Discussion

The molecular parameters for gaseous trimethylphosphine-boron trihalides are listed in Table 6, where the molecular parameters in the solid phase[1] and those for component molecules[18–21] are also listed. The fractional changes in the parameters, $\Delta f/f$, between the complexes and the component molecules are shown in Fig. 4. The electronegativity of halogen atoms[22] is tentatively taken as the abscissa. It is apparent that, on the complex formation, the $|\Delta f|/f$ ratios systematically increase with the increase in electronegativity, that is, with the decrease in the atomic number of halogen atoms, though the P–B bond distances are equal to each other. On the other hand, the calorimetric study has shown that the complexes are stable in the order of $(CH_3)_3P \cdot BF_3 < (CH_3)_3P \cdot BCl_3 < (CH_3)_3P \cdot BBr_3$,[23] though there are no data for $(CH_3)_3P \cdot BI_3$. These results show that the stability of trimethylphosphine–boron trihalides decreases with an increase in the magnitude

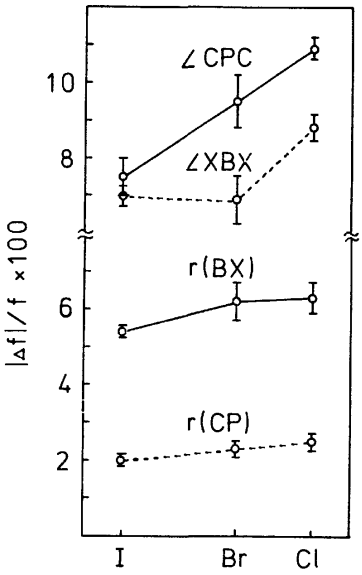

Fig. 4. Parameter changes on complex formation *versus* electronegativities for halogen atoms. Solid lines represent positive Δf and dashed lines negative Δf.

of the structural changes.

By comparing the parameters of the molecules in the solid phase with those of the gaseous molecules, we see that the dative bonds of $(CH_3)_3P\cdot BBr_3$ and $(CH_3)_3P\cdot BI_3$ seem to be enhanced in the solid phase in the order of $(CH_3)_3P\cdot BBr_3 < (CH_3)_3P\cdot BI_3$, while the dative bond of $(CH_3)_3P\cdot BCl_3$ is unchanged in the solid and gas phases.

The gaseous molecule of $(CH_3)_3P\cdot BI_3$ is rigid with respect to the torsional vibration about the P–B bond, while the potential barriers for $(CH_3)_3P\cdot BCl_3$[2] and $(CH_3)_3P\cdot BBr_3$[3] are 3.8 ± 0.7 and about 10 kcal mol^{-1} respectively. Accordingly, the potential barriers about the P–B bonds of $(CH_3)_3P\cdot BX_3$ are in the order of $(CH_3)_3P\cdot BCl_3 < (CH_3)_3P\cdot BBr_3 < (CH_3)_3P\cdot BI_3$, *i.e.*, in the order of the increasing size of the halogen atoms in the complexes. The height of the rotational barriers of these complexes may be controlled by the repulsion due to the nonbonded atomic pairs, such as $X_1\cdots H_6$ (see Fig. 1). The $X_1\cdots H_6$ distances are, however, nearly equal to each other in the above trimethylphosphine complexes; therefore, the above order for the rotational barrier heights is understandable if the large van der Waals radii for halogen atoms with large atomic numbers are taken into consideration.

The Conversion of Methanol into Hydrocarbons over Dodecatungstophosphoric Acid

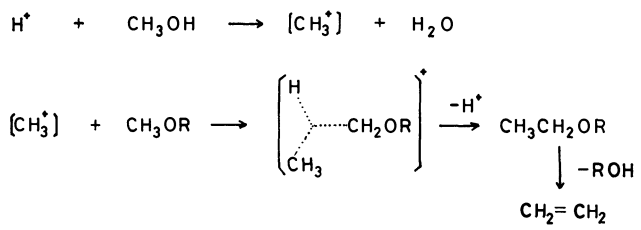
Toshihide Baba, Junya Sakai, Hideki Watanabe, and Yoshio Ono*

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 16, 1981)

Dodecatungstophosphoric acid (TPA) is a very effective catalyst for the conversion of methanol into hydrocarbons. The effects of the reaction parameters, such as the temperature or the methanol partial pressure, were therefore examined. The kinetic features of the conversion over TPA are quite different from those over ZSM-5 zeolites. This difference is caused by the unique nature of the conversion over TPA; methanol molecules are sorbed and undergo the conversion in the bulk of solid TPA.

Zeolites, especially ZSM-5, are very effective catalysts for converting methanol into hydrocarbons.[1-3] Ono and Mori[4] have studied the mechnism of the conversion in detail and have concluded that Brönsted acid sites are responsible for the conversion, refuting the mechanism which involves a carbene-like intermediate.[1] According to this mechanism,[4] the first carbon-carbon bond is formed in the following manner:



The subsequent fast reactions of lower olefins and methanol lead to the formation of a higher molecular weight. The overall reaction proceeds autocatalytically.[4-6] Thus, the yield of the hydrocarbons shows an abrupt increase with a small increase in the reaction temperature,[6] or the rate of hydrocarbon formation is accelerated as the reaction proceeds.[4,5]

Judging from the above mechanism, it seems that the methanol conversion should proceed over solid substances other than zeolites, if they are highly acidic. In fact, Ono *et al.* have reported that heteropolyacids such as dodecatungstophosphoric acid (TPA) are quite effective catalysts for the conversion.[4,7,8] Some heteropolyacids are known to have a high solid acidity and to be very active catalysts for various acid-catalyzed reactions.[9] Thus, TPA has a much higher activity than hydrogen-Y zeolite for the dehydration of 2-propanol.[9] In this work, the influences of the various reaction variables on the methanol conversion over TPA will be described, and the mechanistic characteristics will be discussed with reference to those of the conversion over zeolites.

Experimental

Dodecatungstophosphoric acid (TPA), obtained from Wako Pure Chemicals Ind., was made into pellets, crushed, and sorted into 9—16 mesh. The reaction was carried out with a continuous-flow reactor operating at atmospheric pressure. The catalyst was packed into a reactor of silica-tubing (10 mm i.d.) and placed in a vertical furnace. Methanol was delivered by means of a motor-driven syringe and vaporized in the preheating zone of the reactor, containing 10 cm^3 of quartz. The gas from the outlet of the reactor was analyzed by means of a gaschromatograph equipped with a flame-ionization detector. A 2-m Porapak Q column separated the hydrocarbon products efficiently. The yield or distribution of the products was calculated on a carbon-number basis.

Results and Discussion

Table 1 shows the product and hydrocarbon distribution in the conversion of methanol and dimethyl ether over TPA. The reaction conditions were as follows: reaction temperature, 573 K; methanol pressure, 50.7 kPa, and contact time $(W/F)=72.0$ g h mol^{-1}, where W and F denote the catalyst weight (g) and the total molar flow rate (mol h^{-1}) respectively. As is shown in Table 1, the two reactants gave similar hydrocarbon distributions except that a higher propylene/propane ratio was obtained when dimethyl ether was used as the starting material. At this temperature, the main products are lower aliphatic hydrocarbons, among which isobutane is most predominant. The formation of carbon monoxide

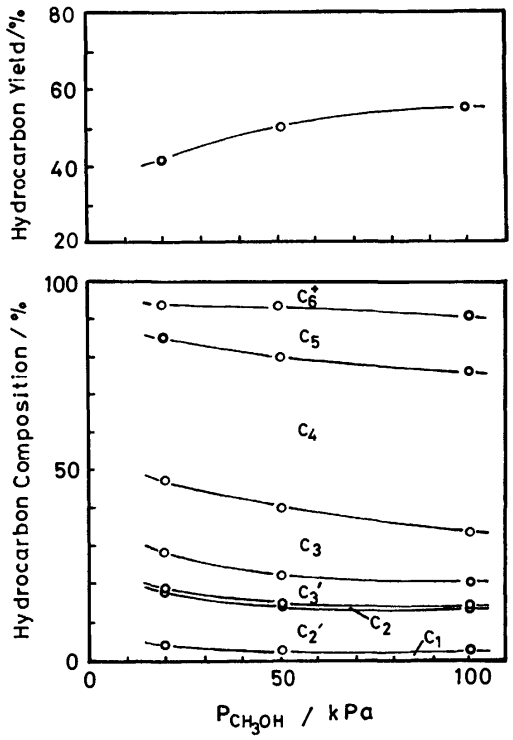

Fig. 2. Effect of the partial pressure of methanol on the total hydrocarbon yield and the composition of the produced hydrocarbons.
Reaction conditions: 573 K, W/F=71 g h mol^{-1}.

and carbon dioxide is negligible. In contrast to the conversion over ZSM-5, only a small amount of aromatic compounds is produced. The loss of the catalytic activity with the process time was small in spite of the accumulation of coke. Thus, under the conditions of 573 K, W/F=140 g h mol^{-1}, and a methanol pressure of 101 kPa, the hydrocarbon yields were 62.8 and 50.2% at 1 and 15 h of process time respectively.

Figure 1 shows the temperature dependence of the yield of hydrocarbons and their distribution in methanol conversion. The hydrocarbon yield increased gradually with the reaction temperature. In contrast to the conversion over ZSM-5,[6] no abrupt increase in the hydrocarbon yield was observed; that is, the reaction seems not to be an autocatalytic one. Among the products, C_4 (hydrocarbons with four carbon atoms) and C_5 hydrocarbons were the predominant products at lower temperatures, and their fractions decreased with the reaction temperature. The fractions of lower olefins (ethylene+propylene) increased with the reaction temperature up to 623 K and decreased at higher temperatures. The fraction of methane was small below 570 K, but increased sharply over 620 K. The optimum temperature for the conversion lies around 570—600 K.

Figure 2 shows the effect of the methanol partial pressure on the hydrocarbon yield and the hydrocarbon

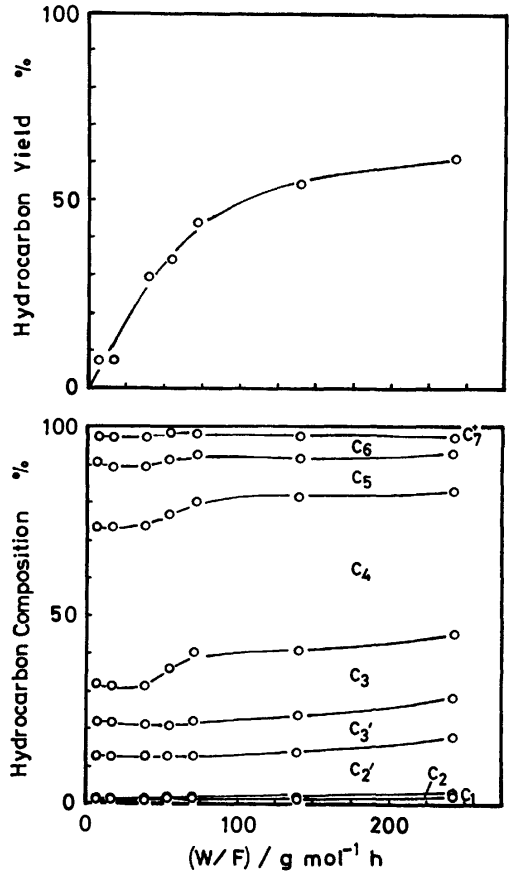

Fig. 3. Effect of the contact time (W/F) on the total hydrocarbon yield and the composition of the produced hydrocarbons.
Reaction conditions: 573 K, methanol pressure 50.7 kPa.

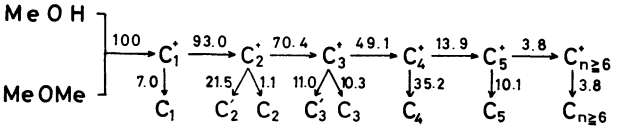
distribution. The yield of hydrocarbons increased only slightly with the methanol partial pressure, indicating that the overall rate of methanol conversion has a slightly higher order than one with respect to the methanol pressure. By lowering the methanol partial pressure, the fraction of lower hydrocarbons in the hydrocarbon products increased slightly.

Figure 3 shows the effect of the contact time (W/F) on the yield of hydrocarbons and their distribution at 573 K. The hydrocarbon yield increased gradually with the increase in the contact time. No acceleration in the rate of hydrocarbon formation was observed, in contrast to the conversion over ZSM-5.[4,5] This again indicates that the methanol conversion over TPA is not an autocatalytic reaction. For the conversion over ZMS-5, the autocatalytic phenomena were explained by assuming that Reaction 2 proceeds much faster than Reaction 1, according to the following reaction scheme:[4,5]

$$CH_3OH \longrightarrow \text{olefins (ethylene)} \quad (1)$$

$$CH_3OH + \text{olefins} \longrightarrow \text{olefins} + \text{paraffins}. \quad (2)$$

The lack of autocatalytic phenomena suggests that this assumption is not valid for the conversion over TPA. In conformity with this, the hydrocarbon distribution does not change appreciably with the total hydrocarbon yield. This is more clearly illustrated in Figs. 4—6, where the yield of each hydrocarbon species is plotted against the total hydrocarbon yield. The yield of each hydrocarbon species increases proportionally with the total hydrocarbon yield until the latter reaches *ca.* 50%, implying that all the hydrocarbon species are produced concurrently. Therefore, the following reaction scheme is plausible, assuming carbonium-ion intermediates.



The numbers in the scheme represent the relative rates of the individual steps, which were calculated from the initial distribution of hydrocarbons.

The distinct difference between the mechanism over heteropolyacids and that over ZSM-5 is that olefins once desorbed from the catalyst surface hardly react at all with methanol in the former catalyst, while over ZSM-5 olefins react with methanol rapidly, as has been described above.

The high catalytic activity of TPA seems to be rather unusual, considering the small surface area of TPA ($\approx 2\ m^2\ g^{-1}$). To determine the effective number of active sites of TPA, the effect of pyridine sorption was examined. The reaction was started by feeding methanol and nitrogen at 573 K. After 2 h, pyridine was added to the feed, and then finally the feed was changed back to the starting mixture. Most of the pyridine introduced was retained by the catalyst. As

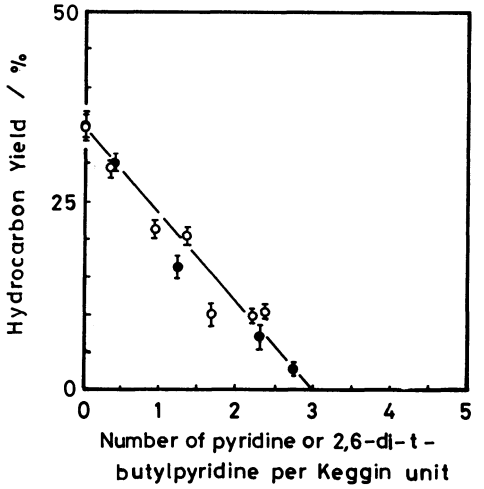

Fig. 7. Change in the hydrocarbon yield with the amount of the sorbed pyridine (○) and 2,6-di-*t*-butylpyridine (●).
Reaction conditions: 573 K, methanol pressure 50.7 kPa, $W/F=55.0$ g h mol^{-1}.

is shown in Fig. 7, the catalytic activity after pyridine sorption decreased linearly with the amount of the sorbed pyridine, a complete loss of the activity being attained when the molar ratio of the sorbed pyridine and the TPA used as a catalyst was three. The use of 2,6-di-*t*-butylpyridine instead of pyridine as a base has the same effect, as is shown in Fig. 7. Since the former poisons

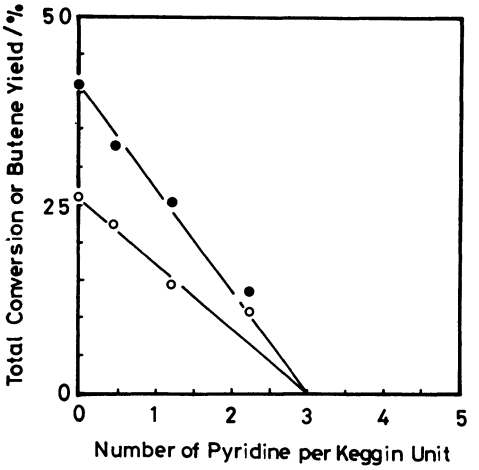

Fig. 8. Change in the conversion of 1-butanol (●) and the yield of butenes (○) in the dehydration of 1-butanol over TPA. The difference between the conversion and butene yield corresponds the formation of dibutyl ether.
Reaction conditions: 433 K, 1-butanol pressure, 24.3 kPa, $W/F=24.0$ g hmol^{-1}.

Brönsted-acid sites, but not Lewis-acid sites, the type of acid responsible for the conversion is Brönsted acid.

The amount of acid thus estimated indicates that all the protons in the solid TPA are accessible to pyridine molecules. The stoichiometric absorption of pyridine by heteropolyacids at 573 K was reported earlier.[10-12] Since methanol and other polar molecules are known to be absorbed by TPA, even at room temperature,[13,14] we presume that methanol molecules penetrate into the bulk of the solid TPA at the reaction temperature and react in the bulk. This explains the high activity of TPA, irrespective of its small surface area. Okuhara *et al.*,[12] on the basis of the correlation of the activity with the bulk acidity, recently proposed that the conversion of methanol occurred also in the bulk.

Methanol conversion was carried out with TPA (50 wt%) supported on three kinds of silica-gel with surface areas of 14.6, 37.5, and 80.9 m^2 g^{-1}. The yield of hydrocarbons depended only slightly on the surface area of the silica-gel. Thus, under the conditions of 573 K, $W/F=48.0$ g mol^{-1} h and a methanol pressure of 101 kPa, the hydrocarbon yields were 10.0, 9.1, and 10.6%. This again indicates that the reaction proceeds in the bulk; otherwise, the yield would depend on the surface area of silica-gel.

To confirm that the phenomenon is not specific to the conversion of methanol, the number of acid sites for the dehydration of 1-butanol to dibutyl ether and butenes was determined in a similar manner. As is shown in Fig. 8, the amount of acid sites responsible for the dehydration of 1-butanol is again three times as large as the amount of TPA used as a catalyst. Thus, the dehydration of 1-butanol is also presumed to proceed in the bulk of the solid. It has been reported that the dehydration of ethanol[13] and 2-propanol proceeds in the bulk of heteropolyacids.

Olefins, nonpolar molecules, cannot penetrate into the bulk of the solid TPA. Therefore, the reaction of olefins

with methanol occurs only on the surface of the solid, while the reaction between methanol molecules can proceed even in the bulk of the solid. This explains why Reaction 2 is not much faster than Reaction 1, and why the autocatalytic phenomena are not observed in the conversion of methanol over TPA.

The authors are deeply grateful to Professor Tominaga Keii for his fruitful discussion and his continuous encouragement throughout the present work.

Tris(2,2'-bipyridine)ruthenium(II)-photosensitized Reductions of Methyl Viologen and Molecular Oxygen in a Network of Water-swollen Cation-exchange Resin

Yoshimi KURIMURA* and Kimiyo KATSUMATA
Department of Chemistry, Ibaraki University, Mito, Ibaraki 310

(Received January 5, 1982)

The visible-light-induced reduction of methyl viologen was found to occur in water-swollen cation-exchange resin, which adsorbed both $Ru(bpy)_3^{2+}$ and methyl viologen (RMCA resin) with the aid of triethanolamine (TEA) as a donor. With illumination, the generation of hydrogen peroxide proceeds in an oxygenated TEA solution containing RMCA resin. Hydrogen peroxide is produced *via* the superoxide ion, which is itself formed by the reaction of the methyl viologen radical in the resin with the oxygen molecule in the bulk of the solution. The $Ru(bpy)_3^{2+}$-photosensitized reaction processes leading to the generation of methyl viologen radical and hydrogen peroxide in the heterogeneous systems are discussed on the basis of the results obtained.

Many recent investigations[1-11] have been focussed on the quenching processes and visible-light-induced reactions *via* the photosensitized reactions of this type:

$$*Ru(bpy)_3^{2+} + A \longrightarrow Ru(bpy)_3^{3+} + A^-,$$

where $*Ru(bpy)_3^{2+}$ (bpy=2,2'-bipyridine) is the lowest excited state of $Ru(bpy)_3^{2+}$. The micellar systems have been examined with an eye to enhancing the charge-separation of this type of reaction.[1,7,10] In the case of a micellar solution, the kinetic features are considered to be different from those in a homogeneous solution. It has been suggested that, in a micellar system, no intermicellar exchange of $*Ru(bpy)_3^{2+}$ and the acceptor molecules can take place; thus, the electron-transfer will occur within groups of only a few molecules that are compartmented within their host aggregate.[7]

Relatively little attention seems to have been paid to such heterogeneous reactions as those which occur in the networks of ion-exchange resins. The quenching of $*Ru(bpy)_3^{2+}$ by various metal ions has been investigated in water-swollen cation-exchange resin (Shphadex-SP)[12] or in a cluster network of perfluorosulfonate membrane (Nafion 120).[13] However, little investigation of the $Ru(bpy)_3^{2+}$ photosensitized reduction in the network of the ion-exchange resin has been reported except for that in water-swollen iminodiacetic acid type chelate resin bead adsorbing $Ru(bpy)_3^{2+}$ and methyl viologen (MV^{2+}).[14] If we use a cation-exchange resin, photosensitizer and acceptor ions having more than two positive charges, such as $Ru(bpy)_3^{2+}$ and MV^{2+} respectively, could be accumulated in the domain of the resin. In such a system, an efficient electron-transfer from $*Ru(bpy)_3^{2+}$ to the acceptor can be expected to occur if the resin is relatively transparent, and the back-reaction can be prevented by scavenging the oxidized species of the Ru(II) complex by a suitable donor, because the electron-transfer efficiency from the excited state of the chromophore to the acceptor should be enhance as a result of the intimate contact of these species in the domain of the resin.

In the present work, we have studied the photosensitized reduction of methyl viologen and the activation of the dissolved oxygen by use of a cation-exchange resin which adsorbs both $Ru(bpy)_3^{2+}$ and MV^{2+} (abbreviated as RMCA resin).

Experimental

The chloride salt of methyl viologen was recrystallized from methanol. The $[Ru(bpy)_3]Cl_2 \cdot 6H_2O$[15] was prepared according to the literature method. The triethanolamine (TEA) and other reagents were of the best commercial grade available. The cation-exchange resin (Dowex 50-W-X-8, 100—200 mesh; sodium form) was used after conditioning by means of a column exchange, washing with water until the effluent was transparent in the UV region, and drying at 60 °C. The exchange capacity of the resin was determined to be 4.51 mequiv. g^{-1}. The concentrations of $Ru(bpy)_3^{2+}$ and MV^{2+} were determined by means of solution spectrometry at 456 nm (ε 13600 M^{-1} cm^{-1}, 1 M=1 mol dm^{-3}) and 257 nm (ε 21000 M^{-1} cm^{-1}) respectively. The cation-exchange resin adsorbing both $Ru(bpy)_3^{2+}$ and MV^{2+} was prepared as follows. The resin beads (5.0 g) in a 100-ml portion of the solution containing the Ru(II) and MV^{2+} were stirred for 1 h. By determining the concentrations of the Ru(II) and MV^{2+} remaining in the solution, the amounts of the adsorbed ions could be ascertained. The resulting resin beads were filtered, washed with water, and dried at 60 °C in the dark. The absorption spectra werer ecorded on a Hitachi Model 320 spectrophotometer. The reflectance spectral change in the RMCA resin was recorded as follows. A mixture of the RMCA resin beads (*ca.* 3 ml) and about 10-ml of the phosphate buffer (pH 7.0, 0.02 M) were bubbled with nitrogen gas for 30 min, and then the resin beads (*ca.* 2 ml) and small amounts of the buffer solution were packed into a photometer cell (10 mm × 10 mm) with a ground-glass cap in a thermostated cell holder at 30± 0.2 °C under nitrogen. The cell was illuminated with a 150-W slide projector with a UV cut-off filter (Kenko Skylight, L-40, UV). The reflectance spectra were recorded on a Hitachi Model 320 spectrometer equipped with an integrating sphere accessory (Model 210-2102), with aluminum oxide as the reference.

A typical procedure for the illumination of a mixture of the RMCA resin and aqueous solution was as follows. The pH of a mixture of 0.50 g of the RMCA resin and 30.0 ml of water in a 100-ml Ehrenmayer flask was adjusted to about 7 by the addition of several drops of dilute hydrochloric acid and, if necessary, dilute sodium hydroxide, by then adding 5.0 ml of a phosphate buffer (0.2 M), and ,finally, by adjusting the volume of the solution to 50.0 ml. The flask was kept in a thermostated water bath, made of transparent polyacrylic acid resin, at 30±0.2 °C. Oxygen or air was flushed through the mixture for 20 min. The mixture was illuminated with a 150-W slide projector located below the water bath. During

the illumination, the mixture was stirred by bubbling in oxygen or air. The concentration of hydrogen peroxide in the illuminated solution was determined colorimetrically using titanium oxalate.[16]

Results and Discussion

The cation-exchange resin adsorbs both Ru(bpy)$_3^{2+}$ and MV^{2+} in an aqueous solution well. When the total amounts (equiv. g^{-1} of the resin) of the adsorbed Ru(bpy)$_3^{2+}$ and MV^{2+} ions were less than 10% of the exchange capacity of the resin, no appreciable amounts of the adsorbed ions were eluted into the solution when the RMCA resin was kept in a 0.1 M TEA solution at pH 8.0 for 3 h at 30 °C. It was also ascertained that no detectable amounts of TEA were found to be adsorbed on the cation-exchange resin when 0.50 g of the cation-exchange resin was stirred in 50 ml of a 0.10 M TEA solution at pH 7 and 30 °C for 2 h.

When RMCA resin was illuminated in a deoxygenated aqueous solution of TEA, the resin turned from the original light brown through light green to dark blue. In the absence of TEA, however, no such color change was observed at all upon illumination.

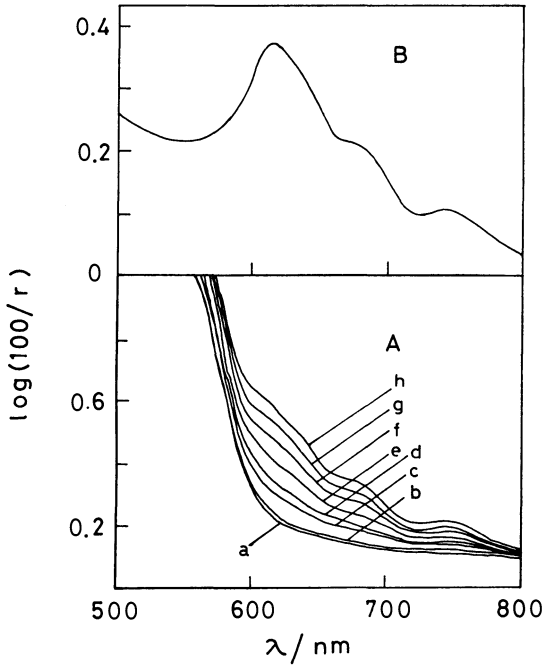

Fig. 1. Reflectance spectral change of the illuminated RMCA resin ([Ru(II)]=2.3×10^{-5} mol g^{-1}, [MV^{2+}]=1.1×10^{-4} mol g^{-1}) in N_2-saturated 0.10 M TEA solution with the illumination time (min) of 0 (a), 5 (b), 15 (c), 20 (d), 30 (e), 40 (f), 50 (g), and 60 (h) (A) and the differential spectrum of the 60 min illuminated RMCA resin (B) at pH 7.0 and 30 °C.

The reflectance spectral change in the RMCA resin in a deoxygenated solution (Fig. 1A) and the differential spectrum of the illuminated resin is essentially the same as the absorption spectrum of the methyl viologen radical in an aqueous solution in the region of 550—800 nm. It may be concluded that the *Ru(bpy)$_3^{2+}$ produced by the photoexcitation of the adsorbed Ru(bpy)$_3^{2+}$ reacts with MV^{2+} to give the methyl viologen radical, MV^{+},[17] in the interior of the domain of the resin and that the oxydized psecies of the chromophore is scavenged by the TEA molecule present in the bulk of the solution. A bead of the illuminated (*ca.* 5 min) RMCA resin in a deoxygenated solution was cut into two hemispheres and then the cut surface was examined under a microscope. The dark blue color of the methyl viologen radical was found to spread homogeneously on the surface. This seems to indicate that the reaction proceeds almost homogeneously in the resin bead.

The photosensitized reduction of methyl viologen using RMCA resin can be explained by the scheme given in Eqs. 1—5. In these equations, the chemical species written in branckets with the suffix *r* represent those adsorbed on the resin, while *m* denotes the ratio of the average number of the MV^{2+} to one Ru(bpy)$_3^{2+}$:

$$[(Ru(II))(MV^{2+})_m]_r \xrightarrow{h\nu} [(*Ru(II))(MV^{2+})_m]_r \quad (1)$$

$$[(*Ru(II))(MV^{2+})_m]_r \longrightarrow [(Ru(II))(MV^{2+})_m]_r + \Delta + h\nu' \quad (2)$$

$$[(*Ru(II))(MV^{2+})_m]_r \longrightarrow [(Ru(III))(MV^{+})(MV^{2+})_{m-1}]_r \quad (3)$$

$$[(Ru(III))(MV^{+})(MV^{2+})_{m-1}]_r \longrightarrow [(Ru(II))(MV^{2+})_m]_r \quad (4)$$

$$[(Ru(III))(MV^{+})(MV^{2+})_{m-1}]_r + TEA \longrightarrow [(Ru(II))(MV^{+})(MV^{2+})_{m-1}]_r + TEA_{ox}, \quad (5)$$

where TEA_{ox} is the oxidized species of triethanolamine. The charge separation, *i.e.*, generation of MV^{+}, takes place as a result of the reduction of the Ru(III) by the TEA molecule *via* Eq. 5.

When RMCA resin was illuminated in an oxygenated solution of TEA, only a slight color change or, in some cases, no color change at all was seen, while the formation of hydrogen peroxide was observed in the bulk of the solution. These facts indicate that the hydrogen peroxide is produced by the reaction of the methyl viologen radical with the oxygen molecule.

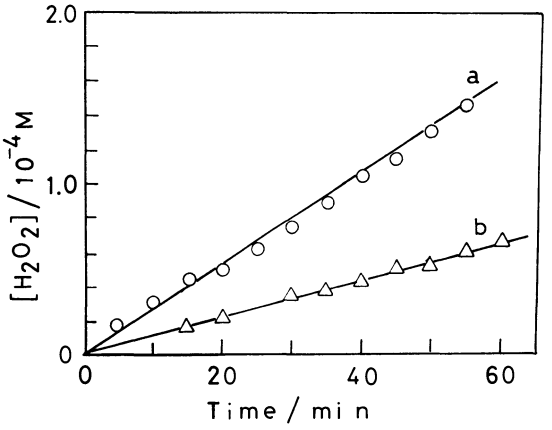

Fig. 2. Plots of the concentration of hydrogen peroxide with the illumination time in the mixture of 0.50 g of RMCA resin ([Ru(II)]=2.3×10^{-5} mol g^{-1}, [MV^{2+}]=1.1×10^{-4} mol g^{-1}) and 50 ml of the O_2-saturated (a) and air-saturated (b) 0.10 M TEA solutions at pH 7.0 and 30 °C.

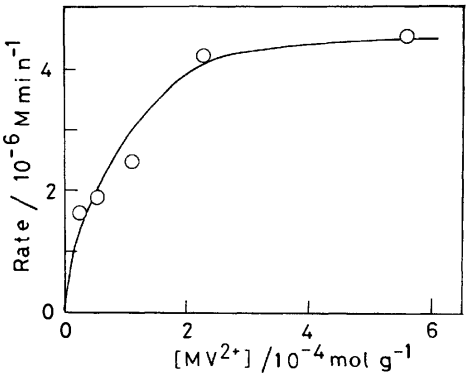

Fig. 3. Dependence of the rate of hydrogen peroxide formation on the concentration of MV^{2+} in the mixture of 0.50 g of RMCA resin ([Ru(II)]$=2.3\times10^{-5}$ mol g^{-1}) and 50 ml of O_2-saturated 0.10 M TEA solution at pH 7.0 and 30 °C.

The concentration of hydrogen peroxide is plotted as a function of the illumination time in Fig. 2. The rate of hydrogen peroxide formation was determined from the slope of the plots of the hydrogen peroxide concentration *vs.* the illumination time. The results shown in Fig. 2 demonstrate that the rate depends on the concentration of the dissolved oxygen: the rate in the oxygen-saturated solution is about two times greater than that in the air-saturated solution under the conditions employed.

The rate also depends on the "concentrations"[19] of the adsorbed $Ru(bpy)_3^{2+}$ and MV^{2+}. The rate dependence on the concentration of MV^{2+} shows that the rate increases sharply at lower [MV^{2+}] values and reaches the saturated value at [MV^{2+}] values higher than about 2×10^{-4} mol g^{-1} (Fig. 3).

The rate is also affected by the concentration of the TEA: the rate increases with the concentration of the TEA and is hardly saturated even at 0.5 M (Fig. 4). The dependence of the rate on the concentration of the

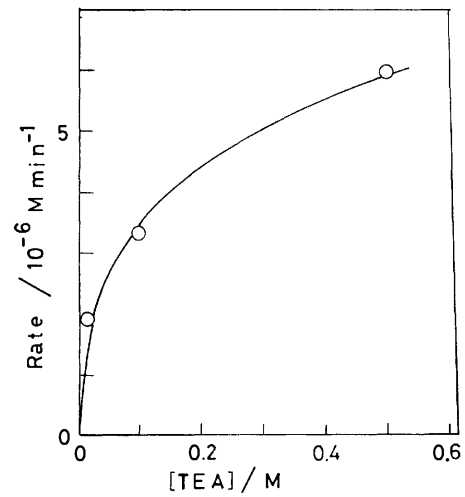

Fig. 4. Dependence of the rate of hydrogen peroxide formation on the concentration of TEA in the mixture of 0.50 g of RMCA resin ([Eu(II)]$=2.3\times10^{-5}$ mol g^{-1}, [MV^{2+}]$=1.1\times10^{-4}$ mol g^{-1}) and 50 ml of O_2-saturated TEA solution at pH 7.0 and 30 °C.

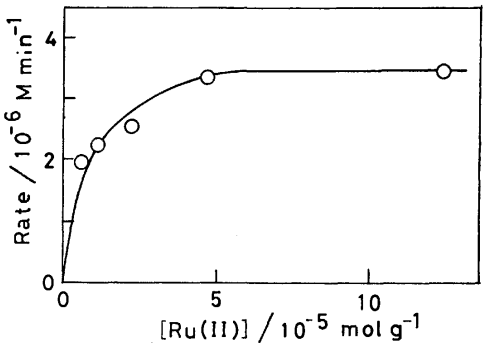

Fig. 5. Dependence of the rate of hydrogen peroxide formation on the concentration of $Ru(bpy)_3^{2+}$ in the mixture of 0.50 g RMCA resin ([MV^{2+}]$=1.1\times10^{-4}$ mol g^{-1}) and 50 ml of O_2-saturated 0.10 M TEA solution at pH 7.0 and 30 °C.

Ru(II) is presented in Fig. 5.

The reaction scheme for the formation of hydrogen peroxide responsible for the results can be explained by Eqs. 1—5, 6, and the subsequent reduction of the superoxide ion, by Eqs. 7—9. Hydrogen peroxide is,

$$[(Ru(II))(MV^{+})(MV^{2+})_{m-1}]_r + O_2 \longrightarrow [(Ru(II))(MV^{2+})_m]_r + O_2^- \quad (6)$$

probably, formed by the disproportionation reaction of the superoxide ions and the reaction of O_2^- with $*Ru(bpy)_3^{2+}$, and/or MV^+. The rate dependence on the

$$O_2^- + O_2^- + 2H^+ \longrightarrow H_2O_2 + O_2 \quad (7)$$

$$[*Ru(II)]_r + O_2^- + 2H^+ \longrightarrow [Ru(III)]_r + H_2O_2 \quad (8)$$

$$[MV^+]_r + O_2^- + 2H^+ \longrightarrow [MV^{2+}]_r + H_2O_2 \quad (9)$$

oxygen concentration may be explained by the fact that the rate of the reaction of MV^+ with O_2 is relatively slow at low O_2 concentrations relative to that of the methyl viologen-radical formation: thus, the rate of hydrogen peroxide increases with an increase in the O_2 concentration in the lower-concentration region.

When 0.50 g of the RMCA resin ([Ru(II)]$=2.3\times10^{-5}$ mol g^{-1} and [MV^{2+}]$=1.1\times10^{-5}$ mol g^{-1}) in 50 ml of 0.10 M TEA was illuminated at 30 °C for 10 h, 1.4×10^{-3} M H_2O_2 was generated: thus, the turnover number for the Ru(II) and MV^{2+} were estimated to be about 10 and 2 respectively in this case (Fig. 6).

A experiment aimed at comparing the efficiencies of hydrogen peroxide formation in the heterogeneous system with the corresponding homogeneous one was

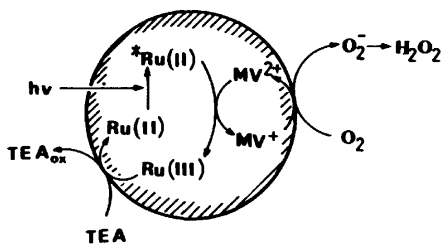

Fig. 6. Schematic representation of the generation of hydrogen peroxide in RMCA resin/O_2/TEA/H_2O system.

TABLE 1. COMPARISON OF THE RATE OF HYDROGEN PEROXIDE FORMATION IN THE RMCA RESIN SYSTEM WITH THE CORRESPONDING HOMOGENEOUS SYSTEM AT pH 7.0 AND 30 °C [a]

System		$[Ru(bpy)_3^{2+}]$	$[MV^{2+}]$	[TEA]/M	$(d[H_2O_2]/dt)$/mol min^{-1}
Heterogeneous[b]	1A	2.3×10^{-5}	1.1×10^{-4}	0.10	2.4×10^{-6}
	1B	5.9×10^{-6}	2.8×10^{-5}	0.012	1.3×10^{-6}
Homogeneous[c]	2A	2.3×10^{-4}	1.1×10^{-3}	0.10	1.4×10^{-5}
	2B	5.9×10^{-5}	2.8×10^{-4}	0.012	1.5×10^{-6}

a) 1A and 1B correspond to 2A and 2B respectively. O_2-saturated solution at pH 7.0 and 30 °C. b) 0.50 g of the RMCA resins in 50 ml of the solution. The unit of the "concentrations" of the Ru(II) and MV^{2+} is represented by mol g^{-1}. c) The volume of the illuminated solutions was 50 ml. The unit of the concentrations of the Ru(II) and MV^{2+} is represented by mol dm^{-3}.

carried out; the results are presented in Table 1. In higher-concentration regions of the Ru(II), MV^{2+}, and TEA, the relative rate in the resin system is lower than that of the corresponding homogeneous system. However, in the lower-concentration regions of those species, the rate in the heterogeneous system was almost the same with that of the corresponding homogeneous system.

A system similar to that used in the present study may be used as a model for the visible light-induced generation of high-energy substances. It seems possible to make a system consinsting of an ion-exchange resin in which the photosensitizer, acceptor, and donor are all localized in its cluster network. When we use such a system, a more efficient model for solar-energy conversion may be designed. Moreover, if we could use a transparent thin film made of ion-exchange resin which adsorbed $Ru(bpy)_3^{2+}$ and a donor such as MV^{2+} instead of the RMCA resin, a more efficient charge-separation system than the present one could be made. Further experiments in this direction are now being undertaken.

The Lowest Triplet State of 2-Methylpyrazine

Takeshi WATANABE, Hiroko SHIMADA,† and Ryoichi SHIMADA*

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

†Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814

(Received February 1, 1982)

The infrared and Raman spectra of 2-methylpyrazine were studied. An assignment was given for all fundamental vibrations based on the polarization behavior of the spectral bands and on the normal coordinate analysis. The magnetic effect on the phosphorescence lifetime and the time-resolved and polarized phosphorescence spectra of this molecule were investigated at 1.4 K. From the analysis of the phosphorescence, (1) the short lifetime phosphorescence was assigned to the emission arising from the most emissive y″ sublevel, as in the case of pyrazine, (2) the long lifetime phosphorescence was assigned to the emissions arising from the x and z″ sublevels, whose lifetimes were roughly equal to each other and (3) the 0-0 and totally symmetric vibronic bands, and the out-of-plane vibronic bands observed in the long lifetime phosphorescence, were ascribed to the z″ and x sublevel emissions, respectively.

The lowest triplet state of pyrazine was assigned to a $^3B_{3u}(n, \pi^*)$ state by Goodman and Kasha[1] and Innes and Gidding.[2] Zalewski, McClure, and Narva[4] pointed out that the lowest triplet state was strongly perturbed by low lying $^3(\pi, \pi^*)$ states through H wagging ν_5 and ν_{10a} vibrations. Through phosphoresscence microwave double resonance (PMDR) and microwave induced delayed phosphorescence (MIDP), a number of workers have discussed the molecular structure of pyrazine in the lowest triplet state and suggested that the molecule, whose equilibrium structure belongs to the point group D_{2h}, whould be distorted to C_{2h} or lower symmetry.[4-7]

Lim *et al.*[8] carried out the vibrational analyses of the phosphorescence spectra of pyrazine and its methyl derivatives at 4.2 K and studied the proximity effects on the $T_1 \rightsquigarrow S_0$ radiationless transitions. The enhancement of the radiationless $T_1 \rightsquigarrow S_0$ rate due to methyl substitution was attributed to the distorsion of the potential surface for the T_1 state due to the decrease of energy separation between vibronically coupled states.

The study of the phosphorescence process of 3-methylpyrazine should be very interesting because the energy separations between $^3W(n, \pi^*)$ and $^3L_a(\pi, \pi^*)$ states, and $^3W(n, \pi^*)$ and $^3L_b(\pi, \pi^*)$ states are closer than in the case of pyrazine due to methyl substitution. In this paper, an assignment for the normal vibrations of 2-methylpyrazine will be given and then the phosphorescence process, vibronic coupling between (n, π^*) and (π, π^*) states, and distorsion of the molecular structure in the lowest triplet state will be discussed.

Experimental

Material. 2-Methylpyrazine obtained from Aldrich Chemical Company was purified by repeated vacuum distillation followed by zone-refining (about 60 passages). Methylcyclohexane of Dotite Spectrosol grade and *m*-xylene of Merck Reference Substance for gas chromatography were used without further purification. *p*-Dibromobenzene obtained from Wako Chemical Industry was purified by zone-refining (about 60 passages), followed by sublimation under reduced pressure.

Optical Measurement. The Raman spectrum was observed in the liquid and solid phases with a JEOL 400T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm line from an Ar^+ ion laser of Toshiba Model LAI-104-A. The depolarization measurement of the individual Raman bands was also made in the liquid.

The infrared spectrum was measured with a Hitachi Infrared Spectrophotometer Model 345 over the range of 4000—250 cm^{-1} in the vapor, liquid, and solid phases. The vapor spectrum was observed at 50 °C with a gas cell 10 cm in optical path. The polarized infrared spectrum was observed in the single crystal with an AgBr wire-grid polarizer by the method described in the previous paper.[9]

The phosphorescence lifetime and spectrum were studied at 1.4 K in methylcyclohexane and *p*-dibromobenzene by the method described in the previous paper.[10] The polarized phosphorescence spectrum of 2-methylpyrazine doped in a *p*-dibromobenzene single crystal was observed at 1.4 K along a, b, and c crystal axes. The single crystal grown in the Bridgman furnace was cut along the cleavage bc plane with a razor. The b and c crystal axes were determined optically with polarized light. Then the crystal was cut along the ac and ab planes. The crystal specimen was held in the dewar so that the normal of the ab or bc plane coincided with the optical axis of the spectrophotometer. The phosphorescence spectra polarized along the a and b axes, or along the b and c axes, were observed. Thus, the relative intensities of individual phosphorescence bands polarized along the a, b, and c axes were obtained.

The magnetic effect of the phosphorescence lifetime of 2-methylpyrazine doped in a *p*-dibromobenzene single crystal was studied at 1.4 K. The sample was set between two poles of a Komatsu Type 100 Electromagnet, which applied a constant magnetic field of 3 K Gauss to the sample. Excitation light from a xenon short arc lamp of Ushio Type UXL-500D was focused on the sample through a Corning glass filter and a solution filter, which acted as a thermal radiation cut filter. The decay of the 0-0 band of the phosphorescence was observed with an oscilloscope by rotating the sample about the crystal axes. The angle between the crystal axis and the magnetic field was calibrated in the following way. After a measurement of the lifetime was over, the xenon lamp was replaced by a miniature lamp. Weak light from the miniature lamp was reflected by the crystal surface in the dewar. The crystal was rotated about the vertical axis, that is, the axis perpendicular to both the magnetic field and the excitation (and phosphorescence) beam, so that the light reflected from the crystal surface went back to the miniature lamp. In this case, the normal of the crystal surface was to coincide with the direction of the excitation beam. The angle of rotation of the crystal directly gave the orientation of

the crystal under measurement.

Procedure of Normal Coordinate Calculation. A normal coordinate calculation was performed through the standard GF matirx method with a FACOM M-200 computer at the computer center of Kyushu University. Although the molecular structure of 2-methylpyrazine was not determined yet, it was assumed that the molecular structure belongs to roughly the C_s point group and that the geometric parameters of the ring and the CH_3 group were nearly identical with those of pyrazine[11] and toluene,[12] respectively. The F matrix elements for the in-plane and out-of-plane vibrations were evaluated with an improved modification of the Urey-Bradley force field given by Cossee and Schachtschneider[13] and with the valence force field, respectively, as described in the previous paper.[9]

Results and Discussion

Normal Vibration. Force constants for the in-plane and out-of-plane vibrations finally obtained after several iterative calculations are given in Tables 1 and 2, respectively. The internal coordinates for the in-plane and out-of-plane vibrations are illustrated in Fig. 1. The calculated vibrational frequencies and modes are given in Table 3.

The infrared spectrum observed in the single crystal and the Raman spectrum observed in the liquid phase are shown in Figs. 2 and 3, respectively. The polarized infrared spectrum measured with the incident light beams polarized parallel and perpendicular to the direction of the crystal growth of the single crystal will be referred to as // and ⊥ spectra, respectively: these are drawn with solid and dotted lines, respectively.

The polarized infrared bands observed in the single crystal could be classified into two types according to their polarization character. The bands belonging to the first type appear strongly in the // spectrum and weakly in the ⊥ spectrum, while the second type bands appear strongly in the ⊥ spectrum and weakly in the // spectrum. These two types of the bands will be referred to as types A and B, respectively.

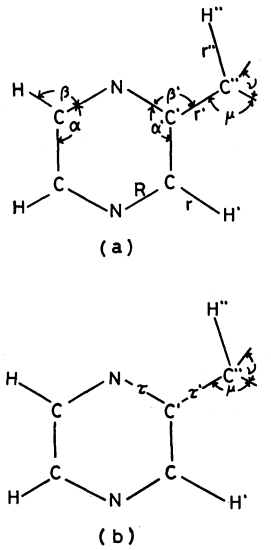

Fig. 1. Internal coordinates for the in-plane (a) and out-of-plane (b) vibrations.

Calculation of the principal moments of inertia indicates that the c axis of the moment is perpendicular to the molecular plane, the a axis is directed nearly along the C–CH_3 bond, and the b axis is perpendicular to both a and c axes. These axes will be referred to as the molecular axes. Careful observation of the rotational band envelopes of the infrared bands observed in the vapor phase showed that the bands could be classified into three types: A, B, and C, according to Ueda and Shimanouchi.[14]

In-plane Vibration: Bands observed at 342, 1031, and 1065 cm^{-1} in the infrared vapor spectrum showed a typical B band envelope and the corresponding bands in the single crystal showed type B character. Bands observed at 631, 1255, 1308, and 1408 cm^{-1} in the vapor showed a typical A band envelope and the corresponding single crystal bands showed type A

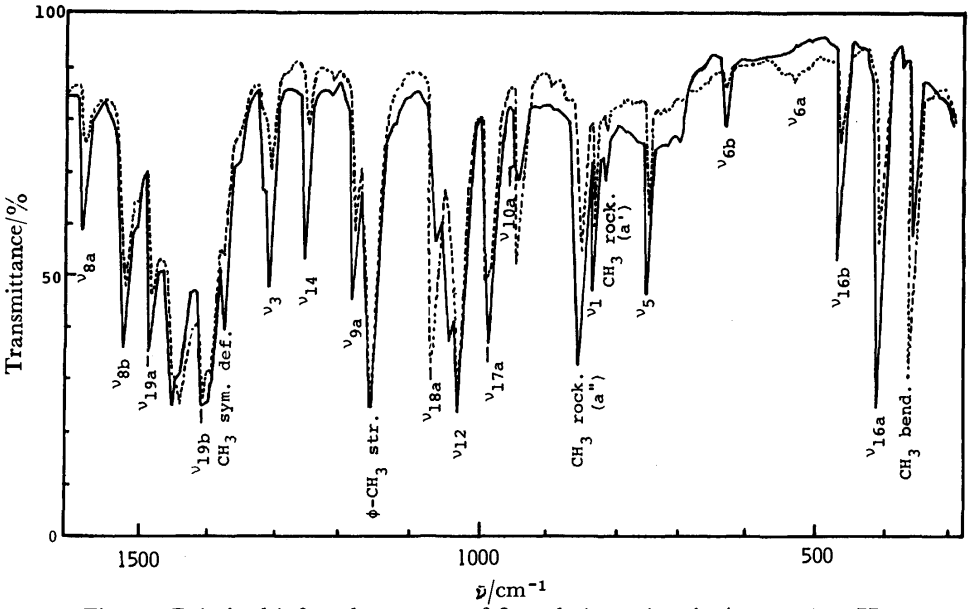

Fig. 2. Polarized infrared spectrum of 2-methylpyrazine single crystal at 77 K.

character. Normal coordinate and INDO calculations suggested that the transition moments of CH_3 bending, ν_{12} and ν_{18a} vibrations lie nearly along the molecular b axis, while those of ν_{6b}, ν_{14}, ν_3, and ν_{19b} vibrations nearly along the molecular a axis. These results definitely indicate that the bands at 342, 1031, and 1065 cm^{-1} should be assigned to CH_3 bending, ν_{12} and ν_{18a}, respectively, and the bands at 631, 1255, 1308, and 1408 cm^{-1} to ν_{6b}, ν_{14}, ν_3, and ν_{19b} vibrations, respectively.

The in-plane vibrations, which correspond to the vibrations belonging to the a_1 and b_2 species in the point group C_{2v}, are the totally symmetric vibrations in 2-methylpyrazine. However, it is expected that the bands which come from the a_1 species will show strongly polarized character and the bands which come from the b_2 species will show somewhat depolarized character in the depolarization measurement of the Raman spectrum. Therefore, the strongly polarized Raman bands at 3056, 3038, 1580, 1480, 1176, 1058, 1022, 826, and 556 cm^{-1} were assigned to ν_2, ν_{13}, ν_{8a}, ν_{19a}, ν_{9a}, ν_{18a}, ν_{12}, ν_1, and ν_{6a}, respectively, and the depolarized Raman band at 1529 cm^{-1} to ν_{8b}. Polarized Raman bands at 1247, 1154, and 635 cm^{-1} could be assigned to ν_{14}, C–CH_3 stretching, and ν_{6b} vibrations, respectively, since calculation suggested that these vibrations have the transition moments nearly along the C–CH_3 bond.

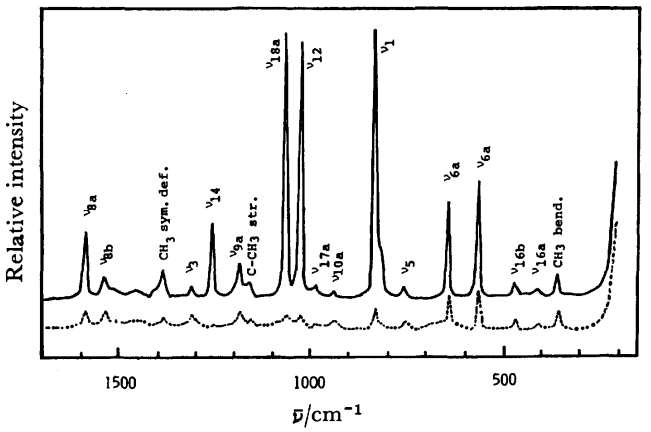

Fig. 3. Raman spectrum at room temperature.

Out-of-plane Vibration: Infrared bands observed at 404, 462, 751, and 831 cm^{-1} in the vapor showed quite clearly a C band envelope and the corresponding infrared single crystal bands showed type A polarization character. Hence, these bands were assigned to the out-of-plane ν_{16a}, ν_{16b}, ν_5, and CH_3 rocking vibrations (a″ species), respectively. The corresponding infrared single crystal bands showed type A polarization character. The other five out-of-plane vibrations of ν_{17a}, ν_{10a}, ν_4, CH_3 wagging, and C–CH_3 torsional vibrations were assigned to depolarized Raman bands observed at 975, 929, 720, 203, and 169 cm^{-1}, respectively. The corresponding infrared single crystal bands at 985 and 948 cm^{-1} showed type A character.

The characteristic vibrations for the CH_3 group were determined based on the observed polarization characters as well as on the normal coordinate calculation. The normal vibrations assigned are summarized in Table 3. The agreement between observed and calculated frequencies is satisfactory.

Phosphorescence. Magnetic Effect on the Phosphorescence Lifetime: Analysis of the phosphorescence decay observed at 1.4 K gave lifetimes of 6.2 and 80 ms in methylcyclohexane and 14 and 37 ms in *p*-dibromobenzene. We tried to identify the three sublevel decays through the MIDP technique, but the MIDP signals were too weak to detect the decays clearly. Therefore, the magnetic effect on the phosphorescence lifetime was studied in the *p*-dibromobenzene host single crystal at 1.4 K in order to investigate the emitting sublevels and to find the unknown third lifetime phosphorescence.

It is necessary to know what orientation a 2-methylpyrazine molecule takes in the *p*-dibromobenzene host crystal. The *p*-dibromobenzene single crystal is known to belong to the space group $P2_{1/a}$ with $Z=2$ and the

a) Vapor. b) Solid.

site group C_i. The van der Waals radii of the methyl group and of hydrogen and bromine atoms may suggest that a *p*-dibromobenzene molecule in the crystal is replaced by a 2-methylpyrazine molecule with the C–CH_3 bond parallel to the Br–Br direction. Thus, the 2-methylpyrazine molecule could take four different orientations; two of these are the same due to the C_i site group symmetry. Therefore, the 2-methylpyrazine molecule could take two different orientations in the *p*-dibromobenzene crystal.

If the 2-methylpyrazine molecule could take two orientations equally, the intensity ratio of the 0-0 bands of the phosphorescences polarized along the b and a crystal axes would be calculated to be 1.9 from the crystal data given by Bezzi and Croatto.[15] The observed ratio was greater than 4 and no splitting of the 0-0 band of the unpolarized phosphorescence spectrum was observed under high resolution. These facts prove that the 2-methylpyrazine molecule could take only one orientation in the *p*-dibromobenzene host crystal.

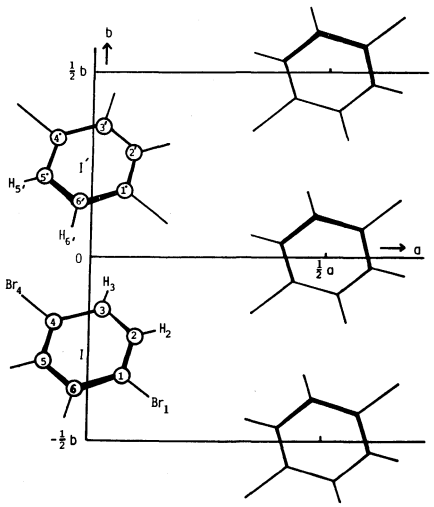

Fig. 4. Projection of *p*-dibromobenzene single crystal on the ab crystal plane.

The two nearest neighbor molecules, labeled I and I′, are shown in Fig. 4. The calculation of the intermolecular atomic distances using the crystal data showed that the distance of H_3–$H_{6'}$ is shorter than that of H_3–$H_{5'}$ and the distance of H_3–$C_{6'}$ is also shorter than that of H_3–$C_{5'}$. Thus, the hydrogen-hydrogen repulsion force between H_3 and $H_{6'}$ would be stronger than that between H_3 and $H_{5'}$ and the hydrogen bonding attraction between H_3 and $C_{6'}$ would be stronger than that between H_3 and $C_{5'}$, if $C_{6'}$ and $C_{5'}$ atoms are replaced with N atoms. These considerations clearly suggest that N atoms of 2-methylpyrazine should occupy the positions of $C_{3'}$ and $C_{6'}$, and thus, the N–N axis and the normal of the 2-methylpyrazine plane are nearly parallel to the b and c crystal axes, respectively.

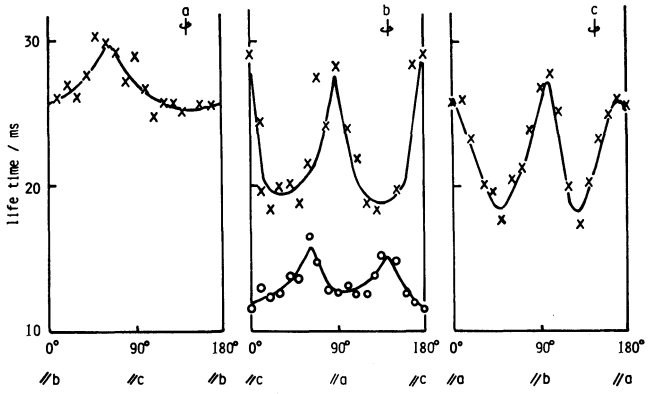

Fig. 5. Magnetic effect on the phosphorescence lifetime. a indicates rotation of the crystal about the a crystal axis. × and ○ indicate long and short lifetimes, respectively.

The magnetic effect on the phosphorescence lifetime is shown in Fig. 5. A remarkable change of the lifetime was observed for the long lifetime phosphorescence by rotation of the crystal about the a, b, and c crystal axes. If the third lifetime, which could not be resolved, were nearly equal to the short lifetime 14 ms, the observed long lifetime would become longer only when the spin axis of the long lifetime sublevel is parallel to the magnetic field. In other orientations of the spin axis, the long lifetime sublevel would mix with the short lifetime sublevels and the observed lifetime would become shorter. In other words, the observed long lifetime would become longer only at two orientations of the crystal, where the spin axis of the long lifetime sublevel is parallel to the magnetic field. But the observed results showed that the long lifetime became longer at more than two orientations of the crystal, as can be seen in Fig. 5. That is, the observed magnetic effect on the long lifetime phosphorescence did not support the assumption that the third lifetime is nearly equal to the short lifetime.

If the third lifetime is nearly equal to the long lifetime, 37 ms, the observed long lifetime would become longer whenever the spin axis of one of the two long lifetime sublevels is parallel to the magnetic field or whenever the spin axes of both the long lifetime sublevels are perpendicular to the magnetic field. In other words, a longer lifetime will be observed when any one of the three spin axes is parallel to the magnetic field. This is exactly consistent with the observation. Thus, it was concluded that the phosphorescence consists of three emission components: one is short and the others are long in lifetime, as in the cases of pyrazine[16] and 2,6-dimethylpyrazine.[17]

The magnetic effect on the short lifetime phosphorescence will be discussed next. An appreciable change of the lifetime was observed only for the rotation of the crystal sample about the b axis. This may suggest that the short lifetime sublevel would not be so sensitive to the mixing, compared with the long lifetime sublevel. Let the decay rate constants of the short and long lifetime sublevels be k_s and k_l, respectively. If the two sublevels mix with each other with a mixing ratio of a/b, the rate constants k_s and k_l may change to $k_{s'}=ak_s+bk_l$ and $k_{l'}=ak_l+bk_s$, respectively, where $a+b=1$. Thus, the new short and long lifetimes are given by $\tau_{s'}=1/(ak_s+bk_l)$ and $\tau_{l'}=1/(ak_l+bk_s)$, respectively. The observed ratio of the rate constants k_s/k_l was approximately 3/1. In our experiment, the magnetic perturbation was not strong enough and thus a would be greater than b. Hence, the magnetic dependence on the short lifetime phosphorescence is expected to be much less sensitive than that on the long lifetime phosphorescence.

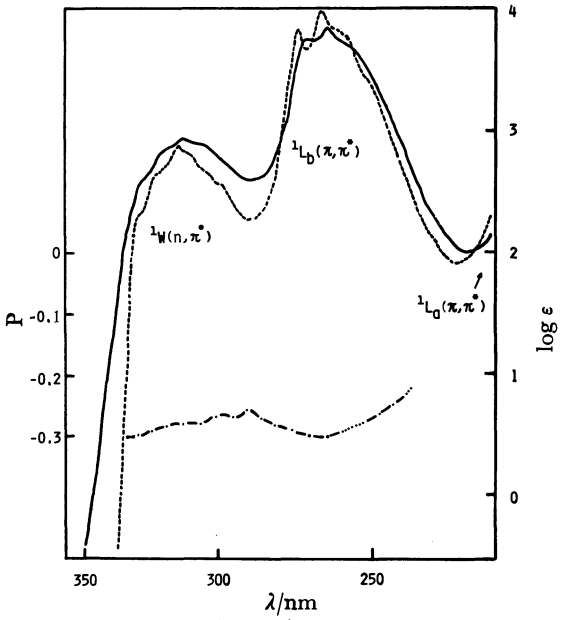

Fig. 6. Near ultraviolet absorption spectrum (—— at 20 °C, ------ at 77 K) and excitation polarization spectrum (-·-·-) monitoring the intensity of the 0-0 band of the phosphorescence at 77 K in EPA.

Phosphorescence Process: The excitation polarization spectrum obtained by the photoselection experiment in EPA at 77 K is shown in Fig. 6, together with the absorption spectrum. These spectra clearly indicate that the lowest triplet state is a $^3W(n, \pi^*)$ perturbed by the $^1L_a(\pi, \pi^*)$ state, as in the case of pyrazine. The coordinate axis for this molecule was taken in such a

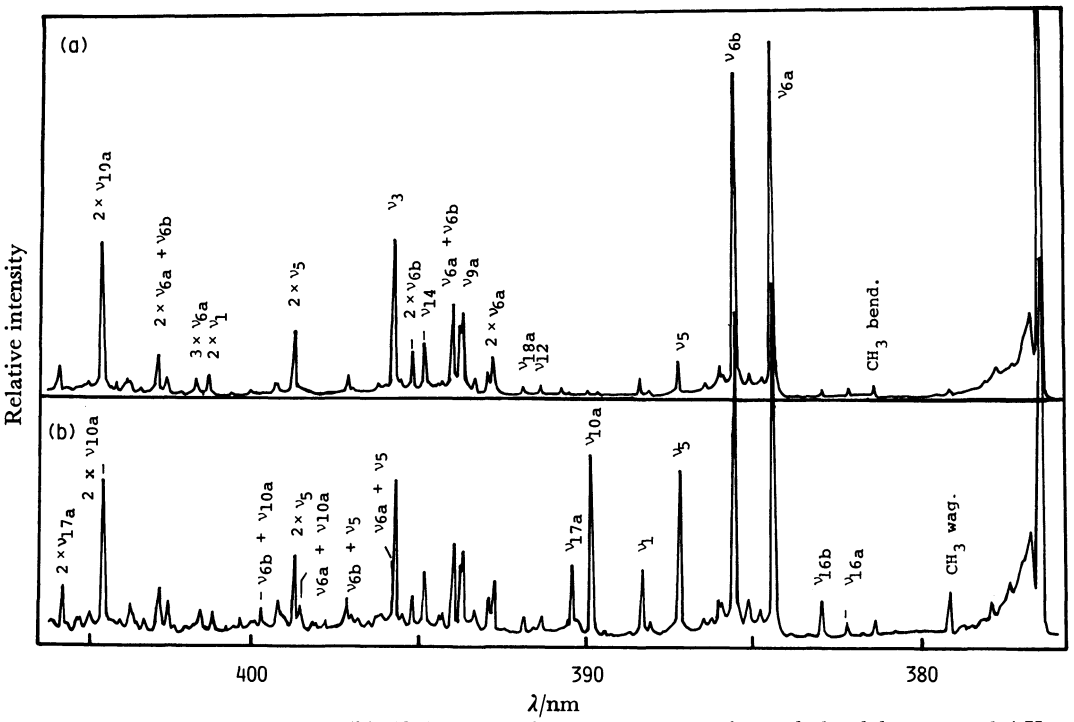

Fig. 7. Short (a) and long (b) lifetime phosphorescence spectra in methylcyclohexane at 1.4 K.

way that the x axis is perpendicular to the molecular plane and the z axis is along the N–N direction. Althrough the axis of the diagonalized spin functions of this molecule is not known, we could suppose that the x″ spin axis may coincide with the x axis and y″ and z″ spin axes would be roughly parallel to the y and x axes, respectively. The spin-orbit coupling matrix element between the $^1L_a(\pi, \pi^*)$ and $^3W(n, \pi^*)$ states gives the atomic integral of $\langle p_z|Hso|p_x\rangle$, where the most effective angular momentum operator is L_y. Hence, we may conclude that the short lifetime phosphorescence may arise from the y″ sublevel of the lowest triplet state, as in the case of pyrazine.

The time-resolved phosphorescence spectrum in methylcyclohexane at 1.4 K is shown in Fig. 7. The short lifetime phosphorescence spectrum was observed in the following way. The sample was excited for 5 ms and the excitation was cut off. 1 ms after ceasing the excitation, the phosphorescence was sampled for 5 ms. The observed spectrum might contain the bands due to the long lifetime phosphorescence, but their intensity is expected to be very weak; hence, all bands of the spectrum except for extremely weak bands could be safely ascribed to the short lifetime phosphorescence. The long lifetime phosphorescence was observed with 100, 100, and 100 ms of the excitation, waiting, and sampling times, respectively. Intensity ratio of the 0-0 bands of the long and short lifetime phosphorescence spectra at $t=0$, when the excitation of the sample was cut off, was calculated to be about 1/30. The spectra shown in Fig. 7 are drawn after normalizing the observed intensities of the 0-0 bands of the short and long lifetime phosphorescences to unity.

The vibrational analysis of the short lifetime phosphorescence will be discussed first. The shortest wavelength band at 376.55 nm, whose intensity is the strongest in the spectrum, was taken as the 0-0 band. Strong bands separated by 557, 636, 1175, 1248, and 1303 cm^{-1} from the 0-0 band were assigned to ν_{6a}, ν_{6a}, ν_{9b}, ν_{14}, and ν_3 vibrations, respectively. The overtone and combination bands of these vibrations were observed with medium intensity.

Medium intense bands separated by 750 and 926 cm^{-1} from the 0-0 band were ascribed to ν_5 and ν_{10a} vibrations, respectively. Progressions of the ν_5 and ν_{10a} vibrations extending up to four quanta were observed with strong intensity in the even quanta and weak intensity in the odd quanta. Extremely weak bands assigned to CH_3 wagging, ν_{16a}, ν_{16b}, and ν_{17a} vibrations were also observed.

Although the long lifetime phosphrescence gave essentially the same spectral structure as that of the short lifetime phosphorescence, the most characteristic feature of the long lifetime spectrum was the remarkable intensification of the bands assigned to the out-of-plane CH_3 wagging, ν_{16b}, ν_5, ν_{10a}, ν_{17a}, and the totally symmetric ν_1 vibrations. The bands assigned to the totally symmetric ν_{6a}, ν_{6b}, ν_{9a}, ν_{14}, and ν_3 vibrations were also observed with strong intensity in the long lifetime spectrum.

The short lifetime phosphorescence cannot sneak into the long lifetime spectrum, because the population of the y″ sublevel must decay out during 100 ms of the waiting time for sampling the phosphorescence. Therefore, the bands assigned to the totally symmetric vibrations observed in the long lifetime spectrum should be ascribed to the bands arising from the x and/or z″ sublevels.

The time-resolved phosphorescence spectrum was also studied in *p*-dibromobenzene at 1.4 K. The short and

long lifetime phosphorescence showed essentially the same spectral structures as those observed in methylcyclohexane. The polarized long lifetime phosphorescence spectrum of 2-methylpyrazine doped in a *p*-dibromobenzene host single crystal was observed at 1.4 K. The phosphorescence spectra polarized along the a, b, and c crystal axes are shown in Fig. 8, where the intensity of the band polarized along the c axis was normalized to unity.

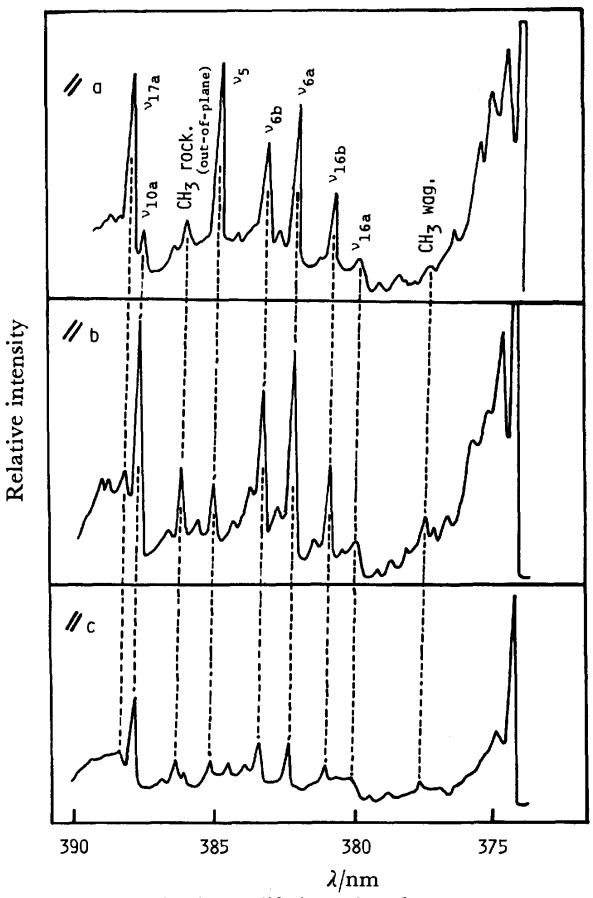

Fig. 8. Polarized long lifetime phosphorescence spectrum in *p*-dibromobenzene single crystal at 1.4 K.

Let the direction of the transition moments of the $^1W(n, \pi^*)\leftarrow S_0$, $^1L_b(\pi, \pi^*)\leftarrow S_0$, and $^1L_a(\pi, \pi^*)\leftarrow S_0$ absorptions be x, y′, and z′, respectively. The INDO calculation indicates that the z′ axis is in between the N–N and C–CH_3 axes and that the y′ axis is perpendicular to both x and z′ axes. Thus, we could suppose that the x, y′, and z′ axes are roughly parallel to the c, a, and b crystal axes, respectively.

Observed polarized spectra showed that the ν_5 and ν_{17a} bands were strongly polarized along the a crystal axis, the bands ascribed to CH_3 wagging, ν_1 and ν_{10a} vibrations were strongly polarized along the b axis, and the 0-0, ν_{6a}, ν_{6b}, ν_{16a}, and ν_{16b} bands were equally polarized along the b and a axes. These observations indicate that the first two y′ polarized vibronic bands get their intensities from the $^1L_b\leftarrow S_0$, the second three z′ polarized bands from the $^1L_a\leftarrow S_0$, and the last five y′ and z′ polarized bands from the $^1L_a\leftarrow S_0$ as well as the $^1L_b\leftarrow S_0$ transitions.

TABLE 4. POLARIZATION DIRECTION OF THE PHOSPHORESCENCE BAND EMITTED FROM EACH SUBLEVELS OF THE LOWEST TRIPLET STATE

Band	Sublevel	Polarization direction
0-0 and in-plane vibronic	x	x
	y″	y′, z′
	z″	y′, z′
Out-of-plane vibronic	x	y′, z′
	y″	x
	z″	x

Polarization directions of the phosphorescence bands emitted from each sublevel of the lowest triplet state are given in Table 4. It was already concluded that the long lifetime phosphorescence consists of two emissions arising from x and z″ sublevels whose lifetimes are roughly equal. Table 4 definitely indicates that the y′ and z′ polarized 0-0 and totally symmetric vibronic bands should be attributed to the emission arising from the z″ sublevel, and the y′ and/or z′ polarized out-of-plane vibronic bands to the emission arising from the x sublevel.

The observed long progressions of the ν_5 and ν_{10a} vibrations extending up to four quanta with strong intensity in the even quanta and relatively weak intensity in the odd quanta suggest that the potential surfaces for these normal coordinates would not be harmonic in the lowest triplet state. Such remarkable ν_5 and ν_{10a} progressions are not observed in pyrazine, and thus the unharmonicity of the potentials for 2-methylpyrazine is expected to be much greater than that for pyrazine.

It should be noted that the observed long lifetime of about 80 ms for 2-methylpyrazine is much shorter than the longest lifetime of about 300 ms for pyrazine. This may be due to the low symmetry of the 2-methylpyrazine molecule caused by methyl substitution.

The authors wish to express their thanks to Dr. Motohiko Koyanagi for his valuable discussions. They are also indebted to Mr. Yoshinori Nibu for his help in the experimental work.

(Received February 4, 1982)

A high-temperature calorimeter of the twin conduction type was designed with the capability of measuring heats of adsorption of gases on solids in the temperature range RT to 700 K. A chromel-alumel thermopile was used as the detector and a volumetric adsorption apparatus was equipped. Its calibration and preliminary experiments on heats of adsorption of ammonia on zeolites are described.

Adsorption of gases on solids at higher temperature occurs, in many cases, by specific interaction of gases with solid surfaces. The energetical analysis of the interaction provides informations on activity and reactivity of solids, and permits effective use of catalysts, adsorbents, fillers and so on. Calorimetric studies on high temperature adsorption have been made mainly by means of dynamic methods such as DTA, TGA, DSC, or TPD. However, these methods are less satisfactory from the standpoint of quantitative analysis and difficult to examine active sites of surfaces in detail. Measurements of isosteric heats of adsorption from temperature change of adsorption are not adequate in view of the possibility that the characteristics of active sites vary with temperature. In particular, as chemisorption depends to a great extent on temperature and is often characterized by hysteresis, its mechanism and capacity cannot be estimated from equilibrium theory.[1] The temperature change of heats of chemisorption is often different from that expected from heat capacity.[2]

The present authors have already designed the adsorption calorimeter available near room temperature[3] and measured heats of adsorption of ammonia on solid acids.[4–9] However, evaluation of active sites must be the most useful when made at the same temperature as the working one. Therefore, direct measurement of heats of adsorption at higher temperature is indispensable.

This paper reports a newly designed microcalorimeter available from room temperature to 700 K for measurements of interaction energy between solids and gases. Heats of adsorption of ammonia on zeolites are measured as a preliminary experiment to illustrate the applications of this calorimeter.

Experimental

Apparatus. The calorimeter of the twin-conduction type; the detector part and cell are schematically illustrated in Fig. 1. Thermal effects were detected by use of a chromel-alumel thermopile (D) made of 128 thermocouples, amplified and recorded. The thermocouples are connected in series, placed in 8 directions and in 16 steps, insulated by alumina, and attached to the stainless-steel cell container (C). Two detectors are arranged in a differential and similar way in order to eliminate thermal effects other than the intended ones. Detectors and cell containers are set in a heat sink (E) made of

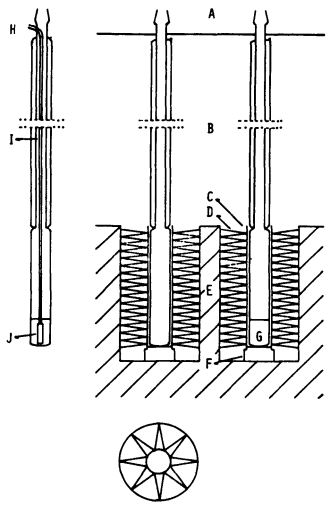

Fig. 1. Schematics of the calorimeter cell and detector. A: Volumetric adsorption line and manometer, B: thermal insulator, C: stainless-steel container, D: thermopile, E: heat sink, F: thermal insulator, G: sample, H: constant voltage circuit, I: platinum lead wire, J: platinum heater.

stainless-steel, the temperature of which is controlled to within $\pm 10^{-3}$K by monitering temperatures and operating noninductively wound Kanthal heaters at three different positions, bottom, side, and top regions. These parts are thermally insulated from the surroundings by bricks and ceramic fibers (B).

Sample and reference cells are made of pyrex or quartz glass, the upper part of which is of dewar-type for thermal insulation. They are symmetrically placed in the stainless-steel container (C) and the thermal insulator (F) in such a way that a good thermal contact is established between them. Both cells are joined together at the top and connected to the volumetric adsorption apparatus (A) outside the calorimeter through vacuum joints and stopcocks, then the dose of gases is introduced simultaneously into both cells. The pressure can be maintained below 1 mPa. Samples (G) in the cell can be heated under vacuum outside the calorimeter and reset in the calorimeter without being exposed to air.

The calibration cell is designed in the same way as for the sample or reference cell, in which a platinum heater (J) (176.7 Ω at 473 K) sealed in a glass tube was inserted, joined to a platinum lead wire (I) and connected to a constant voltage supply (H).

Calibration. In order to ascertain the reliability of the calorimeter, a known amount of electric voltage was fed to the heater and the saturation electromotive force obtained was plotted against the power. The calibration was carried out by feeding a Joule heat and measuring the area under the thermogram, *i.e.* time (t) *vs.* recorder response due to the temperature difference between the calibration cell and the reference cell (ΔT).

Heats of Adsorption. The adsorbent was NH_4–$Y_{4.7}$ zeolite, $0.93(NH_4)_2O \cdot 0.07Na_2O \cdot 4.7SiO_2 \cdot Al_2O_3$, which was obtained by conventional ion-exchange of Na-type zeolite. One gram (dehydrated and decationated basis) of the zeolite was placed in a sample cell and pretreated at 673 K under a pressure of 1 mPa for 10 h. The sample cell was set in a calorimeter and connected to a volumetric line. After the thermal equilibrium was established, a small quantity of adsorbate gas, ammonia, was admitted. The heat evolution was recorded and when the thermal equilibrium was reestablished, another dose of gas was admitted. The adsorption amount was determined by the pressure change before and after adsorption. Since the temperature gradient existed between the thermostated lower part and the top part of the cell, the dead volume of the system was determined by helium under the same conditions as those of calorimetric measurement. The minor temperature change at the gas reservoir which is placed outside the calorimeter was corrected for. The amount of heat evolved was determined by comparison of the area with the area under a calibration curve obtained as mentioned above.

Infrared Spectra. Infrared spectra of adsorbed ammonia which were obtained by the *in situ* method described elsewhere[7] were analyzed in order to interprete the calorimetric data.

Results and Discussion

Calibration of the Calorimeter. The calibration was carried out at 313, 373, 473, 573, and 673 K and the results are shown in Fig. 2. The test at 473 K was carried out under several conditions in order to examine influences of the heat capacity and the heat transfer: the heater was burried in different quantities of inert quartz powder and/or different amount of helium was maintained in the cell.

A linear correlation was obtained between the electrical power and the saturated electromotive force irrespective of calibration conditions; therefore the calibration can be separately carried out by use of the calibration cell. A quantitative determination of the heat by means of a conduction calorimeter is based on Tian's equation,[10]

$$dQ/dt = C \cdot d(\Delta T)/dt + \sigma \cdot \Delta T,$$

where dQ/dt refers to the heat evolved or absorbed in a unit time within the cell, C the heat capacity of the cell and detector, ΔT the temperature difference between the cell and the heat sink, and σ the apparent heat transfer coefficient. Therefore, the calorimeter cell should be devised in such a way that the heat evolved in the cell flows only through the detector to the heat sink. A linear relation of Fig. 2 implies that thermal leak along the wall of the cell could be neglected and that Tian's equation can be considered to hold in this system.

After the saturation, the electric current was turned off and then the cooling curve was obtained from which the time constant was calculated. The time constants with 6.5 g of quartz under 6.67 kPa of helium were 28.0, 22.7, 16.2, 12.2, and 9.0 min at 313, 373, 473, 573, and 673 K, respectively. The decrease with temperature may be explained on the basis of the possibility that, as temperature rises, the thermal flux becomes liable to transfer from the cell to the heat sink by means of radiation, convection or conduction through the thermopile, resulting in an increase in the value of σ.

An electrical energy was supplied through this heater during an appropriate length of time and areas obtained under the thermogram were plotted against the Joule heat in Fig. 3. In this temperature range, the area is proportional to the generated heat, which fact suggests that this calibration is applicable to determine quantitatively the heat evolved in the adsorption cell. A change of the time constant calculated from a change of the area by use of Tian's equation was consistent with that

obtained from the cooling curve as mentioned above. When this calorimeter was used at lower temperature, calibration became more reliable, whereas an increase in the time constant resulted in the tailing phenomenon in the recorder response.

The sensitivity of this calorimeter at 473 K was 300 μJ/s within the error of 1% and the fluctuation below 0.25 μW/h. In favor of the twin system, the calorimeter response was not disturbed by thermal effects other than the intended reaction or adsorption. Such thermal effects were brought about by a temperature change of the surrounding or by a dose of gas. Two kinds of errors must result from the latter effect: the first is due to the work delivered to the cell by dosed gas and the second due to the temperature difference between dosed gas and the adsorbent. The simultaneous introduction of helium into adsorption and reference cells, the former of which contained one gram of zeolite, gave no appreciable thermal response, then the work delivered by dosed gas could be considered to be energetically cancelled. As to the second, although the upper part of the cell served to preheat an adsorbate, its temperature should be still different from that of the adsorbent. However, when the gas was preheated outside the calorimeter before being introduced, the heat value obtained was not different from the corresponding one obtained by the measurement without preheating. Therefore, the gas temperature effect was not corrected.

Heats of Adsorption of Ammonia on Decationated Zeolite. Acidic properties of decationated zeolites have been extensively studied by means of IR spectroscopy, amine titration and so on.[11,12] Calorimetric studies on acidities have also been made by many workers including the present authors.[1,3,7,13-15] The measurement of heats of adsorption of ammonia on zeolites can, therefore, be considered to be a good example to illustrate the application of the calorimeter.

The Brønsted acidity is formed on heating NH_4-type zeolites and originates from the hydroxyl groups. Heating the decationated zeolites to higher temperature results in a decrease in the concentration of Brønsted acid sites, accompanied by the formation of Lewis acid sites.[12]

In this study, NH_4–$Y_{4.7}$ zeolite was evacuated at 673 K and heats of adsorption of ammonia were measured at 473 K. An example of the thermogram of the heat evolved on adsorption of 0.071 mmol of ammonia is shown in Fig. 4 with the calibration thermogram. This adsorption amount corresponds to about one-three hundredth of the total adsorption capacity and about one-sixtieth of acid sites. Therefore, this calorimeter can provide information on fine structure of about one-several hundredth of active sites by considering the precision. The time required for one measurement depended on the adsorption amount as well as the temperature. The measurement at 473 K required from 100 to 150 min.

Differential heats of adsorption are given in Fig. 5. A lower curve shows the results of readsorption of ammonia on the same sample which was evacuated overnight at 473 K at 1 mPa after the first run of the adsorption measurement. Since the number of total

○: Original zeolite, ●: ammonia-preadsorbed zeplite

protons contained in the zeolite is 4.6 mmol/g which was calculated under the assumption that ammonium ions were converted into protons during the course of heat treatment at 673 K, the mutual interactions of adsorbed ammonia can be neglected and the heat should be evolved by the interaction of ammonia with the proton in this experimental condition. In the original sample, heats decrease from the initial value of about 120 kJ/mol, attain a plateau region of about 100 kJ/mol and decrease again. The presence of the plateau region is also observed in the measurement at room temperature.[3,4] The differential heats on the ammonia-preadsorbed sample are lower even in the initial region and decrease in monotonic way. The amount of ammonia which was irreversibly adsorbed after evacuation at 473 K was determined volumetrically to be 0.45 mmol/g, which agrees with the value obtained by comparison of two heat curves. Then relatively strong acid sites can be considered to evolve heats with ammonia adsorption higher than 105 kJ/mol.

The surface adsorption site distribution which was obtained by graphical differentiation of Fig. 5 is given in Fig. 6. The maximum of the distribution is observed at about 100 kJ/mol in the original sample, indicating the existence of considerably homogeneous active sites. About one-fifth of the total protons corresponded to adsorption sites contained in the maximum. However, this distribution was less significant than that observed at 298 K.[4] On the other hand, no maximum is observed

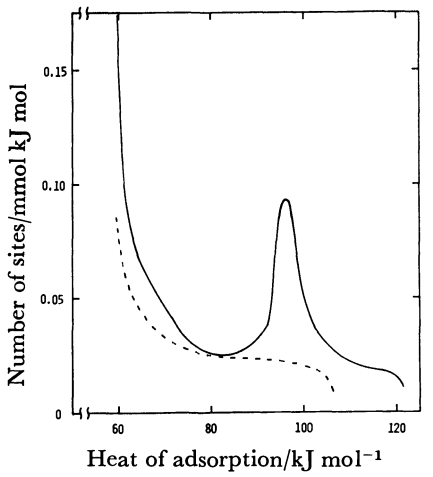

Fig. 6. Adsorption energy distribution on decationated zeolites.
——: Original zeolite, ------: ammonia-preadsorbed zeolite

in the ammonia-preadsorbed sample and more active sites having heats of adsorption above 105 kJ/mol are completely poisoned.

Infrared spectra of hydroxyl groups of the zeolite and adsorbed ammonia are shown in Fig. 7. The elimination of NH bands was completed by evacuation of the NH_4–$Y_{4.7}$ zeolite at 673 K, accompanied by the appearance of OH bands as shown in Fig. 7A, which is consistent with many previous results.[12] Ammonia was adsorbed at 298 K on this sample at the equilibrium pressure of 4 kPa and evacuated at the same temperature, then the spectrum was recorded (Fig. 7B). The reformation of bands from ammonium ion vibrations (1440 and 1670 cm^{-1}) was observed and also Lewis acid-bonded ammonia was detected at 1670 cm^{-1}. The hydroxyl band at 3650 cm^{-1} simultaneously disappeared, which fact indicates that ammonia interacted with these hydroxyl groups. The spectrum in Fig. 7C was taken after the treatment as follows; ammonia was adsorbed at 473 K at the equilibrium pressure of 40 kPa, which corresponded to the adsorbed amount of 4.83 mmol/g and desorbed overnight at the same temperature at 1 mPa. The intensities of bands at 1440 and 1670 cm^{-1} became weaker, whereas the intensity at 1620 cm^{-1} remained constant. This observation suggests that the irreversibly adsorbed ammonia on Brønsted acid sites decreases at higher temperature. In comparison with calorimetric data, the adsorption with heats higher than 105 kJ/mol can be suggested to occur mainly on Lewis acid sites.

In conclusion, this type of adsorption calorimeter is available at higher temperature and capable of providing information on fine structure of active sites of solid surfaces near their working temperature. The results of heats of adsorption of several bases on solids in the temperature range up to 673 K will be presented in another paper.

Syntheses of Sodium-Calcium Zeolites at Atmospheric Pressure and 80 °C. I. Reagents Used: Na_4SiO_4, $Al(OH)_3$, $Ca(NO_3)_2$

Kazuko KATSUKI* and Kyunosuke MAJIMA
Department of Chemistry, Faculty of Science, Toho University, 2-2-1 Miyama, Funabashi, Chiba 274
(Received May 18, 1981)

Sodium-calcium zeolite minerals were synthesized in an electric oven at 80 °C for 1—5 weeks from suspensions of a suitable combination of the starting materials, which had a chemical composition of $2n Na_2O \cdot 2CaO \cdot Al_2O_3 \cdot nSiO_2 \cdot xH_2O$ ($4 \leqq n \leqq 20$, $x = 83$—610). All of the synthetic products were obtained as massive products in the gel. X-Ray and IR analyses and a quantitative analysis of the principal ingredients showed these massive products to be well-crystallized hydroxycancrinites which contained 0—4.9% calcium oxide.

Zeolite minerals have been studied for a long time and have been synthesized extensively by many investigators, because they have useful properties, such as ion-exchange and molecular-sieve. Barrer and his co-workers have reported that the crystallization from active gel of sodium and potassium aluminosilicates could occur at 100 °C or below, but less reactive materials (*e.g.*, calcium and lithium aluminosilicates) were crystallizable only above about 150 °C.[1,2] Most calcium zeolites including sodium-calcium zeolites have thus been far synthesized only above 150 °C. It is now well known, however, that the crystallization of zeolite minerals is considerably influenced by the particular combination of the starting materials. It is also known that either water or salt, singly or in combination, aids the formation of aluminosilicate.[3] If suitable combinations of the starting materials, including salts and excess water, are chosen, sodium-calcium zeolite minerals can therefore be expected to crystallize at atmospheric pressure and at temperatures lower than 150 °C.

Our aim is to examine the reactivity of the starting materials and to make clear what kinds of sodium-calcium zeolite minerals can be synthesized under these mild conditions. In this paper it is reported that the sodium-calcium hydroxycancrinite has been synthesized at 80 °C and under atmospheric pressure from a suspension of sodium silicate (ortho), aluminium hydroxide, and calcium nitrate.

Experimental

Reagents Used. *Sources*: *Silicon*: 1 mol dm^{-3} solution of sodium silicate (ortho); *Aluminium*: finely powdered aluminium hydroxide; *Calcium*: 1 mol dm^{-3} solution of calcium nitrate.

Synthetic Method. The starting materials, composed of $2n Na_2O \cdot 2CaO \cdot Al_2O_3 \cdot nSiO_2 \cdot xH_2O$ ($1 \leqq n \leqq 20$, $x = 83$—610), were prepared as follows. Aluminium hydroxide was stirred well into the source of silicon, and then a calcium nitrate solution was added slowly. After this mixture had been stirred enough, the suspensions finally obtained were placed in 100 cm^3 polyethylene bottles and allowed to stand overnight. These bottles were kept for 1—5 weeks in an electrically heated oven, thermostatically controlled at 80±1 °C, and then the bottles were cooled in air. The reaction products were washed in hot water until the washings were free from alkali. Massive products present in the gel were separated from the gel by decantation and filtered off. All the products were air dried and powdered by the use of a porcelain mortar and 200-mesh sieves.

Analytical Apparatus and Method. *X-Ray*: A powder diffractometer (Rigaku Co.) was used with filtered Cu *Kα* radiation. It was operated at 30 kV; 15 mA; time constant, 1 s, and count range, 1000 cps.

IR: An infrared spectrophotometer of the JASCO DS701-G type was used. Samples were measured by the KBr-wafer method.

Quantitative Analysis of Principal Ingredients: The method of "Speedy Analysis of Silicate"[4] was used.

Results and Discussion

Sodium-calcium zeolite minerals have been synthesized from suspensions having the chemical composition of $2n Na_2O \cdot 2CaO \cdot Al_2O_3 \cdot nSiO_2 \cdot xH_2O$ ($1 \leqq n \leqq 20$, $x = 83$—610). They were obtained in three different states.

Two of them were in gel-like states (these will be referred to as "Gel 1" and "Gel 2" hereafter), while the other was in a massive form. The "Gel 1" minerals were obtained from suspensions with n values from 1 to 3. Mixtures of "Gel 2" and massive products were obtained from suspensions with n values from 4 to 20. X-Ray analysis revealed that the crystallinities of "Gel 1," "Gel 2," and the massive products were very low, low, and high respectively, as is shown in Fig. 1. We can also see in Fig. 1 that "Gel 2" has some peaks in

addition to those of the massive products. "Gel 2" is possibly a mixture of the massive product and another material. As a result, we studied the massive products in detail.

The optimum conditions for the syntheses of massive products are determined from the n values and the synthetic-time dependence of the yield (g dm^{-1}) and the crystallinity. As may be seen from Figs. 2 and 3, the yield is more dependent on the n value than on the synthetic time. In Fig. 3, the data scatter widely because the yield is strongly dependent on the n value, and from the mean value of them it is clear that the yield becomes approximately constant after two weeks. On the other hand, the crystallinity becomes better with the increase in the synthetic time, but has little relation with the n value. From these examinations it may be concluded that the n values 5, 6, and 7 and a synthetic time of more than two weeks are the most suitable conditions for the synthesis.

We analyzed the massive products by means of X-Ray, IR, and quantitative analyses to ensure their identification. The X-Ray results are shown in Table 1. From Table 1, it is clear that the diffraction data of the massive product agree with those of cancrinite[5] and with those of the synthetic hydroxycancrinite reported by Aoki and Abe.[6]

The IR results are shown in Table 2. The data agree with those of the hydroxycancrinite reported

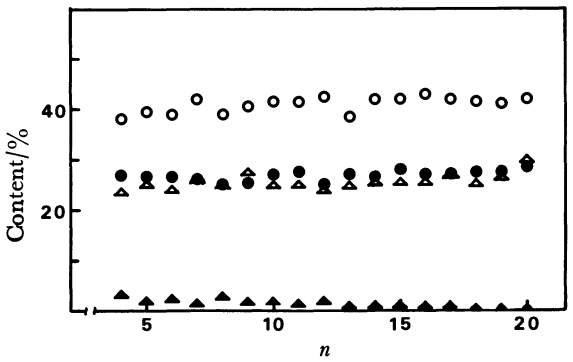

Fig. 4. The relation between the value n in starting materials and quantity of ingredients of massive products.

previously,[7] except for small differences in the regions of 950—1200 and 750—820 cm^{-1} caused by asymmetric and symmetric stretching.

The amounts of the ingredients in massive products as a function of the n value have been determined by quantitative analysis, they are shown in Fig. 4. The dependence of the quantity of the ingredients on the n value is rather weak. Calcium oxide of 0.2—4.0% has been detected in all massive products except for those obtained by synthetic times between 4 and 5 weeks and when the n value equals 20. The mean values of the contents of Na_2O, CaO, Al_2O_3, and SiO_2 for 84 products are 27.5%, 1.5%, 26.7%, and 40.9% respectively. The experimental formula determined by the use of these values is $Na_9Ca_{0.25}Al_5Si_7O_{24}(NO_3)_{4.5}\cdot xH_2O$. The existence of the NO_3^- ion in this formula is deduced from the IR data, which has two characteristic absorption bands caused by the NO_3^- ion at 1384 and 820 cm^{-1}. In this deduction of the existence of the NO_3^- ion, we also referred to the report by Guth.[8] The experimental formula determined here agrees with that of cancrinite. From these three analyses, the massive products obtained here are identified as examples of hydroxycancrinite.

Comparing with the conditions of the conventional synthetic way of hydroxycancrinite, such as a temperature higher than 80 °C and the limited n value of the starting materials, it is remarkable that only hydroxycancrinite has been synthesized over such a wide range of n values as n=4—20 and under such mild conditions as 80 °C and the atmospheric pressure used in this study. This suggests that the present combination of starting materials is especially effective in the synthesis of hydroxycancrinite. It seemed, therefore, that it would be to make clear the facility and characteristics of the present combination of starting materials. Thus, we have performed the following experiments using the most suitable n values 5, 6, and 7.

First we made experiments at shorter synthetic times in order to elucidate the initial crystallization. The

results are shown in Table 3 and Fig. 5. In a one-day run, a faujasite-type zeolite with a strong peak at nearly d(Å)=14.73 was synthesized. In a two-day run, a mixture of the faujasite-type zeolite and hydroxycancrinite was detected. From the four-day run, only hydroxycancrinite was observed in the X-Ray diffraction pattern. From these results, it is clear that the hydroxycancrnite has been synthesized almost completely in such a short time as four days under these mild conditions.

Secondly, we examined the effect of calcium salts on the crystallization. The results of the synthesis without calcium nitrate are shown in Table 4. As may be seen in Table 4, only the faujasite-type zeolite was synthesized in a one-day run. From the second-day run, the zeolite was changed from the faujasite-type into a mixture of sodalite-type zeolite and hydroxycancrinite. The crystallinities of these zeolites were very low. Therefore, we can guess that calcium nitrate as a calcium source plays a very important role in the formation of hydroxycancrinite. It had been believed that the existence of calcium would tend to hinder the formation of the aluminosilicate framework under mild conditions. Our experiment, however, revealed that if the $CaO/(CaO+Na_2O)$ ratio is limited within the range between 0.05—0.2, calcium tends to promote the formation of zeolite.

Lastly, we performed a synthesis experiment using sodium nitrate instead of calcium nitrate in order to make sure of the role of the NO_3^- ion. The results shown in Table 5 are almost the same as those in Table 3, thus indicative that calcium nitrate and sodium nitrate lead to the same effect. Therefore, it is confirmed that the characteristics of the present combination of starting materials are mainly due to the NO_3^- ion. This result is consistent with the report by Guth,[8] who pointed out that AO_m^{n-} favored the hexagonal derivation of cancrinite.

The success of the present synthesis suggests the possibility of preparing other sodium-calcium zeolite minerals under mild conditions if suitable combinations of starting materials are chosen.

We would like to thank Professor Isamu Shinno of Kyushu University for his critical reading of the manuscript. A part of this research was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (264191).

Reactions of Chloroiron(III) Schiff Base Complexes with Superoxide Ion in Dimethyl Sulfoxide

Takayuki MATSUSHITA,* Hiroshi KONO, Mitsuru NISHINO, and Toshiyuki SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received August 10, 1981)

A series of monomeric chloroiron(III) complexes with the quadridentate or quinquedentate Schiff bases such as *N,N'*-disalicylideneethylenediamine or bis[3-(salicylideneamino)propyl]amine react with superoxide ions, O_2^-, in dimethyl sulfoxide to give the corresponding μ-oxo dimers. The polymeric chloroiron(III) complexes with the polymeric (oligomeric) Schiff bases derived from 5,5'-methylenedisalicylaldehyde and triamines react with O_2^- in dimethyl sulfoxide to give the oxygenated complexes, probably dioxygen adducts, Fe^{III}–O_2^-. This is suggested by the absorption spectra and the polarographic measurements.

The reactions of iron complexes with superoxide ions, O_2^-, are of interest in connection with the biological processes: the disproportionation of O_2^- by the iron-containing superoxide dismutases (Fe–SOD) and the catalytic utilization of molecular oxygen by the hemoproteins.

Hill *et al.* reported that $Fe^{III}(ppde)ClO_4$ reacts with O_2^- in *N,N*-dimethylformamide (DMF) to give Fe(ppde)–O_2 at low temperature (−50 °C).[1,2] McClune *et al.* proposed the formation of the peroxo complex, $[Fe^{III}(edta)-O_2]^{2-}$, by the reaction of $[Fe^{III}(edta)]^-$ with O_2^- in water on the basis of a stopped-flow spectrophotometry.[3] Recently, McCandlish *et al.* have reported that four different reaction pathways occurred in the reactions of O_2^- with iron porphyrins, as follows:

$$Fe^{III}(por)^+ + O_2^- \longrightarrow Fe^{II}(por) + O_2$$
$$2\,Fe^{III}(por)^+ + O_2^- \longrightarrow [Fe^{III}(por)]_2O$$
$$Fe^{III}(por)^+ + O_2^- \longrightarrow Fe(por)(O_2)$$
$$Fe^{II}(por) + O_2^- \longrightarrow Fe^{III}(por)(O_2^{2-}).$$

These reactions depend on conditions such as the solvent, the concentration, the presence or absence of traces of water, and the temperature.[4]

We have previously reported on the reactions of the monomeric and polymeric chloromanganese(III) Schiff base complexes with O_2^- in dimethyl sulfoxide (DMSO). With the monomeric complexes, they can be classified into two types in the reactivity toward O_2^-: one gives the oxygenated complexes and the other is reduced to the corresponding manganese(II) complexes. The reactivities toward O_2^- are found to be correlated to the polarographic half-wave potentials corresponding to the reduction from Mn(III) to Mn(II).[5] In the reactions of the polymeric complexes, the formation of their oxygenated complexes has been found.[6]

This paper describes the reactions between O_2^- and the monomeric and polymeric chloroiron(III) Schiff base complexes in DMSO. Some of the polymeric complexes showed a clearly different behavior in the changes of the absorption spectra and polarograms

Experimental

Preparation of Monomeric Chloroiron(III) Schiff Base Complexes Chloro(N,N'-disalicylideneethylenediaminato)iron(III), Fe(salen)Cl: This complex was obtained by a modified method described in the literature[7] as follows. Anhydrous iron(III) chloride (0.81 g) was added to an absolute ethanol solution (100 cm^3) containing *N,N'*-disalicylideneethylenediamine (salenH_2, 1.34 g) and triethylamine (1.01 g). The mixture was stirred at 70 °C for 1 h, and then allowed to stand overnight in a refrigerator. The resulting precipitates were collected on a glass filter, washed with ethanol and ether, and then dried *in vacuo*. They were recrystallized from dichloromethane. The yield was 1.1 g.

The other monomeric chloroiron(III) Schiff base complexes were prepared in a similar manner. The analytical data for some of the complexes are given in Table 1.

Preparation of Polymeric (Oligomeric) Schiff Base Ligands. The oligomers of the Schiff bases were prepared by the polycondensation of 5,5'-methylenedisalicylaldehyde with diamine or triamines under the controlled conditions: the molar ratio of 5,5'-methylenedisalicylaldehyde to amines was maintained at 1.25; the temperature was kept below 20 °C; the reaction was stopped within 5 min; a dichloromethane was used as solvent for the polycondensation.

Polymeric Schiff Base, p-saldienH_2: A dichloromethane solution (20 cm^3) of bis(2-aminoethyl)amine (1.4 g, 0.016 mol) was added to a dichloromethane solution (50 cm^3) of 5,5'-methylenedisalicylaldehyde (5.2 g, 0.02 mol) with stirring below 20 °C. After the solution had been stirred for 5 min, it was poured into a large volume of ether (300 cm^3) with vigorous stirring. The resulting yellow precipitates were collected on a glass filter, washed with ether, and then dried *in vacuo*. They were reprecipitated twice from a mixture of dichloromethane and ether. The yield was 3.1 g. Found: C, 69.95; H, 6.40; N, 11.63%. Calcd for a hexamer: C, 70.54; H, 6.33; N, 11.45%. ^{1}H NMR ($CDCl_3$) δ=12.2 (br, OH), 9.70 (s, CHO), 8.27 (s, CH=N), *ca.* 7 (m, ϕ), 3.80 (s, ϕ-CH_2-ϕ), 3.65 (t, CH_2N=), 2.95 (t, CH_2N–). The specific viscosity (η_{sp}) measured in chloroform (0.4 g/100 cm^3) at 25±0.1 °C was 0.037. The degree of condensation (n) was estimated to be six from the analytical data, the ratios of the peak intensities in the ^{1}H NMR spectra, and the specific viscosity.

The polymeric Schiff bases, p-salplnH_2, p-salchxnH_2, p-saldptH_2, and p-salMedptH_2, prepared previously[6] were used. They were found to be oligomers (n=3 to 5) on the basis of the above measurements. The other polymeric Schiff bases, p-salenH_2 and p-salphenH_2, were prepared in a similar manner. However, their NMR spectra and viscosities could not be measured owing to their poor solubility in organic solvents.

Preparation of Polymeric Chloroiron(III) Schiff Base Complexes. Fe(p-saldien)Cl: To a dichloromethane (50 cm^3)–methanol (20 cm^3) solution containing p-saldienH_2 (1.1 g) and triethylamine (0.6 g), anhydrous iron(III) chloride (0.5 g) was added with stirring at room temperature. The precipitated wine-red solids were collected on a glass filter, washed with water, ethanol, and then ether, and then dried *in vacuo*. They were partly soluble in DMSO or *N,N*-dimethylformamide (DMF) and were insoluble in dichloromethane or methanol. They were extracted with DMF (300 cm^3). The DMF solution was concentrated to *ca.* 30 cm^3 under reduced pressure, and poured into methanol (200 cm^3). The precipitates were collected on a glass filter, washed with ether, and dried *in vacuo*. The yield was 0.2 g.

The other polymeric iron(III) complexes were prepared in a similar manner. They are slightly soluble in DMSO or DMF (*ca.* 0.1 g/100 cm^3) and are insoluble in methanol or dichloromethane. Therefore, the viscosity for them could not be measured. The infrared spectra of the polymeric complexes indicate that the Schiff base ligands coordinate to iron ions in the same features as the corresponding monomeric complexes. The magnetic moments of the polymeric complexes were determined on the basis of their iron contents.

Isolation of the Reaction Products of Monomeric Complexes with KO_2. [Fe(acacen)]$_2O$: To a dichloromethane solution (50 cm^3) containing Fe(acacen)Cl (0.63 g, 0.002 mol) and 18-crown-6 (0.56 g, 0.002 mol), potassium superoxide, KO_2, (0.22 g, 0.003 mol) was added. The mixture was stirred for 1 h at room temperature. The wine-colored solution turned gradually orange. The mixture was filtered, and the filtrate was evaporated under reduced pressure to yield orange solids. They were collected on a glass filter, washed with a little volume of water and methanol, and then ether, and dried *in vacuo*. They were recrystallized from dichloromethane to give orange crystals. The yield was 0.3 g. Found: C, 50.20; H, 6.37; N, 9.84; Fe, 19.23%. Calcd for $Fe_2C_{24}H_{36}N_4O_5$: C, 50.37; H, 6.34; N, 9.79; Fe, 19.52%.

The reaction product of Fe(bzacen)Cl with KO_2 was obtained in a similar manner. The reaction products of the other monomeric complexes with KO_2 were obtained similarly, using DMSO in place of dichloromethane as reaction solvent.

Preparation of KO_2 DMSO Solution. DMSO solutions of KO_2 (*ca.* 10^{-2} M, 1 M=1 mol dm^{-3}) were prepared by dissolving KO_2 (0.018 g) into dry DMSO (25 cm^3) in the presence of 18-crown-6 (0.10 g). The O_2^- concentration of the KO_2 DMSO solution was determined by spectrophotometry.[8] The reactions of the iron(III) complexes with KO_2 in DMSO were carried out in a nitrogen atmosphere.

a) Measured at room temperature. b) Measured in DMSO. c) Measured in DMSO containing 0.1 M Bu_4NClO_4 at 25 °C.

Material. Iron(III) chloride was of reagent grade. Potassium superoxide, KO_2, was purchased from Alfa Products Inc. (above 96.5%). Dimethyl sulfoxide was distilled twice under reduced pressure prior to use. Other solvents were purified by a usual method.

Measurements. All the physical measurements were made by the methods described elsewhere.[5]

Results and Discussion

The monomeric and polymeric chloroiron(III) Schiff base complexes were synthesized and their reactions with O_2^- in DMSO were investigated. The degree of the condensation (n) of the polymeric iron(III) complexes could not be determined by the molecular weight and the viscosity measurements owing to their poor solubility. However, they are considered to be oligomers ($n=3$ to 6) from the degree of the condensation of the Schiff base ligands.

Table 2 includes the magnetic moments, the absorption maxima in the visible region, and the polarographic half-wave potentials corresponding to the reduction from Fe(III) to Fe(II). The magnetic moments of the monomeric complexes fall within the range of 5.29 to 6.05 BM, indicating that these complexes have a d^5 high-spin electron configuration.[7,9] The magnetic moments of the polymeric complexes also fall within the range of 5.17 to 5.85 BM. The low value (5.17 BM) observed for the Fe(p-saldpt)Cl complex may be caused by antiferromagnetic interactions between iron atoms in the complex. No further investigation on the magnetic properties was made in the present work.

The absorption spectra of the monomeric and polymeric complexes in DMSO show an intense absorption band ($\varepsilon \fallingdotseq 4000$) around 500 nm, which can be assigned to a charge-transfer transition.[10] The absorption maxima of the polymeric complexes were observed at lower energies than those of the corresponding monomeric complexes. Similar behavior was observed for the monomeric and the polymeric chloromanganese(III) Schiff base complexes.[6] The monomeric chloroiron(III) complexes with the quadridentate ligands (N_2O_2) in DMSO may have a weak six-coordinate structure by coordination of a DMSO molecule to the central iron atom. It was reported that the Fe(salen)Cl complex is nonelectrolyte in pyridine (py) and has a six-coordinate structure of Fe(salen)Cl–py.[9] The monomeric chloroiron(III) complexes with the quinquedentate ligands (N_3O_2) may have a six-coordinate structure of a donor set of N_3O_2Cl in DMSO. Wilson *et al.* have reported that the Fe(saltrien)$^+$ cation has a six-coordinate structure (N_4O_2) and that the solvent effect on its spin-equilibrium in solution can be attributed to the hydrogen-bonding interactions between the NH groups of saltrien and solvents, where saltrien denotes the dianion of *N,N'*-disalicylidenetriethylenetetramine.[10,11] On the other hand, the coordination features of the polymeric chloroiron(III) complexes are considered to be similar to those of the monomeric complexes. However, the coordination or interaction of DMSO with the polymeric complexes may be weaker than that of the monomeric complexes, because the iron atoms in the former complexes are not so isolated from the surroundings as are the latter complexes. This may be one reason why the lower energy shifts were observed in the polymeric complexes.

The polarograms of the chloroiron(III) Schiff base complexes in DMSO show the cathodic wave at the half-wave potential around −0.1 V (*vs.* Hg pool) in Table 2, which can be assigned to the one-electron reduction of Fe(III) to Fe(II).[12] The reduction of the polymeric complexes occurred at more positive potentials than those for the corresponding monomeric complexes. These results are consistent with the absorption spectral data mentioned above on the basis of the electron density in the central iron atoms of the complexes.

Visible Absorption Spectra. Figure 1 shows the absorption spectral changes of a DMSO solution of Fe(salen)Cl caused by the addition of a KO_2 DMSO solution in different molar ratios. The intensity of the absorption band at 490 nm decreased with increasing the molar ratio of KO_2 to the complex, showing an isosbestic point at 458 nm. The absorption spectrum at the $[KO_2]/[complex]=3$ is almost the same as that of the μ-oxo dimer, $[Fe(salen)]_2O$. This indicates that Fe(salen)Cl reacts with O_2^- in DMSO at room temper-

ature to give a μ-oxo dimer.

All the monomeric chloroiron(III) complexes investigated here showed similar spectral changes to those observed for the above Fe(salen)Cl complex.

Figures 2 and 3 show the comparison of the spectral changes caused by the addition of the KO_2–DMSO solution to the DMSO solutions of Fe(saldien)Cl and Fe(p-saldien)Cl, respectively. The spectral changes for

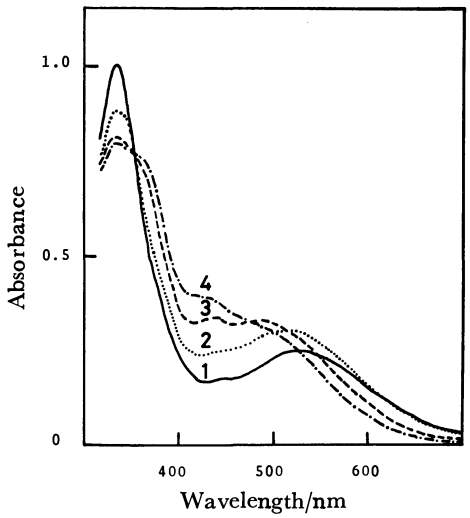

Fig. 3. Spectral changes on the addition of KO_2 to a DMSO solution of 1×10^{-4} unit M Fe(p-saldien)Cl in different molar ratios.

Fe(saldien)Cl are similar to those for Fe(salen)Cl, indicating the formation of the μ-oxo dimer. On the other hand, the spectral changes for the polymeric complex, Fe(p-saldien)Cl, are clearly different from those for the monomeric complex, Fe(saldien)Cl. At the $[KO_2]/[Fe]=2$, the absorption maximum was shifted to higher energy from 524 to 516 nm and the intensity increased slightly. At the $[KO_2]/[Fe]=3$, the absorption maximum was shifted to 492 nm and its intensity increased even more. By the further addition of KO_2 ($[KO_2]/[Fe]=5$), the intensity of the absorption band at 492 nm decreased and a new absorption band appeared around 420 nm. This new absorption band at 420 nm can be assigned to the anion of the Schiff base ligand. This is confirmed by the absorption spectrum of p-saldienH_2 in a KOH–DMSO solution. These spectral changes can be explained as follows. The Fe(p-saldien)Cl reacts with O_2^- in the DMSO solutions ($[KO_2]/[Fe]<3$) to give the oxygenated complex, probably a dioxygen adduct, and it reacts with O_2^- added in excess over the complex ($[KO_2]/[Fe]>3$) to decompose with some dissociation of the Schiff base ligand.

The polymeric iron(III) complexes of Fe(p-saldpt)Cl and Fe(p-salMedpt)Cl showed similar spectral changes to the above Fe(p-saldien)Cl complex. However, the other polymeric complexes, Fe(p-salen)Cl, Fe(p-salphen)Cl, Fe(p-salpln)Cl, and Fe(p-salchxn)Cl, showed the spectral changes similar to those observed for the corresponding monomeric complexes. These results may be attributed to the configurations of the reaction sites in the complexes. As discussed above, the former complexes may have a six-coordinate configuration, while the latter complexes may be taken to have essentially a five-coordinate configuration by neglecting the weak interaction between DMSO molecules and central iron atoms in these polymeric

complexes.

Polarographic Measurements. Figure 4 shows the changes in the polarograms during the reaction of Fe(salen)Cl with KO_2 in DMSO at 25 °C. At the molar ratio of $[KO_2]/[complex]=1$, the wave height at −0.20 V due to the reduction of Fe(III) to Fe(II) decreased and a new cathodic wave appeared around −0.8 V. By the further addition of KO_2 ($[KO_2]/[complex]=2$), the first cathodic wave disappeared and the wave height at −0.8 V increased. The half-wave potential of this cathodic wave is nearly equal to that (−0.89 V) of the μ-oxo dimer, $[Fe(salen)]_2O$. These results indicate that the reaction of Fe(salen)Cl with KO_2 in DMSO at 25 °C produces the μ-oxo dimer. The polarographic observations are consistent with those obtained in the absorption spectra mentioned above. Similar polarographic behavior was observed for all the monomeric iron(III) complexes investigated in this work.

It was reported that the dioxygen adduct of iron(II) porphyrin complexes can be stabilized at low temperature.[13] Thus, we carried out the reaction of Fe(salen)Cl with KO_2 in DMF at −25 °C. Figure 5 shows the changes in the polarograms of Fe(salen)Cl in DMF at −25 °C caused by the addition of a KO_2 DMSO solution. The half-wave potential (−0.19 V) of the first cathodic wave due to the reduction of Fe(III) to Fe(II) is nearly equal to that (−0.20 V) observed in DMSO at 25 °C. At the molar ratio of $[KO_2]/[complex]=0.5$, two new cathodic waves appeared at the half-wave potentials of −0.48 and −0.88 V and the height of the first cathodic wave decreased. By the further addition of KO_2 ($[KO_2]/[complex]=1$), the wave heights of both the first and the second cathodic waves decreased and the third cathodic wave height increased. The second cathodic wave observed at −0.48 V may be attributed to the reduction of the oxygenated complex, Fe(salen)–O_2 or Fe(salen)–O_2·–Fe(salen), formed in the solution. This may further react with O_2^- to give the μ-oxo dimer. Similar polarographic behavior was observed in the reaction of Fe(salphen)Cl with KO_2 in DMF at −25 °C. From the available data we propose this scheme for the reactions of Fe(salen)Cl with O_2^-:

$$FeLCl + O_2^- \longrightarrow FeL\text{–}O_2 + Cl^-$$
$$FeL\text{–}O_2 + FeLCl \longrightarrow FeL\text{–}O_2\text{·–}FeL + Cl^-$$
$$FeL\text{–}O_2\text{·–}FeL + O_2^- \longrightarrow FeL\text{–}O_2\text{–}FeL + O_2$$
$$FeL\text{–}O_2\text{–}FeL \longrightarrow FeL\text{–}O\text{–}FeL,$$

where L denotes the dianion of *N,N'*-disalicylideneethylenediamine. Recently, Chin *et al.* have reported on the mechanism of autoxidation of Fe^{II}(por) and proposed that the intermediate (por)Fe–O_2–Fe(por) can be stabilized at low temperature (−50 °C). This oxygenated complex reacts with Fe^{II}(por) to give (por)Fe–O–Fe(por) or decomposes thermally to (por)-Fe–O–Fe(por) *via* iron(IV) complex, (por)Fe^{IV}=0, in the absence of Fe^{II}(por).[14]

Figures 6 and 7 show the changes in the polarograms during the reactions of Fe(p-saldien)Cl with KO_2 in DMSO. In Fig. 6, the KO_2– DMSO solution was added successively to the DMSO solution of the complex, whereas in Fig. 7, it was added step by step after passing nitrogen gas through the mixed solutions. The changes in the polarograms (in Fig. 6) are clearly different from those observed for Fe(salen)Cl (in Fig. 4). The cathodic wave at the half-wave potential of +0.01 V is due to the reduction of Fe(III) to Fe(II). The addition of KO_2 ($[KO_2]/[Fe]=1$) caused the appearance of a new cathodic wave around −0.3 V. At the $[KO_2]/[Fe]=2$, this wave height decreased slightly and a new cathodic wave appeared at the half-wave potential of −0.6 V; this new wave can be assigned to the reduction of free molecular oxygen liberated during the reactions on the basis of its potential. At the $[KO_2]/[Fe]=3$, the wave height around −0.3 V decreased and the wave

1): No addition, 2): $[KO_2]/[Fe]=1$, 4): 2, 6): 4, 3), 5), and 7): after passing nitrogen gas through the solutions shown by the curves 2, 4, and 6, respectively.

height around −0.6 V increased. By passing nitrogen gas through the mixed solution, both cathodic waves disappeared. The cathodic wave which appeared around −0.3 V may be due to the oxygenated complex, Fe(p-saldien)–O_2. This is confirmed by the observations shown in Fig. 7. The polarograms observed at the $[KO_2]/[Fe]=1$ was identical to that shown by curve 2 in Fig. 6. By passing nitrogen gas through the solution, the wave height around −0.3 V decreased. Such a cycle (adding KO_2 and passing N_2) was made three times. The polarograms shown by curves 2, 4, and 6 in Fig. 7 did not show any cathodic wave at the half-wave potential around −0.6 V. Moreover, the degree of increase in the wave height around −0.3 V lowered gradually by repeating the cycle. These results indicate that the oxygenated complex, Fe(p-saldien)–O_2, may decompose to Fe^{II}(p-saldien) and molecular oxygen by passing nitrogen gas through the mixed solutions. Similar polarographic behavior was observed for the polymeric complexes, Fe(p-saldpt)Cl and Fe(p-sal-Medpt)Cl.

From the observations in the absorption spectra and the polarographic measurements, the reactions of the polymeric iron(III) complexes with O_2^- may occur as follows:

$$\text{(p-L)FeCl} + O_2^- \longrightarrow \text{(p-L)Fe–}O_2 + Cl^- \quad ([KO_2]/[Fe] < 2)$$

$$\text{(p-L)Fe–}O_2 + O_2^- \longrightarrow \text{(p-L)Fe–}O_2^- + O_2 \quad ([KO_2]/[Fe] > 2)$$

$$\text{(p-L)Fe–}O_2^- \longrightarrow \text{(p-L)}Fe^- + O_2$$

$$\text{(p-L)}Fe^- \longrightarrow \text{Decomposition,}$$

where (p-L) denotes the dianion of the polymeric Schiff base ligands.

The reversible oxygenation of the iron(II) porphyrin complexes can be established by preventing the formation of μ-peroxo diiron complex in one or more of the following ways: (1) steric effects, (2) immobilization in rigid surfaces, and (3) low-temperature measurements. In addition, it has been proposed that (4) a five-coordinate structure and (5) a nonpolar, hydrophobic environment around iron(II) complex play an important role for the synthesis of iron(II) porphyrin dioxygen adduct.[13] Recently, Niswander *et al.* have reported that Fe^{II}(salen)·py[15] and Fe^{II}(5-NO_2saldpt)[16] react with molecular oxygen to give only the corresponding μ-oxo dimers.

In the present work, the monomeric chloroiron(III) Schiff base complexes react with O_2^- to give only the μ-oxo dimers. On the other hand, the polymeric complexes of Fe(p-saldien)Cl, Fe(p-saldpt)Cl, and Fe(p-

Table 3. Physical properties of the reaction products of the monomeric iron(III) complexes with KO_2 in DMSO

salMedpt)Cl form the dioxygen adduct in DMSO solution at room temperature by the reaction with O_2^-. Such behavior suggests that these polymeric complexes may satisfy the above requirements (1), (2), and (4).

Reaction Products of the Iron(III) Complexes with KO_2. The reaction products of the monomeric iron(III) complexes, Fe(acacen)Cl, Fe(bzacen)Cl, Fe(salen)Cl, Fe(salphen)Cl, Fe(salpln)Cl, and Fe(salchxn)Cl, were confirmed to be their μ-oxo dimers from the analytical data and physicochemical properties (in Table 3). However, for the other monomeric complexes, Fe(saldien)Cl, Fe(saldpt)Cl, and Fe(salMedpt)Cl, their μ-oxo dimers could not be characterized. On the other hand, the reaction products of the polymeric iron(III) complexes have not been identified with their oxygenated complexes by the analytical data and the physicochemical measurements. This may be caused by the instability of the oxygenated complexes. Further investigation is now in progress.

The Temperature Dependence of the Peak Height of the Lead Ion in Square-wave Polarography

Nobuko HATANAKA

Osaka Environmental Pollution Control Center, Nakamichi 1-3, 62, Higashinari-ku, Osaka 537

(Received September 16, 1981)

The peak height of the square-wave (s.w.) polarogram of lead increased markedly upon the addition of anions forming insoluble compounds with lead, and the temperature coefficient of the peak height showed a negative value, different from the theoretical value in a diffusion-controlled or an electrode-reaction-rate-controlled process at the following concentrations of anions; $[Cl^-]=1$ M†, $[Br^-]=10^{-2}$ M, $[SCN^-]=10^{-1}$ M for 10^{-4} M lead. In the case of the addition of iodide, the s.w. peak height of lead increased at concentrations of iodide above 10^{-4} M for 10^{-4} M lead but the temperature coefficient of the peak height was always positive. Moreover, another peak due to lead appeared superimposed on the oxidation peak of iodide at a more positive potential, and this peak had a negative temperature coefficient. It was found that these phenomena were attributable to a specific adsorption of lead on mercury electrodes, induced by the foremost adsorbed anions. However in the case of the addition of iodide or in that of a high concentration of bromide or thiocyanate, the reversibility of the electrode process decreased and the temperature coefficient varied to a positive value in spite of the increase in adsorbed depolarizers.

The influence of the temperature on polarographic currents has not been much reported on since the theoretical consideration by Ilkovič[1] and the experimental report by Nejedlý[2] using direct-current (d.c.) polarography.

The temperature coefficient of d.c., alternating current (a.c.), s.w., and other polarographic currents has generally been accepted as positive in a reversible or an irreversible process, for it depends on the temperature dependence of the diffusion coefficient of a depolarizer and that of the rate constant of the electrode reaction, too, in an irreversible process.

We reported in a previous paper[3] that, when a chloride ion coexisted as a supporting electrolyte, the temperature coefficient of the s.w. polarographic peak height of lead showed a negative value, different from the theoretical temperature coefficient in a reversible or an irreversible process, on the other hand, the temperature coefficient of the d.c. polarographic wave height agreeded well with the theoretical value in a reversible process.

In this paper, the temperature dependence of the s.w. peak height of lead was studied in the presence of a chloride, bromide, thiocyanate, or iodide ion, as it is known that these anions are adsorbed on dropping mercury electrodes[4] and then give various influences on the electrode reaction.[5-7]

Theoretical

In d.c. polarography, the temperature coefficient of a diffusion-controlled current, $(1/I_{d.c.})\mathrm{d}I_{d.c.}/\mathrm{d}T$, can be expressed theoretically[1] thus;

$$(1/I_{d.c.})\mathrm{d}I_{d.c.}/\mathrm{d}T = (1/2D)\mathrm{d}D/\mathrm{d}T - (1/2\eta_{Hg})\mathrm{d}\eta_{Hg}/\mathrm{d}T, \quad (1)$$

in which D is the diffusion coefficient of the depolarizer and η_{Hg} is the viscosity of mercury.

In s.w. polarography, $(1/I_{s.w})\mathrm{d}I_{s.w.}/\mathrm{d}T$ at the reversible half-wave potential ($E=E_{1/2}$) in the case of a diffusion-controlled process can be expressed theoretically as;

$$(1/I_{s.w.})\mathrm{d}I_{s.w}/\mathrm{d}T = (1/2D)\mathrm{d}D/\mathrm{d}T - 1/T, \quad (2)$$

because $I_{s.w.}$ can be expressed as follows, as reported by Barker,[8]

$$I_{s.w.} = k\,\Delta E\, n^2\, A\, c\, D^{1/2} T^{-1}\, P/(1+P)^2, \quad (3)$$

where k=a constant varing with the apparatus, ΔE= the amplitude of the superimposed square-wave voltage, n= the number of electrons in an electrode reaction, c= the concentration of a depolarizer, A= the electrode area, $P=\exp[(E-E_{1/2})nF/RT]$, and $P=1$ when $E=E_{1/2}$.

It has been reported that the temperature coefficient of the d.c. wave height was in the range of 1.3—2.3%,[2] while that of the a.c. peak height, which should be the same as that of the s.w. peak height, was experimentally found in the range of 0.4—1.6%.[9]

It was reported by Imai and Adachi[10] that, in the case of a reaction-rate-controlled process, the temperature coefficient of the a.c. peak height was much higher than that of a diffusion-controlled process. Kambara and Kunimatsu[11] showed that, in the case of a redox system of a fairly low reversibility, the temperature coefficient decreased with an increase in the temperature, and that when the rate of the electrode process has become fast enough at higher temperatures, the coefficient approached that of the completely reversible system.

Experimental

Square-wave polarographic curves were recorded by a Yanagimoto high-frequency polarograph, Model PF-500, using a mercury pool at the bottom of an electrolysis cell as an anode.

Experiments were carried out under the following conditions; the span voltage =2 V, the gate range=2 to 7, the time constant=5.5.

Direct-current polarographic curves were recorded by a Yanagimoto voltammetric analyzer, P-1000 type, using a spiral platinum wire electrode as an anode and a saturated calomel electrode as a reference electrode.

The electrolysis cell was held in a Tajiri electronic thermo-water bath, ECW-108 type, with an accuracy of ±0.2 °C.

All the chemicals used were guaranteed-grade reagents. As the standard solution of lead, lead nitrate was used. For the addition of anions, potassium chloride, sodium chloride,

† 1 M=1 mol dm^{-3}.

sodium bromide, sodium thiocyanate, and sodium iodide were used.

Results and Discussion

Increased Sensitivity and Negative Temperature Coefficient. The peak height of the s.w. polarogram of lead increased markedly upon the addition of a smaller amount of iodide, bromide or thiocyanate than that of chloride, as is shown in Figs. 1—4. This increase was remarkable at lower temperatures, therefore, the temperature coefficient of the s.w. peak height of lead began to decrease from the theoretical value with an increase in the concentration of anions, except in the case of iodide, and was negative in the presence of the following concentrations, varing with each anion; $[Cl^-]=1$ M, $[Br^-]=10^{-2}$ M, $[SCN^-]=10^{-1}$ M. However, with still more increasing anions, the coefficient changed again to a positive value larger than the theoretical value.

Concerning the influence of the addition of anions

1, 3: 25.0 °C, 2, 4: 0.2 °C, ΔE: 5 mV, sens.: 1/20, 0.200 μA/mm.

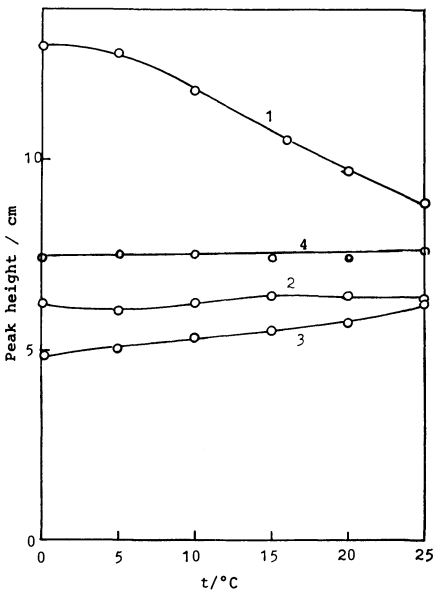

Fig. 4. Temperature dependence of the peak height in the s. w. polarograms of 10^{-4} M Pb^{2+} in 0.1 M $HClO_4$ with 10^{-1} M SCN^- (1), 10^{-2} M SCN^- (2), 10^{-3} M SCN^- (3), and 0.01 M $HClO_4$ with 1.0 M SCN^- (4). ΔE: 5 mV, sens.: 1/20, 0.200 μA/mm.

on the d.c. polarogram, the wave height of lead was constant, and the temperature coefficient coincided with the theoretical value, regardless of the addition of anions, unlike as in the case of the s.w. polarogram.

These experimental results seem to suggest the adsorption of the depolarizer.

In d.c. polarography, in which the mean current in a drop life is measured, a small quantity of adsorbed depolarizer has hardly any influence on the wave height, as the current occasioned by the reduction of an adsorbed depolarizer decreases with the growth of a drop in proportion to $t^{-1/3}$, where t is the time from the beginning of the drop.

In s.w. polarography, in which the electrode potential changes with the frequency of 200 Hz, even a small quantity of adsorbed depolarizer results in an increase in the peak height. The peak height is then increased by this approximate factor;[7]

$$1+\frac{(\gamma_{E_{1/2}})^2\sum_{m=0}^{\infty}(-1)^m(m+\beta)^{-3/2}}{8D_e\tau\sum_{m=0}^{\infty}(-1)^m(m+\beta)^{-1/2}}, \qquad (4)$$

where $\gamma_{E1/2}$ is the adsorption coefficient, which refers to the half-wave potential, τ is the half-period of the square-wave, and $\beta=t/\tau$, t now being the time elapsed since the last sudden potential change. The current occasioned by the reduction of adsorbed depolarizers decreases more rapidly than that occasioned by the reduction of diffusing depolarizers with the elapsed time t. Nevertheless, the current occasioned by the reduction of adsorbed depolarizers is considerably retained, even at the latter half-period of each square pulse, as the τ of 1/400 s is very short.

A temperature coefficient of the adsorption quantity always has a negative value in a physical adsorption, and frequently in a chemical adsorption as well and so

—— 25.0 °C, ------ 0 °C.

these experimental results may be considered reasonable.

Moreover, the following facts support adsorption of the depolarizer. In the presence of high concentrations of anions, s.w. polarograms of lead became noticeably asymmetric, as is shown in Fig. 5. In the presence of 1 M Br^-, a maximum which characterized the adsorption of the depolarizer appeared in the d.c. polarogram of 10^{-4} M lead. The surface-active substances, such as gelatin, Methyl Red, camphor, Eosin, thymol, and Alizarin S, changed the temperature coefficient of the peak height in the s.w. polarogram of lead from negative to positive, as has been shown in a previous paper.[3]

Increased Sensitivity and Positive Temperature Coefficient. Upon the addition of iodide, the temperature coefficient was always positive in spite of the increased peak height of lead in the s.w. polarogram caused by the adsorbed depolarizer, this was different from the cases of the addition of bromide, thiocyanate, and chloride.

However, it was found that another peak attributable to lead, which was superimposed on the oxidation peak of iodide, had a negative temperature coefficient.

When iodide was added to a 10^{-4} M Pb^{2+} solution of 0.1 M $HClO_4$, three peaks appeared in the s.w. polarogram, as is shown in Fig. 7. The first peak, A, at about +0.4 V (*vs.* Hg pool), apparently depends

on the tensammetric process. The height of the second peak, B, which was, at first sight, thought to be the oxidation peak of iodide, was higher than the oxidation peak, B′, of iodide in the absence of lead, and increased progressively with an increase in the concentration of lead or iodide, as is shown in Figs. 8 and 9. The temperature coefficient of B was negative, whereas that of B′ was positive, as is shown in Fig. 10. By substracting the peak height of the oxidation of iodide, B′, from the peak height of B, the plot of (B-B′) against the concentration of iodide shown in Fig. 10 was obtained. At a low concentration of iodide, (B-B′) increased with an increase in the iodide concentration, and the temperature coefficient of (B-B′) was negative. On the other hand, at higher concentrations of iodide, (B-B′) decreased with an increase in the iodide concentration and the temperature coefficient of (B-B′) was positive.

