mp 116—117 °C, $[\alpha]_D^{22.5}$ +99.0° (*c* 1, $CHCl_3$) [lit,[9] mp 115.5—116 °C, $[\alpha]_D^{29}$ +108° (*c* 1, $CHCl_3$)].

*3,4-Di-*O*-acetyl-6-azido-2,6-dideoxy-2-(2,4-dinitroanilino)-α-*D*-glucopyranosyl Chloride (**4**).* This glucosaminyl chloride was prepared from **3** by a slight modification of the known procedure.[9] Hydrogen chloride-saturated ether (0 °C, 30 ml) and acetyl chloride (3 ml) were added to 800 mg (1.61 mmol) of **3**, and the solution was stirred at room temperature in the dark for 19 h. Then, an additional 20 ml of hydrogen chloride-saturated ether was added after 22 h, and stirring was continued for 20 h more; TLC revealed the disappearance of **3** (R_f 0.22; $PhCH_3$: AcOEt=6 : 1) and the formation of a single product (R_f 0.29). The precipitated crystals were collected by filtration, washed with dry ether, and dried to afford 372 mg (73%) of **4** which was used without further purification: mp 173 °C (decomp), $[\alpha]_D^{21.5}$ +150° (*c* 1.0, $CHCl_3$) [lit,[9] mp 170 °C (decomp.), $[\alpha]_D^{25}$ +167° (*c* 1, $CHCl_3$)]; ^{1}H NMR (DMSO-d_6, 90 MHz): δ 1.87 (s, 3H, OAc), 2.09 (s, 3H, OAc), 3.37 (dd, 1H, $J_{6a,6b}$=13.8 Hz, $J_{5,6a}$=4.5 Hz, H-6a), 3.58 (dd, 1H, $J_{6a,6b}$=13.8 Hz, $J_{5,6b}$=3 Hz, H-6b), 4.24—4.49(m, 2H,H-2 and H-5), 5.26(t, 1H, $J_{3,4}$=$J_{4,5}$=9 Hz, H-4), 5.55 (t, 1H, $J_{2,3}$=$J_{3,4}$=9 Hz, H-3), 6.26 (d, 1H, $J_{1,2}$=3.6 Hz, H-1), 7.13 (d, 1H, $J_{5',6'}$=9.3 Hz, H-6′ of DNP), 8.28 (dd, 1H, $J_{5',6'}$=9.3 Hz, $J_{3',5'}$=2.7 Hz, H-5′), 8.75 (d, 1H, $J_{NH,2}$=9 Hz, NH), 9.10 (d, 1H, $J_{3',5'}$=2.7 Hz, H-3′).

*3,4-Di-*O*-acetyl-2-amino-6-azido-2,6-dideoxy-α-*D*-glucopyranosyl Chloride Hydrochloride (**5**).* Dry hydrogen chloride was introduced with ice cooling to a glacial acetic acid solution (50 ml) of **2** (500 mg, 1.36 mmol) containing 2 ml of acetyl chloride until the solution was saturated. The solution was stirred at room temperature in the dark for 24 h, then evaporated. The residue was coevaporated with toluene and triturated with chloroform (30 ml), insolbuble material was removed by filtration, and the filtrate was concentrated to half volume. After addition of 30 ml of ether the solution was cooled at 5 °C overnight. The precipitated crystals were collected by filtration and dried to afford 339 mg, which consisted of **5** and **2** in a 4 : 1 ratio based on the ^{1}H NMR spectrum and elemental analyses: IR (KBr) 2080 (N_3), 1760 (C=O) and 765 cm^{-1} (Cl); ^{1}H NMR (DMSO-d_6, 90 MHz) δ 2.01 (s, 3H, OAc), 2.05 (s, 3H, OAc), 2.16 (s, 0.6H, OAc), 3.53 (m, 3H, H-6a, H-6b, and H-2 or H-5), 4.00—4.25 (m, 1H, H-2 or H-5), 5.01 (t, 1H, $J_{3,4}$=$J_{4,5}$=9 Hz, H-4), 5.24 (t, 1H, $J_{2,3}$=$J_{3,4}$=9 Hz, H-3), 5.92 (d, 0.2H, $J_{1,2}$=8.7 Hz, H-1 on **2**), 6.68 (d, 0.8H, $J_{1,2}$=3.0 Hz, H-1 on **5**), 9.02 (bs, 3H, NH_3^+). The mixture was used without further purification. Found: C, 36.05; H, 4.79; N, 15.86; Cl, 18.42%. Calcd for $C_{12}H_{18}N_4O_7\cdot HCl$ (20%)+$C_{10}H_{15}ClN_4O_7\cdot HCl$ (80%): C, 35.86; H, 4.80; N, 16.12; Cl, 18.46%.

*1,3,4-Tri-*O*-acetyl-2-amino-2-deoxy-6-*O*-tosyl-β-*D*-glucopyranose Hydrochloride (**6**).* To a vigorously stirred solution of **1** (1.28 g, 2.22 mmol) in acetone (15 ml), 2 ml of 5 M hydrochloric acid was added dropwise at 55 °C. The mixture was stored at 5 °C overnight, and the precipitated white crystals were collected by filtration, then dried. The crude crystals were recrystallized from methanol to give 568 mg (52%) of **6**, mp 206 °C (decomp), which was used in the next step without further purification.

*3,4-Di-*O*-acetyl-2-amino-2-deoxy-6-*O*-tosyl-*D*-glucopyranosyl Bromide Hydrobromide (**7**).* A solution of 30% hydrogen bromide in acetic acid (20 ml) was added to a glacial acetic acid (40 ml) solution of **6** (518 mg, 1.04 mmol) and the mixture was stirred at room temperature for 20 h, then evaporated with toluene. The residue was triturated with chloroform, and the insoluble crystals were collected by filtration, washed with chloroform, and dried to afford 559 mg (95%) of **7**, mp 159 °C (decomp), which was used without further purification. Found: C, 36.58; H, 4.10; N, 2.33%. Calcd for $C_{17}H_{23}Br_2NO_8S$: C, 36.38; H, 4.13; N, 2.50%.

*Diphenyl 3,4-Di-*O*-acetyl-2-amino-2-deoxy-6-*O*-tosyl-α-*D*-glucopyranosyl Phosphate Hydrochloride (**8**).* Diphenyl hydrogenphosphate (Aldrich, 0.736 g, 2.94 mmol) and triethylamine (0.42 ml, 3.01 mmol) were added to a suspension of **7** (1.65 g, 2.94 mmol) in dry benzene (45 ml) containing triethylamine (0.42 ml, 3.01 mmol). After the mixture was stirred at room temperature in the dark for 18 h, TLC revealed the presence of a single product (R_f 0.52, positive to UV and ninhydrin, $PhCH_3$: EtOH=5 : 1). Precipitated triethylammonium bromide was removed by filtration and washed with benzene. The combined filtrate and washings were evaporated to afford a pale yellow syrup which was triturated with 2 M hydrochloric acid (10 ml) to give crystals, which were filtered, washed with cold water, and dried. The crude **8** obtained (1.87 g) was recrystallized from methanol and ether to afford 697 mg (35%) of pure **8**: mp 140 °C (sintered), 146 °C (decomp); $[\alpha]_D^{22}$ +88.8° (*c* 0.98, DMSO); ^{1}H NMR (DMSO-d_6, 90 MHz). δ 1.90 (s, 3H, OAc), 2.05 (s, 3H, OAc), 2.40 (s, 3H, Ts–CH_3), 3.48 (sb, 3H, NH_3^+), 3.70—4.11 (m, 4H, H-2, 5, 6a, 6b), 4.98 (t, 1H, $J_{3,4}$=$J_{4,5}$=9 Hz, H-4), 5.25 (t, 1H, $J_{2,3}$=$J_{3,4}$=9 Hz, H-3), 6.22 (t, 1H, $J_{1,2}$=$J_{1,P}$=4.5 Hz, H-1), 7.28 [m, 10H

OPO(OPh$_2$)], 7.41 and 7.66 (m, 4H, Ts-C$_6$H$_4$). Found: C, 49.64; H, 4.90; N, 1.78%. Calcd for $C_{29}H_{33}ClNO_{12}PS \cdot H_2O$: C, 49.47; H, 5.01; N, 1.99%.

3,4-Di-O-acetyl-2-amino-2-deoxy-6-O-tosyl-β-D-glucopyranosyl Azide Hydrochloride (9). After a mixture of **8** (150 mg, 0.219 mmol), sodium azide (178 mg, 2.74 mmol) and triethylamine (0.31 ml, 0.22 mmol) in acetonitrile (10 ml) was stirred at 55 °C for 3 h, TLC revealed the disappearance of **8** (R_f 0.10, $PhCH_3$: MEK=4 : 1) and the formation of two products (R_f 0.20 and 0.00). Insoluble material was removed, the filtrate was evaporated, and the residue was purified on silica gel column (Wako gel C-300, 9.5 g, 12 mm×145 mm, $PhCH_3$: EtOH=5 : 1). Fractions showing R_f 0.45 on TLC ($PhCH_3$: EtOH=5 : 1) were combined and evaporated to afford 51.1 mg of an oily residue, which was triturated with 2 M hydrochloric acid (3 ml). The precipitated crystals were collected and dried to afford 39.8 mg (38%) of **9**: mp 148 °C (decomp); $[\alpha]_D^{22.5}$ +11.6° (*c* 0.23, $CHCl_3$); IR (KBr) 2090 (N_3) and 1765 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$, 90 MHz) δ 1.96 (s, 3H, OAc), 2.03 (s, 3H, OAc), 2.43 (s, 3H, Ts-CH_3), 2.60—2.81 (m, 1H), 3.70—3.91 (m, 1H), 4.07 (d, 2H, J=4 Hz, H-6a and 6b), 4.41 (d, 1H, J=10 Hz, H-1), 4.82—4.92 (m, 2H), 7.29 and 7.73 (AB quartet, 4H, Ts-C$_6$H$_4$). Found: C, 42.36; H, 4.93; N, 11.39%. Calcd for $C_{17}H_{23}ClN_4O_8S$: C, 42.64; H, 4.84; N, 11.70%.

1,3,4-Tri-O-acetyl-6-azido-2-(t-butoxycarbonylamino)-2,6-dideoxy-β-D-glucopyranose (10). Di-*t*-butyl dicarbonate (4.97 g, 23.8 mmol) was added to a solution of **2** (6.58 g, 17.9 mmol) in a mixture of dioxane (60 ml) and water (30 ml) containing 1.71 g (20.3 mmol) of sodium hydrogencarbonate and the mixture was stirred at 0 °C for 2 h, then at room temperature for 16 h. Thin-layer chromatography revealed the disappearance of **2** (R_f 0.02; $PhCH_3$: MEK=5 : 1) and the formation of a sole product (R_f 0.35). The mixture was evaporated and the residue was extracted with ethyl acetate (150 ml). The organic extract was washed with water (150 ml; 75 ml×2), dried over anhydrous sodium sulfate, and evaporated. The crude crystals were recrystallized from ethanol and methanol to afford 6.44 g (84%) of **10**: mp 172—173 °C; $[\alpha]_D^{23}$ +18.5° (*c* 2.1, $CHCl_3$); IR (KBr) 2120 (N_3), 1760 (C=O), 1700 (NC=O), and 1530 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$, 90 90 MHz) δ 1.43 (s, 9H, $COOC(CH_3)_3$, 2.04 (s, 6H, OAc), 2.11 (s, 3H, OAc), 3.33 (d, 2H, J=4 Hz, H-6a and 6b), 3.63—3.83 (m, 2H, H-2 and H-5), 4.58 (d, 1H, $J_{NH,2}$=9 Hz, NH), 4.96 (t, 1H, $J_{3,4}=J_{4,5}$=9 Hz, H-4), 5.15 (1H, $J_{2,3}=J_{3,4}$=9 Hz, H-3), and 5.65 (d, 1H, $J_{1,2}$=9 Hz, H-1). Found: C, 47.30; H, 5.94; N, 12.77%. Calcd for $C_{17}H_{26}N_4O_9$: C, 47.44; H, 6.09; N, 13.02%.

1,3,4-Tri-O-acetyl-2-(t-butoxycarbonylamino)-2,6-dideoxy-6-(2,4-dinitroanilino)-β-D-glucopyranose (11). A solution of **10** (696.3 mg, 1.62 mmol) in a mixture of ethyl acetate (5 ml) and ethanol (50 ml) containing 0.27 ml of 6 M hydrochloric acid was hydrogenated at room temperature in the presence of 10% palladium on charcoal (70 mg) under 345 kPa initial hydrogen atmosphere. After 2.5 h, TLC revealed the disappearance of **10** (R_f 0.36; $PhCH_3$: MEK=5 : 1) and the formation of a single ninhydrin-positive product (R_f 0.00). The catalyst was removed by filtration and the filtrate was evaporated to afford white crystals, which were dissolved in ethanol (7 ml). 2,4-Dinitrofluorobenzene (750 mg, 4.03 mmol) in acetone (28 ml) and sodium hydrogencarbonate (325.5 mg, 3.88 mmol) were added, and the mixture was stirred at room temperature in the dark for 24 h. Thin-layer chromatography revealed the formation of a single product (R_f 0.33, $PhCH_3$: MEK=4 : 1). After evaporation of the mixture, the residue was extracted with chloroform, insoluble material was removed by filtration, and the filtrate was evaporated. The residue was purified on silica gel (Wako gel C-300, 40 g, 23 mm×220 mm, $PhCH_3$: MEK=4 : 1). Fractions showing R_f 0.33 were combined and evaporated to afford crude crystals which were recrystallized from chloroform and ethanol to yield 717 mg (78%) of **11**: mp 238 °C (decomp), $[\alpha]_D^{23}$ +38.3° (*c* 1.9, $CHCl_3$); IR (KBr) 3360 (NH), 1755 (C=O), 1695 (NC=O), 1620 (C=C), 1590 (NO_2), 1525 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$, 90 MHz) δ 1.42 [s, 9H, $COOC(CH_3)_3$], 2.06 (s, 3H, OAc), 2.12 (s, 6H, 2×OAc), 3.39—3.95 (m, 4H, H-2, H-5, H-6a, and H-6b), 4.61 (d, 1H, $J_{NH,2}$=10 Hz, H-2), 4.97 (t, 1H, $J_{3,4}=J_{4,5}$=9 Hz, H-4), 5.25 (t, 1H, $J_{2,3}=J_{3,4}$=9 Hz, H-3), 5.65 (d, 1H, $J_{1,2}$=9 Hz, H-1), 6.91 (d, 1H, $J_{5',6'}$=9 Hz, H-6′ of DNP group), 8.18 (dd, 1H, $J_{5',6'}$=9 Hz, $J_{3',5'}$=3 Hz, H-5′), 8.79 (t, 1H, $J_{NH,6}$=6 Hz, NH), 9.06 (d, 1H, $J_{3',5'}$= 3 Hz, H-3′). Found: C, 48.19; H, 5.27; N, 9.56%. Calcd for $C_{23}H_{30}N_4O_{13}$: C, 48.42; H, 5.30; N, 9.82%.

1,3,4-Tri-O-acetyl-2,6-dideoxy-2,6-bis(trifluoroacetamido)-β-D-glucopyranose (12). Compound **10** (568 mg, 1.32 mmol) was hydrogenated as described for the preparation of **11**, and the crude crystals were dissolved in 20 ml of dry dichloromethane and acylated by adding 1.0 ml (7.19 mmol) of trifluoroacetic anhydride dropwise with mechanical stirring under ice cooling. After the mixture had been stirred at room temperature for 16 h, TLC revealed a single product (R_f 0.40; $PhCH_3$: MEK=3 : 1). The mixture, diluted with 20 ml of dichloromethane, was washed with aqueous sodium hydrogencarbonate until neutral, then with water (20 ml; 10 ml×2), then dried (Na_2SO_4). Evaporation of the extract gave crude crystals which were recrystallized from chloroform–ether to afford 220 mg (39%) of **12**: mp 220—221 °C (decomp); $[\alpha]_D^{23}$ +2.1° (*c* 0.98, MeOH); IR (KBr) 1760 (C=O), 1710 (NC=O), 1555 (NH), 1220 and 1180 (C-F) cm^{-1}; ^{1}H NMR (CD_3OD, 90 MHz) δ 1.95 (s, 3H, OAc), 2.01 (s, 3H, OAc), 2.04 (s, 3H, OAc), 3.43—4.39 (m, 4H, H-2, H-5, H-6a and H-6b), 4.67 (t, 1H, $J_{3,4}=J_{4,5}$=9 Hz, H-4), 5.27 (t, 1H, $J_{2,3}=J_{3,4}$=9 Hz, H-3), 5.75 (d, 1H, $J_{1,2}$=9 Hz, H-1). Found: C, 38.83; H, 3.78; N, 5.71%. Calcd for $C_{16}H_{18}F_6N_2O_9$: C, 38.72; H, 3.65; N, 5.64%.

1,3,4-Tri-O-acetyl-2-(t-butoxycarbonylamino)-2,6-dideoxy-6-trifluoroacetamido-β-D-glucopyranose (13). Compound **10** (991 mg, 2.30 mmol) was hydrogenated as described above and the crude 6-amino derivative in dry dichloromethane (30 ml) and dry pyridine (8 ml) was *N*-acylated directly by adding trifluoroacetic anhydride (0.55 ml, 3.95 mmol) under ice cooling. After the mixture had been stirred at room temperature for 30 min, TLC revealed a single product (R_f 0.51; $PhCH_3$: EtOH=5 : 1). The mixture was diluted with dichloromethane (40 ml) and the organic mixture was washed with diluted aqueous sodium hydrogencarbonate to neutrality, washed with water (80 ml; 40 ml×2), dried, and evaporated to afford a crystalline residue which was recrystallized from chloroform–ether to give 828 mg (72%) of **13**: mp 214 °C (decomp); $[\alpha]_D^{22}$ +20.8° (*c* 2.1, $CHCl_3$); IR (KBr) 1755 (C=O), 1700 (NC=O), 1525 (NH), 1220 and 1170 cm^{-1} (C-F); ^{1}H NMR ($CDCl_3$, 90 MHz) δ 1.41 [s, 9H, $COOC(CH_3)_3$], 2.02 (s, 3H, OAc), 2.04 (s, 3H, OAc), 2.09 (s, 3H, OAc), 3.21—3.95 (m, 4H, H-2, H-5, H-6a, and H-6b), 4.80 (d, 1H, $J_{NH,2}$= 9 Hz, 2-NH), 4.85 (t, 1H, $J_{3,4}=J_{4,5}$=9 Hz, H-4), 5.15 (t, 1H, $J_{2,3}=J_{3,4}$=9 Hz, H-3), 5.60 (d, 1H, $J_{1,2}$=9 Hz, H-1), 6.89 (t, 1H, $J_{NH,6}$=6 Hz, 6-NH). Found: C, 45.74; H, 5.35: N, 5.34%. Calcd for $C_{19}H_{27}F_3N_2O_{10}$: C, 45.60; H, 5.44; N, 5.60%.

3,4-Di-O-acetyl-2-amino-2,6-dideoxy-6-trifluoroacetamido-D-glucopyranosyl Bromide Hydrobromide (14). To a solution of **13** (305 mg, 0.609 mmol) in dry dichloromethane (3 ml), 25% hydrogen bromide in acetic acid (2.0 ml) was added dropwise under ice cooling. The stirred mixture gradually warmed

to room temperature, then was stirred 16 h longer, and finally was evaporated with toluene to afford 306 mg (quantitative) of crude bromide (**14**), mp 174—178 °C (decomp), which was used without further purification. Found: C, 28.42; H, 3.68; N, 5.77%. Calcd for $C_{12}H_{17}Br_2F_3N_2O_6$: C, 28.71; H, 3.41; N, 5.58%.

*Diphenyl 3,4-Di-O-acetyl-2,6-dideoxy-2,6-bis(trifluoroacetamido)-α-D-glucopyranosyl Phosphate (**15**).* Diphenyl hydrogenphosphate (Aldrich, 503 mg, 2.01 mmol) and triethylamine (0.60 ml, 4.30 mmol) were added to a suspension of **14** (1.01 g, 2.01 mmol) in dry benzene (distilled over sodium). The mixture was stirred at room temperature in the dark for 1 h, when TLC revealed formation of a UV-absorbing product (R_f 0.48; $PhCH_3$: EtOH=5 : 1). Triethylamine (1.20 ml, 8.60 mmol) and trifluoroacetic anhydride (0.60 ml, 4.31 mmol) were added to the mixture, under ice cooling, and the mixture was stirred at 0 °C for 30 min, when TLC revealed a single product with UV-absorption (R_f 0.60; $PhCH_3$: EtOH=5 : 1). The mixture was washed with water (80 ml; 20 ml×4), then dried (Na_2SO_4). After removal of the organic solvent, the residue was crystallized from methanol to yield 1.18 g (86%) of **15**: mp 128—132 °C (decomp); $[\alpha]_D^{27.5}$ +59.3° (*c* 0.72, $CHCl_3$); IR (KBr) 1750 (C=O), 1710 (NC=O), 1210, 1180 (C-F), and 970 cm^{-1} (P=O); ^1H NMR ($CDCl_3$, 90 MHz) δ 1.94 (s, 3H, OAc), 2.02 (s, 3H, OAc), 3.21—3.65, 4.06—4.52 (m,4H, H-2, H-5, H-6a and H-6b), 4.93 (t, 1H, $J_{3,4}$=$J_{4,5}$=9 Hz,H-4), 5.29 (t, 1H, $J_{2,3}$=$J_{3,4}$=9 Hz, H-3), 5.95 (dd, 1H, $J_{1,2}$=4 Hz, $J_{1,2}$=4Hz, $J_{1,P}$=6 Hz, H-1), 6.99—7.34 (m, 12H, phenyl, 2-NH and 6-NH). Found: C, 45.60; H, 3.84; N, 3.88%. Calcd for $C_{26}H_{25}F_6N_2O_{11}P$: C, 45.49; H, 3.67; N, 4.08%.

*2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl Phosphate (**16**).* A solution of **15** (120 mg, 0.174 mmol) in glacial acetic acid (5 ml) was hydrogenated in the presence of platinum oxide (30 mg) under 390 kPa initial hydrogen atmosphere at room temperature for 47 h. The catalyst was removed by filtration and the filtrate was evaporated to afford 93 mg of semicrystalline residue. The residue was dissolved in 2.6 ml of methanol and 1.12 ml of 1.25 M potassium methoxide in methanol was added. The mixture was stored at 5 °C for 96 h, an additional 0.56 ml of the base was added, and the mixture stood at room temperature for 20 h longer, when TLC (cellulose, *n*-BuOH : AcOH : H_2O=5 : 2 : 3) revealed two ninhydrin-positive products (R_f 0.36 and 0.27). The reaction mixture was applied to a Dowex 50W×8 column (pyridinium form, 7 ml wet volume, 9 mm×100 mm), which was eluted with water (40 ml), 0.01 M aqueous ammonia (24 ml) and 0.1 M aqueous ammonia (30 ml) successively (6-ml fractions). A concentrate of fractions 1 to 3 consisted of two products [R_f 0.36 and 0.27, BAW 523, IR (KBr) 1670 cm^{-1} (NC=O)], while a concentrate of fractions 13 to 15 (7.4 mg) consisted of pure **16** (R_f 0.27). The concentrate of fractions 1 to 3 (73 mg) was hydrolyzed under reflux for 2 h with 100 mg of sodium hydroxide in water (2 ml), when TLC revealed a single compound, **16**, (R_f 0.27), which was purified on an ion exchange column (Dowex 50W×8, pyridinium form, 2.5 ml wet volume, 6.5 mm×70 mm). The column was eluted with water (8 ml) and 0.1 M aqueous ammonia (10 ml) successively (2-ml fractions). Fractions 6 to 9 gave 14.9 mg (total 22.3 mg, 50%) of pure **16** mp 205 °C (decomp); $[\alpha]_D^{18.5}$ +33.1° (*c* 2.14, H_2O); IR (KBr) 3100 (NH), 1640 (NH), 1540 (NH), 1120 (P=O), 960 cm^{-1} (PO); ^1H NMR (D_2O, 100 MHz) δ 3.00—3.58 ,3.86—4.37 (m, 6H, H-2, H-3, H-4, H-5, H-6a, and H-6b), 5.66 (dd, 1H, $J_{1,2}$=3.2 Hz, $J_{1,P}$=7.2 Hz, H-1); ^{13}C NMR (D_2O, 25 MHz, TMS as internal standard) δ 41.4 (s, C-6), 55.4 (d, $J_{C,P}$=8.5 Hz, C-2), 69.6 (s, C-4), 70.6 (s, C-3), 72.5 (s, C-5), 92.0 (d, $J_{C,P}$=4.3 Hz, C-1). Found: C, 26.94; H, 5.75; N, 10.27%. Calcd for $C_6H_{15}N_2O_7 \cdot \frac{1}{2}H_2O$: C, 27.02; H, 5.86; N, 10.50%.

*Cytidine 5′-(2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl Diphosphate) (CDP-neosamine C) (**18**).* *N*-(Benzyloxycarbonyloxy)succinimide (68 mg, 0.27 mmol) in ethyl acetate (2 ml) was added to an aqueous solution (10 ml) of **16** (70.4 mg, 0.27 mmol) containing 23 mg (0.27 mmol) of sodium hydrogencarbonate. The mixture was stirred vigorously at 0 °C for 2 h, then at room temperature for 17 h. Additional *N*-benzyloxycarbonylating reagent (68 mg, 0.27 mmol) and sodium hydrogencarbonate (23 mg) were added, and stirring continued 15 h longer, when TLC (cellulose, *n*-BuOH : AcOH : H_2O=5 : 2 : 3) showed formation of the bis(benzyloxycarbonylamino) derivative (**17**) (R_f 0.70, UV absorbing). After removal of solvents by evaporation, the residue was dissolved in 50% aqueous ethanol in minimum volume, then applied on Dowex 50W×8 (pyridinium form, 6 ml wet volume). The column was eluted with 50% aqueous ethanol (50 ml), trioctylamine (0.14 ml, 0.32 mmol) was added to the eluate, and the aqueous solution was evaporated. The residue was coevaporated with dry pyridine (32 ml; 8 ml×4), finally dissolved in dry pyridine (10 ml), and cytidine 5′-phosphoromorpholidate *N,N′*-dicyclohexyl-4-morpholinecarboxamidine salt (Sigma, 187 mg, 0.27 mmol, dried over phosphorus pentaoxide *in vacuo* at 80 °C for 28 h) was added to the mixture, which was stirred at room temperature for 5 d, then evaporated. The residue was dissolved in 50% aqueous ethanol (7 ml) and hydrogenated in the presence of 10% palladium on charcoal (30 mg) under 390 kPa initial hydrogen atmosphere at room temperature for 48 h, when TLC (cellulose) revealed a mixture of six compounds (*n*-BuOH : AcOH : H_2O=5 : 2 : 3; R_f 0.70, 0.66, 0.54, 0.29, 0.27, and 0.15 with the latter compound predominant, each compound ninhydrin and/or UV-positive). The mixture was applied to a Dowex 1×8 column (formate form, 90 ml wet volume, 22 mm×260 mm), which was washed with water (200 ml), then gradient eluted with aqueous formic acid (0.0 M to 0.1 M, 4.5 ml fractions). Fractions showing R_f 0.15 were combined and evaporated with water to afford **18** (31.1 mg, 20% pure by TLC) as a colorless glass: $[\alpha]_D^{23}$ +36.5° (*c* 1.0, H_2O); ^1H NMR (D_2O, 90 MHz) δ 2.67—4.36 (m, 11H, H-2′, H-3′, H-4′, H-5′ of D-ribose, H-2″, H-3″, H-4″, H-5″, H-6″ of neosamine C), 5.67—5.90 (m, 3H, H-5 of cytosine, H-1′ and H-1″), 7.78 (d, 1H, $J_{5,6}$=7.5 Hz, H-6); ^{13}C NMR (D_2O, 25 MHz, TMS) δ 41.4 (s, C-6″), 54.9 (d, $J_{C,P}$=8.8 Hz, C-2″), 66.8 (d, $J_{C,P}$=6.1 Hz, C-5′), 70.4, 70.6, 71.2 (s's, C-3″, C-4″, and C-2′), 72.2 (s, C-5″), 75.1 (s, C-3′), 83.2 (d, $J_{C,P}$=8.7 Hz, C-4′), 90.6 (s, C-1′), 93.7 (d, $J_{C,P}$=5.4 Hz, C-1″), 97.5 (s, C-5), 142.3 (s, C-6), 155.9 (s, C-2), 174.6 (s, C-4); FABMS *m/z* 564 (M+H).

*Uridine 5′-(2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl Diphosphate) (UDP-neosamine C) (**19**).* Compound **16** (63.6 mg, 0.25 mmol) was converted to its bis(benzyloxycarbonyl) derivative, **17**, as described in the preparation of **18**. To 50 ml of the 50% aqueous ethanol eluate from the Dowex column, trioctylamine (0.14 ml, 0.32 mmol) was added. Evaporation was followed by evaporation with dry pyridine (32 ml, 8 ml×4) and finally, solution in dry pyridine (10 ml). Uridine 5′-phosphoromorpholidate *N,N′*-dicyclohexyl-4-morpholinecarboxamidine salt (Sigma, 198 mg, 0.29 mmol, dried prior to use) was added to the solution, and the mixture was stirred at room temperature for 12 d. After evaporation of the mixture, the residue was dissolved in 7 ml of 50% aqueous ethanol and hydrogenated for 69 h at room temperature in the presence of 10% palladium on charcoal (30 mg) under 390 kPa initial hydrogen atmosphere. Cellulose TLC (*n*-BuOH : AcOH: H_2O : 5 : 2 : 3) revealed five compounds (R_f 0.71, 0.44, 0.34, 0.28 and 0.16, all UV and/or ninhydrin positive with the latter compound predominant). The reaction mixture was applied

to a Dowex 1×8 column (formate form, 100 ml wet volume, 22 mm×310 mm), which was washed with water (80 ml) and gradient eluted with aqueous formic acid (0.0 M to 0.1 M, 4.5 ml fractions). Fractions showing R_f 0.16 (fractions 29 to 31) were combined and evaporated and finally coevaporated with water (12 ml, 6 ml×2) to afford 46.7 mg (34%) of TLC-homogeneous **19** as a colorless glass: $[\alpha]_D^{23}$ +35.2° (*c* 1.25, H_2O); ^1H NMR (D_2O, 100 MHz, TMS) δ 2.66—4.39 (m, 11H, H-2′, H-3′, H-4′, H-5′ on D-ribose and H-2″, H-3″, H-4″, H-5″, H-6″ on neosamine C), 5.79—5.96 (m, 3H, H-1′, H-1″, and H-5 on uracil), 7.88 (d, 1H, $J_{5,6}$=8.0 Hz, H-6); ^{13}C NMR (D_2O, 25 MHz, TMS) δ 41.4 (s, C-6″), 54.8 (d, $J_{C,P}$=9.4 Hz, C-2″), 66.8 (d, $J_{C,P}$=6.0 Hz, C-5′), 70.2, 70.4, 71.2 (each s, C-2′, C-3″, and C-4″), 72.1 (s, C-5″), 74.7 (s, C-3′), 83.2 (d, $J_{C,P}$=9.4 Hz, C-4′), 89.6 (s, C-1′), 93.2 (d, $J_{C,P}$=5.4 Hz, C-1″), 103.4 (s, C-5), 142.4 (s, C-6), 155.4 (s, C-2), 174.6 (s, C-4); FABMS *m/z* 565 (M+H).

*Adenosine 5′-(2,6-Diamino-2,6-dideoxy-α-D-glucopyranosyl Diphosphate) (ADP-neosamine C) (**20**).* The bis(benzyloxycarbonylamino) derivative (**17**) was prepared as described during the preparation of **18** [63.6 mg (0.25 mmol) of **16**, and 123 mg (0.49 mmol) of *N*-(benzyloxycarbonyloxy)succinimide]. To 50 ml of 50% aqueous ethanol eluate from the Dowex column, trioctylamine (0.14 ml, 0.32 mmol) was added and the mixture was evaporated with dry pyridine (32 ml, 8 ml×4) and finally dissolved in dry pyridine (10 ml). To the solution, adenosine 5′-phosphoromorpholidate *N,N′*-dicyclohexyl-4-morpholinecarboxamidine salt (Sigma, 193 mg, 0.27 mmol, dried prior to use) was added and the mixture was stirred at room temperature for 11 d. After evaporation of the mixture, the residue was dissolved in 7 ml of 50% aqueous ethanol and the solution was hydrogenated at room temperature for 68 h in the presence of 10% palladium on charcoal (30 mg) under 390 kPa initial hydrogen atmosphere. Cellulose TLC (*n*-BuOH : AcOH : H_2O=5 : 2 : 3) revealed five compounds (R_f 0.66, 0.51, 0.32, 0.25 and 0.18, all UV and/or ninhydrin-positive with the latter compound predominant). The reaction mixture was applied to a Dowex 1×8 column (formate form, 85 ml wet volume, 22 mm×250 mm), which was washed with water (80 ml), then gradient eluted with aqueous formic acid (0.0 M to 0.1 M, 4.5-ml fractions). Fractions showing R_f 0.18 (fractions 33 to 36) were combined and evaporated with water (12 ml, 6 ml×2) to afford 47.9 mg (33%) of TLC-homogeneous **20** as a colorless glass: $[\alpha]_D^{23}$ +26.9° (*c* 1.21, H_2O); ^1H NMR (D_2O, 100 MHz, TMS) δ 2.93—4.50 (m, 11H, H-2′, H-3′, H-4′, H-5′ of D-ribose, and H-2″, H-3″, H-4″, H-5″, H-6″ of neosamine C), 5.82 (dd, 1H, $J_{1,2}$=5.2 Hz, H-1′), 8.05 (s, 1H, H-2 of adenine), 8.34 (s, 1H, H-8); ^{13}C NMR (D_2O, 25 MHz, TMS) δ 40.3 (s, C-6″), 53.7 (d, $J_{C,P}$=8.8 Hz, C-2″), 65.4 (d, $J_{C,P}$=6.7 Hz, C-5′), 69.1, 69.3, 70.1, 71.0 (all s's, C-2′ C-3″, C-4″, C-5″), 74.3 (s, C-3′), 83.3 (d, $J_{C,P}$=9.4 Hz, C-4′), 87.1 (s, C-1′), 92.2 (d, $J_{C,P}$=5.4 Hz, C-1″), 117.9 (s, C-5), 139.6 (s, C-8), 148.2 (s, C-4), 151.4 (s, C-2), 154.1 (s, C-6); FABMS *m/z* 588 (M+H).

Structural Studies on Herqueinone. The Configurations at C-4 of Herqueinone and at C-3 and C-4 of Dihydroherqueinone Monomethyl Ether

Takamitsu Yoshioka, Toshifumi Hirata, Tadashi Aoki, and Takayuki Suga*
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received May 11, 1982)

On the basis of the ^{1}H NMR spectroscopy and the X-ray crystallography, the configuration at C-4 of herqueinone was determined to be *S* and the configurations at C-3 and C-4 of dihydroherqueinone monomethyl ether were elucidated to be *R* and *S*, respectively, with relation to the previously established *R*-configuration at the 2′-position of herqueinone.

In the structural studies of herqueinone (**1**) which is a main red pigment isolated from the mycelia of *Penicillium herquei*,[1-5] its structure, except for the absolute configuration, was described as **1** by relating herqueinone to atrovenetin (**2**).[6,7] The configuration at C-2′ of **1** was reported to be *R* on the basis of the studies on the stereochemistry of the degradation product originating from its trimethylfuran ring.[8] On the other hand, the relative configurations at C-3, C-4, and C-5 of "glycol A" derived from dihydroherqueinone were shown as **3** on the basis of the long-range coupling between 3-H and 5-H in the ^{1}H NMR spectrum.[7] However, the relative configurations between C-2′ and C-4 of **1** and **3** have not been clarified yet.

For the biosynthetic studies of herqueinone (**1**),[9,10] it was necessary to determine the configuration at C-4 of **1** for clarifying the mechanism of the prenylation of the phenalenone skeleton. We therefore studied the configuration at C-4 of **1** and the configurations at C-3 and C-4 of dihydroherqueinone monomethyl ether (**4**) on the basis of the ^{1}H NMR spectroscopy and the X-ray crystallography. The results have been partly outlined in the form of the preliminary communications.[11,12] We will here report details of the results.

Results and Discussion

Herqueinone (1) and Dihydroherqueinone Monomethyl Ether (4). Herqueinone (**1**) was isolated from the mycelia of *Penicillium herquei* in the manner as described in the experimental part and identified by comparing its mp and ^{1}H NMR, IR, and UV spectra with those described in the literatures.[2,7] According to the method given in the literature,[7] dihydroherqueinone monomethyl ether (**4**) was prepared from the herqueinone (**1**) by hydrogenation followed by methylation. All the physical and spectral data of **4** are in fair agreement with the data described in the literature.[7] The configurations at C-4 of **1** and **4** were investigated by use of the ^{1}H NMR spectroscopy and the X-ray crystallography as follows.

^{1}H NMR Spectroscopic Study. The carbon atom at the 3′-position of herqueinone (**1**) has the geminal dimethyl groups which are composed of the C-4′ methyl group occupying the *pro-R* position and the C-5′ methyl group doing the *pro-S* position. The ^{1}H NMR signals at δ_H 1.00 and 1.40 were assigned to the C-4′ and C-5′ methyl groups, respectively, on the basis of the nuclear Overhauser effect (NOE),[13] which is shown in **1** of Fig. 1.[14]

The configuration at C-4 of **1** was determined by the application of the anisotropic effect[15-17] to the C-4′ and C-5′ methyl groups, as follows. Models[18] for **1** were examined; the distances between the center of the carbonyl double bond and the geminal dimethyl groups are estimated to be 2.5 Å and 3.5 Å, and the angles between the vectors from the center of the carbonyl double bond to the geminal dimethyl groups and the vector of the carbonyl dipole moment are about 35° and 75°. These data indicate that these methyl groups suffer from the anisotropic effect of the carbonyl group at the 5-position. On the other hand, the contribution of the anisotropic effect of the C-4 hydroxyl group to the geminal dimethyl groups may be excluded, because a shift of a ^{1}H NMR signal of a methyl group due to the introduction of a hydroxy group at its neighboring carbon atom is known to be less than 0.1 ppm in ^{1}H NMR spectra of hydroxy steroids.[17,19] Owing to the anisotropic effect of the carbonyl group at the 5-position, an upfield shift would be expected for the C-4′ methyl group in **1a** with the 4*S*-configuration, whereas a downfield one for the C-4′ methyl group in **1b** with the 4*R*-configuration, as shown in Fig. 2. Appearance of the C-4′ methyl signal in a higher field than methyl signal as described above indicated the configuration at C-4 of herqueinone (**1**) to be *S* as in **1a**.

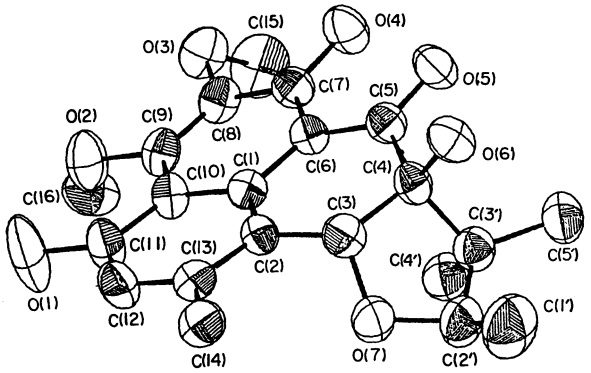

Fig. 3. ORTEP drawing[21] of the molecular structure of dihydroherqueinone monomethyl ether (**4**).

dihydroherqueinone monomethyl ether (**4**) showed also that the C-2′ hydrogen atom is *cis* to the C-4′ methyl group, while the hydrogen atom is *trans* to the C-3 hydrogen atom. This indicates that the configurations at C-3 and C-4 of **4** are *R* and *S*, respectively.

X-Ray Crystallographic Study. The absolute configuration of **4** is finally confirmed by the X-ray crystallography. A total of 1892 independent reflections were collected by use of Mo *Kα* radiation and 1811 reflections were used for structural determination. The structure of **4** was solved by the direct method by use of MULTAN[20] and the positional coordinates were refined by block-diagonal least-squares techniques to $R=0.058$.

Final atomic coordinates, bond lengths, and bond angles are given in Tables 1—3. The relative configuration of **4** is shown in Fig. 3. Attempt to solve the absolute configuration of **4** on the basis of the anomalous dispersion effect of oxygen atoms for Cu $K\alpha$ radiation[22] failed, because the effect on the R index[23] and the Bijvoet inequalities[24] was too small to determine the absolute configuration. However, the 3R- and 4S-configurations of **4** were determined with relation to the previously established absolute configuration of R at the 2′-position.[8]

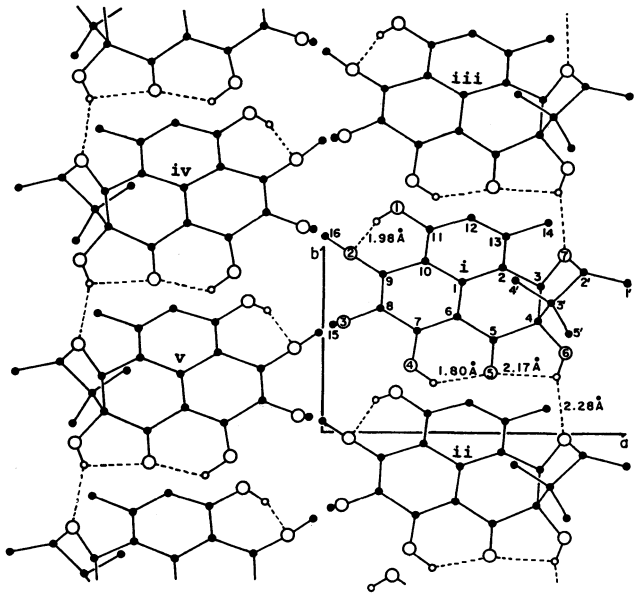

Fig. 4. The projection of dihydroherqueinone monomethyl ether (**4**) along the c axis. The atoms indicated with ●, ○, and ○ denote carbon, oxygen, and hydrogen atoms, respectively. The hydrogen bondings are shown by a broken line. Symmetry codes: (i) x, y, z; (ii) $x, -1+y, z$; (iii) $x, 1+y, z$; (iv) $-x, 1/2+y, -z$; (v) $-x, -1/2+y, -z$. The other molecules related by a 2_1 axis are omitted in order to avoid overlapping.

The molecular arrangement and the hydrogen bond networks in the crystal are shown in Fig. 4. The molecules are packed along the c axis and are linked by the long intermolecular hydrogen bonding between O(6)–H and O(7′)[25] (furan ring) along the b direction. On the other hand, three intramolecular hydrogen bondings between O(1)–H and O(2) (methoxy group), O(4)–H and O(5) (carbonyl group), and O(6)–H and O(5) (carbonyl group) are formed.

The determination of the configuration at C-4 of herqueinone (**1**) and the configurations at C-3 and C-4 of dihydroherqueinone monomethyl ether (**4**) leads to the establishment of the absolute configuration of all the herqueinone- and dihydroherqueinone-type phenalenones.

Experimental

The fungal culture of *Penicillium herquei* Bainier and Sartory (IFO 7904) was purchased from the Institute for Fermentation.[26] The ^{1}H NMR spectra for 60 and 90 MHz were taken on a Varian T-60 and a Hitachi R-22 spectrometers by use of TMS as an internal standard. The ^{13}C NMR spectra were obtained on a Hitachi R-42 FT NMR (22.6 MHz) spectrometer ($\delta_{TMS}=0$). The X-ray intensity data were collected on a Syntex R3 and a Rigaku AFC-5 diffractometers with graphite-monochromated Mo $K\alpha$ and Cu $K\alpha$ radiations, respectively.

Incubation of P. herquei. A spore suspension of *P. herquei* precultured on a malt extract agar medium were inoculated to 200 ml of a Raulin-Thom solution[2] in a 1 L Erlenmeyer flask (total 25 flasks), and incubated at 25 °C in the dark. After cultivation for 5 d, light yellow mycelia covered over the surface of the medium, and then the mycelia

produced spores and became yellow-green. Then, droplets of reddish liquid appeared on the surface of the culture, and the medium became brown after cultivation for 15 d.

Isolation of Herqueinone (1). After incubation for 25 d, the mycelia were filtered off, and the mycelia were immersed in EtOAc. The filtrate was acidified to pH 5 with 10% hydrochloric acid and extracted with EtOAc. Removing EtOAc from the combined EtOAc extract afforded the residue (*ca.* 5 g), which wa ssubjected to centrifugal liquid chromatography on a silica-gel plate (3 mm in thickness and 10 cm in radius) with EtOAc–hexane (1 : 4 v/v) to give a red powder (310 mg). Recrystallization of this powder from EtOH gave herqueinone (**1**) (275 mg): red needles, mp 217—218 °C (lit,[7] 218—222 °C); $[\alpha]_D^{25}$ +374° (*c* 1.68, $CHCl_3$); UV (EtOH) λ_{max} 410 (log ε 4.02) and 300 nm (4.25); IR(Nujol) ν_{max} 3300 (OH) and 1640 and 1620 cm^{-1} (C=O); ^1H NMR ([^2H]-DMSO) δ_H=1.00 (3H, s, 4′-H_3), 1.40 (3H, s, 5′-H_3), 1.55 (3H, d, J=6.5 Hz, 1′-H_3), 2.50 (3H, d, J=1.5 Hz, 14-H_3), 3.80 (3H, s, 15-H_3), 4.83 (1H, q, J=6.5 Hz, 2′-H), and 6.28 (1H, d, J=1.5 Hz, 12-H); ^{13}C NMR ([^2H]DMSO) δ_C=197.0 and 186.4 (each s, C-5 and C-11), 122.8 (d, C-12), 95.9 (d, C-2′), 78.9 (s, C-4), and 59.9 (q, C-15); MS (70 eV), *m/z* (rel intensity), 372 (M^+, 100), 356 (40), 341 (68), 329 (36), and 274 (52); Found: C, 64.51; H, 5.49%.

Derivation of 4 from 1. A slurry of herqueinone (**1**) (206 mg) in EtOAc (20 ml) was hydrogenated in the presence of 10% Pd–C (80 mg). After 1 molar equivalent of hydrogen had been taken up, the hydrogen uptake ceased, and the catalyst was filtered off. The filtrate was treated with ethereal CH_2N_2 (*ca.* 1 molar equiv.) at 0 °C for 30 min. The excess of CH_2N_2 was quenched with a few drops of acetic acid. The solvent was evaporated *in vacuo* to afford a crystalline residue (148 mg). This residue was purified by preparative TLC (silica gel GF_{254}; 0.5 mm thick) with EtOAc–hexane (1 : 1 v/v). The green-yellow fluorescent band at R_f 0.66 under UV light, on extraction with EtOAc, afforded yellow needles (121 mg). Recrystallization of this needles from EtOH gave yellow rods of dihydroherqueinone monomethyl ether (**4**): mp 173—174 °C (lit,[7] 172—174 °C); $[\alpha]_D^{25}$+39.0° (*c* 7.28, EtOH); UV (EtOH) λ_{max} 399 (log ε 3.78), 357 (3.62), and 290 nm (4.09); IR (Nujol) ν_{max} 3460 and 3366 (OH) and 1632 cm^{-1} (C=O); ^1H NMR ([^2H]$CHCl_3$) δ_H=0.80 (3H, s, 4′-H_3), 1.17 (3H, s, 5′-H_3), 1.34 (3H, d, J=6.5 Hz, 1′-H_3), 2.53 (3H, s, 14-H_3), 3.68 (1H, q, J=6.5 Hz, 2′-H), 3.98 (3H, s, 15-H_3), 4.28 (3H, s, 16-H_3), 5.44 (1H, s, 3-H), and 6.72 (1H, s, 12-H); ^{13}C NMR ([^2H]DMSO) δ_c=202.9 (s, C-5), 113.5 (d, C-12), 82.0 (s, C-4), 81.5 (2×d, C-3 and C-2′), 60.9 (q, C-15), and 62.4 (q, C-16); MS (70 eV), *m/z* (rel intensity), 388 (M^+, 100), 302 (74), 287 (38), 259 (34), 244 (15), and 216 (22); Found: C, 64.65; H, 6.33%.

X-Ray Crystallographic Analyses of Dihydroherqueinone Monomethyl Ether (4). *(i) Analysis by Use of Mo Kα Radiation*: The crystal used was about 0.5 mm×0.4 mm×0.7 mm in size. Cell dimensions were derived by the least-squares calculations from 2θ values of 25 well-centered diffraction peaks for **4**. Crystal data are; $C_{21}H_{24}O_7$; M=388.45; monoclinic (space group $P2_1$); Z=2 per unit cell with dimensions a=11.213(4), b=6.229(3), c=14.252(5)Å, β=110.21(3)°; U=934.3 Å^3; D_c=1.38 g cm^{-1}; D_m=1.40 g cm^{-1}; μ(Mo $K\alpha$) =1.1 cm^{-1}. A total of 1892 reflections were collected by use of ω-scan technique ($2\theta_{max}$=50.0°); 1811 reflections with intensity greater than 1.96 times the standard deviations were used as observed reflections. The phases of 244 reflections with $|E|>1.40$ were determined by use of MULTAN.[20] An E map for the best solution yielded positions for all the atoms except hydrogen atoms, followed by a difference map to find the positions for all the hydrogen atoms. Anisotropic refinement for carbon and oxygen atoms and isotropic refinement for hydrogen atoms reduced the R index to 0.058.

(ii) Analysis by Use of Cu Kα Radiation: A total 2784 reflections with the Friedel pair of (h, k, l) and (h, $\bar{k}$, l) were collected by use of ω-scan technique ($2\theta_{max}$=125°); 2697 reflections with $I_o>4.0\sigma(I_o)$ were used as observed reflections. The positional coordinates for the enantiomeric pair were refined by use of two sets of coordinates: (a) the same atomic coordinates determined as above and (b) the atomic coordinates translated by the code of (x, $-y$, z). Final refinement by use of the anomalous dispersion effect of oxygen atoms for Cu $K\alpha$ radiation[22] reduced the R index to 0.0662 for the coordinates (a) and 0.0668 for the coordinates (b). All the $||F_c(h,k,l)|-|F_c(h,\bar{k},l)||/\sigma(F_o)$ values were smaller than 0.8.

The complete F_o-F_c data and the table of anisotropic thermal parameters for **4** are deposited as Document No. 8261 at the Chemical Socity of Japan.

The authors thank Dr. G. A. Morrison for the gift of the ^1H NMR spectrum of herqueinone and for his kind suggestion for the study on the absolute configurations of herqueinone and the dihydroherqueinone derivatives.

Photoinduced Electron Transfer Oxidation. I. 9,10-Dicyanoanthracene-sensitized Photooxidation of Hindered Phenols

Shigeru FUTAMURA, Kazuhiro YAMAZAKI, Hiroyuki OHTA,* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received May 15, 1982)

9,10-Dicyanoanthracene (DCA)-sensitized photooxidation reactions of hindered phenols and catechols (**1**) proceed *via* the initial electron transfer from **1** to ^{1}DCA*. 4-Hydroperoxy-2,5-cyclohexadien-1-ones and 4-hydroxy-2,5-cyclohexadien-1-ones are obtained from 2,4,6-trialkyl-substituted phenols, and an *o*-benzoquinone and furanone derivatives are afforded from 3,5-di-*t*-butylcatechol.

Oxygenation of the phenol and catechol has long been one of the current subjects in connection with model reactions for enzymes[1] and a number of reports both from a synthetic[2] and a kinetic[3,4] viewpoints have been accumulated in the literature. This problem is of interest because their oxidation products highly depend on the reaction conditions, *i.e.*, their substituents,[5] oxidizing reagents,[1,6–13] and solvent,[13] *etc.*

Recently, photoinduced electron transfer reactions have attracted much attention of photochemists.[14] 9,10-Dicyanoanthracene (DCA) can be a good electron deficient sensitizer in the electron transfer oxidation of electron-rich substrates[15] because the second electron transfer process from DCA$^{\cdot-}$ to O_2 (see Scheme 1) is exothermic ($E_{1/2}^{RED}$(DCA)$=-0.97$ V, $E_{1/2}^{RED}$(O_2)$=-0.94$ V, *vs.* SCE in MeCN). It is already reported that electron-rich substrates, such as olefins,[15] acetylenes,[16] aromatics,[17] and sulfides,[18] undergo DCA-sensitized photooxidation reactions as Scheme 1 shows.

Fig. 1.

We now wish to present in this paper the photoinduced electron transfer oxidations of hindered phenols and catechols using DCA as sensitizer.

Experimental

Materials. DCA(Kodak) was purified by silica gel column chromatography. Mp 250.0—251.0 °C. Phenols and catechols were recrystallized twice from hexane–benzene. 1,3,5- and 1,2,4-Trimethoxybenzenes, acetonitrile, and methanol (reagent special grade) were used without further purification.

Instrumental. The GC analyses were done on a Shimadzu GC-6A-FID apparatus equipped with a column of 5% OV 17 on Chromosorb P. The products were analyzed on a waters liquid chromatograph, Model 440-RCM 100 equipped with a column of Radial-PAK (silica gel). The products were isolated by silica-gel chromatography or by preparative TLC (silica gel). The IR spectra were taken on a Shimadzu IR-420 Infrared Spectrophotometer. The NMR spectra were obtained on a Varian EM 360A NMR Spectrometer (60 MHz), using Me_4Si as the internal standard. The UV spectra were recorded on a JASCO NEW-UV-210A Digital Double-beam Spectrophotometer. The fluorescence spectra were taken on a Shimadzu RF-502A Fluorescence Spectrophotometer. The melting points were measured by means of a Yazawa Hot Plate and are uncorrected.

DCA-sensitized Photooxidation of ***1****.* A 100 ml MeCN or MeOH solution of **1** (10^{-2} M) was irradiated externally in the presence of DCA (10^{-4} M) from a 400-W high-pressure mercury arc through an aqueous 75% $NaNO_2$ solution ($\lambda_{irrad.} \geq 410$ nm).

*2,6-Di-*t*-butyl-4-methyl-4-hydroperoxycyclohexadien-1-one (**2b**).* Mp 115.2—115.6 °C (lit,[12a] 115—116 °C). NMR (δ): 1.22 (s, 18H), 1.35 (s, 3H), 6.55 (s, 2H), 7.70 (s, 1H). IR (cm^{-1}): 3400, 1667, 1646, 881. UV (EtOH): $\lambda_{max}=235$ nm ($\varepsilon=11000$). Found: C, 71.27; H, 9.63%; Calcd for $C_{15}H_{24}O_3$: C, 71.45; H, 9.52%.

*2,6-Di-*t*-butyl-4-methyl-4-hydroxycyclohexadien-1-one (**3b**).* Mp 107.0—108.0 °C (lit,[12a] 110 °C). NMR (δ): 1.24 (s, 18H), 1.39 (s, 3H), 1.57 (s, 1H), 6.54 (s, 2H). IR (cm^{-1}): 3370, 1660, 1640, 882. The spectra of **3b** were superimposable on those of the sample obtained by reducing **2b** with triphenylphosphine.

Table 2 summarizes the NMR and IR data of **2** and **3**.

*Bis(1,3,5-tri-*t*-butyl-4-oxo-2,5-cyclohexadienyl)peroxide (**4**).* **4** was synthesized according to Cook's method.[10] Mp 145.2—145.6 °C (lit,[10] 148—149 °C). NMR (δ): 0.84 (s, 18H), 1.31 (s, 36H), 6.66 (s, 4H). IR (cm^{-1}): 1667, 1643, 1365, 1248, 997.

5, **6**, and **7** were identified by comparison of their mp's and spectroscopic data with those of the authentic samples.[19,20]

Results and Discussion

DCA-sensitized Photooxidation of Phenols. As Table 1 shows, 4-hydroperoxy-2,5-cyclohexadien-1-ones (**2**) and 4-hydroxy-2,5-cyclohexadien-1-ones (**3**) were ob-

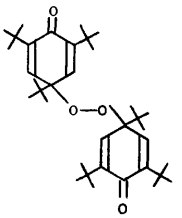

Fig. 2.

tained from 2,4,6-trialkyl-substituted phenols (**1a—c**) in good yields. On the other hand, monoalkyl-substituted phenol **1d** was photooxidized much slower and also its reaction was too complex to obtain isolable products.[21]

Refluxing **2** with the excess of triphenylphosphine in dichloromethane for 3 h gave **3** quantitatively and this fact supports the structure of **2**.

Although the effect of phenol concentration on its oxidation has been reported,[4] no concentration effect was observed concerning the product distribution in this reaction, and no bis(1,3,5-tri-*t*-butyl-4-oxo-2,5-cyclohexadienyl) peroxide (**4**) was formed even when the concentration of **1a** was increased to 10^{-1} M.

Formation of **3** urged us to ascertain the possibility that the redox decomposition of **2** or **4** should give **3**. Under the reaction conditions, however, both of them were highly stable in the absence or presence of hydrogen donor **1**, and **3** was not afforded at all. LC analysis also showed that **3** is a primary product and did not arise from **2** or **4**.

In methanol, the reaction rate was slower than in acetonitrile and **3** was not afforded.

Next, the quenching experiments of DCA fluorescence and the oxidation reaction were performed to obtain further information on the mechanism. The rapid quenching of ^{1}DCA* fluorescence by **1** (see Table 3) supports the occurrence of electron transfer from **1** to ^{1}DCA*, *i.e.*, formation of 1^+ and DCA^-. In fact, the relative rate, k_{rel} of **1** decreases as its oxidation potential increases.

Addition of 1,2,4-trimethoxybenzene (TMB) into the system of **1** and DCA causes the competition between Eqs. 2 and 3 because TMB is a better electron donor.[15] As r_1 and r_2 in Scheme 3 stand for the kinetic expressions for Eqs. 2 and 3, the calculated quenching ratio Q_{calcd} can be obtained by Eq. 6 if $\mathbf{1}^+$ is responsible for the oxidation of **1**.

$$DCA \xrightarrow{h\nu} {}^1DCA^* \quad (1)$$

$$^1DCA^* + \mathbf{1} \xrightarrow{kq} DCA^- + \mathbf{1}^+ \quad (2)$$

$$^1DCA^* + TMB \xrightarrow{kq'} DCA^- + TMB^+ \quad (3)$$

$$r_1 = k_q[\mathbf{1}][^1DCA^*] \quad (4)$$

$$r_2 = k_q[TMB][^1DCA^*] \quad (5)$$

$$Q_{calcd} = 1 - r_1/(r_1+r_2) = k_{q'}[TMB]/(k_q[\mathbf{1}]+k_{q'}[TMB]) \quad (6)$$

Scheme 3. Quenching of ^{1}DCA* fluorescence.

A good coincidence between Q_{calcd} and Q_{obsd} further confirms the involvement of the initial electron transfer process. DCA^- can reduce triplet molecular oxygen to generate O_2^-.[15] Therefore, **2** would be afforded in the subsequent deprotonation of $\mathbf{1}^+$ by O_2^-, followed by the coupling of $\mathbf{1}^\cdot$ with $HO_2^\cdot$. It is well known that a hindered phenoxyl radical is a good trap of a hydroperoxyl radical.[24] The alkylperoxyl radical could be excluded as a chain carrier since hindered phenols are known to act as a good radical inhibitor. They would rather couple with a phenoxyl radical to give **4**[4,10] when the concentration of the phenoxyl radical is high.

It is to note that **1** was stable on DCA-sensitized irradiation under nitrogen. This would be ascribed to the back electron transfer from DCA^- to $\mathbf{1}^+$ or the lack of the deprotonating reagent such as oxygen.[25]

The stability of **2** is delicate, and it rearranges to a 5,6-epoxy-4-hydroxy-2-cyclohexen-1-one under basic conditions,[12b] or it degrades to *p*-benzoquinones, diphenoquinones, *etc.* in the presence of a Cu(I)–amine complex.[11] Our reaction is clearly different from the base- or metal-catalyzed oxygenation of hindered phenols in that **2** is afforded in good yields, irrespective of the alkyl substituents although the path for formation of **3** has to be unraveled.

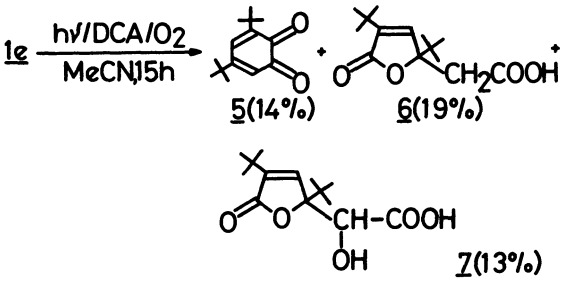
1d		2.06×10^{10}	1.0	41	43
TMB	1.12 e)	6.49×10^{10}			

a) Fluorescence quenching rate constant in acetonitrile under air at room temperature. $\tau_{DCA,Air}=\tau_{DCA,N_2}(I_{DCA,Air}/I_{DCA,N_2})=15.3\times0.52=8.0$ ns. ($\tau_{DCA,N_2}=15.3$ ns.)[22] b) Q_{calcd} was given by Eq. 6 when the conversion of **1** was around 10%. c) Q_{obsd} was given as $1-C_q/C_0$, where C_0 and C_q represent the conversions of **1** in the solutions containing only **1** and **1**–TMB when C_0 was around 10%, respectively. d) See Ref. 23. e) See Ref. 15.



Scheme 4. DCA-sensitized photooxidation of **1e**.

photooxidation of **1e** in acetonitrile gave 3,5-di-*t*-butyl-*o*-benzoquinone (**5**), 3,5-di-*t*-butyl-5-(carboxymethyl)-2(5*H*)-furanone (**6**), and 3,5-di-*t*-butyl-5-(carboxyhydroxymethyl)-2(5*H*)-furanone (**7**) in the yields shown above.

In MeCN–MeOH, **6** and the methyl ester of **7** were obtained in 20% and 10% yields, respectively, along with **5** (6%).

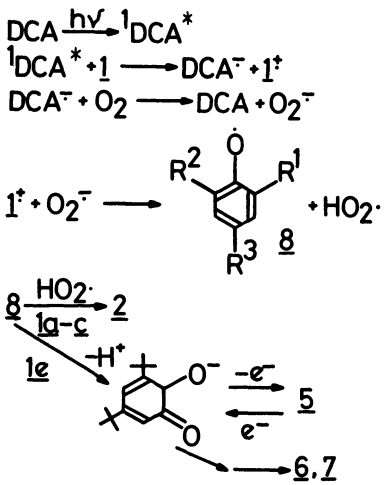
The relative rate of the catechol decreased in the order of **1e**>**1f**>**1g** and no isolable products were obtained from the less hindered catechols, **1f** and **1g**.

As has been discussed in the system of the phenol, the oxygenation of the catechol is also considered to proceed by an electron transfer mechanism because **1e** quenches ^{1}DCA* fluorescence at the diffusion-controlled rate limit ($k_q=1.21\times10^{10}$ $M^{-1}s^{-1}$) and its oxidation reaction is completely suppressed by 1,3,5-trimethoxybenzene.

5 is found to be an early product because **6** and **7** are afforded in the DCA-sensitized photooxidation reaction of **5** in acetonitrile.

The observed product distributions are less complicated than those reported by Foote and Moro-oka with KO_2.[9]

The different reactivities of **1a**—**c** and **1e** can be ascribed to the diphenolic character of **1e**. The phenoxyl radicals from **1a**—**c** couple together with a hydroperoxyl radical, while that from **1e** would further be deprotonated to afford a stable *o*-benzosemiquinone radical which leads to furanone derivatives in the subsequent oxygenation followed by ring cleavage and lactonization.[9]



Scheme 5. A presumed reaction scheme.

Scheme 5 shows a presumed reaction mechanism.[26]

In this paper, we have reported DCA-sensitized photooxidation of hindered phenols and catechols and have shown that the reaction proceeds *via* electron transfer mechanism.

25) DCA can be recovered quantitatively under nitrogen or oxygen.

26) The scheme merely shows a possible route leading to the products; other paths such as radical coupling between ArO· and $^3O_2$, and intervention of $^1O_2$ generated by the reaction of $ArO^+ + O_2^-$ would also be probable reactions. We thank the referee for this point.

An FT-IR Study of Micelle Formation of Ionic Surfactants and Water Solubilization in Nonpolar Organic Solvents

Hideo KISE,* Kazutoshi IWAMOTO,† and Manabu SENŌ†
Institute of Materials Science, The University of Tsukuba, Sakura, Niihari, Ibaraki 305
†*Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106*
(Received May 28, 1982)

The infrared spectra of the solutions of dodecylammonium propionate (DAP), hexadecyltrimethylammonium bromide (HTAB), and sodium bis(2-ethylhexyl) 2-sulfonatosuccinate (SBSS) in organic solvents were recorded in Fourier transform mode. Difference concentration spectra of DAP in dichloromethane exhibited the change in the stretching bands of the carboxylate ions, which was attributed to the formation of micellar aggregates. Difference hydration spectra were also obtained for water-containing DAP–CH_2Cl_2, HTAB–CH_2Cl_2, and SBSS–benzene systems, and the spectra in the region of 3000—3700 cm^{-1} and 1600—1650 cm^{-1} revealed the existence of free water dispersed in the organic phase and water bound to the micelles. The diffreence spectra also revealed the change in the bands of DAP and SBSS due to hydration of the ionic head groups. The absorption frequency of the O–H stretching bands was discussed in terms of the water-surfactant-interaction.

Recently the studies on the formation and structure of reversed micelles in nonpolar organic solvents have received considerable attention. Reversed micelles can solubilize appreciable amount of water and other polar substances. A variety of techniques have been used for the investigation of the nature of reversed micelles and cosolubilized water. A typical method is the direct observation of the change in the physical properties of the solutes by NMR,[1–8] and another is the use of probe molecules which have physical properties sensitive to the change in the environment of the solubilization sites. Examples of the latter are spin lables,[9–12] absorption and fluorescence probes,[13–19] and positron annihilation techniques.[20,21]

These methods assume that the solubilization of the probe molecules causes little or no change in the structure of the micelles. On solubilization of probes, however, perturbation of the micelle structure is likely to occur because of the small aggregation numbers and hence the small size of the reversed micelles. For example, the mean aggregation number of dodecylammonium propionate (DAP) has been reported to be 4 in carbon tetrachloride[1] and 6 ± 1 in dichloromethane.[3]

In this article we present the results on the Fourier transform infrared (FT-IR) spectroscopic investigation on the micelles of ionic surfactants in organic solvents and the nature of solubilized water in the reversed micellar systems. Infrared spectroscopy is a sensitive method for monitoring the interactions between solutes or between solvents and solutes. Fourier transform technique allows the direct observation of surfactants of low concentrations around critical micelle concentration (cmc) and solubilized water by rapid scan and computation of the difference spectra by subtracting the solvent spectra from those of solutions.

Experimental

DAP was prepared by previously described method[22] and recrystallized from hexane. Hexadecyltrimethylammonium bromide (HTAB) was purified by recrystallization from ethanol–ether, and sodium bis(2-ethylhexyl) 2-sulfonatosuccinate (SBSS) was used as received. All the solvents were of guaranteed grade and used without further purification. Water was solubilized in the surfactant solution by stirring the mixture at room temperature for several minutes and then keeping it standing overnight.

The FT-IR spectra were obtained with a Digilab FT-20C instrument with a 50 μm KRS cell. The spectral resolution was 4 cm^{-1}, and 100 to 1000 scans were accumulated.

Results and Discussion

DAP and HTAB Micelles. The difference spectrum obtained by the subtraction of the dichloromethane spectrum from that of the dichloromethane solution of DAP (15 mM, 1 mM = 10^{-3} mol dm^{-3}) exhibits asymmetric and symmetric stretching bands of the carboxylato group around 1580 and 1400 cm^{-1}, respectively. Since the cmc of DAP in dichloromethane obtained by NMR method has been reported to be 27—40 mM,[3] the absorption is considered to be of monomeric DAP dispersed in the solvent. Free carboxylate ions in aqueous solutions have the stretching bands

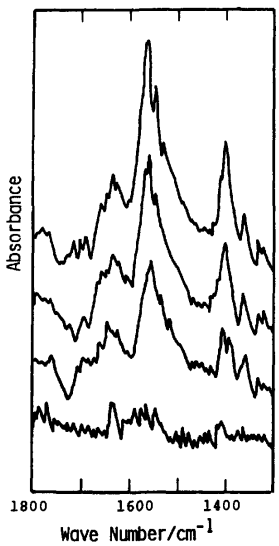

Fig. 1. Difference spectra of DAP in dichloromethane obtained by subtraction of the spectra of 10 mM DAP from those of 20, 30, 40, and 50 mM DAP (from lower to upper). See Ref. 23.

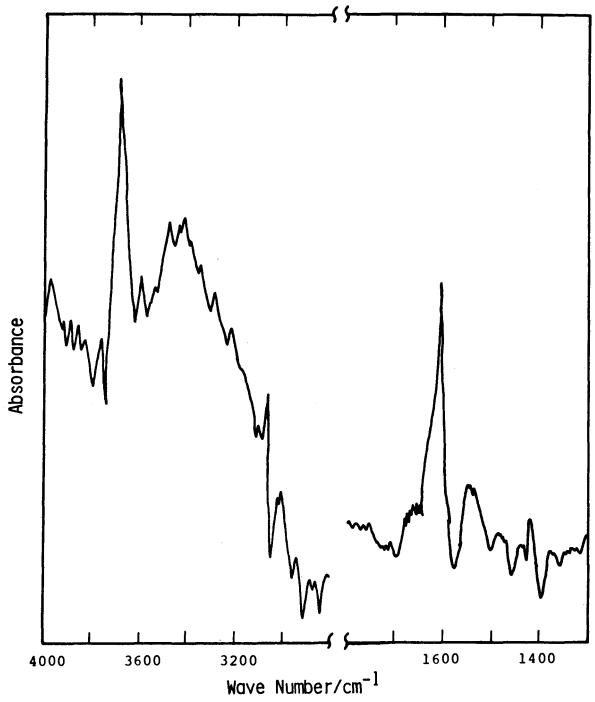

Fig. 2. Difference spectrum obtained by subtraction of the spectrum of anhydrous DAP (50 mM) in dichloromethane from that of the DAP solution of the same concentration containing 200 mM water.

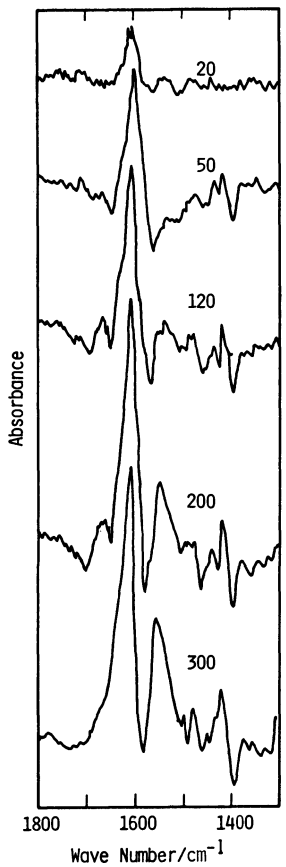

Fig. 3. Difference spectra obtained by subtraction of the spectrum of anhydrous DAP solution (50 mM) in dichloromethane from those of water-containing DAP solutions. Water concentration is indicated in the figure (mM).

around 1550 and 1410 cm^{-1}, and the dispersed DAP is considered to exist as tightly bound ion pairs as suggested by the larger difference between the two stretching bands than free carboxylate ions.

When the concentration of DAP is increased, the carboxylate bands gradually change. The asymmetric band shifts to lower frequencies, while symmetric one shifts to higher frequencies. The change in the spectra is clearly demonstrated by subtracting the spectrum of the solution below cmc from those of the solution above cmc as shown in Fig. 1.[23] With increasing concentration new absorption bands appear around 1550—1570 and 1400—1410 cm^{-1}. These bands are obviously attributed to the formation of DAP aggregates, in which DAP is considered to have more ionic character than monomeric one as suggested by the decrease in the difference between the symmetric and asymmetric stretching bands. The increase in the ionic nature of DAP may be the consequence of the interaction of carboxylato group with two or more ammonium groups. The onset of association seems to fall in the concentration range of 20 to 30 mM, which well agrees with the cmc value obtained by NMR method.[3]

When water was solubilized in a 50 mM DAP solution in dichloromethane, the stretching bands of carboxylate ions shifted in the same direction as that observed in the micelle formation described above. Figure 2 shows the difference spectrum obtained by subtracting the spectrum of DAP–CH_2Cl_2 solution from that of DAP–CH_2Cl_2–H_2O solution. The spectrum exhibits not only the absorption bands of water but also the shift of DAP bands caused by the addition of water. The shift of DAP bands is observed as sigmoid (1550—1570 cm^{-1}) or reversed sigmoid (1400—1410 cm^{-1}) spectra. New DAP bands appear in the regeon closer to that of free carboxylate ions. This may well be understood as a consequence of the formation of water-separated DAP ion pairs due to the hydration of the ionic head groups of the surfactant. The change in the spectra with water concentration is shown in Fig. 3. It is obvious that binding of water to the surfactant occurs even at equimolar concentration of water to DAP.

The spectrum of water saturated in neat dichloromethane exhibited asymmetric (ν_3) and symmetric (ν_1) stretching bands at 3688 and 3600 cm^{-1}, respectively, and bending band (ν_2) at 1604 cm^{-1}. By comparison with this, the sharp absorption bands at 3680, 3600, and 1600 cm^{-1} in Fig. 2 were assigned as that of free water dispersed in bulk organic phase. Since water in gas phase has absorption at 3755, 3654, and 1595 cm^{-1}, while water in liquid phase has absorption at 3430, 3210, and 1650 cm^{-1}, the dispersed water seems to be in a similar state to that in gas phase rather than in liquid phase. The broad bands around 3450 and 1630 cm^{-1} were assigned to the absorption of water bound to DAP micelles. The bands are very close to those of liquid water indicating strong interaction with DAP molecules which is probably a kind of ion-dipole interaction. Although the bands of free and bound water are not fully separated, the competitive solubilization of water seems to occur into the micelles and bulk

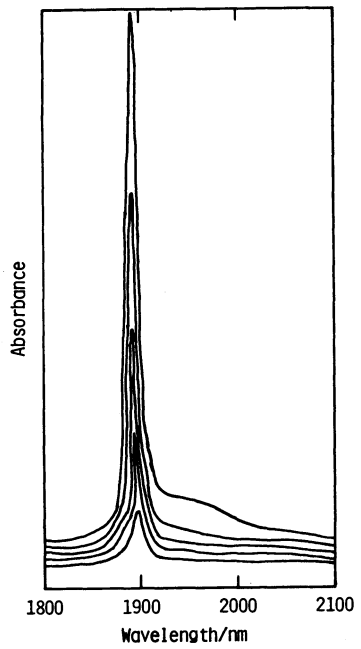

Fig. 4. Near infrared spectra of water-containing DAP solutions (50 mM) in dichloromethane. Water concconcentration is from lower to upper 20, 50, 120, 200, and 300 mM.

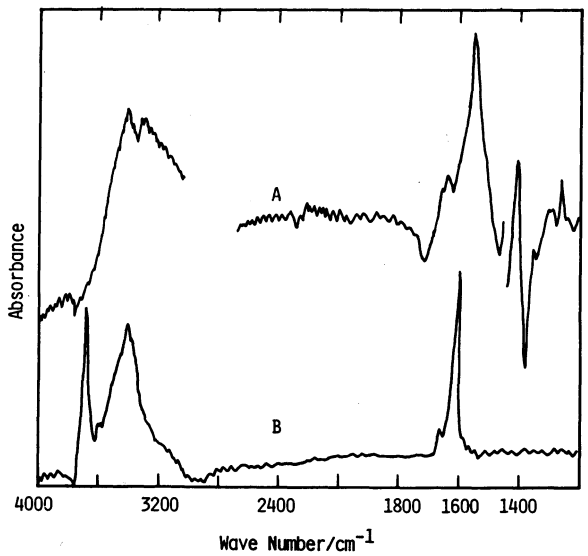

Fig. 5. Spectra of A) water (100 mM) in hexane+DAP (50 mM) and B) water (200 mM) in CH_2Cl_2+HTAB (50 mM).

organic phase.

The existence of free and bound water in this system is confirmed by the near infrared spectra of 1800—2000 nm region due to $\nu_2+\nu_3$ combination mode (Fig. 4). The sharp band at 1890—1900 nm has been ascribed to the free or almost free 1 : 1 complex H–O–H···B in which B denotes a weak base such as dioxane.[24] The position of this band is identical with that of the extremely weakly bonded water in chlorinated hydrocarbons.[24] Furthermore, on the basis of the relationship between the concentration of DAP or waterin chloroform and the absorption intensity of water, the broad band at 1920—1950 nm was assigned towater solubilized in the reversed micelles.[25]

The solution of DAP (50 mM) in hexane afforded a quite similar spectrum to the dichloromethane solution implying the formation of similar kind of DAP aggregates. The shift of the bands of carboxylato group by the addition of water is also quite similar to the dichloromethane solution. In contrast to dichloromethane solution, however, the solubilized water showed no absorption band corresponding to free water (Fig. 5-A), which may be the consequence of low solubility of water in hexane. In addition, the stretching bands of bound water seems to contain lower component around 3300 cm^{-1} than the water in DAP–CH_2Cl_2 system. It has been reported that the cmc of DAP in benzene and cyclohexane is 3—7 mM[1,2] and 1.56 mM,[17] respectively. The lower cmc value in hydrocarbons than dichloromethane[3] or carbon tetrachloride[1,2] implies the formation of more compact and tightly bound aggregates of DAP in hydrocarbons. Although the O–H stretching bands are not well resolved, the band around 3300 cm^{-1} seems to be due to water tightly bound to the ionic head groups of DAP.

In the case of hexadecyltrimethylammonium bromide (HTAB) in dichloromethane, the absorption bands of solubilized water were almost the same as those in DAP–CH_2Cl_2 system (Fig. 5-B), except that the O–H stretching band of bound water appears at slightly lower frequency around 3400 cm^{-1}.

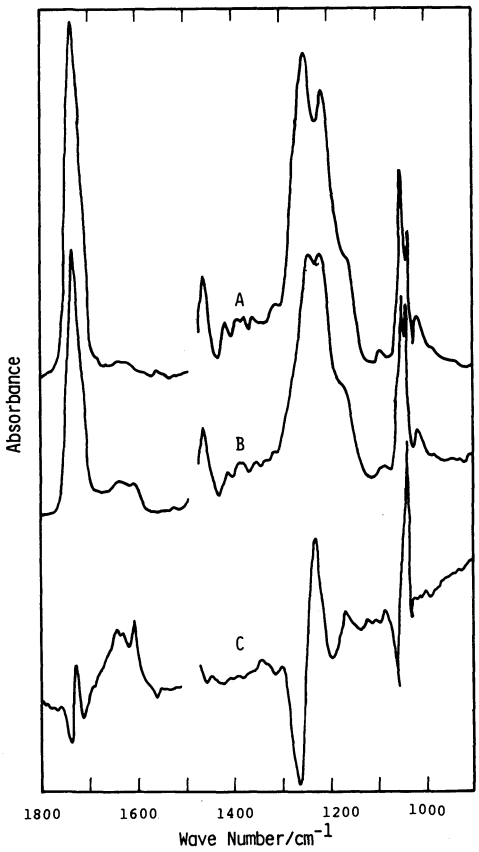

Fig. 6. Spectra of SBSS reversed micelles: A, SBSS 50 mM in benzene; B, SBSS 50 mM+H_2O 100 mM in benzene; C, H_2O 100 mM in (SBSS 50 mM+benzene).

SBSS Micelle. As Fig. 6-A shows the IR spectrum of anionic surfactant SBSS in benzene exhibits SO_3 asymmetric stretching bands at 1252 and 1215 cm^{-1}, and symmetric stretching band at 1050 cm^{-1}. In contrast to DAP in dichloromethane, no effect of the concentration of SBSS on these bands was observed in the range of 2—50 mM. This may indicate the lower cmc of SBSS.

On addition of water, however, distinct change in shape and frequency of SO_3 bands was observed as shown in Fig. 6-B. The change is clearly detected by taking the difference spectrum of solubilized water (Fig. 6-C). The sigmoid spectra around 1250 and 1050 cm^{-1} represent higher shift of 1215 cm^{-1} band and lower shift of 1252 and 1050 cm^{-1} bands due to the hydration of the sulfonato group.

It is interesting to note that the carbonyl band at 1730 cm^{-1} shifts to lower frequency on addition of water as shown in Fig. 6-C. Since the intensity of the new band was found to be almost independent of the water concentration up to 200 mM, the band shift was attributed to the formation of hydrogen bond between the carbonyl oxygen and the water dispersed in bulk benzene phase not in the micelle core. This may be supported by the fact that the bands of water in bulk benzene were observed at 3680 and 1600 cm^{-1}, whose intensity was almost independent of water concentration in the range of 50—200 mM.

Table 1. Absorption maxima of bound water (cm^{-1}) in reversed micelles

Surfactant (Solvent)	IR $\tilde{\nu}/cm^{-1}$	Surfactant (Solvent)	NIR
(H_2O vapor)	3755	(H_2O vapor)	5330
(H_2O in CH_2Cl_2)	3688	(H_2O in CH_2Cl_2)	5280
SBSS (CH_2Cl_2, Benzene)	3500	AOT[a] ($CHCl_3$)	5198[b]
DAP (CH_2Cl_2)	3450	DAP ($CHCl_3$)	5085[b]
HTAB (CH_2Cl_2)	3400	HTAB($CHCl_3$)	5010[b]
DAP (Hexane)	3300		

a) Aerosol-OT. b) From Ref. 8.

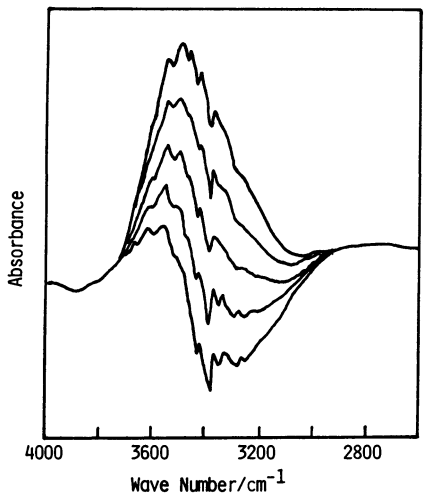

Fig. 7. Difference spectra obtained by subtraction of water spectra from that of 1 M aqueous solution of sodium ethanesulfonate. Scaling factor used in the subtraction is increasing from upper to lower.

O–H Stretching Band of Solubilized Water. The O–H stretching bands of water bound to the micelles are collected in Table 1. Although the spectra are broad and not well resolved, distinct change in the absorption maximum for the different surfactant-solvent system is observed. Assuming that the O–H stretching frequency of the bound water simply reflects the strength of the water-surfactant interaction, the water binding ability of the reversed micelles in dichloromethane is roughly estimated; that is HTAB>DAP> SBSS. The result agrees with that obtained from NIR measurement in chloroform as listed in Table 1.[8]

In order to obtain better understanding of the interaction of water with surfactants, IR spectra of aqueous solutions of several electrolytes which have analogous structure to the ionic head groups of the surfactants were investigated. As Figs. 7 and 8 show, subtraction of water spectra from those of aqueous solutions of sodium ethanesulfonate or tetrabutylammonium bromide (TBAB) afforded the spectra of water associated with

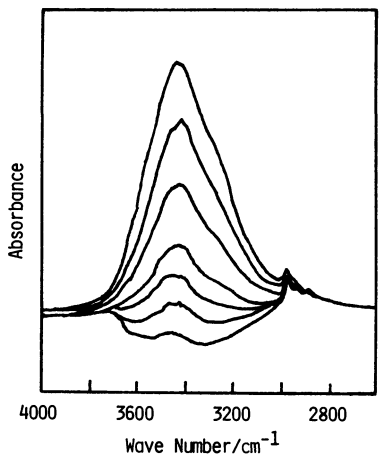

Fig. 8. Difference spectra obtained by subtraction of water spectra from that of 1 M aqueous solution of TBAB. Scaling factor used in the subtraction is increasing from upper to lower.

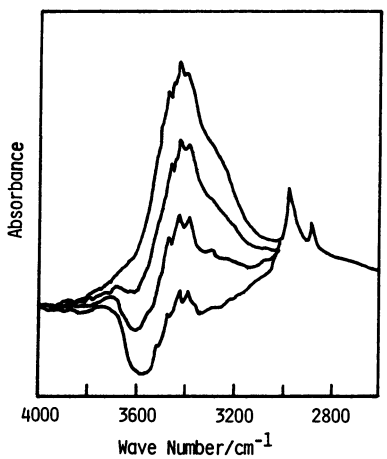

Fig. 9. Difference spectra obtained by subtraction of the spectra of 1 M KBr from that of 1 M TBAB in water. Scaling factor used in the subtraction is increasing from upper to lower.

the electrolytes. It is interesting to note that the maximum frequencies of the bands of water associated with sodium ethanesulfonate and TBAB are close to those in SBSS and HTAB reversed micelles, respectively. This seems to suggest that water in reversed micelles has interaction with ionic head groups of the surfactants like water in the vicinity of electrolytes in aqueous solutions. Further, the difference spectra resulting from the subtraction of the spectra of aqueous sodium bromide solution from that of aqueous TBAB solution allows to estimate approximate frequency of the absorption bands of water associated with sodium and tetrabutylammonium ions, that is around 3560 and 3400 cm^{-1}, respectively. The results indicate that the spectral component of water in HTAB micelles appearing around 3400 cm^{-1} is most likely due to water molecules interacting with ammonium groups. The well established structure-making properties of quaternary ammonium ions may be responsible for the lower shift of O–H stretching band of the water in the reversed micelle core.

Similar technique of difference spectrum has been employed for the study of hydration of ionic species in aqueous solution using the band of HOD near 2500 cm^{-1},[26] and the study on the micelle formation of sodium hexanoate in aqueous solutions.[27]

The Oxidation of the 2-Methyl Group of 3-Substituted 2-Methylindoles by Autoxidation and with Silver Acetate in Carboxylic Acids

Toshio ITAHARA,* Hiroshi OUYA, and Kiyotake KOZONO
Institute of Chemistry, College of Liberal Arts, Kagoshima University, Korimoto, Kagoshima 890
(Received May 29, 1982)

The autoxidation of 3-alkyl-2-methylindoles in carboxylic acids, such as propionic acid and acetic acid, at the reflux temperature resulted in the selective oxidation of the 2-methyl group and the formation of 3-alkyl-2-formylindoles. The formation of the 2-formylindoles was dependent on the nature of the solvent used. The treatment of 3-benzoyl-1,2-dimethylindole with silver acetate gave 2-acetoxymethyl-3-benzoyl-1-methylindole and 3-benzoyl-2-formyl-1-methylindole. The mechanistic implications for the autoxidation and the oxidation with silver acetate are presented.

The autoxidation of 3-alkyl-2-methylindoles (**1**) has been known to give several products. Beer *et al.*[1] reported that the autoxidation of 2,3-dimethylindole (**1a**) in hot petroleum gave 2,3-dimethyl-3*H*-indol-3-yl hydroperoxide (**2a**) and a non-peroxidic product. Taylor[2] also reported the formation of *N*-(2-acetylphenyl)acetamide, together with a small amount of 2-formyl-3-methylindole (**3a**), from **1a**. Recently, the non-peroxidic autoxidation product was reported to be a dimeric compound.[3] The autoxidation of 3-ethyl-2-methylindole (**1c**) was reported to give a similar dimeric compound.[4]

The present paper will deal with the autoxidation of 3-alkyl-2-methylindoles (**1a—e**) in carboxylic acids. The autoxidation in propionic acid or in acetic acid at the reflux temperature gave 3-alkyl-2-formylindoles (**3a—e**) in good yields. The treatment of **1a** in formic acid under oxygen at the reflux temperature gave 2,3-dimethyl-1-formylindole (**1g**), together with a small amount of **3a**. Also, the oxidation of 3-benzoyl-1,2-dimethylindole (**1f**) with silver acetate gave 3-benzoyl-2-formyl-1-methylindole (**3f**) and 2-acetoxymethyl-3-benzoyl-1-methylindole (**5f**).

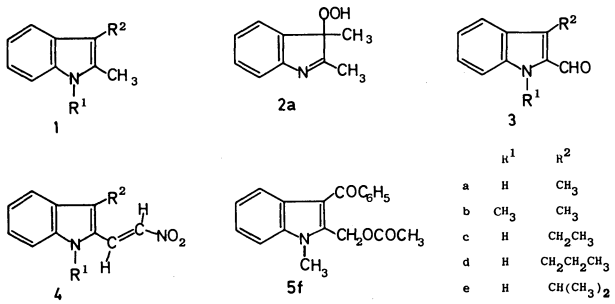

Fig. 1.

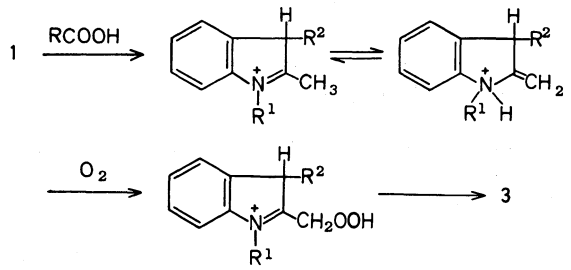
Results and Discussion

A solution of 2-methylindoles (**1a—e**) (100 mg), in propionic acid (100 ml) was bubbled with oxygen at the reflux temperature for 7 h. The reaction mixture was then evaporated and chromatographed on silica gel TLC to give the corresponding 2-formylindoles (**3a—e**). The autoxidation of **1a** in acetic acid under similar conditions also gave **3a**. The treatment of **3a—e** with nitromethane according to the known method[5] gave the corresponding 3-alkyl-2-(2-nitrovinyl)indoles (**4a—e**), which provides additional evidence for the structures of **3a—e**. The structures of **3** and **4** were confirmed on the basis of analytical and spectral(NMR, IR, and mass) data.

The formation of **3** is dependent on the nature of the solvent used. When the autoxidation of **1a** was carried out in formic acid at the reflux temperature, 1-formylindole **1g**[6] was obtained as the main product, together with a small amount of **3a**. Furthermore, no 2-formylindole **3a** was obtained from the reaction mixture in the autoxidation of **1a** in benzene, in methanol, in hexane, and in ethyl acetate. On the other hand, the autoxidation of **1a** in mixtures of methanol and acetic acid and of benzene and acetic acid gave **3a**, although attempts to prepare **3a** by the autoxidation of **1a** in methanol containing phosphoric acid and in benzene containing *p*-toluenesulfonic acid were unsuccessful.

The yield of **3a** is also dependent on the concentration of **1a**. That is to say, the autoxidation of **1a** (0.5 g or 1.0 g) in acetic acid (100 ml) decreased the yields of **3a**. These results are summarized in Table 1. Under similar conditions, an acylindole such as **1f** was unreactive to oxygen. The autoxidation of 2-methylindole and 1,2-dimethylindole gave complex reaction mixtures.

Previously it was reported that the exposure of **2a** to air in acetic acid and in ethyl acetate did not yield **3a**; the only product obtained was *N*-(2-acetylphenyl)-acetamide, although the exposure of 2,3-diethyl-3*H*-indol-3-yl hydroperoxide to air gave 2-acetyl-3-ethylindole.[7] Furthermore, it was found that the autoxidation of a 1-substituted 2-methylindole such as 1,2,3-trimethylindole (**1b**) also gave the corresponding 2-formylindole, such as 1,3-dimethyl-2-formylindole (**3b**). These results suggest that the formation of **3** from **1** in carboxylic acids did not proceed *via* **2**. On the other hand, Gribble *et al.*[8] reported that indoles are protonated at the 3-position of the indole nucleus by carboxylic acids. Therefore, the following scheme might be given for the autoxidation of **1** in carboxylic acids:



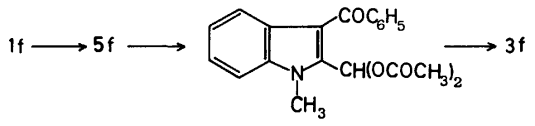
Scheme 1.

Table 1. Synthesis of 3-alkyl-2-formylindoles by the autoxidation of 3-alkyl- 2-methylindoles

Substrate	(g)	Solvent	(ml)	Conv./%	Product	Yield/%[a]
1a	(0.1)	CH_3CH_2COOH	(100)	100	**3a**	56
1a	(0.1)	CH_3COOH	(100)	100	**3a**	45
1a	(0.5)	CH_3COOH	(100)	70	**3a**	18
1a	(1.0)	CH_3COOH	(100)	50	**3a**	11
1a	(1.0)	CH_3COOH	(200)	62	**3a**	12
1a	(0.1)	CH_3COOH[b]	(100)	100	**3a**	60
1a	(0.1)	HCOOH	(100)	93	**3a**[c]	4
1a	(0.1)	Benzene	(50)	78	**3a**	8
		CH_3COOH	(50)			
1a	(0.1)	CH_3OH	(50)	76	**3a**	12
		CH_3COOH	(50)			
1b	(0.1)	CH_3CH_2COOH	(100)	100	**3b**	68
1c	(0.1)	CH_3CH_2COOH	(100)	100	**3c**	60
1d	(0.1)	CH_3CH_2COOH	(100)	100	**3d**	63
1e	(0.1)	CH_3CH_2COOH	(100)	100	**3e**	60

a) Yields based on the indole **1a**—**e** consumed. b) Adding 2 equiv. of AgOAc. c) 2,3-Dimethyl-1-formylindole (52%) was obtained as the main product.

Although **1f** was unreactive to oxygen, **1f** was reacted with silver acetate to give **3f** and **5f**. The treatment of **1f** with 2.0 equiv. of silver acetate in acetic acid at the reflux temperature under both air and nitrogen for 20 h gave **3f** as the main product, together with a small amount of **5f**. On the other hand, the treatment of **1f** with 0.7 equiv. of silver acetate under nitrogen for 15 h gave **5f** as the main product. Under similar conditions, **5f** was reacted with silver acetate to give **3f**, suggesting that **3f** was formed *via* **5f**. Therefore, a pathway for the oxidation of **1f** with silver acetate in acetic acid might be as is shown in the following scheme. In addition, although the oxidation of **1a** with silver acetate under nitrogen gave a complex reaction mixture, the autoxidation of **1a** in acetic acid containing silver acetate increased the yield of **3a** (Table 1).



Scheme 2.

Generally, replacement at the 2-position of the indole nucleus is attained with difficulty;[9] *e.g.*, the acylation of indoles normally gives 1- and 3-acylindoles.[10] The autoxidation of **1** in carboxylic acids and the oxidation of **1f** with silver acetate are, therefore, of interest as an effective method for the preparation of 2-formylindoles, although its scope is somewhat limited, *i.e.*, a substituent is needed at the 3-position of the indole nucleus. That is to say, in contrast to several reports concerning the preparation of **3a** by means of the oxidation of **1a** (*i.e.*, the oxidation of **1a** with H_5IO_6,[11] SeO_2,[12] and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ),[13] and by photo-oxygenation[14] gives **3a** in low yields), the method by means of the autoxidation of **1a** in carboxylic acids provides more satisfactory results.

Experimental

General. All the melting points are uncorrected. The elemental analyses were performed by the Analytical Center of Kyoto University. The infrared spectra were recorded with a JASCO IRA-1 spectrometer. The proton magnetic resonance spectra were recorded with a JEOL-60 spectrometer, using Me_4Si as the internal reference. 2-Methylindole, 1,2-dimethylindole, and 2,3-dimethylindole (**1a**) were obtained commercially. 3-Benzoylindole (**1f**) was prepared according to the procedure described before.[15]

1,2,3-Trimethylindole (1b). To a stirred solution of 2,3-dimethylindole (5.0 g) and sodium hydride (oil suspension, abt. 50%) (1.6 g) in *N,N*-dimethylformamide (100 ml), methyl iodide (5.0 g) in *N,N*-dimethylformamide (20 ml) was added under nitrogen. The solution was then stirred at room temperature for 4 h, after which the reaction mixture was poured into ice-cooled water and extracted with benzene. The benzene extract was dried with sodium sulfate and evaporated to give a brown oily residue. The residue was chromatographed on a silica-gel column with hexane/benzene to give **1b** (4.1 g).

3-Alkyl-2-methylindoles (1c—e). A solution of 2-methylindole (5.0 g) in ethyl iodide (25 ml) was heated at the reflux temperature for 40 h under nitrogen. The reaction mixture was then evaporated to give a red oily residue which was chromatographed on a silica-gel column with benzene to give 3-ethyl-2-methylindole (**1c**) (0.4 g) and 2-methylindole (3.3 g).

Similar treatments of 2-methylindole (5.0 g) in propyl iodide (25 ml) gave 2-methyl-3-propylindole (**1d**) (1.5 g) and 2-methylindole (1.9 g), while treatments in isopropyl iodide (25 ml) gave 2-methyl-3-isopropylindole (**1e**) (1.0 g) and 2-methylindole (2.6 g).

Autoxidation of 3-Alkyl-2-methylindoles. The indole **1a**—**e** (0.1 g) was dissolved in propionic acid (100 ml), and the solution was bubbled with oxygen at the reflux temperature for 7 h. The reaction mixture was then evaporated to give a brown oily residue, which was chromatographed on silica-gel TLC and developed with benzene to give 3-alkyl-2-formylindole (**3a**—**e**). The yields are summarized in Table 1. The spectral and analytical data are given below.

2-Formyl-3-methylindole (3a): Mp 139—140 °C (lit,[16] 139—

140 °C); IR (Nujol) 3300, 1640, 1570, 1430, 1330 cm^{-1}; NMR ($CDCl_3$) δ 2.73 (s, 3H), 7.1—7.6 (m, 3H), 7.75—8.0 (m, 1H) 9.5 (broad, 1H), 10.6 (s, 1H).

*1,3-Dimethyl-2-formylindole (**3b**)*: Mp 35—36 °C (lit,[17] 36 °C); IR (Nujol) 1670, 1610, 1530, 1420, 1350, 1340 cm^{-1}; NMR ($CDCl_3$) δ 2.64 (s, 3H), 4.10 (s, 3H), 7.1—8.0 (m, 4H), 10.65 (s, 1H).

*3-Ethyl-2-formylindole (**3c**)*: Mp 72—73 °C (by distillation at 170 °C/6 Torr†); IR (Nujol) 3300, 1640, 1570, 1530, 1310, cm^{-1}; NMR ($CDCl_3$) δ 1.41 (t, 3H, J=7 Hz), 3.19 (q, 2H J=7 Hz), 7.05—7.6 (m, 3H), 7.8—8.0 (m, 1H), 9.7 (broad, 1H), 10.6 (s, 1H). Found: C, 76.54; H, 6.46; N, 7.91%. Calcd for $C_{11}H_{11}NO$: C, 76.27; H, 6.40; N, 8.09%.

*2-Formyl-3-propylindole (**3d**)*: Mp 40—41 °C (by distillation at 180 °C/6 Torr); IR (Nujol) 3300, 1650—1620 (broad), 1575, 1535, 1335 cm^{-1}; NMR ($CDCl_3$) δ 0.99 (t, 3H, J=7 Hz), 1.82 (sext. 2H, J=7 Hz), 3.13 (t, 2H, J=7 Hz), 7.05—7.65 (m, 3H), 7.8—8.05 (m, 1H), 9.6 (broad, 1H), 10.5 (s, 1H); High-resolution Mass: *m/e* (rel intensity) 187.0993 (M^+, 61), 172.0773 (100). Found: C, 76.79; H, 6.92; N, 7.21%. Calcd for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N, 7.48%.

*2-Formyl-3-isopropylindole (**3e**)*: Mp 65—66 °C (by distillation at 170 °C/6 Torr); IR (Nujol) 3200, 1640, 1630, 1315 cm^{-1}; NMR ($CDCl_3$) δ 1.57 (d, 6H, J=7 Hz), 3.77 (sept, 1H, J=7 Hz), 7.05—7.75 (m, 3H), 7.86—8.10 (m, 1H), 9.6 (broad, 1H), 10.6 (s, 1H); High-resolution Mass: *m/e* (rel intensity) 187.1008 (M^+, 76), 172.0781 (100). Found: C, 76.36; H, 6.87; N, 7.31%. Calcd for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N,7.48%.

Similar procedure were applied for the autoxidation of **1a** in acetic acid, in benzene, in hexane, in methanol, and in ethyl acetate.

*3-Alkyl-2-(2-nitrovinyl)indoles (**4a—e**).* Into a solution of **3a—e** (0.1 g) and nitromethane (0.15 g) in methanol (5 ml), 50% aqueous sodium hydroxide (1.5 ml) was stirred, drop by drop, at 0 °C. After 1 h at 0 °C, ice water (5 ml) wasadded, and the resulting solution was poured into a mixture of concd hydrochloric acid (6.5 ml) and water (24 ml) at 0 °C. The crude product separated as a brownish-orange solid, which was collected and dried. Recrystallization from chloroform/hexane gave **4a—e** as brownish-orange needles. The yields and spectral and analytical data are given below.

*3-Methyl-2-(2-nitrovinyl)indole (**4a**)*: 88% yield; mp 181.5—182.5 °C; IR (Nujol) 3350, 1610, 1480, 1310 cm^{-1}; NMR ($CDCl_3$) δ 2.51 (s, 3H), 7.0—7.9 (m, 5H), 8.40 (d, 1H, J=14 Hz), 8.2—8.6 (broad, 1H); Mass: *m/e* (rel intensity) 202 (M^+, 95), 155 (94), 154 (100). Found: C, 65.74; H, 4.98; N, 13.40%. Calcd for $C_{11}H_{10}N_2O_2$: C, 65.33; H, 4.98; N, 13.86%.

*1,3-Dimethyl-2-(2-nitrovinyl)indole (**4b**)*: 89% yield; mp 159—160 °C; IR (Nujol) 1625, 1500, 1310 cm^{-1}; NMR ($CDCl_3$) δ 2.53 (s, 3H), 3.90 (s, 3H), 7.0—7.9 (m, 5H), 8.40 (d, 1H, J=14 Hz). Found: C, 66.84; H, 5.46; N, 12.95%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%.

*3-Ethyl-2-(2-nitrovinyl)indole (**4c**)*: 85% yield; mp 157—158 °C; IR (Nujol) 3350, 1610, 1480, 1330, 1315 cm^{-1}; NMR ($CDCl_3$) δ 1.29 (t, 3H, J=8 Hz), 2.99 (q, 2H, J=8 Hz), 7.0—7.9 (m, 5H), 8.37 (d, 1H, J=14 Hz), 8.1—8.6 (broad, 1H). Found: C, 66.96; H, 5.48; N, 12.58%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.55; H, 5.59; N, 12.96%.

*2-(2-Nitrovinyl)-3-propylindole (**4d**)*: 89% yield; mp 158—159 °C; IR (Nujol) 3330, 1610, 1490, 1315 cm^{-1}; NMR ($CDCl_3$) δ 0.97 (t, 3H, J=7 Hz), 1.75 (sext, 2H, J=7 Hz), 2.95 (t, 2H, J=7 Hz), 7.1—8.0 (m, 5H), 8.40 (d, 1H, J=14 Hz), 8.3—8.7 (broad, 1H). Found: C, 67.93; H, 6.02; N, 12.36%.Calcd for $C_{13}H_{14}N_2O_2$: C, 67.81; H, 6.13; N, 12.17%.

*2-(2-Nitrovinyl)-3-isopropylindole (**4e**)*: 91% yield; mp 174—175 °C; IR (Nujol) 3360, 1610, 1480, 1330, 1305 cm^{-1}; NMR ($CDCl_3$) δ 1.50 (d, 6H, J=7 Hz), 3.45 (sept, 1H, J=7 Hz), 7.0—8.0 (m, 5H), 8.43 (d, 1H, J=14 Hz), 8.2—8.6 (broad, 1H). Found: C, 68.02; H, 6.16; N, 12.30%. Calcd for $C_{13}H_{14}N_2O_2$: C, 67.81; H, 6.13; N, 12.17%.

*Treatment of 2,3-Dimethylindole **1a** in Formic Acid.* A solution of **1a** (100 mg) in formic acid (100 ml) was bubbled with oxygen at the reflux temperature for 7 h. The reaction mixture was then evaporated to give a brown oily residue, which was chromatographed on silica-gel TLC with benzene to yield **1a** (7 mg), **3a** (5 mg), and 2,3-dimethyl-1-formylindole **1g**, mp 87—88 °C (lit,[18] 87—88 °C) (58 mg).

*Oxidation of 3-Benzoyl-1,2-dimethylindole **1f** with Silver Acetate.* A solution of **1f** (249 mg) and silver acetate (334 mg) in acetic acid (100 ml) was heated at the reflux temperature for 20 h under air. The reaction mixture was then evaporated to dryness and chromatographed on silica-gel TLC with benzene to yield **1f** (35 mg; 14%), 2-acetoxymethyl-3-benzoyl-1-methylindole **5f** (40 mg; 15% yield based on **1f** consumed), and 3-benzoyl-2-formyl-1-methylindole **3f** (125 mg; 55% yield based on **1f** consumed). Furthermore, under nitrogen, the oxidation of **1f** (249 mg) with silver acetate (334 mg) in acetic acid (100 ml) for 20 h gave **1f** (53 mg; 21%), **5f** (38 mg; 17% yield based on **1f** consumed), and **3f** (114 mg; 55%yield based on **1f** consumed).

A similar treatment of **1f** (249 mg) and silver acetate (117 mg) in acetic acid (100 ml) for 15 h under nitrogen gave **1f** (75 mg; 30%), **5f** (100 mg; 47% yield based on **1f** consumed), and **3f** (12 mg; 7% yield based on **1f** consumed). The spectral and analytical data of **5f** and **3f** are given below.

5f: Mp 103—104 °C (from ether/hexane); IR (Nujol) 1740, 1630, 1600, 1580, 1530, 1480, 1410, 1330 cm^{-1}; NMR ($CDCl_3$) δ 2.07 (s, 3H), 3.85 (s, 3H), 5.50 (s, 2H), 7.1—8.1 (m, 9H). Found: C, 74.45; H, 5.48; N, 4.64%. Calcd for $C_{19}H_{17}NO_3$ C, 74.25; H, 5.58; N, 4.56%.

3f: Mp 124.5—125.5 °C (from chloroform/hexane); IR (Nujol) 1675, 1635, 1615, 1605, 1580, 1510, 1480, 1400, 1345 cm^{-1}; NMR ($CDCl_3$) δ 4.24 (s, 3H), 7.3—8.3 (m, 9H), 10.7 (s, 1H). Found: C, 77.57; H, 4.99; N, 5.36%. Calcd for $C_{17}H_{13}NO_2$: C, 77.55; H, 4.98; N, 5.32%.

*Oxidation of 2-Acetoxymethyl-3-benzoyl-1-methylindole (**5f**) with Silver Acetate.* A solution of **5f** (15 mg) and silver acetate (20 mg) in acetic acid (30 ml) was heated at the reflux temperature for 15 h under air. The reaction mixture was then evaporated and chromatographed on silica-gel TLC with benzene to yield **3f** (8 mg).

The authors wish to thank Professor Tsunao Hase and Professor Tsutomu Sakakibara of Kagoshima University for their support throughout the study. They are also grateful to Mr. Tetsuo Iwagawa of Kagoshima University for his mass-spectrometric analyses.

The Photochemistry of the Host-Guest Complex. VII. The Photoreaction of Dicyanopyrazine Derivatives Having a Crown Ether Moiety[1)]

Masaru TADA,* Hirohide HAMAZAKI, and Hideki HIRANO
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 7, 1982)

The irradiation of 4′-(5,6-dicyano-2-pyrazinyl)benzo-15-crown-5 and 5,6-dicyano-2-(3,4-dimethoxyphenyl)-pyrazine in the presence of a tertiary or secondary amine caused reductive decyanation to give 5-decyano derivatives, which in turn gave bis(decyano) derivatives on further irradiation. Free-energy changes upon single-electron transter from the amine to the excited state of dicyanopyrazine derivatives are exothermic for triethylamine and diethylamine, but endothermic for butylamine. The single-electron transfer was evidenced by the effect of the sodium ion on the quantum yields of the reaction products and the fluorescence quenching.

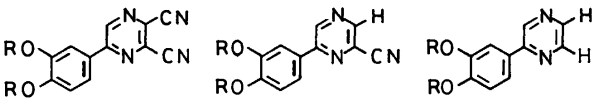
In our studies of crown ether derivatives, we havef previously reported the diverse effects of guest cations on the photoreactivities of the crown ether derivatives. The pairing effect, the variation in the oxidation potential, the change in the intersystem crossing rate, and the destabilization of the transition state are among the effects which we have already discussed.[2)] In this paper we would like to report on other effects by a guest cation, a decrease in the reduction potential and an increase in the excitation energy, on the photoreactivity of the pyrazine derivative having a crown ether moiety, 4′-(5,6-dicyano-2-pyrazinyl)benzo-15-crown-5 (**1**).

The pyrazine derivative having an electronegative substituent can be a mimicry of an oxidation-reduction coenzyme, such as flavin and biopterin, in which the aromatic system containing nitrogen plays an important role in the redox systems.[3)]

Syntheses of Dicyanopyrazine Derivatives. 4′-(5,6-Dicyano-2-pyrazinyl)benzo-15-crown-5 (**1**) and 5,6-dicyano-2-(3,4-dimethoxyphenyl)pyrazine (**2**) were synthesized by the condensation of diaminomaleonitrile (DAMN) with the corresponding dicarbonyl compounds, which had been prepared from benzo-15-crown-5 or 1,2-dimethoxybenzene by acetylation (acetic acid in polyphosphoric acid), followed by oxidation by selenium dioxide.

*The Photoreaction of Dicyanopyrazine Derivatives(**1** and **2**) in the Presence of Amines.* A dry acetonitrile solution of the benzo-15-crown-5 derivative **1** was irradiated in the presence of four equivalents of triethylamine; 4′-(6-cyano-2-pyrazinyl)benzo-15-crown-5 (**3**) was thus obtained in 80% yield. The irradiation of the dimethoxybenzene derivative **2** gave a similar result, affording 6-cyano-2-(3,4-dimethoxyphenyl)pyrazine (**4**) in 80% yield. The structures of both products were deduced from the ^{1}H-NMR spectra, in which a new aromatic hydrogen (C_5–H) at the pyrazine ring (δ 8.95 for **3** and 8.94 for **4**) couples (J=2 Hz) with the meta-hydrogen (δ 9.20 for **3** and 9.18 for **4**).

The irradiations of **1** and **2** in the presence of a large excess of triethylamine (acetonitrile-triethylamine, 3 : 1) gave two bis(decyano) derivatives, 4′-(2-pyrazinyl)-benzo-15-crown-5 (**5**) and 2-(3,4-dimethoxyphenyl)-pyrazine (**6**), in 40 and 46% yields respectively. The same products were also obtained in low yields under the previous reaction conditions (triethylamine; 5.6×10^{-2} mol dm^{-3}) on prolonged irradiation or on the urther irradiation of the isolated **3** or **4**. Therefore, the products **5** and **6** are the secondary products from the primary products, **3** and **4** respectively.



1 , 2 3 , 4 5 , 6

1 , 3 , 5 : R,R = $O(CH_2CH_2OCH_2CH_2)_2$

2 , 4 , 6 : R = CH_3

The irradiation of **1** or **2** in the presence of diethylamine instead of triethylamine gave essentially the same results. Butylamine, however, did not cause a photoreaction under similar conditions, though the use of a large excess of butylamine caused the thermal substitution of one of the cyano group with a butylamino group in the dark.[4)] These photoreactions are accelerated by purging the reaction solution with argon.

Spectroscopic and Electrochemical Studies. The same reaction takes place in benzene, though the reaction is not so clean as in acetonitrile. The fluorescence from **1** and **2** is almost identical, but weaker in acetonitrile than in benzene. The quenching experiment, therefore, was carried out in benzene. Triethylamine ($k_q\tau$=47.0 mol^{-1} dm^3) and diethylamine ($k_q\tau$=28.0 mol^{-1} dm^3) quench the fluorescence efficiently, but butylamine shows no detectable quenching effect. **3** and **4** fluoresce strongly even in acetonitrile, and the emission is quenched by triethylamine ($k_q\tau$=23.0 mol^{-1} dm^3) and diethylamine ($k_q\tau$=18.0 mol^{-1} dm^3), but, again, not with butylamine.

The photoreaction and the fluorescence quenching by animes suggest that a single-electron transfer from the amine to the excited pyrazine derivatives plays an important role. Rehm-Weller's equation,[5)] $\Delta G = E_D^{ox} - E_A^{red} - E_A^* - e^2/(r\varepsilon)$, in which E_D^{ox}, E_A^{red}, E_A^*, and $e^2/(r\varepsilon)$ represent the oxidation potential of the amines, the reduction potential of the pyrazine derivatives, the excitation energy of the pyrazine derivative, and the Coulomb stabilization of the radical ion pairs respectively, shows the numerical value for the free-energy change on the electron transfer. The inter-ion

TABLE 1. FREE ENERGY CHANGE IN THE ELECTRON TRANSFER FROM AMINES TO THE EXCITED STATE OF **1** AND **2**, AND QUANTUM YIELD OF THE PHOTODECYANATION

Compound		E_A^{red}	E_D^{ox}	E_A^*	$\Delta G'$	$\Phi\times10^3$

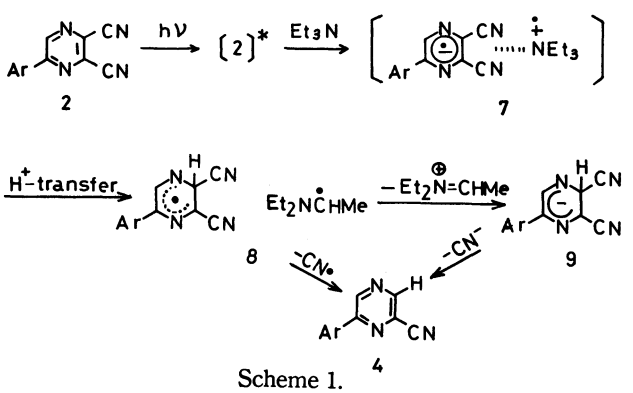
a) Solvent: acetonitrile. V *vs.* S.H.E. (converted from the value *vs.* Ag/AgCl). b) $\lambda_{0\text{-}0}=445$ nm (calculated) in acetonitrile: see text for the calculation. c) $\Delta G'=E_D^{ox}-E_A^{red}-E_A^*$. d) **1**: 5.00 mmol dm^{-3}; $NaClO_4$: 20 mmol dm^{-3}. e) **1**: 1.0×10^{-4} mol dm^{-3}; $NaClO_4$: 5.0 mmol dm^{-3}.

distance (r) in the last term should be essentially large and constant with a similar combination of the donor and acceptor in the same solvent.[6] Therefore, we calculated the $\Delta G'$ ($=\Delta G-e^2/(r\varepsilon)$) from the data of cyclic voltammetry (E^{red} and E^{ox}) and the fluorescence spectrum(E_A^*). The fluorescence of **2** in acetonitrile has fine structure enabling us to assign the 0-0 band; no therefore, the E_A^* was estimated from the ν (0-0) calculated by means of this equation: ν (0-0)$=(\nu^a_{max}+\nu^f_{max})/2$, in which ν^a_{max} and ν^f_{max} represent the frequencies of the maxima of the absorption and the fluorescence respectively. The values of $\Delta G'$ on the electron transfer from amines to the excited state of **2** are negative for triethylamine and diethylamine, but positive for butylamine. These results are perfectly coincident with the photoreactivity and fluorescence quenching.

Reaction Mechanism. The experimental findings described above strongly suggest that the photoreaction proceeds through a single electron-transfer process (Scheme 1). This type of reaction has been reported for the photo-dehalogenation of aromatic halides[7] or a photochemical $S_{RN}1$ reaction,[8] and the intervention of aryl radicals has been well documented.[9] Ohashi *et al.* reported that the photoreaction of dicyanobenzenes in the presence of triethylamine or diethylamine gave substitution products, 4-[1-(diethylamino)ethyl]-benzonitrile or 4-[1-(ethylamino)ethyl]benzonitrile, by means of an electron-transfer mechanism.[10]

As in the case of halobenzenes, the hydrogen abstraction of the 3-cyano-2-pyrazinyl radical seems a plausible path to give the photoproducts; the radical can be expected to be formed by the electron transfer from an amine to the excited dicyanopyrazine derivative, generating a radical anion, followed by the rupture of the cyanide ion. In the case of dicyanopyrazines, however, a proton trasfer is proved to be involved after the electron transfer, and the radicals thus formed couple to give a primary product which looses hydrogen cyanide to give a substitution product.