In the d.c. polarogram, the D and D′ corresponding to B and B′ were equal in wave height, so both D and D′ were only the oxidation waves of the iodide ion.

Therefore, (B-B′), which was superimposed on the peak of the iodide oxidation, must be a peak attributable to the adsorbed lead ion, the same as the C peak.

Next, the plot of $E_{d.e.}$ (a potential of a dropping mercury electrode) *vs.* log $[i/(i_d-i)]$ in the d.c. polarogram of lead (E corresponding to Peak C in the s.w. polarogram) was analyzed; the results are shown in Fig. 11.

In a reversible process, a plot of $E_{d.e.}$ *vs.* log $[i/(i_d-i)]$ shows a straight line, with a slope equal to $0.0591/n$ V at 25.0 °C and $0.0550/n$ V at 0 °C.

The presence of 2×10^{-4}—8×10^{-4} M I^- at 25 °C did not influence the slope, but at 0 °C, with an increase in the concentration of iodide, the slope was larger than the theoretical value and the half-wave potential was more negative.

These results show that the process becomes irreversible with an increase in the concentration of iodide at low temperatures.

In s.w. polarography, which requires a faster electrode reaction than d.c. polarography for an electrode reaction to be reversible because of the frequent periodic change in the electrode potential, the electrode processes in this case should be far more irreversible than in d.c. polarography. In an irreversible process, the temperature coefficient of a Peak height should be positive and larger than in a diffusion-controlled process.

Therefore, in spite of the electrode process accompanied by the depolarizer adsorption, the temperature coefficient of the peak (C) height of lead in the addition of iodide in the s.w. polarogram was positive.

Moreover, the positive temperature coefficient in the presence of bromide or thiocyanate of a high concentration may be attributable to the same reason.

The accelerating effect of halide ions on the electrode reactions of bismuth,[12] copper,[12] and zinc[13] has been reported. Breyer *et al.* suggested that the presence of halide ions decreased the repulsion of the aqueous Bi^{3+} or Cu^{2+} from the positively charged electrode, either because of the formation of a halo-complex or because of the adsorption of negatively charged halide ions on the electrode. Therefore, similar accelerating effects of iodide on the electrode reaction may be expected in the case of lead. Nevertheless, a decreasing reversibility with an increase in the concentration of iodide was observed. It may be that this decreasing reversibility is related to the dissociation rate of the complex preceeding the electrode reaction. A more detailed investigation is, however, necessary to clarify the cause of the decreasing reversibility.

Complex Formation and Adsorption. The half-wave potential shifted to a more negative potential upon the addition of anions in the order of; SCN^-, Cl^-, Br^-, I^- at 25 °C, and in the order of; Cl^-, SCN^-, Br^-, I^- at 0 °C, as is shown in Fig. 12. This order of the shift of a half-wave potential to a negative potential shows a tendency to form complexes of the depolarizer with anions or a tendency to form insoluble compounds. This order coincided with the ability to adsorb lead found from the degree of the increase in the peak height in the s.w. polarogram and also approximately with the ability to adsorb anions on mercury electrodes which was calculated by Grahame[14] and which is shown in Table 1. Therefore, the ability to adsorb lead may depend on both the adsorbed ability of anions on mercury electrodes and the complex-forming ability of lead with anions.

In the case of cadmium, which forms an insoluble

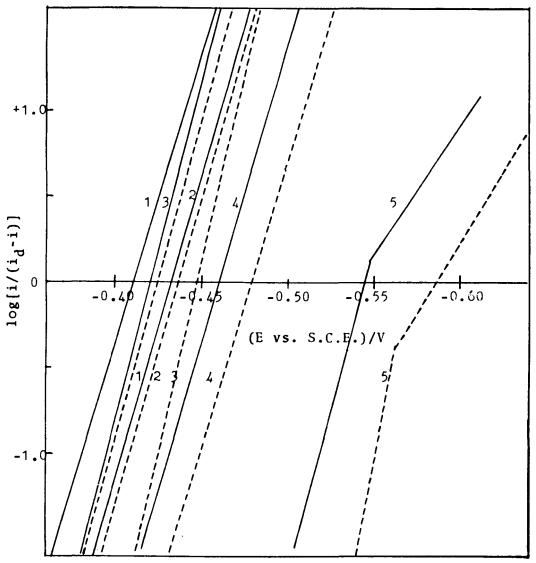

Fig. 12. Log plot analysis of the d. c. polarogram of 10^{-4} M Pb^{2+} in 1.0 M NO_3^- (1), Cl^- (2), SCN^- (3), Br^- (4), and I^- (5) with 0.01 M $HClO_4$.

compound with these anions only with difficulty, no adsorption of cadmium was found by means of s.w. polarography[3] in the presence of chloride, but it was reported in the presence of iodide on the basis of the experimental result from differential-pulse polarography.[15]

In the case of thallium, which forms an insoluble compound with chloride, the adsorption of thallium[16] was found by means of s.w. polarography[3] in the presence of chloride.

Moreover, the adsorption of lead decreased upon the addition of nitrate to chloride, as may be seen in Figs. 1 and 2. These results can be explained as follows; the adsorption of chloride on mercury was decreased by the nonspecific adsorption of nitrate, which did not induce so much adsorption of lead as chloride did.

These facts show that lead is induced by a covalent bonding force with adsorbed anions and adsorbed on mercury electrodes; in other words, lead adsorption is a specific adsorption induced by the foremost adsorbed anions. Therefore, upon the increase in the depolarizer over the inducing ability of anions, the temperature coefficient of the peak height of the depolarizer approached the theoretical value in a diffusion-controlled process, as is shown in Fig. 13.

The auther wishes to express her thanks to Professor Toyokichi Kitagawa of Osaka City University for his continuous encouragement and for his kind guidance in this work.

(Received December 11, 1981)

Vacuum sublimation-recrystallizing temperatures were determined for a tracer amount of actinoid chelates of 2,2,6,6-tetramethyl-3,5-heptanedione in order to obtain information about their sublimation behavior. The influence of the amount of sample (in tracer scale or in milligram scale) on its sublimation-recrystallizing temperature was also examined. The sublimation-recrystallizing zone temperature of the tracer amount of chelate was lower than that of the milligram amount. In addition, the sublimation-recrystallizing zone temperatures of the actinoid chelates were found to be in the following sequence: UO_2^{2+}>Am(III), Cm(III)>Th(IV), Np(IV), Pu(IV)>Cf-(III). These results suggest that the sublimation technique can be applied to separate the actinoid elements in a carrier-free state.

A number of workers have studied the volatility of lanthanoid β-diketone chelates. They reported that 2,2,6,6-tetramethyl-3,5-heptanedione makes a highly volatile and thermally stable lanthanoid chelate.[1-4] In previous work,[5,6] we have studied the sublimation behavior of tris(2,2,6,6-tetramethyl-3,5-heptanedionato)-lanthanoid(III) (La(III)$(thd)_3$) in detail, and have shown that the behavior can be divided into three groups (La to Gd, Tb and Dy, and Ho to Lu) and that the middle lanthanoid chelates (Tb and Dy) change thermally in solid phase at various fixed temperatures. Their volatilities have also been found to affect the two different crystallographic forms. It is therefore important to study the sublimation behavior of actinoid chelates of 2,2,6,6-tetramethyl-3,5-heptanedione. Among the actinoid metal chelates, uranyl(UO_2^{2+}) and thorium-(Th(IV)) chelates of β-diketone have already been examined as to volatility by using a milligram amount of sample.[7,8] Sakanoue and Amano have prepared some other actinoid β-diketonato chelates in tracer scale and described their volatilities.[9]

In the present study, in order to obtain the sublimation-recrystallizing temperatures of actinoid chelates of 2,2,6,6-tetramethyl-3,5-heptanedione, we examined the influence of sample amount (milligram amount or tracer amount) on their sublimation-recrystallizing temperatures. In addition, their sublimation behavior was determined for a tracer amount of actinoid chelates, and this was compared with those of lanthanoid chelates.

Experimental

Reagents. *Actinoid Metal*: Uranyl nitrate and thorium nitrate were purchased commercially in gram quantities, and used without delicate handling because of their low specific radioactivities. Other actinoid metals were used in tracer scale. Some actinoid radioisotopes: ^{227}Ac, ^{241}Am, ^{243}Am, and ^{242}Cm, were purchased from The Radiochemical Centre (England) and from New England Nuclear corporation (U. S. A.). The daughter nuclides, ^{228}Ac and ^{234}Th, were obtained by a milking procedure from the parent nuclides, ^{228}Ra and ^{238}U. Californium radioisotope, ^{252}Cf, was recovered from a nickel foil which had covered a ^{252}Cf neutron source; was obtained enough to prepared its chelate and determine its radioactivity. The plutonium radioisotope, ^{239}Pu, was obained by Inoue.[10] The radioactivities and metal amounts of actinoids used in preparation and their specific radioactivities are summarised in Table 1.

Table 1. Radioactivities, metal amounts, and specific activities of actionoid and gadolinium nuclides, which are used in one preparative procedure[a)]

Radio-nuclide	Radio-activity/μCi	Metal amount/mg	Specific activity/μCi mg^{-1}
^{228}Ac	10	4.5×10^{-9}	2.2×10^{9}
^{228}Th	5	6.1×10^{-6}	8.2×10^{5}
^{232}Th[b)]	3.3×10^{-2}	300	1.1×10^{-4}
^{234}Th	2	8.6×10^{-8}	2.3×10^{7}
^{238}U[b,c)]	1.0×10^{-1}	300	3.4×10^{-4}
^{239}Np	10	4.3×10^{-8}	2.3×10^{8}
^{239}Pu	1.0×10^{-2}	1.6×10^{-4}	6.2×10^{1}
^{241}Am	1	2.9×10^{-4}	3.4×10^{3}
^{242}Cm	2	6.0×10^{-7}	3.3×10^{6}
^{252}Cf	1.0×10^{-3}	1.9×10^{-3}	5.4×10^{-1}
^{153}Gd[d)]	5	2.2×10^{-3}	2.3×10^{3}

a) One-tenth of the amounts in this table was used in one sublimation procedure. b) Thorium and uranium are weighable. c) A depleted uranium sample was used. d) The purchased Gd radioisotope is not carrier-free, and contains other stable Gd isotopes.

Lanthanoid Carriers and Radioisotope: The purified lanthanoid oxides (99.9%) of La_2O_3, Gd_2O_3, and Sc_2O_3 were used as a carrier for the preparation of actinoid chelates in tracer scale. Gadolinium radioisotope, ^{153}Gd, were purchased from The Radiochemical Centre (England).

Preparation of Actinoid Chelates of 2,2,6,6-Tetramethyl-3,5-heptanedione. Macro amounts of thorium and uranyl chelates, $Th(thd)_4$ and $UO_2(thd)_2\cdot2H_2O$, were prepared by mixing 90% methanol solutions of the neutralized 2,2,6,6-tetramethyl-3,5-heptanedione chelating agent and thorium nitrate or uranyl nitrate. The chelates precipitated immediately upon mixing the solutions and were purified by recrystallization from dichloromethane and vacuum sublimation. The purified uranyl chelate was found to be unhydrous form, $UO_2(thd)_2$, by elemental and thermochemical (TG, DTA) analyses.

Tracer amounts of other actinoid chelates of 2,2,6,6-tetramethyl-3,5-heptanedione were prepared according to the preparative method for $Ln(thd)_3$ (Ln=lanthanoid metal) of Eisentraut and Sievers[1] with a slight modification, by the use of about 100 mg of lanthanoid metal as a non-isotopic

carrier. The mixed solution of the lanthanoid salt solution and tracer amounts of each actinoid metal were heated to dryness. The residue was dissolved in a minimum amount of 99% methanol, and the pH of the resultant solution was adjusted between 3 and 5 by dropwise addition of 2 M NH_4OH solution. A solution of Hthd chelating agent was then added to the above solution. The mixture was adjusted to the desired pH. The precipitate was filtered off and then purified by recrystallization from dichloromethane. Several sets of the chelates were prepared as follows: $(La+^{228}Th)(thd)_3$, $(La+^{234}Th)(thd)_3$, $(UO_2+^{234}Th)(thd)_2$, $(La+^{228}Ac+^{228}Th+^{239}Np+^{239}Pu+^{241}Am+^{252}Cf)(thd)_3$, $(UO_2+^{234}Th+^{239}Pu)(thd)_2$, $(La+^{153}Gd)(thd)_3$, $(Sc+^{153}Gd)(thd)_3$, and $(La+^{241}Am+^{242}Cm+^{252}Cf)(thd)_3$.

Measurements of Vacuum Sublimation-recrystallizing Temperatures. Specifications for the vacuum sublimation apparatus for the measurement of the vaccum sublimation-recrysrallizing temperature were reported in the previous paper.[6] Briefly, the apparatus consists of a Pyrex tube (0.8 cm in outer diameter and 100 cm in length) with a continuous temperature gradient (1—3 °C/cm) maintained along its length, and evacuated to $(1-10)\times10^{-3}$ Torr) (1 Torr≈133.322 Pa). Samples were placed in small aluminum or porcelain boat and inserted into the high temperature end of the Pyrex sublimation tube. The samples then heated at 180 °C for 2 h under reduced pressure ($(1-10)\times10^{-3}$ Torr)). Their recrystallizing positions were determined by the scanning of the radioactivity along the sublimation tubes.

Special care has been paid in comparing the recrystallizing position of each actinoid chelate. Two sublimation tubes were inserted in an outer tube to sublimate each sample under the same conditions. The small differences between the sublimation-recrystallizing temperatures of each sample were clearly detected.

Radioactivity Measurement. While the gross gamma and characteristic X-ray were measured with a well-type NaI(Tl) scintillation counter, the gamma ray spectra were taken by using a Ge(Li) semiconductor detector connected with a 4096-channel pulse-height analyzer. Alpha spectra were taken with a Si(Au) semiconductor detector coupled to a 4096-channel pulse-height analyzer. The detection of alpha particles was also done by an α-track method by using a cellulose nitrate film. The ^{252}Cf radioactivity was measured by using Indian mica as a fission track detector. Both track methods (α-track and fission track methods) were very useful for locating clearly the sublimation-recrystallized chelate.

Results and Discussion

Vacuum Sublimation-recrystallizing Temperatures of Tracer Amounts of Metal Chelates of 2,2,6,6-Tetramethyl-3,5-heptanedione. In general, vacuum sublimation-recrystallizing temperature zones for macro amounts of metal chelates (more than 5 mg) can be observed discretely and reproducibly at the higher temperature site of the deposition zone, while the tailing appears in its lower temperature site.[6] In this experiment, the influence of the amount of sample on its sublimation-recrystallizing temperature was examined by the use of $Gd(thd)_3$ and $Th(thd)_4$. Figures 1 and 2 show these results. The peak position of the recrystallizing temperature zone for tracer amounts of $Gd(thd)_3$ or $Th(thd)_4$ shifted to a temperature position lower than that of macro amounts of $Gd(thd)_3$ or $Th(thd)_4$. On the other hand, the recrystallizing range of tracer amounts of

chelate was also found to be equal to those of macro amounts of chelate. The tracer amounts of the sublimated chelates were located in discrete and reproducible temperature ranges. These reasons allow the sublimation behavior of tracer amounts of actinoid thd chelates to be expressed conveniently in terms of the sublimation-recrystallizing temperature range.

Sublimation Behavior of Actinoid Chelates of 2,2,6,6-Tetramethyl-3,5-heptanedione. The shape of the sublimatographic distribution of each actinoid thd chelate was that of tracer amounts of $Gd(thd)_3$ and $Th(thd)_4$. The sublimation-recrystallizing temperatures for the various actinoid thd chelates are graphically presented and compared in Fig. 3. In this figure, the depositing

TABLE 2. VACUUM SUBLIMATION-RECRYSTALLIZING TEMPERATURE RANGES OF ACTINOID thd CHELATES

Actinoid thd chelate	Temperature range/°C
$Th(thd)_4$	60—118
$UO_2(thd)_2$	100—145
$Np(thd)_4$	59—113
$Pu(thd)_4$	59—115
$Am(thd)_3$	77—129
$Cm(thd)_3$	76—126
$Cf(thd)_3$	50—80

zones in a large portion(80%) of sublimated chelate are shown as a thicker line. Table 2 summarizes the sublimation-recrystallizing temperature ranges obtained for actinoid thd chelates. Many actinoid metals, The U, Np, Pu, Am, Cm, and Cf, made a highly volatile, and thermally stable chelate by using 2,2,6,6-tetramethyl-3,5-heptanedione chelating agent. However, Ac(III) thd chelate was not sublimed under the same sublimation conditions. The Ac(III) thd chelate will be unstable on heating.

It is difficult to estimate the valence state of tracer amounts of solid actinoid sublimates. The valence states of Am, Cm, and Cf ions in each starting solution were tervalent, and those of Th, Np, and Pu ions were quadrivalent. In general, valence states of Am, Np, and Pu ions tend to change in various solutions. Therefore special care was paid in each preparative step of these actinoid chelates. On the other hand, according to solvent extraction data of these actinoid chelates of β-diketone agents, β-diketonato chelates of Am(III), Np(IV), and Pu(IV) gives the highest values of formation constants in each actinoid β-diketonato chelates. In this experiment, the recrystallizing positions of these actinoid thd chelates were compared with those of other actinoid and lanthanoid chelates. Under these conditions, the coordination forms between the actinoid metals and the thd chelating ligands were estimated. The estimated chemical forms are shown in the first column in Table 2.

By comparing the above results, it is found that the sublimation-recrystallizing temperature range of actinoid thd chelates decreases in the following order:

$$UO_2(thd)_2 > \begin{matrix} Th((thd)_4 \\ Am(thd)_3 \\ Cm(thd)_3 \\ Pu(thd)_4 \end{matrix} > Np(thd)_4 > Cf(thd)_3$$

The recrystallizing temperature ranges of tervalent $Am(thd)_3$, $Cm(thd)_3$ and $Cf(thd)_3$ were compared with those of the tervalent lanthanoid chelates, $Ln(thd)_3$. The recrystallizing temperature range of Cf(III)$(thd)_3$ was found to resembles those of the heavier lanthanoid (Ho–Lu) chelates, while the recrystallizing temperature ranges of Am(III)$(thd)_3$ and Cm(III)$(thd)_3$ chelates resemble those of the lighter lanthanoid (La, Pr–Gd) chelates.[5,6] Therefore the structures of the Am(III) and Cm(III) thd chelates should be different from that of the Cf(III)chelate. The Am(III) and Cm(III) thd chelates are estimated to be a dimer form, and the Cf(III) thd chelate may be a monomer form. As the dimer chemical forms of $Am_2(thd)_6$ and $Cm_2(thd)_6$ are improbable owing to very low metal concentrations, as shown in Table 1, $LaAm(thd)_6$ and $LaCm(thd)_6$ are possible forms.

The quadrivalent chelates of Th(IV)$(thd)_4$, Np(IV)-$(thd)_4$, and Pu(IV)$(thd)_4$ recrystallized in a similar position of the sublimation tube. Since there are little difference in structure and molecular weight of $M(thd)_4$ (M=Th, Np, Pu), their van der Waals' forces will be equal and their sublimation behaviors would be similar. The recrystallizing temperature of $UO_2(thd)_2$ chelate was found to be higher than those of the other actinoid chelates. This sublimation behavior will be due to the structural characteristic of "nyl" ion.

The actinoid thd chelates gave a high thermal stability during sublimation, but showed a considerable difference in the sublimation-recrystallizing temperature. The differences of their sublimation behaviors may be due to the difference in vapor pressure, molecular weight, heats of sublimation, and surface area of these chelates. The differences in heats of sublimation can be regarded as significant, because the heats of sublimation are correlated with the space arrangement. However, a number of fundamental experiments must be undertaken in order to determine the sublimation behavior of tracer amounts of chelate compound.

The reproducibility of sublimation-recrystallizing temperatures suggests that the sublimation technique can be applied to separate the actinoid elements in a carrier-free state. It is proposed that the ^{238}U–^{234}Th, ^{243}Am–^{239}Np radioactive equilibrium mixture and the Am(Cm)–Cf mixture can be separated by a sublimation technique.

The authors wish to express their deep thanks to Professor Masanobu Sakanoue of the Faculty of Science, Kanazawa University for his continuous encouragement throughout this study.

The present work was partially supported by Grants-

in-Aid for Scientific Research Nos. 574227 and 56040004 from the Ministry of Education, Science and Culture.

The Stereochemistry and Reactivity of Metal-Schiff Base Complexes. V. The Solvent Effect on the Stereoselectivity of Cobalt(III) Complexes Containing a sal_2en-type Schiff Base and L-Amino Acid

Yuki Fujii,* Yasuo Kuwana, Sozo Takahashi,†† Keiko Shimizu, and Kumiko Hiroi
Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo-cho, Mito, Ibaraki 310
††*Department of Chemistry, Ibaraki Technical College, Nakane, Katsuta, Ibaraki 312*
(Received December 12, 1981)

The solvent effect on the stereoselectivity between Λ- and Δ-β_2-diastereoisomers of cobalt(III) complexes with the general formula of [Co(Schiff base)(L-aa)], where Schiff base represents sal_2en^{2-}, α-Me-sal_2en^{2-}, and 5,6-benzo-sal_2en^{2-}, and where L-aa denotes L-alaninate, L-valinate, L-methioninate, and L-phenylalaninate, was studied. Generally, the Λ-β_2-isomer was more stable than the Δ-β_2-isomer in solution, and the stereoselectivity of all the L-ala-complexes and of the L-met-complex with 5,6-benzo-sal_2en increased in the following order of solvents : acetone=DMF$\leqq$*t*-BuOH<*s*-BuOH<*i*-PrOH<*n*-BuOH<*n*-PrOH<EtOH<MeOH. On the other hand, the stereoselectivity of L-val- and L-phe-complexes with sal_2en and 5,6-benzo-sal_2en increased in the following order : acetone=DMF<MeOH<EtOH<*n*-PrOH<*n*-BuOH<*i*-PrOH<*s*-BuOH<*t*-BuOH. In the case of 5,6-benzo-sal_2en complexes with L-val and L-ile, the Δ-β_2-isomer was preferred rather than the Λ-β_2-isomer in acetone and DMF with 8—13% stereoselectivity. From the spectroscopic evidence, a hydrogen bonding between the OH group of alcoholic solvents and phenolic oxygen atoms of a Schiff base ligand was assummed, and the above phenomena were explained in terms of the steric difference between the Λ- and Δ-β_2-isomers for the solvation with the alcoholic solvents by means of the hydrogen bonding.

Detailed studies have been directed toward the thermodynamic stereoselectivity of $Co(N_4)$-complexes with a chiral amino acid. In these studies, the energy differences among the diastereoisomers have been explained mainly in terms of the intramolecular steric interaction (nonbonded interactions, bond deformations, angle deformations, and torsional strain) of the diastereoisomers.[1-3] However, the results of energy-minimization calculations have sometimes disagreed with the observed values. In such cases, an intermolecular interaction between the diastereoisomers and solvent molecules has been suggested.[2-4] In fact, it is well known that racemic *cis*-$[Co(en)_2Cl_2]^+$ and racemic α-$[Co(trien)Cl_2]^+$ antiracemize in an optically active solvent.[5] It has been pointed out recently for *trans*-$[Co((R)\text{-pn})_2X_2]^+$ (X=Cl^- and Br^-) that the conformation of the (*R*)-pn chelate ring changes depending on the nature of the solvents.[6] It has also reported that solvents affect the conformation of the 3,2,3-tet chelate ring of *trans*-$[Co(3,2,3\text{-tet})(N_3)_2]^+$ and the conformation of 1,3-diamine of *trans*-$[Co(1,3\text{-diamine})_2X_2]^{+n}$ (X=Cl^-, CN^-, and NH_3).[7,8] These facts suggest that solvents play an important role in the thermodynamic stereoselectivity of metal complexes.

In the course of our study of the stereoselectivity of Co(III)-Schiff base complexes with a chiral amino acid,[9] we found that the stereoselectivity of Co(III)-Schiff base complexes is much higher than that of $Co(N_4)$-complexes. In order to explain the high stereoselectivity, an X-ray study of $(-)_{435}$-Λ-β_2-[Co(α-Me-sal_2en)(L-ile)]·$1.5H_2O$ was carried out;[10] however, no steric factor stabilizing this configuration has been found. In this paper, the solvent effect on the stereoselectivity of a series of β_2-[Co(Schiff base)(L-aa)] complexes will be investigated in detail.[11]

Experimental

Preparation of Complexes. β_2-[Co(sal_2en)(L-aa)] and β_2-[Co(α-Me-sal_2en)(L-aa)] were prepared as previously repoted.[9] β_2-[Co(5,6-benzo-sal_2en)(L-aa)] was prepared as follows. (Since the preparation is similar for all the amino acids used here, the method for only the L-ala-complex is described.) L-Alanine (0.5 g, 5.5×10^{-3} mol) in a mixed solvent of water (20 cm^3) and methanol (100 cm^3) was added to a slurry of [Co(5,6-benzo-sal_2en)] (2.3 g, 5.4×10^{-3} mol) in 250 cm^3 of chloroform. The mixture was stirred vigorously in the open air for about 3 h to give a green solution. This solution was then filtered, and the filtrate was concentrated to a small volume at room temperature to give green crystals. In the cases of L-alanine, L-threonine, and L-isoleucine, the green crystals were recrystallized from methanol. In the cases of L-valine, L-leucine, L-methionine, and L-phenylalanine, the green crystals were washed with methanol. Yields, about 2.0 g (75%). The elemental analyses data are given in Table 1.

[Co(5,6-benzo-sal_2en)] was prepared as follows: 2-Hydroxy-1-naphthaldehyde (5.2 g, 3×10^{-2} mol) in 50 cm^3 of methanol was mixed with ethylenediamine (0.9 g, 1.5×10^{-2} mol); the Schiff base separated out as an yellow powder in about a 95% yield. $Co(CH_3COO)_2\cdot4H_2O$ (2.5 g, 1×10^{-2} mol), dissolved in methanol (100 cm^3), was added to a slurry of the ligand (3.7 g, 1×10^{-2} mol) in chloroform (200 cm^3). The mixture was heated at about 80 °C for 1 h to give a red complex, [Co(5,6-benzo-sal_2en)] in about an 80% yield. Found: C, 67.67; H, 6.74; N, 6.47%. Calcd for $CoC_{24}H_{18}N_2O_2$: C, 67.78; H, 6.62; N, 6.59%.

Preparation of Solutions. Extra-pure solvents were used after distillation. About 5×10^{-4} mol dm^{-3} solutions of the complexes were used for the AB and CD measurements. The establishment of equilibrium was confirmed from the mutarotation at 435 nm of the complex solutions. In acetone, the isomerization of the complexes was very slow. Therefore, activated charcoal was added to the acetone solutions, and the mixtures were warmed at about 50 °C until the solutions showed a constant rotation at 435 nm. The AB and CD measurements were carried out after the filtration of the activated charcoal. The concentration of the acetone solutions was calibrated by the use of the absorbance at 580 nm. No decomposition was found from the ^1H NMR spectra in the DMF-d_7 of the complexes recovered from acetone solutions. Also, the isomerization in DMF (*N*,*N*-dimethylformamide) was fairly slow; the solutions were warmed at about 40 °C to establish the isomerization equilibrium. No decomposition

was found from the ^{1}H NMR spectra of the complexes in DMF-d_7 at 35 °C.

Measurements. The absorption (AB) and circular dichroism (CD) spectra were measured with a Hitachi 200-10 Spectrophotometer at 23 °C and with a JASCO J-20 Spectropolarimeter ar room temperature respectively. The optical rotation at 435 nm was measured with a JASCO DIP-140 Polarimeter. The ^{1}H NMR spectra were recorded with a Hitachi R-20 Spectrometer (60 MHz) or a Varian CFT-20 Spectrometer (80 MHz) at 35 °C.

Results and Discussion

Structure and Properties of Complexes. In a previous paper,[9] the *cis*-β_1-structure was assigned tentatively to [Co(sal$_2$en)(L-aa)] and [Co(α-Me-sal$_2$en)(L-aa)] (L-aa= L-ala, L-met, L-val, L-leu, L-ile, L-thr, L-phe, L-tyr, and L-trp). However, it has been found recently, in our X-ray study of $(-)_{435}$-[Co(α-Me-sal$_2$en)(L-ile)]·1.5H_2O, that the complex takes the *cis*-β_2-structure.[10] As is shown in Fig. 1, the AB and CD spectra of the L-ile-complex in methanol closely resemble those in the solid state (KBr disk), and the AB and CD spectra of Co(sal$_2$en)- and Co(α-Me-sal$_2$en)-complexes with various L-amino acidates in methanol are very similar to those of the L-ile-complex in methanol.[9] Accordingly, the *cis*-β_2-structure can be assigned to all the Co(sal$_2$en)- and Co(α-Me-sal$_2$en)-complexes with L-amino acidates in methanol.

As has been mentioned previously,[9] [Co(sal$_2$en)(L-aa)] and [Co(α-Me-sal$_2$en)(L-aa)] are isolated as a 1 : 1

mixture of Λ- and Λ-β_2-isomers or as a pure Λ-β_2-isomer. This difference in the isolated form comes from the solubility of the complexes. On the other hand, the isolated complexes exhibit mutarotation in methanol to show a minus rotation at 435 nm under equilibrium conditions.[9] These facts indicate that: 1) the complexes

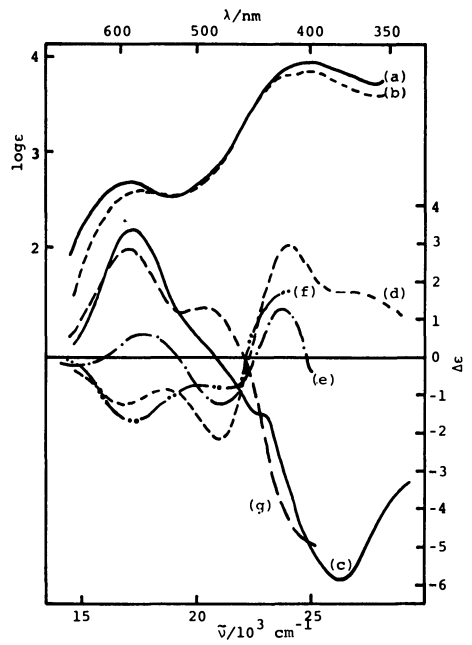

Fig. 5. AB and CD spectra of β_2-[Co(5,6-benzo-sal$_2$en)-L-ile)] in methanol ((a) and (c)) and in DMF ((b) and (d)) under the equilibrium conditions. (e): Vicinal CD of L-ile, (f): CD curve rectified vicinal CD (e) for CD (d), (g): CD curve rectified vicinal CD (e) for CD (c).

are labile in isomerization between Λ- and Λ-β_2-isomers in methanol, 2) the complexes exist as an equilibrium mixture of the two isomers in methanol, and 3) the Λ-β_2-isomer ($(-)_{435}$-isomer) is thermodynamically more stable than the Λ-β_2-isomer ($(+)_{435}$-isomer) in methanol. Also, in the cases of the [Co(5,6-benzo-sal$_2$en)(L-aa)] newly prepared here, they exhibit mutarotation in methanol to show a minus rotation at 435 nm under equilibrium conditions. Some representative mutarotations are shown in Fig. 2. The numerical data are given in Table 3. The plots of $\ln(\alpha_\infty - \alpha_t)$ *vs.* the time gave a straight line, indicating that two species of isomers, $(-)_{435}$- and $(+)_{435}$-isomers, are involved in each mutarotation. On the other hand, the AB spectra showed no clear change during the mutarotation. These facts suggest that: 1) [Co(5,6-benzo-sal$_2$en)(L-aa)] is also labile in isomerization and exists as an equilibrium mixture of $(-)_{435}$- and $(+)_{435}$-isomers in methanol; 2) the $(-)_{435}$-isomer is more stable than the $(+)_{435}$-isomer in methanol, and 3) both isomers have the same geometrical structure with respect to the coordinated atoms around the Co(III) ion.

Figures 3—5 show the AB and CD spectra of the representative 5,6-benzo-sal$_2$en complexes under the equilibrium conditions. The numerical data are listed in Table 4. The AB spectra and the CD spectral patterns of all the 5,6-benzo-sal$_2$en complexes in methanol closely resemble each other and are very similar to those of Λ-β_2-[Co(α-Me-sal$_2$en)(L-ile)] in methanol. Thus, it becomes clear that 1) all the 5,6-benzo-sal$_2$en complexes take the *cis*-β_2-structure, and 2) they favor the Λ-β_2-configuration over the Δ-β_2-configuration in methanol.

a) Data are those under the equilibrium conditions.

The mutarotation of representative complexes in DMF is shown in Fig. 6. The numerical data are given in Table 3. Although the mutarotation in DMF is slow, the curves are very similar to those in methanol, and the plots of $\ln(a_\infty - a_t)$ *vs.* the time give a straight line. The AB spectra show no clear time dependence during the mutarotation. These facts indicate that the complexes have properties in DMF similar to those in methanol. However, L-val- and L-ile-complexes exhibit a plus rotation under the equilibrium conditions in DMF, suggesting that they favor the Δ-β_2-configuration in DMF more than the Λ-β_2-configuration.

The AB and CD spectra of representative complexes in DMF under the equilibrium conditions are shown in Figs. 3—5. Although some shift of the AB and CD spectra is observed as compared with those in methanol, the AB and CD spectra in DMF of L-ala-, L-met-, L-leu-, L-thr-, and L-phe-complexes closely resemble those in methanol, indicating that the complexes take the *cis*-β_2-structure and prefer the Λ-β_2-isomer rather than the Δ-β_2-isomer in DMF. In the case of the L-val- and L-ile-complexes, the AB spectra in DMF are similar to those in methanol, while the CD spectra in DMF show signs different from those in methanol. When the vicinal effect of the coordinated L-amino acidates is subtracted from the CD curves of the L-val- and L-ile-complexes in DMF, it becomes clear that the resulting CD curves ((f) in Figs. 4 and 5) are almost in a mirror-image relation with the rectified CD curves ((g) in Figs. 4 and 5) in methanol. From these facts, it can be concluded that the L-val- and L-ile-complexes prefer the Δ-β_2-isomer in DMF rather than the Λ-β_2-isomer. It is interesting that the stereoselectivity changes depending upon the kind of solvent.

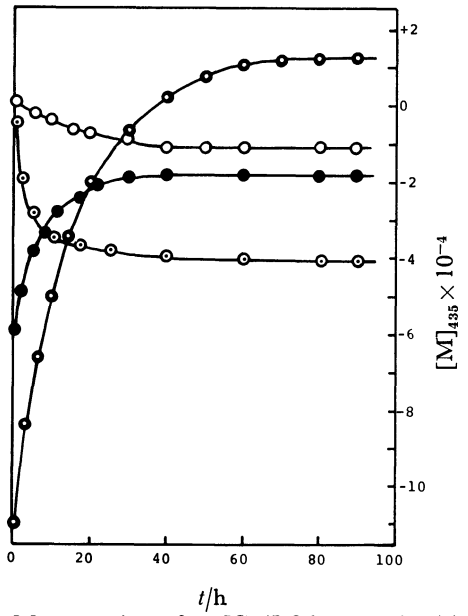

Fig. 6. Mutarotation of β_2-[Co(5,6-benzo-sal$_2$en)(L-aa)] in DMF at 36 °C.
—○—: L-ala-complex, —⊙—: L-thr-complex, —O—: L-val-complex, —●—: L-phe-complex.

From the molar rotation of the 5,6-benzo-sal$_2$en complexes soon after dissolution in DMF (Table 3), it can be assummed that: 1) the L-ala-, L-met-, L-leu-, L-ile-, and L-thr-complexes were isolated as a 1 : 1 mixture of Λ- and Δ-β_2-isomers, 2) the L-val-complex was isolated as the pure Λ-β_2-isomer, and 3) the L-phe-complex was isolated as a 3 : 1 mixture of Λ- and Δ-β_2-isomers. The isomeric ratios of the L-ala-, L-met-, L-thr-, and L-val-complexes will be confirmed below from the ^{1}H NMR spectra of the complexes in DMF.

Stereoselectivity of 5,6-Benzo-sal$_2$en Complexes. Figure 7 shows the representative ^{1}H NMR spectra of the complexes in DMF-d_7 and in a mixed solvent of CD_3OD and DMF-d_7. The numerical data are listed in Table 5. Since the 5,6-benzo-sal$_2$en complexes are not so fully soluble in CD_3OD, the mixed solvent of CD_3OD and DMF-d_7 (20%) was used here in place of CD_3OD. The CD spectra of the complexes in the mixed solvent of methanol and DMF (20%) are almost the same as those in methanol. Thus, we regarded the ^{1}H NMR spectra in the mixed solvent as close to those in CD_3OD.

The signal of the coordinated 5,6-benzo-sal$_2$en ligand showed no observable time dependence, and the signals of all the complexes are very similar to each other. On the other hand, as is shown in Fig. 7, the alkyl signal of the coordinated L-amino acidates exhibits a time dependence. From the time dependence, it is confirmed that only two species of isomer are involved in the mutarotation of the L-ala-, L-met-, L-val-, and L-thr-complexes. Further, by a comparison with the mutarotation at 435 nm, the assignment of the alkyl peaks for Λ- and Δ-β_2-isomers becomes possible. From the relative peak area of the alkyl peaks soon after dissolution in DMF-d_7, it can be confirmed that the L-ala-, L-met-, and L-thr-complexes were isolated as a 1 : 1 mixture of the two isomers, but the L-val-complex was isolated as the pure Λ-β_2-isomer. On the other hand, from the relative peak areas of the alkyl peaks under the equilibrium conditions, the isomeric ratio between the two isomers under the equilibrium conditions can be estimated in the cases of L-ala-, L-met-, and L-thr-complexes; the values are listed in Table 6.

In the case of the L-val-complex, the alkyl signal under the equilibrium conditions is somewhat complicated due to the overlap of the peaks of the two isomers, although it is confirmed from a careful inspection that the Λ-β_2-isomer somewhat predominates over the Δ-β_2-isomer in the mixed solvent of CD_3OD and DMF-d_7, while the selectivity is reversed in DMF-d_7.

In the cases of the L-leu-, L-ile-, and L-phe-complexes, the alkyl signal is complicated due to the overlap of the peaks. Therefore, the isomeric ratio of these complexes was estimated from the $\Delta\varepsilon$ value of the main CD band in the 1st-absorption-band region of the complexes by the use of the following equation:

$$([\Lambda]-[\Delta])/([\Lambda]+[\Delta]) = (\Delta\varepsilon^A-\Delta\varepsilon^B)/(\Delta\varepsilon^C-\Delta\varepsilon^B), \quad (1)$$

where [Λ] and [Δ] represent the concentrations of the Λ- and Δ-β_2-isomers under the equilibrium conditions respectively; $\Delta\varepsilon^A$ denotes the CD intensity of the complexes at the main CD band near 580 nm under the equilibrium conditions; $\Delta\varepsilon^B$ stands for the vicinal effect of the coordinated L-amino acidates at the same wave length as that of $\Delta\varepsilon^A$, and $\Delta\varepsilon^C$ represents the CD intensity of the pure Λ-β_2-isomer at the main CD band near 580 nm. In this study, as the $\Delta\varepsilon^C$ value of various L-amino acidato complexes with 5,6-benzo-sal$_2$en, we used the $\Delta\varepsilon$ value of the pure Λ-β_2-isomer of the [Co(5,6-benzo-sal$_2$en)(L-val)] complex soon after dissolution in DMF. This is because: 1) it is only in the L-val-complex that the pure Λ-β_2-isomer can be isolated, however, 2) the $\Delta\varepsilon^C$ value can be regarded as almost a constant for the following reasons: 1) as is shown in Fig. 8, the vicinal effect of the coordinated L-amino acidates is almost a constant in the 1st-absorption region for various L-amino acidato complexes, and it is small in value as compared with the configurational effect of the complexes, and 2) as is shown in Table 7, the $\Delta\varepsilon^C$ value is almost a constant in sal$_2$en and in α-Me-sal$_2$en complexes. Indeed, as is shown in Table 6, the isomeric ratios of the L-ala-, L-met-, and L-thr-complexes, which were estimated from the CD intensity of the complexes and the $\Delta\varepsilon^C$ value of the L-val-complex, well fitted with the isomeric ratios estimated from the ^{1}H NMR spectra of the complexes.

Figure 8 shows the CD spectra of the 1 : 1 mixture of Λ- and Δ-β_2-isomers soon after dissolution in DMF; these spectra correspond to the vicinal effect of the coordinated

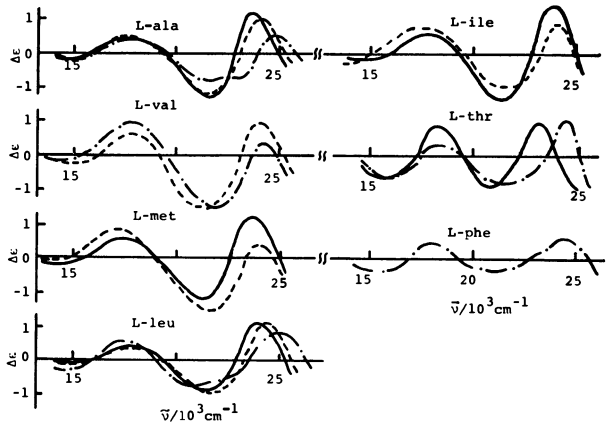

Fig. 8. Vicinal CD of β_2-[Co(Schiff base)(L-aa)] in DMF.

Table 7. The CD intensity of pure Λ-β_2-isomers in DMF

Complex	$\bar{\nu}/10^3$ cm^{-1}($\Delta\varepsilon$)
Λ-β_2-[Co(sal$_2$en)(L-thr)]·H$_2$O	17.24(+14.99)
Λ-β_2-[Co(sal$_2$en)(L-phe)]·4.5H$_2$O	17.15(+15.21)
Λ-β_2-[Co(α-Me-sal$_2$en)(L-ile)]·1.5H$_2$O	16.95(+14.08)
Λ-β_2-[Co(α-Me-sal$_2$en)(L-met)]·2H$_2$O	16.95(+14.14)
Λ-β_2-[Co(5,6-benzo-sal$_2$en)(L-val)]·H$_2$O	17.45(+20.71)

L-amino acidates. The vicinal CD's in the 1st-absorption-band region are very similar to each other; therefore, in the calculation of Eq. 1, we used the vicinal CD's of β_2-[Co(sal$_2$en)(L-val)] and β_2-[Co(α-Me-sal$_2$en)-(L-phe)] for the $\Delta\varepsilon^B$ values of the 5,6-benzo-sal$_2$en complexes with L-val and L-phe respectively. From the similarity in the vicinal CD spectra, it is assumed that all the L-amino acidates take conformations quite similar to each other.

From Table 6, the following conclusions can be drawn: 1) the 5,6-benzo-sal$_2$en complexes have an inclination to prefer the Λ-β_2-isomer rather than the Δ-β_2-isomer in methanol and in a mixed solvent of methanol and DMF, 2) the stereoselectivity of 5,6-benzo-sal$_2$en complexes in methanol increases in the following order of L-amino acidates: L-ala=L-val<L-ile=L-leu<L-met<L-phe<L-thr, 3) this order is not parallel with the increasing order of steric bulkness of the alkyl group of amino acidates, as has been observed for sal$_2$en and α-Me-sal$_2$en complexes,[9] 4) the degree of the stereoselectivity of 5,6-benzo-sal$_2$en complexes in methanol is somewhat lower than that of sal$_2$en and α-Me-sal$_2$en complexes,[9] 5) the stereoselectivity of 5,6-benzo-sal$_2$en complexes in DMF is lower than that in methanol, and 6) in the case of L-val- and L-ile-complexes, which have the secondary β-carbon atom at the alkyl group of amino acid, they exhibit an inclination to prefer the Λ-β_2-isomer rather than the Λ-β_2-isomer in DMF.

Solvent Effect on the Stereoselectivity of Complexes. In order to get information about the stereoselectivity of Co(Schiff base)-complexes with L-amino acidates in various solvents, we measured the AB and CD spectra of Co(sal$_2$en)-, Co(α-Me-sal$_2$en)-, and Co(5,6-benzo-sal$_2$en)-complexes with L-ala, L-met, L-val, and L-phe in H$_2$O, MeOH, EtOH, PrOH, BuOH, DMF, and acetone. The numerical data are given in Tables 8—10, while representative AB and CD spectra in various solvents are shown in Figs. 9 and 10. Although some extent of shift (within 20 nm) with the variation of solvents is observed for the absorption and the associated CD bands in all the complexes, the AB spectral pattern and the intensity of each complex are very similar to those in methanol; this indicates that each complex takes the *cis*-β_2-structure in these solvents. The CD

pattern of each complex in various solvents is also very similar to that in methanol; however, the CD intensity varies depending upon the kind of solvent in some complexes. Especially in the case of [Co(5,6-benzo-sal$_2$en)(L-val)], the CD spectra in DMF and acetone are almost in a mirror-image relation with that in methanol when the vicinal effect is rectified, as has been mentioned previously.

In order to certify that the variation in the CD intensity in various solvents comes mainly from the variation in the isomeric ratio between the *Λ*- and *Δ*-β_2-isomers, the ^{1}H NMR spectra of several complexes were measured in various solvents. Some representative ^{1}H NMR spectra are shown in Fig. 11. Indeed, the relative isomeric ratio changes depending upon the solvent, and the isomeric ratios estimated from the ^{1}H NMR spectra fit well with the isomeric ratios estimated from the CD intensity by the use of Eq. 1. On the other hand, the CD intensity of *Λ*$_{SS}$-β_2-[Co(α-Me-sal$_2$en)(*N*-Bz-L-ala)][12] and *Λ*-β_2-Co(sal$_2$-(*S*,*S*)-chxn)-complexes with L-ala and D-ala,[13] the stereoselectivity of which reaches almost 100% for stereochemical reasons, was nearly constant (the variation in the CD intensity in the 1st-absorption-band region in various

solvents was within a few %) even when the solvent was changed. These facts indicate that: 1) the effect of the solvent on the CD intensity of a pure isomer (so-called solvent effect) is very small in [Co(Schiff base)-(L-aa)] complexes, and thus 2) the CD variation in the equilibrium mixtures of Λ- and Δ-β_2-isomers with the variation in the solvents can be safely ascribed to the change in the isomeric ratio of the complexes. The stereoselectivities of the complexes in various solvents, which were estimated from the CD intensity, are given in Tables 8—10.

It becomes clear from Tables 8—10 that 1) the stereoselectivity in DMF and acetone is generally lower than that in alcoholic solvents, 2) the stereoselectivity of all the L-ala-complexes and of the 5,6-benzo-sal$_2$en complex with L-met increases with a decrease in the pK_a value of alcoholic solvents, whereas 3) the stereoselectivity of the L-val- and L-phe-complexes with sal$_2$en and 5,6-benzo-sal$_2$en increases with the increase in the pK_a value, and 4) the stereoselectivity of the L-met-complex with sal$_2$en and of the L-met-, L-val-, and L-phe-complexes with α-Me-sal$_2$en is almost constant in all the alcoholic solvents.

As may be seen in Figs. 9 and 10 and Tables 8—10, the 1st absorption band and the associated CD band at about 580 nm of all the complexes shift to the lower-energy side in the order of DMF = acetone < *t*-BuOH < *s*-BuOH < *i*-PrOH ≦ *n*-BuOH ≦ *n*-PrOH ≦ EtOH < MeOH ≦ H_2O. On the other hand, the CT and π-π*

bands from 440 to 360 nm and the associated CD bands shift to the higher-energy side in the same order of solvents. These spectral shifts are characteristic of the alcoholic solvents, and are proportional to the decrease in the pK_a values of alcoholic solvents. Therefore, it can be assummed that the alcoholic solvents interact with the complexes by making a hydrogen bond with their OH group. It is known that the coordinated phenolic oxygen atoms of metal-Schiff base complexes act as proton acceptors[14] and as Lewis bases.[15-17] Accordingly it may be mainly at the phenolic oxygen atoms that the hydrogen bonding with alcoholic solvents occurs. When the hydrogen bonding is the stronger, the more the ligand-field strength of the phenolic oxygen atoms can be expected to decrease. It may be as the result of this effect that the 1st absorption band and the associated CD band shift to the lower-energy side, in parallel with the decrease in the pK_a value of the alcoholic solvents, that is, in parallel with the increase in the hydrogen-bonding ability of alcoholic solvents. The higher energy shift of the CT and π-π^* bands and the associated CD bands with the increase in the hydrogen-bonding ability may be due to the stabilization of the π-conjugate system of the Schiff-base ligand by the hydrogen bonding and the alternative instabilization of the π^*-orbital.[18]

The molecular models suggest that: 1) when complexes take the Δ-β_2-structure, the alkyl group of the coordinated L-amino acidates faces one of the phenolic oxygen atoms (O_1 in Fig. 12) of the Schiff-base ligand, whereas 2) when they take the Λ-β_2-structure, the alkyl group somewhat faces one of the Schiff-base chelate rings (B in Fig. 12), which inclines about 30° from the O–Co–N plane.[10,19] However, in either case, the alkyl group does not approach them so closely that any quite strong intramolecular steric interaction seems to exist in either isomer. This corresponds to the finding that the stereoselectivity in DMF and acetone, in which the solvation by the hydrogen bonding is not expected, is generally very small, as has been observed above. In the case of 5,6-benzo-sal$_2$en complexes with L-val and L-ile, as is shown in Fig. 13, the alkyl group has a bulky secondary β-carbon atom, so that the alkyl group approaches the 5,6-benzo-group of the chelate ring B when the complexes take the Λ-β_2-structure. Therefore, the L-val and L-ile-complexes with 5,6-benzo-sal$_2$en favor the Δ-β_2-isomer more than the Λ-β_2-isomer in DMF and acetone.

On the other hand, in alcoholic solvents, solvation at the phenolic oxygen atoms by the hydrogen bonding should be considered. As has been mentioned above, one of the phenolic oxygen atoms (O_1 in Fig. 12) of the Δ-β_2-isomer faces the alkyl group of the coordinated L-amino acidates, but the phenolic oxygen atom of the Λ-β_2-isomer does not. This corresponds to the fact that the alkyl group of L-amino acidates in the Δ-β_2-isomers sterically hinders the alcoholic solvents from approaching to one of the phenolic oxygen atoms, but there is no such steric hindrance in the Λ-β_2-isomer. Therefore, in alcoholic solvents, the Λ-β_2-isomer is more stabilized by the hydrogen bonding than the Δ-β_2-isomer is. A plausible presentation of the difference in hydrogen-bond formation is shown in Fig. 14. Since the steric bulkiness of alkyl groups of L-aa increases generally in the order of L-ala<L-met<L-val<L-phe, it is assummed that the steric hindrance of the alkyl groups for the solvation of alcoholic solvents increases in the order of L-ala<L-met<L-val<L-phe. In fact, the stereoselectivity in alcoholic solvents does indeed increase in this order.

From the above results and discussion, the free energy difference for the isomerization equilibrium between Δ- and Λ-β_2-isomers can be written as follows:

$$\Delta G = -RT\ln([\Lambda]/[\Delta]) = \Delta G^{I} + \Delta G^{S}, \qquad (2)$$

where $[\Lambda]$ and $[\Delta]$ represent the concentrations of Λ- and Δ-β_2-isomers respectively under the equilibrium conditions, ΔG^{I} denotes the free energy difference between the two isomers for the intramolecular steric interaction, and ΔG^{S} means the free energy difference for the hydrogen bonding with alcoholic solvents. In DMF and acetone, the ΔG value comes mainly from

ΔG^I. On the other hand, in alcoholic solvents, the ΔG value comes from both ΔG^I and ΔG^S. However, the degree of stereoselectivity of all the complexes in DMF and acetone is generally much lower than that in alcoholic solvents. Therefore, in alcoholic solvents, the contribution of ΔG^I is assummed to be much smaller than that of ΔG^S.

When the entropy term is neglected and the hydrogen bonding is assummed to be electrostatic,[21] ΔG^S can be written as follows:

$$\Delta G^S = (q_1 q_2 N_\Lambda)/\varepsilon r_\Lambda - ((q_1 q_2 N_\Delta)/\varepsilon r_\Delta, \quad (3)$$

where q_1 and q_2 represent the charge of the phenolic oxygen atom (q_1) and that of the OH-proton of alcoholic solvents (q_2) respectively, ε denotes the dielectric

constant of alcoholic solvents, and N_Λ and N_Δ represent the number of hydrogen-bonded solvent molecules at the phenolic oxygen atoms of Λ- and Λ-β_2-isomers at the mean distances of r_Λ and r_Δ respectively. Here, in order to simplify the explanation, we will use the following assumptions: 1) the hydrogen-bonding distance, r, is the same in both Λ- and Λ-β_2-isomers, and only the number of the hydrogen-bonding solvent molecules differs between the Λ- and Λ-β_2-isomers; 2) the distance, r, is the same for all the L-amino acidato complexes, and 3) the distance is the same for all the alcoholic solvents, and only the number of the hydrogen-bonding

solvent molecules differs among the alcoholic solvents. On the basis of the above assumptions, Eq. 3 is written as follows:

$$\Delta G^{s} = q_1 q_2 (N_\Lambda - N_\Delta)/\varepsilon r. \quad (4)$$

In this paper, as the measure of q_2, we used the pK_a values of the alcoholic solvents. Figures 15—18 show the plots of the ΔG value, calculated from the isomeric ratios in Tables 8—10, *vs.* the pK_a/ε value.

The pK_a/ε value increases in the order of $H_2O <$ MeOH $<$ *n*-PrOH $<$ *n*-BuOH $<$ *i*-PrOH $<$ *s*-BuOH $<$ *t*-BuOH; this order corresponds to the decreasing order of the hydrogen-bonding ability of the solvents. Hence, if the term of q_2 in Eq. 4 is related predominantly to the stereoselectivity of complexes, the ΔG value in alcoholic solvents decreases in parallel with the increasing order of the pK_a/ε value. It may be that, in this case, the ΔG values of all the L-ala-complexes and the L-met-complex with 5,6-benzo-sal_2en decrease in parallel with the increasing order of the pK_a/ε value of alcoholic solvents. Since a water molecule is very small and has quite a strong hydrogen-bonding ability, when the alkyl group of L-aa is not so bulky as those of L-ala and L-met, the value of $(N_\Lambda - N_\Delta)$ in Eq. 4 is expected to be small in water; indeed, the estimated ΔG values of the L-ala- and L-met-complexes are small in water. As may be seen in Fig. 15, the degree of variation in the ΔG value *vs.* the pK_a/ε value of alcoholic solvents becomes greater in the order of 5,6-benzo-sal_2en $<$ sal_2en $<$ α-Me-sal_2en; this suggests that the q_1 value of Schiff-base ligands increases in this same order. This order corresponds to the electron-donating ability of the substituent on the Schiff-base skeleton.

On the other hand, it can also be expected from Eq. 4 that, when the steric bulkiness of solvent molecule is higher, it becomes difficult to make the effective hydrogen bonding at the phenolic oxygen atoms of the Schiff-base ligand. This corresponds to the fact that the higher is the steric bulkiness of the solvent molecule, the larger is the value of $(N_\Lambda - N_\Delta)$. It may be that, in this case, the ΔG values of the sal_2en and 5,6-benzo-sal_2en complexes with L-val and L-phe increase with the increase in pK_a/ε, as may be seen in Figs. 17 and 18. This is because the increasing order of the steric bulkiness of alcoholic solvents is $H_2O <$ MeOH $<$ EtOH $<$ *n*-PrOH $<$ *n*-BuOH $<$ *i*-PrOH $<$ *s*-BuOH $<$ *t*-BuOH, and this order is parallel with the increasing order of their pK_a/ε values.

As has been observed above, the hydrogen-bonding ability and the steric bulkiness of alcoholic solvents affect the stereoselectivity of the complexes as if they were the reverse of each other. Therefore, if both effects are cancelled out, the ΔG value can be expected to be almost constant. It may be that, in this case, the α-Me-sal_2en complexes with L-met, L-val, and L-phe, sal_2en complex with L-met, and 5,6-benzo-sal_2en complex with L-phe, show a nearly constant ΔG value in various alcoholic solvents.

From these results and discussion, the following conclusion can be drawn: 1) the difference in steric hindrance between Λ- and Λ-β_2-isomers for the hydrogen-bond formation with alcoholic solvents plays an important role in the stereoselectivity of [Co(Schiff base)(L-aa)] complexes. 2) The higher the steric bulkiness of the alkyl group of coordinated L-aa, the higher the steric hindrance for the hydrogen-bond formation. 3) When the hydrogen-bonding ability of alcoholic solvents is higher, the stereoselectivity of the complexes becomes higher. 4) When the steric bulkiness of the alcoholic solvents is higher, the stereoselectivity of the complexes becomes higher. 5) However, the effects of 3) and 4) are reversed in the case of usual alcoholic solvents.

The authors wish to express their deep thanks to Professor J. Hidaka and Dr. K. Okamoto of Tsukuba University and to Professor K. Sone and Dr. Y. Fukuda of Ochanomizu University for their kind assistance with the CD spectral measurements. Sorption Behavior of Aromatic Compounds in Water on β-Cyclodextrin Polyurethane Resins

Yoshihiro KAWAGUCHI, Yoshikazu MIZOBUCHI, Minoru TANAKA, and Toshiyuki SHONO*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received December 12, 1981)

The sorption behavior of aromatic compounds in water on β-cyclodextrin polyurethane resins was evaluated by batch and column procedures. The values of their sorption capacities obtained in the batch experiments were comparable to those of Amberlite XAD-2 and/or -7. In the column experiments, β-H6XDI-P-6.0-M showed a quantitative collection of the aromatic compounds at low concentrations, while Amberlite XAD-7 did not.

Since various organic pollutants exist at relatively low concentrations in water, pre-concentration is generally required before their qualitative and quantitative analyses. For this purpose, commercially available porous polymer sorbents (*i.e.*, Amberlite XAD,[1,2] Tenax GC,[2] Separon,[3] and Hitachi gel[4]) have been widely used. In water, the degree of interaction between solutes and these polymers generally increases with increasing hydrophobicity of the solutes because these polymers are hydrophobic. Therefore, it is difficult for these polymers to sorb specific organic solutes selectively. We have been interested in developing sorbents that can collect the solutes in water selectively.

It is well known that cyclodextrins form stable inclusion complexes with specific organic compounds. The polyurethane resins containing cyclodextrin units as specific sorption sites were prepared by cross-linking β-cyclodextrin with diisocyanates.[5] In gas-solid chromatography these cyclodextrin resins exhibited strong interactions with organic compounds containing π-electrons or heteroatoms. It was found that these cyclodextrin resins interact strongly with benzene vapor in a nitrogen or an air stream and that one of these, β-H6XDI-P-6.0-M, retains the polar volatile organic compounds (*i.e.*, methyl and ethyl alcohols, acetone, and ethyl methyl ketone) more than Amberlite XAD-7 does in the gas stripping experiments.[6]

In the present paper we describe the application of β-cyclodextrin polyurethane resins to sorbents which concentrate aromatic compounds in artificial water samples. The sorption capacities of these resins are compared with that of Amberlite XAD-2 and/or -7 in order to evaluate the possibility of using these cyclodextrin resins as sorbents to collect aromatic compounds dissolved in water.

Experimental

Materials. β-Cyclodextrin polyurethane resins were prepared by cross-linking β-cyclodextrin with diisocyanate (hexamethylene diisocyanate (HDI), 1,3-bis(isocyanatomethyl)benzene (XDI), or 1,3-bis(isocyanatomethyl)cyclohexane (H6XDI)).

Amberlite XAD-2 and -7 resins were obtained from Rohm and Hass (Philadelphia, PA, U. S. A.).

These resins were granulated to particle sizes of 80—100 mesh (for batch method) and 100—200 mesh (for column method), purified by Soxhlet extraction with ethyl alcohol, dried *in vacuo* for 8 h at 80 °C, and then used as sorbents.

The reagents for uptake studies were obtained from Wako (Osaka, Japan) or from Aldrich (U. S. A.) and used without further purification.

Procedure. Sorption capacities of β-cyclodextrin polyurethane resins and Amberlite XAD-2 and -7 were determined by the following batch (static) method. A resin (0.1 g) and 100 ml aqueous solution containing one of the model organic compounds at various concentrations (0.08—1 mM; 1 mM= 10^{-3} mol dm^{-3}) in a 300 ml conical flask with a glass stopper was shaken in a thermostated water bath (25±0.1 °C) for 4 h. The resin was then removed by filtration. The concentration of solute in the filtrate was determined spectrophotometrically (Hitachi Model 340 Recording Spectrophotometer) and from this value the sorption capacity (mmol/g resin) and percent uptake were calculated.

The column (dynamic) experiments were carried out by using a 10 cm×0.52 cm I. D. glass column packed by a slurry packing technique with a sorbent bed volume of 2.1 cm^3. The sample solutions (1 mM) were allowed to pass through the column at a flow-rate of 55.3 ml/h using an Adzuma Model MF-1 microfeeder equipped with a 200 ml cylinder. The absorbance of the effluent was monitored at 254 nm (Atto Model SJ-1541 UV Monitor).

Results and Discussion

Sorption Capacities in Batch System. The sorption capacities of the resins for the disubstituted benzenes (0.2 mM) in the bath system are shown in Table 1. The β-cyclodextrin polyurethane resins (β-H6XDI-P-6.0-M, β-HDI-P-5.5-A, and β-XDI-P-5.8-A; see Ref. 5) have much larger capacities than that of the BDOL-HDI-P-M polyurethane resin. Since it was prepared from 1,4-butanediol and HDI, BDOL-HDI-P-M contains no β-cyclodextrin units. This suggests that the inclusion process by β-cyclodextrin units acts efficiently on the sorption of the solutes on the cyclodextrin resins. The sorption capacities of the cyclodextrin resins decrease in the order β-H6XDI-P-6.0-M>β-XDI-P-5.8-A>β-HDI-P-5.5-A, which indicates that the interaction between the resins and the solutes depends upon the cross-linking diisocyanate, in a way similar to the interaction with the organic vapors.[5] Roughly speaking, the β-cyclodextrin resins take up the solutes as well as the commercially available sorbents, Amberlite XAD-2 and -7, do, except for three dinitrobenzene isomers. It is assumed that dinitrobenzene, much more hydrophobic than the other solutes, is taken up more by the latter resins because their hydrophobicity is stronger than that of the β-cyclodextrin resins.

For each given disubstituted benzene solute, the amount of *o*-, *m*-, or *p*-isomer taken up by each β-cyclodextrin resin decreases in one of three orders: *p*>*m*>*o*

5-Phenylvaleric acid	16.6	12.3	10.7	3.5	13.5	15.6

a) Concentration of solute: 0.2 mM.

for toluidine, cresol, and ethylphenol; $p>o>m$ for nitroaniline and aminobenzoic acid; $o>p>m$ for dinitrobenzene. It is of great interest that just the same order is observed in the retention of each isomer on the chemically bonded β-cyclodextrin phase.[7] Except for dinitrobenzene, the *p*-isomers give the largest sorption capacities. This may be reasonably interpreted because the *p*-isomers can enter deep into the cyclodextrin cavity and can participate in the strongest hydrophobic interaction with the cavity. The irregularity of the order for dinitrobenzene is still unexplainable.

Table 2 shows sorption capacities for phenol, aromatic alcohols, and carboxylic acids. Concerning these substances, the β-cyclodextrin resins also have sorption capacities comparable to those of Amberlite XAD-2 or -7. In this case, β-H6XDI-P-6.0-M also exhibits the largest values among these cyclodextrin resins. Therefore, β-H6XDI-P-6.0-M was further investigated.

Effect of Solute Concentration on Sorption Capacities. Percent uptakes (u %) are determined by the equation:

$$u = \left(1 - \frac{\text{concentration of solute in water (filtrate) after sorption}}{\text{initial concentration of solute in water}}\right) \times 100.$$

Figure 1 shows the percent uptakes for phenol, benzyl alcohol, and 3-phenyl-1-propanol in the concentration range of 0.08—1 mM. Phenol is taken up more by Amberlite XAD-7 than by β-H6XDI-P-6.0-M, though slightly, while the reverse is observed for benzyl alcohol and 3-phenyl-1-propanol. The results of similar measurements for three aromatic carboxylic acids are shown in Fig. 2. Compared with Amberlite XAD-7, β-H6XDI-P-6.0-M exhibits the stronger ability to collect these compounds, particularly in the low concentration regions. This phenomenon is presumably attributable to the formation of inclusion complex where the solutes

△▲: 3-Phenyl-1-propanol, ○●: phenol, ◇◆: benzyl alcohol.

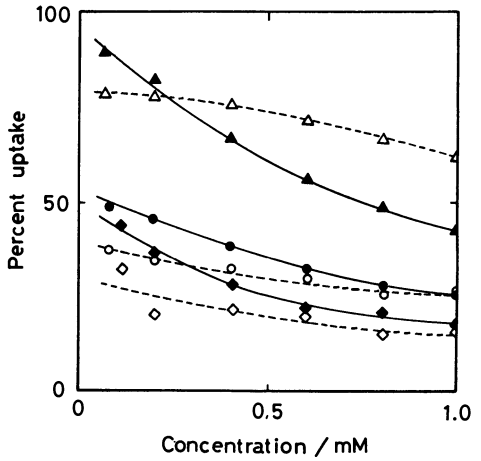

Fig. 2. Uptake of aromatic carboxylic acids in water by β-H6XDI-P-6.0-M (——) and Amberlite XAD-7 (------).
△▲: 5-Phenylvaleric acid, ○●: benzoic acid, ◇◆: phenylacetic acid.

are strongly retained in the β-cyclodextrin cavities. Accordingly, it is expected that the β-H6XDI-P-6.0-M resin will be used as sorbent to collect those compounds in water at trace concentrations.

Sorption Capacities in Column System. In order to achieve practical applications, the breakthrough experiments using the column method were performed, and the breakthrough capacities of the β-cyclodextrin polyurethane resins and Amberlite XAD-7 were compared.

Figure 3 shows the breakthrough curves for phenol (1 mM) on these resins packed separately into 10 cm × 0.52 cm I.D. columns. Ideally, a breakthrough curve should be steep and a solute concentration in an effluent should rise rapidly from zero to that in the influent.[8] The breakthrough curves on the β-cyclodextrin resins are not so steep as the ideal one on Amberlite XAD-7; this is presumably due to slower sorption rates of the solute into the β-cyclodextrin cavities. The breakthrough

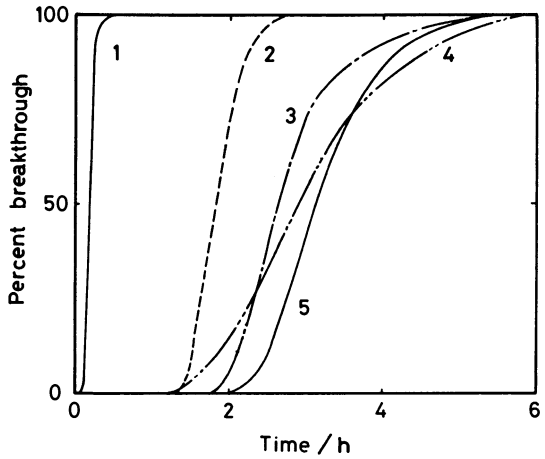

Fig. 3. Breakthrough curves for 1 mM phenol.
1: BDOL-HDI-P-M, 2: Amberlite XAD-7, 3: β-XDI-P-5.8-A, 4: β-HDI-P-5.5-A, 5: β-H6XDI-P-6.0-M.

times for phenol, the points where the tangents of the breakthrough curves intersect the time abscissa, are decreasing in the order β-H6XDI-P-6.0-M>β-XDI-P-5.8-A>β-HDI-P-5.5-A>Amberlite XAD-7>BDOL-HDI-P-M. BDOL-HDI-P-M has only a small breakthrough time. On the other hand, the breakthrough times on the β-cyclodextrin resins are larger than that on Amberlite XAD-7. The β-H6XDI-P-6.0-M resin, which shows the largest breakthrough time of all the three β-cyclodextrin polyurethane resins, was compared in more detail with Amberlite XAD-7.

Table 3. Breakthrough capacities for several aromatic compounds

Solute	Breakthrough capacity/10^{-2} mmol per g resin		
	β-H6XDI-P-6.0-M	BDOL-HDI-P-M	Amberlite XAD-7
p-Nitroaniline	20.0	5.0	44.5
Phenol	13.2	1.7	19.2
p-Cresol	16.2	2.2	41.6
Benzoic acid	10.7	3.6	31.7
Phenylacetic acid	6.6	1.6	23.6

Table 3 shows that the breakthrough capacities (expressed in mmol/g resin) on Amberlite XAD-7 for the aromatic compounds are larger than those on β-H6XDI-P-6.0-M. The weight of β-H6XDI-P-6.0-M and Amberlite XAD-7 per unit bed volume are 0.453 and 0.203 g/ml, respectively; thus there is not much difference in the breakthrough capacities per unit bed volume between β-H6XDI-P-6.0-M and Amberlite XAD-7. In practice, it is of great importance to investigate the sorption behavior of the resins for solutes at lower concentrations than 1 mM.

Each aqueous solution of the four solutes (model concentrations of 0.1, 0.05 or 0.01 mM) was passed at a flow-rate of 55.3 ml/h for 3 h through the column used for the breakthrough studies. The effluent from the column was collected in a graduated cylinder. The concentration of the solute in it was determined spectro-

photometrically, and then the percent uptake by β-H6XDI-P-6.0-M or Amberlite XAD-7 was evaluated (Table 4). In the case of Amberlite XAD-7, the percent uptake for benzoic acid decreases with the concentration of the solute. The β-cyclodextrin polyurethane resin, however, shows a perfectly quantitative collection at these low concentrations. The same statement is true for the percent uptake for phenylacetic acid. *p*-Nitroaniline or phenol is perfectly collected on both β-H6XDI-P-6.0-M and Amberlite XAD-7, as shown in Table 4.

TABLE 4. PERCENT UPTAKE BY COLUMN METHOD

Solute	Concentration/mM	Percent uptake	
		β-H6XDI-P-6.0-M	Amberlite XAD-7
p-Nitroaniline	0.10	100	100
	0.05	100	100
	0.01	100	100
Phenol	0.10	100	100
	0.05	100	100
	0.01	100	100
Benzoic acid	0.10	100	93
	0.05	100	89
	0.01	100	63
Phenylacetic acid	0.10	100	89
	0.05	100	77
	0.01	100	67

In this way, it is found that β-H6XDI-P-6.0-M can quantitatively collect the aromatic solutes at low concentrations and is superior to widely used Amberlite XAD-7. In addition, the β-cyclodextrin resins used in this study can be easily regenerated by Soxhlet extraction with ethyl alcohol and the collecting abilities of the resins after several regenerations remain unchanged. These results suggest that the β-cyclodextrin polyurethane resins will be used satisfactorily as sorbents to collect aromatic compounds at low concentrations in water.

Stepwise Reduction of Samarium and Ytterbium in the Polarographic Reduction Process in the Presence of 1,4,7,10,13,16-Hexaoxacyclooctadecane[1)]

Hajimu YAMANA,† Toshiaki MITSUGASHIRA,* Yoshinobu SHIOKAWA, and Shin SUZUKI
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-1-1, Sendai 980
(Received December 25, 1981)

Polarographic reduction of La, Pr, Nd, Sm, Gd, Dy, Er, and Yb was investigated in the aqueous solutions containing 1,4,7,10,13,16-hexaoxacyclooctadecane (18-CROWN-6). It is shown that Sm(III) and Yb(III) are reduced stepwisely *via* the divalent state in the presence of 18-CROWN-6. The divalent state is stabilized by the complex formation with 18-CROWN-6.

From the view point of f-series element chemistry, it is of great interest to investigate abnormal oxidation states. We are interested in low oxidation states found in aqueous solutions. For lanthanoids, Eu(II) and Yb(II) are farely stable in aqueous solutions. The findings of Sm(II) and Tm(II) were also reported[2,3)] but they are so unstable that they are rapidly oxidized in aqueous solutions. Because of this instability, the findings of Sm(II) and Tm(II) in aqueous solutions are not recognized widely.

Among many experimental techniques, polarographic reduction seems to be most promising for the investigation of low oxidation states of f-series elements in aqueous solutions. It affords useful information about the reduction process and we can inspect whether they are reduced directly to the metallic state or stepwisely *via* an intermediate lower oxidation state. In addition, it can be applied to the investigation of actinoids in tracer concentrations by the use of the radiopolarographic method.[4,5)]

1,4,7,10,13,16-Hexaoxacyclooctadecane(18-CROWN-6) has size selectivity for cations on complex formation.[6,7)] Taking into consideration the facts that the radii of some dipositive cations of lanthanoids(Ln^{2+}) and actinoids(An^{2+}) are very close to the radius of the ring of 18-CROWN-6, we expected that 18-CROWN-6 stabilizes Ln^{2+} and An^{2+} in aqueous solutions by complex formation.

In this report, we describe the stabilization of Sm(II) and Yb(II) by 18-CROWN-6 observed in stepwise reduction waves on a polarogram.

Experimental

Apparatus. Yanagimoto PA-102 was used as a direct current polarograph. An ordinary polarographic cell was used and connected to the standard calomel electrode(SCE) through an agar gel bridge.

Reagents. 18-CROWN-6 produced by Nippon Soda Co., LTD was used without purification. After drying in a vacuum desiccator, 18-CROWN-6 was dissolved into pure water. A 1 M (1 M=1 mol/dm^3) 18-CROWN-6 solution was used as a stock solution. Lanthanoid oxides of 99.99% purity were obtained from the Rare Earth Elements Purification Facility of our institute and converted to trichlorides before use.

Procedures. *Preparation of Sample Solutions*: Tetramethylammonium chloride(TMACl) was used as a supporting electrolyte in the concentration of 0.1 M. Because of the inertness of TMACl toward reduction, the reduction of Ln(II) can be investigated without disturbance by the discharge of the supporting electrolyte. The concentration of lanthanoids in the sample solutions was 4 mM. Sample solutions containing 18-CROWN-6 were prepared by the addition of the stock solution. Sample solutions of Ba(II) and Pb(II), which make stable complexes with 18-CROWN-6, were also prepared and the reduction behaviors were examined.

Determination of Half Wave Potentials. Direct current polarograms were obtained according to the ordinary method. Argon gas was bubbled into the sample solution for 10—15 min. in order to eliminate dissolved oxygen. The half wave potentials were determined after subtracting the back ground current induced by hydrogen discharge, which was observed at more positive potentials than the potentials for the reduction of Ln(II).

Results and Discussion

Reduction of Sm(III). Several authors have reported the stepwise reduction of Sm(III) *via* a divalent state in weakly acidic solutions. Timnic reported the stepwise reduction under experimental conditions very similar to ours using tetramethylammonium iodide for the supporting electrolyte.[8)] However, the ratio of the

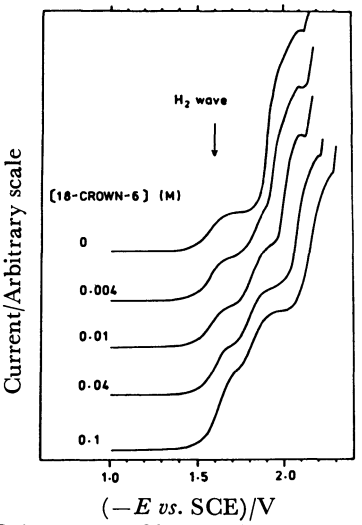

Fig. 1. Polarograms of Sm as a function of the concentration of 18-CROWN-6.

† Present address: Tokai Laboratory of Power Reactor and Nuclear Fuel Developement Corporation, Tokai, Naka-gun, Ibaraki 319-11.

diffusion current of the first wave to that of the second wave estimated from his data was not consistent with his conclusion. The ratio should be 1 : 2 for the reduction *via* the divalent state, while his data for the ratio varied with the concentration of Sm.

Polarograms of Sm are shown in Fig. 1. The small wave at about −1.55 V (*vs.* SCE) is the hydrogen discharge wave. The polarogram exhibits a deformed single wave at −1.8 V (*vs.* SCE) in the absence of 18-CROWN-6. We did not observe stepwise reduction with respect to the sample solutions without 18-CROWN-6. In contrast with this finding, the polarograms of Sm(III) in the presence of 18-CROWN-6 showed two well-defined reduction waves, as shown in Fig. 1. This fact was clearly observed as the splitting of a deformed single wave. The splitting was enhanced by the shift of the first wave to more positive potentials and the second wave to more negative potentials with the increase in the concentration of 18-CROWN-6. The ratio of the diffusion current of the two waves remained at 1 : 2. Therefore, it is quite reasonable to conclude that the first wave is due to a one-electron reduction of Sm(III) and the second wave is due to a two-electron reduction of Sm(II). And the direction of the shift of the second wave, along with the increase in the concentration of 18-CROWN-6, shows qualitatively the stabilization of Sm(II) by 18-CROWN-6.

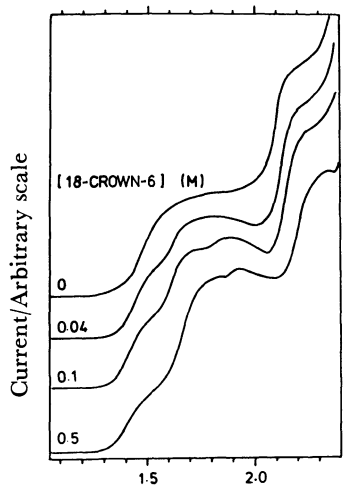

Fig. 2. Polarograms of Yb as a function of the concentration of 18-CROWN-6.

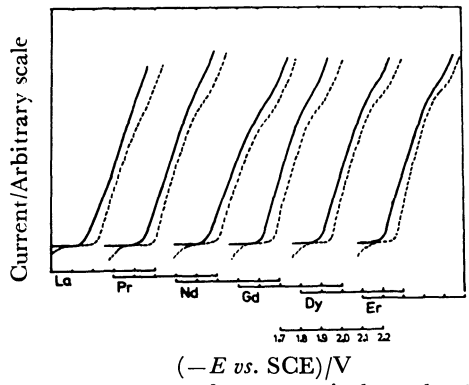

Fig. 3. Polarograms of some trivalent lanthanoids. Polarograms for the samples free from 18-CROWN-6 are shown by solid lines and for the samples of 0.48 M 18-CROWN-6 solutions by dotted lines.

Reduction of Yb(III). Polarograms of Yb are shown in Fig. 2. Yb(II) is more stable than Sm(II) in aqueous solutions. Two reduction waves were observed with respect to the solutions without 18-CROWN-6. The first wave, at about −1.4 V (*vs.* SCE), overlaps with the hydrogen discharge wave when the sample solution does not contain 18-CROWN-6. This wave shifts to more positive potentials with the increase in the concentration of 18-CROWN-6. The second wave, at about −2.1 V (*vs.* SCE), is attributable to the reduction of Yb(II) to Yb(0). The ratio of the diffusion currents of these two waves in the presence of 18-CROWN-6 is 1 : 2. Therefore, the first wave can be assigned to the reduction of Yb(III) to Yb(II). The other wave observed between the hydrogen discharge wave and the second wave seems to be a catalytic wave of hydrogen induced by the presence of 18-CROWN-6 in the sample solution.

Reduction of La(III), Nd(III), Pr(III), Gd(III), Dy(III), and Er(III). Divalent state of La, Nd, Pr, Gd, Dy, and Er are not yet known in aqueous solutions. For comparison to Sm and Yb, the reduction of these six elements were examined under the same condition. The polarograms are shown in Fig. 3. Only a single wave, due to the reduction of trivalent cation to the metallic state, was observed for every element. The presence of 18-CROWN-6 has little influence to the reduction wave. The results indicate that these six elements are reduced directly even in the presence of 18-CROWN-6. A small shift was observed but the magnitude of the shift did not exceed about 20 mV even in the sample solutions of 0.48 M 18-CROWN-6, the highest concentration used in this experiment.

The Influence of 18-CROWN-6 to the Reduction of Ba(II) and Pb(II). The influence of 18-CROWN-6 to the polarograms of Ba(II) and Pb(II) was examined in 0.1 M TMACl, pH 3.0 solutions. A well defined single reduction wave was observed. It was found that the addition of 18-CROWN-6 had no influence on the shape of the reduction wave. But the addition of 18-CROWN-6 induced a very large shift of the reduction wave to more negative potentials, which suggested a strong interaction between Ba(II) or Pb(II) and 18-CROWN-6.

The Relation between the Shift of the Reduction Wave and the Concentration of 18-CROWN-6. The stepwise reduction of the complex is represented by the following reactions.

1st reduction:

$$MX_p^{m+} + rX + (m-n)e^- \longrightarrow MX_q^{n+} + (p+r-p)X \quad (1)$$

2nd reduction (reduction to metallic state in Hg phase):

$$MX_q^n + ne^- \longrightarrow M(Hg) + qX \quad (2)$$

In these expression, X represents a ligand, p and q are the coordination numbers, and $(m-n)$ and n are the numbers of the electrons involved in the reduction. When complex formation proceeds reversibly and the electron transfer is rapid, the magnitude of the shift

induced by the addition of X is expressed as follows for the second reduction.[9]

$$-\Delta E_{1/2} = (E_{1/2})_c - (E_{1/2})_s = \frac{RT}{nF} \cdot q \cdot \ln[X] + \frac{RT}{nF} \cdot \ln \beta_{MX_q} \quad (3)$$

In this equation, $(E_{1/2})_c$ and $(E_{1/2})_s$ represent the half wave potentials of complex and hydrated cation, respectively. β represents the formation constant of the complex. The value of RT/F is 0.059 V under the present experimental condition. The shifts for Ba(II) and Pb(II) are also represented by Eq. 3.

The relation between the shift of the reduction waves and the logarithm of the concentration of 18-CROWN-6 is shown in Fig. 4 for the second waves of Sm and Yb. In the figure, the shifts of the waves of Pb and Ba are also shown. As shown in Fig. 4, an almost linear dependency between $-\Delta E_{1/2}$ and the logarithm of the concentration of 18-CROWN-6 was observed and the slope showed that n was equal to q. Undoubtedly n is equal to 2. Therefore, the coordination number was determined to be 2. Thus, the complex is probably of the sandwich type. From the intercepts, we estimated the values of log $\beta_{MX_2^{2+}}$ to be 3.8—4.3, 5.9—6.2, 6.3—6.9, and 4.1—4.9 for Yb(II), Pb(II), Sm(II), and Ba(II), respectively.

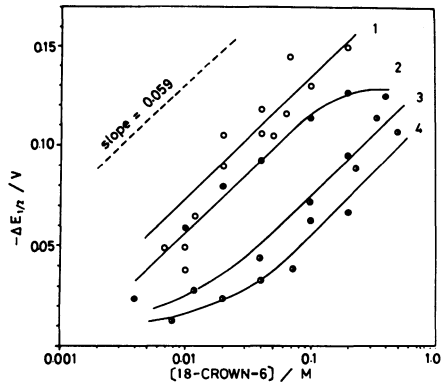

Fig. 4. $\Delta E_{1/2}$ *vs.* log [18-CROWN-6].
1: Sm(II), 2: Pb(II), 3: Ba(II), 4: Yb(II).

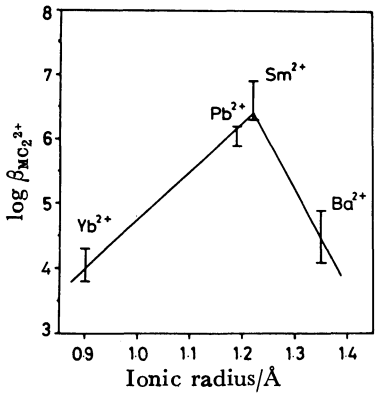

Fig. 5. Plot of log $\beta_{MX_2^{2+}}$ *vs.* cation crystal radius.

Considering that the formation constants of 18-CROWN-6 complexes exhibit a simple relation with the size of the central cations, we examined the dependence of log $\beta_{MX_2^{2+}}$ on the ionic radii of the four divalent cations We cited the ionic radii reported by Shanon.[10] The relation is shown in Fig. 5. A maximum of the stability is clearly observed at 1.2 Å. A similar tendency was reported by Izatt for 1 : 1 complexes of divalent cations.[6,7]

Consequently, we can say that Sm(III) and Yb(III) form stable complexes with 18-CROWN-6 and that Sm(III) is reduced stepwisely *via* divalent states in the presence of 18-CROWN-6.

A part of the expense for this work has been defrayed by Grant-in-Aid for Scientific Research No. 505002 from the Ministry of Education, Science and Culture.

Characterization of Nitrogen-containing Active Carbon Catalysts for SO_2 Removal

Akio Nishijima,* Hiroyuki Hagiwara,† Minoru Kurita, Akifumi Ueno,††

National Chemical Laboratory for Industry 1-1, Higashi, Yatabe, Ibaraki 305
(Received December 10, 1981)

Physical and chemical properties of nitrogen-containing active carbons (ACs), having a much higher activity and capacity for SO_2 adsorption than commercial ACs, were investigated to define suitable properties for SO_2 removal. The capacity of nitrogen-containing ACs for SO_2 adsorption correlates with the amount of their surface basic groups. However, the amount of basic surface groups for the ACs is practically the same as that for commercial ACs, indicating that the ACs have another characteristic property effective for SO_2 removal. A study on the chemical state of surface nitrogen atoms by means of an X-ray photoelectron spectrometer has revealed that surface nitrogen species are effective for SO_2 adsorption.

Recently active carbons (ACs) have been used for simultaneous removal of sulfur oxides (SO_x) and nitrogen oxides (NO_x) from flue gas discharged from stationary combustion equipments.[1-3] In this process SO_x is adsorbed on AC and removed as ammonium sulfate through reaction with NH_3 added in the flue gas,[3] NO_x being reduced to N_2 and H_2O by NH_3. However, those ACs developed so far are available only at low space velocities below 1000 h^{-1}, because of their low catalytic activity for SO_2 adsorption at temperatures effective for NO_x removal. Some of the present authors[3] found a new type of AC effective for SO_2 removal and developed a novel catalyst for the simultaneous removal of SO_x and NO_x by allowing AC to support metal salts effective for NO reduction with NH_3. The ACs developed were prepared from nitrogen-containing compounds such as polyacrylonitrile so as to contain some amounts of nitrogen atoms. It was also found, however, that the capacity of ACs for SO_2 removal is dependent highly on their activating conditions.

A number of mechanisms have been proposed for the catalytic oxidation of SO_2 on AC.[4-8] Daytyan[4] has indicated that the oxygen reversibly adsorbed on AC will oxidize SO_2 to SO_3. Siedlewski[5] has shown that free radicals on AC act as active centers in the chemisorption of SO_2. Kitagawa *et al.*[6] have found that the capacity for SO_2 removal does not depend on the surface area of AC but on the amount of oxygen atoms in AC. The work by Yamamoto *et al.*[7,8] has also shown that the capacity is dependent on preparation conditions and raw materials for AC rather than on the surface area of AC. Then, it was estimated by Kamino *et al.*[9,10] that basic surface group functions are activation points of oxidative chemisorption for SO_2 adsorption. Sano and Ogawa[11] have shown that for AC catalysts with higher activity for SO_2 removal, certain impurities on AC, such as surface nitrogen species, seem to have a good effect on catalytic activity.

The ACs studied in this work are designed to contain a few percent nitrogen atoms. Accordingly, nitrogen species in AC seem to play an important role in the process of SO_2 removal. Activating processes have been known to have an effect on physical and chemical properties of AC.[12,13] It is considered that various properties, especially the chemical state of nitrogen species in AC, are also affected by activating processes. In this work, physical and chemical properties of ACs prepared from polyacrylonitrile were investigated to characterize appropriate surface properties of AC for SO_2 removal.

Experimental

Catalysts. Polyacrylonitrile (100 g) was placed in a reactor made of quartz (length: 500 mm; diam.: 60 mm). The reactor was capable of rotating at desired speeds. Carbonization treatments were performed at 250 °C in an N_2 flow (1 l/h). Activation treatments were performed in the temperature range 400—1000 °C in the presence of water vapor. In the activating process, water (80 ml/h) was vaporized with a conventional vaporizer and supplied into the reactor with

nitrogen (600 ml/h). The duration of activation was in the range 10—60 min. Some ACs now in commercial use for SO_2 removal were also used as reference. The AC catalysts studied are summarized in Table 1.

Activity and Capacity Measurement. The following reaction conditions for activity and capacity measurement was previously established as suitable for development of new processes which make higher space velocities available for SO_2 removal. An AC sample (diam.: about 1.2 mm) of 20 ml was placed in a flow reactor made of stainless steel (length: 300 mm; diam.: 20 mm). Activity and capacity measurements were then carried out at 200 °C at a space velocity of 5000 h^{-1}.[3] The gas mixture used consisted of 500 ppm SO_2, 500 ppm NH_3, 5 vol% O_2, 10 vol% H_2O, and N_2 balance. The analysis for SO_2 was made by means of an NDIR type SO_x analyzer.

Measurement of Catalytic Properties. Measurements of surface area and pore size distribution were carried out by the BET method (CARLO ERBA Sorptomatic 1800) and with a porosimeter (AMINCO 60000 PSI). Benzoic and hydrochloric acids were used to measure the amount of basic groups in AC, sodium hydroxide being used to measure that of acidic groups. For measuring the amount of benzoic acid adsorbed, 0.5 g of sample was dried under vacuum at 110 °C and then immersed in 50 ml of ethyl alcohol solution of benzoic acid (10 mol m^{-3}) for 48 h at room temperature. The amount of benzoic acid adsorbed was determined by titration with sodium hydroxide standard solution (10 mol m^{-3}).[9,14] Similar methods were used to measure amounts of hydrochloric acid and sodium hydroxide adsorbed. Surface chemical properties of AC such as chemical composition and chemical state were obtained by using an X-ray photoelectron spectrometer (Dupont 650 B) and Al anode. Measured areas of spectra, or measured heights in some cases, were used for determing surface elemental compositions, as demonstrated in several recent papers.[15-17] A CHN Corder (Yanaco MT-2) was also used to determine the chemical composition of AC.

Results and Discussion

Activity and Capacity of AC. Figure 1 shows the activity and capacity of ACs for SO_2 removal. The ACs prepared from polyacrylonitrile are superior in activity and capacity to the commercial ACs. However, their capacity is dependent highly on activating conditions. In this work the capacity of AC is defined as the shortest reaction time that brings about 100% SO_2 removal in the activity measurement. For the commercial ACs the capacity is defined as the shortest reaction time for 40% SO_2 removal, because of their lower catalytic activity for SO_2 removal.

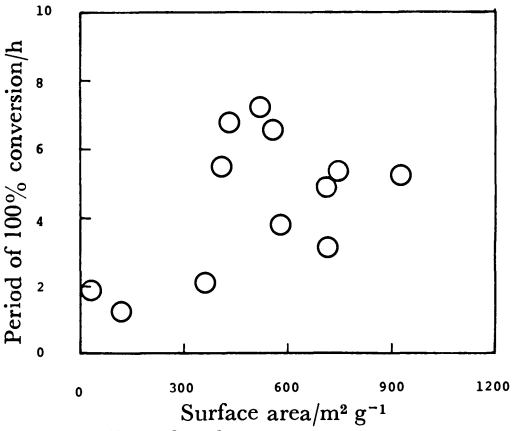

Fig. 3. Effect of surface area on capacity of the AC.

Physical Properties. Figure 2 shows the relationship between the capacity and activating temperature of AC. The activating time used was 30 min. The highest capacity is obtained when the AC is activated at 800 °C. A change in capacity of AC with surface area of AC is shown in Fig. 3. The capacity does not correlate with the surface areas, though the surface area is dependent on activating conditions. Figure 4 shows pore size distributions for the ACs and commercial ACs. Similar pore size distributions are shown between these ACs. No correlation is found between the capacity and pore size distribution. These results seem to indicate that the SO_2 removal capacities of the ACs as well as usual AC catalysts depend on surface chemical propeties rather than on surface physical properties. Thus chemical properties of the ACs were then studied.

Basic and Acidic Surface Group. Figure 5 shows the

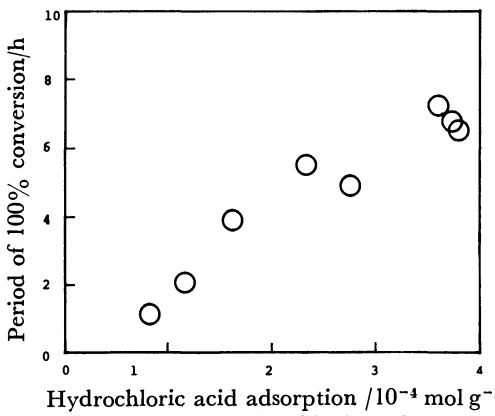

Fig. 6. Effect of hydrochloric acid adsorption on capacity of the AC.

correlation between the capacity and the amount of basic surface groups of the ACs as measured by using benzoic acid. The capacity increases with increase in benzoic acid adsorption, indicating that basic surface groups of AC are effective for the SO_2 adsorption. A similar trend was observed in a case using hydrochloric acid (Fig. 6), though with lowered correlation as compared with that shown in Fig. 5. On the other hand, the amount of acidic surface groups of the ACs decreases with increase in the capacity as shown in Fig. 7, indicating that acidic surface groups are not effective for the capacity. Amounts of benzoic acid adsorbed for the commercial ACs are $1.7—6.5\times10^{-4}$ mol/g-AC and almost the same as those obtained for the ACs which have much higher activities and capacities for SO_2 removal (Fig. 5). These results seem to indicate that the ACs have another characteristic property effective for SO_2 removal, though the presence of basic surface groups is one of important necessities for the high performance catalyst for SO_2 removal. Amounts of sodium hydroxide adsorbed for the commercial ACs are $1—4\times10^{-5}$ mol/g-AC, less than those for the ACs prepared (Fig. 7).

Nitrogen and Oxygen Species. As already mentioned, the ACs studied are designed to contain some amounts of nitrogen species, and hence it is considered that the nitrogen species in the ACs furnishes another property effective for SO_2 removal. A recent work by Kobayashi[18] has indicated that nitrogen species in ACs prepared from polyacrylonitrile exist in the states of C–N and N–N chemical bonds. A previous study[3] using an X-ray photoelectron spectrometer (XPS) has shown existence of two possible surface chemical states C–N and N–N, with the third state, more effective for SO_2 removal, left undefined.

Figure 8 shows change in nitrogen content in the ACs with activating temperature. The nitrogen content decreases with increase in activating temperature. When the same activating temperature is used, the nitrogen content decreases with increasing activating time as shown in Fig. 9. On the other hand, the capacity of the ACs increases up to the maximum with increasing

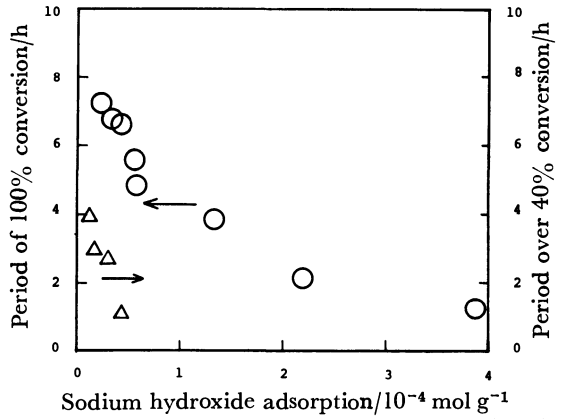

Fig. 7. Effect of hydroxide adsorption on capacity of the AC.

reaction time and then decreases gradually.

Two peaks on N 1s photoelectron spectra were observed for the surface of the ACs, their binding energies being 396.1 and 397.5 eV. The higher binding energy peak (397.5 eV) seems to correspond to the chemical state of C–N bond, from a comparison with XPS spectra of polyacrylonitrile and other compounds which involve the chemical state of C–N bond,[19] whereas the lower binding energy peak seems to correspond to the chemical state of N–N bond.[20] The AC activated at 800 °C for 30 min has the highest capacity for SO_2 removal and gives a lower binding energy peak of maximum intensity (peak area). With the ACs having lower capacity for SO_2 removal, the intensity of lower binding energy peak is lower than that of the ACs with higher capacity. These results seem to indicate that the chemical state of N–N bond is more effective for SO_2 adsorption than that of C–N bond.

Table 1 also shows a comparison of amounts of nitrogen atoms present on the surface and in the bulk as measured by using XPS and CHN Corder, respectively. These results indicate that nitrogen species still exist on outer surface layers of AC particles though the amount of nitrogen atoms on surface layers is much less than that in the bulk. The amount of nitrogen atoms on surface layers decreases with increase in activating temperature. XPS shows that there is no detectable amount of nitrogen atoms on outer surface layers of the AC particles activated at 1000 °C for 30 min.

Oxygen species on surface are also known to affect the activity and capacity of AC for SO_2 removal.[6] No correlation is, however, found between the oxygen content on surface layers as measured by XPS and the capacity for SO_2 removal. Amounts of oxygen atoms on surface layers increase with increasing surface area. No chemical state of oxygen in surface functional groups is clear because of smaller chemical shifts in O 1s photoelectron spectra. Broader peaks of O 1s spectra on the ACs seem to support existence of more than two kinds of oxygen functional groups (acidic and basic) on the surface of the ACs.

The Oxidation Behavior of Various Organic Compounds on the Determination of Chemical-oxygen Demand by Means of Flow-injection Analysis with Acidic Permanganate

Takashi KORENAGA,* Hisayoshi IKATSU, and Tosio MORIWAKE
School of Engineering, Okayama University, Tsushima-naka, Okayama 700
(Received December 21, 1981)

Forty-five organic compounds have been oxidized with an acidic permanganate solution under various oxidation conditions. In an attempt to determine the standard substance for chemical oxygen demand (COD), their oxidation behavior is analyzed in detail with respect to the reaction temperature and the reaction time by means of flow-injection analysis using ammonium iron(II) sulfate as the internal standard. The compounds used are classified into three groups according to the oxidation values obtained by the standard COD_{Mn} method. The results show that the compounds with oxidation values of more than 50% are easily oxidized with acidic permanganate, even under relatively mild conditions; those with oxidation values of 5—50% are severely influenced by the reaction temperature and the reaction time, and those with oxidation values of less than 5% are seldom oxidized at below 100 °C or for less than 30 min. As a standard substance for COD, it has been established that a mixture of the compounds has to be properly chosen from the aforementioned three groups according to the oxidation behavior of the water sample. The addition of silver nitrate to the oxidation system accelerates the oxidation reaction with acidic permanganate, whereas that of phosphoric acid suppresses the oxidation of organic compounds.

There is a growing interest on the part of environmental researchers in determining the contribution of organic substances to water pollution. For measurements of the chemical oxygen demand (COD), however, there is no specific substance to be used as a standard. Hence, skillful and complicated procedures have been established based on the standard methods with permanganate (COD_{Mn})[1,2] and dichromate (COD_{Cr}).[2,3] It is, however, difficult to obtain correct values of COD in water samples, because of the lack of a standard substance for COD.[4] To select a proper standard substance for the COD measurements, therefore, the oxidation behavior of D-glucose[5,6] and lactose[7] has been studied in detail with dichromate and permanganate. Also, the oxidation values of various organic compounds[8-10] have been examined to some extent with the standard method previously established,[1-3] but their oxidation behavior has not yet been determined in detail with regard to the reaction temperature and the reaction time.

Recently, the present authors have developed a useful method, based on flow-injection analysis (FIA),[11] for the simple and continuous determination of COD (COD_{FIA}) using potassium permanganate ($COD_{FIA\cdot Mn}$)[12-18] or potassium dichromate ($COD_{FIA\cdot Cr}$).[19] These methods for the COD determination always need a standard substance for COD, so sodium oxalate,[12] D-glucose,[13-19] lactose,[17,18] *etc.* were used to obtain the calibration curves. However, the oxidation behavior of these standards did not always accord with those of various organic pollutants in environmental water samples. Hence, the oxidation behavior with permanganate and dichromate should be investigated further in connection with various fundamental organic compounds in order to design a more complete FIA apparatus for COD measurements.

Therefore, this paper will mainly described the oxidation behavior of forty-five organic compounds as determined by means of the $COD_{FIA\cdot Mn}$ method developed in this laboratory,[12-18] and the effects of silver nitrate[17] and phosphoric acid,[18] added to the FIA system with acidic permanganate. It will also describe some problems of the present official Japanese method using COD_{Mn},[2] as considered in view of the oxidation behavior of the organic compounds obtained in this work.

Experimental

Materials. All the reagents used were of an analytical reagent grade except antipyrine, *o*-cresol (guaranteed), disodium dihydrogen ethylenediaminetetraacetate (EDTA), soluble starch (guaranteed), and sodium dodecylbenzesulfonate (DBS; standard for the determination of alkylbenzenesulfonate). These reagents were used as received after dissolution with distilled water. Preparations of potassium permanganate and sulfuric acid solutions were the same as those reported previously.[17]

Apparatus. The FIA apparatus used in this work is basically the same as those used in the previous works,[13-17] as is shown in Fig. 1. To obtain flexible operating conditions, however, it was composed of a double reciprocating micropump (Kyowa-Seimitsu Model KHU-W-52), a sampling valve (Kusano, sampling volume: 20 mm^3), a water bath (Yamato Model BM-41), a spectrophotometer (Shimadzu Model UV-100-01), a quartz tubular flow-through cell (path length: 10 mm, inner volume: 18 mm^3), a multirange recorder (Nippon-Denshi-Kagaku Model U-228), and poly(tetrafluoroethylene) (PTFE) tubings with various inner diameters (i. d.) and lengths.

Procedure. Both a suitable concentration of potassium permanganate solution (*ca.* 1 mol m^{-3}) and a 10% v/v sulfuric

Length of PTFE reaction tube/m	20	20	20	20	4	10	20	20
Peak height of Mohr's salt[a)]/mm	54.5	61.5	77.0	96.0	169.5	82.5	96.0	98.0
Peak height of water blank[b)]/mm	2.0	1.5	1.0	0.5	6.0	0.5	0.5	0.0

a) Mohr's salt can be completely oxidized in spite of changes in the reaction temperature and time. The flowing and mixing patterns of the sample zones are variable according to the viscosities of the carrier streams, so that peak heights are stably changed to some extent only with a change in the reaction temperature. However, the peak areas of Mohr's salt are almost equal in all FIA systems in this work. b) For the same reason as in a), the peak heights of the water blank are changed according to the peak-broadening phenomena based on the flowing and mixing patterns of their FIA systems.

acid solution are individually pumped up with the micro-pump in a 1 : 1 ratio. The concentrations of the potassium permanganate solution are adjusted to obtain absorbances of about 0.9 at 525 nm when this FIA apparatus system is operated.[17] Also, the flow rates of the two solutions are constant at the 1 : 1 flow-ratio and are adjusted between the potassium permanganate and sulfuric acid solutions in order to obtain a proper residence time of the injected samples. Twenty-mm^3 portions of sample solutions are continuously injected into the stream of the sulfuric acid solution by means of the sampling valve just before a PTFE mixing joint. The sample is merged with the mixing joint and carrier solutions and then introduced into the PTFE reaction tube. The tube is properly selected from the various PTFE tubings with many inner diameters and lengths in order to minimize the dispersion of the sample zones and to keep a suitable residence time of the samples. The reaction tube is placed in an accurately thermostated water bath to control the oxidation reaction. The reaction mixture is detected by means of a spectrophotometer with a flow cell at 525 nm. The absorbances are continuously recorded with the recorder; the peaks in the recordings are then compared with that of an internal standard substance (Mohr's salt: ammonium iron(II) sulfate). The peak-height ratio of each organic compound (see below) is used to evaluate its oxidation behavior. The operating conditions of the apparatus, such as the temperature of the water bath, the flow rates, the kind of PTFE reaction tube, and the residence time, are given in Table 1.

Calculation of Peak-height Ratio. To symbolize the extent of oxidation for various fundamental organic compounds, the idea of the peak-height ratio is used for each organic compound in this work. The peak height of a certain organic compound is widely changed when the operating conditions are changed in the apparatus, according to the parameters in Table 1. Hence, ammonium iron(II) sulfate, which is readily and quantitatively oxidized with potassium permanganate, even at room temperature, is used as the internal standard substance to obtain a standardized peak value. The calculation of the peak-height ratio is as follows;

$$\textit{Peak-height ratio} = \frac{H_{\text{organic compound}}(\text{mm}) - H_{\text{blank}}(\text{mm})}{H_{\text{Mohr's salt}}(\text{mm}) - H_{\text{blank}}(\text{mm})}, \quad (1)$$

where H is the peak height using 20-mm^3 portions of organic compounds or an ammonium iron(II) sulfate solution as 200 mg-COD_{Mn} dm^{-3} and 20 mm^3 of distilled water (blank) in the recordings.

Results and Discussion

Choice of Organic Compounds. From the previous papers,[5-10] forty-five organic compounds were chosen and classified into three groups according to their oxidation values with acidic permanganate by means of the standard COD_{Mn} method.[2] Fifteen of the forty-five compounds (Group 1 in Table 2), all of which showed oxidation values of more than 50% in comparison with the theoretical oxidation values (COD_{Th}) of the compounds,[8] were first examined in order to evaluate their oxidation behavior with permanganate at various reaction temperatures and reaction times. Fourteen compounds (Group 2 in Table 2), all of which showed oxidation values of from 5 to 50% in comparison with the COD_{Th} values, were then examined. Sixteen compounds (Group 3 in Table 2), which showed oxidation values of less than 5%, were also examined. Almost all the organic compounds are adjusted to 200 mg-COD_{Mn} dm^{-3} solutions according to their own oxidation values by means of the standard COD_{Mn} method in use, but several compounds showing oxidation values of less than 1% were prepared to make them as close to 200 mg-COD_{Mn} dm^{-3} as possible.

Oxidation Behavior of Group 1. In the ten organic compounds in Group 1, the effect of the reaction temperature was examined in order to evaluate their oxidation behavior at a residence time of 30 min; the results are shown in Figs. 2a and 2b. The effect of the reaction time on the oxidation behavior (reaction temperature: 98 °C) is also shown in Figs. 2c and 2d. The organic compounds used in Group 1 have turned out to be easily oxidizable. Figures 2a and 2b show that the oxidation reactions with acidic permanganate easily occurred at a relatively low temperature and were seldom changed in the temperature range between 80 and 100 °C except soluble starch, lactose, and glycine. As for the reaction time (Figs. 2c and 2d), the oxidation with permanganate at 98 °C occurred at a relatively short residence time (2—10 min), so that almost all the values of the peak-height ratio were apparently constant, even with a change in residence time.

TABLE 2. CLASSIFICATION OF FORTY-FIVE ORGANIC COMPOUNDS USED

Group 1[a)]	Group 2[a)]	Group 3[a)]
Sodium oxalate (1)	Acetaldehyde (1)	Ethyl acetate (1)
Citric acid (2)	Ethanol (2)	1-Propanol (2)
EDTA (3)	1-Butanol (3)	Urea (3)
Saccharose (4)	Methanol (4)	DBS (4)
Starch, soluble (5)	Acetic acid (5)	Butyric acid (5)
Glycerol (6)	1-Propanol (6)	Acetone (6)
o-Cresol (7)	Formic acid (7)	Pyridine (7)
Aniline (8)	Lactic acid (8)	Benzoic acid (8)
D-Glucose (9)	L-Glutamic acid (9)	Glycine (9)
Lactose (10)	Propionic acid (10)	Valeric acid (10)
Tartaric acid	Isobutyric acid	Isovaleric acid
Malic acid	Formaldehyde	Diethyl ether
Phenol	2-Butanol	2-Propanol
Salicylic acid	L-Cystine	Isobutyl acetate
Antipyrine		*β*-Alanine
		L-Methionine

a) Number in parenthesis denotes those compounds in Groups 1, 2, and 3 in Figs. 2, 3, and 4 respectively.

Oxidation Behavior of Group 2. Of ten organic compounds in Group 2, the effects of the reaction temperature (residence time: 30 min) and the reaction time (reaction temperature: 98 °C) are shown in Figs. 3a and 3b, and Figs. 3c and 3d, respectively. The compounds in Group 2 are considered oxidizable in the middle region of many of the organic compounds used in this work. Of the reaction temperature, all the compounds except acetaldehyde, acetic acid, and propionic acid gave an almost linear relationship, obtained by means of the increases in the peak-height ratio values with increases in the reaction temperature, as is shown in Figs. 3a and 3b. From Figs. 3c and 3d, it was found that the residence time severely affected methanol, ethanol, 1-propanol, 1-butanol, formic acid, and glutamic acid, but not acetaldehyde, lactic acid, acetic acid, and propionic acid. Also, the peak-height-ratio values of acetic and propionic acids were found to be very small in the absence of silver salt. Acetaldehyde, ethanol, 1-propanol, 1-butanol, and formic acid gave very large peak-height-ratio values of more than 1.5 in this work. Therefore, the values in Figs. 3a—d were plotted on a reduced scale of from 1 to 2 or 4.

Oxidation Behavior of Group 3. Of ten organic compounds in Group 3, the effects of the reaction temperature and the reaction time were also examined in a similar way (Figs. 4a—d). The compounds in Group 3 were generally considered to be difficult to oxidize by the use of an acidic permanganate solution. As for the effect of the reaction temperature on oxidation behavior, all the compounds in Figs. 4a and 4b gave exponential increases in the peak-height-ratio value when the reaction temperature increased. Therefore, the compounds in Group 3 were found to be much less oxidizable than those in Groups 1 and 2 in the low-temperature region. Of course, the former were further oxidized by acidic permanganate at a temperature of more than 100 °C, since the slopes of the oxidation-behavior curves were very abrupt between the reaction

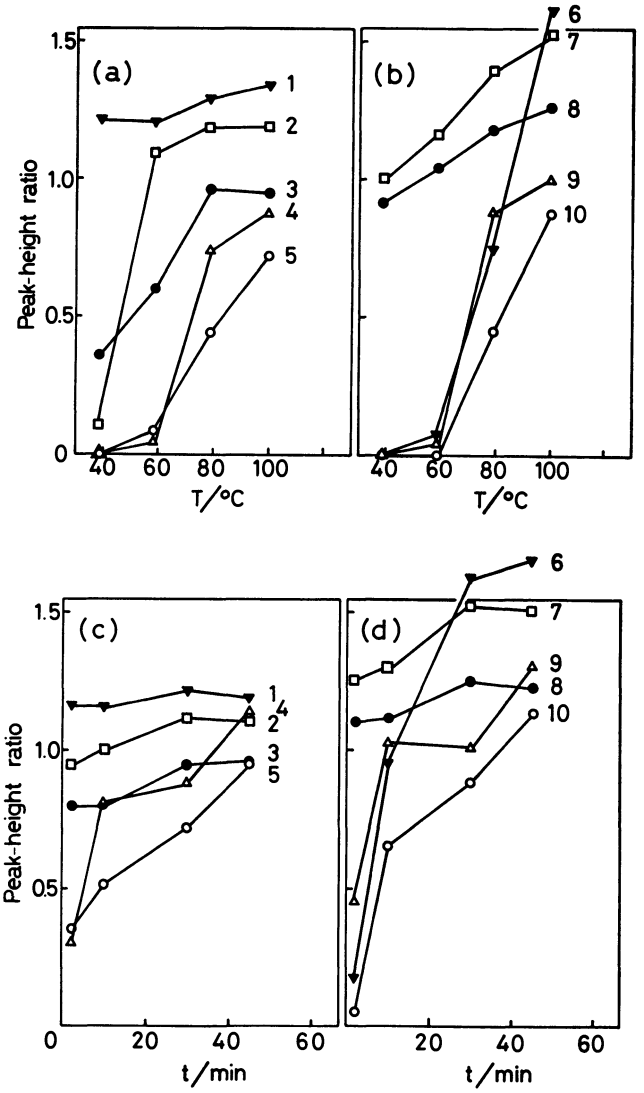

Fig. 2a—d. Effect of the reaction temperature (a, b) and the reaction time (c, d) on oxidation behavior of Group 1.
(a) and (b): Change in reaction temperature for a residence time of 30 min, (c) and (d): change in reaction time at a reaction temperature of 98 °C, 1: sodium oxalate, 2: citric acid, 3: EDTA, 4: saccharose, 5: soluble starch, 6: glycerol, 7: *o*-cresol, 8: aniline, 9: D-glucose, 10: lactose.

temperature and the peak-height ratio. As for the reaction time, almost all the compounds except butyric acid and glycine gave abruptly sloped relationships between the reaction time and the peak-height ratio at 98 °C, as is shown in Figs. 4c and 4d. In Figs. 4a—d, however, ethyl acetate, 2-propanol, and acetone gave outstandingly large peak-height-ratio values of more than 1.5, so those values in these figures had to be plotted on a reduced scale of from 1 to 4 or 8. Moreover, the peak-height-ratio values of butyric acid, glycine, and valeric acid showed oxidation behavior typical of much less oxidizable compounds when an acidic permanganate solution was used at more or less than 100 °C in the absence of silver salt.

As a result of these oxidation-behavior studies,

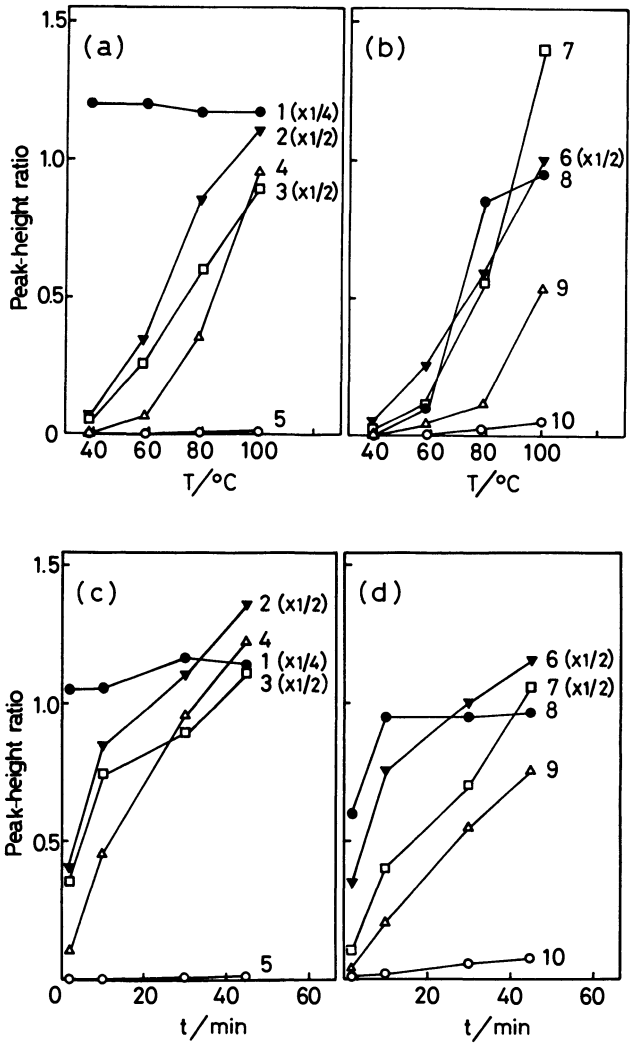

Fig. 3a—d. Effect of the reaction temperature (a, b) and the reaction time (c, d) on oxidation behavior of Group 2.
(a) and (b): Change in reaction temperature for a residence time of 30 min, (c) and (d): change in reaction time at a reaction temperature of 98 °C, 1: acetaldehyde, 2: ethanol, 3: 1-butanol, 4: methanol, 5: acetic acid, 6: 1-propanol, 7: formic acid, 8: lactic acid, 9: L-glutamic acid, 10: propionic acid.

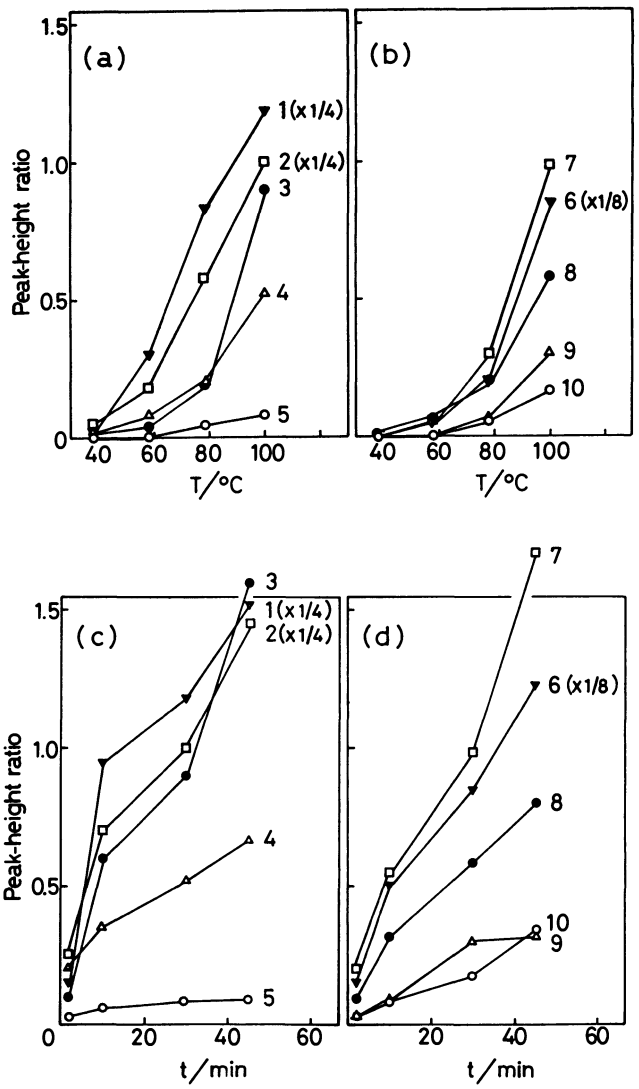

Fig. 4a—d. Effect of the reaction temperature (a, b) and the reaction time (c, d) on oxidation behavior of Group 3.
(a) and (b): Change in reaction temperature for a residence time of 30 min, (c) and (d): change in reaction time at a reaction temperature of 98 °C, 1: ethyl acetate, 2: 1-propanol, 3: urea, 4: DBS, 5: butyric acid, 6: acetone, 7: pyridine, 8: benzoic acid, 9: glycine, 10: valeric acid.

although the COD_{Mn} values[2] of the eight organic compounds with large peak-height-ratio values in Groups 2 and 3 were precisely adjusted to 200 mg dm^{-3}, the peak-height-ratio values were inconceivably large in comparison with those of the ammonium iron(II) sulfate used as the internal standard. Accordingly, it is noteworthy that organic compounds with small oxidation values[8] really had quite large COD_{Mn} values. Consequently, organic compounds with relatively low boiling points (*e.g.*, acetaldehyde, methanol, ethanol, propanols, butanols, formic acid, acetone, and ethyl acetate) potentially exhibit amazingly high peak-height-ratio values in this closed-flow injection system with acidic permanganate,[12-18] even when the permanganate values are precisely measured after digestion with acidic permanganate at about 100°C by means of the manual-titration method.[1,2] It was, therefore, considered that these organic compounds almost evaporated from the opened Erlenmeyer flask when the mixed solution was heated with a boiling-water bath in the official Japanese method for COD_{Mn}.[2]

Oxidation Behavior of Actual Waste Waters. As for actual waste water samples (*ca.* 200 mg-COD_{Mn} dm^{-3}) from civil sewage, the chemical industry, the food industry, the textile industry, and university laboratories, their oxidation behavior was also investigated with this useful methodology; the results are shown in Figs. 5a and 5b. Figure 5a shows the results on the reaction temperature obtained for the five samples at a residence time of 30 min. Figure 5a shows that waste waters from the food and textile industries gave almost linear increases in the peak-height-ratio values when the reaction temperature increased, while civil sewage and

waste water from the chemical industry reacted with acidic permanganate beyond 80 °C, but not up to 60 °C. Figure 5b also shows the effect of the reaction time at 98 °C for the same samples. The civil-sewage sample gave almost constant peak-height-ratio values for more than 30 minutes' residence time, while the waste water from the chemical industry showed a linear increase with an increase in the reaction time. Waste water from the food and textile industries gave constant peak-height-ratio values between 10 and 30 min of reaction time and then proceeded to a new oxidation step for more than 30 min. As is shown in both Figs. 5a and 5b, waste water from university laboratories gave very large peak-height-ratio values which were far beyond 1.0, so it was considered that the water sample contained some volatile organic compounds, such as methanol, ethanol, or acetone. However, it should be noted that the oxidation behavior on the samples used in this work was not found in each sample of the waste water of the same industrial groups, but was particular to their own waste-water samples.

As for a standard substance for COD measurements, it can, therefore, be considered that oxidation behavior of the series of samples has to be first examined with regard to the effects of the reaction temperature and the time with acidic permanganate; an optimum substance (single or mixture) is then chosen according to these oxidation-behavior studies. Of course, the correlation between $COD_{FIA\cdot Mn}$ and standard COD_{Mn} methods shall also be considered whenever the substance chosen is used as a standard for $COD_{FIA\cdot Mn}$ measurement.

Effect on the Addition of Silver Nitrate or Phosphoric Acid. Table 3 shows the results of the additions of silver nitrate or phosphoric acid to a sulfuric acid stream when the reaction temperature and reaction time of the present FIA system were 98 °C and 30 min respectively. With waste-water samples, the peak-height-ratio values increased when 0.05% silver nitrate was added to a carrier solution containing 5% sulfuric acid and potassium permanganate, whereas they decreased when 10% phosphoric acid was added to the carrier solution, as is shown in Table 3. Of the organic substances used in this work, D-glucose, citric acid, ethanol, *o*-cresol, *etc.* were not affected by the addition of silver nitrate or phosphoric acid. However, lactose, starch, glycine, urea, 1-butanol, benzoic acid, *etc.* obviously showed the same phenomena as waste-water samples. These results prove the catalytic effect of silver(I) salt and the formation of manganese(III) phosphate. These effects on oxidation behavior with acidic permanganate are important for deciding on a standard substance for measuring the $COD_{FIA\cdot Mn}$ values in a series of waste-water samples.

Conclusion

The present study fundamentally proves various aspects of the oxidation behavior of common organic substances with an acidic permanganate solution with reference to COD measurements based on the value of the permanganate consumed. By applying a continuous $COD_{FIA\cdot Mn}$ analyzer[18] to the monitoring of industrial and municipal waste water, a standard substance containing one or a mixture of organic substances can easily be found out from Groups 1, 2, and 3 after the oxidation behavior of each waste water sample has been analyzed in detail.

Besides, this paper has provided concomitant useful suggestions for preparing a standard substance for the

official COD_{Mn} method now being studied in the Japanese Ministry of International Trade and Industry.[20]

This work has also established the orders of oxidizability to sugars, alcohols, carboxylic acids, and benzene derivatives for reference in considering oxidation behavior. The oxidizability to sugars is in this order: D-glucose>saccharose>lactose≈starch; that to alcohols is in this order: ethanol>1-propanol≈2-butanol≳1-butanol>2-propanol≳methanol; that to carboxyl acids is in this order: formic acid>isovaleric acid≳valeric acid>isobutyric acid≈butyric acid>propionic acid>acetic acid, and that to benzene derivatives is in this order: *o*-cresol>phenol>salicylic acid≳aniline≫benzoic acid≈dodecylbenzenesulfonic acid. These results show that the activity of the α-hydrogen in alcohols and carboxylic acids may affect their oxidation behavior.

The authors wish to express their thanks to Professors Kyoji Tôei and Teruo Takahashi of Okayama University for their helpful suggestions and encouragement. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Japanese Ministry of Education, Science and Culture, and also the Nissan Science Foundation.

Conformational Characterization of *S*-Methyl Dithiocarbazate by Infrared Spectra and Vibrational Assignments

Sadasivam MANOGARAN and Dixit Narayanarao SATHYANARAYANA*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

(Received November 9, 1981)

Infrared spectra are recorded for *S*-methyl dithiocarbazate and its *N*-deuterated compound in two molecular conformations in the solid state and in solution between 4000 and 30 cm^{-1}. The assignments have been supported from a complete normal coordinate analysis; the conformation sensitive bands of the $-CSNHNH_2$ grouping are discussed. The assignments are compared with those of related molecules to check the internal consistency and to obtain the pattern of the characteristic bands of thiocarbazoyl ($-CSNHNH_2$) group. The magnitudes of the C–N and S–CH_3 torsional barriers are estimated from the force constants.

The structural and spectroscopic studies[1-6] of the methyl ester of dithiocarbazic acid and its *N*-substituted derivatives are currently of interest. The impetus for this and similar work arises from the wide ranging applications of these compounds in industry and medicine[7,8] and their varying ligational[9] and conformational properties.[1,10] *S*-methyl dithiocarbazate (SMDTCZ) is itself a very interesting compound which has been isolated as solid in two planar molecular conformations[1,2] shown below (Fig. 1).

(a) *cis-trans* (b) *trans-cis*

Fig. 1.

The infrared spectra of SMDTCZ have been reported;[2,6] some assignments have been made empirically. In order to note more precisely the conformation-sensitive vibrations and discuss the vibrational spectra of SMDTCZ more fully, we have investigated the infrared spectra of SMDTCZ in two molecular conformations as well as their *N*-deuterated species. Based upon the force function previously developed,[11,12] normal coordinate analyses have been accomplished. The results are compared with those of chemically and structurally related molecules[11-15] for which detailed vibrational assignments have recently become available to provide a test for the general validity of the assignments derived and to obtain a pattern characteristic of the bands arising from thiocarbazoyl $-C(=S)NHNH_2$ grouping. The magnitude of the torsional barriers about the C–N and S–CH_3 bonds is estimated from the force constants.

Experimental

SMDTCZ having *cis-trans* and *trans-cis* conformation was prepared according to the literature methods.[16,17] Recrystallization from aqueous solution of the *trans-cis* conformer yields the *cis-trans* conformer of SMDTCZ. The purity of the compounds was checked by microanalyses. The *N*-deuterated samples were obtained by repeated exchange reaction with D_2O.

The infrared spectra from 4000 to 200 cm^{-1} were measured on a Perkin-Elmer 580 spectrophotometer in KBr pellets and nujol mulls which yielded identical spectra. The observed spectra are shown in Fig. 2. The solution spectra

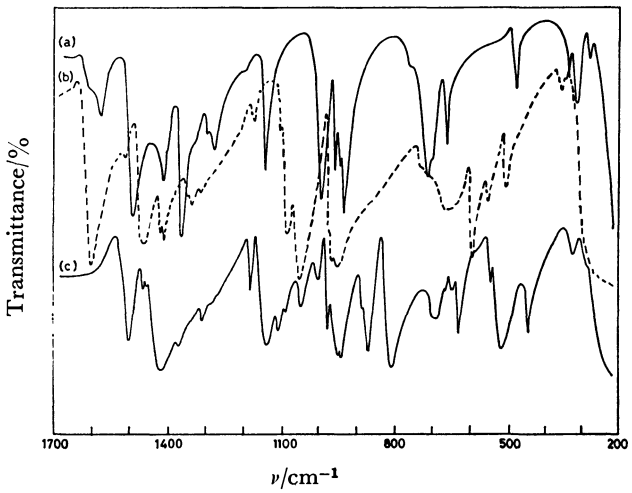

Fig. 2. Infrared spectra of SMDTCZ in (a) *cis-trans*, (b) *trans-cis*, and (c) of SMDTCZ-d_3 in *cis-trans* conformations.

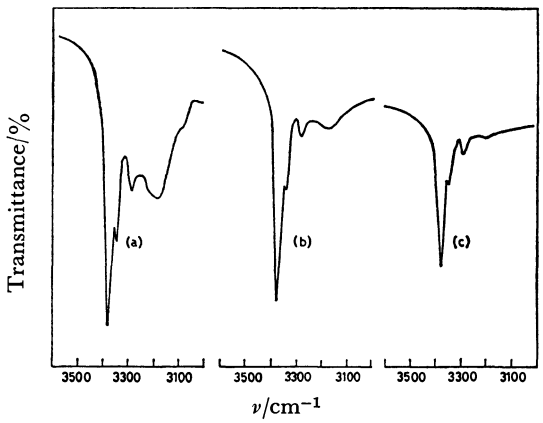

Fig. 3. Infrared spectra of *S*-methyl dithiocarbazate in $CHCl_3$ at concentrations of (a) 1.0×10^{-1} M, (b) 0.6×10^{-1} M, and 0.3×10^{-1} M (1M = 1 mol dm^{-3}).

were run on the same instrument using NaCl cells of path length of 0.4 mm (Figs. 3 and 4). The spectra between 400 and 30 cm^{-1} were recorded on a Polytec FIR 30 Michelson interferometer as polyethylene disks. The instruments were calibrated with usual standards.

Normal Coordinate Analysis

The conformations adopted for the calculations are shown in Fig. 1. In the molecular symmetry C_s, the 30 normal modes of vibration of SMDTCZ span

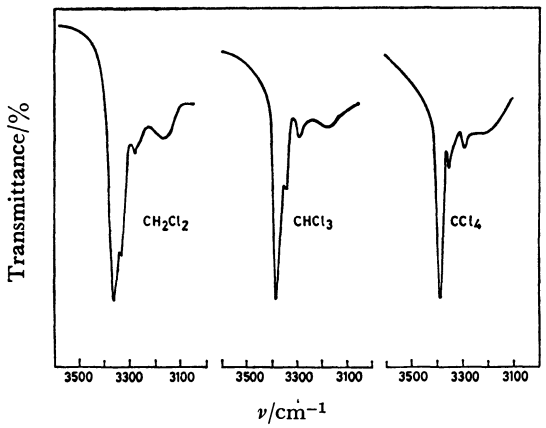

Fig. 4. Infrared spectra of *S*-methyl dithiocarbazate in different solvents.

19 of species a′ (in-plane) and 11 of species a″ (out-of-plane) vibrations. The internal and symmetry coordinates were selected in the usually accepted form. The bond length and valence angle values for SMDTCZ, were transferred from the X-ray crystal structure data.[1,2] The potential energy was expressed in terms of a Urey-Bradley force function employing valence force field type constants for the out-of-plane and torsional coordinates. The initial values of the force constants were transferred from thiosemicarbazide[11] (hydrazinecarbothioamide) and *S*-methyl *N*-methyldithiocarbamate.[12] The refinement of the force constants was carried out as already described.[11,12] The computations were made on a DEC 1090 digital computer employing a program similar in form to that of Schachtschneider.[18]

The final force constants of SMDTCZ listed in Table 1 are considered physically reasonable. Good fit reached between the observed and calculated frequencies for SMDTCZ and its deuterium labelled molecule also lends confidence to the values of the force constants and the assignments derived (Tables 2 and 3).

Results and Discussion

We noted that recrystallization of the *trans-cis* conformer of SMDTCZ from aqueous solution transformed it to the *cis-trans* form, while recrystallization from organic solvents including alcohols did not effect any conformational change, contrary to an earlier report.[2] Further, heating the *trans-cis* isomer to its melting and then cooling it also did not bring about any conformational change. The *N*-deuterated product of both isomeric forms of SMDTCZ interestingly yielded identical infrared spectrum; it was found to correspond to that of the *cis-trans* conformer which is the stablest form.

The frequencies of the observed infrared bands of SMDTCZ are listed in Table 2, together with the calculated vibrational frequencies along with approximate descriptions of the modes in terms of the potential energy distributions (PED) amongst the symmetry coordinates including only terms having greater than 15 percent for simplicity. Similar data for the *N*-deuterated compound are presented in Table 3. Despite the general asymmetry of the molecule, most of the fundamental frequencies may be described as group vibrations. A perusal of Table 2 shows that most of the frequencies for the two conformers differ, to a lesser or a greater extent.