In the present study, the addition of deuterium oxide to the reaction solution of **2** afforded the product **4** in which the C_5–H of the pyrazine ring was replaced by C_5–D. However, the photoreaction of **2** in acetonitrile-d_3 did not give any deuterated product. These results



Scheme 1.

clearly indicate that a proton transfer is involved in the present photoreaction. In the absence of a protic solvent, therefore, the proton must be derived from the α-hydrogen of triethylamine, while in the presence of a protic solvent, the proton comes competitively from the solvent and triethylamine. These results suggest the mechanism shown in Scheme 1. The radical-ion pair **7**, formed by the electron transfer between amine and the excited **2**, collapses into a radical pair **8** by means of a proton transfer. The dicyanohydropyrazinyl radical in **8** gives the product **4** by the direct rupture of a cyano-radical or *via* an additional electron transfer, followed by the loss of a cyanide ion *via* **9**.

As has been described earlier, the addition of a deuterated protic solvent induces C_5–D in the product **4**; therefore, the protonation of the radical anion **7** must occur at the *ipso*-position. This selectivity of protonation at the *ipso*-position can be understood in terms of the increased electron density and, consequently, the basicity at the C_5-position of the pyrazine ring.[11] On the other hand, the protonation to the excited state of **2** may occur at one of the nitrogen atoms to afford the pyrazinium ion in its ground state or excited state. This can be expected because of the increased basicity of nitrogen heterocycles in those excited states.[12] The addition of water to the reaction mixture, indeed, quenched the fluorescence and the photoreaction of **2**; this quenching indicates the presence of another relaxation path of the excited state which participates in the photoreaction. In the case of dicyanobenzenes, the radical pair corresponding to **8** couples to give the substitution product,[10] but the radical pair **8** does not coupled, probably because of the stability of the hydropyrazinyl radical resulting from the conjugation with the aryl group at the C_2-position of the dicyanopyrazine ring.

The Effect of the Sodium Ion on the Photochemical Behavior of the Crown Ether Derivative. The formation of a host-guest complex between the crown ether moiety of **1** and the sodium ion must affect the reduction potential (E_A^{red}) and the excitation energy (E_A^*) and, therefore, the photoreactivity of **1**. The absorption spectrum of **1** changes upon the addition of sodium perchlorate (Fig. 1); the analysis of the change by the Benesi-Hildebrand method[13] gave the association constant ($K_{ass}=2900$ mol^{-1} dm^3, 25 °C). This value indicates that the complex formation is almost complete upon the addition of two equivalents of sodium perchlorate

under the present reaction conditions (**1**: 1.4×10^{-2} mol dm^{-3}). On the other hand, the absorption of the dimethoxybenzene derivative **2** does not show any change upon the addition of the sodium ion. The quantum yields of the decyanation products **3** and **4** in the presence of sodium perchlorate are shown in Fig. 2. The pyrazine derivative **1** has a strong absorption between 300—400 nm both in the free form, $\lambda_{max}^{CH_3CN}$ (ε) 370 nm (18600), and in its sodium complex, 356 nm (18400). The concentration of **1** for the reaction (1.4×10^{-2} mol dm^{-3}) is enough to absorb essentially all the photons from a high-pressure mercury lamp (313, 334, and 366 nm) in these regions. The yield of the product, therefore, safely gives the quantum yield at the early stage of the reaction, less than 10% conversion. No effect was observed upon the addition of tetrabutylammonium perchlorate to the reaction systems of **1** and **2**. The photoreaction of **2** was, again, not affected by sodium perchlorate (Fig. 2). These findings show that the effect of the sodium salt is due to the sodium ion, not the perchlorate anion, and that the crown ether moiety is essential to show the salt effect. This conclusion clearly indicates that the effect is closely associated with the formation of the host-guest complex.

The fluorescence quenching of the monocyanopyrazine derivative **3** by triethylamine in acetonitrile is stimulated by the addition of sodium perchlorate (Table 2). The variation in the quenching efficiency ($k_q\tau$) is possibly due to the change in the k_q value by the complex formation, since the rather small spectral change indicates only a small variation in the τ-value. In contrast, sodium perchlorate does not affect the fluorescence quenching of the dimethoxybenzene derivative **4** by triethylamine. The fluorescence of some sorts of aromatic compounds can be quenched by sodium salts consisting of a counter ion with a low oxidation potential, such as iodide, but the quenching is negligible by the salts consisting of an anion with a high oxidation potential, such as perchlorate.[14]

The salt effect discussed in this section is in good accordance with the single-electron transfer in the photochemical behavior of pyrazine derivatives, **1**, **2**, **3**, and **4**. The variation in the quantum yields of the photo-product and the fluorescence quenching are closely related to the changes in the reduction potential (E_A^{red}) and the energy of the singlet excited state (E_A^*) of the pyrazine derivatives. The quantum yield of the photo-decyanation and the free-energy changes by the electron transfer from triethylamine to the crown ether derivative **1** or its sodium complex are included in Table 1.

Table 2. Fluorescence quenching of **3**[a] by triethylamine in the psesence of sodium perchlorate

Conclusion. The excitation of the dicyanopyrazine derivative with a benzo-15-crown-5 or dimethoxyphenyl group causes a single-electron transfer from amines with a low oxidation potential. This process is responsible for the photochemical decyanation and the fluorescence quenching. The formation of the host-guest complex from the benzo-15-crown-5 moiety with the sodium ion enhances the electron-transfer process and, hence, the photoreactivity.

Experimental

*Syntheses of Dicyanopyrazine Derivatives (**1** and **2**).* Benzo-15-crown-5 (31.0 g, 115 mmol) was dissolved in 80 cm^3 of polyphosphoric acid, and the mixture was treated with acetic acid (10.5 g, 173 mmol) for 1.0 h at 40—50 °C under stirring. After cooling, 60 cm^3 of water was added to decompose the polyphosphoric acid and the product was extracted with chloroform. The subsequent evaporation of the extract after drying over magnesium sulfate gave a crude product, which was purified by passing it through an alumina column (5.0 $\phi\times$ 18.0 cm) with chloroform to give 4′-acetylbenzo-15-crown-5

75%) (mp 90 °C). 4′-Acetylbenzo-15-crown-5 (27.0 g, 87 mmol) and selenium dioxide (14.5 g, 131 mmol) were heated for 40 h in 500 cm^3 of dioxane-water (3 : 1) under reflux. After the evaporation of most of the solvents under reduced pressure, chloroform was added to the residue and the solid selenium was removed by filtration. The filtrate was dried over magnesium sulfate, condensed, and passed through an alumina column (5.0 $\phi \times$ 15.0 cm) with chloroform. The crude product thus obtained was 4′-(1-oxo-2,2-dihydroxyethyl)benzo-15-crown-5, which lost water by heating under reduced pressure (100 °C/3066 Pa) to give 4′-(1,2-dioxoethyl)-benzo-15-crown-5 (87%). The dioxo compound (24.0 g, 74 mmol) thus obtained was treated with diaminomaleonitrile (10.4 g, 96 mmol) in 200 cm^3 of THF and stirred at room temperature. Soon after mixing, yellow precipitates appeared and further stirring with gentle heating completed the reaction. The yellow precipitates were collected by filtration and recrystallized from acetonitrile–ethanol (1 : 1) to give the yellow crystal of 4′-(5,6-dicyano-2-pyrazinyl)benzo-15-crown-5 (**1**) (62%); mp 151 °C. Found: C, 60.35; H, 5.19; N, 13.83%. Calcd for $C_{20}H_{20}N_4O_5$: C, 60.60; H, 5.09; N, 14.14%. UV (CH_3CN): λ_{max} (ε) 237 (10200), 258 (11400), 319 (10800), and 370 nm (18600). ^1H NMR ($CDCl_3$): δ 3.76 (s, 8H), 3.96 (m, 4H), 4.22 (m, 4H), 6.98 (d, 1H, J=9 Hz), 7.75 (m, 2H), and 9.23 (s, 1H).

5,6-Dicyano-2-(3,4-dimethoxyphenyl)pyrazine (**2**) was obtained in a higher yield by the same procedure, but starting from 1,2-dimethoxybenzene. **2**: Mp 203 °C. Found: C, 63.18; H, 3.73; N, 21.14%. Calcd for $C_{14}H_{10}N_4O_2$: C, 63.15; H, 3.79; N, 21.04%. UV (CH_3CN): λ_{max} (ε) 236 (10600), 257 (11200), 316 (10600), and 369 nm (19300). ^1H NMR ($CDCl_3$): δ 4.02 (s, 3H), 4.04 (s, 3H), 7.08 (d, 1H, J=9 Hz), 7.74 (m, 2H), and 9.25 (s, 1H).

*Photoreaction of **1** and **2** in the Presence of Amines.* Irradiations were carried with a 450 w high-pressure mercury lamp mounted in a rotary irradiation apparatus (Rikosha RH-400), unless otherwise mentioned. The reaction tubes were 1.0 cm in diameter, and the distance between the lamp and reaction tubes was 5 cm. In quantitative experiments to obtain the relative quantum yields under varying conditions, the reaction tubes were rotated around the lamp so that all reaction tubes absorbed the same quanta. The quantum yield of the product **3** was determined by benzophenone-benzhydrol actinometry;[15] the reaction samples were irradiated through a solution filter ($CoSO_4 \cdot 7H_2O$, 480 g dm^{-3}; thickness, 1.3 cm) to cut a 404-nm radiation.

(i) Photoreaction in Dry Acetonitrile: A solution of **1** or **2** (14.0 mmol dm^{-3}) and an amine (triethylamine, diethylamine, or butylamine, 0.56 mol dm^{-3}) in dry acetonitrile (16 cm^3) was irradiated for 10 h. The reaction solution from four tubes were collected and condensed under reduced pressure. The condensate was passed through a silica-gel column (1.5 $\phi \times$ 10 cm), using benzene as the eluent, and the condensate was purified by repeated chromatography on silica gel to give the product as the eluate from chloroform (**3**) or chloroform–benzene (3 : 1) (**4**). The photoreaction was accelerated by the purge of the dissolved oxygen by bubbling a stream of argon into the reaction solution after it had been dipped in an ultrasonic bath. The quantum yields were determined by the measurement of the product yield by means of HPLC (Corasil II, acetonitrile).

3; Mp 137 °C. Found: C, 61.29; H, 5.52; N, 11.40%. Calcd for $C_{19}H_{21}N_3O_5$: C, 61.44; H, 5.70; N, 11.32%. UV (CH_3CN): λ_{max} (ε) 236 (13500), 266 (9000), 305 (10200), and 354 nm (19400). IR (Nujol): 2248 cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.75 (s, 8H), 3.93 (m, 4H), 4.20 (m, 4H), 7.03 (d, 1H, J=9 Hz), 7.75 (m, 2H), 8.95 (d, 1H, J=2 Hz), and 9.20 (d, 1H, J=2 Hz).

4; Mp 143 °C. Found: C, 64.88; H, 4.44; N, 17.24%. Calcd for $C_{13}H_{11}N_3O_2$: C, 64.72; H, 4.60; N, 17.42%. UV (CH_3CN): λ_{max} (ε) 234 (13400), 266 (8600), 304 (9800), and 354 nm (19500). IR (Nujol): 2250 cm^{-1}. ^1H NMR ($CDCl_3$): δ 4.01 (s, 3H), 4.03 (s, 3H), 7.07 (d, 1H, J=9 Hz), 7.72 (m, 2H), 8.94 (d, 1H, J=2 Hz), and 9.18 (d, 1H, J=2 Hz).

The photoreaction described above gave a small amount of a bis (decyano) derivative **5** or **6**, but the irradiation of **1** or **2** for 16 h in the presence of a large excess of triethylamine (CH_3CN–Et_3N, 3 : 1) and a similar work-up gave the bis (decyano) derivative **5** (40%) or **6** (44%) respectively as the main product. The irradiation of **3** or **4** under similar conditions also gave **5** or **6** respectively.

5; Mp 110 °C. Found: C, 62.71; H, 6.37; N, 7.98%. Calcd for $C_{18}H_{22}N_2O_5$: C, 62.41; H, 6.40; N, 8.08%. UV (CH_3CN): λ_{max} (ε) 223 (18700), 260 (10600), 289 (10400), and 318 nm (11300). ^1H NMR ($CDCl_3$): δ 3.77 (s, 8H), 3.92 (m, 4H), 4.18 (m, 4H), 6.95 (d, 1H, J=9 Hz), 7.55 (dd, 1H, J=9 and 2 Hz), 7.62 (d, 1H, J=2 Hz), 8.44 (d, 1H, J=2 Hz), 8.57 (diffused t, 1H), and 8.98 (d, 1H, J=2 Hz).

6; Mp 75 °C. Found: C, 66.66; H, 5.60; N, 13.05%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%. UV (CH_3CN): λ_{max} (ε) 225 (18800), 261 (12400), 288 (12300), and 320 nm (13800). ^1H NMR ($CDCl_3$): δ 3.94 (s, 3H), 3.97 (s, 3H), 6.99 (d, 1H, J=9 Hz), 7.58 (dd, 1H, J=9 and 2 Hz), 7.67 (d, 1H, J=2 Hz), 8.48 (d, 1H, J=2 Hz), 8.60 (diffused t, 1H), and 9.02 (d, 1H, J=2 Hz).

(ii) Photoreaction in the Presence of Salts: To the same solutions described in Part *(i)* of this section (amine: triethylamine) were added 0.0—6.0 equivalents of sodium perchlorate monohydrate to the pyrazine derivative **1** or **2**, and the mixtures were irradiated in a similar manner for 1 h. Without the addition of sodium perchlorate, less than 10% of the starting material was converted to the decyano derivatives (**3** or **4**) during 1 h. The reaction mixture was concentrated under reduced pressure, and the product was determined by NMR analyses in DMSO, using 1,1,2,2-tetrachloroethane as the internal reference. The quantum yields obtained in this method are shown in Fig. 2. The reaction of **1** in the presence of tetrabutylammonium perchlorate was carried out in the same manner; the results are shown in Fig. 2.

Absorption Spectra and Fluorescence Spectra. The absorption and fluorescence spectra were measured with a Shimadzu UV-200 spectrophotometer and a Hitachi MPF-4 spectrophotometer in acetonitrile or benzene. The acetonitrile was purified by refluxing and distillation over phosphorus pentaoxide. The benzene was purified by washing with conc sulfuric acid and distillation over metallic sodium. In all the fluorescence measurements, 1.00×10^{-4} mol dm^{-3} solution of the pyrazine derivative (**1**, **2**, **3**, or **4**) were employed; the concentrations of the amine (triethylamine, diethylamine, or butylamine) for the quenching were 0.0, 2.0, 4.0, and 6.0 mmol dm^{-3}. The fluorescence quenching of **3** in acetonitrile in the presence of sodium perchlorate was carried out in the same mammer, with the results shown in Table 2.

Measurement of Redox Potential. The redox potential was measured by means of cyclic voltammetry at 25 °C and at the scan rate of 0.5 V s^{-1} using platinum disk electrodes and Ag/AgCl couple as the reference electrode. The oxidation potentials of triethylamine, diethylamine, and butylamine were measured by using 5.0 mmol dm^{-3} solution in acetonitrile containing tetrabutylammonium perchlorate (1.0×10^{-1} mol dm^{-3}) as the electrolyte. The reduction potentials of **1** and **2** were measured in exactly the same method; the results are shown in Table 1. The first oxidation and reduction potentials in cyclic voltammetry are both reversible for the scan to

−2.0 V (**1** and **2**) and +2.0 V (amines).

This work was supported by a Grant-in-Aid for Fundamental Science Research (1980) from the Ministry of Education, Science and Culture and by an Annual Project Organized by Waseda University, 1981—1982.

Synthesis of Four Diastereoisomers of Histopine

Yasuo KITAJIMA,* Michinori WAKI, and Nobuo IZUMIYA
Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
(Received June 15, 1982)

Four isomers of histopine, N^2-(1-carboxyethyl)histidine, were prepared to provide their physicochemical properties. A diastereomeric mixture, (*RS*),(*S*)-histopine (N^2-[(*RS*)-1-carboxyethyl]-(*S*)-histidine), was synthesized from 2-oxopropionic acid and (*S*)-histidine by reduction with sodium cyanoborohydride. The mixture was separated into its components, (*S*),(*S*)-histopine and (*R*),(*S*)-histopine, by an ion-exchange column chromatography. In a similar manner (*R*),(*R*)-histopine and (*S*),(*R*)-histopine were prepared. Configurations of the four isomers obtained were assumed from their ORD data by comparison with those of the isomers of octopine (N^2-(1-carboxyethyl)arginine) with a definite configuration.

Histopine is a natural compound isolated from crown gall tissue inoculated with *Agrobacterium tumefaciens* B_6.[1] A number of opines structurally related to histopine have recently been found in crown gall tumors of plants.[2] Octopine (N^2-[(*R*)-1-carboxyethyl]-(*S*)-arginine) first isolated from octopus muscle[3,4] is representative of such opines. Although little is known concerning the significance of the presence of these opines in plants and animals, the use of them as markers of a possible transfer of gene from the tumor-inducing bacterium into host plant cells[2,5] has roused further interest in these compounds.

The chemical structure of histopine was established by Kemp as N^2-(1-carboxyethyl)histidine.[1] The configuration of natural histopine, however, has not been determined. Kemp assumed that the configuration of the histidine (His) part was (*S*) only based on the following fact: natural histopine showed the same chromatographic behavior on thin-layer or ion-exchange column as that of a diastereomeric mixture of histopine which was synthesized from (*S*)-histidine and (*RS*)-2-bromopropionic acid.[1]

A synthetic attempt leading to a diastereomeric mixture of histopine has been reported.[1] However, none of the optically pure isomers of histopine has been isolated and characterized. Even for natural histopine, its physicochemical properties (elemental analysis, melting point and specific rotation) have not been given. Thus we were interested in preparing four isomers of histopine in pure state to provide their physicochemical properties.

This paper first describes the preparation of (*RS*),(*S*)-histopine (N^2-[(*RS*)-1-carboxyethyl]-(*S*)-histidine) by sodium cyanoborohydride reduction of a mixture of 2-oxopropionic acid and (*S*)-histidine, subsequent separation into its components by column chromatography, and similar experiments with (*R*)-histidine. Second, the configurations of the four isomers of histopine are assumed by comparison of their ORD patterns with those of octopine isomers having a definite configuration.

Results and Discussion

*Synthesis of (*RS*),(*S*)-Histopine (*N^2*-[(*RS*)-1-Carboxyethyl]-(*S*)-histidine) from (*S*)-Histidine.* Kemp reported the preparation of (*RS*),(*S*)-histopine from (*RS*)-2-bromopropionic acid and (*S*)-histidine in the presence of $Ba(OH)_2$ at 55 °C without describing the yield.[1]

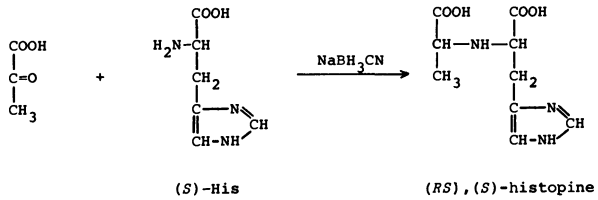

Fig. 1. Synthesis of a diastereomeric mixture of histopine from (*S*)-histidine.

Under these conditions, however, there is some risk of partial racemization of (*S*)-histidine part during the reaction. Recently Jensen *et al.* prepared a distereomeric mixture of nopaline (N^2-(1,3-dicarboxypropyl)arginine) in a high yield from 2-oxoglutaric acid and (*S*)-arginine by reduction with sodium cyanoborohydride ($NaBH_3CN$) under mild conditions at neutral pH and at room temperature.[6]

Taking advantages of this new reagent, $NaBH_3CN$, we intended to synthesize four isomers of histopine from 2-oxopropionic acid and (*S*)- or (*R*)-histidine by reductive amination (Fig. 1). We could obtain (*RS*),(*S*)-histopine in a high yield of 98% based on (*S*)-histidine after the reaction of 2-oxopropionic acid, (*S*)-histidine, and $NaBH_3CN$ in 5 : 1 : 3 molar ratio at pH 7.0 for 3 d. In a similar manner (*RS*),(*R*)-histopine was synthesized from (*R*)-histidine in a yield of 97%.

*Separation of (*RS*),(*S*)-Histopine into Components.* Separation of a diastereomeric mixture of octopinic acid (N^2-(1-carboxyethyl)ornithine) on an amino acid analyzer was already reported.[4] Then we tried to separate (*RS*),(*S*)-histopine into its components by an amino acid analyzer, and found the conditions to achieve the separation (see Experimental section). A faster eluting isomer was determined as (*S*),(*S*)-histopine, and a slower eluting isomer as (*R*),(*S*)-histopine by separate-runs using each pure isomer.

Preliminary experiments for separation of (*RS*),(*S*)-histopine were performed with a column of Dowex 50 at different concentration and pH in sodium citrate buffer system, in order to find optimal conditions for the preparative separation of histopine isomers. According to the above results (see Experimental section), we carried out preparative separation of (*RS*),(*S*)-histopine with a large column (1.8 cm × 190 cm) of Dowex 50. Thus (*S*),(*S*)-histopine with $[\alpha]_D$ +27.7° was isolated from the faster eluting fractions and (*R*),(*S*)-histopine

with $[\alpha]_D$ +30.2° from the slower eluting fractions respectively in a weight ratio of 1 : 1.7. In a similar manner, (*R*),(*R*)-histopine and (*S*),(*R*)-histopine were isolated by the column chromatography of (*RS*),(*R*)-histopine respectively in a weight ratio of 1 : 1.6. Interestingly each isomer in synthetic diastereomeric mixture was not in an equal ratio, which shows occurrence of diastereoselective reduction during the formation of diastereomeric mixture with $NaBH_3CN$.

Attempts to Prepare Histopine Isomers from (S)-Alanine. Chemical synthesis of histopine isomers was attempted by reactions starting from (*S*)-alanine to determine the configuration of the Ala part in histopine isomers. Biellmann *et al.* reported that octopine isomers were obtained from (*S*)-alanine and 2-oxo-5-guanidinopentanoic acid by reduction with $NaBH_3CN$.[7] In the present study, however, the reaction of (*S*)-alanine and 2-oxo-3-(5-imidazolyl)propionic acid with $NaBH_3CN$ under the same conditions gave no expected product. Changes of reaction conditions (*e.g.*, molar ratios of the reactants and pH) also resulted in no formation of histopine isomers. Instead, 2-hydroxy-3-(5-imidazolyl)-propionic acid was detected as a main product by ^1H NMR analysis of the reaction mixture. Previously, Izumiya *et al.* observed a similar result that palladium-catalyzed hydrogenation of (*S*)-alanine and 2-oxo-5-guanidinopentanoic acid did not produce octopine isomers.[8] We assume that easy formation of 2-hydroxy-3-(5-imidazolyl)propionic acid instead of the desired product is due to the instability of a Schiff's base formed from (*S*)-alanine and 2-oxo-3-(5-imidazolyl)-propionic acid or difficult formation of the Schiff's base because of the presence of basic imidazolyl group in the α-keto acid. Condensation of (*S*)-alanine and (*S*)-2-bromo-3-(5-imidazolyl)propionic acid derived from (*S*)-histidine was also unsuccessful.

Configurations of Four Diastereoisomers of Histopine. The configuration of the His part in histopine isomers obtained from 2-oxopropionic acid and (*S*)- or (*R*)-histidine is unequivocally defined, because the configuration of the His part is retained during the reduction with $NaBH_3CN$.

The configuration of the Ala part of histopine isomers was deduced from the results of ORD measurements (see Fig. 2) of four histopine isomers and two octopine isomers with a definite configuration as follows. ORD Pattern of (*S*),(*S*)-octopine (N^2-[(*S*)-1-carboxyethyl]-(*S*)-arginine)[4] is similar to that of a histopine isomer, which has an $[\alpha]_D$ value of +27.7°, prepared from (*S*)-histidine. Thus the configuration at the Ala part in this isomer of histopine is assumed to be (*S*), and the isomer is designated as (*S*),(*S*)-histopine as shown in Table 1. Similar ORD curves are obtained for (*R*),(*S*)-octopine[4] and for a histopine isomer, which has an $[\alpha]_D$ value of +30.2°, prepared from (*S*)-histidine. Thus the configuration of the Ala part in this isomer of histopine is assumed to be (*R*), and the isomer is designated as (*R*),(*S*)-histopine. It is apparent from Fig. 2 that histopine isomers, with $[\alpha]_D$ −27.2° and −29.8°, both prepared from (*R*)-histidine, are antipodes of (*S*),(*S*)- and (*R*),(*S*)-histopine, respectively.

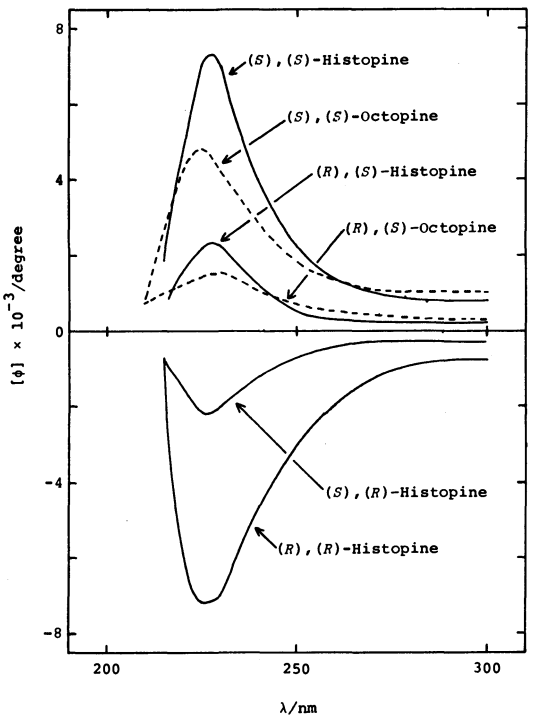

Fig. 2. ORD Curves of isomers of histopine and octopine in 5 M HCl.

Table 1. Configurations of diastereoisomers of histopine

Nomenclature	Configuration of		$[\alpha]_D$/° (5 M HCl)
	Ala part	His part	
(*S*),(*S*)-Histopine	(*S*)	(*S*)	+27.7
(*R*),(*S*)-Histopine	(*R*)	(*S*)	+30.2
(*R*),(*R*)-Histopine	(*R*)	(*R*)	−27.2
(*S*),(*R*)-Histopine	(*S*)	(*R*)	−29.8

Experimental

TLC was carried out on silica gel G (Merck) with the following solvent systems: R_f^1, *n*-BuOH–AcOH–pyridine–H_2O (4 : 1 : 1 : 2, v/v); R_f^2, MeOH–H_2O–pyridine (20 : 5 : 1, v/v). Paper chromatography shown as R_f^1 (PPC) was carried out on Toyo Roshi No. 52 paper with the same solvent system as for R_f^1. Material possessing an imidazolyl group was detected by spraying with the Pauly's reagent.[9] Other compounds on TLC were detected by spraying with 10% H_2SO_4, followed by heating on a hot plate. Optical rotations were measured on a Union high sensitivity polarimeter PM-71. Amino acid analyses were performed with a Hitachi amino acid analyzer KLA-5.

(RS),(S)-Histopine. A solution of (*S*)-histidine monohydrochloride (960 mg, 5 mmol) and freshly distilled 2-oxopropionic acid (2.20 g, 25 mmol) in water (7.5 ml) was adjusted to pH 7.0 with 2 M NaOH at 0 °C, and $NaBH_3CN$ (950 mg, 15 mmol) was added. After stirring for 3 d at room temperature, 12 M HCl (5 ml) was added to the reaction mixture. The solution was diluted with water and then put on a column (2.8 cm × 16.5 cm) of Dowex 50X8 (H^+ form), and the column was washed with water and eluted with 1 M aq pyridine (300 ml). The eluate was evaporated to give the desired product: yield, 1.11 g (98%); R_f^1 0.21, R_f^2 0.77, R_f^1 (PPC) 0.18. A part of the product was recrystallized from

water–EtOH for elemental analysis.

Found: C, 47.45; H, 5.76; N, 18.34%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

(RS),(R)-Histopine. This was prepared from (*R*) histidine monohydrochloride and 2-oxopropionic acid as described above: yield, 97%; R_f^1 0.21, R_f^2 0.77.

Separation of (RS),(S)-Histopine into Components. By an Amino Acid Analyzer: A solution of (*RS*),(*S*)-histopine (3 mg) in 0.2 M sodium citrate buffer (0.5 ml) of pH 2.2 was subjected to the analyzer. The following conditions were sufficient to permit the separation of two isomers; a column with spherical fresin; 0.6 cm × 55 cm; buffer, 0.2 M sodium citrate buffer of pH 3.25; flow rate, 30 ml/h; jacket temperature, 55 °C. The eluate from the column was taken in a fraction collector (each fraction, 1-ml), the fractions being monitored as follows. An aliquot (0.1 ml) of each fraction was diluted with water (2.4 ml). To the solution, 10% Na_2CO_3 (1 ml) and a solution of the Pauly's reagent (0.5 ml)[9] were added. The absorbance of the mixture at 500 nm was measured on a Hitachi spectrophotometer 124. A peak for (*S*),(*S*)-histopine was at 32, ml and that for (*R*), (*S*)-histopine at 45 ml.

By Dowex 50 Column Chromatography: A column (0.9 cm × 100 cm) was packed with Dowex 50X8 (200—400 mesh; Na^+ form) equilibrated with a specified eluting solvent. The eluting solvents used were sodium citrate buffers at different concentrations and pHs as follows; 0.2 M at pH 2.51, 0.1 M at pH 3.25 or 0.2 M at pH 3.25. (*RS*),(*S*)-Histopine (6 mg) was applied to a column and eluted with one of these eluting solvents at room temperature. An aliquot (0.02 ml) of each fraction (2 ml) was spotted on a paper strip, and the spots containing histopine were visualized by spraying with the Pauly's reagent. Partial separations were observed with each buffer, however, the buffer of 0.2 M at pH 3.25 gave the most favorable pattern. (*RS*),(*S*)-Histopine was separated completely on a longer column (1.8 cm × 190 cm) with the buffer of 0.2 M at pH 3.25.

(S),(S)-Histopine. A solution of (*RS*),(*S*)-histopine (30 mg) in 0.2 M sodium citrate buffer (1 ml) of pH 3.25 was put on a column (1.8 cm × 190 cm) of Dowex 50X8 (Na^+ form). Elution was performed with the same buffer (each fraction, 8-ml) at a flow rate of 37 ml/h. The same chromatography was further repeated twice; thus total amount of 90 mg of (*RS*),(*S*)-histopine was separated into two components. The 3 faster eluting fractions 115—138 were combined and applied to a column (3.2 cm × 25 cm) of Dowex 50X8 (H^+ form). The column wa swashed with water and eluted with 2 M NH_3 aq (450 ml). The eluate was evaporated to afford a residue (33 mg), and the crude product was crystallized from water-EtOH to give pure (*S*),(*S*)-histopine: yield, 18 mg (20% from (*S*)-His); mp 252—253 °C (decomp); $[\alpha]_D^{20}$ +27.7° (*c* 1, 5 M HCl); R_f^1 0.21, R_f^2 0.53.

Found: C, 47.44; H, 5.80; N, 18.25%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%'.

(R),(S)-Histopine. The 3 slower eluting fractions 143—165 obtained above were treated with Dowex 50X8 (H^+ form) as described for (*S*),(*S*)-histopine. Crude product (57 mg) was crystallized from water–EtOH: yield, 20 mg (22% from (*S*)-His); mp 240—241 °C (decomp); $[\alpha]_D^{20}$ +30.2° (*c* 1, 5 M HCl); R_f^1 0.21, R_f^2 0.53.

Found: C, 47.22; H, 5.83; N, 18.27%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

(R),(R)-Histopine. This was prepared from (*RS*),(*R*)-histopine (90 mg) as described for the preparation of (*S*),(*S*)-histopine. The crude product (35 mg) obtained was crystallized from water–EtOH: yield, 25 mg (27% from (*R*)-His); mp 253—254 °C (decomp.); $[\alpha]_D^{20}$ −27.2° (*c* 1, 5 M HCl); R_f^1 0.21, R_f^2 0.53.

Found: C, 47.34; H, 5.90; N, 18.12%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

(S),(R)-Histopine. This was prepared from the slower eluting fractions obtained above. The crude product (55 mg) was crystallized from water–EtOH: yield, 26 mg (28% from (*R*)-His); mp 241—242 °C (decomp); $[\alpha]_D^{20}$ −29.8° (*c* 1, 5 M HCl); R_f^1 0.21, R_f^2 0.53.

Found: C, 47.52; H, 5.76; N, 18.04%. Calcd for $C_9H_{13}O_4N_3$: C, 47.57; H, 5.77; N, 18.49%.

ORD Measurements. These were performed with a JASCO spectropolarimeter Model ORD/UV-5. A cell of the path length 0.1 cm was used and the runs were at ambient temperature. ORD Patterns of solutions of four histopine isomers, (*S*),(*S*)- and (*R*),(*S*)-octopine[4] in 5 M HCl (each, 1 mg/ml) are shown in Fig. 2.

We thank Dr. T. Kato and Dr. H. Aoyagi in this Laboratory for their helpful discussions.

The Effect of Solvent on the Liquefaction of Coal as a Function of Coal Rank

Yoshio KAMIYA,* Tadashi YAO, and Shinichi NAGAE
Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received June 18, 1982)

In order to study the effect of solvent on the liquefaction of coal as a function of coal rank, the liquefaction of five kinds of coals from carbon content of 66% to 83% were carried out in the presence of various aromatic solvents. It was found that three ring aromatic hydrocarbons were more powerful solvent for the liquefaction. Hydrogen donor solvents such as tetralin and hydrophenanthrenes were most effective of all solvents tested independent of coal rank. A mixture of hydrogen donor and polar compounds such as phenol and quinoline was confirmed to be effective to bituminous coal but not so effective to brown coal. It should be stressed that hydrogen donating property of solvent is most important for low rank coals. The chemical analyses of products have shown that the properties of solvent refined coal are a little affected by the quality of solvent.

It has been stressed that the aromatic solvent plays an important role in coal liquefaction reaction.[1,2] At the initial stage coal is thermally decomposed to lower molecular fragments being dissolved and stabilized by the solvent. Otherwise the unstable fragments will be polymerized to form carbonaceous materials.

Partially hydrogenated aromatic compounds such as tetralin are very effective solvent because of hydrogen donating property. Polar compounds such as phenols[3-5] and quinolines[6] are also effective in the presence of hydrogen donors probably because of acceleration of cleavage of aromatic ether structures.[7]

Although the solvent effect on the coal liquefaction has been studied by many workers, the generalization of experimental results seems very difficult because of differences in preparation of coal sample, experimental conditions and apparatus. There has been hardly reported the relative effectiveness of aromatic solvents in the presence of hydrogen donor on a variety of coals.

Evaluation of solvent effect as a function of coal rank must be very important not only for designing the optimum solvent composition but also for studying the difference in the chemical structure of coals.

In this paper, is reported the effect of various aromatic solvents being contained in coal liquefaction products as a function of coal rank.

Experimental

Coal Sample and Solvent. Five kinds of Japanese and Australian coal with carbon content from 66% to 83% were selected and the analytical data of these coals are shown in Table 1. All coals were dried in a vacuum oven at 105 °C. 1,2,3,4-Tetrahydronaphthalene (tetralin) and 1-methyl-naphthalene were of reagent grade and distilled at 70 °C under reduced pressure after washing with sulfuric acid, alkali and water. Various solvents were reagent grade and used as received.

The properties of mixed solvent, creosote oil, anthracene oil, and middle distillate and heavy distillate from SRC-II process are shown in Table 2.

Middle and heavy distillates[8] were produced from Powhatan coal and supplied by Pittsburgh and Midway coal Mining Company, and these solvents seem to have some hydrogen-donating property because H_β content was 2.5% and 1.8% respectively.

Coal Liquefaction Procedure. Solvent and coal of minus 60 mesh were added to 300 ml magnetic stirring (500 min^{-1}) autoclave. After pressurizing with hydrogen, the autoclave was heated to the reaction temperature within 45 min and maintatined at the temperature during reaction time.

At the completion of a run, the autoclave was cooled by electric fan to room temperature and the autoclave gases were vented through gas meter and analyzed by gas chromatography.

The liquid products were removed through glass filter, and the residual solids were extracted with tetrahydrofuran and weighed after drying.

The amount of moisture-ash-free (maf) coal liquefied during the reaction was calculated as a percentage of the maf feed coal by subtracting the percentage undissolved to give the conversion.

The recovered solution was distilled off using a Buchi GKR-50 rotary evaporator at 200 °C and 0.01 bar, and subjected to various chemical analyses.

Liquid portions of the samples were subjected to gas chromatographic analysis to determine the composition of solvent.

Analysis of THF-soluble Fraction. THF-soluble fraction, so called Solvent Refined Coal, was obtained by distilling off the tetrahydrofuran-soluble products by using rotary evaporator at 200 °C and 0.01 bar.

THF-soluble fraction was submitted to the elementary analyses, molecular weight, ^{1}H-NMR.

Results and Discussion

The conversion of Akabira coal in a mixed solvent composed of 1-methylnaphthalene and one testing solvent was measured at 425 °C for 30 min in order to compare the relative effectiveness of solvent. At initial hydrogen pressure of 20 bar, the conversion to benzene-soluble fraction was generally very low and the conversion to THF-soluble was as low as 50% except in the case of tetralin. Then, the initial hydrogen pressure was raised to 50 bar and the results are shown in Table 3. The effect of hydrogen-donating solvent was most remarkable, since the most effective solvent was tetralin and the second was acenaphthene, both of which have benzylic and donating hydrogen atoms.

Consumed tetralin could be entirely recovered as naphthalene, but reacted acenaphthene corresponding to 36% of the feed could not be recovered probably due to polymerization of dehydrogenated product, acenaphthylene.

Highly condensed aromatic hydrocarbons such as pyrene and fluoranthene have shown higher conversion of coal as reported by Davies and coworkers.[9] The order of effectiveness of solvent for Akabira coal was as follows; fluoranthene = pyrene > phenanthrene > naphthalene.

This result can be ascribed to several effects such as solubility and solvent hydrogenation as reported by Derbyshire,[10] but partly to free radical stabilization effect, because polycondensed aromatic compounds can easily react with free radicals and subsequently donate hydrogen atom to another free radical. Polar solvents such as phenol and quinoline were not so effective in the absence of hydrogen donors.

Dibenzofuran	50

a) Reaction conditions: 1-Methylnaphthalene 40 ml, additive 20 ml, coal 20 g, 425 °C, 30 min, initial H_2 pressure 50 bar.

In a practical coal liquefaction process, there exist usually some amounts of hydrogen-donating compounds, because the recycle solvent is nearly in equilibrium with high pressure of hydrogen, or solvent is used after hydrotreatment. When we compare the solvent effect of aromatic hydrocarbons, the effect will be varied depending on the pressure of hydrogen gas and reaction conditions. Therefore, it can be quite reasonable to use a solvent containing some amounts of hydrogen donors such as tetralin, in order to compare the effect of various solvents.

The yields of benzene-soluble fraction as well as THF-soluble fraction increased remarkably by replacing anthracene oil with tetralin, indicating that the formation of lower molecular products by the thermal treatment can be drastically increased in the presence of hydrogen-donating compounds. The yield of benzene-soluble fraction increased from 15% to 55%, when anthracene oil was completely replaced by tetralin.

The effect of tetralin as a function of coal rank was studied as shown in Table 4. In the case of brown coal, the conversion of coal has shown a higher value in the presence of tetralin, but the consumption of tetralin showed also a similar tendency. This result represents a higher reactivity of brown coal. Analyses of gaseous products indicated that Yallourn coal yielded very high amount of carbon dioxide and in contrast the yield of methane on the daf basis was not so varied depending on coalification grade.

The effect of various solvents of five kinds of coal from carbon content of 66% to 83% is shown in Table 5.

Generally, 1-methylnaphthalene seems slightly more effective than naphthalene, and phenanthrene a little better solvent than naphthalene, and as well anthracene oil than creosote oil. These results suggest that three ring aromatic compounds are favorable solvent than two ring aromatics due to the solubility of coal fragments and also probably due to the higher hydrogen donating ability. Recently, Whitehurst and his coworkers[10] made clear that highly condensed aromatic compounds such as pyrene can easily accept hydrogen as hydrogen shuttlers and subsequently donate hydrogen atom to another free radical.

The effect of hydrogen-donating solvents having benzyl hydrog ensuch as hydroaromatics with relatively low bond dissociation energy was most remarkable. The higher conversion was clearly observed in the case of low rank coals such as Yallourn and Taiheiyo, indicating that hydrogen donating property is most important for

coals with low coalification grade. It has been reported that the liquefaction of brown coal is sensitive to hydrogen donating property of solvent.[1,2)] The order of effectiveness of hydrogen-donor solvent has shown that tricyclic hydroaromatics give higher conversion of coal than bicyclic hydroaromatics.

Previously, we have shown that a mixture of hydrogen-donating solvent and phenolic compounds is a very effective solvent for liquefaction of bituminous coal[5)] and this result can be ascribed to the acceleration of scission of ether linkage[7)] in coal structure.

Again, in this experiment, polar compounds such as phenol, 1-naphthol and quinoline in the presence of hydrogen donor were confirmed to be effective solvent for bituminous coals.

In contrast, it was observed that the conversion of brown coal was increased in the presence of 1-naphthol but not affected in the presence of phenol at concentrations below 20 wt% in solution at 400 °C. However, it should be mentioned that at lower temperature of 350 °C, phenolic compounds became effective for dissolution reaction as shown in Fig. 1.

These different effect due to phenol on coal rank can be explained by the difference of chemical structure of coal, probably due to aromatic ether linkage.

A condensed diaryl ether can be decomposed considerably at 450 °C. On the other hand, the carbon-oxygen bond of benzyl phenyl ether or dibenzyl ether can be cleaved rapidly at temperatures below 400 °C. The rapid decomposition of brown coal can be attributed to the benzyl ether structures, which would not give the enhancing effect due to phenol at 425 °C. The slower decomposition of bituminous coal seems to be due to diaryl ether linkage.

Middle distillate as well as heavy distillate from SRC-II process contained some amounts of hydrogen donors along with about 10% of phenolic compounds.

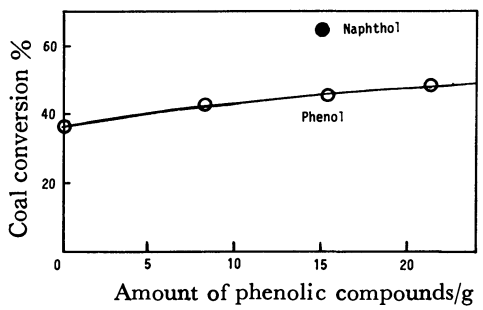

Fig. 1. Effect of phenolic compounds on the liquefaction of Yallourn coal.
Reaction conditions: Coal 20 g, tetralin 15 ml, 1-methylnaphthalene 45 ml, 350 °C, 30 min, initial H_2 pressure 20 bar.

Therefore, it is reasonable that these distillates show a little better result than aromatic hydrocarbons but not so good results as hydrogen donors such as tetralin.

Conversion of solvents in the liquefaction of Yallourn coal is shown in Table 6. In the presence of tetralin, phenanthrene was hardly consumed in the course of reaction. Dihydrianthracene and hydrophenanthrenes were remarkably decreased, but they were recovered as the dehydrogenated products, that is, anthracene and phenanthrene.

It can be concluded that, from the conversion values of tetralin and coal, the most effective hydrogen donors are octahydrophenanthrene and dihydrophenanthrene far reactive than tetralin.

In the case of Akabira coal, as shown in Table 7, 98% of phenanthrene was recovered as it is. Hydrophenanthrenes were converted to phenanthrene with higher conversions than tetralin.

a) 1-MN: 1-Methylnaphthalene.

Solvent effect by hydrogen donor must be mainly in the stabilization of free radical fragment. In the absence of hydrogen donor, for example, 1,2-diarylethane structure[1] will be converted to a more stable form of diarylmethane after cleavage reaction and a benzyl ether structure to a diarylmethane structure.[7]

While, considerable amounts of naphthol and quinoline could not be recovered.

1-Naphthol gave a high value of coal conversion probably due to the reactive property. Recently, Derbyshire and coworkers[10] made clear that naphthol was remarkably consumed in the presence of coal. This result can be attributed to the hydrogen abstraction from 1-naphthol by alkoxyl radicals resulting from coal fragments and the subsequent reaction of naphthyloxyl radical.

The consumption of 1-naphthol is much higher in the case of Yallourn coal as compared with Akabira coal, suggesting that a lot of alkoxyl radicals are evolved when a lower rank coal is thermally decomposed.

We consider that 1-naphthol can be converted to naphthalene derivative or dimeric furan compounds *via* naphthyloxyl radical.

In the case of Yallourn brown coal, the obtained THF-soluble fraction has shown the lowest value in carbon content of 84% (Table 8). A hydrogen donating solvent as compared with phenanthrene seems to give slightly lower values in *fa* and higher values in H_{au}/C_a, indicating that solvent quality affects the properties of liquefaction products.

Table 9 shows analytical results of Wandoan coal,

in this case, hydrogen-donating solvents give higher values in hydrogen content and lower values in *fa*. In the case of 1-naphthol, the characteristic points were in high *fa* and low σ, which can be ascribed to the addition of 1-naphthol to coal molecule or condensation reaction of 1-naphthol.

In the case of Liddell coal (Table 10), the hydrogenating effect due to hydrogen-donating solvent can be seen in hydrogen content, *fa* and H_{au}/C_a.

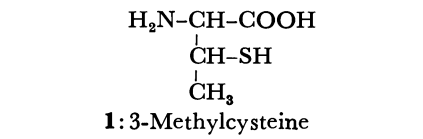
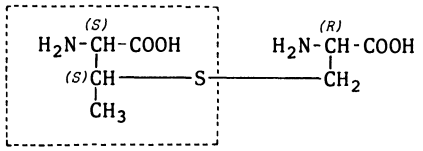
(Received June 21, 1982)

threo-3-Methyl-D-cysteine as a moiety of β-methyllanthionine in the peptide antibiotic nisin was synthesized stereospecifically. The reaction of (2*R*,3*R*)-3-methyl-2-aziridinecarboxylic acid derivative prepared from D-threonine with thiobenzoic acid gave the β-mercapto α-amino acid derivative of the same configuration as the starting material. A stereochemistry of the product was retained as a result of double inversion mechanism through the reactions. Thus, we could prepare *threo*-3-methyl-D-cysteine, *i.e.*, (2*S*,3*S*)-2-amino-3-mercaptobutanoic acid which is required for the synthetic study of nisin.

3-Methylcysteine (**1**)[2)] is a moiety of β-methyllanthionine (**2**) which is a constituent amino acid of the peptide antibiotic nisin.[3)] The absolute structure of 3-methylcysteine in natural β-methyllanthionine in nisin can be represented as (2*S*,3*S*)-2-amino-3-mercaptobutanoic acid[4,6)] whose stereochemistry corresponds to D-threonine. A convenient preparative method of this amino acid is required for the purpose of the synthesis of nisin which contains four cyclic peptide parts involving sulfide bridge of β-methyllanthionine. One reasonable method for the synthesis of this amino acid could be a conversion of β-hydroxy α-amino acid into β-mercapto α-amino acid by use of substitution reaction of β-tosylate with thioacetic acid.[5,6)] However, a configuration of the carbon atom carrying hydroxyl group in β-hydroxy α-amino acid must be inverted through the reaction.[6)] Therefore, by application of this reaction, the required *threo* form of β-mercapto α-amino acid can not be obtained from threonine which is mostly available as starting material.



1: 3-Methylcysteine



2: β-Methyllanthionine

On the other hand, when 2-aziridinecarboxylic acid derivative prepared from *threo*-β-hydroxy α-amino acid was treated with ammonia or carboxylic acid, β-amino or β-*O*-acyl compound having the original *threo* stereochemistry was obtained respectively.[7,8)] The retention of configuration on the β-carbon atom is clearly explained with a double inversion mechanism as shown in Fig. 1. Namely, the first inversion occurs at aziridine ring formation through *E*2 reaction of β-tosylate or β-mesylate and the second one at the ring opening through S_N2 substitution with ammonia or carboxylate anion.

In a similar way, we now used thiobenzoic acid for the preparation of β-*S*-acyl compound in order to synthesize *threo*-3-methyl-D-cysteine from D-threonine. The aziridine compound was prepared in the usual manner[9)] as shown in Scheme 1. The reaction of (2*R*,3*R*)-*N*-benzyloxycarbonyl-3-methyl-2-aziridinecarboxylic acid methyl ester (**6**) with thiobenzoic acid in the presence of boron trifluoride gave the desirable *S*-benzoyl-β-mercapto derivative **7** accompanying *O*-thiobenzoyl-β-hydroxy derivative **8** as a by-product. The formation of both *S*-acyl and *O*-acyl compounds might be ascribed as a result of possible equilibrium in thiobenzoic acid, *i.e.*, $C_6H_5COSH \rightleftarrows C_6H_5CSOH$, although the higher reactivity of the former gave the preferable *S*-acyl derivative as a main product. The compounds **7** and **8** were separated by column chromatography and characterized by chemical shifts of their β-methine protons which appeared at 4.34 ppm in **7** and 6.22 ppm in **8**.

debenzyloxycarbonylation with 30% HBr in acetic acid did not give a good result presumably because of the formation of 5-methyl-2-phenyl-Δ^2-thiazoline-4-carboxylic acid. Therefore, benzyl group was first removed with methylamine in methanol and the product obtained was immediately oxidized to prepare disulfide compound **9**. Hydrolysis of **9** with hydrochloric acid proceeded smoothly and the desired *threo*-3-methyl-D-cysteine was obtained in an oxidized form **10**.

The procedure mentioned above is of course applicable to prepare simple D-cysteine and D-cystine which are commercially very expensive materials. Moreover, threonine residue in peptide chain was next tried to be converted into cysteine residue. A reaction of the peptide **11** containing *N*-acyl-3-methyl-2-aziridinecarboxylic acid derived from threonyl peptide[10] with thiobenzoic acid yielded exclusively *S*-benzoyl-3-methylcysteinyl peptide **12** without contamination with *O*-thiobenzoyl derivative. (Scheme 2) For this reaction, boron trifluoride as a catalyst was not necessary. The sole formation of *S*-acyl derivative may indicate that an amide form of 2-aziridinecarboxylic acid is preferable to an ester form on the opening reaction of the aziridine ring, presumably since the amide form reacts with thiobenzoic *S*-acid much faster than with thiobenzoic *O*-acid. We are now undertaking an application of this method to the synthesis of nisin ring B and the results will be reported soon elsewhere.

Experimental

All melting points are uncorrected. The specific rotations were measured with a Perkin-Elmer 141 polarimeter. NMR spectra were obtained with a Varian XL-100-15 spectrometer and the chemical shifts were given in δ values (ppm) from tetramethylsilane in $CDCl_3$ and from sodium 2,2-dimethyl-2-silapentane-5-sulfonate in DCl. The abbreviations used for coupling patterns were as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br., broad.

N-*Trityl*-D-*threonine Methyl Ester* (**4**). A suspension of D-threonine (10 g, 0.084 mol) in 300 ml of methanol was saturated with hydrogen chloride under stirring in an ice bath to make a clear solution. The solution was allowed to stand overnight at room temperature and then concentrated *in vacuo*. Colorless oily product was obtained in almost quantitative yield by repetition of vacuum concentration with an addition of anhydrous benzene to remove water.

D-Threonine methyl ester hydrochloride (14 g, 0.083 mol) thus obtained was dissolved in 40 ml of chloroform. To the solution was added triethylamine (17 g, 0.17 mol) and then trityl chloride (23 g, 0.083 mol) in 50 ml of chloroform dropwise under stirring in an ice bath. The reaction mixture was concentrated *in vacuo* after stirring for 2 d under cooling. The residue was dissolved in ethyl acetate and the solution was washed successively with saturated sodium chloride solution, 10% citric acid solution, 1 M sodium hydrogencarbonate solution, and saturated sodium chloride solution. Evaporation of the solvent after drying over magnesium sulfate gave 30 g (96%) of **4** as colorless oil. A crop of the product was purified by silica gel column chromatography to remove a slight contaminant of triphenylmethanol. Elution with benzene–ethyl acetate (19 : 1 v/v) gave a crystalline material:

mp 87—89 °C; $[\alpha]_D^{17}$ −6.4° (*c* 1.1, $CHCl_3$).

Found: C, 76.68; H, 6.74; N, 3.71%. Calcd for $C_{24}H_{25}NO_3$: C, 76.78; 6.71; N, 3.73%.

*(2*R, *3*R*)-1-Trityl-3-methyl-2-aziridinecarboxylic Acid Methyl Ester (5).* To a solution of **4** (4.91 g, 0.0131 mol) in 20 ml of pyridine was added methanesulfonyl chloride (4.5 g, 0.039 mol) under cooling in an ice–salt bath. The mixture was stirred for 8 h at room temperature and the solvent was evaporated *in vacuo*. A solution of the residue in ethyl acetate was washed with saturated sodium chloride solution and dried over magnesium sulfate. The reddish brown oil was obtained by vacuum concentration of the solvent. The oily product was dissolved in 40 ml of anhydrous tetrahydrofuran and triethylamine (3.9 g, 0.039 mol) was added to the solution. The mixture was heated under reflux at 80 °C for 2 d and the reaction mixture was concentrated *in vacuo*. An ethyl acetate solution of the residue was washed, successively, with saturated sodium chloride solution, 10% citric acid solution, saturated sodium hydrogencarbonate solution, and saturated sodium chloride solution. Organic layer was dried over magnesium sulfate and the solvent evaporated *in vacuo*. An oily residue was crystallized by trituration with hexane. Recrystallization of the crude product from methanol gave 3.64 g (78.0%) of colorless needles: mp 111—112.5 °C; $[\alpha]_D^{20}$ +98° (*c* 1.0, $CHCl_3$).

Found: C, 80.66; H, 6.51; N, 3.94%. Calcd for $C_{24}H_{23}NO_2$: C, 80.64; H, 6.48; N, 3.92%.

*(2*R, *3*R*)-1-Benzyloxycarbonyl-3-methyl-2-aziridinecarboxylic Acid Methyl Ester (6).* To a solution of **5** (3.17 g, 8.88 mmol) in 14 ml of chloroform and methanol (1 : 1 v/v) was added 7 ml of trifluoroacetic acid under an ice cooling. The mixture was stirred for 2.5 h in an ice bath and then concentrated *in vacuo*. Evaporation with ether newly added was repeated several times to remove trifluoroacetic acid as completely as possible. The residue was dissolved in ether again and 3-methyl-2-aziridinecarboxylic acid ester trifluoroacetate was extracted with water three times. To the aqueous extract was added sodium hydrogencarbonate (3.5 g, 0.042 mol) and 30 ml of ethyl acetate. Benzyloxycarbonyl chloride (1.51 g, 8.9 mmol) was added to the mixture under vigorous stirring in an ice bath. After stirring for 1.5 h, ethyl acetate layer was separated from aqueous layer which was extracted with another portion of ethyl acetate once again. Organic layer combined was washed with saturated sodium chloride solution, dried over magnesium sulfate, and concentrated *in vacuo*. Crude product thus obtained was purified by column chromatography (Merck silica gel 60, 70 g, 1.9 cm × 60 cm). Elution with ethyl acetate and hexane (1 : 5 v/v) yielded 2.12 g (95.9%) of pure **6** as an oily product: $[\alpha]_D^{18}$ +73° (*c* 2.0, $CHCl_3$).

Found: C, 62.75; H, 6.15; N, 5.55%. Calcd for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62%.

*S-Benzoyl-*N*-benzyloxycarbonyl-*threo*-3-methyl-*D*-cysteine Methyl Ester (7).* A mixture of **6** (5.2 g, 2.1 mmol) and boron trifluoride etherate (47%, 1.0 ml) in thiobenzoic acid (40 ml) was stirred for 1 d at room temperature. To a reaction mixture was added a large amount of ethyl acetate and the solution was washed with saturated sodium hydrogencarbonate solution and saturated sodium chloride solution. Organic layer was dried over magnesium sulfate and concentrated *in vacuo*. A yellow oily residue was subjected to a silica gel column (Merck, 280 g, 2.7 cm × 110 cm). Elution with benzene and ethyl acetate (19 : 1 v/v) separated thiobenzoic acid, *N*-benzyloxycarbonyl-*O*-thiobenzoyl-D-threonine methyl ester (**8**), and desired **7** in this order. The compound **8** was obtained in a yield of 15% (1.2 g) as pale yellow oil: $[\alpha]_D^{13}$ −183° (*c* 1.44, $CHCl_3$); NMR ($CDCl_3$) δ=1.49 (3H, d, >CH–C<u>H</u>$_3$), 3.68 (3H, s, –OC<u>H</u>$_3$), 4.73 (1H, dd, –NH–C<u>H</u><), 5.14 (2H, s, Ph–C<u>H</u>$_2$–), 5.61 (1H, br. d, –N<u>H</u>–), 6.22 (1H, dq, –O–C<u>H</u>–CH$_3$), 7.3—7.6 (8H, m, aromatic protons), 8.01 (2H, dd, *o*-protons on C_6H_5CS). Found: C, 62.09; H, 5.49; N, 3.50; S, 8.49%. Calcd for $C_{20}H_{21}NO_5S$: C, 62.00; H, 5.4 N, 3.62; S, 8.28%.

Main product **7** was obtained as oil in a yield of 53% (4.3 g); $[\alpha]_D^{18}$ −64° (*c* 1.0, $CHCl_3$); NMR ($CDCl_3$) δ=1.48 (3H, d), 3.73 (3H, s), 4.34 (1H, dq, –S–C<u>H</u>–CH$_3$), 4.66 (1H, dd), 5.11 (2H, s), 5.61 (1H, br. d), 7.3—7.6 (8H, m), 7.90 (2H, dd, *o*-protons on C_6H_5CO). Found: C, 61.67; H, 5.47; N, 3.54; S, 8.15%.

*N,N′-Bisbenzyloxycarbonyl-*threo*-3,3′-dimethyl-*D*-cystine Dimethyl Ester (9).* To a solution of **7** (0.59 g, 1.5 mmol) in 20 ml of methanol was added 1 M methylamine in methanol (2.3 ml, 2.3 mmol) during 15 h at 10—15 °C. After an additional stirring overnight, 0.5 M solution of iodine in methanol was added to the reaction mixture until a brown color remained. Oxidation reaction was completed within 30 min and the solution was then concentrated *in vacuo*. Colorless crystalline product **9** formed on addition of ether to the residue was filtered, 0.39 g (91%). The product was recrystallized from ethanol and hexane to obtain an analytical sample, yield 0.35 g (81%): mp 108—110 °C; $[\alpha]_D^{18}$ −167° (*c* 1.00, $CHCl_3$) NMR ($CDCl_3$) δ=1.31 (β-CH_3, d), 3.52 (β-CH, dq), 3.72 (–OCH_3, s), 4.59 (α-CH, dd), 5.12 (Ph–CH_2, s), 5.63 (NH, br. d), 7.34 (C_6H_5, s).