N–H Stretching. The characteristic N–H stretching frequencies are sensitive to structural and electronic variations. The existence of conformational isomers in solution is clearly manifested in the infrared spectra of SMDTCZ (Figs. 3 and 4) which possess

two distinguishable bands in the N–H frequency region. The first band observed in the 3365—3390 cm^{-1} range is attributable to a *trans* –CS–NH– grouping and the second appearing in the 3340—3350 cm^{-1} interval to a *cis* –CS–NH– conformation. If we assume the extinction coefficients of the *cis* and *trans* forms to be nearly equal as is usually done, it is seen that the *cis-trans* conformer (a) with *trans* –NH–CS– grouping predominates in solution. Further, the relative intensities of the doublet peaks were found to be concentration independent (Fig. 3) ruling out the doublets being ascribed to molecular association. The infrared spectra of SMDTCZ in a series of solvents were obtained to note the influence of solvent dielectric on the spectra. The experimental data are presented in Fig. 4. It is observed that changing the solvent causes considerable alterations in the relative intensities of the two bands, which supports the presence of a conformational equilibrium. Increasing the solvent polarity favours transition to a *trans-cis* form (with *cis* –CS–NH– grouping). The spectra (Figs. 3 and 4) further exhibit a weak band around 3285 cm^{-1} and another weak but broad absorption centred around 3180 cm^{-1}. The former band has the characteristics of the intermolecularly hydrogen-bonded N–H stretching band; the region being same as in the solid. The latter absorption arise from the $-NH_2$ stretching motions.

According to the literature data, and as already pointed out, in the infrared spectra, of the two N–H stretching bands, a high frequency band is assigned to the *trans*(–NH–CS–) form and a low frequency band for the *cis* conformation. Interestingly, a reverse situation—the *trans* NH stretching band occurring at a lower frequency than the *cis* NH stretching mode—is realised for SMDTCZ in the solid phase. It may be ascribed essentially to intermolecular hydrogen bonding. Both rotamers exist as intermolecularly hydrogen bonded dimers. In the *cis-trans* isomer, N–H···N hydrogen bonds exist while in the *trans-cis* conformation N–H···S hydrogen bonds are present.[1,2] Since the former hydrogen bonds are stronger than the latter ones, the greater downward shift of the –NH stretching frequency may be expected pro-

a) c and t refer to *cis* and *trans* groups to C=S bond.

ducing *cis*-NH band at a frequency higher than the *trans*-NH band.

Comparison. The assignments for SMDTCZ are compared with those available for related compounds[11-15] in Table 4. It is satisfactory that most of the assignments for SMDTCZ are compatible with the general features of the spectra of thiosemicarbazide and thiocarbonohydrazide and the pertinent portions from their isoelectronic thioureas and from *S*-methyl *N*-methyldithiocarbamate. Some of the differences in the characteristic frequencies could be explained on the basis of the different nature of the coupling with other vibrations. On the whole, there is internal consistency in the assignments and some pattern characteristic of –CSHN– grouping as well as those of the $-HNNH_2$ vibrations could be recognized. A brief discussion of the spectra of SMDTCZ will now be given.

$-CSNHNH_2$ Group Vibrations. An important band in the spectra of hydrazo derivatives is the N–N stretching band. The stretching frequency of N–N bond *cis* to C=S group is found 80 cm^{-1} lower than that for the *trans* N–N group. This is compatible with a similar assignment for *trans* and *cis* N–N bond stretching in thiosemicarbazide[11,21] but a reverse situation is found in thiocarbonohydrazide.[13] This may partly be explained on the basis of the mixing of the other vibrations.

The other bands of interest are those arising from the thioureide vibrations. The thioamide II and III bands arise from coupled modes of in-plane NH bending and C–N stretching; the former band is predominantly due to NH bending while the latter one arises chiefly from C–N stretching. These bands are conformation-sensitive. For SMDTCZ, the *trans* –CSNH– group has CN stretching band at a higher frequency than N–H in-plane bending. Similar findings have been made in other related systems.

The thioamide I band corresponding to C=S stretching is sensitive to the molecular environment and conformation. SMDTCZ provides a dramatic example of this; both rotamers have however no bands which could be attributed unequivocally to the C=S stretching mode.

The wagging and twisting modes of the $-NNH_2$ group appear to be conformation-sensitive. The vibrations of the $-NH_2$ group *cis* to the C=S moiety occur at higher wave numbers compared to $-NH_2$ group bands trans to the C=S grouping. A similar trend is noticeable for NH_2 torsional mode but is complicated by the more extensive mixing with other vibrations.

Torsional Barriers. From the value of the torsional force constants we may roughly estimate the potential barriers for C–N and S–C bonds. Following the procedures of Uno *et al.*,[22,23] we obtained 6.4 and 5.6 kJ mol^{-1} (1.53 and 1.34 kcal mol^{-1}) as barriers to internal rotation for $S-CH_3$ bond for the *cis-trans* and *trans-cis* conformers respectively. The values obtained are similar to that of acetamide[22] and *N*-methylurea[23] (5.4—7.1 kJ mol^{-1}). The C–N barrier is calculated to be 100.7 and 70.6 kJ mol^{-1} (24.06 and 16.87 kcal mol^{-1}) respectively for the *cis-trans* and *trans-cis* isomers, assuming an energy difference of 6.7 kJ mol^{-1} (1.6 kcal mol^{-1}) between the *cis* and *trans* NH_2 forms.[10] The estimates of the barrier heights over the amide C–N bond from torsional force constants in related thioamides and thioureas are similar and are usually higher than those determined by NMR methods.[24]

Spectrophotometric Determination of Osmium by Ternary Complex Formation with Thiocyanate and Rhodamine 6G

Sambamurthy JAYA and Tiruvesaloor Venkatrama RAMAKRISHNA*
Department of Chemistry, Indian Institute of Technology, Madras-600036, India
(Received June 18, 1981)

Osmium in trace amounts is determined by use of its reaction with thiocyanate and Rhodamine 6G to form an ion-association complex at pH 3.0. Aided by stabilization with gelatin, measurement of absorbance at 565 nm permits the determination of osmium in the range 0.04—1.2 ppm. The colour system is very stable and provides a molar absorptivity of 6.84×10^4 l mol^{-1} cm^{-1}. A few elements interfere and methods are suggested for handling them except ruthenium and rhodium.

Although many spectrophotometric methods have been suggested for the determination of osmium in the literature, the most often used are based on its reaction with thiourea[1-2] or thiocyanate.[3-4] These methods, besides being insensitive, call for considerable skill on the part of analysts as they are unselective and hence subjected to many sources of errors.

A highly sensitive method based on reaction of osmium with diphenyl carbazide[5] ($\varepsilon=1.5\times10^5$ l mol^{-1} cm^{-1}) has been described. This method lacks adequate selectivity and is not reliable because of its dependence on various experimental parameters such as acid concentration, temperature, and duration of heating. Prior extraction of OsO_4 into chloroform and subsequent colour development in the organic phase have been attempted to improve the selectivity,[6] but this caused considerable dimunition in the sensitivity ($\varepsilon=3.1\times10^4$ l mol^{-1} cm^{-1}). We ourselves had examined the osmium-diphenyl carbazide reaction and found that the determination can be made highly selective by extracting the complex into isobutyl methyl ketone at pH 5.0.[7]

The investigation reported here is based on the interaction of Rhodamine 6G cation with the anionic osmium–thiocyanate complex. The introduction of Rhodamine 6G in the reaction medium resulted in formation of a new coloured species with a molar absorptivity of 6.84×10^4 l mol^{-1} cm^{-1}. A detailed study indicated that under certain conditions most other ions do not duplicate the colour reaction, concluding that the analytical method may facilitate the determination of osmium with high degree of selectivity.

Experimental

Reagents. *Osmium (VIII) Solution*: This solution was prepared by dissolving 1 g of osmium tetroxide in 250 cm^3 of water as described elsewhere.[2] A working solution containing 10 μg cm^{-3} of osmium was prepared by suitably diluting the stock solution with water.

Potassium Thiocyanate Solution (5%): This solution was prepared by dissolving 5 g of potassium thiocyanate in water and diluting the solution to 100 cm^3.

Rhodamine 6G Solution (0.005%): This solution was prepared by dissolving 0.05 g of the reagent (BDH) in water and diluting the solution to 1 dm^3 with water.

Buffer Solution: This solution was prepared by dissolving 34 g of sodium aecetate trihydrate in water, adding 15 cm^3 of glacial acetic acid, adjusting to pH 3.0 with dilute HCl, and diluting to 250 cm^3.

Gelatin Solution (1%): This solution was prepared by dissolving 1 g of gelatin in boiling water and diluting the solution to 100 cm^3.

Apparatus. A Carl Zeiss PMQ-II Spectrophotometer with 10 mm quartz cells was used.

Procedure. To an aliquot of sample solution upto 15 cm^3 containing not more than 30 μg of osmium were added 2.5 cm^3 each of the thiocyanate and buffer solutions. The solution was heated on a boiling water bath for 20 minutes and cooled. The solution was transferred to a 25 cm^3 volumetric flask, 5 cm^3 of Rhodamine 6G solution added, 1 cm^3 of gelatin mixed, and distilled water was added to the mark. Absorbence was measured at 565 nm with 10 mm cells against a reagent blank.

Results and Discussion

The addition of Rhodamine 6G to a weakly acidic solution of osmium containing excess thiocyanate resulted in formation of a pink coloured complex. Maximum intensity was developed about an hour after the addition. Further standing of the mixture caused the colour to begin to fade owing to gradual separation of the ion-associate as a precipitate. The addition of gelatin retarded the precipitation since, in its presence, the colour system was found to remain stable for at least 24 h. Later experiments showed that the reaction can be made to proceed rapidly by first heating the osmium solution with thiocyanate for about 20 min on a boiling water bath and then adding Rhodamine 6G and gelatin to the cooled so-

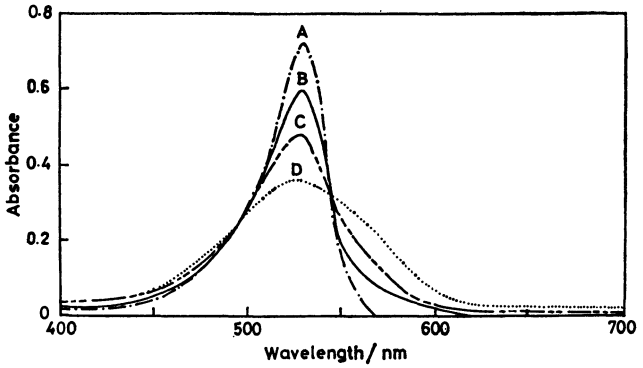

Fig. 1. Absorption spectra (2.5 cm^3 each of 1 mol dm^{-3} acetate buffer and 5% potassium thiocyanate, 1 cm^3 of 1% gelatin).
A: 2 cm^3 of 1.07×10^{-4} mol dm^{-3} Rhodamine 6G, total volume 25 cm^3, reference water 10 mm cells, B, C, and D: as in A with 0.5, 1.0, and 2 cm^3 of 1.07×10^{-4} mol dm^{-3} osmium.

lution. The resulting complex was characterised by its absorption maximum at 565 nm as taken against that of the reagent blank at 530 nm (Fig. 1).

Effect of Experimental Variables. Two sets of experiments were carried out to investigate the influence of acidity of the colour development in the range 2 mol dm^{-3} HCl to pH 9.0. In one set, solutions containing osmium and thiocyanate were adjusted to various acidities and then heated to expedite the formation of the binary complex. The solutions were then adjusted to pH 3.0 before treating with Rhodamine 6G and gelatin for colour development. In the other, the binary complex was first formed at pH 3.0 and then adjustment was made to varying acidities before the binary complex was brought into reaction with Rhodamine 6G. It is apparent from Fig. 2 that the interaction with Rhodamine 6G proceeds over a wide range of pH from 1 to 9, provided the binary complex is formed in the pH range 1—3.5. The most favourable pH for the colour development is 3.0.

Experiments were then made to ascertain the optimal concentrations of potassium thiocyanate and Rhodamine 6G for obtaining the maximum and constant absorbance. The results indicate that the absorbance increases with increasing concentration of potassium thiocyanate and Rhodamine 6G and that it reaches a limiting value when the concentrations are 2 cm^3 of 5% thiocyanate and 4 cm^3 of 0.005% Rhodamine 6G. The presence of the reagents in excess of the amounts indicated did not affect the absorbance.

The effect of temperature on the formation of the anionic thiocyanate complex was studied by thermostating reaction mixtures for 30 min at various temperatures ranging from 40 to 98 °C. Colour was developed after the solutions were cooled to room temperature. The results indicate that a constant and maximum absorbance is obtainable for the solutions that have been kept at 65 °C and above. Further studies using a boiling water bath showed that 15-min heating was sufficient to provide maximum absorbance and that prolonged heating upto 40 min did not affect the recovery of osmium.

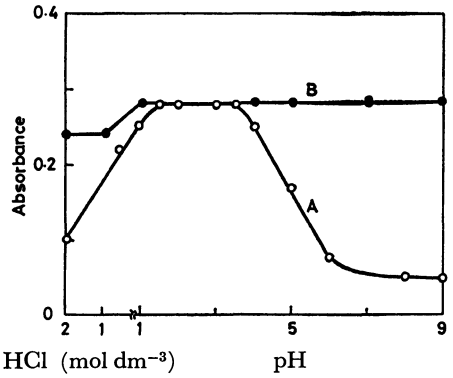

Fig. 2. Effect of pH/acidity (20 μg of osmium, 2.5 cm^3 each of 5% potassium thiocyanate and buffer, 5 cm^3 of 0.005% Rhodamine 6G, 1 cm^3 of 1% gelatin, final volume 25 cm^3, 565 nm, 10 mm cells). A: Formation of Os-SCN^- complex, B: association of SCN^- with Rhodamine 6G.

With the above optimal conditions a linear calibration graph was obtained over the range of 0—30 μg of osmium. The molar absorptivity was calculated to be 6.84×10^4 l mol^{-1} cm^{-1} at 565 nm and the sensitivity of the reaction was 0.0028 μg cm^{-1}.

Ten replicate determinations of standard osmium solutions each containing 20 μg of osmium gave an average recovery of 100.4% with a relative standard deviation of 1.8%.

Nature of the Complex. Experiments were then conducted to find reaction ratios between osmium and Rhodamine 6G by the mole-ratio and continuous var-

a) Two cm^3 of 2% thiourea added before addition of Rhodamine 6G. b) In the presence of 1 cm^3 of 5% ascorbic acid. c) One cm^3 of 0.1 mol dm^{-3} EDTA added before addition of Rhodamine 6G. d) In the presence of 2 cm^3 of 2% sodium fluoride.

iation methods. The equilibrium shift method was employed to establish combining ratios of osmium and thiocyanate. The results indicate the empirical formula of the complex as $R^+[Os^{II}(SCN)_3]^-$ where R^+ represents the Rhodamine 6G cation.

Though 0.5 cm^3 of 1% solution of gelatin was found to be sufficient to stabilize the system, a significant effect was observed when gelatin was added prior to the addition of Rhodamine 6G solution. In this instance the sensitivity of the colour reaction diminished considerably. It was also noticed that the ion-associate breaks down when heated to higher temperature or treated with miscible organic solvent like acetone. Since Rhodamine 6G is known to exist as aggregates in aqueous solution,[8] and from the fact that acetone raises the "critical micelle concentration" of the dye and that the addition of gelatin or increase in temperature can cause deaggregation of the dye,[9] it appeared reasonable to conclude that the resulting colour change was due to interaction of the thiocyanate complex of osmium with micelles of Rhodamine 6G. The addition of gelatin after the addition of Rhodamine 6G prevents further aggragation of ion-associates, thus stabilising the colour system. The observed spectral shift possibly arises due to short range electrostatic interaction of the π-cloud of the dye with the polarising anion or π-cloud of another dye molecule or both, which can lower the energy gap between the highest occupied and lowest unoccupied molecular orbitals.

Effects of Diverse Ion. The influence of amounts of several ions were studied on the determination of 20 μg of osmium. No interference was noticed in the presence of 1 mg amount of Br^-, NO_3^-, ClO_4^-, I^-, SeO_3^{2-}, $B_4O_7^{2-}$, AsO_4^{3-}, PO_4^{3-}, Li^+, Be^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Ni^{2+}, UO_2^{2+}, Cr^{3+}, Al^{3+}, Bi^{3+}, La^{3+}, Tl^{3+}, Th^{4+}, Ce^{4+}, or Sb^{5+}. Other metal ions, which interfered, were dealt with as summarised in Table 1. The data clearly show that only ruthenium and rhodium interfere seriously with the determination.

Synthesis, Ion Exchange Properties, and Analytical Applications of a Novel Tin(IV)-edta Ion Exchanger

Syed Ashfaq Nabi* and Rifaqat Ali Khan Rao
Department of Chemistry, Aligarh Muslim University, Aligarh-202001, India

(Received June 11, 1981)

Tin(IV)-edta compound has been synthesized by mixing aqueous solutions of tin(IV) chloride and disodium salt of ethylenediaminetetraacetic acid (EDTA=H_4 edta) in different conditions. The most stable sample is prepared by mixing 0.1 mol dm^{-3} solution of tin(IV) chloride with 0.1 mol dm^{-3} solution of disodium salt of edta in the volume ratio of 3:2 at pH 2.5 and refluxing the mixture for 16 h. Ion exchange capacities of the material for alkali metals are significantly smaller (0.26—0.20 mequiv./g) than for alkaline earths (0.74—0.40 mequiv./g). The thermal and chemical stability of this material has been compared with amine-tin hexacyanoferrate-(II). Analytical importance of this material has been established by achieving a number of quantitative separations on its columns.

The advancement in the field of synthetic inorganic ion exchangers has been reviewed by various authors.[1,2] Their importance in analytical chemistry has been firmly established. It has been found that inorganic ion exchangers often exhibit their own characteristic properties. It is therefore, always of interest to synthesize new ion exchange materials and to utilize them to solve analytically difficult problems of specific nature.

Of the various ion exchangers studied earlier, have been synthesized either by interaction of pure organic or inorganic compounds. As far as we are aware only limited efforts have been made to develop this new class of ion exchange material which is based on the interaction of metal ions with organic compounds. Amine-tin hexacyanoferrate(II) and zirconium(IV)-bis(carboxymethanephosphonate)[3,4] have been found to exhibit exchange properties. However, detailed studies have not been made on these materials due to their limited chemical and thermal stability.

Crystalline edta complexes of zirconium, hafnium, thorium and tin at pH 1.5 have been described fairly stable.[5] However these compounds have not been studied for their ion exchange properties. In continuation to our studies in these directions we have been able to synthesize amorphous tin(IV)-edta compound as a new cation exchanger. EDTA has been chosen because of its enormous usefulness as an analytical reagent. The present paper deals with the preparation, properties and applications of tin(IV)-edta compounds.

Experimental

Reagents. Tin(IV) chloride pentahydrate (Poland) and ethylenediaminetetraaceticacid disodium salt (E. Merck, Germany) were used. All the other chemicals were of reagent grade.

Apparatus. pH was measured with an Elico LI-10 pH meter. A spectronic 20 colorimeter and a Perkin Elmer 137 spectrophotometer were used for spectrophotometric and IR studies respectively. An electric temperature controlled shaker (SICO) was used for shaking. X-Ray studies were performed on a philips diffractometer and Stanton-Thermobalance type H_4 was used for thermogravimetric studies.

Synthesis. Tin(IV)-edta precipitates were prepared by mixing 0.1 mol dm^{-3} aqueous solution of ethylenediaminetetraacetic acid disodium salt to 0.1 mol dm^{-3} aqueous solution of tin(IV) chloride in different volume ratio as indicated in Table 1. The desired pH was adjusted by adding either dilute hydrochloric acid or dilute sodium hydroxide solution. The precipitate formed, was allowed to settle for 24 h at room temperature. It was then filtered off, washed with distilled water and dried at 40 °C. Sample 1, 2, and 3 so prepared were powder like and yellowish white in appearance. Sample 4 was prepared by adding 0.1 mol dm^{-3} aqueous solution of disodium salt of edta gradually to 0.1 mol dm^{-3} aqueous solution of tin(IV) chloride in volume ratio 2:3 while continuously stirring the mixture. The pH was adjusted to 2.5 by adding dilute solution of sodium hydroxide. The white precipitate obtained was refluxed for 16 h with mother liquor. It was then filtered off under suction, washed several times with distilled water and then dried at 40 °C. This dirty yellow substance when immersed in water, broke down into smaller particles with cracking. Out of these four samples, sample 4 was found to be fairly stable in water and some mineral acids and further studies were therefore, performed on sample 4. The material was immersed in 1 mol dm^{-3} nitric acid solution for 24 h to convert it into H^+ form. Excess of acid was removed by repeated washing with demineralized water. The conditions of synthesis and few properties are summarized in Table 1.

Chemical Stability. Sample 4 was washed several times to remove excess of tin or EDTA adhered to the surface of the particles. 0.5 g of the material was then treated with 50 cm^3 of the solvent in a 250 cm^3 Erlenmeyer flask. The mixture was shaken for 6 h in a shaker incubator at 25±2 °C and then kept for 24 h. Tin released was determined spectrophotometrically using hematoxylin as a colouring reagent[6] and edta in the solution was determined volumetrically using magnesium nitrate solution.[7] These results are given in Table 2.

Chemical Composition. Since the material is not completely soluble in concentrated hydrochloric acid and EDTA is damaged by hot concentrated sulfuric acid, potassium hydroxide was utilized for its dissolution. A 0.2 g of the exchanger was dissolved in 1.0 mol dm^{-3} potassium hydroxide solution. The pH of the solution was decreased by adding hydrochloric acid drop by drop till precipitation was complete. It was then filtered off. The precipitate was dried and tin was estimated as tin dioxide. The filtrate left was made to 100 cm^{-3} and edta was determined titrimetrically against a standard solution of mangnesium nitrate.[7]

Ion Exchange Capacity. Ion exchange capacities of some uni- and bivalent ions are shown in Table 3. 0.5 g

Table 1. Synthesis of tin(IV)-edta

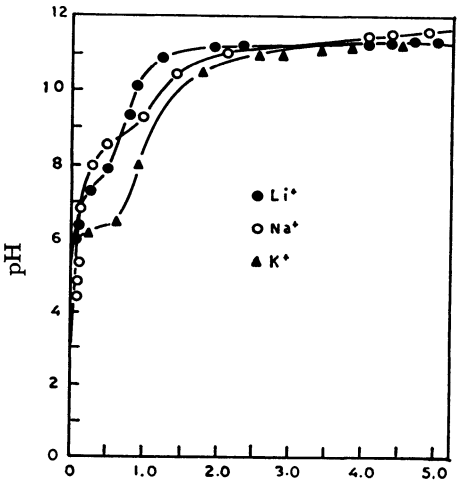
Ca^{2+}	Calcium nitrate	0.74
Sr^{2+}	Strontium nitrate	0.60
Ba^{2+}	Barium chloride	0.40

of the exchanger in H^+ form was taken into the column with glass wool support. The H^+ ions eluted by passing 1 mol dm^{-3} of the electrolyte solutions (pH=6) through the column. The eluted H^+ ions in the effluent were determined volumetrically using standard sodium hydroxide solution as titrant.

pH Titrations. pH titrations were performed using Topp and Papper's method[8] for LiCl–LiOH, NaCl–NaOH, and KCl–KOH systems at 25±2 °C (Fig. 1).

Distribution Coefficient. The K_d values of metal ions in different solvent systems were determined with the method reported earlier.[9] The results are given in Tables 4 and 5.

Quantitative Separations of Metal Ions. Quantitative separations of some metal ions were achieved on a 0.3 cm diameter (id) glass column using 2.0 g of exchanger (mesh size 100—200) in H^+ form. The cation mixture was poured on the top of the column. The stop cock open so that the mixture passed through the column with a very slow rate. The column was rinsed with distilled water. The cations



$\overline{OH}$ added (mequiv./0.5 g exchanger)

Fig. 1. pH titration curves of tin(IV)-edta.

adsorbed were then eluted with suitable eluting agents. The flow rate during elution was maintained 1.0 cm^3/min. The 10 cm^3 fraction of the effluent was collected and the metal ions were determined by standard methods.[6,7] Quantitative separations of metal ions achieved on the columns of tin(IV)-edta are summarized in Table 6.

X-Ray Analysis. Nickel-filtered Cu $K\alpha$ radiation was used for X-ray analysis of sample 4.

Infrared Spectra. IR spectrum of tin(IV)-edta compound in H^+ form was performed using Nujol technique and compared with IR spectrum of disodium salt of EDTA (Fig. 2).

Thermal Treatment. Thermogravimetric analysis of 0.3310 g of sample 4 in Mg^{2+} form was performed at a heating rate of 10 °C/min (Fig. 3). To examine the effect of

drying temperatures on the ion exchange capacity, the material was dried at various temperatures in a muffle furnace for 1 h. The exchange capacities at various temperatures are given in Table 2.

Discussion

It is apparent from Tables 1 and 2 that the mixing ratio of the reactants and conditions of reaction greatly affects the chemical stability and physical appearance of the product. It has been observed that when the precipitate is refluxed for several hours, the chemical stability of the product is significantly increased. The optimum pH for the precipitation of the material which can exhibit exchange properties has been found to be 2.5. However, if the precipitation is done below this pH value, the product obtained is

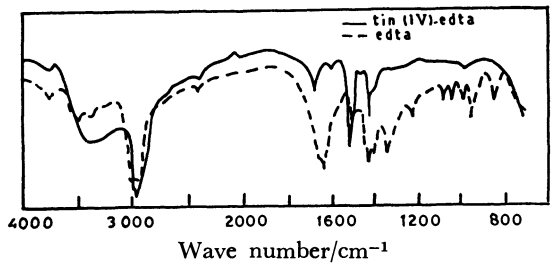

Fig. 2.

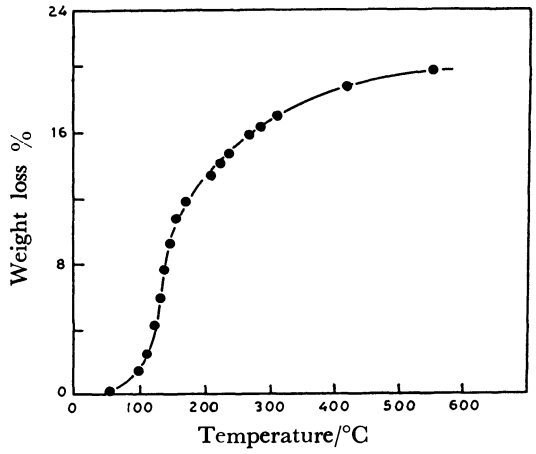

Fig. 3. Thermogram of tin(IV)-edta in Mg^{2+} form.

unstable and therefore has not been studied in detail.

The ion exchange capacities of tin(IV)-edta sample 4 varies with different metal ions (Table 3). The maximum ion exchange capacity is recorded as 0.74 mequiv./g for Ca^{2+} ion. The values of ion exchange capacity for alkali metals are almost constant and small as compare to the ion exchange capacities for alkaline earth metals. However, the ion exchange capacities for alkaline earths has been found to be in the order $Ca^{2+} \geqslant Mg^{2+} > Sr^{2+} > Ba^{2+}$. The peculiar feature which has been noticed regarding this material is that the ion exchange capacities for the univalent ions differ significantly from the ion exchange capacities for the bivalent ions. These data (Table 3) suggest the potentiality of the ion exchanger for the separation of almost all the alkali metals from alkaline earth series.

The pH-titration curves reveal some interesting features regarding the uptake of alkali metals which is affected by pH. The uptake of these metals below pH 6 is almost equal which is supported by ion exchange capacity data (Table 3). However, in the pH range 6 to 8.5 the uptake order is $K^+ > Li^+ > Na^+$. In the pH range 8.5 to 11.2, Na^+ ions are more strongly adsorbed than Li^+ ions and beyond pH 11.2 again the uptake of Li^+ ions becomes higher than Na^+ ions. The two inflection points in all the curves show the bifunctional behaviour of the ion exchanger.

The specificity of inorganic ion exchangers for metal ions is greatly dependent on the nature of the material. Thus tin(IV) antimonate[10] and titanium(IV) antimonate[11] are selective for alkaline earths while zirconium(IV) antimonate[12] and tin(IV) selenite[13] for alkali metals. Tin(IV)-edta is found to be selective for alkaline earth metals when compared to alkali metals as it is evident from ion exchange capacity data. K_d values of some important metal ions on tin(IV)-edta in different solvent systems are given in Tables 4 and 5. The adsorption sequence for some metal ions in water is found to be $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$: $Pb^{2+} > Mn^{2+} > Fe^{3+} > Ni^{2+}$: $Sm^{3+} > Pr^{3+} > Ce^{4+}$. It is clear from Table 4 that K_d values decreases gradually with the increase in nitric acid concentration as expected. A marked difference in K_d values of metal ions has been observed in perchloric acid and sodium perchlorate system. K_d values for bivalent ions in general, are found to be higher then ter and quadrivalent ions. The sequence of adsorption in 0.01 mol dm^{-3} perchloric acid is found to be $Hg^{2+} > Pb^{2+} > Cu^{2+} > Cd^{2+} > Ni^{2+} > Mn^{2+} > Co^{2+} > Al^{3+}$: $Sm^{3+} > Ho^{3+} > Dy^{3+} > Pr^{3+} > Ce^{4+} > UO_2^{2+}$. K_d values reveal the possibility of numerous separations of metal ions. Some of the binary separations achieved on the columns of tin(IV)-edta are listed in Table 6.

The usual interferences which are encountered in the determination of Mg are Fe, Cu, Co, Ni, Zn, Pb, *etc*, and are frequently removed by precipitation with diethyldithiocarbamate.[14] However, separation of Mg from these metal ions using this ion exchange material offers additional advantages being a simple and inexpensive method.

The X-ray analysis of sample 4 in H^+ form indicates amorphous nature of the material.

The infrared absorption spectrum of tin(IV)-edta in H^+ form when compared with infrared spectrum of disodium salt of EDTA, tin(IV) selenite and those explained by Sawyer and Paulsen[15] yield the following interpretations.

IR spectrum of disodium salt of EDTA shows four important peaks. The different peaks at 1630 cm^{-1}, 1390 cm^{-1}, 1360 cm^{-1} to 1310 cm^{-1}, and 1000 cm^{-1} to 900 cm^{-1} are due to -COO- groups. Infrared spectrum of tin(IV)-edta shows three strong peaks. A broad peak in the 3400—3000 cm^{-1} region represents the interstitial water and OH groups. Another strong peak in the 1700—1500 cm^{-1} region with a maximum at 1650 cm^{-1} may be due to interstitial water molecules. The peaks appearing at 1380, 1500, and 3000 cm^{-1} are also the standard peaks of nujol mull.

The thermogram of tin(IV)-edta sample 4 in Mg^{2+} form (Fig. 3) shows that there is continuous loss in weight upto 170 °C which can be attributed to loss of water molecules. If temperature is raised further, decomposition of the material starts which continues upto 550 °C. This conclusion is also confirmed by the ion exchange capacity data (Table 2). The exchange capacity decreases gradually as the drying temperature is increased. The capacity of the exchanger however completely lost beyond 500 °C.

The authors thank Prof. W. Rahman for research facilities. Thanks also due to C. S. I. R. (INDIA) for financial assistance to one of us (R. A. K. Rao).

A Comparative Study on the Synthesis and Ion-exchange Behaviour of Tin(IV) Salts of Different Heteropolyanions. Separations of Metal Ions on Tin(IV) Boratomolybdate Columns

Syed Ashfaq Nabi,* Zia Mahmood Siddiqi, and Wajahat Umar Farooqi
Department of Chemistry, Aligarh Muslim, University, Aligarh-202001, India
(Received October 9, 1981)

Various samples of tin(IV) boratomolybdate, tin(IV) boratotungstate, tin(IV) boratophosphate, tin(IV) arsenatoborate and tin(IV) boratosulfate has been synthesized by mixing aqueous solutions of appropriate reagents in different volume ratios at pH=1. One of the samples of tin(IV) boratomolybdate has been studied in greater detail for its ion-exchange capacity, thermal and chemical stability, pH-titration and chemical composition. A comparison of few properties of tin(IV) boratomolybdate has been made with other tin(IV) salts of different heteropolyanions. Distribution coefficients of 24 metal ions on tin(IV) boratomolybdate in water, nitric acid, water–dioxane, and nitric acid–dioxane systems have been determined. The effect of temperature on the sorption behaviour of metal ions has also been studied. It has been found that K_d value increases in general with the increase in temperature. The differential selectivity of metal ions on tin(IV) boratomolybdate reveals that tin(IV) boratomolybdate is a useful ion exchanger for the separation of metal ions. As a result ten important separations have been quantitatively achieved on the columns of this ion-exchange material.

The wide spread applications of synthetic inorganic ion-exchangers has now been well established.[1] Recently they have been found useful in portable renal dialysis units. Simple salts of metals as ion-exchanger have been much studied as compared to double salts. Earlier studies[2-4] show that mixed salts usually exhibit higher ion-exchange capacities and better thermal and chemical stability as compared to simple salts. A literature survey shows that a number of tin(IV) salts[5-8] have been studied as ion-exchangers. But no systematic comparison has been made on the ion exchange properties of these materials. In the present paper we therefore describe a comparative study on the synthesis and ion-exchange behaviour of a new series of tin(IV) ion-exchangers based on boron. Tin(IV) boratomolybdate have been chosen for detailed study owing to its high exchange capacity and better chemical stability.

Experimental

Reagents. Tin(IV) chloride pentahydrate (Reachim U.S.S.R.), potassium tetraborate (B. D. H.), ammonium molybdate (B. D. H.) sodium tungstate (B. D. H.); sodium arsenate (B. D. H.); sodium sulfate (E. Merck) and potassium dihydrogenphosphate (E. Merck) were used. Other chemicals were of analytical reagent grade.

Apparatus. The spectrophotometry and pH-measurements were performed using Bausch & Lomb Spectronic 20 Colorimeter, Elico LI-10 pH-meter respectively. A temperature controlled shaker "SICO" was used for shaking.

Synthesis. Samples of tin(IV) boratophosphate, tin(IV) boratosulfate, tin(IV) arsenatoborate, tin(IV) boratotungstate, tin(IV) boratomolybdate were prepared by mixing aqueous solutions of appropriate reagents under the conditions indicated in Table 1a—e. The desired pH was adjusted by adding either dilute hydrochloric acid solution or dilute sodium hydroxide solution. The precipitate so formed was allowed to settle down for 24 h washed several times with demineralized water (DMW) and filtered under suction. It was then dried at 40 °C in an oven. The dried material was then treated with DMW resulting cracking of the substance into smaller particles with slight evolution of heat. To convert the sample in hydrogen ion form, the material was kept for 48 h in 1 mol dm^{-3} nitric acid solutions. It was then washed with DMW to remove excess acid. Tin(IV) boratomolybdate sample (TBM_1) has been chosen for detailed study owing to its higher ion-exchange capacity and higher chemical stability as compared to other materials.

Ion-exchange Capacity. To determine the ion-exchange capacity of the sample, 0.5 g of the ion-exchanger material in hydrogen form was placed in column with glass wool support. The hydrogen ions were eluted with 1 mol dm^{-3} solution of different salt (Table 2). The hydrogen ions released from the exchanger were then determined by titrating the effluent with standard solution of sodium hydroxide. The ion-exchange capacities for Cu(II), Al(III), and Fe(III) were determined as follows.

10 cm^3 solution of the metal ion of known strength was passed through 1 g exchanger in hydrogen form with a flow rate of 1.2 cm^3 min^{-1}. The effluent was passed through the column several times to ensure replacement of maximum hydrogen ion of the exchanger. The column was then

washed with water till the effluent free from metal ions. The whole effluent is titrated with standard EDTA solution. The amount of metal ions adsorbed by the exchanger was calculated. The ion-exchange capacity for different metal ions is reported in Table 2.

Thermal Treatment. To examine the effect of drying temperature on the ion-exchange capacity the materials were heated at different temperatures in Muffle Furnace for 1 h. The ion-exchange capacity for potassium ion at different drying temperatures is given in Table 3.

pH-titration. pH-titrations for sample TBM_1 was performed by the earlier method[9] using sodium chloride–sodium hydroxide system. The pH titration curve is shown in Fig. 1.

Chemical Stability. A 0.5 g of the exchanger material (sample TBM_1) was equilibrated with 50 cm^3 of the solution of analytical interest at room temperature (25±2 °C) and kept for 24 h with occasional shaking. Tin and molybdenum released in the solution were determined spectrophotometrically using hematoxylin[10] and thiocyanate[11] as colouring reagents respectively. The amount of boron released in the solvent was determined titrimetrically[12] using sodium hydroxide as titrant. The results are summarized in Table 4.

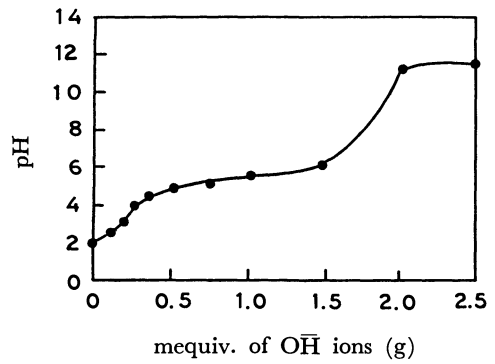

Fig. 1. pH titration curve of tin(IV) boratomolybdate.

Chemical Composition. For the determination of chemical composition of sample TBM_1, 0.2 g of exchanger was dissolved in hot concentrated hydrochloric acid. Then the solution was diluted to 100 cm^3 with water. Tin and molybdenum were determined spectrophotometrically[10,11] while boron is determined titrimetrically.[12] The mole ratio of Sn, B, and Mo is found to 1:1:1.

Distribution Coefficient. The distribution coefficient (K_d) for 24 metal ions in different solution system were determined. 0.5 g of exchanger in hydrogen form (150—200 mesh size) was treated with 50 cm^3 of cation solution in 250 cm^3 Erlenmeyer flask. The mixture was then shaken for 6 h at 25±2 °C in a shaker incubator. The ionic strengths of various metal ion solutions lies between 0.0006 to 0.0057. The amount of cation left in the solution was then determined by titrating against the standard solution of EDTA. The K_d values were calculated according to the formula,

$$K_d = \frac{I-F}{F \times W} \times 50,$$

where F is the volume of EDTA consumed by the solution after equilibrium, I is the volume of EDTA consumed by the original solution (*i.e.* before equilibrium) and W is the weight of ion exchanger in g.

The results of K_d values are summarized in Table 5. The adsorption of metal ions was also studied at different temperatures. The effect of temperature on K_d (values) are described in Table 6 and in Fig. 2.

Quantitative Separations. For separation purpose the column was prepared using 2.0 g of exchanger (150—200

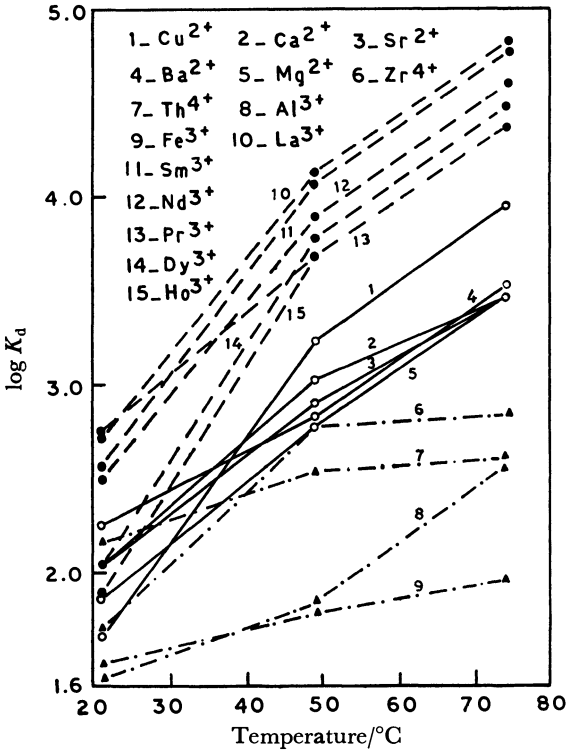

Fig. 2. Plot log K_d *vs.* temperature.

mesh size) in hydrogen form in a glass tube of internal diameter 0.6 cm in each case. A mixture of metal ion solution was applied on the column. The solution was allowed to flowdown very slowly through the column as a result metal ions are adsorbed at the top of exchanger bed forming initial zone. The column was washed with water. The metal ions were then eluted by appropriate eluting reagent. The flow rate of effluent was maintained 1.4 cm^3 min^{-1} throughout the elution process. The effluent was collected in 10 cm^3 fractions and titrated with 0.002 mol dm^{-3} EDTA solution. Ten important separations of metal ions have been quantitatively achieved. The elution curves for each set of separation are shown in Figs. 3(a)—(c).

Results and Discussion

Tables 1a to 1e describe the preprations of samples of tin(IV) salts of different heteropolyanions under identical conditions. Ion exchange capacity of each samples has been compared with single salts prepared under the same conditions. It has been observed that capacity of double salts is higher than the single salts with the exception of tin(IV) boratophosphate and tin(IV) arsenatoborate. An interesting feature is emerged when tin(IV) boratosulfate is compared with tin(IV) sulfate, the latter has a negligible ion-exchange capacity (0.17 mequiv./dry g). Moreover the capacity is significantly increased for sample TBS_1 (0.55 mequiv./dry g). It is important to note that mixing volume ratio of different components affect the ion-exchange capacity of the final product. Also in the case of tin(IV) boratomolybdate the exchange capacity becomes almost two times as high as the exchange capacity of single salts namely tin(IV) molybdate and tin(IV) borate prepared under the same conditions. The order of ion-exchange capacity (for K^+ ions) for tin(IV) salts of different heteropolyanions is as follows:

> Tin(IV) boratotungstate (TBT_2)>Tin(IV) boratomolybdate (TBM_1)>Tin(IV) boratophosphate(TBP_2) >Tin(IV) arsenatoborate (TBA_1, TBA_2)> Tin(IV) boratosulfate (TBS_1).

Results of Table 4 show that tin(IV) boratomolybdate is quite stable in water, hydrochloric acid, perchloric acid, nitric acid, sulfuric acid, and in common salts of moderate concentrations. This material appreciably dissolves in 0.01 mol dm^{-3} solutions of LiOH, NaOH, and KOH on prolonged shaking. The material is apparently stable in various common organic solvents like acetone, dioxane, ethanol, acetaldehyde, formic acid, acetic acid, tartaric acid, and citric acid. Tin(IV) boratomolybdate is relatively more chemically stable than tin(IV) molybdate prepared earlier.[13,14]

Results of Table 2 show that the exchange capacity of all the compounds increases with the decrease in hydrated radii. The ion exchange capacity followed the order $K^+>Na^+>Li^+$ for alkali metals. However, for alkaline earths the exchange capacity remains almost the same as hydrated radii do not vary appreciably.

It is apparent from Table 3 that tin(IV) boratophosphate, tin(IV) boratosulfate, tin(IV) boratomolybdate, and tin(IV) boratotungstate loose ion exchange capacity as the drying temperature of the material is subsequently increased. The thermal stability of these materials can be represented in the order TBS_4>

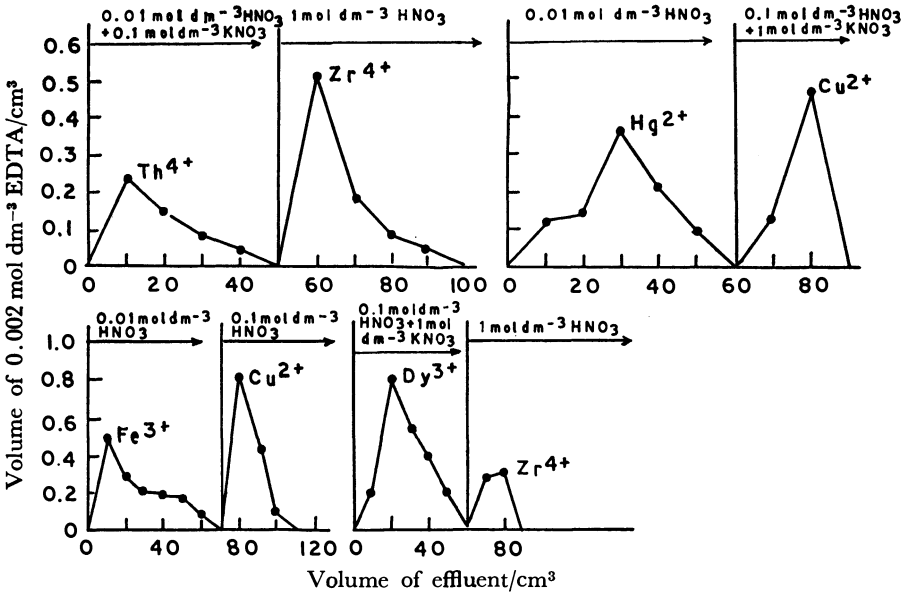

Fig. 3(a). Separation of Th^{4+}-Zr^{4+}, Hg^{2+}-Cu^{2+}, Fe^{3+}-Cu^{2+}, and Dy^{3+}-Zr^{4+}.

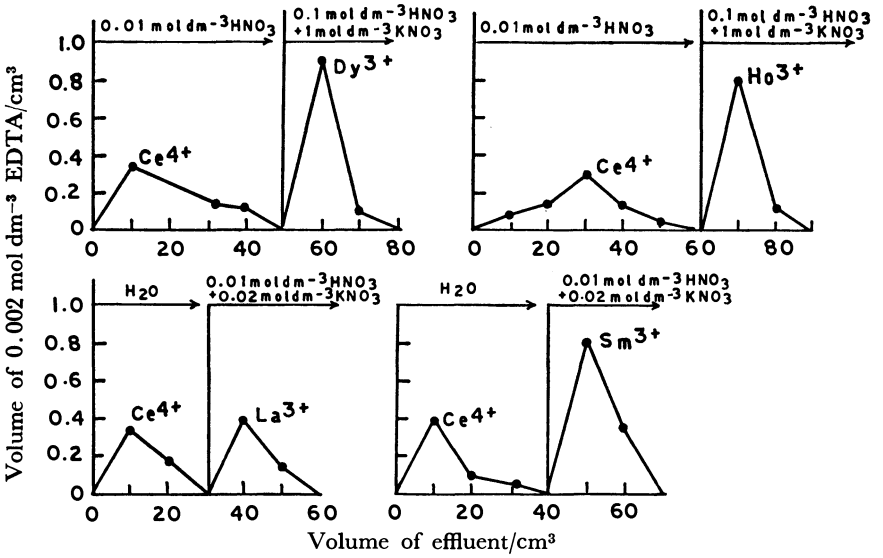

Fig. 3(b). Separation of Ce^{4+}-Dy^{3+}, Ce^{4+}-Ho^{3+}, Ce^{4+}-La^{3+}, and Ce^{4+}-Sm^{3+}.

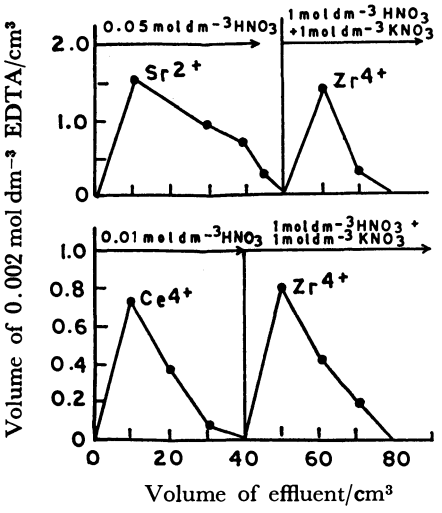

Fig. 3(c). Separation of Sr^{2+}-Zr^{4+} and Ce^{4+}-Zr^{4+}.

$TBP_2 > TBM_1 > TBT_2$. It is observed however, in the case of tin(IV) boratosulfate, the increasing temperature does not affect the capacity significantly. Tin(IV) boratotungstate and tin(IV)boratomolybdate lost their exchange capacity more than 70% when their drying temperature increased to 100 °C. The capacity falls to a negligible value when the drying temperature is raised upto 500 °C (0.08 mequiv./dry g for tin(IV) boratomolybdate and 0.14 mequiv./dry g for tin(IV) boratotungstate). This may be due to conversion of material into their oxides as is also indicated by their colors at these temperatures. Tin(IV) boratotungstate is more thermally stable than tin(IV) tungstate[15] and also tin(IV) boratomolybdate is more stable than tin(IV) molybdate.[13] Tin(IV) boratosulfate and tin(IV) boratophosphate retain their exchange capacity to a greater extent. The capacity of boratosulfate remains almost the same up to 300 °C. Tin(IV) boratophosphate and tin(IV) boratosul-

fate can be conveniently used as ion exchangers even when the drying temperature is raised up to 500 °C. However, when these materials (dried at 40 °C) are heated at 95±5 °C in the presence of water no loss in ion-exchange capacity is observed in all the cases.

pH titration curve (Fig. 1) for NaCl–NaOH system indicates two breaks in the curve showing thereby that tin(IV) boratomolybdate behaves as a bifunctional weak cation exchanger.

It is clear from Table 5 that values of distribution coefficients vary with the composition and nature of solvent system. The K_d values of metal ions are decreasing in general with the increase in dioxane content of the medium. The increased amount of dioxane in dioxane–water system decreases the dielectric constant and thus decreases the K_d value. This is probably due to the fact that the ions of an electrolyte are more ionized in a solvent of relatively high dielectric constant. However, a definite conclusion can only be drawn in the presence of other experimental data. An increase in the K_d value for most metal ions are also observed as one goes from pure dilute acid (0.01 mol dm^{-3}) to a mixture of dioxane+0.01 mol dm^{-3} HNO_3 in 1:1 volume ratio and the increase in the pH of the solvent causes higher adsorption of metal ions as expected.

A study of the adsorption of metal ions on tin(IV) boratomolybdate at different temperatures reveals that extent of adsorption increases with the increase in temperature (Table 6). Thus K_d values are found to be highest in 75±1 °C. From Fig. 2 it can be concluded that the K_d value for quadrivalent and rare earth metal ions increases sharply below 50 °C and then slowly after this temperature.

The sequence of K_d values of some important metal ions in different solvent systems and at different temperatures on tin(IV) boratomolybdate can be shown as follows:

Water	$Th^{4+}>Zr^{4+}>La^{3+}>Nd^{3+}>Pr^{3+}>Sm^{3+}>Ho^{3+}>Ce^{4+}>Dy^{3+}$
0.01 mol dm^{-3} HNO_3	$Zr^{4+}>Sm^{3+}>La^{3+}>Pr^{3+}>Th^{4+}>Nd^{3+}>Ce^{4+}>Dy^{3+}>Ho^{3+}$
Dioxane:Water (1:4)	$Zr^{4+}>Th^{4+}>La^{3+}>Nd^{3+}>Pr^{3+}>Ho^{3+}>Sm^{3+}>Dy^{3+}>Ce^{4+}$
Dioxane:Water (4:1)	$Th^{4+}>Zr^{4+}>Sm^{3+}>Ce^{4+}>Pr^{3+}>Nd^{3+}>La^{3+}>Ho^{3+}>Dy^{3+}$
Dioxane:0.01 mol dm^{-3} HNO_3 (1:1)	$Zr^{4+}>Th^{4+}>Pr^{3+}>Sm^{3+}>Nd^{3+}>Ho^{3+}>Dy^{3+}>La^{3+}>Ce^{4+}$
0.005 mol dm^{-3} HNO_3 (22±1 °C)	$Pr^{3+}>La^{3+}>Nd^{3+}>Sm^{3+}>Th^{4+}>Ce^{4+}>Dy^{3+}>Ho^{3+}>Zr^{4+}$
0.005 mol dm^{-3} HNO_3 (50±1 °C)	$La^{3+}>Sm^{3+}>Nd^{3+}>Dy^{3+}>Ho^{3+}=Pr^{3+}>Zr^{4+}>Th^{4+}>Ce^{4+}$
0.005 mol dm^{-3} HNO_3 (75±1 °C)	$La^{3+}>Sm^{3+}>Nd^{3+}>Dy^{3+}>Ho^{3+}=Pr^{3+}>Zr^{4+}>Ce^{4+}>Th^{4+}$

The sorption studies on tin(IV) boratomolybdate for different metal ions reveal many important separations. As a result ten binary separations of analytical and industrial importance have been achieved successfully on small columns of tin(IV) boratomolybdate (Figs. 3(a)—3(c)). Separation of iron from copper may be utilized in the removal of iron impurities from chalcopyrite ($CuFeS_2$) and Bornite (Cu_5FeS_4) ores.

In the determination of thorium as oxalate good separation from zirconium can not be achieved because of the possible hydration of zirconium.[16] Zirconium also seriously interferes probably in all the spectrophotometric determination of thorium by various coloring reagents such as thoron, dinitrosochromotropic acid, quercetin, SPADN, and Di SNADNS.[16] Therefore columns of tin(IV) boratomolybdate can be conveniently used for separating zirconium impurities prior to the determination of thorium. Tin(IV) boratomolybdate can also be utilized for the recovery of zirconium free thorium from thorianite.

The authors are thankful to Prof. W. Rahman, Head, Department of Chemistry for providing research facilities. C. S. I. R., New Delhi is also acknowledged for financial assistance to one of us (ZMS).

A Convenient Synthesis of Linear 2-Methylpyranochromones

Vinod Kumar AHLUWALIA,* Anjula JAIN, and Ranjna GUPTA
Department of Chemistry, University of Delhi, Delhi-110007, India
(Received November 5, 1981)

A convenient synthesis of linear 2-methylpyranochromones, *viz.*, spatheliachromen(5-hydroxy-2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-6-one), *O*-methylspatheliachromen (5-methoxy-2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-6-one) (**8**) and *O*-methylallopteroxylin (5-methoxy-2,8,8-trimethyl-4*H*,8*H*-benzo[1,2-*b*:3,4-*b'*]dipyran-4-one) is described by blocking the eighth position of the corresponding 7-propargyl ether derivative 7-(1,1-dimethyl-2-propynyloxy)-8-iodo-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one with iodine followed by thermal cyclization. The linear pyranochromones 2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-6-one and **8** are also synthesized starting with the easily available appropriate 3,4-dihydro-2,2-dimethyl-2*H*-1-benzopyran-7-ols following the steps of Claisen condensation with ethyl acetate, cyclization with ethanolic sulfuric acid followed by dehydrogenation with NBS.

The occurrence[1] of 2-methyl linear pyranochromones, *viz.*, spatheliachromen prompted us to devise a convenient method for their synthesis. A few syntheses of these chromones are known[2,3] but these involve a number of steps and the overall yield is poor.

Attempts have now been made for the synthesis of linear pyranochromones by using our earlier finding[4] that if position-8 of a coumarin ring is blocked by an iodo group, the cyclization of the corresponding 7-propargyl ethers of 2*H*-1-benzopyran-2-ones (coumarins) on heating with *N,N*-dimethylaniline gives rise to linear pyranocoumarins, cyclization taking place at position 6 with simultaneous removal of iodine. As a test case 7-hydroxy-2-methyl-4*H*-1-benzopyran-4-one[5] (**1**) was used. Its iodination with iodine and periodic acid gave 7-hydroxy-8-iodo-2-methyl-4*H*-1-benzopyran-4-one[6] (**2**), which on propargylation with 3-chloro-3-methyl-1-butyne gave 7-(1,1-dimethyl-2-propynyloxy)-8-iodo-2-methyl-4*H*-1-benzopyran-4-one (**3**). Compound **3** on heating with *N,N*-dimethylaniline gave a mixture of two products which were separated by preparative TLC. The lower band on elution gave the linear product *i.e.* 2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-6-one (**4**). Its structure was assigned on the basis of ^{1}H NMR spectral data which showed besides other signals, two singlets at δ 6.65 and 7.65 for the two para aromatic protons. The upper band on elution gave the angular pyranochromone, *viz.*, 2,8,8-trimethyl-4*H*,8*H*-benzo[1,2-*b*:3,4-*b'*]dipyran-4-one (**5**). Its structure was assigned on the basis of its ^{1}H NMR spectral data which showed two doublets at δ 6.89 and 8.00 (J=10 Hz each) for two ortho-coupled aromatic protons. It was also found to be identical (mp, mixed mp, superimposed IR) with an authentic sample[1] prepared by cyclization of 7-(1,1-dimethyl-2-propynyloxy)-2-methyl-4*H*-1-benzopyran-4-one (**6**).

Using the above method, spatheliachromen (**7**) and *O*-methylspatheliachromen (**8**) have now been synthesized starting from 7-(1,1-dimethyl-2-propynyloxy)-8-iodo-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**9**), which was prepared as follows: 2-Hydroxy-4-benzyloxy-6-methoxyacetophenone[7] on Claisen condensation with ethyl acetate in the presence of pulverized sodium followed by the cyclodehydration with concd sulfuric acid in ethanol gave 7-benzyloxy-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**10**). Its catalytic debenzylation afforded 7-hydroxy-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**11**). Iodination of **11** with iodine and periodic acid gave 7-hydroxy-8-iodo-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**12**), which on propargylation afforded **9**. Its thermal cyclization by heating with *N,N*-dimethylaniline gave a product which showed the absence of iodine indicating that iodine was knocked out in the above reaction. It was found to be a mixture of three products. The slowest moving band on elution gave a product which gave a green iron(III) chloride reaction indicating that the 5-hydroxyl was free. It gave positive Gibbs' test, indicating that the para position to the hydroxyl group was free. On the basis of this, it was assigned the linear chromone structure, *viz.*, 5-hydroxy-2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-*b*:5,4-*b'*]dipyran-6-one (**7**). It was identical in mp and ^{1}H NMR spectral data with spatheliachromen isolated from *Spathelia sorbifolia*.[1] The middle band on elution gave a product, which was identical with the product obtained by the methylation of **7**. On the basis of this, it was assigned the structure *O*-methylspatheliachromen (**8**). The upper band on elution gave a product which gave a negative iron(III) chloride reaction and Gibbs' test. On the basis of this it was assigned the angular chromone structure, *viz.*, 5-methoxy-2,8,8-trimethyl-4*H*,8*H*-benzo-[1,2-*b*:3,4-*b'*]dipyran-4-one (**13**). It was found to be identical with *O*-methylallopteroxylin isolated from *Ptaeroxylon obliquum*.[8]

In another convenient approach 6-acetyl-3,4-dihydro-2,2-dimethyl-2*H*-1-benzopyran-7-ol (**17**) (obtained[9] in one step by the reaction of isoprene with 2,4-dihydroxyacetophenone) on Claisen condensation with ethyl acetate in the presence of pulverized sodium gave 6-acetoacetyl-3,4-dihydro-2,2-dimethyl-2*H*-1-benzopyran-7-ol (**18**). Its cyclization with ethanolic sulfuric acid afforded 2,2,8-trimethyl-3,4-dihydro-2*H*,6*H*-benzo-[1,2-*b*:5,4-*b'*]dipyran-6-one (**19**). Dehydrogenation of **19** with NBS gave the required linear pyranochromone **4**, identical in all respects with the product obtained above.

Similarly 6-acetyl-3,4-dihydro-5-methoxy-2,2-dimethyl-2*H*-1-benzopyran-7-ol (**20**) (obtained[9] by the reaction of 2,4-dihydroxy-6-methoxyacetophenone with isoprene) on Claisen condensation with ethyl acetate in the presence of pulverized sodium gave 6-acetoacetyl-3,4-dihydro-5-methoxy-2,2-dimethyl-2*H*-1-benzopyran-7-ol (**21**). Its cyclization with ethanolic sul-

Discussion

A synthesis of linear pyranochromones lacking an oxygen function at 5-position has not previously been available. Blocking the more reactive 8-position by iodine represents the potential route for achieving the same. In the preparation of linear pyranochromones the thermal cyclization of **3** and **9** gives a mixture of the linear and the angular pyranochromones. It shows that the reaction is nonregiospecific, as compared to the thermal cyclization in coumarins[4] which is regiospecific. A possible explanation for the nonregiospecificity in the case of chromones is due to more fixation of double bonds as compared to that of coumarins. It is believed that in this case, the loss of iodine and its cyclization are competing reactions. All attempts to make the above cyclization regiospecific, using a variety of conditions, are unsuccessful.

The alternate route employed for the synthesis of linear pyranochromones involving the use of the corresponding 3,4-dihydro-2*H*,6*H*-benzo[1,2-*b*:5,4-*b*']-dipyran-6-ones (**17** and **20**) is more convenient.

Experimental

Melting points are uncorrected. The NMR spectra were recorded on Perkin Elmer R-32 instrument with TMS as an internal standard.

*2,2,8-Trimethyl-2*H,*6*H-*benzo*[*1,2*-b:*5,4*-b']*dipyran-6-one* (**4**) *1-(4-Benzyloxy-2-hydroxyphenyl)-1,3-butanedione* (**14**): A solution of 4-benzyloxy-2-hydroxyacetophenone[8] (1 g, 4.1 mmol) in dry ethyl acetate (5 ml) was added to pulverized sodium (0.5 g), the mixture being shaken and cooled. After the initial vigorous reaction had subsided, the reaction mixture was heated in a boiling water bath for 3 h. The mixture was cooled, diluted with water and extracted with ether to remove excess of ethyl acetate. The clear alkaline solution was acidified in cold with dilute acetic acid when yellow solid separated. It crystallized from benzene–petroleum ether as shining needles of **14** (0.6 g, 1.75 mmol) (46%) mp 120—121 °C. Found: C, 71.8; H, 5.7%. Calcd for $C_{17}H_{16}O_4$: C, 71.9; H, 5.6%. ^{1}H NMR($CDCl_3$) δ=2.12 (s, CH_3 of enol); 2.30(s, CH_3 of keto); 4.02(s, $-\underset{\underset{O}{\|}}{C}-\underline{CH_2}-\underset{\underset{O}{\|}}{C}-$ of keto) 5.10(s, 2H, $-O\underline{CH_2}C_6H_5$); 6.08(s, $-CH=\underset{\underset{OH}{|}}{C}-$ of enol); 6.55(m, 2H, H3 and H5); 7.45(s, 5H, $-OCH_2C_6\underline{H_5}$); 7.60 (d, J=10 Hz, 1H, H6); 12.50(s, 1H, –OH exchangeable with D_2O). The integration of the spectrum showed that the ratio of keto-enol forms is 1:2.

*7-Benzyloxy-2-methyl-4*H-*1-benzopyran-4-one* (**15**): **14** (0.2 g, 0.64 mmol) in absolute ethanol (15 ml) containing concd sulfuric acid (few drops) was refluxed for 20 min on a water bath. The mixture was cooled, diluted with water (30 ml) and rendered alkaline by adding few drops of sodium hydroxide solution (5%). The separated solid was filtered and crystallized from methanol as cream-colored crystals of **15** (0.15 g; 0.67 mmol) (88%) mp 115—116 °C. Found: C, 76.8; H, 5.3%. Calcd for $C_{17}H_{14}O_3$: C, 76.7; H, 5.3%. ^{1}H NMR($CDCl_3$) δ=2.29(s, 3H, CH_3); 5.05(s, 2H,

$-OCH_2C_6H_5$); 6.02(s, 1H, H3); 6.90(m, 2H, H6 and H8); 7.25(s, 5H, $-OCH_2C_6H_5$); 7.95(d, J=10 Hz, 1H, H5).

7-Hydroxy-2-methyl-4H-1-benzopyran-4-one (1): Palladium charcoal (0.5 g, 5%) in ethyl acetate (30 ml) was saturated with hydrogen gas with stirring. A solution of the above chromone **15** (0.5 g) in ethyl acetate (40 ml) was then added and hydrogenation continued till the rapid absorption ceased. The reaction mixture was freed from catalyst by filtration and solvent distilled to give required product **1** (0.2 g; 1.14 mmol) (60.6%) mp 254—255 °C (lit,[5] 254—255 °C).

7-Hydroxy-8-iodo-2-methyl-4H-1-benzopyran-4-one (2): It was prepared following the method described in literature.[6]

7-(1,1-Dimethyl-2-propynyloxy)-8-iodo-2-methyl-4H-1-benzopyran-4-one (3): A solution of **2** (1 g, 3.90 mmol) in dry acetone (175 ml) was refluxed with 3-chloro-3-methyl-1-butyne (4 ml, 39.2 mmol) in the presence of anhydrous potassium carbonate (3 g) and anhydrous potassium iodide (1.9 g) for 24 h. The solvent was distilled off and the residue treated with ice. The separated solid was filtered, washed with a dilute solution of sodium carbonate and water and crystallized from benzene–petroleum ether to give **3** (0.65 g, 2.14 mmol) (54%) as colorless needles mp 144—145 °C. Found: C, 56.1; H, 4.2%. Calcd for $C_{15}H_{13}O_3I$: C, 56.0; H, 4.0%. ^{1}H NMR($CDCl_3$) δ=1.75(s, 6H, $C(CH_3)_2$); 2.40 (s, 3H, CH_3); 2.62(s, 1H, C≡CH); 6.05(s, 1H, H3); 7.54 (d, J=10 Hz, 1H, H6); 8.00(d, J=10 Hz, 1H, H5).

2,2,8-Trimethyl-2H,6H-benzo[1,2-b:5,4-b']dipyran-6-one (4): The above 1,1-dimethyl-2-propynyl ether (**3**) (0.5 g, 1.65 mmol), was refluxed with *N,N*-dimethylaniline (3 ml) for 12 h. The cooled reaction mixture was poured over ice cold hydrochloric acid. The solution was extracted thrice with ethyl acetate (150 ml); washed with 5% HCl, 5% NaOH, and finally with water and dried (Na_2SO_4). Distillation of ethyl acetate yielded a mixture of two products, which were separated by preparative TLC (benzene–acetone, 9:1). Elution of lower band with ether yielded **4** which crystallized from benzene–petroleum ether to give shining white crystals (0.15 g, 0.61 mmol) (38%) mp 163—164 °C. Found: C, 74.5; H, 5.8%. Calcd for $C_{15}H_{14}O_3$: C, 74.3; H, 5.79%. ^{1}H NMR($CDCl_3$) δ=1.45(s, 6H, $C(CH_3)_2$); 2.35(s, 3H, CH_3); 5.65(d, J=10 Hz, 1H, H4); 6.00(s, 1H, H7); 6.35(d, J=10 Hz, 1H, H3); 6.65(s, 1H, H10); 7.65 (s, 1H, H5). The compound **4** is identical (mp, mixed mp, superimposed IR) with the sample obtained below.

The upper band on elution with ether gave a product which was crystallized from benzene–petroleum ether to give colorless needles of 2,8,8-trimethyl-4*H*,8*H*-benzo[1,2-*b*:3,4-*b'*]dipyran-4-one (**5**) (0.25 g, 1.0 mmol) (64%) mp 130—131 °C (lit,[10] mp 130—132 °C). Found: C, 74.2; H, 5.6%. Calcd for $C_{15}H_{14}O_3$: C, 74.3; H, 5.79%. ^{1}H NMR($CDCl_3$) δ=1.45(s, 6H, $C(CH_3)_2$); 2.35(s, 3H, CH_3); 5.70(d, J=10 Hz, 1H, H10); 6.05(s, 1H, H3); 6.89(m, 2H, H6 and H9); 8.00(d, J=10 Hz, 1H, H5).

2,2,8-Trimethyl-2H,6H-benzo[1,2-b:5,4-b']dipyran-6-one (4). *6-Acetoacetyl-3,4-dihydro-2,2-dimethyl-2H-1-benzopyran-7-ol (18)*: 6-Acetyl-3,4-dihydro-2,2-dimethyl-2*H*-1-benzopyran-7-ol[9] (**17**), (1 g, 4.5 mmol) dissolved in dry ethyl acetate (20 ml) was treated with pulverized sodium (0.5 g). The mixture was refluxed on a boiling water bath for 4 h, cooled and treated with crushed ice very slowly. The brownish alkaline layer was separated and extracted with ether to remove excess of ethyl acetate and unreacted ketone. Acidification of cold alkaline solution with dilute acetic acid (10%) gave a white solid. It was crystallized from benzene–petroleum ether (0.75 g, 2.8 mmol) (75%) mp 108—109 °C. Found: C, 68.5; H, 6.8%. Calcd for $C_{15}H_{18}O_4$: C, 68.7; H, 6.9%). ^{1}H NMR ($CDCl_3$) δ=1.31(s, 6H, $C(CH_3)_2$); 1.75 and 2.70 (t, each, J=7 Hz, 2H each, H3 and H4); 2.05(s, CH_3 of enol); 2.25(s, CH_3 of keto); 3.95(s, –C(=O)–C$\underline{H}_2$–C(=O)– of keto); 5.98(s, –CH=C(OH)– of enol); 6.28(s, 1H, H8); 7.30(s, 1H, H5); 13.8(s, 1H, –OH exchangeable with D_2O). The integration of the spectrum showed that the ratio of keto-enol is 1:2.

2,2,8-Trimethyl-3,4-dihydro-2H,6H-benzo[1,2-b:5,4-b']dipyran-6-one (19): The diketone **18** (0.2 g, 0.76 mmol) in absolute ethanol (25 ml) containing concd sulfuric acid (2 ml) was refluxed for 2 h on a boiling water bath. The mixture was cooled, diluted with water (25 ml) and rendered alkaline with aq sodium hydroxide. The separated solid was filtered and crystallized from ethanol as pale yellow needles of **19** (75%) (0.15 g, 0.61 mmol), mp 149—150 °C. Found: C, 74.3; H, 6.4%. Calcd for $C_{15}H_{16}O_3$: C, 74.4; H, 6.8%. ^{1}H NMR($CDCl_3$) δ=1.35(s, 6H, $C(CH_3)_2$) 1.82 and 2.85(t, each, J=7 Hz, 2H each, H3 and H4); 2.32(s, 3H, CH_3); 6.01(s, 1H, H7); 6.7(s, 1H, H10), 7.86(s, 1H, H5).

2,2,8-Trimethyl-2H,6H-benzo[1,2-b:5,4-b']dipyran-6-one (4): A solution of the chroman **19** (0.1 g, 0.41 mmol), *N*-bromosuccinimide (0.07 g) and benzoyl peroxide (0.008 g) in anhydrous carbon tetrachloride (10 ml) was refluxed for 6 h. The solution was filtered. The solvent was removed and the residue on column chromatography and elution with benzene gave **4** which crystallized from benzene–petroleum ether as light yellow needles (0.05 g, 0.20 mmol) (50%), mp and mixed mp, 163—164 °C.

5-Hydroxy-2,2,8-trimethyl-2H,6H-benzo[1,2-b:5,4-b']dipyran-6-one (spatheliachromen) (7). *1-(4-Benzyloxy-2-hydroxy-6-methoxyphenyl)-1,3-butanedione (16)*: A solution of 4-benzyloxy-2-hydroxy-6-methoxyacetophenone[7] (1 g, 3.70 mmol) in dry ethyl acetate (5 ml) was added to pulverized sodium (0.5 g). The mixture was shaken and cooled. After the initial vigorous reaction had subsided, the reaction mixture was heated in a boiling water bath for 3 h. The mixture was cooled, diluted with water and extracted with ether to remove an excess of ethyl acetate. The clear brownish alkaline solution was acidified in cold with dilute acetic acid when a yellow solid separated. It crystallized from benzene–petroleum ether as pale yellow shining needles of **16** (0.6 g, 1.89 mmol) (52%), mp 135—136 °C. Found: C, 68.9; H, 5.7%. Calcd for $C_{18}H_{18}O_5$: C, 68.7; H, 5.9%. ^{1}H NMR($CDCl_3$) δ=2.08(s, CH_3 of enol); 2.15(s, CH_3 of keto); 3.85(s, 3H, $-OCH_3$); 3.92(s, –C(=O)–C$\underline{H}_2$–C(=O)– of keto); 4.95(s, 2H, $-OC\underline{H}_2C_6H_5$); 5.85(s, –C$\underline{H}$=C(OH)– of enol); 6.00 and 6.15(d, each, J=2.5 Hz each, 2H, H3 and H5); 7.35 (s, 5H, $-OCH_2C_6\underline{H}_5$); 13.50(s, –OH at C-2 of enol, exchangeable with D_2O); 13.80(s, –OH at C-3 of keto, exchangeable with D_2O). The integration of the spectrum showed that the ratio of keto and enol forms is 3:1.

7-Benzyloxy-5-methoxy-2-methyl-4H-1-benzopyran-4-one (10): **16** (0.2 g, 0.63 mmol) in absolute ethanol (15 ml) containing concd sulfuric acid (few drops) were refluxed for 30 min on a water bath. The mixture was cooled, diluted with water (30 ml) and rendered alkaline by adding few drops of sodium hydroxide solution (5%). The separated solid was filtered and crystallized from methanol as colorless shining needles of **10** (0.16 g, 0.61 mmol) (80%) mp 90—91 °C. Found: C, 73.1; H, 5.3%. Calcd for $C_{18}H_{16}O_4$: C, 73.0; H, 5.4%. ^{1}H NMR($CDCl_3$) δ=2.20(s, 3H, CH_3); 3.85(s, 3H, $-OCH_3$); 5.00(s, 2H, $-OC\underline{H}_2C_6H_5$); 5.90(s, 1H, H3); 6.29 and 6.32 (d, each, J=2 Hz each, 1H each, H6

and H8); 7.25 (s, 5H, $-OCH_2C_6\underline{H}_5$).

*7-Hydroxy-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**11**)*: Palladium charcoal (0.5 g, 5%) in ethyl acetate (20 ml) was saturated with hydrogen gas with stirring. A solution of the above chromone **10** (0.5 g, 1.70 mmol) in ethyl acetate (40 ml) was then added and hydrogenation continued till the rapid absorption ceased. The reaction mixture was freed from catalyst by filtration and solvent distilled to give **11** (0.2 g, 0.98 mmol) (57%) mp 215—216 °C. Found: C, 64.2; H, 4.9%. Calcd for $C_{11}H_{10}O_4$: C, 64.0; H, 4.85%.

Its acetate (prepared by acetic anhydride–pyridine) melted at 114—115 °C. ^{1}H NMR($CDCl_3$) δ=2.32(s, 3H, CH_3); 2.38(s, 3H, $-COCH_3$); 3.95(s, 3H, $-OCH_3$); 6.08(s, 1H, H3); 6.55 and 6.82(d, each, J=2.5 Hz each, 1H each, H5 and H8).

*7-Hydroxy-8-iodo-6-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**12**)*: **11** (2 g, 6.80 mmol) was dissolved in a minimum amount of ethanol and to this solution iodine (1.20 g) and periodic acid (0.38 g in water) were added. The mixture was stirred for 2 h at a room-temperature and then diluted with water to give chromone **12** (2.5 g, 8.75 mmol) (89%). It crystallized from ethanol as light yellowish needles, mp 225—226 °C. Found: C, 46.5; H, 3.10%. Calcd for $C_{11}H_9O_4I$: C, 46.3; H, 3.15%.

Its acetate (prepared by acetic anhydride–pyridine) melted at 145—146 °C. ^{1}H NMR($CDCl_3$) δ=2.39(s, 3H, CH_3); 2.43(s, 3H, $-COCH_3$); 3.95(s, 3H, $-OCH_3$); 6.10(s, 1H, H3); 6.65(s, 1H, H6).

*7-(1,1-Dimethyl-2-propynyloxy)-8-iodo-5-methoxy-2-methyl-4*H*-1-benzopyran-4-one (**9**)*: A solution of **12** (1 g, 3.50 mmol) in dry acetone (200 ml) was refluxed with 3-chloro-2-methyl-1-butyne (4 ml, 38.9 mmol) in the presence of anhydrous potassium carbonate (3 g) and anhydrous potassium iodide (1.5 g) for 24 h. Working up of the reaction mixture yielded **9** (0.7 g, 1.99 mmol) (58.3%) which crystallized from benzene–petroleum ether as white needles mp 185—186 °C. Found: C, 54.8; H, 4.30%. Calcd for $C_{16}H_{15}O_4I$: C, 54.7; H, 4.27%. ^{1}H NMR($CDCl_3$) δ=1.80(s, 6H, $C(CH_3)_2$); 2.25(s, 3H, CH_3); 2.70(s, 1H, C≡CH); 3.90(s, 3H, $-OCH_3$); 6.00(s, 1H, H3); 7.29(s, 1H, H6).

*5-Hydroxy-2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-b:5,4-b']dipyran-6-one (Spatheliachromen) (**7**)*: The above 1,1-dimethyl-2-propynyl ether (**9**) (0.5 g, 0.7 mmol) was refluxed with *N,N*-dimethylaniline (3 ml) for 12 h. The cooled reaction mixture was poured over ice cold hydrochloric acid and worked up (as in case of **4**) to yield a mixture of three products, which were separated by preparative TLC. The slowest moving band on elution with ether gave **7**. It crystallized from ethyl acetate–petroleum ether to give colorless needles (0.100 g, 0.39 mmol) (27%), mp 139—140 °C (lit,[1] mp 139—140 °C). Found: C, 70.0; H, 5.60%. Calcd for $C_{15}H_{14}O_4$: C, 69.75; H, 5.50%. ^{1}H NMR($CDCl_3$) δ=1.45 (s, 6H, $C(CH_3)_2$); 2.32(s, 3H, CH_3) 5.60(d, J=10 Hz, 1H, H4); 6.01(s, 1H, H7); 6.28(s, 1H, H10); 6.71(d, J=10 Hz, 1H, H3); 13.06(s, 1H, –OH, exchangeable with D_2O).

The middle band on elution gave a product which was assigned the structure *O*-methylspatheliachromen (**8**). It crystallized from benzene–petroleum ether (0.150 g, 0.455 mmol) (37.5%), mp 121—122 °C (lit,[1] mp 120—122 °C). Found: C, 70.35; H, 6.0%. Calcd for $C_{16}H_{16}O_4$: C, 70.6; H, 5.9%). ^{1}H NMR($CDCl_3$) δ=1.47(s, 6H, $C(CH_3)_2$); 2.28 (s, 3H, CH_3); 3.90(s, 3H, $-OCH_3$); 5.71(d, J=10 Hz, 1H, H4); 6.00(s, 1H, H7); 6.58(s, 1H, H10) and 6.75(d, 1H, J=10 Hz, H3). The compound **8** was identical (mp, mixed mp, superimposed IR) with the sample obtained below.

The upper most band on elution with ether gave a solid product which was crystallized from benzene–petroleum ether to give *O*-methylallopteroxylin (**13**) (0.100 g; 0.39 mmol) (25%) mp 152—154 °C (lit,[8] mp 150—152 °C). Found: C, 70.35; H, 6.09%. Calcd for $C_{16}H_{16}O_4$: C, 70.6; H, 5.9%. ^{1}H NMR($CDCl_3$) δ=1.48(s, 6H, $C(CH_3)_2$); 2.29 (s, 3H, CH_3); 3.93(s, 3H, $-OCH_3$); 5.56(d, J=10 Hz, 1H, H10); 6.01(s, 1H, H3); 6.31(s, 1H, H6) and 6.71(d, J=10 Hz, 1H, H9).

*5-Methoxy-2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-b:5,4-b']dipyran-6-one (**8**).* *6-Acetoacetyl-3,4-dihydro-5-methoxy-2,2-dimethyl-2*H*-1-benzopyran-7-ol (**21**)*: 6-Acetyl-3,4-dihydro-5-methoxy-2,2-dimethyl-2*H*-1-benzopyran-7-ol[9] (**20**) (0.5 g, 2.0 mmol) dissolved in dry ethyl acetate (10 ml) was treated with pulverized sodium (0.25 g). The mixture was refluxed on a boiling water bath for 4 h. The reaction mixture was worked up as usual and the solid obtained was crystallized from benzene–petroleum ether as pale yellow needles (0.35 g, 1.2 mmol) (70%) mp 104—105 °C. Found: C, 60.2; H, 7.91%. Calcd for $C_{16}H_{20}O_5$: C, 60.23; H, 7.94%. ^{1}H NMR($CDCl_3$) δ=1.34(s, 6H, $C(CH_3)_2$), 1.75 and 2.7(t, each, J=7 Hz, each 2H, H3, and H4); 2.13(s, CH_3 of enol); 2.22(s, CH_3 of keto), 3.75(s, 3H, OCH_3), 4.02(s, $-\underset{\underset{O}{\|}}{C}-C\underline{H}-\underset{\underset{O}{\|}}{C}-$ of keto); 5.86(s, $-CH=C-$); 6.1(s, 1H, H8); 13.7(s, 1H, $-\underset{|}{\underset{OH}{}}$ –OH exchangeable with D_2O). The integration of the spectrum showed that the ratio of keto and enol is 1:2.

*5-Methoxy-2,2,8-trimethyl-3,4-dihydro-2*H*,6*H*-benzo[1,2-b:5,4-b']dipyran-6-one (**22**)*: The diketone **21** (0.2 g, 0.68 mmol) in ethanol (25 ml) containing concd sulfuric acid (2 ml) was refluxed for 2 h on a boiling water bath. Working up of the reaction mixture as in the case of **19** gave **22** which crystallized from ethanol as yellow needles (0.15 g, 0.55 mmol) (75%) mp 114—115 °C. Found: C, 70.54; H, 6.52%. Calcd for $C_{16}H_{18}O_4$: C, 70.59; H, 6.57%. ^{1}H NMR($CDCl_3$) δ=1.34(s, 6H, $C(CH_3)_2$), 1.78 and 2.76(t, each, J=7 Hz, 2H each H3, and H4), 2.23(s, 3H, CH_3); 3.81 (s, 3H, $-OCH_3$); 5.85(s, 1H, H7); 6.44(s, 1H, H10).

*5-Methoxy-2,2,8-trimethyl-2*H*,6*H*-benzo[1,2-b:5,4-b']dipyran-6-one (**8**)*: Dehydrogenation of **22** (0.1 g, 0.36 mmol) with NBS as in the case of **4** gave **8** (0.06 g, 0.22 mmol) (60%) mp 120—121 °C.

The Promotion Effect of Rare Earth Oxides on the Hydrogenation of Carbon Monoxide over Rh-Al_2O_3 Catalyst

Yusaku TAKITA,* Tamiyasu YOKO-O, Naoyoshi EGASHIRA, and Fumiaki HORI
Department of Environmental Chemistry and Engineering, Faculty of Engineering, Oita University, Dannohara, Oita 870-11

(Received June 1, 1981)

Synopsis. The addition of Dy_2O_3, Nd_2O_3, Yb_2O_3, La_2O_3, or Gd_2O_3 to the Rh–Al_2O_3 catalyst enhanced the activity of the hydrogenation of CO to methane. There was the linear relationship between the carbon skeleton propagation of the hydrocarbons formed and the basicity of the rare earth oxides.

Catalytic behaviors of rare earth oxides have been explored for many reactions and a wide variety of catalytic properties has been known.[1] Rare earth oxides are hardly reducible, La_2O_3 and Ce_2O_3, for example, remain three valent oxides after treatment in hydrogen at 673 K,[2] and Lu_2O_3 generates two valent ions even at 823—973 K by treatment in hydrogen.[3] These character is suited for the catalyst support which is applied under reducing atmosphere, there is, however, only a few paper investigated rare earth oxides as a catalyst support. It has been known that the incorporation of a small amount of La_2O_3 or Ce_2O_3 to supported Ni, Ni–Rh, and Ni–Ru catalysts brought about considerable increase of activity in the methanation of carbon oxides[4]. It was reported that the Rh carbonyl clusters dispersed on La_2O_3, Nd_2O_3, and CeO_2 were the effective catalysts for ethanol and C_2 oxygenated products formation as well as the catalysts dispersed on TiO_2, ZrO_2, and ThO_2.[5] However the effect of rare earth oxides other than these three oxides on the catalytic property of noble metals has remained obscure. The present paper dealt with the effect of rare earth oxides on the catalytic property of Rh–Al_2O_3 catalyst in the hydrogenation of carbon monoxide.

The results are given in Table 1 together with apparent activation energies. The products formed over these catalysts were similar to those over Rh–Al_2O_3 catalyst. The CO conversion at the temperatures below 573 K slightly decreased by the addition of Dy, Nd, Yb, or La, but it increased at above 613 K. The addition of Gd oxide and Ho oxide gave positive effect on the conversion only at 633 K. The addition of Pr oxide gave no significant effect on the CO conversion, while Tm or Eu oxide reduced the conversion over the temperature range examined.

The selectivity of CO_2 was raised by the addition of any rare earth oxide, especially high over the Nd and La containing catalysts.

Since water vapor should be formed during the reaction by the amount counterbalanced with the formation of hydrocarbons, there must be two possible reactions for CO_2 formation, *viz.*, water gas shift reaction and disproportionation of CO. The reaction were achieved in a good carbon balance (100±3%) at

Catalyst: Rh(1 wt%)–rare earth oxide(5%)–Al_2O_3, 1.50 g; reactant gas composition: CO 10 mol%, H_2 30 mol%, N_2 60 mol%; SV: 1970+30 cm^3 STP $g\text{-}cat^{-1}$ h^{-1}. a) Starting material, E_a: apparent activation energy of methanation (kJ mol^{-1}).

least within initial 12 h even on the catalyst containing Nd oxide which showed the highest selectivity of CO_2. A small amount of carbon deposition was observed on the catalysts after the reaction for 3 d or more, so that the latter reaction is believed to be dominant under these reaction conditions.

The apparent activation energy was calculated to 66 kJ mol^{-1} for Rh–Al_2O_3 and those for the catalysts containing rare earth oxides were distributed in 85—110 kJ mol^{-1}. Although these values are considerably small comparing with those in references,[6] a distinction of activation energy between Rh supported on an acidic support such as Al_2O_3 and the basic catalysts containing rare earth oxides strongly suggests the direct interaction of Rh with rare earth oxide on Al_2O_3. The following facts would support this speculation. Specific surface area of the catalysts including Dy and Yb oxides, 197 and 247 m^2 g^{-1} respectively, were not smaller than 280 m^2 g^{-1} of the Rh–Al_2O_3 catalyst. Assuming that La_2O_3 makes a monolayer on Al_2O_3 as oriented its (0001) plane to the Al_2O_3 surface, the coverage of La_2O_3 is calculated to 27—40% of the surface.

The formation of CO_2 reduces the yield of hydrocarbons, the oder of the effect of the oxides as evaluated from the yield of hydrocarbons is

Dy, Nd, Yb>La>Gd>Ho, Pr, none>Tm>Eu.

This order is essencially the same as reported for hydrogenation of ethene.[7]

The selectivity of methane was relatively less sensitive to the reaction temperature over the catalysts, and it remained about 70—85% even at 573 K. As for the hydrocarbons with carbon-carbon bond, the lowering of temperature from 633 to 573 K resulted in a passable increase of selectivity. $\sum n_i S_i$ was plotted in Fig. 1 against logarithmic solubility product constant (log K) of hydroxides of tervalent rare earth metals[8] which is regarded as a scale of the basicity of the oxides. Where n_i represents the number of carbon-carbon bond of hydrocarbon i among hydrocarbons produced, so that $\sum n_i S_i$ is an index of chain growth over catalyst.[9] The figure shows an approximately linear relationship. Due to explaine the wide diversity of the products in the hydrogenation of CO, many reaction mechanisms have

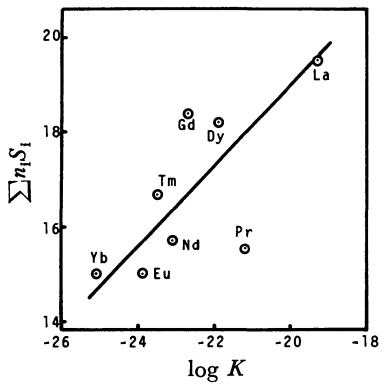

Fig. 1. The relation between carbon-carbon bond formation and the basicity of rare earth oxides.
n_i: The number of carbon-carbon bond in hydrocarbon i, S_i: selectivity of hydrocarbon i among the hydrocarbons produced in the reaction at 573 K, K: solubility product constants in aqueous solution at 291—298 K.

been proposed. These are divided broadly into three categories.[10] In the first category it is assumed that the CO dissiciates completely on adsorption and carbon chain is formed by the linking up of CH_2 or CHR. In the second category it is presumed that the CO chemisorbs associatively and chain growth occurs by H_2O elimination between neighbouring species such as R–C(=M)–OH and R–CH(=M)–OH where M represents a catalyst surface site and R represents H or alkyl. The associative CO chemisorption and CO insertion into M–H or M–CH_2R bond are assumed in the third category. Seeing the steps of the carbon chain propagation, carben type intermediates[11] take part in the first two categories, while the surface alkyl participates in the third one. It can not be decided which mechanism is dominant on the catalyst used in this work. However, it would be expected the stronger the basicity of the rare earth oxides added, the weaker the bond between surface carben or alkyl and Rh metal. Therefore the addition of strongly basic rare earth oxides to the catalyst would bring about the encouragement of either aggregation of the carben type intermediates or CO insertion into Rh–alkyl bond.

Experimental

Rh–Al_2O_3 catalyst was prepared by impregnation method. Al_2O_3 (Sunbead AN from Catalysts and Chemicals Ind. Co., 24—32 mesh) was poured into the solution of $RhCl_3 \cdot 3H_2O$ and the solution was then evaporated to dryness at about 363 K. The catalyst was calcined at 573 K for 4 h in air and it was then reduced in hydrogen stream at 723 K for 4 h.

Rh–rare earth oxide–Al_2O_3 catalysts were prepared as following procedure. Rare earth nitrate was supported on Al_2O_3 using its acidic solution. After the calcination at 823 K for 5 h, the catalyst was subjected to impregnation of Rh in the same manner as above.

Reactions were carried out using ordinary flow type reactor under atmospheric pressure. Reaction products were analyzed by gas chromatograph. Surface areas of the catalysts were determined by nitrogen adsorption at 77 K using BET method.

The Effect of Ultraviolet Radiation on Wettability of Silane Coupling Agents Coated on Glass

Kunio Esumi,* Kenjiro Meguro, Anthony M. Schwartz,† and Albert C. Zettlemoyer†

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 16, 1981)

Synopsis. The effect of ultraviolet irradiation on wettability of silane coupling agents coated on glass was studied by using contact angle measurements. The water contact angle for the silane coupling agents decreased due to photooxidation as the irradiation progressed. It was found that silane coupling agents which contain vinyl, allyl, or phenyl groups were easily photooxidated by the irradiation.

Silane coupling agents are well known to alter surfaces from hydrophilic to hydrophobic. There are many papers[1-4] about wettability of silane coupling agents coated on silica particles or glass; these attempt to understand the adhesion mechanism between a matrix and reinforcing medium. Lee[5] determined critical surface tensions for silane coupling agents on glass and found a relationship between the wettability of functional groups of silanes and their solubility parameters.

Silane coupling agents coated on substrates, under normal condition, were put in contact with atmospheric oxygen and exposed to various temperatures, humidities, and lights. It is expected that silane coupling agents on substrates would undergo a photochemical change at their surfaces. Indeed, vinyl and [3-(methacryloyloxy)-propyl] silane agents on glass[6] were found to change very readily in the presence of air at room temperature or at 80 °C and their critical surface tensions increased, presumably due to increase in polarity. Accordingly, it is very interesting to study the stability of silane coupling agents on substrates against different exposure conditions, especially light exposure. To evaluate the change in a surface composition, contact angle measurements have often been used. This work describes the effect of ultraviolet radiation on the wettability of silane coupling agents coated on glass by using contact angle technique.

The silane coupling agents used in this study were chloromethylphenylvinylsilane, chlorodimethylvinylsilane, allyltriethoxysilane, trichloro(1-methyl-2-phenylethyl)silane, chlorotrimethylsilane, and hexamethyldisilazane, which were supplied by Petrarch Systems, Inc. The liquid used for contact angle measurement was deionized water.

A micro slide glass was used as a substrate. The slide glass was cleaned by chromium trioxide solution, washed with distilled water and then dried carefully.

Coating of silanes on slide glass was carried out with about 3 wt% solution of silanes in 2-propanol. The

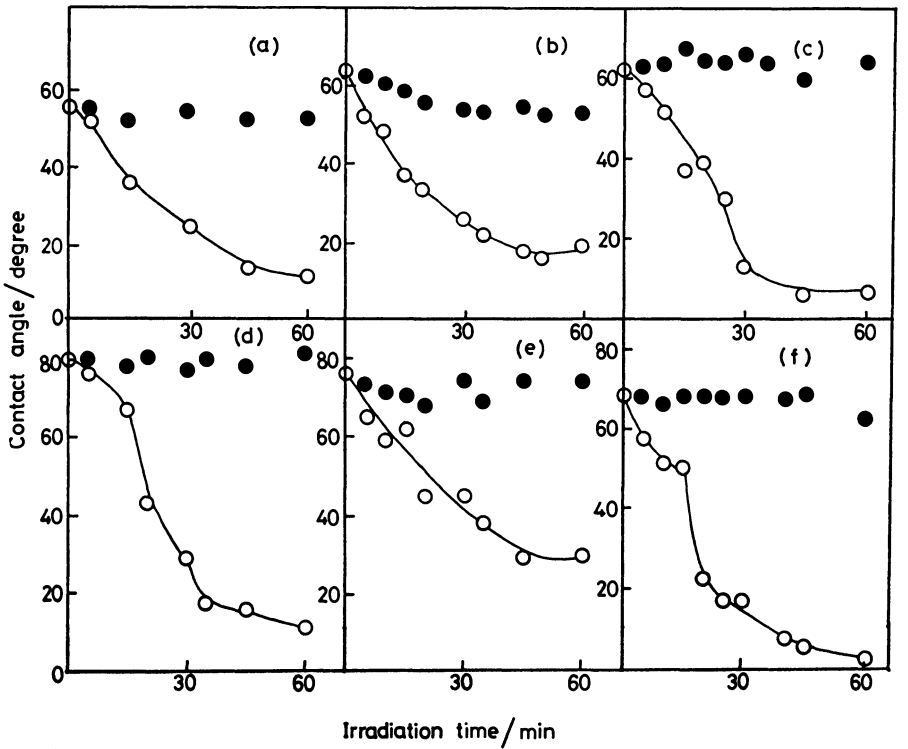

Fig. 1. Water contact angle *vs.* irradiation time.
(○) Water contact angle on irradiated portion, (●) on unirradiated portion. (a) Chloromethylphenylvinylsilane, (b) chlorodimethylvinysilane, (c) allyltriethoxysilane, (d) trichloro(1-methyl-2-phenylethyl)silane, (e) chlorotrimethylsilane, and (f) hexamethyldisilazane.

clean slide glass was dipped into the solution for 30 min, this was followed by washing with 2-propanol and drying *in vacuum*. In the case of hexamethyldisilazane, coating was conducted in vapor state on the slide glass. After exposing the slide glass to the vapor, the treated glass was heated at 100 °C for 20 min to eliminate ammonia generated during the coating.

Contact angles were measured on sessile drops of water by using a goniometer at 20 °C. Three drops for water were measured on both sides of the drops and the six values were averaged. The overall variation in the contact angle measurement was about ± 3 degrees.

Exposures were carried out in air in a hood with a unfiltered radiation from 55.2 W low pressure mercury lamp supplied by Oriel Co. The distance between the sample and the lamp was 5 cm.

The contact angle of water for the silanes on the slide glass was measured as a function of exposure time of ultraviolet irradiation. The results are shown in Fig. 1.

Chloromethylphenylvinylsilane. The initial contact angle of water was 55°. The contact angle decreased with increasing the exposure time and reached to about 10° in 60 min exposure.

Chlorodimethylvinylsilane. The contact angle of water was 60° at initial stage and became 20° during 60 min exposure. During irradiation, however, the unirradiated portion of sample lost hydrophobicity significantly, so that the contact angle on this unirradiated sample went to about 50°.

Allyltriethoxysilane. The contact angle was 60° initially and reached 10° after 30 min exposure.

Trichloro(1-methyl-2-phenylethyl)silane. The initial contact angle was 80°. Irradiation for 30 min dramatically dropped the contact angle to 15°.

Chlorotrimethylsilane. The initial contact angle was 75°. Irradiation for 40 min brought the contact angle down to 30°. This result is somewhat unexpected because methyl groups seem to be stable against ultraviolet irradiation.

Hexamethyldisilazane. The initial contact angle was 65°. The contact angle decreased remarkably to 10° after 40 min exposure.

Generally, the use of a monohalogenosilane[7] prevents the formation of polymeric films on substrates and the coating by the monohalogenosilane is envisioned as a monolayer of silane monomers. On the other hand, trialkoxysilane or trihalogenosilanes undergo the hydrolysis and polymerization to form a polysiloxane network structure, which is much thicker than a monolayer of monomer. Lee[6] studied the conformation of hydrolyzed silanes on glass and concluded that the interaction between the hydrolyzed silanes and the glass surface could take place with the attachment of one hydroxysilyl group to the surface.

In this study, all the silanes except trichloro(1-methyl-2-phenylethyl)silane and allyltriethoxysilane are considered not to form polymeric films on the glass. If chlorotrimethylsilane as a monohalogenosilane is coated on a glass, the water contact angle on the surface would be predicted[8] to be about 73°, while the water contact angle on a fully methylated surface like paraffin wax is taken as 110°. This predictable value of 73° was in good agreement with the experimental value. The above difference of water contact angle between that on monolayer film and that on polymeric film depends on the surface coverage of silane on glass. That is, the polymeric film of silane would give a larger water contact angle than the monolayer of silane.

From Fig. 1, it is seen that by using different silane coupling agents, a variety of functional groups can be exposed on the surface of glass, and each functional group shows a different water contact angle value. When all the samples were irradiated in air by ultraviolet light, the water contact angles decreased as a function of irradiation time. Furthermore, it was found that the water contact angles of silane coupling agents which contain vinyl, phenyl, or allyl groups changed very readily over a short irradiation time.

It is interesting to compare the results obtained with the silane coupling agents on the glass irradiated in air and *in vacuum*. All the silane coupling agents in this study on the glass irradiated *in vacuum* showed no changes in the water contact angles after exposures up to 60 min. This result supports the assertion that during irradiation in air the surface of silane coupling agents on the glass is photooxidated to yield hydrophilic products on the surface.

The Conversion of Methanol into Hydrocarbons over Metal Salts of Heteropolyacids

Toshihide BABA, Junya SAKAI, and Yoshio ONO*

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 16, 1981)

Synopsis. Metal salts of heteropolyacids are active catalysts for the conversion of methanol into hydrocarbons. Though the activity depends on the kind of metal salt, the reaction mechanism for the conversion is common to most of the metal salts, and the active centers are probably Brönsted acid centers.

Heteropolyacids such as dodecatungstophosphoric acid (TPA) have a high catalytic activity for the conversion of methanol into hydrocarbons.[1,2] This high activity is caused by the high Brönsted acidity of the heteropolyacids.[2,3] The metal salts of heteropolyacids are effective catalysts for many reactions, for which Brönsted acid sites are supposed to be responsible.[4-8] In this paper, the catalytic activities of various metal salts of TPA and dodecatungstosilicic acid (TSiA) for the conversion of methanol into hydrocarbons will be examined. The mechanistic features of the conversion over the salts will also be discussed.

Metal salts of heteropolyacids were prepared as follows. To the aqueous solution of TPA or TSiA, a stoichiometric amount of metal carbonate in the powder form was added slowly. For metals of which carbonates were not available, metal nitrates in an aqueous solution were used instead. When the metal salts of the heteropolyacids were obtained as precipitates (metal salts of TPA: Al, K, Ag, Cd, Cs, La, and Tl; metal salts of TSiA: Rb, Ag, Cs, La, and Tl), they were filtered, washed with water and dried. To obtain metal salts of heteropolyacid soluble in water, the aqueous solutions were heated to dryness over a water-bath.

The metal salts thus prepared were made into pellets, crushed, and sorted into grains of 9—16 mesh. The reaction was carried out at 573 K with a continuous-flow reactor at atmospheric pressure. The catalyst (3 g) was packed in a reactor of silica tubing (10 mm i.d.), placed in a vertical furnace, and then heated under a nitrogen stream at the reaction temperature. Methanol was delivered at the rate of 2.12×10^{-2} mol h^{-1} by means of a motor-driven syringe; it was vaporized by the preheating zone of the reactor, containing 10 cm^3 of quartz. The gas from the outlet of the reactor was analyzed by means of gas chromatography.

Table 1. Product distribution of the conversion of methanol into hydrocarbons

	Catalyst					
	Cu-TPA[a]	Fe-TPA	Al-TPA	Cu-TSiA[a]	Fe-TSiA	Al-TSiA

a) TPA and TSiA indicate dodecatungstophosphate and dodecatungstosilicate respectively. b) Calculated on a carbon-number basis.

In Table 1, the product and the hydrocarbon distribution for several metal salts of TPA and TSiA are listed. In every case, methanol is converted into dimethyl ether and hydrocarbons, the formation of carbon monoxide and carbon dioxide being negligible. The main hydrocarbon products are lower aliphatic hydrocarbons; the fraction of aromatic hydrocarbons in the products was very low. The catalytic activities of most of the metal salts did not change appreciably with the running time, though the rather high fraction of paraffins in the products indicates coke deposition in the catalyst bed. Thus, in the case of the conversion over copper(II) salts of TPA, the hydrocarbon yields were 63.1% and 62.4% at the running times of 2.5 h and 32 h respectively.

The activities of the series of metal salts of TPA and TSiA are listed as follows:

For salts of TPA:

Ag (98.0) > Cu (61.3) > Cd (61 0) > H (60 1) > Fe (48 3) > Tl (37.3) > Al (35.8)

Cs (35.4) > Pb (25.6) > La (23 6) > Na (23 5) > K (20 9) > Cr (20.4) > Zn (12.8)

Li (12.0) > Ni (11.8) > Mn (10.7) > Co (7.7) > Mg (6.9) > Ca (4.1) > NH_4 (2.6)

For salts of TSiA

Ag (78.9) > Cu (60.7) > H (38.6) > Cs* (38.4) > Rb (28.7) > Fe (24 2) > Na (22.2)

Al (14.5) > Zn (7.3) > Tl (5.5) > La (2.4) > Mg (1 2)

* $HCs_3SiW_{12}O_{40}$[9]

The numbers in parentheses indicate the hydrocarbon yield at a running time of 2—6 h except for the cadmium salt of TPA, for which the yield at 1 h was adopted because of the rapid deactivation. In general, the metal salt of TPA is more active than the same metal salt of TSiA. As has been reported previously,[10] silver and copper salts are most active among the metal salts; they are even more active than the protonic forms.

In Figs. 1 and 2, the yields of specific hydrocarbons over metal salts are plotted against the total hydrocarbon yield. It is worthy of note that the points obtained for a variety of catalysts fall onto one common line for each hydrocarbon species. Moreover, when the hydrocarbon yield over Cu(II) salt of TPA was reduced by decreasing the contact time, the yield of each hydrocarbon species was decreased, as was to be expected from the lines

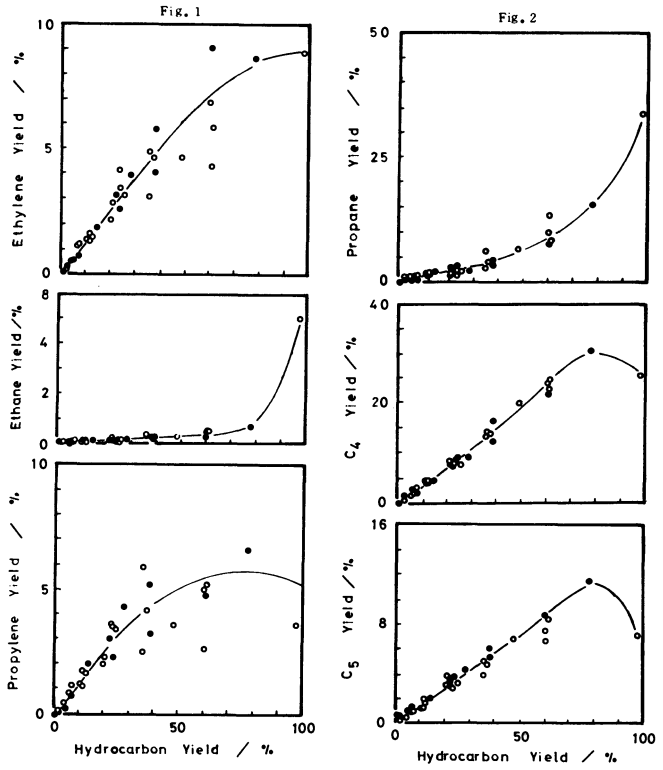

Fig. 1. The yields of ethylene, ethane, and propylene, as a function of the total yields of hydrocarbons obtained over metal salts of dodecatungstophosphoric acid (○) and dodecatungstosilicic acid (●).

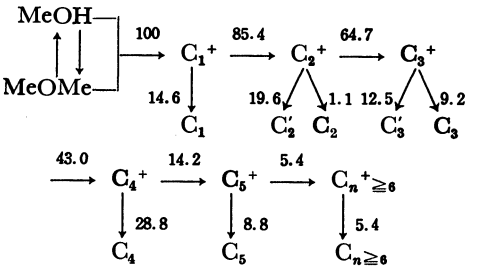
Fig. 2. The yields of propane, C_4-, and C_5-hydrocarbons, as a function of the total yields of hydrocarbons obtained over metal salts of dodecatungstophosphoric acid (○) and dodecatungstosilicic acid (●).

drawn in Figs. 1 and 2. These facts strongly suggest that the reaction mechanism is common for most of the metal salts, although the activity depends on the kind of metal salt. Thus, the active centers for the methanol conversion should be common, and they are presumably Brönsted acid sites. In fact, the activities of copper and silver salts of TPA were poisoned by the addition of pyridine under the present reaction conditions. Presumably, Brönsted acid is produced by the reduction of metal cations by hydrogen molecules or atoms formed by the decomposition of methanol:

$$Ag^+ + 1/2H_2(H) \longrightarrow Ag^0 + H^+.$$

This explains why the salts with highly reducible metal cations, like Ag(I) or Cu(II), have high catalytic activities. The formation of Brönsted acid by the dissociation of water[5] could also be operative for salts with less reducible metals.

Figures 1 and 2 also show that the yield of each hydrocarbon is nearly proportional to the total hydrocarbon yield until the latter reaches 30%, indicating that the hydrocarbon products are formed concurrently at the first stage of the reaction; the products once desorbed from the catalysts do not react easily with methanol or other products. Thus, the reaction scheme of the reaction may be expressed as follows:



Furthermore, one can estimate the relative rate of each reaction step from the initial distribution of hydrocarbons given in the above scheme.

Figures 1 and 2 indicate that the situation is different at the later stage of the conversion. The fraction of propane in the product hydrocarbons increases at the expense of the fractions of light olefins, especially propylene. This change in the product distribution is apparently caused by the presence of water, one of the products, since the addition of water to the starting methanol has a similar effect on the product distribution. Thus, when the feed was composed of methanol (20.2 kPa) and nitrogen (80.8 kPa), the conversion of methanol over copper(II) salt of TPA gave the propane/propylene and butanes/butenes ratio of 0.99 and 2.9 respectively, while the ratios were 4.8 and 8.7 when water (80.8 kPa) was added to the feed instead of nitrogen.

The great difference in the conversion over heteropolyacids from that over zeolites is that olefins, once formed, react with methanol only slowly,[3] while, over zeolites, the reaction of olefins with methanol is so fast that the overall reaction proceeds autocatalytically.[11,12]

The authors are deeply grateful to Professor Keii Tominaga for his fruitful discussions and for his continuous encouragement throughout the present work.

Efficient Photoreduction of Methylviologen Sensitized by Chlorophyll Derivatives and Hydrogen Evolution by Visible Light

Takashi Koiso, Masataka Okuyama,* Tadayoshi Sakata,*,† and Tomoji Kawai†

Depatrment of Engineering Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

†*Institute for Molecular Science, Myodaiji, Okazaki 444*

(Received December 22, 1981)

Synopsis. The photoreduction of methylviologen sensitized by chlorophyll derivatives and porphines was investigated using EDTA as a reducing agent. The quantum yield of the photoreduction depends greatly on the kind of central metal ion of chlorophyll derivatives and porphines. Zn–chlorophyll-a and Zn–tetraphyenylporphine show a high quantum efficiency amounting 0.4, which is higher than that of chlorophyll-a.

Redox reactions induced by photoexcitation of chlorophyll play an important role in the photosynthesis in green plants and some bacteria. Much work has been done to construct an artificial system having such a function by making use of photochemical reactions of chlorophyll, its derivatives and porphyrins.[1-9] Here we would like to report an efficient photoreduction of methylviologen (MV^{2+}) by chlorophyll derivatives.

Methylviologen was used as an electron acceptor and EDTA as an electron donor. Photochemical reactions were carried out in the mixture of dimethyl sulfoxide (DMSO) and water (9 : 1 in volume ratio) which dissolves chlorophylls and porphines. The solution of MV^{2+} and EDTA in a quartz cell was deaerated to remove oxygen before illumination. A Xe lamp (500 W, Ushio) and a monochromator (Nikon, p-250) were used for monochromatic illumination (≈1 mW) at the peak wavelength of the visible absorption band of each dye molecule. A strong absorption band at 610 nm of the reduced methylviologen, $MV^{+\cdot}$, was monitored by a spectrophotometer to follow the reaction. The quantum yield of the reaction (the number of $MV^{+\cdot}$ formed/the number of absorbed photons) was determined by using a thermopile (Eppley Lab. Inc.).

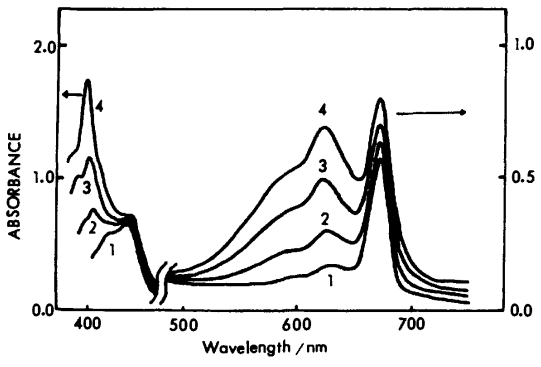

Fig. 1. Spectral changes of the solution (photocatalyst: Chl-a, electron donor: EDTA, electron acceptor: MV^{2+}) due to the reduction of MV^{2+} during illumination by a monochromatic light (≈ 1 mW) at 665 nm.
1) 0.0 min, 2) 2.0 min, 3) 12.0 min, 4) 37.0 min.
$[MgChl\text{-}a] = 9.4 \times 10^{-6}$ M, $[EDTA] = 1.0 \times 10^{-2}$ M, $[MV^{2+}] = 2.0 \times 10^{-3}$ M. Solvent; DMSO: water= 1: 1 (in volume ratio).

When chlorophyll-a was excited by visible light, it turned out to oxidize EDTA and reduce methylviologen. The net reaction is considered to be as follows.[9]

$$EDTA + 2MV^{2+} + H_2O \longrightarrow C_2H_4N_2(CH_2COOH)_3H + 2\,MV^{+\cdot} + CH_2O + CO_2 + 2H^+$$

$$\Delta G^0 = 20 \text{ kcal/mol.}$$

Due to the formation of reduced methylviologen the deaerated solution colored blue by illumination. Besides (Chl-a, its derivatives such as ZnChl and CuChl were found to work well as a photocatalyst for the reduction of methylviologen (MV^{2+}). Figure 1 shows the spectral change of the solution (photocatalyst: Chl-a, electron donor: EDTA, electron acceptor: MV^{2+}) during illumination with a monochromatic light at 665 nm. The introduction of air into the solution after illumination extinguished the blue color of the reduced methylviologen ($MV^{+\cdot}$) but did not cause any change of the absorption intensity of photocatalysts such as Chl-a and its derivatives, which indicates that they work reversibly as photocatalysts. Table 1 shows the quantum yield of the photoreduction for chlorophyll derivatives and porphines determined spectrophotometrically. One interesting thing is that the quantum yield depends remarkably on the kind of the central metal and is comparatively high, as seen in this table. Another interesting thing is that the quantum yield of an artificial compound such as ZnChl and ZnTPP is higher than that of MgChl, Chlorophyll-a (a natural compound). This suggests a possibility of constructing an artificial photosysnthetic device which is superior to the photosysnthetic system in the nature.

As is shown in Table 1, TPP derivatives have a similar tendency with Chl derivatives in the dependence of the quantum yield on the kind of central metal ion. Since the fluorescence intensity of Chl-a and ZnTPP is hardly influenced by adding EDTA and MV^{2+}, the triplet

Table 1. Quantum yield of phoreduction of methylviologen by chlorophyll derivatives, porphines, and dyes. They were excited by a monochromatic light at the peak wavelength of the visible absorption band

$[MV^{2+}] = 2.0 \times 10^{-3}$ M, $[EDTA] = 1.0 \times 10^{-2}$ M,
Solvent; DMSO: Water=9 : 1.
The concentration of each dye is about 1×10^{-5} M.

	Dye	Quantum yield/%
a	MgChl-a (Chl-a)	23
	ZnChl-a	40
	CuChl-a	13
b	MgTPP	10
	ZnTPP	40
	CuTPP	1

state is considered to be responsible for the above reaction. MgTPP has the longest lifetime (46 ms[11]). ZnTPP the next one (25 ms[11]) and CuTPP the shortest one (0.6 ms[11]) at liq. N_2 temperature. Although the life-time was measured at liq. N_2 temperature, the order of their magnitude would be the same at room temperature. Therefore, it seems reasonable to attribute the lowest quantum yield of photoreduction for CuTPP to the shortest triplet life-time. However, it can not be explained in terms of the triplet life-time (τ_T) that the quantum yield for MgTPP is smaller than that for ZnTPP. Another factor to be taken into consideration would be the rate of triplet population (γ_T: the quantum yield of intersystem crossing). It is 0.97 for ZnTPP,[11] 0.84 for MgTPP[11] and 1.0 for CuTPP.[12] Since the reactivity would depend on the product, $\tau_T\gamma_T$, we compared its value for ZnTPP with that for MgTPP. The value for MgTPP (39 ms) is still larger than that for ZnTPP (24 ms). Therefore these factors could not explain the fact that ZnTPP is better than MgTPP for photoreduction of MV^{2+}. Another important factor to be taken into consideration is the energetical relation. Since the oxidation potential of ZnTPP (0.95 V *vs.* NHE) is more positive than that of MgTPP (0.78 V *vs.* NHE),[13] the cation radical of ZnTPP would oxidize EDTA more efficiently than that of MgTPP would if the reaction rate of the recombination between the dye cation and $MV^{+\cdot}$ is assumed not to depend on the kind of the central metal ions.

We tried hydrogen evolution by adding Pt or Pt/TiO_2 catalyst which is already a popular method.[9,14-16] After Pt catalyst was added to the solution of EDTA, MV^{2+}, and Chl-a (or ZnTPP) either in DMSO–water (1 : 1) mixture or in MeOH–water (8 : 2) mixture, it was irradiated by visible light (λ>440 nm) for 3 h. The hydrogen evolution was confirmed by a quadrupole mass spectrometer. The hydrogen evolution rate was about 5 μmol/h in MeOH–water mixture for ZnTPP.

Liquid Crystals of Binary Mixtures. Induction of Nematic Phase by Intermolecular Charge-transfer Interaction and Application of Solid-solution Model

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 15, 1982)

Synopsis. Nematic phase induced by binary mixture consisting of electron donor and acceptor was examined by using modified solid-solution model. The experimental results of Araya and Matsunaga were explained by this approach, and the charge-transfer interaction energy between donor and acceptor in the nematic phase was estimated by analyzing their phase diagrams.

Much attention has been paid to a great number of liquid crystals, which show intermediate state between crystalline solid and isotropic liquid.[1] Binary systems have been often used to achieve extended liquid crystalline temperature ranges. In binary mixtures consisting of electron donors and acceptors, parallel molecular arrangement required by liquid crystal formation becomes observable if an electron donor-acceptor charge-transfer interaction acts as the orientational forces.[2-5] Park *et al.* examined nematic phase→isotropic liquid transition temperature (T_{NI}) in the binary system of *N*-(*p*-methoxybenzylidene)-*p*-butylaniline (MBBA) and 4-cyano-4′-pentylbiphenyl (CPB), because there was a weak charge-transfer interaction between a donor of MBBA and an acceptor of CPB.[2] In this case, although both components of MBBA and CPB exhibit nematic phase→isotropic liquid phase transition, the relation of T_{NI} to the composition of MBBA–CPB mixture shows a broad curve whose maximum is located near 1 : 1 mole ratio, and T_{NI} of mixture is higher than the straight line joining T_{NI} of the two components. In order to understand the thermodynamic properties of the nematic phase, we applied a modified solid-solution model to the binary mixture of electron donor and acceptor, and explained well the relation of T_{NI} to composition.[5]

In binary mixture of donor and acceptor, even if the components show no liquid crystalline state, they may be considered to be potentially mesomorphic. Then, there is a possibility of induction of mesophase if those components are mixed. This was achieved by Araya and Matsunaga,[3] who observed nematic phase in the binary mixtures of potentially-mesomorphic electron donors and acceptors of the type *N*-(*p*-X-benzylidene)-*p*-Y-aniline. It acts as a donor if X or Y is dimethylamino group, and as an acceptor if X or Y is nitro group. The remaining substituents are methoxy, ethoxy or propoxy groups. For the binary systems of ethoxy derivatives, the experimental relations of T_{NI} to composition are given in Fig. 2 of Ref. 3, where nematic liquid crystals are stable in the hatched areas. In the present paper, for purposes of comparison with theoretical results, the T_{NI} *versus* composition curves of those combinations are reproduced in Fig. 1, where curves (a) show the experimental relation. It is to be noted that the relationship also shows a broad curve whose maximum is located near 1 : 1 mole ratio.

Let us consider these experimental results on the basis of our previous theoretical approach of binary solid-

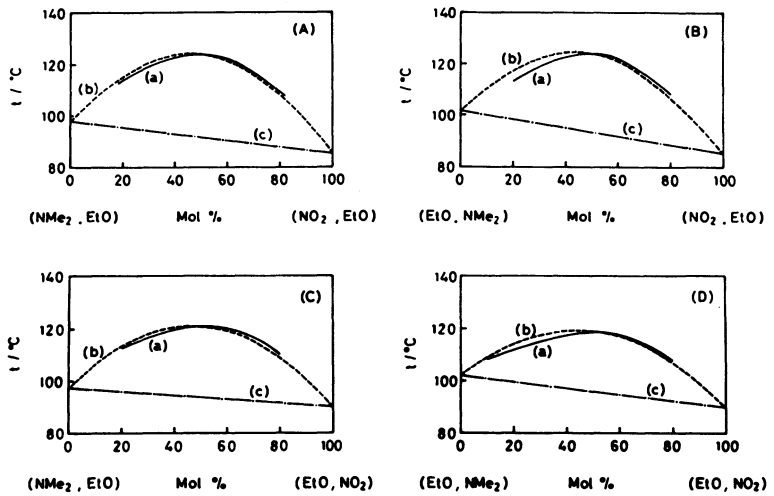

Fig. 1. Nematic phase→isotropic liquid transition temperature (T_{NI}) in the binary mixtures of *N*-(*p*-X-benzylidene)-*p*-Y-anilines, where the compounds are indicated by (X, Y). Curves (a) show experimental relation of T_{NI} to composition as reported by Araya and Matsunaga;[3] curves (b), theoretical relation of transition temperature (T_c) of order-disorder phase transition to composition as given by our modified solid-solution model; curves (c), straight lines joining T_{NI} of the two components. For further details, see text.

solution model. We examine binary mixtures of electron donor and acceptor, where donor is (X, Y)=(NMe_2, EtO) or (EtO, NMe_2), and where acceptor is (NO_2, EtO) or (EtO, NO_2). The mole fractions of donor and acceptor are x_D and x_A, respectively, where $x_D+x_A=1$. The model assumes that each of the components has nematic phase→isotropic liquid phase transition. In our compounds, however, each of the donor and acceptor shows no apparent nematic phase, but is considered to be potentially nematic. Araya and Matsunaga estimated the latent T_{NI} of the components as 97.5 °C for (NMe_2, EtO), 102 °C for (EtO, NMe_2), 85 °C for (NO_2, EtO) and 90 °C for (EtO, NO_2).[3] Let us denote the latent T_{NI} of pure donor or acceptor as T_D or T_A, respectively. Our model also assumes that the nematic phase of binary mixture is taken as three dimensional lattice, which is divided into two sublattices D and A, and the effect of mixing of donor and acceptor was only discussed.[5] For mixture with composition ($x_D \geq x_A$), when all acceptor molecules occupy sites of A sublattice, the system is called in order state. When donor and acceptor molecules occupy sites of D and A sublattices randomly, it is in disorder state. The situation is similar in the case of the composition ($x_D \leq x_A$). Then, if the charge-transfer interaction between donor and acceptor is essential for parallel molecular arrangement to induce nematic phase, the order→disorder phase transition with respect to mixing of donors and acceptors should correspond to nematic→isotropic phase transition. In other words, if the order of molecular arrangement of donors and acceptors remains, the system is supposed to be in nematic phase, while if the order is lost, it goes to isotropic liquid.

According to our previous study,[5] the temperature at which the order→disorder phase transition of such a binary system occurs is given by $T_C=x_DT_D+x_AT_A+4x_Dx_AT_C^\circ$, where $T_C^\circ=zv/2k$. Here, it is assumed that one site of D or A sublattice is surrounded by z equivalent nearest neighbor sites of A or D sublattice, respectively, and v is given by $v=(1/2)(v_{DD}+v_{AA})-v_{DA}$. The terms v_{DD}, v_{AA}, and v_{DA} indicate the energies between a pair of donor-donor, acceptor-acceptor and donor-acceptor molecules in nearest neighbor sites, respectively. Note that v_{DD} and v_{AA} arise from weakly attractive van der Waals forces between the same kind of molecules, while v_{DA} comes from rather strongly attractive forces due to the charge-transfer interaction between donor and acceptor. When the charge-transfer interaction is strong enough, we have $|v_{DA}| \gg (1/2)(|v_{DD}|+|v_{AA}|)$ and $v \approx -v_{DA} > 0$. In this case, $T_C^\circ=zv/2k(>0)$ increases considerably, and the relation of T_C to composition shows a broad curve whose maximum is located near 1 : 1 mole ratio. If the order→disorder phase transition corresponds to the nematic phase→isotropic liquid transition, we can observe considerable induction of the nematic phase upon mixing donors and acceptors. On the other hand, when the charge-transfer interaction is so small as $v_{DA} \approx (1/2)(v_{DD}+v_{AA})$, we have $v \approx 0$, $T_C^\circ \approx 0$ and $T_C=x_DT_D+x_AT_A$. Then, T_C *versus* composition is simply a straight line joining T_D at $x_D=1$ and T_A at $x_A=1$, and no stability enhancement of the nematic phase occurs.

In the following, we discuss how the relation of T_C to composition agrees with the observed T_{NI} *versus* composition curve. For example, we take the binary system of (NMe_2, EtO) donor and (NO_2, EtO) acceptor. The experimental relation between T_{NI} and composition is given by curve (a) of Fig. 1 (A). Here, curve (c) shows $x_DT_D+x_AT_A$, a straight line connecting T_D=97.5 °C and T_A=85 °C. Curve (b) represents $T_C=x_DT_D+x_AT_A+4x_Dx_AT_C^\circ$ with parameter value of T_C°=32 °C, which was chosen so as to obtain best fit between T_{NI} and T_C. Agreement between the curvatures of (a) and (b) is fairly good. The maximum value of T_{NI} occurs at x_D=0.50, while that of T_C, at x_D=0.45. This agreement is also satisfactory. In view of these results, the relation of T_C to composition corresponds well to that of T_{NI} to composition, and we can conclude that the charge-transfer interaction is essential for parallel molecular arrangement to induce nematic phase. From the estimated value of T_C°, zv is calculated as 0.53 kJ mol^{-1}.

In a similar way, the combination of the donor (EtO, NMe_2) with the acceptor (NO_2, EtO) gave values of T_C°=31 °C and zv=0.52 kJ mol^{-1}; the combination of (NMe_2, EtO) with (EtO, NO_2), T_C°=27 °C and zv=0.45 kJ mol^{-1}; the combination of (EtO, NMe_2) with (EtO, NO_2), T_C°=23 °C and zv=0.38 kJ mol^{-1}. For these systems, the relations of T_C to composition are compared with the experimental relations of T_{NI} to composition in Figs. 1 (B)—(D). In each case, the agreement between the two relations is satisfactory. Since the charge-transfer interaction is considerably strong, it appears that $|v_{DA}| \gg (1/2)(|v_{DD}|+|v_{AA}|)$ and that $zv_{DA} \approx -zv$ in each case. In order to estimate the v_{DA} value, it is necessary to determine the z value, but no further information has yet been obtained in the nematic phase of such binary mixtures.

Reactions of Polymeric Chloromanganese(III) Schiff Base Complexes with Superoxide Ion in Dimethyl Sulfoxide

Takayuki MATSUSHITA,* Mitsuru NISHINO, and Toshiyuki SHONO
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received April 30, 1981)

Synopsis. The polymeric Mn(III) Schiff base complexes react with superoxide ions (O_2^-) in dimethyl sulfoxide (DMSO) to give the oxygenated complexes, while the corresponding monomeric Mn(III) complexes are reduced with O_2^- to the Mn(II) complexes.

Manganese ions play an important role in biological redox processes, the disproportionation of O_2^- by manganese-containing superoxide dismutases, and the photosynthetic water oxidation in green plants.[1-3] In the previous paper,[4] the monomeric Mn(III) Schiff base complexes are classified into two types according to their reactivity toward O_2^-: one gives the oxygenated complexes and the other is reduced to the Mn(II) complexes. This behavior can be correlated to the polarographic half-wave potentials for the reduction of Mn(III) to Mn(II). In this Note, the reactions of the polymeric Mn(III) complexes (shown below) with O_2^- in DMSO will be reported.

Polymeric Mn(III) Schiff base complexes studied.

Experimental

The monomeric Mn(III) complexes, Mn(salpln)Cl, Mn(salchxn)Cl, Mn(saldpt)Cl, Mn(salMedpt)Cl, and chlorobis(*N*-alkylsalicylideneaminato)manganese(III), Mn(*N*-Rsai)$_2$Cl (R=*n*-C_3H_7 (Pr), *n*-C_4H_9 (Bu), and *c*-C_6H_{11} (*c*-Hx)), were prepared by a modification of the method described elsewhere;[4] salplnH$_2$: *N*,*N*′-disalicylidenepropylenediamine, salchxnH$_2$: *N*,*N*′-disalicylidene-1,2-cyclohexanediamine, saldptH$_2$: bis[3-(salicylideneamino)propyl]amine, salMedptH$_2$: bis[3-(salicylideneamino)propyl]methylamine.

Polymeric Schiff Bases. The polymeric Schiff base, p-salplnH$_2$ was obtained by polycondensation of 5,5′-methylenedisalicylaldehyde (disalH$_2$) with propylenediamine in dichloromethane (CH_2Cl_2). This was reprecipitated from a mixture of CH_2Cl_2–ether. The other polymeric Schiff bases, p-salchxnH$_2$, p-saldptH$_2$, and p-salMedptH$_2$, were obtained in a similar manner. The analytical data, specific viscosities (Table 1), and ^{1}H NMR data indicate that these polymeric Schiff bases are oligomers whose degrees of condensation (n) are within a range of three to five.

N,*N*′-Dibutyl-5,5′-methylenedisalicylideneamine, *N*-BudisaiH$_2$, was obtained by the condensation of disalH$_2$ with *n*-butylamine in tetrahydrofuran. This was recrystallized from a mixture of ether–petroleum ether. The other Schiff bases, *N*-PrdisaiH$_2$ and *N*-*c*-HxdisaiH$_2$ were obtained in a similar manner.

Preparation of Polymeric Mn(III) Complexes. The polymeric Mn(III) complex, Mn(p-salpln)Cl, was obtained by reacting p-salplnH$_2$ with Mn(CH$_3$COO)$_3$·2H$_2$O and LiCl in a mixture of CH_2Cl_2–MeOH, and was reprecipitated from a mixture of MeOH–ether. Mn(p-salchxn)Cl, Mn(p-saldpt)Cl, and Mn(p-salMedpt)Cl were obtained in a similar manner. The other polymeric complexes, Mn(*N*-Rdisai)Cl (R=Pr, Bu, and *c*-Hx), were obtained in a manner similar to that used for Mn(p-salpln)Cl, and were reprecipitated from a mixture of CH_2Cl_2–ether. These polymeric complexes are soluble in MeOH and DMSO. The analytical data and specific viscosities (Table 1) indicate that they are oligomers whose degrees of condensation are within a range of three to five.

Measurements. ^{1}H NMR spectra were taken on a JEOL JNM-PS 100 spectrometer using TMS as the internal standard. The specific viscosities were determined using an Ostwald's viscometer at 25±0.1 °C (0.40 g/solvent 100 cm^3). The other physical measurements were carried out by the method described elsewhere.[4]

Reactions of the Mn(III) complexes with KO_2 in DMSO were made by the procedure described elsewhere.[4]

Results and Discussion

We have previously found that the absorption spectral and polarographic changes can be used to distinguish clearly between the formation of the oxygenated complexes and the reduction of Mn(III) to Mn(II)

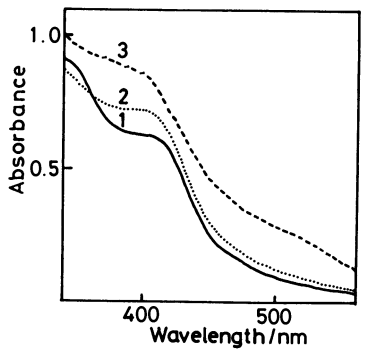

Fig. 1. Spectral changes of a DMSO solution of Mn(p-salpln)Cl (1×10^{-4} unit mol dm^{-3}) caused by the addition of KO_2.

in the reactions of the Mn(III) Schiff base complexes with O_2^- in DMSO.[4] Figure 1 shows the spectral changes of a DMSO solution of Mn(p-salpln)Cl caused by the addition of a KO_2 DMSO solution. A broad absorption band appeared around 500 nm at the KO_2/Mn$=3$, indicating the formation of the oxygenated complex. The other polymeric Mn(III) complexes show spectral changes similar to the above.

Figures 2-A and 2-B show the changes in polarograms in the reactions of O_2^- with the monomeric Mn(*N*-Prsai)$_2$Cl and polymeric Mn(*N*-Prdisai)Cl in DMSO, respectively. In the case of Mn(*N*-Prsai)$_2$Cl, as the ratio of KO_2/Mn increased, the wave height at −0.03 V due to the reduction of Mn(III) to Mn(II) decreased and a new cathodic wave appeared at −0.55 V; this can be assigned to the reduction of free molecular oxygen. This indicates that Mn(*N*-Prsai)$_2$Cl is reduced to the Mn(II) complex and O_2^- is oxidized to O_2. In the case of Mn(*N*-Prdisai)Cl, a new cathodic wave was observed at *ca.* −0.25 V by the addition of KO_2 (KO_2/Mn$=$ 1—3), indicating the formation of the oxygenated complex. The other polymeric Mn(III) complexes show polarograms similar to the above. These results indicate that all the polymeric Mn(III) complexes investigated here react with O_2^- to give the oxygenated complexes, although the corresponding monomeric Mn(III) complexes are reduced with O_2^- to the Mn(II) complexes, with the exception of Mn(salchxn)Cl which gives the oxygenated complex.[4]

The polymeric complexes showed slightly positive reduction potentials compared with those for the monomeric complexes (Table 1). Nevertheless, the oxygenated complexes are found to be stabilized in the polymeric complexes. This may be caused by a polymeric sturcture in which the central manganese atoms are not isolated from the surroundings, unlike the monomeric complexes. In such an environment, interaction between DMSO molecules and the central manganese atom may be weakened by steric repulsion and thus the oxygenated complex may be protected from dissociation into the Mn(II) complex and O_2, because the dissociation should proceed *via* displacement of coordinated dioxygen with DMSO molecules. This consideration is not inconsistent with the spectral data (Table 1): the ligand field bands assignable to the $d_{xy}\rightarrow d_{x^2-y^2}$ transition[5] are observed at lower energies in the polymeric complexes than those for the monomeric complexes.

The Color Isomerism of Oxovanadium(IV) Complexes with Tetradentate Schiff Base

Kuninobu KASUGA,* Takeo NAGAHARA,† and Yasuo YAMAMOTO
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690

(Received November 24, 1981)

Synopsis. An oxovanadium(IV) complex with *N,N'*-bis(1-methyl-2-bromo-3-oxobutylidene)ethylenediamine gave green and yellow forms in the solid state, depending upon the solvents used for recrystallization. A polymeric structure was proposed for the yellow form.

As has been reviewed elsewhere,[1-3] there have been a considerable number of spectroscopic and magnetic studies of oxovanadium(IV) complexes. Almost all complexes are blue or blue-green and exhibit strong V=O stretching frequencies around 1000 cm^{-1}. On the other hand, oxovanadium(IV) complexes of salicylideneamine, β-thioxo ketones, and dithiophosphinic acids with electron-withdrawing substituents,[4-6] and *N,N'*-disalicylidenepropylenediamine,[7,8] are yellow and shift their V=O bands to lower frequencies (around 900 cm^{-1}). The shift in the V=O stretching frequencies has been considered to be an indication of an oxygen bridging, V–O–V, polymeric-chain formation.[5,7,9] Recently, the yellow color and low V=O frequencies of oxovanadium(IV) complexes with some bidentate Schiff bases were explained in terms of distorted trigonal bipyramidal structure.[10] In the trigonal bipyramid, the three oxygen and vanadium atoms are on the equatorial plane, while the two nitrogen donors occupy axial positions. We wish to report here that an oxovanadium(IV) complex with *N,N'*-bis(1-methyl-2-bromo-3-oxobutylidene) ethylenediamine (VO(L-Br)) yields two color isomers in the solid state.

Experimental

Syntheses. [*N,N'*-Bis(1-methyl-3-oxobutylidene)ethylenediaminato]oxovanadium(IV) (VO(L)) was synthesized according to the method reported by Martin *et al.*[11]

[N,N'-Bis(1-methyl-2-bromo-3-oxobutylidene)ethylenediaminato]-oxovanadium(IV) (VO(L-Br)): *N*-Bromosuccinimide (1.8 g) was added to 20 cm^3 of a dichloromethane solution of VO(L) (1.4 g) at 0 °C, and the mixture was stirred below 0 °C for 20 min. After small amounts of precipitates had been filtered off, the filtrate was concentrated to 2—3 cm^3 under reduced pressure. The precipitates were subsequently obtained by the addition of adequate amounts of methanol. The yellow needles were recrystallized from dichloromethane (yield, 65%); IR: 902 cm^{-1} (V=O). Found: C, 32.51; H, 3.59; N, 6.69%. Calcd for $C_{12}H_{16}N_2O_3Br_2V$: C, 32.24; H, 3.66; N, 6.27%. An yellow [*N,N'*-bis(1-methyl-2-chloro-3-oxobutylidene)ethylenediaminato]oxovanadium(IV) (VO(L-Cl)) complex was synthesized using *N*-chlorosuccinimide instead of *N*-bromosuccinimide (yield, 67%); IR: 892 cm^{-1} (V=O). Found: C, 39.94; H, 4.13; N, 7.53%. Calcd for $C_{12}H_{16}N_2O_3Cl_2V$: C, 40.24; H, 4.51; N, 7.82%. Hydrogen chloride was bubbled through a dichloromethane solution of VO(L-Cl) for a few min to obtain a free ligand. The ligand thus precipitated was separated out; it was washed with water and subsequently with ethanol. On the other hand, no free L-Br ligand was obtained because of the decomposition of VO(L-Br) with hydrogen chloride.

Adducts of VO(L-Br) and VO(L-Cl) with 1-Methylimidazole: A 5 cm^3 portion of 1-methylimidazole was added to 20 cm^3 of a dichloromethane solution containing 1.3 g of VO (L-Br). After the solution had been refluxed for a few min, it was condensed to 2—3 cm^3. The brown adduct was precipitated by the addition of adequate amounts of hexane and subsequently washed with ether (yield, 68%); IR: 959 cm^{-1} (V=O). Found: C, 35.94; H, 4.14; N, 10.90%. Calcd for $C_{16}H_{22}N_4O_3Br_2V$: C, 36.31; H. 4.20; N, 10.59%. A brown adduct of the chloro derivative was obtained by a method similar to that described above (yield, 75%); IR: 959 cm^{-1} (V=O). Found: C, 43.36; H, 4.95; N, 12.67%. Calcd for $C_{16}H_{22}N_4O_3Cl_2V$: C, 43.65; H, 5.04: N, 12.73%.

Measurements. The infrared spectra were measured using nujol mull methods, on a Hitachi 215 spectrophotometer. The electronic spectra in sloution and in the solid state were measured on a Hitachi 124 spectrotometer and a Shimadzu spectrophotometer Model MPS-5000 respectively. The NMR spectra were recorded with a JEOL-MH 100 spectrophotometer at a frequancy of 100 MHz. The chemical shifts were determined in ppm, using TMS as the internal standard. The ESR spectra (X-band) of polycrystalline samples were obtained on a JEOL-1X apparatus. The X-ray powder diffraction analyses were carried out on a Toshiba ADG-301 apparatus.

Results and Discussion

Structures of Schiff-base Ligands. An NMR spectrum of the free L-Cl ligand eliminated from VO(L-Cl) shows three proton signals in 1,1,2,2-tetrachloroethane-d_2 (TCE-d_2); δ=2.16 (12H, d, CH_3), 3.36 (4H, m, CH_2), and 11.40 ppm (2H, broad s, OH). An unsubstituted free ligand, L, also shows four proton signals in TCE-d_2 at 1.86 (12H, d, CH_3), 3.30 (4H, m, CH_2), 4.92 (2H, s, CH), and 10.92 ppm (2H, broad s, OH). The signals of the methine protons in L disappeared in the chloro derivative, indicating the chlorination on the 2-position carbon of the complex. All the proton signals of the chloro derivative were shifted to a lower magnetic field compared with those of L. This tendency is attributable to an inductive effect of the chlorine atom. The bromination must also occur on the 2-position carbon.

Isolation of the Green and Yellow Forms. The yellow form was obtained by the recrystallization of the VO(L-Br) complex from dichloromethane, and the green, from tetrahydrofuran. However, the VO(L-Cl) complex only gave the yellow form upon recrystallization from both dichloromethane and tetrahydrofuran. On the other hand, the green form of VO(L) was easily recrystallized from common organic solvents, though the yellow was not obtained at all. The yellow forms seem to be easily isolated according to an increase in the electron negativities of the substituents. In the case of

† Present address: Izumo Technical High School, Izumo, Shimane 693.

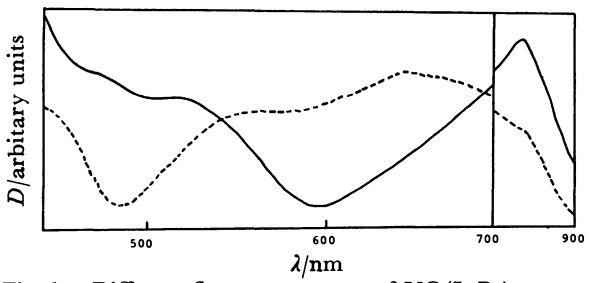

Fig. 1. Diffuse-reflectance spectra of VO(L-Br).
——: Yellow form, ------: green form.

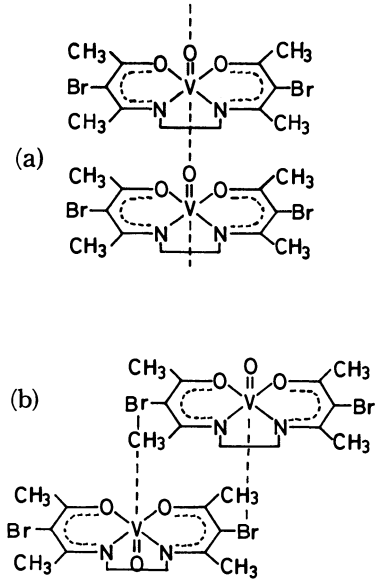

Fig. 2. The proposed structures for the yellow VO(L-Br) form.

VO(L-Br), the thermodynamic stabilities of the green and yellow forms might be similar, so that the two forms can be individually isolated by selecting appropriate solvents for recrystallization.

IR, Electronic, ESR, and X-Ray Powder Spectra. The V=O stretching frequencies of the green and yellow forms appear at *ca.* 980 and *ca.* 900 cm^{-1} respectively. This shift to lower frequencies for the yellow forms is in accord with the previously reported data for the yellow polymeric oxovanadium(IV) complexes.[4-8] The V=O stretching frequencies (959 cm^{-1}) of the 1-methylimidazole adducts lie between the values for the green and yellow forms. Both the green and yellow forms of the bromo derivative are dark green in common organic solvents, and they exhibit the same electronic spectra. The diffuse-reflectance spectra of VO(L-Br) are shown in Fig. 1. The spectrum of the yellow form significantly differs from that of the green in the solid state; the absorption band around 660 nm of the green form disappears in the yellow. The spectrum of the yellow VO(L-Br) form is similar in pattern to that of the yellow polymeric oxovanadium(IV) complex with β-thioxo ketone.[5] The ESR spectra for the green and yellow forms of VO(L-Br) were obtained in the powdered solid state at room temperature with no hyperfine structures. The g_0 value (1.972) of the yellow form is smaller than that of the green (g_0=1.984). This suggests that the electron delocalization increases in going from the green form to the yellow. The ESR spectra of VO(L-Br) diluted with Ni(II)(L) were also measured, but no clear hyperfine structures were obtained. In the X-ray powder-diffraction spectra of VO(L-Br), the peak at 14.5° of the green form became weak and a new intense peak appeared at 9.3° in the yellow. This shows different crystal forms between the green and yellow isomers.

Structure of the Yellow Form. A polymeric or distorted trigonal bipyramidal structure might be proposed for the yellow form, judging from previous reports.[5,7,9,10] The distorted trigonal bipyramid reported for the bidentate Schiff-base complexes seems difficult for the present tetradentate Schiff-base complex because of its steric hindrance. Either of the structures in Fig. 2 would be possible for the yellow form. The nitrogen atom of 1-methylimidazole must be coordinated to the vanadium(IV) ion more strongly than the bromine atom. Thus, the V=O stretching frequency of the adduct should be shifted to a lower frequency compared with that of the dimer, in which the vanadium(IV) ion is coordinated by bromine (Fig. 2b). However, the V=O stretching frequency of the adduct is higher than that of the yellow form of VO(L-Br). Therefore, the (a) structure seems more reasonable for the yellow form.

The authors wish to thank Dr. Kunihisa Sogabe of this University for his measurements of the ESR and Dr. Yuzo Nishida of Kyushu University for his measurements of the diffuse-reflectance spectra. This work was partially supported by a Grant-in-Aid for Scientific Research No. 00547042 of the Ministry of Education, Science and Culture.

Gas-chromatographic Measurements of Dinitrogen Oxide in Surface Air

Michio HIROTA* and Hisafumi MURAMATSU
Meteorological Research Institute, Nagamine, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received September 30, 1981)

Synopsis. The mixing ratio of N_2O in surface air was measured at Tsukuba between July and September, 1980. The mean was 0.32_5 ppm, and the standard deviation was 0.00_8 ppm. No difference in the N_2O content was found between the air blowing from the northeast or south and calm air.

Recently many measurements of atmospheric dinitrogen oxide have been performed by gas-chromatographic (GC) methods using an electron-capture detector (ECD),[1] and the mixing ratio of the tropospheric N_2O has been found to be almost constant in the range from 0.31 to 0.34 ppm, within about a 10% systematic error among many laboratories.[2-7] In this study, the results of measurements of N_2O in the surface air at the Meteorological Research Institute, Tsukuba, will be reported, since the major source of the atmospheric N_2O is the activity of microorganisms in soils and waters, and since the diurnal variation has, for example, previously been reported in surface air.[8,9]

Experimental

Air 1 m above a ground surface covered with weeds was sampled by means of an air pump into a 2-ml gas sampling tube and was then transferred into a stainless steel column (6 ft× 1/8″ o. d.) filled with Porapak Q or QS (50—80 mesh, 35 °C). GC measurements were performed using a Perkin-Elmer Gas Chromatograph Sigma 1-Sigma 10 system equipped with an ECD (350 °C). A 95% Ar–5% CH_4 mixture was used as the carrier gas at a flow rate of 25 ml min^{-1}. The reference air, which was compressed into a 50-l stainless steel container up to 7 kg cm^{-2} and which could be used for 40—50 d, was first analyzed; then, after one hour, the outdoor air was sampled and analyzed. Such a pair of measurements was repeated every 6 h. The mixing ratio of N_2O in the reference air was determined by a previously reported method.[7] The error in the repeating measurements of the reference air was about 1%, and the detection limit was about 0.00_4 ppm. The total error in the measurements was estimated to be about ±5%.

Results and Discussion

Figure 1 shows the measurement results at Tsukuba from July to September, 1980, together with the temperature and wind data, which were obtained from the Aerological Observatory. The mean value for 60 measurements was 0.32_5 ppm, and the standard deviation (*SD*) was 0.00_8 ppm. Similar results have been obtained in many measurements of surface air in the U.S.A.,[2-5] Japan,[10,11] New Zealand,[2] Australia,[6] and England;[12] *i.e.*, the mixing ratio of N_2O in surface air is almost constant, more than 0.30 ppm.

In Fig. 2, the results are plotted for each wind direction. Figures 1 and 2 show that no difference in the mixing ratio of N_2O was found between the air blowing from the northeast or south and calm air, though a high mixing ratio of N_2O was expected to be observed under calm meteorological conditions at Tsukuba, a suburban agricultural area. The mixing ratios also showed no correlation with the temperature, even under calm conditions. Accordingly, no diurnal variation was observed. Similar results were obtained in Yokohama[13] and Kobe.[11] This must be due to the height of the air sampling;[9] 1 m above the ground surface, N_2O would be well mixed.

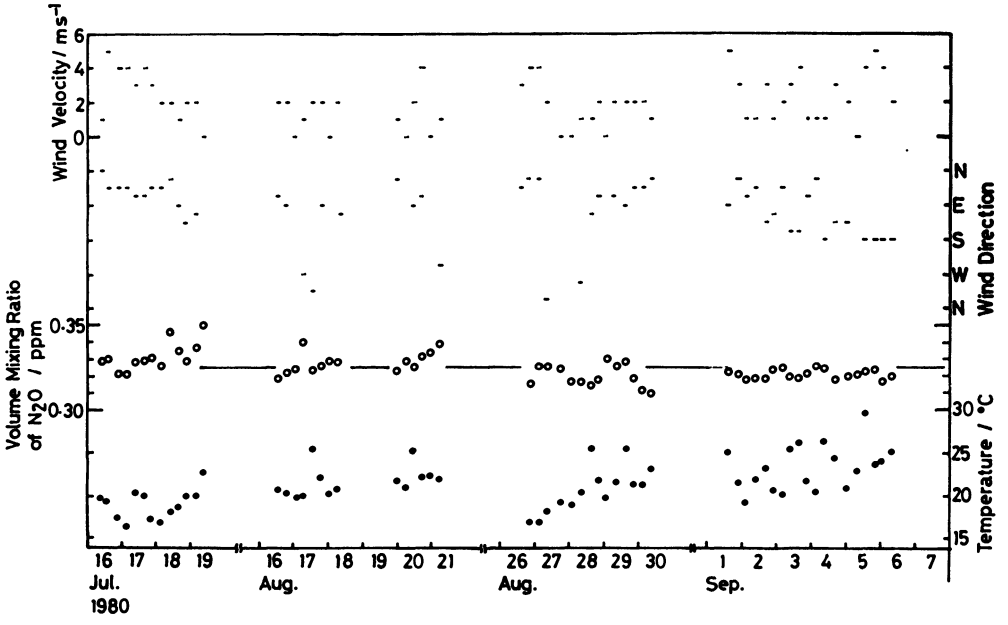

Fig. 1. The mixing ratio of N_2O in the surface air at Tsukuba between July and September, 1980.
——: Mean value (0.32_5 ppm). Wind and temperature data are also shown.

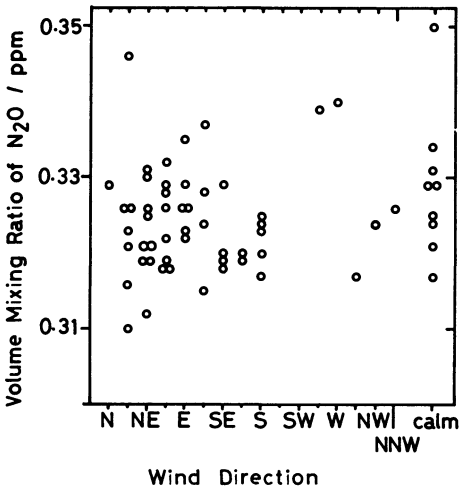

Fig. 2. The dependence of the mixing ratio of N_2O on the wind direction at Tsukuba.

The mean mixing ratio of N_2O observed at Tsukuba was almost equal to that of urban air at Kobe in the same year (mean value=0.319 ppm; *SD*=0.011 ppm).[11] Nearly the same mixing ratios were also observed from several measurements at Koenji, Tokyo, in the previous year (1979). The mean value was 0.32_7 ppm, and the *SD* was 0.00_9 ppm for 16 measurements between March and June.† This also shows that no difference in the mixing ratio of N_2O between urban and suburban air was found.

Much lower mean mixing ratios have been reported: 0.26 ppm in the summer of 1976[14] and 0.25 ppm in the summer of 1977[13] at Yokohama. The analytical method was improved from a GC-TCD one to a GC-MS one without preconcentration, and the *SD* of the measurement values decreased from 0.04 ppm to 0.015 ppm. One reason for the discrepancy between the GC-ECD method in the present study and the GC-MS one[13] would be that the calibration gas was composed of pure N_2 instead of purified air in the latter study. It is known at least that the sensitivity of ECD is raised by the presence of O_2.[15]

† Measurements were performed using a column filled with molecular sieve 5A.[7]

Substitution Reaction of In-plane Ligand in Bis(dimethylglyoximato)-cobalt(II) Complex with *N,N'*-Disalicylideneethylenediamine

Keisuke MITA,* Kazuhiko HOTTA, and Shoji WATANABE
Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka 536

(Received November 30, 1981)

Synopsis. A spectrophotometric study of the reaction $Co(dmgH)_2+salenH_2 \rightarrow Co(salen)+2\ dmgH_2$, in which $dmgH_2$ is dimethylglyoxime and $salenH_2$ is *N,N'*-disalicylideneethylenediamine, was carried out in methanol at 22 °C. The reaction rate decreased with increased amounts of added pyridine, and reached a stationary value at the molar ratio [pyridine]/[$Co(dmgH)_2$]=1. The form of the rate expression was $d[Co(salen)]/dt=k[Co(dmgH)_2]$ where the rate constant $k=0.023\ min^{-1}$.

In vitamin B_{12}, it has been reported that the 5,6-dimethylbenzimidazole axial base dissociates from the central cobalt atom very easily and that probably the base-off form contributes as a reactive intermediate during enzymatic reactions.[1] Therefore it is significant to study the properties of the base-off form in vitamin B_{12} or in a suitable model system. The high reactivity of the base-off form has been known in the electrochemical reduction of central cobalt atom[2] or in the cleavage of carbon-cobalt bond for vitamin B_{12} or for the model compounds.[3] However there have been few reports concerning the difference between the base-off form and base-on form in the reactivity of the in-plane ligand.

In the present work the substitution reaction of in-plane ligand in $Co(dmgH)_2$ complex (dmgH is the monoanion of dimethylglyoxime), which has been known as a good model compound of vitamin B_{12r}, was carried out in the presence and in the absence of axial base pyridine. $SalenH_2$ (*N,N'*-disalicylideneethylenediamine) was chosen as the substrate for the substitution reaction, because the reaction with $salenH_2$ was found to be a clean reaction, as expressed by

$$Co(dmgH)_2 + salenH_2 \longrightarrow Co(salen) + 2dmgH_2 \quad (1)$$

and it proceeds at an appropriate reaction rate in methanol solution at room temperature.

Experimental

A 30 cm^3 deoxygenated methanol solution of $Co(dmgH)_2$ complex was prepared at 2.0 mM† with 14.94 mg (0.06 mmol) of cobalt acetate tetrahydrate, 13.92 mg (0.12 mmol) of dimethylglyoxime, 4.8 mg (0.12 mmol) of sodium hydroxide and an appropriate amount of pyridine by the method of Schrauzer.[4] *N,N'*-Disalicylideneethylenediamine and Co(salen)was prepared by the method of Pfeiffer.[5]

The substitution reaction of $Co(dmgH)_2$ with $salenH_2$ was initiated by the injection of the deoxygenated methanol solution of $salenH_2$, which was prepared just before use, into the solution of $Co(dmgH)_2$ complex. After a small quantity of the reaction mixture was transferred to a 1 mm quartz cell, which was joined to the reaction vessel, the reaction progress was monitored by the measurement of the change in the visible absorption spectra in the thermostated cell compartment. The concentration of $Co(dmgH)_2$, $salenH_2$ and Co(salen) could then be determined by solving the equation described elsewhere.[6]

† 1 M=1 mol dm^{-3}.

Results and Discussion

Methanol solutions of $Co(dmgH)_2$ were prepared from cobalt acetate tetrahydrate and dimethylglyoxime without pyridine in concentrations ranging from 1 to 3 mM, and the visible absorption spectra were measured. When pyridine was added to the solutions no detectable change in the spectra was observed. When the absorbances of the spectra of those solutions at 472 nm were plotted against the amount of cobalt acetate tetrahydrate used for the complexation reaction, the plot showed a straight line with zero intercept. The results exhibit that, both in the presence and in the absence of pyridine, the complexation reaction between cobalt acetate tetrahydrate and dimethylglyoxime is complete in the present experimental conditions and that in both cases the spectra are almost the same. Similarly, at the concentrations ranging from 1 to 3 mM, cobalt acetate tetrahydrate and $salenH_2$ formed the 1 : 1 complex completely and the spectra of the solution showed no detectable change with the addition of pyridine.

The time-dependent change of spectra in the reaction between $Co(dmgH)_2$ and $salenH_2$ at equimolar ratio was measured in the molar ratios of pyridine to Co-$(dmgH)_2$, [py]/[$Co(dmgH)_2]_o$, =0.5, 0.8, 1.0, and 2.0 respectively. All of them showed distinct isosbestic points at 449 and 488 nm. A typical example is shown in Fig. 1. After the reaction was completed, the spectrum, for example of in Fig. 1, was found to be

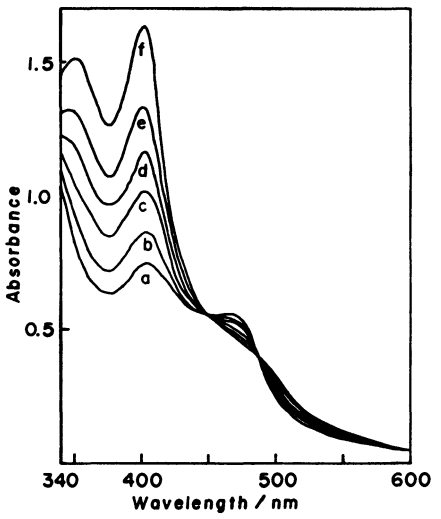

Fig. 1. Visible absorption spectra in the reaction between $Co(dmgH)_2$·py and $salenH_2$ in methanol at 22 °C after mixing 10(a), 15(b), 25(c), 35(d), 55(e), and 120 min(f) respectively.
Initial concentration: $Co(dmgH)_2$; 1.80, $salenH_2$; 1.80, and pyridine; 1.80 mM.

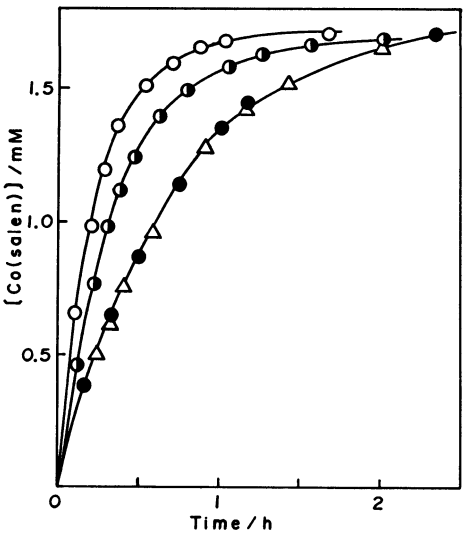

Fig. 2. Plots of the concentration of Co(salen) against reaction time for the substitution reaction at 22 °C.
Initial concentration of $Co(dmgH)_2$: 1.71 (○), 1.75 (◑), and 1.80 mM (△, ●).
$[py]/[Co(dmgH)_2]_o$=0.5 (○), 0.8 (◑), 1.0 (△), and 2.0 (●).

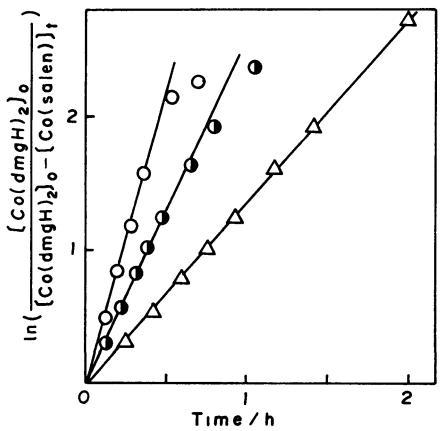

Fig. 3. First-order plots for the substitution reaction.
$[py]/[Co(dmgH)_2]_o$=0.5 (○), 0.8 (◑), and 1.0 (△).

similar to that of Co(salen) which was prepared in the same concentration as that of $Co(dmgH)_2$ at the reaction time t=0. The results of stoichiometry and the presence of isosbestic points indicate that they are clean reactions as expressed by Eq. 1.

The change of concentration of Co(salen) during the reaction was determined by using the above mentioned time-dependent change of the spectra. The results are shown in Fig. 2. In the absence of pyridine the reaction rate is so rapid that the result is not shown in the figure. From this result and Fig. 2 it was found that the reaction rate decreased with an increase of pyridine concentration and reached a stationary value at $[py]/[Co(dmgH)_2]_o$= 1.

Then $\ln(C_o/(C_o-C_t'))$, where C_o is the concentration of $Co(dmgH)_2$ at reaction time 0 and C_t' is the concentration of Co(salen) at reaction time t, was plotted against reaction time for the reaction between $Co(dmgH)_2$ and $salenH_2$ at $[py]/[Co(dmgH)_2]_o$=0.5, 0.8, and 1.0 respectively. Each of the plots, as is shown in Fig. 3, gives a straight line with a slope of 0.075, 0.042 and 0.023. Especially in the case of $[py]/[Co(dmgH)_2]_o$ =1, the plot showed linearity over at least 90% reaction. When $salenH_2$ was used in 2 times the concentration of $Co(dmgH)_2$ for the reaction, no detectable change was observed in the reaction rate. These results indicate that the reaction is first-order with respect to the concentration of $Co(dmgH)_2$ and zero-order with respect to the entering ligand concentration and that the rate equation is given by Eq. 2.

$$d[Co(salen)]/dt = k[Co(dmgH)_2] \quad (2)$$

in which rate constant k=0.023 at 22 °C in $[py]/[Co(dmgH)_2]_o$=1.

Recently Corey *et al.* have proposed a mechanism for the catalytic action of vitamin B_{12}.[1] A key feature of the proposal is the cleavage of the bond between carbon 1 and 19, which directly joins the A and D ring, and tridentate ligation of the seco-corin, by prior axial base ligand dissociation. The authors[7] and Tyrlik *et al.*[8] have proposed a mechanism involving lability of an in-plane dimethylglyoxime ligand for the hydrogenation of benzil catalyzed by $Co(dmgH)_2py$. These results do not contradict the present results.

Syntheses and Configurations of Copper(II) and Nickel(II) Complexes of *trans*-1,2-Dicyano-1,2-cyclohexanediamine

Hisashi ŌKAWA,* Miyuki KAKIMOTO, Tatsuo IZUMITANI, and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received March 12, 1982)

Synopsis. Complexation of the solid and oily isomers of 1,2-dicyano-1,2-cyclohexanediamine (abbreviated as s-cychd and o-cychd respectively) with nickel(II) and copper(II) ions have been investigated. Only s-cychd formed the complexes Ni(s-cychd)$_2$Cl$_2$ and Cu(s-cychd)$_2$X$_2$ (X=Cl, Br, NO$_3$, ClO$_4$). Based on the configuration of the nickel complex, s-cychd was shown to be the (*E*)-isomer and thence o-cychd the (*Z*)-isomer. Configurations of the copper complexes have been dicussed on the basis of electronic spectra of DMF solution and of powder sample.

Recently we have shown that the Schiff bases derived from 1,2-bis(aminomethyl)-1,2-cyclohexanediamine and salicylaldehydes are novel binucleating ligands, which can form "strati-bis" metal complexes.[1,2] However, we have not yet determined if the geometrical structure of 1,2-bis(aminomethyl)-1,2-cyclohexanediamine is (*Z*) or (*E*); the amine having been prepared by reducing the solid form of two isomers (crystal melting at 170 °C and oily substance) of 1,2-dicyano-1,2-cyclohexanediamine. It is known that the *trans*-1,2-cyclohexanediamine differs from the *cis*-isomer in complexation with nickel(II) chloride.[3] Thus, in order to determine the geometrical structures of the solid and oily isomers of 1,2-dicyano-1,2-cyclohexanediamine (abbreviated as s-cychd and o-cychd respectively), we attempted to synthesize nickel(II) and copper(II) complexes of s-cychd and o-cychd and to examine their configurations.

Experimental

Preparations. *Ni(s-cychd)$_2$Cl$_2$*: A solution of s-cychd (0.50 g) and nickel(II) chloride hexahydrate (0.36 g) in ethanol (40 cm^3) was stirred at a temperature lower than 25 °C. Pale blue crystalline powder, which was deposited, was collected, washed with ethanol, and dried *in vacuo*.

Cu(s-cychd)$_2$X$_2$ (X=Cl, Br, NO$_3$, ClO$_4$). These complexes were obtained as purple to bluish purple crystalline powder by the reaction of s-cychd and a copper(II) salt in ethanol.

Elemental analyses of the complexes are given in Table 1.

Measurements. Electronic spectra were recorded on a Shimadzu MPS-5000 spectrometer in *N,N*-dimethylformamide (DMF) and on powder sample. Infrared spectra were recorded on a Hitachi 215 spectrometer on KBr disks. magnetic susceptibilities were measured by the Faraday method and magnetic moments were calculated by the equation, $\mu_{eff}=2.828(\chi_A \times T)^{1/2}$.

Results and Discussion

By the reaction of s-cychd with nickel(II) chloride hexahydrate, blue-colored Ni(s-cychd)$_2$Cl$_2$ was prepared. However, the reaction of s-cychd with nickel(II) bromide, nitrate or perchlorate afforded a white amorphous compound, which is free from nickel and practically insoluble in water and most organic solvents. Infrared spectrum of this compound reveals a band at 1640 cm^{-1} attributable to amide group. We presume that this compound is a self-condensation product of s-cychd. On the other hand, s-cychd reacted with copper(II) salts to form copper(II) complexes with chloride, bromide, nitrate, and perchlorate.

All the attempts to obtain a metal complex from o-cychd and a nickel(II) salt or a copper(II) salt were unsuccessful. Instead, a white amorphous compound was produced, which is supposed to be a self-condensation product of o-cychd.

Infrared spectrum of Ni(s-cychd)$_2$Cl$_2$ showed two CN stretching bands at 2240 and 2150 cm^{-1}, while the spectra of the copper complexes showed one band near 2300 cm^{-1}. Nitrate and perchlorate ions are not coordinated to the metal in the copper complexes

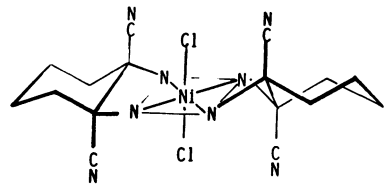

Fig. 2. Possible structure of $Ni(s\text{-}cychd)_2Cl_2$.

judging from their ν(NO) and ν(ClO) bands (NO_3^- 1360; ClO_4^- 1100 cm^{-1}).[4]

Magnetic moments and band frequencies of electronic spectra are given in Table 2. The electronic spectra of $Ni(s\text{-}cychd)_2Cl_2$ and $Cu(s\text{-}cychd)_2Cl_2$ in DMF are shown in Fig. 1. Electronic spectra of the nickel complex in DMF and on powder clearly indicate that the geometry around the metal is essentially octahedral. Splitting of the band $^3T_{1g} \leftarrow {}^3A_{2g}$ into two components may be attributed to the lowering of symmetry. The magnetic moment of this complex is quite normal for an octahedral nickel(II) complex.

Saito and Kidani[3] have shown that *trans*-1,2-cyclohexanediamine forms an octahedral nickel(II) complex, while the *cis*-isomer forms a planar complex. Hence, isolation of octahedral $Ni(s\text{-}cychd)_2Cl_2$ indicates that s-cychd is of the (*E*)-form. Thus, we may conclude that o-cychd is of the (*Z*)-form. A plausible structure of the nickel complex is shown in Fig. 2. The amino groups of s-cychd are equatorial when s-cychd coordinates to a metal and hence cyano groups are axial. Judging from the orientation of the cyano groups in $Ni(s\text{-}cychd)_2Cl_2$, it seems that there is little steric hinderance between the cyano groups and the chloride ion coordinated at the apical position.

Reflectance spectra of the copper complexes showed a broad band around $(15—18) \times 10^3$ cm^{-1} attributable to the d-d band. Relatively high frequencies of the bands for the nitrate and perchlorate complexes indicate the planar configuration around the metal ion, being consistent with the infrared spectral data implying non-coordination of the anions. On the other hand, the coordination geometry of the chloride and bromide copper complexes was assumed to be of a five-coordination with a halide ion at the apical position. Absorption spectra of all the copper complexes in DMF showed d-d band centered at $(14—15) \times 10^3$ cm^{-1}. This suggests that an anion or a solvent molecule coordinates to the metal to form a five- or six-coordinate configuration in DMF. Notably, the spectra of the complexes with halide ions in DMF showed an additional band at $(22—23) \times 10^3$ cm^{-1}, which was not clearly recognized in the reflectance spectra owing to the poor resolution. It seems reasonable to assign this band to the CT transition from halide ion to copper(II) ion. The molar extinction coefficient (ε) of the band of $Cu(s\text{-}cychd)_2Cl_2$ was practically independent of the concentration examined in this study (3.36×10^{-3}–1.03×10^{-4} mol dm^{-3}). On the other hand, that of the band of $Cu(s\text{-}cychd)_2Br_2$ was remarkably dependent on the concentration; ε decreased upon dilution and the band almost disappeared at the concentration 9.05×10^{-5} mol dm^{-3}. Thus, it is likely that the bromide ion is readily replaced by the solvent molecule in DMF.

Photoredox Chemistry of Copper(II) Perchlorate in Methanolic Medium

Paulo Augustro Correa da SILVA and Pazhayirayyathu Geeverghese DAVID*
Departamento de Quimica, Universidade de Brasilia, Brasilia-DF, Brazil
(Received November 16, 1981)

Synopsis. Ultraviolet irradiation of copper(II) perchlorate in methanol yields copper(I) and formaldehyde as the products. The primary photoprocess is believed to be the homolytic cleavage of copper(II)-methanol bond. Secondary reactions of oxidized solvent species with copper(II), copper(I), and solvent molecules affect the product quantum yields. Variation of the quantum yield for copper(I) as a function of irradiating wavelength indicates the existence of methanol-to-copper(II) charge transfer band in the 200—250 nm region.

Most of the reports on the photochemistry of copper(II) salts such as copper(II) chloride, bromide, perchlorate, *etc.*, describe only qualitative observations. Eventhough the observation of the photoxidation of organic solvents by copper(II) chloride dates back to 1804,[1] no report on the quantitative aspects has appeared hitherto. Kochi reported the use of UV irradiation of methanolic solutions of copper(II) chloride in the chlorination of organic compounds.[2] Qualitative observation of the photochemistry of methanolic solutions of copper(II) perchlorate to 254 nm radiations were reported by Murai and Tsutsumi.[3] The present report deals with the quantitative aspects of the photoreduction of copper(II) perchlorate in methanolic medium.

Experimental

Copper(II) perchlorate hexahydrate (Alfa Inorganics) and benzoic acid were purified by recrystallization from hot water and dried under vacuum. Methanol and methyl methacrylate were purified by published procedures.[4-6] Copper(I) solution was prepared by exhaustive photolysis of methanolic solution of copper(II) perchlorate (2.0×10^{-3} M, 1 M = 1 mol dm^{-3}) deaerated by bubbling oxygen-free nitrogen. A Rayonet Photochemical Reactor fitted with RPR 2540 Å lamps was used for this photolysis. All the quantum yields were determined at 25 ± 0.2 °C using deaerated solutions. Photochemical techniques[4] and chemical scavenging experiments[4-6] have been described. Copper(I) was determined spectrophotometrically as the $[Cu(dmp)_2]^+$ complex (dmp=2,9-dimethyl-1,10-phenanthroline). Formaldehyde and ethylene glycol were determined by the literature procedures.[7,8]

Results and Discussion

The electronic absorption spectrum of copper(II) perchlorate in anhydrous methanol is presented in Fig. 1 along which the variation of quantum yields for the formation of copper(I) ($\Phi_{Cu(I)}$) and formaldehyde (Φ_{CH_2O}) as a function of irradiating wavelength. Being a weak ligand coordination of ClO_4^- to copper(II) may be excluded and, hence, the broad absorption in the 200—250 nm region may reasonably be attributed to the charge transfer from methanol to copper(II). The existence of the CT absorption in this region is substantiated by the variation of the photoredox quantum yield as a function of irradiating wavelength (Fig. 1). The quantum yields show a tendency to level off for $\lambda<230$ nm and exhibit a threshold energy at approximately 333 nm.

In addition to copper(I), formaldehyde was formed during the irradiation at all wavelengths studied and its quantum yield was half of that of copper(I). It is important to point out that, contrary to the report of Murai and Tsutsumi,[3] we did not detect the formation of any precipitate of copper metal during or after the irradiations. It is quite probable that the disproportionation of copper(I) reported by these authors might be a consequence of its higher concentration (approximately 0.5 M copper(I) produced by exhaustive photolysis of copper(II) perchlorate). Copper(I) is apparently stable in methanol at the lower concentrations ($<10^{-1}$ M) encountered in our system.[9]

The primary photoprocess in the photolysis of methanolic solutions of copper(II) perchlorate may be represented as given below.

$$[Cu(CH_3OH)_6]^{2+} \longrightarrow [Cu(CH_3OH)_5]^+ + [CH_3OH]^+ \quad (1)$$

The $[CH_3OH]^+$ may be converted to $CH_3O\cdot$ or $\cdot CH_2OH$ by the following reactions.

$$[CH_3OH]^+ \longrightarrow CH_3O\cdot + H^+ \quad (2)$$

$$^*CH_3O\cdot + CH_3OH \longrightarrow {}^*CH_3OH + \cdot CH_2OH \quad (3)$$

The formation of $CH_3O\cdot$ during the photolysis of copper(II) perchlorate in methanol has been substantiated by Murai and Tsutsumi,[3] while our chemical scavenging experiments using methyl methacrylate clearly indicate the incorporation of $-CH_2OH$ end group in the polymer as was shown by the strong positive test for the OH end group in the photopolymer obtained by irradiating methanolic solutions of copper(II) perchlorate at 254 nm in the presence of methyl methacrylate. Polymer obtained from methanol solution which did not contain copper(II) perchlorate gave a negative test for OH end group.

In addition to Reaction 3, $CH_3O\cdot$ radical may disproportionate according to Reaction 4. Since Reaction 4 is second order, it may be considered insignificant due to the insufficient rate of production of $CH_3O\cdot$ during the photolysis of methanolic solutions of copper(II) perchlorate. Hence, we consider that Reaction 3 is the only significant thermal reaction in which $CH_3O\cdot$ disappears.

$$2CH_3O\cdot \longrightarrow CH_2O + CH_3OH \quad (4)$$

In methanolic medium $\cdot CH_2OH$ may dimerize, disproportionate, or reduce copper(II).[10,11] Ethylene glycol was not detected in our system after the photolysis and, hence, Reaction 5 may be considered insignificant. It is known that Reaction 6 has a second order rate constant slower than that of Reaction 5 by approximately a factor of ten.[12] Consequently, we consider the disproportionation reaction (6) insignificant. Therefore, the principal reaction of the reducing radical $\cdot CH_2OH$ is (7) leading to the formation of copper(I) and formaldehyde. This is further substantiated by our quantum yield data in the

$$2\cdot CH_2OH \longrightarrow (CH_2OH)_2 \quad (5)$$

$$2\cdot CH_2OH \longrightarrow CH_2O + CH_3OH \quad (6)$$

$$\cdot CH_2OH + [Cu(CH_3OH)_6]^{2+} \longrightarrow [Cu(CH_3OH)_6]^+ + CH_2O + H^+ \quad (7)$$

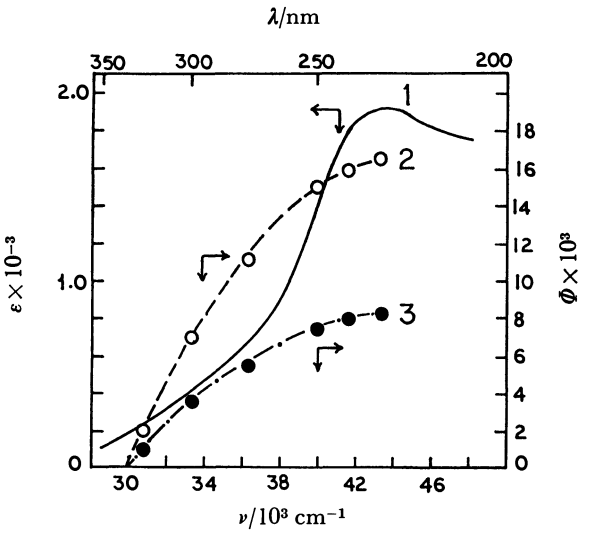

Fig. 1. Electronic absorption spectrum of copper(II) perchlorate in methanol (1), and the quantum yields for the formation of copper(I) (2), and formaldehyde (3) as a function of wavelength of irradiation. The quantum yields were determined for an initial concentration of copper(II) perchlorate 2.0×10^{-3} M, incident intensity $1.5\pm0.1\times10^{14}$ photons s^{-1}, and time of irradiation 10 h.

presence of added concentrations of benzoic acid for an initial concentration of copper(II) perchlorate 2.0×10^{-3} M, wavelength of irradiation 300 nm, incident intensity 1.5×10^{14} photons s^{-1}, and time of irradiation 10 h. The 300 nm irradiating wavelength was chosen to avoid the partial absorption of light by benzoic acid which absorbs at $\lambda<300$ nm. Gradual decreases in $\Phi_{Cu(I)}$ and Φ_{CH_2O} occur with increase in the concentration of benzoic acid. At benzoic acid concentrations 0.05 M or higher $\Phi_{Cu(I)}$ dropped to half of the value 0.007 obtained in the absence of benzoic acid and the Φ_{CH_2O} dropped to zero. This is in agreement with our prediction that, in the absence of benzoic acid which is known to act as a scavenger for $CH_3O\cdot$ and $\cdot CH_2OH$ radicals,[5] $\cdot CH_2OH$ reacts with copper(II) leading to copper(I) and formaldehyde (Reaction 7). If the thermal reactions (2), (3), and (7) follow Reaction 1, Φ_{CH_2O} should be half of $\Phi_{Cu(I)}$. Suppression of Reaction 7 by added $\cdot CH_2OH$ scavengers will affect $\Phi_{Cu(I)}$ and Φ_{CH_2O} and their relative values. Complete scavenging of $\cdot CH_2OH$ by benzoic acid will lead to $\Phi_{CH_2O}=0$ and $\Phi_{Cu(I)}$ equal to half of that in the absence of added radical scavengers, as was observed.

Quantum yields (wavelength of irradiation 250 nm, incident intensity 1.5×10^{14} photons s^{-1}, and time of irradiation 5 h) for the formation of copper(I) for initial concentrations of copper(II) perchlorate ($M\times10^5$) 1000, 500, 100, 50, 10, and 5 were, respectively, 0.006, 0.010, 0.016, 0.030, 0.102, and 0.120 (all± 0.002). The decrease in the product quantum yield with the increase in the initial copper(II) concentration suggests the importance of the reoxidation of copper(I) by the radicals generated in the reaction. Assuming a steady-state concentration for $CH_3O\cdot$ (or $[CH_3OH]^+$), the recombination $Cu^+ + CH_3O\cdot + H^+ \rightarrow [Cu(CH_3OH)]^{2+}$ (or $Cu^+ + [CH_3OH]^+ \rightarrow [Cu(CH_3OH)]^{2+}$) depends on the effective concentration of Cu^+. Increase in the concentration of copper(II) increases the absorbed intensity of light and/or decreases the pathlength of the solution absorbing light. This amounts to the increase in the photoreduction and/or restriction of the photoreduction to a narrower and narrower region of the photolysis cell nearest to the source (depth effect) with the consequent increase in the effective concentration of Cu^+. We have also observed decreases in the product quantum yields with the increase in time of irradiation indicating further the probable importance of the reoxidation of copper(I) by $CH_3O\cdot$ or $[CH_3OH]^+$. For 250 nm irradiating wavelength (incident intensity 1.5×10^{14} photons s^{-1} and initial concentration of copper(II) perchlorate 2.0×10^{-3} M) $\Phi_{Cu(I)}$ for time of irradiation 5, 10, 15, 20, and 40 h were, respectively, 0.014 (6.27), 0.012 (10.76), 0.010 (13.45), 0.008 (14.34), and 0.005 (17.93), the numbers in parentheses indicating the concentrations (mmol$\times10^5$) of copper(I) in 4.5 cm^3 of the solution after the irradiation. As we may observe, increase in the copper(I) concentration occurs with increasing time of irradiation, thus rendering the second order recombination (see above) more probable.[4] The quantum yields determined in the presence of added initial concentrations of copper(I) (mmol$\times10^5$) 0, 5, 10, 15, 20, and 25 in 4.5 cm^3 of the solution (other experimental conditions remaining same as indicated above) support this hypothesis. The quantum yields ($\Phi_{Cu(I)}$) were, respectively, 0.014, 0.012, 0.008, and 0.002 (all±0.002) for the first four solutions while it was zero for the last two. Photolysis appears to reach a steady-state for copper(I) concentrations higher than 1.5×10^{-4} mmol in 4.5 cm^3 (3.33×10^{-5} mol dm^{-3}).

The authors thank the National Research Council of Brazil (CNPq) for partial support to this work.

The Preparation and Catalytic Properties of the Silica-supported Rhodium Complex

Tamon OKANO,* Teruyuki KOBAYASHI, Hisatoshi KONISHI, and Jitsuo KIJI*
Department of Environmental Chemistry and Technology, Faculty of Engineering, Tottori University, Tottori 680
(Received September 21, 1981)

Synopsis. The $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ complex is attached to the phosphinated silica prepared from a new linking agent, $Ph_2PCH_2CH_2CH_2Si(OCH_3)_3$. The supported complex is an active catalyst for the hydrogenation of methyl cinnamate with CO and H_2O, and it can be used repeatedly with little loss of activity, whereas the polystyrene-supported one is not recoverable because of the insufficient complexation of the rhodium.

Recently, much attention has been focused on the chemistry of polymer-supported complex catalysts[1] because of their potential advantages. Functionalized polystyrenes have widely been studied as support, but few reports on silica have appeared. In contrast with polystyrene, silica is rigid and hydrophilic, and it is superior in thermal stability. Making good use of these characteristics, we have tried utilizing the silica-supported rhodium catalyst in the hydrogenation, using H_2O and CO as reducing agents.

The phosphinated silica[2] was synthesized by the following reactions.

$$ClCH_2CH_2CH_2Si(OCH_3)_3 \xrightarrow{Ph_2PH,\ NaH} Ph_2PCH_2CH_2CH_2Si(OCH_3)_3$$

$$Ph_2PCH_2CH_2CH_2Si(OCH_3)_3 \xrightarrow[HCl\ aq]{silica} Ph_2PCH_2CH_2CH_2Si\text{–}O\text{–}SiO_2$$

The linking agent, $Ph_2PCH_2CH_2CH_2Si(OCH_3)_3$, was prepared by the reaction of 3-chloropropyltrimethoxysilane with diphenylphosphine in the presence of sodium hydride. This reaction is a convenient alternative to the general synthetic method, which is based on the slow photochemical addition of diphenylphosphine to vinylsilanes.[3] The phosphination of silica was achieved by the hydrolysis of the linking agent in the presence of hydrochloric acid. The IR spectrum of the phosphinated silica thus prepared showed strong absorptions (3600—3200, 1200—1000, 960, 800 cm^{-1}) attributed to silica and weak absorptions (2930, 2870, 1420, 720, 685 cm^{-1}) attributed to the organofunctional group. The elemental analysis for phosphorus showed the content of the phosphine group to be 0.56 mmol/g. The hydrogen content observed was higher than the value calculated on the basis of the phosphorous content. This may be attributed to ≡Si–OH groups and/or adsorbed water on the silica surface. Since the surface area of the parent silica is 362 m^2/g, the average distance between the phosphino groups is estimated to be about 10 Å (1.8×10^{-6} mol/m^2).[4] Possessing some flexibility attributed to the trimethylene chain, the adjacent phosphines may act as a bidentate ligand with regard to the coordination to metals.

We have previously reported that halide-free rhodium phosphine complexes, such as $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ and $RhH(CO)(PPh_3)_3$, are efficient catalysts for the homogeneous hydrogenation of olefins with CO and H_2O.[5] The catalytic properties of the silica-supported catalyst were examined in hydorgenation of methyl cinnamate with CO in aqueous THF, in comparison with a polystyrene-supported one. The polystyrene support, which contains a diphenylphosphinomethyl group (7.9×10^{-4} mol/g, 1.7×10^{-6} mol/m^2), was prepared from a highly cross-linking polystyrene (divinylbenzene content, >30%; surface area, 590 m^2/g). The results are shown in Fig. 1. In the first run (R-0), a mixture of the silica or polystyrene support and $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ was used as a catalyst without any prior isolation of the supported complex. The catalysts were recovered by filtration and then reused in the succeeding runs. It seems that the homogeneous

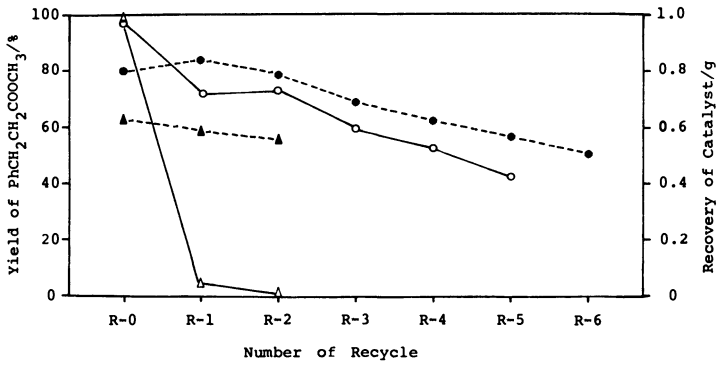

Fig. 1. Recycling of silica- and polystyrene-supported rhodium catalysts.
——: Yield, ------: recovery, ○, ●: silica-supported complex, △, ▲: polystyrene-supported complex. The weight of catalyst in R-0 is represented by the sum of the weight of support and $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$.

catalyst is anchored on the supports during the first reaction (R-0), and that the anchoring complex, which is able to exist stably under these reaction conditions, remains on the supports. The high activities of both fresh catalysts (R-0) may be attributed to the presence of some rhodium species uncomplexed on the supports. The polystyrene-based catalyst recovered after the first run was no longer active. In fact, the filtrate of the first run using the silica support was slightly pale yellow, while that using the polystyrene support was deeply colored. The leach of the rhodium from the pre-supported catalyst, which had been prepared by immersing the phosphinated polystyrene in a toluene solution of $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ at room temperature for 20 h, was not repressed by the use of double the amount of the support. Therefore, the complexation of the rhodium complex on the polystyrene support was insufficient. On the other hand, the loss of activity in the silica-supported catalyst was still gradual for several repeated uses. The amount of the supported catalyst recovered was also gradually decreased due to the loss in manipulation, except for the first recovery, where the weight was increased by the adsorption of water. Consequently, the corrected activities (R-0, 11.9; R-1, 7.8; R-2, 8.8; R-3, 8.5; R-4, 8.4; R-5, 7.4 mol of product/g of catalyst) of R-2, R-3, and R-4 suggest that the true activity was scarcely affected by the repeated uses. Additionally, the silica-supported catalyst was stable in air for a short time. The catalyst for the last use (R-5) was handled in air, but the loss of activity was small.

The supported complex prepared by immersing the phosphinated silica in a toluene solution of $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ at room temperature for 20 h did not show any observable IR absorptions attributed to the anchoring complex. On exposure to carbon monoxide (1 atm), three weak bands (2020, 1975, 1945 cm^{-1}) appeared. Therefore, the active species on the support may be mononuclear because these IR bands are in the region of the stretching vibrations of terminal metal carbonyls and metal hydrides containing phosphine ligands.

Experimental

Unless otherwise noted, all reactions and manipulations were carried out under an atmosphere of nitrogen. Literature methods were employed for the preparations of diphenylphosphine, $PHPh_2$,[6] and bis(triisopropylphosphine)dihydrido(hydrogencarbonato)rhodium(III), $RhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$.[7] The IR spectra were recorded on a JASCO IRA-1 spectrometer.

Preparation of $Ph_2PCH_2CH_2CH_2Si(OCH_3)_3$. A suspension of NaH (1.7 g, 71 mmol) in diphenylphosphine (12 g, 64 mmol) and Dimethyl Carbitol (30 ml) was heated at 120 °C for 1 h. The resulting red solution was cooled, and then $ClCH_2CH_2CH_2Si(OCH_3)_3$ (10.8 g, 54 mmol) was added. The mixture was heated at 130 °C for 1 h and subsequently, distilled under reduced pressure to give a viscous liquid (14 g, 150—180 °C/1 mmHg, 1 mmHg≈133.322 Pa). The crude product was redistilled to give the pure linking agent (10 g, 157—160 °C/0.5 mmHg) in a 53% yield.

Phosphination of Silica. Silica gel (Wakogel C-300, for column chromatography) was used without further purification. To a suspension of the silica (25 g) in toluene (150 ml) and concd hydrochloric acid (5 ml), we added $Ph_2PCH_2CH_2CH_2Si(OCH_3)_3$ (26 g, 75 mmol). The mixture was then slowly stirred with refluxing for 20 h. After cooling, the silica was collected by filtration, washed successively with water, methanol, benzene, methanol, water, methanol, benzene, and hexane, and then dried in a vacuum oven at 50 °C for 20 h to give white powder of phosphinated silica (28 g). Found: C, 11.70; H, 1.78; P, 1.72%.

Preparation of Phosphinated Polystyrene. Cross-linking polystyrene (Mitsubishi Chemical Ind., Ltd., Dia-ion HP-50: was purified by previously reported methods.[8] Chloromethylation was achieved according to literature methods[9] under the following condition: polystyrene (10 g), CH_3OCH_2Cl (9 ml), $SnCl_4$ (1.1 ml), in CH_2Cl_2 (50 ml), at 25 °C, for 1 h. The resulting chloromethylated polystyrene, which contained 4.41%. of chlorine, was phosphinated by previously reported methods[10] with a large excess of $LiPPh_2$ ($LiPPh_2/-CH_2Cl$= 50 mol/mol) in THF at room temperature for 60 h.

Hydrogenation of Methyl Cinnamate. A stainless steel autoclave (65 ml in capacity)was charged with phosphinated silica (724 mg, $-PPh_2$; 0.4 mmol), $PhH_2(O_2COH)[P(i\text{-}Pr)_3]_2$ (97 mg, 0.2 mmol) methyl cinnamate (1.62 g, 10 mmol), H_2O (0.9 g, 50 mmol), and THF (15 ml). The reactor was pressurized with CO (15 atm) and then heated at 130 °C for 20 h. After cooling, the suspension was filtered, and the silica-supported catalyst was washed with benzene. The filtrate was analyzed by GC, using naphthalene as the internal standard The silica was dried at room temperature under reduced presure and then weighed. The silica was used as the catalyst for the next run.

We wish to thank Mitsubishi Chemical Ind., Ltd., for its generous gift of polystyrene.

Ozonization of Organic Compounds. VI. Relative Reactivity of Protic Solvents toward Carbonyl Oxide

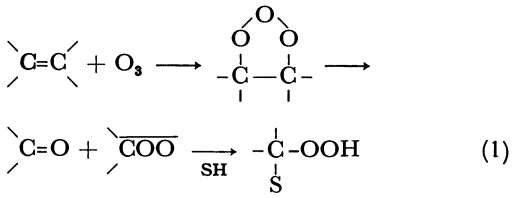
Yorihiro YAMAMOTO, Etsuo NIKI,* and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 8, 1981)

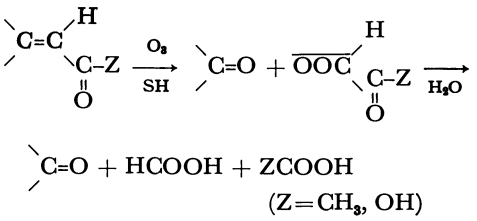
Synopsis. Tetramethylethylene was ozonized at 0 °C in several binary protic solvents and the relative reactivities of the solvents toward acetone carbonyl oxide were measured. The reactivity was found to decrease in the order methanol, ethanol, propyl alcohol, isopropyl alcohol, water, *t*-butyl alcohol, and acetic acid.

Carbonyl oxide is a key intermediate in the ozonolysis of olefinic compounds. It reacts with protic solvent (SH) to give hydroperoxide according to Eq. 1.[1] To understand the reactions of carbonyl oxide it is interesting and fundamental to know how the rate changes with solvents. For example, we reported previously[2]



(1)

that the anomalous ozonolysis of α,β-unsaturated carbonyl compounds proceeded in protic solvents mainly by the rearrangement of carbonyl oxide substituted by carbonyl or carboxyl group (Eq. 2) and that the ratio of anomalous ozonolysis to total ozonolysis depend on the solvents. These results suggest that the rate of reaction of carbonyl oxide with protic solvent varies with solvents.

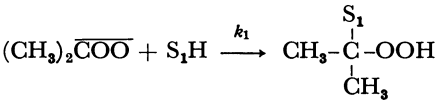


(2)

($Z=CH_3$, OH)

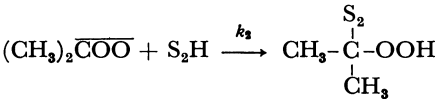
We wish to report here the relative reactivities of several protic solvents toward carbonyl oxide. We ozonized tetramethylethylene in binary protic solvents at 0 °C and measured the relative reactivities of protic solvents toward acetone carbonyl oxide, $(CH_3)_2\overline{COO}$ (Eqs. 3, 4).

The relative reactivity of S_1H and S_2H toward $(CH_3)_2\overline{COO}$, k_1/k_2, is expressed by Eq. 5 when the initial concentrations of S_1H and S_2H are high enough. It was difficult to measure the amounts of hydroperoxides **A** and **B** separately, so the relative reactivity k_1/k_2 was estimated from Eq. 6, where ΔS_1H and ΔS_2H represent the amount of S_1H and S_2H reacted, respectively.



(3)

A



(4)

B

$$\frac{k_1}{k_2}=\frac{\Delta A\cdot[S_2H]_0}{\Delta B\cdot[S_1H]_0} \quad (5) \qquad \frac{k_1}{k_2}=\frac{\Delta S_1H\cdot[S_2H]_0}{\Delta S_2H\cdot[S_1H]_0} \quad (6)$$

5 mmol of tetramethylethylene, S_1H, S_2H, and 15 ml of inactive solvent such as carbon tetrachloride, nitromethane, and ethyl methyl ketone were mixed in a reactor and O_3/O_2 gas was introduced into the reactor at 0 °C. Total amount of hydroperoxide was measured by iodometric titration. Both production of acetone and decrease of S_1H and S_2H were followed by GLC using PEG 20M, Porapak Q, and Apiezon Grease L columns. A part of tetramethylethylene was missed because of its high vapor pressure, so the amount of tetramethylethylene decreased was more than that of ozone introduced. Nevertheless, the ozonation was controlled so that some tetramethylethylene remained in the reaction mixture even at the end of ozonolysis in

order to avoid overozonization. Conversion of S_1H and S_2H was kept below 15%. It should be noted that α-methoxyalkyl hydroperoxide, $(CH_3)_2C(OCH_3)OOH$ decomposed to acetone quantitatively on GLC and that methanol was not detected.

It is necessary to confirm that the protic solvents react with carbonyl oxide quantitatively and peroxides, **A** and **B**, are the sole products in the reaction. As shown in Table 1, the amounts of peroxide formed (ΔHPO) and those of protic solvents reacted ($\Delta SH = \Delta S_1H + \Delta S_2H$) are in satisfactory agreement, which suggests that the hydroperoxides **A** and **B** are formed exclusively and that other peroxides such as diperoxide, triperoxide, and oligomers were not formed under the present conditions. It may be safely assumed that the inactive solvents used in Table 1 have little effect on the *relative* reactivities of protic solvents toward carbonyl oxides. From Table 1, the ratio $k_{MeOH}/k_{n\text{-}PrOH}$ is obtained as 2.5 in Run 3, which is in satisfactory agreement with the ratio calculated from the results of Runs 1 and 6, $2.0 \times 1.4 = 2.8$. Similarly, Run 4, and Runs 3 and 7 show that $k_{MeOH}/k_{i\text{-}PrOH}$ is 2.8.

Table 1 indicates that the reactivity of protic solvents toward $(CH_3)_2\overline{COO}$ decreased in the order of MeOH (1) > EtOH (0.50) > *n*-PrOH (0.40) > *i*-PrOH (0.36) > H_2O (0.28) > *t*-BuOH (0.077) > AcOH (0.063). The numbers in parentheses are the calculated reactivities of various protic solvents toward $(CH_3)_2\overline{COO}$ relative to methanol. The reactivity of alcohols has a close relation with the solvent polarity parameters, E_T, Z, S, and pK_{auto} as shown in Table 2. This suggests that the ionic transition state (**C**) plays an important role in the reaction of carbonyl oxide with protic solvent. In fact, the *ab initio* calculations[3] for carbonyl oxide suggest that the zwitterions (**D**, **E**) are favored over biradical (**F**) in protic solvents. However, the low reactivities of water and acetic acid toward carbonyl oxide in spite of their strong protic character (Table 2) suggest that this is not the only factor that determines the reactivity. Table 2 also shows that the bond dissociation energies of O–H bonds of water and acetic acid are much larger than those of alcohols. This might imply some contribution of homolytic scission of O–H bond (**G**) as well as the ionic one. Recent report by Sawaki, Kato, and Ogata[6] on the hydrogen atom abstraction by carbonyl oxide from toluene, cumene, and cyclohexane also suggests the importance of biradical character of carbonyl oxide.

CIDNP Studies of the Oxidation of *N*-(*p*-Tolylsulfonyl)-*N'*-triphenylmethylhydrazine

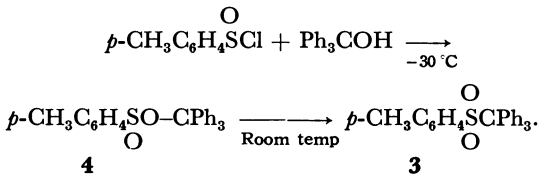
Masato Yoshida,* Akira Yano, and Michio Kobayashi
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received October 8, 1981)

Synopsis. The ^{13}C-CIDNP spectra were observed during the oxidation of *N*-(*p*-tolylsulfonyl)-*N'*-triphenylmethylhydrazine. The formation of sulfone and sulfinic ester as recombination products in a solvent cage was established from the signs of polarization.

In continuing the studies of the decomposition mechanism of the arylazo aryl sulfone,[1] we are interested in the reaction of *p*-tolyl triphenylmethylazo sulfone (**1**). Although *N*-(*p*-tolylsulfonyl)-*N'*-triphenylmethylhydrazine (**2**) is oxidized fairly easily by various oxidizing agents, such as mercury(II) oxide or potassium permanganate, the expected azo sulfone (Ph_3C–N=N–SO_2–Tol-*p*) is too unstable to be isolated as such; it decomposes immediately, with the evolution of nitrogen. The main product is *p*-tolyl triphenylmethyl sulfone (**3**; yield 51.7%), whose formation has been ascribed to the recombination of the *p*-toluenesulfonyl and triphenylmethyl radicals.[2] In order to clarify the details of the decomposition mechanism of *p*-tolyl triphenylmethylazo sulfone, we have studied the ^{13}C-CIDNP spectra observed during the oxidation of *N*-(*p*-tolylsulfonyl)-*N'*-triphenylmethylhydrazine.

Results and Discussion

CIDNP signals appeared when a mixture of *N*-(*p*-tolysulfonyl)-*N'*-triphenylmethylhydrazine (**2**) and yellow mercury(II) oxide in benzene or toluene was inserted into an NMR probe heated to 60—90 °C and the ^{13}C-NMR was measured. One of the spectra thus obtained is shown in Fig. 1. The signals were assigned by comparison with the chemical shifts of the authentic samples. Triphenylmethyl *p*-toluenesulfinate (**4**) was expected to isomerize quickly to the sulfone (**3**) at room temperature, so its chemical shifts were determined as follows: *p*-toluenesulfinyl chloride was added to a solution of triphenylmethanol in carbon tetrachloride in the presence of pyridine in an NMR sample tube at −30 °C, and then its ^{13}C-NMR spectrum was immediately determined at −30 °C. Strong, new ^{13}C-NMR signals assigned to sulfinate (**4**) were observed; when this solution was subsequently warmed to room temperature, though, different signals corresponding to sulfone (**3**) began to appear:



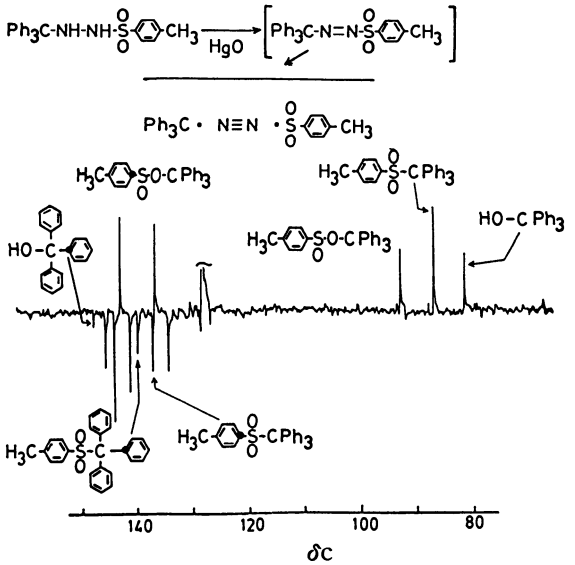


Fig. 1. ^{13}C-CIDNP spectrum in the oxidation of *N*-(*p*-toluenesulfonyl)-*N'*-triphenylmehtylhydrazine in benzene at 60 °C.

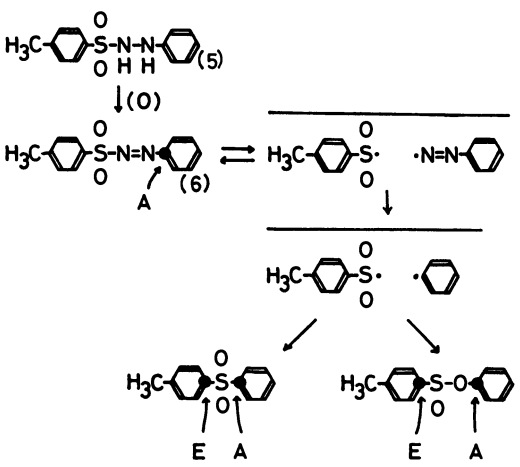
The formation of sulfone (**3**) and the sulfinic ester (**4**) as geminate recombination products in a solvent cage is established from the signs of polarization, as is shown in Fig. 1. The generated sulfonyl radical is ambident and acts as either an S- or O-centered radical to give both sulfone and the sulfinic ester, with triphenylmethyl radicals. The azo sulfone (**1**) did not show polarization. This indicates that hydrazine (**2**) is oxidized by mercury(II) oxide to the azo sulfone (**1**), which might decompose to the sulfonyl radical, the triphenylmethyl radical, and nitrogen simultaneously. On the other hand, it has been established that phenylazo *p*-tolyl sulfone (**5**) decomposes to the aryldiazenyl radical and the sulfonyl radical.[1] When a mixture of *N*-phenyl-*N'*-(*p*-tolylsulfonyl)hydrazine (**6**) and yellow mercury(II) oxide in toluene was warmed at 90 °C, the CIDNP signals of not only sulfone and the sulfinic ester, but also of azo sulfone (**5**), were observed. The obtained spectrum was identical with that observed in the thermal decomposition of

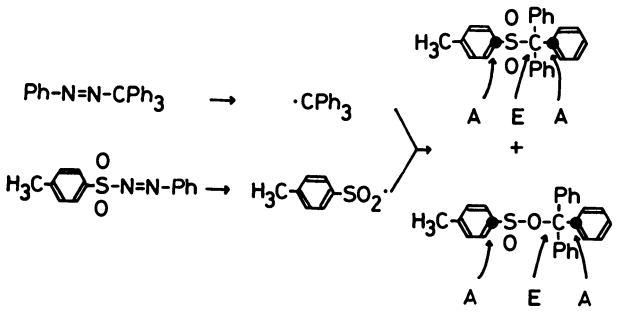


Scheme 1.

phenylazo *p*-tolyl sulfone in toluene.

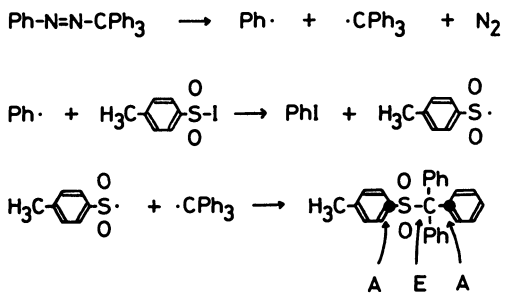
In order to examine the possibility of the recombination of the sulfonyl radical and the triphenylmethyl radical escaped from the solvent cage, the following two experiments were carried out.

(i) When the ^{13}C-NMR of a mixture of phenylazo *p*-tolyl sulfone and phenylazotriphenylmethane (PAT) in toluene at 90 °C was measured, CIDNP signals assignable to *p*-tolyl triphenylmethyl sulfone (**3**) and triphenylmethyl *p*-toluenesulfinate (**4**) were observed, besides the signals observed in the thermal decomposition of the azosulfone or PAT alone.



Scheme 2.

(ii) When the ^{13}C-NMR spectrum of a mixture of *p*-toluenesulfonyl iodide and PAT in toluene was measured at 90 °C, the CIDNP signals of *p*-tolyl triphenylmethyl sulfone (**3**) were obtained. The formation of the sulfone can be explained by the following reaction Scheme;



Scheme 3.

The sulfone and the sulfinic ester must be the result of the encounter of free radicals escaped from the original solvent cage, as has been shown before, and the signs of polarization should be the opposite of those obtained in the oxidation of hydrazine (**2**). The predicted signs of the recombination of the encounter of free radical, according to Kaptein's rule[3] are shown below:

	μ	ε	Δg	a	Γ_{ne}
C_1	+	+	+	(+)[4]	(+)
C_α	+	+	−	+[5]	−
$C_{1'}$	+	+	−	−[5]	+
C_1	+	+	+	(+)[4]	(+)
C_α	+	+	−	+[5]	−
$C_{1'}$	+	+	−	−[5]	+

$g = 2\ 0041(\cdot SO_2C_6H_4CH_3\text{-}p)$, $g = 2\ 0026(\cdot CPh_3)$.

Experimental

The ^{13}C-NMR spectra were taken with a JEOL Fx-60 FT-NMR spectrometer. The *N*-(*p*-tolylsulfonyl)-*N'*-triphenylmethylhydrazine was prepared from triphenylmethyl chloride and *p*-tolylsulfonylhydrazine and recrystallized from ethanol. The details have been described in Ref. 1. The *p*-tolyl triphenylmethyl sulfone was obtained from the reaction mixture of *N*-(*p*-tolylsulfonyl)-*N'*-triphenylmethylhydrazin and yellow mercury(II) oxide; it was recrystallized from benzene–ether (mp, 175—178 °C, lit, 171 °C[2]).

The Thermal Decomposition of *N,O*-Diacyl-*N*-*t*-butylhydroxylamines. IV. A Novel Acyloxyl Migration in *N,O*-Diacyl-*N*-*t*-butylhydroxylamines

Yuzuru UCHIDA* and Seizi KOZUKA†

Department of Applied Chemistry, Osaka Institute of Technology, Asahi-ku, Osaka 535

†*Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558*

(Received November 2, 1981)

Synopsis. Several *N,O*-diacyl-*N*-*t*-butylhydroxylamines were prepared, and their thermal decompositions were studied. *N*-Propionyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine gave *N*-*t*-butyl-2-benzoyloxypropanamide, together with the decomposition products, *N*-*t*-butylpropanamide and benzoic acid, upon thermal decomposition in tetralin. Similar benzyloxyl migrations were found in the thermal decomposition of *N*-butyryl, *N*-valeryl, and *N*-(3-phenylpropionyl) derivatives.

In the previous papers, we have reported that *N,O*-diaroyl-*N*-*t*-butylhydroxylamines gave amides and carboxylic acids upon the thermolysis in tetralin.[1] On the other hand, *N*-[2-(methylthio)benzoyl]-*O*-acyl-*N*-*t*-butylhydroxylamines gave rearranged products, *N*-*t*-butyl-2-(acyloxymethylthio)benzamides.[2] As a continuation of those studies, we have now studied the thermal decomposition of *N*-acyl-*O*-benzoyl-*N*-*t*-butylhydroxylamines (**1**) and found a novel benzoyloxyl migration reaction.

Results and Discussion

Several *N*-acyl-*O*-benzoyl-*N*-*t*-butylhydroxylamines (**1a**—**g**) were prepared by the reaction of *O*-benzoyl-*N*-*t*-butylhydroxylamine and the corresponding acyl chlorides in the presence of pyridine in benzene at 70 °C. However, the reaction of *O*-benzoyl-*N*-*t*-butylhydroxylamine with phenylacetyl chloride under the same conditions did not afford the corresponding *N*-phenylacetyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1h**), but *N*-*t*-butyl-2-chloro-2-phenylacetamide (**3**), as the major product. When the reaction was carried out in diethyl ether at room temperature, **1h** was detected as the product, together with **3**, but the attempted isolation of **1h** from the mixture was unsuccessful.

The thermal decomposition of **1** was carried out in tetralin at 210 °C in a degassed ampule. In the thermal decomposition of *N*-acetyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1a**), the products isolated were *N*-*t*-butylacetamide (**4a**), benzoic acid (**5**), acetic acid (**6a**), *N*-*t*-butylbenzamide (**7**), and carbon dioxide. 1,1′-Bitetralyl (**8**) and 1,2-dihydronaphthalene (**9**) were formed from the solvent. The yields of the products are summarized in Table 1. Similar results were also obtained in the thermal decomposition of *N*-isopropionyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1b**) and *N*-cyclohexylcarbonyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1c**).

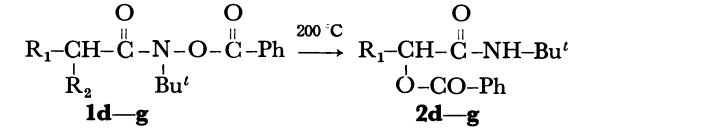
The results given in Table 1 show that two kinds of amides and acids, originating from the two acyl groups of the starting materials, were formed in each decomposition. The mode of decomposition is quite similar to that previously reported for the thermolysis of *N,O*-diaroyl-*N*-*t*-butylhydroxylamines.[1] The minor acid (**6**) and the amide (**7**) must be formed by means of an acyl-exchange reaction between the major acid (**4**) and the amide (**5**).[1]

On the other hand, *N*-propionyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1d**) gave the rearranged product, *N*-*t*-butyl-2-benzoyloxypropanemide (**2d**), together with the decomposition products: *N*-*t*-butylpropanamide (**4d**), **5**, propionic acid (**6d**), **7**, and a small amount of carbon dioxide. A similar benzoyloxyl migration from the nitrogen atom to the α-carbon atom of the *N*-acyl group was found in the thermal decompositions of *N*-butyryl- (**1e**), *N*-valeryl- (**1f**), and *N*-(3-phenylpropionyl)-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1g**), all of which have α-methylene in the *N*-acyl group. The products were identified by a comparison of their physical properties with those of authentic samples. The structures of the rearranged products (**2**) were established by means of elemental and spectral analyses. The IR spectra of **2** showed bands at 3300—3320 (N–H), 1720—1725, and 1660—1665 cm^{-1} (C=O). The yields of the products were estimated by means of GLC analysis.



1d—g **2d—g**

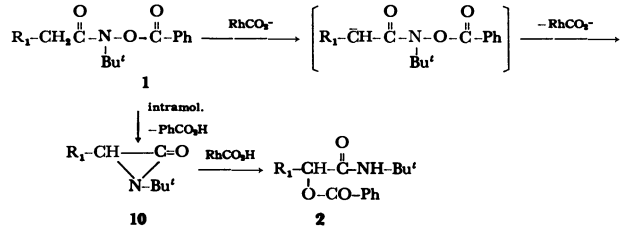
1d, 2d; $R_1 = CH_3$, $R_2 = H$ **1e, 2e**; $R_1 = C_2H_5$, $R_2 = H$
1f, 2f; $R_1 = C_3H_7$, $R_2 = H$ **1g, 2g**; $R_1 = PhCH_2$, $R_2 = H$

When the thermal decomposition of **1e** was carried out in the presence of an equimolar amount of *p*-toluic acid, both the benzoate (**2e**) and the toluate (**2i**) were formed. These results suggest that the rearrangement is an intermolecular reaction.

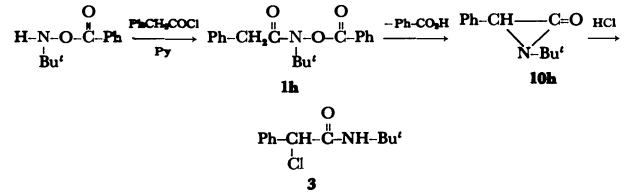
Baumgarten[3] reported that *N*-*t*-butylphenylacetamide gave *N*-*t*-butyl-2-*t*-butoxy-2-phenylacetamide on treatment with potassium *t*-butoxide and *t*-butyl hypochlorite. The formation of 1-*t*-butyl-3-phenylaziridinone (**10h**) *via* *N*-*t*-butyl-*N*-chlorophenylacetamide as an intermediate was suggested.

Although, a strong base was not used in the present thermolysis of **1**, α-lactam (**10**) may also contribute to the benzoyloxyl migration reaction as an intermediate. In previous papers,[1,2] we have proposed that nucleophilic displacement at the nitrogen atom was involved in the thermal decomposition of *N,O*-diacyl-*N*-*t*-

butylhydroxylamines. By analogy, the following scheme can be presented for the reaction involving the initial abstraction of the α-proton by the carboxylate ion; the resulting anion would cyclize to give **10**. Another possibility is the intramolecular elimination of benzoic acid from **1**, by either a 5- or 7-membered transition state, directly giving **10**. The α-lactam would react with carboxylic acid to give the rearranged product (**2**).



The unexpected results of the reaction of *O*-benzoyl-*N*-*t*-butylhydroxylamine with phenylacetyl chloride, which gave **3** instead of **1h** in benzene, may also proceed by a similar process involving the reaction of the α-lactam with hydrogen chloride.[4]



The absence of the rearranged products in the thermal decompositions of **1a**—**c** may be due to the instability of the intermediate (**10**). 1-*t*-Butylaziridinone (**10a**) is an unknown compound, and 1-*t*-butyl-3,3-dimethylaziridinone (**10b**)[5] and 1-*t*-butyl-3,3-pentamethyleneaziridinone (**10c**)[6] are known to decompose under milder conditions (above 75 °C). Thus, **2a**—**c** if formed, would decompose under the conditions employed for the thermolysis of **1**.

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were recorded on a Shimadzu IR-430 infrared spectrometer. The NMR spectra were recorded on a Varian EM-360 spectrometer, using TMS as the internal standard.

Preparation of N-*Acyl*-O-*benzoyl*-N-t-*butylhydroxylamine* (*1*). A typical procedure was as follows: A mixture of propionyl chloride (9.3 g, 100 mmol), *O*-benzoyl-*N*-*t*-butylhydroxylamine (19.3 g, 100 mmol),[1] and pyridine (7.9 g, 100 mmol) in benzene (100 cm³) was stirred at 70 °C for 6 h. The reaction mixture was washed with dil HCl, aq $NaHCO_3$, and water, and then dried over Na_2SO_4. The benzene was removed *in vacuo* to give crude *N*-propionyl-*O*-benzoyl-*N*-*t*-butylhydroxylamine (**1d**) (24.7 g), which was recrystallzed from petroleum ether (17.9 g, 72%): mp 56.5—57.5 °C. Found: C, 67.60; H, 7.83; N, 5.60%. Calcd for $C_{14}H_{19}NO_3$: C, 67.45; H, 7.68; N, 5.62%. By the same procedure, **1a**—**c** and **1e**—**g** were prepared by the reactions of *O*-benzoyl-*N*-*t*-butylhydroxylamine with the corresponding acyl chlorides. The results were as follows: **1a**; 86%, bp 125 °C/3 mmHg.†† Found: C, 66.49; H, 7.49; N, 5.98%. Calcd for $C_{13}H_{17}NO_3$: C, 66.36; H, 7.28; N, 5.95%. **1b**: 87%, mp 79—80 °C. Found: C, 68.44; H, 8.25; N, 5.22%. Calcd for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32%. **1c**: 92%, mp 118.5—119.5 °C. Found: C, 71.26; H, 8.49; N, 4.42%. Calcd for $C_{18}H_{25}NO_3$: C, 71.26; H, 8.31; N, 4.62%. **1e**: 68%, bp 136 °C/4 mmHg. Found: C, 68.13; H, 8.19; N, 5.21%. Calcd for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32%. **1f**: 67%, mp 41—42 °C. Found: C, 69.32; H, 8.37; N, 4.90%. Calcd for $C_{16}H_{23}NO_3$: C, 69.28; H, 8.36; N, 5.05%. **1g**: 71%, mp 76—77 °C. Found: C, 74.00; H, 7.22; N, 4.13%. Calcd for $C_{20}H_{23}NO_3$: C, 73.82; H, 7.12; N, 4.30%.

Reaction of O-*Benzoyl*-N-t-*butylhydroxylamine with Phenylacetyl Chloride*. A mixture of phenylacetyl chloride (15.4 g, 100 mmol), *O*-benzoyl-*N*-*t*-butylhydroxylamine (19.3 g, 100 mmol), and pyridine (7.9 g, 100 mmol) in benzene (300 cm³) was stirred at 70 °C for 3 h. The reaction mixture was washed with dil HCl, aq $NaHCO_3$, and water, and then dried over Na_2SO_4. The benzene was removed *in vacuo* and the residue was recrystallized from petroleum ether–dichloromethane to give *N*-*t*-butyl-2-chloro-2-phenylacetamide (**3**) (37%); mp 125.5—126.5 °C. NMR (CCl_4): δ 1.38 (9H, s), 5.14 (1H, s), 6.38 (1H, broad), 7.35 (5H, s). IR (KBr); 3300, 1550 (N–H), and 1655 cm⁻¹ (C=O). Found: C, 64.04; H, 7.38; N, 6.12%. Calcd for $C_{12}H_{16}ClNO$: C, 63.85; H, 7.15; N, 6.21%.

Thermal Decomposition of N-*Acyl*-O-*benzoyl*-N-t-*butylhydroxylamine* (*1*). A solution of **1** (2 mmol) in tetralin (20 cm³) was sealed in a degassed tube and heated at 210 °C in a constant-temperature bath. The product analyses and isolation were the same as those reported previously.[1] The properties of the rearranged products (**2**) were as follows: **2d**; mp 160—161 °C. IR (KBr); 3300 (N–H), 1720, 1660 cm⁻¹ (C=O). NMR (CCl_4): δ 1.35 (9H, s), 1.54 (3H, d, J=7 Hz), 5.28 (1H, q, J=7 Hz), 6.0 (1H, broad), 7.2—8.2 (5H, m). Found: C, 67.42; H, 7.91; N, 5.84%. Calcd for $C_{14}H_{19}NO_3$: C, 67.45; H, 7.68; N, 5.62%. **2e**; mp 124—125 °C. IR (KBr): 3300 (N–H), 1725, 1665 cm⁻¹ (C=O). NMR (CCl_4): δ 0.98 (3H, t, J=7 Hz), 1.34 (9H, s), 1.98 (2H, m), 5.14 (1H, t, J=7 Hz), 5.8 (1H, broad), 7.2—8.2 (5H, m). Found: C, 68.50; H, 8.34; N, 5.06%. Calcd for $C_{15}H_{21}NO_3$: C, 68.41; H, 8.04; N, 5.32%. **2f**; mp 98—99 °C. IR (KBr): 3300 (N–H), 1720, 1660 cm⁻¹ (C=O). NMR (CCl_4): δ 0.97 (3H, t, J=7 Hz), 1.33 (9H, s), 1.4—2.3 (4H, m), 5.18 (1H, t, J=6 Hz), 5.8 (1H, broad), 7.2—8.2 (5H, m). Found: C, 69.23; H, 8.51; N, 4.92%. Calcd for $C_{16}H_{23}NO_3$: C, 69.28; H, 8.36; N, 5.05%. **2g**; mp 153—154 °C. IR (KBr): 3320 (N–H), 1720, 1665 cm⁻¹ (C=O). NMR (CCl_4): δ 1.23 (9H, s), 3.25 (2H, d, J=6 Hz), 5.38 (1H, t, J=6 Hz), 5.6 (1H, broad), 7.20 (5H, s), 7.2—8.1 (5H, m). Found: C, 73.66; H, 7.21; N, 4.13%. Calcd for $C_{20}H_{23}NO_3$: C, 73.82; H, 7.13; N, 4.30%. **2i**; mp 123—124 °C. IR (KBr): 3300 (N–H), 1720, 1660 cm⁻¹ (C=O). Information Chemistry and Molecular Evolution of Protein. Evolutionary Tree of Calmodulin

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 10, 1981)

Synopsis. The amino acid sequences of calmodulin, one of calcium-binding proteins, taken from bovine brain, scallop, sea anemone, and tetrahymena were compared to examine its molecular evolution. By the use of maximum parsimony method, its evolutionary tree was constructed, It was found that this protein has changed much more slowly than have such proteins as cytochrome c.

Origin and evolution of life is one of the most important problems in biology and biochemistry. One of the best ways to approach this problem is to study molecular evolution of proteins.[1] In the course of evolution, natural selection improved the functions of protein molecules and preserved the improvements. However, it has been known that there are rapidly changing and slowly changing proteins against evolution. An advantage of studying the molecular evolution arises from this phenomenon. If the broad outlines of the history of life are wanted, then a widely distributed, slowly evolving protein must be studied. On the other hand rapidly changing proteins such as fibrinopeptides are most useful to study the details of one branch of the evolutionary tree of living organisms.

So far, cytochrome c has been known to be a typical example of widely distributed, slowly evolving proteins, and its evolutionary tree has been constructed.[1] In the present paper, we examine the molecular evolution of calmodulin (CM). It is also widely distributed throughout eukaryotes, and changes much more slowly than does cytochrome c. This implies that the evolution of CM is useful to measure the history of life with much longer time scale than that of cytochrome c. By applying maximum parsimony method (a technique of information chemistry) to the primary amino acid sequence, we construct an evolutionary tree of CM taken from various biological species.

CM is one of the calcium-binding proteins.[2,3] It has four calcium-binding sites, and interacts reversibly with Ca^{2+} to form a calmodulin–Ca^{2+} complex, whose activity is controlled by the cellular flux of Ca^{2+}. Once bound to Ca^{2+}, CM assumes a more helical conformation to become the active form. Thus, CM plays an important role in regulating other enzymatic reactions or cellular processes. The complete amino acid sequence of bovine brain CM was determined by Watterson *et al.*[4] and by Kasai *et al.*[5] It contains 148 amino acids and has a trimethylated lysine at position 115. The primary structure of CM appears to be highly conservative throughout the phylogenetic scale. For example, the amino acid sequence of CM from bovine brain is virtually identical with the partially completed sequences of CM from rat testis and bovine uterus.[3] Recently, in order to examine such a highly conservative structure, Toda *et al.*,[6] Takagi *et al.*,[7] and Yazawa *et al.*[8] determined the amino acid sequences of CM from phylogenetically more distant species, such as scallop (*Patinopecten*), sea anemone (*Metridium senile*), and tetrahymena (*Tetrahymena pyriformis*).

For the complete amino acid sequences of CM from (A) bovine brain, (B) scallop, (C) sea anemone, and (D) tetrahymena, refer to those references. In the following, we discuss only the positions and the species of amino acid residues which are different from each other. For this purpose, we take an expression of {position, (a), (b), (c), (d)}, where (a), (b), (c), or (d) indicates the amino acid residue of CM from the biological species of (A), (B), (C), or (D) at the corresponding position, respectively. Using this expression, we can only find the following differences; {70, Thr, Thr, Thr, Ser}, {71, Met, Met, Met, Leu}, {85, Ile, Ile, Ile, Leu}, {86, Arg, Arg, Arg, Ile}, {90, Arg, Arg, Arg, Lys}, {94, Lys, Lys, Lys, Arg}, {99, Tyr, Phe, Phe, Leu}, {101, Ser, Ser, Ser, Thr}, {135, Gln, Gln, Gln, His}, {136, Val, Val, Val, Ile}, {143, Gln, Thr, Lys, Arg}, {146, Thr, Thr, Thr, Deletion}, and {147, Ala, Ser, Ser, Ala}. The amino acids at the other positions are common with the four biological species. Highly conservative property of the amino acid sequence of CM is well demonstrated, if we compare the difference of the amino acid residues at the same position. For example, only three amino acid differences are found between bovine brain and sea anemone. Concerning the sequences of bovine brain and tetrahymena, only eleven amino acid changes and one lack of amino acid residue at position 146 are found in tetrahymena.

It is generally known that codons of m RNA are translated into amino acids of protein.[1] Any codon is composed of a series of three nucleotides and is expressed by "the genetic code." Therefore, the observed difference of amino acid residues of CM between two biological species is attributable to the difference of nucleotides between the corresponding codons. Referring to the genetic code, we assume that the difference of amino acids of CM between the two species is given

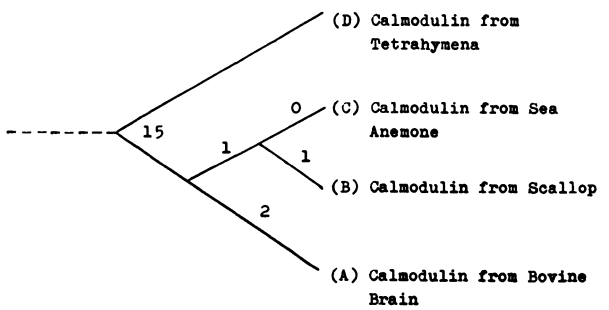

Fig. 1. The evolutionary tree estimated by applying maximum parsimony method to the difference in the amino acid sequences of calmodulin taken from (A) bovine brain, (B) scallop (*Patinopecten*), (C) sea anemone (*Metridium senile*), and (D) tetrahymena (*Tetrahymena pyriformis*). Numbers indicate nucleotide replacements.

by the least number of nucleotide replacements of the codons. This approach is called "maximum parsimony method." It is considered that the distance between two biological species may be also expressed by such a number of replacements. According to this method, the number of nucleotide replacements in CM between two biological species of (A) and (B) is 4, that between (A) and (C) is 3, that between (A) and (D) is 17, that between (B) and (C) is 1, that between (B) and (D) is 17, and that between (C) and (D) is 16. Here, the lack of amino acid residue at position 146 of (D) is counted as three nucleotide replacements. From these data, an evolutionary tree of CM is constructed as is shown in Fig. 1, where numbers indicate nucleotide replacements. Using this evolutionary tree together with the data on the difference of amino acid residues given previously, we can reconstruct the amino acid sequence of the common ancestor of (A), (B), and (C) as ···-$\overset{99}{\text{Phe}}$-··· -$\overset{143}{\text{Lys}}$-···-$\overset{147}{\text{Ala}}$-···, where the remaining amino acid residues are common to those of the three species. In order to reconstruct the amino acid sequence of the common ancestor of (A), (B), (C), and (D), it is necessary to know the amino acid sequences of CM of fungi and plants, which had diverged earlier than the common ancestor of (A), (B), (C), and (D) diverged. However, no such data are available at present.

Next, we compare evolutionary rate of CM with that of cytochrome c, which contains 104 amino acid residues. In cytochrome c, the primates differ from other mammals by 8—12 residues; mammals and birds differ by an average of 9.9; mammals and reptiles and amphibia by 14; the vertebrates of all kinds differ from insects by 26.[1] On the other hand, as was mentioned, only three amino acid differences were found in CM between bovine brain and sea anemone. Biologically speaking, these two biological species are phylogenetically more distant from each other than those species given in cytochrome c. Therefore, CM appears to be much more conservative against evolution than cytochrome c. Why CM is so conservative? One of the reasons for this is that CM is a finely tooled molecule which must mesh with a number of other macromolecules to regulate various enzymatic reactions or cellular processes.[2,3] This means that a slight structural change in CM will have great influence upon such reactions and processes and that the vast majority of chance alternations are intolerable. On the other hand, cytochrome c, although it meshes with some other proteins, has less influence upon other reactions, and a chance mutation which is tolerable will occur more frequently. In this respect, if the primary amino acid sequences of CM are determined with more variety of biological species, we can measure the history of life with considerably longer time scale.

The author would like to express his appreciation to Professor Koichi Yagi for his kind advice and stimulating discussion regarding this work.

Anormalous Halogen to Dimethylamino Replacement with *N,N*-Dimethylformamide Catalyzed by Ethylenediamine or 2-Aminoethanol

Hiroshi YAMAMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received January 11, 1982)

Synopsis. 1- And 2-chloroanthraquinone and 2-amino-4-chloro-6-hydroxypyrimidine exclusively gave the dimethylamino derivatives upon heating in DMF at 90 °C in the presence of ethylenediamine or ethanolamine. A possible reaction pathway for this unusual exchange reaction was discussed.

The active chlorine atoms that are attached to an acyl group[1] or certain aromatic and heteroaromatic nuclei[2-7] (*e.g.*, nitrobenzene[2] and pyridine[6]) are replaced by dimethylamino groups upon boiling with *N,N*-dimethylformamide (DMF) for a prolonged period according to Scheme 1. We will describe here a similar type of exchange reaction which is, however, characteristically catalyzed by ethylenediamine (EDA) or 2-aminoethanol at *ca.* 90 °C.

$$RCl + Me_2NCHO \longrightarrow RNMe_2 + HCl\ (or RN^+HMe_2Cl^-) + CO$$

Scheme 1.

The treatment of 1- and 2-chloroanthraquinone (**1** and **2**) and the chloropyrimidines (**3** and **4**) with 1.0—2.0 mol equiv. of EDA or 2-aminoethanol in DMF at 90 °C afforded exclusively the dimethylamino compounds (**5**—**8**) instead of the normally expected substitution products (*e.g.*, **9**—**11**), as is recorded in Entry 1 of Table 1. Since all these chloro compounds were stable in DMF alone at this temperature, EDA and 2-aminoethanol are thought to act as catalysts for the dimethylamination. The catalytic efficiency was shown best by EDA or 2-aminoethanol, moderately by 1,3-propanediamine, and only slightly by 1,4-butanediamine, *N,N*- and *N,N'*-dimethylethylenediamine, 2-(methylamino)ethanol, or butylamine (Entry 2). No catalytic effect was found with triethylamine or ethylene glycol.

N-Methylformamide and *N*-formylmorpholine afforded a moderate yield of the corresponding exchange products (**12**—**15**), along with an appreciable amount of the substitution products (**9**, **10**), whereas, with *N,N*-diethylformamide and *N,N*-dimethylacetamide, the chloro compounds (**1**—**3**) either remained unreactive or preferably produced **9** and **10**. Thus, the reactivities of the aminating reagents depended upon the combination of the amines and the *N*-acyl groups (Entry 3).

The use of ethanol as a solvent in the reaction of **1** with DMF–2-aminoethanol (2 mol equiv. each) suppressed the formation of both **5** and **9** (Entry 4). It should also be noticed that the reaction temperature plays an important role, as was observed in the predominant formation of **9** when **1** was heated with DMF or *N*-formylmorpholine in the presence of 2-aminoethanol at a lower temperature, such as 60 °C (Entry 4).

Benzoyl chloride, bearing a chlorine atom highly reactive towards nucleophiles, reacted with EDA in DMF, even at 0 °C, to give solely the *bis*-compound (**16**); without EDA, *N,N*-dimethylbenzamide is slowly produced upon heating in DMF only above 150 °C.[1] On the other hand, 2,4-diamino-6-chloropyrimidine (**17**), with a less reactive chlorine atom than **3** or **4**, remained almost unchanged, even on heating with DMF–EDA at 120 °C (Entry 4).

Chlorine atoms in hydroxy- or amino-chloropyrimidines are known to be replaced by alcoholic solution of amines, usually at relatively elevated temperatures in a sealed tube;[8] *e.g.*, 6-methylaminouracil is obtained from **4** at 130 °C, and 2,4,6-triaminopyrimidine, from **17** at 200 °C. However, such nucleophilic substitution with liberated dimethylamine is not conceivable in the present, unusual exchange reaction, since no dimethylamine was produced upon the heating of a 1 : 1 mixture of DMF and EDA (or 2-aminoethanol) at 90—100 °C for 2—20 h (by ^{1}H-NMR and GLC). Instead, DMF is likely to form a certain complex with EDA or 2-aminoethanol at *ca.* 90 °C; this complex subsequently reacts with chloro compounds (**1**—**4**) to give the dimethylamino derivatives at much faster rates than those of the exchange reaction (without using such catalysts) as are illustrated in Scheme 2. The predominant formation of the substitution products (**9**, **16**) with the catalysts at 0—60 °C can be explained in terms of the sluggish formation of such an intermediate complex at low temperatures.

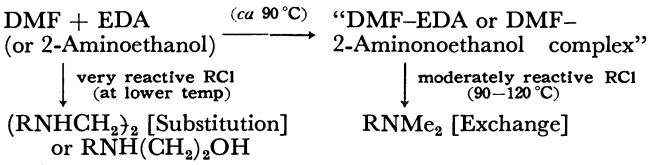

Scheme 2.

Although the exact nature of the complex and the reaction mechanism remain to be clarified further, the present procedure is apparently a convenient method for the dimethylamination of some aromatic and heteroaromatic compounds bearing a reactive chlorine atom. The results also demonstrate the necessity of

taking precaution in employing DMF as a solvent in combination with certain amines, such as EDA and 2-aminoethanol.

Expermiental

The ^{1}H-NMR Spectra were measured with a Hitachi High-resolution NMR Spectrometer, R 20A (60 MHz), at 27 °C, using TMS as the internal standard, and the IR spectra, with a JASCO IRA-1 Spectrophotometer. Column chromatograhpy was carried out with alumina (Merck, Activity I, basic) or silica gel (Wako C-200), with ether–benzene or methanol–chloroform as the eluant. All the reactions were monitored by means of TLC.

Materials. The starting materials and products cited in this study are all known compounds except for **10** and **15**; thus, they are either commercially availabel or are prepared according to the literature methods (*cf.* Table 1) and purified before use.

General Procedures. A mixture of 50 mg of the active chloro compounds (**1**—**4**, PhCOCl, and **17**), 1.0 mol equiv. of the ethylenediamines (or 2.0 mol equiv. of 2-amonoethanol or other amines), and 1 ml of freshly distilled DMF (or the aminating reagent) was heated under nitrogen (or, in some cases, in a sealed tube); the reaction time and temperature are shown in Table 1. In many cases, the pure product was precipitated and subsequently isolated simply by filtration. The dilution of the filtrate with water gave the second crop. When the reaction products were a mixture, they were extracted with benzene after being diluted with water. The combined organic extracts were concentrated, and the residue was chromatographed. The products were characterized by a mixed-melting-point determination and by means of comparative TLC with authentic specimens prepared by alternative routes (Table 1) as well as by means of their ^{1}H-NMR and IR spectra.

*2-(2-Hydroxyethylamino)anthraquinone (**10**)*: Brown prisms; mp 206—207 °C (from EtOH); IR (Nujol) 3390, 3280 (OH, NH), 1660 (C=O), 1595 and 1560 cm^{-1} (C=C); ^{1}H-NMR δ ($CDCl_3$–DMSO-d_6, 1 : 1) 3.29† (1H, s, HO-2'), 3.40 (2H, brt, J=5.0 Hz, H_2-1'), 3.80 (2H, brt, J=5.0 Hz, H_2-2'), 4.91† (1H, m, NH), 6.90 (1H, dd, J=9.0, 2.5 Hz, H-3), 7.40 (1H, d, J=2.5 Hz, H-1), 7.80 (2H, m, H-6,7), 8.15 (1H, d, J=9.0 Hz, H-4), and 8.25 (2H, m, H-5,8), Found: C, 72.08; H, 4.82; N, 4.93%. Calcd for $C_{16}H_{13}NO_3$: C, 71.89; H, 4.91; N, 5.25%.

*2-Morpholinoanthraquinone (**15**)*: Reddish orange needles; mp 223—224 °C (from benzene); IR ($CHCl_3$) 1670 (C=O), 1595 (C=C), 1325, 1290 and 915 cm^{-1}; ^{1}H-NMR δ ($CDCl_3$–DMSO-d_6) 3.3—3.8 (8H, m, morpholino) and 7.0—8.3 (7H, m, aromatic). Found: C, 73.65; H, 5.28; N, 4.43%. Calcd for $C_{18}H_{15}NO_3$: C, 73.70; H, 5.15; N, 4.77%.

The author wishes to thank to Professor Wolfgang Pfleiderer of Universität Konstanz, West Germany, for his valuable discussions and encouragement.

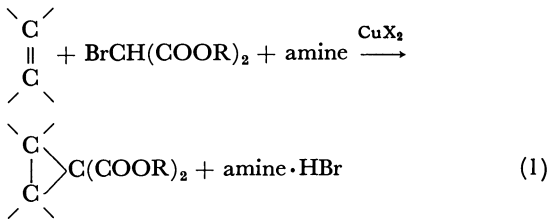
Copper(II) Halide Catalyzed Cyclopropanation of Olefins Involving Dehydrobromination of Bromomalonic Ester by Amine

Nariyoshi KAWABATA,* Shinji YANAO, and Jun-ichi YOSHIDA
Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received January 21, 1982)

Synopsis. The reaction of olefins with bromomalonic ester and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) proceeded in the presence of a catalytic amount of copper(II) halide to give 1,1-bis(alkoxycarbonyl)cyclopropane derivatives. DBU was converted into DBU-hydrobromide during the reaction. The reaction was electrophilic and proceeded nonstereospecifically.

Cyclopropane derivatives activated by two electron-withdrawing substituents at geminal position are called electrophilic cyclopropanes, and have recently been recognized as useful intermediates in organic synthesis.[1] Their inter- and intramolecular ring opening reactions by various nucleophiles have been investigated intensively, and applied to the synthesis of several natural products.[1] Recently we have reported a new cyclopropanation reaction of olefins with *gem*-dibromides such as dibromomalonic ester using a stoichiometric amount of copper[2] or copper(I) salt.[3] In this paper we wish to describe that electrophilic cyclopropanes were obtained by use of only a catalytic amount of copper(II) salt in the reaction of olefins with bromomalonic ester and amine (Eq. 1).



(1)

When bromomalonic ester was allowed to react with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and olefins in the presence of a catalytic amount of copper(II) bromide, 1,1-bis(alkoxycarbonyl)cyclopropane derivatives were obtained. For example, the reaction with styrene proceeded smoothly at room temperature in benzene to give 1,1-bis(ethoxycarbonyl)-2-phenylcyclopropane in 87% yield. During the course of the reaction, a solid material precipitated which was identified as DBU-hydrobromide by comparison of its IR spectrum with that of an authentic sample.

The effect of a variety of amines on the yield of the cyclopropane derivative was examined in the reaction with styrene (Table 1). DBU (pK_a 11.5) was the most effective amine among the examined. Triethylamine (pK_a 10.7), diethylamine (pK_a 10.9), and butylamine (pK_a 10.6) were less effective. 1,4-Diazabicyclo[2.2.2]-octane (DABCO) (pK_{a1} 3.0; pK_{a2} 8.6), pyridine (pK_a 5.2), and aniline (pK_a 4.6) were scarcely effective. In the absence of amine, the cyclopropane derivative was not formed. These results seemed to indicate that basicity of the added amine was of major importance. It should be noted, however, that sodium hydride was inactive in spite of its higher basicity than that of DBU.

Table 1. Effect of amine on the copper(II) bromide catalyzed cyclopropanation of styrene involving dehydrobromonation of diethyl bromomalonate by the amine[a]

Amine	Yield of cyclopropane/%[b]	
DBU	87	
Triethylamine	Trace[c]	(26)
Diethylamine	47	(59)
Butylamine	16	(25)
DABCO	Trace[c]	(Trace[c])
Pyridine	0	(0)
Aniline	0	(Trace[c])
Sodium hydride	Trace[c]	(Trace[c])

a) Reactions were carried out with styrene (2.0 mmol), diethyl bromomalonate (3.0 mmol), amine or sodium hydride (3.6 mmol), copper(II) bromide (0.10 mmol), and benzene (2.0 ml) at room temperature for 1 h. b) Determined by GLC, based on the olefin. Yields after 24 h are given in parentheses. c) GLC analysis of the reaction mixture showed a very small peak having the identical retention time with that of the cyclopropane derivative, but the product was not fully identified.

Table 2. Synthesis of 1,1-bis(alkoxycarbonyl)-cyclopropanes from various olefins[a]

Olefin	Yield of cyclopropane/%[b]	
Styrene	87	(Trace[c])
p-Methylstyrene	76	(Trace[c])
m-Trifluoromethylstyrene	27	(Trace[c])
p-Chlorostyrene	53	(Trace[c])
Acrylonitrile	62	(63)
Methyl vinyl ketone	56	(56)
Ethyl acrylate	18	(20)

a) Reactions were carried out with an olefin (2.0 mmol), diethyl bromomalonate (3.0 mmol), DBU (3.6 mmol), and benzene (2.0 ml) in the absence or presence of copper(II) bromide (0.10 mmol). b) Determined by GLC, based on the olefin. Yields obtained in the absence of copper(II) bromide are given in parentheses. c) See footnote (c) in Table 1.

Presumably the amine played some important role, *e.g.*, coordination to the copper ion and accelerating the reaction, in addition to functioning as a simple base.

Copper(II) bromide was the catalyst of choice for the reaction of styrene with diethyl bromomalonate and DBU in benzene, and the yield of the cyclopropane derivative was 87%. Copper(II) chloride (50% yield), copper(I) chloride (76%), and copper(I) iodide (51%) were somewhat less effective. Use of copper(II) acetate and copper(II) acetylacetonate resulted in very low yields. In the absence of catalyst, the cyclopropane derivative was not obtained. The yield was also greatly

influenced by the nature of the solvent. In methanol and hexane, the cyclopropane derivative was not obtained in an appreciable amount. Polar aprotic solvents such as dimethyl sulfoxide (82%), *N,N*-dimethylformamide (54%), and acetonitrile (52%) were effective, but benzene was the most suitable solvent among the examined.

Other examples of the reaction (Eq. 1) are summarized in Table 2. The reaction with substituted styrenes gave the corresponding cyclopropane derivatives in moderate to high yields. Electron-deficient olefins such as acrylonitrile and methyl vinyl ketone also reacted smoothly to give the cyclopropane derivatibes in good yields. Electron-rich olefins such as isobutyl vinyl ether were inactive under the conditions. The reaction with alkyl-substituted olefins such as 1-octene and cyclooctene gave the cyclopropane derivatives only in very low yields.

The cyclopropanation reactions of (*E*)- and (*Z*)-β-methylstyrene were studied to determine the stereospecificity of the reaction. From both olefins were obtained the (*E*)- and (*Z*)-cyclopropane derivatives in essentially the same ratio (*E*/*Z*=95/5), indicating that the reaction proceeded in a non-stereospecific way. Isomerization of (*E*)- and (*Z*)-β-methylstyrene and that of (*E*)- and (*Z*)-cyclopropane derivatives were not observed under the conditions.

The relative reactivity of substituted styrenes was also investigated. The logarithm of relative reactivity was plotted against Hammett σ value to obtain a straight line with good correlation. A slope of −0.8 indicates that the reaction is electrophilic.

It should be noted that the reaction with electron-deficient olefins such as acrylonitrile proceeded even in the absence of the catalyst, whereas the reaction with styrene derivatives essentially required the copper salt as catalyst. Therefore it seems reasonable to consider that the reaction with electron-deficient olefins proceeded through a different reaction pathway from that with styrene derivatives. A mechanism involving Michael type addition of the carbanion of bromomalonic ester may be plausible for the reaction with electron-deficient olefins.[4] For the copper(II) bromide catalyzed reaction with styrene derivatives, a mechanism involving a free radical intermediate or an organocopper intermediate seems to be plausible. Relatively low reactivity of unconjugated olefins such as isobutyl vinyl ether or 1-octene may accommodate the free radical mechanism. Further mechanistic studies will hopefully delineate the detailed mechanism.

Experimental

Infrared spectra were measured with a Hitachi Model 215 grating spectrophotometer. ^{1}H NMR spectra were obtained with a Varian Model T-60A spectrometer in CCl_4 using Me_4Si as the internal standard. GLC analysis and preparative purification were performed by a Shimadzu GC-4C gas chromatograph equipped with a 1 m×3 mm column (Silicone DC-550 5% on Celite 545, 60—80 mesh) and a thermal conductivity detector. Diethyl bromomalonate was prepared by light-induced bromination of diethyl malonate[5] and purified by fractional distillation under reduced pressure. *p*-Methylstyrene,[6] *p*-chlorostyrene,[6] *m*-trifluoromethylstyrene,[6] (*E*)-β-methylstyrene,[6] and (*Z*)-β-methylstyrene[7] were prepared according to the literature procedures with minor modifications. Other olefins were commercially available and were distilled before use. An authentic sample of DBU-hydrobromide was prepared by treatment of DBU with dry hydrogen bromide in benzene. All solvents were dried in a usual manner and distilled before use. Other chemicals including copper salts and amines were used as obtained commercially.

General Reaction Procedure for Synthesis of 1,1-Bis(alkoxycarbonyl)cyclopropanes from Olefins. A mixture of an olefin (2.0 mmol), DBU (548 mg, 3.6 mmol), and anhydrous copper(II) bromide (22 mg, 0.10 mmol) in benzene (2.0 ml) was placed in a 20-ml one-necked flask fitted with a magnetic stir bar and a stopcock. Diethyl bromomalonate (717 mg, 3.0 mmol) was added dropwise with stirring under cooling in a water bath (15—25 °C). An exothermic reaction took place and DBU-hydrobromide gradually precipitated. After the addition was completed, the mixture was stirred for 1 h. An appropriate hydrocarbon internal standard was added and the mixture was analyzed by GLC. The products were isolated by preparative GLC and identified by comparison of their IR and ^{1}H NMR spectra with those of authentic samples.[2] DBU-hydrobromide was separated from the reaction mixture by filtration, washed with ether, dried under vacuum, and identified by comparison of its IR spectrum with that of an authentic sample (88% yield based on diethyl bromomalonate).

The reaction with other amines, sodium hydride, or other copper salts, and the reaction in other solvents were carried out in a similar fashion.

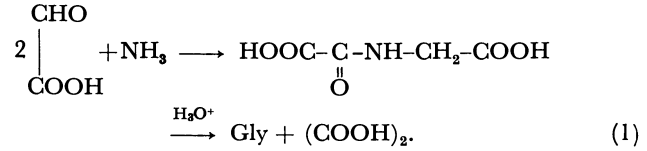
An Experimental Approach to the Prebiotic Synthesis of α-Amino Acids under UV Irradiation in Aqueous Medium

Masato NISHIZAWA* and Fujio EGAMI
Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194
(Received March 3, 1982)

Synopsis. *N*-Oxaloglycine obtained from a glyoxylic acid and ammonia mixture was allowed to produce various α-amino acids under UV irradiation using an alkylating agent such as an olefin in the presence of acetone as the initiator. Aspartic acid, norvaline, valine, leucine, phenylalanine, and tyrosine were identified by TLC, amino acid analysis, GC, and GCMS techniques.

On the basis of a generally accepted working hypothesis that life originated in the primeval sea, research at our laboratory has been directed toward the synthesis of biomolecules in modified sea medium from primitive compounds such as formaldehyde and hydroxylamine.[1] Particular attention has been paid to synthetic pathways of amino acid formation in the primeval sea. An understanding of these pathways of amino acid formation may possibly provide a clue to the origin of genetic code, in view of the relation between amino acid and nucleic bases. Our purpose has been to find possible synthetic routes of amino acids prebiotically in a neutral aqueous medium. Besides the well-known Strecker synthesis,[2] we found a new route through *N*-acyl amino acid from α-oxo acid and ammonia.[3] *N*-Oxaloglycine is synthesized from a glyoxylic acid and ammonia mixture simply by combining it with a neutral or weak acidic aqueous solution to obtain a yield of about 20% even at room temperature. The reactions involved are as follows:



This general reaction scheme was demonstrated in the synthesis of sarcosine, alanine, glutamic acid, and phenylalanine.[3,4] In this paper, our effort has been directed to the conversion of *N*-oxaloglycine into other α-amino acids by introducing C_n moieties on the α-carbon of the glycine residue photochemically.

Experimental

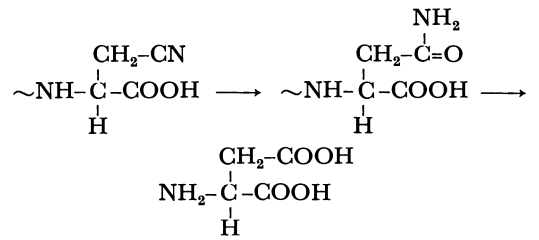
Materials. Disodium salt of *N*-oxaloglycine was prepared by two methods. By one method, this compound was isolated from a reaction mixture of glyoxylic acid and ammonia.[3] The other method was the traditional organic synthesis.[5] The purity was determined by elemental analysis, UV, IR, and NMR. And the results were as follows; Calcd for $C_4H_3N_1O_5Na_2 \cdot 1/2\ H_2O$: C, 24.16; H, 1.78; N, 6.74%. Found: C, 23.80; H, 1.55; N, 6.46%. λ_{max} (ε)=214 nm (4.5×10^3 cm^{-1} M^{-1} (1 M=1 mol dm^{-3})) in 0.6 M HCl. 1680—1600, 1550 cm^{-1}. δ=4.29 (s). Research grade propylene, isobutylene and 2-butene (*cis* and *trans*) were purchased from Seitetsu Kagaku Co. Ltd. *N,N*-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) was obtained from Pierce Chemical Co. Acetonitrile was refluxed with phosphorus pentaoxide and distilled.

Method. An aqueous solution containing 20—40 mg of disodium salt of *N*-oxaloglycine, 10—20% (v/v) of acetone and an alkylating agent was made up, deaerated by charging it with nitrogen gas using the syringe technique and irradiated with a high pressure Hg-lamp (Ushio electric Co. UM-102, 100 W) through a Pyrex-filter. When using a gas as an alkylating agent, it was made to pass through the reaction mixtures under irradiation. After 20 h irradiation, the reaction mixture was evaporated and hydrolyzed with 6 M HCl at 105 °C in Dri-block DB-3H (M & S instrument) over night. A hydrolysate was used to determine what amino acids were present. The spots on silica gel TLC (ethanol : water=6 : 4, 1-butanol: acetic acid : water=4 : 1 : 1, and 1-propanol : ammonia= 3 : 1) were investigated with UV light and ninhydrin spraying. Amino acid analysis was performed with a Hitachi KLA-5 automatic analyzer.

Analysis of Trimethylsililated Amino Acid (TMS-Amino Acid). An aqueous solution of hydrolysate was treated with an appropriate amount of $CaCl_2$ to remove calcium oxalate, and the supernatant was lyophilized and dried at 80 °C under vacuum. A 5—10 mg of residue was heated with 0.5 ml distilled acetonitrile and 0.5 ml of BSTFA at 140 °C for 2 h. After concentrated under vacuum, a 0.5—5 μl sample was charged on a GC (Shimadzu GC-4M) and GCMS (Shimadzu 7000) using an OV-11 (10%) column. The technical data obtained were as follows. I) Reaction with acetonitrile: GC, col. temp 195 °C, inj. temp 250 °C. Retention time was 4.51 min (TMS-aspartic acid). GCMS *m/e* 349 (M^+), 232, 218. II) Reaction with propylene: GC, col. temp 80—200 °C at 5 °C/min, inj. temp 220 °C. Peaks appeared at 14.56 (TMS-valine) and 15.43 min (TMS-norvaline). GCMS *m/e* 218, 144 for both peaks. III) Reaction with isobutylene: GC, col. temp 80—200 °C at 5 °C/min, inj. temp 220 °C. Retention time was 17.55 min (TMS-leucine). GCMS *m/e* 218, 158. IV) Reaction with toluene: GC, col. temp 190 °C, inj. temp 250 °C. A peak corresponding to TMS-phenylalanine appeared at 5.50 min. GCMS *m/e* 218, 192, 91. V) Reaction with *p*-cresol: GC, col. temp 240 °C, inj. temp 280 °C. A peak of 5.05 min corresponded to TMS-tyrosine. GCMS *m/e* 280, 218, 179. The carrier gas flow rates were 40 ml/min and 15—20 ml/min for nitrogen (GC) and helium (GCMS), respectively.

Results and Discussion

N-Oxaloglycine was useful as a starting material in this experiment, since it could be obtained simply by mixing glyoxylic acid and ammonia in a neutral or weak acidic aqueous solution at room temperature.



The introduction of a C_2 unit to *N*-oxaloglycine was achieved with the use of acetonitrile. Since aspartic acid was found to be one of the final product following acid hydrolysis, following scheme has been proposed

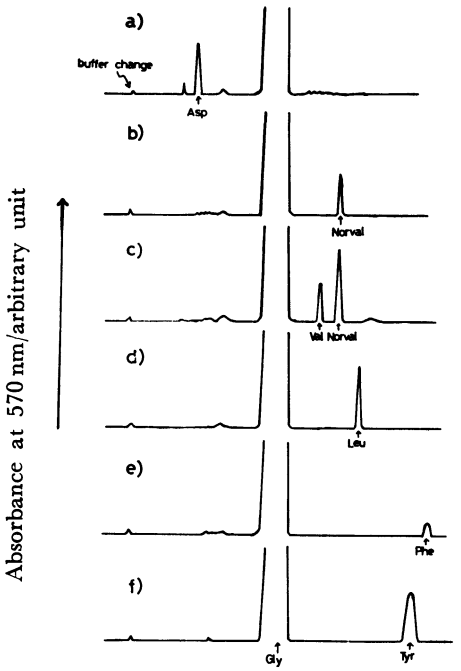


Fig. 1. Amino acid analyses of acid hydrolysates from reaction mixtures.
a): Reaction with acetonitrile, b): reaction with propylene, c): reaction with propylene in the presence of 10^{-4} M palladium(II) chloride, d): reaction with isobutylene, e): reaction with toluene, f): reaction with *p*-cresol.

as a plausible hydrolysis route. The cyanoalanine residue is finally hydrolysed to asparagine and aspartic acid. Acetate could not be introduced onto *N*-oxaloglycine in this experiment.

Norvaline was formed using propylene in the absence of metal ions (Fig. 1-(b)). The formation of valine (Fig. 1-(c)) may be inconsistent with the anti-Markownikov mode, if a radical mechanism is operative. However, added metal ions can react with propylene under the experimental conditions to result in a different product. This phenomenon was observed when either $PdCl_2$, $CoCl_2$, or $MnCl_2$ was added. Other metal ions such as Fe^{2+}, Cu^{2+} gave no valine peak. When acrylonitrile was put into the reaction system, the resulting considerable precipitation under UV irradiation precluded an analysis of glutamic acid.

The C_4 unit was inserted onto *N*-oxaloglycine by using isobutylene as an alkylating agent. Except glycine only a leucine peak is evident in Fig. 1-(d). Only a trace amount of *cis* and *trans*-2-butene resulted in the formation of isoleucine as indicated by amino acid analysis sensitivity. Decisive identification was not possible under our experimental conditions.

In the system which included *p*-cresol as an alkylating agent, tyrosine was obtained from *N*-oxaloglycine. The hydroxyl group of *p*-cresol probably had no need of protection since there was no ninhydrin-positive by-product as evident from Fig. 1-(f). Since toluene is not very soluble in the aqueous-acetone mentioned above, *N*-oxaloglycine was suspended in a 1 : 1 aqueous acetone mixture under vigorous stirring, resulting in the formation of phenylalanine.

When using a low pressure Hg-lamp to excite *N*-oxaloglycine ($\varepsilon_{254}=450\ cm^{-1}\ M^{-1}$) and alkylating agents, no expected amino acids were produced. Acetone was then introduced into the system so as to initiate a photochemical process. Similar photochemical reactions were reported by Elad *et al.*[6] in organic solvents. The n-π^* transition of a carbonyl compound brings about a biradical expressed as $>\dot{C}-\dot{O}$, which can abstract a active hydrogen on α-carbon of glycine residue. The radical species can react with an alkylating agent to possibly form a branched α-amino acid. On the other hand, it is necessary for the rather stable radicals to combine with the glycine residue. In fact, when this combination occurs, unsaturated bonds are situated close to the radical site. When glycine was used as a starting material, no converted amino acid was found. In this connection, *N*-oxaloglycine synthesized from glyoxylic acid and ammonia is suitable for conversion to other amino acids, in view of prebiotic synthesis and the organic chemistry involved. In strong acidic or basic media, the above reaction was found to be negligibly. In a non-deaerated system ninhydrin-positive by-products were formed to a considerable extent and the production of expected amino acids decreased by about one third. This may possibly confirm that a prebiotic neutral aqueous medium is suitable for forming amino acids photochemically, though the conversion yield was *ca.* 1% at this stage.

Also of interest is the relation between the synthetic route of amino acids and the origin of genetic code, for which a working hypothesis has been proposed by Egami.[7] The most important aspect of this matter is the interdependent genesis of protein amino acids and nucleic bases. According to Egami, synthetic route is reasonable in the case of aspartic acid from a glycine residue plus a C_2 unit, and valine from a glycine residue plus a C_3 unit.

In conclusion, several protein amino acids were formed from common materials such as glyoxylic acid, ammonia, nitrile, and hydrocarbons under UV light.

We should like to express our sincere appreciation to Miss Yumiko Makino for her technical assistance in the amino acid analysis.

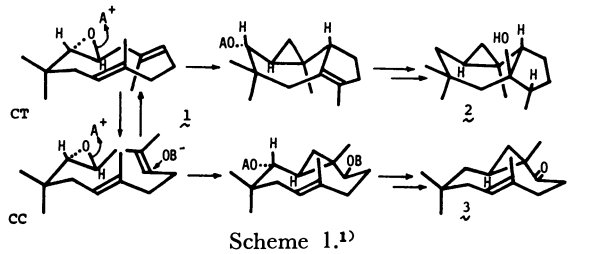
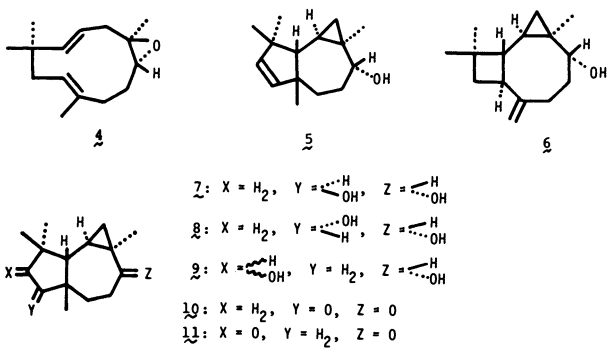
(Received January 30, 1982)

Synopsis. Humulene 6,7-epoxide was converted by treatment with trimethylsilyl triflate to 5-hydroxy-4,8,11,11-tetramethyl[6.3.0.0^{2,4}]undec-9-ene in 81% yield.

Recently we reported a conversion of humulene 9,10-epoxide (**1**) to africanol (**2**) and bicyclohumulenone (**3**) through a "conformationally selective reaction"[1] (Scheme 1). The conversion means achievement of a high grade simulation of cyclohumulanoid biosynthesis.[1] In this paper we would like to describe a conversion of humulene 6,7-epoxide (**4**) by means of trimethylsilyl triflate (TMSOTf)[2] into a tricyclic alcohol, 5-hydroxy-4,8,11,11-tetramethyltricyclo[6.3.0.0^{2,4}]undec-9-ene (**5**) in good yield. The transannular cyclization (**4**→**5**) was first described by Takahashi *et al.*[3] who treated **4** with sulfuric acid and obtained a hydrated form of **5**, namely, **7** in 25% yield with several other products. Our reaction was quite clean and gave **5** as an essentially sole product.



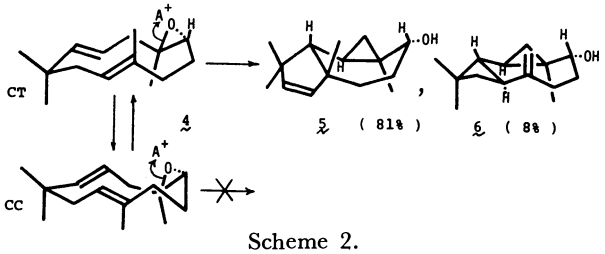
Scheme 1.[1]



The epoxide **4**[4] was treated with TMSOTf in toluene at −78 °C to give a crystalline mass. Chromatographic separation of the products gave tricyclic alcohol **5** in 81% yield accompanied by a small amount (8%) of another tricyclic alcohol **6**. The alcohol **6** was previously obtained by acid treatment of a tricyclohumuladiol by Naya and Kotake.[5]

The compound **5** exhibited the same molecular weight as that of the original epoxide (M^+=220) and an OH band (3300 cm^{-1}) in its Mass and IR spectra respectively. The NMR spectrum displayed signals at δ 0.1—0.8 (3H, m, cyclopropane), 1.00, 1.10, 1.12, 1.14 (each 3H, s, Me×4), 3.39 (1H, dd, J=6, 10 Hz, H+OH), 5.24 (2H, s, olefinic). These observations together with consideration of the reaction course led to structure **5** for this compound. Stereochemistry of **5** was determined through its chemical conversion to known compounds. Treatment of **5** with B_2H_6 in THF followed by oxidation with H_2O_2 gave a mixture to alcohols which was separated by column chromatography into three diols **A**, **B**, and **C** in 39, 14, and 12% respectively. The IR and NMR spectra of diol **C** were superimposable with those of compound **7** which was previously obtained by Takahashi *et al.*[3] by the reaction of **4** with H_2SO_4 in acetone. On oxidation with Collins reagent diols **B** and **C** gave the same diketone **10**[3] and diol **A** yielded a new diketone **11**. Therefore, the configuration of **B** is represented by the formula **8** and that of **A** by **9**. The original olefinic alcohol is hence formulated as **5**.

Humulene is at equilibrium between two strain minimum conformers, CT and CC.[6] Assuming that these two stable conformers are effective for the epoxide **4**, the stereochemistry of the present transannular reaction was reasonably figured as Scheme 2, based on the configuration of the products **5** and **6**.



Scheme 2.

Experimental

All melting points were uncorrected. IR spectra were recorded on a JASCO IR-S spectrometer. NMR spectra were measured with HITACHI R-20B (60 MHz) and JEOL JNM PS-100 (100 MHz) instruments in $CDCl_3$ using TMS as an internal standard. Mass spectra were obtained on a HITACHI M-52 spectrometer.

TMSOTf Induced Cyclization of Humulene 6,7-Epoxide (4). A solution of TMSOTf (1.86 ml) and 2,6-lutidine (1.39 ml) in toluene (40 ml) was stirred and cooled at −78 °C under argon. To this solution was added a solution of **4** (2.324 g) in toluene (12 ml) by portions. The mixture was stirred at this temperature for 5 h till the epoxide **4** was completely consumed. After removal of the cooling bath, DBU (2.8 ml) was added and the mixture was stirred for 2 h at room temperature. By addition of 1 mol dm^{-3} HCl the mixture was neutralized at

0 °C and extracted with hexane four times. The combined extracts were evaporated *in vacuo* to leave a brown mass which was dissolved in MeOH (10 ml). Mixing the solution with 1 mol dm^{-3} HCl (0.5 ml) for a few minutes effected desilylation. The methanol was removed and the residue was extracted with $CHCl_3$ four times. The combined extracts were dried and evaporated to leave a crystalline mass (2.331 g) which was subjected to silica gel chromatography. Elution of the column with 2.5% AcOEt–hexane afforded tricyclohumulenol (**6**)[5] (186 mg, 8%) first and then 5-hydroxy-4,8,11,11-tetramethyltricyclo[6.3.0.$0^{2,4}$]undec-9-ene (**5**) (1.822 g, 81%); mp 120—122 °C. Spectral data were described in the text.

Found: C, 81.75; H, 10.95%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

Hydroboration-Oxidation of **5**. To a solution of borane–THF (1.5 ml, 1 mol dm^{-3}) was added **5** (220 mg) in THF (3 ml) under argon at 0 °C. After standing for 3 h at 0 °C, the reaction mixture was quenched by the successive addition of ice, NaOH aq (10 ml, 3 mol dm^{-3}) and H_2O_2 (1.5 ml, 30%). The reaction mixture was stirred at room temperature for further 1.5 h till the oxidation was complete. After usual workup it gave a colorless liquid (200 mg) which was chromatographed on a column of $AgNO_3$ impregnated silica gel. Elution with hexane–ether (7 : 3) gave successively three crystalline diols, A (93 mg, 39%), B (33 mg, 14%), and C (29 mg, 12%). Further elution with ether gave a mixture which was not studied. Diol **C** showed the IR and NMR spectra superimposable with those of an authentic sample of **7**.[3]

Diol ***A*** *(**9**)*: Mp 150 °C; IR 3200—3400 cm^{-1}; NMR δ 1.02 (9H, s), 1.08 (3H, s), 3.40 (1H, t, J=6 Hz), 3.86 (1H, dd, J=8, 6 Hz).

Found: C, 75.57: H, 11.17%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

Diol ***B*** *(**8**)*: Mp 140 °C; IR 3200—3400 cm^{-1}; NMR δ 0.95, 1.05, 1.12, 1.20 (each 3H, s), 3.38 (1H, dd, J=10, 7 Hz), 3.70 (1H, br).

Found: C, 75.65; H, 11.44%. Calcd for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

Collins Oxidation of Diol ***A*** *(**9**), **B** (**8**), and **C** (**7**)*. To a solution of dry pyridine (1 ml) in dry dichloromethane (15 ml) at 0 °C was added dry chromium trioxide (600 mg) under argon. The temperature of the mixture was raised to room temperature and the solution was stirred until it colored wine-red (20 min). At the end of this period a solution of diol ***A*** (**9**, 150 mg) in dry dichloromethane (5 ml) was added dropwise. A tarry black deposit separated immediately. After stirring for 20 min, the reaction mixture was worked up as usual and evaporation of the solvent gave a crystalline diketone (**11**); mp 149 °C. IR 1693, 1735, 1450 cm^{-1}; NMR δ 1.00, 1.12, 1.18, 1.32 (each 3H, s), 2.25 (2H, s).

Found: C, 76.86; H, 9.47%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

Oxidation of Diol ***B*** *(**8**)* in the same manner gave an oily diketone whose IR and NMR spectra were superimposable with those of an authentic sample of **10**.[3]

Diol ***C*** *(**7**)* was converted to the same diketone (**10**) by the same procedure as above.

The authors are grateful to Dr. T. Murae (The University of Tokyo) for sending spectra of compounds **7** and **10**.