Found: C, 55.50; H, 5.72; N, 4.90; S, 10.92%. Calcd for $C_{26}H_{32}N_2O_8S_2$: C, 55.30; H, 5.71; N, 4.96; S, 11.36%.

*threo-3,3′-Dimethyl-*D*-cystine (10).* A suspension of **9** (0.33 g, 0.58 mmol) in 6 M HCl (2 ml) and acetic acid (2 ml) was heated under reflux for 5 h at 110 °C. The hydrolyzat was concentrated *in vacuo* and the residue was dissolved in water. The aqueous solution was once extracted with ether, neutralized with pyridine, and concentrated *in vacuo*. Ethanol was added to the residue and an insoluble material was recrystallized from water and ethanol to obtain pure **10**6; colorless powder: yield 0.13 g (82%); mp 183—193 °C (decomp); $[\alpha]_D^{13}$ −416° (*c* 0.50, 1 M HCl) [lit,[6] $[\alpha]_D^{19}$ −414° (*c* 1, 1 M HCl)]; NMR (2 M DCl) δ=1.43 (β-CH_3, d), 3.96 (β-CH, dq), 4.45 (α-CH, d).

Found: C, 34.32, H, 6.18; N, 10.10; S, 22.70%. Calcd for $C_8H_{16}N_2O_4S_2 \cdot \frac{2}{3}H_2O$: C, 34.27; H, 6.23; N, 9.99; S, 22.87%.

*S-Benzoyl-*N*-benzyloxycarbonyl-*threo*-3-methyl-*L*-cysteinylglycine Benzyl Ester (12a).* (2*S*, 3*S*)-*N*-Benzyloxycarbonyl-3-methyl-2-aziridinylcarbonylglycine benzyl ester (**11a**)[10] (86 m, 0.23 mmol) was dissolved in 2 ml of dichloromethane and thiobenzoic acid (62 mg, 0.45 mmol) was added to the solution. The mixture was stirred at room temperature for 18 h and at 40 °C for 30 h. The reaction mixture diluted with ethyl acetate (20 ml) was washed once with saturated sodium hydrogencarbonate solution and twice with water. Organic layer dried over magnesium sulfate was concentrated *in vacuo* and an oily residue obtained was treated with hexane to crystallize. Crude product was recrystallized from ethyl acetate and hexane: yield 97 mg (83%); mp 131—133 °C; $[\alpha]_D^{16}$ +1.5° (*c* 0.83, $CHCl_3$); NMR ($CDCl_3$) δ=1.46 (3H, d), 4.03 (2H, dd), 4.21 (1H, m, C_6H_5COS–C<u>H</u>–), 4.46 (1H, t), 5.04 (2H, s), 5.11 (2H, s), 5.91 (1H, d), 6.88 (1H, br. t), 7.2—7.6 (13H, m), 7.80—7.93 (2H, m).

Found: C, 64.50; H, 5.51; N, 5.26; S, 6.26%. Calcd for $C_{28}H_{28}N_2O_6S$: C, 64.60; H, 5.42; N, 5.38; S, 6.16%.

*S-Benzoyl-*N*-t-butoxycarbonyl-*threo*-3-methyl-*L*-cysteinylglycine Benzyl Ester (12b).* To a solution of (2*S*,3*S*)-*N*-*t*-butoxycarbonyl-3-methyl-2-aziridinylcarbonylglycine benzyl ester (**11b**)[10] (94 mg, 0.28 mmol) in 2 ml of dichrolomethane was added thiobenzoic acid (77 mg, 0.56 mmol) and the mixture

was stirred for 25 h. The reaction mixture diluted with 20 ml of ethyl acetate was washed once with saturated sodium hydrogencarbonate solution and three times with water. Organic layer was dried over magnesium sulfate and concentrated *in vacuo*. An oily residue was crystallized by addition of hexane and a crystalline product was recrystallized from ethyl acetate and hexane: yield 101 mg (75%); mp 125—127 °C; $[\alpha]_D^{16}$ −2.7° (*c* 0.89, CH_3OH); NMR ($CDCl_3$) δ=1.37 (9H, s), 1.47 (3H, d), 4.06 (2H, d), 4.24 (1H, m, C_6H_5COS–C<u>H</u>–), 4.40 (1H, t), 5.12 (2H, s), 5.54 (1H, d), 6.89(1H, br. t), 7.2—7.6 (8H, m), 7.87 (2H, m).

Found: C, 61.70; H, 6.23; N, 5.74; S, 6.73%. Calcd for $C_{25}H_{30}N_2O_6S$: C, 61.71; H, 6.21; N, 5.76; S, 6.59%.

Pyridine-containing Acyclic Crown Ethers and Their Polymers as Specific Carrier of Biogenetic Amine Derivatives[1)]

Hiroshi Tsukube
Department of Chemistry, College of Liberal Art and Science, Okayama University, Okayama 705
(Received June 26, 1982)

A variety of crown ethers and their analogs which contain powerful hydrogen bonding sites such as pyridine and quinoline moieties were examined as new synthetic carrier. Among the examined carriers, acyclic crown ethers and their polymers having pyridine groups were found to be selective and efficient carriers for some organic ammonium cations of great biological significances. Their transport properties were largely different from those of usual crown ether compounds, and essentially dependent on the combined characteristics of polyether sequence, hydrogen bonding site, co-transported anion, and others.

There has been much interest in synthetic cyclic and acyclic crown ethers[2)] because of their unique coordination abilities. Various modifications have been made to the basic polyether structures and attained a variety of functions. In particular, introduction of donor atoms such as sulfur and nitrogen atoms provided stronger and interesting coordination properties for ammonium cations and transition metal ions.

Cram *et al.*[3)] and Christensen *et al.*[4)] have shown that pyridine-containing cyclic crown ethers such as **2** form more stable complexes with organic ammonium cations than corresponding parent crown ethers. Vögtle *et al.*[5)] have also reported that quinoline-bearing acyclic crown ethers such as **4** show higher complex stabilities for ammonium cation complexes. These findings strongly suggest that pyridine nitrogen atoms of the cyclic and acyclic crown ethers can form stronger hydrogen bonding with guest ammonium hydrogen atoms than does as ether oxygen atoms.

Here we examine a variety of pyridine unit-containing polyethers ("pyridino-crown ethers") as artificial carrier in the chloroform liquid membrane system (see Fig. 1). They include cyclic crown ethers, acyclic crown ethers, and their polymers. Among them, acyclic crown ether **4**, containing quinoline-terminal groups, was found to discriminate some kinds of organic ammonium cations from K^+ ion in the transport process. Since such a unique transport selectivity was not attained by using cyclic crown ether compounds **1** and **2**, this is an important example of acyclic crown ether which shows more excellent property than corresponding cyclic crown ethers. Although some pyridino-crown ethers were known to effectively transport Ag^+ [4)] and Pb^{2+} [6)] ions, a series of pyridino-crown ethers were firstly applied to the highly selective transport of "biogenetic amines and drugs" of great biological significances.[7)]

Results and Discussion

Transport Properties of Cyclic and Acyclic Crown Ether Carriers (1—5). We measured the transport rates of several cations through a chloroform liquid membrane which contains one of the carriers **1**—**5** and which separates two aqueous phases. As shown in Fig. 1, guest cation salts are complexed with carrier and transported from aqueous phase I to an aqueous phase II using an experimental apparatus previously reported (see Experimental Section). Hence, the present transport process occurs by carrier-mediated facilitated diffusion along the concentration gradient of the guest salts.

Among the employed carriers (see Fig. 2), **2** and **4** contain nitrogen atoms as stronger hydrogen bonding sites for ammonium cations, and are expected to be an effective carrier of them. In particular, acyclic crown ether **4** provides interesting structural features:[5)] (a) The quinoline moiety also functions as anchoring points with locally fixed donor sites on which guest cation can take hold; (b) The flexible nature of acyclic carrier can permit effective conformational changes in the binding and releasing processes, like as naturally occurring acyclic ionophores.[8)] Recently a number of acyclic crown ethers have already been prepared as ionophore models, and most of them form pseudocyclic conformations on complexations of guest cations, which are stabilized by intramolecular interactions between two terminal groups. Since their transport selectivities may be determined by the sizes and shapes of the formed cavities, they may be similar to those observed in the cyclic crown ether systems.[2)] In a marked contrast, the transport selectivity of the present carrier **4** can be controlled mainly by the nature of terminal donor group *via* terminal group-guest cation interaction. This is largely different from those of previously reported acyclic crown ethers. Hence, new and characteristic transport properties are expected by using this type of acyclic crown ether.

Other cyclic and acylic crown ethers (**1**, **3**, and **5**) were also examined for comparisons. Typical results of passive transport experiments are shown in Table 1. Blank experiments (no carrier present) were performed

Initial concentrations: aqueous phase I; salt, 0.3 mmol. Additive ($NaClO_4$), 0 mmol(A) or 1.5 mmol(B)/H_2O, 3 ml. Membrane; carrier, 0.0372 mmol/$CHCl_3$, 8 ml. Aqueous phase II; distilled water, 9 ml.

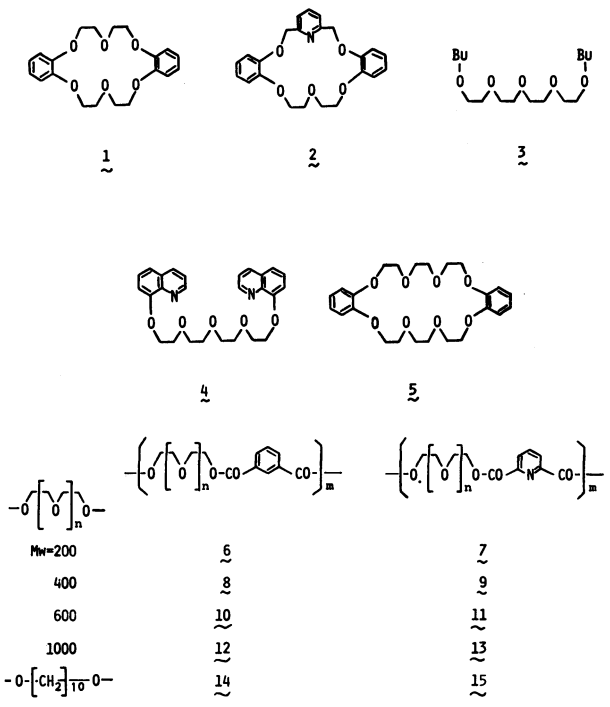

Fig. 2. Examined synthetic polyether carriers.

for each system to determine membrane leakages. The obtained amounts of cation leakages varied with used cations, but were generally much smaller than those indicated in Table 1.

Pyridino-crown ether **2** showed somewhat different transport behaviors from parent crown ether **1**. Although it has been reported that substitution of pyridine nitrogen for an oxygen in 18-crown-6 gives slight influences on the complex stabilities of K^+ and other cations, the transport rates of K^+ ion appreciably weakened in the carrier **2** system, while organic ammonium cation-transport rates were slightly influenced. These facts clearly indicate that pyridine nitrogen atom plays a more significant role in the transport of organic ammonium cations than in the transport of K^+ ion. Probably hydrogen bonding between pyridine nitrogen and guest ammonium cations would be effectively operated.

A pronounced effect of introducing donor sites into the carrier on the transport properties was observed in the quinoline-bearing acyclic crown ether **4** system. The carrier **4** was found to be an effective and selective carrier of some organic ammonium cations, compared to the cyclic crown ethers (**1** and **2**). Acyclic crown ether **4** preferentially transported several biogenetic amines and drugs of great significance such as phentermine, norephedrine, and homoveratrylamine. In marked contrast, cyclic crown ethers were confirmed to effectively transport a variety of ammonium cations as well as K^+ ion as reported before. Although Vögtle *et al.* have demonstrated that this type of acyclic crown ethers complex with a number of cations such as Li^+, Na^+, K^+, and others,[5] it was firstly found to show highly discriminative transport abilities for ammonium cations. Therefore, this is an important example of acyclic crown ether which shows more excellent functions than corresponding cyclic crown ether. As well-known, nigericin, monensin, and other acyclic bioionophores change their conformations on guest complexations, and form "pseudocyclic conformations."[8] This affects not only the rates of complexation and of decomplexation, but also transport selectivities. These coordination behaviors of naturally occurring antibiotics could be mimicked in the present artificial system. Quinoline-nitrogen atoms of the carrier **4** can act as stronger hydrogen bonding sites, and their coordination to the

Initial concentrations: carrier, 0.0372 mmol/Ph or Py unit base. Other conditions, See Table 1 (B).

ammonium cations may induce the conformational changes of the carrier, promoting the successive interactions of polyether sequence with ammonium cations. Butyl-bearing acyclic crown ether **3**, which has similar polyether linkages to the carrier **4**, was confirmed to hardly transport ammonium cations and other metal ions. Therefore, attachment of quinoline moiety as terminal groups to the open polyether chain can offer both high efficiencies and excellent selectivities in the transport phenomena. In particular, it was noted that such a higher transport selectivity could not be attained in the cyclic crown ether systems.

The larger ring crown ether **5** with higher flexibility was also attempted as membrane carrier. It exhibited relatively higher transport selectivity for ammonium cations than the 18-membered crown ether **1**, even though its transport rates were modestly lower. This fact may suggest that molecular flexibility of the carrier is an another important factor to design a selective carrier for ammonium cation salts.

The employed crown ether carriers (**1**, **2**, **4**, and **5**) showed similar cation selectivities for a series of organic ammonium cations. As substrates, we chose a variety of phenethylammonium salts to which the biogenetic amines and drugs of great biological importance belong. Their transport efficiencies were clearly dependent on the hydrophobicities of the guest cations: phentermine> phenethylamine> norephedrine> tyramine> dopamine. Inorganic cation, NH_4^+, was found to be hardly transported because of its higher hydrophilicity.[10] Lehn *et al.* have studied crown ether-mediated transport of a similar series of phenethylamine salts,[7] and found that substitution beyond the nitrogen atom of the phenethylamine diminishes the transport rates: phentermine< phenethylamine. Although the natures of employed crown ethers were somewhat different, the results obtained here demonstrate that the hydrophobicity of the guest cation is more essential factor to determine the transport rate than the steric hindrance around the coordination site. Other experiments show that this type of carrier appeared of little use for hydroxy group containing ammonium cations such tyramine and dopamine derivatives. Probably, hydroxy group would enhance the hydrophilicity of the cation and occupy the coordination site of the carrier for ammonium cation hydrogen atom.

Transport Properties of "Acyclic Crown Ether Polymers." The polymer carriers, in which pyridine unit and acyclic crown ether moiety were incorporated, were applied to the membrane transport of ammonium cation salts. Many investigators have already prepared a variety of polymers which contain the crown ether units in the main chain and/or side chain. The former shows a parallel cation coordination property to that of monomeric analog,[11] while the latter favors the formation of the sandwich-type 2 : 1 crown ether/guest

cation complexes.[12] Since they are mostly limitted to the cyclic crown ether polymers, the present study will present interesting examples of "acyclic crown ether polymers" as cation-carrier.[13] Transport experiments were performed in a similar cell as described above, and the typical results are summarized in Table 2.

Table 2 shows that an increase in the number of ether oxygen atoms raises the transport efficiencies. Polymer carriers (**14** and **15**) having no ether oxygen atom were confirmed to exhibit lower transport rates than other polymer carriers (**6**—**13**). Hence, coordination properties of acyclic crown ether moieties can be significantly involved in the present transport system. Chaput *et al.*[14] have measured the complex stability constants of monomeric "acyclic crown ethers" of various polyether chain lengths for alkali metal cations, and observed a similar relationship between number of ether oxygen atoms and complex stabilities. Therefore, this may be characteristic behaviors of acyclic crown ether families.

Introduction of pyridine moiety into the polymer carrier also allows effective transport of organic ammonium cation salts. Since pyridine-containing polymer carriers (**7**, **9**, **11**, and **13**) offered higher transport abilities for some organic cations, same factors would be involved to determine the transport behaviors both in crown ether system and in crown ether polymer system.

Acyclic crown ether polymers (**6**, **8**, **10**, and **12**) showed somewhat effective transport of organic ammonium cations, though their transport abilities were generally lower than those of pyridine-containing polymers (**7**, **9**, **11**, and **13**). These facts may suggest that effective interaction between aromatic moieties of guest cation and of polymer carrier can attribute the higher stability of ammonium cation-carrier complex. Similar observations have been reported in the cyclic crown ether systems.[15]

Anion Effects on Transport Rates. Recently some investigators have demonstrated that the rates of cation-transport by using crown ethers are largely influenced by the natures of anion species which accompanies the guest cation-crown ether complex. Lamb *et al.* revealed an empirical correlation between transport rate of alkali metal cation and anion hydration energy.[16]

By using four kinds of crown ether compounds (**1**, **4**, **10**, and **11**) the transport rates of phentermine ammonium cation were determined in the presence of several inorganic anions. The obtained results, listed in Table 3, indicate that the anion has a large effect on the rate of cationt-ran sport mediated by acyclic crown ethers as well as by cyclic crown ethers. It was clearly demonstrated that perchlorate and thiocyanate anions allow faster transport of ammonium cation than carbonate, sulfate, and chloride anions, suggesting that similar factors determined transport behaviors both in the crown ether system and in the crown ether polymer system.

Table 3. Anion effect on transport rate of phentermine ammonium cation

Anion	Transport rate/10^{-6} mol h^{-1}			
	1	**4**	**10**	**11**

Experimental

Polymer Carrier Synthesis. The polymer carriers (**6**, **8**, **10**, and **12**) were prepared from isophthaloyl dichloride and corresponding polyethylene glycols. Typically, the carrier **12** was obtained by the reaction of isophthaloyl dichloride (0.01 mol), polyethylene glycol, Mw=1000, (0.01 mol), and pyridine (0.02 mol) in chloroform (100 ml) at 60 °C. After 15 h's refluxing, reaction solution was washed with water repeatedly. White wax polymer was obtained (65% yield) by removal of chloroform and dried *in vacuo*. The other polymers (**7**, **9**, **11**, **13**, **14**, and **15**) were similarly prepared. Some characteristic properties of them are summarized in Table 4.

Transport Experiments. The transport experiments were performed at room temperature in a similar apparatus as described before.[17] A cylindrical glass cell (4.0 cm, i.d.) holds a glass tube (2.0 cm, i.d.) which separates two aqueous phases. Typically, the inner aqueous phase (aqueous phase I) contains ammonium cation salt and additive such as $NaClO_4$ in 3 ml of water. The aqueous phase II, outer aqueous phase, contains 9 ml of distilled water. The membrane phase (8 ml of chloroform), in which carrier is dissolved, lies below two aqueous phases, and bridges them. This membrane phase is stirred constantly by magnetic stirrer. A similar experiment was carried out in the absence of carrier. The ammonium cation concentration in the aqueous phase II, monitored spectroscopically, was confirmed to increase linearly with running time ($<$12 h), and the initial transport rates were calculated. The values indicated in Tables 1, 2, and 3, were estimated from the differences in the transport rates of carrier-containing systems and blank systems (no carrier present).

The co-transported anion was also observed to move from aqueous phase I to II. When the perchlorate anion was employed as symport anion, we found that the amount of

(Received January 9, 1982)

The crystal structure of μ-oxo-bis[(octaethylporphinato)ruthenium(IV) chloride] benzene solvate, [Ru(IV)(oep)Cl]$_2$O–C_6H_6, was determined by the X-ray method. The complex crystallizes in the tetragonal space group P4/nnc, $a=13.912(2)$ Å, $c=17.821(4)$ Å, and $Z=2$. The structure was solved by the heavy-atom method and refined to $R=0.084$ for 958 reflections. The [Ru(IV)(oep)Cl]$_2$O complex has the crystallographic D_4-422 symmetry and contains the binuclear (Cl)N_4Ru–O–RuN_4(Cl) coordination group with the Ru–O(μ) distance of 1.793(2) Å, the Ru–Cl distance of 2.320(6) Å, and the Ru–N distance of 2.038(9) Å. The Ru–O–Ru bond is explicitly linear, and the two porphinato cores rotate around the Ru–O–Ru bond by 21.0° from the eclipsed form. The porphinato core is planar within 0.04 Å, and the Ru atom is displaced only by 0.07 Å out of the plane defined by the four porphinato nitrogen atoms toward the bridging O atom. These results are compared with those of the previously reported [Ru(IV)(oep)(OH)$_2$]O–CH_3OH crystal.

The stereochemistry of ruthenium-porphyrins has been intensively investigated, primarily by regarding them as a model of heme protein systems,[1,2] since the Ru ion has been established to serve as a suitable substitute for the Fe ion. We have previously reported the crystal structure of μ-oxo-bis[(octaethylporphinato)ruthenium(IV) hydroxide] methanol solvate, [Ru(IV)(oep)(OH)]$_2$O–CH_3OH, as a model of the iron(IV) porphyrin observed in oxidative reaction of the native Fe(III) hemoprotein of peroxidase.[2] The title crystal, [Ru(IV)(oep)Cl]$_2$O–C_6H_6, is isomorphic with the [Ru(IV)(oep)(OH)]$_2$O–CH_3OH crystal.[2] In this paper, we report the structure of the [Ru(IV)(oep)Cl]$_2$O–C_6H_6 crystal, and discuss the geometry of these isomorphous crystals.

Experimental

[Ru(IV)(oep)Cl]$_2$O was prepared by treatment with dilute hydrochloric acid of a dichloromethane solution of [Ru(IV)(oep)(OH)]$_2$O.[3] Purple-red, plate-like crystals were obtained by recrystallization from a 1 : 1 mixture of benzene and dichloromethane. A prelimenary X-ray photographic examination indicated a centrosymmetric space group P4/nnc with Laue symmetry 4/mmm and systematic absences of $hk0$ for $h+k$ odd, $0kl$ for $k+l$ odd, and hhl for l odd. A crystal with dimensions of $0.2\times0.2\times0.1$ mm^3 was mounted on a Rigaku AFC-5 diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\bar{\lambda}=0.71073$ Å). The unit cell dimensions refined by a least-squares treatment of the setting angles of 47 reflections are $a=13.912(2)$ Å, $c=17.821(4)$ Å, $D_x=1.304$ g/cm^3 (for two [Ru(IV)(oep)Cl]$_2$O and two benzene molecules per unit cell), and $D_m=1.300$ g/cm^3 (by flotation in an aqueous calcium chloride solution).

Intensity data of 1826 reflections in the range $2\theta<50°$ were collected in the ω-2θ scan mode with a scan rate of 5° min^{-1} in ω. Three reflections were monitored every 60 reflections. The intensity data were converted to the $|F_o|$ data in the usual manner, and a total of 958 independent reflections with $|F_o|>3.0\sigma(F_o)$ were retained as observed, where the standard deviations $\sigma(F_o)$ were estimated from counting statistics. No absorption correction was applied ($\mu=5.53$ cm^{-1} for Mo $K\alpha$).

The structure was solved by the heavy-atom method and refine by full-matrix least-squares. The Ru atom was located from sharpened Patterson maps, and the C, N, O, and Cl atoms of the [Ru(IV)(oep)Cl]$_2$O complex were picked up from successively synthesized Fourier maps. Subsequent least-

aquares refinement and difference Fourier synthesis revealed a disordered solvent benznene molecule. All hydrogen atoms were located geometrically (C–H=1.00 Å) and included in the structure factor calculations of the least-squares refinement by assuming their isotropic thermal parameters as 8.0 Å^2. A further refinement with the weighting scheme of $w=1/(\sigma(F_o)^2$ was carried out to convergence. The final R value was 0.084. Atomic scattering factors[4a] and anomalous terms[4b] were taken from the International Tables for X-Ray Crystallography. All computations were performed on a FACOM M-200 computer at the Data Processing Center, Kyoto University by using the program system KPAX.

Results

The atomic parameters are listed in Table 1. Tables of anisotropic thermal parameters and of observed and calculated structure factors are kept as a Document No. 8254 at the Chemical Society of Japan. Figure 1 displays a single $[Ru(oep)Cl]_2O$ complex and two disordered benzene molecules. The $[Ru(oep)Cl]_2O$ binuclear complex exists at a crystallographic D_4-422 symmetry position. The required fourfold axis passes through the Cl–Ru–O–Ru–Cl bond, and the two twofold axes perpendicular to the fourfold axis pass through the central oxygen atom. One-fourth of the porphinato moiety is an asymmetric unit. The numbering scheme for the independent atoms is given in Figs. 1 and 2. The benzene molecules exist at another 422 symmetry position, and they are disordered in two different orientations about the fourfold axis.

The bond lengths and angles for the porphyrin skeleton (Fig. 2) are similar to those of the $[Ru(oep)(OH)]_2O$ crystal[2] and they are normal in comparison with those reported for the planar porphyrins.[5] Deviations from the least-squares plane of the 24 ring atoms of the porphinato core are given on the left-hand side in Fig. 2. The porphinato core is planar within 0.04 Å,

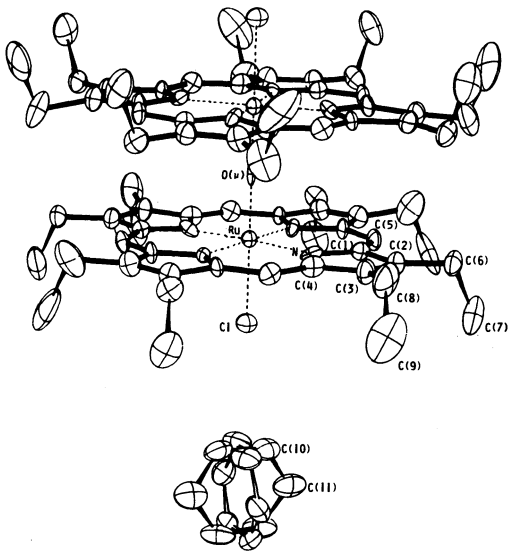

Fig. 1. Computer-drawn model in perspective of the $[Ru(oep)Cl]_2O$ molecule and the disordered benzene molecules. The vibrational ellipsoids are drawn at the 30% probability level. The labeling scheme used for the atoms in the molecules is also shown.

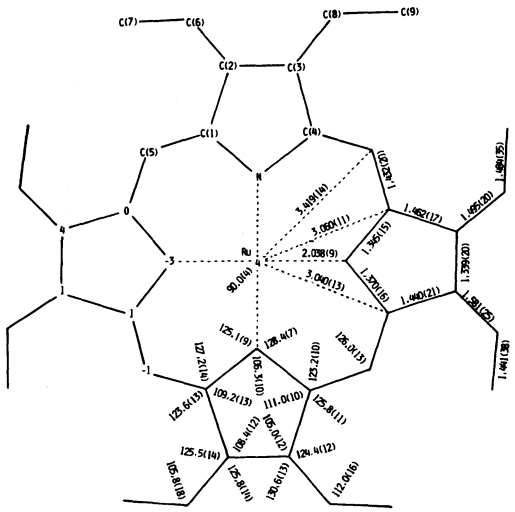

Fig. 2. Formal diagram of the porphinato skeleton in $[Ru(oep)Cl]_2O$. On the top of the diagram, the numbering scheme for the atoms is displayed. On the left-hand side of the diagram, the numbered symbol for each atom is replaced by its perpendicular displacement, in units of 0.01 Å, from the mean plane of the porphinato core. On the right-hand side and the bottom of the diagram are the structurally independent bond distances and angles. The numbers in parentheses are the standard deviations.

and the ruthenium ion is displaced only by 0.07 Å out of the plane defined by the four porphinato nitrogen atoms toward the bridging O(μ) atom. Figure 3 presents a perspective diagram of the environment of one ruthenium ion. The Ru(IV)–N distance, 2.038(9) Å, is slightly shorter than the Ru(IV)–N distance (2.067(14) Å) observed in $[Ru(oep)(OH)]_2O$[2] and than the Ru(II)–N distances (2.041—2.052 Å) reported in ruthenium(II) porphyrin complexes.[1] The Ru(IV)–O(μ) distance, 1.793(2) Å, is shorter than that reported for Ru(IV)–O(μ), 1.847(13) Å, in $[Ru(IV)(oep)(OH)]_2O$[2] and is comparable with that reported for Ru(IV)–O(μ), 1.80 Å, in $(Cl_5Ru(IV)ORu(IV)Cl_5)^{4-}$.[6] The Ru(IV)–Cl distance, 2.320(6) Å, is similar to that reported for Ru(IV)–Cl, 2.34 Å, in $(Cl_5Ru(IV)ORu(IV)Cl_5)^{4-}$[6] and is in good agreement with the sum of single-bond radii, 2.32 Å.

The Ru–O–Ru* bond is explicitly linear, and the two porphinato cores, related to each other by the twofold symmetry, rotate about the straight Ru–O–Ru* bond by 21.0° from the eclipsed form. (The atom with or without an asterisk superscribed is associated with the upper or lower core of the binuclear porphyrin complex, respectively.) The interplanar separation between the mean planes of the porphinato cores is 3.66 Å; the interatomic distances are 3.59 Å for Ru–Ru*, 3.79 Å for N–N*, 3.79 Å for C_a–C_a*, 3.67 Å for C_b–C_b*, and 3.70 Å for C_m–C_a*. (C_a, C_b, and C_m are used for the three chemically and structurally distinctive types of carbon atoms, pyrrole-α, pyrrole-β, and methine carbons, respectively.) The rotation angle and interplanar distance between the two porphinato cores are slightly less than the corresponding angle and distance in the $[Ru(IV)(oep)(OH)]_2O$ crystal.[2] However, in

the same way as described in the report on $[Ru(IV)(oep)(OH)]_2O$,[2] the binuclear porphyrin structure of the present complex is stabilized by the intramolecular π-π interactions between the face-to-face contact porphyrins and by the $d\pi$-$p\pi$-$d\pi$ interaction in the Ru(IV)–O–Ru(IV) bond, and diamagnetism of the present complex is also well interpreted in terms of the π-π interactions in the Ru(IV)–O–Ru(IV) bond system with the low-spin Ru(IV) atom.

The average C–C bond length and the average C–C–C bond angle of benzene molecule are 1.39(5) Å and 119(5)°, respectively. The disordered benzene molecules are surrounded by the six $[Ru(oep)Cl]_2O$ complexes. The molecular plane of each benzene molecule is perpendicular to the porphinato planes, and the shortest interatomic distance is 3.62(4) Å between the Cl and C(10) atoms along the c axis. The $[Ru(IV)(oep)Cl]_2O$ complexes and solvate benzene molecules are packed with van der Waals contacts.

Discussion

The $[Ru(IV)(oep)Cl]_2O-C_6H_6$ crystal is isomorphic with $[Ru(IV)(oep)(OH)]_2O-CH_3OH$.[2] Table 2 summarizes the unit cell dimensions and the geometric parameters of the coordination groups for the two μ-oxo ruthenium porphyrin derivatives. As shown in Fig. 4, the absorption spectra of the Cl-derivative ($[Ru(IV)(oep)Cl]_2O$) exhibit a large bathochromic shift as compared with those of the OH-derivative ($[Ru(IV)(oep)(OH)]_2O$). These spectroscopic shifts suggest that the Cl^- and OH^- ligands on the Ru(IV) atom obey the general order of the spectrochemical series, $OH^- > Cl^-$. Thus the Cl^- ion is considered to be a weaker ligand for the Ru(IV) atom than the OH^- ion. The difference of the ligand strengths reflects the geometric parameters of the two coordination groups. As shown in Table 2, the deviation of the Ru atom out of the porphinato mean plane for the Cl-derivative is larger than that for the OH-derivative. This large Ru deviation toward the O^{2-} atom in the Cl-derivative is reasonable, since the O^{2-} atom is a stronger ligand for the Ru(IV) atom than the Cl^- and OH^- atoms, and the degree of Ru(IV) displacement toward the strong ligand depends on the ligand strengths at the opposite side. The Ru(IV)–O(μ) bond of the Cl-derivative is significantly shorter than the corresponding bond of the OH-derivative, and the Ru–N bond of the Cl-derivative is also slightly shorter than that of the OH-derivative. These shortening effects of the Ru–O(μ) and Ru–N bonds of the Cl-derivative will be explained in terms of "the structural trans and cis effects." That is, when a ligand of the six coordinated metal complex is replaced by a weaker ligand, the other trans and cis ligand-metal bonds will be strengthened because of the neutralization of the electric charge around the central metal ion. In the present case, replacement of the axial OH^- ligand by a weaker Cl^- ligand strengthens the trans Ru–O(μ) and cis Ru–N bonds, and consequently results in the shortening of these bonds. As to the shortening values of these bonds, the Ru–O(μ) bond is more shortened than the Ru–N bond. Thus the trans effect

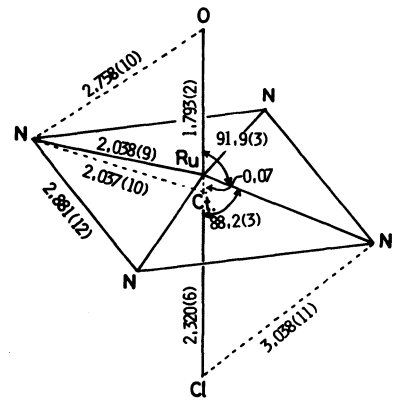

Fig. 3. Perspective diagram of the six-coordination group around the ruthenium(IV) atom in the $[Ru(oep)Cl]_2O$ molecule. C_t represents the center of the porphinato skeleton.

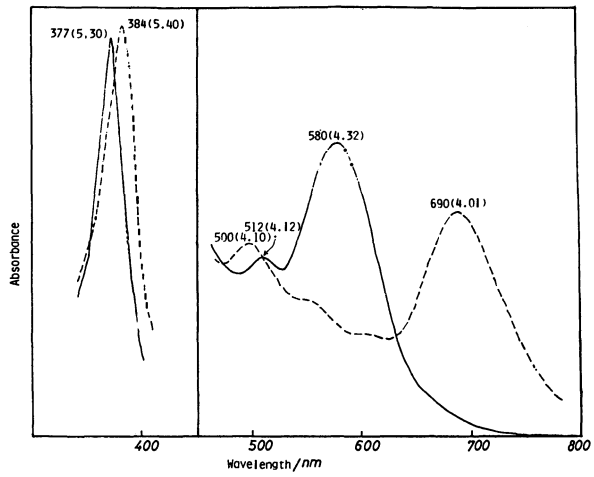

Fig. 4. Absorption spectra for $[Ru(oep)Cl]_2O$ (----) and $[Ru(oep)(OH)]_2O$ (——) in CH_2Cl_2. Extinction coefficients (log ε_{max}) are given in parentheses following λ_{max} (nm).

seems to be more effective than the cis effect. This inference is correct in view of the fact that the Ru–O(μ) distance of the Cl-derivative is very close to that in the case of the $Cl_5Ru-O-RuCl_5$ system in which the strong equatorial nitrogen ligands of the porphyrin complex is replaced by the weak Cl^- ligands;[6] the Ru–O(μ) bond distance depends largely on the trans Cl^- ligand and depends less on the cis ligand. Other examples of such dominant trans effect have been found in the Ru(II)(tpp)(CO)X (X=Py and EtOH) complexes[1b,1c] and in the Fe(II)(tpp)(NO)X (X=1-MeIm, 4-MePip, and none) complexes.[7] It may, therefore, be pointed out that the dominant trans effect is a general tendency in the six coordinated metalloporphyrin complexes.

Another noticeable point in Table 2 is that the unit cell volume of the Cl-derivative is significantly smaller than that of the OH-derivative. This volume change is due mainly to the lattice deviation along the c axis, in which direction the substitution of Cl^- for OH^- or of C_6H_6 for CH_3OH is allowed to take place. The Cl^- and C_6H_6 groups in the Cl-derivative have normal van der

a) Deviation out of the plane defined by the four porphinato nitrogen atoms. b) Deviation from the 24-atom porphinato mean plane. c) P–P means the interplanar distance between the mean planes of the porphinato cores.

Waals contacts along the c axis, while the disordered CH_3OH molecule in the OH-derivative occupy an excessively large space.[2] This space difference of solvent occupation may be a main factor for the large lattice deviation along the c axis. Deformation of the six-coordinate Ru(IV) group, of course, has a contribution to the anisotropic lattice deviation. The large trans effect and the small cis effect mentioned above are consistent with the large lattice deviation along the c axis.

The authors wish to thank Professor Nobuo Morimoto and Dr. Katsutoshi Tomita, Faculty of Science, Kyoto University for theuse of the Rigaku AFC-5 diffractometer. They also wish to express their sincere thanks to Dr. Tsuneyuki Higashi for his valuable advices.

(Received January 9, 1982)

The crystal structure of (octaethylporphinato)bis(tetrahydrofuran)iron(III) perchlorate was determined by the X-ray method. The complex crystallizes in the monoclinic space group C2/m, $a=13.916(3)$ Å, $b=16.509(3)$ Å, $c=10.659(5)$ Å, $\beta=118.18(1)°$, and $Z=2$. The structure was solved by the direct method and refined by the full-matrix least-squares method. The final R value was 0.079 for 597 reflections. The complex has a crystallographically imposed twofold axis and a mirror of symmetry. The porphinato core is planar within 0.06 Å. The iron(III) ion lies at the center of the octahedron formed by the four porphinato nitrogen atoms and the two tetrahydrofuran oxygen atoms. The axial Fe–O distance, 2.187(11) Å, is considerably longer than the reported distances for high-spin porphinatoiron(III) complexes, while the equatorial Fe–N distance, 1.978(12) Å, is comparable to those for low-spin and intermediate-spin porphinatoiron(III) complexes. The Fe–O and Fe–N bond distances are well explained in terms of an intermediate-spin state of the iron(III) ion.

The existence of an intermediate-spin state ($S=3/2$) with the outer electron configuration $(d_{xy})^2(d_{yz})(d_{xz})(d_{z^2})$ in iron(III) porphyrins has been progressively recognized, since Maltempo *et al.*[1] suggested a possibility of the quantum-mechanically mixed spin state of iron(III) ($S=3/2$ and 5/2) to explain anomalous magnetic properties of ferricytochrome c′. Since Dolphin *et al.*[2] assigned octaethylporphinatoiron(III) perchlorate, [Fe(III)(oep)]ClO_4, as an intermediate-spin complex, several synthetic intermediate-spin porphinatoiron(III) complexes were reported[3] on the basis of magnetic susceptibility, ESR spectra, and Mössbauer spectra. So far six structures of the intermediate-spin or probably its admixed spin state complexes have been studied by the X-ray method.[3a,3b,3d,4,5] Through these studies, the structures of the intermediate-spin complexes were characterized by the short Fe–N distance resembling those of low-spin derivatives and the long Fe–O distance rather than those of low- and high-spin derivatives. In an X-ray study of diaquatetraphenylporphinatoiron(III) cation, [Fe(III)(tpp)$(H_2O)_2$]$^+$,[3a,6a] Scheidt *et al.*[3d] claimed that if the axial Fe–O bond distances were increased to some values greater than 2.09 Å, the complex would become an intermediate-spin complex. The critical Fe–ligand distance to distinguish the intermediate-spin state from others is, however, still not clear. The title (octaethylporphinato)bis(tetrahydrofuran)iron(III) perchlorate, [Fe(III)(oep)$(thf)_2$]ClO_4, has recently been prepared by Ogoshi *et al.*,[3c] and from their magnetic and spectroscopic studies the single intermediate-spin state was certainly assigned for this complex. Then, the Fe(III)–O(thf) distance in this complex was anticipated to give a typical Fe(III)–O distance for a pure $S=3/2$ iron(III), so that we took up this complex for the present X-ray study.

Experimental

[Fe(III)(oep)$(thf)_2$]ClO_4 was prepared by adding thf to [Fe(III)(oep)]ClO_4 in CH_2Cl_2.[3c] Dark-violet, plate-like single crystals were obtained by recrystallization from a thf solution. A preliminary X-ray photographic examination established a monoclinic unit cell containing two chemical units of [Fe(III)(oep)$(thf)_2$]ClO_4. The systematic absences of hkl for $h+k=2n+1$ led to three possible space groups C2/m, Cm, and C2. The unit cell dimensions, $a=13.916(3)$ Å, $b=16.509$ (3) Å, $c=10.659(5)$ Å, and $\beta=118.18(1)°$, were determined by the least-aquares refinement of setting angles of 47 reflections on a Rigaku AFC-5 diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\bar{\lambda}=0.71073$ Å). $D_x=1.28$ g/cm^3 and $D_m=1.24$ g/cm^3 (by flotation in aqueous calcium chloride solution).

Intensity data of 2212 reflections in the range $2\theta<50°$ were collected in the ω-2θ scan mode with a scan rate of 5° min^{-1} by the use of a crystal with dimensions of $0.2\times0.2\times0.1$ mm^3. The crystal was gradually damaged by X-ray exposure, so that the intensities were corrected by standard measurements of three reflections every 60 reflections. The intensity decline of the standard reflections throughout the measurements was about 20%. In view of a large systematic error caused by the crystal damage, 597 reliable data ($|F_o|>5\sigma(|F_o|)$) were used for the analysis. No absorption correction was applied ($\mu=4.59$ cm^{-1} for Mo $K\alpha$).

The structure was solved by the heavy atom method. The space group C2/m was tentatively assumed and successive Fourier syntheses revealed the approximate structure. The block-diagonal least-squares refinements to examine the three possible space groups, C2/m, C2, and Cm, resulted in rejection of the space groups C2 and Cm because these space groups gave several wrong positional shifts from the normal bond lengths and angles and non-positive temperature factors for some light atoms. Several cycles of refinement including the anisotropic thermal parameters were carried out to convergence with the weighting scheme of $w=1/\sigma(F_o)^2$. The hydrogen atoms were included as a fixed contribution in the last cycle: their positions were assumed to be in accord with the idealized geometry (C–H=1.00 Å), and their temperature factors were assumed

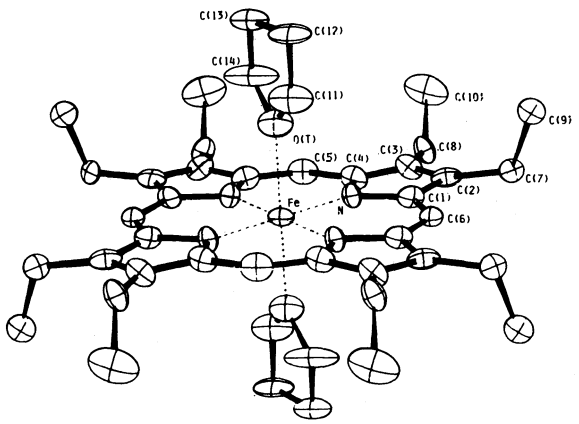

Fig. 2. Computer-drawn model in perspective of the $[Fe^{III}(oep)(thf)_2]^+$ cation. The vibrational ellipsoids are drawn at the 30% probability level. The labeling scheme used for the atoms in the molecule is also shown.

to be isotropical (B=8.00 Å). The final R value was 0.079. The final difference Fourier map showed the high peak (*ca.* 0.6 electron/Å^3) to remain around the disordered perchlorate anion, but it was judged to be essentially featureless.

Atomic scattering factors[7a)] and anomalous terms[7b)] were taken from the International Tables for X-Ray Crystallography. All computations were performed on a FACOM M-200 computer at the Data Processing Center of Kyoto University by using the program system KPAX.

Results

The atomic parameters for all atoms except hydrogen atoms are listed in Table 1. Tables of anisotropic temperature factors for non-hydrogen atoms, positional parameters for hydrogen atoms, and observed and calculated structure factors are kept as a Document No. 8255 at the Chemical Society of Japan.

As shown in Fig. 1, the crystal structure consists of the discrete $[Fe(III)(oep)(thf)_2]^+$ cations and perchlorate anions packed in layers parallel to the (001) plane. The layers are stacked with van der Waals contacts along the c axis. The plane normal to all the porphinato rings is in the approximate [101] direction.

A stereographic view of $[Fe(III)(oep)(thf)_2]^+$ cation is provided in Fig. 2. The numbering scheme of the porphyrin is given in Figs. 2 and 3. The iron atom exists

a) Estimated standard deviations are in parentheses. The one-primed atom notes the atom translated by mirror plane. The two-primed atom notes the atom translated by twofold axis. The three-primed atom notes the atom translated by twofold and mirror plane.

at the center of symmetry, and lies on the plane of the oep macrocycle. The four porphinato nitrogens and the two oxygen atoms of thf molecules complete a deformed octahedron. The porphinato core is planar within 0.06 Å. The C(5) atom lies on the mirror plane and the C(6) atom lies on a twofold axis. The orientation of the ethyl groups attached to the core is similar to that in [Fe(III)(oep)]ClO$_4$.[4a)]

Bond distances and bond angles are given in Table 2. The axial Fe–O(thf) distance, 2.187(11) Å, is considerably longer than the sum of ionic radii for high-spin Fe(III) (0.65 Å) and O (1.40 Å),[10)] and is also larger than those of typical high-spin six-coordinate porphinatoiron(III) complexes, [Fe(III)(tpp)(tetrahydrothiophene 1-oxide)$_2$]$^+$ (average 2.078 Å)[6b)] and [Fe(III)(tpp)(H$_2$O)$_2$]$^+$ (average 2.095 Å).[3a,6a)] It is rather close to those in the mixed (S=5/2, 3/2) or high-spin [Fe(III)(oep)(EtOH)$_2$]$^+$ (average 2.137 Å)[5a)] and [Fe(III)(tpp)(EtOH)$_2$]$^+$ (2.142 Å).[5b)] The Fe–N bond distance, 1.978(12) Å, is significantly shorter than those of typical high-spin six-coordinate complexes, diaquatetraphenylporphinatoiron(III) cation ([Fe(III)(tpp)(H$_2$O)$_2$]$^+$) (average 2.045 Å)[3a,6a)] and [Fe(III)(tpp)(tetrahydrothiophene 1-oxide)$_2$]$^+$ (average 2.045 Å).[6b)] It is, however, in agreement with those observed in intermediate-spin [Fe(III)(tpp)C(CN)$_3$] (average 1.995 Å),[3d)] and is also comparable with those of typical low-spin six-coordinate porphinatoiron(III) complexes, [Fe(III)(tpp)(imidazole)$_2$]$^+$ (average 1.989 Å)[9a)] and [(protoporphyrin IX)iron(III)(1-methylimidazole)$_2$]$^+$ (average 1.991 Å),[9b)] and [Fe(III)(tpp)(CN)$_2$]$^-$ (average 2.000 Å).[9c)]

The thf molecule lies approximately on the mirror plane *xoz*. The O(T) atom exactly lies on the mirror plane, but the C(11), C(12), C(13), and C(14) atoms are disordered out of the mirror plane with 1/2 occupancy. The large thermal motion of the thf ligand presumably permits a number of possible conformations including the twisting form with an approximate C2 symmetry. The average C–O bond distance of 1.391 Å

a) Relative to Fe metal. b) C_t notes the center of four nitrogen atoms.

and the average C–C bond distance of 1.467 Å are within the range of those for the metal coordinated thf molecules.[8]

The perchlorate anion is disordered around the center of symmetry. The Cl, O(1), and O(2) atoms lie on the mirror plane, and the O(3) atom exists at a general position. The perchlorate anion is surrounded by the six $[Fe(III)(oep)(thf)_2]^+$ cations, and the short intermolecular distances are 3.295 Å between O(3) and C(5), and 3.417 Å between O(2) and C(11).

Discussion

The bond distances and bond angles observed in several intermediate-spin iron(III)-porphyrins are listed in Table 3. Data of ESR spectra, effective magnetic moments, and Mössbauer spectra are also included in Table 3. The ESR spectrum of $[Fe(III)(oep)(thf)_2]ClO_4$ shows one broad signal at $g=4.16$ in the solid state, and the anisotropic $g_{//}$ and $g_\perp$ values are quite different from those of the usual high-spin complex ($g_{//}=2$, $g_\perp=6$) and those of the low-spin complexes ($g=2.2$—2.8). The effective magnetic moments, μ_{eff}, of 4.21 μ_B at 77 K and 4.73 μ_B at 275 K[3c] are close to 3.87 μ_B calculated for $S=3/2$ rather than to 5.92 or to 1.73 μ_B for $S=5/2$ or 1/2, respectively. The large quadrupole splitting in the Mössbauer spectrum eliminates both possibilities of a low-spin complex and a high-spin complex. Hence, these spectroscopic data suggest that the iron(III) complex has a pure $S=3/2$ ground state.

Generally, a low-spin six-coordinated iron(III)-porphyrin becomes a high-spin complex when the axial ligand is replaced by a more weakly interacting ligand.[3b] In this case, both the axial and equatorial bond distances

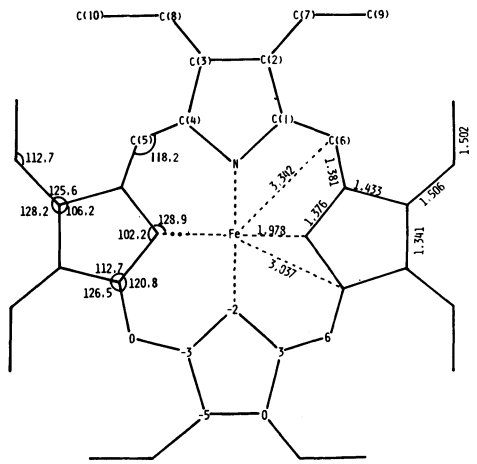

Fig. 3. Formal diagram of the porphinato skeleton in [Fe^{III}(oep)(thf)$_2$]ClO$_4$ molecule. On the top of the diagram, the numbering scheme for the atoms is displayed. On the right-hand side and left-hand side of the diagram, the chemically equivalent bond distances and angles. On the bottom of the diagram, the numbering symbol for each atom is replaced by its perpendicular displacement, in units of 0.01 Å, from the mean plane of the porphinato core.

increase without change of the octahedral symmetry around the central metal ion. If the axial ligand becomes very weak, the axial bond distance is further increased, while the equatorial distance is decreased, and then the octahedral symmetry falls down to the lower D_{4h} symmetry. The intermediate-spin state may be arisen in this situation. Scheidt *et al.*[6a] gave 2.096 Å for the critical Fe–O distance in the transition from the high-spin to intermediate-spin state. The Fe–O distance of 2.137 Å has, however, been observed in the quantum mechanically $S=5/2$ and 3/2 mixed spin complex, [Fe(III)(oep)(EtOH)$_2$]$^+$,[5a] and the Fe–O distance of 2.142 Å was reported for a high-spin complex [Fe(III)-(tpp)(EtOH)$_2$]$^+$.[5b] The present Fe–O(thf) distance of 2.187 Å is longer than these Fe–O distances. The long axial Fe–O distance and short equatorial Fe–N distance strongly suggest that this complex has a pure intermediate-spin state, since in view of the stability of chemical bonds, the vacant $d_{x^2-y^2}$ and singly occupied d_{z^2} orbital levels in the intermediate-spin state are consistent with the long axial and short equatorial bond distances. Hence the Fe–O distance of 2.187 Å observed here may be a typical Fe–O distance for a pure $S=3/2$ state.

For cytochrome c′ it has been believed that its protein ligation to heme occurs at the fifth coordination site through the histidine residue,[12] and that the π-bonding mode of the ligation is definitely related to the function of hemoproteins. In the synthetic intermediate-spin complexes as a model heme for cytochrome c′, however, the weak σ-characterisities of the axial ligands seems to play an important role in the intermediate-spin complex formation, and the weakness of the ligand field strength may be necessary for the occurrence of the intermediate-spin states. Therefore, the coordination aspect in the cytochrome c′ may be speculated by the electronically weak bonding of histidine as in the manner of a long Fe–imidazole N distance and/or of a large tilting angle of histidine with respect to the porphinato core of heme.

The authors wish to thank Professor Nobuo Morimoto and Dr. Katsutoshi Tomita, Faculty of Science, Kyoto University, for the use of the Rigaku AFC-5 diffractometer.

(Received January 20, 1982)

The cation radicals of three [2.2]pyrenophanes in which two pyrene moieties are twisted each other by 0°, 35°, and 60° were investigated by ESR, ENDOR, and cyclic voltammetry. Considerable variations of the spin density distribution and the stabilization energy with the twisting angle have been observed. The obtained results are discussed in terms of modified Hückel-McLachlan type calculation.

A number of dimer cation radicals of aromatic hydrocarbons have been observed by electron spin resonance (ESR).[1-3] From the analysis of the hyperfine coupling constants (hfcc) it was confirmed that the unpaired electrons in the dimer cation radicals are distributed equally over the two aromatic moieties. Based on the ESR results and theoretical calculations it has been postulated that these dimer cations have eclipsed configurations in which one moiety lies upon the top of the other symmetrically.

On the other hand, X-ray studies indicate that the aromatic cation radical salts $(Ar)_2^{+\cdot}X^-$ ($X=PF_6$) have twisted configurations with the twisting angles of 90° and 180°.[4] These observations show that the dimer configuration is very sensitive to the environment. Thus it is of interest to examine how the orbital energy and spin distribution vary with configuration.

In this work, we have measured the ESR, ENDOR (electron nuclear double resonance) spectra and the oxidation potentials of three [2.2]pyrenophanes, **1** to **3**, shown in Fig. 1. From their molecular models the twisting angles between the upper and lower pyrene moieties (θ) are estimated to be 0°, 35°, and 60° in **1**, **2**, and **3**, respectively. The obtained results are discussed based on a simple molecular orbital calculation of the spin density distributions and the orbital energies of the highest occupied molecular orbitals (HOMO) as a function of θ.

Experimental

Synthetic methods of the compounds **1** to **3** were reported elsewhere.[5] The cation radicals were generated by oxidation with CF_3COOH or CF_3COOD in CH_2Cl_2, or by electrochemical oxidation. The oxidation potentials ($E^\circ_{1/2}$) were measured by cyclic voltammetry (CV). Further experimental details were similar to those described previously.[3,6]

Results and Discussion

In Fig. 1 are shown the ENDOR spectra of $\mathbf{1}^{+\cdot}$, $\mathbf{2}^{+\cdot}$, and $\mathbf{3}^{+\cdot}$ observed at −85 °C. The obtained hfcc are given in Table 1 with those of pyrene dimer cation radical ($\mathbf{P}_2^{+\cdot}$).[1] The ESR spectra of $\mathbf{1}^{+\cdot}$ and $\mathbf{3}^{+\cdot}$ measured at −65 °C were well resolved but that of $\mathbf{2}^{+\cdot}$ was only partially resolved. These ESR spectra were all reconstructed well by the computer simulation using the hfcc obtained from the ENDOR spectra. The observed and simulated ESR spectra of $\mathbf{3}^{+\cdot}$, for example, are shown in Fig. 2. For the help of assignment, we also measured the ESR spectra of $\mathbf{1}^{+\cdot}$, $\mathbf{2}^{+\cdot}$, and $\mathbf{3}^{+\cdot}$ which were oxidized by excess amounts of CF_3COOD instead of CF_3COOH. Their ESR spectra clearly showed the hyperfine splittings due to deuterons exchanged with the ring protons with the hfcc larger than about 2.0 G.** It is known that no H–D exchange takes place for the protons of the alkyl groups by CF_3COOD.[7] The hfcc of protons exchanged by deuterons are indicated in Table 1.

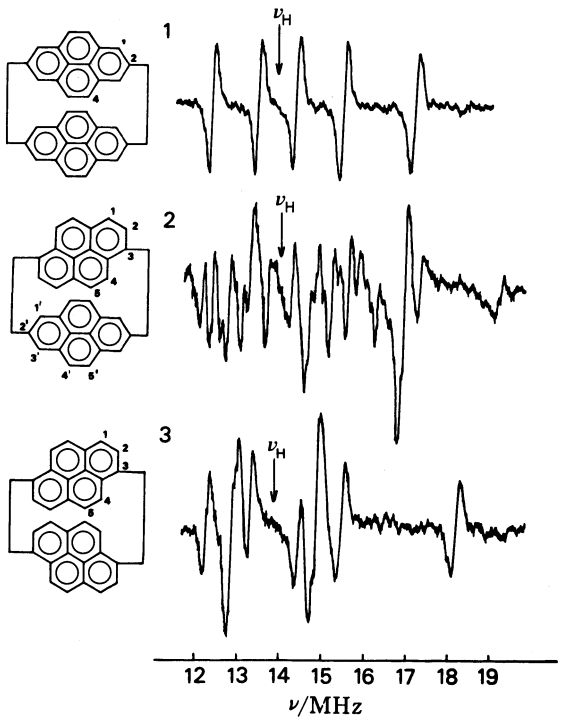

Fig. 1. Molecular structures and ENDOR spectra of three [2.2]pyrenophanes, **1** to **3**.

The hfcc of $\mathbf{1}^{+\cdot}$ are similar to those of $\mathbf{P}_2^{+\cdot}$ and can be assigned easily. Therefore, $\mathbf{1}^{+\cdot}$ can be regarded as a good model for $\mathbf{P}_2^{+\cdot}$. The hfcc of $\mathbf{2}^{+\cdot}$ and $\mathbf{3}^{+\cdot}$, however, are different from those of $\mathbf{1}^{+\cdot}$ and $\mathbf{P}_2^{+\cdot}$ and cannot be assigned uniquely because of the presence of a large

** 1 G=10^{-4} T.

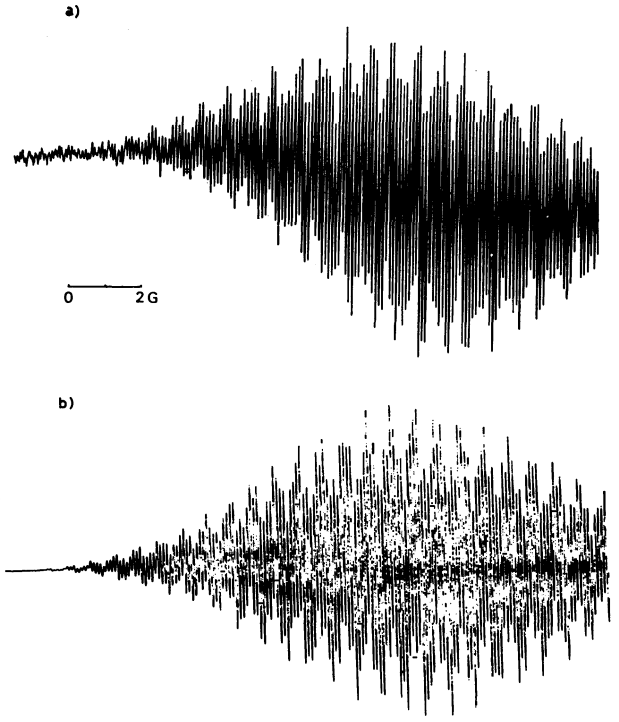

Fig. 2. The observed (a) and simulated (b) ESR spectra of $3^{+\cdot}$.

number of hfcc. It should be noted here that the largest hfcc of $2^{+\cdot}$ and $3^{+\cdot}$, 3.702 G and 3.080 G, respectively, are much larger than that of $1^{+\cdot}$, 2.342 G. This fact indicated that a considerable redistribution of the spin density takes place in $2^{+\cdot}$ and $3^{+\cdot}$.

We also measured the oxidation potentials ($E^{\circ}_{1/2}$) of these compounds by the CV technique to investigate the energy changes due to the twisting. $E^{\circ}_{1/2}$ of pyrene and **1** to **3** are also shown in Table 1. $E^{\circ}_{1/2}$ of **1** is 0.81 V, being lower than that of **P** by 0.41 V because of the transannular interaction, as we reported previously in the case of multilayered compounds.[3] On the other hand, $E^{\circ}_{1/2}$ of **2** was appreciably higher than that of **1**. This increase is likely to be caused by the reduction of the resonance integral due to the twisted structure of **2**. Such a reduction of the stabilization energy has also been observed in the photoelectron spectra of several twisted naphthalenophanes.[8] However, $E^{\circ}_{1/2}$ of **3** becomes comparable to that of **1** (0.80 V) in spite of its twisted structure.

In order to clarify the effects of the twisting angle in the dimer structure we calculated the spin density and the orbital energy by modified Hückel-McLachlan's method. We carried out the calculation with the assumption that the resonance integrals between the upper and lower atoms of pyrene moieties (β_{1-u}) are proportional to the $2p\sigma$-$2p\sigma$ type overlap integral between the upper and lower carbon atoms (S_{1-u}) and are given by[9]

$$\beta'_{1-u} = A \cdot S_{1-u} \cdot \beta_{C-C}, \qquad (1)$$

where A is the proportionality constant. Two pyrene moieties were assumed to be 3.5 Å apart with the molecular planes parallel to each other. The effects

a) Measured at room temperature. Solvent: CH_2Cl_2. Supporting eletrolyte: $(C_4H_9)_4NPF_6$. b) Protons exchanged to deuterons by using CF_3COOD. c) Bridge protons calculated with Q=11 G. d) Assignments of these hfcc are not unique.

of the bridging ethylene groups were taken into account by changing the Coulomb integrals of the carbon atoms ($\alpha_{C'}$) attached by the ethylene groups to $\alpha_{C'}=\alpha_C-0.1\beta$. In the first place, we calculated S_{1-u} in Eq. 1 and estimated β'_{1-u} using the parameter A. Subsequently we calculated the spin density by the McLachlan's method. Hfcc were calculated by using $Q=-25$ G for the ring protons and $Q=11$ G for the bridge protons. The latter value was estimated from the calculated spin density on the bridged carbon atoms and the hfcc of the ethylene protons obtained experimentally for $1^{+\cdot}$. The bridge protons of $2^{+\cdot}$ and $3^{+\cdot}$ are not equivalent with those of $1^{+\cdot}$ because of the torsion of the ethylene groups, but the deviations from the equivalent positions are not so large. Therefore, this value was used for the bridge protons of $2^{+\cdot}$ and $3^{+\cdot}$ in order to make a rough estimate of their hfcc. The calculated hfcc for A=4.0 are given in Table 1.

The agreement between the calculated and observed hfcc in $\mathbf{P}_2^{+\cdot}$ and $1^{+\cdot}$ is very good. The spin density distribution in $1^{+\cdot}$ and $3^{+\cdot}$ does not depend much on the choice of A and the unpaired electron is equally distributed over the two pyrene moieties, whereas the unpaired electron in $2^{+\cdot}$ is almost localized on one moiety (upper moiety in Fig. 1). This is due to the fact

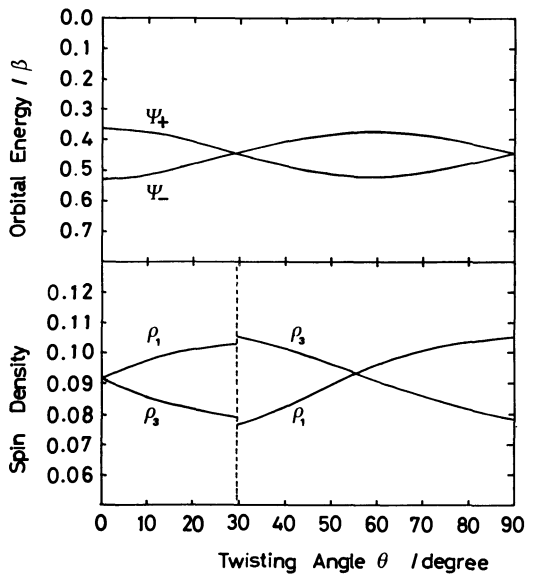

Fig. 3. Twisting angle (θ) dependences of the Hückel orbital energies and the spin densities at positions 1 and 3 in the pyrene dimer cation radical ($\mathbf{P}_2^{+\cdot}$).

that the positions attached by the bridging ethylene groups in the two pyrene moieties of **2** are not equivalent. At $A=4.0$ a fairly good agreement between the observed hfcc of $\mathbf{2}^{+\cdot}$ and the calculated one was obtained in spite of the simple calculation. Comparing the observed hfcc of $\mathbf{2}^{+\cdot}$ and $\mathbf{3}^{+\cdot}$ with those calculated, the largest hfcc of $\mathbf{2}^{+\cdot}$ and $\mathbf{3}^{+\cdot}$, 3.702 G and 3.080 G, respectively, can be assigned both to the protons attached to the position 1 shown in Fig. 1. However, there remains some ambiguities in the assignment of smaller hfcc of $\mathbf{2}^{+\cdot}$ and $\mathbf{3}^{+\cdot}$.

The variation of $E^{\circ}_{1/2}$ and the increase of the spin density on position 1 can be caused by the effect of the twisting and the difference in the position attached by the ethylene groups. It is necessary to decide which is the main cause. In Fig. 3 are shown the dependences of the orbital energies in unit of β and the spin densities on the twisting angle θ, which were obtained by Hückel-McLachlan's method without the effects of the ethylene groups. At $\theta=0°$ the energies of the bonding orbital ϕ_- and antibonding orbital ϕ_+ constructed by the combination of HOMO of the two pyrene moieties are split into two due to the transannular interaction. As θ increases, the energies of these two orbitals approach each other because of the reduction of the resonance stabilization. At $\theta=30°$ the two orbitals invert their energies and the energy of ϕ_- reaches a maximum at $\theta=60°$. The energy of ϕ_- at $\theta=60°$ is almost equal to that of ϕ_+ at $\theta=0°$. The orbital energies of HOMO at 0°, 35°, and 60° calculated including the effects of the ethylene groups are indicated in Table 1 for the sake of comparison. These values are about 0.04β higher than those with the corresponding angles given in Fig. 3. This means that the effect of the ethylene groups to the HOMO only lifts the orbital energies by 0.04β. This behavior corresponds well to the variation of the $E^{\circ}_{1/2}$ of **1** to **3**.

The spin densities on the position 1 and 3, ρ_1 and ρ_3, respectively, also vary with θ as shown in Fig. 3. The spin densities change discontinuously at $\theta=30°$, corresponding to the inversion of the energies of ϕ_+ and ϕ_-. ρ_1 at $\theta=35°$ can be converted to the hfcc of 2.0 G, which is much smaller than 3.702 G obtained experimentally in $\mathbf{2}^{+\cdot}$. On the other hand, the calculated hfcc at position 1 with the bridge effects (Table 1) are close to the experimental values. It is then concluded that the effect of the bridging ethylene groups is the main cause of the large hfcc at position 1 in **2**. ρ_1 at $\theta=60°$ is close to ρ_1 at $\theta=0°$ irrespective of the effects of ethylene groups. However, the largest hfcc obtained experimentally in $\mathbf{3}^{+\cdot}$ (3.080 G) does not agree so well with that calculated (2.443 G).

In conclusion, as the twisting angle θ between the two moieties increases, the spin redistribution occurs because of the change in the resonance integral β'_{1-u} accompanying the loss of the resonance stabilization. As the angle increases further, ϕ_+ and ϕ_- invert their energies and gradually regain the resonance stabilization.

Brillouin Scattering and Ultrasonic Absorption Measurements of Chloroform-Eicosane Mixtures

Hiroyasu NOMURA,* Hayao SHIMIZU, Yasuharu TANAKA, Shinobu KODA, Toshio OKUNISHI, Shigeo KATO, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 27, 1982)

An apparatus for the accurate measurement of Brillouin scattering of liquids and solutions was constructed using a multi-pass Fabry-Perot interferometer. The Brillouin scattering spectra of chloroform–eicosane mixtures were obtained at various concentrations. The sound velocity dispersion curves of this system could be expressed by a single relaxation equation. With increasing concentration of eicosane, the relaxation frequency shifted to the higher frequency side, but the relaxation strength was independent of concentration. It is concluded that this relaxation was due to the vibrational-translational energy transfers of chloroform molecules due to the collisions between chloroform and eicosane molecules.

The recent development of laser spectroscopy has opened a way to the study of the dynamical nature of molecules, such as the vibrational and reorientational relaxation times in liquid and dissolved states. The Brillouin scattering method in the only technique so far which can give information of the dynamic nature of a substance in the liquid state in the GHz range. This method has attracted the attention of many investigators.

In a previous paper,[1] we reported that the ultrasonic absorption coefficients of solutions of polycarbonate in chloroform were lower than those of solvent chloroform at all frequencies investigated. The negative value of $\Delta\alpha/f^2$ $(=(\alpha/f^2)_{\text{solution}}-(\alpha/f^2)_{\text{solvent}})$, where α is the ultrasonic absorption coefficient, could be interpreted by the shift of the relaxation frequency of chloroform to a higher frequency.

In order to confirm the above interpretation, the relaxation spectra of chloroform solutions must be determined as a function of concentration of solute in the wide frequency range from MHz to GHz. For this purpose, we constructed an apparatus for the accurate measurement of Brillouin scattering of liquids and solutions, using a multi-pass Fabry-Perot interferometer and measured the sound velocity and attenuation of chloroform solutions in the GHz region. In addition, the ultrasonic absorption coefficients of the same solutions were measured in the MHz region.

Eicosane was chosen as a solute for the following reasons. Eicosane molecule is a linear hydrocarbon containing only twenty methylene groups. One may suppose therefore that the ultrasonic relaxation due to the segmental motion is not observed in the MHz region.[2] Moreover, as the eicosane molecule has no phenyl group which may interact with chloroform molecules, there is no specific interaction between chloroform and eicosane. Therefore, eicosane is a suitable sample in which to investigate the relaxation phenomena of chloroform solutions.

Apparatus and Experimental

Brillouin Scattering Spectrometer. The experimental arrangement of the apparatus is shown in Fig. 1. This is basically the same as used by Stegeman *et al.*[3] and is one of the standard methods for the Brillouin scattering. In the present case, a multi-pass Fabry-Perot interferometer was used. The light source was a helium-neon laser (NEC, GLG 2051) with an output of about 25 mw and it was operated in TEM_{00} mode ($\lambda=632.8$ nm). The beam was focused at the center of the scattering cell by a lens (L_1) and a total reflection mirror (M_1). The scattered light collected by a lens (L_2) was collimated and analyzed by a pressure-scanned triple-pass Fabry–Perot interferometer. The fused quartz plates of the interferometer used were 8 cm in diameter and 1.5 cm thick, and each plate has one surface with flatness $\lambda/200$ and more. This surface was dielectrically coated to reflectivity of 97% at $\lambda=$ 632.8 nm, while the other surface ($\lambda/10$) of the plate had an antireflection coating. The spacers of the interferometer used were 6.04_0, 10.03_1, and 12.02_0 mm long, giving a free spectral range of 24.81_7, 14.94_3, and 12.47_1 GHz, respectively. In operating the interferometer in triple-pass system a pair of total reflection prisms was used. They were arranged with the angle of 120° to each other. All optical parts and instruments were manufactured by Mizojiri Optical Instrument Co., Ltd.

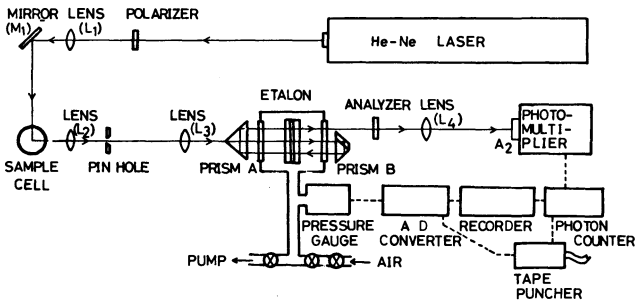

Fig. 1. Block diagram of the experimental set up.

At the beginning of the measurements, the chamber of the interferometer was evacuated with a vacuum pump, then air was introduced into the chamber through a filter, needle valve, and flow controller. The amount of air flow was controlled by a two-step flow control system consisting of two flow control valves (Ohkura Electric Co., Ltd., type CF-221). The pressure in the chamber was detected as a d. c. voltage by means of a piezoelectric pressure gauge (Tokyo Aircraft Instrument Co., Ltd., type TP-310A) and was converted to a digital signal by an AD converter (Takeda Electric. Co., Ltd., type TR-6935). Light incident on the aperture (A_2) was detected by a cooled photomultiplier (Hamamatsu TV Co., Ltd., type R-649), amplified by a preamplifier (Hamamatsu TV Co., Ltd., type HTV C-716) and then counted by a photon-counting system (Hamamatsu TV Co., Ltd., type HTV-C 767).

Spectra were recorded on the chart and at the same time punched up as digital data.

The scattering cell, of cylindrical shape (5.0 cm in diameter), was made of pyrex glass. The cell was firmly placed in an aluminium block having a horizontal slit through which to observe the scattered light. The temperature of the block was regulated at 25 ± 0.1 °C by the circulation of water at constant temperature. In our arrangement, the scattering angle was changed from 20° to 160° through the variation of the reflecting angle of the laser beam by the aid of a mirror and a rotating table. The scattering angle could be read with the precision of $\pm2'$. The sample liquids were introduced into the cell after being passed through the Milliporefilter FG of pore size 0.22 μm.

The refractive index of the samples was measured with a modified differential refractometer manufactured by Shimadzu Instrument Co., Ltd.

Brillouin spectra of chloroform and chloroform-eicosane mixture (at 30.0 ± 0.1 °C) were recorded at various scattering angles in the range from 20° to 160°. At each scattering angle, the interferometer was scanned at least over five free spectral ranges.

Ultrasonic Absorption and Velocity Measurements. Ultrasonic absorption measurements were carried out over the frequency range from 10 to 60 MHz using a standard two crystal r.f. pulse technique with an apparatus described elsewhere.[4] Absorption measurements in the frequency range from 4.5 to 10.5 MHz were carried out using a long measuring cell (effective path length was 20 cm) with a crystal of 3.0 cm in diameter having the fundamental frequency of 1.5 MHz.

The sound velocities were measured with an ultrasonic interferometer working at 4.000 MHz.

Sample. Chloroform used was of spectral grade supplied by Nakarai Chemicals Co., Ltd. and was used without further purification. Eicosane used was also supplied by Nakarai Chemicals Co., Ltd.

Data Analysis of Brillouin Spectra

The observed Brillouin spectrum can be expressed explicitly as a convolution of the true Brillouin spectrum, the instrumental function, and the intensity spectrum of the laser source, as discussed in detail by Leidecker and LaMacchia.[5] However, in our experiment, the latter two response functions were not known exactly, so we have assumed that the observed spectrum, $I(\omega)$, is given by the relation,

$$I(\omega) = \int_{-\infty}^{\infty} I'(\omega-\omega')S(\omega')\mathrm{d}\omega', \tag{1}$$

where $S(\omega)$ represents the total effective response function which involves the laser intensity spectrum and the instrumental broadening function and $I'(\omega)$ is the true Brillouin spectrum. According to the treatment of Stegeman *et al.*,[3] an experimental determination of the convolution of laser and instrumental line profiles was carried out using the light scattered by a white paper. The profile of the diffuse laser was well expressed by a Gaussian function. As the profiles of Brillouin lines of liquids and solutions are expressed by a Lorentzian function, the observed Brillouin spectrum, $I_B(\omega)$, can be written as;

$$I_B(\omega) = \int_{-\infty}^{\infty} \frac{\Gamma_B}{\Gamma_B^2+(\omega'-\omega)^2} \exp\left[-\frac{1}{2}\left(\frac{\omega'}{\sigma_g}\right)^2\right]\mathrm{d}\omega', \tag{2}$$

where Γ_B is the true half-width of Brillouin line, and σ_g the half-width of a Gaussian function which is obtained from the observed profile of the diffuse light.

In order to determine the Brillouin shift accurately, the decomposition of the Rayleigh-Brillouin spectrum was carried out using the non-linear least-mean square method of Fletcher and Powell.[6] The Brillouin frequency shift, $\Delta\omega$, of the scattered light is related to the velocity of sound, V, as follows:[7]

$$\frac{\Delta\omega}{\omega_0} = 2n\left(\frac{V}{c}\right)\sin\left(\frac{\theta}{2}\right), \tag{3}$$

where ω_0 is the frequency of the incident light wave, c the velocity of light, n the refractive index of the liquids and θ the scattering angle. The true half-width of Brillouin line, Γ_B, is obtained by the fitting of Eq. 2 to the observed spectrum. Γ_B is related to the attenuation coefficient of sound by[7]

$$\alpha = \frac{\Gamma_B}{V}. \tag{4}$$

Results

Brillouin Spectra. In Fig. 2 are shown the Brillouin spectra of liquid chloroform recorded at the scattering angles of 87.0° and 88.8° in single and triple-pass systems, respectively. The effective finesse of these systems was about 38—40 in single-pass system and about 59—60 in triple-pass. As seen in Fig. 2, the triple-pass operation gives a much better Brillouin spectrum than that obtained by the single-pass system. In Fig. 3 are shown the Brillouin spectra of liquid chloroform recorded at three scattering angles, 40.0°, 74.7°, and 151.5°. At the largest scattering angle, the Rayleigh and Brillouin components do not overlap. The background scattering of the spectrum extends symmetrically from the central Rayleigh component to the Stokes and anti-Stokes Brillouin components. This fact indicates that there is a significant new component. This new component should be a Mountain line[8] which was found originally in carbon tetrachloride by Stegeman *et al.*[3]

The estimation of the sound velocity and attenuation

of liquid chloroform and chloroform solutions was carried out from the method indicated in the section of Data Analysis of Brillouin Spectra. As an example, the results for liquid chloroform at 30 °C are summarized

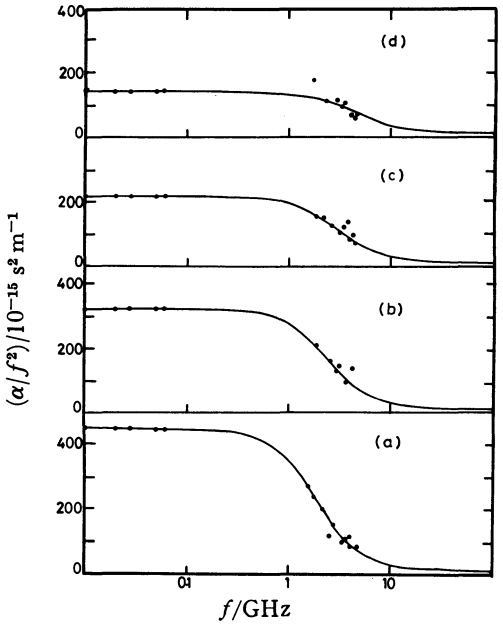

Fig. 5. Sound attenuation of chloroform–eicosane mixtures at 30 °C. The data in GHz region are obtained from the analysis of the Brillouin spectra and the data in MHz region from the ultrasonic absorption measurement. (a): Pure chloroform, (b): 3.1 wt% of eicosane, (c): 6.8 wt% of eicosane, and (d): 14.4 wt% of eicosane. The solid lines are the best fit curves for a single relaxation.

in Table 1 together with their experimental errors. The sound velocity and the attenuation of chloroform–eicosane mixtures thus obtained are shown in Figs. 4 and 5. The sound velocity dispersion curve of neat chloroform at 30 °C was in good agreement with that obtained by Takagi *et al.*[9] in the GHz region.

As can be seen in Figs. 4 and 5, the sound velocity dispersion and relaxation curves were observed in the GHz region for all mixtures investigated. Our data in Fig. 4 are analyzed with the following single relaxation formula:

$$\frac{V_0^2}{V^2-V_0^2}=\left(\frac{1}{\varepsilon}-1\right)\left(1+\frac{f_r^2}{f^2}\right), \tag{5}$$

TABLE 2. RELAXATION PARAMETERS IN CHLOROFORM–EICOSANE MIXTURES AT 30 °C

6.85	5.80	986.7	1103.2	0.2000
14.38	8.05	1010.6	1129.9	0.2000

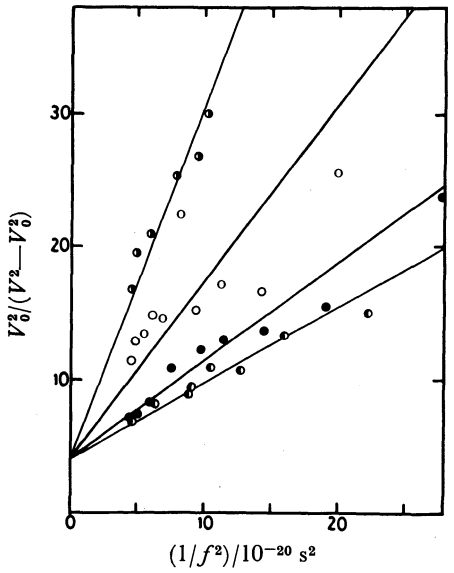

Fig. 6. Relationship between $V_0^2/(V^2-V_0^2)$ and $1/f^2$. The symbols are the same as those in Fig. 4.

$$\varepsilon = \frac{V_\infty^2 - V_0^2}{V_\infty^2},$$

where ε is the relaxation strength and V_0 and V_∞ are sound velocities at low frequency and at high frequency limits, respectively. Figure 6 shows the relation between $V_0^2/(V^2-V_0^2)$ and $1/f^2$ where the values of V_0 are those obtained by the ultrasonic interferometer working at 4 MHz. As shown in Fig. 6, a linear relationship is obtained in every chloroform–eicosane mixture. The relaxation parameters obtained are summarized in Table 2. As shown in Figs. 4 and 5, the experimental data can be well expressed by the single relaxation equation with the relaxation parameters shown in Table 2. The relaxation frequency shifts to the higher frequency side with increasing concentration of eicosane.

Ultrasonic Absorption Spectra. Figure 7 shows the ultrasonic absorption coefficients of chloroform-eicosane mixtures as a function of frequency. As shown in Fig. 7, no relaxation is observed either in chloroform-eicosane mixtures or in neat liquid eicosane over the frequency range investigated. However, the ultrasonic absorption coefficients of chloroform–eicosane mixtures are always smaller than those of neat chloroform at all frequencies investigated. The ultrasonic absorption coefficient, α/f^2, of chloroform–eicosane mixtures decreases rapidly with increasing concentration of eicosane (Fig. 8).

Discussion

Recently, Takagi *et al.*[9] found a sound velocity dispersion of chloroform in the frequency range from 3 MHz to 5 GHz and reported that the dispersion reveals two relaxation processes. On the basis of the quantitative analysis of specific heat capacity, they argued that the two relaxation processes of chloroform are ascribable to the vibrational-translational relaxation, that is, the lowest ν_6 (261 cm^{-1}) and the second lowest ν_3 (366 cm^{-1}) foundamental vibrational modes have a common relaxation time, 50 ps, and the group of all above the third mode ν_2 (667 cm^{-1}) has a time of 290 ps.

As is seen in Fig. 4, our data are limited to the GHz region and the two relaxation processes can not be seen. Therefore, we are forced to analyzed our data with a

single relaxation process expressed in Eq. 5. The relaxation frequency of neat chloroform obtained in this experiment corresponds to the higher relaxation frequency obtained by Takagi *et al.*[9] but ours is slightly smaller than that obtained by them. This may be due to the lack of data at the low frequency region. However, the relaxation strength obtained ($\varepsilon=0.200$) is in good agreement with the total relaxation strength obtained by Takagi *et al.*[9] ($\varepsilon=0.216$).

As in the case of a gas mixture, if a relaxing liquid, A, such as chloroform, is mixed with a non-relaxing liquid, B, such as eicosane, two collision processes become possible in which vibrational-translational energy transfer may occur:

$$A^* + A \longrightarrow A + A, \quad (6)$$

$$A^* + B \longrightarrow A + B. \quad (7)$$

Since the processes of (6) and (7) will have different collisional efficiencies, a composite relaxation time for A*, should be considered, as given by[10]

$$\frac{1}{\beta} = \frac{1-x}{\beta_{AA}} + \frac{x}{\beta_{AB}}, \quad \beta = \frac{1}{2\pi f_r}, \quad (8)$$

where x is the mole fraction of the component B in the mixture, β_{AA} is characteristic of process (6), and β_{AB} of process (7). This may be represented graphically by a linear plot of relaxation time $1/\beta$ against mole fraction x (Fig. 9). In the chloroform–eicosane system, since the relaxation time of neat chloroform is 4.5×10^{-11} s, it follows that $\beta_{AB}=2.0\times10^{-12}$ s for the relationship shown in Fig. 9. This result indicates that a collisional efficiency between different molecules is larger than that between the same molecules, as reported by Hunter *et al.*[11,12] It is concluded that the observed relaxation of chloroform–eicosane mixture concerns mainly the vibrational-translational relaxation of the solvent chloroform itself, originating from a molecular collision between chloroform and eicosane.

In the MHz region, no ultrasonic relaxation phenomena were observed in either chloroform–eicosane mixtures or in eicosane in the temperature range investigated (see Figs. 5 and 7). As expected, the twenty methylene groups were not sufficient for the local segmental motion to be observed in the MHz frequency range.

As illustrated in Fig. 8, the values of α/f^2 in the MHz region decreased rapidly with increasing concentration of eicosane in the chloroform–eicosane mixture. In this system the value of α/f^2 can be supposed to be the ultrasonic relaxation amplitude, A, because of the very low value of the classical absorption (α/f^2 at high frequency limit), as shown in Fig. 5. The relaxation strength, r, can be given in terms of relaxation frequency, relaxation amplitude, and sound velocity at low frequency limit as shown below:[13]

$$r = Af_r V_0/\pi. \quad (9)$$

Table 2 shows that the concentration dependence of V_0 is very small. Since the relaxation strength remains constant in the concentration range investigated, the increase of the relaxation frequency results in the decrease of the relaxation amplitude. Therefore, it is concluded that the rapid decrease of α/f^2 in the mixture is mainly due to the shift of the relaxation frequency to the higher frequency side under the constant relaxation strength.

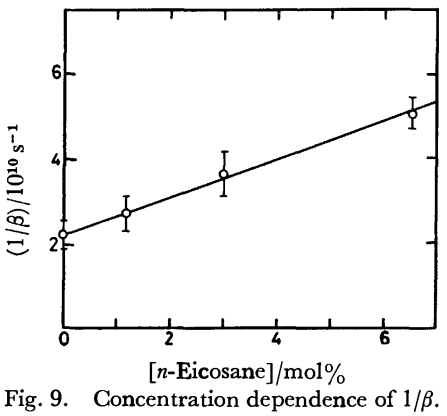

Fig. 9. Concentration dependence of $1/\beta$.

The authors should like to express their appreciation to Profs. A. Mitsuishi and S. Nakajima of Osaka University and also to Prof. K. Takagi of the University of Tokyo for their advice on constructing the apparatus for measuring Brillouin scattering. The authors are also thankful to Prof. S. Ikeda of Nagoya University for permitting them to use the differential refractometer. Some of the present experimental results were obtained by T. Matsuoka.

This work was partially supported by the Grant-in-Aid for Scientific Research No. 247005 from the Ministry of Education, Science and Culture.

(Received May 17, 1982)

The crystal structure of the hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin (abbreviated to methyl-α-CDx) complex with *p*-nitrophenol, $C_{54}H_{96}O_{30}\cdot C_6H_5NO_2\cdot H_2O$, was investigated by the X-ray method. The crystal is monoclinic, the space group being $P2_1$ with $Z=2$; the cell dimensions are $a=11.307(1)$, $b=14.578(1)$, $c=22.118(2)$ Å, and $\beta=93.62(1)°$. The structure was determined by means of the Patterson map and the trial-and-error method combined with the rigid-body least-squares technique, and refined by the block-diagonal least-squares method to the final *R*-value of 0.048 for 4976 reflections ($\sin\theta/\lambda<0.54$). The methyl-α-CDx molecule has the shape of a truncated hexagonal cone, into which the *p*-nitrophenol molecule is inserted. The phenolic hydroxyl group is located at the center of the methyl-α-CDx cavity, while the nitro group protrudes outside from the base-side of the host cone and is in contact with the adjacent methyl-α-CDx molecule. The water molecule, which is also located within the cavity, links the methyl-α-CDx and *p*-nitrophenol molecules by hydrogen bonds. Methyl-α-CDx molecules are stacked along the crystallographic a axis in a heat-to-tail mode to form a channel-type structure.

Crystal structures of cyclodextrins and their inclusion complexes have been intensively investigated, as the crystal structure analysis is a most powerful tool to visualize how a guest molecule is included within the cavity of macrocyclic oligosaccharides. We have shown the structures of α-cyclodextrin complexes with mono- and disubstituted benzenes, and demonstrated that the guest molecules are bound inside the α-cyclodextrin ring or situated within a column which is formed by the stack of α-cyclodextrin rings. In the complexes with monosubstituted benzenes,[1,2] the phenyl group is located inside the host cavity, but the substituent group protrudes from the secondary hydroxyl side of the α-cyclodextrin ring. When disubstituted benzenes are included,[3-5] the bulkier substituent is inserted into the α-cyclodextrin ring, while the smaller substituent is located outside the cavity. Such characteristics found in the inclusion geometry have been interpreted mainly in terms of the stereospecific relationship between α-cyclodextrin and guest molecules.

Permethylated α-cyclodextrin, hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin (abbreviated to methyl-α-CDx), also forms inclusion complexes. It is quite interesting to compare structures of these complexes with those of α-cyclodextrin complexes in respect to the macrocyclic conformation and geometry of inclusion. Previously, we have shown that *p*-iodoaniline[6] and benzaldehyde[7] are included in the methyl-α-CDx cavity in a manner which is quite different from that found in the corresponding α-cyclodextrin complexes. This paper will describe the crystal structure of the methyl-α-CDx complex with *p*-nitrophenol, and will discuss its comparison with other methyl-α-CDx complexes and the α-cyclodextrin–*p*-nitrophenol complex.[4]

Experimental

An aqueous solution, which contains methyl-α-CDx and *p*-nitrophenol in a 1 : 1 molar ratio, was allowed to stand at 40 °C. The methyl-α-CDx–*p*-nitrophenol (1 : 1) complex monohydrate was crystallized in a prismatic form. Lattice parameters and reflection intensities were measured on a Nicolet P3/F diffractometer with graphite-monochromated Cu *Kα* radiation. By using the θ-2θ scan mode, 4976 independent reflections with $|F_o|\geqq 3\sigma(F)$ were obtained up to 118° in 2θ. No corrections were made for absorption and extinction effects.

Crystal Data: $C_{54}H_{96}O_{30}\cdot C_6H_5NO_3\cdot H_2O$; *F. W.*=1382.5; monoclinic; space group $P2_1$; $Z=2$; $a=11.307(1)$, $b=14.578(1)$, $c=22.118(2)$ Å, $\beta=93.62(1)°$; $V=3638.6$ Å^3; $D_x=1.262$, $D_m=1.25$ g cm^{-3}.

Determination and Refinement of the Structure

A Patterson map showed that the *pseudo* hexagonal axis of the methyl-α-CDx molecule makes an angle of *ca.* 10° with the crystallographic a axis. The rotational parameters around this molecular axis and translational parameters along the a and c axes were determined by the trial-and-error method. After the correction of positional and orientational parameters of each 2,3,6-tri-*O*-methylglucose residue by the rigid-body least-squares technique, the atomic parameters of methyl-α-CDx were refined by the block-diagonal least-squares method. Then, a Fourier map was calculated, and *p*-nitrophenol and water molecules were found on the map. Hydrogen atoms were found on a difference-Fourier

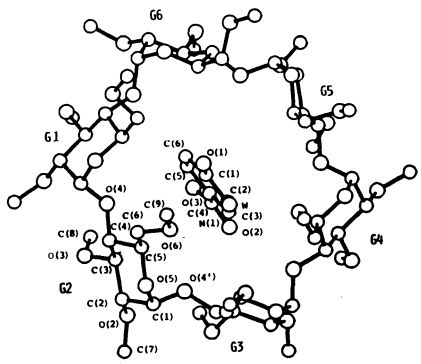

Fig. 1. The numbering scheme of the methyl-α-CDx–*p*-nitrophenol complex monohydrate. The water molecule is denoted by W.

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

map in the course of further refinement. The block-diagonal least-squares refinement including 100 hydrogen atoms achieved the R-value of 0.048. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections. The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography."[8] Final atomic coordinates and B_{eq} values of non-hydrogen atoms are listed in Table 1. Tables of observed and calculated structure factors, anisotropic temperature factors of non-hydrogen atoms, atomic parameters of hydrogen atoms, and bond distances, bond angles, and conformation angles of methyl-α-CDx are kept at The Chemical Society of Japan (Document No. 8258). The calculations were carried out on a FACOM M-200 computer at the RIPS Center, Tsukuba.

Description and Discussion of the Structure

Outline of the Structure. The numbering scheme of the complex is shown in Fig. 1. A space-filling representation of the inclusion feature is given in Fig. 2. The hydroxyl group of *p*-nitrophenol is inserted into the methyl-α-CDx ring, while the nitro group protrudes outside from the O(2), O(3) methoxyl side of the methyl-α-CDx ring. The water molecule is located at the O(6) side of the cavity, forming hydrogen bonds with two O(6) atoms of methyl-α-CDx and the phenolic hydroxyl group. Methyl-α-CDx molecules are stacked along the crystallographic a axis to form a head-to-tail channel-type structure as shown in Fig. 3.

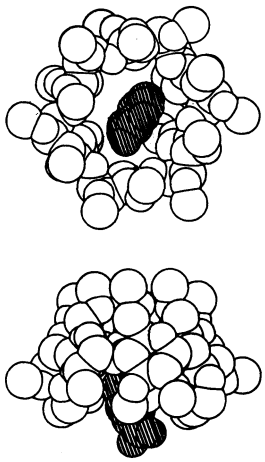

Fig. 2. A space-filling representation of the inclusion feature.

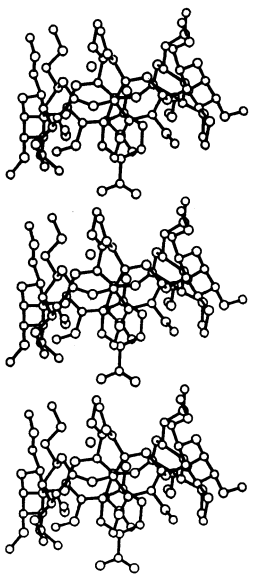

Fig. 3. The stacking feature of the methyl-α-CDx complex.

Conformation of Methyl-α-CDx. Average bond distances and angles over six 2,3,6-tri-*O*-methylglucose residues are shown in Fig. 4. Geometrical data for the macrocyclic ring are given in Tables 2 and 3. Except for the orientation of C(6)–O(6) bonds, the six 2,3,6-tri-*O*-methylglucose residues are in the same conformation. The C(6)–O(6) bonds in the G2, G3, and G4 residues take *gauche-trans* conformations about the C(5)–C(6) bonds, while the others have *gauche-gauche* conformations. Each O(6)–C(9) bond is *trans* to the corresponding C(5)–C(6) bond. The six O(2)–C(7) bonds are oriented outside the methyl-α-CDx ring, the six O(3)–C(8) bonds turning inside the ring. The conformations of the pyranose rings in cyclodextrins have been discussed in terms of the torsion-angle index and distance between glycosidic oxygen atoms.[4] The values of the torsion-angle index, which are in the range 120.4—144.4°, are similar to those found in the α-cyclodextrin–*p*-nitrophenol complex. The O(4)···O(4) distances between adjacent residues range from 4.16 to 4.53 Å. The average value of 4.31 Å is somewhat larger than the corresponding value (4.24 Å) found in the α-cyclodextrin complex. French and Murphy[9] have shown that there is a linear correlation between the O(4)···O(4) distance and the torsion-angle index in mono- and oligosaccharides. The same relationship has been also found in α-cyclodextrin complexes.[4] But, as shown in Fig. 5, no such correlation appears in the methyl-α-CDx complexes. This suggests that the methyl groups affect the conformation of the pyranose ring so as to break the linear correlation between the O(4)···O(4) distance and the torsion-angle index.

The six glycosidic oxygen atoms form an elliptically-distorted hexagon. The longest diagonal is found parallel to the guest plane. These O(4) atoms are roughly coplanar with a maximum deviation of 0.202 Å from their least-squares plane. This indicates that the planarity of the O(4) hexagon is not significantly affected by the methylation, since the corresponding maximum deviation in the α-cyclodextrin–*p*-nitrophenol complex is 0.163 Å. The O(2)···O(3) distances between the adjacent residues are in the range 3.26—3.48 Å, which are markedly larger than those found in the α-cyclodextrin–*p*-nitrophenol complex (2.65—3.07 Å). These large

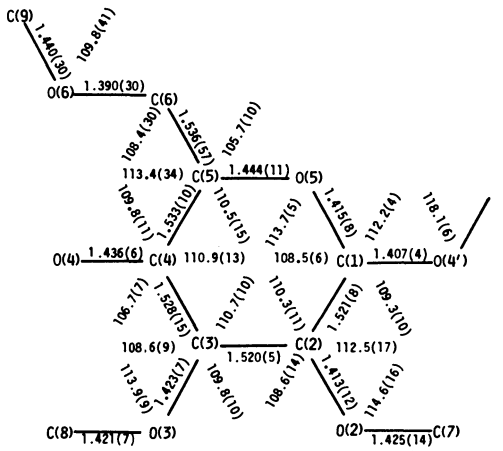

Fig. 4. Average bond distances (l/Å) and angles (ϕ/°) over six 2,3,6-tri-*O*-methylglucose residues. Standard deviations in parentheses were estimated according to the equation: $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$, where x_i refers to the bond distance or angle in the i-th residue and $\bar{x}$ is the average value.

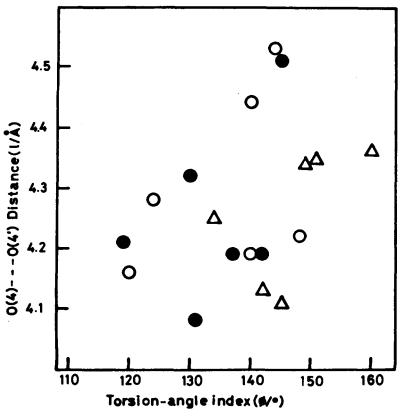

Fig. 5. Plot of the O(4)···O(4′) distance against the torsion-angle index in the methyl-α-CDx complexes with *p*-nitrophenol (○), *p*-iodoaniline (△), and benzaldehyde (●).

O(2)···O(3) distances may be ascribed to the repulsive interaction between the C(8) methyl group and two adjacent O(2) atoms. The C(8) methyl group is nearly equidistant from these two O(2) atoms; the C(8)···O(2) distances of these two kinds are in the ranges 3.17—3.45 Å and 3.21—3.45 Å, respectively. Such repulsive interaction also inclines 2,3,6-tri-*O*-methylglucose residues in such a way that the O(6) side of the cavity becomes smaller. The tilt-angles range from 9.3° to 28.1°. The average value of 18.8° is larger than the corresponding values of 16.7° in the *p*-iodoaniline complex[6] and 17.7° in the benzaldehyde complex.[7] This suggests that the methyl-α-CDx ring changes its macrocyclic conformation so as to fit itself to the shape of included group or molecule.

Methyl-α-CDx–Guest Interaction. Bond distances and angles in *p*-nitrophenol and intermolecular distances between the methyl-α-CDx and guest molecules are given in Fig. 6. The hydroxyphenyl group of the guest is inserted into the methyl-α-CDx ring. The phenolic hydroxyl group is located nearly at the center of the cavity, while the benzene ring is surrounded by O(2)-C(7)H_3 and O(3)C(8)H_3 methoxyl groups. The nitro group, which protrudes outside the ring from the O(2), O(3) side of methyl-α-CDx, is in contact with methyl groups of the next methyl-α-CDx molecule. The guest plane is nearly perpendicular to the O(4)-hexagon plane, making an angle of 89.1°. The molecular axis of *p*-nitrophenol deviates from the normal of the O(4)-hexagon plane; the nitro group approaches to the G3 and G4 residues. As a result, the C(6,NP)–H bond is oriented toward the C(3)H methine groups of the G1 and G6 residues, while the C(2,NP)H group is in contact with the C(5)H methine groups of the G3 and G4 residues. All the intermolecular hydrogen-hydrogen distances are greater than 2.35 Å, as shown in Fig. 6. This indicates that the benzene ring has weak van der Waals contacts with the atoms which constitute the interior surface of the methyl-α-CDx cavity.

The host-guest interaction in the present complex is quite different from that found in the α-cyclodextrin–*p*-nitrophenol complex,[4] in which the guest molecule is

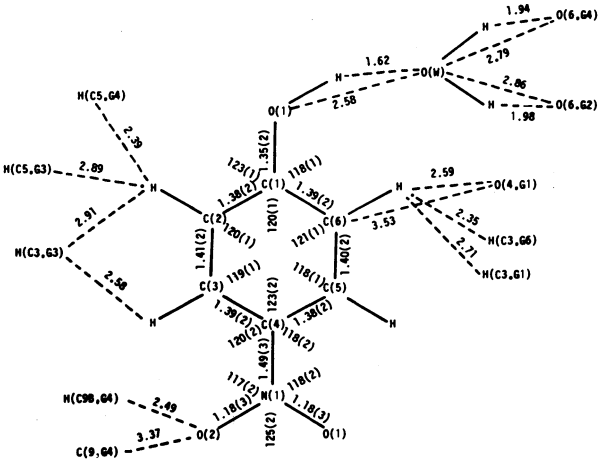

Fig. 6. Bond distances (l/Å) and angles (ϕ/°) in *p*-nitrophenol and intermolecular distances (l/Å) among methyl-α-CDx, water, and *p*-nitrophenol molecules.

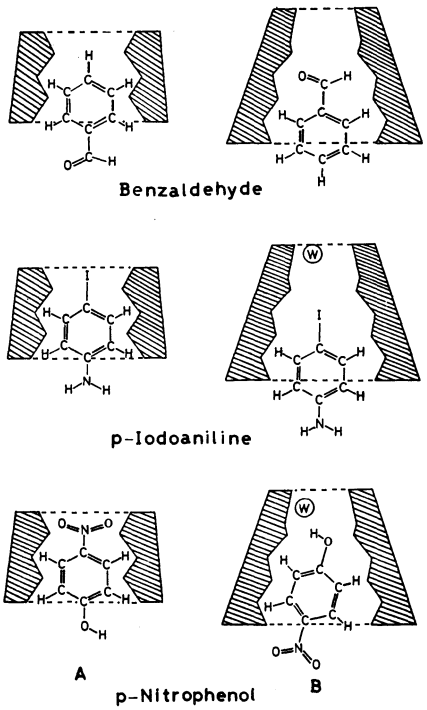

Fig. 7. Schematic drawings of the inclusion features of α-cyclodextrin (A) and methyl-α-CDx (B) complexes. Water molecules are denoted by W.

included upside down. As shown in Fig. 7, the nitrophenyl group is tightly bound in the α-cyclodextrin cavity, while the hydroxyl group protrudes from the O(2), O(3) hydroxyl side of the cavity, forming hydrogen bonds with adjacent α-cyclodextrin molecules. Such a change in the inclusion geometry may be ascribed to the difference in the shape and size of the host cavity. The α-cyclodextrin cavity is quite suitable to accomodate the nitrophenyl group. The methylation enlarges the O(2), O(3) side of the cavity, but the large inclination of 2,3,6-tri-*O*-methylglucose residues makes the O(6) side of the cavity so narrow that the nitrophenyl group can not be deeply inserted. In this case, the choice of the substitutent group to be included seems to depend upon the steric hindrance. A similar upside-down inclusion has also been observed in the benzaldehyde complex[7] (Fig. 7). In that case, the inclusion of the whole molecule may be more suitable to fulfill the methyl-α-CDx cavity than the inclusion of the phenyl group only. Unlike these two methyl-α-CDx complexes, the *p*-iodoaniline molecule is included in the same orientation in α-cyclodextrin and methyl-α-CDx rings, although the iodophenyl group slides to the O(2), O(3) side in the methyl-α-CDx ring. The inclusion of either the iodophenyl group or the aminophenyl group is sterically possible, but the iodophenyl group may be more suitably accomodated because of the stronger van der Waals interaction. The water molecule in the *p*-nitrophenol complex, which is located on the O(6) side of the cavity, links the *p*-nitrophenol molecule to the host methyl-α-CDx molecule through the hydrogen bonds (Fig. 6), O(1,NP)–H···O(W), O(W)–H···O(6,G2), and O(W)–H···O(6,G4). These hydrogen

bonds may play an important role to fix the guest molecule inside the cavity, as the benzene ring is in loose contact with methyl-α-CDx.

Molecular Packing. Projections of the crystal structure are shown in Figs. 8 and 9. The crystal is composed of endless columns formed by the stack of

methyl-α-CDx along the a axis. The normal of the methyl-α-CDx ring plane inclines at 10.3° with respect to the column axis. A similar packing of methyl-α-CDx is also found in the complexes with *p*-iodoaniline[6] and benzaldehyde.[7] But, as shown in Fig. 10, there are significant differences in the packing mode among these complexes. In the *p*-iodoaniline complex, the methyl-α-CDx ring is almost perpendicular to the a axis, so that the straight channel runs through methyl-α-CDx rings. On the other hand, the normal of the methyl-α-CDx ring plane in the benzaldehyde complex inclines at 17.0° with the column axis. Since the adjacent methyl-α-CDx rings along the column axis are laterally shifted within their molecular plane, the channel runs not straight but zigzag along the axis. The methyl-α-CDx ring in the *p*-nitrophenol complex also inclines, but the angle of inclination is smaller than that of the benzaldehyde complex. The channel runs almost straight through the methyl-α-CDx rings, and the guest molecules are linearly arranged in the channel. The rings planes of the methyl-α-CDx molecules related by the two-fold screw axis make an angle of 20° with each other. This is the most significant difference in the molecular packing between the *p*-nitropenol complex and the complexes with *p*-iodoaniline and benzaldehyde (Fig. 10).

An Aspect of Driving Force of the Complex Formation. The binding force of cyclodextrin complexes has been discussed on structural,[10] spectroscopic,[11–15] thermodynamic,[16] and theoretical[1,17] bases, and several interactions and forces have been proposed to explain the inclusion phenomena. Saenger and his co-workers[10] have suggested in their model to explain the inclusion mechanism that the intramolecular hydrogen bonds between O(2)H and O(3)H hydroxyl groups play an important role in the complex formation. The methyl-α-CDx complexes, however, indicate that such hydrogen bonds are not necessarily required to form the inclusion complex. Since the macrocyclic conformation of methyl-α-CDx is relatively restricted by the steric hindrance involving the $C(8)H_3$ methyl groups, the participation of the conformational change may be small, although the conformation of the uncomplexed methyl-α-CDx has not yet been defined. The inclusion geometry of methyl-α-CDx complexes indicates that the selection of groups to be included is made mainly by van der Waals interaction and repulsive interaction. Therefore, van der Waals force may significantly participate in the complex formation. Since the thermodynamic data of methyl-α-CDx complexes have not been published, it is difficult to estimate the degree of contribution of hydrophobic interaction to the complex formation in aqueous solution. But, it is possible to speculate the importance of the hydrophobic interaction from the structures of methyl-α-CDx complexes. Both ends of α-cyclodextrin cavity are rimmed with hydroxyl groups which form hydrophilic environment around the cavity The methylation not only enlarges the hydrophobic cavity of the host molecule but also makes the environment around the cavity highly hydrophobic. Therefore, compared with α-cyclodextrin, the contribution of hydrophobic interaction can be expected to be enhanced.

(Received June 28, 1982)

A dispersive-type in-laboratory EXAFS spectrometer was constructed by combining a transmission-type dispersing crystal and a position-sensitive proportional counter. FeK absorption spectra were measured by use of this apparatus on $FeCl_3 \cdot 6H_2O$, $Fe(ClO_4)_3 \cdot 6H_2O$ and anhydrous $FeCl_3$. Discussion is given on the results obtained from the analyses of observed EXAFS data concerning the structure around Fe ions in these compounds. AsI_3-like structure is proposed for anhydrous $FeCl_3$.

Extended X-ray absorption fine structure (EXAFS) spectroscopy has rapidly grown up to the most important method to study the local structure around an X-ray absorbing atom in solids and liquids since its usefulness as a structural tool was first demonstrated by Stern *et al.*[1-5]

This rapid development of EXAFS spectroscopy also comes from the utilization of synchrotron radiation. Because usually EXAFS oscillation is only a few percent or less of absorption coefficient, we need to measured absorption coefficient of a sample with a high accuracy as a function of X-ray wavelength over the concerned spectral region. It takes a very long measuring time to obtain reliable EXAFS data if we use a conventional X-ray spectrometer composed of an ordinary X-ray source and a crystal monochromator. The time required to obtain EXAFS data has been drastically shortened by use of synchrotron radiation. This has opened wide new fields of application of EXAFS spectroscopy.

Although the use of synchrotron radiation is evidently of great value in EXAFS spectroscopy, the use of a synchrotron radiation facility inevitably has various restrictions concerned with place and time. For some type of applications, there are large advantages of having an in-laboratory EXAFS spectrometer if it can provide EXAFS data of satisfactory quality with a tolerable measuring time. Even if one is considering to use a synchrotron radiation facility to obtain accurate EXAFS data, it may be of great value to carry out preliminary experiments with an in-laboratory apparatus.

One approach to reduce the data acquisition time of an in-laboratory EXAFS spectrometer is naturally to increase X-ray intensity as high as possible by employing a very-high-power X-ray generator[6] and/or a bent-crystal monochromator.[7,8] In fact, it was reported by Cohen *et al.*[9] that the time required to obtain EXAFS data could be markedly reduced by combining a bent-crystal monochromator with a high-power rotating anode X-ray generator.

Another approach is to improve the data collection efficiency by simultaneously measuring the intensities of X-rays over the concerned spectral region by use of a system composed of a dispersing crystal and a position-sensitive detector.[10,11] We constructed an EXAFS spectrometer by use of transmission-type dispersing method which has been developed by Kaminaga *et al.*,[10] and studied FeK EXAFS of $FeCl_3 \cdot 6H_2O$, $Fe(ClO_4)_3 \cdot 6H_2O$, and anhydrous $FeCl_3$.

EXAFS Spectrometer

Figure 1 illustrates the principle of the EXAFS spectrometer constructed in the present study. When a divergent white X-ray beam hits the surface of a thin single crystal, X-ray incident direction is different at different positions of the crystal surface, hence the X-ray wavelength which satisfies the diffraction condition, is different at different positions. It may be easily understood from a geometrical consideration that X-rays of different wavelengths which have been diffracted at different positions, will be focused at the position (SP in Fig. 1) which is symmetrical to the X-ray source (X) with respect to the diffracting crystal, and then diverge. Thus the diffracting crystal works as a transmission type X-ray polychromator. With this optical system, X-ray intensities over the interested spectral region can be simultaneously measured by placing a position-sensitive detector at some distance after the focusing position. An absorption Spectrum can be obtained by performing intensity measurements with and without a sample in the X-ray path. Most conveniently a sample is placed at the focusing position, since the sample area in X-ray path, hence the required sample amount will be minimized and, at the same time, the troubles concerned with the ununiformity of the sample can be largely avoided.

We used a molybdenum sealed X-ray tube (Philips

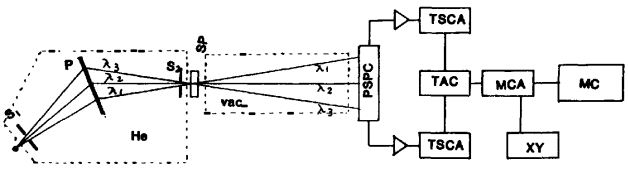

Fig. 1. Block diagram of EXAFS spectrometer.

fine focus tube or Toshiba normal focus tube) as the X-ray source, which was operated with a conventional X-ray power supply (Rigaku D-2F, 1 kW) mostly with 25 mA at 20 kVp. A silicon single crystal of 50 μm thick was used as the dispersing crystal, Si(111) plane having been chosen as the diffraction plane so that the (222) harmonics could be eliminated. Both the distance from X-ray source to silicon crystal and that from the crystal to sample were 250 mm, and the distance from sample to detector was mostly set as 600 mm. In order to minimize X-ray intensity loss, the X-ray path between source and sample was replaced with helium gas, and that between sample and detector was evacuated with a mechanical vacuum pump. By this way, available X-ray flux became 2.5 times of that obtainable when all X-ray path is in the ordinary atmosphere.

We used a multi-cathode position-sensitive proportional counter (PSPC) of delay line readout type as the detector. For the gas filled in PSPC, we used either PR gas (Ar 90%, $CH_3$10%) or Xe-CH_4 mixture (Xe 90%, CH_4 10%), pressurized to about 3 kg cm^{-2}. The block diagram of the electronic system is also shown in Fig. 1. The information about the incident position of an X-ray photon is taken out as the signal pulse height, which is digitized through an ADC (NAIG E-551) to determine the address in a process memory (NAIG E-562) at which the count is to be stored. After count data have been sufficiently accumulated, the data are transfered to a microcomputer (NEC PC-8001), with which initial data treatments are carried out.

By examining the X-ray spectrum recorded on a photographic film placed at the position of the detector, the spectral resolution of our optical system was confirmed to be about 4 eV around the FeK absorption edge, but the overall resolution of obtained EXAFS data was about 7 eV or a little more, because of the positional resolution of our detection system. Although we used a conventional sealed X-ray tube operated at a low power, we were able to obtain EXAFS data within a torelable measuring time. For example, the FeK absorption spectrum (shown in Fig. 2) of an iron foil of 4 μm thick was obtained with a measuring time of about 4 h with a fine-focus Mo X-ray tube operated with 25 mA at 20 kVp, taking 10^5 counts at each measured energy point, the number of measured points being 250 over the observed spectral region, 6.7—8.3 keV.

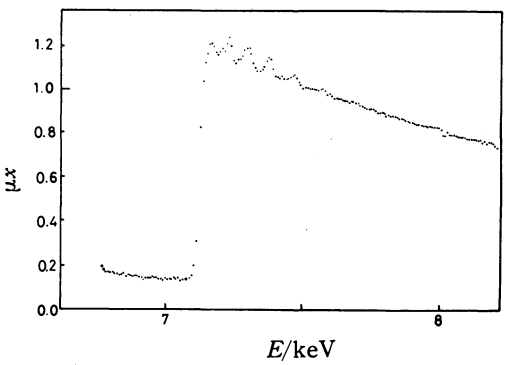

Fig. 2. X-Ray absorption spectrum of Fe foil of 4 μm thick. The data acquisition time was 3 h 45 min.

EXAFS of Some Fe(III) Compounds

By use of the apparatus described in the preceeding section, we obtained EXAFS data on $FeCl_3 \cdot 6H_2O$, $Fe(ClO_4)_3 \cdot 6H_2O$, and anhydrous $FeCl_3$. In the cases of $FeCl_3 \cdot 6H_2O$ and $Fe(ClO_4)_3 \cdot 6H_2O$, crystalline powder was mixed with well-dried Nujol to be used as the sample for EXAFS measurement, and FeK absorption spectra were measured by keeping such a mixture between two polyethylene plates separated with a PTFE spacer of an appropriate thickness. A special care had to be taken for the deliquescence in the case of anhydrous $FeCl_3$. We prepared anhydrous $FeCl_3$ powder in a glove box filled with dry nitrogen, and carried out X-ray absorption measurement on a compaction of the powder kept in a dry nitrogen atmosphere. The measurement of FeK absorption spectrum was repeated two or three times on each sample to check the reproducibility.

Figure 3 shows the FeK absorption spectra of the three compounds. Note that the first peak near FeK absorption edge is very weak in the case of anhydrous $FeCl_3$ as compared with $FeCl_3 \cdot 6H_2O$ and $Fe(ClO_4)_3 \cdot 6H_2O$. This difference is likely to be associated with the difference in the number of the H_2O molecules coordinated around Fe ion. Another aspect that can be seen clearly from the comparison of the three spectra, is the difference of the position of third peak.

We extracted EXAFS oscillations from the observed spectra and analyzed them to derive structural information. The analysis was performed by use of the computer program system written by Sato in our laboratory.[12] The program system consists of the programs for background subtraction, extraction of EXAFS oscillation $\chi(k)$, Fourier transformation of $k^n\chi(k)$, Fourier filtering and back transofrmation, and curve-fitting analysis. In the curve-fitting analysis, we assumed the following formula for $\chi(k)$.

$$\chi(k) = C_0 \sum_i N_i k^{-1} r_j^{-2} F_i(k) \times \exp(-2\sigma_i^2 k^2) \cdot \sin[2kr_i + \phi_i(k)] \quad (1)$$

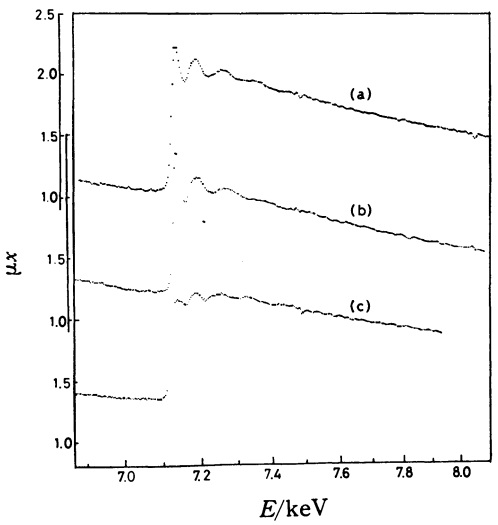

Fig. 3. X-Ray absorption spectra of (a) $FeCl_3$–$6H_2O$, (b) $Fe(ClO_4)_3$–$6H_2O$, and (c) Anhydrous $FeCl_3$.