Phase Transitions of the 1 : 2 Complex of *N*-Ethyl-*N*-methylmorpholinium and 7,7,8,8-Tetracyanoquinodimethan, MEM(TCNQ)$_2$ above Room Temperature

Hayao KOBAYASHI

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

(Received July 21, 1981)

The thermal expansion coefficient, the electrical conductivity, and the crystal structure (at 325 K) of MEM-(TCNQ)$_2$ were examined. A new phase transition was observed at 315 K, where the thermal expansion coefficient jumps. This second-order transition may be triggered by the molecular motion of MEM cations and can be regarded as a precursor of the first-order transition around 62 °C. The molecular motion of MEM cations reduces the electrostatic lattice energy and leads to a structural change. The structural instability of TCNQ columns around 335 K is not attributable to the electron-electron correlation effect in the one-dimensional system, but to the change in the energy balance between the charge-transfer interaction and the electrostatic energy.

In the crystals of anion radical salts of 7,7,8,8-tetracyanoquinodimethan(TCNQ), TCNQ molecules stack to form one-dimensional columns. The periodicity of TCNQ columns frequently reflects a lattice instability characteristic of one-dimensional electronic systems. The "$2k_F$-structure" is associated with the Peierls instability, which has been observed in such well-known one-dimensional metals as TTF–TCNQ and KCP.[1] The "$4k_F$-instability" has also been observed in TTF–TCNQ. Sawatzky, Huizinga and their co-workers[2] have performed extensive studies of the physical properties of the 1:2 complex of *N*-ethyl-*N*-methylmorpholinium and TCNQ (MEM(TCNQ)$_2$) and found a series of the phase transitions. When $T>335$ K, MEM(TCNQ)$_2$ has nearly uniform columns of TCNQ and shows metallic behavior. The nearly uniform columns are transformed to diadic ones at 335 K, below which point MEM(TCNQ)$_2$ is semiconductive. The diadic columns change to tetradic ones at 19 K, where a non-magnetic spin-Peierls state appears. Although the 335 K transition has been reported to be a (electronic) Peierls transition,[2] the electrical conductivity of the "metallic phase" is relatively small (50 $(\Omega\,\mathrm{cm})^{-1}$). Therefore, it may be worthwhile to try to make clear the lattice instability which causes the 335 K transition.

The thermal expansion, the electrical resistivity, and the crystal structure of MEM(TCNQ)$_2$ at 325 K were studied.

Experimental

Black crystals were grown from a mixture of hot solutions of TCNQ and *N*-ethyl-*N*-methylmorpholinium iodide in acetonitrile. X-Ray oscillation and Weissenberg photographs showed that the well-developed plane of the crystal is (010). The maximum dimensions of the specimen are about 10 mm × 2 mm × 1 mm.

Thermal Expansion. The thermal expansion was measured over the temperature range of 293—363 K along the c and b* directions, which are parallel and perpendicular respectively to the TCNQ stacks. The results are shown in Figs. 1 and 2. The values of $L_\perp(\alpha_\perp)$ are less accurate than those of $L_{//}(\alpha_{//})$ because of the diffculty of the crystal alignment ($L_{//}(L_\perp)$ is the length of the crystal parallel (perpendicular) to TCNQ columns, and $\alpha_{//}(\alpha_\perp)$ is the corresponding thermal expansion coefficient). The typical crystals used had the dimensions of 7 mm and 0.7 mm along the c (//)

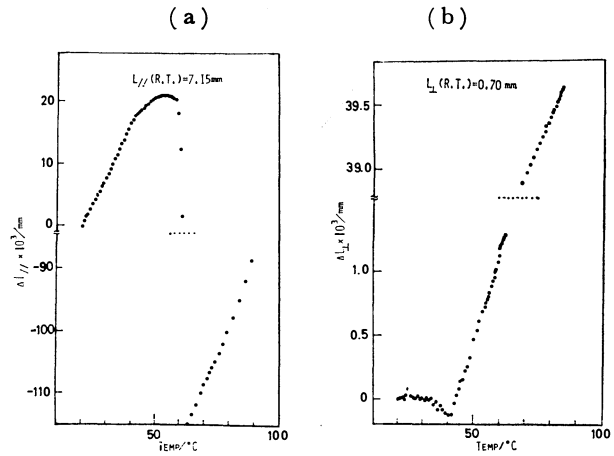

Fig. 1. Thermal expansion parallel to c(a) and b*(b).

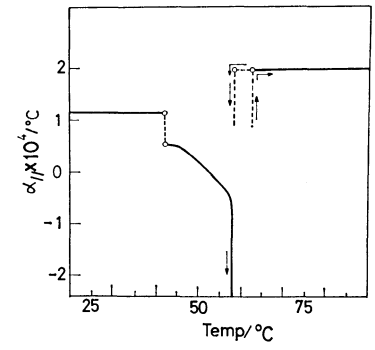

Fig. 2. Thermal expansion coefficient $\alpha_{//}$ (parallel to c).
The arrows indicate the cooling and heating processes. The hysteresis are observed around 60 °C.

and b* ($\perp$) directions respectively.

The discontinuous change in $L_{//}(L_\perp)$ at 335 K (Tc_1) and $\alpha_{//}(\alpha_\perp)$ at 315 K (Tc_2) show the first-order phase transition at Tc_1 and the second-order phase transition at Tc_2. Above Tc_2, the thermal expansion coefficient ($\alpha_{//}$) decreases with the temperature and becomes negative above 326 K. Thus, the second-order phase transition is a precursor of the discontinuous contraction of the crystal at Tc_1. The transition temperature, Tc_1 agrees well with that obtained from the electrical conduction experiment.[2] The temperature dependences of $\alpha_{//}$ and $\alpha_\perp$ are as follows:

(i) $T>Tc_1$: Around Tc_1, $L_{//}$, $L_\perp$, $\alpha_{//}$, and $\alpha_\perp$ show hysteresis. Since the crystals were cracked at Tc_1, it was difficult to obtain accurate data above Tc_1. The transition

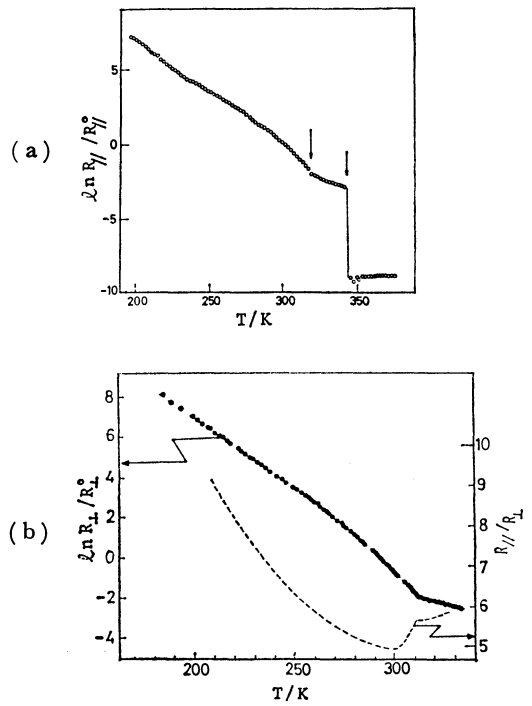

Fig. 3. (a) Electrical resistivities parallel to the TCNQ columns ($R_{//}$). The room-temperature value of $R_{//}$ ($=R^{\circ}_{//}$) is $10^4\,\Omega$ cm. (b) Electrical resistivities perpendicular to the TCNQ columns ($R_{\perp}$) and anisotropy of the resistivities ($R_{//}/R_{\perp}$). The room-temperature value of $R_{\perp}(R^{\circ}_{\perp})$ is $5\times10^4\,\Omega$ cm.

temperature, Tc_1 determined from the heating process is 335 K, but that determined from the cooling process is about 328 K. The crystal shrinks along the TCNQ column (//c) and elongates along the direction perpendicular to it (//b*). The thermal expansion coefficients above Tc_1 are $\alpha_{//}=2\times10^{-4}$/deg and $\alpha_{\perp}=9\times10^{-5}$/deg.

(ii) $Tc_2<T<Tc_1$: With an increase in the temperature, $\alpha_{//}$ decreases and becomes negative, while $\alpha_{\perp}$ is almost constant (9.6×10^{-5}/deg).

iii) 293 K$<T<Tc_2$: $\alpha_{//}$ is 1.15×10^{-4}/deg, and $\alpha_{\perp}$ is much smaller than $\alpha_{//}$ ($<10^{-5}$/deg).

Electrical Resistivity. Huizinga and Sawatzky[2] have reported a "metal-semiconductor transition" at 335 K (Tc_1). The conductivity of the ' metallic state" is 10^3 times larger than that of the semiconducting state. Since the thermal-expansion experiments revealed a second-order phase transition, the d. c. electrical resistivities were measured around the transition temperature by the use of a standard four-probe technique. Gold wires 0.025 mm in diameter were bonded to the crystal by means of silver conducting paint. The results are shown in Fig. 3. The room-temperature resistivities were $R_{//}=10^4$ cmΩ and $R_{\perp}=5\times10^4\,\Omega$ cm, where $R_{//}$ and $R_{\perp}$ indicate the resistivities parallel (//c) and perpendicular (//a*) to the c axis. Since the crystals were cracked at Tc_1, it was difficult to obtain the resistivities accurately above Tc_1. As has previously been reported,[2] the parallel resistivity, $R_{//}$, jumps at Tc_1 by a factor of 10^2—10^3. A slight anomaly was observed at Tc_2, where $d\ln(R_{//}/R^{\circ}_{//})/dT^{-1}$ becomes very large (>1500 K). The perpendicular resistivity, $R_{\perp}$, shows a similar temperature dependence.

Crystal Structure at 325 K. Since the new phase transition has been found at Tc_2, the crystal-structure analysis was made to obtain the structure information above Tc_2.

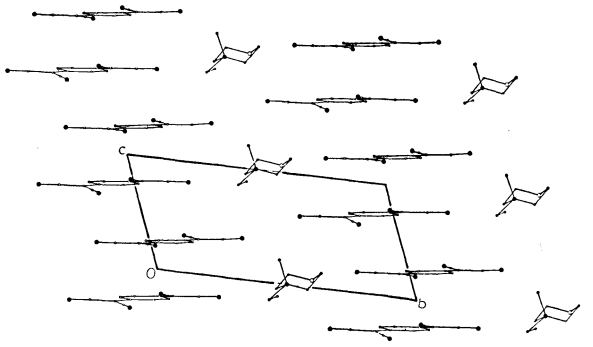

Fig. 4. The crystal structure of MEM(TCNQ)$_2$ at 325 K.

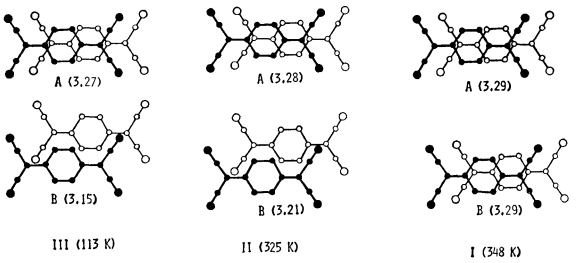

Fig. 5. The mode of intermolecular overlappings of TCNQ of the three phases (at 325 (this work), 113[3] and 348 K.[6] The interplanar distances are given in parentheses.

The lattice constants were determined by the use of a Rigaku automated four-circle diffractometer. The crystal data are: $(C_7H_6NO)^+(C_{12}H_4N_4)^-$, $F.W.=538.6$, triclinic, $P\bar{1}$, $a=7.796(5)$, $b=15.308(8)$, $c=6.993(5)$ Å, $\alpha=111.96(6)$, $\beta=74.87(4)$, $\gamma=111.82(6)^{\circ}$, $U=711.3$ Å^3, $F=(000)=281$, $Z=1$, and $\mu(\text{Mo }K\alpha)=0.9$ cm^{-1}. The intensity data were collected at 52 °C with monochromated Mo $K\alpha$ radiation up to $2\theta=55^{\circ}$. The number of the significant reflections ($|F_o|>3\sigma(|F_o|)$ is 1710.[3,4]

Starting with the atomic parameters of the low-temperature structure reported by Bosh and Bodegom,[3] the crystal structure was refined. The hydrogen atoms of TCNQ were included; however, those of MEM could not be located. The final R value was 0.088. The atomic parameters are given in Table 1.*

The crystal structure, shown in Fig. 4, is almost identical to the structure at 113 K[3] and that at 323 K reported very recently.[5] The TCNQ columns have a diadic structure. The TCNQ molecules the centers of the coordinates of which lie at $z=0.27$ and those with centers $z=-0.27$ form a dimer. The least-squares plane through two crystallographically independent TCNQ molecules are: $0.0168X+0.1106Y-0.9441Z+1.6284=0.0$ and $0.0350X+0.1002Y-0.9382Z-1.6513=0.0$, where X, Y, and Z are the coordinates(Å) referred to the crystal axes, a, b, and c respectively. These two planes are almost parallel to each other (the dihedral angle between the planes is *ca.* 1.1°). The angles between the normals to TCNQ planes and c are 19.2 and 20.2°, slightly smaller than those observed at 113 K (20.5 and 21.3°).[3] The mode of overlapping between adjacent TCNQ molecules is shown in Fig. 5, together with those obtained at different temperatures.[3,6] The interplanar distances between

* A list of the observed and calculated structure factors and a table of anisotropic thermal parameters are kept as Document No. 8231 at the Chemical Society of Japan.

a) Equivalent isotropic temperature factor as defined by H. C. Hamilton (*Acta Crystallogr.*, **12**, 609 (1959)).

the neighbouring TCNQ molecules are 3.21 Å (interdimer) and 3.28 (intradimer). They are 3.15 and 3.27 Å at 113 K.[3] The interdimer distance increases by 0.06 Å with an increase in the temperature from 113 K to 325 K, while the intradimer distance stays nearly constant. That is, the difference in the interplanar distances decreases. The bond lengths and angles are shown in Fig. 6.

The anomalous molecular structure and thermal parameters indicate a large thermal motion of MEM, which is consistent with the NMR observation of the onset of molecular motion around 300 K.[2] Since no significant structural change in TCNQ columns occurs at Tc_2, the second-order phase transition is considered to be triggered by the thermal motion of the MEM cations.

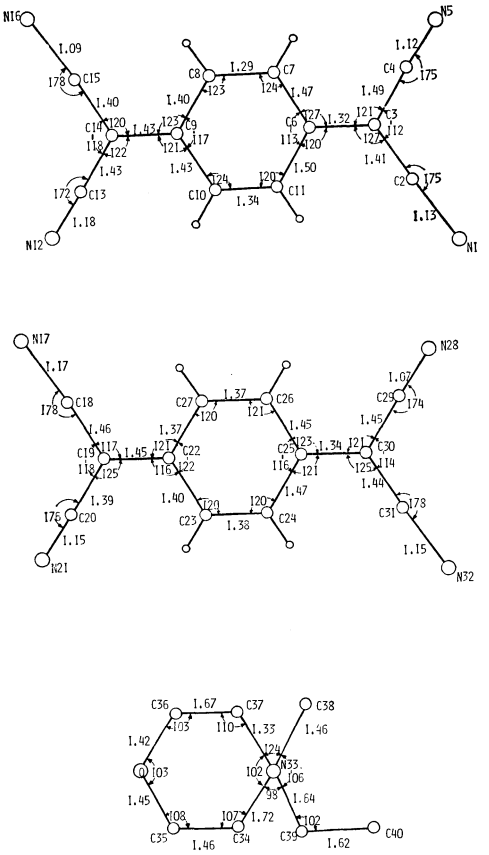

Fig. 6. The bond lengths and the bond angles. The e.s.d's of the bond lengths are 0.02 Å(TCNQ) and 0.02—0.04 Å(MEM) and those of the bond angles are 1—2°(TCNQ) and 1—3°(MEM). The bond lengths of C–H is 0.98—1.06 Å.

Discussion

In a quarter-filled system like MEM(TCNQ)$_2$, the diadic and tetradic columns of TCNQ correspond to the $4k_F$- and $2k_F$-structures respectively. The $4k_F$-structure has been frequently discussed in connection with the electron correlation. Sumi[7] has proposed a series of possible structural-phase transitions in a highly correlated linear-chain system: a uniform-$4k_F$ transition and $4k_F$-$2k_F$ transition. Since both types of transitions have been found, MEM(TCNQ)$_2$ has been regarded as a typical high-U material. The origin of the $2k_F$- and $4k_F$-structures has been considered to be correlated with the general principle of the periodical instability of the one-dimensional electronic system.[2]

However, as has been shown in this paper, the "$4k_F$-phase" contains an additional second-order phase transition at Tc_2. The thermal-expansion anomalies suggest that the second-order phase transition at Tc_2 is a precursor of the first-order phase transition at Tc_1. The diadic structure of TCNQ columns is transformed into an almost regular one at Tc_1.[2] Since the phase transition does not alter the intermolecular overlapping between intradimer molecules, TCNQ molecules are considered to move in pairs on passing through Tc_1. The change in the mode of the intradimer overlapping indicates the rotation of the TCNQ

dimer about 20°.

The thermal expansion experiments showed that the length of the crystal ($L_{//}$) is shortened by about 4.5% at Tc_1.[8] If the transition does not change the interplanar distances, the crystal must be shortened along the TCNQ columns by the rotation. The magnitude of the contraction is estimated as $\Delta L_{//}/L_{//}=1-\cos 20°$ (=0.05). Since the observed contraction (4.5%) agrees well with the estimated value, the discontinuous contraction of the crystal is considered to be mainly due to the rotation of the TCNQ dimers.

Each TCNQ dimer has an excess electron. The structure is stabilized by the Coulomb interaction between the MEM cations and the excess electrons in dimers. The small interplanar distance between TCNQ molecules indicates that the charge-transfer interaction also plays an important role. At high temperatures ($T>Tc_2$), the Coulomb interaction is reduced by the large thermal motion of MEM cations. Then, the MEM cations cannot restrain the movement of the excess electrons along the column. The interdimer charge-transfer interaction becomes importants. Figure 5 shows that in a diadic structure, the interdimer charge-transfer interaction is negligibly small, but it becomes as large as the intradimer one in a nearly uniform structure. This indicates that the diadic structure is transformed to a uniform one to gain a larger charge-transfer stabilization energy. As has been mentioned before, the crystal contracts along the direction parallel to the TCNQ columns (//c) and expands along the direction perpendicular to it (//b*). The expansion suggests a decrease in the Coulomb interaction between MEM cations and the excess electrons in TCNQ columns (see Fig. 4), while the contraction implies an increase in the charge-transfer interaction along the columns.

Lacoe, Gruner, and Chaikin have reported on the thermoelectric power(TEP) of MEM(TCNQ)$_2$.[9] Above Tc_1, TEP is $-65\ \mu$V/K, which suggests that the spin entropy of the excess electron makes the dominant contribution, as in other highly correlated quarter-filled band TCNQ salts. This indicates that the excess electrons are uniformly distributed in the TCNQ columns above Tc_1. As the temperature is lowered, the TEP increases faster, suggesting a change in the semiconducting gap.

However, the temperature dependence of $R_{//}$ (see Fig. 3) shows that the semiconducting gap does not alter around Tc_2. The anomaly around Tc_2 may be attributable to the change in $\mu(T)$. The mobility, $\mu(T)$, is considered to change by an order of magnitude. In other words, the mobility depends strongly on the thermal motion of MEM.

Synthesis, Luminescence Quantum Yields, and Lifetimes of Trischelated Ruthenium(II) Mixed-ligand Complexes Including 3,3′-Dimethyl-2,2′-bipyridyl

Katsumi NAKAMARU

Department of Chemistry, Faculty of Science, Hirosaki University, Bunkyo, Hirosaki, Aomori 036

(Received October 28, 1981)

New five complexes of the type of $[RuL_{3-x}(dmby)_x]X_2$(x=1,2,3, L=2,2′-bipyridyl or 1,10-phenanthroline, dmby=3,3′-dimethyl-2,2′-bipyridyl, X=halide ion) have been synthesized in order to investigate the effects of two methyl groups of dmby on the absorption and emission spectra, luminescence quantum yields, and lifetimes. Values of the radiative and nonradiative rate constants have been calculated from these data at 77 K. Although the absorption and emission maxima and the lifetimes are not much affected by the dmby ligand substitution, the molar extinction coefficients and emission quantum yields are decreased compared with trischelated complexes of the parent bipyridyl or phenanthroline ligands. At 25 °C the emission yields of the complexes containing dmby decrease by 3—4 orders of magnitude than at 77 K. Possible causes of the decrease in the quantum yields are discussed.

Tris(2,2′-bipyridyl)ruthenium(II) ion, $[Ru(bpy)_3]^{2+}$, has attracted widespread attention in recent years because of its strong charge transfer (CT) luminescence[1,2] even in fluid solutions at room temperature as well as at 77 K and because of higher redox ability in the excited state than in the ground state.[3-5] In particular, the latter property has accelerated many investigations on photoredox chemistry of this ion and related complexes in the hope of possible catalytic activity in solar energy conversion to chemical potential energy.[6-10]

There have been a few studies on the effects of ligand substituents on the spectral and excited state properties of bipyridyl or 1,10-phenanthroline (phen) complexes with ruthenium(II). Phenyl substitution on the 4,4′-positions of bipyridyl and 4,7-positions of phenanthroline ligands has been shown to produce an increase in the luminescence quantum yields and a slight decrease in the measured lifetimes. These effects have been interpreted on the basis of a model of intensity borrowing *via* spin-orbit coupling interaction between a luminescing triplet state and a lending singlet state.[11-13] Temperature dependence of the quantum yields and lifetimes of ruthenium(II) complexes with the unsubstituted and methyl- or phenyl-substituted ligands at low temperature has been reported[14,15] (at higher temperatures, only for the $[Ru(bpy)_3]^{2+}$ [16,17]). Recently, some sterically hindering bi- and tridentate ligand complexes have been prepared and their effects on the relaxation processes of the excited state have been discussed.[18-20]

3,3′-Dimethyl-2,2′-bipyridyl(dmby), which was first synthesized by Case,[21] is an interesting ligand in that upon coordination to metal it is expected to take a twisted, and hence non-coplanar conformation owing to the steric hindrance of the two methyl groups.[22,23] Photophysical and photochemical studies, however, on the transition metal complexes with this dmby have scarcely been found. This paper reports the preparation of several trischelated ruthenium(II) complexes including dmby and bipyridyl (or phenanthroline); also the effects of dmby on the absorption and emission spectra, emission quantum yields, and lifetimes of these complexes.

Experimental

Materials. $RuCl_3 \cdot 3H_2O$ (Aldrich Chemical Co.), 2,2′-bipyridyl and 1,10-phenanthroline (Wako Pure Chemicals Co.), and substituted ligands (G. Frederick Smith Chemical Co.) other than dmby were used as obtained. 2-Amino-3-methylpyridine was prepared by reflux of 3-methylpyridine with sodium amide in xylene.[24] 2-Bromo-3-methylpyridine was synthesized from 2-amino-3-methylpyridine by the Sandmeyer reaction.[25]

Preparation of 3,3′-Dimethyl-2,2′-bipyridyl. A slight modification of the method of Case[21] was used. A dried mixture of 200 ml of *p*-cymene, 75 g of copper powder, and 75 g of sodium chloride was refluxed with stirring in an oil bath. To this 120 g of 2-bromo-3-methylpyridine was added slowly and the reflux continued for two hours at 180—200 °C. After cooling to 100 °C, 200 ml of 6 mol dm^{-3} HCl was added. This reaction mixture was made alkaline with NaOH and distilled with steam. About 10 L of the aqueous distillate was extracted with chloroform. After the chloroform was removed, the remainder was distilled under reduced pressure. On redistillation 26 g of pale yellow liquid boiling at 157—158 °C (20 mmHg, 1 mmHg≈133.322 Pa) was obtained (yield, 40%). Purification of the crude product was accomplished by conversion of the base to its hydrochloric acid salt and repeated recrystallization from 330 ml of the mixture of ethanol and concentrated HCl (90:10%, v/v). 19 g of the pure white crystals (yield, 21%) were again converted to the base with NaOH and the liberated product was extracted with diethyl ether. Evaporation of the ether gave 12 g of viscous, colorless liquid (final yield, 19%). Its absorption spectrum agreed well with the authentic sample.[23]

cis-$[Ru(bpy)_2Cl_2] \cdot 2H_2O$ and *cis*-$[Ru(phen)_2Cl_2] \cdot 3H_2O$ were prepared by the method described in the literature.[26]

Preparation of cis-$[Ru(dmby)_2Cl_2] \cdot 3H_2O$. Since all attempts to prepare this compound according to the method described in literature were unsuccessful, the following procedure was adopted. 3.0 g of $RuCl_3 \cdot 3H_2O$ and 4.3 g of dmby in 104 ml of *N,N*-dimethylformamide and 12 ml of 0.2 M (1 M=1 mol dm^{-3}) phosphate buffer solution (pH 6.8—7.0) were refluxed together for 6 h. The solvent was distilled off, and the residue was dissolved in about 400 ml of hot water containing 10 ml of phosphate buffer solution. The dark red brown solution was quickly filtered and 57 g of LiCl added to the filtrate. The product, which precipitated on standing overnight in refrigerator, was collected by suction filtration, washed several times with cold water and

dried. The dark, almost black, fine powder product was obtained in 44% yield (4.0 g).

$[Ru(bpy)_3]Cl_2 \cdot 5H_2O$ was prepared according to the method reported.[27] $[Ru(4,4'\text{-dimethylbpy})_3]Cl_2 \cdot 7H_2O$, $[Ru(4,4'\text{-diphenylbpy})_3]Cl_2 \cdot 5H_2O$, $[Ru(dmby)_3]Br_2 \cdot 7H_2O$, $[Ru(phen)_3]Cl_2 \cdot 7H_2O$, and $[Ru(4,7\text{-diphenylphen})_3]Cl_2 \cdot 5H_2O$ were prepared analogously.

Preparation of $[RuL_{3-x}(dmby)_x]X_2 (x=1,2)$. The preparation of this type of compounds all follows the same procedure as described for $[Ru(phen)_2(dmby)]Cl_2 \cdot 8H_2O$.

$[Ru(phen)_2(dmby)]Cl_2 \cdot 8H_2O$: 2.0 g of *cis*-$[Ru(phen)_2Cl_2] \cdot 3H_2O$ (3.2 mM) and 0.7 g of dmby (3.8 mM) in 200 ml of ethanol and 15 ml of 0.2 M phosphate buffer solution were refluxed for 72 h. The dark red brown solution was filtered and then evaporated to dryness. The residue was first purified on a column of silica gel eluting with acetone–ethanol (1:2, v/v). Final purification was achieved by repeated recrystallization from water. The pure chloride product is a deep red brown crystalline material.

For the preparation of the other trischelated complexes, *cis*-$[Ru(bpy)_2Cl_2] \cdot 2H_2O$ or *cis*-$[Ru(dmby)_2Cl_2] \cdot 3H_2O$ was used as the starting material instead of *cis*-$[Ru(phen)_2Cl_2] \cdot 2H_2O$. The chloride and bromide salts of $[Ru(bpy)_2(dmby)]^{2+}$ and $[Ru(bpy)(dmby)_2]^{2+}$ were too soluble to crystallize from water. Hence, for the purpose of elemental analysis, they were converted to the iodide salts by treatment with KI. For the same reasons, the chloride salt of $[Ru(dmby)_3]^{2+}$ was converted to the bromide salt by KBr. Elemental analysis was performed by Chem. Dept., Fac. Sci., Tohoku Univ. and the results are listed in Table 1.

Spectroscopic Measurements. Absorption spectra were measured with a Hitachi 124 double-beam spectrophotometer thermostated at 25 °C. All luminescence measurements were made with a Hitachi MPF-4 fluorescence spectrophotometer. Emission spectra were corrected using 2-naphthol in (0.020± 0.001) mol dm^{-3} sodium acetate–acetic acid buffer solution, *N,N*-dimethyl-*m*-nitroaniline in benzene–hexane (30:70%, v/v), and 4-dimethylamino-4'-nitrostilbene in *o*-dichlorobenzene as the standard. The true emission spectra of these substances were reported by Lippert *et al.*[28] For emission measurements at 77 K the complexes were dissolved in methanol–ethanol (1:4, v/v) mixed-solvent and frozen in liquid nitrogen by immersion of a 5-mm quartz tube. The sample absorbance at an exciting wavelength was kept as low as possible to avoid fluorescence errors. The usual concentrations were $(3—5) \times 10^{-6}$ M. For excitation at 436 nm, light from a 150 W xenon lamp was passed through a monochromater and a Toshiba V-Y43 cut-off filter. For the emission intensity measurements a Toshiba V-O58 cut-off filter was further placed in front of the PM tube.

Quantum yields were measured by the modified Parker and Rees method.[29] As the quantum yield standard, $[Ru(4,7\text{-diphenylphen})_3]Cl_2$ was used assuming a value of 0.682.[13] Preliminary measurements using $[Ru(4,4'\text{-diphenylbpy})_3]Cl_2$ as a test sample gave a value of 0.563±0.014, in good agreement with the reported value of 0.573±0.032.[13]

Measurements at 25 °C were done in aqueous solutions with the same apparatus and procedures except that the usual fluorescence cell was used and that the emission quantum yield standard was fluorescein in 0.1 mol dm^{-3} NaOH or $[Ru(bpy)_3]Cl_2$ in air saturated aqueous solution. Each yield is 0.90[13] and 0.028,[30] respectively. All the ruthenium(II) complexes in H_2O were thermally stable, but the samples were daily prepared prior to use. If necessary, nitrogen was bubbled through the sample solutions for 15 min. More details have been described previously.[30]

For the lifetime measurements, an apparatus constructed by Kokubun (Chem. Dept., Fac. Sci., Tohoku Univ.) was used. The sample was excited at 337 nm with a pulsed nitrogen laser. Lifetimes were determined from the slope of a linear plot of ln intensity *vs.* time.

The absorption spectra of the iodide salts of $[Ru(bpy)_2(dmby)]^{2+}$ and $[Ru(bpy)(dmby)_2]^{2+}$ differ in the ultraviolet region from their chloride or bromide salts owing to the iodide absorption. Therefore the chloride salts of these complexes were used for the absorption measurements. For the emission measurements, however, the iodide salts of these complexes and the bromide salt of $[Ru(dmby)_3]^{2+}$ were used since no effect of the counterions was observed on the emission spectra and intensities.

Results

The absorption and luminescence spectra of the ruthenium(II) complexes studied are shown in Figs. 1—3. The wavelengths of the absorption maxima and the corresponding molar extinction coefficients as well as the wavelengths of the emission maxima for all the ruthenium(II) complexes are summarized in Table 2.

The quantum yields and lifetimes for all the complexes at 77 K are tabulated in Table 3. A value of the quantum yield, 0.328, for the $[Ru(bpy)_3]Cl_2$ is smaller than that of 0.376 reported by Demas and Crosby.[11] A once recrystallized sample also gave the same value. When $[Ru(4,4'\text{-diphenylbpy})_3]Cl_2$ was used as the quantum yield standard with a value of 0.563 measured in this study, again the same result

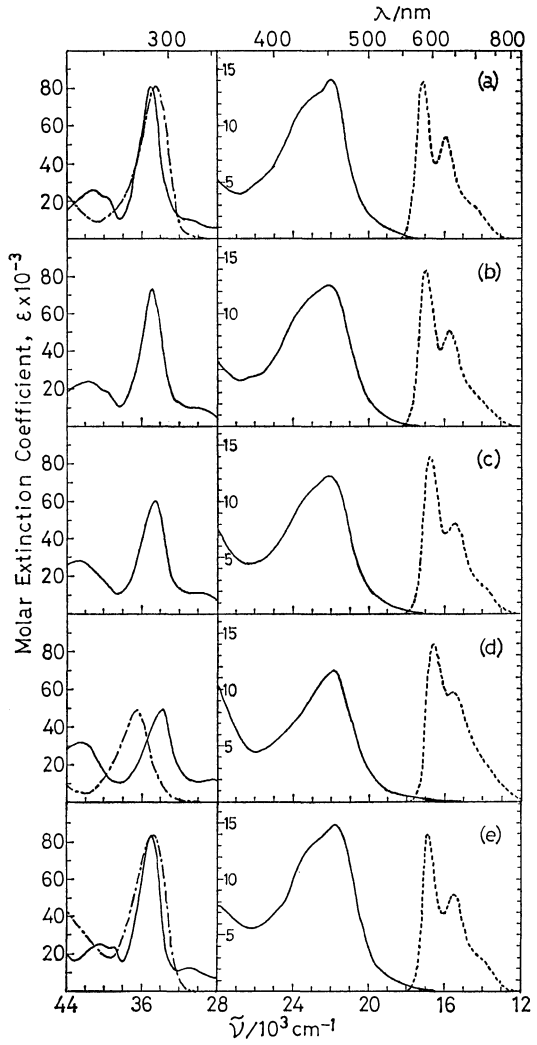

Fig. 1. Absorption and emission spectra of (a) [Ru(bpy)$_3$]Cl$_2$, (b) [Ru(bpy)$_2$(dmby)]Cl$_2$, (c) [Ru(bpy)(dmby)$_2$]Cl$_2$, (d) [Ru(dmby)$_3$]Br$_2$, (e) [Ru(4,4′-dimethylbpy)$_3$]Cl$_2$: (——) and (— — —) absorption spectra of complexes in H_2O and ligands in 50% H_2SO_4 at 25 °C, respectively; (----) emission spectra in methanol–ethanol (1:4, v/v) glass at 77 K. ε of bpy and dmby free ligands is multiplied by 5.07 and 3.54, respectively.

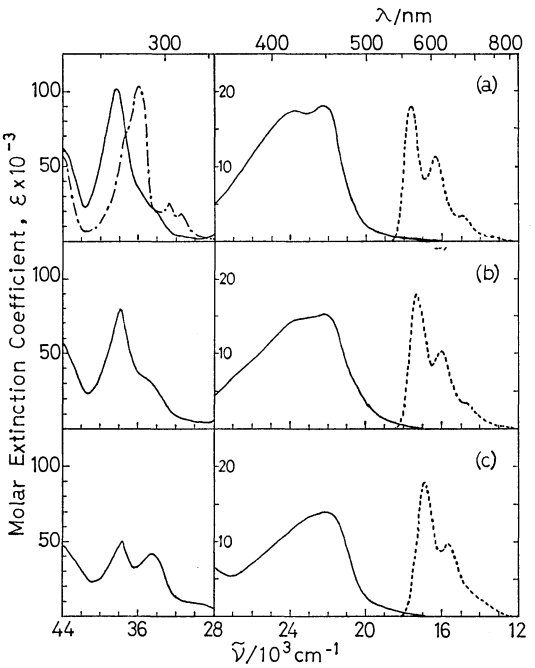

Fig. 2. Absorption and emission spectra of (a) [Ru(phen)$_3$]Cl$_2$, (b) [Ru(phen)$_2$(dmby)]Cl$_2$, (c) [Ru(phen)(dmby)$_2$]Cl$_2$: (——) and (— — —) absorption spectra of complexes in H_2O and ligands in 50% H_2SO_4 at 25 °C, respectively; (- - -) emission spectra in methanol–ethanol (1:4, v/v) glass at 77 K. ε of phen and dmby free ligands is multiplied by 2.52 and 3.54, respectively.

was obtained. The quantum yield, 0.328, for the [Ru(bpy)$_3$]Cl$_2$ complex is acceptable in view of the fact that the present quantum yields for the [Ru(phen)$_3$]Cl$_2$ (0.578) and [Ru(4,4′-diphenylbpy)$_3$]Cl$_2$ (0.563) agree well with the values of 0.584 and 0.573 measured by Demas and Crosby,[11,13] respectively, and the lifetimes for [Ru(bpy)$_3$]Cl$_2$, [Ru(4,4′-diphenylbpy)$_3$]Cl$_2$, [Ru(phen)$_3$]Cl$_2$, and [Ru(4,7-diphenylphen)$_3$]Cl$_2$ (5.1, 4.8, 9.9, and 10.2 μs, respectively) are also in good agreement with the values reported for these complexes (5.21, 4.68, 9.79, and 9.58 μs, respectively[11,13]).

Radiative (k_r) and nonradiative (k_{nr}) rate constants were calculated using the following expressions,

$$Q = k_r/(k_r+k_{nr}) = k_r\tau_m, \quad (1)$$

$$k_{nr} = \tau_m^{-1} - \tau_r^{-1}, \quad (2)$$

where Q is the emission quantum yield, τ_m is the measured lifetime, and τ_r is the radiative lifetime ($=1/k_r$). In Eq. 1 the efficiency of populating the emitting CTTL excited state (see Discussion) is assumed to be unity as is generally accepted.[2,31] The results are included in Table 3.

At 25 °C the emission intensity largely decreases, especially for the complexes including the dmby ligand. This is the reason why the lifetimes of the complexes including dmby (except that of [Ru(bpy)$_2$(dmby)]Cl$_2$) and the quantum yield of [Ru(dmby)$_3$]Br$_2$ could not be measured. As for the two complexes of [Ru(bpy)(dmby)$_2$]I$_2$ and [Ru(phen)(dmby)$_2$]Cl$_2$, it was difficult to obtain the exact corrected emission spectra because of their low intensities. The yields were estimated, however, by an assumption that the ratio of the integrated area under the corrected emission spectrum to the intensity in height at the observed wavelength (600 nm)[29] is equal to those of [Ru(bpy)$_2$(dmby)]I$_2$ and [Ru(phen)$_2$(dmby)]Cl$_2$, respectively. The errors in these procedures mainly stem from the estimate of the height in the ratio because the area is almost the same within the bipyridyl or phenanthroline complex series. Since the red shift in the emission spectra on introduction of dmby is evident but small (Table 2), the errors caused by the above assumption seem not so large that the order in the yield is varied. The results are listed in Table 4. The quantum yields using the excitation wavelength of 480 nm agreed well with those at 436 nm. Moreover, an excellent coincidence was seen between the yields obtained by means of fluorescein and [Ru(bpy)$_3$]Cl$_2$ as the standard.

Discussion

Absorption and Emission Spectra. The intense visible absorption bands of the tris-type ruthenium(II) complexes of bipyridyl,[2] phenanthroline,[2,32] and 4,4'-dimethylbipyridyl[14] have been all assigned to the spin-allowed charge transfer transitions from the metal d orbitals to the ligand π^* orbitals (CTTL), while the more intense bands below 300 nm have been assigned to intraligand π-π^* transitions.[14,33] Because of the similarities in the spectra of the complexes containing the dmby ligand, the same band assignments can be made for the new complexes reported here.

The following features can be seen from Figs. 1 and 2 or Table 2. First, the absorption spectra of the parent complexes of $[Ru(bpy)_3]^{2+}$ or $[Ru(phen)_3]^{2+}$ regularly change to that of $[Ru(dmby)_3]^{2+}$ without any appearance of new bands in the mixed-ligand complexes other than the characteristic bands already present in these three homotrischelated complexes. Moreover, a slight red shift is seen except for the 240 nm band in the bipyridyl complex series which shows a blue shift. Secondly, the π-π^* absorption maximum of the dmby free ligand lies in a considerable shorter wavelength than that of the parent bipyridyl. This contrasts with 4,4'-dimethylbipyridyl in which the position and intensity of the absorption maximum are comparable with the parent ligand, and hence suggests that due to the steric interactions of the two methyl groups of dmby the delocalization of π-electrons is limited to a narrow range. Such hypsochromic effect of a substituent(s) at the sterically hindering

a) In water at 25 °C. b) Luminescence quantum yields. Excited at 436 nm. Q(F) and Q(R) denote the yields measured by using fluorescein and $[Ru(bpy)_3]Cl_2$ as the standard, respectively. c) Value from Ref. 30. d) As for the procedures to obtain these values, see Results.

positions of various organic compounds is well known (for example, biphenyl, a similar compound to 2,2'-bipyridyl).[34] The π-π^* absorption maximum of dmby (274 nm), however, greatly shifts to the longer wavelength (296 nm) upon coordination to ruthenium, contrasted with that of phenanthroline (278 nm) which shifts to shorter wavelength (262 nm). Finally, as the number of the dmby ligand increases, maximum molar extinction coefficients decrease step by step except also for the 240 nm band, where an increase rather than a decrease is observed. This decrease can be explained, at least in part, by a broadening of the visible CT band.[18] The oscillator strengths in Table 2, though by a rough calculation, are almost the same; a reduction in the extinction coefficients is recovered by an increase in the bandwidths.

The emission at 77 K from the trischelated ruthenium(II) complexes with the unsubstituted and substituted bipyridyl or phenanthroline arises from a CTTL excited state.[11,13,14] However, a discussion about the assignment of a spin multiplicity is inappropriate due to strong spin-orbit coupling.[35] As is similar to these complexes, the emission spectra reported here clearly show the vibrational progression indicative of a CT luminescence[2] although the vibrational structure is somewhat obscure in the tris(dmby) complex. It is therefore concluded that the observed luminescence of the complexes including dmby is also due to the radiative transitions from the CTTL excited state. It should be pointed out that the red shift of the emission peak of $[Ru(dmby)_3]^{2+}$ from that of $[Ru(bpy)_3]^{2+}$ is larger than any other ruthenium(II) complexes of substituted bipyridyls reported until now.

The emission spectra at 25 °C (Fig. 3) are broader and indicate red shifts in comparison with those at 77 K. These large changes in the shape of the spectra when the solvent medium is transformed from a rigid glass to a fluid have been used as an evidence for the argument that in fluid solutions charge transfer to solvent (CTTS) configurations interact with the CTTL excited state of $[Ru(bpy)_3]^{2+}$.[16,17]

Lifetimes and Quantum Yields. The observed lifetimes for the bipyridyl complex series produce only a relatively minor variation as well as for the phenanthroline series. The longer lifetimes for the latter are plain enough.

The most notable effect of dmby is seen in a large decrease in the emission quantum yield of its tris complex, that is, 66% and 80% decreases compared with the parent complexes of bipyridyl and phenanthroline, respectively. Dimethyl substitution on the normal (sterically not hindering) positions such as 4,4'- for bipyridyl or 4,7- and 5,6-positions for phenanthroline has been known to result in relatively slight changes in the yields (3—12%), whereas diphenyl substitution causes a larger increase (20—50%).[14,15,36] However,

a) Calculated using the values of 0.0213 for a bpy, 0.0193 for a phen, and 0.006 μs^{-1} for a dmby. These values were obtained by division of k_r for the corresponding parent tris complexes by 3. b) Calculated using the values of 0.0467 for a bpy, 0.014 for a phen, and 0.0467 μs^{-1} for a dmby obtained by division of k_{nr} for the corresponding parent tris complexes by 3. c) Calculated from $1/(k_r+k_{nr})$. d) Calculated from $k_r\tau$.

methyl- or dimethyl-substitution on the sterically hindering positions such as 6,6'- for bipyridyl or 2,9-positions for phenanthroline has been shown to bring about a great decrease in the yields (72% for the monomethyl and 92% for the dimethyl ligands).[20] It should be noted that the latter values are comparable to the present case.

A perusal of Table 3 shows that introduction of the dmby ligand into the parent tris complexes causes a decrease in the yields at almost the same rate for both series of complexes. According to Hipps and Crosby,[37] the lowest CTTL excited state of the ruthenium(II) complexes is viewed as the one in which an electron has been essentially promoted from the central metal core to an antibonding orbital delocalized over the three ligands. Therefore the electronic properties of the excited state are described as weighted averages of the properties of the individual ligands. In line with this point of view, the quantum yields of the mixed-ligand complexes can be calculated as follows. An assumption that the values of radiative and nonradiative rate constant for the tris(bipyridyl) complexes can be alloted equally to each of three bipyridyl molecules gives the values of 0.0213 and 0.0467 μs^{-1}, respectively. An analogous procedure for the tris-(phenanthroline or dmby) complexes gives 0.0193 and 0.014 μs^{-1} for a phenanthroline, 0.006 and 0.0467 μs^{-1} for a dmby. Then using these values the quantum yields are computed by Eq. 1 and the results are listed in Table 5. It is seen that the calculated and observed quantum yields agree well although somewhat low calculated values are obtained for the phenanthroline mixed-ligand complexes.

As Eq. 1 shows, the observed decrease of the emission quantum yield is due both to the decrease in k_r and to the increase in k_{nr}. The relative contributions of these two factors to the decrease in the yield are illustrated in Fig. 4. The line on the left of each diagram represents the quantum yield of the parent complex while the line on the right represents the observed quantum yield of the complex including dmby. The line in the middle represents the hypothetical quantum yield (Q_h) that the dmby complex would have if only a change in the radiative rate constant (Δk_r) were caused by the dmby ligand substitution (the values of Q_h are also listed in Table 3). Δk_{nr} represents the change in the quantum yield due to the change in k_{nr}. The figure shows that both factors

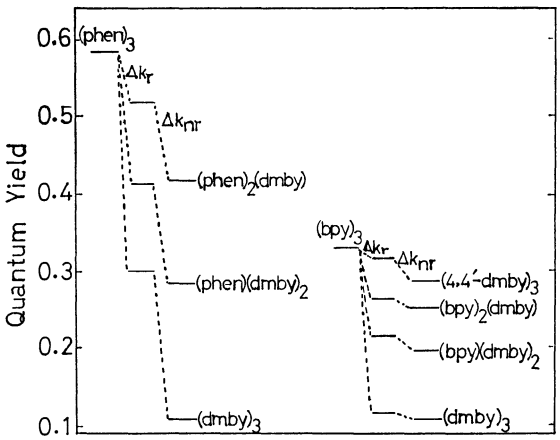

Fig. 4. Dmby substitution-induced changes in quantum yields resolved into radiative(Δk_r) and nonradiative(Δk_{nr}) factors for Ru(II) complexes in methanol–ethanol (1:4, v/v) glass at 77 K.

comparably contribute to the decrease in the yield for the phenanthroline complexes, although a detailed examination indicates that as the number of dmby increases the role of Δk_r factor becomes more important while the role of Δk_{nr} factor decreases. In sharp contrast to the phenanthroline complexes, however, the decrease in the yield for the bipyridyl complexes is almost ascribed to the decrease in k_r. Similar results have been also reported for the other ruthenium(II) complexes.[38]

The decrease in k_r can be, at least qualitatively, explained by the model by Demas and Crosby[11] which assumes that the emitting (triplet) state (the energy, E_T) borrows intensity from the lending, highly spin-allowed (singlet) state (the energy, E_S) through the spin-orbit coupling interaction (magnitude, $K|M_{SO}|^2$). On the basis of this model, they have expressed the radiative rate constant as follows:

$$k_r = \varepsilon(S)K|M_{SO}|^2(E_T^3/E_S)/(E_T-E_S)^2, \quad (3)$$

where $\varepsilon(S)$ is the maximum molar extinction coefficient of the first visible CT band. E_S is taken as the energy of the first absorption maximum of the highly allowed CT band, and E_T is assumed to be the energy of the shortest wavelength emission peak.[11] In calculating the radiative rate constant by Eq. 3, two additional approximations are made. First, the values of $\varepsilon(S)$ at 25 °C in Table 2 are used because the absorption spectra have not been measured at 77

Table 6. Caculated and experimental radiative rate constants of Ru(II) complexes at 77 K*)

a) Maximum molar extinction coefficient of the first visible CT band (in unit of $10^4\,M^{-1}\,cm^{-1}$). b) Singlet state energy of the absorption maximum of the first visible CT band(in unit of $10^3\,cm^{-1}$). c) Triplet state energy assumed to be the energy of the shortest emission peak at 77 K(in unit of $10^3\,cm^{-1}$). d) Calculated radiative rate constant using a value of $K|M_{SO}|^2$ of 4.87×10^{-7} for the bipyridyl complexes and 2.87×10^{-7} ($M\,cm\,\mu s^{-1}$) for the phenanthroline complexes. e) Experimentally obtained radiative rate constant (see Table 3). *) Normalized figures of k_r for the bipyridyl and phenanthroline complexes are shown in parentheses.

K. Secondly, value of $K|M_{SO}|^2$ is assumed not to be so much affected by dmby substitution. Hence, a value of 4.87×10^{-7} and 2.87×10^{-7} ($M\,cm\,\mu s^{-1}$) is used as $K|M_{SO}|^2$ for the bipyridyl and phenanthroline complexes, respectively, in order to normalize the calculated values to the experimentally obtained radiative rate constants for the parent complexes (the latter value reasonably agrees with 2.43×10^{-7} for $[Ru(phen)_3]^{2+}$, but the former is somewhat larger than 3.78×10^{-7} for $[Ru(bpy)_3]^{2+}$ reported by Demas and Crosby[11]). The results in Table 6 show that agreement between the calculated and experimental radiative rate constant is excellent for the phenanthroline complexes, whereas poor agreement is observed for the bipyridyl complexes. However, it may safely be said that the observed decrease in k_r is, at least qualitatively, due to the decrease in ε(S) and E_T^3/E_S term and the increase in the energy gap term for both the complex series as is expected from Eq. 3.

The larger nonradiative rate constant for the parent bipyridyl complex than for the parent phenanthroline complex is attributed to the difference between the structure of the two ligands; the rigid ring system and planarity of phenanthroline considerably slow down the nonradiative processes. The effect of dmby substitution on the nonradiative rate constant would be largely observed for the complex which has a small value of k_{nr}, *i.e.* the phenanthroline complexes as compared with the bipyridyl complexes. In such a case the values of k_{nr} for the bipyridyl complexes are hardly influenced by dmby if the effect is not large. Nearly the constant values of k_{nr} observed for the bipyridyl complexes may be a reflection of such circumstances.

The above discussion reveals that methyl substituents on the 3,3'-positions of the bipyridyl ligand decrease the visible CTTL absorption intensity and increase the energy gap between the intensity-lending singlet and the emitting triplet state, and that this leads to the decrease in k_r and hence the emission quantum yield. On the contrary, methyl substitution on the 4,4'-positions of the parent ligand, which is considered not to change chelate conformation of the parent ligand

Table 7. Lifetimes of $[Ru(bpy)_3]Cl_2$ and $[Ru(bpy)_2(dmby)]Cl_2$ in various solvents at 25 °C[a]

Solvent	$[Ru(bpy)_3]Cl_2$[b] $\tau_m/\mu s$	$[Ru(bpy)_2(dmby)]Cl_2$ $\tau_m/\mu s$	AN[c]

Ethanol	0.74±0.02	0.39±0.02	37.1
Acetonitrile	0.89±0.03	0.59±0.02	19.3
Pyridine	0.92±0.05	0.63±0.03	14.2

a) In nitrogen-bubbled solutions. Excited at 337 nm. b) Ref. 40. c) Gutmann's acceptor number from Ref. 39.

believed to be coplanar, produces only a minor change in these factors and thus a relatively small decrease in the yield. Fabian, *et al.*,[20] have reported more marked decreases in the absorption intensities and emission yields of the ruthenium(II) complexes caused by methyl substituents on the sterically hindering 6,6'-positions for bipyridyl and 2,9-positions for phenanthroline than the complexes reported here, and have pointed out that the effects can be reduced to some extent by relief of the steric hindrance by twisting of the ligands. From these comparisons with the other substituted ligand complexes, it may be reasonable to consider that 3,3'-dimethyl-2,2'-bipyridyl in the ruthenium(II) complexes studied takes a twisted, noncoplanar conformation owing to the steric hindrance of the two methyl groups.

At 25 °C, only the lifetime of $[Ru(bpy)_2(dmby)]Cl_2$ in the dmby-mixed complexes can be measured because of the low emission intensities. As is seen from Table 7, the lifetimes of the bis(bipyridyl) complex in several solvents are about 2/3 compared with those of the tris(bipyridyl) complex and increase with the decrease in the Gutmann's acceptor number[39] as in the parent complex. This may suggest that the emitting state of the bis(bipyridyl) complex is similar to that of the tris(bipyridyl) complex, *i.e.* CTTL excited state contributed by the CTTS configurations.[16,17]

Values of the radiative (k_r) and nonradiative (k_{nr}) rate constants calculated from Eqs. 1 and 2 using the data in H_2O are 0.065, 1.5 μs^{-1} for $[Ru(bpy)_3]Cl_2$ and 8.8×10^{-4}, 2.4 μs^{-1} for $[Ru(bpy)_2(dmby)]Cl_2$, respectively; namely, the drastical decrease in the yield of the bis(bipyridyl) complex at 25 °C is due mainly to the large decrease in k_r. However, such a result does not agree with the usual understanding that the radiative rate constant is characteristic of a molecule and not dependent on the surrounding conditions, such as temperature or solvent properties. In fact, the value of k_r for $[Ru(bpy)_3]Cl_2$ is nearly the same both at 77 K and 25 °C. On the other hand, the above calculations show another important point that the nonradiative rate constant of the bis(bipyridyl) complex at 25 °C is only slightly larger than that of the parent tris complex, and thus the large decrease in the yield of the bis(bipyridyl) complex cannot be ascribed to the increase in k_{nr}. Consequently two reasons are possible for the decrease in the yield of the bis(bipyridyl) complex at 25 °C; (i) decrease of the formation efficiency of the emitting state (φ_{isc}) and (ii) changes of the circumstances of the excited states in contrast with those at 77 K. According to the first alternative, Eq. 1 does not hold any more and must be replaced by the following expression:

$$Q = \varphi_{isc}k_r/(k_r+k_{nr}) = \varphi_{isc}k_r\tau_m. \quad (4)$$

φ_{isc} can be estimated if k_r at 25 °C is assumed to be the same as that at 77 K (0.048 μs^{-1}). The value of φ_{isc} obtained in this way is 1.8×10^{-2}, *i.e.* decreased by two orders of magnitude. The cause of the large decrease in φ_{isc}, however, is not obvious at this stage. In order to argue about the second alternative, it is necessary to know about various aspects such as the contributions of the CTTS configurations to the emitting state,[16,17] equilibrium between the CTTL and d-d excited state (this problem is neglected at 77 K),[17,41] as well as the detailed knowledge of the energy levels of each excited states. These data, however, are also insufficient. It is likely that changes in the excited state features result in the decrease of φ_{isc}, but further experiments are needed to establish this view.

Finally it should be noted that the quenching effect of dissolved oxygen in the solvent reported for the tris(bipyridyl)ruthenium(II) complex[42] is also seen in the complexes studied here (Table 4).

The author wishes to thank Associate Professor Hiroshi Kokubun and Dr. Koichi Kikuchi of Tohoku University for their kindness in allowing the use of their apparatus for lifetime measurements, and Dr. Toshishige Suzuki of the Government Industrial Research Institute of Tohoku, Sendai, for kindly supplying his authentic sample of the dmby ligand.

The Oxidation of Carbon Monoxide on Pt/Al_2O_3 Containing a Metal Oxide

Yukio Kosaki,* Akira Miyamoto, and Yuichi Murakami
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received November 25, 1981)

By using a three-way catalyst containing a metal oxide, CO is removed as CO_2 even in the "rich" region of the air/fuel ratio. In order to elucidate the mechanism of this action of the added metal oxide, the reaction of CO with O_2 on a $Pt–V_2O_5/Al_2O_3$ catalyst was investigated using a rectangular pulse-reaction apparatus. In the $CO–O_2$ reaction on a Pt/Al_2O_3 catalyst, a significant amount of unreacted CO was exhausted in the "rich" region of the reactants. Furthermore, the conversion of CO decreased markedly with an increase in the CO/O_2 ratio in the reactants. In the $CO–O_2$ reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst, on the other hand, the conversion of CO was high and did not decrease markedly with an increase in the CO/O_2 ratio in the "rich" region. As for the reaction on the $Pt–V_2O_5/Al_2O_3$ at 558 K and above, the CO was completely removed as CO_2 at any of the CO/O_2 ratios examined. These effects of the added V_2O_5 were found to be due to: (i) the reaction of CO with an oxygen of V_2O_5 in the $Pt–V_2O_5/Al_2O_3$ catalyst and (ii) the enhanced oxidation of CO with a gaseous O_2 on the Pt/Al_2O_3 catalyst upon the addition of V_2O_5. On the basis of the kinetics of the oxidation of CO with the oxygen of V_2O_5 in the $Pt–V_2O_5/Al_2O_3$ and Pt black–V_2O_5 mixtures, its mechanism was proposed to be as follows; the oxygen of V_2O_5 at the $Pt–V_2O_5$ interface is activated by contact with Pt (this activated oxygen is denoted by [Pt···O···V]). The oxidation of CO with the oxygen of the $Pt–V_2O_5/Al_2O_3$ and Pt black–V_2O_5 mixtures proceeds according to the following two steps. Step I is the reaction of a gaseous CO with the active oxygen at the $Pt–V_2O_5$ interface, [Pt···O···V], to form CO_2 and a reduced site, [Pt V]. Step II is the oxidation of the reduced site with the bulk oxygen in V_2O_5 to reproduce [Pt···O···V]. The enhanced oxidation of CO with a gaseous O_2 caused by the addition of V_2O_5 to Pt/Al_2O_3 was found also to be understandable in terms of the active site, [Pt···O···V], where the reduced site, [Pt V], is oxidized by the gaseous O_2 to reproduce [Pt···O···V] instead of the bulk oxygen in V_2O_5.

The three-way catalyst system is used for the simultaneous removal of nitrogen monoxide, carbon monoxide, and hydrocarbons in automotive exhaust emissions.[1–5] Furthermore, attention has been focused on finding a three-way catalyst containing a metal oxide in order to deal with the fluctuation in the air/fuel ratio and broaden the "window" width.[6,7] It has been found, for the reaction of synthetic exhaust gas, that the conversion of CO in the "rich" region is much increased by the addition of a metal oxide to a three-way catalyst.[7,8] Although the mechanisms of the $CO–O_2$ reaction on precious metal[9–17] and metal oxide[18–21] catalysts have been the subject of many investigations, the mechanism of the action of a metal oxide added to a three-way catalyst in the $CO–O_2$ reaction has scarcely been investigated. The purpose of this study, then, was to establish the mechanism of the action of V_2O_5 in the $CO–O_2$ reaction on a $Pt–V_2O_5/Al_2O_3$ catalyst, particularly the mechanism of the reaction in the "rich" region. The $CO–O_2$ reaction was investigated, since this reaction is one of the most important reactions involved in the real three-way catalyst system.[22,23] The reason why V_2O_5 was chosen as the metal oxide has already been described in a previous paper,[24] where a mechanism of the action of the V_2O_5 in the $NO–H_2$ reaction on the $Pt–V_2O_5/Al_2O_3$ catalyst has been proposed. It should also be noted that a rectangular pulse-reaction technique was employed in this study in order to investigate the kinetics of the reaction more precisely than the conventional pulse-reaction technique makes possible. The pulse-reaction technique is considered to be useful for the investigation of the effect of the addition of a metal oxide to a three-way catalyst.[24] Furthermore, it seemed interesting to compare the synergistic effect between Pt and V_2O_5 in the $CO–O_2$ reaction with that in the $NO–H_2$ reaction.

Experimental

Catalysts. A Pt/Al_2O_3 catalyst (the Pt loading was 0.5 wt%) was purchased from Nippon Engelhard, Ltd. The $Pt–V_2O_5/Al_2O_3$ (the Pt loading was 0.5 wt%, and, unless otherwise specified, the content of V_2O_5 in the catalyst was 9 wt%, although a catalyst with a 36 wt% V_2O_5 loading was also used), $Pt/Al_2O_3–V_2O_5$(M) (the ratio of Pt/Al_2O_3 to V_2O_5 was 1/1 in weight), and Pt black–V_2O_5(P) (the ratio of Pt black to V_2O_5 was 1/1 in weight) were the same as the catalysts used in the previous study.[24] The Pt black and Pd black were purchased from Mitsuwa's Pure Chemicals Co. The Rh black was prepared using the method employed by Feulgen.[25] The precious metal black–metal oxides(M), that is, Pt black–V_2O_5(M), Pd black–V_2O_5(M), Rh black–V_2O_5(M), Pt black–MoO_3(M), Pt black–WO_3(M), and Pt black–Cr_2O_3(M), were prepared by mixing powders of the precious metal black and the metal oxide in a mortar for 20 min without water.

Characterizations of the catalysts were made by means of X-ray diffraction on a GFD-35, by scanning-electron microscope on JSM-T 20, by ESR on JES ME 1X, by IR on JASCO EDR-31,[26] and by UV on UVIDEC-505. The number of surface Pt atoms on the Pt/Al_2O_3 catalyst was determined using a conventional hydrogen adsorption apparatus.

Reagents. Commercial CO (99.9% purity) and O_2 (99.9% purity) were used without further purification. The helium used as a carrier gas was purified with a titanium metal sponge heated at 1073 K and a Molecular Sieve column at room temperature.

Apparatus and Procedure. Experiments were conducted using the rectangular pulse-reaction apparatus shown in Fig. 1. Reactants of given compositions were prepared and stor-

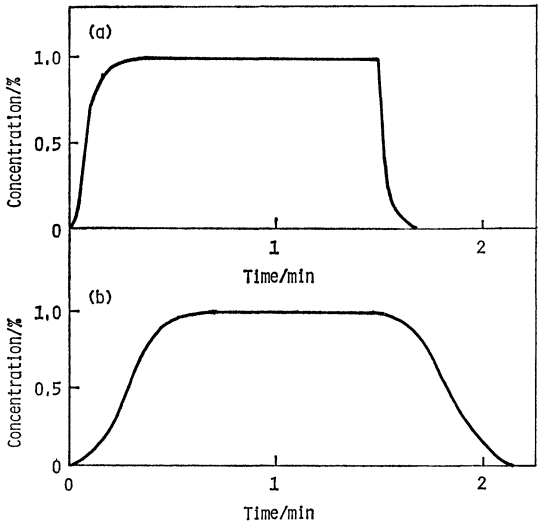

Fig. 2. Shapes of the inlet reactants and outlet CO_2.
(a): Concentration profile for the inlet mixture of CO and O_2 detected by TCD (14) (inlet concentration of the mixture=1.0%), (b): concentration profile for the CO_2 detected by TCD (15) when CO_2 is introduced (inlet concentration of CO_2=1.0%). Carrier gas flow rate=31 cm³/min. Pulse width=90 s (total amount of a single pulse=5 cm³-STP).

ed in two syringes (4), and the sampling loop of a 6-way valve (6) was filled by means of them. The 6-way valve was turned so that the reactant gas in the sampling loop could be pushed out through a stainless steel capillary (7) to the main stream of the carrier gas (Stream A) and then carried to the reactor (9). Before all of the reactant gas in the sampling loop had been pushed out from the sampling loop, the 6-way valve (6) was returned. In such a way, the rectangular pulse could be obtained. The concentration was varied by changing the composition of the sample gas and the flow rates of the carrier gas and pusher gas. The pulse width was varied by changing the time interval between turning and returning the 6-way valve (6). The shape of the input pulse was recorded by means of a thermal conductivity detector, TCD, (14). The shape of the CO_2 produced by the oxidation of CO was observed by means of TCD (15). The carrier-gas flow rate and the length of the Porapak Q column (12) were regulated so that the shape of the CO_2 detected by means of TCD (15) gave the best rectangular pulse. The conversions of the unreacted CO and O_2 were also measured by using TCD (16). Unless otherwise specified, experiments were carried out under the following conditions. The carrier gas flow rate was 31 cm³-STP/min, and the length of the Porapak Q column was 2 m. The pulse width was 1.5 min, and the total amount of a single pulse was 5 cm³-STP. The concentrations of CO were 0.26—10.3%. The reaction temperatures were 341—773 K.

Results

Shapes of the Inlet Reactants and Outlet CO_2. Figure 2(a) shows an example of the Shape of the inlet mixture of CO and O_2. It was almost rectangular except for a small tailing at the front and tail of the pulse. This indicates a constant concentration of individual reactants in a pulse, a behavior significantly different from that of a conventional pulse technique. Figure 2(b) shows the shape of the CO_2 pulse detected by TCD (15) when CO_2 was pulsed instead of a mixture of CO and O_2. The concentration of CO_2 detected was independent of the time except for that at the front and tail of the pulse. This means that the shape of CO_2 is not deformed by the Porapak Q column [(12) in Fig. 1] except for the front and tail of the pulse. This also means that the rate of CO_2 formation, R_{CO_2}, can be measured from the shape of the outlet CO_2; for example, a constant concentration of CO_2 indicates a constant R_{CO_2}, because the flow rate of the carrier gas was constant. It was found that the dispersion at the front and tail of the outlet CO_2 is mainly caused when the CO_2 pulse passes through the Porapak Q column.

The CO–O_2 Reaction on the Pt/Al_2O_3 and Pt–V_2O_5/Al_2O_3 Catalysts. Figures 3 and 4 show the results of the CO–O_2 reaction on the Pt/Al_2O_3 and Pt–V_2O_5/Al_2O_3 catalysts at various inlet CO/O_2 ratios. The unsupported V_2O_5 or V_2O_5/Al_2O_3 was inactive for the CO–O_2 reaction under the experimental conditions used in this study. As is shown in Fig. 3, the conversion of CO (X_{CO}) for the Pt–V_2O_5/Al_2O_3 catalyst was larger than that of X_{CO} for the Pt/Al_2O_3 catalyst under any conditions shown in this figure. Although the X_{CO} for the Pt/Al_2O_3 catalyst decreased abruptly in the "rich" region (*i.e.*, CO/O_2>2) with an increase in the CO/O_2 ratio, the X_{CO} for the Pt–V_2O_5/Al_2O_3 catalyst did not decrease markedly with an increase in the CO/O_2 ratio. Even in the absence of gaseous O_2 (CO/O_2=∞), the X_{CO} for the Pt–V_2O_5/Al_2O_3 catalyst was quite high, indicating a significant contribu-

Fig. 3. Fig. 4. Effect of the CO/O_2 ratio on the conversion of O_2 (X_{O_2}) in the CO–O_2 reaction on the Pt/Al_2O_3 and $Pt–V_2O_5/Al_2O_3$ catalysts at various temperatures. ○,●: 558 K, △,▲: 448 K, □,■: 423 K (open symbols, Pt/Al_2O_3; closed symbols, $Pt–V_2O_5/Al_2O_3$). Catalyst weight; Pt/Al_2O_3=200 mg, $Pt–V_2O_5/Al_2O_3$=218 mg (Pt weight in catalysts=1 mg). Concentration of CO=1.0%.

tion of the oxygen of V_2O_5 to the oxidation of CO. For the reaction on this catalyst at temperatures above 558 K, CO was completely oxidized (*i.e.*, X_{CO}=100%), irrespective of the inlet CO/O_2 ratio. These data clearly indicate that the added V_2O_5 plays an important role in the oxidation of CO on the $Pt–V_2O_5/Al_2O_3$ catalyst. As is shown in Fig. 4, the conversion of O_2 (X_{O_2}) in the "rich" region for the $Pt–V_2O_5/Al_2O_3$ catalyst was higher than X_{O_2} for the Pt/Al_2O_3 catalyst. This indicates that the oxidation of CO with a gaseous O_2 on Pt/Al_2O_3 is also promoted by the addition of V_2O_5 to Pt/Al_2O_3.

Concentration Profiles of the CO_2 Produced by the Oxidation of CO on the Pt/Al_2O_3 and $Pt–V_2O_5/Al_2O_3$ Catalysts. Figure 5 shows the concentration profiles of the CO_2 produced by the oxidation of CO under various conditions. Since the flow rate of the carrier gas was constant, the measured concentration of CO_2 at a given time is proportional to R_{CO_2} at this same time. As is shown in Fig. 5(a), the R_{CO_2} on Pt/Al_2O_3 at the stoichiometric point (*i.e.* CO/O_2=2) decreased markedly with the time after its maximum. On the other hand, the R_{CO_2} on the $Pt–V_2O_5/Al_2O_3$ catalyst decreased only slightly with the time; in fact, it was almost independent of the time. As for the reaction in the "rich" region (*i.e.*, CO/O_2=4)[Fig. 5(b)], the R_{CO_2} on the Pt/Al_2O_3 catalyst was significantly slower than the R_{CO_2} on the $Pt–V_2O_5/Al_2O_3$ catalyst. It is also noted that the R_{CO_2} for the $Pt–V_2O_5/Al_2O_3$ catalyst decreases slightly with an increase in the time. As for the reaction in the absence of gaseous O_2(*i.e.*, $CO/O_2=\infty$)[Fig. 5(c)], the R_{CO_2} on the $Pt–V_2O_5/Al_2O_3$ catalyst decreased markedly with the time; on the other hand, no CO_2 was produced on the Pt/Al_2O_3 catalyst, irrespective of the time. It can also be noted in Fig. 5(c) that the R_{CO_2} for the reaction on $Pt–V_2O_5/Al_2O_3$ in the absence of O_2 is independent of the concentration of CO.[27] This can also be seen in the relationship between the yield of CO_2(Y_{CO_2}) and the concentration of CO(C_{CO}; 1%=2.24 μmol/cm³ under the experimental conditions in this study) shown in Fig. 6; Y_{CO_2} was independent of C_{CO} at both 341 and 423 K.[27]

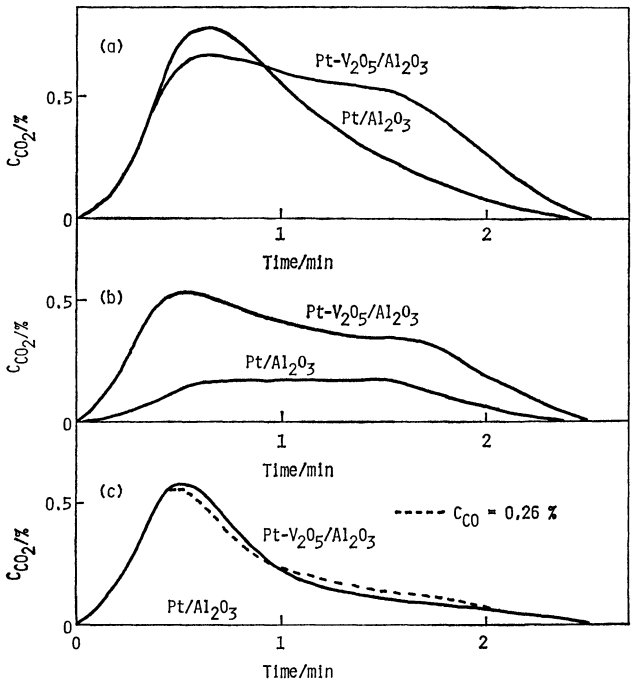

Fig. 5. Shapes of the outlet CO_2 in the CO–O_2 reaction on the Pt/Al_2O_3 and $Pt–V_2O_5/Al_2O_3$ catalysts at 423 K.
(a): CO/O_2=2.0, (b): CO/O_2=4.0, (c): $CO/O_2=\infty$ (concentration of CO=1.0%). Catalyst weight; Pt/Al_2O_3=200 mg, $Pt–V_2O_5/Al_2O_3$=218 mg (Pt weight in catalysts=1 mg).

Kinetics of the Oxidation of CO with the Oxygen of Metal

Oxides. Since the unsupported V_2O_5 or V_2O_5/Al_2O_3 was inactive for the reaction with CO, the formation of CO_2 observed for the Pt–V_2O_5/Al_2O_3 [Fig. 5(c)] is due to the oxidation of CO with the oxygen of V_2O_5 promoted by Pt. However, as is shown in Fig. 5(c), the R_{CO_2} for the Pt–V_2O_5/Al_2O_3 catalyst changes greatly with the time, which makes it difficult to investigate the mechanism of the synergistic effect between Pt and V_2O_5. This is the reason why various mixtures of precious metal and metal oxide were used in this study as catalysts for investigating the mechanism of the reaction of CO with the oxygen of metal oxides promoted by precious metals.[28] The Pt/Al_2O_3–V_2O_5(M) or Pt black–V_2O_5 (P) did not oxidize CO to CO_2 under the present experimental conditions. Pt black–V_2O_5(M) was active for the oxidation of CO, and, as is shown in Fig. 7, R_{CO_2} did not change significantly with the time. Similarly, the R_{CO_2} on Pd black–V_2O_5(M), Rh black–V_2O_5(M), and Pt black–MoO_3(M) was almost independent of the time. The Pt black–WO_3(M) or Pt black–Cr_2O_3(M) was inactive for the reaction. Therefore, the Pt black–V_2O_5(M), Pd black–V_2O_5(M), Rh black–V_2O_5(M), and Pt black–MoO_3(M) are considered to be catalysts which can be used for detailed investigations of the mechanism of the synergistic effect between a precious metal and a metal oxide on the oxidation of CO with the oxygen of the metal oxide.

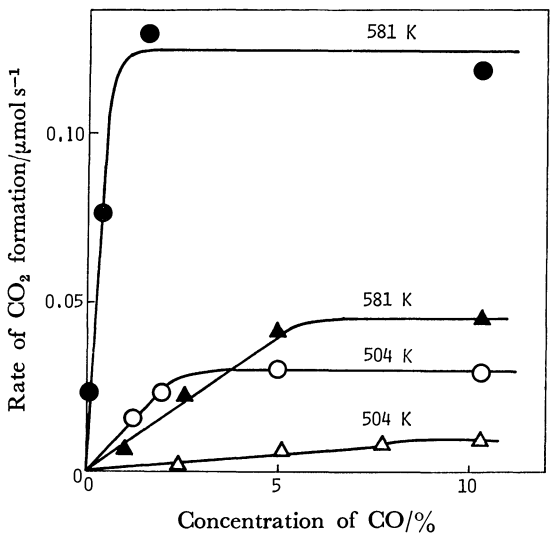

Fig. 8. Effect of the concentration of CO on the reaction of CO with 1 and 5 wt% Pt black–V_2O_5(M) catalysts at various temperatures.
●,▲: 581 K, ○,△: 504 K [circle symbols, 5 wt% Pt black–V_2O_5(M); triangle symbols, 1 wt% Pt black–V_2O_5(M)]. Catalyst weight=40 mg.

Figure 8 shows some of the findings regarding R_{CO_2} for the reaction of CO with Pt black–V_2O_5(M) at various C_{CO} values. Here, R_{CO_2} is calculated from the average value of R_{CO_2} at the plateau of the concentration profile shown in Fig. 7. As is shown in Fig. 8, R_{CO_2} was of the first order with respect to C_{CO} when C_{CO} was low(this region will hereafter be referred to as R1). When C_{CO} was high, R_{CO_2} was of the zeroth order with respect to C_{CO}(this region will hereafter be referred as R0). The boundary between R1 and R0 for 1 wt% Pt black–V_2O_5(M) was located at C_{CO}, higher than that for 5 wt% Pt black–V_2O_5(M). It may also be noted in Fig. 8 that the boundary between R1 and R0 moves to a lower C_{CO} with an increase in the reaction temperature. From the observed R_{CO_2} values at various C_{CO} levels, the first-order and zeroth-order rate constants were determined. These rate constants, measured at various temperatures, satisfied the Arrhenius equations, and the activation energies(E_1 and E_0) and pre-exponential factors(A_1 and A_0) were determined to be as is shown in Table 1. Here, A_1 and A_0 are normalized to have a unit weight of the precious metal. The Arrhenius parameters were also determined for the Pd black–V_2O_5(M), Rh black–V_2O_5(M), and Pt black–MoO_3(M) catalysts; these are also shown in Table 1. The E_1 for 1 wt%Pt black–V_2O_5(M) was almost the same as the E_1 for 5 wt% Pt black–V_2O_5(M); on the other hand, both values are larger than the E_1 for Pd black–V_2O_5(M) or Rh black–V_2O_5(M). The E_0 for 1 and 5 wt% Pt black–V_2O_5(M), Pd black–V_2O_5(M), and Rh black–V_2O_5(M) was almost constant and independent of the kind of catalyst. However, the E_0 for Pt black–MoO_3(M) was larger than the E_0 for the former catalysts. The A_1 or A_0 did not change markedly with the kind of catalyst; that is, the A_1 and A_0 changed at the maximum by factors of only

Table 1. The activation energies and pre-exponential factors in the reaction of CO with the cataly

7 and 5 respectively. The A_0 and E_0 for Pt-V_2O_5/Al_2O_3 were similarly determined, though these values are considered not to be correct for the reasons presented above. The E_0 for Pt-V_2O_5/Al_2O_3 was slightly lower than the E_0 for Pt black-V_2O_5(M), while the A_0 for Pt-V_2O_5/Al_2O_3 was about 20 times larger than the A_0 for Pt black-V_2O_5(M).

Characterizations of the Pt-V_2O_5/Al_2O_3 and Pt Black-V_2O_5(M) Catalysts. The number of surface Pt atoms on the Pt/Al_2O_3 catalyst was determined, by using the H_2 adsorption technique, to be 5.0 μmol/g-cat, which leads to an average Pt diameter of 30 Å. The X-ray diffraction pattern of Pt black-V_2O_5(M) indicated that it is a mixture of Pt metal and V_2O_5 crystallines; therefore, no other compound was detected. On the basis of the SEM measurements of Pt black-V_2O_5(M), the average diameters of Pt and V_2O_5 in the catalyst were determined to be 5000 and 2000 Å respectively. ESR, IR, and UV measurements of Pt-V_2O_5/Al_2O_3 and Pt black-V_2O_5(M) indicated that the vanadium oxides in these catalysts are mainly in the highest oxidation state, *i.e.*, V^{5+}. The structure of V_2O_5 in V_2O_5/Al_2O_3 catalysts with various contents of V_2O_5 has been determined by using the NO-NH_3 rectangular pulse technique, coupled with the IR, ESR, and UV techniques.[29]

Discussion

Removal of CO in the "Rich" Region Using the Pt-V_2O_5/Al_2O_3 Catalyst. As is shown in Fig. 3, CO is almost completely removed in the "lean" region of the reactants (*i.e.*, $CO/O_2<2$) by using the Pt/Al_2O_3 catalyst. However, the X_{CO} in the CO-O_2 reaction in the "rich" region (*i.e.*, $CO/O_2>2$) decreases markedly with an increase in the CO/O_2 ratio. This means that a considerable amount of unreacted CO is exhausted in the "rich" region. This behavior in the CO-O_2 reaction on the Pt/Al_2O_3 catalyst is similar to that in the reactions of synthetic exhaust gas in three-way catalysts without metal oxides.[22,23] The X_{CO} in the reaction on the Pt-V_2O_5/Al_2O_3 catalyst is high even in the "rich" region. As for the reaction at temperatures above 558 K, X_{CO} is 100% at any CO/O_2 ratio, indicating a complete removal of CO. This behavior in the CO-O_2 reaction on the Pt-V_2O_5/Al_2O_3 catalyst is similar to that in the reactions of synthetic exhaust gas on three-way catalysts containing metal oxides.[7,8]

The Amounts of Gaseous O_2 and Oxygen of V_2O_5 Consumed for the Oxidation of CO on the Pt-V_2O_5/Al_2O_3 Catalyst. In addition to a gaseous O_2, the oxygen of V_2O_5 participates in the oxidation of CO on the Pt-V_2O_5/Al_2O_3 catalyst (Fig. 3). Also, as is shown in Fig. 4, the oxidation of CO with a gaseous O_2 on the Pt/Al_2O_3 catalyst is promoted by the addition of V_2O_5 to the catalyst. It is, therefore, necessary to calculate the amounts of gaseous O_2 [Q_G(Pt) and Q_G(Pt-V)] and the oxygen of V_2O_5 [Q_V(pt) and Q_V(Pt-V)] consumed for the oxidation of CO on the Pt/Al_2O_3 and Pt-V_2O_5/Al_2O_3 catalysts before discussing in detail the mechanism of the action of the added V_2O_5. In the pulse experiment, material balances with respect to the oxygen atoms lead to the following equations:

$$Q_G(\text{Pt}) = 2Q^\circ_{O_2}\cdot X_{O_2}(\text{Pt}), \quad (1)$$

$$Q_V(\text{Pt}) = Q_{CO_2}(\text{Pt}) - Q_G(\text{Pt}), \quad (2)$$

$$Q_G(\text{Pt-V}) = 2Q^\circ_{O_2}\cdot X_{O_2}(\text{Pt-V}), \quad (3)$$

$$Q_V(\text{Pt-V}) = Q_{CO_2}(\text{Pt-V}) - Q_G(\text{Pt-V}), \quad (4)$$

where Q_G is the number of oxygen atoms in O_2 consumed for the oxidation of CO; Q_V is the number of the oxygen of V_2O_5 consumed for the oxidation of CO; $Q^\circ_{O_2}$ is the number of gaseous O_2 injected as a reactant of the pulse experiment; X_{O_2} is the conversion of O_2; Q_{CO_2} is the number of CO_2 molecules produced; and (Pt) and (Pt-V) refer to the Pt/Al_2O_3 and Pt-V_2O_5/Al_2O_3 catalysts respectively. On the basis of the experimental results for the Pt/Al_2O_3 catalyst shown in Figs. 3 and 4, Eq. 2′ is obtained for Q_V(Pt):

$$Q_V(\text{Pt}) = 0. \quad (2')$$

This relationship is reasonable, since the Pt/Al_2O_3 catalyst does not contain V_2O_5. From Eqs. 1 and 3, the increase in Q_G caused by the addition of V_2O_5 to Pt/Al_2O_3(ΔQ_G) is given by Eq. 5:

$$\Delta Q_G = Q_G(\text{Pt-V}) - Q_G(\text{Pt}). \quad (5)$$

Similarly, from Eqs. 2′ and 4 the increase in $Q_V(\Delta Q_V)$

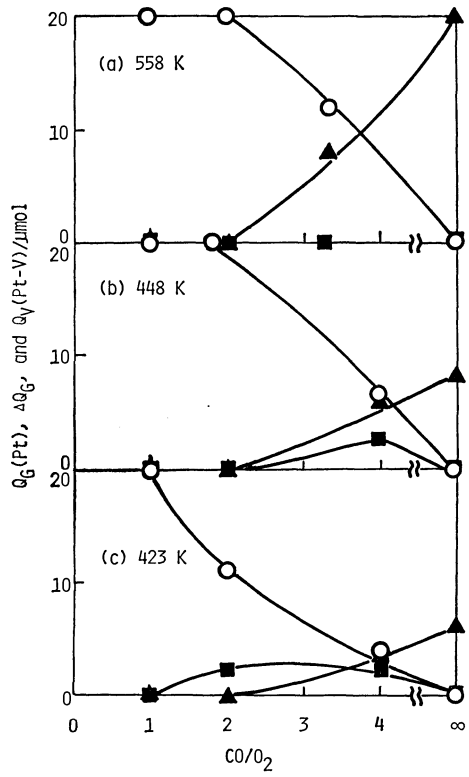

Fig. 9. Relationship between the CO/O_2 ratio and $Q_G(Pt)$, ΔQ_G, and $Q_V(Pt\text{-}V)$ in the $CO\text{-}O_2$ reaction on the $Pt\text{-}V_2O_5/Al_2O_3$ catalyst.
○: $Q_G(Pt)$, ■: ΔQ_G, ▲: $Q_V(Pt\text{-}V)$. Concentration of CO=1.0%. Catalyst weight=218 mg.

is given by Eq. 6:

$$\Delta Q_V = Q_V(Pt\text{-}V). \quad (6)$$

Figure 9 shows the results for $Q_G(Pt)$, ΔQ_G, and $Q_V(Pt\text{-}V)$, which were calculated from the experimental results shown in Figs. 3 and 4. As is shown in Fig. 9, $Q_G(Pt)$ mainly contributes to the $CO\text{-}O_2$ reaction on the $Pt\text{-}V_2O_5/Al_2O_3$ catalyst in the "lean" region ($CO/O_2<2$), and the synergistic effect between Pt and V_2O_5, *i.e.*, ΔQ_G or $Q_V(Pt\text{-}V)$, is not important. As the CO/O_2 ratio increases in the "rich" region ($CO/O_2>2$), $Q_G(Pt)$ decreases, but $Q_V(Pt\text{-}V)$ and ΔQ_G become significant. In particular, $Q_V(Pt\text{-}V)$ mainly contributes to the reaction in the "rich" region. It should also be noted that ΔQ_G plays an important role in the reaction in the "rich" region at temperatures as low as 423 K.

Structures of $Pt\text{-}V_2O_5/Al_2O_3$ and Pt Black-V_2O_5(M). On the basis of the above-mentioned characterizations of $Pt\text{-}V_2O_5/Al_2O_3$ and Pt black-V_2O_5(M), the structures of these catalysts shown in Fig. 10 can be proposed. The average diameter of Pt particles on $Pt\text{-}V_2O_5/Al_2O_3$ is about 30 Å, which has been determined by the H_2 adsorption measurement. In the V_2O_5/Al_2O_3 catalyst(V_2O_5 loading is 9 wt%), 1—2 layers of V_2O_5 lamellae cover a small percentage of the Al_2O_3 surface.[29] Since the content of Pt is very low (0.5 wt%), the V_2O_5 in the $Pt\text{-}V_2O_5/Al_2O_3$ catalyst is considered to be almost the same as the V_2O_5 in the V_2O_5/Al_2O_3 catalyst. The coverage of V_2O_5 and the particle size of Pt thus determined lead to

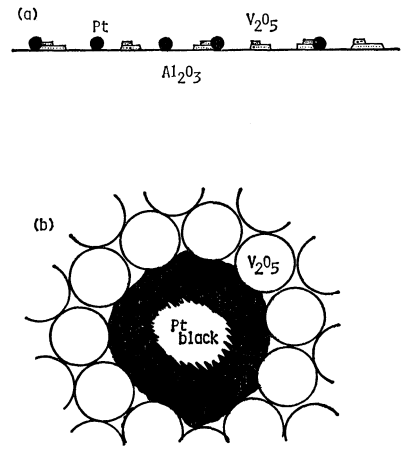

Fig. 10. Structures of $Pt\text{-}V_2O_5$ mixed catalysts.
(a): $Pt\text{-}V_2O_5/Al_2O_3$; the average diameter of Pt particles is about 30 Å, 1—2 layers of V_2O_5 lamella cover a few percentage of the Al_2O_3 surface, (b): Pt black-V_2O_5(M); a Pt black particle (about 5000 Å in diameter) is surrounded by many V_2O_5 particles [about 2000 Å in diameter (about 500 layers of V_2O_5 lamella)].

the structure of V_2O_5 and Pt on Al_2O_3, indicating that Pt particles are partly in contact with V_2O_5 and are partly separated from V_2O_5. The vanadium oxides in the $Pt\text{-}V_2O_5/Al_2O_3$ catalyst are mainly in the highest oxidation state, *i.e.*, V^{5+}, judging from the ESR and UV measurements of $Pt\text{-}V_2O_5/Al_2O_3$. On the basis of the SEM and XRD investigations of Pt black-V_2O_5(M), the structure shown in Fig. 10(b) can be proposed; Pt black-V_2O_5(M) is a mixture of Pt black(about 5000 Å in diameter) and V_2O_5 particles(about 2000 Å in diameter). The V_2O_5 in Pt black-V_2O_5(M) is composed of about 500 layers of V_2O_5 lamellae.

Mechanism of the Oxidation of CO with the Oxygen of V_2O_5 in Pt Black-V_2O_5(M). From the experimental results shown in Table 1 and in Figs. 7 and 8, the mechanism of the oxidation of CO with the oxygen of V_2O_5 in Pt black-V_2O_5(M) shown in Fig. 11(a) can be proposed. According to this mechanism, the oxygen of V_2O_5 at the $Pt\text{-}V_2O_5$ interface is activated by contact with Pt; this is a new type of active site and will hereafter be denoted by [Pt···O···V]. Also, the oxidation of CO with the oxygen of Pt black-V_2O_5(M) proceeds according to the following two steps. Step I is the reaction of a gaseous CO with the active oxygen at the $Pt\text{-}V_2O_5$ interface, [Pt···O···V], to form CO_2 and a reduced site, [Pt V]. Step II is the oxidation of the reduced site, [Pt V], with the bulk oxygen in V_2O_5 to reproduce [Pt···O···V]. The validity of this mechanism can be proved as follows.

Kinetics: Since Step I is the reaction of a gaseous CO with the activated surface oxygen, its rate will increase with the increase in the concentration of CO. Since a gaseous CO does not participate in Step II, on the other hand, the rate of Step II will be independent of C_{CO}. Therefore, the rate of Step I relative to Step II would decrease with a decrease in C_{CO}. In other words, Step I becomes the rate-

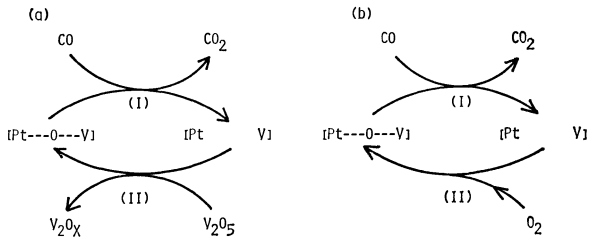

Fig. 11. Mechanism of the CO–O_2 reaction on Pt–V_2O_5 mixed catalysts.
(a): Mechanism of the oxidation of CO with the oxygen of V_2O_5 in the Pt black–V_2O_5(M) catalyst, (b): mechanism of the oxidation of CO with a gaseous O_2 caused by the synergistic effect between Pt and V_2O_5 [ΔQ_G].

determining step when C_{CO} is low. On the other hand, when C_{CO} is high, Step II becomes the rate-determining step. This is in accordance with the observed kinetics shown in Fig. 8, because the rate is of the first order with respect to C_{CO} when C_{CO} is low, while it is of the zeroth order when C_{CO} is high.

Activation Energies: Judging from the above-mentioned discussion on the kinetics of the reaction, E_1 and E_0 can be regarded as the activation energies of Steps I and II respectively. Since a precious metal plays an important role in Step I of the mechanism shown in Fig. 11(a), E_1 should vary depending on the kind of precious metal used. Step II is the migration of the bulk oxygen atom of a metal oxide to its surface, followed by the interaction of the surface oxygen atom with Pt. Since the adsorption of an atomic oxygen on the Pt surface is considered to be a non-activated process, the migration of the bulk oxygen to the surface may limit the rate of Step II. This leads to the value of E_0, which should be independent of the kind of precious metal, but which should change with the kind of metal oxide. This inference is in accordance with the experimental results shown in Table 1.

Boundary between R1 and R0: According to the mechanism shown in Fig. 11(a), the boundary between R1 and R0 is determined by the rate of Step I relative to Step II. Judging from the structure of Pt black–V_2O_5(M), the number of [Pt···O···V] sites can be expected to increase in proportion to the content of the Pt black. This leads to the increase in the rate of Step I in proportion to the content of the Pt black in the catalyst. Since the quantity of oxygen atoms consumed for the reaction in the R0 region was much larger than the amount of the surface oxygen atoms of V_2O_5,[29] the rate in the R0 region may refer to the rate of the diffusion of oxygen in the bulk of V_2O_5 particles, but not to the rate of the diffusion of the subsurface oxygen atoms to the reduced active site, [Pt V]. This means that the rate of Step II is less sensitive to the increase in the content of Pt black than the rate of Step I, suggesting that the rate of Step I relative to Step II increases with an increase in the content of the Pt black in the catalyst. The boundary between R1 and R0 for 5 wt% Pt black–V_2O_5(M) is thus considered to be located at a C_{CO} point lower than the C_{CO} for 1 wt% Pt black–V_2O_5(M). This is in accordance with the experimental results shown in Fig. 8.

The above discussion indicates that all of the experimental data shown in Table 1 and Figs. 7 and 8 can reasonably be understood in terms of the mechanism shown in Fig. 11(a). In order to establish the validity of the mechanism, however, a discussion of possible alternative mechanisms is indispensable.

AM-1: CO is activated on the Pt surface, migrates onto V_2O_5, and reacts with the oxygen of V_2O_5 to form CO_2.[30]

CO is not dissociatively, but molecularly, adsorbed on the Pt surface[31–34] under the present experimental conditions. V_2O_5 is not active for the reaction with a molecular CO; CO is scarcely oxidized by the oxygen of V_2O_5, even at a temperature as high as 773 K. These data indicate that AM-1 does not play an important role in the oxidation of CO with Pt black–V_2O_5(M).

AM-2: The oxygen of V_2O_5 migrates onto the surface of Pt and reacts with CO to form CO_2.

The reaction of CO with an adsorbed oxygen atom on Pt proceeds so rapidly that the activation energy for this process is low.[9,11,35] and every 10 collisions of CO molecules with the oxygen atom adsorbed on Pt lead to the formation of one CO_2 molecule, even at room temperature.[31] This is not consistent with the observed activation energy shown in Table 1.

AM-3: The CO adsorbed on the Pt surface reacts with the oxygen of V_2O_5 at the Pt–V_2O_5 interface; therefore, the R_{CO_2}–C_{CO} curves are determined by the coverage of CO on the Pt surface.

The amount of CO adsorbed on Pt decreases with an increase in the temperature.[31–33] If the boundary between R1 and R0 is determined by the coverage of the adsorbed CO, then it should move to a higher C_{CO} value as the temperature increases. However, this is not consistent with the experimental results shown in Fig. 8.

Mechanism of the Oxidation of CO on the Pt–V_2O_5/Al_2O_3 Catalyst. As has been mentioned above, the amount of CO_2 molecules produced by the CO–O_2 reaction on the Pt–V_2O_5/Al_2O_3 catalyst is determined by following three factors: Q_G(Pt), ΔQ_G, and Q_V (Pt–V). The mechanisms of the reactions responsible for the individual factors will be discussed below.[36]

The CO–O_2 Reaction on the Pt Surface[Q_G(Pt)]: The mechanism of the CO–O_2 reaction on the Pt surface has already been investigated extensively.[9–11,13,37] According to the mechanism, the CO adsorbed on Pt retards the CO–O_2 reaction at low temperatures.[9,10,38–41] In accordance with this mechanism, the observed rate of the CO–O_2 reaction on the Pt/Al_2O_3 catalyst decreases markedly with an increase in the CO/O_2 ratio at low temperatures, especially at 423 K (Fig. 3). The concentration profile of CO_2 produced by the CO–O_2 reaction on Pt/Al_2O_3 shows that the rate of CO_2 formation decreases significantly with the time [Fig. 5(a)]. This phenomenon may be interpreted in terms of the proposed mechanism of the CO–O_2 reaction on the Pt surface as follows; as the time increases, the coverage of CO on the Pt surface in-

creases, which then leads to the decrease in the rate of the reaction with an increase in the time.

The Oxidation of CO with the Oxygen of V_2O_5 Promoted by Pt [Q_V(Pt–V)]: Since the electronic state of V_2O_5 supported on Al_2O_3 is almost the same as that of the unsupported V_2O_5, the mechanism shown in Fig. 11(a) can be applied to the reaction of CO with the oxygen of V_2O_5 in the Pt–V_2O_5/Al_2O_3 catalyst. Although the kinetics for Pt–V_2O_5/Al_2O_3 is different from that for Pt black–V_2O_5(M), this difference can be explained in terms of the structures of Pt–V_2O_5/Al_2O_3 and Pt black–V_2O_5(M) as follows. As is shown in Fig. 10, both Pt and V_2O_5 for Pt–V_2O_5/Al_2O_3 are much better dispersed than those for Pt black–V_2O_5-(M). The number of the active sites, [Pt···O···V], for Pt–V_2O_5/Al_2O_3 is thus considered to be greater than that for Pt black–V_2O_5(M). This in turn leads to a rate of Step I for Pt–V_2O_5/Al_2O_3 which is faster than that for Pt black–V_2O_5(M). On the other hand, the amount of V_2O_5, which can supply oxygen atoms to the active site, is limited for Pt–V_2O_5/Al_2O_3, because the V_2O_5 on Al_2O_3 is highly dispersed. This is the reason the rate of CO_2 formation decreases markedly with the time for Pt–V_2O_5/Al_2O_3 [Fig. 5(c)] and why the R1 region does not appear in the R_{CO_2}–C_{CO} curves for Pt–V_2O_5/Al_2O_3 (Fig. 6). The A_0 for Pt–V_2O_5/Al_2O_3 is larger than the A_0 for Pt black–V_2O_5(M) (Table 1). This may also be due to the high dispersion of Pt and V_2O_5 on Al_2O_3 in Pt–V_2O_5/Al_2O_3. The E_0 for Pt–V_2O_5/Al_2O_3 is a little lower than the E_0 for Pt black–V_2O_5(M); this difference may be ascribable to the lack of a supply of the bulk oxygen in V_2O_5 at high temperatures for Pt–V_2O_5/Al_2O_3. Although the results for Pt–V_2O_5/Al_2O_3 can well be understood on the basis of the mechanism shown in Fig. 11(a), a discussion of a following alternative mechanism is indispensable:

AM-4: The oxygen of V_2O_5 migrates to the Pt surface through Al_2O_3 and reacts with CO on Pt.

As for Pt/Al_2O_3–V_2O_5(M), Pt is considered to be separated from V_2O_5 by Al_2O_3, and CO is not oxidized with the oxygen of this catalyst. Therefore, AM-4 is not important in the reaction on Pt–V_2O_5/Al_2O_3.

The Oxidation of CO with a Gaseous O_2 Caused by the Synergistic Effect between Pt and V_2O_5[ΔQ_G]: According to the mechanism of the reaction of CO with the oxygen of V_2O_5 in the Pt black–V_2O_5(M) and Pt–V_2O_5/Al_2O_3 catalysts shown in Fig. 11(a), [Pt V] is formed by the reaction of CO with the [Pt···O···V] site. If a gaseous O_2 is present in the system, [Pt V] can be expected to be oxidized by the gaseous O_2 to reproduce the [Pt···O···V] site, which may in turn increase the rate of the oxidation of CO with a gaseous O_2 on Pt–V_2O_5/Al_2O_3 more than that on Pt/Al_2O_3. This means that ΔQ_G can be explained in terms of the mechanism of the CO–O_2 reaction shown in Fig. 11(b). This mechanism is similar to the mechanism of the oxidation of CO with the oxygen of V_2O_5 shown in Fig. 11(a), but the reduced site, [Pt V], is reoxidized to [Pt···O···V] by a gaseous O_2, not by the bulk oxygen in V_2O_5. As is evident from the mechanism shown in Fig. 11(b), the reaction of CO with [Pt···O···V] is not retarded by the adsorbed CO, behavior which is different from the behavior in the CO–O_2 reaction on the Pt surface. This explains why ΔQ_G mainly contributes to the reaction in the "rich" region at low temperatures (Fig. 9). In the practical three-way catalyst system, the fluctuation in the air/fuel ratio takes place rapidly with a frequency of 1—10 Hz;[42,43] therefore a part of the CO adsorbed on Pt on the "rich" side may still remain on Pt even on the "lean" side. This suggests that the CO–O_2 reaction on Pt, [Q_G(Pt)], is retarded by the CO remaining on Pt under practical three-way catalyst conditions. Since the reaction of CO at the [Pt···O···V] site, [Q_V(Pt–V) and ΔQ_G], is not retarded by CO remaining on Pt, it may play an important role under certain conditions.

Synergistic Effect between Pt and V_2O_5 in the CO–O_2 Reaction as Compared with That in the NO–H_2 Reaction. The conversion of CO in the CO–O_2 reaction on the Pt/Al_2O_3 catalyst in the "rich" region has been markedly enhanced by the addition of V_2O_5 to Pt/Al_2O_3. This effect of V_2O_5 has been found to be brought about by the formation of a new type of active site, [Pt···O···V], at the Pt–V_2O_5 interface, which plays an important role in the oxidation of CO with the oxygen of V_2O_5 and the enhanced oxidation of CO with a gaseous O_2 on Pt/Al_2O_3 caused by the addition of V_2O_5 to Pt/Al_2O_3. The mechanism of the action of V_2O_5 in the oxidation of CO is much different from that in the NO–H_2 reaction found in the previous study.[24] In the NO–H_2 reaction on the Pt–V_2O_5/Al_2O_3 catalyst, the selective reduction of NO to N_2 or N_2O in the "rich" region is brought about by the "hydrogen spillover"—the dissociation of H_2 on Pt, followed by the spillover of the dissociated hydrogen from Pt to Al_2O_3 and then to V_2O_5 and the subsequent reduction of V_2O_5 with the spilled-over hydrogen. The synergistic effect between Pt and V_2O_5 in the NO–H_2 reaction can, therefore, appear even if Pt and V_2O_5 are separated from each other by Al_2O_3; this behavior is different from that in the CO–O_2 reaction. This means that the mechanism of the action of a metal oxide added to a three-way catalyst can change greatly depending on the kind of reaction. Since the real three-way catalyst system is composed of various types of reactions, the accumulation of investigations such as the present one can lead to the scientific development of a three-way catalyst with a sufficiently broad "window". In addition, the activity of the Pt/Al_2O_3 catalyst for the oxidation of CO with the gaseous O_2 enhanced by the addition of V_2O_5 suggests the possibility that the amount the precious metals used for the three-way catalyst system can be saved by the addition of a metal oxide to a three-way catalyst.

36) According to our preliminary ^{18}O-tracer experiments, a considerable amount of $C^{16}O^{16}O$ was obtained by the reaction of $C^{16}O$ with $^{18}O_2$ on the Pt–V_2O_5/Al_2O_3 catalyst. This means that the reduced site, [Pt V], is considerably reoxidized by the bulk oxygen of V_2O_5 and that the V^{4+} in V_2O_5 thus produced is oxidized by $^{18}O_2$. The details of the results will be reported in a subsequent paper.

(Received December 9, 1981)

Electronic structures of the lactim and lactam forms of 2-, 3-, and 4-pyridinols, and of their anions and protonated cations were calculated by a modified CNDO-CI (mCNDO-CI), CNDO/S-CI, and a modified π-SCF-MO-CI methods. The theoretical results agree well with the observed spectra of both the neutral and ionic species, and predict satisfactorily the shorter wavelength shift of lower excited π-π^* and n-π^* bands of the lactim form compared to the corresponding bands of the lactam form. The π-π^* assignment to the lowest triplet states of 2- and 4-pyridones, and of 2- and 3-pyridinols, together with the n-π^* assignment to the lowest singlet state of 4-pyridone was predicted by the mCNDO-CI method, in agreement with the suggestion based on emission properties. The orbital energies calculated by the mCNDO method were compared with the observed photoelectron spectra; the results show that the fourth highest occupied orbital is π-orbital in 2- and 3-pyridinols, and σ-orbital in 4-pyridinol and 4-pyridone.

N-heterocyclic compounds having hydroxy substituents show the lactim-lactam tautomerism. This is important in photochemical reaction and in molecular biology. The electronic structure of uracil has recently been studied theoretically in our previous paper.[1] For pyridinols which are the simplest hydroxy-substituted *N*-heterocyclic compounds, quantum mechanical studies have been devoted to the estimation of the relative stabilities of the tautomers and to the assignment of the electronic spectra using the semiempirical methods considering π-electrons[2-6] or all-valence electrons,[6-9] as well as the nonempirical SCF-LCAO-MO method.[8,10] However, as far as we are aware, the neutral and ionic forms of pyridinols have not been studied systematically by any all-valence electron (AVE) SCF-MO-CI methods. The aim of the present paper is to apply both the AVE-SCF-MO-CI and π-SCF-MO-CI methods to understand the electronic structures and spectra of different forms of pyridinols and of their ions. Ultraviolet photoelectron spectra (UPS) of neutral forms of the molecules are also discussed in comparison with the calculated orbital energies.

Theoretical

The details of a modified CNDO-CI (mCNDO-CI) method and a modified π-SCF-MO-CI (mPPP) method, as well as the semiempirical parametrization in these methods are described in previous papers.[1,11,12] In the mPPP method a polarizable σ-core is introduced in the evaluation of the π-electron Hartree-Fock matrix elements.[1]

The molecular structures of the lactim and lactam forms of isomeric pyridinols were the same as in a previous paper[10] and they are shown in Fig. 1, together with the coordinate system. The molecular structures of the anions were assumed to be the same as those of the corresponding neutral forms except that the proton of either N–H (in the lactam forms) or O–H (in the lactim forms) was removed. In the case of protonated cations the additional proton was located at either the nitrogen atom (in the lactim forms) or at the oxygen atom (in the lactam forms) with the assumed distance of the proton-protonated atom to be equal to 1.03 or 1.00 Å, respectively.

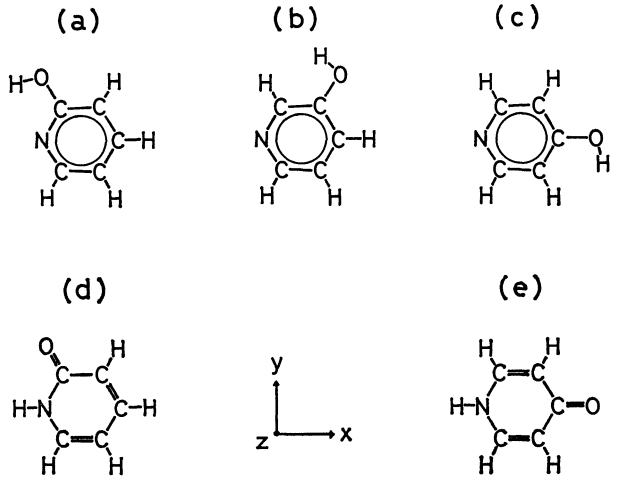

Fig. 1. Molecular structures of (a) 2-pyridinol, (b) 3-pyridinol, (c) 4-pyridinol, (d) 2-pyridone, and (e) 4-pyridone, and coordinate system.

Results and Discussion

Electronic Structures of Pyridinols. Electronic structures of the lactam and lactim forms of 2-, 3-, and 4-pyridinols have been calculated by the mCNDO-CI, the original CNDO/S-CI,[13] and the mPPP methods. The theoretical results calculated by the mCNDO-CI and mPPP methods are compared with the corresponding experimental data[2,9,14-16] in Tables 1—3. Electronic spectra of the lactam form (*i.e.*, 2- and 4-pyridones) are predicted well by all the three methods. In the case of 4-pyridone, the first π-π^* absorption band is predicted to be composed of two π-π^* bands. Both the AVE methods predict the weak first π-π^* band to appear on the longer wavelength side of the strong 2nd π-π^* band, whereas the mPPP method predicts the reverse order of the two π-π^* states.

3-pyridinols are predicted satisfactorily by the mPPP and CNDO/S-CI methods. The mCNDO-CI method predicts the first π-π^* band to be 0.4—0.8 eV higher than the observed values. This is due to overestimation ($\approx$0.8 eV) in transition energy of the first π-π^* band of the reference molecules (*i.e.*, of benzene, phenol, and pyridine)[17] by the use of the semiempirical parameters adopted in the present calculation. Electronic structure of 4-pyridinol is predicted less satisfactorily by all the three methods compared with the ones of 2- and 3-pyridinols. Absorption bands of lower excited π-π^* (and n-π^*) states of the lactim form shift to shorter wavelengths than the corresponding bands of the lactam form. This is well reproduced by the three methods as is listed in Tables 1 and 2.

The assignment of the lowest excited state is important to understand the photophysical properties of substituted pyridines. In mCNDO-CI method, calculated transition energy for n-π^* state corresponds to that of the triplet manifold.[11] Considering the underestimation ($\approx$0.7 eV) of transition energy of the ^{3}n-π^* state,[1] calculated results by mCNDO-CI method listed in Tables 1—3 clearly predict the lowest triplet state is π-π^* state for 2-pyridone, 2-pyridinol, 3-pyridinol, and 4-pyridone in agreement with the suggestion based on phosphorescence quantum yield and lifetime.[22] In mCNDO-CI method, transition energy of the first ^{1}n-π^* state may be estimated to be $\approx$1.7 eV (or less) higher than the calculated value for the triplet manifold when we consider the singlet-triplet separation energy[1] of $\approx$1 eV (or less) and underestimation of ^{3}n-π^* transition energy ($\approx$0.7 eV).[1] In 2-pyridone, 2-pyridinol, and 3-pyridinol, energy separation between the first $^1\pi$-π^* and the first ^{3}n-π^* states is calculated to be 1.3—1.7 eV. Therefore, the calculation shows that the first $^1\pi$-π^* state locates near to the first ^{1}n-π^* state. However, owing to the approximations employed, it is difficult to decide which is the lowest excited singlet state. In 4-pyridone, the lowest excited singlet state is safely assigned to n-π^* state in agreement with the suggestion based on fluorescence properties.[22]

Electronic Structures of the Anions and Cations of Pyridinols. Two different molecular structures based on the neutral parent molecules of either the lactam or lactim forms were assumed for each ionic species. Difference in calculated results between the two structures is due to the changes in geometrical structure and in mesomeric structure. As is shown in Tables 4 and 5, the difference in calculated π-π^* transition energies is more significant for the mPPP method (0.1—0.5 eV) than for the AVE method (0—0.2 eV). This is due to the fact that the electronic structures calculated by π-SCF-MO-CI method are much more sensitive to the assumed mesomeric structure of a system, *i.e.*, to the assumed numbers of π-electrons on each atom. However, in mPPP method, the mesomeric effect is reduced in some extent compared to the original PPP method, because consideration of σ-polarizable core in mPPP method partly cancels the effect of change in mesomeric structures.

In Table 4, the calculated results by the mCNDO-CI and mPPP methods are tabulated for the anions which are derived from the lactim forms of pyridinols. Compared with the results of the neutral molecules listed in Tables 1—3, the first n-π^* states of 2-, 3-, and 4-pyridinolate anions in Table 4 are shifted toward longer wavelengths (by $\approx$0.8 eV by mCNDO-CI method) by deprotonation. n-Orbitals pertinent to the first n-π^* states of the anions are localized on O atom, while those of pyridinols on N atom, thus the character of the first n-π^* state being changed. The third n-π^* states in 2-, 3-, and 4-pyridinolate anions have essentially n(N)-π^* character (calculated at 4.89, 4.37, and 4.21 eV, respectively, by mCNDO-CI method). Therefore, by deprotonation, n(N)-π^* state shifts toward shorter wavelength (by 0.3—1.0 eV by mCNDO-CI method). In the case of 4-pyridone and its anion, the first n-π^* states correspond to n(O)-π^* state. As in the case of n(N)-π^* state, n(O)-π^* state also shifts toward shorter wavelength (by 0.8 eV by mCNDO-CI method) by deprotonation. The first two π-π^* bands of the lactim forms were observed to shift toward longer wavelengths (by 0.3—0.5 eV) by deprotonation.[14-16] This is correctly predicted by the present calculations.

a) Molecular structures based on the corresponding lactim forms were employed in the calculations. For the purpose of comparison, calculated results for the ions, molecular structures of which are based on the lactam forms were listed in part in parentheses. b) See footnote (a) in Table 1. c) Refs. 2 and 16. d) Molar extinction coefficient at the band maximum.

As is shown in Table 5, theoretical calculations for the protonated cations predict satisfactorily the shorter wavelength shift of the first n(σ)-π^* state by protonation. The first two π-π^* bands of the lactam forms are correctly predicted to shift to shorter wavelengths by protonation in agreement with observations.[16)]

Orbital Assignment in UPS of Pyridinols. Ionization potentials (IP's) of the lactam and lactim forms of pyridinols were evaluated by the mCNDO method according to Koopmans' theorem.[23)] The results are shown in Fig. 2, compared with the observed values in ultraviolet photoelectron spectra (UPS).[24)] In the

figure, the calculated and observed values for pyridine[25)] are also shown for the purpose of comparison. A good correlation between observed and calculated values for pyridinols (Fig. 2a) and pyridones (Fig. 2b) clearly indicates that the order of the first three highest occupied molecular orbitals is $\pi > n > \pi$ for 2- and 3-pyridinols, and 2- and 4-pyridones in agreement with the assignment by Cook, *et al.*[24)] Assignments to the fourth and fifth bands in UPS have not yet been established for pyridinols and pyridones. In pyridine, the fifth IP (which is from π-orbital)[25)] was calculated to be $\approx$2.5 eV higher by the present calculation. When we adjust the relative shift of the calculated fourth and fifth IP's, a good correlation can be obtained in Fig. 2a between the observed and calculated IP's for pyridinols, indicating that the fourth and fifth bands in UPS are π- and σ-orbitals, respectively, for both 2- and 3-pyridinols, and that the fourth band of 4-pyridinol is σ-orbital. From the correlation diagram in Fig. 2b, the fourth band of 4-pyridone can safely be assigned to σ-orbital, and the one of 2-pyridone, plausibly to σ-orbital, too.

From the orbital energy calculations by the CNDO/S method, a correlation diagram which is qualitatively similar to the one in Fig. 2 was obtained. Although the sequence in the calculated molecular orbitals by the CNDO/S method is partly incorrect, the argument mentioned to Fig. 2 also holds in the results by the CNDO/S method, and the same conclusion as to the orbital assignment in UPS could be drawn.

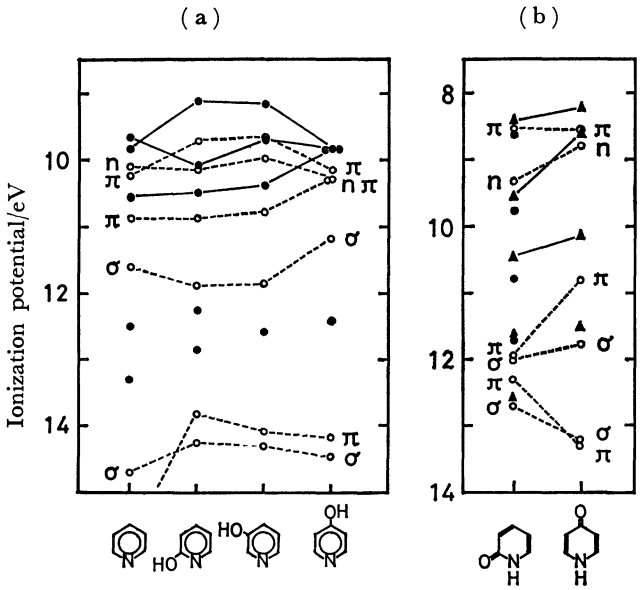

Fig. 2. Ionization potentials (IP's/eV) observed in UPS (●) and calculated by mCNDO method (○) for (a) pyridine, and 2-, 3-, and 4-pyridinols, and (b) 2- and 4-pyridones. ▲; IP's observed for 1-methyl-2(or 4)-pyridone.

This work was initiated during the stay of J. S. K. at the Institute for Solid State Physics, the University of Tokyo. J. S. K. wishes to thank the Japan Society for the Promotion of Sciences for support of his stay in Japan. This work was also supported in part by the Ministry of Science and Higher Education/Poland/ within the project MR. I. 5.

Association of Inclusion Compounds of β-Cyclodextrin in Aqueous Solution

Sanyo Hamai

Department of Physics, Miyazaki Medical College, Kiyotake, Miyazaki 889-16

(Received December 9, 1981)

Inclusion compounds in the systems naphthalene–β-cyclodextrin (CDx) and 2-methoxynaphthalene (MN)–o-dicyanobenzene (DB)–β-cyclodextrin in aqueous solution were studied by means of absorption and fluorescence spectra. In the former system a naphthalene excimer fluorescence was observed. By the analyses of the concentration dependence of the absorption spectra and the excimer fluorescence intensities, the species responsible for the excimer fluorescence is identified as a 2:2 inclusion compound which is formed by association of two 1:1 naphthalene–CDx inclusion compounds, not a 2:1 inclusion compound in which two naphthalene molecules enter into the cavity of one CDx molecule. In the latter system, absorption and fluorescence spectra due to a charge transfer complex of MN with DB were observed. By analyses similar to the naphthalene case, the existence of a 1:1:2 association compound formed between a MN–CDx inclusion compound and a DB–CDx inclusion compound is confirmed. Fluorescence quenching by I^- and IO_3^- was also studied for the inclusion compounds in both systems.

Recently, much attention has been focused on cyclodextrin as a model compound for enzymatic processes. It is interesting to note that such a relatively small molecule can promote a stereospecific reaction although in organisms much larger molecules act catalytically. This catalytic action is based on the fact that cyclodextrin forms inclusion compounds with many kinds of organic compounds in aqueous solution. The component ratios of substrates to β-cyclodextrin are 1:1 for most compounds.[1–5] However, 1:2 or 2:1 inclusion compounds have been reported for α-, β-, γ-, and capped cyclodextrins.[6–8] Ueno *et al.*[9] suggested that γ-cyclodextrin forms a 2:1 inclusion compound with 1-naphthyl acetate in aqueous solution by observing an excimer fluorescence of 1-naphthyl acetate. For some systems, formation of a 2:2 inclusion compound by association of two 1:1 inclusion compounds has been speculated,[10,11] but ambiguity remains as to whether such an association really occurs. By study of fluorescence quenching in the system in which two kinds of 1:1 inclusion compounds can exist, Kano *et al.*[12] predicted the existence of a 1:1:1 inclusion compound. Thus it appears that the compositions of the inclusion compounds other than the 1:1 compounds depend critically on the types of cyclodextrin and the physicochemical properties of the substrates involved.

In the present study, we have investigated inclusion compounds in the systems naphthalene–β-cyclodextrin and 2-methoxynaphthalene–o-dicyanobenzene–β-cyclodextrin in aqueous solution by analyses of the absorption and fluorescence spectra.

Experimental

β-Cyclodextrin (CDx) purchased from Nakarai Chemical Co. was recrystallized three times from water and the molecular weight of CDx was calculated as the dodecahydrate.[13] Naphthalene (Nakarai Chemical Co.) and 2-methoxynaphthalene (MN) (Tokyo Kasei Kogyo Co.) were recrystallized three times from ethanol. o-Dicyanobenzene (DB) (Tokyo Kasei Kogyo Co.) was recrystallized first from water and then from cyclohexane. Potassium iodide (Wako Pure Chemical Industries) and potassium iodate (Nakarai Chemical Co.) were used without further purification. Water was doubly distilled.

Absorption spectra were measured with a Hitachi 124 spectrophotometer and fluorescence spectra with a Shimadzu RF-501 fluorescence spectrophotometer (modified by employing a cooled EMI 9789QA photomultiplier). Both instruments were equipped with thermostatically controlled sample compartments. Fluorescence was detected at right angles to the direction of excitation. Fluorescence spectra were corrected for the spectral sensitivity of the detection system.[14]

Absorption and fluorescence spectra were measured at (25±0.1) °C unless otherwise stated. Aerated sample solutions were used throughout the present work because nitrogen bubbling caused considerable decreases in the concentrations of naphthalene and MN in aqueous solution (containing no CDx).

Fluorescence decay times were determined by means of an Ortec 9200 nanosecond decay time fluorescence spectrometer. Light from a nanosecond light pulser (filled with H_2 or air) was passed into a 0.3 m Ritsu MC-30 monochromator and the 270 nm (for naphthalene–CDx system, H_2 gas) or the 316 nm (for MN–DB–CDx system, air) exciting light was isolated. Fluorescence from sample solutions was collected through appropriate filters.

Results

Inclusion Compounds in Naphthalene–β-Cyclodextrin System. Absorption spectra of naphthalene aqueous solutions containing varying concentrations of CDx are shown in Fig. 1. At concentrations of CDx between 0 and $\approx 3\times10^{-3}$ M (1 M=1 mol dm^{-3}), isosbestic points are observed at 267, 271, 276, and 283 nm, indicating the following 1:1 equilibrium in this concentration range:

$$\mathrm{N} + \mathrm{CDx} \overset{K_1}{\rightleftharpoons} \mathrm{NC}, \tag{1}$$

where N and NC represent naphthalene and the 1:1 inclusion compound of CDx with naphthalene, respectively, and K_1 is the equilibrium constant for the formation of NC. The Benesi-Hildebrand relation for such an equilibrium is[1]

$$\frac{1}{A-A_0} = \frac{1}{(\varepsilon_1-\varepsilon_0)[\mathrm{N}]_0} + \frac{1}{(\varepsilon_1-\varepsilon_0)[\mathrm{N}]_0K_1}\frac{1}{[\mathrm{CDx}]_0}, \tag{2}$$

where A and A_0 are the absorbances per cm of the naphthalene aqueous solutions in the presence and absence of CDx, ε_1 and ε_0 are the molar absorption coefficients of NC and naphthalene, and $[\mathrm{N}]_0$ and $[\mathrm{CDx}]_0$

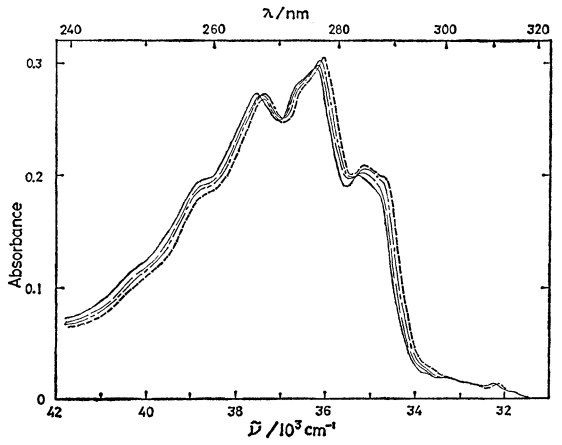

Fig. 1. Absorption spectra of naphthalene (5.80×10^{-5} M) in aqueous solution in the presence of CDx. Initial concentration of CDx, ——: 0 M, — —: 8.40× 10^{-4} M, — — —: 2.52×10^{-3} M, - - - -: 8.40×10^{-3} M.

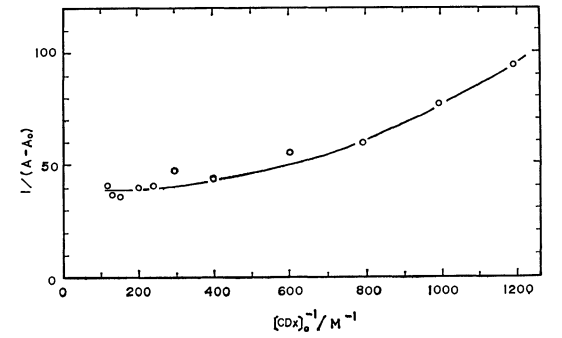

Fig. 2. Benesi-Hildebrand plot for absorbance changes at 277 nm of naphthalene aqueous solutions containing varying concentrations of CDx. $[N]_0=5.80\times10^{-5}$ M.

are the initial concentrations of naphthalene and CDx, respectively. We choose 277 nm as the analyzing wavelength for the absorbance changes. A plot of $1/(A-A_0)$ *vs.* $1/[CDx]_0$ gives a concave upward curve as shown in Fig. 2. This combined with the fact that the spectral curves no longer pass through the isosbestic points at higher CDx concentrations (see Fig. 1) suggests the existence of another species other than NC in the naphthalene–CDx system.

Figure 3 shows the fluorescence spectra of naphthalene in the absence and presence of CDx in aqueous solution. By addition of CDx the fluorescence band at around 330 nm is enhanced, and at the same time a broad structureless band having λ_{max} at 410 nm appears. This new band grows in intensity at the expense of the 330 nm band with decreasing temperature as shown in Fig. 4. The enhancement of the 330 nm band seen in Fig. 3 can be interpreted as due to the formation of NC having the higher fluorescence yield than naphthalene. The new band is assignable to the well-known naphthalene excimer fluorescence.[15,16] The appearance of this band indicates the existence of another species beside NC because the excimer cannot be formed from uncomplexed naphthalene molecules at the concentrations as low as $\approx6\times10^{-5}$ M.

As the species responsible for the excimer fluorescence, two kinds of inclusion compounds represented by the following two mechanisms can be considered:

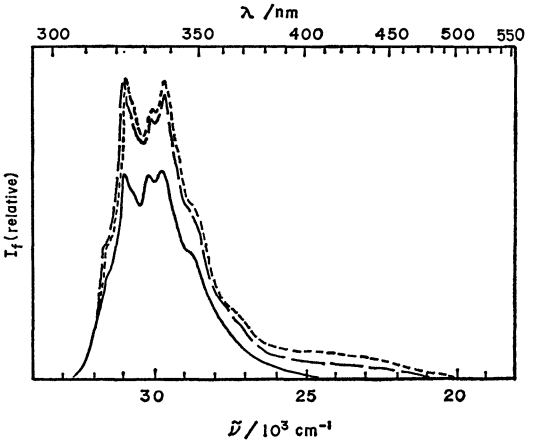

Fig. 3. Fluorescence spectra of naphthalene (5.80×10^{-5} M) in aqueous solution in the presence of CDx. Initial concentration of CDx, ——: 0 M, — —: 2.52×10^{-3} M, - - - -: 8.40×10^{-3} M. $\lambda_{exc}=283$ nm.

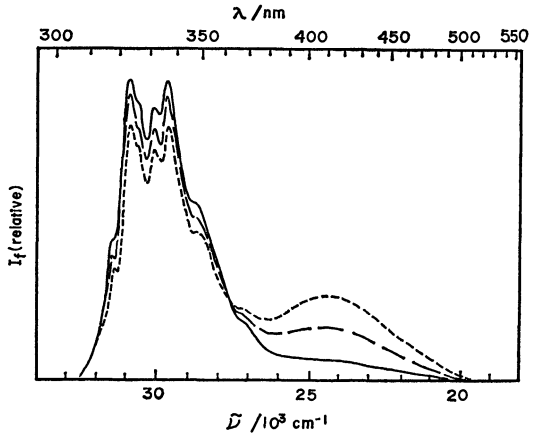

Fig. 4. Temperature dependence of the fluorescence spectra of naphthalene (4.90×10^{-5} M) in aqueous solution in the presence of CDx (8.40×10^{-3} M). ——: 25 °C, — —: 12 °C, ----: 3 °C. $\lambda_{exc}=283$ nm.

Mechanism 1) $$N + NC \overset{K_2'}{\rightleftharpoons} N_2C, \quad (3)$$

Mechanism 2) $$NC + NC \overset{K_2}{\rightleftharpoons} N_2C_2. \quad (4)$$

One of these is a 2:1 inclusion compound N_2C which is composed of two naphthalene molecules entering into the cavity of a CDx molecule. The other is a 2:2 inclusion compound N_2C_2 which is formed by association of two 1:1 inclusion compounds. For Mechanism 1, the relation that the concentration of the uncomplexed naphthalene [N] should satisfy is

$$2K_1K_2'[CDx]_0[N]^2 + (1+K_1[CDx]_0)[N]-[N]_0 = 0, \quad (5)$$

whereas for Mechanism 2, it is

$$2K_1^2K_2[CDx]_0^2[N]^2 + (1+K_1(CDx]_0)[N]-[N]_0 = 0. \quad (6)$$

The concentration of N_2C or N_2C_2 can be evaluated after obtaining [N] from Eq. 5 or 6. To solve these equations for [N] we must first know the equilibrium constant K_1. The value of K_1 was determined as following.

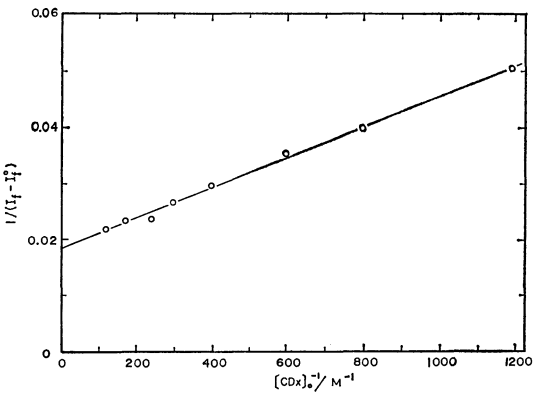

Fig. 5. Benesi-Hildebrand plot for fluorescence increments at 336 nm of naphthalene aqueous solutions containing varying concentrations of CDx. $[N]_0=6.10\times10^{-6}$ M.

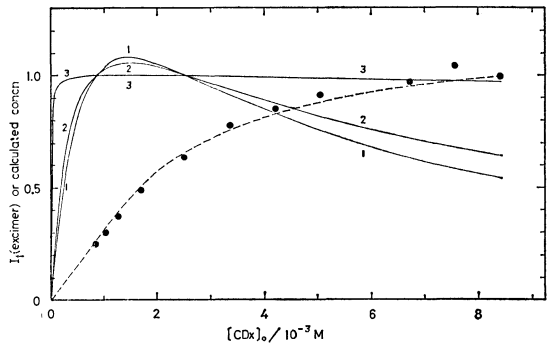

Fig. 6. Comparison of the observed excimer intensities, I_f(excimer), with calculated concentrations $[N_2C]$ and $[N_2C_2]$.
●: I_f(excimer), ——: $[N_2C]$ calculated with $K'_2=1\ M^{-1}$ (curve 1); $K'_2=10^4\ M^{-1}$ (curve 2); $K'_2=10^7\ M^{-1}$ (curve 3), - - - -: $[N_2C_2]$ calculated with $K_2=4000\ M^{-1}$. $[N]_0=5.80\times10^{-5}$ M. I_f(excimer) and $[N_2C_2]$ are normalized to unity at the highest concentration of $[CDx]_0$, and $[N_2C]$ at the lowest concentration of $[CDx]_0$.

The fluorescence intensity was measured at a naphthalene concentration of 6×10^{-6} M at which no excimer fluorescence appears and thus only NC exists as the inclusion compound. For our experimental geometry in the fluorescence measurements, the observed intensity was always proportional to the concentration of the emitting species. Under these conditions, the following relation holds:[7]

$$\frac{1}{I_f-I_f^0}=\frac{1}{a[N]_0}+\frac{1}{a[N]_0K_1}\frac{1}{[CDx]_0}, \tag{7}$$

where I_f and I_f^0 are the fluorescence intensities of the 330 nm band in the presence and absence of CDx, and a is a proportionality constant. A plot of $1/(I_f-I_f^0)$ *vs.* $1/[CDx]_0$ yields a good straight line as shown in Fig. 5, and from the intercept-to-slope ratio $K_1=685\ M^{-1}$ is obtained.

The value of [N] for Mechanism 1 can then be calculated from Eq. 5 for an assumed value of K'_2 from which the concentration of N_2C can be evaluated. The concentration of N_2C_2 will be similarly evaluated for an assumed value of K_2 through Eq. 6. Figure 6 shows the dependence of the observed excimer fluorescence intensity on CDx concentration and the calculated concentrations of N_2C and N_2C_2 using various values of K'_2 or K_2. As seen in Fig. 6 even when K'_2 is varied from 1 M^{-1} to 10^7 M^{-1}, none of the concentration curves for N_2C fit the intensity curve of the excimer fluorescence. On the other hand, the calculated curve for N_2C_2 fits the data quite well when K_2 is taken equal to 4000 M^{-1}. These findings strongly support Mechanism 2. We will therefore assume in the following that N_2C_2 is the species responsible for the excimer emission in the naphthalene–CDx system.

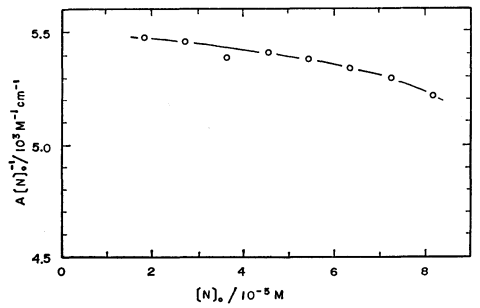

Fig. 7. Plot of $A/[N]_0$ at 277 nm *vs.* $[N]_0$. $[CDx]_0=8.40\times10^{-3}$ M.

So far, we have dealt with the spectroscopic data which were obtained at a fixed concentration of naphthalene with varying amounts of CDx. We will now examine the dependence of the naphthalene concentration (at a fixed CDx concentration) on the absorption and fluorescence spectra. No appreciable spectral change was observed in the absorption spectra when the varying concentrations of naphthalene were added to the solution containing a fixed concentration of CDx. However, as displayed in Fig. 7, the apparent molar absorption coefficient ($A/[N]_0$) at 277 nm decreases with increasing $[N]_0$. Obviously, the molar absorption coefficient of N_2C_2 per naphthalene molecule, $\varepsilon_2/2$, must be smaller than ε_1.

The data shown in Fig. 7 can further be analyzed as following. The absorbance A at 277 nm is given by

$$A=\varepsilon_0[N]+\varepsilon_1[NC]+\varepsilon_2[N_2C_2], \tag{8}$$

which can be rewritten using the equilibrium constants K_1 and K_2 as

$$\frac{A}{[N]}=(\varepsilon_0+\varepsilon_1K_1[CDx]_0)+\varepsilon_2K_1^2K_2[CDx]_0^2[N]. \tag{9}$$

The concentration of uncomplexed naphthalene [N] can be calculated from Eq. 6 as functions of $[N]_0$ and $[CDx]_0$ since K_1 and K_2 have already been determined. A plot of $A/[N]$ *vs.* [N] gives a straight line as presented in Fig. 8, and from this plot the values $\varepsilon_1=5690\ M^{-1}\ cm^{-1}$ and $\varepsilon_2=9160\ M^{-1}\ cm^{-1}$ are obtained using the known value of ε_0 (4870 $M^{-1}\ cm^{-1}$). As expected, $\varepsilon_1>\varepsilon_0$ and $\varepsilon_2/2<\varepsilon_1$. These relationships amongst ε_0, ε_1, and $\varepsilon_2/2$ explain the temperature variation of the absorption spectra given in Fig. 9 which shows the decrease of the absorbance at 277 nm on cooling. As is apparent from the temperature depend-

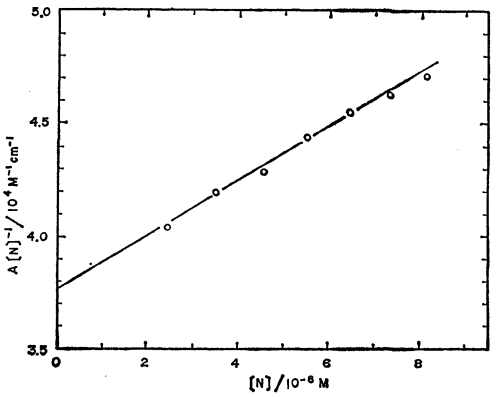

Fig. 8. Plot of $A/[N]$ at 277 nm *vs.* [N]. [N] is calculated from Eq. 6.

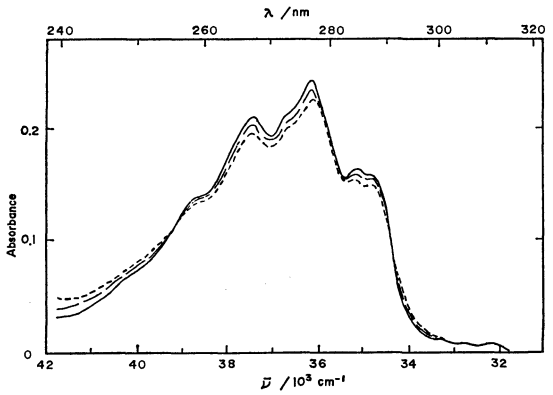

Fig. 9. Temperature dependence of the absorption spectra of naphthalene (4.90×10^{-5} M) in aqueous solution in the presence of CDx (8.40×10^{-3} M). ——: 25 °C, — —: 12 °C, - - - -: 3 °C.

ence of the fluorescence spectra (Fig. 4), $[N_2C_2]$ increases on lowering temperature, accompanied by the decrease in [NC].

The good linearity obtained in Fig. 8 indicates that any aggregates higher than a 2:2 adduct (N_nC_n, $n>2$) do not exist at least in the concentration range we have examined. That the species other than NC in the naphthalene–CDx system is indeed the 2:2 inclusion compounds, and is not a higher aggregate can also be shown from the dependence of the excimer intensity, I_f(excimer), on the naphthalene concentration at a fixed CDx concentration. For Mechanism 2,

$$I_f(\text{excimer}) = b'[N_2C_2] = b'K_1^2K_2[\text{CDx}]_0^2[N]^2 = b[N]^2, \tag{10}$$

where b' is an instrumental constant. Taking logarithm of both sides of Eq. 10,

$$\log I_f(\text{excimer}) = 2\log[N] + \log b. \tag{11}$$

A plot of $\log I_f$(excimer) *vs.* log [N], [N] being calculated from Eq. 6, gives a good straight line with the slope 1.9 ($\simeq2$) as shown in Fig. 10, indicating the square dependence of I_f(excimer) on [N].

By measuring I_f(330 nm) over the temperature range from 3 to 25 °C and obtaining the value of K_1 at each temperature from the plot as shown in Fig. 5, the enthalpy and entropy changes for the equilibrium constant K_1 were determined to be -19 kJ mol^{-1} and

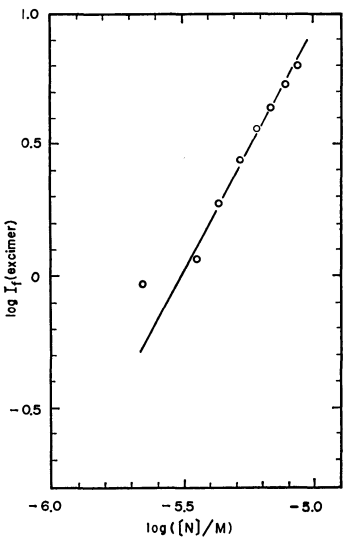

Fig. 10. Plot of $\log I_f$(excimer) *vs.* log [N].

-10 J mol^{-1} K^{-1}, respectively. These thermodynamic quantities are similar to those obtained for other 1:1 inclusion compounds with CDx.[1,17] Unfortunately, these quantities could not be obtained for K_2 since the shape of the I_f(excimer) curve shown in Fig. 6 was relatively insensitive to the temperature change.

Fluorescence decay times and fluorescence quenching by I^- and IO_3^- were also studied for the three components in the naphthalene–CDx system. An aqueous solution of naphthalene alone for the uncomplexed naphthalene and a solution of naphthalene (6.0×10^{-5} M) and CDx (8.4×10^{-3} M) for NC and N_2C_2 were examined. With the 283 nm excitation the quenching of the 330 nm fluorescence bands for N and NC and the 410 nm band for N_2C_2 was studied by adding varying amounts of KI or KIO_3. Strictly speaking, the 330 nm band of the naphthalene–CDx solution contains the fluorescence from the uncomplexed naphthalene, but since its contribution was calculated to be only about 10%, no corrections were applied for the quenching data for NC. The results were analyzed by the usual Stern-Volmer relation:

$$\frac{I_f^0}{I_f} = 1 + k_q\tau'[Q], \tag{12}$$

where I_f^0 and I_f represent the fluorescence intensities in the absence and presence of a quencher Q (using the same notations for N, NC, and N_2C_2 for simplicity), k_q is the rate constant for quenching, and τ' is the fluorescence lifetime of each species in aerated solution. As an example, the Stern-Volmer plots for quenching by IO_3^- are shown in Fig. 11. In Table 1 are summarized the fluorescence lifetimes and the rate constants k_q.[18,19] The reduction of the quenching efficiencies by forming the 1:1 inclusion compounds has already been shown for many other systems and has been attributed to the CDx molecule partly preventing the quencher molecule to penetrate into its cavity.[10,20] The further reduction of the quenching efficiencies for N_2C_2 indicates that it is more difficult for the quencher molecule to approach the naphthalene molecules contained in the two CDx molecules

than in NC, the extreme case being that no quenching was observed by IO_3^- ion which is bulkier than I^-.

Inclusion Compounds in 2-Methoxynaphthalene–o-Dicyanobenzene–β-Cyclodextrin System. Absorption spectra of 2-methoxynaphthalene (MN) aqueous solutions containing varying concentrations of CDx are shown in Fig. 12. Isosbestic points observed at 310 nm and ≈300 nm indicate the following equilibrium:

$$MN + CDx \overset{K_3}{\rightleftharpoons} MC, \qquad (13)$$

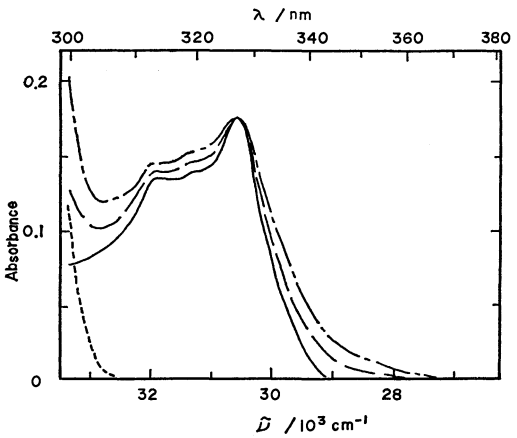

Fig. 13. Absorption spectra of MN (9.60×10^{-5} M)–CDx (8.40×10^{-3} M) in aqueous solution in the presence of DB.
Initial concentration of DB, ——: 0 M, — —: 7.0×10^{-4} M, — — —: 2.0×10^{-3} M. - - - -: absorption spectrum of DB (2.0×10^{-3} M) in the presence of CDx (8.40×10^{-3} M).

where MC is the 1:1 inclusion compound of CDx with MN and K_3 is the equilibrium constant for the formation of MC. The value of K_3 was determined from the Benesi-Hildebrand plot (Eq. 2) using the absorbance changes at 330 nm. $K_3=630$ M^{-1} was obtained.

Very little changes were observed in the absorption spectrum of an *o*-dicyanobenzene (DB) aqueous solution on adding CDx. However, the fluorescence intensity of DB ($\lambda_{max}=307$ nm) decreased with increasing the CDx concentration. We attribute this change as being due to the formation of a 1:1 inclusion compound, DC, *i.e.*,

$$DB + CDx \overset{K_4}{\rightleftharpoons} DC. \qquad (14)$$

From the Benesi-Hildebrand plot for the change in fluorescence intensity (Eq. 7), the value of the equilibrium constant K_4 was determined to be 15 M^{-1}.

Figure 13 shows the absorption spectra of the MN–CDx solutions containing varying amounts of DB. The appearance of a new band extending to longer wavelengths is seen on adding DB. This band is most plausibly due to an MN–DB charge transfer (CT) complex since MN is an electron donor and DB an electron acceptor. Such a CT band, however, could not be observed for the solutions containing only MN and DB in 1,4-dioxane, ethyl ether, and toluene (up to the DB concentrations of 0.2 M, 0.1 M, and 0.1 M, respectively) or in water ($<4\times10^{-3}$ M).

Figure 14 shows the fluorescence spectra of the aqueous solutions of MN alone, MN with CDx, and MN with DB and CDx. The enhancement of the 350 nm band with the addition of CDx indicates that the fluorescence quantum yield of MC is higher than that of MN.[21,22] On adding DB, a structureless band having λ_{max} at 480 nm appears at the expense of the 350 nm band. The excitation spectrum of this band is found to coincide with the long wavelength tail of the absorption spectrum, and thus this band can be assigned to the fluorescence from the CT complex of

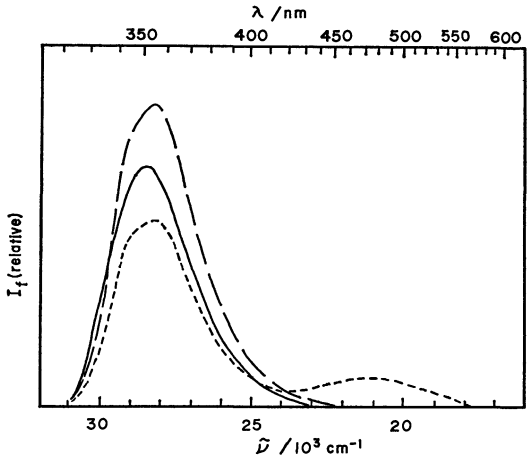

Fig. 14. Fluorescence spectra of MN (——), MN-CDx (— —), and MN–DB–CDx (- - - -) in aqueous solution.
$[MN]_0=9.60\times10^{-5}$ M; $[CDx]_0=8.40\times10^{-3}$ M; $[DB]_0=2.0\times10^{-3}$ M. $\lambda_{exc}=310$ nm.

MN and DB. This assignment is supported by our findings that the fluorescence from an exciplex formed between MN and DB in 1,4-dioxane, the dielectric constant of which is almost the same as that in the CDx cavity,[1] peaks at 480 nm.

Since, as mentioned above, MN and DB alone do not form a CT complex in their ground states in the solvents we have examined, the two substrate molecules are obviously forced to approach each other by virtue of the presence of CDx. Two alternatives can be considered as the species which forms the CT complex in the ground state and which emits the CT fluorescence in the excited state. One is a 1:1:1 inclusion compound, MDC, which is composed of one CDx molecule filled with an MN molecule and a DB molecule. The other is a 1:1:2 inclusion compound, MDC_2, formed by association of MC and DC. The formation of such species is represented by

Mechanism 3) $$MC + DB \overset{K'_5}{\rightleftharpoons} MDC, \quad (15)$$

$$MN + DC \overset{K'_6}{\rightleftharpoons} MDC, \quad (16)$$

and

Mechanism 4) $$MC + DC \overset{K_5}{\rightleftharpoons} MDC_2. \quad (17)$$

In the following, we will examine which of the two species, MDC or MDC_2, is the real species present in the MN–DB–CDx system using analyses somewhat similar to those employed for the naphthalene–CDx system. The fluorescence intensity of MC, I_f(MC), which is proportional to [MC] in the MN–DB–CDx system, should satisfy the following relations for Mechanism 3 and 4, respectively:[23]

$$\frac{1}{I_f(MC)}=\frac{K_3K'_5[CDx]_0}{c[MN]_0(1+K_4[CDx]_0)}[DB]_0 + \frac{(1+K_3[CDx]_0)}{c[MN]_0}, \quad (18)$$

and

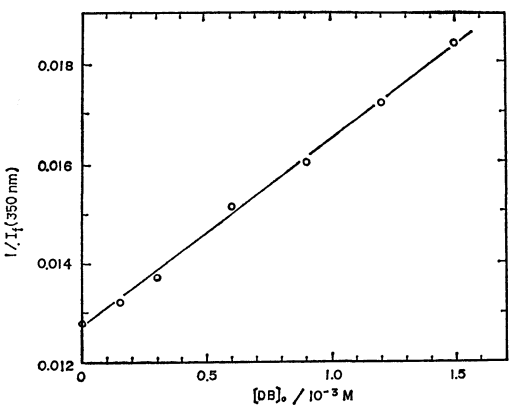

Fig. 15. Plot of $1/I_f$(350 nm) *vs.* $[DB]_0$.
$[MN]_0=9.60\times10^{-5}$ M; $[CDx]_0=8.40\times10^{-3}$ M.

$$\frac{1}{I_f(MC)}=\frac{K_4K_5[CDx]_0}{c[MN]_0(1+K_4[CDx]_0)}[DB]_0 + \frac{(1+K_3[CDx]_0)}{cK_3[MN]_0[CDx]_0}, \quad (19)$$

where $[MN]_0$, $[DB]_0$, and $[CDx]_0$ refer to the initial concentration of each substrate, and c is an instrumental constant. When I_f(MC) is measured as a function of the DB concentration at fixed concentrations of MN and CDx, both Eq. 18 and Eq. 19 predict the plots of $1/I_f$(MC) *vs.* $[DB]_0$ to be linear. We cannot, therefore, discriminate between the two mechanisms from such plots alone. However, we should be able to determine the values of K'_5 and K_5, since the equilibrium constants K_3 and K_4 have already been obtained ($K_3=630$ M^{-1}, $K_4=15$ M^{-1}). Our next step is the following. Whichever of the two mechanisms is operating, we should be able to calculate the expected concentration of MDC or MDC_2 as a function of the CDx concentration through the relation containing either K'_5 or K_5 with the common values of K_3 and K_4. We will then compare the measured intensity of the CT fluorescence, I_f(CT), with the calculated curves of [MDC] and [MDC_2] and see which of the concentration curves better reproduce the observed I_f(CT) curve.

As a first step of the analysis, the reciprocal of the fluorescence intensities of the 350 nm band, $1/I_f$(350 nm), is shown plotted against $[DB]_0$ in Fig. 15. Simple kinetics shows that I_f(350 nm), which contains the fluorescence from the uncomplexed MN too (amounting to $\approx10\%$ of I_f(350 nm)), is proportional to I_f(MC), and thus the analyses by Eqs. 18 and 19 are possible. The values we obtain from Fig. 15 are: $K'_5=400$ M^{-1}, $K_5=3200$ M^{-1}. We now advance to the second step.

In order to make a comparison with the naphthalene–CDx system easier, it will be preferable to keep the concentrations of the two kinds of inclusion compound, MC and DC, approximately the same at each CDx concentration. We therefore employed the system in which $[MN]_0$ was fixed but $[DB]_0$ was varied according to the relation: $[DB]_0/[MN]_0=K_3/K_4(1+K_3[CDx]_0)$. (If the equilibriums involving MN–CDx and DB–CDx stop at the first stage of forming 1:1 inclusion compounds, [MC]=[DC] when $[DB]_0$ is varied by this relation.)

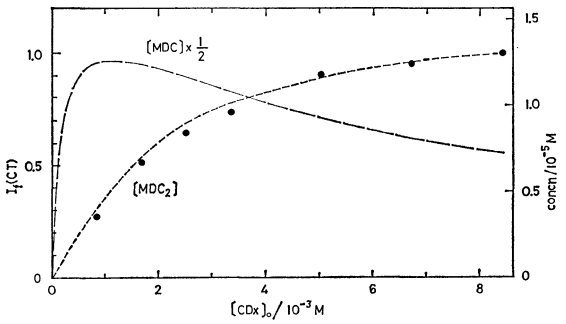

Fig. 16. Comparison of the observed CT fluorescence intensities, I_f(CT), with calculated concentrations [MDC] and [MDC_2].
●: I_f(CT), ——: [MDC], - - - -: [MDC_2].
$[MN]_0=5.0\times10^{-5}$ M. I_f(CT) is normalized to match the calculated [MDC_2] at the highest concentration of $[CDx]_0$.

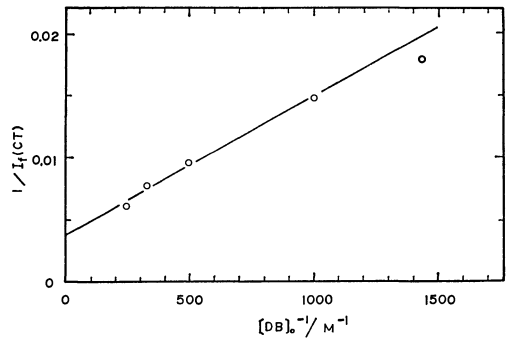

Fig. 17. Plot of $1/I_f$(CT) *vs.* $1/[DB]_0$.
$[MN]_0=9.60\times10^{-5}$ M; $[CDx]_0=8.40\times10^{-3}$ M.

The comparison of the variation of the experimentally observed I_f(CT) with $[CDx]_0$ under such conditions with the calculated curves of [MDC] and [MDC_2] is displayed in Fig. 16. It is immediately apparent that the calculated [MDC_2] curve reproduces the I_f(CT) curve fairly well, whereas the [MDC] curve nowhere matches the experimental curve. We are therefore led to conclude that MDC_2, not MDC, is the species responsible for the CT absorption and CT fluorescence in the MN–DB–CDx system.

Once Mechanism 4 is established, a simpler analysis of the CT fluorescence than that used above can be made. Namely, if we measure the CT fluorescence intensities as a function of $[DB]_0$ at fixed concentrations of MN and CDx, I_f(CT) can be expressed by

$$\frac{1}{I_f(CT)}=\frac{(1+K_3[CDx]_0)(1+K_4[CDx]_0)}{dK_3K_4K_5[MN]_0[CDx]_0^2}\frac{1}{[DB]_0}+\frac{1}{d[MN]_0}, \quad (20)$$

where d is an instrumental constant. A plot of $1/I_f$(CT) *vs.* $1/[DB]_0$ should give a linear relationship. Figure 17 shows such a plot, and with the known values of K_3 and K_4, the value $K_5=3700$ M^{-1} is obtained.[24] The K_5-value can also be determined from the absorbance of the CT absorption band, A(CT), of the same system which should have the same dependence on $[DB]_0$ as in Eq. 20. The value of K_5 evaluated from this type of analysis was 3300 M^{-1}.

Table 2. Equilibrium constants K_3, K_4, and K_5 at 25 °C, and enthalpy changes (ΔH) and entropy changes (ΔS) for K_3, K_4, and K_5 in the MN-DB-CDx system

	M^{-1} (at 25 °C)	ΔH / kJ mol^{-1}	ΔS / J mol^{-1} K^{-1}
K_3	630	−17	−5.0
K_4	15	−11	−16
K_5	3200[a]	−41	−16

a) The value obtained from I_f(MC) by Eq. 19.

These values of K_5 are close to the equilibrium constant obtained for the association of the 1:1 inclusion compounds in the naphthalene–CDx system ($K_2=4000$ M^{-1}). The previously determined value of K_5(=3200 M^{-1}) from Eq. 19 is solely from the intensity variation of the MC fluorescence (at 350 nm). The fairly good agreement between this K_5 and those obtained above from the CT bands implies that an exciplex type fluorescence is not involved in the observed 480 nm band which we have attributed to the CT type fluorescence.

The temperature dependence of the equilibrium constants, K_3, K_4, and K_5 was examined by measuring, respectively, the absorption spectra of the MC–CDx system, the fluorescence intensities of the DB–CDx system, and I_f(MC) of the MC–DB–CDx system in the temperature range from 3 to 25 °C, and by obtaining at each temperature the equilibrium constants as was done at 25 °C. The enthalpy changes ΔH and the entropy changes ΔS for K_3, K_4, and K_5 obtained from such measurements are summarized in Table 2.

It will be noted that the values of both $-\Delta H$ and ΔS for K_4 are smaller than those for K_3. This is consistent with the much smaller value of K_4 than K_3. The relatively inefficient formation of DC from DB and CDx may be due probably to the fact that the solubility of DB in water is about an order of magnitude larger than that of MN, and also that the steric effect of the two ortho-substituted linear cyano groups of DB may hinder the efficient complexing with CDx. The smaller value of $-\Delta S$ for K_3 than those for K_4 and K_5 indicates the less rigid structure of MC than DC and MDC_2.

As in the case of the naphthalene–CDx system, fluorescence decay times and fluorescence quenching by I^- and IO_3^- were studied for MN, MC, and MDC_2. Aqueous solutions of MN alone, MN–CDx, and MN–DB–CDx ($[MN]_0=9.6\times10^{-5}$M, $[CDx]_0=8.4\times10^{-3}$M, and $[DB]_0=2.0\times10^{-3}$ M) were examined. With the 316 nm excitation, the quenching of the 350 nm bands for MN and MC and of the 480 nm band for MDC_2 was measured by adding varying amounts of KI or KIO_3. No corrections were applied for quenching of the 350 nm band of MC which contains about 10% of MN fluorescence. The fluorescence lifetimes and the quenching rate constants for each species are presented in Table 3. One immediately finds upon comparison with Table 1 that the quenching behavior of these ions for MN, MC, and MDC_2 is very similar to that for the corresponding species in the naphthalene–CDx system. Thus, nearly the same structure of

TABLE 3. FLUORESCENCE LIFETIMES (τ') IN AERATED SOLUTION AND RATE CONSTANTS FOR QUENCHING (k_q) FOR MN, MC, AND MDC_2 IN THE MN-DB-CDx SYSTEM

		MN	MC	MDC_2
τ'/ns		11	12	39
$k_q/10^9\ M^{-1}\ s^{-1}$	I^-	6.0	2.6	1.7
	IO_3^-	2.8	0.60	−0.06

the 1:1:2 inclusion compound as that of the 2:2 inclusion compound (N_2C_2) is implicated from these quenching results.

Discussion

Sodium 1-naphthyl acetate (electron donor) and picric acid (electron acceptor) do not form a complex under usual conditions, but recently Kobayashi *et al.*[25] reported the formation of a charge transfer complex (CT) between them in the presence of γ-cyclodextrin but not significantly in the presence of β-cyclodextrin. They attributed these results to the capability of γ-cyclodextrin to include both electron donor and acceptor molecules in its cavity simultaneously.[26] What we have found in the MN–DB–CDx study is a similar promotion of the CT complex formation between MN and DB, but in this case by virtue of the association of two β-cyclodextrin molecules each of which accommodates one electron donor or acceptor molecule in its cavity. Much less efficient complex formation by β-cyclodextrin found in the Kobayashi *et al.*'s system appears to imply the incapability of the β-cyclodextrin molecule to hold the two molecules in its cavity, probably due to its smaller cavity size than in γ-cyclodextrin. Their results are thus consistent with our interpretation assigning the species responsible for the CT absorption and CT fluorescence to the 1:1:2 inclusion compound, not to the 1:1:1 inclusion compound.

Our results on the naphthalene–CDx system show that a similar type of association of two 1:1 inclusion compounds can occur when an aromatic hydrocarbon molecule is included in the CDx molecule. We did not find an excimer-type emission in the benzene–CDx system. Solubility restrictions prevented us from pursuing the same type of experiment for an anthracene–CDx or pyrene–CDx system. We therefore do not know at present whether the deciding factor for the formation of the 2:2 inclusion compound in an aromatic–CDx system is merely the molecular size of the substrate or if some other specific physicochemical properties of the substrate are involved. Such an association may be hindered for inclusion complexes containing a molecule larger than naphthalene by its protrusion out of the CDx cavity.

What remains to be discussed here is the problem of what kind of binding force brings the two 1:1 inclusion compounds together. One possible explanation is that the CDx molecules in aqueous solution (in the absence of any substrates) may be capable of forming a dimer by themselves. To the author's knowledge, however, there has been no experimental evidence pointing to the occurrence of such phenomena in cyclodextrin systems. Another explanation is to consider such an association as a first stage of the precipitation process. This idea comes from the fact that the solubility of the inclusion compounds is generally smaller than that of CDx. Once a 2:2 or 1:1:2 adduct is formed by adhesion of two 1:1 adducts in the course of precipitation, its unique structure of two CDx shells shielding completely the substrate molecules within them may prevent the attack of other 1:1 adducts to form a higher aggregate. That is, the first stage of the precipitation process may persist over a fairly wide range of concentration owing to the peculiar properties of the CDx inclusion compounds. Of course, this is only a speculation. Elucidation of further details in various aspects of 2:2 or 1:1:2 inclusion compounds will require more systematic studies using a variety of substrate materials and will have to wait for future study.

The author wishes to thank Professor Fumio Hirayama for his valuable comments and critical review of the manuscript.

17) M. Otagiri, T, Miyaji, K. Uekama, and K. Ikeda, *Chem. Pharm. Bull.*, **24**, 1146 (1976).
18) CDx also forms inclusion compounds with inorganic anions. Rohrbach *et al.* (*J. Phys. Chem.*, **81**, 944 (1977)) reported that the equilibrium constant for the formation of an inclusion compound with I^- is 18.0 M^{-1} in aqueous so-

lution at 25 °C. They employed a competition method in which the indicator was an azo dye. We obtained, however, the values of 4.1 and 4.7 M^{-1} for I^- using neutral substances, 2-naphthol and 1,4-naphthoquinone, respectively, by a similar competition method. It is not apparent why such a discrepancy occurs between our values and their value. The equilibrium constant for IO_3^- was determined to be 1.0 M^{-1} using 1,4-naphthoquinone. Because of these small values of the equilibrium constants, formation of the inclusion compounds of CDx with I^- and IO_3^- does not seriously change the concentration of CDx in the quenching experiments.

19) The viscosity of water increases only about 2% on adding 8.4×10^{-3} M of CDx. Thus, the viscosity effect on the quenching constant k_q is negligible.

20) H. Kobashi, M. Takahashi, Y. Muramatsu, and T. Morita, *Bull. Chem. Soc. Jpn.*, **54**, 2815 (1981).

21) The equilibrium constant K_3 for formation of MC can also be determined from the Benesi-Hildebrand plot for the fluorescence increment (Eq. 7). The value obtained is 660 M^{-1} which is close to 630 M^{-1} determined from the absorption spectra.

22) In more concentrated solutions of MN ($>5\times10^{-4}$ M), an excimer-like fluorescence appeared at around 420 nm. Although this emission is not as pronounced as in the case of naphthalene–CDx system, this observation suggests the possibility of the presence of a 2:2 inclusion compounds in the MN–CDx system in the high MN concentration region.

23) In deriving Eqs. 18 and 19, the fluorescence intensity of MC is regarded as that solely from the 1:1 inclusion compound MC, *i.e.*, a monomer-like emission from the MC part of MDC or MDC_2 is assumed not to occur. Since we define here MDC or MDC_2 as the species which exhibits the CT absorption, and the CT interaction is generally stronger in the excited state than in the ground state, this assumption seems reasonable.

24) The plots of $1/I_f(CT)$ *vs.* $1/[DB]_0$ shown in Fig. 17 can also be analyzed by Mechanism 3 which we have already discarded. Such an analysis gives $K'_5=8.7$ M^{-1} whereas the K'_5-value obtained from $I_f(MC)$ by Eq. 18 is 400 M^{-1} as stated before. This vast inconsistency further supports the inadequacy of Mechanism 3.

26) The capability of γ-cyclodextrin to include two molecules of different kinds has also been reported in: A. Ueno, T. Takahashi, Y. Hino, and T. Osa, *J. Chem. Soc., Chem. Commun.*, **1981**, 194.

Freezing-Thawing Hysteresis Phenomena of Biological Systems by the New Method of Proton Magnetic Resonance

Ei-ichiro Suzuki* and Nobuya Nagashima

Central Research Laboratories, Ajinomoto Co. Inc., 1-1 Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received December 11, 1981)

An automatic recording system was developed for unfrozen water content and spin-spin relaxation time measurements as continuous functions of temperature, by using a broad-line pulsed NMR spectrometer and a minicomputer. The advantages of this system are that the exact quantitative measurements can be done by calibrating the nonlinearity of the NMR sensitivity, and that for high sensitivity temperature measurement the thermocouple with special device is directly immersed in a sample. Three types of freezing-thawing hysteresis phenomena, (1) recrystallization of solute(hydroxy-L-proline, D-mannitol) and refreezing of released hydrated water molecules in frozen aqueous solutions, and (2) hysteresis as the characteristic feature of gels(gelatin, α_{s1}-casein), and (3) supercooling of capillary water in water-insoluble materials(zein, yeast RNA, cellulose) were analysed. The usefulness of this system as an analytical instrument of hydration properties of biological materials is emphasized.

The state of water in biological systems has been one of the most important subjects in life science studies. Proton magnetic resonance gives most useful information in the study of water motions,[1,2] although there are many other methods, for example, dielectric relaxation, thermal analysis, and neutron scattering[3] *etc.* There have been many publications concerning the application of proton magnetic resonance to studies of the state of water in biological systems or food.[4,5] At room temperature, a distinction between the state of water, *i.e.* bound or free, is given by a graphical resolution of the triple exponential decay curve due to the three kinds of spin-spin relaxation times(T_2) as observed using the Carr-Purcell/Meiboom-Gill method.[6] However this method presents experimental difficulties and is not applicable to homogeneous aqueous solutions, which have both bound and free water but show only the averaged T_2. Then the measurements of unfrozen water(UFW) content and its relaxation times as functions of temperature are effective for the investigation of wider range of samples.[2,7] We have developed a convenient system for some purposes; it involves a broad-line pulsed NMR spectrometer and an X-Y analogue recorder.[8] By using this system, only the variation of the free induction decay(FID) amplitude in the voltage value at about 40 μs with temperature change can be measured. This is acceptable as a qualitative method for the measurement of the UFW content as a function of temperature, which is called the freezing curve.

A quantitative method was developed for the freezing curve measurement, by adding a minicomputer system and a special thermocouple device which is directly immersed in a sample. By this means the UFW content and the spin-spin relaxation time as functions of temperature can be recorded automatically.[9] This new freezing curve method is a powerful tool for the investigation of the state of water in biological systems, especially those which show freezing-thawing hysteresis phenomena. The essencial cause of freezing-thawing hysteresis is only supercooling, but it was found by this method that there are three types of supercooling. In this study, water systems of sugar alcohols(D-sorbitol, D-mannitol[9]), and amino acids(glycine, L-alanine, L-methionine, L-proline, hydroxy-L-proline), and proteins(gelatin,[9] α_{s1}-casein, glycinin, bovin serum albumin, ovalbumin, zein) and other polymers(cellulose, polyethylene glycols, yeast RNA) were measured. In this paper, some aspects of freezing-thawing hysteresis are described to illustrate the usefulness of our freezing curve method.

Experimental

Sample Preparation. All samples were commercially available, except for α_{s1}-casein and glycinin (soybean protein 11s unit), which were obtained by preparative gel filtration chromatography.

Freezing Curve Measurements. The block diagram of the system, which consists of a broad-line pulsed NMR spectrometer with proton Larmor frequency of 20 MHz (Bruker, minispec p 20) and a disc based minicomputer system (Yokogawa-Hewlett-Packard, HP 1000) is shown in Fig. 1. Each sample of about 250 mg in a 6.8 mm inner diameter glass tube is cooled or warmed at the usual rate of about three degrees per minute, by using gas and liquid nitrogen, if necessary, whose temperature can be controlled by a variable temperature unit (Bruker B-ST 100/700). The freezing-thawing processes are observed using the NMR spectrometer and the chromel-constantan thermocouple.

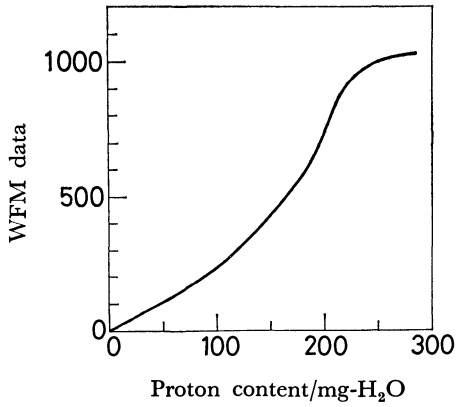

Fig. 3. The sensitivity of the NMR spectrometer. Proton content shows the water amount in the cupric sulfate solution whose sample volume is constant at about 0.27 cm³. A WFM datum is a digital value, which ranges from 0 to 1023.

The signal values at intervals of two μs of free induction decay (FID) curve after a 90° pulse and the sample temperature are A/D converted and memorized at every few seconds by a two channel wave form memory (WFM) apparatus (Kikusui, modified 8702S). The data are transferred to the minicomputer by a fiber optic Hewlett-Packard interface bus(HP-IB) link system (HP, 12050A).

One of the advantages of this system is that the special thermocouple device is directly immersed in a sample as shown in Fig. 2. High sensitivity measurement of the temperature change of a sample can be achieved with this thermocouple. The WFM apparatus and the NMR spectrometer generate the electric clock pulses from quartz oscillators. The noise so generated make it impossible to detect the FID curve; the thermocouple acts like an antenna here. For shielding from this noise, grounded aluminum tape is used. A thermal insulator is necessary to reduce the heat conduction to the sample through the aluminum metal.

Another advantage is that the exact quantitative measurement can be done by calibrating of the FID curve at each 90° pulse. The real FID curves are obtained after calibrating the sensitivity of NMR by using fifteen standards of 0.65 M (1 M=1 mol dm^{-3}) cupric sulfate solutions in water–heavy water mixtures which have various proton concentrations and the same sample volume of about 0.27 cm³ at the bottom of a sample tube. This calibration is required because of the nonlinear relationship between the proton content and the signal intensity, as shown in Fig. 3. This calibration curve is stored in our system memory and is used in every measurement of each FID curve.

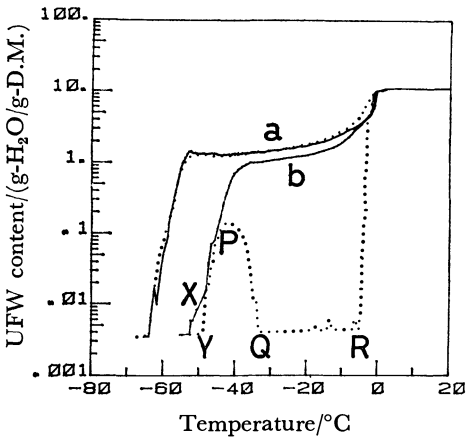

Fig. 4. Freezing (——) and thawing (·····) curves of 9.1% aqueous solutions of L-proline(a) and hydroxy-L-proline(b).
X and *Q* are the liquid signal vanishing temperatures, and *Y* and *R* are the liquid signal appearing temperatures, and *P* shows the top of the peak.

On the measurement of FID curves, it generally occurs that a sample exhibits at least two different spin-spin relaxation times T_{2s} and T_{2l}, which correspond to solid (short T_2) and liquid (long T_2) state protons, respectively. The shape of the FID curve of liquid state protons is exponential, but that of solid state protons is Gaussian. The population of liquid state or unfrozen protons (UFP) is obtained by extrapolating the FID curve from 40 to 100 μs back to zero time. Then this point is corrected according to the well-known Curie law; the lower the temperature, the greater the sensitivity. For practical purposes, this UFP value is reduced to a UFW content and converted to a dry basis, *i.e.* gram water per gram dry matter (g-H_2O/g-D.M.), using the dry matter value obtained by drying a sample for about 8 h at 115 °C. The UFW content is plotted as a function of temperature on a semilogarithmic graph by a graphic plotter (HP, 9872A). This function was named the freezing curve (liquid content curve). The solid content versus temperature can be obtained in a similar way. Also T_{2s} versus temperature and T_{2l} versus temperature can be obtained.

All of the programs used were written in FORTRAN language of the software package (HP, RTE IVB) of the minicomputer system.

Results and Discussions

Recrystallization of Solutes in Frozen Aqueous Solutions. It has been found that freezing curves of some aqueous solutions show peculiar freezing-thawing hysteresis. The example of D-mannitol aqueous solution has been reported previously.[9] Figure 4(b) shows the remarkably large hysteresis of hydroxy-L-proline aqueous solution, in contrast with the case of L-proline (a). The following mechanism is suggested for this large hysteresis of hydroxy-L-proline. In the cooling process,

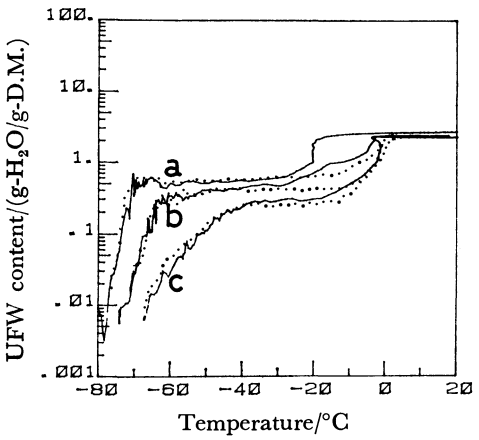

Fig. 5. Freezing (——) and thawing (·····) curves of 32% aqueous colloids of gelatin(a), α_{s1}-casein(b), and glycinin(c).

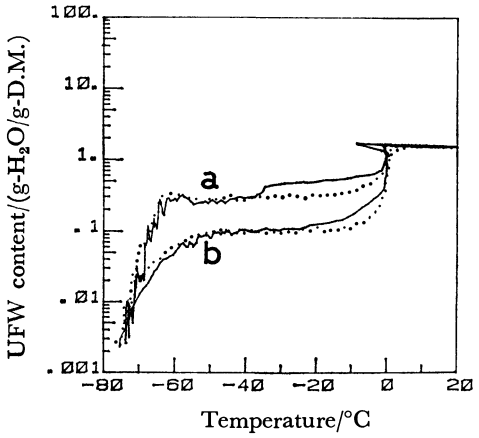

Fig. 6. Freezing (——) and thawing (·····) curves of aqueous suspensions of zein(a, 37%) and cotton cellulose(b, 39%).

free water in aqueous solution is frozen at near 0 °C, and water hydrated(bound) to solute remains as UFW until about −40 °C, and vitrification of the cluster which consists of solute and hydrated water molecules occurs(point *X*). In the warming process, after beginning of thawing(point *Y*), hydrated water molecules are released from the cluster with the beginning of recrystallization of solute, and their refreezing takes place at the point *P*. The difference between D-mannitol and hydroxy-L-proline is that the *X* and *Y* points are not the same in the former case.

Materials such as L-proline and D-sorbitol, which have comparatively high water solubilities, showed no hysteresis loops, at any cooling rates. At the usual cooling rate of about three degrees per minute, materials of low water solubilities such as glycine, L-alanine, L-methionine *etc.* do not show this type of hysteresis loop, but show simple hysteresis without a peak in the thawing curve, due to completion of recrystallization in the cooling process. The solubilities of hydroxy-L-proline and D-mannitol are medium, and these substances also show simple hysteresis loops, at the cooling rate of one degree per minute or more slowly.

The shape of the thawing curves of polyethylene glycols depends upon their molecular weight or crystallinity. In the case of low molecular weight, the shape of the thawing curve is almost the same as that of the freezing curve. But in the high molecular weight(about 6000) case, a remarkably large hysteresis can be observed. This hysteresis loop is similar to that of hydroxy-L-proline, but the rehydration temperature *R* is about −20 °C.

Characterization of Biopolymer Colloids——Gels and Sols. Figure 5 shows the freezing and thawing curves of 32% aqueous colloids of three kinds of proteins; α_{s1}-casein, glycinin, and gelatin. The UFW content of glycinin, which is known as a "cold-precipated protein,"[10] is much lower than that of gelatin, which forms a viscous aqueous gel. The freezing-thawing curve of gelatin has a remarkably large hysteresis loop, but that of glycinin has a very small hysteresis loop; that of α_{s1}-casein is situated between the two.

It is thought that water molecules in gelatin gel are structured in a gel network and supercooled until about −20 °C, and then a phase separation occurs due to freezing, and micro ice crystals are formed, which do not melt until 0 °C during thawing. Hence the freezing-thawing curve of gelatin has large hysteresis, and that of α_{s1}-casein has hysteresis of a medium value, due to the high viscosity and comparatively large UFW content of the liquid.

Table 1. UFW contents and signal vanishing temperatures for several proteins

Proteins	Concentrations/%	UFW[a] g-H_2O/g-D.M.	SVT[b]/°C
Glycinin	32	0.24	−68
Ovalbumin	31	0.32	−78
Bovine serum albumin	29	0.38	−80
α_{s1}-Casein	32	0.41	−72
Gelatin	32	0.60	−77

a) At about −30 °C. b) Signal vanishing temperature, which is defined as the temperature at which the apparent UFW content becomes lower than 0.01 g-H_2O/g-D.M.

The UFW values at −30 °C, which correspond to tightly-bount water content,[8] and signal vanishing temperatures(SVT) are shown for several proteins in Table 1. The freezing-thawing curve of an aqueous colloid of bovine serum albumin has no hysteresis, although its UFW content at −30 °C is near to that of α_{s1}-casein. The viscosity of this colloid is much smaller than that of α_{s1}-casein. This suggests that the measurement of weakly-bound water, which is frozen between 0 and −30 °C and does not melt in this case until near 0 °C, is very important to characterize the hydration properties of biopolymers, and that the freezing curve method is very useful for this purpose. The SVT data show the vitrification points of the clusters, which consist of protein and unfrozen water molecules. This data are also useful for the characterization of biopolymers.

Special Problems for Water-insoluble Biopolymers——Cellulose and Corn Protein etc. Figure 6(a) shows the freezing-thawing hysteresis phenomenon of aqueous sus-

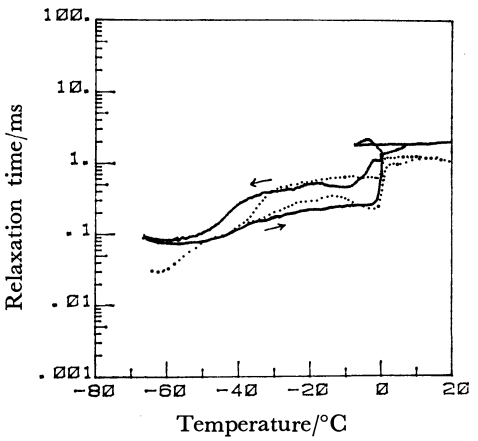

Fig. 7. Temperature dependence of spin-spin relaxation time of aqueous suspensions of zein (·····, 37%) and cotton cellulose (——, 39%).

pension of corn protein(zein). It is shown that a part of the UFW is frozen at about −37 °C in the cooling process. Freeze-drying from the homogeneous solution in 90% ethanol gave fine powder, which does not show such a phenomenon. Hence the cause of this hysteresis is thought to be the freezing of weakly-bound water in capillaries of water-insoluble materials. A similar phenomenon was observed for water-insoluble yeast RNA powder. A related type of freezing-thawing hysteresis is studied in relation to the mechanism of frost avoidance in plant tissues by Burke *et al.*,[11] using NMR and thermal analysis. We think that our method is more convenient and powerful for these studies.

Figure 6(b) shows the freezing-thawing curve of cotton cellulose, which has no obvious hysteresis loop. But the remarkable hysteresis phenomenon of spin-spin relaxation time (T_{21}) was observed, which is similar to the case of zein, as shown in Fig. 7. By the thermal analysis for cotton cellulose suspension with a differential scanning calorimeter(DSC; Daini Seikosha, SSC 560U), a broad exothermic peak was observed at about −42 °C. The cause of this phenomenon is not clear but it is obvious from Fig. 6(b) that no water is frozen at about −42 °C. One of the possible speculations is that the mobility of UFW is lowered by the change of surroundings accompanied with the crystal transformation of cotton cellulose at about −42 °C, because cellulose has polymorphism. In general, the freezing curve method would be powerful to elucidate the mechanism of an exothermic or endothermic peak observed in a DSC curve.

Conclusion

The new freezing curve method is a useful tool for the analysis of hydration properties of biological materials, from the viewpoint of freezing-thawing hysteresis phenomena. Three types of phenomena, (1) recrystallization of solutes and refreezing of released hydrated water in frozen aqueous solutions, (2) hysteresis as the characteristic feature of biopolymer gels, (3) supercooling of capillary water in water-insoluble biopolymers, were discussed and useful information was obtained. Our method can be applied to many practical problems in the food and drug industry *etc.*

The authors are grateful to Professor Masamichi Tsuboi of Tokyo University for his keen interest and valuable discussions.

Elementary Patterns in Protein-Nucleic Acid Interactions. IV.† Crystal Structure of 3-(Adenin-9-yl)propionamide : 1-Methylthymine (1 : 1) Complex Dihydrate

Midori Takimoto,* Akio Takenaka, and Yoshio Sasada
Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received December 21, 1981)

As a ternary interaction model between adenine:thymine base pair and carbamoyl group, 3-(adenin-9-yl)-propionamide: 1-methylthymine complex was prepared and its crystal structure was examined. The crystal exhibits a disordered structure, and the structure unit is a monoclinic cell with dimensions $a=11.368(1)$, $b=6.909(1)$, $c=12.708(2)$ Å, and $\beta=114.49(1)°$. The space group is $P2_1$ and the unit cell contains two complexes and four water molecules. The base pairing pattern between adenine and thymine is the Hoogsteen type. The carbamoyl group is hydrogen-bonded to N(A1) of adenine in this base pair, the distance NH···N(A1) being 2.94(2) Å. With two kinds of hydrogen bonds of the carbamoyl group, NH···N(A1) above-mentioned and NH···O(carbamoyl), the 3-(adenin-9-yl)propionamide molecules form a sheet extending perpendicular to the c axis; the base-paired thymine molecules extrude alternately from the sheet. Diffused spots along c* with half integers of l can be interpreted as a stacking disorder of the sheets.

In the studies of the elementary patterns in protein: nucleic acid interactions, we have reported several modes of hydrogen bonding between cytosine and carboxyl group,[1-4] between adenine and indolyl group,[5,6] between adenine and carboxyl group,[7,8] and between adenine and carbamoyl group.[9]

It is well-known that nucleic acid tends to form double strands by the hydrogen bonds between the complementary bases. Rich *et al.* proposed a recognition pattern between the carbamoyl group and base-paired adenine.[10] It is interesting to examine whether some base pair shows special affinity to the carbamoyl group, and where is the preferential binding site of the bases.

We have succeeded in preparing crystals of 3-(adenin-9-yl)propionamide : 1-methylthymine complex as one of the ternary interaction models between purine:pyrimidine base pair and the side chain of amino acid, and an X-ray analysis of the crystal structure has been performed. In this paper, we will report a mode of hydrogen bonding between adenine: thymine base pair and the carbamoyl group, and discuss the capability of the interaction of carbamoyl group with a double-stranded polynucleotides.

Experimental

Equimolar quantities of 3-(adenin-9-yl)propionamide[9] and 1-methylthymine (purchased from Cyclo Chem. Co.) were dissolved in a water–methanol (1:1) solution. Thick plate crystals of the 1:1 complex were obtained after standing the solution for 10 d. Density was measured by flotation in a mixture of cyclohexane and carbon tetrachloride. Preliminary X-ray photographs indicated the space group to be $P2_1$ or $P2_1/m$, but on the upper-layer Weissenberg photographs diffused spots extending along c* appeared at the positions with half-integer of l, as shown in Fig. 1. It apparently suggests the stacking disorder with two kinds of sheets along c. To obtain the crystals without such disorder, we tried crystallization from water-methanol solutions of the adenine and thymine with different molar ratios (1:2, 1:3, 2:1 and 3:1) at different temperatures (2—25 °C), but failed.

A crystal from the solution with 1:1 molar ratio, $0.2\times0.2\times0.05$ mm³ in size, was used for data collection. The intensities for 2767 independent reflexions in the range $4°<2\theta<122°$ were measured on a Rigaku automated four-circle diffractometer with nickel filtered Cu $K\alpha$ radiation ($\lambda=1.54184$ Å). A scan speed was 4° (in 2θ) min^{-1} and a scan width was 1.2° (in ω) plus α_1-α_2 divergence. After every 50 reflexions, five standard reflexions were monitored, the intensities of which showed no significant change. The intensities were corrected for Lorentz and polarization effects, but not for absorption. Only 73 reflexions had no net intensities; the observational threshold value, F_{11m}, was 1.98. The standard deviations were estimated by the equation of $\sigma^2(F_o)=\sigma_P^2(F_o)+qF_o^2$, where q, 8.1×10^{-6}, was derived from the variations of the monitored reflexions.[11]

Crystallographic data are summarized in Table 1.

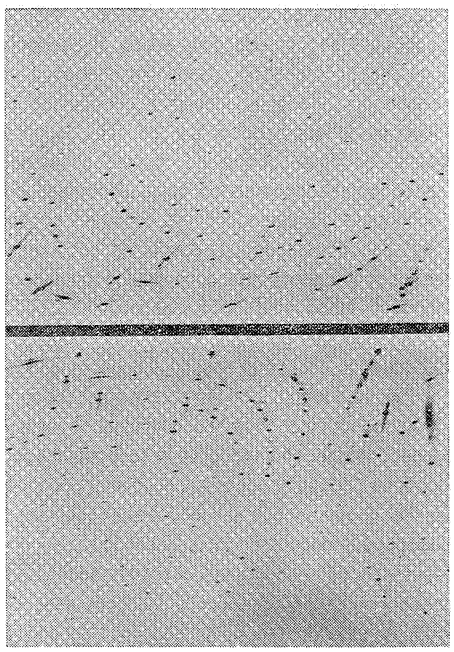

Fig. 1. An hll layer Weissenberg photograph of the title crystal.

Structure Determination and Refinement

Structure determination was unsuccessful on the basis of the space group $P2_1$ and $P2_1/m$. As stated in the

† Part III of this series is Ref. 8.

$\beta=114.49(1)°$	$D_m=1.40$ g cm^{-3}

previous section, diffused spots appeared at the positions with half-integer of l, but the spreads of these spots were rather small. If these spots were regarded to be Bragg reflexions, the space group should be $P2_1/c$. Values of l for all normal spots became even and those for diffused ones were odd. On the basis of the space group $P2_1/c$, however, the analysis by the use of the MULTAN 74 Programme[12] was not straightforward. As E values of reflexions with odd l's were much less than those with even l's, the former reflexions were not included in the data set for phase determinations, if the normal criterion for the magnitudes of E was applied. So, we prepared a starting data set by picking up the largest 30 reflexions in each parity group. An E map with the fifth lowest R value revealed a reasonable molecular skeleton. Successive refinement of the structural parameters, however, was not successful in getting a reasonably low R value. Therefore, we tried to modify the refinement process from the view of rather special character of the present crystal including some stacking disorder along the c axis. As will be described in the later section, the molecules related by 2_1 symmetry form a sheet parallel to the ab plane by the hydrogen bonds. If such a sheet is represented by P, the stacking mode in the space group $P2_1/c$ is $P\bar{P}\bar{P}P\cdots$, where $\bar{P}$ stands for an inversed sheet. The unit cell for P contains equivalent positions x, y, z, and $\bar{x}$, $1/2+y$, $\bar{z}$, and that for $\bar{P}$ $\bar{x}$, $\bar{y}$, $\bar{z}$ and x, $1/2-y$, z (the unit cell dimensions are those given in Table 1). Therefore, a reasonable model of disorder was constructed by putting the stacking mode $PP\cdots$ or $\bar{P}\bar{P}\cdots$ into the alternate P's and $\bar{P}$'s. Intensity profiles of the diffused spots on hll Weissenberg photographs were measured with a microdensitometer (SAKURA PDM-5) and interpreted on such a disordered model by the use of Wilson's equation.[13] The probability α of finding P after P was estimated to be 0.16 from half-value width of a diffused spot (2,1,3/2), after correction for spot size. Low value of α means that the major part of the crystal consists of the $P2_1/c$ domains. So, intensities can be approximately expressed as a sum of the intensity from the $P2_1/c$ domains and that from the $P2_1$ domains. Refinement on such approximation is equivalent to the improvement of the structural parameters and w in the equation:

$$F = K[wF_P + (1-w)F_{\bar{P}}],$$

Table 2. Fractional coordinates and isotropic temperature factors

The B values accompanied with $\langle\ \rangle$ are the equivalent isotropic temperature factors calculated from anisotropic thermal parameters using the equation $B=8\pi^2(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are the principal components of mean square displacement matrix $\boldsymbol{U}$. Values in $\langle\ \rangle$ are anisotropicity defined by $(\sum(B-8\pi^2U_i)^2/3)^{1/2}$. The e.s.d.'s in ( ) refer to last decimal places.

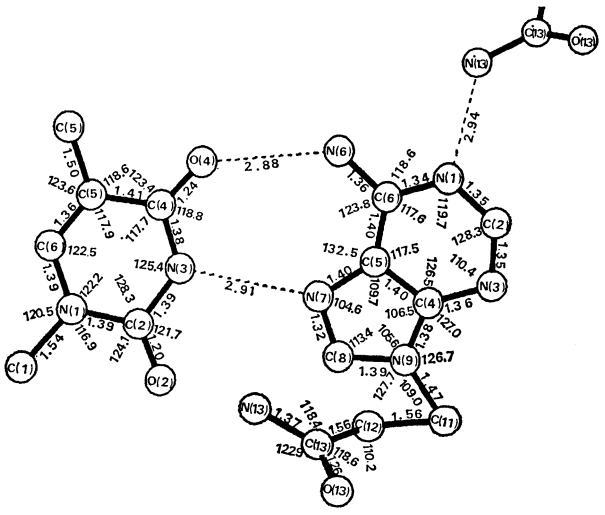

Fig. 3. Atomic numbering and bond distances (l/Å) and angles (ϕ/°) in 3-(adenin-9-yl)propionamide:1-methylthymine complex.

Numbers for the atoms in 3-(adenin-9-yl)propionamide and 1-methylthymine should be prefixed by A and T, and methyl carbon atoms, C(1) and C(5), should be read C(T1M) and C(T5M), respectively. E.s.d's for the bond distances and angles are 0.03 Å and 1.2—2.1°, respectively.

where F_P and $F_{\bar{P}}$ are structure factors for P and $\bar{P}$, respectively, and K scale factor. The value of w is related to the volume fraction W of the $P2_1/c$ domain by equation

$$(1-W)/W = \pm(1-2w)/2\sqrt{w(1-w)}.$$

The parameters were refined by the full-matrix least-squares method. The quantity minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, where $\omega=1/(\sigma^2(F_o))$. As the adenine-thymine pair lies near the plane at $y=1/4$, the matrix became ill-conditioned. In order to resolve such difficulty, only F_P was differentiated in the least-squares calculations. The R value converged to 0.091. The maximum shift of parameters in the last cycle was 0.1σ for C, N, and O atoms. From the final w of 0.763, the volume fraction of the $P2_1/c$ domains was estimated to be 0.62, which is compatible to the expectation from the value of α.

Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[14] The final atomic parameters are listed in Table 2.[15]

Results and Discussion

system, and the geometries of hydrogen bonds in Table 3. The displacements of atoms from the least-squares planes of adenine, thymine and carbamoyl moieties are given in Table 4.

The dimensions of 3-(adenin-9-yl)propionamide in the present complex are in good agreement with those in the crystal of 3-(adenin-9-yl)propionamide.[9] The N(A6) atom is almost on the purine ring plane and the C(A11) atom deviates by 0.1 Å from it. The conformation of the ethyl chain with the carbamoyl group is different from that of 3-(adenin-9-yl)propionamide. In the present crystal the torsion angle of N(A9)–C(A11)–C(A12)–C(A13) and C(A11)–C(A12)–C(A13)–N(A13) are 78.1 and −135.1°, respectively, while in 3-(adenin-9-yl)propionamide they are −170.0 and 173.3°.

In 1-methylthymine, the C(T4)–O(T4) bond is longer than C(T2)–O(T2). Such difference is also found in 1-methylthymine:9-methyladenine complex.[16] The methyl carbon atoms, C(T1M) and C(T5M), deviate by 0.15 and 0.08 Å from the pyrimidine plane, respectively.

Crystal Structure. As seen in Fig. 3, the adenine and thymine moieties form a pair through the two hydrogen bonds between N(A6) and O(T4) and between N(A7) and N(T3), their distances being 2.88(2) and 2.91(3) Å, respectively. This pattern is the "Hoogsteen" pairing found in 1-methylthymine:9-methyladenine complex.[16] The purine and pyrimidine planes are twisted to each other by 10.8(5)°, as commonly observed in the other Hoogsteen base pairs.[16,17] Such a twisting is favourable to relieve the bending of hydrogen bonds.

The crystal structure viewed along the b axis is shown in Fig. 4. The carbamoyl group branching from the adjacent base pair related by 2_1 around (1/2, y,1/2) is hydrogen-bonded to the adenine moiety; in the NH···N(A1) hydrogen bond, the NH···N(A1) distance is 2.94(2) Å and the dihedral angle between the carbamoyl group and the adenine moiety is 106.7(6)°. The adenine moieties in the molecules connected by this hydrogen bond are, at the same time, stacked to form a molecular column around the 2_1 axis at $x=1/2$ and $z=1/2$. The remaining carbamoyl hydrogen atom participates in hydrogen bond to the carbamoyl group, the O(A13) atom in the complex related by 2_1 around (0,y,1/2) being an acceptor. This hydrogen bond links the molecular columns to form a sheet parallel to the ab plane.

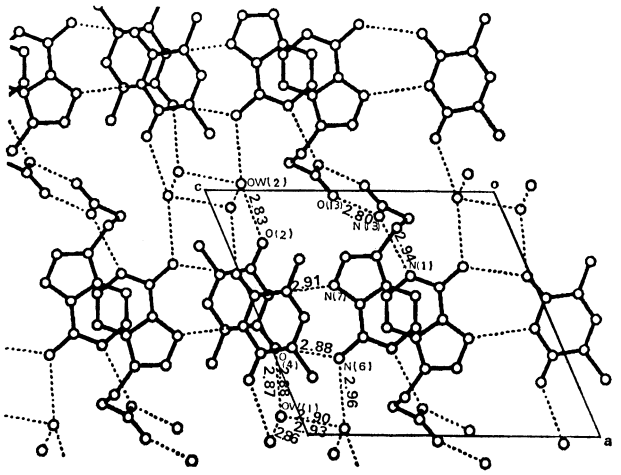

Fig. 4. Crystal structure of 3-(adenin-9-yl)propionamide : 1-methylthymine complex dihydrate projected along the b axis.
In hydrogen bond distances (l/Å) doubly indicated, the upper one corresponds to the value in the PP̄ junction and the lower one in the PP junction.

As shown in Fig. 5, the molecular sheets are joined along the direction of c by the alternate stacking of the 1-methylthymine molecules extruded perpendicular to the sheets. Although there are two kinds of stacking in PP and PP̄ junctions, the spacings are almost the same. In the latter junction, however, the N(A6) atom at $1-x$, $-y$, $2-z$ is close to the C(T1M) atom, the distance being 3.13(3) Å.

In addition, there are two different hydrogen bonding patterns for PP and PP̄ junctions. In both junctions, the water oxygen atoms, O(W1) and O(W2), are hydrogen bonded to O(T4) and O(T2), respectively, and the O(W2) atom is an acceptor of hydrogen bond from N(A6) of adenine moiety. In PP junction, two water molecules are connected by hydrogen bonds, to form a chain around the 2_1 axis at $x=0$, and $z=1$. In PP̄ junction, the hydrogen bonding scheme between waters is a loop around the inversion centre. There is no significant difference in hydrogen bond distances and angles between the two junctions.

Interaction between Carbamoyl Group and Adenine:Thymine Base-pair. In the present model crystal, it is found that the carbamoyl group interacts with the Hoogsteen base pair of adenine and thymine through the hydrogen bond between the adenine N(A1) and the car-

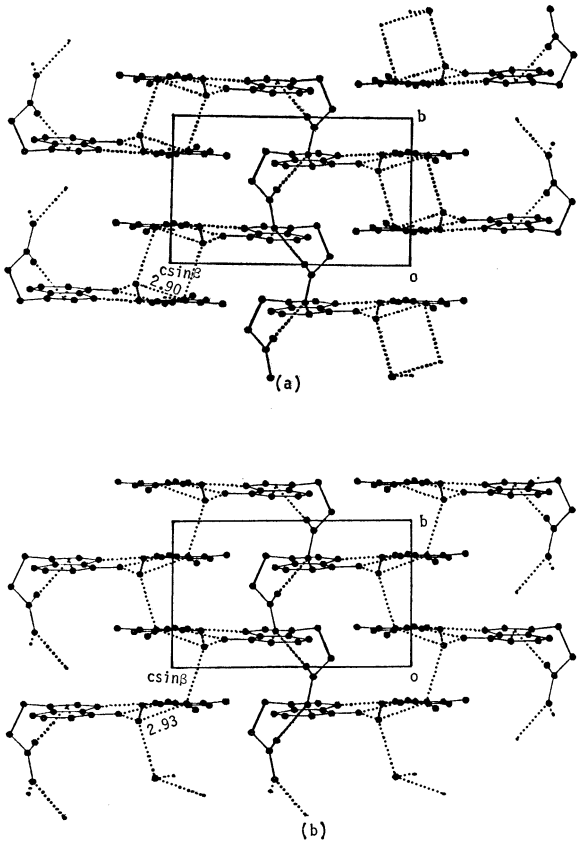

Fig. 5. Crystal structure of 3-(adenin-9-yl)propionamide : 1-methylthymine complex dihydrate projected along the a axis.

bamoyl N(A13) atoms, as shown in Fig. 3. For adenine: thymine pair in Hoogsteen type, the carbamoyl group seems to have a preferential interaction with adenine.

To examine whether the present mode is possible in the protein:nucleic acid interaction, we need geometrical data of the Hoogsteen base pair in the nucleic acids. This type of base pair has been found to occur actually between Uracil 8 and Adenine 14 in tRNA,[18–20] though it is reversed. Model building by computer graphics[21] proves that the observed interaction geometry can be incorporated into $tRNA^{Phe}$ [22] at Adenine 14, with minor adjustment. It is indicated that ethidium bromide[23] and magnesium ion[24] bind to tRNA in the vicinity of this pair. Enzymes involved in protein synthesis would also possibly interact with this region. If glutamine or asparagine residue in the protein would participate in such an interaction, the carbamoyl group might combine to tRNA in a mode shown in Fig. 3.

The authors are grateful to Professor Yoshito Takaki of Osaka Kyoiku University for the valuable suggestion on treating the disordered structure, and to Professor Jumpei Tsujiuchi of this Institute for the use of the microdensitometer (SAKURA PDM-5). The present work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, to which the authors' thanks are due.

(Received January 12, 1982)

From the point of view of the rotational isomeric state for the side groups (π- and o-conformation), the steric compression effect on the ^{13}C chemical shift of the aliphatic carbons in poly(1-vinylnaphthalene)(P1VN) and poly(2-vinylnaphthalene)(P2VN) were evaluated according to H. J. Schneider's method. In addition to the steric compression effect, the ring current effect by the naphthyl groups in P1VN and P2VN was taken into account. The numerical results suggested that the marked higher field shifts of the methine carbon of P1VN in comparison with that of P2VN, was attributed to the strong steric compression with the 1-naphthyl group (occupied the stable π-conformation) in the same monomer units. While in the P2VN chain, the resonances of the aliphatic carbons were calculated to be in the vicinity of those of polystyrene. Naphthyl ring current contribution to ^{13}C-NMR chemical shifts was found to be small in comparison to the dominant steric compression effect.

The two isomeric polymers of vinylnaphthalene (PVN), poly(1-vinylnaphthalene)(P1VN) and poly(2-vinylnaphthalene)(P2VN), differ from each other in some solution properties and the latter polymer behaves rather similar to polystyrene (PS) in a transition phenomenon[1,2] or ^1H-NMR spectral pattern.[3] In a previous paper,[4] we reported the results of evaluations of the steric energy of the RIS (Rotational Isomeric State) of the pendant groups in P1VN and P2VN. Since the naphthyl groups in P1VN or P2VN have no symmetry axis along the plane of the ring, there are distinguished two RIS (π- and o-conformation, see Fig. 1) of the side groups. The conclusions from the result are as follow; a) in the P1VN chain, the π-conformation is preferred but in paticular conditions, there are possibilities of formation of the o-conformations, and b) in P2VN chain, both the π- and o-conformations are stable; the choice of the RIS would not have a great influence upon the total stability of the P2VN chain and there are little conformational differences in the rotational states of P2VN and PS. We also pointed out a characteristic nonbonded interaction between the hydrogen atoms of a rotating 1-naphthyl ring and the methine hydrogen, found in the same monomer unit of P1VN chain.

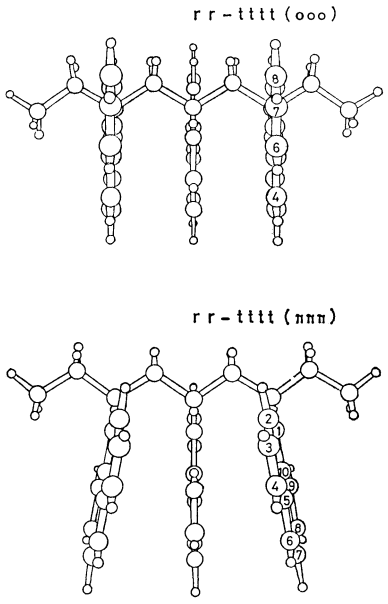

Fig. 1. Schematic representation of the rotational isomeric states of the side groups in (rr)-P1VN chain: (top) o-conformation; (bottom) π-conformation. In the P2VN chain, the α-carbon is bonded to the C(2) atom in the naphthyl group.

Recently, Tonelli[5] revealed that the ^{13}C-NMR chemical shifts of the aliphatic carbons in PS were attributable to a "γ-effect" (steric interaction between carbon atoms in the gauche arrangement) and to the ring current shielding effect (RCSE) of the aromatic groups. The γ-effect in PS depended on the stereoregularity or the skeletal conformations of the polymer chain. The apparent resemblance of the conformational situation between P2VN and PS described above suggests that the ^{13}C chemical shift of the former would be elucidated by γ-effect and RCSE of the aromatic rings, as reported by Tonelli for PS.[5] In the P1VN chain, the characteristic steric compression produced by the π-conformation would control the chemical shifts of the methine carbons. This effect depends only on the range accesible to the rotation of the 1-naphthyl ring, so that it would not depend on the steric regularity of the chain.

In this paper, we will discuss the distinct differences of the observed ^{13}C-NMR spectral patterns between P1VN and P2VN, based on the steric compression effect. In this spectra of P2VN and PS, there is no such unique effect as in P1VN, in addition to the γ-effect and RCSE.

Experimental

Instead of PVN polymers of high molecular weight, we used polymer samples of relatively low molecular weight, to obtain better resolved NMR spectra. The monomer of P1VN and P2VN were prepared from methyl naphthyl ketones,[6] and polymerized[7] in THF at -78 °C, using sodium naphthalenide as an initiator. The polymers were precipitated in about 10 times their volume of methanol in order to free them from any residual monomer and initiator, and were dried *in vacuo*.

The number-average molecular weights of these polymers were determined using a "KUNAUAR's Vapor Pressure

Osmometer" in chloroform solutions at 37 °C. The number-average degrees of polymerization ($\overline{DP}$) of the polymer samples were 80 for P1VN and 60 for P2VN. The molecular weight distributions of the polymers were determined by gel permeation chromatography ($\overline{Mw}/\overline{Mn}$: 1.90 for P1VN and 1.22 for P2VN).

^{13}C-NMR spectra were obtained using a JEOL JNM PS-100 spectrometer equipped with a PFT-100 Fourier transform system operating at 25.03 MHz, and a EC-100 computer with a memory capacity of 16 kilo words. samples were contained in 8 mm O.D. glass tubes and were degassed. The solvent used was chloroform-d_1, obtained from E. Merck A. G. The polymer concentration was *ca.* 30%. The 45° pulse width was about 13 μs. The apparatus was equipped with an internal ^{2}D field-frequency lock and a noise-modulated proton decoupler. The time-domain signal was digitized in 8192 channels, to provide 4096 data points after Fourier transformation. All spectra were observed at 30 °C.

Calculation

The chemical shifts of sterically perturbed carbon atoms are generally found at higher magnetic fields than those of unperturbed carbons which are not spatially crowded by neighboring atoms. The magnitude of these shifts exhibits a strong dependence upon the repulsive interactions between the ^{13}C–H bond and its surrounding groups. In order to evaluate the extent of the steric compression effect on ^{13}C-NMR chemical shifts, some equations of the steric force vector were proposed.[8,9] The steric compression effect was found to be directly related to the force component along the direction of the ^{13}C–H bond associated with nonbonded repulsive interaction. The repulsive interactions between nonbonded atoms or groups are sensitive to small changes in their separation distances and are produced not only by the hydrogen atom but also by the carbon atom. The numerical results reported here were obtained according to the H. J. Schneider's method[9] which has been applied to the fully relaxed molecular model in Force Field Method (FFM).[10] In defining the force vector F on the ^{13}C–H bond, H. J. Schneider *et al.*,[9] proposed an equation which was derived from a potential for nonbonded interactions:[11]

$$F = 0.6952\times10^{-5}(18\varepsilon/r^*)((r^*/r)^{10} - (r^*/r)^7)\times\cos\theta, \quad (1)$$

where r represents the distance of the hydrogen atom attached to ^{13}C from the interacting H or C; θ is the angle between the force vector and the perturbed ^{13}C–H bond. Equation 1 was applied to the hydrogen-hydrogen interaction ($\varepsilon=0.004109$, $r^*=3.632$) and also to the carbon-hydrogen interaction ($\varepsilon=0.026102$, $r^*=3.575$).[11] ε is an energy parameter which measures the depth of the van der Waals energy minimum, and r^* is the parameter which is correlated to the combined van der Waals radii of atoms. The steric compression effect on the methine and methylene carbons for P1VN was estimated by using a pentamer and a tetramer model, respectively, in which the terminal naphthyl groups were replaced by methyl groups.

To estimate the steric compression effect on the methylene carbon, the conformations of a relaxed tetramer model were chosen by the following procedure. A set of the initial models of trial conformations were obtained by combinations of each RIS for side groups (π- and o-conformations) and the backbone bonds (t, g, and $\bar{g}$). Before optimization[4] was completed (mainly in terms of the variation of the internal rotation for side groups and main chain, and bond angles for CH_2–αC–CH_2 and αC–CH_2–αC of the energy of these conformers), we carried out several examinations of the rotational angle of the naphthyl ring from the plane made by the adjoining backbone bonds. If the rotational angle in the conformer exceeded 10°, the subsequent optimization was rejected and this model of conformation was excluded from the relaxed conformations. In the pentamer model, the conformation of the relaxed model and their steric energies were adopted from the results in the previous paper.[4]

In addition to the steric compression effect, the ring currents of the naphthyl groups in PVN may also affect the ^{13}C-NMR chemical shift. The shift parameter $(\delta)_{RC}$ for this effect can be approximately calculated from the equation of McConnell,[12]

$$\delta_{RC} = \Delta\chi(1-3\cos^2\Omega)/3r^3, \quad (2)$$

where r is the distance of ^{13}C from the center of each ring, Ω is the angle made by the r vector and the plane of the ring, and $\Delta\chi$ is the anisotropy of the magnetic susceptibility. In naphthalene, the intensity of the ring current of each ring will be 1.093 times[13] larger than that of the benzene ring.[14] Therefore, we used -65.5×10^{-6} cm^3 mol^{-1} as the values of $\Delta\chi$ for each ring of naphthalene. The ring anisotropic effects on the methine and the methylene carbon were evaluated by using a pentamer and a hexamer model, respectively. In previously calculated results[4] of steric energies for pentamer models, the optimized rotational angles of the 1- and 2-naphthyl ring did not exceed ±4.5°, from the perpendicular position. Accordingly, it is resonable to consider that the naphthyl planes are almost perpendicular to the plane defined by adjoining skeletal bonds. The skeletal chains were assumed to have the same set of conformations which are generally preferred for vinyl polymers.[15]

Results and Discussion

Based on the calculation described above, we obtained six conformations as the relaxed conformations of PS, P1VN and P2VN, respectively. The steric energies of the relaxed conformations were shown in Table 1. The rotational angles for backbone bonds were denoted by the convention of Flory *et al.*[16] The steric interactions involving the bulky naphthyl group precluded $\bar{g}$ conformation. The backbones in PVN were limited to just two rotational states, the trans (t) and gauche (g) conformations, as in the case of PS.[16] The steric energy of the P2VN chain was hardly influenced by the change of RIS of the side groups. The steric energy of the P2VN chain, (except meso-tt conformer), was 0.5—0.9 kcal mol^{-1}**

** 1 kcal mol^{-1}=4.184 kJ mol^{-1}.

Table 1. Steric energies[a] of the tetramer model of P1VN, P2VN, and PS with terminal methyl groups (kcal mol^{-1})

		Meso			Racemic		
		tt[b]	tg	gg	tt	tg	gg
PS		−0.71	1.24	3.64	0.0	2.10	2.59

larger than that of PS. The difference in the energy was attributed to the steric interaction of the bulky 2-naphthyl groups. In the meso-tt conformer, the 2-naphthyl planes are parallel to the adjoining one, and oriented in the same direction; the distance between the two planes was estimated to be about 2.87—3.64 Å. The nonbonded interaction energies between the two 2-naphthyl groups are mainly attributable to the attractive van der Waals force. The steric energy of the meso-tt conformer for P2VN was found to be smaller than that of PS.

The difference of the steric energies between racemic-tt($\pi\pi$) and other conformers of P1VN was obviously larger than that of PS and P2VN. In the conformers with the same skeletal conformation, $\pi\pi$-conformer is more stable than πo-, $o\pi$- and oo-conformer (represented by full line in Fig. 3). However, the $\pi\pi$-conformer may not always be of lower energy in comparison with another conformer, which has the skeletal conformation different from that of $\pi\pi$-conformer: m-tt(oo)<m-tg($\pi\pi$) and r-tt($o\pi$)<r-gg($\pi\pi$). In case of the tetramer model, in which the terminal naphthyl groups were replaced by methyl groups, the steric repulsion produced by o-conformation (the steric interaction of the adjacent naphthyl groups) was appreciably relaxed, and the total steric energy was underestimated. When the tetramer model containing four naphthyl groups was used, the curves in Fig. 3 might slope to the right. On the other hand, the summation of the force components, F_{sum}, along the methine or methylene bond, will not be affected by the choice of model. This is because the total steric energy would not be so much influenced by the steric interaction with respect to the F_{sum} values in this model.

Figure 2 shows the correlation of the steric energy E_{steric} for the pentamer model with the steric force F_{sum} directed along the methine bond, where F_{sum} is the arithmetical average of the steric forces directed along each methine bond in the same model chain.

a) The minus and plus signs represent paramagnetic and diamagnetic shielding, respectively. b) Rotational isomeric states for side groups in the P1VN chain. c) (h) and (l) represent ($\delta_{P2VN}-\delta_{PS}$) for the most upfield conformer and for the most downfield conformer, respectively. d) * represents the preferred conformation.

An arrow in Fig. 2 designates the calculated value of F_{sum} for the PS chain. When all RIS of the side groups in the model chain occupied the stable π-conformation ($\pi\pi\pi$-conformer), the methine group undergoes the maximum repulsive force in comparison with other conformers. The methine group in the *ooo*-conformer of this model experiences the same force as in the PS chain. The calculated values of F_{sum} for the P2VN model were located in the vicinity of that of the PS chain. Thus, the steric force directed along the methine bond in the P1VN chain was estimated to be $(1.73—2.08)\times10^{-10}$ N larger than that of PS or P2VN. As described above, whenever the P1VN chain occupies a π-conformation, the steric compression effect on the methine carbon was mainly caused by the intramolecular interaction of 1-naphthyl hydrogen in the same monomer unit. This effect was almost independent of the tacticity of the polymer chain. The methine group was slightly affected by other steric compression effects (*e.g.* γ-effect and detailed descriptions of γ-effect on the methine carbon in PS were given by Tonelli[5]). The backbones in PS are restricted to the trans and gauche states, excluding $\bar{g}$ state, and the methine carbons are always in the gauche arrangement with $C_{aromatic}$ connected to αC or CH_2 without regard to stereosequences, and should not exhibit any stereosequence-sensitive γ-effect. As the backbones in PVN are also restricted to the t and g, the methine carbons in PVN are not affected by the γ-effect and by the chain stereoregularity, as well as in PS.

The correlation of the steric energy E_{steric} for the tetramer model with the steric force F_{sum} directed along the central methylene bond is shown in Fig. 3. The numerical results of the γ-effect on methylene bond were excluded due to the interaction of the backbone atoms in the special case of the tetramer model. In contrast, with methine bond in P1VN chain, the methylene bond undergoes a repulsive force when the RIS of the side groups are in *o*-conformation. The repulsive force was produced by the steric overlap between the hydrogen in a rotating naphthyl ring and one of the methylenes. The magnitude of the steric force directed along the methylene bond in P1VN (occupied by the π-conformation) was not very different from that of the PS or the P2VN chain.

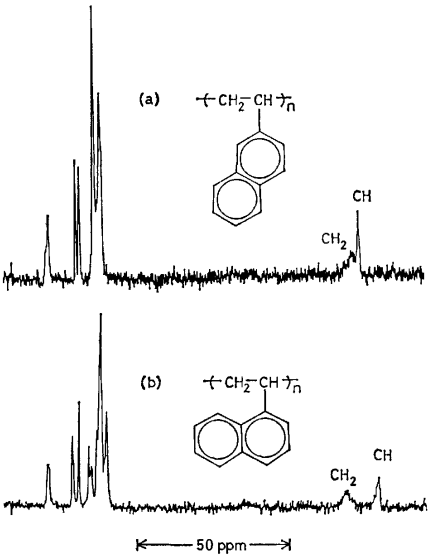

Fig. 4. Proton-decoupled, natural abundance ^{13}C FT NMR spectra of (a) P2VN and (b) P1VN in chloroform-d_1 at 25.03 MHz and 30 °C.

The correlation between the chemical shift and the steric force F_{sum} can be interpreted as follows, a) In the P1VN chain, the resonance of the methine carbon shifts to higher field in comparison with that of PS, owing to the steric interaction of the 1-naphthyl group (π) in the same monomer unit. The chemical shift of the methylene carbon is attributed to the γ-effect,[5] and the resonance peak is located in the vicinity of the position of PS. b) The resonance of the aliphatic carbons in the P2VN chain would appear at the same positions as the resonance of PS.

Figures 4a and 4b show the proton-decoupled ^{13}C-NMR spectra of P2VN ($\overline{DP}=60$) and P1VN ($\overline{DP}=80$), respectively. The experimental values of the chemical shifts of methine carbon or methylene carbon for PVN at 30 °C are represented relative to the chemical shifts of PS ($\overline{DP}=20$), and are summarized as follow.

$(\delta_{P1VN}-\delta_{PS})_{CH} = 6.83$, $(\delta_{P1VN}-\delta_{PS})_{CH_2} = 0.43$ ppm,

$(\delta_{P2VN}-\delta_{PS})_{CH} = -0.37$, $(\delta_{P2VN}-\delta_{PS})_{CH_2} = 0.85$ ppm.

The spectrum of the aliphatic region in the P2VN chain shows a similar pattern as that of PS. The resonance of the methine carbon in the P1VN chain appears at higher field in comparison with that of PS and P2VN. These experimental results correspond to the conclusion derived from Figs. 2 and 3.

The calculated results for ring anisotropic effect on methine and methylene carbon are given in Table 2. In RCSE on methylene carbon, the numerical results of those polymer chain (PS, P1VN, and P2VN) depend slightly on the chain regularity and conformation, indicating that the resonance of the methylene carbon spread to a broad band. On the other hand, the numerical results for RCSE on the methine carbon were little affected by the chain stereoregularity and backbone conformation. RCSE shifts of P2VN relative to PS, $(\delta_{P2VN}-\delta_{PS})_{CH,\,RCSE}$ for the preferred conformation were about -0.30——-0.44 ppm. The resonance of the methine carbon for the P2VN chain was not influenced by the steric interaction, resulting in an upfield shift of the methine in the P1VN chain, and was simply governed by the anisotropy of the 2-naphthyl ring. The experimental value of -0.37 ppm was in the range of the calculated values (-0.30——-0.44 ppm). For methine carbon in the P1VN chain, $(\delta_{P1VN}-\delta_{PS})_{CH,\,RCSE}$ the values for preferred conformations were about -0.48——-0.54 ppm. Evidently, the RCSE contributions to the observed ^{13}C chemical shift of methine carbon in P1VN are found to be small in comparison to the dominant steric compression effect.

Finally, we are tried to obtain the proportional constant between the magnitude of the steric compression force of methine bond in a P1VN chain and the chemical shift values. The shift values which depend on the steric compression effect only, could be obtained from substracting the $(\delta_{P1VN}-\delta_{PS})_{CH,\,RCSE}$ value from the experimental values. The constant obtained was $(3.5—4.2)\times10^{10}$ ppm N^{-1}. H. J. Schneider's constant was 20×10^{10} ppm N^{-1},[9] which was obtained for deshielded carbon atoms in substituted cyclohexane and in norbornane derivatives. D. M. Grant's constant for shielded carbon obtained from the non-relaxed model (*o*-xylene and methyl cyclohexane) was 1.30×10^{10} ppm N^{-1}.[8] Taking into account that the extent of the shift by the shielding force is smaller than that of the deshielding force, and that our constant was derived from shielding carbon in a relaxed model, the value of the calculated constant is considered to be resonable.

In ^{1}H-NMR spectra of P1VN, in addition to the RCSE by the 1-naphthyl ring, such a steric compression effect on the methine proton would also be revealed. However, it is difficult to estimate numerically this steric compression effect on the chemical shift of the proton in P1VN. The deshielding associated with the steric compression increases with increasing the repulsive interaction, but the distance between the hydrogen atoms does not simply relate to the extent of deshielding. Moreover, the nature of the deshielding mechanism by the steric interaction on the chemical shift of the proton is not very apparent at present.[17]

(Received January 16, 1982)

The adsorption behavior of dodecylammonium chloride (DAC) and sodium dodecyl sulfate (SDS) at their aqueous micellar solution/hexane interface has been studied by measuring the interfacial tension as a function of temperature at concentrations around the critical micelle concentration (cmc). The derivative of the interfacial tension with respect to temperature has been observed to change abruptly at the cmc and very little thereafter with increasing concentration in a limited range above the cmc. By applying the thermodynamic treatment of adsorption from micellar solution developed previously to the present experimental results, the entropy changes associated with the adsorption of DAC and SDS from monomeric state and from micellar state and the corresponding energy changes have been calculated. Further, the entropy and energy changes of micelle formation have been obtained from these quantity changes. These values have been compared with those obtained for DAC at water/air interface. It has been observed that the behavior of the micelle in the limited concentration range is controlled solely by temperature and pressure and bears resemblance to that of the adsorbed film at the interface. It has also been observed that the entropy and energy of micelle and adsorbed film are lowered by the hexane existing in the system.

In a recent paper,[1] we have investigated the adsorption of dodecylammonium chloride (DAC) at water/air interface by measuring the surface tension of the solution as a function of temperature at various concentrations around critical micelle concentration (cmc). It has been clarified with the aid of the entropy and energy changes associated with the adsorption of DAC evaluated by applying the thermodynamic treatment of adsorption[2-5] that the thermodynamic properties of the micelle of DAC in the aqueous solution are closely related to those of adsorbed film of DAC at water/air interface. It is now interesting to see if a similar conclusion is obtained at water/oil interface by measurement of the interfacial tension.

The purposes of the present work are to confirm the validity of our thermodynamic treatment of the adsorption from micellar solution[1] and to reveal the difference of the behavior of adsorbed film at water/hexane interface from that of micelle. In order to attain these purposes, we adopt as surfactants DAC and sodium dodecyl sulfate (SDS), of which the adsorbed films at water/hexane interface have well been investigated in the range of concentration below cmc.[3,6] The interfacial tension is measured as a function of temperature at various concentrations around cmc. The thermodynamic quantity changes associated with adsorption from micellar solution are evaluated by applying the thermodynamic equations and compared with corresponding changes of DAC at water/air interface.

Experimental

DAC and SDS were synthesized and purified by the method described in the previous papers.[3,6] Water was distilled three times from alkaline permanganate solution. Hexane was purified by distillation after passing through an activated alumina column.

The equilibrium interfacial tension was measured as a function of temperature at constant total concentration around cmc under atmospheric pressure. The value of the interfacial tension of the system of aqueous SDS solution and hexane was determined by the pendant drop technique[7,8] within the experimental error of 0.05 mN m^{-1}. Since the system of aqueous DAC solution and hexane had a very small interfacial tension (about 2 mN m^{-1}) in the neighborhood of cmc, we adopted the sessile drop technique[8,9] for the determination of the equilibrium interfacial tension.

The sessile drop of hexane made in the DAC solution in the glass cell was allowed to stand for about an hour in order to establish the thermal equilibrium. The enlarged photograph of the sessile drop was taken by the camera and the shape and size of the drop on the photographic film were determined to a precision of μm by Nikon Measurescope. The value of the interfacial tension γ was calculated by the equation

$$\gamma = (1/2)g\Delta d a^2, \quad (1)$$

where g is the acceleration of gravity, Δd the difference in density between aqueous solution and hexane, and a the capillary constant. The value of a^2 is obtained from the experimental values of the radius r of the sessile drop in the equatorial plane and the height h from this plane to the top of the drop:

$$a^2 = r^2 f(h/r),$$

where $f(h/r)$ is a function of h/r. We took the value of $f(h/r)$ from the tables of Tawde and Parvatikar.[10-12] In the case where the value of h/r is too small and deviates from these tables, we calculated it by the equations presented by Blaisdell.[13] The error estimated for the value of the interfacial tension was 0.05 mN m^{-1}.

The densities of pure hexane and water were used instead of those of hexane and aqueous solutions, because the mutual solubility between hexane and water was small and the concentrations of the solution were low. Temperature was kept constant within 0.05 K by circulating thermostated water around the cell.

Results and Discussion

The variation of the interfacial tension γ with temperature T at constant total molality $m_t^{\ddagger}$ of surfactant around cmc under atmospheric pressure is shown in Figs. 1a and 1b for DAC and SDS, respectively. The γ *vs.* T curve of the pure water/hexane interface is

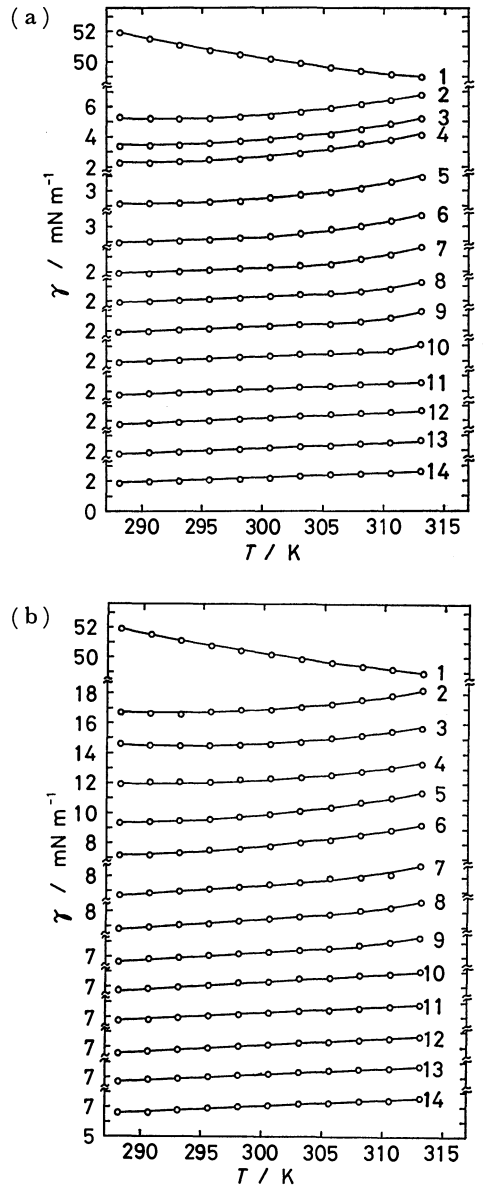

Fig. 1. Interfacial tension *vs.* temperature curves of DAC (a) and SDS (b) at constant total molality under atmospheric pressure.
(a): (1) $m_1^t = 0$ mmol kg^{-1}; (2) 11.08; (3) 12.04; (4) 12.51; (5) 12.65; (6) 12.80; (7) 12.98; (8) 13.04; (9) 13.14; (10) 13.29; (11) 15.04; (12) 16.53; (13) 18.03; (14) 20.13. (b): (1) $m_1^t = 0$ mmol kg^{-1}; (2) 3.99; (3) 4.59; (4) 5.49; (5) 6.36; (6) 7.20; (7) 7.40; (8) 7.54; (9) 7.67; (10) 7.70; (11) 8.46; (12) 9.97; (13) 11.29; (14) 12.69.

included for comparison. These figures seem to resemble each other. The γ *vs.* T curve at a concentration below cmc is slightly concave upward, while at a concentration above cmc γ increases linearly with increasing T in the range of 288.15 K to 313.15 K in contrast with that of the pure water/hexane interface. Examining the γ *vs.* T curve at a concentration near cmc, it is found that the curve consists of linear and curved portions and the linear portion is made longer by the increase of m_1^t. This fact suggests that the values of cmc of DAC and SDS vary with temperature.

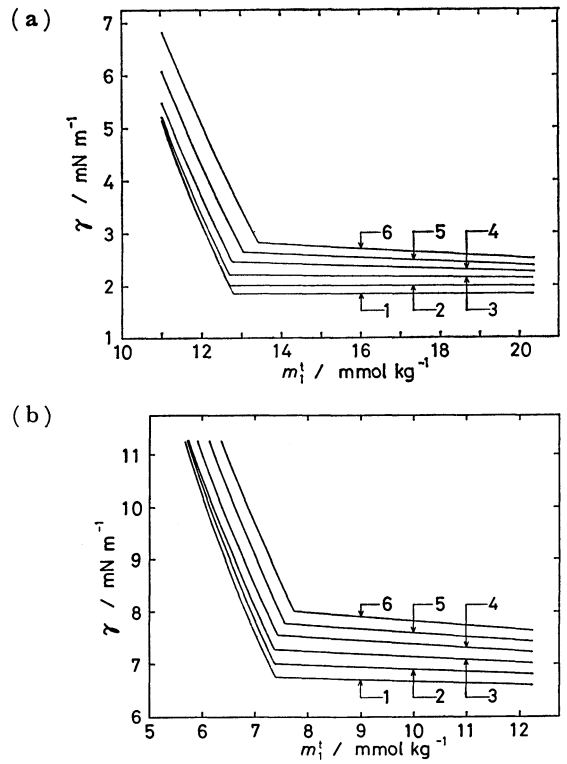

Fig. 2. Interfacial tension *vs.* total molality curves of DAC (a) and SDS (b) at constant temperature under atmospheric pressure.
(a): (1) 288.15 K; (2) 293.15 K; (3) 298.15 K; (4) 303.15 K; (5) 308.15 K; (6) 313.15 K. (b): (1) 288.15 K; (2) 293.15 K; (3) 298.15 K; (4) 303.15 K; (5) 308.15 K; (6) 313.15 K.

The values of the interfacial tension taken from Figs. 1a and 1b are plotted against m_1^t at constant temperature in Figs. 2a and 2b for DAC and SDS, respectively. The γ *vs.* m_1^t curve has a visible break point at a certain concentration which provides the value of cmc. In the concentration range above cmc, γ is observed to decrease linearly and slightly with m_1^t. When we are concerned with a limited range of m_1^t close to the cmc, we may say that γ remains constant.

In Fig. 3, the cmc *vs.* T curves of DAC and SDS obtained from Figs. 2a and 2b are shown together with the curve, for comparison, of the system of aqueous DAC solution and air taken from our previous paper.[1] It is found that the curves are concave upward and have a distinct minimum; the temperature of minimum is near 295 K for the curves of DAC and SDS in this work and near 300 K for the curve of DAC in the previous paper. Further, the value of cmc of DAC measured by the interfacial tension is different from that measured by the surface tension. This fact may be attributable to the difference of the phase coexisting with the DAC solution.

Next, we will consider the derivative of the interfacial tension with respect to temperature at constant concentration under atmospheric pressure. The values of $-\partial\gamma/\partial T$, which are evaluated from Figs. 1a and

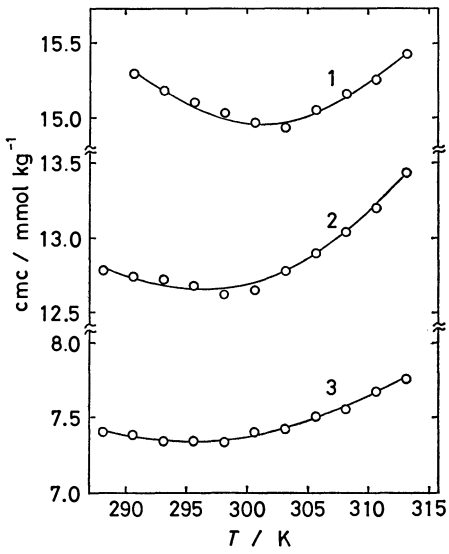

Fig. 3. Critical micelle concentration *vs.* temperature curves under atmospheric pressure.
(1): DAC water/air, (2): DAC water/hexane, (3): SDS water/hexane.

1b, are plotted against m_1^t in Figs. 4a and 4b for DAC and SDS, respectively. It is seen clearly that $-\partial\gamma/\partial T$ varies discontinuously at the cmc. Above cmc it has a negative and almost constant value in the limited range of concentration near cmc. The same observation has been obtained with the adsorption of DAC at water/air interface.[1] The constancy of $-\partial\gamma/\partial T$ and γ in the limited range of m_1^t suggests that the concentration of monomeric surfactant is not varied significantly by m_1^t and the behavior of the micelle in this concentration range is controlled solely by temperature and pressure.

According to our thermodynamic treatment of the adsorption from micellar solution developed previously,[1] we can evaluate the two types of the thermodynamic quantity changes denoted by $\Delta y(1)$ and $\Delta y(\mathrm{M})$, which are associated with the adsorption of surfactant from its monomeric state and micellar state, respectively. Let us assume that the surfactant is a strong electrolyte and that the behavior of micelle is described by using thermodynamic properties of an imaginary micelle particle which contains the surrounding counterions so as to satisfy the condition of electroneutrality. Since the total differential of its chemical potential μ^{M} is expressed as a function of T and p:

$$\mathrm{d}\mu^{\mathrm{M}} = -s^{\mathrm{M}}\mathrm{d}T + v^{\mathrm{M}}\mathrm{d}p, \tag{2}$$

where s^{M} and v^{M} are the molar entropy and volume of micelle, respectively, $\Delta y(1)$ and $\Delta y(\mathrm{M})$ are defined by the equations

$$\Delta y(1) = y^{\mathrm{H}} - \Gamma_1^{\mathrm{H}} y_1^{\mathrm{W}}, \tag{3}$$

and

$$\Delta y(\mathrm{M}) = y^{\mathrm{H}} - \Gamma_1^{\mathrm{H}}(y^{\mathrm{M}}/N_1^{\mathrm{M}}), \tag{4}$$

where Γ_1^{H} is the interfacial density of surfactant, y^{H} the interfacial excess quantity per unit area, y_1^{W} the partial molar quantity of surfactant in the solution, and N_1^{M} the number of surfactant ions in the micelle.

In the first place, the entropy changes, $\Delta s(1)$ and

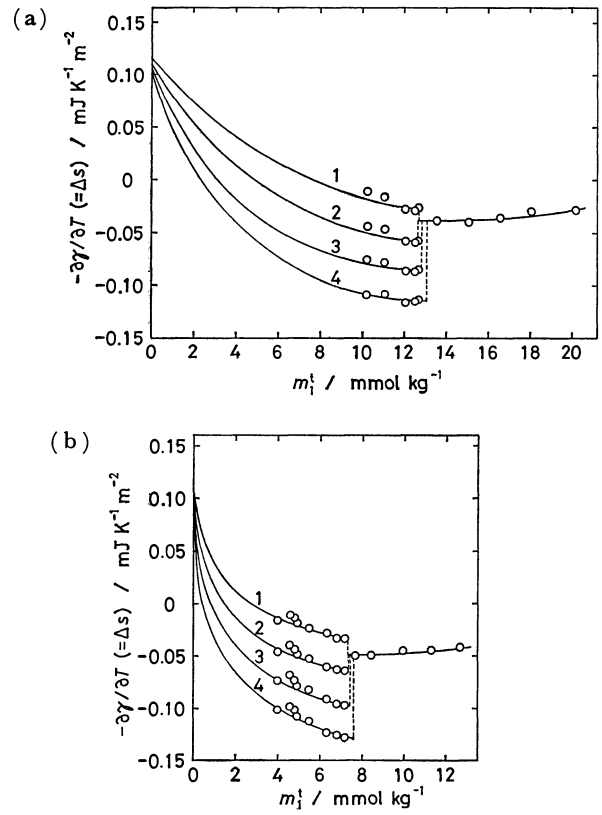

Fig. 4. Derivative of interfacial tension with respect to temperature *vs.* total molality curves of DAC (a) and SDS (b) at constant temperature under atmospheric pressure.
(a): (1) 293.15 K; (2) 298.15 K; (3) 303.15 K; (4) 308.15 K. (b): (1) 293.15 K; (2) 298.15 K; (3) 303.15 K; (4) 308.15 K.

$\Delta s(\mathrm{M})$, can be calculated by applying the following equations to the present experimental results:

$$\Delta s(\mathrm{M}) = -(\partial\gamma/\partial T)_{p,m_1^t}, \tag{5}$$

and

$$\Delta s(1) = -(\partial\gamma/\partial T)_{p,m_1^t} - 2(RT/\mathrm{cmc})\Gamma_1^{\mathrm{H}}(\partial\mathrm{cmc}/\partial T)_p, \tag{6}$$

where it is presumed that the micellar solution behaves ideally and the concentration of monomeric surfactant is equal to the value of cmc. On the other hand, in the case where the system is free from micelle, $\Delta s(1)$ is provided directly by the equation

$$\Delta s(1) = -(\partial\gamma/\partial T)_{p,m_1^t}. \tag{7}$$

Thus, it is evident from Eqs. 5 and 7 that the value of $-\partial\gamma/\partial T$ in Figs. 4a and 4b provides $\Delta s(\mathrm{M})$ at the concentration above cmc and $\Delta s(1)$ at the concentration below cmc. Therefore, the discontinuous change in $-\partial\gamma/\partial T$ at the cmc corresponds to the difference between $\Delta s(1)$ and $\Delta s(\mathrm{M})$ and its value is related to the temperature dependence of cmc by the equation

$$\Delta s(1) - \Delta s(\mathrm{M}) = -2(RT/\mathrm{cmc})\Gamma_1^{\mathrm{H}}(\partial\mathrm{cmc}/\partial T)_p \text{ at cmc.} \tag{8}$$

The right side of Eq. 8 is calculated easily, since the value of Γ_1^{H} is estimated by applying the equation

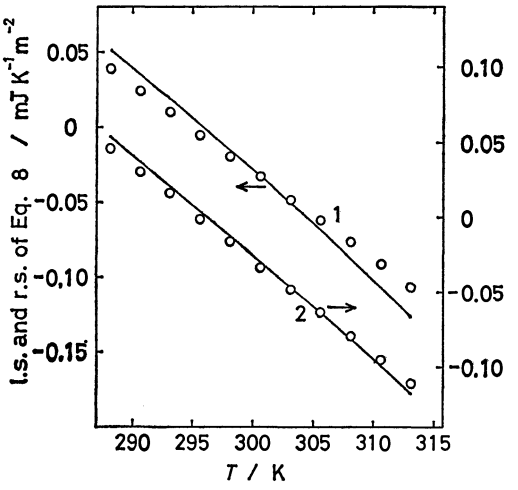

Fig. 5. Comparison between left side $(\Delta s(1)-\Delta s(M))$ and right side $(-2(RT/\text{cmc})\Gamma_1^H(\partial \text{cmc}/\partial T)_p)$ of Eq. 8. Left side ○ and right side ——; (1) DAC; (2) SDS.

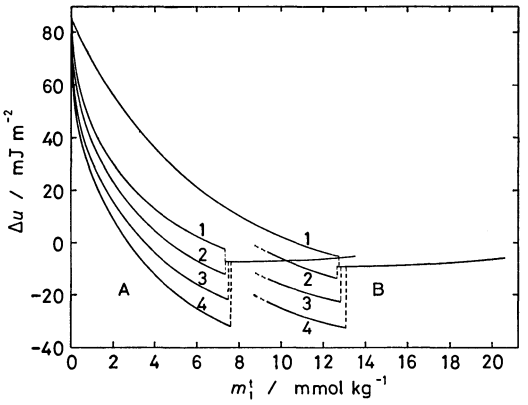

Fig. 6. Energy change associated with adsorption *vs.* total molality curves of DAC and SDS at constant temperature under atmospheric pressure.
(A): SDS; (B): DAC; (1) 293.15 K; (2) 298.15 K; (3) 303.15 K; (4) 308.15 K.

$$\Gamma_1^H = -(m_1^t/2RT)(\partial\gamma/\partial m_1^t)_{T,p}, \quad (9)$$

to the γ *vs.* m_1^t curves in Figs. 2a and 2b, and the values of cmc and $\partial \text{cmc}/\partial T$ are obtained from the cmc *vs.* T curves in Fig. 3. The left side of Eq. 8 is evaluated by extrapolating the values of $\Delta s(1)$ and $\Delta s(M)$ to the cmc. Both sides of Eq. 8 are compared in Fig. 5. They seem to be in fair agreement with each other. A similar result has been obtained for the system of aqueous solution of DAC and air.[1] This fact indicates that Eq. 2 is a useful approximation for the behavior of micelle in a limited concentration range near the cmc.

Next, let us evaluate the energy changes, $\Delta u(1)$ and $\Delta u(M)$, by the use of the relations

$$\Delta u(1) = \gamma + T\Delta s(1) - p\Delta v(1), \quad (10)$$

and

$$\Delta u(M) = \gamma + T\Delta s(M) - p\Delta v(M). \quad (11)$$

Since the terms of $p\Delta v(1)$ and $p\Delta v(M)$ on the right sides of these equations are usually negligible compared with the other terms under atmospheric pressure,[3,6,14]

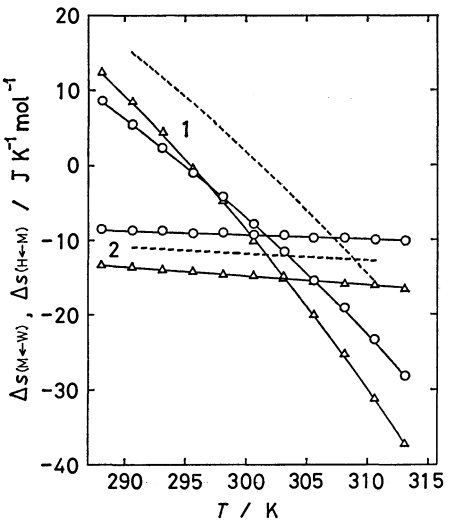

Fig. 7. Entropy change of micelle formation $(\Delta s(M\leftarrow W))$ *vs.* temperature curves and entropy change associated with adsorption from micellar state $(\Delta s(H\leftarrow M))$ *vs.* temperature curves under atmospheric pressure.
(1): $\Delta s(M\leftarrow W)$, (2): $\Delta s(H\leftarrow M)$, ○: DAC water/hexane, △: SDS water/hexane, - - - -: DAC water/air.

the numerical values of $\Delta u(1)$ and $\Delta u(M)$ can be obtained by making use of Figs. 2a, 2b, 4a, and 4b. They are plotted against m_1^t in Fig. 6 for both DAC and SDS. It is apparent that the values of $\Delta u(1)$ and $\Delta u(M)$ depend on m_1^t in a similar manner as the corresponding entropy changes in Figs. 4a and 4b.

Now, it is instructive to look more closely at the behavior of DAC and SDS molecules in the adsorbed film and micelle. In order to do this, it is convenient to introduce the thermodynamic quantity changes per mole of surfactant, which are defined by the equations

$$\Delta y(H\leftarrow M) = y^H/\Gamma_1^H - y^M/N_1^M = \Delta y(M)/\Gamma_1^H, \quad (12)$$

and

$$\Delta y(M\leftarrow W) = y^M/N_1^M - y_1^W = [\Delta y(1)-\Delta y(M)]/\Gamma_1^H, \quad (13)$$

where Eqs. 3 and 4 have been used.

In Fig. 7, the entropy changes, $\Delta s(H\leftarrow M)$ and $\Delta s(M\leftarrow W)$, which are obtained from Figs. 4a, 4b, and 5, are plotted against temperature. Included in this figure for comparison are those obtained for the system of DAC solution and air.[1] Their values are found to be fairly different between DAC and SDS and between the water/hexane and water/air interfaces. It is also seen that the value of $\Delta s(H\leftarrow M)$ is negative and slightly dependent on T while the value of $\Delta s(M\leftarrow W)$ decreases from a positive value to a negative one with increasing T.

The corresponding energy changes, $\Delta u(H\leftarrow M)$ and $\Delta u(M\leftarrow W)$, obtained from Fig. 6 and the previous paper,[1] are shown in Fig. 8. It is noteworthy that the $\Delta u(H\leftarrow M)$ has nearly equal negative values for DAC and SDS at water/hexane interface and has a positive value for DAC at water/air interface. It is also seen that $\Delta u(H\leftarrow M)$, likely $\Delta s(H\leftarrow M)$, depends slightly on T. These facts indicate that the tempera-

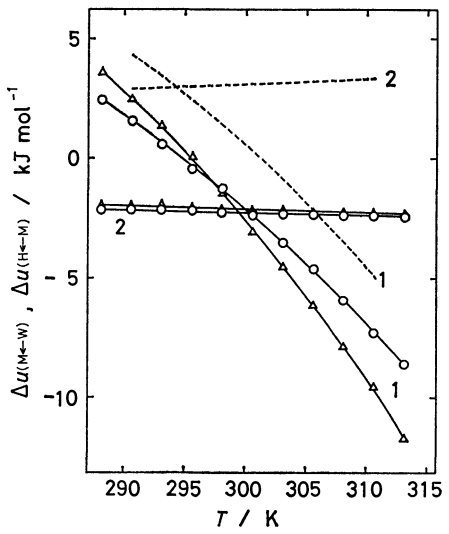

Fig. 8. Energy change of micelle formation (Δu(M←W)) *vs.* temperature curves and energy change associated with adsorption from micellar state (Δu(H←M)) *vs.* temperature curves under atmospheric pressure.
(1): Δu(M←W), (2): Δu(H←M), ○: DAC water/hexane, △: SDS water/hexane, ----: DACwater/air.

ture dependence of energy and entropy of the micelle bears resemblance to that of the adsorbed film. The resemblance of the behavior between the adsorbed film and the micelle will be further confirmed by evaluating the corresponding volume changes from the pressure dependence of the interfacial tension, which will be reported in the near future.[14]

Finally, let us examine the temperature dependence of Δu(M←W) and Δs(M←W). According to Eq. 13, they may be respectively referred to as the energy and entropy changes of micelle formation. As can be seen in Figs. 7 and 8, the values of Δu(M←W) and Δs(M←W) vary with temperature in a similar manner. It is also seen that the temperature dependence of Δu(M←W) and Δs(M←W) of DAC at water/hexane interface is smaller than that of SDS. This result may be attributable to the difference in charge and size of the ionic head group and counterion of surfactant between DAC and SDS. Furthermore, we notice that the values of Δu(M←W) and Δs(M←W) for the aqueous DAC solution–hexane system are fairly smaller than those for the aqueous DAC solution–air system. We may conclude that such a behavior results from the lowering of the energy and entropy of micelle of DAC by the solubilization of hexane into the micelle.

Photon Echo of Pentacene Molecules Introduced in Crystals with High Concentration

Yuzo Yoshikuni,† Arao Nakamura,†† and Shigeo Shionoya*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received January 20, 1982)

Photon echo decay time is measured for pentacence molecules introduced in naphthalene and *p*-terphenyl crystals with rather high concentrations (10^{-6}—10^{-5} mol/mol) at temperatures between 1.6 K and 4.1 K, using a tunable picosecond laser system consisting of a mode-locked YAG laser and a parametric oscillator. In naphthalene echo decay time increases with lowering temperature approaching a constant value below 2 K, but in *p*-terphenyl it is almost constant. The phase relaxation time at very low temperature is much shorter than twice the population relaxation time in both crystals, indicating that pure dephasing processes exist. Analyzing the results it turns out that there exsists a pure dephasing process which is temperature-independent and is very probably due to interactions between pentacene molecules, in addition to the temperature-dependent dephasing process due to the scattering of pseudolocalized phonons.

Recently, with the progress of coherent transient techniques in the optical region, for example photon echo observation, much information on optical dephasing processes associated with electronic transitions has been obtained for organic molecules introduced in crystals. From the optical line shape, useful information on phase relaxation can be obtained, but usually the optical homogeneous line shape is masked by inhomogeneous line broadening. Coherent transient techniques enable to obtain homogeneous line width buried in inhomogeneous line width.

Photon echo measurements were performed recently by Wiersma and his coworkers for a number of organic molecules, such as pyrene,[1] pentacene,[2-4] and naphthalene[5] introduced in organic crystals. Especially, for pentacene molecules very dilutely introduced (10^{-8}—10^{-7} mol/mol) in naphthalene and *p*-terphenyl crystals as hosts, detailed studies were made using nanosecond and picosecond lasers. It turned out[2] in the case of *p*-terphenyl host that at very low temperature of 1.5 K where phonons are not active, the phase relaxation time (T_2) is determined by the population relaxation time (T_1), in other words T_2 is equal to $2T_1$. The temperature dependence of the phase relaxation time was measured in a wide range above 4.2 K up to 20 K.[3,4] It was found that the homogeneous line width is exponentially activated with phonon-like activation energy. This exponential activation of the homogeneous line width was interpreted by assuming optical dephasing due to the scattering of pseudolocalized phonons,[4,6] and the energy and the lifetime of such phonons were determined.

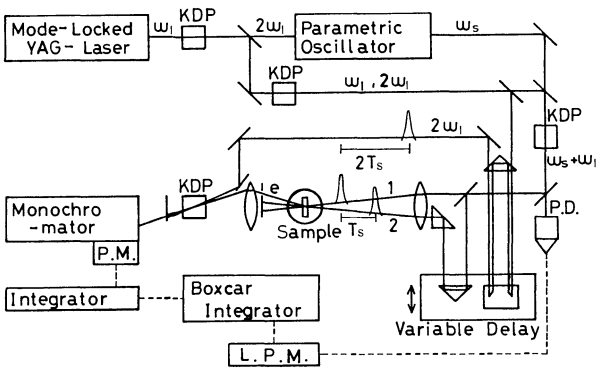

Fig. 1. Experimental set-up for photon echo measurements using a parametric oscillator (output frequency: ω_s) pumped by second harmonics of a mode-locked YAG laser (output frequency: ω_1). 1: first excitation pulse, 2: second excitation pulse, e: echo signal, T_s: separation of the first and second pulse, P.D.: photodetector, P.M.: photomultiplier, L.P.M.: laser power monitor.

If pentacene molecules are introduced in host crystals with high concentration, interactions between guest molecules would influence optical dephasing. The temperature dependence of T_2 in such cases are not yet studied. In this paper, we report picosecond photon echo measurements for pentacene molecules introduced in naphthalene and *p*-terphenyl crystals with rather high concentrations (10^{-6}—10^{-5} mol/mol) at temperatures between 1.6 and 4.2 K. As will be mentioned below, the temperature dependence of T_2 is observed, and it is found that at very low temperature, T_2 is independent of temperature, but is much shorter than $2T_1$.

Experimental

Pentacence-doped naphthalene and *p*-terphenyl crystals were grown by the Bridgman technique. In the case of naphthalene zone-refined reagent was used as the starting material. In the case of *p*-terphenyl, zone-refined reagent is not available, so ordinary reagent was vacuum-sublimed, zone-refined and then used. Crystals were cleaved in parallel to the *ab* cleavage plane to thickness of about 1 mm with a sharp razor blade.

Pentacene molecule in naphthalene has the zero-phonon absorption line of the S_0-S_1 transition at 602.7 nm. In the case of *p*-terphenyl host there exist four zero-phonon absorption lines originating from different sites. Measurements were made for the lowest energy line located at 592.2 nm. The spectral width of these absorption lines is about 1 cm^{-1} in both host crystals. The transition dipole moment for these absorption lines is known to be about 1 D.[7] The concentration of pentacene molecules in a sample was determined combining the absorption intensity and the transition dipole moment of this value.

In photon echo experiments a tunable picosecond laser

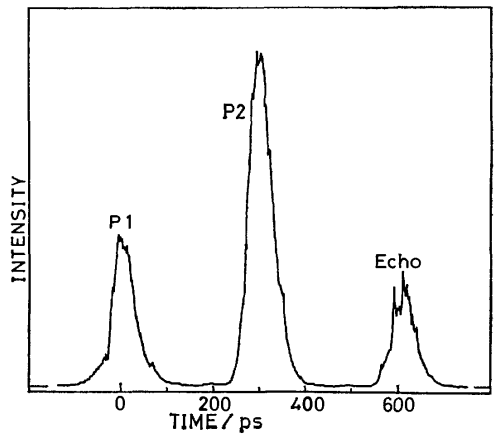

Fig. 2. Photon echo observation for pentacence in naphthalene (5×10^{-6} mol/mol) at 1.6 K. P1 and P2 are the first and second excitation pulses observed in the direction of the echo signal as leaked light. The pulse separation T_s is 300 ps.

system consisting of a repetitively mode-locked YAG:Nd^{3+} laser and a parametric oscillator was used.[8] Figure 1 shows the experimental set-up employed. The parametric oscillator using a temperature-controlled $LiNbO_3$ crystal was pumped by 532 nm second harmonic pulses of the YAG laser output. Excitation pulses tunable in the range around 600 nm were generated by the sum-frequency mixing of tunable pulses around 1300 nm produced by the parametric oscillator with 1064 nm fundamental pulses of the YAG laser by using a KDP crystal. Their characteristics are duration of about 20 ps, spectral width of about 2 cm^{-1} and peak power of about 200 kW.

The two pulses needed for the photon-echo experiments were generated by a beam splitter, and one pulse was delayed by an optical delay to obtain variable pulse separation (T_s). The intensity ratio of the first to second pulse was made to be almost 1:4 according to the standard way in photon echo experiments. Two excitation pulses were focused on the sample at an angle of about 0.5 degree. The size of the excitation spot was about 300 μm in diameter, and excitation densities of the first and the second pulses were 20 and 80 MW/cm^2, respectively. These power densities nearly correspond to the conditions of the $\pi/2$ and π pulses, respectively, since the transition dipole moment in the present case is about 1 D. The echo was emitted in a direction separated from the second pulse by the same angle as that between the first and second pulses as expected. It is sure that this configuration is useful to reduce the background by spatially separating the echo signal from the excitation pulses.

The echo signal was made to pass through a diaphragm to remove the excitation pulses as much as possible. Then the echo signal was mixed with the second harmonic pulse of the YAG laser output to generate the sum-frequency pulse. This second harmonic pulse acts as the time-gate pulse, which selects the echo signal from the excitation pulses. The gate pulse was delayed by the variable optical-delay so as to coincide with the echo in time. The optical delay consists of two prisms located on a moving stage driven by a pulse motor. The second excitation pulse passes one prism and the gate pulse passes the other prism. The gate pulse passes the delay twice, so that the time delay of the gate pulse is double that of the second pulse from the first pulse. Thus the synchronization of the gate pulse with the echo is maintained. The mixed pulse of the echo and gate pulse

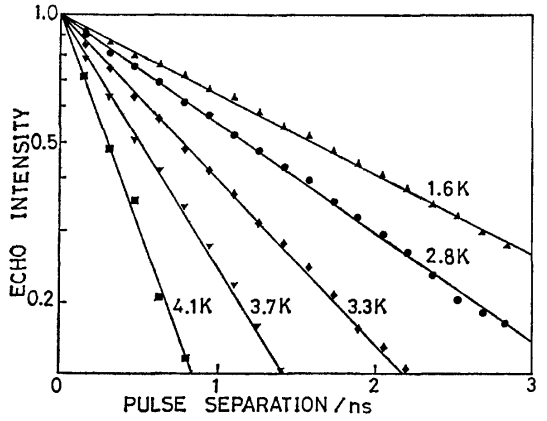

Fig. 3. Logarithmic plots of photon echo decay of pentacene in naphthalene (5×10^{-6} mol/mol) at temperatures between 1.6 and 4.1 K. Solid lines are the least square fitting to the experimental data.

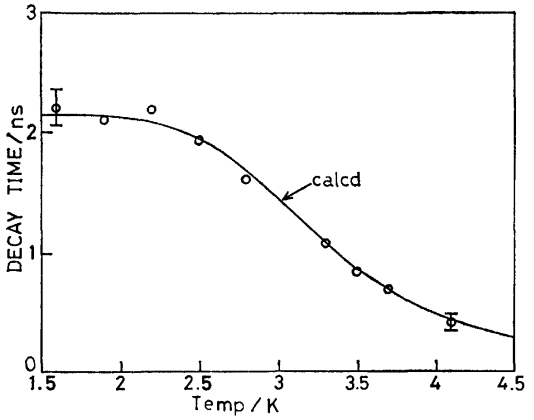

Fig. 4. Temperature change of echo decay time of pentacene in naphthalene (5×10^{-6} mol/mol). Solid line is calculated curve; see the text.

was made to pass through a monochromator, and then was detected by a photomultiplier. The output of the photomultiplier was integrated and held by an integrator. On the other hand, a part of excitation pulses were detected by a phototube, and the power was checked by a laser power monitor. Only when the power is within $\pm5\%$ for a certain fixed value, the echo signal held in the integrator was accumulated by a Boxcar integrator.

Results and Discussion

Figure 2 demonstrates an observation of photon echo for pentacene molecules in a naphthalene crystal (5×10^{-6} mol/mol) at 1.6 K. This data was obtained by changing the arriving time of the gate pulse but fixing the separation of the two excitation pulses at 300 ps. P1 and P2 are the first and second excitation pulses observed in the direction of the photon echo signal as leaked light through the diaphragm. It is seen that the photon echo appears after the second pulse with the interval the same as that between the first and second pulses.

To obtain the relaxation time of photon echo, the echo intensity was measured as a function of the separation of the two excitation pulses. The separation was changed by scanning the variable optical delay,

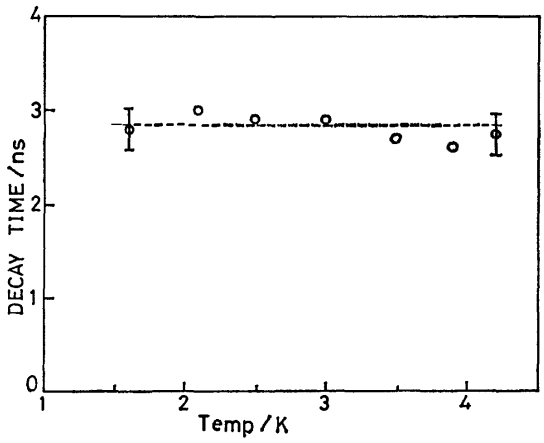

Fig. 5. Temperature change of echo decay time of pentacene in *p*-terphenyl (1×10^{-5} mol/mol).

maintaining the synchronization of the gate pulse with the echo signal. The echo intensity as a function of the excitation pulse separation is given by

$$I(T_s) = I_0\exp(4T_s/T_2). \quad (1)$$

Figure 3 shows logarithmic plots of the relative echo intensity versus the pulse separation for pentacene in naphthalene (5×10^{-6} mol/mol) at temperatures between 1.6 K and 4.1 K. The functional form of the photon echo decay is exponential at the whole temperature range. The echo decay time decreases with elevating temperature.

Decay times obtained, *i.e.* $T_2/4$, are plotted in Fig. 4 as a function of temperature. It is seen that the decay time becomes constant at temperature below 2 K. Figure 5 shows results of the echo decay time in the case of pentacene in *p*-terphenyl (1×10^{-5} mol/mol). It is found that the decay time is almost constant in the whole temperature range and is slightly longer than that in the case of the naphthalene host below 2 K.

The echo decay time is governed by the phase relaxation time T_2 given by

$$1/T_2 = 1/2T_1 + 1/T_2^*, \quad (2)$$

where T_1 is the population relaxation time and T_2^* is the pure dephasing time. T_1 in the present case was reported to be 19.5 ns in naphthalene and 23.5 ns in *p*-terphenyl.[4]

As shown in Fig. 5, the decay time of the echo in the *p*-terphenyl host is almost constant below 4.1 K and is about 2.9 ns giving the value of about 11.6 ns as T_2. This value of T_2 is much shorter than $2T_1$. This suggests that the pure dephasing process that is independent of temperature exists below 4.1 K in this host. From Eq. 2, the pure dephasing time T_2^* is obtained to be 15 ns.

In the case of the naphthalene host, T_2 increases with lowering temperature but approaches a constant value which is much shorter than $2T_1$. One may consider that the temperature-independent, pure dephasing process exists also in this host at very low temperature. As mentioned already, it is known that in dilutely doped crystals T_2 is dominated by the dephasing process due to the scattering of pseudolocalized phonons at temperature above 4.2 K.[4] Such a dephasing process dominated by phonons should exist also in highly doped crystals.

One may assume that T_2^* in the present case of the naphthalene host consists of two components, one T_{2c}^* which is temperature-independent and the other T_{2ph}^* which is temperature-dependent and is dominated by phonon scattering, that is

$$1/T_2^* = 1/T_{2c}^* + 1/T_{2ph}^*. \quad (3)$$

The temperature-dependence of T_{2ph}^* may be expressed by

$$T_{2ph}^* = \tau_{ph}\exp(E_{ph}/kT), \quad (4)$$

where τ_{ph} is the lifetime of relevant phonons and E_{ph} is their energy. The observed temperature change of the decay time in Fig. 4 was attempted to fit with the calculation based on the assumption of Eqs. 3 and 4. Adjustable parameters are τ_{ph}, E_{ph}, and T_{2c} which is the temperature-independent component of T_2 given by

$$1/T_{2c} = 1/T_{2c}^* + 1/2T_1. \quad (5)$$

The result of the calculation is shown by the solid curve in the figure. It is seen that observed decay times are well represented by the calculation. The values of the adjustable parameters used are $\tau_{ph}=7.4$ ps, $E_{ph}=16.1$ cm^{-1} and $T_{2c}=8.7$ ns. It is noted that these values of τ_{ph} and E_{ph} well coincide with those obtained in the dilutely doped naphthalene host at temperature above 4.2 K.[4] It is sure that also in the highly doped host the same kind of the pseudolocalized phonon is active for dephasing. Further from the above value of T_{2c}, T_{2c}^* is obtained to be 11.2 ns.

Also in the case of the dilutely doped *p*-terphenyl host, the values of τ_{ph} and E_{ph} are known from the temperature dependence of T_2 above 4.2 K. If T_2 is calculated using such values for temperatures below 4.2 K, it is found that T_2 becomes constant below about 3 K. Therefore, the results shown in Fig. 5 for the highly doped *p*-terphenyl host are regarded as reasonable.

From the above-mentioned discussion, it is definitely concluded that when pentacene molecules are introduced with high concentration, a pure dephasing process, represented by T_{2c}^*, exists and dominates dephasing at very low temperature where phonon-dominated processes are not active. This fact is a distinct difference of the high concentration case from the low concentration case, and allows us to consider that the origin of this pure dephasing is interactions between pentacence molecules.

Cooper *et al.*[9] observed the photon echo of pentacence molecules introduced in naphthalene crystals with rather high concentrations (10^{-7}—10^{-5} mol/mol) at 1.4 K, and found that concentration-dependent, pure dephasing takes place. Although they did not measure the temperature dependence of this process, it is certain that the same kind of origin as that of the present case dominates this process, considering the concentration and the temperature in their experiments.

They explained this concentration-dependent dephasing as caused by the fluctuation of the dipole-dipole interaction between pentacene molecules due to phonons. According to this phonon-modulated dipolar in-

teraction model, T_{2c}^* is given by[9]

$$1/\pi T_{2c}^* = \{(dE/dr) \times \Delta r\}^2/h^2\nu, \quad (6)$$

where E is the excitation energy of molecules, Δr is fluctuation of intermolecular distance and ν is the rate of the fluctuation. The value of ν should be comparable to the thermal average acoustic phonon frequency, so that it is expected to increase linearly with temperature. On the other hand, the value of Δr is known to be almost constant in the temperature range below 4.2 K in the present case.[10] Then T_{2c}^* given by Eq. 6 should be temperature-dependent, increasing linearly with temperature. According to our experimental results, T_{2c}^* is temperature-independent in this temperature range. Therefore, the model proposed by Cooper *et al.* can not account for the dephasing process in the case of the high pentacene concentration.

Morsink *et al.*[11] also found concentration-dependent dephasing in photon echo measurements of naphthalene molecules in durene. This dephasing was interpreted as the effect of dipolar broadening due to energy migration among resonant molecules. However, this interpretation was based on the assumption, which has no solid experimental evidence, that the crystal consists of large domains of resonant molecules.

Anyway we need more detailed information on the temperature- and concentration-dependence of the dephasing time to discuss the mechanism of dephasing in the high concentration case as observed here. Measurements of the concentration depnedence for pentacene molecules in naphthalene and *p*-terphenyl are now in progress, and results will be reported shortly.**

(Received December 14, 1981)

The mechanism of the quenching of the triplet state of zinc phthalocyanine (ZnPc) and Methylene Blue (MB^+) by low-spin complexes of Fe(III) and Co(III) and aromatic oxidants was studied. The quenchers studied included $Fe^{III}(CN)_6^{3-}$, $Fe^{III}(CN)_4$(2,2-bipyridyl)$^-$, $Fe^{III}(CN)_2$(2,2-bipyridyl)$^+$, ferrocenium ion, Co^{III}(2,2′: 6′-2″-terpyridyl)$^{3+}$, Co^{III}(1,10-phenanthroline)$^{3+}$, dimethylviologen, 1,4-benzoquinone, and 2,4,7-trinitro-9-fluorenone (TNF). The rate constants of the quenching of ^{3}ZnPc varied from a diffusion-controlled one to 6×10^5 dm^3 mol^{-1} s^{-1} in the mixed solvent of dimethylacetamide (DMA) and water (7:3 by volume). The metal complexes quenched $^3MB^+$ and the triplet state of protonated MB^+ with a rate constant of more than 2×10^6 dm^3 mol^{-1} s^{-1} in an aqueous solution with 0.5 mol dm^{-3} of $MgCl_2$. The fractions of electron transfer yielding $ZnPc^{+\cdot}$ in the quenching process (F_1) were high except for TNF and the iron(III) compounds. The F_1 fractions were also obtained in the quenching of $^3MB^+$ and the triplet state of the protonated MB^+. The absence of radical production in the quenching by the doublet iron(III) compounds can be explained in terms of spin-allowed reverse electron transfer in the life of the geminate radical pair. Fractions of the reverse electron transfer between the half-reduced quencher and $ZnPc^{+\cdot}$ or $MB^{2+\cdot}$ were also measured; they are very close to those of $1-F_1$. The data reported in this study are consistent with the following mechanistic features. (1) Every quenching encounter produces a geminated radical pair. (2) The geminated pair is common to the quenching of the triplet excited state by oxidants and to the reverse electron transfer between the free radicals formed in the quenching. The molar extinction coefficient of $ZnPc^{+\cdot}$ was determined to be 2.9×10^4 dm^3 mol^{-1} cm^{-1} at 520 nm.

Electron transfer between an excited molecule and a quencher to produce redox products is a necessary step in the conversion of solar into chemical energy. Either the dissociation of the radicals or the reverse electron transter may follow the electron-transfer quenching of the excited state within the lifetime of the geminate radical pair, the former of which yields redox products. The fraction of the radical formation in quenching has been called "the efficiency of electron transfer in the quenching process,"[1,2] which corresponds to "the cage-escape probability"[3,4] provided every quenching yields a geminate radical pair. Reverse electron transfer in a singlet radical pair reproducing the singlet reactant pair is spin-allowed,[5,6] so F_1 is nil unless the reverse electron transfer is unfavourable with respect to the free-energy change. On the other hand, reverse electron transfer in a triplet radical pair is spin-forbidden,[5-7] so F_1 is high except multiplicity restriction is broken by means of spin-orbit interaction.[2,8] The rate of the reverse electron transfer can be estimated by using Marcus' equation[9] or an empirical equation proposed by Rehm and Weller,[10] which is written in terms of the free-energy change and rearrangement energy involved in the electron transfer, provided the electron-transfer process is spin-allowed.

This paper will describe a study of electron-transfer quenching rates and the efficiency of electron transfer in the quenching of the triplet state of zinc phthalocyanine (ZnPc) and Methylene Blue (MB^+) by a substitution-inert coordination compound of iron(III) and cobalt(III) and some aromatic oxidants, such as 1,4-benzoquinone and dimethylviologen. The efficiency of the reverse electron transfer between the half-reduced quencher and half-oxidized ZnPc or MB^+ is also studied in order to make the quenching mechanism clear.

Metal phthalocyanine compounds are regarded as inert and stable metal complexes in which photoexcitation energy may not be dissipated before the conversion of solar to chemical energy. Since the phthalocyanine compounds resemble porphyrins in both geometrical and electronic structures, they have been studied by several workers. More recently, different results with respect to the efficiency of photo-electron transfer has been reported. Harriman and Richoux[11] reported F_1 to be less than 5% in the quenching of zinc phthalocyanine tetrasulfate by methylviologen in water. On the other hand, Tanno, Wöhrle, Kaneko, and Yamada[12] reported a high quantum yield of the production of the methylviologen radical on exciting magnesium phthalocyanine in a mixed solvent of dimethylsulfoxide and water.

MB^+ is a photosensitizer of the photogalvanic cell proposed by Rabinowitch[13] and developed by the present author (N. N. L.);[14] in the method, the reduction of MB^+ to $MBH^{+\cdot}$ is coupled by the oxidation of Fe^{II} to Fe^{III}. Recently, $Fe^{III}(H_2O)_6^{3+}$ was reported to oxidize the singlet excited state of MB^+ with a very small yield.[15] The unfavorable process of MB^+-oxidation by iron(III) compound is worth examining.

Experimental

Materials. Water was purified by passage through a Millipore deionizer and a filter. Dimethylacetamide (DMA) was purified by vacuum distilation. The Puriss-grade $MB^+Cl^-\cdot3H_2O$ (Fluka), $HClO_4$ (Wako Junyaku), dimethylvio-

logen** (Tokyo Kasei), 2,4,7-trinitro-9-fluorenone** (Tokyo Kasei), and 2,3,5,6-tetrachloro-1,4-benzoquinone** (Wako Junyaku) were used as supplied. The ZnPc (Tokyo Kasei), 1,4-benzoquinone** (Wako Junyaku), and 1,4-naphthoquinone (Wako Junyaku) were purified by vacuum sublimation immediately before use. The Co^{III}(2,2′:6′-2″-terpyridyl**)$_2$-$(ClO_4)_3$ and Co^{III}(1,10-phenanthroline**)$_3(ClO_4)_3$ were prepared by the method of Maki.[16] The ferrocenium ion was prepared immediately before use by the oxidation of ferrocene with iron(III) nitrate in 0.01 mol dm^{-3} of a $HClO_4$ aqueous solution. Fe^{III}(2,2′-bipyridyl**)$_2(CN)_2(NO_3)$ and $H[Fe^{III}(CN)_4(bpy)]$ were prepared by the method of Schilt.[17] The solvent for ZnPc was a mixture of DMA and water (7:3 by volume). The ionic strengths of the sample solution were kept to be 1—1.5 mol/dm^3 by using $MgCl_2$ or $NaClO_4$. All the test solutions were deaerated by purging nitrogen for 15—20 min.