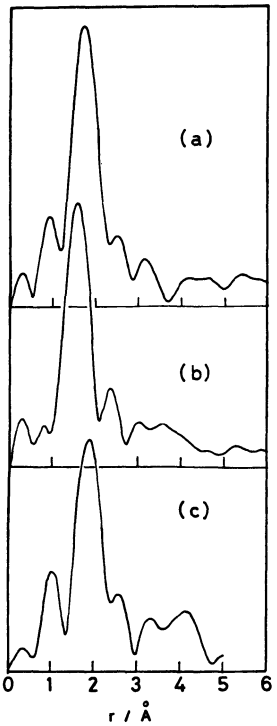

Fig. 4. Fourier transforms of $k^3\chi(k)$ for (a) $FeCl_3 \cdot 6H_2O$, (b) $Fe(ClO_4)_3 \cdot 6H_2O$, and (c) anhydrous $FeCl_3$.

where N_i and r_i are the number and distance of atom(i), $F_i(k)$ and $\phi_i(k)$ are back-scattering amplitude and phase shift, σ_i is Debye-Waller factor, and C_0 is a normalizing constant. In the present study, we used theoretical $F_i(k)$[13] and $\phi_i(k)$,[14] and treated C_0, r_0, and σ_i as adjustable parameters, an appropriate assumption being done on N^i value. We introduced the following R index as the measure of the agreement between experimental and calculated $k^n\chi(k)$.

$$R(k^n\chi) = \sqrt{\frac{\sum_j [k^n\chi_{expt}(\chi_j) - k^n\chi_{calcd}(k_j)]^2}{\sum_j [k^n\chi_{expt}(k_j)^2]}}$$

All calculations were performed by use of a HITAC M-200H at the Computer Center of The University of Tokyo.

The results of Fourier transformation of $k^3\chi(k)$ are shown in Fig. 4. A prominent peak is found around 2 Å for all three compounds studied here. This peak corresponds to the first back-scattering shell around Fe ion, its position being a little different for the three salts reflecting the difference of the local structure around Fe ion. Fe ion is likely to be surrounded by six oxygen atoms of coordinating H_2O molecules in $Fe(ClO_4)_3 \cdot 6H_2O$, while it is surrounded by six chlorine ions in anhydrous $FeCl_3$. In $FeCl_3 \cdot 6H_2O$, Fe ion is known to be surrounded by two chlorine ions and four oxygen atoms of coordinating H_2O molecules.[15] Thus it seems quite reasonable that the peak due to the first back-scattering shell is shift to larger distance in anhydrous $FeCl_3$ in comparison with other two compounds.

Back-Fourier transforming the region of the above-mentioned peak, we carried out curve-fitting analysis. The results are summarized in Table 1, the experimental and calculated $k^3\chi(k)$ curves being shown in Figs. 5

Table 1. Bond distances obtained by the analyses of EXAFS data of Fe(III) compounds

The coordination numbers assumed in the analyses are given in parentheses.

Sample		Bond	Bond length d/Å (EXAFS	diffraction)
$FeCl_3 \cdot 6H_2O$		Fe–Cl(2)	2.28	2.30[a]
		Fe–O(4)	2.03	2.07[a]
$Fe(ClO_4)_3 \cdot 6H_2O$		Fe–O(6)	2.00	—
$(Fe(NO_3)_3 \cdot 9H_2O$		Fe–O	—	1.99[b]
$FeCl_3$	(Model 1)[d]	Fe–Cl(6)	2.25	2.48[c]
	(Model 2)[e]	Fe–Cl(3)	2.24	
		Fe–Cl(3)	2.59

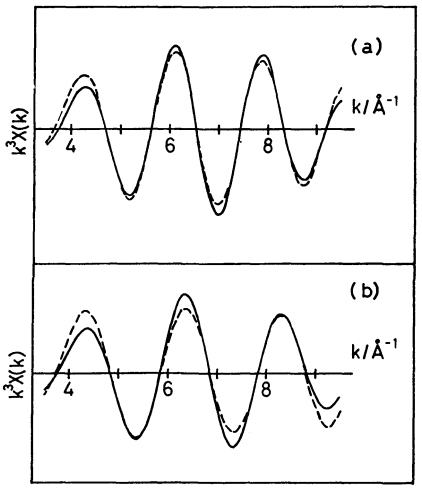

Fig. 5. Curve-fitting results of (a) $FeCl_3 \cdot 6H_2O$ and (b) $Fe(ClO_4)_3 \cdot 6H_2O$ (——: experimental, ------: theoretical).

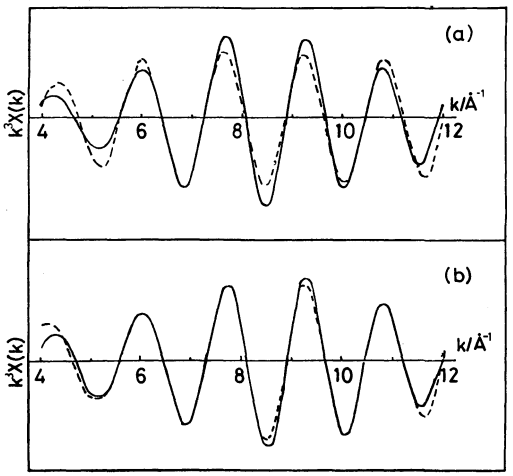

Fig. 6. Curve-fitting results of anhydrous $FeCl_3$: (a) one-shell fitting and (b) two-shell fitting (——: experimental, ------: theoretical).

and 6.

The crystal structure is known for $FeCl_3 \cdot 6H_2O$, according to which Fe ion is surrounded by two chlorine ions with the Fe–Cl distance of 2.30 ± 0.02 Å and four oxygen atoms of H_2O with the Fe–O distance of 2.07 ± 0.02 Å.[15] We performed curve-fitting analysis assuming two back-scattering shells, the one corresponding to four oxygen atoms and the other corresponding two chlorine ions. The best-fit result gave 2.03 ± 0.02 Å for Fe–O and 2.28 ± 0.04 Å for Fe–Cl. These values are in good agreement with the distances known from the crystal structure analysis. This indicates the reliability of our EXAFS data and that of the analysis.

In the case of $Fe(ClO_4)_3 \cdot 6H_2O$, the crystal structure is not known, but there is a good reason to believe that six H_2O molecules are coordinating to Fe ion as in the crystal of $[Fe(H_2O)_6](NO_3)_3 \cdot 3H_2O$.[16] Our EXAFS data are consistent with this assumption. The curve-fitting analysis gave 2.00 ± 0.02 Å for Fe–O distance, which coincides well with 1.986 ± 0.017 Å found by the crystal structure analysis of $[Fe(H_2O)_6] \cdot (NO_3)_3 \cdot 3H_2O$ for the average Fe–O distance between Fe ion and octahedrally coordinating H_2O molecules.[16]

Anhydrous $FeCl_3$ has been considered to have bismuth iodide structure, namely an iron ion is assumed to be surrounded by six chlorine ions with equivalent Fe–Cl distance.[17] Using this model, Fe–Cl distance in anhydrous $FeCl_3$ was deduced to be 2.48 Å from the observed lattice parameters.[17b] From the curve-fitting analysis of EXAFS data, we obtained 2.25 ± 0.05 Å for Fe–Cl distance under the assumption that Fe ion is surrounded by six equivalent chlorine ions. This value is 0.23 Å shorter than the interatomic distance estimated from the lattice parameters. The discrepancy between the two values seems to be too large to be ignored when we consider the fact that the interatomic distances determined from EXAFS data coincide well with those from diffraction data in the cases of other two compounds. If Fe ion is actually surrounded by six equivalent chlorine ions with the Fe–Cl distance of 2.25 Å, the spacing between the two chlorine layers which are sandwiching Fe ions will be 1.98 Å and that between the other pair of chlorine layers will be 3.84 Å. The former value seems to be too small while the latter seems to be too large in comparison with the ionic radius of chlorine ion.

It is worthwhile to note that, although AsI_3 and SbI_3 were previously believed to have bismuth iodide structure,[17a] the detailed crystal structure analyses revealed latter that these compounds were built up from discrete triiodide molecules such as AsI_3 (or SbI_3), consequently six iodine atoms surrounding As (or Sb) atom are not at equivalent distance, three being at a shorter distance and three others at a longer distance.[18,19] Thus we analyzed the EXAFS data of anhydrous $FeCl_3$ with two-shell model assuming AsI_3-like structure. The curve-fitting analysis gave 2.24 ± 0.05 Å and 2.59 ± 0.05 Å for the two Fe–Cl distances with an excellent agreement between the experimental and calculated $k^3\chi(k)$ (Fig. 6b); the R index was found to be only 0.155 while it was 0.274 in the analysis with one-shell model (Fig. 6a). Therefore it is most likely that anhydrous $FeCl_3$ has AsI_3-like structure.

Summary

We constructed an in-laboratory EXAF Sspectometer combining a transmission-type dispersing crystal with a position-sensitive proportional counter, and demonstrated that EXAFS data of a sufficient quality for structural study could be obtained with a torelable measuring time. This EXAFS spectrometer is easily constructed with a relatively small cost, and might have wide applications.

By analyzing EXAFS data obtained on $FeCl_3 \cdot 6H_2O$, $Fe(ClO_4)_3 \cdot 6H_2O$ and anhydrous $FeCl_3$ by use of the constructed in-laboratory apparatus, we studied the local structures around Fe ions, and showed that anhydrous $FeCl_3$ has AsI_3-like structure, having three chlorine atoms at a shorter Fe–Cl distance and other three chlorine atoms at a longer Fe–Cl distance.

The authors would like to express their thanks to Dr. H. Hashizume and Dr. K. Mase for their kind advise for the construction of PSPC.

(Received July 15, 1982)

Photoelectron spectra of isoxazole, 5-methylisoxazole, and 3,5-dimethylisoxazole were studied by the technique of photoelectron angular distribution measurements combined with a first order perturbation theoretic approach. Photoelectron spectra of oxazole, 4-methyloxazole, furan, and 2-methylfuran, which are closely related to isoxazole, were also discussed at the same time for the sake of comparison. The first three bands of the isoxazoles were assigned to the π, π, and n bands from the top, respectively, while those of the oxazoles were identified as the π, n, and π bands from the top.

Isoxazole is one of the typical five-membered heteroaromatics with two heteroatoms and important from the pharmacological standpoint also. In this paper photoelectron spectra of isoxazole, 5-methylisoxazole, and 3,5-dimethylisoxazole are studied by the technique of photoelectron angular distribution measurements combined with a perturbation theoretic approach. Photoelectron spectra of oxazole, 4-methyloxazole, furan, and 2-methylfuran, which are closely related to isoxazole, are also discussed at the same time for the sake of comparison.

Baker *et al.*[1] and Palmer *et al.*[2] reported the photoelectron spectrum of isoxazole formerly and considered that the first band is a π band and that the second band group is composed of a π band and an n (nonbonding) one highly overlapping with each other. But the relative ordering of the π and n bands in the second band group is not yet established. In this paper we focus our attention especially on this complicated second band group region of isoxazole and try to establish the assignments of the lower energy photoelectron spectral bands of the isoxazoles.

Formerly an empirically parameterized method based on the first order perturbation theory was developed for photoelectron spectral band assignments and applied to azaaromatics.[3] With this technique one can easily distinguish π bands from n or σ bands by regarding azareplacements, for example, as perturbations. The same technique is applicable to the case of alkyl substitutions also.[4] In this paper at first this type of approach will be used.

Concerning photoelectron angular distributions, differential cross section (σ_Q) for photoelectron ejection is given by the following expression[5,6] for the case of an unpolarized light and an ensemble of randomly oriented molecules:

$$\sigma_Q \propto \{1+(1/4)\beta(3\sin^2\theta-2)\}, \quad (1)$$

where β is an asymmetry parameter and θ is the angle between the propagation direction of an ejected photoelectron and that of an incoming photon. The β value depends not only on the kinetic energy of the photoelectron but also on the character of the MO from which the photoelectron is ejected. Therefore, the β values can be used for photoelectron spectral band assignments as exemplified in the case of benzene,[7] pyridine,[8] aliphatic alcohols, amines, and halides.[9] In this paper the combination of the photoelectron angular distribution experiments with the perturbation theoretic approach will be demonstrated to be very powerful in solving photoelectron spectral band assignment problems.

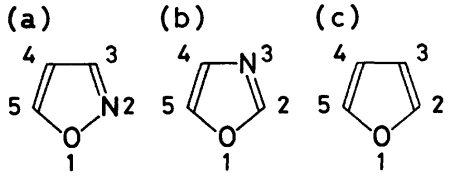

Fig. 1. Structural formulae of isoxazole (a), oxazole (b), and furan (c) with numberings of atoms.

Experimental

Materials. Pure samples of isoxazole, 5-methylisoxazole, 3,5-dimethylisoxazole, and 4-methyloxazole were kindly supplied by Dr. T. Honma of Shionogi Research Laboratories. Commercially available furan and 2-methylfuran were used without furthur purifications. Commercially available isoxazole, 5-methylisoxazole, and 3,5-dimethylisoxazole were also used without furthur purifications for the photoelectron angular distribution experiments.

Measurements. The vapor phase HeI photoelectron spectra of these compounds were measured at first using the photoelectron spectrometer described formerly.[10] Xe gas was used as the internal reference standard compound for the energy scale calibrations. The HeI photoelectron angular distributions of isoxazole, 5-methylisoxazole, 3,5-dimethylisoxazole, furan, and 2-methylfuran in the vapor phases were measured using the instrument described formerly,[7] the vapor pressures of the samples being kept at 4×10^{-4} Torr (1 Torr= 133.322 Pa). The β values were obtained according to formula (1) using the photoelectron spectral intensities measured at two angles, $\theta=45°$ and 90°.

Computational

The CNDO/S[11] calculations of furan, oxazole, and isoxazole were carried out by the FACOM 230-75

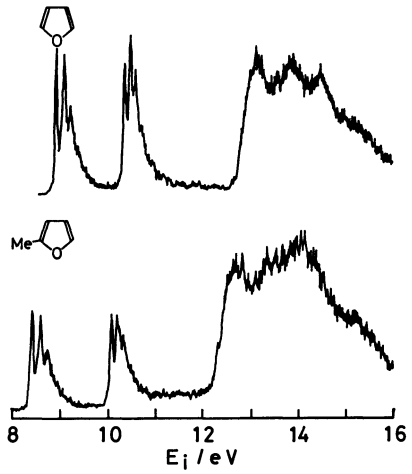

Fig. 2. Vapor phase HeI photoelectron spectra of furan and 2-methylfuran.

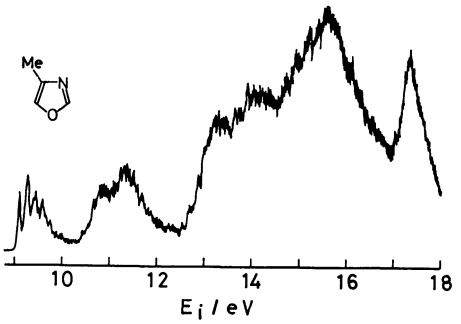

Fig. 3. Vapor phase HeI photoelectron spectrum of 4-methyloxazole.

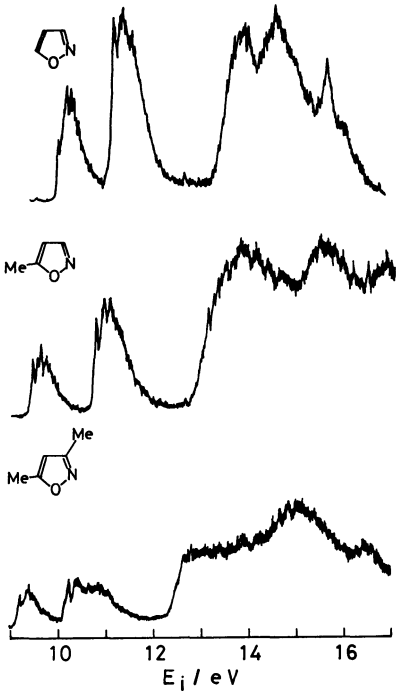

Fig. 4. Vapor phase HeI photoelectron spectra of isoxazole, 5-methylisoxazole, and 3,5-dimethylisoxazole.

computer at the Institute of Physical and Chemical Research. The geometrical structural parameters of furan and isoxazole were taken from Refs. 12 and 13, respectively, and those of oxazole were assumed to be similar to those of furan.

Results and Discussion

The HeI photoelectron spectra of furan, 2-methylfuran, 4-methyloxazole, isoxazole, 5-methylisoxazole, and 3,5-dimethylisoxazole are shown in Figs. 2, 3, and 4. Of these compounds the ultraviolet photoelectron spectrum of furan was reported by various authors[1,14-20] formerly, and that of isoxazole by Baker *et al.*[1] and by Palmer *et al.*[2] also. Their spectra are consistent with ours. The vertical ionization energy (E_{iv}) values of those compounds are summarized in Table 1 for the region of interest with those of oxazole.[2]

Perturbation Theoretic Approach. At first let us try to make assignments of the lower energy photoelectron spectral bands of isoxazole and its methyl derivatives from the perturbation theoretic standpoint.

According to the first order perturbation theory, E_{iv} changes (ΔE_{iv}'s) of π bands caused by substitutions (replacements) can be estimated by using the following formula:[3]

$$-\Delta E_{ivj} = a + b\sum_{\mu,\nu}(C_{\mu j}^2 + m C_{\nu j}^2), \qquad (2)$$

where j denotes the j-th MO corresponding to a certain photoelectron spectral band in question, a is a constant introduced for statistical treatments, b is also a constant and corresponds to the HMO level one-centre Coulomb integral change of a certain atom caused by a certain substitution (replacement) at this atom, $C_{\alpha j}$ is the AO coefficient of atom α in the j-th MO, μ denotes atom μ at which a certain substitution (replacement) is introduced, ν denotes atom ν just adjacent to atom μ, and m is a kind of damping factor.

The a, b, and m values for formula (2) were taken from Ref. 3 for aza-replacements and from Ref. 21 for methyl substitutions. The $C_{\alpha j}$ values used are those obtained by the CNDO/S[11] calculations for furan, oxazole, and isoxazole. The E_{iv} values of the five-membered ring compounds estimated by this perturbation theoretic approach regarding aza-replacements or methyl substitutions as perturbations are summarized in Table 1. The reference standard compounds in this table denote the compounds, the E_{iv}'s of which are used to estimate the E_{iv}'s of the compounds in question by being corrected for the ΔE_{iv} values calculated by formula (2) with the $C_{\alpha j}$ values of those compounds.

At first in order to check the validity of the method used here, let us examine the apparent case of furan and 2-methylfuran. As is seen in Fig. 2 the first two bands of furan are rather vertical and well separated from the following bands. These bands have already been unambiguously assigned to the $a_2\pi$ and $b_1\pi$ bands from the top, respectively.[1,14-20] By introducing 2-methyl group into furan, the first two bands are slightly shifted to the lower ionization energy (E_i) side, but their band shapes remain still rather vertical indifferent to this substitution and these bands are well separated from the following bands. It is quite natural to assign straightforwardly the first two bands of 2-methylfuran to the

Table 1. Observed vertical ionization energy (E_{iv}) values of isoxazoles and related compounds with Π ones calculated by perturbation theoretic approach

a) The root mean square error for the calculated π E_{iv}'s. b) The standard compound, the E_{iv}'s of which were used as the starting points to estimate the E_{iv}'s of the compound in question, by being corrected for the ΔE_{iv} values calculated by formula (2). c) This value is a possible candidate for the second E_{iv} of isoxazole, and 11.3 eV may be another one. d) Taken from Ref. 2.

a_2-like π and b_1-like π bands from the top, respectively. On the other hand, as is seen in Table 1, starting from the E_{iv} values of the first two bands of furan, the perturbation theoretic calculations reproduce well the observed E_{iv} values for the first two bands of 2-methylfuran, strongly supporting the above qualitative assignments.

Now let us examine the next rather slightly more complicated case of oxazole and 4-methyloxazole. As is seen in Fig. 1 of Ref. 2 and Fig. 3 both these compounds show three bands in the energy region from 9 eV to 12.5 eV separated from the following bands. In this energy region two π bands corresponding to the first two bands of furan and one n band mainly related to the nitrogen atom n orbital are expected to appear from the analogy to the case of furan and pyridine.[8,22] Concerning oxazole Palmer *et al.*[2] assigned the first and third bands to the π bands and the second band to the n band on the basis of an *ab initio* calculation and band shape considerations. Their assignment seems to be probable, because the second band is nonvertical, that is, rather broad just as in the case of the n bands of pyridine and other azaaromatics,[3,4,8,22] the first and the third bands being rather vertical as in the case of the first two π bands of the furans just we have seen above.

On the other hand, by the perturbation theoretic calculations using furan as the reference standard compound, as is seen in Table 1, the first and third bands of oxazole can be unambiguously assigned to the π bands corresponding to the first and second bands of furan, respectively, and the remaining second band is ascribed to the n band. Thus, Palmer and coworkers' assignments[2] have now been definitely substantiated.

By comparing the band shapes and the E_{iv} values of the first three bands of 4-methyloxazole with those of oxazole we may qualitatively assign the first and third bands to the π bands and the second to the n band in the case of 4-methyloxazole also. On the other hand, starting from either furan or oxazole as the reference standard compound, in the case of 4-methyloxazole also, the first three bands can be definitely assigned to the π, n, and π bands from the top, respectively, by the first order perturbation theoretic approach, supporting the above qualitative consideration. Thus, the orderings of the first three bands of the oxazoles have now been firmly established to be π, n, and π from the top.

As we have seen in the above examples, the perturbation theoretic approach seems to be very powerful to establish band assignments. Now let us move to the complicated case of the isoxazoles in question. These compounds show three photoelectron spectral band groups in the energy region from 9 eV to 12 eV. And in this energy region three bands, two of which are π bands and one of which is an n band, are expected to appear just as in the case of the oxazoles. From the relative intensity ratio of the first and second band groups of isoxazole and 5-methylisoxazole the second band groups of these compounds are naturally regarded to be composed of two bands. In the case of isoxazole Baker *et al.*[1] and Palmer *et al.*[2] formerly regarded the first band as a π band and the second band group to be composed of a π band and an n band overlapping with each other highly.

In the case of 3,5-dimethylisoxazole the first band is rather vertical and the second and third bands can be recognized separately, the second band being rather vertical with the first strong sharp peak, while the third band seems to be rather broad. From the band shape considerations we may assign the first and second bands to the π bands and the remaining third band to the n

band in this case. On the other hand, according to the first order perturbation theoretic calculations using furan as the reference standard compound, the first two bands of 3,5-dimethylisoxazole can be definitely assigned to the π bands corresponding to the first two π bands of furan from the top, respectively, and the remaining third band is ascribed to the n band as is seen in Table 1, the above qualitative considerations being strongly supported.

The vertical features of the first band and the lower energy part of the second band group can be recognized in the case of either isoxazole or 5-methylisoxazole also, and it is quite reasonable to correlate the first band and the lower energy part of the second band group of either isoxazole or 5-methylisoxazole with the first two π bands of 3,5-dimethylisoxazole from the top, respectively. The higher energy part of the second band group of either isoxazole or 5-methylisoxazole is now ascribed to the n band.

On the other hand, according to the first order perturbation theoretic approach the first band of isoxazole is definitely assigned to the π band corresponding to the first band of furan and the lower energy part rather than the higher energy part of the second band group is suggested to be assigned to the second π band, if we start from the E_{iv} values of furan. This is consistent with the qualitative conclusion described above.

In the case of 5-methylisoxazole, based on the perturbation theoretic calculations, the first band and the lower energy part and higher energy part of the second band group can be assigned to the π, π, and n bands from the top, respectively, by starting from either furan or 2-methylfuran. The same assignments can be obtained by starting from the E_{iv} values of isoxazole on the assumption that the assignments in the case of isoxazole given above are correct. This fact supports the validity of the band assignments for the first three bands of isoxazole given above.

According to the first order perturbation theoretic calculations starting from either isoxazole or 5-methylisoxazole on the assumption of the validity of the band assignments given above, we can get the same band ordering for the first three bands of 3,5-dimethylisoxazole as obtained above. This fact also supports the validity of the band assignments of isoxazole and 5-methylisoxazole given above.

Thus, from the first order perturbation theoretic standpoint supported by the qualitative discussions the band orderings of the first three bands of the isoxazoles are π, π, and n from the top, while those of the oxazoles are π, n, and π from the top.

Photoelectron Angular Distributions. In order to establish the assignments of the second and third bands of the isoxazoles more firmly, the photoelectron angular distributions of isoxazole, 5-methylisoxazole, 3,5-dimethylisoxazole, furan, and 2-methylfuran were measured. The β values (see formula (1)) for these compounds are plotted in Figs. 5 and 6 with the photoelectron spectra measured at the magic angle, $\theta=54.7°$. The β values of these compounds for several E_{iv} values are summarized in Table 2. Sell and Kuppermann[19] measured the HeI photoelectron angular distributions of furan, their results being almost consistent with ours.

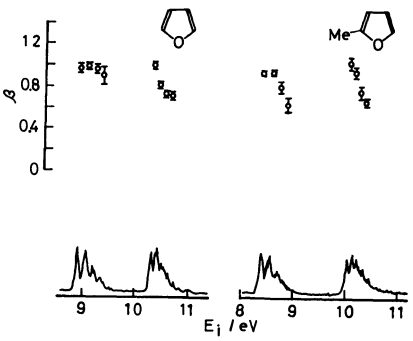

Fig. 5. HeI photoelectron angular distribution asymmetry parameter (β) values plotted with photoelectron spectra measured at $\theta=54.7°$ for furan and 2-methylfuran.

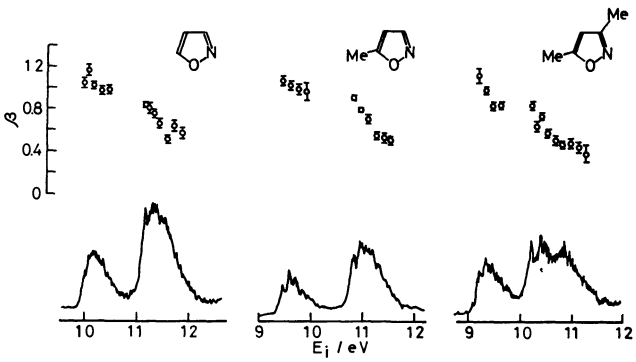

Fig. 6. HeI photoelectron angular distribution asymmetry parameter (β) values plotted with photoelectron spectra measured at $\theta=54.7°$ for isoxazole, 5-methylisoxazole, and 3,5-dimethylisoxazole.

TABLE 2. PHOTOELECTRON ANGULAR DISTRIBUTION ASYMMETRY PARAMETER (β) VALUES OF ISOXAZOLES AND FURANS AT SOME KEY POINTS WITH IONIZATION ENERGY (E_i) VALUES INDICATED

Compound	E_i/eV	β[a]
Isoxazole	10.15	1.02±0.03
	11.15	0.84±0.02
	11.31	0.75±0.04
	11.57	0.51±0.04
5-Methylisoxazole	9.61	1.02±0.04
	10.79	0.90±0.02
	10.95	0.78±0.02
	11.17	0.54±0.04
3,5-Dimethylisoxazole	9.34	0.98±0.04
	10.20	0.84±0.04
	10.35	0.73±0.04
	10.81	0.47±0.03
Furan	8.89	0.97±0.04
	10.44	0.82±0.03
2-Methylfuran	8.38	0.93±0.03
	10.15	0.94±0.05

a) The root mean square errors are given.

At first let us examine the results for furan and 2-

methylfuran, the assignments of the first two bands of which are definitely the a_2(-like) π and b_1(-like) π from the top, respectively. As is seen in Fig. 5 in the case of furan and 2-methylfuran the first two π bands show large β values from 0.8 to 1 at the band maxima indifferent to the symmetries of the corresponding MOs. Keeping this point in mind let us move to the case of the isoxazoles in question.

In the case of 3,5-dimethylisoxazole, the first three bands can be well recognized separately, and the first two bands show relatively high β values from 0.7 to 1 at their band maxima, while the third band shows relatively low β value, 0.47, at the band maximum. Remembering the fact that isoxazole and furan are iso-π-electronic with each other, the first and second bands of 3,5-dimethylisoxazole may be assigned to the π bands by comparing the β values of the first three bands of this compound with those of the first two π bands of furan, the remaining third band of 3,5-dimethylisoxazole with low β value being ascribed to the n band. These assignments may be further supported by the fact that the n band of pyridine iso-π-electronic with isoxazole shows low β value around 0.2, the following two π bands showing relatively high β values.[8] Combining this result with the perturbation theoretic discussions given above, the first three bands of 3,5-dimethylisoxazole are now definitely assigned to the π, π, and n bands from the top, respectively.

Moving to the case of isoxazole and 5-methylisoxazole, the first bands of these compounds show high β values around 1.0 at the band maxima, and by comparing these values with those of the lower energy π bands of 3,5-dimethylisoxazole and the furans, it is definite that the first bands of isoxazole and 5-methylisoxazole are the π bands as assigned by the first order perturbation theoretic discussions given above. The lower energy parts of the second band groups of isoxazole and 5-methylisoxazole show high β values comparable to those of the lower energy part of the second band of 3,5-dimethylisoxazole, and the higher energy parts of the second band groups of isoxazole and 5-methylisoxazole show low β values just as the third band of 3,5-dimethylisoxazole which is definitely the n band as discussed above. From these facts we can definitely assign the lower energy parts of the second band groups of isoxazole and 5-methylisoxazole to the π bands and the higher energy parts to the n bands. These assignments are consistent with those obtained by the first order perturbation theoretic considerations.

Summing up the discussions given above the orderings of the first three bands of the isoxazoles treated here have now been firmly established to be π, π, and n from the top, and those of the oxazoles π, n, and π from the top. Combination of the photoelectron angular distribution experiments with the perturbation theoretic approach has been demonstrated to be very powerful in the photoelectron spectral band assignments.

We express our sincere thanks to Dr. T. Honma of Shionogi Research Laboratories for the pure samples.

(Received September 7, 1982)

The chemical desalting technique was applied to the concentrated Steffen fluid using concd sulfuric acid and methanol. The chemical components of the isolated salt were studied by scanning electron microscopy, infrared spectroscopy, X-ray diffraction, and fluorescence analyses. The main constituent of the salt was determined to be $K_3Na(SO_4)_2$ and then synthesized.

One recovery technique of residual sugar from molasses is the Steffen method using calcium oxide. This treatment discharges waste fluid which is generally concentrated in order to avoid pollution of rivers and sea. General analytical data and the infrared spectra of the concentrated Steffen fluid are summarized and shown in Table 1 and Fig. 1.

How to isolate the components of the concentrated Steffen fluid for manufacturing the products is a matter of interest and importance to the beet sugar industry. This interest in the chemical components led us to isolate the inorganic components and determine their chemical constituents. This paper describes a chemical desalting technique of the concentrated Steffen fluid and the chemical components, and the chemical structure and syntheses of the main constituents of the salt isolated.

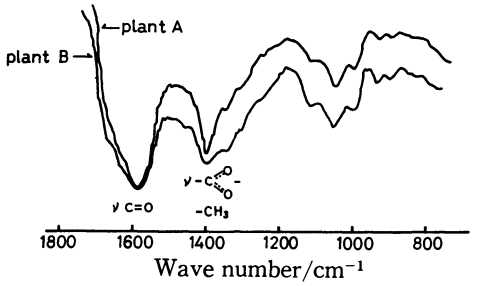

Fig. 1. Infrared spectra of concentrated Steffen fluids applied to KBr disk.

Table 1. General chemical components of concentrated steffen fluid (pH 9.0)

Solid matter	55%
Carbohydrates, total	13 (sucrose 12.4%)

Potassium	6.6
Calcium	0.01
Phosphorus as P_2O_5	0.01
Others	0.4

It is known that acidification of the concentrated Steffen fluid causes a desalting phenomenon.[1] This elementary knowledge was developed into the desalting process to be reported below. And also, the chemical structure of the main constituent of the isolated salt was determined as tripotassium sodium bis (sulfate) by the X-ray diffraction data and identified by the synthesis starting from the related known inorganic compounds. The by-components and the impurities were identified with the X-ray diffraction data and the fluorescent X-ray data.

Experimental

The IR spectra were determined on a Shimadzu IR-400 spectrometer. The X-ray diffraction and fluorescence analyses were performed on a Toshiba ADG-102 X-ray diffractometer and a AFV-202F X-ray fluorescence spectrometer.

General Procedure for Desalting Treatment of the Concentrated Steffen Fluid. A solution of the concentrated Steffen fluid in methanol, was acidified by addition of a suitable amounts of concd sulfuric acid till pH 4 or 3 of the solution was attained. After standing over night or on chilling, the salt which precipitated was filtered. The salt obtained was recrystallized from water for further purification as needed. Isolation of the salt can be efficiently carried out in *ca.* 20—24% yield for the concentrated Steffen fluid used, and the yield was almost quantitative.

Preparation of Potassium Sodium Sulfate. Procedure 1: Aqueous solution of 3 mol of KOH and 1 mol of NaOH was treated with concd sulfuric acid until pH 3 and the salt was deposited by addition of methanol.

Procedure 2: Aqueous solution of 3 mol K_2SO_4 and 1 mol of Na_2SO_4 was concentrated by rotary evaporator until deposition of the salt.

Procedure 3: The salt was deposited from aqueous solution of 3 mol K_2SO_4 and 1 mol Na_2SO_4 by addition of methanol.

Procedure 4: Aqueous solution of 3 mol of K_2SO_4 and 1 mol of Na_2SO_4 was controlled at pH 3 and then salt deposition treatment was carried out by addition of methanol. The results of preparations starting from potassium and sodium compounds are summarized in Table 4.

Results and Discussion

Effective desalting out treatment of concentrated Steffen fluid using concd sulfuric acid in methanol was carried out. Addition of concd sulfuric acid is for the

most efficient precipitation of sulfate salt; the addition of methanol makes a contribution to reduce the solubility of the inorganic salts. Incidentally, methanol alone added to concentrated Steffen fluid or reconcentrated Steffen fluid precipitates the salt in *ca.* 1.5% yield for concentrated Steffen fluid. Furthermore, addition of concd sulfuric acid until pH 4 or 3 of concentrated Steffen fluid or reconcentrated Steffen fluid in methanol solution makes for efficient precipitation of the salt, as shown in Table 2. The salt obtained by the above treatment was crystalline matter, shown in the scanning electron microscopic photographs in Fig. 3.

Infrared spectra of the salts precipitated by addition of methanol alone and by addition of concd sulfuric acid in methanol solution have the characteristic absorption in 1000—1200 cm^{-1} region, as shown in Fig. 2. The IR spectrum of the salts purified by recrystallization from pure water showed an adsorption at 1090 cm^{-1} alone, which suggests it to be a sulfate ion. The shoulder band on the IR spectrum of the crude salt

which appears at slightly higher wavelength (1170 cm^{-1}) should be attributed to the HSO_4^- ion which disappears from the spectrum of the purified salt. The X-ray diffraction data of the crude salt allowed us to the chemical structure of the salt to be $K_3Na(SO_4)_2$ as shown in Table 3; the presence of the compounds $K_2S_4O_6$ and $K_2S_3O_{10}$ were found as by-products in *ca.* 30—40%. The results were confirmed with ASTM data, No. 20928 ($K_3Na(SO_4)_2$), No. 5631 (Na_2SO_4), and No. 5613 (K_2SO_4). The fluorescent X-ray data showed the presence of Cu, Rb, and Zn (below 0.0%) as the small impurities.

The syntheses of tripotassium sodium bis(sulfate) known hitherto as a natural occurring material was carried out starting from the corresponding sulfates or hydroxides and sulfuric acid for the purpose of identification of the salt. It is known[2,3] that potassium sodium sulfate naturally occurs in volcanic districts, *e.g.* the glaserita or aphthitalite $K_3Na(SO_4)_2$ found as an incrustation on Vesuvian lava, in the salt deposit of Douglashall (Westeregeln), at Rucalmuta (Sicily), and in a sea water system, for example B. Gossner[4] regards glaserite as a definite mineral species, but J. H. Van't Hoff and H. Barshall[5] considered it to be a mixture of the two component sulfates: $3K_2SO_4+Na_2SO_4$. An impure form of this salt containing 75 to 85 per cent of K_2SO_4 and 9 to 21 per cent of Na_2SO_4 and known as platosulfate[6] has been separated from a concentration of kelp-liquors.

The authors wish to express their thanks to Hokkaido-Togyo Co., Ltd. for financial support and Dr. Yoshihisa Yamamoto of the Faculty of Pharmaceutical Sciences, Higashi-Nippon-Gakuen University, for his helpful discussion.

Solvent Intensification Effects on the $S_1(n\pi^*) \leftarrow S_0$ Absorption Spectra of Benzaldehyde in Fluid Solutions

Kenichi NAKASHIMA† and Motohiko KOYANAGI*

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 9, 1982)

Synopsis. The near ultraviolet absorption spectra of benzaldehyde have been studied in various fluid solutions at room temperature. The intensity enhancements observed are explainable in terms of perturbation of dispersion forces between solute and solvent molecules.

Recently we showed that the environmental intensity enhancements of the near ultraviolet absorption spectra of aliphatic ketones such as acetone and cyclopentanone are parallel to those of the Ham effects in benzene.[1] Despite many studies of solvent effects on the electronic transition energies of aromatic carbonyls,[2] there has, to the best of our knowledge, been reported no work on their quantitative intensity correlation. One of the reasons is due to some experimental difficulty in discriminating between overlapping $S_2(\pi\pi^*) \leftarrow S_0/S_1(n\pi^*) \leftarrow S_0$ electronic transition absorptions for the evaluation of the oscillator strength, $f[S_1(n\pi^*) \leftarrow S_0]$. Another is possibly in their chemical and photochemical reactivities. In the present work we studied the absorption spectra of a prototype aromatic carbonyl molecule, benzaldehyde, and found that a like solvent correlation also held. The employment of this molecule is advantageous because the $S_1(n\pi^*) \leftarrow S_0$ absorption spectrum in a certain solution shows a banded structure even at room temperature and there are somewhat detailed available vibronic data on it.[3]

Experimental

Benzaldehyde (a reagent from Wako Pure Chemical Industries, Ltd.) was purified through several vacuum distillations. It was stored in a sealed-off glass tubing *in vacuo*. In order to avoid oxydation into benzoic acid, the tubing was located in the dark at 77 K. The solvents employed were of spectroscopically pure or reagent grade. They were deoxygenated by nitrogen gas bubbling before measurements and used without further purification. Absolute oscillator strengths for the solutions are difficult to obtain from integrated intensities because there is almost always some overlap between the $S_1(n\pi^*) \leftarrow S_0$ and $S_2(\pi\pi^*) \leftarrow S_0$ absorptions. Integration over only part of the band should give correct relative oscillator strengths as long as there are no changes in the Franck-Condon factors and as long as there are no specific intramolecular interactions whose matrix elements are beyond the order of the ordinary Boltzmann energy, $\approx kT$. In almost all cases we employed the band maxima $0+2\nu(C{=}O)$ as the upper wave number limit of the integration. The exceptions are for several high polar solvents such as nitriles, chloroform, and dichloromethane; for these solution systems the integrations were taken up to the band maximum of each spectrum and then the integration values were compared with the intensity integration over wave numbers to the band at $\approx$30200 cm^{-1} in a standard solvent, hexane. The other experimental details are similar to those described previously.[1]

Results and Discussion

In the $S_1(n\pi^*) \leftarrow S_0$ absorption system of benzaldehyde, both allowed and forbidden characters are important because of the breakdown of the local (C=O group) C_{2v} symmetry. This is in contrast with the $S_1(n\pi^*) \leftarrow S_0$ absorption spectra of acetone and cyclopentanone. Despite this geometrical difference, however, the transition still remains substantial forbidden character. The very small oscillator strengths observed confirm

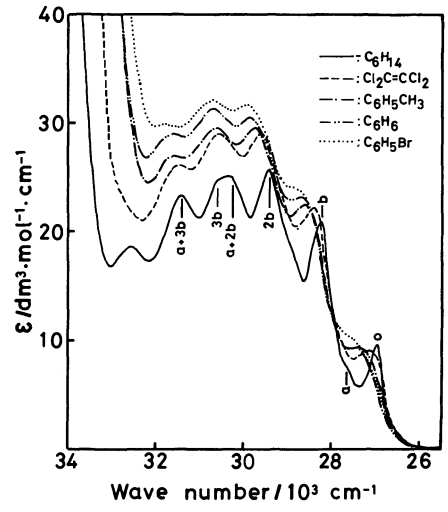

Fig. 1. The $S_1(n\pi^*) \leftarrow S_0$ absorption spectra of benzaldehyde in several solvents at 20 °C.

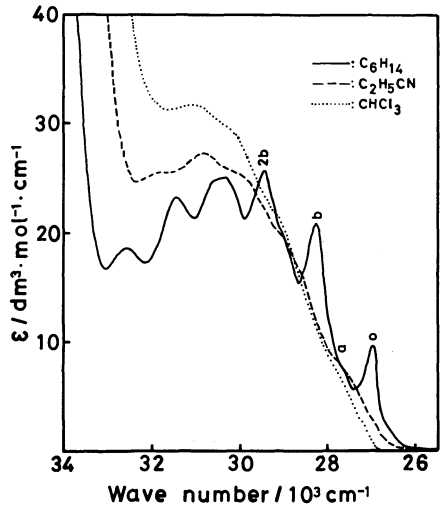

Fig. 2. The $S_1(n\pi^*) \leftarrow S_0$ absorption spectra of benzaldehyde in polar solvents at 20 °C.

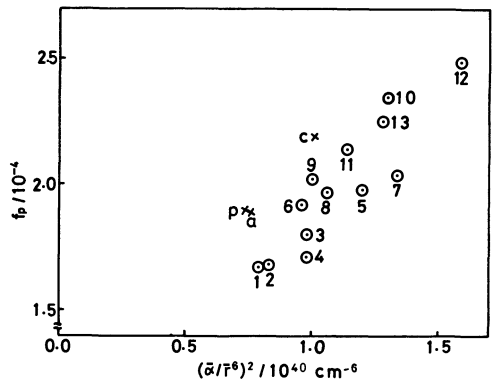

Fig. 3. A correlation diagram between the partial oscillator strength of benzaldehyde, f_p, and the squared value of the relative dispersion energy of solvents, $(\bar{\alpha}/\bar{r}^6)^2$. The numbering of the plots is as follows: (1) C_6H_{14}; (2) *i*-C_8H_{18}; (3) *cyclo*-C_6H_{12}; (4) $C_6H_{11}CH_3$; (5) CCl_4; (6) CH_2Cl_2; (7) C_2Cl_4; (8) CH_2Cl-CH_2Cl;(9) $(CH_3)_2NCHO$; (10) C_6H_6; (11) $C_6H_5CH_3$; (12) C_6H_5-Br; (13) *p*-$(CH_3)_2C_6H_4$; (p) C_2H_5CN; (a) CH_3CN; and (c) $CHCl_3$.

that this is the case.

The absorption spectrum of benzaldehyde was studied in various solvents at room temperature. Some typical spectra are shown in Figs. 1 and 2. The spectra in nonpolar or weakly polar solvents (*cf.* Fig. 1) give somewhat prominent vibronic bands. Although the $n\pi^*$ spectra of benzaldehyde at $\approx$300 K are generally accompanied by several sequence bands relevant to CHO-group localized vibrations in the gas phase[3], *i.e.*, $36_i^i(i=1\text{—}4)$, $35_j^j(j=1,2)$, and $25_k^k(k=1\text{—}3)$, almost all of the "bands" in Fig. 1 are essentially assignable in terms of the band groups of 0_0^0 (designated as *o* in Fig. 1) and 31_0^1 (*a*), and in terms of the 7_0^n (*nb*) progression bands ($n=1\text{—}3$) thereof.[4]

The spectral bands in high polar solvents such as chloroform and propionitrile, on the other hand, become considerably broad and shift toward the shorter wavelengths in contrast to the longer wavelength shifts of the $S_2(\pi\pi^*)\leftarrow S_0$ bands (see Fig. 2). It has been known that these solvents form stoichiometric complexes with several aromatic carbonyl compounds.[5] We confirmed this is also true for the present benzaldehyde case.[6] As for these complex-forming solvent systems, it is extremely difficult to discriminate between the spectra of non-complex-forming benzaldehyde and complex-forming one because of weakness in their complex formation forces and little knowledge on the Franck-Condon factors of the complexes' spectra.

In Fig. 3 the partial oscillator strength of benzaldehyde, f_p, is plotted as a function of the squared value of a relative dispersion energy between the solute and solvent molecules, $(\bar{\alpha}/\bar{r}^6)^2$. Here $\bar{\alpha}$ denotes the mean molecular polarizability of the solvent and $\bar{r}$ the mean intermolecular distance between the solute and solvent molecules. Nevertheless roughness in the approximation for $\bar{r}$, the observed intensities plotted by circles show an approximately linear increase with an increase in $(\bar{\alpha}/\bar{r}^6)^2$. This behavior is parallel to those in benzene[7] and aliphatic ketones.[1] For comparison, the data on the relative intensities in complex-forming solvents are also plotted by crosses. These intensities are presumed to be of overestimation because of considerable band overlap with the close lying $S_2(\pi\pi^*)\leftarrow S_0$ absorption. Only a little intensity enhancements, however, were found; it should be noted that this contrasts with a characteristic correlation reported in the $S_1(L_b)\leftarrow S_0$ spectra of pyrene.[8]

We have also observed similar environmental enhancements in the $S_1(n\pi^*)\leftarrow S_0$ absorption spectra of benzophenone and acetophenone. However, each band system was so diffuse that we found some difficulty in obtaining an appropriate intensity for it.

One of the authors (K. N.) wishes to express thanks to Professor R. Shimada for his warm hospitality and encouragements in Kyushu University. This work has in part been supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Synthesis and Magnetic Susceptibility of Dimeric Copper(II) Acetate Adducts with Triphenylphosphine or Triphenylphosphine Oxide

Tadashi Tokii, Toyoaki Ikeda, and Yoneichiro Muto*
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received November 25, 1981)

Synopsis. Two compounds of stoichiometry $Cu(CH_3COO)_2 \cdot L$ (L = triphenylphosphine or triphenylphosphine oxide) were prepared. These compounds display the antiferromagnetic behavior typical of dimeric copper(II) carboxylates. The singlet-triplet splitting energy is 371 cm^{-1} for the phosphine adduct and 319 cm^{-1} for the phosphine oxide adduct.

A large number of dimeric copper(II) carboxylates have been studied because of their interesting magnetic and structural properties. However, the factors that determine the degree of antiferromagnetic interaction in these carboxylates still remain almost unsettled.[1] In this work, we prepared two copper(II) acetate adducts of stoichiometry $Cu(CH_3COO)_2 \cdot L$, where L = triphenylphosphine (Ph_3P) or triphenylphosphine oxide (Ph_3PO), and measured their magnetic susceptibility as a function of temperature in order to study the effect of the additional ligand L on the magnetic interaction in these complexes.

Experimental

Synthesis. *$Cu(CH_3COO)_2 \cdot Ph_3P$*: A solution of Ph_3P (5 mmol) in 30 ml of ether was added to a solution of $Cu(CH_3COO)_2 \cdot H_2O$ (5 mmol) in 30 ml of ethanol with a few drops of glacial acetic acid. After the solution had been allowed to stand for several days at *ca.* 5 °C in a freezer, the separated green crystals were collected, washed twice with ethanol and once with ether, and dried *in vacuo*. Found: C, 59.36; H, 4.78; Cu, 14.40%. Calcd for $C_{22}H_{21}O_4PCu$: C, 59.52; H, 4.77; Cu, 14.31%.

$Cu(CH_3COO)_2 \cdot Ph_3PO$: A solution of Ph_3PO (5 mmol) in 30 ml of ethanol was added to a solution of $Cu(CH_3COO)_2 \cdot H_2O$ (5 mmol) in 30 ml of ethanol and 2 ml of 2,2-dimethoxypropane. After the mixed solution had been concentrated to one-half of its volume, it was allowed to stand overnight at *ca.* 5 °C in a freezer. The green crystals were collected, washed with ethanol, and dried at *ca.* 70 °C. Found: C, 57.38; H, 4.67; Cu, 13.84%. Calcd for $C_{22}H_{21}O_5PCu$: C, 57.45; H, 4.60; Cu, 13.82%.

Physical Measurement. Magnetic suceptibilities in the temperature range of 80—300 K were determined by the Gouy method. The correction for diamagnetic contributions was made by use of Pascal's constant.[2] Effective magnetic moments per copper ion at room temperature were calculated from the equation

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)\cdot T}, \quad (1)$$

where χ_A is the corrected molar magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism per gram-ion of copper(II); a value of $N\alpha = 60 \times 10^{-6}$ cgs emu mol^{-1}† was used.[3] The results are given in Table 1. The cryomagnetic susceptibility data are shown in Fig. 1 as plots of χ_A *vs.* T.

Results and Discussion

The variable-temperature magnetic susceptibility data were analyzed by the Bleaney-Bowers equation for isotropic exchange in a copper(II) dimer:[4]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha, \quad (2)$$

where g is the average g factor and J is the exchange integral. As can be seen in Fig. 1, the thermal magnetic data are well represented by Eq. 2. The best fit values for g and $-2J$ (a measure of the magnitude of magnetic interaction) are given in Table 1. On the basis of the magnetic behavior, a dimeric structure similar to that found in copper(II) acetate monohydrate can be proposed for the present acetate complexes.

The $-2J$ value of 371 cm^{-1} found for the Ph_3P adduct is considerably larger than that observed for any other dimeric copper(II) acetate adducts, indicating that the coordination of Ph_3P to dimeric copper(II) acetate units will cause a marked increase in antiferromagnetic interaction. On the other hand, the Ph_3PO adduct has a $-2J$ value (319 cm^{-1}) comparable to those found for well-characterized dimeric copper(II) acetate adducts (300—325 cm^{-1}).[5]

Edmonson and Lever[6] observed, in their study of dimeric copper(II) vinyl acetate and allyl acetate

Table 1. Magnetic data

Complex	μ_{eff}/BM[a]	T/K	g	$-2J$/cm^{-1}
$Cu(CH_3COO)_2 \cdot Ph_3P$	1.23	283	2.20	371
$Cu(CH_3COO)_2 \cdot Ph_3PO$	1.39	293	2.24	319

a) 1 BM = 9.27×10^{-24} A m^2.

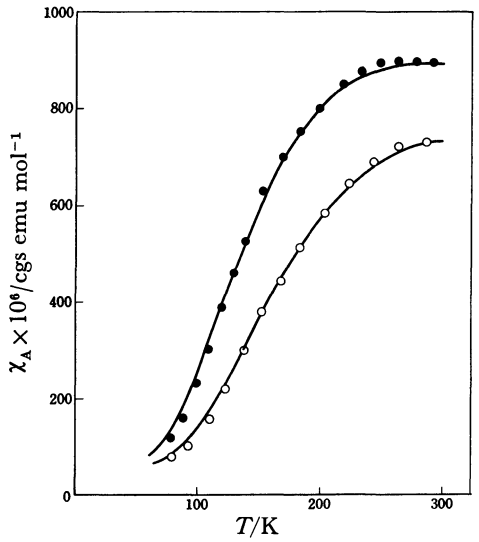

Fig. 1. Variation of magnetic suceptibilities with temperature. (○) $Cu(CH_3COO)_2 \cdot Ph_3P$ and (●) $Cu(CH_3COO)_2 \cdot Ph_3PO$. The solid curves were calculated by Eq. 2 with the parameters listed in Table 1 and $N\alpha$ of 60×10^{-6} cgs emu mol^{-1}.

† 1 cgs emu $mol^{-1} = 4\pi \times 10^{-6}$ m^3 mol^{-1}.

complexes with pyrazine (pz), pyridine (py), and Ph_3P, that the effective magnetic moments (μ_{eff}) at room temperature decreased in the order of pz adducts> py adducts$\gg$$Ph_3P$ adducts; the decrease in μ_{eff} for the Ph_3P adducts was attributed to the polarizable nature of the phosphorous ligand. The corresponding acetate complexes show a similar trend: pz adduct[7] $\approx$py adduct[8] ($\approx$1.35 BM)>Ph_3P adduct (1.23 BM). Ph_3P acts as a π-acceptor as well as a good σ-donor toward transition metals, while Ph_3PO functions simply as a σ-donor.[9] A metal→ligand π-back-donation generally facilitates the ligand→metal σ-donation, leading to a strengthening of the bond through the synergic interaction. Thus, the Cu–P bond in $Cu(CH_3COO)_2\cdot Ph_3P$ should be stronger than the Cu–O bond in $Cu(CH_3COO)_2\cdot Ph_3PO$.

It has been noted that, in dimeric copper(II) carboxylate adducts, the variation of $-2J$ with properties of additional ligands is not a simple function of the base strength of the ligands or of any other readily evident parameters.[10,11] However, the present magnetic data indicate that the bonding nature between Cu–L in $Cu(CH_3COO)_2\cdot L$ is important in determining the magnitude of $-2J$.

Synopsis. X-Ray structural determination of $Ru_2(HCOO)_4Br$ showed that the unit cell contains two crystallographically independent formato bridged dinuclear units, $Ru_2(HCOO)_4^+$, each of which is centrosymmetric. Two adjacent units are bridged by bromide ion to make infinite zigzag chains.

Since the $Ru_2(RCOO)_4X$ type of complexes were prepared by Stephenson *et al.* and one of the present authors independently,[1,2] extensive studies of the complexes have been reported.[3-12] These studies showed that the complexes can be classified into three types with different crystal structures; an infinite zigzag chain structure bridged by halide ions,[5,7] an infinite linear chain structure bridged by halide ions,[12] and a structure comprizing discrete dinuclear unit.[6] The basic structural parameters for the dinuclear unit in each type are essentially identical.

Here we wish to report the crystal structure analysis of $[Ru_2(HCOO)_4Br]$. This work was carried out to clarify whether the bonding mode of formate ion in the title complex is similar to that of the analogous monocarboxylate or not.

There existed twinned crystals. By taking oscillation and Weissenberg photographs, a single crystal (*ca.* $0.08\times0.07\times0.18$ mm^3) was chosen and mounted on a RIGAKU four-circle automatic diffractometer with graphite-monochromatized Mo $K\alpha$ radiation. Unit cell parameters were refined by least-squares for 19 strong reflections in the 2θ range of 12—15°. Crystal data: $Ru_2(HCOO)_4Br$, F.W.=462.12, monoclinic, space group $P2_1/c$ (systematic absences: $h0l$, l=odd and $0k0$, k=odd), a=9.944(1), b=7.728(1), c=12.679(1) Å, β=93.52(1)°, V=972.46(19) Å^3, D_m=3.175 g cm^{-3} (by flotation in CCl_4/CH_2I_2 mixture), D_c=3.158 g cm^{-1} for Z=4, μ(Mo $K\alpha$)=74.06 cm^{-1}.

Intensity data were collected within the range of $2\theta\leqq70°$ using the ω-scan mode up to $2\theta=30°$, and 2θ-ω mode above $2\theta=30°$ at a scan speed of 4° min^{-1}. Three strong standard reflections were measured every 100 reflections; no significant change in intensity was noted during the data collection. The observed intensities were corrected for Lorentz and polarization factors, but no absorption correction was applied; 2654 unique reflections with $|F_o|\geqq3\sigma(|F_o|)$ were obtained. The structure was solved by the heavy atom method and refined by block-diagonal least-squares to R=0.036, anisotropic temperature factors being used. The final difference Fourier map showed no significant peak. Atomic scattering factors from tables[13] with correction for anomalous dispersion were used; the unit weight was given to all reflections. Calculations were performed on the FACOM 230-75 Computer using the UNICS III program system.[14]†† Atomic parameters are given in Table 1.

The crystal consists of two independent formato-bridged dinuclear units, $Ru_2(HCOO)_4^+$, and a bridging

bromide ion as is shown in Fig. 1. Each of the units is composed of two rutheniums and four formate ions and has a crystallographic center of inversion on the middle of the Ru–Ru bond. Bromide ion bridges adjacent dinuclear units to form infinite zigzag chains, with Ru(1)–Br–Ru(2) angle of 109.99(3)°. These chains are on planes parallel to {1 1 0} as shown in Fig. 2. One chain extends along ⟨1 1 0⟩ on $z=0$, and the other on $z=1/2$. The two crystallographically independent dinuclear units show no significant differences in geometrical parameters except the Ru–Br bond (Table 2). The average Ru–Ru and Ru–O bond lengths are 2.290 and 2.026 Å, respectively. The Ru–Ru–Br angles slightly deviate from 180°. Such anglar bend appears in the zigzag chains as well as in the discrete complex ions.[6] Dihedral angles of the planes defined by Ru_2O_2C group are nearly 90°, as expected. Two oxygens in every group deviate from the plane by 0.01—0.03 Å to twist the plane. The Ru deviates more than 0.02 Å from the plane formed by the four equatorial O atoms, in the direction to elongate the Ru–Ru distance. In agreement with a previous prediction,[2] the present result shows that the $[Ru_2(RCOO)_4X]$ type of complexes reported so far have the same bonding mode in reference to the monocarboxylato ligand.

Thanks are due to Miss K. Kobayashi (The Institute of Physical and Chemical Research) for her assistances with the calculations, and to Mr. Y. Iimura (The Institute of Physical and Chemical Research) for providing X-ray facilities. We also thank to Dr. F. S. Howell (Department of Chemistry, Sophia University) for correcting the manuscript.

(Received May 12, 1982)

Synopsis. Two complexes of *fac*(NH_3)-[Co(L)(NH_3)$_3$]$^+$ type (where L denotes (*R*)-2-(carboxymethylthio)propionate and (*R*)-2-(2-carboxyethylthio)propionate) were newly prepared and separated into two isomers, *R*(*S*), *R*(*C*) and *S*(*S*), *R*(*C*), by column chromatography. The absolute configurations of the isomers are suggested on the basis of the ^{13}C NMR spectra.