Apparatus. A *NEC* ruby laser *SLG*-2018 with a *Q*-switch capable of providing up to 0.85 J per flash at 694.3 nm with a pulse width of 20 ns was used. The laser beam (ϕ=10 mm) is vertically converged and longtudinally expanded by means of two cylindrical lenses to 6 mm×12 mm on the photolysis cell (10 mm×10 mm). The laser intensity was stabilized within a fluctuation of a few percent by controlling the temperature of the circulating water for the ruby rod. The absorption changes in the sample were measured by the use of the monitoring beam of a 150 W Xenon arc lamp, which was operated at 20 V (8 A) and which could be pulsed to 30—70 V by the use of a transistor-switched discharging circuit, made by Dr. N. Tatebe. The probe-beam is also focussed by a means of a convex lens on the sample cell with a pin hole (ϕ=1 mm). A shutter driven by a pulse motor is put between the focusing lens and the sample cell to minimize photolysis. The intensity of the monitoring beam was measured by means of a Hamamatsu R955 photomultiplier tube and a Tektronix 456 synchroscope. Another ruby apparatus was used for the study of the MB^+-oxidation; it has been described in the literature.[18]

Measurements. The decay of ^{3}ZnPc was monitored at 450 or 490 nm. The decays of $^3MBH^{2+}$ and $^3MB^+$ were monitored at 710 and 820 nm respectively.[1] The yields of ZnPc† were measured at 520 nm (ε_{520}=2.9×10^4 dm^3 mol^{-1} cm^{-1}). The yields of MB^{2+} were measured at 520 nm (ε_{520}=5.7×10^4 dm^3 mol^{-1} cm^{-1} [19]). The rate of disappearance of ZnPc† were monitored through the decay of its absorbance at 835 nm. The rates of the disappearance of MB^{2+} were monitored through its absorbance at 520 nm or through its increase in absorbance due to MB^+.

Results and Discussion

T-T Absorption. On exposure to 694.3 nm light, the S_1-S_0 absorption of ZnPc was reduced and a transient species was observed with a lifetime of 200 μs. Its absorption spectrum, shown in Fig. 1, is very similar to the absorption spectrum of the triplet excited state of ZnPc in neutral 2-propanol previously reported.[20] The conversion of ZnPc to its triplet state can be estimated from the decrease in the peak absorbance of ZnPc at 672 nm almost completely disappeared for several hundred nano seconds on exposure to a laser beam intensified by means of a cyclindrical convex lens. The molar extinction coefficient of the triplet state at 490 nm can be calculated to be 3.25×10^4 mol^{-1} dm^3 cm^{-1}, which is very close to that reported in 2-propanol.

	0	0.53	0.70

The absorption spectra and molar extinction coefficients of $^3MB^+$ and the triplet state of protonated MB^+ ($^3MBH^{2+}$) have already been measured by the present authors, S.K.,[20] T.O., and N.N.L.[18] The decay-rate constants of $^3MBH^{2+}$ and $^3MB^+$ in the presence of a charged compound of iron(III) or cobalt(III) were measured in an aqueous solution with $MgCl_2$ of 0.5 mol/dm^3, where the electrostatic effect on the rate constant of the bimolecular process between $^3MBH^{2+}$ and the metal compound can be neglected.

Quenching Reactions of ^{3}ZnPc, $^3MBH^{2+}$, and $^3MB^+$. ^{3}ZnPc is quenched by an oxidant, such as the ferrocenium ion, $Fe^{III}(CN)_6^{3-}$, $Co^{III}(tpy)_2^{3+}$, BQ, 1,4-naphthoquinone, TNF, TCBQ, and MV^{2+}. The addition of the quencher did not change the ^{3}ZnPc

** The following abbreviations are used; dimethylviologen:MV^{2+}, 2,4,7-trinitro-9-fluorenone:TNF, 2,3,5,6-tetrachloro-1,4-benzoquinone:TCBQ, 1,4-benzoquinone:BQ, 2,2′:6′-2″-terpyridyl:tpy, 1,10-phenanthroline:phen, 2,2′-bipyridyl:bpy.

production immediately after flashing, but it did increase the decay rate of ^{3}ZnPc. However, TNF of more than 50 μmol/dm^3 reduced both the fluorescence and the ^{3}ZnPc production; this effect is ascribed to complex formation in the ground state.[22] An analysis of the pseudo-first order decay of ^{3}ZnPc in the presence of the oxidant gives the quenching-rate constant listed in Table 1. The quenching-rate constant with a charged quencher was changed in an acidic solution by $HClO_4$ of 0.01 mol/dm^3; *i.e.*, that with a cation, MV^{2+} or $Co^{III}(tpy)_2^{3+}$, decreased and that with an anion, $Fe^{III}(CN)_6^{3-}$, increased compared to those in the neutral solution. No change in the quenching rate was observed with BQ in the $HClO_4$ solution. The dependence of the rate constants on the charge of the quencher suggests that ^{3}ZnPc in a 0.01 mol/dm^3 $HClO_4$ solution takes a proton, so electrostatic interaction between the cation triplet state and the charged quencher modifies the quenching-rate constant.

The largest rate constant was obtained using TCBQ as a quencher; it is assumed to quench ^{3}ZnPc at the rate of the encounter. The decreasing order of the quenching rate constants is: TCBQ > TNF > BQ > 1,4-naphthoquinone > MV^{2+}, which agrees with the decreasing order of the redox potential ($E^\circ(Q/Q^-)$ except for MV^{2+} (see Table 2). Since the free-energy change in the electron-transfer reaction between ^{3}ZnPc and the quencher (Q) is written by Eq. 1:

$$-\Delta G = F \times [E^\circ(Q/Q^-) - E^\circ(ZnPc^+/ZnPc)], \quad (1)$$

where $E^\circ(ZnPc^+/^3ZnPc)$ is the redox potential of ^{3}ZnPc and F is the Faraday constant, the quenching can be ascribed to electron transfer. The abnormally small rate constant with MV^{2+} can be explained by the large reorganization energy involved in electron transfer,[23] which Marcus,[9] Rehm and Weller[10] have introduced in explanation of the rate of an adiabatic electron-transfer reaction. The quenching-rate constants with the metal compounds studied in this work were much slower than that expected from the free-energy change. The rate constant observed with $Co^{III}(tpy)_2^{3+}$ can be explained by the fairly large reorganization energy involved in the electron transfer:[24] it is very close to the one estimated by using the equations of Marcus (Eq. 2) and Rehm and Weller (Eq. 3) to get the free energy of activation (ΔG^*_{12}) by using the self-exchange rate constants, electrostatically corrected, of 800 dm^3 mol^{-1} s^{-1} for $Co^{III}(tpy)_2^{3+} - Co^{II}(tpy)_2^{2+}$ and of 1×10^9 dm^3 mol^{-1} s^{-1} for $ZnPc^+$–^{3}ZnPc and by assuming that the electron-transfer rate constant (k) is written as in Eq. 4:

$$\Delta G^*_{12} = \frac{\Delta G^*_1(0) + \Delta G^*_2(0)}{4} + \frac{\Delta G_{12}}{2} + \frac{(\Delta G_{12})^2}{8 \times [\Delta G^*_1(0) + \Delta G^*_2(0)]}, \quad (2)$$

$$\Delta G^*_{12} = \frac{\Delta G_{12}}{2} + \left\{ \frac{(\Delta G_{12})^2}{4} + \frac{[\Delta G^*_1(0) + \Delta G^*_2(0)]^2}{4} \right\}^{1/2}, \quad (3)$$

where $\Delta G^*_1(0)$, $\Delta G^*_2(0)$, and ΔG_{12} are the free energies of activation for the self-exchange reaction of Reactants 1 and 2, and the free-energy change of the cross reaction between Reactants 1 and 2, and,

$$k = \kappa Z \exp(-\Delta G^*_{12}/RT), \quad (4)$$

where κ and Z are the adiabatic parameter and the collision frequency (-10^{11} s^{-1}) respectively. The estimated rate constants are shown in Table 3. However, the estimated rate constant with $Fe^{III}(CN)_6^{3-}$ is still sixty times as large as the observed one, so some non-adiabaticity in the electron transfer may exist.

Spin restriction on any dynamic phenomenon of transition-metal compounds is still effective; for example, the rate constant of an exchange-type energy transfer between a triplet excited state of an organic compound

and a quartet ground state of the chromium(III) compound, yielding the singlet ground state of the organic compound and the doublet excited state of chromium(III), is limited to the spin-statistical factor of the process.[25] Therefore, it is reasonable to think that the spin non-conserved channel of electron transfer is still non-adiabatic ($\kappa<1$). In the quenching by the doublet $Fe^{III}(CN)_6^{3-}$, the formation of the encounter complex preceeds the electron transfer, which has the spin multiplicity of the doublet or quartet. The doublet complex is converted to ^{2}ZnPc† and $^1Fe^{II}(CN)_6^{3-}$, but the quartet complex dissociates into the original reactants, ^{3}ZnPc and $^2Fe^{III}(CN)_6^{3-}$, without spin-inverted conversion into the redox products. Consequently, this kind of non-adiabaticity may reduce the quenching-rate constant to one quarter (the spin-statistical factor of the process), provided the spin restriction is firm. Another kind of non-adiabaticity may come from some specific hindrance to electron-exchange interaction between the reactants.

The decay rates of $^3MBH^{2+}$ and $^3MB^+$ increased in the presence of the oxidant; this did not, however, affect the triplet production immediately after flashing. The quenching rate constants of $^3MB^+$ in an ammonia alkaline aqueous solution by $Fe^{III}(CN)_6^{3-}$ and $Fe^{III}(CN)_4(bpy)^-$ are 4.3×10^9 and 4.5×10^9 $dm^3\ mol^{-1}\ s^{-1}$ respectively; these values are close to the diffusion-controlled rate constant of the bimolecular process in water. Each of the cobalt(III) compounds quenched $^3MB^+$ at a slower rate than did $Fe^{III}(CN)_6^{3-}$ as Table 4 shows. All the oxidants studied quenched $^3MBH^{2+}$ at a slower rate in an acidic solution than in the ammonia alkaline solution. It is reasonable to assume that $^3MB^+$, with the excitation energy of 1.44 eV,[26] is more susceptible to electron-transfer quenching than $^3MBH^{2+}$ with an excitation energy of 1.02 eV,[18] because $E°(MB^{2+}/{}^3MB^+)$ is more positive than $E°(MBH^{3+}/{}^3MBH^{2+})$. The smaller quenching rate constant by the cobalt(III) compounds can not be explained without reference to the self-exchange rates being smaller than those with the iron(III) compounds (see Table 3). Though $Fe^{III}(H_2O)_6^{3+}$ of 0.04 mol/dm^3 quenched MB^+ fluorescence, the decay of $^3MBH^{2+}$ was not effectively quenched, so the increase in the decay rate with $Fe^{III}(H_2O)_6^{3+}$ of 1 mmol/dm^3 is one hundredth of the spontaneous decay rate of $^3MBH^{2+}$. This means that the $Fe^{III}(H_2O)_6^{3+}$ produced in the reduction of MB^+ has practically no effect on the photoreduction of MB^+ in the MB^+–$Fe^{II}(H_2O)_6^{2+}$ photogalvanic cell.

Production of Half-oxidized ZnPc and MB^+. An intermediate was produced in the quenching of ^{3}ZnPc by TCBQ, BQ, 1,4-naphthoquinone, MV^{2+}, and $Co^{III}(tpy)_2^{3+}$. A transient absorption with maxima at 420, 530, 730, and 840 nm was observed immediately after the decay of ^{3}ZnPc, irrespective of the kind of oxidant, as Fig. 2 shows, so it can be identified as the half-oxidized form of ZnPc ($ZnPc^+$). In Fig. 2, the band at 394 nm can also be ascribed to the half-reduced form of MV^{2+}, which is well known to have absorp-

tion maxima at 394 and 604 nm in water.[27] The molar extinction coefficient of $ZnPC^+$ is calculated to be 2.9×10^4 dm^3 mol^{-1} cm^{-1} at 520 nm by assuming that MV^+ has the same molar extinction coefficient at 394 nm as that in water. Assuming that the conversion of ZnPc to $ZnPc^+$ can be estimated from the decrease in the strong absorbance of ZnPc ($\varepsilon_{672}=2.3\times10^5$ dm^3 mol^{-1} cm^{-1}), the same extinction coefficient of $ZnPc^+$ was obtained at 520 nm. The production of half-reduced quinone was not clearly observed, for the molar extinction coefficients are in the order of 10^3 dm^3 mol^{-1} cm^{-1}.[28] Since the extinction coefficient of $Co^{II}(tpy)_2^{2+}$ is less than 1.6×10^3 dm^3 mol^{-1} cm^{-1} in the visible region,[29] the transient absorption spectrum observed with the cobalt complex can be fully ascribed to $ZnPc^+$. It is a little different from the spectra of either chemically oxidized forms of ZnPc in crystal[30] or of magnesium phthalocyanine in dichloromethane,[31] the former of which has been reported to exhibit three bands at 446, 550, and 730 nm.

The half-oxidized form of MB^+ (MB^{2+}) was also produced in the quenching of $^3MBH^{2+}$ and $^3MB^+$ by the cobalt(III) compounds, which have an absorption maximum at 520 nm, like that observed in the self-quenching reaction of $^3MBH^{2+}$ [19] and in the electrolytic oxidation of MB^+.[32] The iron(III) compounds produced no MB^{2+} in the quenching.

The production of $ZnPc^+$ in the quenching process can be written as Eq. 5;

$$[ZnPc^+]_0 = [^3ZnPc]_0\frac{k_{et}[Q]}{k_d} \quad (5)$$

where $[^3ZnPc]_0$ and $[ZnPc^+]_0$ are productions in mol/dm^3 per flash, k_{et} is the rate constant of overall electron transfer, and k_d is the decay-rate constant of ^3ZnPc in the presence of a quencher. As Fig. 3 shows, the ratio of $[ZnPc^+]_0$ to $[^3ZnPc]_0$ is proportional to $[Q]/k_d$ so the value of k_{et} can be obtained. The ratio of k_{et} to the quenching-rate constant can be regarded as the fraction of free-radical formation in the quenching, which is expressed as k_{et}/k_g and designated as F_1. F_1 can also be defined as a fraction dissociating to

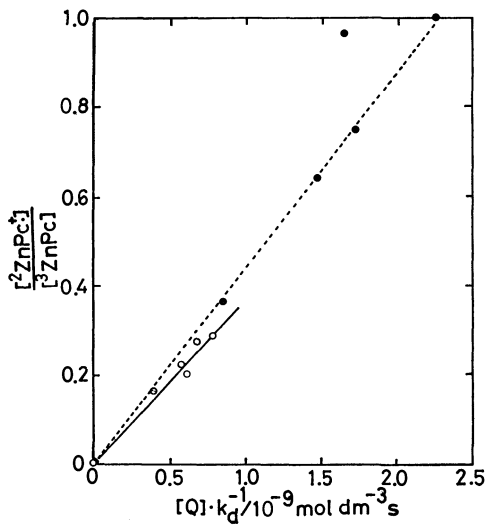

Fig. 3. Determination of k_{et} in the quenching of ^3ZnPc by BQ, ●, and by TCBQ, ○. $[ZnPc]=2\times10^{-5}$ mol/dm^3 and $[HClO_4]=0.01$ mol/dm^3.

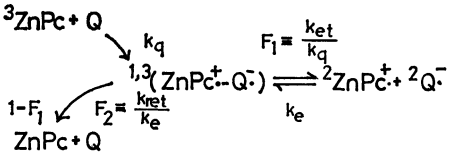

Fig. 4. Reaction scheme.

two free radicals, and the residue $(1-F_1)$, as a fraction performing a reverse electron-transfer reaction, as is shown in Fig. 4. F_1s are fairly high with BQ, MV^{2+}, TCBQ, and $Co^{III}(tpy)_2^{3+}$. However, the iron(III) compounds did not yield $ZnPc^+$ in the quenching of ^3ZnPc, nor did TNF produced $ZnPc^+$ in the quenching of the excited singlet and the excited triplet states of ZnPc.

Two of the present authors (T.O. and N.N.L.) have previously demonstrated that the fraction, F_1, in a homogeneous solution can be explained in terms of the rate of reverse electron transfer in the life of cage complex with triplet multiplicity.[1,2] The rate of reverse electron transfer can be estimated from : (i) the breaking down of spin-conservation, (ii) the free energy change involved in electron transfer, and (iii) the reorganization energy of the reactants involved in electron transfer. If the spin-multiplicity restriction is firm for the reverse electron-transfer, F_1 is unity. However, intersystem crossing from the triplet complex to the singlet one occurs by means of two mechanisms, hyperfine interaction in a weakly interacting cage complex[33] and the spin-orbit interaction of the cage complex on the surrounding reaction surface, the latter of which may be strengthened by a heavy atom and σ-π and/or n-π interaction.

The small value of F_1 with TNF can be explained by means of the spin-orbit interaction of the cage complex on the surrounding reaction surface. The three nitro groups of TNF may induce intersystem crossing through charge transfer and/or σ-π interac-

tion. It has also been reported that no nitro aromatic compound produces $Ru^{III}(bpy)_3^{3+}$ in the quenching of the excited state of $Ru^{II}(bpy)_3^{2+}$.[23] The high efficiencies with BQ, TCBQ, and MV^{2+} can be explained in terms of the spin-multiplicity restriction of reverse electron transfer within the life-time of the geminate pair. The dissociation rate of the geminate pair is too fast, compared to spin-inverted reverse electron transfer, to generate the free radicals in these cases. This is contrary to the fact that the radical yield in the quenching of excited $Ru^{II}(bpy)_3^{2+}$ depends on the charges of half-reduced oxidants; the yield of $Ru^{III}(bpy)_3^{3+}$ and $MV^{+\cdot}$ is 0.4, but that of $Ru^{III}(bpy)_3^{3+}$ and $BQ^{-\cdot}$ is only 0.05.[34] The much larger dependence on the reactant charge may be interpreted in terms of a faster spin-inverted geminate recombination which is caused by a heavy atom (ruthenium) of the reactant pair. The high F_1 of $MV^{+\cdot}$ formation in the ^{3}ZnPc quenching is consistent with a high yield of $MV^{+\cdot}$ with magnesium phthalocyanine in a 90% dimethyl sulfoxide aqueous solution containing of 10^{-3} mol/dm^3 of EDTA.[12]

The highly efficient production of $ZnPc^{+\cdot}$ and $MB^{2+\cdot}$ with the cobalt(III) compounds is attributable to the larger reorganization energy of the $Co^{III}(tpy)_2^{3+}$–$Co^{II}(tpy)_2^{2+}$ reaction or the $Co^{III}(phen)_3^{3+}$–$Co^{II}(phen)_3^{2+}$ reaction, since the large reorganization energy hinders the reverse electron transfer in the geminate radical pair, even though the free-energy change involved in the reverse process is so largly negative.

On the other hand, the reverse electron transfer from the iron(II) compounds to $ZnPc^{+\cdot}$ or $MB^{2+\cdot}$ in the geminate pair is a spin-allowed process, because both the total spin multiplicity of reactants and products are doublet;

$$^2[^2ZnPc^{+}\cdots{}^1ferrocene] \rightarrow {}^2[^1ZnPc\cdots{}^2ferrocenium\ ion]. \quad (6)$$

In this case, the rate of electron transfer can be estimated only from the free energy change and the reorganization energy. This situation is the same as that in the electron-transfer quenching of a singlet excited state. The singlet excited state of chlorophyll-a yields no cation radical in the quenching reaction by BQ.[5]

Decay of $ZnPc^{+\cdot}$ and $MB^{2+\cdot}$. The $ZnPc^{+\cdot}$ produced in the quenching of ^{3}ZnPc decayed in a complex way, resulting in a complete recovery of ZnPc within 0.1 s. The absorption spectrum of $ZnPc^{+\cdot}$ was changed to a broader one (shown in Fig. 2), which can be ascribed to a product in the decay of $ZnPc^{+\cdot}$, because the broad band around 700 nm appeared with the disappearance of the 835 nm band of $ZnPc^{+\cdot}$ in several milliseconds. The fact that both the disappearance rate of $ZnPc^{+\cdot}$ of the 700 nm band increased proportionally to the $ZnPc^{+\cdot}$ production suggests a bimolecular reaction of $ZnPc^{+\cdot}$, dimerization and/or disproportionation, although a single run of the decay of the absorbance at 835 nm could be analysed by means of the first-order kinetics. The recovery of ZnPc was accompanied by not only the disappearance of $ZnPc^{+\cdot}$, but also the decay of the second intermediate. An electron-transfer reaction may take place between oxidized species, $ZnPc^{+\cdot}$, and the second intermediate of ZnPc, and the reduced species of the oxidant. Actually, when $Co^{II}(tpy)_2^{2+}$ ($1\text{—}5\times10^{-5}$ mol/dm^3) was added to a sample solution containing ZnPc and $Co^{III}(tpy)_2^{3+}$, which is one of the products in the electron-transfer quencing, $ZnPc^{+\cdot}$ was completely converted to ZnPc without the appearance of the second intermediate. The rate constant of the electron-transfer reaction shown in Eq. 7 was obtained as 4.55×10^8 dm^3 mol^{-1} s^{-1} by analysing the pseudo-first-order decay of $ZnPc^{+\cdot}$ monitored at 835 nm:

$$^2ZnPc^{+\cdot} + {}^2Co^{II}(tpy)_2^{2+} \rightarrow ZnPc + Co^{III}(tpy)_2^{3+}. \quad (7)$$

The reverse electron transfer from the bulk proceeds via encounter complexes with either singlet or triplet multiplicity, the latter of which needs spin-inversion to the singlet complex on the surrounding reaction surface just as the reverse electron transfer in the geminate pair needs spin-inversion, triplet→singlet. Therefore, the second-order rate constant of the reverse reaction (k_{ret}) is expected to be correlated to the rate of the reverse electron transfer from the geminate pair in the forward process. It is conveinent to define the fraction of the reverse electron transfer (F_2) as the ratio of k_{ret} to the encounter-rate constant (k_e), which is assumed to be equal to the largest quenching-rate constant of ^{3}ZnPc (1.3×10^9 dm^3 mol^{-1} s^{-1}); *i.e.*, F_2 calculated as k_{ret}/k_e with $Co^{III}(tpy)_2^{3+}$ is 0.35, which is close to the fraction of geminate recombination ($1-F_1=0.30$). After $^3MBH^{2+}$ was converted to $MB^{2+\cdot}$ by $Co^{III}(phen)_3^{3+}$, $MB^{2+\cdot}$ disappeared *via* second-order kinetics with a rate constant of 1.3×10^9 dm^3 mol^{-1} s^{-1} in a solution with a high ionic strength: this process coincides with that of the product between $1-F_1$ (0.29) and the encounter-rate constant (k_e) of 4.5×10^9 dm^3 mol^{-1} s^{-1} in water.

The coincidence between the fractions of geminate recombination ($1-F_1$) and bulk recombination (F_2) supports mechanistic conclusions which have already been reached in the reductive quenching of $^3MBH^{2+}$ and $^3MB^{+}$ by iron(II) compounds[1] and aromatic compounds[2] and in the oxidative quenching of $^3Ru^{II}(bpy)_3^{2+}$ by $Cu^{II}(H_2O)_6^{2+}$.[35] On the basis of these studies, we can conclude that: (1) every quenching of the triplet state produces a geminate radical pair, unless the free energy change involved in electron transfer is largely positive and energy transfer to the quencher is possible; (2) the fraction of free-radical formation in the quenching is limited to the "cage escape probability," and (3) the fraction of geminate recombination, $1-F_1$, in the quenching process is close to k_{ret}/k_e. Consequently, we can predict F_1 from the rate constant of the thermal reverse electron-transfer process, which is itself possibly estimated from the free-energy change and the reorganization energy. Unfortunately, k_{ret} values estimated by using the equations of Marcus or Rehm and Weller are a little smaller than those observed for $^2ZnPc^{+\cdot}$–$^2Co^{II}(tpy)_2^{2+}$ and $^2MB^{2+}$–$^4Co^{II}(phen)_3^{2+}$. Though the estimated rate constants of the reverse process are considerably scat-

tered (see Table 3), the smaller rate constants estimated are consistent with the spin-statistical factor of the reverse process, as may be seen in the following reaction scheme;

$$^2ZnPc^{\dagger} + {}^2Co^{II}(tpy)_2^{2+} \begin{cases} \xrightarrow{1/4} {}^1(ZnPc^{\dagger}\text{--}Co^{II}(tpy)_2^{2+}) \\ \xrightarrow{3/4} {}^3(ZnPc^{\dagger}\text{--}Co^{II}(tpy)_2^{2+}) \end{cases} \rightarrow {}^1ZnPc + {}^1Co^{III}(tpy)_2^{3+}. \quad (8)$$

The Dehydrogenation of Cyclohexane by the Use of a Porous-glass Reactor††

Osamu SHINJI,† Makoto MISONO,* and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 22, 1982)

The dehydrogenation of cyclohexane was studied by the use of a double tubular reactor; the inner tube was made of porous glass, and the outer tube, of non-porous glass. The Pt/Al_2O_3 catalyst was placed inside the inner tube. It was demonstrated that dehydrogenation proceeded beyond the equilibrium conversion to be expected in the absence of a porous tube, by separating the hydrogen produced from the central reaction zone through the porous tube. When the reaction rate was so high that the reactant gas reached equilibrium near the inlet of the reactor, the dehydrogenation conversion became greater (more than twice the equilibrium conversion) as the flow rate in the inner path decreased and the flow rate in the outer path increased. The experimental data obtained by using the porous reactor were well reproduced by a computer simulation based on a simple model, in which such parameters as the flow rate, the gas permeability, and the reaction rate, were considered. The potential application of the present porous-reactor system was also discussed.

The dehydrogenation reaction, which usually requires a high reaction temperature because of the restriction caused by equilibrium, can be expected to proceed seemingly beyond equilibrium if the hydrogen produced by the reaction is removed selectively. Based on this idea, a palladium-alloy membrane was successfully applied to hydrogenation and dehydrogenation reactions.[1,2] Palladium acts as a barrier through which only hydrogen penetrates, and also as a catalyst. However, this membrane may not be used when palladium causes undesirable side-reactions and when poisons to palladium like sulfur are present. In these cases, porous glass[3] is sometimes very useful as the separation medium, since porous glass is fairly inert against chemicals and still has considerable physical strength. The permeability of gases can be controlled to some extent by changing the size and number of pores. Because of these advantages, the permeability of gases through porous glass has already been studied,[4] and application to isotope separation has been attempted.[5] Recently a porous-glass reactor was used to increase the hydrogen yield in the thermal decomposition of hydrogen sulfide.[6,7]

In the present study, a porous-glass reactor was constructed and the effectiveness of the reactor was experimentally examined by applying it to the dehydrogenation of cyclohexane. To confirm the effectiveness, the observed results were semi-quantitatively compared with the results of a computer simulation. On the basis of this comparison, the desirable properties of porous glass and the operation conditions are discussed.

Experimental

The porous reactor used in the present study was a double tubular reactor, as is illustrated in Fig. 1. The inner tube was made of porous Vycor glass (Corning Code No. 7930, outer diameter: 17.3 mm, wall thickness: 1.4 mm), with a mean pore size of 40 Å. The outer tube was ordinary non-porous Pyrex glass. Additional non-porous glass tubes were inserted tightly inside the upper and lower parts of the inner tube in order to minimize the permeation of gases outside the reaction zone (catalyst bed). By the insertion of these two tubes, the gas permeation outside the reaction zone was made negligible. 11 g of a Pt/Al_2O_3 catalyst (Pt: 0.38 wt%) in the form of 1.6 mm beads were packed in the inner tube (the length of the catalyst bed was 14 cm). Prior to the reaction, the catalyst was treated at 400 °C in an oxygen stream for 1 h and then reduced in a hydrogen stream for 1 h. No change in the catalytic activity during the reaction was detectable. Nitrogen, to which 16.0±0.5 mol% cyclohexane was mixed by passing it through an evaporator-saturator kept at 31 °C, was fed into the inner tube (inner path), and pure nitrogen into the outer path (path between the two tubes). The reaction temperature, as measured by an iron-constantan thermocouple, was 215—218 °C at the center of the catalyst bed. The outlet gases of the inner and outer paths were sampled by operating the valves and analyzed by two gas chromatographs directly connected to the valves. The material balance of the reaction was above 90%. The total pressures in the inner and outer paths were both close to 1 atm. A non-porous reactor, both tubes of which were non-porous glass of the same sizes as those of the porous reactor, was also used for purposes of comparison.

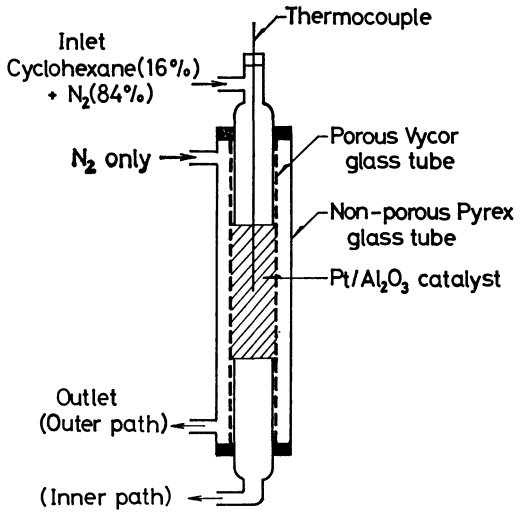

Fig. 1. Schematic diagram of porous reactor.

Results and Discussion

Permeability of Gases. If the diffusion of gases through the porous glass tube is effusion (Knudsen

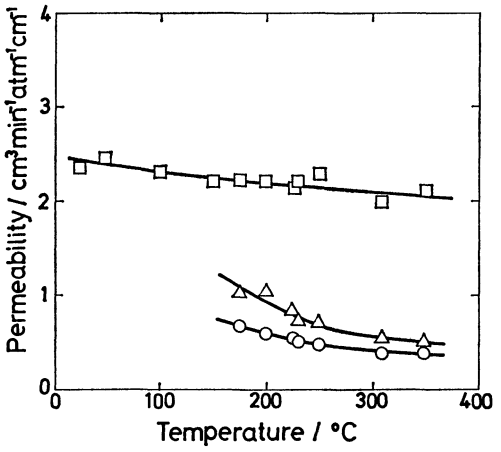

Fig. 2. Gas permeability of the porous tube as a function of temperature.
○: Cyclohexane, △: benzene, □: hydrogen.

flow), the rate of gas permeation can be described by:[4,5,8]

$$N_i = Q_i(P_i - p_i) \tag{1}$$

where N_i is the molar flow rate of the i component per unit of length of the porous glass tube, Q_i is the permeability of the i component, and P_i and p_i are the partial pressures of the inner and outer paths respectively. The permeability, Q_i, depends on the molecular weight, M_i, as in Eq. 2:

$$Q_i = \frac{a}{\sqrt{M_i T}}, \tag{2}$$

where T is the absolute temperature and a is a constant which depends on the properties of the porous barrier. The permeabilities, Q_i, of cyclohexane, benzene, and hydrogen for the porous glass tube used in the present work were measured in the following way. Mixtures of the three gases diluted with nitrogen were conducted into the inner tube loaded with glass beads in the same form as the catalyst, and then the outlet compositions of the reactor were analyzed. The Q_i value was calculated by means of Eq. 3:

$$f_{iL} = Q_i\left(\frac{P_{i0}+P_{iL}}{2} - \frac{p_{iL}}{2}\right)L, \tag{3}$$

where f_{iL} is the flow rate of the i component in the outlet gas of the outer path. The suffixes 0 and L indicate the inlet and outlet respectively, and L is the length of the reactor zone (catalyst bed). By increasing the flow rates in both paths, the changes in the flow rates along the reactor caused by gas permeation were made negligible. In this case, Eq. 3 is readily obtained by integrating Eq. 1 from l (the distance from the inlet of the catalyst bed)=0 to L.

Figure 2 shows the temperature dependence of the permeability. The permeation of hydrogen was obviously dominant, and hydrogen was effectively separated from the other two gases at higher temperatures. The Q_i ratio, as calculated from the molecular weight by means of Eq. 2, is cyclohexane:benzene:hydrogen= 1.00:1.04:6.48, while the observed ratio at 230 °C was 1.0:1.4:4.4. Hydrogen permeation was less preferential than was expected from Eq. 2. Moreover, the permeabilities of cyclohexane and benzene increased rapidly at low temperatures, indicating that diffusion processes other than effusion (probably surface diffusion[4]) increase for cyclohexane and benzene at lower temperatures.

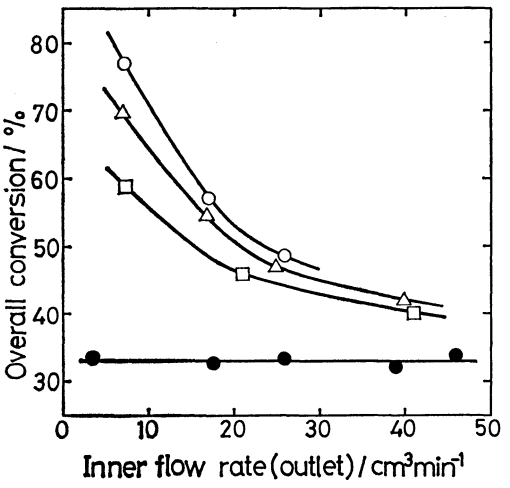

Fig. 3. Comparison of porous and non-porous reactors as applied to dehydrogenation of cyclohexane at 215 °C.
Open symbols: porous reactor [outer flow rate (outlet) was ○: 110 cm³ min⁻¹, △: 60 cm³ min⁻¹, and □: 20 cm³ min⁻¹]. ●: Non-porous reactor.

Dehydrogenation of Cyclohexane by the Use of a Porous Reactor. Comparison of Porous and Non-porous Reaction: The overall conversions obtained with the porous and non-porous reactors are compared in Fig. 3 as functions of the inner and outer flow rates. The overall conversion, X, for the porous reactor is defined and calculated by means of:

$$X = \frac{F_L P_{BL} + f_L p_{BL}}{F_L(P_{CL}+P_{BL}) + f_L(p_{CL}+p_{BL})}, \tag{4}$$

where F and f are the inner and outer flow rates respectively. The suffixes C and B denote cyclohexane and benzene components respectively, while the suffix L indicates the values at the outlet. The relation of the conversion *vs.* W/F obtained with the non-porous reactor showed that the catalytic activity was so high that the reactant gas reached equilibrium within 2 cm from the inlet of the catalyst bed. Consequently, the conversion for the non-porous reactor was constant in Fig. 3 and independent of the inner flow rate. Figure 3 shows clearly that the conversion for the porous reactor was higher than that for the non-porous reactor, which gave an equilibrium conversion. The lower the inner flow rate was, and the higher the outer flow rate was, the greater the overall conversion became. The highest conversion was more than twice the equilibrium conversion which would be expected in the absence of the preferential separation of hydrogen.

Effects of Inner and Outer Flow Rates. The outlet-gas compositions in the inner and outer paths are plotted against the inner flow rate in Fig. 4, together with the conversion. In these experiments, the outer

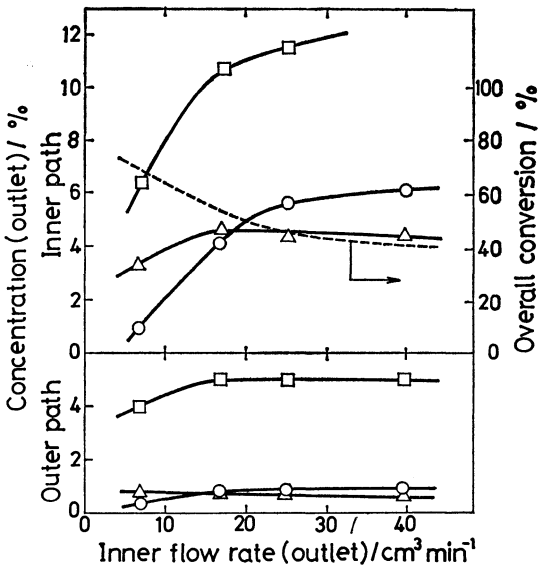

Fig. 4. Effects of inner flow rate on the composition at outlet and overall conversion.
Temperature: 215 °C, outer flow rate (outlet): 60 $cm^3\ min^{-1}$. ——: Composition, - - -: overall conversion, ○: cyclohexane, △: benzene, □: hydrogen.

flow rate was kept constant at 60 $cm^3\ min^{-1}$. The following things may be noted in this figure: (i) The hydrogen concentration in the outer path was much higher than the concentrations of cyclohexane and benzene in the outer path. This dominant permeation of hydrogen into the outer path is the reason why higher conversions were obtained for the porous reactor. (ii) At low inner flow rates, the conversion was high, and the concentrations of hydrogen and cyclohexane in the inner path were very low. The residence time of the reactant gas was probably so high as to remove sufficiently the produced hydrogen from the reaction zone, resulting in the marked increase in the conversion. (iii) The hydrogen concentration in the outer path decreased at a low inner flow rate, in spite of the sufficient removal of hydrogen from the inner path to the outer. This was, however, due to the insufficient supply of the reactant; therefore, it is not contradictory.

The higher conversions at high outer flow rates shown in Fig. 3 are apparently caused by the dilution of hydrogen in the outer path; hydrogen permeation is accelerated by the greater difference in the partial pressure of hydrogen between the inner and outer paths (see Eq. 1). In fact, the hydrogen concentration in the outer path decreased constantly with an increase in the outer flow rate.

Effectiveness of Porous Reactor when the Catalytic Activity is Low. Another experiment was carried out in which the apparent reaction rate was reduced by diluting the Pt/Al_2O_3 catalyst with glass beads of the same size as the catalyst. At 230 °C, the conversion for the porous reactor was 65% (inner flow rate: 7.0 $cm^3\ min^{-1}$, outer flow rate: 90 $cm^3\ min^{-1}$, while that for the non-porous was 40% (flow rate: 7.0 $cm^3\ min^{-1}$). Those results demonstrate that dehydrogenation, even in the case of a low catalytic activity,

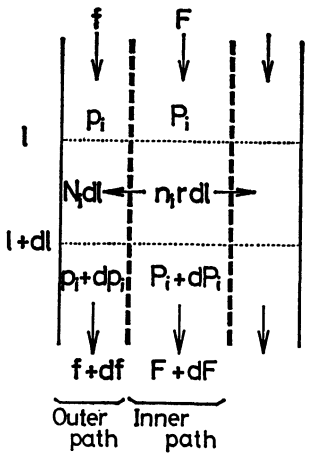

Fig. 5. Material balance in differential length of reactor, l—$l+dl$. F, f, *etc.*: See text.

proceeds beyond the equilibrium conversion (50% at 230 °C) which is to be expected in the absence of the hydrogen permeation, when the porous reactor is used.

Simulation of Reaction with Porous Reactor. A computer simulation was attempted to clarify further the characteristics of the porous reactor obtained experimentally, as has been described in the preceding sections.

Method of Calculation. (i) The rate equation for dehydrogenation was empirically approximated by:

$$r = k\left(P_C - \frac{P^2_{H,e}}{K} P_B P_H\right), \tag{5}$$

where r is the rate of benzene produced; P_i, the partial pressures of cyclohexane (C), benzene (B), and hydrogen (H) respectively; K, the pressure equilibrium constant; $P_{H,e}$, the partial pressure of hydrogen at equilibrium, and k, the rate constant. The k value was experimentally determined as a function of the temperature by the use of the non-porous reactor. The values of K were calculated as a function of the temperature and were experimentally justified in the present temperature region. The conversion calculated by Eq. 5 agreed well with those observed in the W/F range from 0.004 to 0.06 g min cm^{-3} at 200—230 °C. Because the total mass in the inner path changes along the catalyst bed, $P_{H,e}$ was calculated from the gas composition and the K value at every position of the reactor. (ii) The temperature distribution along the catalyst bed was measured (see Fig. 7) and approximated by a biquadratic function of l, the distance from the inlet of the catalyst bed. (iii) The permeation of the three gases was calculated by means of Eq. 1, where the permeabilities, Q_i, measured at 230 °C were used. The permeation of nitrogen was neglected because the reactant gases were very dilute. (iv) By assuming a plug flow in the reactor, a set of equations are obtained from the material balance for the three components in a differential length of the reactor, dl (see Fig. 5). For the inner path,

$$FP_i = (F+dF)(P_i+dP_i) + N_i dl + n_i r dl, \tag{6}$$

where $n_i = 1$, -1, and -3 for i=C, B, and H respec-

——: Cyclohexane, - - -: benzene, —·—: hydrogen, ·····: overall conversion.

tively. For the outer path,

$$fp_i = (f+df)(p_i+dp_i) - N_i dl \quad (i=C, B, H,). \qquad (7)$$

The flow rates, F and f, in Eqs. 6 and 7 are described in terms of P_i and p_i:

$$F = \frac{F_N}{1-\sum P_i} \text{ and } f = \frac{f_N}{1-\sum p_i} \quad (i=C, B, H,), \qquad (8)$$

where F_N and f_N are the flow rates of nitrogen (constant) in the inner and outer paths respectively. Equations 6, 7, and 8 are rewritten into six simultaneous differential equations in terms of P_i and p_i (i=C, B, and H); they were solved numerically by the Runge-Kutta method.

Results of Calculation. The calculated results are compared with the observed data in Fig. 6. A good agreement is seen in conversion, and the trend of the outlet compositions is essentially reproduced by the simulation. The simulation data given in Fig. 7 show how the compositions change in the reactor from the inlet to the outlet. Equilibrium is reached within 2 cm from the inlet of the catalyst bed. The hydrogen concentration decreases in the inner path, and increases in the outer path, along the reactor, as expected.

Conclusion

Both the experiments and the simulation proved that the dehydrogenation of cyclohexane proceeds beyond the equilibrium (expected in the absence of a porous tube) by means of the selective separation of hydrogen from the reaction zone by the use of a porous reactor. For example, the conversion for the porous reactor was 80% at 215 °C as compared with the equilibrium conversion of 35% for the non-porous reactor. Since the 80% conversion corresponds to the equilibrium conversion at 255 °C, the porous reactor reduces the reaction temperature by 40 °C. However, a low inner flow rate and a high outer flow rate are necessary to obtain a high conversion. The former is disadvantageous for the reaction efficiency, and the latter for the recovery of hydrogen, because of its low concentration. Thus, the efficiency of the porous reactor is significantly dependent on the permeation rate. It is, therefore, important, for the improvement of efficiency, to select a material with a high and highly selective permeability and to design a reactor with a large area for gas permeation. When such factors as the reaction rate, the permeability, *etc.* are once known, a computer simulation such as is shown in this study may be helpful for the design of a more efficient reactor and the optimization of the operation conditions.

With the aid of a porous reactor, characterized by simultaneous reaction and separation, the reaction temperature can be lowered. By taking advantage of this, the porous reactor may be used for the conversion of low-temperature thermal energy to hydrogen or other chemical energies. The reduction of the reaction temperature is also suitable for reactions that use thermally unstable catalysts or reactants.

The authors are grateful to Professor Toshio Uchijima (The University of Tsukuba), Mr. Hiromitsu Takeyasu, and Mr. Koichi Katamura for the preliminary experiments and discussions; they also wish to acknowledge the helpful advice of Dr. Masayuki Dokiya (National Chemical Laboratory for Industry) for the helpful discussions.

(Received January 25, 1982)

The polarized Raman spectrum of the maleic anhydride single crystal was studied. Prominent polarization behavior of the Raman bands was observed. Assuming the oriented gas model, the relative intensities of the non-totally symmetric intramolecular vibrations in various polarized Raman spectra were studied based on the data of the crystal structure. The assignments of the fundamental vibrational frequencies for maleic anhydride were reinvestigated through the polarization behavior of the Raman bands as well as the normal coordinate calculation.

The infrared and Raman spectra of maleic anhydride were first studied by Mirone and Chiorboli.[1] Most of their assignments were confirmed by the study of the polarized infrared spectrum of the single crystal observed by Di Lauro *et al.*[2] They also carried out the normal coordinate analysis for the in-plane vibrations.[2] Rogstad *et al.*[3] reexamined the vibrational analyses made by earlier workers on the basis of the band contours of the infrared vapor spectrum as well as the isotopic product and sum rules for deuterated molecules.

In this work, the fundamental vibrational assignments are reinvestigated based on the study of the polarized Raman spectrum of the single crystal of maleic anhydride as well as the normal coordinate analyses for in-plane and out-of-plane vibrations.

Experimental

Material. Maleic anhydride obtained from Nakarai Chemicals, Ltd. was purified by zone-refining of about 60 passages followed by sublimation under reduced pressure.

Optical Measurement. The polarized Raman spectrum of maleic anhydride was observed in the single crystal with a JEOL 400T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm line from an Ar^+ ion laser of Toshiba Model LAI-104-A.

Single crystals were grown in a closed tube by sublimation. Cubic crystals, about $(3\ mm)^3$, were obtained. A well-grown single crystal was selected and the crystal axes were determined by the observation of the birefringence under a polarization microscope. The direction of the crystal growth was selected as the c axis and the two-fold axis of the crystal as the b axis.

The crystal sample was excited with the laser beam polarized along the y axis in the z direction and the Raman scattering was observed in the x direction. The two polarized components of the scattering were analyzed by a polarizer inserted between the sample and the condenser lens. A compensator was placed between the condenser lens and the entrance slit in order to compensate the preferential sensitivity of the spectrophotometer for the light beams polarized along the y and z axes. The crystal was placed in the sample holder equipped with a goniometer in such a way that the crystal axes a, b, and c were parallel to the space-fixed axes x, y, and z. Thus, there are six ways of orientation of the crystal cube and a pair of polarized spectra are observed by the use of the polarizer for each orientation.

Twelve polarized Raman spectra were measured in total. The polarized Raman spectrum was denoted with four symbols following the notation adopted by Porto *et al.*,[4] such as a(ba)c. The letters inside the parentheses refer to the polarization directions of the excitation and scattering light beams in order, and the first and last letters refer to the propagation directions of the excitation and scattering light beams, respectively.

Depolarization measurements of the Raman spectrum were also made in the molten phase.

Calculation of Derived Polarizability Tensors

The crystal structure of maleic anhydride has been determined by Marsh *et al.*[5] Maleic anhydride crystallizes in the orthorhombic system of the space group D_2^4 with four molecules in the unit cell. The projection of the crystal structure on the ab plane is shown in Fig. 1. The correlation among the molecular point group C_{2v}, the factor group D_2, and the site group C_1 of the crystal is given in Table 1. No factor group splitting was observed for the bands due to the molecular vibrations. Thus, the relationship between the two derived polarizability tensors, for the free molecule and the crystal, was derived based on the sim-

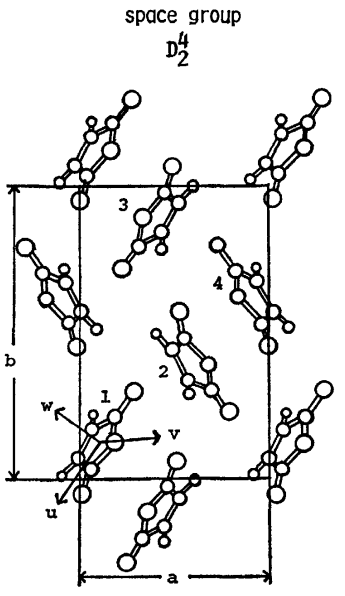

Fig. 1. Projection of the maleic anhydride crystal on the ab plane.

Table 1. Correlation diagram for maleic anhydride crystal

	Molecular group C_{2v}	Site group C_1	Factor group D_2
a_1	α_{uu}, α_{vv}, α_{ww}	a	a
a_2	α_{uv}		b_1
b_1	α_{uw}		b_2
b_2	α_{vw}		b_3

plified oriented gas model.

The evaluation of the matrix elements of the derived polarizability tensors of maleic anhydride was made following the procedures applied for naphthalene and anthracene crystals by Ito *et al.*[6] If the transformation matrix between the molecular-fixed coordinates u, v, w and the crystal fixed a, b, c is expressed by

$$T_1 = \begin{vmatrix} a_u & a_v & a_w \\ b_u & b_v & b_w \\ c_u & c_v & c_w \end{vmatrix}$$

for molecule 1, then the matrices for molecules 2, 3, and 4 are given for the D_2^4 crystal by

$$T_2 = \begin{vmatrix} -a_u & -a_v & -a_w \\ -b_u & -b_v & -b_w \\ c_u & c_v & c_w \end{vmatrix}, \quad T_3 = \begin{vmatrix} -a_u & -a_v & -a_w \\ b_u & b_v & b_w \\ -c_u & -c_v & -c_w \end{vmatrix},$$

and

$$T_4 = \begin{vmatrix} a_u & a_v & a_w \\ -b_u & -b_v & -b_w \\ -c_u & -c_v & -c_w \end{vmatrix},$$

respectively, where a_u is the direction cosine of the a and u axes, and so on. The derived polarizability tensor of a free molecule with respect to a normal vibration Q is given by

$$\alpha'_m(Q) = \begin{vmatrix} \alpha'_{uu} & \alpha'_{uv} & \alpha'_{uw} \\ \alpha'_{vu} & \alpha'_{vv} & \alpha'_{vw} \\ \alpha'_{wu} & \alpha'_{wv} & \alpha'_{ww} \end{vmatrix},$$

where $\alpha'_{uu}=\partial\alpha_{uu}/\partial Q$, and so on. The molecular tensors with respect to the crystal-fixed coordinates are given by

$$\alpha'_{m_1} = T_1\alpha'_m\tilde{T}_1$$

for molecule 1, and

$$\alpha'_{m_2} = T_2\alpha'_m\tilde{T}_2$$

for molecule 2, and so on. Under the assumption of the oriented gas model, the polarizability tensor of the unit cell, α_u, is assumed to be

$$\alpha_u = \alpha'_{m_1}Q_1 + \alpha'_{m_2}Q_2 + \alpha'_{m_3}Q_3 + \alpha'_{m_4}Q_4.$$

Using the symmetry coordinates S_{A_1}, S_{B_1}, S_{B_2}, and S_{B_3} appropriate to the four molecule unit cell, the derived polarizability tensors with respect to the unit cell vibrations are given for each symmetry species by

$$\alpha'_u(S_{A_1}) = \begin{vmatrix} A_{aa} & 0 & 0 \\ 0 & A_{bb} & 0 \\ 0 & 0 & A_{cc} \end{vmatrix} \quad \alpha'_u(S_{B_1}) = \begin{vmatrix} 0 & A_{ab} & 0 \\ A_{ba} & 0 & 0 \\ 0 & 0 & 0 \end{vmatrix}$$

where the A's are the functions of the direction cosines and of the elements of the derived polarizability tensor of the free molecule.

According to the character table and selection rules for the C_{2v} molecule, we derived simple analytical expressions of A's for the vibrations belonging to the different species of the molecule. These results are given in Table 2.

Normal Coordinate Calculation

A normal coordinate calculation was performed through the standard ***GF*** matrix method with a Facom M-200 computer at the computer center of Kyushu University. Heiderbrandt *et al.*[7] showed that the maleic anhydride molecule is planar and gave geometric parameters for this molecular structure. We used their geometric parameters for the construction of the ***G*** matrix elements.

The ***F*** matrix elements for the in-plane vibrations were evaluated with the potential field of an improved modification of the Urey-Bradley force field as described in the previous paper.[8] The potential field is given by

$$\begin{aligned} 2V = 2V_{UB} &+ \sum k^o(\Delta r, \Delta r) \\ &+ \sum k^m(\Delta r, \Delta r) + \sum k^m(\Delta R, \Delta R) \\ &+ \sum h^m(\Delta R, \Delta\alpha) + \sum h^m(\Delta R, \Delta\beta) \\ &+ \sum f^o(\Delta\alpha, \Delta\alpha) + \sum f^o(\Delta\beta, \Delta\beta), \end{aligned}$$

where V_{UB} is the basic Urey-Bradley force field, and k, h, and f are due to the valence force field. k^o and k^m are the interaction terms between two stretching coordinates oriented in the ortho and meta positions to each other, respectively, h^m is the interaction term between stretching and bending coordinates oriented in the meta position, and f^o is the interaction term between two bending coordinates oriented in the ortho position. R and α refer to the bond distances and angles constructing the ring, and r and β to the bond

distances and angles relating to the C=O and C–H side bonds, respectively.

For the out-of-plane vibrations, the valence force field and ϕ-type torsional coordinates were used. The notations of the force constants Q, q, P, p, and t are the same as those given by Whiffen.[9] The procedure of the calculation was exactly the same as described in the previous paper.[8]

Table 3. Force constants for in-plane vibrations of maleic anhydride

$K_{C'=C'}$ [a]	8.34	$F_{C'\cdots H}$	0.53
$K_{C'-C}$	3.67	$F_{C\cdots H}$	0.25

$H_{C'-C-O}$	0.49	$k^m_{r_O,r_O}$	0.06
H_{C-O-C}	0.50	$k^m_{R,R}$	−0.02
$H_{C'-C'-H}$	0.20	h^m_{R,α_O}	0.03
$H_{C-C'-H}$	0.08	h^m_{R,α_C}	0.01
$H_{C'-C-O}$	0.28	h^m_{R,β_O}	−0.02
H_{O-C-O}	0.66	h^m_{R,β_H}	−0.03
$F_{C\cdots C'}$	0.60	$f^o_{\alpha,\alpha}$	0.03
$F_{C'\cdots O}$	0.70	$f^o_{\beta_H,\beta_O}$	0.03
$F_{C\cdots C}$	0.96	$f^o_{\beta_H,\beta_H}$	0.06

Force constants denoted by K, H, F, and k are given in J/dm² (=mdyn/Å) units, and those denoted by h and f are in pJ/dm·rad (=mdyn/rad) and aJ/rad² (=mdyn·Å/rad²) units, respectively. a) C′ is a carbon atom bonded to H.

Results and Discussion

The force constants finally obtained after several iterative calculations for the in-plane and out-of-plane vibrations of maleic anhydride are given in Tables 3 and 4, respectively. The calculated frequencies and modes are given in Table 5, together with the experimental results.

The direction cosines were calculated using the X-ray diffraction data given by Marsh *et al.*[5] and the matrix elements of the derived polarizability tensors given in Table 2 were evaluated. The squares of the calculated elements of the derived polarizability tensors, which are proportional to the Raman intensities, are given in Table 6 for the non-totally symmetric vibrations. In this calculation, the values of α'_{uw}, α'_{vw}, and α'_{uv} are taken to be 1.

$(A_{bc})^2$	0.20	0.60	0.05

It is well known that all Raman bands belonging to one and the same symmetric species, except for the totally symmetric species, show the same polarization behavior in the various different polarized Raman spectra. Thus, the non-totally symmetric Raman bands were clearly classified into the specific symmetry species through the observation of the polarization behavior of the Raman bands. It is expected from Table 6 that the b_1 vibrations appear strongly in the (cc) and (aa) spectra, the b_2 vibrations in the (bc) spectrum, and the a_2 vibrations in the (bb) and (aa) spectra.

The six polarized Raman spectra observed in the different orientations of the single crystal are shown in Fig. 2. The vibrational frequencies observed in the crystal agreed well with the frequencies observed in the liquid.

a_1 Species. The totally symmetric vibrations were straightforwardly identified by depolarization measurements of the Raman bands observed in the molten state. The assignments given for the totally symmetric vibrations were the same as those given by earlier workers,[2,3] except for the C=O stretching (ν_1), C–H bending (ν_5), and ring deformation (ν_7) vibrations. The strong and polarized Raman bands observed at 1848, 1069, and 638 cm^{-1} in the molten state split into doublets, 1856 and 1843, 1065 and 1056, and 638 and 632 cm^{-1}, respectively, in the solid and single crystal. The 1843, 1056, and 638 cm^{-1} bands are stronger in intensity than the other components of the doublets, and do not show the polarization behavior characteristic to the non-totally symmetric species. Therefore, these bands were assigned to ν_2, ν_5, and ν_7 vibrations, respectively, although earlier workers have assigned the weaker components of the doublets, 1856, 1065, and 632 cm^{-1} to ν_2, ν_5, and ν_7 vibrations, respectively. As discussed later, the 1065 and 632 cm^{-1} bands should be assigned to the b_2 and b_1 vibrations, respectively, because of the polarization behavior of the Raman bands. The 1856 cm^{-1} band does not show polarization character of the non-totally symmetric vibrations, and thus, this band was assigned to the combination band of $\nu_{11}+\nu_{15}$ of the a_1 species.

b_1 Species. The non-totally symmetric Raman bands observed in the polarized Raman spectrum were divided into three types according to their relative intensities. The Raman bands of the first type, observed at 838, 632, and 188 cm^{-1}, are characterized by stronger intensity in the (cc) and (aa) spectra

compared with the intensity in the other polarized spectra. The 838, 632, and 188 cm^{-1} bands were observed with weak intensity in the (ca) spectrum and with very weak intensity in the (bc) spectrum, and were hardly detectable in the (bb) and (ab) spectra. The polarization behavior of these bands is consistent with b_1 vibrations according to Table 6. Therefore, these Raman bands were assigned to ring deformation (ν_{19}), H wagging (ν_{20}), and C=O wagging (ν_{21}) vibrations of the b_1 species, respectively.

a_2 Species. The Raman bands of the second type are those appearing strongly in the (bb) and (aa) spectra. A strong Raman band observed at 269 cm^{-1}, a medium intense band at 766 cm^{-1}, and a weak band at 548 cm^{-1} belong to this type. These Raman bands decrease their intensities in the order

of the (bb)>(aa)>(ab)>(ac)>(cc)>(bc) spectra, as can be seen in Fig. 2. Table 6 indicates that these bands should definitely be assigned to the a_2 bands. Therefore, these bands were to be assigned to C=O wagging (ν_{18}), H wagging (ν_{16}), and ring deformation (ν_{17}) vibrations of the a_2 species, respectively. Although Rogstad *et al.* have assigned a Raman band observed at 959 cm^{-1} to the ν_{16} vibration, which shows the a_2 polarization character, we assigned this band to the combination band of $\nu_8+\nu_{17}$, based on the weak intensity of this band as well as the normal coordinate calculation.

b_2 Species. The Raman bands of the third type are characterized by stronger intensity in the (bc) spectrum compared with the intensity in the other spectra. Medium intense bands observed at 1785 and 1065 cm^{-1}, a weak band at 1306 cm^{-1}, and very weak bands at 890, 700, and 564 cm^{-1} belong to this type, as can be seen in Fig. 2. According to Table 6, the Raman bands appearing strongly only in the (bc) spectrum should be assigned to the b_2 bands. Thus, these bands were assigned to the C=O stretching (ν_{10}), C–H bending (ν_{12}), C–C stretching (ν_{11}), C–O stretching (ν_{13}), ring deformation (ν_{14}), and C=O bending (ν_{15}) vibrations of the b_2 species, respectively.

Polarization behavior of these bands in the various polarized Raman spectra is consistent with the predicted ones except for ν_{10} and ν_{14} vibrations. Although the vibrations belonging to the b_2 species are expected to appear with about equal intensity in the (aa), (cc), (ab), and (ac) spectra according to Table 6, the intensity of the ν_{10} Raman band is weaker in the (aa) and (cc) spectra compared with that in the (ab) and (ac) spectra. The intensity of ν_{14} Raman band is expected to be strongest in intensity in the (bc) spectrum, but this is not the case in our spectrum. One of the reasons for these discrepancies is considered to be that the oriented gas model is not quite suitable for the prediction of the intensity of the off-diagonal spectra, such as (ab) and (ac), as discussed by Ito *et al.*[6]

The detailed vibrational analysis of the polarized Raman spectrum is given in Table 7.

The assignments given for the fundamental bands based on the polarized Raman spectra are consistent with the polarization behavior and band envelope of the infrared spectrum observed in the crystal and vapor phases, respectively. The agreement between the observed and calculated frequencies is satisfactory.

Estimation of Compressibility and Volume of Electrostriction Layer in Water–Methanol System and Its Application to the Partial Molar Volumes of LiCl, KCl, and CsCl in This System

Fumio KAWAIZUMI,* Hiroshi SUZUKI, Hiroyasu NOMURA, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 25, 1982)

A theory of electrostriction based on the spherical symmetry of electric field around ion and the dielectric continuum of solvent has been applied to the mixed solvent of water–methanol. The isothermal compressibility, κ_T, and the volume decrease, ΔV of primary solvation layer have been calculated for univalent ions. Calculation procedure consists of two steps; 1) calculation of the variation of electric field strength and dielectric constant with the distance from ion, 2) calculation of the compressibility and the volume decrease of electrostriction layer. In step 2), the calculation method proposed by Desnoyers *et al.* (*J. Chem. Phys.*, **43**, 243 (1965)) was used. Parameters necessary for the calculation were estimated in an appropriate manner and the results of calculation are shown as plots of κ_T and ΔV, *vs.* the distance from the center of ion. Partial molar volumes of LiCl, KCl, and CsCl in water–methanol system have been measured and the disordered part of partial molar volume has been determined after taking account of the values of κ_T and ΔV of the primary solvation layer.

The problem of electrostriction in solutions of electrolyte has an intimate relation to those of ionic hydration and partial molar volume of ion. Since the pioneering work of Webb,[1] numerous investigators have discussed the theories of electrostriction of aqueous solutions, most important of which are, in our opinion, those proposed by Padova[2] and Desnoyers *et al.*[3] The electrostriction is a universal phenomenon and it is not inherent to aqueous media. However, only a few works[4,5] have been reported dealing with the theoretical estimation of electrostriction effects in nonaqueous solution.

On the other hand, in recent years much progress has been achieved in the determination of various physicochemical properties of ion in nonaqueous solvent. The data obtained are now summarized in the form of review.[6,7] For the discussion of these data, the consideration on the effects of electrostriction in nonaqueous solvents should be required. Generally speaking, the interpretation of the differences among the data found in different solvents is often disputable. The sound comparison of the data on the behavior of ions in different solvents or different compositions of the solvent system can only be possible after the electrostriction effects are subtracted from what has been observed in each solvent. This is one of our fundamental points of view. The purposes of this work consist of two parts; one is to develop a method to estimate the electrostriction effects in mixed solvent system for which the reliable physical constants necessary for the estimation are often lacking, while the other is to discuss the numerical values obtained by applying the results of the present calculation to the actual system. In this study we have chosen the mixed solvent consisting of water and methanol and have estimated the compressibility and the volume decrease of the primary solvation layer in this system at 25 °C. The study of the solution properties in mixed aqueous solvents leads to the firm interpretation of the behavior of the ion in nonaqueous solvents. In addition, this mixed solvent system is widely used for inorganic solute species and a limited number of physical constants are known.

Desnoyers *et al.*,[3] concentrating attention on the local behavior of the solvent itself, assumed that the only role of the ions is to provide the polarizing electrostatic field which acts on the solvent and that an ion is a hard incompressible sphere surrounded by a spherical primary coordination shell whose thickness is equal to the diameter of the solvent. In their treatment the volume decrease due to the electrostriction was given as a function of the distance from the center of ion and the total electrostriction volume was evaluated for some particular ions such as Na^+ and F^- after considering the number of the coordinated (hydrated) water. The validity of the present calculation of the electrostriction effects in the mixed solvent system is limited in the frame of the idea and the procedure proposed by Desnoyers *et al.*[3] It should be stressed that this work is a macroscopic approach for the elucidation of the solute-solvent interactions. In addition to the calculation, the partial molar volumes of three kinds of alkali chlorides, LiCl, KCl, and CsCl in water–methanol mixture have been measured and the results of the present calculation have been applied to obtain the disordered part of the partial molar volumes. The reason for the choice of these alkali chlorides will be mentioned in the section of the discussion of this paper.

Theory and Calculation

The calculation of the electrostriction effects will be divided into two part; one is the calculation of the dielectric saturation effects, namely the variation of field strength and dielectric constant with the distance from the center of ion, while the other is that of the compressibility and volume decrease of the electrostriction layer. In what follows, each part will be described separately.

Throughout the calculation, the spherical symmetry of the electric field around ion and the dielectric continuum of the solvent are assumed. A controversy may exist for the application of the dielectric continuum model to the mixed solvent such as water-methanol mixture, as the preferential hydration is often observed in mixed aqueous solvent. If the preferential

hydration (more generally, solvation) occurs in a mixed solvent system, this obviously contradicts the basic assumption of the dielectric continuum of the solvent. Nevertheless, we would like to employ the spherical symmetry of the electric field and continuum model of solvent on the ground of the conviction that the *macroscopic* approach can give information on the *microscopic* level of solute-solvent interactions, as for the case of the application of the Debye-Hückel theory to the evaluation of association constant and interionic distance parameter from the conductivity data.

Calculation of Dielectric Saturation Effects. Calculation procedure is the same as given by Laidler.[8] The dielectric behavior in the vicinity of ions can be expressed in terms of differential dielectric constant, ε_d, which is defined and given by the relation[3,8,9]

$$\varepsilon_d \equiv d\boldsymbol{D}/dE = [(\varepsilon_o - n^2)/(1+bE^2)] + n^2, \quad (1)$$

where $\boldsymbol{D}$ is the dielectric displacement, E, the field strength, ε_o, the dielectric constant at zero field strength, n^2, the square of refractive index, and b a constant as described below. The electric displacement $\boldsymbol{D}$ at a distance r from the center of an ion of charge ze is ze/r, which should be equal to $\boldsymbol{D}$ obtained by the integration of Eq. 1. It follows then that

$$\frac{ze}{r^2} = n^2E + [(\varepsilon_o - n^2)/b^{1/2}]\tan^{-1}b^{1/2}E. \quad (2)$$

Equation 2 can not give the explicit solution of E as a function of r, but it can afford tabulated values of r for assumed values of E. Then, the substitution of the numerical values of $E=E(r)$ into Eq. 1 permits to show the variation of ε_d with the distance from the center of ion. Values used in calculation are as follows:

ε_o; given or estimated from the data found in Ref. 10.

b; 1.08×10^{-8} e.s.u. for water[3,8] and 2.2×10^{-8} e.s.u. for methanol.[5] Values in the mixture are calculated on the assumption of linear variation of b with mole fraction of the component in the solvent.

n^2; determined by the present authors.

Results of calculation are illustrated as a series of curves in Fig. 1 (E *vs.* r) and Fig. 2 (ε_d *vs.* r) for univalent ion at various compositions of water–methanol system at 25 °C. Figure 1 shows that the field strength at a certain distance from the center of the ion becomes higher with the content of methanol. Figure 2 is essentially the same as Fig. 1 but it has an advantage to give us an explicit image of the dielectric saturation effects and the extent of the dielectric saturation layer. In Fig. 2, the smallest values of ε_d is determined by the relation that $\varepsilon_d=n^2$, which is approximately 1.8 for both water and methanol at 25 °C. If the distance at which ε_d begins to be effectively field-dependent is determined on the criterion of $\varepsilon_d=1.9$, following values are obtained: 1.68, 1.74, 1.96, 2.19, 2.52, 2.87, and 3.00×10^{-8} cm for the contents of methanol equal to 0, 10, 30, 50, 70, 90, and 100 mol%, respectively. The dielectric saturation layer becomes larger with the content of methanol in the mixed solvent. The distinction between bulk solvent and dielectric saturation layer is less clear in methanol than in water as is seen in Fig. 2.

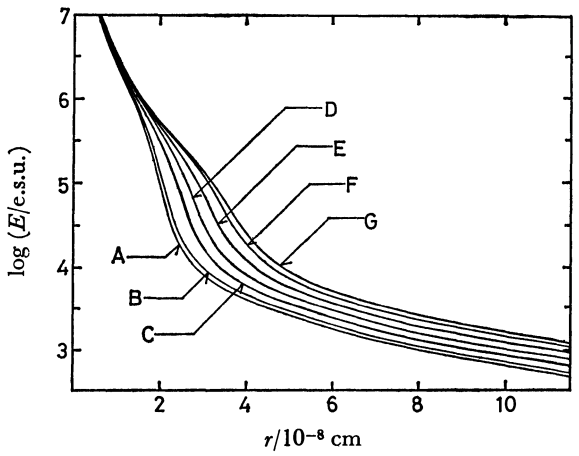

Fig. 1. Relation between the logarithm of the field strength, E, and the distance from the center of univalent ion in water–methanol system at 25 °C.
Symbols A, B, C, D, E, F, and G correspond to the mole per cent of methanol equal to 0, 10, 30, 50, 70, 90, and 100, respectively.

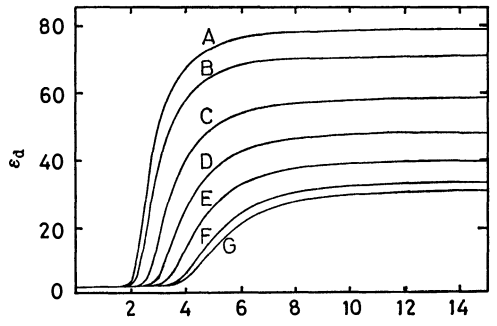

Fig. 2. Variation of differential dielectric constant with the distance from univalent ion in water–methanol system at 25 °C.
Symbols A—G are the same as in Fig. 1.

Calculation of the Compressibility of Electrostriction Layer. According to Desnoyers *et al.*,[3] the relation between the field strength and the effective pressure, defined as the pressure which, in the absence of the field E, would produce the same volume change of the solvent that E produces is expressed as (Eq. 13 in Ref. 3),

$$dP = [4\pi D(1+bE^2)]^{-1} \times \left[\varepsilon_o A\left(1+\frac{P}{B}\right)^A - n^2C\left(1+\frac{P}{B}\right)^C\right]EdE + \frac{n^2C}{4\pi D}\left(1+\frac{P}{B}\right)^C EdE, \quad (3)$$

where parameters, A, B, C, and D are the constants involved in the following equations:

$$\frac{1}{\varepsilon}\left(\frac{\partial\varepsilon}{\partial P}\right)_{T,E} = \frac{A}{B+P}, \quad (4)$$

$$\frac{1}{n^2}\left(\frac{\partial n^2}{\partial P}\right)_{T,E} = \frac{C}{B+P}, \quad (5)$$

$$\kappa_T = -\frac{1}{v}\left(\frac{\partial v}{\partial P}\right)_{T,E} = \frac{D}{B+P}. \quad (6)$$

In other words, the pressure dependence of dielectric constant, square of the refractive index, and isothermal compressibility can be represented in terms of so-called Tait equation.[11] The use of the Tait-form equation and the adoption of the same value of B through Eqs. 4—6 for such high pressures as in the electrostriction layer are the two essential points employed by Desnoyers *et al.* in deriving Eq. 3 which made the calculation very tractable. The expression of pressure dependence of dielectric constant and square of refractive index in terms of Tait-form equation is understandable if we consider that the variation of these properties with pressure is mainly ascribed to the variation of volume with pressure, as seen by Clausius-Mosotti and Lorenz-Lorentz equations.

In order to carry out the integration of Eq. 3 values of the parameters A, B, C, and D must be known for the solvent composition under consideration. However, in water–methanol mixture, limited data are available on the pressure dependence of the dielectric constant,[12] and for the (P, n) and (P, κ_T) relations, no reliable data can be found at present. Therefore, we are obliged to do much effort for the estimation of the values of these parameters in the mixture. A rather expounded description of the estimation procedure may be permitted in the light of the future application for other solvent systems.

Parameter B: In the first step of the estimation procedure, the parameter B is to be considered. As B is assumed to be the same in Eqs. 4—6, its value can be otained from any one of the three sets of relationships, (P, ε), (P, n), and (P, κ_T). Even with excellent data, to obtain a set of unique parameter (A, B), (C, B), and (D, B), is not an easy task. Several sets of parameters may equally well represent the available data for a fluid. For example, as shown in Table 1, values of B and D have been known for water,[3,13] and methanol.[13] But this value of B for water differs considerably from the value reported by other investigators from the variation of dielectric constant with pressure ($B=4.547\times10^8$ Pa and $A=0.1916$).[14] As it will be shown later, the parameter A plays only a minor role in the calculation of the electric field of practical interest ($E\geqq5\times10^5$ e.s.u.). On considering this factor along with the fact that the Tait equation was originally derived to express the volume change with pressure, the value of B in the set (B, D) was preferred.

For mixture of water and methanol, Schadow and Steiner[12] have given the data of the pressure dependence of dielectric constant at 30 °C for weight per cent of methanol equal to 0, 20, 40, 60, 80, and 100. Their data are, however, not accurate enough to be usable for the simultaneous determination of the parameters B and A. No theory has been proposed for the estimation of the value of B in mixture from its value in pure component. Therefore, values of B in mixture were estimated on the simple assumption of the linear variation of parameter B with mole fraction of the component in the mixed solvent system, without taking account of the values of other parameters.

Parameter D: Values of D in the mixed solvent were calculated from the data of isothermal compressibility. Under the condition of $B\gg P$, Eq. 6 should lead to the compressibility at ordinary pressures. In fact, the relation $\kappa_T(P=10^5\text{ Pa})=D/B$ holds for the reported values of B and D for water and methanol, as seen in Table 1. It is remembered that errors involved in the estimated values of B are largely compensated for by the evaluation process of the parameter D.

Values of κ_T necessary for the estimation of D were obtained by the aid of the thermodynamic relation,

$$k_T=\kappa_s+\left(\frac{Tv\alpha^2}{C_p}\right). \tag{7}$$

Meaning of the symbols used in Eq. 7 and the values used are;

κ_s; adiabatic compressibility, whose values are given from the measurements of ultrasonic propagation velocity and density. For the measurements of ultrasonic velocity, an ultrasonic interferometer was used.

v; volume.

α; thermal expansion coefficient. The value at 25 °C is calculated from the density at 20 and 30 °C.

C_p; specific heat capacity, whose values are found in the literature.[15]

Parameter A: Slightly different values of B have been given for water and methanol for the pressure dependence of dielectric constant.[17] Therefore, the parameters A in water and methanol were recalculated using the value of B obtained from the pressure dependence of the isothermal compressibility. For mixture, values of parameter A were determined by the fitting of experimental results of (P, ε) relation[12] using the estimated values of B. Average values of A determined for pressures higher than 7×10^7 Pa were adopted. Surprisingly values of A thus determined vary linearly with mole fraction of the component. To illustrate the validity of the estimated values of A and B in the mixture, the comparison between (P, ε) relation determined experimentally and that calculated from Eq. 4 using the estimated values of A and B is represented in Table 2. The agreement is satisfactory.

Parameter C: Two reports have been published on the pressure dependence of the refractive index of water.[18,19] These results were combined and recalculated to obtain the parameter C in Eq. 5, irrespective of the difference in the experimental conditions in two works (in Ref. 18, at 25 °C and up to 1.50×10^8 Pa, while in Ref. 19, at 24.8 °C and *ca.* to 1.1×10^8 Pa). Recalculation yields $C=0.0678$ for $B=2.996\times10^8$ Pa. This value is in fair accordance with the one used by Desnoyers *et al.* ($C=0.0685$).[3] Data on methanol[20] were similarly recalculated as for the case of water. Values of C in the mixture were estimated on the assumption of the linear variation of parameter C with the mole fraction of the component. This assumption seems reasonable in view of the linear variation of parameter A and the small difference in the value of C in water and methanol.

Final results of the numerical values of the parameters A, B, C, and D as well as κ_T are summarized in Table 1. Once the values of these parameters are determined, the integration of Eq. 3 reduces to a problem of mathematics.

At low field intensities ($bE^2\ll1$) or at high field

TABLE 2. COMPARISON BETWEEN EXPERIMENTAL (30 °C) AND CALCULATED (P, ε) RELATIONS OF WATER–METHANOL MIXTURE

MeOH wt%	$P/10^5$ Pa					
	0.980	257	505	717	913	1107
20	69.01	69.75	70.50	71.52	72.73	73.51
		69.97	70.84	71.55	72.17	72.79
40	60.48	61.10	61.75	62.72	63.71	64.69
		61.38	62.18	62.84	63.40	63.94
60	53.02	53.60	54.28	55.13	56.10	57.00
		53.96	54.80	55.46	56.03	56.56
80	43.72	44.20	44.75	45.61	46.54	47.52
		44.68	45.50	46.14	46.68	47.18

Values in upper and lower rows correspond respectively to experimental[12] and calculated results.

($bE^2 \gg 1$), Eq. 3 can be simplified and the integration leads to low-field limit (Eq. 6 of Ref. 3) and high-field limit solutions (Eq. 14 or Ref. 3), respectively. In high-field limit solution, the parameter A has little effect. Low-field limit corresponds to Born approximation in which dielectric saturation effects are neglected. It has been shown that the field near ordinary ions in water is of such value as to make the simplification of Eq. 3 inapplicable.[3] In the present work dealing with water–methanol system, Eq. 3 was directly integrated by means of a digital computer FACOM M-200 of Nagoya University Computer Center. Runge-Kutta-Gill method was used. Results of the integration of Eq. 3 are represented in Fig. 3, where the curves related to 10, 30, 70, and 90 mol% of methanol are eliminated for the sake of simplicity. The slope in low-field limit is independent of the composition of the solvent, taking the value of 2, while the slope in high-field limit depends weakly on the properties of the solvent concerned.

Experimental

The determination of the partial molar volumes of LiCl, KCl, and CsCl which was done as a part of the present study is briefly mentioned here. Salts used are of guaranteed grade reagent supplied from Nakarai Chemicals and they were used without further purification. Densities of solutions containing the salt were measured with pycnometer of 20 cm^3.

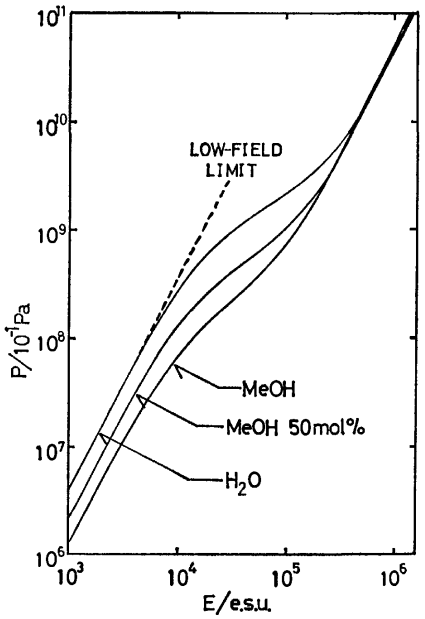

Fig. 3. Numerical solutions to pressure-field relationships in Eq. 3 for univalent ion in water, 50 mol% of methanol, and pure methanol.

Results and Discussion

Results of Calculation. In Fig. 3, the high-field limit approximation holds for $E > 4 \times 10^5$ e.s.u., which corresponds to $r < 2.5 \times 10^{-8}$ cm in methanol in Fig. 1. It follows then that the calculation of electrostriction effects in methanol must at least be done on high-field approximation for the familiar alkali metal and halide ions. Figure 3 also indicates that in methanol the low-field approximation which corresponds to the simple Born approximation holds only for $E < 10^4$ e.s.u., a value equivalent to $r > ca.\ 5 \times 10^{-8}$ cm in Fig. 1, namely, the Born approximation is generally unacceptable in the solvent methanol. On the other hand, the combination of the results shown in Figs. 1 and 3 enables P to be expressed as a function or r. Substitution of the pressure given as $P(r)$ along with the numerical values of parameters B and D into Eq. 6 can offer the relation between κ_T and the distance from the ion, which is represented in Fig. 4. Desnoyers *et al.*[3] have shown the variation of κ_T with the field strength in water, but to discuss the dependence of ionic hydration on the dimension of ion, the relation

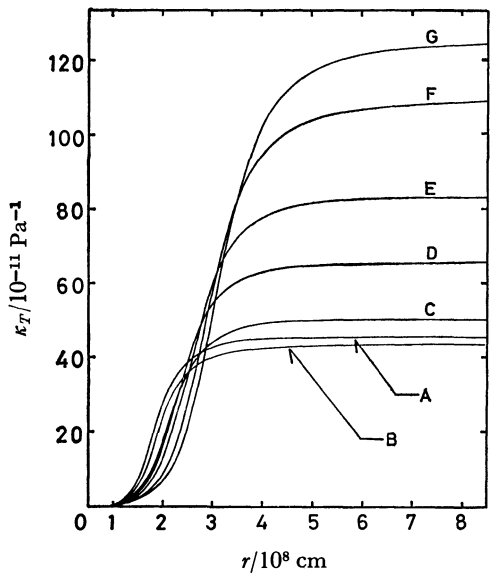

Fig. 4. Variation of the compressibility of solvent with the distance from the center of univalent ion in water–methanol system.
Symbols A—G are the same as in Fig. 1.

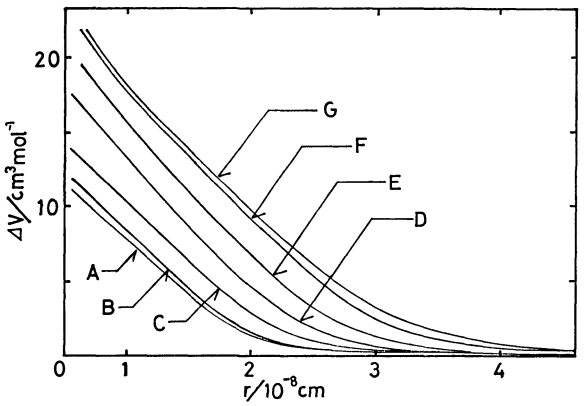

Fig. 5. Volume decrease of one molar of solvent expressed as a function of the distance from the center of univalent ion in water–methanol system at 25 °C.
Symbols A—G are the same as in Fig. 1.

as shown by Fig. 4 is preferable. As a consequence of the estimation procedure of the parameters B and D, the value of κ_T approaches asymptotically that of the pure solvent with increasing distance from the center of ion.

The volume decrease of solvent defined as $\Delta V = v^\circ - v(P)$, where $v(P)$ is the molar volume of the solvent at the effective pressure P, can be evaluated from the relation,

$$\ln (v^\circ/v(P)) = D \ln\left(1+\frac{P}{B}\right). \quad (8)$$

This equation derives from the integration of Eq. 6. It should be noted that the quantity ΔV does not refer to the absolute amount of volume decrease of the solvent but to the relative decrease of volume assigned to one molar of solvent at distance r from the center of the univalent ion. The variation of the volume decrease ΔV for univalent ion in mixed solvent system of water–methanol at 25 °C is illustrated in Fig. 5.

Table 3. Partial molar volumes of CsCl, KCl, and LiCl in water-methanol system at 25 °C

MeOH mol%	$\overline{V}_2^\circ$/cm^3 mol^{-1}		
	CsCl	KCl	LiCl
0	39.1	26.8	18.2
30	39.2	27.7	15.9
50	37.5	27.3	13.4
70	32.6	22.4	8.5[a)]
90	25.3	13.4	4.2[a)]
100	23.6[b)]	5.9[b)]	−4.9[b)]

a) Owing to the limited solubility of LiCl, uncertainties are larger than the other cases. b) Values found in Ref. 21.

At this point it seems worth while to sum up ambiguities involved in the estimation and the results obtained:

I) Can Tait-form equation containing only two parameters really represent the pressure dependence of ε, n^2, and κ_T in such high pressure regions as in electrostriction layer with the same accuracy?

II) Even if the Tait-form equation is correct, should the parameter B be the same for three physical quantities? Nearly the same numerical values have been found for B associated with ε and that associated with κ_T.[17] But is the fact a mere coincidence?

III) Parameters A, B, C, and D have not been known with the same precision. Moreover, errors involved in estimating the values of these parameters in the mixed solvent differ for each parameter.

Authors admit that the present treatments of electrostriction are not free from the controversy on the ambiguities mentioned just above. None the less, the result of calculation can afford much information on the order and the magnitude of electrostriction in the mixed solvent system as described below. For example, Fig. 4 shows that for many ordinary univalent ions the compressibility of the primary solvation layer in methanol can be neglected in comparison with that of bulk solvent if the electrostriction layer is assumed to correspond to the primary solvation layer.

Application of the Calculated Results to the Partial Molar Volumes of LiCl, KCl, and CsCl. As mentioned at the begining of this paper, the partial molar volumes of ions are discussed in their relation to electrostriction effects. In order to apply the results of the calculation, the partial molar volumes, $\overline{V}_2^\circ$, of salts LiCl, KCl, and CsCl have been determined in water–methanol system. The reasons for the choice of these salts are as follows: Throughout the present work, the continuum model of the solvent has been assumed. This assumption does not hold well for transition metal ions in mixed aqueous solvent, because the ligand-field is generally strong for these ions and the preferential hydration occurs, which contradicts our basic assumption. For alkali metal, in particular for lithium, and chloride ions, preferential hydration may occur, but to much lesser extent than for the case of transition metal

TABLE 4. EFFECTIVE RADIUS AND VOLUME DECREASE OF ONE MOLAR OF SOLVENT FOR IONS Cs^+, K^+, Li^+, AND Cl^- IN WATER–METHANOL SYSTEM AT 25 °C

MeOH mol%	$r_e/10^{-8}$ cm				$\Delta V/cm^3\ mol^{-1}$

ions, and ionic associations are seldom observed for alkali chlorides. Thus alkali chlorides are considered to be the best salts for the present work. In pure methanol, the determination of the reliable values of $\overline{V}_2^\circ$ was difficult on account of the low solubility of the salts and the values in the literature[21] were adopted. Results of the determination of $\overline{V}_2^\circ$ are given in Table 3. For three alkali chlorides investigated, the variation of $\overline{V}_2^\circ$ is small up to 50 mol% of methanol but in concentration of methanol above 70 mol%, $\overline{V}_2^\circ$ decreases remarkably with the content of methanol in the solvent.

In the application of the theoretically estimated electrostriction effects to the actual ions in solution, a problem of crucial importance is how to evaluate the effective radius of the solvated ion. This problem is inherent to any theory dealing with the electrostriction effects. It is not the ion but the solvent around ion which contracts under electrostrictive pressures. Therefore, the effective radius of the solvated ion concerned in the present treatment must be larger than the crystallographic radius, r_c. In this respect, the use of Stokes radius, r_s, derived from the hydrodynamic consideration of ion in solution, is inappropriate, as $r_s/r_c<1$ has been observed for large alkali and halide ions. On the same ground, Gourary-Adrian radii[22] are rejected, though sometimes they have been used. Desnoyers *et al.*[3] considered the distance from the center of ion to the center of a neighboring water molecule. Their consideration, however, is not free from the disputation. We have evaluated the effective ionic radius, r_e, by the aid of the relationship between $\overline{V}_{ion}^\circ$ and r_e given by Padova.[2,5] In his papers,[2,5] r_e was defined as the intrinsic radius of ion and the intrinsic volume of the ion in solution $\overline{V}_{int}$, was expressed as $\overline{V}_{int}=4/3\pi N_0 r_e^3$, where N_0 is the Avogadro number. On the contrary, we have used the value of r_e as a *literal* effective radius of the solvated ion, without taking account of the original physical significances of r_e in the Padova's model for the calculation of $\overline{V}_{ion}^\circ$. As Padova used incorrect values of $\overline{V}_{ion}^\circ$,[2,5] effective ionic radii have been determined using the generally accepted values of $\overline{V}_{ion}^\circ$ in water[23] and methanol.[21] The estimated values of r_e are given in Table 4. In both solvents values of r_e are larger than those of r_c and the variation of r_e with the ionic species seems to be reasonable. In the mixed solvent system, it was assumed that r_e varies linearly with the mole fraction of the component. Corresponding to each value of r_e, the amount of volume decrease of one molar of solvent, ΔV, is determined from Fig. 5. Table 4 shows the numerical values of r_e and ΔV thus determined for ions Cs^+, K^+, Li^+, and Cl^- in water–methanol system. Padova,[5] using the theoretical coefficients of the concentration dependence of the partial molar volume and partial molar compressibility, estimated the average theoretical electrostriction volume per mole of solvent methanol, which is equal to 7.54 $cm^3\ mol^{-1}$. In comparison with this value, the results of the present calculation are larger by 1—4 $cm^3\ mol^{-1}$ for cations, while the agreement is satisfactory for Cl^- ion. The total electrostriction volume arising from the addition of one molar of 1-1 type salt into solvent, expressed as $\overline{V}_e$, is given by the relation,

$$\overline{V}_e = \Delta V(M^+)n_s(M^+) + \Delta V(X^-)n_s(X^-), \quad (9)$$

where $n_s(M^+)$ and $n_s(X^-)$ are solvation numbers for cation and anion, respectively. However, the solvation number is experimentally determined for salt MX and the assignment of solvation number to cationic and anionic components requires further assumptions. Accordingly, instead of Eq. 9 we have adopted the following relation to calculate $\overline{V}_e$ of the salt MX:

$$\overline{V}_e = [\Delta V(M^+)+\Delta V(X^-)]\bar{n}_s(M^+, X^-), \quad (10)$$

where $\bar{n}_s(M^+, X^-)$ is the solvation number averaged over cation and anion and it is assumed to be equal to a half of n_s for the salt MX. The determination of solvation number in taking account of the volume decrease and the compressibility of the primary solvation layer can be attained by the use of an expression,[24]

$$\bar{\kappa}_2^\circ = \kappa_2 + \frac{n_s v_s}{\bar{v}_2}(\kappa_{sol}-\kappa_1) \quad (11)$$

In Eq. 11, κ stands for the compressibility and $\bar{v}_2$ is the partial specific volume of solute, and the subscripts s and sol (to avoid the confusion with κ_s used in Eq. 8) refer to the solvation layer, while subscripts 1 and 2 refer to solvent and solute, respectively. The derivation of Eq. 11 and the determination of the value of $\bar{\kappa}_2^\circ$ from the data of compressibility and density of solution is described elsewhere.[24] For the measurements of the compressibility of solutions, an ultrasonic interferometer was used.[25]

In the calculation of n_s of salt MCl from Eq. 11, the compressibility of the solvation layer, κ_{sol}, was not considered for each ion but a mean value of κ_{sol} for salt MCl was considered and a value of κ_T at r equal

Table 5. Compressibility of solvation layer, solvation number, total electrostriction volume, $\overline{V}_e$, and disordered partial molar volume, $\overline{V}_d$, of CsCl, KCl, and LiCl in water-methanol system at 25 °C

70	20.4	14.2	11.4	0.8	2.6	4.7	4.2	16.9	34.1	9.7	18.5	27.2
90	16.2	12.1	9.7	1.3	3.5	5.9	9.5	29.4	53.1	7.7	22.0	41.9
100	13.0	9.9	8.6	1.6	3.5	5.8	12.4	30.3	53.4	8.9	15.4	33.1

The numerical values of $\overline{V}$(crystal)/cm^3 mol^{-1} for CsCl, KCl, and LiCl are 27.1, 20.8, and 15.4 respectively.

to $1/2(r_e(M^+)+r_e(Cl^-))$ was taken. This step of calculation corresponds to the use of Eq. 10 in place of Eq. 9. As mentioned above, it has been assumed that no preferential solvation occurs in the mixed solvents, n_s being the average solvation number.

It is generally admitted that the partial molar volume of an ion at infinite dilution, $\overline{V}_{ion}^{\circ}$, can be attributed to the following components:

$$\overline{V}_{ion}^{\circ} = \overline{V}(\text{crystal}) - \overline{V}(\text{electrostriction}) + \overline{V}(\text{disordered}) \quad (12)$$

$\overline{V}$(crystal) can be evaluated using the radius of the ion. Pauling radius was used in the evaluation of $\overline{V}$(crystal). Upon substituting into Eq. 12 the values of $\overline{V}$(crystal) and $\overline{V}$(electrostriction) obtained in the present calculation, the $\overline{V}$(disordered) is evaluated. According to the treatment of Padova,[2,5] the following relation should hold and the amount of $\overline{V}$(disordered) is calculated without recourse to Eq. 12;

$$\overline{V}(\text{disordered}) = \overline{V}_{int} - \overline{V}(\text{crystal}) = \frac{4}{3}\pi N_0(r_e^3 - r(\text{crystal})^3), \quad (13)$$

However, we do not calculate $\overline{V}$(disordered) in this manner. As mentioned earlier, the numerical value of r_e was evaluated as to be a mere effective radius of the solvated ion. Moreover, the fundamental point of the present study lies to see to what extent the consideration of the electrostriction effects can explain the observed fact, and for this purpose the contribution of the electrostriction effects must be substracted from the values determined by experiments. If the consideration of the electrostriction term suffices to the interpretation of $\overline{V}_{ion}^{\circ}$, then the contribution of $\overline{V}$(disordered) disappears, otherwise it will appear as a correction term.

Final results are shown in Table 5 along with the value of n_s. In Table 5, three significant figures are used to express the values of $\overline{V}_e$ and $\overline{V}_d$. But apart from the problem related with the estimation procedure of the effective radius of the solvated ion, r_e, on account of the cumulation of various kinds of assumptions and ambiguities involved in the present calculation, physical significance of the figures of $\overline{V}_e$ and $\overline{V}_d$ is not so much reliable. However, we can mention and discuss the general features of the variation of $\overline{V}_e$, $\overline{V}_d$, and n_s with the composition of the solvent system as follows.

1) The variation of partial molar volume with composition of the solvent is rather small up to 50 mol% of methanol but in methanol-rich regions partial molar volume decreases rapidly with the content of methanol in the solvent (see Table 3). Corresponding to this fact, the amount of total electrostriction volume increases remarkably in the same concentration ranges of methanol for three chlorides investigated.

2) Values of $\overline{V}_d$ are smaller for CsCl and larger for LiCl than the corresponding values in water, while values of $\overline{V}_d$ for KCl are comparable in both solvents. Smaller value of $\overline{V}_d$ of CsCl in methanol than in water is compatible with the finding of Kawaizumi and Zana[21] that the void space around ions appears to be smaller in methanol than in water. Results related to KCl and LiCl may be interpreted as follows: In an early paper[21] and in many other references[26] the contributions of electrostriction volume and void space to the partial molar volume of ions are evaluated as the parameters A and B of Hepler equation,[27]

$$\overline{V}_{ion}^{\circ} = Ar^3 - \frac{B}{r}, \quad (13)$$

and A and B are determined independently, while in the present estimation the disordered part of the partial molar volume of the salt is determined through the subtraction of $\overline{V}$(crystal) and $\overline{V}_e$ from the value of $\overline{V}_{ion}^{\circ}$. For K^+ and Li^+ ions, the present estimation of electrostriction effects seems to give somewhat larger electrostriction volume than the actual volume decrease in solutions, as is seen from the comparison of the values of ΔV of Table 4 with the value of 7.54 cm^3 mol^{-1} estimated by Padova.[5] The small differences of ΔV can affect largely the values of $\overline{V}_d$ as a result of the multiplication of ΔV by n_s, this being especially the case for LiCl. It is noteworthy that the value of $\overline{V}_{ion}^{\circ}$ allotted to Li^+ ion in methanol clearly departs from the relationships given by Hepler equation and observed for all small univalent ions.[21] Also we would like to say that the result relative to CsCl seems to support the conclusion drawn by Kawaizumi and Zana,[21] but one should retain prudence in discussing $\overline{V}_d$ and $\overline{V}_e$ separately, as they are essentially interrelated in the present treatment.

3) Values of $\overline{V}_e$ and $\overline{V}_d$ are the largest for LiCl, then for KCl, and the smallest for CsCl at any compositions of the solvent system. In other words, the quantities $\overline{V}_e$ and $\overline{V}_d$ are inversely proportional to the cationic size.

4) For three alkali chlorides investigated, the average solvation number of the salt, n_s, first decreases, then increases, with increasing amount of methanol in the solvent and finally in pure methanol values of n_s are larger than those in water.

5) As for $\overline{V}_2^\circ$ of LiCl, the contribution of $\overline{V}$(crystal) is minor than that of $\overline{V}_e$ and $\overline{V}_d$ in the solvents containing more than 50 mol% of methanol.

To be free from the speculation, further discussion of the results of present study is postponed until more data are available on this mixed solvent system.

The authors wish to express their thanks to Professor Keizo Suzuki of Ritsumeikan University and Associate Professor Takashi Moriyoshi of Tokushima University for their kindness of informing them the source of the pressure dependence of dielectric constant and refractive index of the system concerned in the present work.

Temperature Dependence of Raman Spectra of Pyridine in Hydrogen Bonding Solvents

Kunio FUKUSHIMA* and Masahiro YAMAJI

Department of Chemistry, Faculty of Science, Shizuoka University 836, Oya, Shizuoka 422

(Received February 2, 1982)

Raman spectra of pyridine in solvents of various hydrogen bonding powers were recorded and frequency shifts of some bands were measured. With methanol as solvent, Raman spectra recorded at temperatures between 128 and 293 K exhibit a remarkable change with temperature. Results are interpreted on the basis of possible existence of a $\sigma\pi$-complex.

It was found by Takahashi *et al.*,[1] that some infrared bands of pyridine will shift to higher frequencies by its hydrogen bonding with solvents. They ascribed the frequency shifts to formation of σ-complexes (one-to-one and one-to-two complexes) by hydrogen bonding to the nitrogen atom of pyridine, and also to change in state of electrons in the molecule. On the other hand, Stidham and DiLella[2] measured frequency shifts of Raman bands of pyridine in various hydrogen bonding solvents. Infrared spectral change due to change in pyridine concentration in aqueous solution was investigated by Takahashi *et al.*,[1] but no works have been done on change in the above mentioned bands with temperature, although a temperature dependence of infrared spectra of hydrogen-bonded pyridine at 3 μ region was reported by Wolff *et al.*[3] On the other hand, a series of recent studies[4-7] on one-to-one σ-complexes by *ab initio* molecular orbital calculation made it clear that the π electron density on the nitrogen atom in the complexes is larger than that in pyridine itself,[8] and, therefore, existence of $\sigma\pi$-complex, in which a molecule is hydrogen-bonded to a one-to-one σ-complex by π-bonding, is probable. If $\sigma\pi$-complex coexists with one-to-one σ-complex, some peculiar temperature dependence of Raman spectra of pyridine in methanol is expected. In the present study, Raman spectra of pyridine in methanol were measured at various temperatures, and results were examined along with those of Raman spectral measurements at various concentrations, with the possibility of formation of $\sigma\pi$-complex taken into consideration.

Experimental

Raman spectra of pyridine and its aqueous and methanol solutions at various concentrations and those of pyridine in other hydrogen bonding solvents were measured. For a methanol solution (a mixture of pyridine and methanol in a mole ratio of 1 to 0.526), Raman spectra were measured at various temperatures between 128 and 293 K. Raman spectra of solutions at room temperature were measured using 0.3 ml Raman cells, while those at lower temperatures were measured by use of an Oxford-type cryostat using liquid nitrogen for cooling. Raman spectra were recorded on a Model R-800T Raman Spectrophotometer (Japan Spectroscopic Co., Ltd.) and the 514.5 nm line (300 mW) of a Spectra Physics argon ion laser (model 165).

Results and Discussion

(a) Raman Spectral Change Associated with Concentration Change. Change in spectra of pyridine in its aqueous solution with concentration is shown in Figs. 1, 2, and 3, in comparison with spectra of pure pyridine ((A) in the figures). In Figs. 1(B), (C), and (D), with decreasing concentration of pyridine, the intensity of the band at 1585 cm^{-1} (Fig. 1(B)) decreases and a new band at 1591 cm^{-1} (Fig. 1(B)) increases its intensity. At lower concentrations (Fig. 1(D)), the former almost disappears and changes into the band at 1594 cm^{-1} (Fig. 1(D)). This change confirms that the band at 1585 cm^{-1} forms a couple with the band at 1591 cm^{-1} (Fig. 1(B)), as the authors of Refs. 1 and 2 described. The reason why the intensity of the band at 1576 cm^{-1} (Fig. 1(B)) is not affected much by concentration change of pyridine is that a new band appears at 1578 cm^{-1} increasing its intensity with decreasing concentration of pyridine. In the same way as Fig. 1, Figs. 2 and 3 show that the bands at 998 and 992 cm^{-1} (Fig. 2(B)) and those at 612 and 605 cm^{-1} (Fig. 3(B)) form two couples. The

same type of spectral change was observed for methanol solutions of pyridine.

(b) Raman Spectral Change with Temperature. Results of measurement are shown in Figs. 4(A), (B), and (C). In the spectrum at 293.0 K in Fig. 4(A), the band at 1576 cm^{-1} is an overlapped band composed of a pyridine band and bands of bonded pyridine as discussed in *(a)*. As temperature falls, the intensity of this band increases greatly, as compared with those of other bands. The band at 1591 cm^{-1} also increases its intensity. However, its degree of change is smaller than that of the band at 1576 cm^{-1}. Moreover, the real increase in intensity of the band of bonded pyridine at 1576 cm^{-1} is far greater than it appears, because the band of nonbonded pyridine overlapping with the bands of bonded pyridine decreases its intensity. Therefore, the band at 1576 cm^{-1} is concerned with a larger enthalpy difference, while the band at 1591 cm^{-1} is concerned with a smaller enthalpy difference. As the band at 1591 cm^{-1} forms a couple with the band at 1585 cm^{-1}, the smaller increase in intensity of the former band relative to the latter band suggests that the couple bands correspond to a species whose enthalpy difference is very small. Thus, the band at 1585 cm^{-1} is not due to only nonbonded pyridine, but to both bonded and nonbonded pyridines. However, it is not the same bonded pyridine that corresponds to the band at 1591 cm^{-1}. For other band couples, as shown in Figs. 4(B) and (C), the bands at 992 and 605 cm^{-1} behave like the one at 1585 cm^{-1}, and those at 998 and 612 cm^{-1} behave as the one at 1591 cm^{-1}. The above results can be interpreted as follows: It is expected that the enthalpy difference for the reaction, pyridine+CH_3OH→σ-complex (one-to-one complex), has a negative value whose absolute value is greater than that of the enthalpy difference for the reaction, σ-complex (one-to-one complex)+CH_3OH→$\sigma\pi$-complex. In accordance with this expectation, as shown in Figs. 4(A), (B), and (C), the degree of relative intensity increase of the bands assigned to $\sigma\pi$-complex (1591, 998, and 612 cm^{-1}), compared with their partner bands (1585, 992, and 605 cm^{-1}), is far smaller than that of the band at 1576 cm^{-1} assigned to σ-complexes, $\sigma\pi$-complex, and pyridine. Thus, the band at 1576 cm^{-1} is assigned to nonbonded pyridine, σ-complexes, and $\sigma\pi$-complex, while the band at 1585 cm^{-1} corresponds to nonbonded pyridine and σ-complexes. The band at 1591 cm^{-1} is assigned to $\sigma\pi$-complex. The bands at 992 and 605 cm^{-1} are assigned to nonbonded pyridine and σ-complexes, while those at 998 and 612 cm^{-1} correspond to $\sigma\pi$-complex.

(c) Raman Spectra of Pyridine in Carboxylic Acids. Acetic acid solutions: Though the band of pyridine at 1575 cm^{-1} shifts only by 1 cm^{-1} in aqueous solution, it shifts by 5 cm^{-1} in acetic acid solution. Shift of the band at 1584 cm^{-1} is 16 cm^{-1}, which is larger than that in aqueous solution (10 cm^{-1}). A similar large shift (15 cm^{-1}) is observed for the band of pyridine at 993 cm^{-1}. In acetic acid solution, pyridinium ion coexists with hydrogen bonded pyridines since the bands at 646 and 617 cm^{-1} appearing in the spectrum of the solution correspond to the bands at 642 and 614 cm^{-1} of pyridine dissolved in hydrochloric

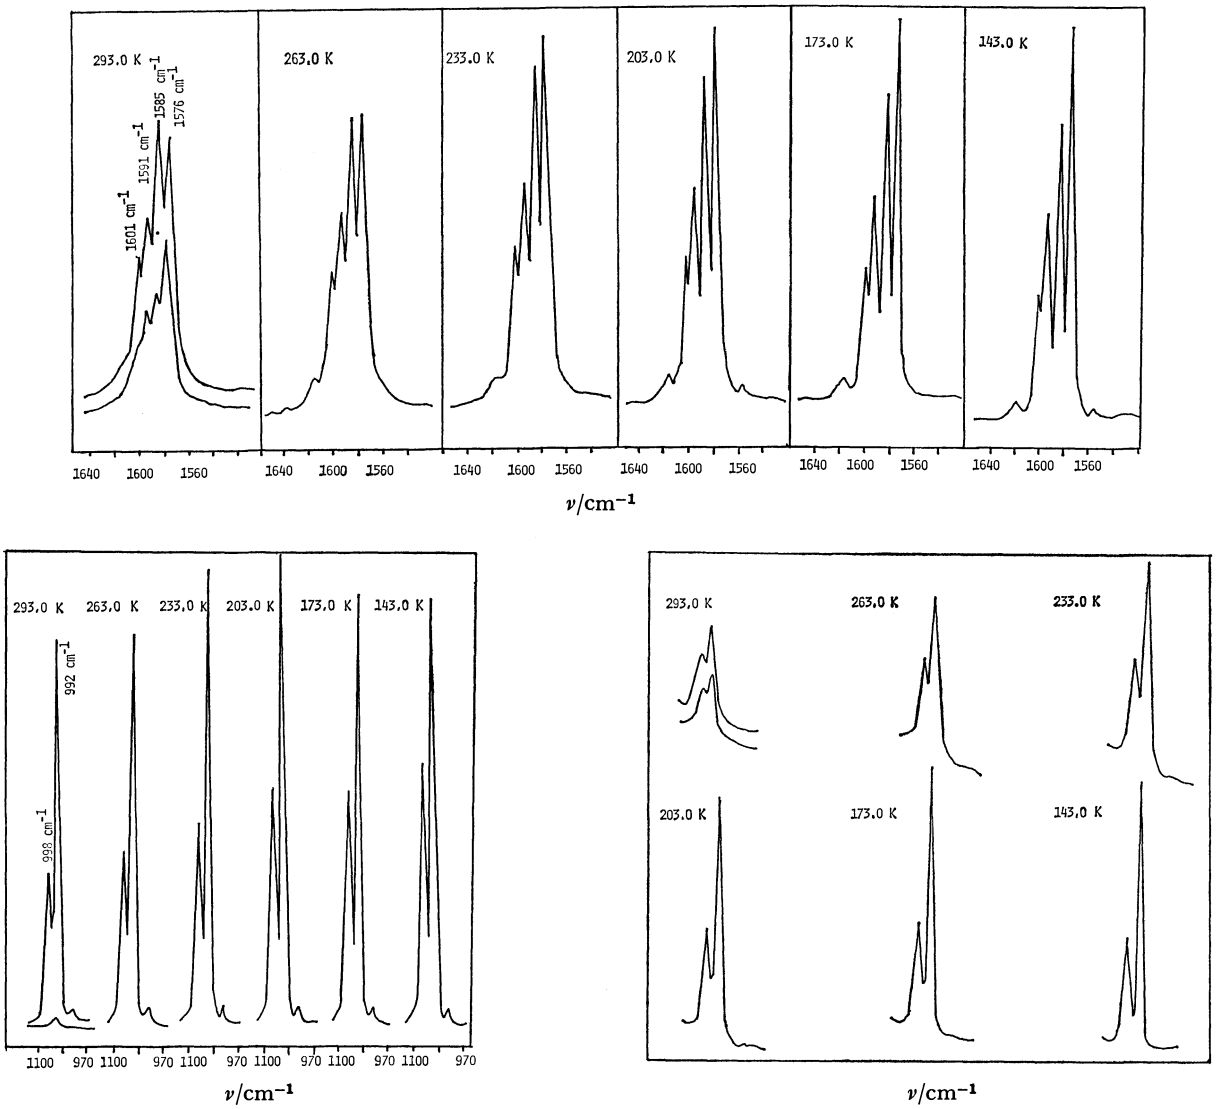

Fig. 4. Raman spectra of a methanol solution of pyridine (a mixture of pyridine and methanol in mol ratio of 1 to 0.526) at various temperatures.

acid (refer to Table 1 for the solution with a mixing mole ratio of pyridine 1: hydrogen chloride 1.451: water 5.239). Results of measurement are shown in Table 1.

Among the bands of pyridine which shift by hydrogen bond formation, those at 1584, 993, and 605 cm^{-1} are assigned to the C–C ring stretching vibration, the ring breathing vibration, and the CCC and CNC deformation vibration, respectively.[9] As the bonds in the ring are formed primariliy by π-electron bonding, the ring vibrations may be affected by hydrogen bonding to π electrons, and the strength of the bonding may be influenced by the hydrogen bonding power of proton donors. The experimental results in Table 1 show that the shifts of the three bands differ in compliance with the hydrogen bonding power of the two acids. This is consistent with the assignment of the above-mentioned bands to $\sigma\pi$-complex.

(d) Propriety of the Band Assignment. The following calculation suggests that the band assignment discussed in *(a)* and *(b)* above is reliable.

Expressing the peak intensity of a band having frequency f by I_f, we have

$$I_{1576} = I_{1576,\sigma} + I_{1576,\sigma\pi} + I_{1576,P}, \quad (1)$$

$$I_{1585} = I_{1585,\sigma} + I_{1585,P}, \quad (2)$$

$$I_{992} = I_{992,\sigma} + I_{992,P}, \quad (3)$$

$$I_{998} = I_{998,\sigma\pi}, \quad (4)$$

where σ, $\sigma\pi$, and P denote σ-complexes, $\sigma\pi$-complex, and pyridine, respectively. Denoting the ratio $I^{\circ}_{1575}/I^{\circ}_{1585}$ for pure pyridine by r and assuming that $I_{1576,\sigma}+I_{1576,P}=(I_{1585,\sigma}+I_{1585,P})r$, the quantity $r_{\sigma\pi}$, proportional to the mole fraction of $\sigma\pi$-complex, will be obtained from Eqs. 1 and 2 for the solution corresponding to Fig. 1(B):

$$r_{\sigma\pi} = (I_{1576}-I_{1585}r)/I_{1576} = 0.38,$$

for which the observed value of r=0.638 is used. On the other hand, $r_{\sigma\pi}$ can be obtained by Eqs. 3 and 4 for the same solution as

$$r_{\sigma\pi} = I_{998}/(I_{998}+I_{993}) = 0.36.$$

	1644 (1)	1644 (sh, ?)	1644 (3)

a) Figures in parentheses represent relative intensity. b) Mixture of pyridine and acetic acid in a mole ratio of 1 to 1.487 (pH=4.17). c) Mixture of pyridine and formic acid in a mole ratio of 1 to 1.519 (pH= 3.65).

In the same way, $r_{\sigma\pi}$ for the solution corresponding to Fig. 1(C) is obtained as 0.60 and 0.58 from Eqs. 1 and 2 and from Eqs. 3 and 4, respectively. This good agreement of the $r_{\sigma\pi}$ values from the two sets of equations suggests a reliability of the assignment of the band at 1576 cm^{-1} to σ-complexes, $\sigma\pi$-complexes, and pyridine, and those at 1585, 993, and 606 cm^{-1} to σ-complexes and pyridine, and those at 1591, 998, and 616 cm^{-1} to $\sigma\pi$-complex.

(e) Quantitative Relation between the Relative Intensities of the Bands at 992 and 998 cm^{-1} and Temperatures. As shown in Fig. 5, an almost linear relation holds between $\ln(I_{992}/I_{998})$ and $(1/T)$. Although equilibria in the solution are not known, this result suggests that (I_{992}/I_{998}) is approximately proportional to an equilibrium constant. The quantity ΔH obtained from the straight line in the figure on the basis of the equation

$$\ln (I_{992}/I_{998}) = -\frac{\Delta H}{RT} + \text{const.}$$

may be related to the enthalpy difference for the reaction concerning the equilibrium constant. The value for the ΔH is 0.9 ± 0.2 kJ mol^{-1}, whose absolute value is very small compared with those of enthalpy differences for ordinary σ-type hydrogen bonds. Therefore, the equilibrium which predominates the temperature change in (I_{992}/I_{998}) might be the equilibrium between $\sigma\pi$-complex and σ-complexes.

Laser Flash Photolysis of Benzene. IV. Physicochemical Properties of Mist Produced by Laser Excitation†

Nobuaki NAKASHIMA and Keitaro YOSHIHARA*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received February 3, 1982)

Mist formation is observed when gaseous benzene (8—75 Torr) (1 Torr=133.322 Pa) with oxygen ($\lesssim 10^{-5}$—860 Torr) is irradiated by a KrF excimer laser. By measuring the falling speed, the size of droplets in the mist is determined to be 2 to 6 μm depending on gas pressure. The number of droplets produced by irradiation with a 100 mJ/cm² pulse is estimated to be 1×10^5/cm³ by measuring the benzene pressure change and by turbidity measurement. The disappearance yield of benzene is 0.1 and phenol is identified with a quantum yield of 0.01. The nucleus is produced by two-photon excitation of benzene and allowed to grow into mist through a subsequent oxidation and/or polymerization reaction.

During the course of a laser-flash photolytic study of gaseous benzene,[1,2] we observed that laser beam will often cause mist to appear. The mist causes intense Mie scattering of monitor laser light and is easily visible in the form of falling "mist" or "rain." This laser-induced mist or particle formation seems to be the first observation with organic systems.

In this paper we report some physical and chemical properties of the mist studied with light scattering and transient absorption. The size of droplets in the mist was determined by measuring the falling speed. The number of droplets was estimated by observing the benzene pressure change and also by turbidity measurement. A possible mechanism for the photochemical formation of nucleus and for the enhancement of mist formation with oxygen is discussed.

Laser-induced solid particle formation has recently been observed in several other systems with simple molecules and/or metal vapors. Formation of solid alkali hydrides from alkali metal vapor and H_2 (Refs. 3 and 4) is induced by irradiation with a CW laser. Produced particles are called "laser snow," because they are white solid and fall down by gravity. Evolution of particles from NO_2 and SO_2 (Ref. 5) and of sulfur or aerosols from SF_6+H_2, CS_2, and Cl_2CS (Refs. 6,7, and 8) are also recognized.

Experimental

Gaseous benzene was excited by a KrF excimer laser (Lambda Physik EMG 500), at 248 nm, with typical output energy of 100 mJ and a pulse halfwidth of 15 ns. The laser beam with an area of 2.5×0.5 cm² was not focused for most experiments unless otherwise indicated. Transient absorption[2] and light scattering were measured in the perpendicular direction with a pulsed Xe lamp (EG & G 265UV) and a He–Ne laser, respectively. The intensity of light from a He–Ne laser scattered by mist was monitored with a photomultiplier at right angles through an $f=1.5$ lens and recorded on an X-T recorder.

A monitoring light at 260 nm was obtained from a D_2 lamp through a Shimadzu-Bausch & Lomb monochromator and was used for determining the concentration (pressure) of benzene. The output signal, run through a Nikon P250 monochromator and two Ortec Brookdeal 9503 lock-in amplifiers, was further normalized with a ratio meter model 5043. The linearity of absorbance at 260 nm held up to 0.9 in absorbance units, corresponding to 100 Torr cm of gaseous benzene, when the smallest slit width ($\Delta\lambda\approx$ 0.15 nm) of the monochromator was used. Absorption spectra were measured on a Cary 17 spectrophotometer.

A conventional greaseless vacuum line was used for sample preparation with a Baratron pressure gauge 310BHS-1000. Back pressure was 1×10^{-5} Torr. A quartz cell was closed with a J. Young greaseless stopcock. Our "oxygen free" sample was prepared by complete degassing with freeze-pump-thaw cycles and closed off by fusing the tubing. Quartz cells were baked at about 490 °C for several hours before use. Usually the sample was excited at intervals of 15 min and was renewed after 5 laser shots.

Benzene (J. T. Baker, stated purity of 99.98%), oxygen (99.98%), nitrogen (99.9995%), SF_6 (99.9%), and *cis*-2-butene (99%) were used without further purification. All the gases were produced by Nippon Sanso.

Results

Observation of Mist Formation. In the flash photolysis experiment with a KrF excimer laser we visually observed mist formation when the sample was viewed under room light. Scattering from a He–Ne laser makes the presence of mist much clearer as shown in Fig. 1. Figure 2 shows the intensity of 90° light scattering by mist produced from a sample with 20 Torr of benzene and 0.08 Torr of oxygen. The mist formation is enhanced by oxygen; it is observable even in an "oxygen free" condition with the same pressure of benzene.

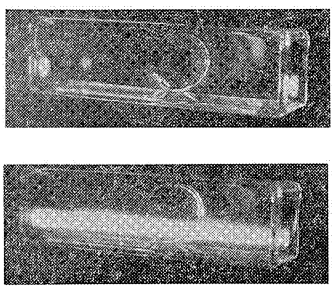

Fig. 1. Mie scattering by mist produced from gaseous benzene excited by a KrF laser.
a): Sample cell before irradiation, b): after irradiation of 40 Torr of benzene and 2 Torr of oxygen. The size of the sample cell is $4.0\times1.0\times1.0$ cm³. The area of the laser beam is 2.5×0.5 cm². The sample is irradiated without focusing the beam.

† Part III of this series is Ref. 2.

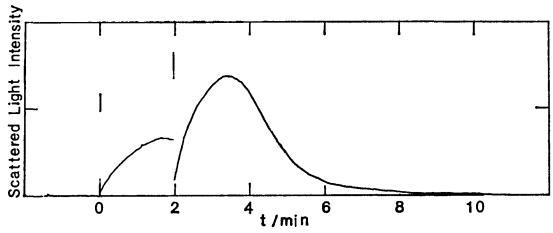

Fig. 2. Time course of the light scattered at 90° with 20 Torr of benzene and 0.08 Torr of oxygen.
The spikes indicate noise due to laser pulses. The light scatterings are quenched very quickly by subsequent laser excitations and then regenerated slowly.

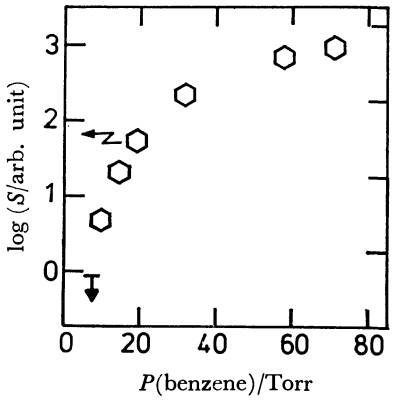

Fig. 3. Dependence of pressure of benzene on the scattered light intensity.
Peak height of the scattered light is plotted by ○; each sample contains 2 Torr of oxygen. A bar with an arrow at 7.5 Torr shows that the scattered signal was lower than the detection limit (the bar).

It takes the signal about 50 s to reach its peak and about the same time to decay. The rise time of the scattered light intensity is related to the rate of the nucleation process. Decay times simply depend on the falling speed of droplets, as discussed in the next section.

The scattered light intensity is decreased immediately by subsequent laser shots as shown in Fig. 2. This indicates that the mist absorbs the subsequent laser pulse and is destroyed easily. It is suggested that component molecules of the mist are relatively small and bound together by a small molecular interaction.

The scattered light intensity is increased more than 300 times upon increasing the pressure of benzene from 8 to 75 Torr. Figure 3 shows scattered light intensity *vs.* pressure of benzene in the presence of 2 Torr of oxygen. We do not observe any signal if the benzene pressure is less than 7.5 Torr. The concentration of nuclei is suggested to be too low to start nucleation at pressures less than 7.5 Torr.

The size of droplets has been determined to be 2—6 μm by measurement of the falling speed. The size can be evaluated using the equations[9]

$$mg = 6\pi\eta rv, \quad m = \frac{4}{3}\pi r^3\rho, \tag{1}$$

where η is viscosity of mixed gas, r is radius of droplet, v is falling speed, ρ is density of droplet, and g is gravity. For the system consisting of 21 Torr of benzene, 2.1 Torr of oxygen, and 207 Torr of nitrogen, η is evaluated to be 1.57×10^{-4} P (1 P=0.1 Pa s). We do not know all of the compositions of the droplets, so that ρ cannot be given any accurate value. However, we presume $\rho=1.0$ g/cm^3. This seems to be a feasible approximation since the starting materials for the droplets are benzene and oxygen and densities of most organic hydrocarbons are close to unity. For example, the density of benzene is 0.88 g/cm^3 and that of phenol (one of photoproducts) 1.07 g/cm^3. If we measure v, the size will be given by Eq. 1.

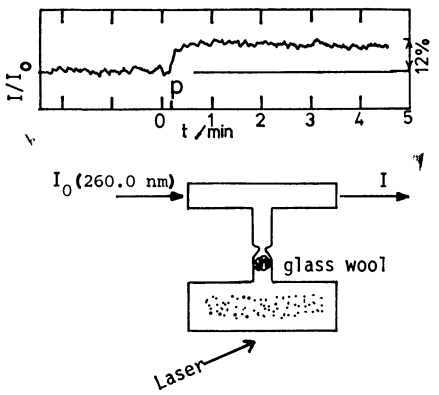

Fig. 4. Junction cell experiment. The larger cell was irradiated with 20 laser shots at 2 Hz.
Irradiation started at 0 min and stopped at p in the figure. Pressure change was monitored at 260 nm ($6_0^1 16_1^1$ transition). The actual change in transmittance was 3%, which corresponds to a quantum yield of 0.12 after correcting the volume of irradiation and the laser energy. The sample cell contains 23.2 Torr of benzene and 2.3 Torr of oxygen.

The mist produced by irradiation begins to fall. The speed is so low as to be measured visually. The position of the fastest droplet is plotted as a function of time. For the above case v was $(1.8\pm0.5)\times10^{-2}$ cm/s. Then, the diameter ($2r$) of the droplets is $(2.3\pm0.3)\times10^{-4}$ cm. The size of 2—6 μm is obtained in the benzene pressure range 8—75 Torr. An increase in the size accompanies an increase in the pressure of benzene.

By knowing the approximate size of droplets, we can determine an approximate number of the droplets produced, in two independent ways: one uses pressure change of gaseous benzene due to mist formation and the other is based on turbidity measurement of mist. Decrease in benzene pressure can be determined by change in absorbance at 260 nm, which corresponds to the $6_0^1 16_1^1$ transition. As shown in Fig. 4, two quartz cells are connected by a thin neck, one being the sample cell for excitation of benzene and the other being the monitoring cell.

The yield for the decrease in benzene pressure is 0.13 ± 0.02 with and without oxygen. Taking into account the size of droplet (2.5 μm), the number of droplets is obtained to be 1.3×10^5 /cm^3 at a laser excitation of 125 mJ/cm^2. Experimental details are as follows: A mixture of benzene (23.2 Torr) and oxygen (2.3 Torr) is irradiated by 20 pulses of a 156

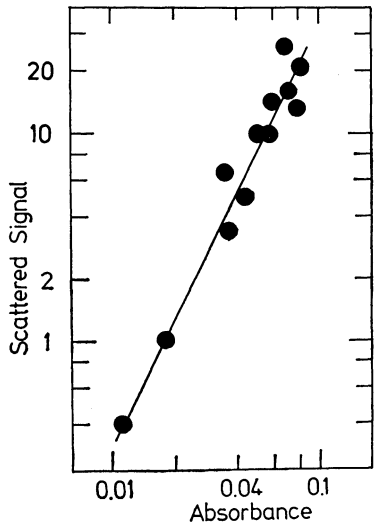

Fig. 5. Scattered light intensity *vs.* absorbance of the excited singlet state observed at 256 nm.
Pressure of benzene is 20 Torr with 0.08 Torr of oxygen. The straight line shows a slope of 2.0.

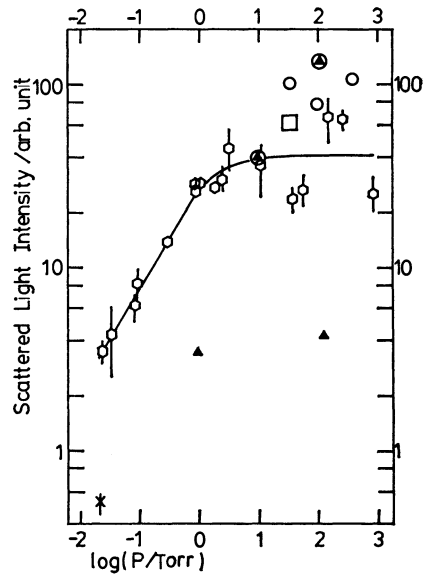

Fig. 6. Dependence of foreign gases on the scattered light intensity.
The benzene pressure for all experiments is 20 Torr. ⬡: Pressure of oxygen is denoted on the abscissa, □, ◭, ○: effects of *cis*-2-butene, SF_6, and nitrogen, respectively are given. In these cases 2 Torr of oxygen is included and the total pressures of foreign gases are denoted on the abscissa. x: 20 Torr of benzene with an oxygen pressure less than 10^{-5} Torr, ▲: benzene and SF_6 with oxygen pressure also less than 10^{-5} Torr.

mJ laser with a cross section of 1.25 cm^2 at 2 Hz. About 2×10^{18} photons are absorbed in a total volume of 5 cm^3. In order to estimate the number of droplets, it is necessary to assume the volume of component molecules. The approximate volume of phenol (0.53 nm^3 is used here as that of the component molecules. Glass wool was inserted at the neck of the quartz cell in order to prevent photoproducts from flowing into the monitoring cell. If the glass wool was not added, photoproducts canceled out the change in absorbance due to mist formation.

During the sample irradiation at 2 Hz, the signal shows no change. Just after stopping the irradiation (denoted as p in Fig. 4), the pressure of benzene begin to decrease, reaching the minimum value within 10 s. This observation indicates that the mist is destroyed by the subsequent laser shots as seen in Fig. 2. The slow increase after a few minutes indicates a flowing-in of photoproducts.

Turbidity was measured in order to estimate the number of droplets. Extinction change due to scattering by droplets is expressed as

$$\tau = \frac{1}{a}\ln\frac{I_0}{I} = \pi r^2 KN, \qquad (2)$$

where a is the path length of the monitoring cell (2.5 cm), r is the radius of the droplet (1.25 μm), and K is the average total Mie scattering cross section (2.0 used here). In the case of 45 Torr benzene with 2 Torr of oxygen, τ was 1×10^{-2} /cm for the first laser shot of 100 mJ/cm^2 and then the number (N) is given as 1×10^5 /cm^3, which is in agreement with that obtained by the pressure change of benzene in the previous section. The value K=2.0 is a good approximation, considering the size parameter of Mie scattering.[10]

Power Dependence, Effect of Foreign Gases, and Photoproducts. Figure 5 shows scattered light intensity *vs.* absorbance of the excited state of benzene. The scattered light intensity clearly gives a quadratic dependence on the S_1 concentration. The latter quantity was obtained by observing the intensity of the $S_n\leftarrow S_1$ absorption at 256 nm.[1,2] The absorbance of 0.1 corresponds to *ca.* 0.4 Torr of the S_1 concentration.

We could not observe any scattered signal when a Xe lamp was used as an exciting light source instead of the laser. These results indicates clearly that multiphoton excitation makes the mist formation possible, but that one-photon excitation does not. The energy of the Xe lamp was 1.3 mJ in the range of 220—250 nm at the sample cell. In order to avoid exciting benzene into the S_3 state and heating it up by IR light, methanol in a 2 cm cell was used as a filter.[11] A sample with 42 Torr of benzene and 8 Torr of oxygen was excited at 0.7 Hz and a total energy of 200 mJ was dumped in.

Pressure effect of foreign gases on scattered light intensity makes the role of oxygen clear. An oxygen-free sample shows a very weak signal as shown in Fig. 6 (denoted by ×). An increase in oxygen pressure (denoted by ⬡) is accompanied by an enhancement of scattered light intensity in the range from 2×10^{-2} to 2 Torr. This observation indicates that oxidation reaction is the major reaction which causes the mist formation.

cis-2-Butene, SF_6, or nitrogen does not seem to have any significant effect on the intensity when added to a system of 20 Torr of benzene and 2 Torr of oxygen. It is worth noting that only SF_6 makes aerosol. This may occur according to a mechanism similar to that for other sulfur-containing compounds.[6-8] This is the

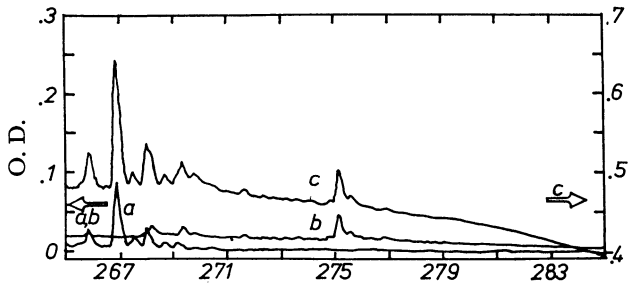

Fig. 7. Absorption spectra of 48 Torr of benzene with 5 Torr of oxygen after irradiation with 15 shots of 150 mJ laser energy.
a: Benzene (reference spectrum), b: reference absorption spectrum of phenol with a pressure of 0.35 Torr, and c: after laser irradiation.

reason that the oxygen free sample with SF_6 shows a larger signal than the ones without SF_6.

The consumption yield of benzene upon excitation was 0.08 ± 0.02 with and without oxygen after several hours. In order to avoid photolysing mist, the sample was irradiated only every 4 min so that most of the droplets fell down to the bottom of the cell before the subsequent laser shot came. The comsumption yield of 0.08 roughly coincides with the yield of pressure change of 0.13 obtained in the previous section. This reasonable agreement suggests that the major part of the pressure change due to mist formation can be ascribed to the nucleation of permanent photoproducts of benzene and not to aggregation of pure benzene.

Phenol was observed with a quantum yield of 0.01 as shown in Fig. 7. In addition to phenol, we obtained volatile species with absorption spectra shorter than 230 nm and nonvolatile species with a shoulder around 290 nm. The latter was observed only in the sample with oxygen. Phenol has been reported as a major photo-oxidation product in the gas phase,[12,13] though there is no report on the quantum yield of phenol formation. The shoulder around 290 nm might be for mucondialdehyde, which has been detected as a photo-oxidation product in the gas phase[13] as well as in pure liquid benzene.[14] A larger yield of polymer formation was observed in the sample without oxygen.

Discussion

Two-photon Absorption and Primary Photoproducts. There are a few possible processes for the two-photon mechanism leading to the formation of nuclei: 1) simultaneous two-photon absorption; 2) two-step excitation by energy transfer between excited singlet and/or triplet molecules, 3) consecutive two-step absorption *via* excited state. The major process is suggested to result from effects of foreign gases. Oxygen quenches the lowest excited singlet state of benzene with a rate constant of 1.02×10^{11} M^{-1} s^{-1} and the triplet state with 9.5×10^{9} M^{-1} s^{-1} (the same order of magnitude as that of *cis*-2-butene) (Refs. 15 and 16). Then the lifetime in the presence of 860 Torr of oxygen is expected to be 0.12 ns for the singlet state and 1.2 ns for the triplet state. These lifetimes are too short for excited molecules to collide among themselves and not long enough to absorb the second photon consecutively. The scattered signal intensity does not decrease at higher pressures of oxygen. Therefore, two-step excitation by energy transfer between two excited molecules can be excluded. The consecutive two-step excitation mechanism *via* excited states may be included to a small extent. The major process is suggested to be the simultaneous two-photon absorption.

In any two-photon processes, benzene is excited in the VUV region of 8.6—10 eV. The photochemistry of benzene by continuous light sources in the VUV region suggests that precursors for the mist produced by two-photon absorption are likely to be radicals with linear structure. With Kr (116.5 nm) and Xe (147 nm) lines, polymer formation is the major process and acetylene is produced with a quantum yield of *ca.* 0.1. The photochemical consumption yield has been estimated to be almost 1.0 at lower pressures.[17,18] On the other hand, the photochemical consumption yield is 0.1 by laser excitation in our experiment. The cross section of the absorption at the laser wavelength is expected to be larger under higher power irradiation. Several percent of increase in the cross section was observed at 80 Torr of benzene when incident laser power is varied from 40 to 150 mJ/cm^2. Hexatriene is accumulated easily by irradiation of benzene in cyclohexane with a KrF laser,[19] and the yield of polymer is higher in the absence of oxygen. These observations also support that the major primary photoproducts are linear radicals. The major processes are suggested to be

$$\mathrm{B} \xrightarrow{2h\nu} \mathrm{B^{**}} \longrightarrow \mathrm{R\cdot} \begin{cases} \nearrow \text{polymer} \\ \searrow \text{oxygenated compound} \end{cases} \searrow \text{mist}, \qquad (3)$$

where B** is a higher excited state of benzene and R· is a linear radical. Other minor photoproducts are also conceivable, *i.e.*, cationic species (monomer or dimer cations) and phenyl radicals, which may be a primary source of phenol.