(*R*)-2-(Carboxymethylthio)propionate (*R*-cmtp) and (*R*)-2-(2-carboxyethylthio)propionate (*R*-cetp) function as terdentate-*O*,*S*,*O* ligands. When this type of ligand coordinates to a cobalt(III) ion and three ammonia molecules occupy the remaining three coordination sites, the resulting complexes have one chirality due to the coordinated sulfur atom (*R*(*S*) or *S*(*S*) configuration) and another due to the asymmetric carbon atom (*R*(*C*) configuration). There have been only a few works on such kinds of chirality due to the rigid chiral sulfur atom.[1] This note is concerned with the preparation and isolation of diastereomers, *R*(*S*),*R*(*C*) and *S*(*S*),*R*(*C*), of the *fac*(NH_3) triammine cobalt(III) complexes with *R*-cmtp and *R*-cetp ligands. The ^{13}C NMR and CD spectra for the four isomers are presented.

Experimental

R-H_2cmtp was prepared by the well-established procedure,[2] using (*S*)-2-bromopropionic acid and mercaptoacetic acid. The $[\alpha]_D^{23}=+87.6°$ (*c* 2.2, $CHCl_3$) for the *R*-H_2cmtp·0.1NaBr in this work agreed with the value in the literature.[3]

R-H_2cetp was prepared by the same procedure as that of *R*-H_2cmtp,[2] using 3-mercaptopropionic acid instead of mercaptoacetic acid. This reaction proceeds without racemization.[2,4] Found: C, 40.17; H, 5.58%. Calcd for *R*-H_2cetp: C, 40.44; H, 5.56%. $[\alpha]_D^{23}=+64.1°$ (*c* 4.4, water) and $[\alpha]_D^{23}=+106.1°$ (*c* 2.2, $CHCl_3$).

[*Co*(R-*cmtp*)(*NH*$_3$)$_3$]*Cl*. This complex was prepared by the reaction of *R*-H_2cmtp (5 g) with [Co(NO_3)$_3$(NH_3)$_3$][5] (5 g) in 40 cm^3 of water at 50 °C for 1.5 h. The reaction mixture was filtered and the filtrate was poured onto a column of Dowex 50W-X8 (H^+ form, 3×40 cm). After the column had been swept with water, the adsorbed band was eluted with 0.1 mol dm^{-3} aqueous solution of sodium chloride, of which the pH was adjusted to 3 by addition of concentrated hydrochloric acid. Two red-violet bands, F1 and F2 (the formation ratio of F1 to F2 was *ca.* 46 : 54), were eluted in this order. Each eluate was concentrated to *ca.* 10 cm^3 with a rotary evaporator. The deposited NaCl was filtered off and the filtrate was passed through a column of Sephadex G-10 (2×150 cm). The solution eluted with water was concentrated to a small volume again and kept in a refrigerator overnight. The crystals obtained were collected by filtration. Found for F1: C, 19.93; H, 4.88; N, 13.56%. Found for F2: C, 19.48; H, 4.88; N, 13.77%. Calcd for [Co(*R*-cmtp)(NH_3)$_3$]Cl=$CoC_5H_{15}N_3O_4SCl$: C, 19.51; H, 4.92; N, 13.66%.

[*Co*(R-*cetp*)(*NH*$_3$)$_3$]*Cl*. This complex was prepared and separated into two isomers, G1 and G2 (the formation ratio of G1 to G2 was *ca.* 44 : 56), by a procedure similar to that for [Co(*R*-cmtp)(NH_3)$_3$]Gl complex, using *R*-H_2cetp instead of *R*-H_2cmtp. Found for G1: C, 21.98; H, 5.33; N, 12.86%. Calcd for [Co(*R*-cetp)(NH_3)$_3$]Cl·0.25H_2O=$CoC_6H_{17}N_3O_4SCl$·0.25H_2O: C, 22.09; H, 5.42; N, 12.88%. Found for G2: C, 21.29; H, 5.64; N, 12.22%. Calcd for [Co(*R*-cetp)(NH_3)$_3$]Cl·H_2O: C, 21.21; H, 5.65; N, 12.37%.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra, with a JASCO J-20 spectropolarimeter. The ^{13}C NMR spectra were recorded on a JEOL JNM-FX-100 NMR spectrometer at the probe temperature in a D_2O solvent. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as the internal reference.

Results and Discussion

Two geometrical isomers, *fac*(NH_3) and *mer*(NH_3), are possible for [Co(terdentate-*O*,*S*,*O*)(NH_3)$_3$]$^+$, as shown in Fig. 1(a). The two isomers for each of the *R*-cmtp and *R*-cetp complexes isolated show the similar absorption spectra over the whole region, and the pattern of their first absorption bands is in line with that of the *s*-*cis*(*O*)-*fac*-(thiodiacetato)(diethylenetriammine)cobalt(III) complex (Fig. 2).[6] Therefore, it is possible to assign the present isomers to be *fac*(NH_3).

The *fac*(NH_3) complexes have two chiral centers at carbon and sulfur atoms. Namely, two diastereomers due to the chirality of the sulfur atom are possible for each of the complexes, since the chiral carbon atom has the *R*(*C*) configuration (Fig. 1(b)). In the ^{13}C NMR spectra, the methyl, methylene, and methine carbons of F2 resonate at higher magnetic field than those of F1, as shown in Fig. 3. When the chiral sulfur atom takes the *R*(*S*) configuration, the interaction between a methyl group of a coordinated *R*-cmtp ligand and another chelate ring of the same ligand is probable (Fig. 1(b)). On the contrary, there is no spatial crowd for the methyl group of the *S*(*S*),*R*(*C*) isomer (Fig. 1(b)). Taking the steric effects for the chemical shift of carbon into consideration,[7] the ^{13}C NMR spectra seem to suggest that F1 takes the *S*(*S*),*R*(*C*) configuration and F2 the *R*(*S*),*R*(*C*) one. In the same manner, G1 is assigned to

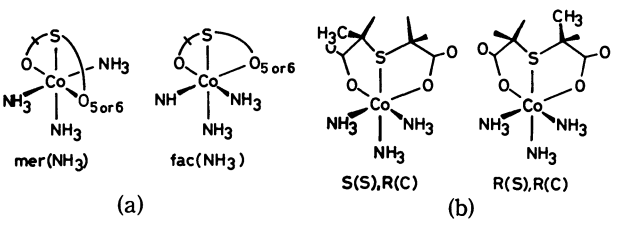

Fig. 1. (a) Two geometrical isomers of [Co(terdentate-*O*,*S*,*O*)(NH_3)$_3$]$^+$ and (b) two optically active isomers of *fac*(NH_3)-[Co(*R*-cmtp)(NH_3)$_3$]$^+$.

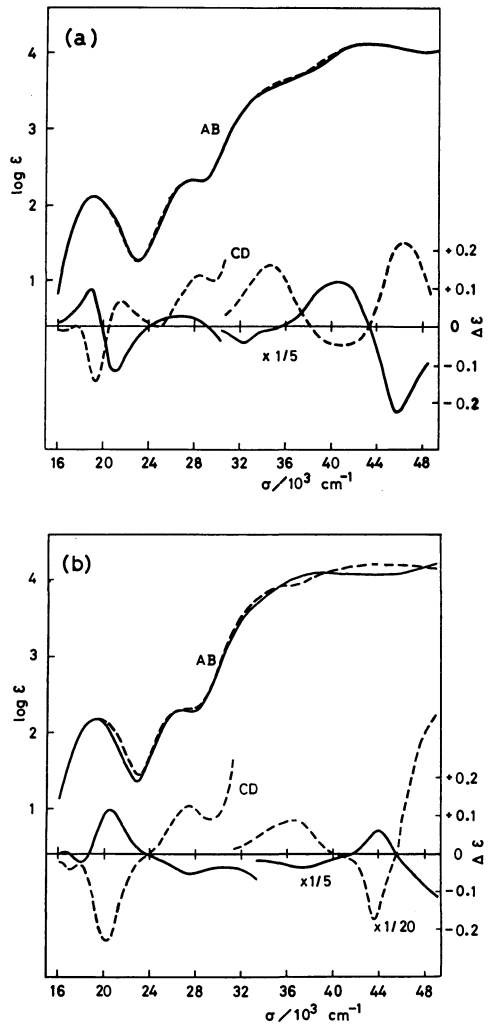

Fig. 2. Absorption and CD spectra of the triammine complexes: (a) F1 (——) and F2 (------) of [Co(*R*-cmtp)$(NH_3)_3$]$^+$, and (b) G1 (——) and G2 (------) of [Co(*R*-cetp)$(NH_3)_3$]$^+$.

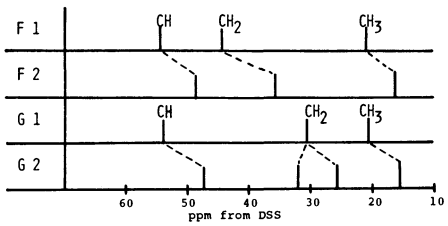

Fig. 3. Distribution of ^{13}C NMR chemical shifts.

the *S*(*S*),*R*(*C*) configuration and G2 to the *R*(*S*),*R*(*C*) one. These assignments are supported by the ^{13}C NMR spectral study of the cobalt(III) complexes with the *N*-(carboxylatomethyl)-L-alaninate ligand which has a similar framework to the *R*-cmtp one.[8]

As shown in Figs. 2(a) and (b), the CD spectra of two isomers for each of the *R*-cmtp and *R*-cetp complexes are almost enantiomeric over the whole region. In the first absorption band region, the *R*(*S*),*R*(*C*) isomer (F2) of the *R*-cmtp complex, which consists of two five-membered chelate rings, shows three CD bands ((—), (—) and (+) from lower energy side) (Fig. 2(a)). The *R*(*S*),*R*(*C*) isomer (G2) of the *R*-cetp complex, which consists of one five- and one six-membered chelate ring, shows almost opposite signs ((—) and (—)) for that of the *R*-cmtp one (Fig. 2(b)), although the two complexes show a similar CD behavior in the region of (32—48) × 10^3 cm^{-1}. A similar CD spectral behavior in the first absorption band region was observed for the *R*(*N*),*S*(*C*) triammine cobalt(III) complexes with the *N*-(carboxylatomethyl)-L-alaninate and *N*-(2-carboxylatoethyl)-L-alaninate,[9] which have the chiral nitrogen atoms instead of the sulfur atoms of the *R*-cmtp and *R*-cetp ligands. The CD intensity in the *R*-cmtp and *R*-cetp complexes is very much smaller than that of the mixed cobalt(III) complexes with the 1,1,1-tris(aminomethyl)-ethane (tame) and terdentate-*N*,*S*,*O* such as (2-aminoethylthio)acetate, which have a similar CD contribution to the present complexes.[1] The CD spectra of the present isomers seem to indicate that the arrangement chirality of the donor atoms in the *R*-cmtp and *R*-cetp complexes little affects the CD spectra, or that the chelate rings of the tame ligand in the tame cobalt(III) complexes[1] are significant for CD contribution.

Synthesis of *cis*-Jasmone *via* the Retroaldol-aldol Condensation of 3-(*cis*-3-Hexenyl)-2-cyclopentenone in an Autoclave

Takashi YOSHIDA* and Shojiro SAITO

Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashimita, Tama-ku, Kawasaki 214

(Received April 26, 1982)

Synopsis. *cis*-Jasmone was efficiently synthesized from 2-cyclcpentenone. The treatment of 2-cyclopentenone with sodium *p*-toluenesulfinate gave 3-(*p*-tolylsulfonyl)cyclopentanone in a 92.5% yield. The alkylation of the sulfone, after the protection of the ketone, with *cis*-1-bromo-3-hexene, followed by desulfonylation with 5% hydrochloric acid in tetrahydrcfuran, afforded 3-(*cis*-3-hexenyl)-2-cyclopentenone in a good yield. The retroaldol-aldol condensation of the cyclopentenone in a stainless steel autoclave in presence of 5% sodium hydroxide yielded *cis*-jasmone in a 80% yield.

Among the *cis*-jasmone syntheses, the cyclization of 1,4-diketone employing weak alkali is well known.[1] We reported previously a new synthesis of *cis*-jasmone (**6**) *via* 1,4-diketone prepared by the condensation of *cis*-1-(*p*-tolylsulfonyl)-3-hexene with ethyl 4,4-ethylenedioxypentanoate.[2] On the other hand, 3-(*cis*-3-hexenyl)-2-cyclopentanone (**5**) is also a key intermediate for the synthesis of **6**.[3] Two examples involve the intermediate **5**. McCurry *et al.* reported in 1974 that **5** was synthesized by the addition of alkyllithium to 2-cyclopentenone, followed by chromium-trioxide oxidation,[3] giving **6** in a 29% overall yield by the retroaldol-aldol condensation of **5**. Torii *et al.* reported in 1979 that **5** was obtained by the electrolytic acetoxylation reaction of 1-(*cis*-3-hexenyl)-2-cyclopentene-1-carboxylic acid in several steps.[4] In a previous paper, we ourselves reported that the treatment of the tertiary alkyl sulfones bearing carbonyl groups at the β-position with 5% hydrochloric acid in tetrahydrofuran (THF) at 30—60 °C afforded β-substituted α,β-unsaturated ketones and aldehydes in good yields.[5] Using this method, **5** was obtained from 2-cyclopentenone in a good yield. In this paper, we wish to report a new approach which allows a relatively simple and effective synthesis of **6**.

As shown in Fig. 1, 3-(*p*-tolylsulfonyl)cyclopentanone (**2**) was obtained in a 92.5% yield by the addition of *p*-toluenesulfinic acid to 2-cyclopentenone (**1**). The keto sulfone **2** was treated with ethylene glycol in benzene to give 1,1-ethylenedioxy-3-(*p*-tolylsulfonyl)cyclopentane (**3**) in a 95% yield. The sulfone **3** was alkylated using *cis*-1-bromo-3-hexene to afford 1,1-ethylenedioxy-3-(*cis*-3-hexenyl)-3-(*p*-tolylsulfonyl)cyclopentanone (**4**) in a quantitative yield.

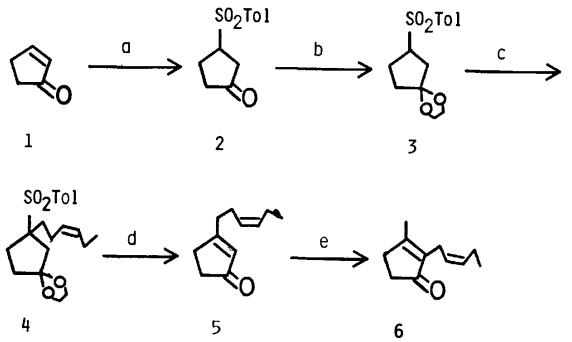

Fig. 1. a: *p*-Toluenesulfinic acid, b: ethylene glycol, c: LDA, −78 °C, *cis*-1-bromo-3-hexene, d: 5% HCl THF, 30 °C, e: 120 °C, (autoclave).

The treatment of the sulfone **4** with 5% hydrochloric acid gave 3-(*cis*-3-hexenyl)-2-cyclopentenone (**5**) in a 90% yield. Generally, the desulfonylation for making a variety of double bonds is carried out by the treatment of the allylic sulfones with a strong base. β-Keto sulfones are decomposed by dilute aq alkali. However, we found that the treatment of the sulfone **4** with 5% hydrochloric acid in THF afforded **5** in a good yield[5] when stirring was done at 45 °C for 4 h. When these conditions, **5** and its *trans* isomer were obtained in the ratio of 5 : 5. However, the reaction at a temperature below 30 °C gave pure **5** in a 90% yield.

Next, we investigated the details of the retroaldol-aldol condensation of **5** to **6**. McCurry *et al.* reported that the treatment of 0.160 g of **5** with 160 ml of 0.75 mol dm^{-3} sodium hydroxide by refluxing under argon for 72 h provided **6** in an 80% yield.[3] However, we could obtained the desired **6** by this method, only resinous substances were isolated. Thus, the reaction was carried out in a stainless steel autoclave using a dilute aq sodium hydroxide solution. The product-selectively in the conversion of **5** to **6** in an autoclave mainly depends on the reaction temperature, the reaction time, and the condensation of sodium hydroxide. The reaction conditions at 95 °C for 12 h using 5% sodium hydroxide did not give **6**, only the starting material, **5**, was recovered. When the reaction temperature was kept at 120 °C, the desired **6** was obtained in an 80% yield and in a 94% purity, along with the double-bond isomer, 3-methyl-2-(*trans*-1-penteny)-2-cyclopentenone (**7**) in a 6% yield. The sructure of **7** was determined from the ^1H NMR and IR spectra.[6] The ^1H NMR spectra of the olefin protons of the side chain of **7** appeared at δ 6.00 (d, J=16.5 Hz) and δ 6.78 (dt, J=16.5 and 6.0 Hz). The IR spectra of the compound show a characteristic absorption band at 970 cm^{-1} due to the *trans*-alkene bond. The mechanism produced may be assumed to proceed *via* the migration of the *cis*-olefin of the resulting **6** for the compound **7** was not obtained from 3-(*trans*-2-hexenyl)-2-cyclopentenone under similar conditions, only resinous substances being almost entirely produced. In addition, **6** isomerized to **7** with 5% sodium hydroxide in the autoclave in a ratio of 6%. Under the constant temperature of 120 °C, the employment of 1% sodium hydroxide gave **6** in a 40% yield, whereas 5% sodium hydroxide yielded **6** in an 80% yield. A higher concentration of more than 5% can easily give resinous substances as by-products.

Experimental

All the melting and boiling points are uncorrected. The melting points were taken on a Yanagimoto micro-melting-point apparatus. The infrared spectra were recorded on a Shimadzu IR-27G spectrophotometer. The ^{1}H NMR spectra were measured on a Varian EM-390 spectrometer at 90 MHz, using CCl_4 as solvent and TMS as an internal standard.

3-p-Tolylsulfonylcyclopentanone (2). Sodium *p*-toluenesulfinate tetrahydrate (8 g, 33 mmol) in 30 ml of MeOH, AcOH (2 g, 33 mmol), and 2-cyclopentenone (**1**) (2 g, 24 mmol) were placed in an Erlenmeyer flask and heated to reflux. After 10 h, the reaction product was neutralized by the use of a dilute sodium hydrogencarbonate solution and extracted with chloroform. The extract was washed with water, dried (Na_2SO_4), and concentrated to give **2**, as solid substances. Recrystallization from benzene–hexane afforded 5 g (92.5% yield) of pure **2** as white needles, mp 58—58.5 °C. IR (Nujol) 2980, 1750, 1600, 1410, 1300, 1140 cm^{-1}. ^{1}H NMR (CCl_4) δ 2.05—2.90 (9H, m), 3.78 (1H, m), 7.45 and 7.85 (4H, an A_2B_2 pattern, J=8.7 Hz). Found: C, 61.11; H, 5.96%. Calcd for $C_{12}H_{14}O_3S$: C, 60.48; H, 5.92%.

1,1-Ethylenedioxy-3-(p-tolylsulfonyl)cyclopentanone (3). Ethylene glycol (2 g, 31 mmol) was stirred into a solution of **2** (6.5 g, 27 mmol) in benzene (50 ml) in the presence of *p*-toluenesulfonic acid (20 mg), and the mixture was refluxed for 5 h. The reaction mixture was then worked up in the usual manner to give **3** (6.5 g, 95% yield) after recrystallization from hexane–benzene as white crystals, mp 61.5—62 °C. IR (Nujol) 2900, 1600, 1430, 1310, 1140 cm^{-1}. ^{1}H NMR (CCl_4) δ 1.75—2.40 (6H, m), 2.50 (3H, s), 3.45—3.90 (1H, m), 3.96 (4H, s), 7.50 and 7.90 (4H, an A_2B_2 pattern, J=8.7 Hz). Found: C, 60.41; H, 6.53%. Calcd for $C_{14}H_{18}O_4S$: C, 59.55; H, 6.43%.

1,1-Ethylenedioxy-3-(cis-3-hexenyl)-3-(p-tolylsulfonyl)cyclopentane (4). To lithium diisopropylamide, prepared from *n*-BuLi (15% hexane solution, 8.5 g, 20 mmol) and diisopropylamine (2.1 g, 20 mmol) in dry THF (15 ml), was added a solution of **3** (4 g, 16 mmol) in dry THF (15 ml) at −78 °C under nitrogen. After the mixture has been stirred for 1 h, *cis*-1-bromo-3-hexene (2.8 g, 17 mmol) in dry THF (15 ml) was added. The mixture was then stirred for 1 h at −78 °C and an additional 3 h at room temperature. The mixture was then poured onto cold 2% sulfuric acid. The usual workup gave **4** as a viscous liquid in a quantitative yield after purification by column chromatography (SiO_2, 60—80 mesh) with benzene. IR (neat) 2930, 1600, 1460, 1300, 1140 cm^{-1}. ^{1}H NMR (CCl_4) δ 0.99 (3H, t, J=7.2 Hz), 1.6—2.8 (15H, m), 3.90 (4H, s), 5.05—5.60 (2H, m), 7.33 and 7.77 (4H, an A_2B_2 pattern, J=8.7 Hz). Found: C, 66.13; H, 7.75%. Calcd for $C_{20}H_{28}O_4S$: C, 65.90; H, 7.74%.

3-(cis-3-Hexenyl)-2-cyclopentenone (5). To a stirred solution of **4** (3 g, 8.24 mmol) in THF (60 ml) was added 5% hydrochloric acid (18 ml). The mixture was then stirred for 5 h at 30 °C. After the removal of the THF, the mixture was poured into 500 ml of water and worked up to give **5** (1.2 g, 90% yield) as a colorless liquid, bp 104—106 °C/6 mmHg (1 mmHg=133.322 Pa). IR (neat) 2950, 1715, 1620, 1440, 1185 cm^{-1}. ^{1}H NMR (CCl_4) δ 0.95 (3H, t, J=7.2 Hz), 1.8—2.6 (10H,m), 5.15—5.75 (2H, m), 5.93 (1H, br s). The product was identified by comparing its NMR spectrum with the reportedone.[3]

cis-Jasmone (6). **5** (0.4 g, 2.24 mmol) and 5% sodium hydroxide (30 ml) were placed in a stainless steel autoclave equipped with a magnetic stirrer. The autoclave was heated in an oil bath maintained at 120 °C for 12 h and then allowed to cool. The reaction mixture was acidified with dilute hydrochloric acid. The organic layer was extracted with ether. The extract was worked up in the usual manner to give 0.32 g (80% yield after being chromatographed, SiO_2 with benzene–hexane (7 : 3)) of **6**, whose gas chromatographic analysis showed a *cis/trans* isomer ratio of 94/6. The NMR and IR spectra of the **6** synthesized here were identical with those of an authentic sample.

We are deeply indebted to Dr. Tetsuo Miyakoshi and Mr. Hiroaki Omichi of Meiji university for their valuable discussions and suggestions throughout this work.

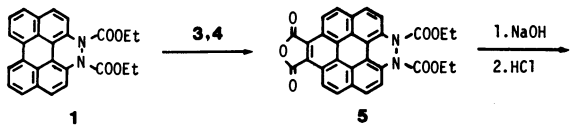
The Synthesis of 1,2-Diazacoronene

Sumio Tokita,* Kimihiro Hiruta, Kiyoshi Kitahara, and Hisao Nishi
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-Ohkubo, Urawa, Saitama 338

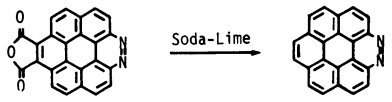
(Received December 10, 1981)

Synopsis. 1,2-Bis(ethoxycarbonyl)-1,2-dihydro-1,2-diazacoronene-7,8-dicarboxylic anhydride (**5**) was obtained from diethyl 1,2-dihydro-1,2-diazabenzo[*ghi*]perylene-1,2-dicarboxylate, maleic anhydride, and chloranil. Treatment of the anhydride **5** with sodium hydroxide gave 1,2-diazacoronene-7,8-dicarboxylic anhydride (**7**). When **7** was heated with soda lime, 1,2-diazacoronene was obtained.

Much attention is being given to the heterocyclic analogs of highly annelated polycyclic hydrocarbons found in urban suspended particulate matter, especially to the compounds suspected of tumorigenic activities. There are, however, few reports about the synthesis of authentic samples of highly annelated heterocycles, in spite of the existence of many reports on heterocyclic analogs of benzene,[1-3] naphthalene,[1-3] anthracene,[2,4] or phenanthrene.[3,4] In the case of nitrogen heterocyclic analogs of coronene, only 1,2,7,8-tetraazacoronene has been synthesized.[5] The preparation of 1,2-diazacoronene (**9**), however, proved to be more difficult.[5] Thus, the attempted Diels-Alder reaction of benzo[*ghi*]perylene with diethyl azodiformate (**2**) did not give any diethyl 1,2-dihydro-1,2-diazacoronene-1,2-dicarboxylate, a precursor of **9**. This paper deals with the synthesis of **9** by another route.



1 **5**



7 **9**

When diethyl 1,2-dihydro-1,2-diazabenzo[*ghi*]perylene-1,2-dicarboxylate (**1**) was treated with maleic anhydride (**3**) in the presence of chloranil (**4**), the expected adduct, 1,2-bis(ethoxycarbonyl)-1,2-dihydro-1,2-diazacoronene-7,8-dicarboxylic anhydride (**5**) was obtained in fair yield. But the treatment of benzo[*ghi*]-perylene-1,2-dicarboxylic anhydride (**6**) with **2** in an autoclave at 160 °C for 144 h did not result in the formation of **5** but in the recovery of **6**.

Hydrolysis of the anhydride **5** with sodium hydroxide followed by acidification gave 1,2-diazacoronene-7,8-dicarboxylic anhydride (**7**) almost quantitatively. The reaction of 1,2-diazabenzo[*ghi*]perylene (**8**) with **3** in the presence of **4** at 200 °C for 20 min gave a very complex mixture, in which **7** could not be detected.

1,2-Diazacoronene (**9**) was prepared by the action of soda lime on anhydride **7**. On the other hand, the reaction of **5** with the same reagent at 280—300 °C for 2 h gave a dark solid from which no definite products could be isolated.

1,2-Diazacoronene (**9**) was soluble in trifluoroacetic acid and bis(2-hydroxyethyl) ether, whereas it was almost insoluble in common organic solvents. It could be recrystallized from bis(2-hydroxyethyl) ether in fine needles. It is yellow with a considerably deeper shade than coronene. The electronic spectrum of **9** (see experimental section) and that of coronene[6,7] were quite similar with respect to the positions of absorption maxima, but differ in that the absorption band of **9** in the visible region has a higher intensity ($\varepsilon \approx 10^4$) than that of coronene ($\varepsilon \approx 10^2$). These findings may be accounted for by the same symmetry argument that explains the difference between the spectra of benzene and pyridine.[8] Incidentaly, the electronic spectrum of an analogous isoelectronic compound, *viz.*, benzo-[6,7]perylo[1,12-*bcd*]thiophene (**10**),[9] shows essentially the same characteristics as **9**.

10

The NMR spectrum of **9** was as expected. In **9**, there were aromatic proton signals at lower field than in coronene, and at higher field than in 1,2,7,8-tetraazacoronene.[5]

Experimental

^{1}H NMR spectra were recorded on a Varian Model A-60 Spectrometer in CF_3COOH using Me_4Si as an internal standard. IR spectra were recorded on a JASCO Model A-3 grating spectrophotometer using the KBr technique. Mass spectra were obtained on a JEOL JMS-01-SG-2 spectrometer at an ionization potential of 35 eV. Electronic spectra were measured with a Hitachi EPS-3T recording spectrophotometer.

Materials. Diethyl azodiformate (**2**)[10] and benzo-[*ghi*]perylene-1,2-dicarboxylic anhydride (**6**)[6] were prepared and purified according to the procedures in the literature. Diethyl 1,2-dihydro-1,2-diazabenzo[*ghi*]perylene-1,2-dicarboxylate (**1**) and 1,2-diazabenzo[*ghi*]perylene (**8**) were prepared and purified by the methods reported previously.[5]

1,2-(Bis(ethoxycarbonyl)-1,2-dihydro-1,2-diazacoronene-7,8-dicarboxylic Anhydride (5). A mixture of **1** (212 mg, 0.50 mmol), chloranil (**4**, 369 mg, 1.50 mmol), and maleic anhydride (**3**, 1.45 g, 15 mmol) was heated under reflux for 20 min. The reaction mixture was then allowed to cool to about 80 °C, and 2 ml of xylene was added. After cooling, 10 ml of methanol was added and the resulting precipitate was filtered off to give 205 mg of crude **5**. Recrystallization from xylene afforded 158 mg of **5** as a reddish brown solid (61% yield): mp 305 °C (decomp); IR 3000 (ν_{C-H}^{arom}), 2950 (ν_{C-H}^{aliph}), 1840 ($\nu_{C=O}$), 1765 ($\nu_{C=O}$), 1730 ($\nu_{C=O}$), 1325 (ν_{C-O}), 1260 (ν_{C-O}),

845 cm^{-1} (δ_{C-H}); ^{1}H NMR δ 1.54 (t, 6H, J=7.3 Hz), 4.60 (q, 4H, J=7.3 Hz), 6.78 (d, 2H, J=9.1 Hz), 7.22 (d, 2H, J=9.1 Hz), 7.89 (d, 2H, J=8.8 Hz), 8.22 (d, 2H, J=8.8 Hz); MS *m/e* 518 (7%, M$^+$), 446 (10%), 445 (26%), 401 (20%), 373 (100%). Found: C, 69.93; H, 3.37; N, 5.73%. Calcd for $C_{30}H_{18}N_2O_7$: C, 69.49; H, 3.51; N, 5.40%.

1,2-Diazacoronene-7,8-dicarboxylic Anhydride (7). To a stirred benzyl alcohol (30 ml) solution of **5** (104 mg, 0.20 mmol) at 100 °C, sodium hydroxide pellets (93% pure, 260 mg, 6 mmol) were added in one portion. The stirring was continued at this temperature for 30 min. After cooling, the reaction mixture was acidified with concentrated hydrochloric acid. Evaporation of the mixture and trituration of the residue with methanol followed by filtration gave crude **7**, 74 mg (99%). Recrystallization from nitrobenzene or sublimation at 330—350 °C/20 mmHg† for 5 h gave yellowish brown fine needles of pure **7** (59% or 70% yield respectively): mp 400 °C (decomp); IR 3100 (ν^{arom}_{C-H}), 1840 ($\nu_{C=O}$), 1765 ($\nu_{C=O}$), 1290 (ν_{C-O}), 850 cm^{-1} (δ_{C-H}); ^{1}H NMR δ 9.68 (d, 2H, J= 8.8 Hz), 9.72 (m, 4H), 10.52 (d, 2H, J=8.8 Hz); MS *m/e* 372 (70%, M$^+$), 300 (65%), 272 (100%). Found: C, 77.30; H, 2.04; N, 7.28%. Calcd for $C_{24}H_8N_2O_3$: C, 77.41; H, 2.17; N, 7.53%.

1,2-Diazacoronene (9). Anhydride **7** (75.6 mg, 0.20 mmol) and soda lime (300 mg, Wako Pure Chemical Industries Ltd.) were powdered together and heated in a sublimation apparatus at 320 °C for 1 h. The apparatus was then evacuated (20 mmHg) and the temperature raised to 350 °C for 2 h. The sublimate (24 mg), recrystallized from bis(2-hydroxyethyl)ether, gave 1,2-diazacoronene in pale yellow needles, 16 mg (26% yield): mp 468— 470 °C (decomp); IR 3060 (ν^{arom}_{C-H}), 850 cm^{-1} (δ_{C-H}); ^{1}H NMR δ 8.62 (s, 2H), 8.82 (d, 2H, J=9.0 Hz), 8.91 (d, 2H, J=9.0 Hz), 9.10 (m, 4H); MS *m/e* 302 (74%, M$^+$), 274 (76%), 137 (100%); UV (in C_6H_6) λ_{max} (log ε) 437 (3.89), 413 (3.62), 321 (4.79), 308 (4.64). Found: C, 87.34; H, 3.14; N, 9.53%. Calcd for $C_{22}H_{10}N_2$: C, 87.39; H, 3.34; N, 9.27%.

† 1 mmHg=133.322 Pa.

The authors wish to express their sincere thanks to Emeritus Professor Osamu Simamura for the correction of this manuscript.

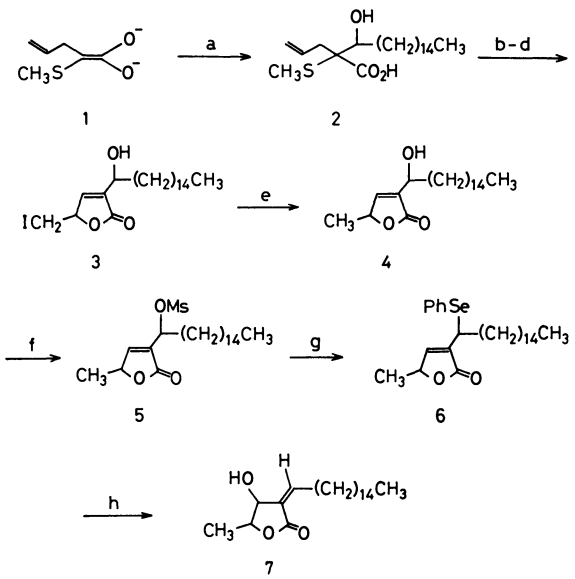
Synthesis of (±)-Dihydromahubanolide Using 2-Methylthio-4-pentenoic Acid Dianion

Kazuhiko TANAKA,* Makoto TERAUCHI, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 12, 1982)

Synopsis. A new and mild method for the synthesis of (±)-dihydromahubanolide has been developed by the use of 2-methylthio-4-pentenoic acid dianion.

The several compounds isolated from the Japanese Lauraceae, *Lindera obtusiloba Blume*[1] and *Litsea japonica*[2] have the basic skeleton of the 3-alkylidene-4-hydroxydihydro-2(3*H*)-furanone, identical with the lactones from the Amazonian Lauraceae, *Licaria mahuba*.[3] A great deal of effort has been devoted to the development of novel methods for the construction of 3-alkylidene-4-hydroxydihydro-2(3*H*)-furanone unit[4] and for the total synthesis of these lactones.[5]

Recently we reported that the dianion **1** derived from 2-(methylthio)-4-pentenoic acid can be used as a building block to furnish 5-methylene-2(5*H*)-furanone from alkyl halides or aldehydes under extremely mild reaction conditions.[6]



Scheme 1. (a) n-$C_{15}H_{31}CHO$, THF, −40 °C, 7 h. (b) KI-I_2, $NaHCO_3$, H_2O. (c) MCPBA, CH_2Cl_2, −78 °C, 30 min. (d) $CaCO_3$, toluene, reflux. (e) n-Bu_3SnH, AIBN, benzene, reflux. (f) MsCl, CH_2Cl_2, Et_3N. (g) PhSeNa, EtOH, −10 °C. (h) 30% H_2O_2, CH_3CN, −40 °C—r.t., 43 h.

We now report a new route to (±)-dihydromahubanolide, isolated from the Amazonian Lauraceae, *Licaria mahuba*[3] starting from the dianion **1**. The preparation of hydroxy acid **2** was accomplished by the reaction of **1** with 1.1 equiv. of hexadecanal in THF.[6] Iodolactonization, oxidation with *m*-chloroperbenzoic acid (MCPBA), and subsequent dehydrosulfenylation[7] proceeded smoothly to give 5-iodomethyl-2(5*H*)-furanone **3** in good overall yield from the hydroxy acid **2**. The furanone **3** is extremely sensitive to a base; on treatment of **3** with amine bases or even sodium hydrogencarbonate, the compound **3** gave 5-methylene-2(5*H*)-furanone in high yield.[6] Reduction of **3** with 2 equiv. of tributyltin hydride[5d] cleanly gave the 5-methyl-2(5*H*)-furanone **4** in 90% yield. The mesylate **5** was smoothly transformed by reaction in dichloromethane at 0 °C with 1.2 equiv. of methanesulfonyl chloride in the presence of 1.3 equiv. of triethylamine. Treatment of **5** with sodium benzeneselenolate[8] in ethanol at −10 °C for 2 h gave the selenide **6** in 70% yield. Rearrangement of **6** with 30% hydrogen peroxide[9] in dichloromethane afforded a mixture of (±)-dihydromahubanolide and (±)-dihydroisomahubanolide (*Z*/*E* ratio 67 : 33 in 52% yield). Enhancement in *Z*-selectivity and increase in yield were observed when the oxidation was carried out at −10 °C and the mixture was slowly warmed to room temperature (43 h).[9,10] The IR and 200-MHz ^{1}H-NMR spectra were identical with those of the published spectra.[2,3,5] Although the stereochemical relationship between CH_3 and OH groups is still uncertain due to the overlapping of methyl signals (doublet) of four isomers at 1.34—1.50 ppm region, the present method provides the efficient stereoselective synthesis of (*Z*)-3-alkylidene-4-hydroxy-2(3*H*)-furanones.

Experimental

2-(1-Hydroxyhexadecyl)-2-methylthio-4-pentenoic Acid (2): To a solution of lithium diisopropylamine (22 mmol) in THF (60 ml) was added a solution of 2-methylthio-4-pentenoic acid (**1**) (1.46 g, 10 mmol) in 5 ml of THF at −78 °C. The reaction mixture was stirred at −78 °C for 1 h, and warmed to −40 °C over 8 h. After the solution was cooled to −78 °C,

Table 1. Stereochemistry in rearrangement of selenide **6**

	Reaction conditions		Solvent	Yield of **7** %	*Z*/*E* ratio of **7**[a]
	Temp/°C	Time			
H_2O_2 (3 equiv.)	−10	15 min	CH_3CN	Trace	—
H_2O_2 (3 equiv.)	−10—r.t.	2 h	CH_3CN	63	71/29
H_2O_2 (3 equiv.)	−10—r.t.	43 h	CH_3CN	82	77/23
H_2O_2 (3 equiv.)	−10—r.t.	18 h	CH_2Cl_2	52	67/33
MCPBA (1 equiv.)	−78—r.t.	20 h	CH_2Cl_2	73	75/25

a) The *Z* and *E* assignments are based on the differences of ^{1}H-NMR chemical shift of olefinic protons.[10]

a solution of hexadecanal (2.62 g, 10.9 mmol) in 15 ml of THF was added dropwise. The solution was stirred at −78 °C to −40 °C for 7 h and then quenched with saturated aqueous ammonium chloride (10 ml). The mixture was allowed to warm to room temperature, and was extracted with ether (4×50 ml). From the combined extracts was obtained the crude product which was purified by column chromatography (silica gel; eluent hexane–acetone, 3 : 1) to give 3.12 g (81%) of **2** as viscous liquid: ^{1}H-NMR ($CDCl_3$) δ 7.02 (br, 2H COOH and OH), 5.50—6.30 (m, 1H, CH=C), 4.80—5.30 (m, 2H, CH_2=C), 3.60—4.16 (m, 1H, CH), 2.20—2.90 (m, 2H, CH_2), 2.13 (d, J=6 Hz, 3H, CH_3), 0.70—2.00 (m, 31H, CH_2 and CH_3).

*3-(1-Hydroxyhexadecyl)-5-iodomethyl-2(5H)-furanone (**3**)*: To a solution of **2** (3.00 g, 7.76 mmol) in water (60 ml) was added sodium hydrogencarbonate (1.96 g, 23.3 mmol), and stirring was continued at room temperature for 20 min. After a solution of iodine (1.97 g, 7.76 mmol) and potassium iodide (3.87 g, 23.3 mmol) in water (60 ml) was added over 1 h, the mixture was stirred at room temperature for 1 h, treated with 10% sodium thiosulfate solution (100 ml), and extracted with chloroform (4×50 ml). The combined organic layers were washed with brine, dried over anhydrous Na_2SO_4, and concentrated to give iodo lactone as an oil which was used without further purification. To a solution of this product (7.76 mmol) in dichloromethane (40 ml) at −78 °C was added a solution of MCPBA (1.68 g, 7.76 mmol) in dichloromethane (60 ml) over 20 min. After the addition was completed, the reaction mixture was stirred at −78 °C for 30 min, poured into water. The organic layer was dried over anhydrous Na_2SO_4 and concentrated to give an oil. The oil was dissolved in toluene (120 ml), and powdered calcium carbonate (1.16 g, 11.6 mmol) was added. After the mixture was heated at reflux for 30 min, the product was isolated in the usual manner to afford an 82% yield of **3** (2.59 g; unstable) as colorless crystals which were purified by column chromatography (silica gel, eluent benzene to chloroform); mp 35.0—36.0 °C: ^{1}H-NMR ($CDCl_3$) δ 7.02—7.36 (m, 1H, CH=C), 4.76—5.20 (m, 1H, CH), 4.28—4.64 (m, 1H, CH), 2.92—3.70 (m, 3H, CH_2 and OH), 0.70 (m, 31H, CH_2 and CH_3).

*3-(1-Hydroxyhexadecyl)-5-methyl-2(5H)-furanone(**4**)*: The mixture of **3** (1.86 g, 4 mmol), azobisisobutyronitrile (0.656 g, 4 mmol), and tributyltin hydride (2.32 g, 8 mmol) in benzene (40 ml) was heated at reflux for 2 h under argon. After cooling, the mixture was poured onto 10% hydrochloric acid (50 ml), and extracted with benzene (4×50 ml). The combined extracts were washed with brine, dried over anhydrous Na_2SO_4, and concentrated. Chromatography on silica gel (eluent hexane–ether, 5 : 1 to ether) gave **4** in 91% yield (1.23 g); ^{1}H-NMR ($CDCl_3$) δ 7.14—7.30 (m, 1H, CH=C), 4.80—5.08 (m, 1H, CH), 4.32—4.52 (m, 1H, CH), 2.60—3.00 (m, 1H, OH), 0.70—1.90 (m, 34H, CH_2 and CH_3). IR (Nujol) 3400 (OH), 1740, 1720 (C=O) cm^{-1}. MS (20 eV) *m/e* 338 (M^+), 320 ($M^+ - H_2O$). Preparative TLC on silica gel (Merck 60-F254s; hexane–ethyl acetate, 4 : 1) gave an analytical sample as colorless plates; mp 78—80 °C. Found: C, 74.03; H, 11.18%. Calcd for $C_{21}H_{38}O_3$: C, 74.51; H; 11.31%.

*5-Methyl-3-[1-(phenylseleno)hexadecyl]-2(5H)-furanone (**6**)*: To a solution of **4** (1.26 g, 3.73 mmol) in dichloromethane (30 ml) was added triethylamine (0.49 g, 4.85 mmol) at 0 °C, and the mixture was stirred for 10 min under argon. After the addition of methanesulfonyl chloride (0.50 g, 4.40 mmol) was completed, the mixture was stirred at 0 °C for 3 h. The usual workup gave mesylate **5** in 90% yield (1.39 g). To a solution of sodium benzeneselenolate prepared from diphenyl diselenide (0.255 g, 0.750 mmol) and sodium borohydride (0.057 g, 1.50 mmol) in ethanol (30 ml) was added at −10 °C the mesylate **5** (0.417 g, 1 mmol) in ethanol (10 ml). After the mixture was stirred for 2 h at −10 °C, the solution was poured onto dilute hydrochloric acid and extracted with ether (4×30 ml). The ethereal extracts were washed with brine, dried over anhydrous Na_2SO_4, and concentrated. Chromatography on silica gel first with hexane and then with benzene as eluent gave 0.335 g of **6** in 70% yield: ^{1}H-NMR ($CDCl_3$) δ 7.12—7.52 (m, 5H, CH, and aromatic), 6.44—6.60 (m, 1H, CH=C), 4.50—4.92 (m, 1H, CH), 3.74—4.04 (m, 1H, CH), 0.70—1.92 (m, 34H, CH_2 and CH_3). IR (Nujol) 1740 (C=O), 1680 (C=C), 745, 725, 695 cm^{-1}. Preparative TLC on silica gel (hexane–ethyl acetate, 3 : 1) gave an analytical sample as pale yellow crystals; mp 45—47 °C. Found: C, 67.61; H, 8.98%. Calcd for $C_{27}H_{42}O_2Se$: C, 67.90; H, 8.87%.

*(±)-Dihydromahubanolide (**7**)*: To a solution of **6** (0.33 g, 0.69 mmol) in acetonitrile (30 ml) was added at −10 °C 30% H_2O_2 (0.178 g, 1.57 mmol). The mixture was slowly warmed to room temperature (43 h) with stirring. The usual workup gave **7** in 82% yield (0.19 g) as a ratio of 77 : 23 of *Z*/*E* mixture. The analytical sample was obtained by silica gel column chromatography (hexane–ethyl acetate, 2 : 1); mp 39.0—50.0 °C (broad). TLC analysis (Merck silica gel plate 60-F254; hexane–ethyl acetate, 3 : 1) indicated a single spot (R_f=0.25). IR (nujol) 3400 (OH), 1740 (C=O), 1675 (C=C) cm^{-1}. MS (20 eV) *m/e* 338 (M^+), 320 ($M^+ - H_2O$). Found: C, 74.32; H, 11.56%. Calcd for $C_{21}H_{38}O_3$: C, 74.51; H, 11.31%.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 57118004). We also express our appreciation to Professor John A. Katzenellenbogen of University of Illinois for supplying ^{1}H-NMR (200 MHz) and IR spectra of (±)-dihydroisomahubanolide and other Lauraceae lactones.

11) The 200 MHz ^{1}H-NMR analysis showed a mixture of (±)-dihydrmabubanolide A and B. However, the cis and trans ratio was not determined by 200 MHz ^{1}H-NMR due to the fact that they could not be separated by preparative TLC.

Facile Conversion of Thiosulfinic *S*-Ester to Sulfinic Ester

Toshikazu TAKATA and Shigeru OAE*
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received May 7, 1982)

Synopsis. Thiosulfinic *S*-esters are readily converted to the corresponding sulfinic eaters in good yields by treating in alcohols with a catalytic amount of I_2, Br_2, or HCl in the presence of H_2O_2, replacing sulfenyl groups by alcohols. The mechanism of this reaction is also discussed.

Thiosulfinic *S*-esters (thiolsulfinates) have generally been considered to be unstable and to disproportionate readily.[1] Meanwhile, thiolsulfinates were shown by us to be selectively oxidized with $NaIO_4$ to the corresponding stable thiosulfonic *S*-esters (thiolsulfonates) in nearly quantitative yields. In the oxidation in aqueous alcohols, however, considerable amounts of the corresponding sulfinates were also obtained as by-products. Yields of the sulfinates were high with primary alcohols but low with tertiary alcohols.[2] We have studied on the reaction to form the alkyl sulfinates in connection with our investigation on the mechanism of the selective oxidation of the thiolsulfinates.

This paper describes facile transformation of thiolsulfinates to the corresponding stable sulfinates by replacing sulfenyl groups with alcohols, in the treatment with catalytic I_2, Br_2, or HCl in appropriate alcohols in the presence of H_2O_2. Therefore, this transformation would be quite useful for elucidation of the structure of the original thiolsulfinate and also for estimation of the amount of the unstable thiolsulfinate.

When an unsymmetrical thiolsulfinate (**1**, 1.0 mmol) was treated with a small amount of I_2, Br_2, or HCl (3—40 mg, see Table 1) in excess alcohol (5—10 ml) as a solvent at r.t., the sulfinate **2**, in which the sulfenyl group is replaced by the alcohol used, was readily (within 2 h) obtained in 61—70% yields, along with considerable amounts of disulfides (**3** and **4**) (Eq. 1). Yields of the products were determined by GLC and NMR. When acetonitrile was used as a solvent instead of alcohol, thiolsulfinate disappeared more readily

$$\underset{\underset{\underset{\mathbf{1}}{}}{}}{\overset{\overset{\overset{\mathrm{RSSR'}}{\downarrow}}{\mathrm{O}}}{}} \xrightarrow[\mathrm{R''OH}]{\mathrm{Cat.(XY)}} \underset{\underset{\underset{\mathbf{2}}{}}{}}{\overset{\overset{\overset{\mathrm{RSOR''}}{\downarrow}}{\mathrm{O}}}{}} + \underset{\mathbf{3}}{\mathrm{R'SSR'}} + \underset{\mathbf{4}}{\mathrm{RSSR'}} \qquad (1)$$

$$\mathrm{XY} = \mathrm{I_2}, \mathrm{Br_2}, \mathrm{HCl}$$

than in alcohol, but afforded the disproportionation products (a mixture of disulfides and thiolsulfonates).

When an equimolar or excess amount of H_2O_2 was added into the reaction system besides the catalyst, the yield of **2** increased dramtically (entries 10—12), and the formation of unsymmetrical disulfide (**4**) was markedly reduced. Thus, the thiolsulfinate **1** was readily transformed to the corresponding stable sulfinate **2** in high yield (Eq. 2).

$$\mathbf{1} \xrightarrow[\mathrm{R''OH,r.t.,}\ <2\ \mathrm{h}]{\mathrm{Cat.(XY)},\ \mathrm{H_2O_2}} \mathbf{2} + \mathbf{3} \qquad (2)$$

These observations in addition to the previous results[2] seem to indicate that the reaction involves incipient formation of sulfinyl halide (RS(O)Y) which is derived by the reaction with the catalyst (XY), as shown in Scheme 1. The resulting mixture of RS(O)Y and R'SX then would react much more readily with a large excess of alcohol than with **1** to afford **2** and thiol (R'SH) which is capable of reducing **1** to give two disulfides (**3** and **4**).[3] However, in the *presence* of H_2O_2 R'SH is quickly oxidized to R'SSR' which no longer has the reducing ability. Therefore, the increase of

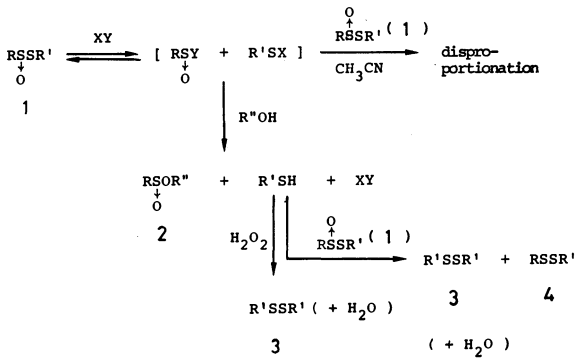
a) Thiolsulfinate (*ca.* 1 mmol) was used as a substrate and the procedure is shown in Experimental section. b) The amount of 30% H_2O_2 is based on that of the substrate. c) Yields are determined on the basis of the amount of the substrate. d) A disproportionation product, $RS(O)_2SR$, was also obtained. e) Not determined. f) The yield could not be determined.



Scheme 1.

the yield of **2** by addition of H_2O_2[4] can be attributed to the decrease of the reductant R'SH, by the oxidation of R'SH to the unreactive disulfide (R'SSR') with H_2O_2.

The disproportionation rate of **1** in CH_3CN in the presence of halogen or hydrogen halide (XY) was faster than the rate of the formation of **2** in alcohol in the presence of both XY and H_2O_2. However, the disproportionation hardly occured in alcohol in which the formation of **2** must predominate over the disproportionation. Namely, the amount of alcohol used was in large excess so that RS(O)Y reacts much more easily with alcohol to form **2** than with **1** to disproportionate. The amount of solvent alcohol did not affect the yield of **2** (entries 1—3) and therefore, it is not necessary to use a very large amount of the alcohol.

This scheme is in good accordance with the data shown in Table in which the yield of **2** was rarely affected by the change of the bulkiness of alcohols used. This result is quite different from that in the oxidation of **1** with $NaIO_4$ in aqueous alcohol,[2] and it may be explained by assuming that RS(O)Y reacts only with the alcohol. Meanwhile, other catalysts such as H_2SO_4 and $HClO_4$ were found not to be effective enough to catalyze the reaction (entries 8 and 9), suggesting that RS(O)Y cannot be formed by the interaction with such catalysts in which the counter anions possess very little nucleophilicity. At lower temperatures, the reaction of RS(O)Y with alcohol to the sulfinate may slightly predominate over that with **1** to form the disproportionation products (entry 6). Change of the amount of H_2O_2 added (1—10 equiv.) did affect little the yield of **2** in the reaction of *S-p*-tolyl benzenethiosulfinate in EtOH. Similarly, the change of the amount of iodine (2.5—12.5%) as a catalyst also affected rarely the yield of **2** while the reaction time was shortened with increase of the amount of iodine. Iodine may be a better catalyst than HCl because of its easy handling and product selectivity. With hydrochloric acid the solution becomes acidic and may promote both the hydrolysis of the sulfinate formed with water present and the oxidation with H_2O_2.[4]

Thus, a new route of transformation of unstable thiolsulfinate to stable sulfinate has been found and is expected to be used as a facile method.

Experimental

General Procedure for Conversion of Thiosulfinic S-Ester to Sulfinic Ester: To an alcohol solution (10 ml) of thiosulfinic *S*-ester (*ca.* 1.0 mmol) in a 30 ml Erlenmeyer flask, 30% H_2O_2 (*ca.* 1.0 mmol) and 2.5 mg of solid iodine were added to initiate the reaction. The mixture was stirred at r.t. for 1—2 h. An aliquot of the reaction mixture was withdrawn and injected to GLC to determine the yields of the products. The structures and the yields of the products were also confirmed by NMR spectra of organic layer which was obtained by extracting the reaction mixture with $CHCl_3$, followed by usual work-up. The sulfinates thus obtained were identified by comparison of their retention times in GLC charts and then NMR spectra with those of the authentic samples prepared independently.[5,6] Purification of the sulfinate was carried out by column chromatography in which the residue after evaporation of $CHCl_3$ of the organic extract was eluted on silica gel by using hexane and then benzene or benzene as a sole solvent. The first fraction was a mixture of disulfides and the second was the sulfinate.

All thiosulfinic *S*-esters were prepared by the reported method.[7,8] S-*Phenyl Benzenethiosulfinate*: mp 69—70 °C (lit,[7] 69—70 °C), S-p-*Tolyl Benzenethiosulfinate*: mp 52 °C (lit,[7] 54 °C), S-*Phenyl* p-*Toluenethiosulfinate*: mp 78—80 °C (lit,[7] 76 °C), S-*Ethyl Benzenethiosulfinate*:[9] Colorless oil, NMR (δ, $CDCl_3$) 1.44 (t, 3H, CH_3, J=7.1 Hz), 3.13 (q, 1H, H_A or H_B of CH_2, J=7.1 Hz), 3.16 (q, 1H, H_B or H_A, J=7.1 Hz), 7.38—7.80 (m, 5H, arom); IR (neat, cm^{-1}) 3050, 2970, 2920, 1575, 1473, 1440, 1085 (S=O).

Authentic sulfinates were all known and prepared by the reactions of sulfinyl chlorides and excess alcohols.[5,6] Physical and spectroscopic data of these sulfinates were well consistent with their structures.

Photolyses of [2-Substituted 2-(alkoxycarbonyl)propyl]cobaloximes

Masaru TADA,* Shiro AKINAGA, and Masami OKABE
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received May 12, 1982)

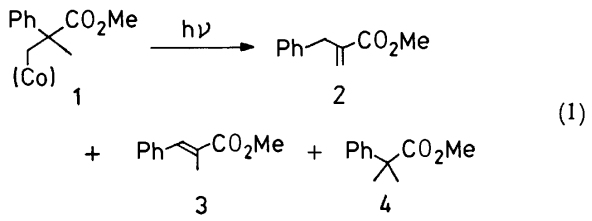
Synopsis. Photolysis of (2-methoxycarbonyl-2-phenylpropyl)cobaloxime (**1**) gives two phenyl-migrated products, methyl 2-methylene-3-phenylpropanoate and methyl *trans*-2-methyl-3-phenylpropenoate, and a hydrogen-abstracted product, methyl 2-methyl-2-phenylpropanoate. The alkoxycarbonyl groups do not migrate in the photolysis of either **1** or [2,2-bis(ethoxycarbonyl)propyl]cobaloxime.

Coenzyme B_{12}, 5'-deoxyadenosylcobalamin, is involved in 1,2-migration of the thioester group in an enzymatic system.[1] It is well known that organo-bis(dimethylglyoximato)(pyridine)cobalt(III), *R*-(Co) (organo-cobaloxime hereafter), is a good model compound of organo-cobalamin.[1] Photolysis of an organocobaloxime generates an organic radical and paramagnetic cobaloxime[2] which must be a reasonable mimicry of a pair of a substrate radical and paramagnetic cobalamin in an enzymatic system.[1]

In our previous studies[3,4] we photolyzed organocobaloximes having an acyl group at the β-position of the alkyl group attached to the cobalt atom, and observed acyl-migration in preference to alkyl, phenyl, and alkoxycarbonyl groups. This paper reports photolyses of [2-substituted 2-(alkoxycarbonyl)propyl]cobaloximes carried out to examine the migration ability of alkoxycarbonyl groups.

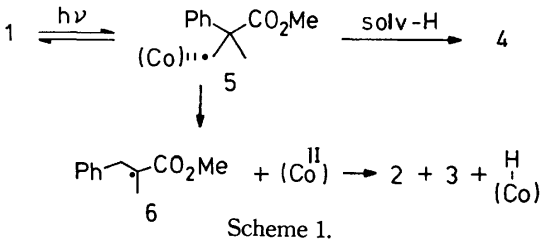
Results and Discussion

Photolysis of (2-methoxycarbonyl-2-phenylpropyl)-cobaloxime (**1**) gave methyl 2-methylene-3-phenylpropanoate (**2**), methyl *trans*-2-methyl-3-phenylpropenoate (**3**), and methyl 2-methyl-2-phenylpropanoate (**4**) (Eq. 1); the results are summarized in Table 1.



(1)

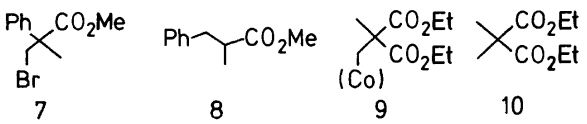
These results show that the phenyl group migrates in preference to the methoxycarbonyl group, and that no migration of the ester group takes place. The photolysis of **1** in chloroform is faster than in dichloromethane, which in turn is faster than in benzene. This indicates that the photolysis rate is dependent on the hydrogen-donating ability of the solvents. Since the formation of **2**, **3**, and **4** competes with the recombination of the radical pair **5** (Scheme 1), the faster rate of photolysis of **1** in chloroform is accounted for in terms of the faster hydrogen abstraction of **5**. The phenyl group migration is likewise competitive with the hydrogen abstraction. Thus, the photolysis of **1** in chloroform, a strong hydrogen donor,[5] gave only hydrogen-abstracted product **4**. On the other hand, the photolysis in benzene, having hardly any ability of hydrogen donation, gave only the phenyl-migrated products **2** and **3**.



Scheme 1.

The formation of the product having a methylene group is common in the photolysis of (2,2-disubstituted propyl)cobaloximes.[4] This is interpreted in terms of the steric hindrance on the hydrogen abstraction from **6** by cobaloxime(II).

The methoxycarbonyl group did not migrate in the reaction of the corresponding bromide **7** with tributyltin hydride. The reaction gave **4** and methyl 2-methyl-3-phenylpropanoate (**8**) formed by the radical migration of the phenyl group; **4** : **8**=77 : 23 (Bu_3SnH, 0.01 mol dm^{-3}) and 19 : 81 (Bu_3SnH, 0.001 mol dm^{-3}).



The product composition depends on the concentration of tributyltin hydride, and this result shows that the direct hydrogen capture of the intermediate radical from tributyltin hydride competes with the radical rearrangement of the phenyl group.

Bildingmaier *et al.*[6] reported that the photochemical decomposition of [2,2-bis(ethoxycarbonyl)propyl]cobaloxime (**9**) gave diethyl methylsuccinate without reproducibility, *via* the migration of the ethoxycarbonyl group, and diethyl dimethylmalonate (**10**). However, we did not detect the migrated product in the photolyses of **9** after several trials even under the same conditions as reported by Bildingmaier *et al.*[6] On a photolysis of **9** in the same procedure as for the photolysis of **1** for

TABLE 1. PHOTOLYSIS OF ORGANO-COBALOXIME **1**

Solvent	Product yield/%[a]		
	2	**3**	**4**
$CHCl_3$	Trace	0	84
CH_2Cl_2	21	15	30
C_6H_6	8	16	Trace

a) Yields after irradiation for 4 h (see Experimental section). Material balance was kept fairly well as examined on the basis of starting material.

90 min, **9** gave **10** in 100% (chloroform), 82% (dichloromethane), 34% (ethanol), and 18% (acetonitrile) yields. The photolysis in benzene gave diethyl benzylmethylmalonate (**11**) in addition to **10** only in low yield. Material balance was kept fairly well as examined on the basis of the residual starting cobaloxime **9**. The rate of the photolysis thus depends on the hydrogen-donating ability of the solvent.[5]

In conclusion the photolyses of [2-substituted 2-(alkoxycarbonyl)propyl]cobaloximes **1** and **9** cause no migration of the alkoxycarbonyl groups. The ester group seems to have the least or no ability for the radical rearrangement. Thus no ester group is any good mimicry of the (alkylthio)carbonyl group in methylmalonyl-CoA. Study on the migration property of the (alkylthio)carbonyl group is currently under way at our laboratory.

Experimental

The Preparation of Methyl 3-Bromo-2-methyl-2-phenylpropanoate (7). To a suspension of sodium hydride (55% oil dispersion) (1.86 g, 21.5 mmol) in 20 cm^3 of anhydrous 1,2-dimethoxyethane was added a solution of methyl 2-phenylproanoate (3.54 g, 21.5 mmol) in 5 cm^3 of anhydrous 1,2-dimethoxyethane under N_2. After the mixture had been refluxed for 5 h, excess dibromomethane (5 cm^3, 70 mmol) was added dropwise. The reaction mixture was refluxed for 15 h, cooled to room temperature, neutralized with acetic acid, and evaporated. After addition of water (50 cm^3) to the residue, the mixture was extracted with ether (50 $cm^3 \times 3$). The combined etheral extracts were washed with water and dried over anhydrous sodium sulfate. After removal of the solvent the residue was distilled under reduced pressure to give 2.96 g (54%) of methyl 3-bromo-2-methyl-2-phenylpropanoate (**7**), bp 84—87 °C/1070 Pa. Found: C, 51.35; H, 5.11%. Calcd for $C_{11}H_{13}BrO_2$: C, 51.38; H, 5.10%. IR (CCl_4) 1740 and 699 cm^{-1}; ^{1}HNMR (CCl_4) $\delta=1.77$ (s, 3H), 3.68 (d, 1H, $J=10$ Hz), 3.77 (s, 3H), 4.11 (d, 1H, $J=10$ Hz), and 7.50 (s, 5H).

The Preparation of (2-Methoxycarbonyl-2-phenylpropyl)cobaloxime (1). The organo-cobaloxime **1** was prepared from the bromide **7** (10 mmol) and cobaloxime (I) (15 mmol) in methanol (30 cm^3) in the conventional manner.[7] Recrystallization from methanol yielded pure **1** (70%), mp 120 °C (decomp). Found: C, 53.09; H, 5.69; N, 12.67%. Calcd for $C_{24}H_{32}N_5O_6Co$: C, 52.85; H, 5.91; N, 12.84%. IR ($CHCl_3$) 1711, 1560, 1450, and 1084 cm^{-1}; ^{1}H NMR ($CDCl_3$) $\delta=1.67$ (s, 3H), 1.86 (d, 1H, $J=10$ Hz), 1.97 (s, 6H), 2.03 (s, 6H), 2.75 (d, 1H, $J=10$ Hz), 3.63 (s, 3H), 7.30—7.65 (m, 7H), 7.78—8.00 (m, 1H), and 8.70—8.85 (m, 2H).

The Photolysis of the Organo-cobaloxime 1. A solution of the organo-cobaloxime **1** (6×10^{-3} mol dm^{-3}) in an appropriate solvent (see Table 1) was placed in a Pyrex tube and immersed in an ultrasonic bath with argon bubbling from a syringe needle for 30 min. The solution was then irradiated externally for 4 h with a 450-W high pressure Hg lamp mounted in a rotary irradiation apparatus (Rikosha RH-400), the distance between the lamp and the reaction tube being *ca.* 5 cm. The reaction mixture was condensed and the residue was placed on a Florisil column and eluted with chloroform to give methyl 2-methylene-3-phenylpropanoate (**2**),[8] methyl *trans*-2-methyl-3-phenylpropenoate (**3**),[9] and methyl 2-methyl-2-phenylpropanoate (**4**).[10] Elution with chloroform–ethyl acetate (1 : 1) gave the residual starting organo-cobaloxime. The results are summarized in Table 1. The products **2**, **3**, and **4** were identified by comparison with authentic samples.

The Reaction of the Bromide 7 with Tributyltin Hydride. A mixture of tributyltin hydride (1.6 mmol), the bromide **7** (0.4 mmol), and AIBN (trace) in benzene (160 cm^3) was refluxed for 4 h under N_2. A concentrate of the reaction mixture was passed through a short column of silica gel with chloroform and further purified by preparative TLC (silica gel) using benzene. The products were **4** and methyl 2-methyl-3-phenylpropanoate (**8**) (**4** : **8**=77 : 23, 75% yield). The product **8** was identified by comparison with an authentic sample.[11]

Rearrangement of *vic*-Diol Monoacetates Promoted by Organoaluminium Compounds

Shigekazu KANEMOTO, Yoshitomi MORIZAWA, Koichiro OSHIMA,* and Hitosi NOZAKI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received May 27, 1982)

Synopsis. Treatment of pinacol monoacetate with organoaluminium reagent R_3Al caused the rearrangement under uptake of R as a nucleophile on the resulting carbonyl carbon, while R_2AlSPh produced the pinacolone itself upon workup.

Lewis acid catalysis of Diels-Alder reaction[1] or ene reaction[2] has been recently well documented. We have reported that the common Lewis acids such as $TiCl_4$ and $BF_3 \cdot OEt_2$ failed to catalyze the aliphatic Claisen rearrangement, meanwhile amphoteric organoaluminium compounds facilitated the rearrangement.[3] Another application of this new strategy with combined acid-base attack of organoaluminium reagent to the pinacol rearrangement[4] has been studied.

Treatment of pinacol monoacetate **1** with $Et_2AlC{\equiv}CPh$ in hexane provided alcohol **2** which was produced apparently by the rearrangement and successive alkynylation. Hexane, benzene, and dichloromethane were equally effective as the solvents. In ether or THF no rearrangement was observed.

Table 1 summarizes the reaction between *vic*-diol monoacetates and organoaluminium compounds. Epoxide **7** has afforded a rearranged product as *vic*-diol monoacetate (Entry 4). The reagent Et_2AlSPh has been found to be effective for the rearrangement to give ketones without introduction of a nucleophile.

It is worth noting that this new method can be used to change the nature of rearrangement from that expected in a strong acid-catalyzed reaction of the corresponding glycol. In the case of a glycol, $Ph_2C(OH)-CH(Me)-OH$, that contains one secondary and one tertiary hydroxyl, the secondary hydroxyl group could be selectively acetylated and removed preferentially upon treatment with organoaluminium compound (Entry 6 and 7). In contrast, the tertiary hydroxyl was exclusively removed to give $Ph_2CHC(O)Me$ (**13**) under sulfuric acid-catalyzed conditions.

A glycol monoacetate, $PhC(Me)(OH)-CH_2OAc$, that contains a tertiary hydroxyl and a primary acetate did not give any rearranged products on treatment with Et_2AlSPh. Benzenethiolate attacked carbonyl carbon

of the acetate to provide the original diol.

Experimental

Infrared spectra were determined on a Shimadzu IR-27-G spectrometer, mass spectra on a Hitachi M-80. NMR spectra were recorded on a Varian EM-390H spectrometer using TMS as an internal standard. Microanalysis was performed at the Elemental Analyses Center of Kyoto University. All the experiments were carried out under an argon atmosphere. Purification of the product was performed by preparative thin layer chromatography (TLC) or column chromatography on silica gel (Merck Kiesel Gel 60).

Preparation of Diol Monoacetates ***1***[5] *and* ***4***: The title compounds were prepared by acetylation of the corresponding diols with acetic anhydride in the presence of 4-dimethylaminopyridine.[6]

Reaction between Pinacol Monoacetate ***1*** *and* $Et_2AlC{\equiv}CPh$: Butyllithium (1.6 M, 1.75 ml, 2.8 mmol) was added to a solution of phenylacetylene (0.21 g, 3.0 mmol) in benzene (2.0 ml) at 0 °C under an argon atmosphere. A solution of Et_2AlCl in hexane (1.0 M, 2.8 ml, 2.8 mmol) was added to the resulting suspension and the whole was stirred for 30 min at 25 °C. A solution of pinacol monoacetate **1** (0.16 g, 1.0 mmol) in benzene (2.0 ml) was added dropwise and the resulting mixture was stirred at 25 °C for 1 h, then at 80 °C for an additional 0.5 h. The mixture was diluted with dichloromethane (30 ml) and successively treated with NaF[7] (1.8 g) and water (0.6 ml). Vigorous stirring of the resulting suspension was continued at 25 °C for 0.5 h. The semi-solid was filtered and the remaining solid was washed with ether (3×10 ml). The combined filtrate and washings were dried (Na_2SO_4) and concentrated *in vacuo*. The residue was submitted to preparative TLC (hexane : ethyl acetate=5 : 1) to give the rearranged product **2** (0.13 g, 62% yield) as a yellow oil: bp 103—107 °C (bath temp, 133 Pa); IR (neat) 3450, 2980, 1495, 1375, 1135, 900, 750, 685 cm^{-1}; NMR (CCl_4) δ 1.08 (s, 9H), 1.45 (s, 3H), 7.06—7.49 (m, 5H). Found: C, 83.32; H, 9.18%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%.

3,4,4-Trimethyl-1-trimethylsilyl-1-pentyn-3-ol (***3***): Bp 100 °C (bath temp, 1995 Pa); IR (neat) 3475, 2980, 2180, 1368, 1259, 1160, 842, 759 cm^{-1}; NMR (CCl_4, benzene as an internal standard) δ 0.08 (s, 9H), 0.93 (s, 9H), 1.27 (s, 3H), 1.70 (bs, 1H). The compound **3** was treated with potassium fluoride in *N,N*-dimethylformamide[8] to give 3,4,4-trimethyl-1-pentyn-3-ol whose IR and NMR spectra were identical with those reported.[9]

2,2-Dimethyl-1-(phenylethynyl)cycloheptanol (***5***): Bp 135—137 °C (bath temp, 133 Pa); IR (neat) 3470, 2940, 1600, 1497, 1448, 993, 750, 688 cm^{-1}; NMR (CCl_4) δ 1.06 (s, 3H), 1.13 (s, 3H), 1.3—2.3 (m, 10H), 7.1—7.5 (m, 5H). Found: *m/e* 242.1750. Calcd for $C_{17}H_{22}O$: M, 242.1668.

2-(1-Methylcyclohexyl)-4-phenyl-3-butyn-2-ol (***6***): Bp 140 °C (bath temp, 133 Pa); IR ($CHCl_3$) 3300, 2925, 1595, 1490, 1105, 895 cm^{-1}; NMR (CCl_4) δ 1.03 (s, 3H), 1.46 (s, 3H), 1.2—2.5 (m, 10H), 7.12—7.67 (m, 5H). Found: *m/e* 242.1668. Calcd for $C_{17}H_{22}O$: M, 242.1668.

Reaction between 2,3-Diphenyl-2,3-epoxybutane (***7***) *and* Me_3Al: A mixture of **7** (0.13 g, 0.58 mmol) and Me_3Al (1.0 M hexane solution, 2.9 ml, 2.9 mmol) in hexane was heated at reflux for 1 h. The resulting mixture was worked-up as described above and the purification by preparative TLC gave alcohol **8** (97 mg, 69% yield) as an oil: bp 150 °C (bath temp, 133 Pa); IR (neat) 3560, 2990, 1600, 1497, 1023, 742, 698 cm^{-1}; NMR (CCl_4) δ 1.3 (s, 6H), 1.05 (s, 3H), 7.0—7.45 (m, 10H). Found: *m/e* 240.1434. Calcd for $C_{17}H_{20}O$: M, 240.1512.

Preparation of 2-Acetoxy-1-phenylcyclohexanol (***9***): Treatment of 1-phenylcyclohexene (4.0 g, 25 mmol) with *N*-methylmorpholine *N*-oxide (4.0 g, 26 mmol) in the presence of OsO_4 (76 mg, 0.3 mmol) according to the reported procedure[10] gave 1-phenyl-1,2-cyclohexanediol (2.9 g, 60% yield) which was transformed into monoacetate with acetic anhydride in pyridine quantitatively.

2-Phenylcyclohexanone: Benzenethiol (0.28 g, 2.5 mmol) was added dropwise to a solution of triethylaluminium (1.0 M hexane solution, 2.5 ml, 2.5 mmol) in hexane (3.0 ml) at 0 °C. After stirring for 30 min, a solution of monoacetate **9** (0.12 g, 0.5 mmol) in dichloromethane (2.0 ml) was added to the resulting solution at 0 °C and the mixture was stirred for another 30 min at 0 °C. Workup followed by purification by preparative TLC afforded a title compound as white crystals which was spectrometrically identical with an authentic sample.[11]

2-Phenylpropiophenone (***12***) *and 1,1-Diphenyl-2-propanone* (***13***): Reaction between diol monoacetate **11** (0.14 g, 0.5 mmol) and Et_2AlSPh (2.5 mmol) gave two isomeric ketones **12** and **13** (**12**/**13**=3/1) which were spectrometrically identical with authentic samples.[5,12]

Sulfuric Acid-catalyzed Rearrangement of Ph_2COH–$CH(Me)OH$: Two drops of concentrated sulfuric acid (≈40 mg) was added to a solution of diol (76 mg, 0.33 mmol) in dichloromethane (2.0 ml) at 25 °C and the whole was stirred for 15 min. Workup (ether, $NaHCO_3$) and purification gave methyl ketone **13** (56 mg, 80% yield) as a single product.

1,3,4-Triphenyl-1-pentyn-3-ol (***14***): Bp 167—168 °C (bath temp, 133 Pa); IR (neat) 3430, 3070, 2990, 2945, 2245, 1600, 1500, 1450, 1270, 1122, 757, 700 cm^{-1}; NMR (CCl_4) δ 1.24 (d, J=6.0 Hz, 3H), 4.38—4.78 (m, 1H), 6.87—8.22 (m, 15H). Found: C, 88.65; H, 6.32%. Calcd for $C_{23}H_{20}O$: C, 88.43; H, 6.45%.

Financial support from the Asahi Glass Foundation for Industrial Technology is acknowledged. We are grateful to Nippon Aluminum Alkyls, Ltd., for a gift of Et_2AlCl and Me_3Al.

Reinvestigation of the Pd-catalyzed Reaction of Azidoformate with Allylic Ethers

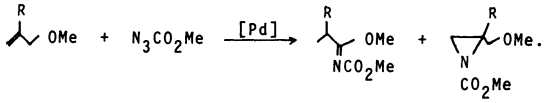
Toshihiko MIGITA,* Mitsuo CHIBA, Katsuyuki TAKAHASHI, Nobuhiro SAITOH, Setsuko NAKAIDO, and Masanori KOSUGI

Department of Chemistry, Faculty of Technology, Gunma University, Tenjin-cho, Kiryu, Gunma 376

(Received May 31, 1982)

Synopsis. The most effective catalyst for leading reaction between azidoformate and allylic ethers to formation of 1-alkoxy-1-(alkoxycarbonylimino)alkane is $PdCl_2(PhCN)_2$; $Pd(PPh_3)_4$ can hardly show catalytic activity when pure reactants are employed.

Our previous report[1] showed that allylic ethers react with azidoformate in the presence of tetrakis(triphenylphosphine)palladium, $Pd(PPh_3)_4$, to give *N*-alkoxycarbonyl imines besides aziridines:



R: H, Me

During a further investigation on the scope and limitation or mechanism of the reaction, some problems were found with respect to the reproducibility of the yield of the imine. Careful surveys to establish reaction conditions revealed that impurities in the reactants, *e.g.*, chloroformate in azidoformate and allyl chloride in allyl ether, affected seriously the yield of the imine, and that dichlorobis(benzonitrile)palladium, $PdCl_2(PhCN)_2$, was a much more effective catalyst than $Pd(PPh_3)_4$ if well refined reactants were used.

Table 1 shows the effect of chloroformate added to a mixture of well refined azidoformate and allylic ethers free of the corresponding allylic chlorides, on the yield of the imines from the reaction carried out at 80 °C for 20 h in the presence of $Pd(PPh_3)_4$. When pure reactants were employed, $Pd(PPh_3)_4$ could hardly promote the formation of imines, and considerable amounts of azidoformate were recovered. However, the presence of a slight amount (1 mol%) of chloroformate enhanced the yield of imine.

This fact suggests that the species effective as a catalyst is not of Pd(0) but of Pd(II), since chloroformate may oxidatively add to Pd(0). Then, catalytic efficiencies of several Pd(II) complexes were examined for the reaction of azidoformate with 2-methyl-2-propenyl ether, which was found to be a better substrate for imine formation than allyl ether. Among the complexes examined, $PdCl_2(PhCN)_2$ was particularly effective, while $Pd(acac)_2$ and $Pd(OAc)_2$ were poor catalysts as shown in Table 2.

The substrate allylic ethers also should be well refined; particularly they should be free of allylic chlorides from which the ethers have been prepared. Table 3 shows that the presence of a small amount of allyl chloride remarkably retards the formation of imine, even with $PdCl_2(PhCN)_2$ used as a catalyst, the reason for the retardation being not yet made clear.

In conclusion, the reaction between allylic ether and azidoformate is led to form *N*-alkoxycarbonyl imines by the presence of catalytic amounts of $PdCl_2(PhCN)_2$ but hardly by $Pd(PPh_3)_4$. The previous observation[1] on the catalytic effect of $Pd(PPh_3)_4$ must have resulted from the presence of small amounts of impurities in the reactants, perhaps chloroformate from which the azidoformate was prepared.

Table 1. The effect of chloroformate on the reaction of azidoformate with allylic ethers in the presence of $Pd(PPh_3)_4$[a]

Substrate	$ClCO_2CH_3$ (mmol)	Yields of products/%[b] Imine	Aziridine
$CH_2{\equiv}CHCH_2OCH_3$	0	0	24
	0.02	28	—
	0.04	40	18
	0.04[c]	37	4
$CH_2{=}C(CH_3)CH_2OCH_3$	0.04	63	28

a) $N_3CO_2CH_3$ (2 mmol), $Pd(PPh_3)_4$ (0.02 mmol) in allylic ether (2 ml), 80 °C, and 20 h. b) Based on $N_3CO_2CH_3$, by GLPC. c) $N_3CO_2CH_3$ (2 mmol), allyl ether (25 mmol), and $Pd(PPh_3)_4$ (0.02 mmol) in benzene (1 ml).

Table 2. The reaction of azidoformate with 2-methyl-2-propenyl ether in the presence of some Pd-complexes[a]

Pd-complex	Yields of products/%[b] Imine	Aziridine
$Pd(PPh_3)_4$	5	24
$Pd(acac)_2$	7	18
$Pd(OAc)_2$	12	22
$PdCl_2(PhCN)_2$	95	Trace

a) $N_3CO_2CH_3$ (2 mmol), 2-methyl-2-propenyl ether (1 ml), Pd-complex (0.02 mmol), 80°C, and 20 h. b) Base on $N_3CO_2CH_3$, by GLPC.

Table 3. Effect of allyl chloride on the reaction of azidoformate with allylic ethers catalyzed by $PdCl_2(PhCN)_2$

Substrate	Allyl chloride (mmol)	Yields of products/% Imine	Aziridine
$CH_2{=}CHCH_2OCH_3$	0	53	8
	1	9	10
	2	0	10
$CH_2{=}C(CH_3)OCH_3$	0	95	Trace
	1	6	6

a) $N_3CO_2CH_3$ (2 mmol), $PdCl_2(PhCN)_2$ (0.02 mmol) in allylic ether (1 ml), 80 °C, and 20 h. b) Based on $N_3CO_2CH_3$, by GLPC.

Experimental

Materials. Methyl azidoformate was prepared by the known method[2] from sodium azide and methyl chloroformate and purified by repeating distillation under reduced pressure, bp 33—34 °C (8×10^3 Pa). Allylic ethers were prepared by the usual method,[3] and the products were collected by distilling the reaction mixtures. The distillates were washed several times with saturated brine in order to remove allylic chloride or alcohols, and dried over $MgSO_4$, then distilled under atmospheric pressure. Allyl methyl ether: bp 42.5—43 °C, 2-methyl-2-propenyl methyl ether: bp 66—67 °C. The purities of these reactants were checked by GLPC. The catalysts $Pd(PPh_3)_4$,[4] $PdCl_2(PhCN)_2$,[5] and Pd $(acac)_2$[6] were prepared by the methods described in the literature.

Reaction Procedure. A solution of methyl azidoformate (2 mmol) and a catalyst (0.02 mmol) in an allylic ether (1 ml) was prepared in a tube and degassed. Then the tube was sealed and immersed in a bath kept at 80 °C. After about 20 h, the products were collected from the reaction mixture by GLPC, and their structures were determined by elemental and NMR and IR spectroscopic analyses. The yields of the products were determined by GLPC.

Products. Analytical data for two aziridines[7] and 1-methoxy-1-(methoxycarbonylimino)propane[1] have been described elsewhere. 1-Methoxy-1-(methoxycarbonylimino)-2-methylpropane: ^1H NMR (CCl_4) $\delta = 1.17$ (6H, d, $-CH_3$), 2.76 (1H, m, CH), 3.62 (3H, s, OCH_3), and 3.63 (3H, s, CO_2CH_3); IR 1670 (C=N), 1725 (C=O), and 1100 (C–O–C) cm^{-1}. Found: C, 52.55; H, 8.22: N, 8.70%. Calcd for $C_7H_{13}O_3N$: C, 52.81; H, 8.23; N, 8.80%.

Protonation of *syn*-Bicyclo[4.2.1]nona-2,4,7-trien-9-ol with Fluorosulfuric Acid. Direct Evidence for Protonation Sites

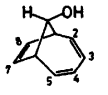
Shuji TOMODA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received June 18, 1982)

Synopsis. Treatment of *syn*-9-hydroxybicyclo[4.2.1]-nona-2,4,7-triene (**1**) with fluorosulfonic acid in sulfur dioxide-dichloromethane-d_2 cleanly provided protonated dimeric ether and the 7-hydroxytricyclo[4.2.1.$0^{2,8}$]nona-3-en-5-yl cation. Direct NMR observation as well as quenching experiment of these cations unequivocally established protonation at C-2 (or C-5) and C-7 (or C-8) of **1**.

The bicyclo[4.2.1]nona-2,4,7-triene-9-yl system has been of considerable theoretical interest[1] and practical use.[2] As a part of our investigation on the cationic rearrangement of this system,[3] we have studied the protonation of *syn*-bicyclo[4.2.1]nona-2,4,7-trien-9-ol (**1**) with fluorosulfuric acid. Four possibilities of protonation sites are available—C-2(C-5), C-3(C-4), C-7(C-8), and the oxygen. The last one may lead to the formation of the stabilized, but not bicyclo aromatic cation (**2**).[1] We report herein direct evidence for exclusive protonation at C-2(C-5) and C-7(C-8) in super acid media.



1

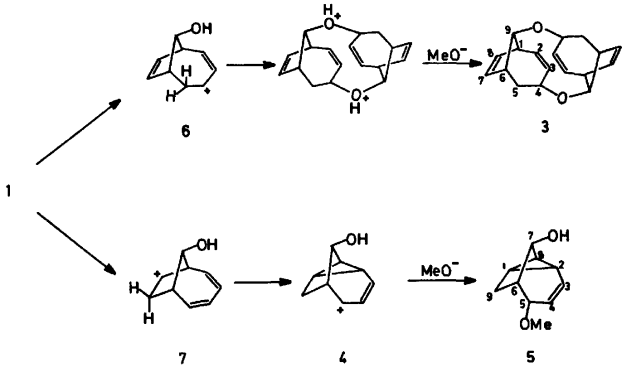
2

The precursor **1** was prepared by hydride reduction of the corresponding ketone according to the literature method.[3,4] When a solution of **1** in a mixture of sulfur dioxide and dichloromethane-d_2 was mixed with an excess fluorosulfuric acid in an NMR tube at −90 °C, there was obtained a well-defined proton NMR spectrum that could be rationalized as due to a mixture of protonated diether (**3**) and 7-hydroxytricyclo[4.2.1.$0^{2,8}$]-nona-3-en-5-yl cation (**4**) (see Table 1).

When this solution was quenched, either with sodium acetate in methanol or sodium methoxide in methanol, two products **3** and 5-methoxytricyclo[4.2.1.$0^{2,8}$]nona-3-en-7-ol (**5**) were isolated. The first of these was assigned the structure **3** on the basis of its spin-decoupled proton NMR spectrum, IR, UV, mass spectrum, and elemental analysis. The proton NMR spectrum of **3** showed that **3** is a symmetric molecule. Moreover since most of the protons exhibited the first order splitting, connectivity pattern of these protons was easily established by complete spin-decoupling experiments. The absence of a conjugated diene moiety was confirmed by its UV spectrum; only end absorption was detected.

The other quenched product, isolated as a single stereoisomer, was assigned the structure **5**. This assignment was consistent with its spin-decoupled proton NMR spectrum, IR, and elemental analysis. In particular, complete spin-decoupling experiment strongly supported structure **5**. Stereochemistry at C-5(OMe) cannot be inferred at present.

When the dimeric ether **3** was redissolved in a super acid solution at −82 °C, it produced peaks in three regions of the proton NMR spectrum that coincided entirely with several peaks present in the original solution from which the ether **3** had been obtained. The structure of cation **4** was therefore tentatively assigned by subtracting the NMR spectrum of **3** in super acid solution from that of the products (*i.e.* **3** and **4**) obtained



Scheme 1. Protonation of **1**.

Table 1. ^{1}H-NMR spectra of protonated **3** and cation **4** in superacid solution[a]

Mixture of **3** and **4**[b]	Protonated **3**[c]	**4**[d]
10.42(t, J=8.8 Hz)	—	10.42(1H, t, J=8.8 Hz, H-3)

1.02(d, J=17.6 H)	—	1.02(1H, d, J=17.6 Hz, H-9)

a) Observed at −90 °C——82 °C in SO_2-$CDCl_2$-FSO_3H (60 MHz). $CHDCl_2$ as an internal standard (δ=5.30). b) Obtained by treatment of **1** with FSO_3H at −90 °C. c) Dimeric ether **3** in the acid solution at −82 °C. d) Tentative assignments by spectral subtraction. Proton numbering indicated in structure **4** (Scheme 1). e) Obscured by **3**.

from the reaction of **1** with fluorosulfuric acid. The resulting NMR spectrum of **4** is listed in Table 1. The three low-field protons at $\delta=10.42$, 8.74, and 8.51 are characteristic of an allyl cation.[5]

The formation of **3** and **5** upon quenching with methanol could be explained as the products of protonated **3** and cation **4** (Scheme 1). Protonation on C-2(C-5) of **1** would give an allyl cation **6** which would undergo dimerization to give **3**. On the other hand, protonation on C-7(C-8) would initially give cation **7** which rearranges to the 3-cyclopropylallyl cation **4**.

Experimental

Direct NMR Observation of Protonated 3 and Cation 4. Alcohol **1** (17 mg, 0.13 mmol)[4] was dissolved in dichloromethane-d_2 (0.22 ml) in a thin-walled NMR tube. The solution was cooled to −78 °C and sulfur dioxide (0.22 ml) was distilled into the NMR tube. The sample was then cooled to −120 °C (pentane-liquid N_2 slush) to which freshly distilled fluorosulfuric acid (0.10 ml) was added. The tube was stirred in a −90 °C bath using vortex mixer for 30 s and was quickly set in the NMR probe which had been maintained at −90 °C.

Quenching of the Cation Solution with Methanol. The alcohol (**1**, 643 mg, 4.83 mmol) in a mixture of dichloromethane and sulfur dioxide (1 : 1, 10 ml) was treated with fluorosulfuric acid (2 ml) at −78 °C for 1 h. The mixture was quenched with 150 ml methanol saturated with sodium acetate at room temperature. The methanol was removed by rotary evaporator at 0 °C. 100 ml water was added to the residue. The mixture was then extracted with three portions of ether and the combined ether layers washed with water, saturated aqueous sodium hydrogencarbonate and water, and then dried over magnesium sulfate. Concentration provided 534 mg crude oil, which was separated by preparative TLC to afford **3** (146 mg) and **5** (85 mg) as colorless oils.

Spectral Data of 3. MS (70 eV) *m/e* 268 (M^+). IR (CCl_4) 3070, 2960, 1450, 1062, 1040, and 694 cm^{-1}. UV (cyclohexane) 217.5 (ε 2400). ^{1}H-NMR (CCl_4) δ (numbering of protons indicated in structure **3**) 6.13 (1H, dd, $J=9.6$, 5.0 Hz, H-3), 5.86 (2H, d, $J=1.1$ Hz, H-7 and 8), 5.76 (1H, dd, $J=9.6$, 4.1 Hz, H-2), 5.00 (1H, dd, $J=6.5$, 6.6 Hz, H-9), 4.40 (1H, dd, $J=7.0$, 5.0 Hz, H-4), 3.15 (1H, ddd, $J=6.4$, 4.1, 1.8 Hz, H-1), 2.83 (1H, ddd, $J=3.2$, 10.4, 6.6 Hz, H-6), 1.94 (1H, ddd, $J=11.4$, 10.4, 6.8, H-5), 1.44 (1H, ddd, $J=11.4$, 3.2, 0.5 Hz, H-5).

Found: C, 80.19, 80.27; H, 7.57, 7.67%. Calcd for $C_{18}H_{20}O_2$: C, 80.55; H, 7.51%.

Spectral Data of 5. MS (70 eV) *m/e* 134 (M^+ −MeOH). IR (CCl_4) 3500, 3020, 1660, 1390, and 1092 cm^{-1}. ^{1}H-NMR (CCl_4) δ (numbering of protons based on nomenclature) 6.05 (1H, ddd, $J=12.0$, 7.5, 1.5 Hz, H-3), 5.57 (1H, ddd, $J=12.0$, 4.0, 3.0 Hz, H-4), 4.64 (1H, ddd, $J=6.0$, 4.0, 4.0 Hz, H-7), 3.81 (1H, ddd, $J=1.5$, 4.0, 4.0 Hz, H-5), 3.47 (1H, d, $J=4.0$ Hz, OH), 3.40 (3H, s, OMe), 2.65 (1H, dddd, $J=9.0$, 6.0, 4.0, 3.0 Hz, H-6), 2.25 (1H, ddd, $J=12.0$, 9.0, 4.0 Hz, H-9), 1.98 (1H, ddd, $J=8.0$, 6.0, 4.0 Hz, H-8), 1.63 (1H, ddd, $J=8.0$, 7.0, 4.0 Hz, H-1), 1.45 (1H, d, $J=12$ Hz, H-9), 1.35 (1H, ddd, $J=7.5$, 7.0, 4.0 Hz, H-2).

Found: C, 72.11; H, 8.43%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

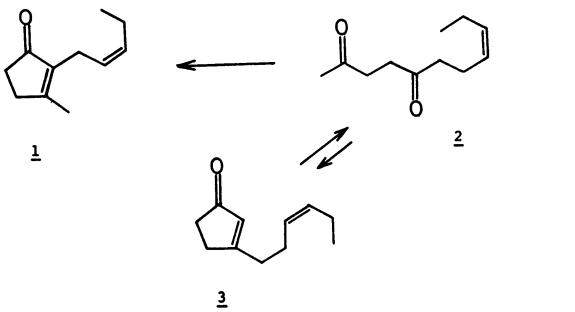
(Received June 24, 1982)

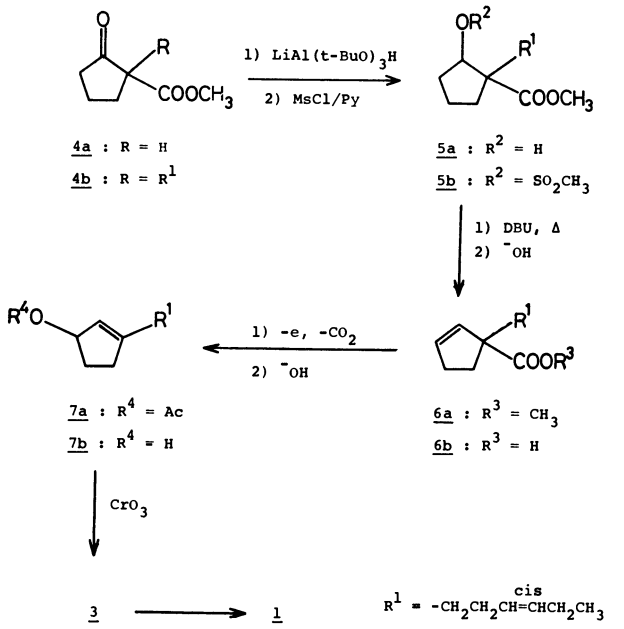
Synopsis. A regioselective electro-acetoxylation of 1-(*cis*-3-hexenyl)-2-cyclopentene-1-carboxylic acid in a Et_3N–AcOH–AcOEt–*t*-BuOH–(Pt electrodes) system afforded 3-acetoxy-1-(*cis*-3-hexenyl)-1-cyclopentene (**7a**) (98%). Alkaline hydrolysis of **7a** followed by the oxidation with chromium trioxide gave the desired 3-(*cis*-3-hexenyl)-2-cyclopenone smoothly.

The cyclization of 1,4-diketone (**2**) with base is a key strategy in *cis*-jasmone synthesis.[1] As an extension of the investigation, a device has been made by McCurry and co-worker since 3-(*cis*-3-hexenyl)-2-cyclopentenone (**3**) can be smoothly converted into **1** *via* the intermediate **2** by a simple retro-aldol-aldol condensation reaction in an aqueous alkaline solution[2] (Scheme 1).

In the course of our investigation on electrolytic decarboxylation of aliphatic carboxylic acids (non Kolbe type reactions), we have found that the electrolytic decarboxylation of β,γ-unsaturated carboxylic acids affords exclusively γ-acetoxy-α,β-unsaturated compounds.[3] The success prompted us to synthesize the important intermediate **3** by the electro-decarboxylative acetoxylation of 1-(*cis*-3-hexenyl)-2-cyclopentene-1-carboxylic acid (**6b**) (Scheme 2).



Scheme 1.



Scheme 2.

The β,γ-unsaturated carboxylic acid **6b** was obtained by the following manner: Treatment of methyl 2-oxocyclopentanecarboxylate (**4a**) with *cis*-3-hexenyl *p*-toluenesulfonate in acetone in the presence of KI and K_2CO_3 gave **4b** (89%), which was subjected to reduction with $LiAl(t\text{-}BuO)_3H$ in tetrahydrofuran (THF) to give the alcohol **5a** (99%). Dehydration of **5a** was performed by heating the corresponding methanesulfonate **5b** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in *N*,*N*-dimethylformamide (DMF), yielding **6a** (86%). Hydrolysis of **6a** in a methanolic alkaline solution afforded **6b** (98%).

Electrolytic decarboxylation of **6b** was carried out in either a divided or an undivided cell using two Pt electrodes. A solution of **6a** in acetic acid, ethyl acetate, and *t*-butyl alcohol (2/5/0.3) containing triethylamine was charged into the anode compartment of the divided cell, and a regulated DC power (terminal voltage: 35 V) was supplied for 21 h. In the course of the electrolysis, the initial current of 6 mA/cm^2 dropped onto 1 mA/cm^2. Workup of the anolyte gave the acetate **7a** (68%). On the other hand, the electrolysis of **6a** in the same medium was carried out in an undivided cell (without separation of the two electrode compartments), there was also obtained **7a** (98%) without detectable amounts of the hydrogenated products on the C–C double bond. This is in contrast to the results of the electrolytic decarboxylation of some carboxylic acids bearing isopropenyl moiety,[4] in which, the hydrogenation of the C–C double bond proceeds competitively at the cathode.

The transformation of **7a** into 3-(*cis*-3-hexenyl)-2-cyclopentenone (**3**) was performed by the hydrolysis of **7a** followed by the oxidation with chromium trioxide.[5] The spectral data and physical properties of **3** were fully identical with those of the reported one.[2]

Experimental

All boiling points are uncorrected. IR spectra were determine with a JASCO IRA-I infrared spectrometer. ^1H NMR spectra were obtained at 60 MHz with a Hitachi R-24 spectrometer.

*Methyl 1-(*cis*-3-Hexenyl)-2-oxocyclopentane-1-carboxylate (**4b**).* A mixture of **4a** (480 mg, 3.38 mmol), *cis*-3-hexenyl *p*-toluenesulfonate (1.05 g, 4.12 mmol), KI (1.03 g, 6.18 mmol), and K_2CO_3 (4.73 g, 34.3 mmol) in acetone (40 ml) was heated to reflux for 2 d. After removal of the solids by filtration, the filtrate was concentrated and the residue was chromatographed (SiO_2, hexane–AcOEt: 35/1), giving **4b** (676 mg, 89%): bp 93—96 °C/2 Torr†; IR (neat) 3101 (HC=C), 1755 (C=O),

† 1 Torr=133.322 Pa.

1723 cm^{-1} (C=O); ^1H NMR (CCl_4) δ 0.96 (3H, t, J=7.4 Hz, CH_3), 1.36—2.67 (12H, m), 3.65 (3H, s, CH_3O), 5.23—5.43 (2H, m, HC=CH).

Found: C, 69.76; H, 9.11%. Calcd for $C_{13}H_{20}O_3$: C, 69.91; H, 8.99%.

*Methyl 1-(*cis*-3-Hexenyl)-2-hydroxycyclopentane-1-carboxylate(5a).* A mixture of **4b** (200 mg, 0.89 mmol) and $LiAl(t\text{-}BuO)_3H$ (453 mg, 1.25 mmol) in THF (10 ml) was stirred at 0—5 °C for 3 h. The usual workup gave **5a** (200 mg, 99%): bp 130—132 °C/7 Torr; IR (neat) 3439 (OH), 3000 (HC=C), 1731 cm^{-1} (C=O); ^1H NMR (CCl_4) δ 0.94 (3H, t, J=7.2 Hz, CH_3), 1.20—2.32 (12H, m), 2.62 (1H, br s, OH), 3.62 (3H, s, CH_3O), 4.15 (1H, m, CH-O), 5.12—5.45 (2H, m, HC=CH).

Found: C, 68.85; H, 9.74%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

*1-(*cis*-3-Hexenyl)-2-cyclopentene-1-carboxylic Acid (6b).* To a solution of **5a** (178 mg, 0.79 mmol) in pyridine (3 ml) was added methanesulfonyl chloride (270 mg, 2.36 mmol) at 0 °C. After being stirred for 3 h at this temperature, the usual workup gave methanesulfonate **5b** (239 mg, 100%): IR (neat) 3012 (HC=C), 1729 (C=O), 1356, 1177 cm^{-1} (CH_3SO_3); ^1H NMR (CCl_4) δ 0.96 (3H, t, J=7.2 Hz, CH_3), 1.21—2.40 (12H, m), 2.91 (3H, s, CH_3SO_3), 3.67 (3H, s, CH_3O), 5.07—5.38 (3H, m, HC-O, HC=CH). The product **5b** was heated in DMF (1 ml) containing DBU (122 mg, 0.8 mmol) at 140 °C for 8 h. The mixture was diluted with water and the extractive workup with benzene-ether (1/1) followed by column chromatography (SiO_2, hexane-AcOEt: 12/1) gave **6a** (141 mg, 86%): bp 82—83 °C/10 Torr; IR (neat) 3050, 3005 (HC=C), 1733 (C=O), 1650 cm^{-1} (C=C); ^1H NMR CCl_4) δ 0.95 (3H, t, J=7.4 Hz, CH_3), 1.21—2.61 (10H, m), 3.61 (3H, s, CH_3O), 5.12—5.44 (2H, m, HC=CH), 5.49—5.81 (2H, m, HC=CH).

Hydrolysis of **6a** (585 mg, 2.81 mmol) in aqueous 80% MeOH (10 ml) containing KOH (1.26 g, 22.5 mmol) at 65 °C for 6 h gave **6b** (534 mg, 98%) after column chromatography (SiO_2, hexane-AcOEt: 4/1): IR (neat) 3690—2230 (OH), 1697 cm^{-1} (C=O); ^1H NMR (CCl_4) δ 0.94 (3H, t, J=7.4 Hz, CH_3), 1.38—2.75 (10H, m), 5.07—5.46 (2H, m, HC=CH), 5.50—5.92 (2H, m, HC=CH), 12.15 (1H, s, COOH).

Found: C, 74.38; H, 9.45%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34.

*Electrolysis of 1-(*cis*-3-Hexenyl)-2-cyclopentene-1-carboxylic Acid (6b).* *Procedure A*: Electrolysis was carried out in an undivided cell fitted with two Pt electrodes (2×3 cm^2), a thermometer, and a gas lead pipe. A solution of **6b** (120 mg, 0.61 mmol) in AcOH (2 ml), AcOEt (5 ml), and *t*-BuOH (0.27 ml) containing Et_3N (0.85 ml) was charged in the cell and electrolysed at 20—22 °C under a constant applied voltage (30 V) for 7 h. The initial current of 30 mA/cm^2 dropped onto 20 mA/cm^2 durring the electrolysis. The mixture was concentrated to *ca.* 2 ml and the residue was taken up with ether, washed with brine, and dried (Na_2SO_4). Evaporation of the solvents followed by column chromatography (SiO_2, hexane-ether: 2/1) gave **7a** (125 mg, 98%): bp 64—66 °C/2 Torr; IR (neat) 3054, 3005 (HC=C), 1728 cm^{-1} (C=O); ^1H NMR (CCl_4) δ 0.93 (3H, t, J=7.4 Hz, CH_3), 1.48—2.73 (10H, m), 1.91 (3H, s, CH_3CO), 5.11—5.56 (4H, m, HC=CH, HC=C, CH-O).

Found: C, 74.77; H, 9.86%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

Procedure B: Electrolysis was carried out in a divided cell, separated with glass-frit, using two Pt electrodes (2×3 cm^2). A mixture of AcOH (8 ml), AcOEt (20 ml), *t*-BuOH (1.2 ml), and Et_3N (3 ml) was charged into both anode and cathode compartments, and **6b** (80 mg, 0.41 mmol) was added to the anode compartment. DC powder (35 V) was supplied for 21 h (6—1 mA/cm^2) and workup of the anolyte in the same manner as described above gave **7a** (58 mg, 68%).

*3-(*cis*-3-Hexenyl)-2-cyclopentenone (3).* A mixture of **7a** (75 mg, 0.36 mmol) and KOH (80 mg) in aqueous 90% MeOH (5 ml) was stirred at room temperature for 2 h and the extractive work-up with ether followed by column chromatography (SiO_2, hexane-ether: 1/1) gave **7b** (57 mg, 95%): bp 62—64 °C/2 Torr: IR (neat) 3330 (OH), 3305 (HC=C), 1650 cm^{-1} (C=C); ^1H NMR (CCl_4) δ 0.96 (3H, t, J=7.4 Hz, CH_3), 1.47—2.80 (10H, m), 4.67 (1H, m, HC-O), 4.50—4.84 (3H, m, HC=CH, HC=C), which was treated with aqueous chromium trioxide (1.3 M, 0.5 ml) in CH_2Cl_2 (2 ml) at 0 °C for 4 h. The organic layer was worked up in the usual manner to give **3** (40 mg, 71%), whose spectral data were identical with those of the reported one.[2]

The Function of Magnesium(II) *N,N'*-Dicyclohexylamidinide Complexes as a Carbon Dioxide Carrier

Noboru MATSUMURA,* Takayuki OHBA, and Hiroo INOUE
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591
(Received June 26, 1982)

Synopsis. It is found that magnesium(II) *N,N'*-dicyclohexylamidinide complexes are useful reagents for the fixation of carbon dioxide and the transfer of the captured carbon dioxide moiety to active methylene compounds.

A carbon dioxide carrier,[1] which performs its function in the fixation of carbon dioxide and transcarboxylation, is of interest in connection with a biological biotin-dependent carboxylation[2] and in applications to organic syntheses. Recently we have reported that 2-morpholino-4,5-dihydro-1-imidazolylmagnesium complex (**1**) acts effectively as a carbon dioxide carrier in the carboxylation of active methylene compounds under mild conditions.[3] In our continuing investigation of carbon dioxide carrier, we have studied the transcarboxylating function of magnesium(II) complexes **2a—d** having an amidinide-type ligand which is derived readily from available dicyclohexylcarbodiimide (DCC). Herein, we wish to report that complexes **2a** and **2b** are the useful carbon dioxide carriers and that the C=N bond, the substituent Y of the amidinide type ligand and the magnesium(II) ion play an important role in the transcarboxylation process.

a: Y=C$_6$H$_5$, X=Br
b: Y=n-C$_4$H$_9$, X=Br
c: Y=CH$_3$O, X=CH$_3$O
d: Y=, X=Br

The transcarboxylating ability of complexes **3a—d**, prepared by the reactions of **2a—d** with carbon dioxide, was investigated using acetophenone as the substrate. The reaction afforded benzoylacetic acid and **4a—d** as the products. The yield of benzoylacetic acid shown in Table 1 indicated that complexes **3a** and **3b** exhibit activity for the transfer of their carbon dioxide moiety to acetophenone, but complexes **3c** and **3d** are much less active. Thus, contrary to complex **1**, the morpholino group of complex **3d** was undesirable for the activation of the carbon dioxide moiety.

Next, the transcarboxylating activity of complex **3b** was compared with that of the lithium–carboxylato complex (**5**). It was observed that acetophenone is carboxylated by **5** in only 10% yield. The fact that the magnesium(II) complex is much more effective than the lithium complex was the same as that in the case of the imidazolinide complex **1** described previously.[3]

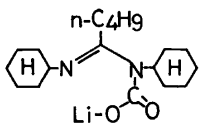
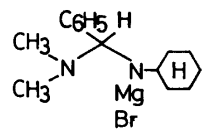
a) Solvent; DMF. Temperature; r. t. Reaction time; 40 h.
b) Besed on acetophenone.

In order to investigate whether the C=N bond of the *N,N'*-dicyclohexylamidinide ligand is required for the transcarboxylating function or not, we carried out the carboxylation of acetophenone using complex **6** under the similar conditions. The complex **6** absorbed an equimolar amount of carbon dioxide, but the resulting magnesium(II)–carboxylato complex was found not to transfer the carbon dioxide moiety to acetophenone at all. This fact demonstrates that the C=N bond is necessary for transcarboxylation.

Other active methylene compounds described in Table 2 also were carboxylated by the magnesium(II)–carboxylato complex **3a**. It is interesting that *S*-benzyl thioacetate is carboxylated though in a low yield, since it may be related to CH_3CO–CoA in a biological system.



5



6

Experimental

Materials. Active methylene compounds were distilled or recrystallized prior to use. Tetrahydrofuran (THF) was refluxed over $LiAlH_4$, distilled and stored in argon atmosphere.

Carboxylation of Active Methylene Compounds with 2a—d. A typical experiment was as follows: a solution of phenylmagnesium bromide, butylmagnesium bromide, magnesium dimethoxide, or morpholinomagnesium bromide (8.16 mmol) in THF (10 cm^3) was under argon added to a solution of DCC (6.81 mmol) in THF (10 cm^3) and the solution was stirred for 1 h. After removal of the solvent, the residue was dissolved in 25 cm^3 of *N,N*-dimethylformamide (DMF) by bubbling

carbon dioxide and the solution was stirred at room temperature for 1 h. The solvent was evaporated *in vacuo* at room temperature and the residue was dried *in vacuo* at 40 °C. The resulting white solid, which contains complex **3**, was allowed immediately to react under argon with active methylene compounds (1.7 mmol) in dry DMF (35 cm^3) at room temperature for 40 h. The formation of complex **3** was confirmed by the method described previously:[3)] complex **3a** was confirmed by the facts that the IR spectrum of the solid has the carbonyl absorption at 1665 cm^{-1} and that complex **2a** absorbs an equimolar amount of carbon dioxide and the fixed carbon dioxide is released quantitatively by treatment with a dilute sulfuric acid solution. The reaction was stopped by adding water. The carboxylation products and **4a**—**d** were isolated in the usual manner and were identified by a comparison of their melting points, IR, ^1H NMR, and mass spectra, and elemental analyses with those of the respective authentic specimens.

*The Reaction of Acetophenone with Complex **6**.* A solution of phenylmagnesium bromide (6.81 mmol) in 10 cm^3 of THF was added under argon, drop by drop, to a solution of N^2-cyclohexyl-N^1,N^1-dimethylformamidine (6.81 mmol), which was prepared by the method described in the literature,[4)] in 10 cm^3 of THF at room temperature. The mixture was magnetically stirred at this temperature for 1 h. After removal of the solvent in vacuo, the residue was dissolved in 25 cm^3 of DMF under bubbling carbon dioxide and the solution was stirred under bubbling carbon dioxide at room temperature for 1 h. The solvent was evaporated *in vacuo* at room temperature and the residue was dried *in vacuo* at 40 °C. The resulting white solid, which contains complex **6**, was allowed immediately to react under argon with acetophenone. The reaction mixture was treated by the method being similar to that in the cases of **2a**—**d**. Acetophenone and benzaldehyde were obtained in good yields, but benzoylacetic acid was not detected at all.

Homologation of Methyl Esters Catalyzed by Ruthenium-Cobalt Bimetallic Systems[1]

Masanobu HIDAI,* Yukio KOYASU, Makoto YOKOTA, Masami ORISAKU, and Yasuzo UCHIDA
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 8, 1982)

Synopsis. Reactions of methyl esters such as methyl acetate with synthesis gas have been investigated by use of the mixed clusters such as $[Et_4N][RuCo_3(CO)_{12}]$ and $[Et_4N][Ru_3Co(CO)_{13}]$ or a combination of $Ru(acac)_3$ and $Co_2(CO)_8$ as catalyst and methyl iodide as promoter. In the homologation of methyl acetate, the catalytic activity for formation of ethyl acetate was much improved when both ruthenium and cobalt existed in the reaction system.

Mixed transition metal clusters have recently attracted much attention since the compounds might be used as unique homogeneous catalysts or precursors to well defined bimetallic or multimetallic heterogeneous catalysts.[2] In a previous paper[3] we reported that both a combination system of $RuCl_3 \cdot 3H_2O$ and $Co_2(CO)_8$ with the Ru/Co ratio of about 1/3 and the mixed clusters containing the $[RuCo_3(CO)_{12}]^-$ moiety show a more remarkable catalytic activity for methanol homologation. We wish here to describe that the similar bimetallic catalysts are also effective for the homologation of methyl esters, especially methyl acetate.

Recently Braca *et al.*,[4] repoted that methyl esters such as methyl acetate and propionate were homologated to the corresponding ethyl esters with $Ru(acac)_3$ as catalyst and methyl iodide as promoter (Eq. 1). For example, the reaction of methyl acetate with synthesis

$$CH_3COOCH_3 + CO + 2H_2 \longrightarrow CH_3COOC_2H_5 + H_2O \quad (1)$$

gas ($CO/H_2=4.5$; initial pressure at room temperature, 165 kg/cm^2) at 200 °C gave 73% conversion of methyl acetate into ethyl acetate with the selectivity of 28% after 76 h.[4b] More recently, Jenner *et al.*,[5] reported the homologation of methyl acetate catalyzed by group VIII metals and their various binary combinations. We have here independently investigated the similar type of reaction with ruthenium–cobalt bimetallic catalysts.[6]

Results and Discussion

The results are shown in Table 1. When $Ru(acac)_3$ was used as catalyst, ethyl acetate was formed in 16% yield based upon methyl acetate initially added, together with acetic acid in 11% yield (Run 1). On the other hand, $Co_2(CO)_8$ gave ethyl acetate in 11% yield as well as acetaldehyde and acetic acid in moderate yields (Run 8). The combination of these two kinds of compounds or ruthenium–cobalt mixed clusters such as $[Et_4N][RuCo_3(CO)_{12}]$ and $[Et_4N][Ru_3Co(CO)_{13}]$ where the total amount of metals was kept constant (0.4 mg atom) increased the catalytic activity for formation of ethyl acetate; the yield of ethyl acetate was about twice as much as that with $Ru(acac)_3$ alone and three times as much as that with $Co_2(CO)_8$ alone, although acetic acid was formed in *ca.* 20—30% yield. Both the yield and selectivity of ethyl acetate were not so much affected by the ratio of cobalt to ruthenium as in the case of the homologation of methanol.[3] However it is of interest to note that the cluster $[Et_4N][Ru_3Co(CO)_{13}]$ gave the best yield of ethyl acetate among the catalysts shown in Table 1. As the ratio of carbon monoxide to hydrogen was increased, formation of ethyl acetate and acetic acid was promoted (Runs 9, 10, and 11). Methyl propionate was also transformed into ethyl propionate (8.7% yield) and propionic acid (15.5% yield) under the same reaction conditions with the cluster $[Et_4N][RuCo_3(CO)_{12}]$ as catalyst.

The reaction mechanism is at present not clear. It is known that catalysts based on Ni, Co,[7-8] or Rh[9] compounds can convert methyl acetate into acetic

Table 1. Homologation of methyl acetate with Ru–Co bimetallic catalysts[a]

Run	Catalyst[b]	Co/Ru	CO/H_2[c] (kg/cm^2)	Conversion/%	Yields[d] of products[e]/%

a) Methyl acetate 125 mmol, methyl iodide as promoter 3—5 mmol, benzene as internal standard 5 mmol, 180 °C, 18 h. b) The total amount of metals was 0.4 mg atom. c) Initial pressure at room temperature. d) Yield of the product was calculated as follows; [product (mmol)/AcOMe charged (mmol)] × 100. e) CH_4 was formed in *ca.* 5—10% yield in every reactions. f) Yield of ethers was calculated by [Me_2O (mmol)+MeOEt (mmol)+E t_2O(mmol)/AcOMe charged (mmol)] × 2 × 100.

anhydride under a high pressure of carbon monoxide and the anhydride is transformed into ethyl acetate and acetic acid under a pressure of hydrogen with $H_4Ru_4(CO)_8(PBu_3)_4$ as catalyst.[10] Thus, one possible mechanism for the homologation of methyl acetate is a combination of the above two types of reactions. Investigation of the product distribution showed that the total amount of acetyl groups (AcOMe%+AcOEt%+AcOH%) was in the range of 90—110% while that of methyl groups (AcOMe%+AcOEt%+EtOH%+CH_4%+ethers%) lay between 90% and 110%. This fact may exclude the above mechanism. A possible reaction mechanism compatible with the above finding is proposed below. In the first step, methyl acetate is hydrolyzed to give methanol and acetic acid (Eq. 2). A trace amount of water involved in methyl acetate may initiate the first reaction. The methanol is then converted into ethanol *via* the homologation reaction (Eq. 3) followed by condensation of ethanol with acetic acid to give ethyl acetate (Eq. 4).

$$CH_3COOCH_3 + H_2O \longrightarrow CH_3COOH + CH_3OH \quad (2)$$

$$CH_3OH + CO + 2H_2 \longrightarrow C_2H_5OH + H_2O \quad (3)$$

$$CH_3COOH + C_2H_5OH \longrightarrow CH_3COOC_2H_5 + H_2O \quad (4)$$

Experimental

Materials. Methyl acetate and benzene were purified by the conventional methods and distilled under nitrogen atmosphere. The compounds $RuCl_3 \cdot 3H_2O$, $[Et_4N]Cl$, and $Co_2(CO)_8$ were commercially obtained and used without further purification. The compounds $Ru(acac)_3$,[11] $NaCo(CO)_4$,[12] and $[Et_4N][Ru_3Co(CO)_{13}]$[13] were prepared by the published methods. The mixed metal cluster $[Et_4N][RuCo_3(CO)_{12}]$[3] was prepared with $RuCl_3 \cdot 3H_2O$ and $NaCo(CO)_4$ followed by the cation exchange with $[Et_4N]Cl$ in a aqueous solution.

General Procedures. A 100 ml stainless-steel autoclave was used as a reactor. In a typical run, $[Et_4N][RuCo_3(CO)_{12}]$ (0.10 mmol), methyl acetate (125 mmol), methyl iodide (3—5 mmol) as a promoter, and benzene (5 mmol) as initial standard were placed into the reactor under nitrogen atmosphere. The reactor was then pressurized to 120 kg/cm^2 with CO/H_2 in a typical run, 1/1) at room temperature, and heated up to 180 °C within 30 min. The reaction was allowed to proceed at that temperature for 17.5 h and then the autoclave was cooled to room temperature within 1 h. The gas phase and the reaction solution were immediately analyzed by gas chromatography.

Analysis. Analysis of the off-gas was carried out by using gas chromatography with a 2 m column of Porapak Q (100 °C, 20 ml/min He). Liquid products were quantitatively analyzed by gas chromatography equipped with a flame ionization detector using a 3 m column of PEG20M (the oven temperature was elevated at the ratio of 5 °C/min from 70 °C; N_2 30 ml/min).