Effect of Oxygen on Mist Formation. Organic mist formation requires accumulation of condensable species in excess of their gas-phase saturation conditions. Linear radicals are known to react with one another as well as to react with benzene and produce various derivatives by photolysis in solution.[20] All of these photoproducts are expected to show vapor pressures lower by several orders of magnitude than those of six-carbon parent molecules. Thus they would form mist even in the absence of oxygen according to the upper process of Scheme 3.

Linear biradicals formed by ring cleavage will be very easily oxidized and will give many kinds of bifunctional oxygenated compounds. Rates of addition reaction of oxygen have been reported as a few percent of the collisional frequency for simple radicals and equilibrium constants are very large, of the order of 10^{10} $Torr^{-1}$ (Ref. 21). Oxidation makes volatility

lower by more than several orders of magnitude; in particular, those of dicarboxylic acids are about 9 orders of magnitude lower than those of the parent molecules. The nucleation is much enhanced in the presence of oxygen according to the lower process of Scheme 3.

Formation of phenol was observed as shown in Fig. 7. In the course of formation of phenol, atomic oxygen (^3P) can be produced upon excitation of gaseous benzene.[12,22] It is well known that atomic oxygen reacts with benzene to produce phenol and also allows linear radicals to be oxidized.[23] These oxidation reactions contribute to the enhancement of mist formation.

The mechanism for the photochemical aerosol formation in urban atomosphere has been studied in detail.[24] Hydrocarbons are oxidized by ozone and/or hydroxyl radicals to form aldehydes, alcohols, or carboxylic acids. These oxygenated compounds have a low volatility. Then, no polymerization is necessary to form aerosols from cyclic olefins, even when they are present at trace concentrations (below 10^{-6} Torr) in ambient air.[24] These processes are similar to what we observed with benzene.

We reported that the initial stage of light-induced condensation of benzene was found in nanosecond time-resolved difference spectra.[1] However, we have recently found that these spectra can also be explained in terms of temperature rise due to nonradiative transitions.[25] The observations presented in this report, *i.e.*, the effects of foreign gas and laser power on mist formation and the results from the junction cell experiment, do not support the tentative explanation given in the previous report.

We thank Dr. I. Chabay for critical reading of the manuscript and valuable suggestions and Dr. N. Washida for discussion on the mechanism of aerosol formation. The present work was supported in part by the Grant-in-Aid from the Ministry of Education, Science and Culture of Japan.

The Structure of Liquid Water by Neutron Scattering. II. Temperature Dependence of the Liquid Structure

Norio Ohtomo,† Kazuo Tokiwano,† and Kiyoshi Arakawa*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
† *Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received March 1, 1982)

The structure factors for heavy water at 25, 50, 70, and 95 °C were determined in the range of Q, 1.4—20 Å^{-1}, by means of the time-of-flight (TOF) neutron diffraction method using the electron linear accelerator (LINAC). An analysis of the neutron diffraction data was made by applying a new general theoretical procedure of analysis for the fluid system composed of molecular clusters with various sizes. Structure factors were calculated according to the general procedure for the pentamer-monomer mixture model as a mixture of regular tetrahedral pentamers and non-bonded monomers with a due assignment of pentamer fraction at each temperature. Excellent agreement was obtained between the calculated and observed structure factors at temperatures in 25—95 °C. Combined with the preceding result (N. Ohtomo, K. Tokiwano, and K. Arakawa, *Bull. Chem. Soc. Jpn.*, **54**, 1802 (1981)), it was concluded that the pentamer-monomer mixture model is the best one for water from room temperature to near the boiling point.

In the preceding paper[1]# we reported an analysis of the liquid structure of water by combining neutron and X-ray diffraction data, and showed that liquid water at room temperature has a basic structure as an aggregate of regular tetrahedral pentamers. The analysis was performed concerning the structure of water only at a temperature, 15 °C. Then, we attempt here to perform structure analysis of liquid water at more elevated temperatures. For this purpose, we have carried out a neutron diffraction measurement on water at 25—95 °C, and further, have made an analysis of the data by applying a newly devised theoretical procedure of analysis for the fluid system composed of molecular clusters with various sizes.

Neutron Diffraction Data

Measurement. Neutron scattering intensities were measured for liquid water at 25, 50, 70, and 95 °C by means of the LINAC-TOF neutron diffraction method. Basic architecture of the diffractometer and experimental procedures were reported elsewhere.[2] In the present study measurements were made simultaneously at two scattering angles (2θ=40° and 65°). Neutrons scattered towards two directions were detected in a bifurcated array of two counters (Fig. 1). The angular divergence of the Soller slit as a collimator, which governs primarily the resolving power, was 30′ and 38′ for the slit used at lower and higher scattering angles, respectively.

A sample of 99.9% deuterium oxide contained in a thin-walled cylindrical quartz vessel (100 mm long, 10 mm internal diameter, and 0.1 mm wall thickness) was placed within a thin aluminum cylindrical reflector of an elliptical contour (Fig. 1). A Digital Thermometer (FLUKE Model 2190A) and a rod heater were used, and the vertical axis of the heating rod and the cylindrical sample container are placed exactly at the two focussing points of the elliptic contour. Temperature measurement was made by thermocouples inserted into the top and bottom of the sample. The temperature was controlled within the fluctuation of 1 °C through all the measurements in the present experiment (Fig. 2).

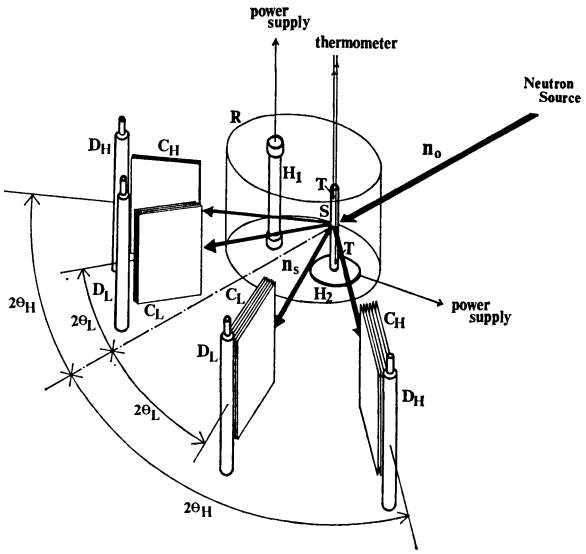

Fig. 1. A perspective view of the diffractometer. n_0: Incident neutron beam, n_s: scattered neutron beam, S: sample, H_1: heater rod, H_2: auxiliary heater, R: reflector, T: thermocouple, C: Soller collimator, D: detector, 2θ: scattering angle. Suffixs H and L denote higher and lower scattering angles, respectively.

Correction Procedures and Structure Factors. For obtaining the structure factors $S_m(Q)$ from the measured raw data, several corrections (multiple scattering, ab-

We cite Ref. 1 as paper I in the following.

○: 25 °C, ●: 95 °C.

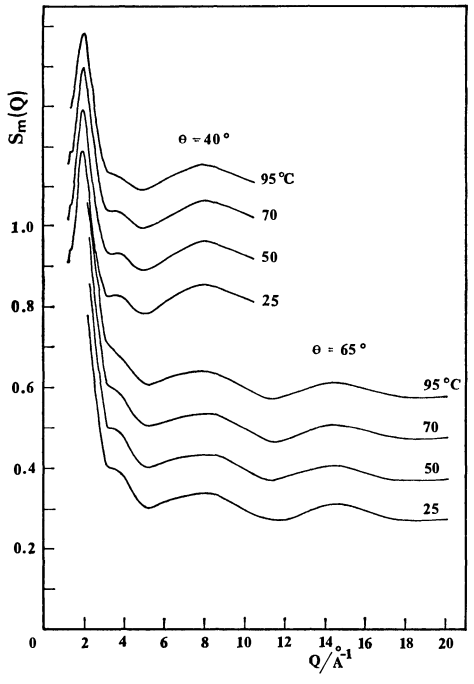

Fig. 4. Partially-corrected neutron structure factors $S_m(Q)$ (corrected with respect to background counting, multiple scattering, and absorption).

sorption, background counting, inelastic scattering, and incoherent scattering) and absolute normalization of data were carried out according to similar procedures as made in the preceding studies.[2-4] In applying these correction procedures to the present raw data, however, a due consideration on the influence of temperature variations must have been taken into account. In order to examine the temperature variation of background counting including the scattering from the container, we measured the intensity of neutrons scattered from the empty container at two temperatures (25 and 95 °C). It was found that differences between the

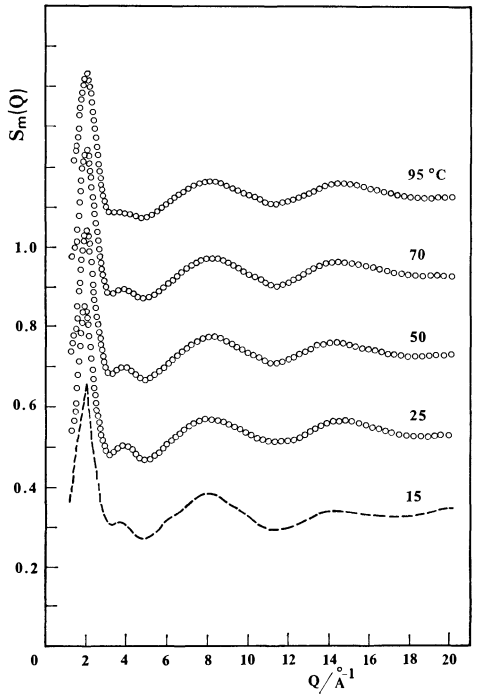

Fig. 5. Observed neutron structure factors $S_m(Q)$ for heavy water at 25, 50, 70, and 95 °C, together with the previous data at 15 °C.

two temperatures were negligibly small (Fig. 3). This is attributed to the thin wall-width of the container. Then, for the background counting, we could safely use the value at 25 °C through all the temperatures. With respect to multiple scattering and absorption, the temperature-dependent variation was assumed to be negligible for the temperature range in the present study. The partially-corrected $S_m(Q)$ curves after corrected with respect to background counting, multiple scattering, and absorption are shown in Fig. 4.

With respect to inelastic scattering which is important for D_2O, the following feature is clearly seen in Fig. 4. All the $S_m(Q)$ data at the same scattering angle at different temperatures are in full agreement with each other except the first peak and the hump at 4 $Å^{-1}$. This indicates that the inelastic correction is insensitive to temperature variation within the range of the present experiment. The $S_m(Q)$ data at $2\theta=65°$ in Fig. 4 exhibit a larger effect due to inelastic scattering than the data at $2\theta=40°$. This is explained theoretically as follows: the greater descending trend in the $S_m(Q)$ curve with increasing Q at larger scattering angle is typical of the Placzek corrections[5] and is almost entirely due to the self-scattering by the deuterons.[5,6] It can be said that the inelastic correction contributes a temperature-independent monotonic variation as a function of Q. Thus, the Placzek and Wick correction methods used in the previous studies at room temperature[2-4] were safely applied to the present data in lower and higher Q region, respectively, at 25—95 °C.

Absolute normalization of data was carried out with the use of scattering data from a vanadium standard. Calibration of absolute values for high Q data was performed according to the limiting procedure that

$S_m(Q)\to\Sigma b_n^2/(\Sigma b_n)^2$ as $Q\to\infty$, where incoherent scattering is duely considered. Calibration for low Q data was done by overlapping the $S_m(Q)$ curves in the Q range of 3—5 Å^{-1}. Combining the two corrected data at each scattering angle, the final $S_m(Q)$ curves for a range of Q=1.4—10.5 Å^{-1} and those for a range of Q=2.5—20 Å^{-1} were obtained from the data sets of $2\theta=40°$ and from those of $2\theta=65°$, respectively. The values are tabulated in Table 1. These data at two angles at the same temperature agree very well in the region of Q=2.5—10.5 Å^{-1} (Table 1). Thus, by combining these data at two angles, we obtain the final $S_m(Q)$ curves at each temperature as shown in Fig. 5, together with the curve at 15 °C obtained previously.[1] A marked feature of the structure factors obtained is a gradual falling of the hump at *ca.* 4 Å^{-1} as the temperature is raised.

Experimental accuracy has been improved at more satisfactory level in this study. The statistical error for values of $S_m(Q)$ is smaller than 0.5% in the range of Q=2—6 Å^{-1}, and the resolving power $\Delta Q/Q$ less than a few % in the whole range of Q.

Theoretical Procedure of Analysis

Theory. In paper I we derived a formula of $S_m(Q)$ for liquid consisting of identical clusters (Eqs. 7—11 in I). For the analysis of the present data, the $S_m(Q)$ formula for liquid composed of molecular clusters of various sizes including monomers is required. In the following, we will state the details of derivation of the formula, which is an extension of the theory reported in I, with the addition of due assumptions.

The coherent neutron structure factor $S_m(Q)$ is given in general by

$$S_m(Q) = N_m^{-1}\Sigma^{-2}\langle\sum_{i,j}\sum_{n_i,n_j} b_{n_i}b_{n_j}\exp(i\vec{Q}\cdot\vec{r}_{n_in_j})\rangle, \quad (1)$$

where i and j label molecules in a liquid and n_i denotes the n-th nucleus in the molecule i. $\vec{r}_{n_in_j}$ is the vector distance between the nuclei n_i and n_j, b_{n_i} the scattering length of nucleus n_i, $\vec{Q}$ the scattering vector, and $\Sigma=\sum_n b_n$. We sum over all the scatterers in the N_m molecules in the system.

We now consider the case of a fluid system consisting of molecular cluster of various sizes including monomers, where the number of clusters composed of ν molecules is N_ν, and its fraction in molecular number x_ν.

$$x_\nu = \frac{\nu N_\nu}{N_m}, \quad \text{and} \quad \sum_\nu \nu N_\nu = \sum_\nu x_\nu N_m = N_m, \quad (\nu=1, 2, \cdots).$$

Then, Eq. 1 is written as follows,

$$S_m(Q) = N_m^{-1}\Sigma^{-2}\langle\sum_\nu\sum_{\alpha_\nu}\sum_{l,l'}\sum_{n_l,n_{l'}} b_{n_l}b_{n_{l'}}\exp(i\vec{Q}\cdot\vec{r}_{n_ln_{l'}})\rangle + N_m^{-1}\Sigma^{-2}\langle\sum_{\nu,\mu}\sum_{\substack{\alpha_\nu,\beta_\mu\\(\alpha_\nu\neq\beta_\mu)}}\sum_{l,\kappa}\sum_{n_l,n_\kappa} b_{n_l}b_{n_\kappa}\exp(i\vec{Q}\cdot\vec{r}_{n_ln_\kappa})\rangle, \quad (2)$$

α_ν denotes the α-th cluster in the clusters composed of ν molecules, β_μ the β-th one in the ones composed of μ molecules ($\alpha_\nu=1,\cdots,N_\nu$ and $\beta_\mu=1,\cdots,N_\mu$), l and l′ the l-th and l′-th molecule within the cluster α_ν (l, l′: $1,\cdots,\nu$) respectively, and κ the κ-th molecule within the cluster β_μ($\kappa=1,\cdots,\mu$). The first term in Eq. 2 is the contribution of atom pairs within clusters and the second term the one of inter-cluster atom pairs.

Let us use $\vec{r}_{cll'}$ to denote the vector distance from the center of the l-th molecule to that of the l′-th one within the cluster α_ν, and $\vec{r}_{cl\kappa}$ the vector distance from the center of the l-th molecule in the cluster α_ν to the center of the κ-th molecule in the cluster β_μ. Then, $\vec{r}_{n_ln_{l'}}=\vec{r}_{cll'}-\vec{r}_{cn_l}+\vec{r}_{cn_{l'}}$ and $\vec{r}_{n_ln_\kappa}=\vec{r}_{cl\kappa}-\vec{r}_{cn_l}+\vec{r}_{cn_\kappa}$, where $\vec{r}_{cn_l}$ is the vector distance from the center of the molecule l to its n_l-th nucleus, and Eq. 2 is rewritten as follows,

$$S_m(Q) = N_m^{-1}\Sigma^{-2}\langle\sum_\nu\sum_{\alpha_\nu}\sum_{l,l'}\exp(i\vec{Q}\cdot\vec{r}_{cll'})\sum_{n_l,n_{l'}} b_{n_l}b_{n_{l'}} \times\exp\{i\vec{Q}\cdot(-\vec{r}_{cn_l}+\vec{r}_{cn_{l'}})\}\rangle + N_m^{-1}\Sigma^{-2}\langle\sum_{\nu,\mu}\sum_{\substack{\alpha_\nu,\beta_\mu\\(\alpha_\nu\neq\beta_\mu)}}\sum_{l,\kappa}\exp(i\vec{Q}\cdot\vec{r}_{cl\kappa})\sum_{n_l,n_\kappa} b_{n_l}b_{n_\kappa} \times\exp\{i\vec{Q}\cdot(-\vec{r}_{cn_l}+\vec{r}_{cn_\kappa})\}\rangle. \quad (3)$$

We adopt here the following assumption: all clusters of equal size have an identical structure on the average (assumption I). Then, the first term of Eq. 3 becomes as follows,

the first term in Eq. 3

$$= N_m^{-1}\Sigma^{-2}\sum_\nu N_\nu\langle[\sum_{l,l'}\exp(i\vec{Q}\cdot\vec{r}_{cll'})\sum_{n_l,n_{l'}} b_{n_l}b_{n_{l'}} \times\exp\{i\vec{Q}\cdot(-\vec{r}_{cn_l}+\vec{r}_{cn_{l'}})\}\rangle, \quad (4)$$

and further, with respect to the second term in Eq. 3, we assume that $\vec{r}_{cl\kappa}$, $\vec{r}_{cn_l}$, $\vec{r}_{cn\kappa}$ are all statistically independent. That is, the molecules belonging to different clusters are assumed to be orientationally-uncorrelated (assumption II). Then,

the second term in Eq. 3

$$= N_m^{-1}\Sigma^{-2}\sum_{\nu,\mu}\sum_{\alpha_\nu,\beta_\mu}\langle\sum_{l,\kappa}\exp(i\vec{Q}\cdot\vec{r}_{cl\kappa})\rangle \times\langle\sum_{n_l} b_{n_l}\exp(-i\vec{Q}\cdot\vec{r}_{cn_l})\rangle\langle\sum_{n_\kappa} b_{n_\kappa}\exp(i\vec{Q}\cdot\vec{r}_{cn_\kappa})\rangle - N_m^{-1}\Sigma^{-2}\sum_\nu N_\nu\sum_{l,l'}\langle\exp(i\vec{Q}\cdot\vec{r}_{cll'})\rangle \times\langle\sum_{n_l} b_{n_l}\exp(-i\vec{Q}\cdot\vec{r}_{cn_l})\rangle\langle\sum_{n_{l'}} b_{n_{l'}}\exp(i\vec{Q}\cdot\vec{r}_{cn_{l'}})\rangle. \quad (5)$$

From Eqs. 3—5, the $S_m(Q)$ for the liquid becomes

$$S_m(Q) = \sum_\nu\frac{x_\nu}{\nu}f^\nu(Q) + N_m^{-1}\Sigma^{-2}\sum_{\nu,\mu}\sum_{\alpha_\nu,\beta_\mu}\sum_{l,\kappa}\langle\exp(i\vec{Q}\cdot\vec{r}_{cl\kappa})\rangle \times\langle\sum_{n_l} b_{n_l}\exp(-i\vec{Q}\cdot\vec{r}_{cn_l})\rangle\langle\sum_{n_\kappa} b_{n_\kappa}\exp(i\vec{Q}\cdot\vec{r}_{cn_\kappa})\rangle, \quad (6)$$

where

$$f^{\nu}(Q) = \Sigma^{-2}[\langle \sum_{l,l'} \exp(i\vec{Q}\cdot\vec{r}_{cll'}) \sum_{n_l, n_{l'}} b_{n_l} b_{n_{l'}} \times \exp\{i\vec{Q}\cdot(-\vec{r}_{cn_l}+\vec{r}_{cn_{l'}})\}\rangle - \sum_{l,l'} \langle \exp(i\vec{Q}\cdot\vec{r}_{cll'})\rangle \langle \sum_{n_l} b_{n_l} \exp(-i\vec{Q}\cdot\vec{r}_{cn_l})\rangle \times \langle \sum_{n_{l'}} b_{n_{l'}} \exp(i\vec{Q}\cdot\vec{r}_{cn_{l'}})\rangle]_{\nu}. \quad (7)$$

In order to express the second term in Eq. 6 as a practically applicable form, we take the factor $\langle \sum_{n_l} b_{n_l} \exp(i\vec{Q}\cdot\vec{r}_{cn_l})\rangle$ to be independent of ν and replace it by the averaged value

$$\left\{\sum_{\nu} \frac{x_{\nu}}{\nu}\left[\sum_{l}[\sum_{n_l} b_{n_l}\langle \exp(i\vec{Q}\cdot\vec{r}_{cn_l})\rangle]^2\right]_{\nu}\right\}^{1/2}, \quad \text{(assumption III)}. \quad (8)$$

Thus, we obtain finally the formula for the $S_m(Q)$ in the form

$$S_m(Q) = \sum_{\nu} \frac{x_{\nu}}{\nu} f^{\nu}(Q) + S_c(Q)\cdot \bar{f}_{2U}(Q), \quad (9)$$

$$S_c(Q) = N_m^{-1}\langle \sum_{i,j} \exp(i\vec{Q}\cdot\vec{r}_{cij})\rangle = 1 + N_m^{-1}\langle \sum_{i\neq j} \exp(i\vec{Q}\cdot\vec{r}_{cij})\rangle, \quad (10)$$

$$\bar{f}_{2U}(Q) = \Sigma^{-2} \sum_{\nu} \frac{x_{\nu}}{\nu}\left[\sum_{l}[\sum_{n_l} b_{n_l}\langle \exp(i\vec{Q}\cdot\vec{r}_{cn_l})\rangle]^2\right]_{\nu}. \quad (11)$$

The Eqs. 7—11 are an extension of the formula Eqs. 7—11 in I, which are applicable to the liquid consisting of molecular clusters of various sizes including monomer molecules. For $x_{\mu}=1$ and $x_{\nu(\neq\mu)}=0$, Eq. 9 reproduces Eq. 7 in I.

Further, in order to elucidate the physical meaning of Eqs. 7—11, we rewrite Eq. 9 and obtain, separating the intramolecular contribution from the intermolecular one, in the form

$$S_m(Q) = \sum_{\nu} \frac{x_{\nu}}{\nu} f_1^{\nu}(Q) + \bar{f}_{2U}(Q)[S_c(Q)-1] + \sum_{\nu\geqq 2} \frac{x_{\nu}}{\nu} f_c^{\nu}(Q), \quad (12)$$

$$f_1^{\nu}(Q) = \Sigma^{-2}[\langle \sum_{l} |\sum_{n_l} b_{n_l} \exp(i\vec{Q}\cdot\vec{r}_{cn_l})|^2\rangle]_{\nu}, \quad (13)$$

and

$$f_c^{\nu}(Q) = \Sigma^{-2}[\langle \sum_{l\neq l'} \exp(i\vec{Q}\cdot\vec{r}_{cll'}) \sum_{n_l, n_{l'}} b_{n_l} b_{n_{l'}} \times \exp\{i\vec{Q}\cdot(-\vec{r}_{cn_l}+\vec{r}_{cn_{l'}})\rangle - \sum_{l\neq l'} \langle \exp(i\vec{Q}\cdot\vec{r}_{cll'})\rangle \langle \sum_{n_l} b_{n_l} \exp(-i\vec{Q}\cdot\vec{r}_{cn_l})\rangle \times \langle \sum_{n_{l'}} b_{n_{l'}} \exp(i\vec{Q}\cdot\vec{r}_{cn_{l'}})\rangle]_{\nu}, \quad (14)$$

where $f_1^{\nu}(Q)$ is the intramolecular contribution within the cluster composed of ν molecules. The first sum $\sum_{\nu}(x_{\nu}/\nu)f_1^{\nu}(Q)$ $(\equiv f_1(Q))$ is the overall averaged intramolecular contribution in the liquid. The Eqs. 12—14 are compared to Eqs. 176—179 in a text by Hansen and McDonald[7] (originally derived by Gubbins *et al.*[8,9]), though the latters are impractical except for very simple cases because of the difficulties arising from the calculation of higher order spherical harmonics expansions. The third term $\sum_{\nu}(x_{\nu}/\nu)f_c^{\nu}(Q)$ in Eq. 12 corresponds to the sum of the higher order expansion terms in Gubbins *et al.*'s formula.

In the expression of Eq. 9, it can be seen that for $Q\to 0$ $S_m(Q)\to S_c(Q)$ because $f^{\nu}(Q)\to 0$ and $\bar{f}_{2U}(Q)\to 1$. On the other hand, in the expression of Eq. 12, $S_m(Q)\to f_1(Q)$ when $Q\to\infty$ as is directly seen.

Structure Factor $S_m(Q)$ for the Pentamer–Monomer Mixture Model. From Eqs. 7—11, we can give here the formula of $S_m(Q)$ for the pentamer–monomer mixture model[10,11] for the later analysis of neutron diffraction data, where the form of the pentamer is such as shown in Fig. 3 of paper I. In this case, we put $x_1\neq 0$ and $x_5\neq 0$ (others=zero). Eq. 9 becomes

$$S_m(Q) = x_1 f^1(Q) + \frac{x_5}{5} f^5(Q) + \bar{f}_{2U}(Q) S_c(Q), \quad (15)$$

where the factors $f^1(Q)$ and $f^5(Q)$ are expressed by applying Eq. 7 for the case of $\nu=1$ and $\nu=5$, respectively, as

$$f^1(Q) = f_1^1(Q) - f_{2U}^1(Q) = f_1^1(Q) - \Sigma^{-2}[\sum_{n} b_n\langle \exp(i\vec{Q}\cdot\vec{r}_{cn})\rangle]^2_{\nu=1} \quad (16)$$

and

$$\frac{1}{5}f^5(Q) = S_m^p(Q) - f_{2U}^5(Q)[S_{m,p}^{(00)}(Q)+1] = S_m^p(Q) - \Sigma^{-2}\frac{1}{5}\sum_{l}^{5}[\sum_{n_l} b_{n_l}\langle \exp(i\vec{Q}\cdot\vec{r}_{cn_l})\rangle]^2_{\nu=5} \times [S_{m,p}^{(00)}(Q)+1]. \quad (17)$$

The factor $f_1^1(Q)$ is the intramolecular structure factor for monomer molecules and the two factors, $f_{2U}^1(Q)$ and $f_{2U}^5(Q)$, are the molecular form factor for monomers and pentamers, respectively, which are given in relation to the assumption II. $S_m^p(Q)$ is the intrapentamer structure factor (Eq. 13 in I) and $S_{m,p}^{(00)}(Q)$ the contribution from intra-pentamer O–O pairs only (Eq. 16 in I). For $x_5=1$ and $x_1=0$, Eq. 9 becomes Eq. 12 in I and for $x_1=1$ and $x_5=0$ we obtain a formula for the completely-uncorrelated orientation model proposed by Egelstaff, Page, and Powles.[12,13]

Eq. 12 becomes

$$S_m(Q) = x_1 f_1^1(Q) + \frac{x_5}{5} f_1^5(Q) + \bar{f}_{2U}(Q)[S_c(Q)-1] + \frac{x_5}{5} f_c^5(Q). \quad (18)$$

The first two terms in Eq. 18 are the averaged intramolecular structure factor for the pentamer–monomer mixture and are grouped as $f_1(Q)$ according to the definition described above,

$$x_1 f_1^1(Q) + \frac{x_5}{5} f_1^5(Q) = f_1(Q). \quad (19)$$

$f_1^5(Q)$ $(\equiv 5S_m^{(1)}(Q)$, Eq. 15 in I) in Eq. 18 is the intramolecular contribution within the pentamer and $f_c^5(Q)$ is obtained from Eq. 14 for the case of $\nu=5$ as

$$\frac{x_5}{5} f_c^5(Q) = x_5[S_m^p(Q) - \frac{1}{5}f_1^5(Q) - f_{2U}^5(Q) S_{m,p}^{(00)}(Q)]. \quad (20)$$

Interpretation of Experimental Data

Procedure of Calculation of the $S_m(Q)$ of Pentamer–Monomer Mixture Model. Now, we can determine the liquid structure of water at each temperature by making the calculated $S_m(Q)$ curve fit with the observed curve shown in Fig. 5. In the preceding study (paper I) it has turned out that the liquid structure of water at 15 °C can be regarded as an aggregate of the regular tetrahedral pentamers. This is the case $x_5=1$ and $x_1=0$ in Eqs. 15—17. At more elevated temperatures, a part of the pentamers is supposed to be destroyed. Then, we can use here Eqs. 15—17 for the calculation of the $S_m(Q)$ of the pentamer-monomer mixture model with due assignment of x_5 values as parameter.

In applying Eqs. 15—17, the structure of the pentamer is taken to be identical with that shown in Fig. 3 in I ($r_{OD}=0.98$ Å, $r_{DD}=1.60$ Å, and DOD angle= 109.5°) and the molecular structure of the monomer is that for the vapour ($r_{OD}=0.96$ Å, $r_{DD}=1.52$ Å, and DOD angle=104.5°).[1,2,14] For the molecular-centers structure factor of the liquid, $S_c(Q)$, the observed X-ray intensity data reported by Narten and Levy (25, 50, 75, and 100 °C)[15] were used, together with the data by Hajdu *et al.* (25 and 50 °C)[16] when required for comparison. Some appreciable differences are observed in these X-ray data, especially with respect to the first peak, and a discussion for the X-ray data will be made in the later section.

Figure 5 shows that a monotonous falling of the main peak at 2 Å^{-1} and the neighboring hump at *ca.* 4 Å^{-1} is produced by increasing temperature while the $S_m(Q)$ curves are quite unchanged in the range of $Q\gtrsim 6$ Å^{-1}. This latter fact is explained as: the $S_m(Q)$ in higher Q region is determined primarily by the intramolecular contribution only. The main interest in recent studies of liquid water has been, thus, concentrated upon the behaviors of the $S_m(Q)$ curves in the region of $Q\lesssim 6$ Å^{-1}.[1,13,17]

Determination of the Best Fit Model by Comparison of $S_m(Q)_{calcd}$ with $S_m(Q)_{obsd}$. We first determined the value of pentamer fraction x_5 by fitting the calculated $S_m(Q)$ curves with the experimental data. The calculated $S_m(Q)$ associated with the variation of x were compared with the observed neutron $S_m(Q)$ data at 25, 50, 70, and 95 °C, respectively, in Fig. 6. For the experimental data at 25 °C, the best fit $S_m(Q)$ curve was obtained in the case of $x_5=0.85$, at 50 °C $x_5=0.75$, at 70 °C $x_5=0.65$, and 95 °C $x_5=0.55$. The agreement of the calculated $S_m(Q)$ curves with the experimental ones is very excellent at all temperatures. Taking account of experimental errors, the deviations of x_5 are found to be ±0.05 for all cases. The x_5 values determined are shown in Fig. 7 including the result for the data at 15 °C reported in I.

Thus, the variation of the structure of liquid water with temperature is fundamentally explained by the pentamer-monomer mixture model with appropriate pentamer fractions according to Eqs. 15—17. It is concluded that liquid water is regarded as a mixture of regular tetrahedral pentamers and non-hydrogen-bonded monomers at 25—95 °C.

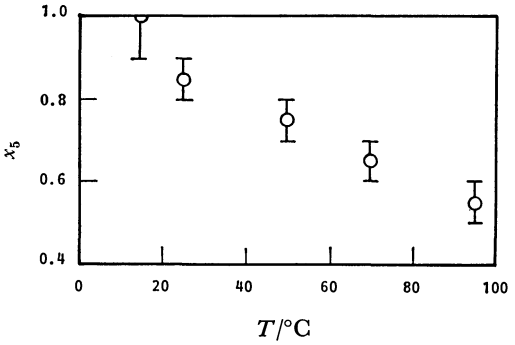

Fig. 7. Pentamer fraction x_5 determined by fitting the $S_m(Q)_{calcd}$ with the $S_m(Q)_{obsd}$ at each temperature. The vertical rod indicates the range of deviations of x_5.

Change of the Principal Peak at 2 Å^{-1} with Temperature. As seen in Table 1, when the temperature is raised, the intensity of the principal peak at *ca.* 2 Å^{-1} is found to decrease gradually, while the position of that to shift slightly to the higher Q-value side. Temperature dependence of the peak intensity and that of its position are shown in Figs. 8(a) and (b), respectively. The trend of the intensity change of the calculated result agrees with that of the experimental data, and the absolute intensity is in agreement with the measured one within the spread of the X-ray data used for $S_c(Q)$. With respect to the shift in the position

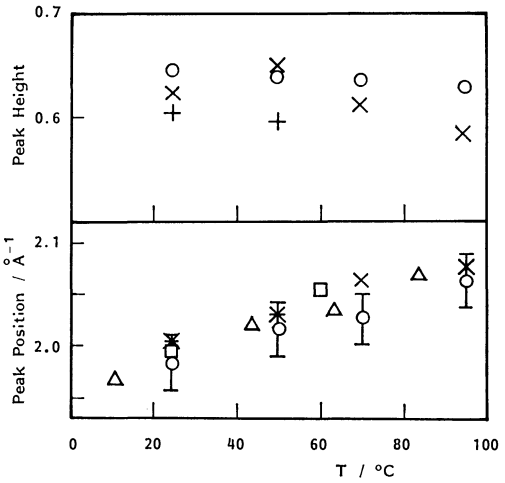

Fig. 8. The change of the intensity and the position of the principal peak at 2 Å^{-1} with the variation of temperature.
○: Observed by the authors, △: observed by Walford and Dore ($\lambda_0=1.13$ Å),[17] □: observed by Walford and Dore ($\lambda_0=0.84$ Å),[17] ×: calculated by the authors with the use of Narten and Levy's X-ray intensity data,[15] +: calculated by the authors with the use of Hajdu *et al.*'s X-ray intensity data.[16]

of the peak, the agreement between the calculated and observed results is very good as a whole within the experimental accuracy.

X-Ray Intensity Data. We used the observed X-ray intensity data mainly provided by Narten and Levy[15] for the calculation of $S_c(Q)$. The X-ray data are shown in Fig. 9, together with the data by Hajdu *et al.*[16] As clearly seen in Fig. 9, the two intensity data show some appreciable discrepancies certainly. However, with respect to the intensity and position of the principal peak of $S_m(Q)_{calcd}$, the influence of the discrepancies on the final $S_m(Q)$ for neutrons through the calculated values of $S_c(Q)$ is within the range of experimental errors: concerning the peak intensities of $S_m(Q)$, it is within the range of circles and concerning the positional shift, within the range of vertical rod (Fig. 8). It is certain that this discrepancies does not affect the conclusion of the present study, and we have used the data by Narten and Levy on the whole.

The values of $x_5[1+S^{(00)}_{m,p}(Q)]$ calculated are shown together in Fig. 9. The overall agreement of the values with the experimental data is fairly good except in the range of $Q \lesssim 2$ Å^{-1}, though the factor $x_5[1+S^{(00)}_{m,p}(Q)]$ is the intra-pentamer contribution only. This shows that it is a main contribution to total intensities in the case of X-rays. And, to see in details, the calculated curves are in better agreement with the data of Narten at various temperatures on the whole, except for the deviation in the first peak[1] and that in the range of $Q=4.5$—6 Å^{-1}. Thus, the X-ray data also is expected to support the essential effectiveness of the pentamer-monomer mixture model as a whole.

Discussion and Conclusions

Physical Meaning of the Ingredient of $S_m(Q)$. In the preceding sections we have shown that the pentamer–monomer mixture model with a due assignment of x_5 value is a best structure model in the interpretation of neutron diffraction data at 25—95 °C. Here, overall features of the temperature variation of $S_m(Q)_{calcd}$ for the model are shown in Fig. 10. It is clear in the figure that the intensities in the hump at *ca.* 4 Å^{-1} as well as those in the main peak at 2 Å^{-1} decrease gradually with increasing temperature.

In order to elucidate further the physical meaning of temperature dependence of the structure factor $S_m(Q)$, we examine ingredients of the $S_m(Q)$, by considering the terms in Eq. 18. As clearly seen in Fig. 11, the first peak is mainly composed of the sum of the curve (a)$\equiv f_1(Q)$ and the curve (c)$\equiv \bar{f}_{2U}(Q)[S_c(Q)-1]$, expressing the averaged separation between two adjacent centers of water molecules to be about 3 Å, and, on the other hand, the hump at *ca.* 4 $Å^{-1}$ is originated from the curve (b)$\equiv (x_5/5)f_c^5(Q)$, which is ascribed to the presence of the tetrahedral pentamer. The sum of curves (a) and (c) ($\equiv f_1(Q)+\bar{f}_{2U}(Q)[S_c(Q)-1]$) corresponds to the $S_m(Q)$ for completely-uncorrelated (at molecular level) orientation model, as described by Egelstaff, Page and Powles.[12,13] Hence, it is stated that the contribution of curve (b) (Eq. 20) originated from the presence of the tetrahedral pentamers forms the essential character of the liquid structure of water, producing the hump at *ca.* 4 $Å^{-1}$ in the $S_m(Q)$ curves.

Concluding Remarks. Neutron structure factors $S_m(Q)$ of D_2O were determined at 25, 50, 70, and 95 °C. The diffraction data were analyzed by using a general expression of $S_m(Q)$ derived from a new

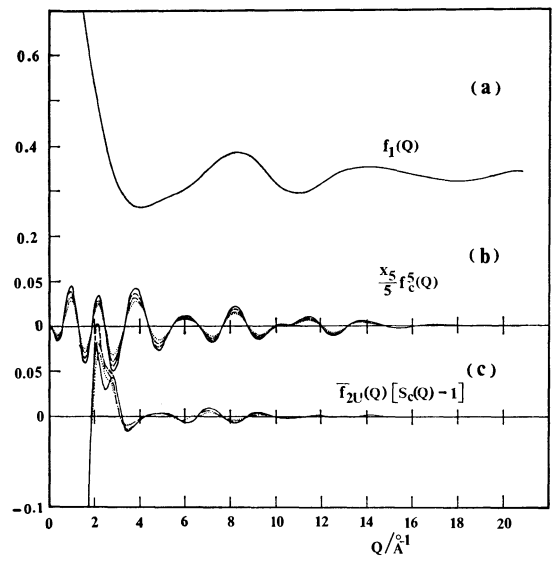

Fig. 11. Contributions of (a) $f_1(Q)$ (Eq. 19), (b) $\frac{x_5}{5}f_c^5(Q)$ (Eq. 20), and (c) $\bar{f}_{2U}(Q)[S_c(Q)-1]$ to the $S_m(Q)_{calcd}$ (Eq. 18).
——: $x_5=0.85$, - - -: $x_5=0.75$, —·—: $x_5=0.65$, ……: $x_5=0.55$.

theoretical procedure of analysis which is generally applicable to the fluid system composed of molecular clusters with various sizes. The following conclusions were obtained:

1) The pentamer–monomer mixture model with the due value of pentamer fraction x_5 assigned is the best one as a fundamental structure model of water at temperatures, 25—95 °C, for the explanation of diffraction data.

2) The x_5 values determined by fitting the $S_m(Q)_{calcd}$ with the $S_m(Q)_{obsd}$ at each temperature are $x_5=0.85\pm0.05$ at 25 °C, $x_5=0.75\pm0.05$ at 50 °C, $x_5=0.65\pm0.05$ at 70 °C, and $x_5=0.55\pm0.05$ at 95 °C, respectively.

3) The decrease of x_5 with temperature rise indicates the destruction of pentamers expected at elevated temperatures and the effect of the destruction appears mainly as the gradual decrease of intensities in the first peak at 2 Å^{-1} and the hump at *ca.* 4 Å^{-1} in the neutron structure factor curves.

4) The hump at *ca.* 4 Å^{-1} in the $S_m(Q)$ curves is originated from the presence of the tetrahedral pentamers forming the essential character of the liquid structure of water.

However, their data are unreliable for its experimental inaccuracy because "it was discovered that the incident beam was contaminated by a contribution from 2.26 Å neutrons (arising from second-order reflections in the monochrometor) which was estimated to be 28 per cent" as they stated in their article.

One-photon and Two-photon Electronic Spectra of Two Caged Amines

Narishi GONOHE, Norio YATSUDA, Naohiko MIKAMI, and Mitsuo ITO*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai, 980

(Received March 1, 1982)

The one-photon fluorescence excitation and two-photon resonant multiphoton ionization spectra of the $S_1 \leftarrow S_0$ transition of 1,4-diazabicyclo[2.2.2]octane (DABCO) in a supersonic free jet have been obtained and analyzed. It was found from the vibrational analysis that the $S_1 \leftarrow S_0$ transition is one-photon forbidden, two-photon allowed and the one-photon absorption appears by the vibronic interaction between the S_1 and S_2 states through the e′ vibrations. In addition, from the fluorescence spectrum and the polarization studies of the two-photon spectrum using the two linearly polarized laser beams of different wavelengths, it was concluded that the S_1 state is $^1A_1'$. The sequence structure involving the low-frequency cage torsional vibration has been observed in the two-photon resonant multiphoton ionization spectra of DABCO and 1-azabicyclo[2.2.2]octane (ABCO). The potential functions with respect to the torsional motion for both ground and excited states have been determined by utilizing the observed vibrational levels. It was found that the torsional potential has a broad minimum near the D_{3h} (for DABCO) and C_{3v} (for ABCO) conformations.

The electronic spectra of 1,4-diazabicyclo[2.2.2]octane (DABCO) and 1-azabicyclo[2.2.2]octane (ABCO) (Fig. 1) have been studied by many workers[1–6] with special interest in their cage structures. The spectra of these molecules with the rigid structure generally show a well-resolved vibrational structure compared with the broad and structureless spectra of non-rigid saturated amines such as trimethylamine and triethylamine. However, the one-photon absorption spectra of DABCO and ABCO due to the $S_1 \leftarrow S_0$ transition (280—260 nm for DABCO and 250—230 nm for ABCO) are still broad and show only a faint vibrational structure. Recently, Parker and Avouris[7] have observed the corresponding two-photon absorption spectra by means of fluorescence excitation (FE) and multiphoton ionization (MPI) techniques and found a rich vibronic structure. They concluded from their laser polarization studies that the S_1 state is a totally symmetric Rydberg state which is one-photon forbidden and two-photon allowed in the transition from the S_0 state. The two-photon absorption spectrum of DABCO is characteristic of extensive sequence bands involving the low-frequency torsional vibration in which the two N pyramids are twisted in the opposite sense about the C_3 symmetry axis. Although the potential of the torsional motion has been discussed by several workers[8–10] for DABCO, no conclusive result is obtained yet. The corresponding potential for ABCO has never been studied.

In the present paper, we report the one-photon fluorescence excitation spectra and the two-photon resonant multiphoton ionization spectra of the $S_1 \leftarrow S_0$ transition of DABCO seeded in a supersonic free jet. On account of temperature cooling effect through the free expansion, most of the hot bands in the room temperature spectrum disappeared and a well resolved vibrational structure showed up. Vibrational analysis of the one-photon and two-photon absorption spectra thus obtained and the $S_1 \leftarrow S_0$ fluorescence spectrum as well as the laser polarization studies of the two-photon absorption spectrum led us to a definite assignment of the S_1 state of DABCO. The torsional potential was also obtained for both S_0 and S_1 states of DABCO and ABCO from the two-photon resonant multiphoton ionization spectra of the vapor and the supersonic free jets.

Experimental

The experimental setup for measurements of the FE and MPI spectra of a supersonic free jet was already described elsewhere.[11,12] A Molectron scanning dye laser (DL-14) pumped by a nitrogen laser (UV-22) was used as an exciting light source for measurements of the two-photon resonant MPI spectrum and the second harmonic of the dye laser for the one-photon resonant FE spectrum. The FWHM of the dye laser light was about 0.5 cm^{-1}. Coumarin 540 (Exciton) was used to cover the spectral region of the $S_1 \leftarrow S_0$ transition. The MPI spectra of the vapor at room temperature were measured with a metal gas cell equipped with windows and a pair of electrodes instead of the supersonic jet cell. The fluorescence spectrum of DABCO vapor at room temperature excited by the frequency-doubled dye laser was obtained with a Nikon grating monochromator having reciprocal dispersion of 3 nm/mm in the second order and recorded by photon counting method. The fluorescence decay was also measured by the use of a boxcar integrator (Brookdeal 9415).

In polarization studies of the two-photon resonant MPI spectrum of DABCO at room temperature, two linearly polarized laser beams of different wavelengths were used; the second harmonic of the Nd:YAG laser (Quanta-Ray) and dye laser pumped by the same second harmonic. The laser beam was depolarized by passing through a polarization scrambler and then the linear polarization was achieved by a polaroid sheet. The two linearly polarized light beams thus obtained were focussed from opposit directions into the center of the metal gas cell described above. The ions produced by MPI process were detected by biassed parallel electrodes equipped inside the cell. In order to avoid the MPI process by the single beam, the laser power was sup-

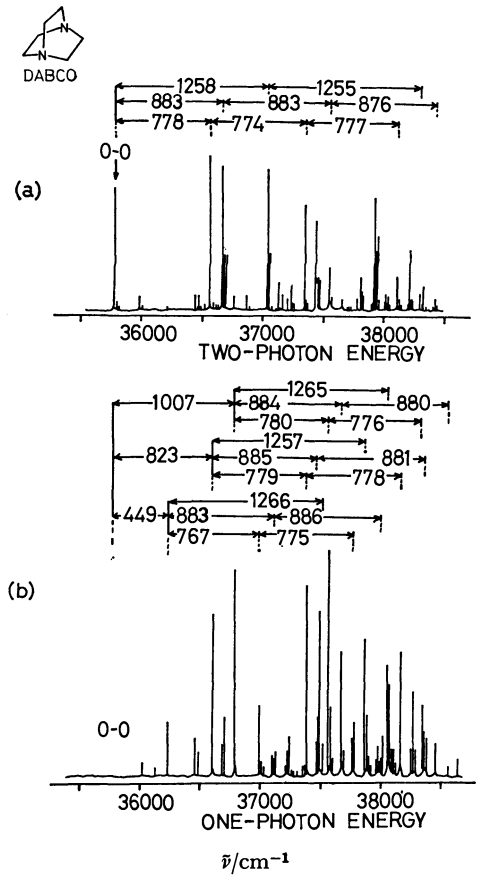

Fig. 2. (a) Two-photon resonant MPI and (b) one-photon fluorescence excitation spectra of the $S_1 \leftarrow S_0$ transition of DABCO in a supersonic free jet. The spectra are corrected for laser intensity variation.

pressed to such an extent that the ions are not produced by the signle beam.

The samples used were obtained from Tokyo-kasei Co. Ltd. DABCO was sublimed several times in vacuum. ABCO was prepared from its hydrochloride and purified by sublimation in vacuum.

Results and Discussion

One-photon and Two-photon Absorption Spectra of DABCO in a Supersonic Free Jet. The two-photon resonant MPI spectrum of DABCO in a supersonic free jet of He carrier gas at 2.5 atm. is shown in Fig. 2a. First ionization potential of DABCO is 7.2 eV. Therefore, using the dye laser in the visible region (≈540 nm), four photons are necessary to excite the molecule into the ionization continuum. Since the S_1 state of DABCO is located at around 270 nm, the spectrum shown in Fig. 2a is due to two-photon resonant four-photon ionization process. It is seen from the figure that the spectrum exhibits a well-resolved vibrational structure. Comparing with the two-photon spectrum of the vapor at room temperature reported by Parker and Avouris,[7] the individual vibronic bands become extremely sharp (with FWHM of 4 cm^{-1}) and most of the vibrational hot bands are swept out in the supersonic jet spectrum, indicating very low rotational and vibrational temperatures of the jet. The observed main vibronic bands are listed in Table 1 together

a) Frequency difference from the 0-0 transition at 35783 cm^{-1}. b) We follow the notations given in Ref. 7. c) We tentatively designate these vibrations as ν_α' (889 cm^{-1}), ν_β'(902 cm^{-1}), and ν_γ'(1269 cm^{-1}), respectively.

with their assignments. The overall spectral pattern is rather simple. The longest wavelength band at 35783 cm^{-1} [13] is readily assigned to the 0-0 band and most of other intense bands are interpreted as the vibronic bands involving the fundamentals, overtones and combinations of three excited-state totally symmetric vibrations of 778, 883, and 1258 cm^{-1}.

The one-photon absorption spectrum of the same $S_1 \leftarrow S_0$ transition of DABCO in a supersonic free jet is shown in Fig. 2b, which was taken by FE method. In contrast with the broad spectrum in vapor at room temperature, the supersonic jet spectrum exhibits a well-resolved vibrational structure. The vibrational structure is similar to that of the two-photon absorption spectrum with respect to repeated appearance of the excited-state vibrations of 778, 883, and 1258 cm^{-1}. A great difference between the two spectra is that the 0-0 band at 35783 cm^{-1} appearing strongly in the two-photon spectrum is completely missing in the one-photon spectrum. Moreover, in the one-photon spectrum, the progressions and combinations of

a) Frequency difference from the 0-0 transition at 35783 cm^{-1} (which is observed in the two-photon spectrum). b) The assignments of these vibrations were carried out on the basis of the fluorescence spectrum in Fig. 3. The numbering of the vibbration is in accord with that in Ref. 15. c) The assignment of this vibration is not established yet. We designate this vibration as ν'_{ω}.

the totally symmetric vibrations start from the bands at 36232, 36606, and 36792 cm^{-1}, which act as false origins of the spectrum. The detailed vibrational analysis is listed in Table 2.

The vibrational structures of the one-photon and two-photon spectra mentioned above are typical for one-photon forbidden and two-photon allowed transition. It is concluded, therefore, that the S_1 state of DABCO should be of either A'_1 or E'' symmetry from the optical selection rule for D_{3h} point group. Based on this conclusion, the frequency differences between the 0-0 band and the three false origins of the one-photon spectrum (449, 823, and 1007 cm^{-1}) must represent some non-totally symmetric vibrations in the excited state which make the one-photon forbidden transition allowed by vibronic coupling. Determination of the symmetry species of these excited state vibrations will lead to unambiguous assignment of the S_1 state. With this aim in mind, we measured the fluorescence spectrum of DABCO in vapor, which will be described in the next section.

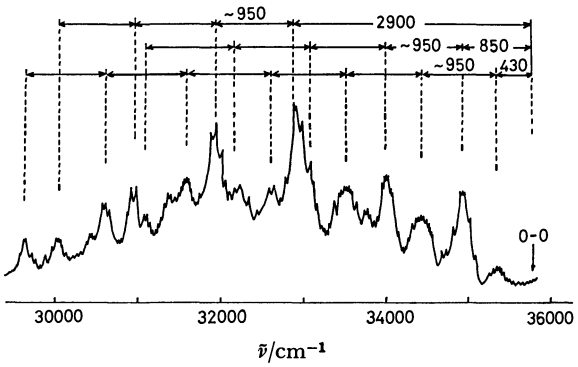

Fig. 3. Fluorescence spectrum of DABCO vapor at room temperature.

Fluorescence Spectrum of DABCO. The fluorescence spectrum of DABCO vapor was excited by frequency-doubled dye laser light at 271.7 nm, which coincides with the strongest band at 36792 cm^{-1} of the one-photon absorption spectrum. In order to obtain the fluorescence spectrum originating from the vibrationless level of the S_1 state, 2-methylbutane vapor (≈5300 Pa) was added to DABCO vapor to accelerate vibrational relaxation. The fluorescence spectrum thus obtained is shown in Fig. 3. The effective vibrational relaxation is proved by absence of band in the region of shorter wavelength than 0-0 band position.

As is seen from the figure, the 0-0 band does not appear as in the case of the one-photon absorption spectrum. There are long progressions of 950 cm^{-1} starting from 0—430, 0—850, and 0—2900 cm^{-1} bands.[14] Assignments of the ground state vibrations of DABCO are fairly well established from the IR and Raman studies.[9,15,16] According to their assignments, the ground-state frequencies of 430, 850, and 2900 cm^{-1} may be identified as $\nu_{27}(e')$, NC_3 deformation mode), $\nu_{26}(e')$, NC_3 stretching mode), and $\nu_{20}(e')$, C–H stretching mode), respectively. The frequency of 950 cm^{-1} should be a totally symmetric vibration and assigned to $\nu_4(a'_1)$ of a cage squashing mode in which the two N pyramids move along the C_3 axis in the opposite directions. The corresponding excited-state vibrational frequency is 882 cm^{-1}. Thus, the bands at 0—430, 0—850, and 0—2900 cm^{-1} are assigned as the false origins involving the ground-state e′ vibrations. The vibrations of 430 and 850 cm^{-1} correspond to the excited-state vibrations of 449 and 823 cm^{-1}, respectively, which make the false origins in the one-photon absorption spectrum. The excited-state vibration corresponding to the $\nu_{20}(e')$ of 2900 cm^{-1} is hard to find in the one-photon absorption spectrum. Remained excited-state vibration forming the false origin in the absorption spectrum is of 1007 cm^{-1}. This suggests that the 1007 cm^{-1} vibration corresponds to the ground-state vibration of 2900 cm^{-1}. If it would be the case, a drastic frequency decrease should occur for $\nu_{20}(e')$ in the transition from the ground state to the excited state.

It is established from the above results that the perturbing vibrations of the one-photon forbidden $S_1 \leftarrow S_0$ transition are of e′ symmetry. Taking into account the results obtained in a previous section, this leads

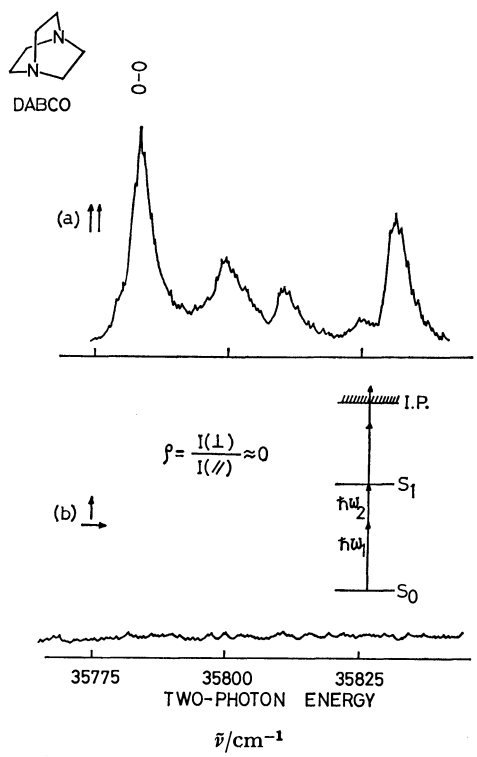

Fig. 4. Polarized two-photon resonant MPI spectrum of the $S_1 \leftarrow S_0$ transition of DABCO in the region around the 0-0 band at room temperature.

to the conclusion that the S_1 state is A_1'. The $S_1(A_1') \leftarrow S_0(A_1')$ transition should appear in the one-photon spectrum by borrowing intensity from the one-photon allowed $S_n(E') \leftarrow S_0(A')$ transition through vibronic coupling between $S_1(A_1')$ and $S_n(E')$. The $S_n(E')$ state is probably the second excited state (S_2) around 39813 cm^{-1}, which has been assigned to E' symmetry by Parker *et al.*[5,7]

Laser Polarization Studies. It was found from the vibrational analysis described in a previous section that the S_1 state is A_1'. This result is in agreement with the conclusion derived by Parker and Avouris[7] from their laser polarization studies of the two-photon absorption spectrum. In their polarization studies, they used two identical photons and measured the ratio of the two-photon absorption signal from a circularly polarized source to that from a linearly polarized source of the same intensity. We carried out a different polarization measurement. In our measurement, two linearly polarized laser beams of different frequencies were used; the frequency of one laser beam was fixed at 530 nm (second harmonic of YAG laser) and that of another beam was varied between 590 and 583 nm to observe the 0-0 band region. Two-photon resonant MPI spectrum of DABCO at room temperature was taken for both parallel and perpendicular polarizations of the two laser beams. The results obtained is shown in Fig. 4. It is seen from the figure that the spectrum appears strongly in the parallel polarization while it is extremely weak in the perpendicular polarization. The ratio ρ of the intensity of perpendicular polarization to that of parallel one (which corresponds to depolarization ratio in Raman scattering) is nearly zero. Since ρ should be 3/4 for non-totally symmetric state and less than 3/4 for totally symmetric state,[17,18] it is concluded that the S_1 state is A_1' in agreement with the result derived from the vibrational analysis.

Low Frequency Torsional Motion of DABCO and ABCO. The two-photon absorption spectrum of DABCO vapor at room temperature has been studied in detail by Parker and Avouris.[7] They found the presence of extensive sequence structure in the spectrum. The sequence structure was attributed by them to the $\Delta v = 0$ and ± 2 transitions of the $\nu_{13}(a_1'')$ low-frequency torsional motion in which the two N pyramids are twisted in the opposite sense about the C_3 symmetry axis. We also observed the identical sequence structure which is shown in Fig. 5a for the 0-0 band region. In order to confirm the assignments given by Parker and Avouris, the two-photon resonant MPI spectrum was measured for DABCO in a supersonic free jet. The result is shown in Fig. 5b. It is seen that the bands assigned to the torsional motion (which are indicated by arrows in Fig. 5a) completely disappear in the supersonic jet spectrum, supporting their assignment. Our supersonic jet spectrum adds nothing more than the results obtained by Parker and Avouris about the sequence of the a_1'' torsional vibration.

In the two-photon absorption spectrum of DABCO vapor at room temperature, Parker and Avouris also noted the presence of a minor sequence in addition to the major sequence described above. The bands belonging to the minor sequence are indicated by

open circles in Fig. 5a. Most of these bands disappear or appear weakly in the supersonic jet spectrum, indicating that they are also hot bands. These bands may be assigned to the $\Delta v=0$ transitions of a low-frequency vibration. By assuming same Franck-Condon factor for these bands as that for the 0-0 band, the frequency of the ground-state vibration involved is estimated to be about $\approx$150 cm^{-1} for a non-degenerate vibration and about $\approx$300 cm^{-1} for a degenerate vibration from the intensities of these bands relative to that of the 0-0 band of the room temperature spectrum. It is known from the vibrational spectra that the lowest-frequency fundamental vibration except the torsional vibration $\nu_{13}(a_1'')$ is $\nu_{36}(e'')$ of the rocking mode of N pyramids with the frequency of 332 cm^{-1}. Therefore, we assign the minor sequence as the $\Delta v=0$ transitions of $\nu_{36}(e'')$. It is noticed in Fig. 5 that in the supersonic jet spectrum 1′←1″ and 2′←2″ bands of $\nu_{36}(e'')$ still remain with weak intensity, while the $\Delta v=0$ and ±2 bands of $\nu_{13}(a_1'')$ are absent. Since the ground-state vibrational frequency of $\nu_{36}(e'')$ is higher than that of $\nu_{13}(a_1'')$, the above result indicates a non-Boltzmann distribution between the levels of $\nu_{13}(a_1'')$ and $\nu_{36}(e'')$ in a supersonic free jet.

Table 3 summarizes the observed transitions of DABCO associated with $\nu_{13}(a_1'')$, which will be used later for determination of the potentials of the torsional mode in the ground and excited states.

The two-photon resonant MPI spectrum of ABCO was also observed for the vapor at room temperature as well as for the supersonic jet and they are shown in Fig. 6 for the 0-0 band region. An extensive sequence structure similar to that of DABCO was found in the room temperature spectrum. The bands of the major sequence indicated by arrows in the figure are assigned to the $\Delta v=0$ and ±2 transitions of the torsional motion corresponding to $\nu_{13}(a_1'')$ of DABCO. The band indicated by the open circle is probably due to the 1′←1″ transition of the rocking motion similar to $\nu_{36}(e'')$ of DABCO. The observed transitions are summarized in Table 4. In a supersonic free jet, the intensities of all these sequence bands greatly decrease, but the 1′←1″, 2′←2″, and 3′←3″ transitions for the torsional mode and the 1′←1″ transition for the rocking mode still seen with weak intensities. This suggests that ABCO is less efficient in the vibrational cooling than DABCO.

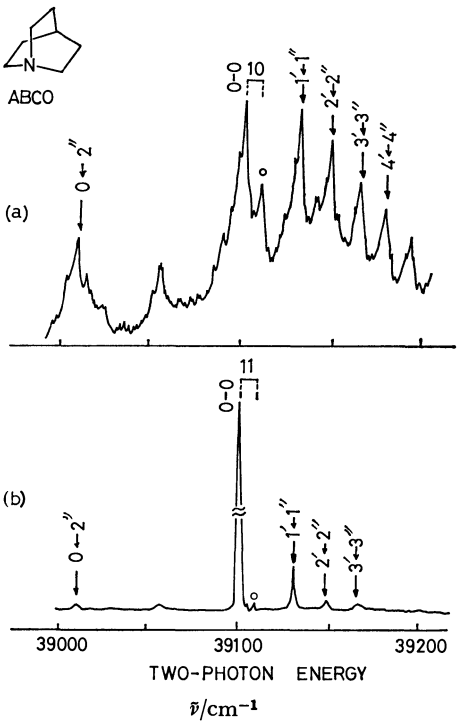

Fig. 6. Sequence structures for the 0-0 band region of ABCO in the two-photon resonant MPI spectrum. (a): At room temperature, (b): in a supersonic free jet.

By utilizing the observed transitions associated with the torsional motion given in Tables 3 and 4, we can obtain the potentials and the vibrational levels for

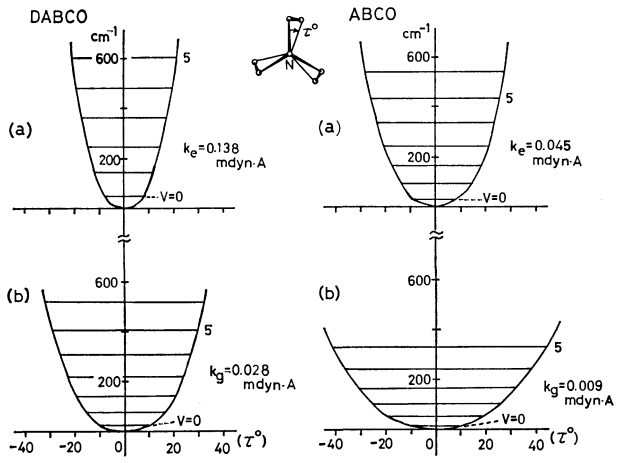

Fig. 7. The calculated potential function of the torsional vibration (a) in the excited state and (b) in the ground state of DABCO (left side) and ABCO (right side). The observed values for $v=2$ and $v=4$ are used as a reference of the calculation for the other levels.

both ground and excited states. Since only the transitions accompanying with even quantum changes are allowed in the two-photon absorption spectrum, the vibrational levels of even quantum number states are directly obtained from the experiment. We attempted to determine the torsional potentials and energy levels by assuming an anharmonic potential of $V(Q)=(1/2)kQ^2+bQ^4$, where Q is the normal coordinate of the torsional motion, $k(=4\pi^2\nu_0^2m)$ is the force constant, ν_0 and m being the zeroth-order harmonic frequency and reduced mass, respectively. Applying the first-order perturbation theory, the vibrational energy[19] is given by

$$w=\left(v+\frac{1}{2}\right)h\nu_0+\frac{3}{64\pi^4}(2v^2+2v+1)\frac{h^2b}{m^2\nu_0^2},$$

where v is the vibrational quantum number. The calculation was carried out by using the observed values of $v=2$ and $v=4$ levels for the ground and excited states with the effective reduced mass of 26.8 amu A^2/rad^2 [10] for both ground and excited states. The calculated transition energies are compared with the observed ones in Tables 3 and 4, where the values of the vibrational levels and ν_0 obtained from the calculation are also given. It is found that the calculated transition energies agree very well with the observed energies. Figure 7 shows the potential energies as a function of the "twist angle" τ about the C_3 axis. The ground-state potential is considerably flat and has a broad minimum near D_{3h} or C_{3v} conformation. Yokozeki and Kuchitsu[10] determined the ground-state potential of DABCO from their electron diffraction studies and obtained a double minimum potential with the barrier of $\approx 35\ cm^{-1}$. Since our potential without the barrier reproduces the observed energies very well, the deviation from D_{3h} or C_{3v} conformation seems to be not significant.

As is seen from Fig. 7, the torsional potential becomes sharp in the excited state. In fact, the force constant for the excited state is five times larger than that for the ground state. The sharpening may qualitatively be explained from the electronic character of the S_1 state. According to Parker and Avouris, the S_1 state of DABCO or ABCO is a totally symmetric Rydberg state arising through the excitation of a non-bonding electron localized on the nitrogen atom to the 3s nitrogen atomic orbital. Thus, the s character of the nitrogen atom increases in the S_1 state compared with that in the ground state, leading to a more rigid cage.

Conclusion

We have obtained and analyzed the one-photon FE and two-photon resonant MPI spectra due to the $S_1 \leftarrow S_0$ transition of DABCO in a supersonic free jet. It was found from the vibrational analysis that the $S_1 \leftarrow S_0$ transition is one-photon forbidden, two-photon allowed and the one-photon absorption appears by the vibronic interaction between the S_1 and S_2 states through the e′ vibrations. The S_1 state was definitely assigned to A_1' from the vibrational analyses of the absorption and fluorescence spectra as well as from the laser polarization studies. The sequence structures appearing in the two-photon absorption spectra of DABCO and ABCO have been analyzed and the potentials of the torsional motion have been determined for both ground and excited states. It has been found that the torsional potential has a broad minimum in the ground state and it becomes sharp in the excited state.

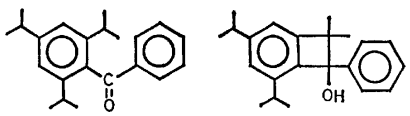
(Received March 8, 1982)

Standard energy of combustion and standard enthalpy of sublimation were determined for the title compounds with static bomb combustion calorimetry and with sublimation calorimetry, respectively. Derived standard enthalpies of combustion and of formation at 298.15 K were as follows: $\Delta H_c^\circ(c) = -(12354.3 \pm 1.8)$, $\Delta H_f^\circ(c) = -(304.6 \pm 3.4)$, and $\Delta H_f^\circ(g) = -(189 \pm 8)$ kJ mol^{-1}, respectively, for 2,4,6-triisopropylbenzophenone(**1**), and $\Delta H_c^\circ(c) = -(12440.6 \pm 1.6)$, $\Delta H_f^\circ(c) = -(218.3 \pm 3.3)$, and $\Delta H_f^\circ(g) = -(101 \pm 10)$ kJ mol^{-1}, respectively, for 3′,5′-diisopropyl-4,4-dimethyl-3-phenyl-1,2-benzocyclobuten-3-ol(**2**). The enthalpy change for the reaction: **1**(g)→**2**(g), of 88 kJ mol^{-1}, which may be supposed to be the magnitude of light energy stored in the latter molecule, has been discussed.

2,4,6-Triisopropylbenzophenone (**1**) undergoes photo-isomerization under irradiation in solution to afford 3′,5′-diisopropyl-4,4-dimethyl-3-phenyl-1,2-benzocyclobuten-3-ol (**2**) in quantitative yield[1] and the latter compound is converted to the former quantitatively, when it is heated above 120 °C or reacted with base catalyst.[2] The mechanism of the photo-isomerization has been elucidated,[2] and the hindered rotation of **1**,[3] the effect of 4′-substitution on the life-time of the triplet state of **1**,[4] and the influence of ring substitution on the life-time of the biradical from **1**[5] have been studied. Crystal structure of **1** has been determined by X-ray diffraction method.[21]

In the present study, standard energies of combustion and standard enthalpies of sublimation were determined for **1** and **2** by calorimetric methods, in order to evaluate the magnitude of light energy, stored in the latter molecule as a result of the photo-isomerization reaction. The stored energy has been discussed in terms of the strain energy of the molecule.



1 **2**

Experimental

Materials. **1**[6] and **2**[1] were prepared according to the procedure described previously. **1** was purified by recrystallization from ethanol solution followed by vacuum fractional sublimation. **1** was treated throughout with minimum exposure to light. **2** was purified by recrystallization from petroleum ether solution followed by vacuum fractional sublimation. The procedure for **2** was undertaken at temperatures below 60 °C.

Combustion Calorimetry. An isoperibol rotating bomb calorimeter with a platinum-lined bomb, described elsewhere,[7,8] was used without rotating the bomb. The calorimeter was calibrated by burning thermochemical standard benzoic acid(U.S. National Bureau of Standards SRM 39i) under certificate conditions. The certified specific energy of combustion of the benzoic acid Δu_c(ba) is $-(26434 \pm 1)$ J g^{-1}, where uncertainty is our estimate of the standard deviation of the mean. Mean and standard deviation of the mean for the energy equivalent of the empty calorimetric system ε(calor)[12] were determined to be (15157.32 ± 0.67) J K^{-1} from seven calibration experiments. A pellet of **1** was ignited in a deep crucible with a small lid[9] together with a pellet of the thermochemical standard benzoic acid(approximately 0.25 g) in order to prevent incomplete combustion of **1**. The auxiliary benzoic acid contributed to approximately one fourth of total energy change. **2** was pressed into pellets and a pellet was burnt in an ordinary open crucible without a promoter at 3.040 MPa of oxygen pressure.

Nitric acid was determined by measuring the absorbance at 202 nm of the bomb solutions. Carbon dioxide recovery was determined for **2** by the method described elsewhere[8] in order to examine the purity and/or completeness of combustion.

Sublimation Calorimetry. Sublimation enthalpy was measured as a function of temperature with the sublimation calorimetric system described elsewhere,[10] in which a Calvet microcalorimeter (DAM, ambient to 473 K type), homemade sublimation apparatuses, and Knudsen-type sample containers were incorporated. Sublimation apparatus Mark II and sample containers Mark C were employed. Both the diameter and the depth of the effusion orifice were 1.0 mm. Thin-walled Pyrex glass tubes with a closed end were used for both compounds in order to prevent the samples from contact with the metallic container.

Auxiliary Quantities. Relative atomic masses were taken from the recommendation of IUPAC Commission on Atomic Weights (1977). Densities, specific heat capacities, $(\partial U/\partial p)_T$ values, and other auxiliary quantities, which were used to reduce weights to masses in vacuum and to deduce standard energies of combustion from calorimetric data, are collected in Table 1.

Results

Results of combustion calorimetric experiments are presented in Tables 2 and 3 for **1** and **2**, respectively. Molar standard energies of combustion given in these tables refer to the following idealized combustion reaction at 298.15 K:

$$C_{22}H_{28}O(c) + (57/2)O_2(g) = 22CO_2(g) + 14H_2O(l).$$

Most of the symbols in these tables are essentially similar to those used by Hubbard *et al.*[12] ΔU_Σ denotes the sum of contributions from items 81—85 and 87—94 as defined by Hubbard *et al.*[12] $\{m(CO_2, obsd)/$

$m(CO_2, calcd)\}$ is the ratio of the observed total mass of recovered carbon dioxide to the calculated one. Mean and standard deviation of the mean for the ratio were (0.9997±0.0001) for five experiments on **2**. While trace of soot was found in the crucibles in experiments Nos. 1, 3, 5, 6, and 7 for **1** and No. 3 and 5 for **2**, no correlation was found between the soot formation and the resultant standard energy of combustion. In addition, carbon monoxide was barely detected in the bomb gas. Mean and standard deviation of the mean for molar standard energy of combustion ΔU_c°(c) were −(12338.18±0.55) and −(12424.48±0.32) kJ mol^{-1} for **1** and **2**, respectively.

Results of sublimation calorimetric experiments are summarized in Table 4. Molar standard enthalpy of sublimation ΔH_s° (T)was calculated with the equation:

$$\Delta H_s^\circ(T) = E_{calib}(S_T/S_B)(M/m),$$

where E_{calib} is the electrical energy used for calibration, (S_T/S_B) is the ratio of the sublimation enthalpy to the calibration energy, which was determined by the calorimetric experiment, m is the mass of material that effused from the sample container, and M is the molar mass of the material.

For **1**, measurements were performed at two temperatures. Observed enthalpies of sublimation were subjected to a regression analysis for linear relations between two variables.[11] The derived function was as follows: ΔH_s° (T)/kJ mol^{-1} = −0.1452(T/K) +158.8, with standard deviation from the fit of 0.3 kJ mol^{-1}. Standard enthalpy of sublimation at 298.15 K was evaluated by extrapolating the function to the reference temperature, since no heat capacity anomaly was found over the relevant temperature range in DSC heating curves of **1**. Derived standard enthalpy of sublimation at 298.15 K was (116±7) kJ mol^{-1}, where uncertainty is the one at the 95 per cent level.

The temperature dependence of $\Delta H_s^\circ(T)$ for **2** does not seem to be normal, although the observed values themselves are of reasonable magnitude: $\Delta H_s^\circ(T)$ should decrease with temperature rise. The observed values are supposed to include experimental errors of considerable magnitude, since the output voltage from the microcalorimeter was small. Although the output voltage could be increased by rising the temperature, this is not desirable for **2** owing to its thermal instability. Consequently, the observed values for **2**, given in Table 4, were averaged with equal weights, and the mean value was taken to be the value at the mean temperature. The value at 298.15 K was then estimated by assuming that the temperature dependence of $\Delta H_s^\circ(T)$ for **2** is identical with that of **1**. No heat capacity anomaly was detected in the DSC heating curves of **2** over the relevant temperature range. The estimated value at 298.15 K was (117±9) kJ mol^{-1}, where uncertainty was assigned rather arbitrarily.

Table 5. Derived thermodynamic quantities of 2,4,6-triisopropylbenzophenone(**1**) and 3′,5′-diisopropyl-4,4-dimethyl-3-phenyl-1,2-benzocyclobuten-3-ol(**2**) at 298.15 K

Compound	**1**	**2**
$-\Delta U_c^\circ$(c)/kJ mol^{-1}	12338.2±1.8	12424.5±1.6
$-\Delta H_c^\circ$(c)/kJ mol^{-1}	12354.3±1.8	12440.6±1.6
$-\Delta H_f^\circ$(c)/kJ mol^{-1}	304.6±3.4	218.3±3.3
ΔH_s°/kJ mol^{-1}	116±7	117± 9
$-\Delta H_f^\circ$(g)/kJ mol^{-1}	189±8	101±10

Derived thermodynamic quantities are presented in Table 5. Uncertainties in this table are the overall values. The overall uncertainties for ΔU_c°(c) and ΔH_c°(c) are twice the overall standard deviation of the mean for ΔU_c°(c), $\{2s(\bar{U})_\Sigma\}$. $s(\bar{U})_\Sigma$ was calculated according to:

$$s(\bar{U})_\Sigma = [s(\bar{U})^2 + \{\Delta U_c^\circ(c)s(\varepsilon)/\varepsilon(calor)\}^2 + \{\Delta \bar{U}_c^\circ(c)s(ba)/\Delta u_c(ba)\}^2 + \{M(compd)\bar{m}(ba)s(ba)/\bar{m}(compd)\}^2]^{1/2},$$

where $s(\bar{U})$, $s(\varepsilon)$, and s(ba) are the standard deviations of the mean for ΔU_c°(c), ε(calor), and Δu_c°(ba), respectively, and $\bar{m}$(ba) and $\bar{m}$(compd) are the mean masses of the benzoic acid as used as the promoter and of the compound, respectively. For **2**, m(ba)=0, and so the fourth term in the bracket of the equation is deleted. $s(\bar{U})_\Sigma$ amounted to 0.9 and 0.8 kJ mol^{-1} for **1** and **2**, respectively. Standard enthalpies of formation in the crystalline state were calculated by use of the following CODATA key values for thermodynamics:[13] $\Delta H_f^\circ(CO_2, g) = -(393.51\pm0.13)$ and $\Delta H_f^\circ(H_2O, l) = -(235.830\pm0.042)$ kJ mol^{-1}, respectively, where uncertainties are those at the 95 per cent confidence level. Overall uncertainties for ΔH_f°(c) and ΔH_f°(g), $\delta(\Delta H_f^\circ, c)$ and $\delta(\Delta H_f^\circ, g)$, respectively, were calculated as follows:

$$\delta(\Delta H_f^\circ, c) = [\delta(\Delta U_c^\circ, c)^2 + \{22\times0.13\}^2 + \{14\times0.042\}^2]^{1/2}$$

and

$$\delta(\Delta H_f^\circ, g) = [\delta(\Delta H_f^\circ, c)^2 + \delta(\Delta H_s^\circ)^2]^{1/2},$$

where $\delta(\Delta H_s^\circ)$ is the uncertainty assigned to ΔH_s°(298.15 K).

Table 6. Comparison between calculated and observed values of $\Delta H_f^\circ(g)$ for 2,4,6-triisopropylbenzophenone(**1**), 3′,5′-diisopropyl-4,4-dimethyl-3-phenyl-1,2-benzocyclobuten-3-ol(**2**), and related compounds

Discussion

Comparison between the standard enthalpies of formation in gaseous state of **1** and **2**, given in Table 5, leads to the standard enthalpy change of 88 kJ mol^{-1} for the isomerization reaction: **1**(g)→**2**(g). Since combustion and sublimation calorimetric experiments were carried out for **1** and **2** quite similarly, part of the uncertainties assigned to ΔH_f°(g) of **1** and **2** would be cancelled in calculating the difference in ΔH_f°(g) between **1** and **2**. Uncertainty for the difference is estimated to be around 10 kJ mol^{-1}. This enthalpy change may be identified with the magnitude of light energy stored in a molecule of **2** as a result of the reaction. Note that this enthalpy change is twice as large as that for the reaction: norbornadiene(g)→quadricyclane(g), with standard enthalpy change of 41.6 kJ mol^{-1} at 298.15 K.[14]

In order to interpret the large enthalpy change for the present isomerization, destabilization (strain) energy was evaluated for **1** and **2**, by use of the Laidler scheme of bond energy[15,16] and the group contribution method.[22,23] Calculated and observed standard enthalpies of formation in gaseous state are presented and compared with each other in Table 6, together with those of related compounds. As is shown in the table, both the schemes are capable of reproducing ΔH_f°(g) for benzene and isopropylbenzene reasonably well. The same is true by the group contribution method for benzophenone, but the Laidler scheme gives ΔH_f°(g) which is by 15 kJ mol^{-1} less negative than the experimental value. Destabilization energy for **1** was estimated to be 15 and −11 kJ mol^{-1} by the Laidler scheme and the group method, respectively. In view of the large uncertainty assigned to the experimental value of ΔH_f°(g) and possible uncertainty of at least 4 kJ mol^{-1} for the calculated values, these destabilization energies appear to be barely significant.

The destabilization energy of **2** amounts to 141 and

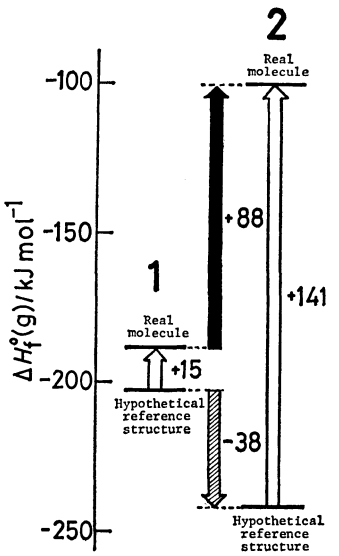

Fig. 1. Enthalpy diagram, based on the Laidler scheme of bond energy, of the gas phase photo-isomerization: 2,4,6-triisopropylbenzophenone(**1**)→3′,5′-diisopropyl-4,4-dimethyl-3-phenyl-1,2-benzocyclobuten-3-ol(**2**). Black and shaded arrows denote real and hypothetical enthalpy changes, respectively, for the reaction, and blank arrows denote estimated destabilization energies.

123 kJ mol^{-1} by the Laidler scheme and the group method, respectively. It is to be noted that these values are of similar magnitude with the destabilization energy of cyclobutene. The molecular structure of **2** has not been reported. However, according to X-ray diffraction studies on *cis*-3,4-dihalo-1,2-benzocyclobutenes (halogen=Cl, Br, and I)[17] and *cis*-1,2-benzocyclobuten-3,4-diol dinitrate,[18] carbon atoms in these molecules are almost coplanar, bond angles of the four-membered ring are similar with the corresponding ones of a cyclobutene molecule,[19] and the benzene ring is slightly elongated along the line connecting 3′ and 6′ carbon atoms. The presence of a highly strain-

ed four-membered ring and the concomitant distortion of the benzene ring seem to be among the principal origins of the enhanced destabilization observed for **2**. Another posible contribution would come from the steric hindrance between the substituents of the four-membered ring. If this contribution is neglegibly small, the destabilization energy of 123 kJ mol^{-1} would be identified with the ring correction for a 1,2-benzocyclobutene ring in the group method.[23]

In the meantime, if both **1** and **2** were neither stabilized nor destabilized as compared with each hypothetical reference structure, enthalpy change for the reaction: **1**(g)→**2**(g), would have been −38 kJ mol^{-1} (the Laidler scheme) or −46 kJ mol^{-1} (the group method), in contrast to the real value of 88 kJ mol^{-1}. The large positive enthalpy change for the real reaction is brought about by the large destabilization energy of **2**, which is far superior to the destabilization energy of **1** and also to the enthalpy change for the reaction between the hypothetical reference structures, as illustrated in Fig. 1, by use of the Laidler scheme. A similar diagram based on the group contribution method may be drawn.

Thermochemical Studies on Thioacetamide and Tetramethylthiourea. Estimation of Stabilization Energies Due to Interaction between Thiocarbonyl Group and Neighbouring Nitrogen Atom**

Sadayasu INAGAKI,† Shigeo MURATA, and Minoru SAKIYAMA*

Chemical Thermodynamics Laboratory and Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received March 10, 1982)

Standard energy of combustion at 298.15 K and standard enthalpy of sublimation as a function of temperature were determined for thioacetamide and tetramethylthiourea by oxygen bomb combustion calorimetry and sublimation calorimetry. Derived standard enthalpies of formation in crystalline and gaseous states at 298.15 K are $-(70.6\pm1.1)$ and (12.7 ± 1.2) kJ mol^{-1}, respectively, for thioacetamide, and $-(38.3\pm2.3)$ and (44.7 ± 2.4) kJ mol^{-1}, respectively, for tetramethylthiourea. Stabilization energies of these molecules were evaluated by estimating the standard enthalpies of formation in gaseous state for the hypothetical reference structures by use of the group contribution method.

While ketones are usually stable substances, thioketones are very unstable at ambient temperatures. This suggests the inherent instability of a thiocarbonyl group as compared with a carbonyl group. However, when a thiocarbonyl group neighbours a nitrogen atom in a molecule, the group is substantially stabilized: Thioamides and thioureas are fairly stable at room temperatures. The stabilization seems to be caused by the interaction of a thiocarbonyl π-electrons with nitrogen lone pair electrons. Analogous but more enhanced stabilization is observed in amides and ureas.

In this paper, standard enthalpies of combustion and of sublimation at 298.15 K are reported on thioacetamide and tetramethylthiourea. Derived standard enthalpies of formation in gaseous state are compared with those estimated for the hypothetical reference structures to evaluate the stabilization energies for these molecules.

Experimental

Materials. Thianthrene, which was used to test the reliability of our combustion calorimetric equipment and procedure for sulfur-containing organic compounds, was synthesized by the method of Fries and Vogt,[1] and was purified by recrystallization from benzene solution followed by vacuum fractional sublimation and zone-melting. Commercial thioacetamide (Nakarai, G. R.) and tetramethylthiourea (Tokyo Kasei, G. R.) were purified by recrystallization from benzene and ligroine solutions, respectively, followed by vacuum fractional sublimation. The purity of the samples was assessed from DSC heating curves in the melting region as follows: thianthrene, 99.93; thioacetamide, 99.99; and tetramethylthiourea, 99.97 mol%, respectively.

Combustion Calorimetry. An isoperibol rotating bomb calorimeter, described elsewhere,[2,3] was employed. The calorimeter was calibrated by burning thermochemical standard benzoic acid (U. S. National Bureau of Standards, SRM 39i) in the presence of 10 g of water at 3.040 MPa of oxygen pressure. The certified value for the specific energy of combustion of the benzoic acid is $-(26434\pm1)$ J g^{-1} under certificate conditions and it follows[4] that the specific energy of combustion is $-(26414\pm1)$ J g^{-1}, where uncertainties are our estimates of standard deviation of mean. The calibration experiments were carried out in the bomb rotation mode to be described below. Mean and standard deviation of the mean for the energy equivalent of the empty calorimetric system ε(calor),[7] derived from nine experiments, were (15162.31 ± 0.55) J K^{-1}.

Thianthrene, thioacetamide and tetramethylthiourea were pressed into pellets. The bomb was charged with a sample, water (10 g), and oxygen (3.040 MPa at 298.15 K). The bomb was not flushed before charging the oxygen in thianthrene and thioacetamide experiments. Every sample was ignited in an ordinary platinum crucible by discharging a 7.184 mF capacitor bank, previously charged to 36.5 V, through a platinum wire.

Both calibration and combustion experiments were designed to include successive four rating periods, denoted with $i(=1\text{—}4)$. Each period is composed of twelve 101.5 s intervals. At the end of each interval, a temperature reading displayed on a Hewlett-Packard quartz thermometer (2801A with option M40) with the resolution of 1×10^{-5} K was recorded. Although the temperature reading is the mean during a 100 s duration in the interval, it was taken to be the mean temperature for the whole interval. A sample was ignited at the end of the first rating period. Bomb rotation was started at the end of the first interval of the second rating period and continued to the end of the third rating period.

Temperature readings of the first and fourth rating periods and of the third rating period were fitted to the following integrated forms of the Newton's cooling law equation: For $i=1$ or 4,

$$\theta = \theta_\infty^s - (\theta_\infty^s - \theta_i^0)\exp[-k(t-t_i^0)], \quad (1)$$

and for $i=3$,

$$\theta = \theta_\infty^r - (\theta_\infty^r - \theta_i^0)\exp[-k(t-t_i^0)], \quad (2)$$

where θ_∞^r and θ_∞^s are the convergence temperatures for the calorimeter in which the bomb is rotating and not rotating, respectively, θ_i^0 is the temperature at time t_i^0, which is the starting time of the i-th rating period, and k is the cooling constant throughout an experiment.

In the first step of analysis, an appropriate value was assumed for k and a least squares procedure for linear relation between θ and $\exp[-k(t-t_i^0)]$ was conducted for the temperature readings of the first and fourth rating periods, respectively, to determine θ_∞^s and θ_i^0. By use of the derived equations, temperature and rate of temperature change were calculated for the midtimes of the first and fourth rat-

ing period. Then, k was calculated with the following equation:

$$k = [(d\theta/dt)_1^m - (d\theta/dt)_4^m]/(\theta_4^m - \theta_1^m),$$

where θ_1^m and θ_4^m are the tempertures at the midtimes of the first and fourth rating periods, respectively, and $(d\theta/dt)_1^m$ and $(d\theta/dt)_4^m$ are the corresponding rates of temperature change. By using successively renewed k values, the procedure described above was repeated, until a consistent set of k and θ_∞^s was obtained. The temperature readings of the third period were fitted to Eq. 2 by the least squares procedure by use of the final k value to determine θ_∞^r and $\theta_3{}^0$.

Corrected temperature rise, $\Delta\theta_c$, was calculated with the following equation:

$$\Delta\theta_c = \theta_e - \theta_b - 101.5k[\theta_\infty^s + 11\theta_\infty^r - \sum_1^{12} \theta_2(j)],$$

where θ_b and θ_e are the temperatures at the start and end of the second rating period, respectively, and $\theta_2(j)$ is the j-th reading of the period. θ_b was calculated from Eq. 1 with $i=1$ by letting $(t-t^0{}_1)=1218$ s, and θ_e is equal to $\theta^0{}_3$.

Nitric acid in the bomb solution was converted to ammonia with Devarda's alloy and the ammonia was absorbed in aqueous sulfuric acid of known concentration. The unreacted sulfuric acid was determined with aqueous sodium hydroxide. Nitrous acid was determined by use of Griess-Ilosvay reagent. The amount of nitrous acid was less than 0.1% of nitric acid. Carbon monoxide was scarcely detected from the bomb gas after combustion experiments.

Sublimation Calorimetry. Sublimation enthalpy was measured as a function of temperature with a sublimation calorimetric system described elsewhere,[5] in which a Calvet microcalorimeter (DAM, ambient to 473 K type), homemade sublimation apparatus (Mark II) and sample containers (Mark C) were incorporated. Both the diameter and the depth of the effusion orifice were 1.0 mm.

Auxiliary Quantities. Relative atomic masses were taken from the recommendation of IUPAC Commission on Atomic Weights (1977). Densities, specific heat capacities, $(\partial U/\partial p)_T$ values, and other auxiliary quantities, which were used to reduce weights to masses in vacuum and to deduce standard energies of combustion from observed calorimetric data, are collected in Table 1. The internal volume of the bomb was 0.3469 dm^3.

Results

Molar standard energies of combustion given in this paper refer to the following idealized combustion reaction at 298.15 K:

$$C_aH_bN_cS_d(c) + [(4a+b+6d)/4]O_2(g) + (116d-b/2)H_2O(1) = aCO_2(g) + (c/2)N_2(g) + d[H_2SO_4 + 115H_2O](1),$$

where $a=12$, $b=8$, $c=0$, and $d=2$ for thianthrene, $a=2$, $b=5$, $c=1$, and $d=1$ for thioacetamide, and finally $a=5$, $b=12$, $c=2$, and $d=1$ for tetramethylthiourea.

Table 2. Comparison of the present result on thianthrene with literature values

Investigator	$-\Delta H_c^\circ(c)$ / kJ mol^{-1}

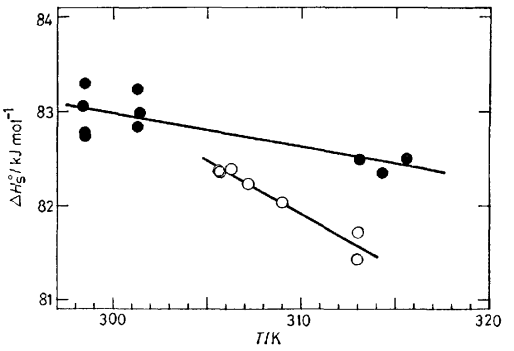

Fig. 1. Standard enthalpy of sublimation versus temperature plot of thioacetamide(○) and tetramethylthiourea(●).

Standard energies of combustion of thianthrene obtained from four experiments were −7241.71, −7245.19, −7242.42, and −7244.05 kJ mol^{-1} with the mean and standard deviation of the mean of −(7243.34±0.79) kJ mol^{-1}. Derived standard enthalpy of combustion is compared with literature values in Table 2. The uncertainty assigned to the present value given in Table 2 is twice the overall standard deviation of mean, to be described below.

Six combustion experiments were carried out for thioacetamide and tetramethylthiourea, respectively. Clean combustion was achieved in every combustion experiment. Combustion calorimetric results on thioacetamide and tetramethylthiourea are presented in Tables 3 and 4, respectively. Most of the symbols in these tables are essentially similar to those used by Hubbard *et al.*[7] ΔU_Σ denotes the contribution from items 81—85, 87—91, and 93—94 defined by Hubbard *et al.*[7] The mean and standard deviation of the mean for molar standard energies of combustion were −(2027.79±0.17) and −(4238.05±0.40) kJ mol^{-1} for thioacetamide and tetramethylthiourea, respectively.

Sublimation calorimetric results are summarized in

Tables 5 and 6 for thioacetamide and tetramethylthiourea, respectively. The sublimation enthalpies are plotted against temperature in Fig. 1 in the temperature range below 320 K. Molar standard enthalpy of sublimation $\Delta H^{\circ}_{s}(T)$, was calculated with the following equation:

$$\Delta H^{\circ}_{s}(T) = E_{calib}(S_T/S_B)(M/m),$$

where E_{calib} is the electrical energy used in the calibration, (S_T/S_B) is the ratio of sublimation enthalpy to the electrical energy, as determined by calorimetry, and m and M are the mass and the molar mass, respectively, of the material effused from the sample container.

Observed enthalpies of sublimation for each substance were subjected to a regression analysis for linear relations between two variables.[8] Derived results are as follows: ΔH°_{s}/kJ mol^{-1} $= -(0.11314\pm0.03179)(T/\mathrm{K}) + (116.99\pm9.81)$ with estimated standard deviation from the fit s_f of 0.10 kJ mol^{-1} for thioacetamide, and ΔH°_{s}/kJ mol^{-1} $= -(0.03534\pm0.00965)(T/\mathrm{K}) + (93.57 \pm2.93)$ with s_f of 0.21 kJ mol^{-1} for tetramethylthiourea, where uncertainties are those at the 95% confidence level. Three values at 320.8 K of thioacetamide were not employed in the analysis, since they showed significant deviations from the fit.

Standard enthalpies of sublimation at 298.15 K were obtained by extrapolation of the smoothed functions to the reference temperature. Derived values were (83.26±0.34) and (83.04±0.20) kJ mol^{-1} for thioacet-

amide and tetramethylthiourea, respectively, where uncertainties are those at the 95% confidence level.

Derived standard thermodynamic quantities are presented in Table 7. Uncertainties given in this table are the overall values. The following contributions were taken into consideration in assigning uncertainties to $\Delta U_c^\circ(c)$: (1) Calculated standard deviation of mean (sdm) for the experimental values of $\Delta U_c^\circ(c)$, $s(\bar{U})$; (2) calculated sdm for those of ε(calor), $s(\varepsilon)$; (3) estimated sdm for the certified specific energy of combustion of the thermochemical standard benzoic acid Δu_c(ba), s(ba); and (4) likely systematic error of 0.05%. The former three were used to calculate the overall standard deviation of mean for $\Delta U_c^\circ(c)$, $s(\bar{U})_\Sigma$:

$$s(\bar{U})_\Sigma = [s(\bar{U})^2 + \{\Delta U_c^\circ(c)s(\varepsilon)/\varepsilon(\text{calor})\}^2 + \{\Delta U_c^\circ(c)s(\text{ba})/\Delta u_c(\text{ba})\}^2]^{1/2}.$$

$s(\bar{U})_\Sigma$ was 0.20 and 0.46 kJ mol^{-1} for thioacetamide and tetramethylthiourea, respectively. The overall uncertainty for $\Delta U_c^\circ(c)$, $\delta(\Delta U_c^\circ, c)$, was calculated by combining $\{2s(\bar{U})\}$ with the likely systematic error, mentioned above, by use of the following equation:

$$\delta(\Delta U_c^\circ, c) = [\{2s(\bar{U})_\Sigma\}^2 + \{0.0005\Delta U_c^\circ(c)\}^2]^{1/2}.$$

The overall uncertainty for $\Delta H_c^\circ(c)$ is equal to that for $\Delta U_c^\circ(c)$ and that for ΔH_s° is the uncertainty at the 95% confidence level.

The following CODATA recommended key values for thermodynamics[9] and the value[6] compatible with them were used to calculate standard enthalpies of formation in the crystalline state: $\Delta H_f^\circ(CO_2, g) = -(393.51 \pm 0.13)$,[9] $\Delta H_f^\circ(H_2O, l) = -(285.830 \pm 0.042)$,[9] and $\Delta H_f^\circ(H_2SO_4 \text{ in } 115H_2O) = -(888.263 \pm 0.042)$[6] kJ mol^{-1}, respectively, where uncertainties are those at the 95% confidence level for the former two, and that for the latter one is an estimated value.

Table 7. Standard thermodynamic quantities at 298.15 K of thioacetamide and tetramethylthiourea

Compound	Thioacetamide	Tetramethylthiourea
$-\Delta U_c^\circ(c)$ / kJ mol^{-1}	2027.8 ±1.1	4238.1 ±2.2
$-\Delta H_c^\circ(c)$ / kJ mol^{-1}	2033.4 ±1.1	4246.7 ±2.2
$-\Delta H_f^\circ(c)$ / kJ mol^{-1}	70.6 ±1.1	38.3 ±2.3
ΔH_s° / kJ mol^{-1}	83.26±0.34	83.03±0.20
$\Delta H_f^\circ(g)$ / kJ mol^{-1}	12.7 ±1.2	44.7 ±2.3

The overall uncertainties for $\Delta H_f^\circ(c)$ and for $\Delta H_f^\circ(g)$, $\delta(\Delta H_f^\circ, c)$ and $\delta(\Delta H_f^\circ, g)$, respectively, were calculated according to:

$$\delta(\Delta H_f^\circ, c) = [\delta(\Delta U_c^\circ, c)^2 + \{a\delta(CO_2)\}^2 + \{(b/2-d)\delta(H_2O)\}^2 + \{d\delta(H_2SO_4)\}^2]^{1/2},$$

and

$$\delta(\Delta H_f^\circ, g) = [\delta(\Delta H_f^\circ, c)^2 + \delta(\Delta H_s^\circ)^2]^{1/2},$$

where $\delta(CO_2)$, $\delta(H_2O)$, $\delta(H_2SO_4)$ and $\delta(\Delta H_s^\circ)$ are the uncertainties assigned to $\Delta H_f^\circ(CO_2, g)$, $\Delta H_f^\circ(H_2O, l)$, $\Delta H_f^\circ(H_2SO_4 \text{ in } 115H_2O)$, and ΔH_s°, respectively.

Discussion

Thianthrene is a test substance for combustion calorimetry of organic sulfur compounds, recommended by IUPAC.[15] The standard enthalpy of combustion of thianthrene, obtained in this study, agrees with the value of Hu *et al.*[13] and that of Johnson[14] within the sum of each uncertainty, among the literature values given in Table 2. The difference between the recommended value[15] and the present value amounts to 3.7 kJ mol^{-1}, which is 0.05% of total. The relative deviation of 0.05% was assumed to be the relative systematic error for $\Delta H_c^\circ(c)$ and the contribution from this source has been included in the overall uncertainties for $\Delta U_c^\circ(c)$ and $\Delta H_c^\circ(c)$, $\delta(\Delta U_c^\circ, c)$, as described in the preceding section. Standard enthalpy of combustion has not been reported so far for thioacetamide and tetramethylthiourea.

As was pointed out briefly, amides are stabilized considerably due to interaction between a carbonyl group and a neighbouring nitrogen atom, as compared with the hypothetical reference structures, where no such interaction exerts. Stabilization energy may be evaluated by comparing observed and calculated standard enthalpies of formation in gaseous state, for example, as shown in Table 8 for normal alkanamides, $CH_3(CH_2)_{n-1}CONH_2$. The calculated values were obtained by means of the group contribution method[16] as follows:

Table 8. Estimated stabilization energies, U_s, of normal alkanamides, $CH_3(CH_2)_{n-1}CONH_2$

n	$-\Delta H_f^\circ$(g)/kJ mol^{-1}		U_s[c]
	Obsd[a]	Calcd[b]	kJ mol^{-1}
1	238.3	155.5	82.8
2	258.9	176.1	82.8
3	278.1	196.7	81.4
4	290.2	217.3	73.0
5	328.1	237.8	90.3
6	—	258.4	—
7	362.7	279.0	83.7

a) Ref. 20. b) See the text. c) $U_s=\Delta H_f^\circ$(g, calcd)$-\Delta H_f^\circ$(g, obsd).

$$\Delta H_f^\circ(\text{g, calcd}) = [\mathbf{C}\text{-}(C)(H)_3] + (n-1)[\mathbf{C}\text{-}(C)_2(H)_2] + [\mathbf{CO}\text{-}(C)_2] + [\mathbf{N}\text{-}(C)(H)_2],$$

where [**C**-(C)(H)$_3$], [**C**-(C)$_2$(H)$_2$], [**CO**-(C)$_2$], and [**N**-(C)(H)$_2$] are the contributions from methyl, methylene, ketonic carbonyl, and amino groups, respectively. These contributions are such that standard enthalpies of formation in gaseous state at 298.15 K for normal alkanes, normal alkanones, and normal alkylamines are reproduced satisfactorily as an appropriate sum of these contributions. Values selected by Cox and Pilcher[21] were used for these contribution terms. Table 8 shows that the normal alkanamides are stabilized as much as 83 kJ mol^{-1} in average, as compared with the corresponding reference structures.

In order to achieve a similar analysis for thioacetamide and tetramethylthiourea, it is necessary to know the value of an additional contribution, [**CS**-(C)$_2$], which is the contribution from a thioketonic thiocarbonyl group. Since thioketones are very unstable compounds, this value has not been presented. Only thermochemical data that is available for unstabilized thiocarbonyl compounds is the standard enthalpy of formation in gaseous state of thioformaldehyde, $\Delta H_f^\circ(H_2C{=}S, g)$, of (100±11) kJ mol^{-1}, which was determined by electron impact method.[17] Consequently, the value of [**CS**-(C)$_2$] was estimated by adding the difference $\{\Delta H_f^\circ(H_2C{=}S, g)-\Delta H_f^\circ(H_2C{=}O, g)\}$ to [**CO**-(C)$_2$] (= −132.47 kJ mol^{-1}).[21] By adopting −(108.7±0.7) kJ mol^{-1} [20] for $\Delta H_f^\circ(H_2C{=}O, g)$, [**CS**-(C)$_2$] was estimated to be 77 kJ mol^{-1}.

Standard enthalpies of formation in gaseous state were calculated for hypothetical reference structures:[21] For thioacetamide,

$$\begin{aligned}\Delta H_f^\circ(\text{g, calcd}) &= [\mathbf{C}\text{-}(C)(H)_3] + [\mathbf{CS}\text{-}(C)_2] + [\mathbf{N}\text{-}(C)(H)_2] \\ &= (-42.34) + (77) + (19.33) \\ &= 54\ \text{kJ mol}^{-1},\end{aligned}$$

and for tetramethylthiourea,

$$\begin{aligned}\Delta H_f^\circ(\text{g, calcd}) &= 4[\mathbf{C}\text{-}(N)(H)_3]^{ass} + 2[\mathbf{N}\text{-}(C)_3] + [\mathbf{CS}\text{-}(C)_2] \\ &= 4\times(-42.34) + 2\times(103.30) + (77) \\ &= 114\ \text{kJ mol}^{-1},\end{aligned}$$

where [**C**-(N)(H)$_3$]^{ass} and [**N**-(C)$_3$] are the contributions from a methyl group attached to a nitrogen atom and from a tertiary nitrogen atom, respectively.

Comparison of the observed values of ΔH_f°(g), given in Table 7, with these calculated values leads to stabilization energies of 41 and 69 kJ mol^{-1} for thioacetamide and tetramethylthiourea, respectively. The stabilization energy of thioacetamide amounts to about 50% of the corresponding value of acetamide and the value for tetramethylthiourea is 1.7 times as large as that of thioacetamide. Although uncertainties approaching 15 kJ mol^{-1} should be assigned to the estimated stabilization energies, in view of the large uncertainty of $\Delta H_f^\circ(H_2C{=}S, g)$ and the assumption made in the course of estimation of [**CS**-(C)$_2$], it may be stated conclusively that thioacetamide and tetramethylthiourea are stabilized considerably, as compared with the corresponding reference structures. This fact may be the reason why these compounds are fairly stable at ambient temperatures, while thioketones are not. This stabilization is possibly due to the interaction between thiocarbonyl π-electrons and nitrogen lone pair electrons.

According to an X-ray diffraction study, a thioacetamide molecule is almost planar except for methyl hydrogen atoms.[18] Although the molecular structure is not known for tetramethylthiourea, sulfur, carbon and nitrogen atoms in a thiourea molecule are coplanar.[19] These findings seem to be an indication of possible intramolecular interaction between thiocarbonyl π-electrons and nitrogen lone pair electrons.

Specific Anion Effects on Water Structure at Polypeptide Monolayer-Water Interface

Akira SHIBATA,* Shinsuke YAMASHITA, and Takuya YAMASHITA
Faculty of Pharmaceutical Sciences, Tokushima University, Shomachi, Tokushima 770
(Received March 8, 1982)

The specific anion effects on water structure at the polypeptide monolayer-water interface were investigated. It was found that the effects of anions on increasing the film transition pressure were in the order of $SCN^->Br^->Cl^->F^-$ in line with that of those anions as breakers of water structure. The SCN^- ion disrupts the hydrophobic hydration surrounding the hydrocarbon moieties of polypeptides and lipids at the interface. On the other hand, the presence of F^- ion as a structure maker tends to stabilize the hydrophobic bonding. The increase of the film transition pressure on KSCN subsolution was associated with a difference in the conformation between poly(γ-benzyl L-glutamate) and poly(γ-benzyl DL-glutamate). The infrared spectra of polymers obtained from single and mixed films were practically identical with the collapsed films in the presence and the absence of SCN^- and F^- ions.

In recent years, a number of attentions have been focused on the structure of water in living cells and the role of hydration of water around protein molecules in life processes. It is currently believed that the structure of water at biosurface is significantly influenced and ordered by constituent macromolecules.[1] In other words, water adjacent to biosurface differs appreciably from bulk water.[2]

A wide variety of electrolyte effects on biological systems has been found to give rise to the same sequence observed by Hofmeister.[3] The unifying principle underlying the effects of electrolytes on macromolecules and on water itself is that the order of effectiveness of anions is nearly the same for all. The anions are considered to exert their effects by altering the structure of water, thus weakening the tendency toward hydrophobic bonding. Recent evidence suggests that the electrolyte effects are associated with the structure of water at an interface.[2]

The structure breaking and structure making effects of electrolytes on the water structure should have application to interfacial water structure. One way of enhancing water structure at the interface is the application of monolayer technique. Weil[4] and Goddard *et al.*[5] reported on the effects of electrolytes on the interfacial water structure at "ionized" monolayers. It is necessary to use "un-ionized monolayer to emphasize the specific electrolyte effects on water structure at the interfaces. Ralston and Healy[6] have studied the effects of cations on 1-octadecanol monolayers in connection with the interfacial water structure.

In relation to the structure of water in the surface region, we have reported the effects of monovalent anions on the surface pressure-area(π-A) curves of poly(N^ϵ-benzyloxycarbonyl-L-lysine) monolayer.[7] The effects of anions on increasing the surface pressure were in the order of $SCN^->Br^->Cl^->F^-$ in line with that of these anions as breakers of water structure.[8]

The purpose of this work is to clarify the effects of anions on the conformation of polypeptide and on the interaction of polypeptide and lipid in relation to the structure of water in the interfacial region.

Experimental

Poly(N^δ-benzyloxycarbonyl-L-ornithine) (PLO(Z)), poly(N^ϵ-benzyloxycarbonyl-L-lysine) (PLL(Z)), poly(γ-benzyl L-glutamate) (PBLG), and poly(γ-benzyl DL-glutamate) (PBDLG) were prepared by the polymerization of the *N*-carboxy anhydrides of respective amino acids. The molecular weights determined from the viscosities in *N*,*N*-dimethylformamide (DMF)[9] or dichloroacetic acid[10] are 3.5×10^5 for PLO(Z), 3.8×10^5 for PLL(Z), 3.1×10^5 for PBLG, and 6.0×10^4 for PBDLG, respectively. Infrared spectra indicated that PLO(Z), PLL(Z) and PBLG are in the α-helical conformation in the solid state. The helical content of PBDLG was 13% regular α-helix and 60% perturbed α-helix. Lipids used were myristic acid(C_{14} acid) and stearic acid(C_{18} acid). These materials were purified by fractional distillation, and were chromatographycally pure.

The spreading solvents (DMF, dichloromethane (DCM)) were distilled under nitrogen atmosphere. The subsolution, 0.01 M HCl, was made up from twice distilled water and distilled 6 M HCl (1 M = 1 mol dm^{-3}). The spreading solvents were DCM for PBLG- and PBDLG-lipid systems and a 9:1 (v/v) mixture of DCM and DMF for PLO(Z)- and PLL(Z)-lipid systems. The solutions of polypeptide and lipid were prepared separately, and mixed in the desired ratio immediately before spreading. The spreading solution was deposited from a micrometer syringe onto the surface of subsolution, and left to stand for 15 min. The initial spreading-area was 0.5 nm^2/residue or molecule. The trough (60 cm × 15 cm × 1 cm) and compressing barrier were made of Teflon.

Electrolyte solutions (KSCN, KBr, KCl, and KF) were treated with activated charcoal in order to remove surface active contaminants, and were used as a subsolution after being adjusted to contain 0.01 M HCl. A 10 to 1 compression of the surface of the electrolyte subsolutions, after standing for 10 min, produced less than 0.1 mN m^{-1} film pressure. The surface pressure was measured by the Wilhelmy method at 25±0.5 °C. The film was compressed at a rate of 10 mm/min (0.01 nm^2 min^{-1} per residue or molecule).

The polarized infrared spectra of collapsed films were measured by JASCO-701G instrument. The monolayer was spread and compressed until collapse under the same conditions as in the case of surface pressure measurements. In order to remove the monolayer, it was compressed between two Teflon barriers, until the separation was about 1.5 cm. The polymer was then removed by drawing a stainless steel net across the trough between the barriers.

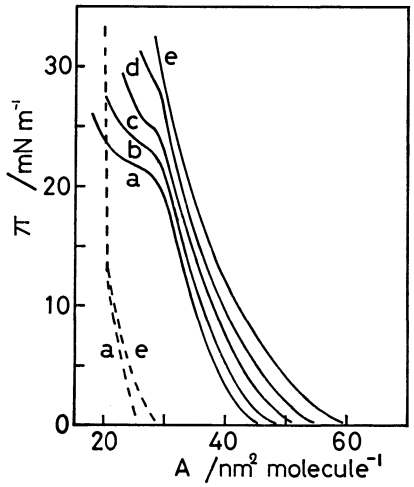

Fig. 1. Surface pressure-area curves of C_{14} acid (——) and C_{18} acid (- - -) on HCl and KSCN subsolutions. 1 dyn=10^{-5} N, 1 Å=0.1 nm. a: 0.01 M HCl, b: 1 M KSCN, c: 2 M KSCN, d: 3 M KSCN, e: 4 M KSCN.

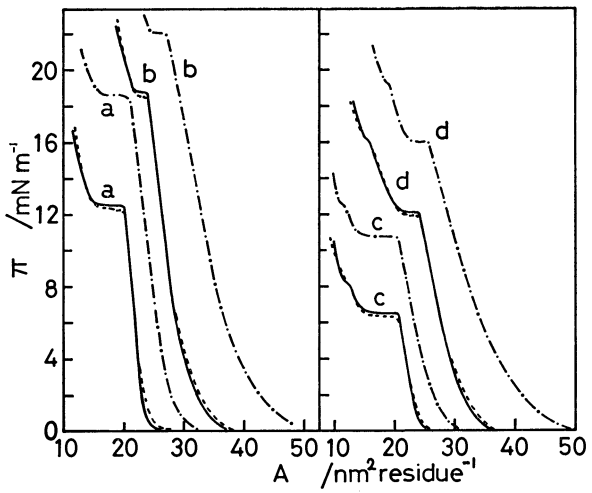

Fig. 2. Surface pressure-area curves of single and mixed monolayers on 0.01 M HCl(——), 2 M KSCN (—·—) and 2 M KF(- - -) subsolutions.
a: PLO(Z), b: PLO(Z)-C_{14} acid(1:1(residue mol: mol)), c: PLL(Z), d: PLL(Z)-C_{14} acid(1:1(residue mol:mol)).

The transferred collapsed films were dried at a room temperature.

Results

Figure 1 shows the π-A curves for C_{14} acid and C_{18} acid monolayers on 0.01 M HCl and KSCN subsolutions containing 0.01 M HCl. The increasing concentration of KSCN causes the increase of transition pressure and the expansion of C_{14} acid monolayer. The transition point of C_{14} acid monolayer tends to disappear with increasing concentration of KSCN, and is no longer detectable at 4 M KSCN. The expansion of C_{18} acid monolayer on KSCN subsolution is considerably small compared with C_{14} acid monolayer.

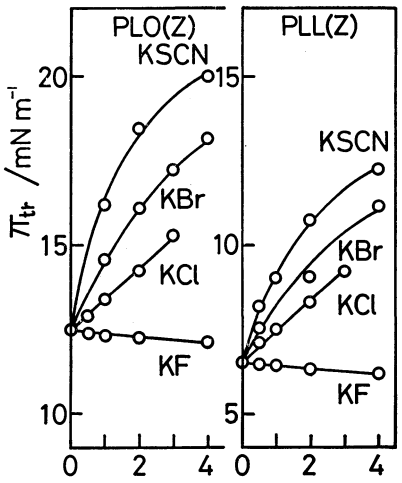

Fig. 3. Transition pressures of PLO(Z) and PLL(Z) monolayers as a function of electrolyte concentration.

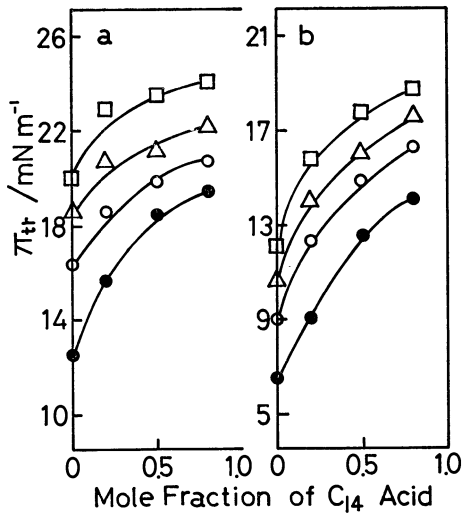

Fig. 4. Transition pressures of mixed monolayers of C_{14} acid with PLO(Z) (a) or PLL(Z) (b) as a function of C_{14} acid mole fraction on HCl and KSCN subsolutions.
●: 0.01 M HCl, ○: 1 M KSCN, △: 2 M KSCN, □: 4 M KSCN.

Figure 2 shows the π-A curves for PLO(Z), PLL(Z), PLO(Z)-C_{14} acid and PLL(Z)-C_{14} acid mixtures(1:1 (residue mol:mol)) spread on 0.01 M HCl, and on 2 M KSCN and 2 M KF subsolutions containing 0.01 M HCl. In the π-A curves of PLO(Z) and PLL(Z) monolayers, the height of plateau which is associated with the transition pressures is much higher on the subsolution containing KSCN than 0.01 M HCl. On the other hand, in the presence of KF, the film transition pressure becomes slightly lower. The film expansion is observed for PLO(Z) and PLL(Z) in the presence of KSCN. The effect of KF on expansion is quite small.

Figure 3 shows the transition pressures of PLO(Z) and PLL(Z) monolayers as a function of electrolyte concentration. The transition pressures of PLO(Z) and PLL(Z) increase with electrolyte concentration

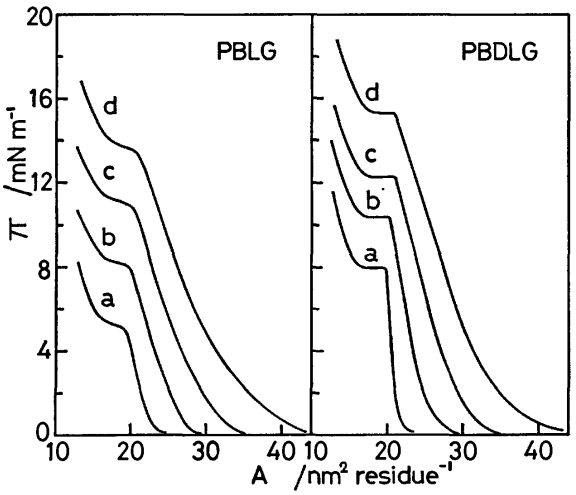

Fig. 5. Surface pressure-area curves of PBLG and PBDLG monolayers on HCl and KSCN subsolutions. a: 0.01 M HCl, b: 2 M KSCN, c: 4 M KSCN, d: 6 M KSCN.

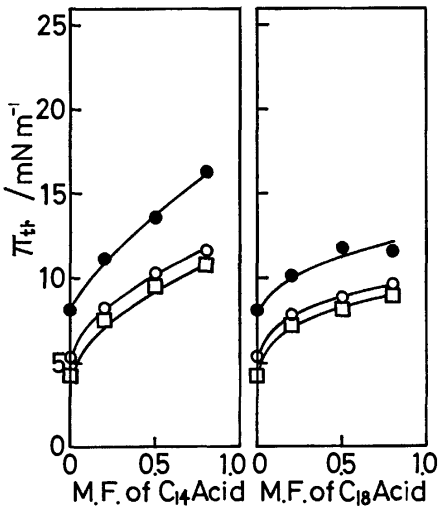

Fig. 7. Transition pressures of mixed monolayers of PBLG with C_{14} acid or C_{18} acid as a function of lipid mole fraction on 0.01 M HCl(○), 2 M KSCN(●), and 2 M KF(□) subsolutions.

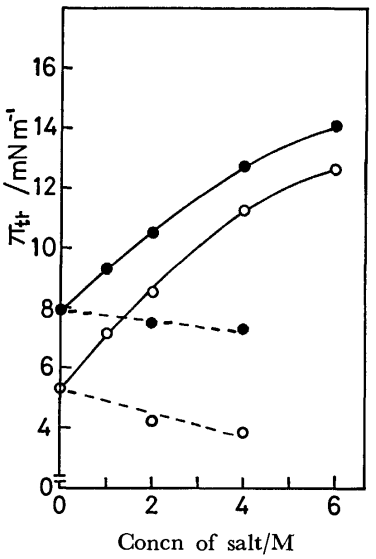

Fig. 6. Transition pressures of PBLG(○) and PBDLG (●) as a function of electrolyte concentration. ——: KSCN, – – –: KF.

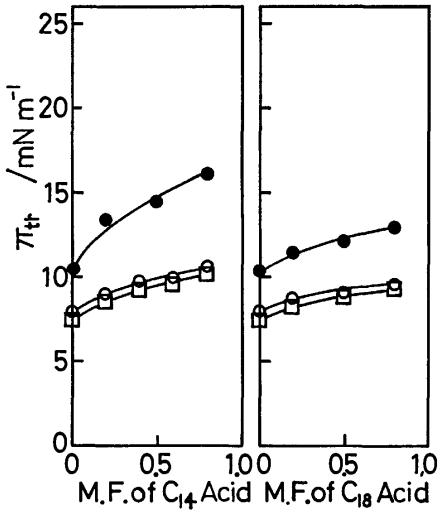

Fig. 8. Transition pressures of mixed monolayers of PBDLG with C_{14} acid or C_{18} acid as a function of lipid mole fraction on 0.01 M HCl(○), 2 M KSCN (●), and 2 M KF(□) subsolutions.

except for KF. In the lower concentration of KSCN or KBr, in particular, the transition pressures show the marked increase.

Figure 4 shows the transition pressures of mixed monolayers of C_{14} acid with PLO(Z) or PLL(Z) on 0.01 M HCl and KSCN subsolutions as a function of the mole fraction of C_{14} acid. The phase rule of the surface predicts that two film components are miscible in the presence and the absence of KSCN in the subsolution.[11,12] The increasing concentration of KSCN causes the increase of transition pressure. The effect of KSCN on the transition pressure for mixed PLO(Z)–C_{14} acid monolayer is smaller than for mixed PLL(Z)–C_{14} acid monolayer.

Figure 5 shows the π-A curves for PBLG and PBDLG monolayers on 0.01 M HCl and KSCN subsolutions containing 0.01 M HCl. As such case of benzyloxycarbonyl derivatives of basic poly(α-amino acid), PLO(Z) and PLL(Z), the film expansion is also observed on KSCN subsolution.

The transition pressures of PBLG and PBDLG monolayers as a function of KSCN and KF concentration is shown in Fig. 6. The transition pressures of PBLG and PBDLG monolayers increase with KSCN concentration, and in the presence of KF, decrease linearly.

Figures 7 and 8 show the relationship between transition pressure and lipid mole fraction for mixed PBLG–fatty acid and PBDLG–fatty acid monolayers on 0.01 M HCl, and 2 M KSCN and 2 M KF subsolutions, respectively. The transition pressures for both mixed PBLG–fatty acid and PBDLG–fatty acid systems increase with the mole fraction of C_{14} acid or C_{18} acid. The increments of transition pressure for mixed PBLG–fatty acid systems are larger than for mixed PBDLG–fatty acid systems. The effect of

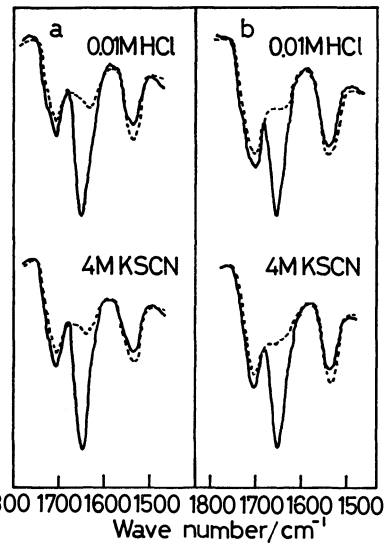

Fig. 9. Polarized IR spectra of collapsed films of PLL(Z) (a) and 4:1 (residue mol:mol) mixture of PLL(Z) and C_{14} acid(b) formed on 0.01 M HCl and 4 M KSCN subsolutions.
——: Electric vector parallel to the barrier used to collapse the film, - - -: electric vector perpendicular.

C_{14} acid on the transition pressure is larger compared with C_{18} acid.

As typical examples, the polarized infrared spectra for collapsed films of PLL(Z) and a 4:1 (residue mol: mol) mixture of PLL(Z) and C_{14} acid are shown in Fig. 9. The spectra which are characteristic of polypeptide designated as a α-helix form have major diagnostic peaks at about 1650 cm^{-1} (amide I band) and 1550 cm^{-1} (amide II band). Dichroism is also observed at about 1700 cm^{-1}(assignable to streching of C=O bond of the side chain). A similar tendency was observed for other single and mixed films.

Discussion

Mixed PLO(Z)–C_{14} Acid and PLL(Z)–C_{14} Acid Systems. C_{14} acid and C_{18} acid monolayers are of expanded and condensed type at 25 °C, respectively (Fig. 1).[13] The transition is seen in the π-A curves of C_{14} acid. The transition region becomes short with increasing KSCN concentration, and ultimately disappears at 4 M. A similar tendency is also recognized for the effect of temperature on transition pressure of C_{14} acid.[14] If the monolayer expansion is due to the flexibility of the hydrophobic moieties of C_{14} acid, the rotation of the flexible hydrophobic moieties may be hindered with compressing monolayer. The hindered molecular rotation may lead to the discontinuity of compressibility associated with the onset of the transition.[15] In analogy with the effect of temperature, the addition of SCN^- ion as a breaker of water structure may favor the molecular rotation of C_{14} acid at the interface.

A complex polymer like a protein will be sheathed in a complex hydration envelope consisting of regions of differing local water structure at the interface.[16] The polypeptides used in this work will also have two types of water structure arising from the hydrophobic and Coulombic hydrations. The nonpolar moieties will be encased by the same hydrophobic hydration that one associates with nonpolar solutes and neutral interface, whereas polar regions will be surrounded by the same Coulombic hydration that surrounds ion in solution.

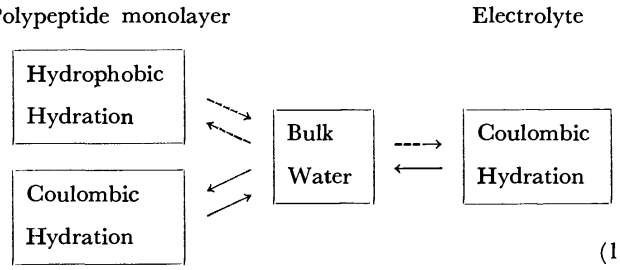
There exist plateaux in the π-A curves for PLO(Z) and PLL(Z) monolayers(Fig. 2). The plateau was found for a number of synthetic polypeptide monolayers, and ascribed to the transition from a two-dimensional ordered state to a three-dimensional disordered state.[17,18] The height of plateau can be regarded as a measure of the adhesion force of monolayer to water. As shown in Fig. 3, the transition pressures increase with concentration of electrolyte, and the effects of anions on the transition pressure are in the order of $SCN^- > Br^- > Cl^- > F^-$ in accordance with that of these anions as breakers of water structure.[8] A structure breaker like SCN^- is more easily accomodated in the interface than F^-, a structure maker, due to the fact that it introduces more disorder in the structure region at the air-water interface.[19] The hydration atmosphere of SCN^- ion is compatible with the Coulombic hydration surrounding the polar group of polypeptide and enable SCN^- ion to penetrate, and profoundly alter the hydration. In addition, the hydrophobic hydration surrounding the polypeptide side chain is disrupted by the action of SCN^- ion. This will be accompanied by a decrease in adhesion of the hydrophobic moieties of the side chains to water, followed by an increase in the surface pressure.[20]

Comparing the π-A curves of PLO(Z) with PLL(Z) monolayers, the difference in height of the transition pressures is accounted for as arising essentially from the additional methylene group (Fig. 2). The effects of anions on the transition pressure of PLO(Z) are larger than PLL(Z) (Fig. 3). If the α-helix form can be stable at the air–water interface, the geometry of the α-helix is such that the side chains of adjacent helices can interpenetrate to form good hydrophobic contacts.[18]

It can be assumed that the hydrophobic and Coulombic hydrations surrounding polypeptide monolayers are in equilibrium with the Coulombic hydration for electrolyte in the presence of electrolyte. As the electrolyte is added. In other words, hydrophobic hydration is disrupted, the equilibrium indicated in the scheme (1) is shifted to right along the dotted line, and after that, shifted to left along the full line. Therefore, the compatibility of Coulombic hydration between polypeptide and electrolyte may cause the increase of transition pressure.

In the presence of F^- ion, the transition pressure decreases slightly with increasing concentration(Fig. 3). Increasing concentration of F^- ion as a maker of water structure, the equilibrium in the scheme (1) will be shifted to the direction of the stabilization of hydrophobic hydration. In the present case, the effect of F^- ion on the transition pressure may imply the stabilization of hydrophobic hydration surrounding the monolayers.

For mixed monolayers of C_{14} acid and either PLO-(Z) or PLL(Z) on 0.01 M HCl subsolution, the increase of transition pressure is due to the hydrophobic bonding between polypeptide side chain and C_{14} acid (Fig. 4).[21] The effect of C_{14} acid on the transition pressure caused by PLL(Z) is larger than that of PLO(Z). This is caused by the additional methylene group for PLL(Z).[21] A similar tendency was also recognized on KSCN subsolutions (Fig. 4).



(1)

In the presence of KSCN, the relationship between transition pressure and the mole fraction of C_{14} acid gives a parallel shift to the direction of the increase of transition pressure in the range of 1 to 4 M KSCN concentration. This parallel shift suggests that the hydrophobic hydration surrounding polypeptide–C_{14} acid complex is "partially" disrupted with increasing concentration of SCN^- ion. If, however, the hydrophobic bonding between polypeptide and C_{14} acid is "essentially" disrupted by the action of SCN^-, the value of transition pressure caused by polymer will have of coming close to that of polypeptide itself or the lower value compared with that of mixed monolayer different from our results.

Mixed PBLG–Fatty Acid and PBDLG–Fatty Acid Systems. The perturbed helix portion of PBDLG is unfolded at the interface owing to relatively weak stability of the helix.[22] As is shown in Fig. 5, the difference in shape of the π-A curves between PBLG and PBDLG is accounted for as arising essentially from the conformation of these polymers at the interface.[21] The more increase of the transition pressure of PBDLG compared with PBLG may be caused by the hydration surrounding the perturbed helix portion of PBDLG. The water structure beneath the monolayer must be also reflected to the monolayer compressibility. We have reported that the compressibilities at closed packed area are 0.027 for PBLG and 0.015 for PBDLG.[21] The film expansion on KSCN subsolution suggests that SCN^- ion is transferred into the interface relative to the surface without monolayer(Fig. 5).

The change in the transition pressures of mixed monolayers is larger for PBLG than for PBDLG(Figs. 7 and 8). The flexible side chains of PBLG in α-helical conformation might undergo rearrangement more easily into the position favorable to the interaction with hydrophobic moieties of fatty acids. Chatelain *et al.*[23] reported that the maximum interaction of lipid monolayer with polypeptides occurs when the polypeptides dissolved in the subsolution in α-helical conformation.

Comparing the transition pressures of mixed PBLG–C_{14} acid and PBLG–C_{18} acid monolayers, the state of fatty acid monolayers(expanded and condensed films) seems to affect the degree of interaction (Fig. 7). The C_{14} acid interacts more strongly than C_{18} acid with PBLG.

The transition pressures of mixed PBLG– and PBDLG–fatty acid monolayers on 2 M KSCN subsolution become higher compared with those on KSCN free subsolution (Figs. 7 and 8). The increase of transition pressure is larger for mixed PBDLG–fatty acid systems than for mixed PBLG–fatty acid systems. In the presence of SCN^- ion, the hydrophobic hydration surrounding mixed monolayer is disrupted, and then, the increase of the compatibility of Coulombic hydration around unfolded PBDLG may be caused. Therefore, this may be associated with a difference in the conformation between PBLG and PBDLG in mixed monolayers.

As shown in Figs. 7 and 8, the transition pressures of mixed monolayers on 2 M KF subsolution become low compared with those on KF free subsolution. In the presence of F^- ion as a maker of water structure, the adhesion force of polypeptide to water becomes weak with the formation of hydrated structure surrounding the mixed films. The effect of F^- ion on the transition pressure of mixed monolayer is slightly large for PBLG compared to PBDLG. This suggests that the hydrophobic hydration around PBLG–C_{14} acid complex tends to be stabilized by the action of F^-. PBLG is expected to be more hydrophobic than PBDLG since the polypeptide main chain is considerably shielded from the interaction with water molecules.

Infrared Spectra of Collapsed Films. The parallel dichroism of the amide I band and the perpendicular dichroism of the amide II are those known to be characteristic of the α-helix, with the molecules showing alignment parallel to the barrier used to collapse the monolayer (Fig. 9). Similar spectra of the collapsed films were obtained in the presence and the absence of electrolyte. This is an evidence that as mentioned above, SCN^- ion disrupts partially hydrophobic hydration surrounding the monolayers, and that, in other words, the monolayers are stabilized by the hydrophobic bonding. The dichroism for the side chains suggests that the side chains are considerably ordered at the interface. This might favor the polypeptide-lipid interaction at close packed state in monolayers.

Tunnel Electrode I. Electron Transfer Process at Highly Doped SnO_2 Electrode with Ce^{4+} in High Overvoltage Region

Kenkichiro KOBAYASHI,* Yoshihiro AIKAWA, and Mitsunori SUKIGARA
Institute of Industrial Science, The University of Tokyo,
7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received February 24, 1982)

Electron transfer theory at tunnel semiconductor electrode was derived from the double adiabatic perturbation theory. The cathodic current of Ce^{4+} with very positive redox potential was measured at highly doped SnO_2 electrode. The rearrangement energy of 0.65 eV for Ce^{4+} was estimated from the relationship of transfer coefficient *vs.* electrode potential. Large electron transfer rate in the high overvoltage region can be explained in terms of the contribution of excited vibrational states in the first coordination sphere into electron transfer.

The effect of electrode potential on the characteristics of an usual semiconductor electrode is such that the electrode potential cannot modify the energy of electrons and holes at the surface, but can change the surface density of electrons and holes through the band bending. When the carrier density of a semiconductor is very large, the thickness of the space charge layer is so small that electrons or holes can move through the depletion layer by tunneling. If such a highly doped semiconductor is used as an electrode, the electron transfer by tunneling through the space charge layer and the Helmholtz layer may occur in a certain potential range.[1-3] Thus, such a electrode may be called "tunnel semiconductor electrode." The electrochemical characteristic of a tunnel electrode is that the energy of a transferring electron or hole can be easily varied by the electrode potential.

For the rate of electron transfer reactions, Marcus[4] predicted that, in the so called normal region where the energy change of a reaction, $|\Delta E|$, is smaller than the rearrangement energy λ_s, the reaction rate should increase with $|\Delta E|$, while in the abnormal region where $|\Delta E|>\lambda_s$, the reaction rate should decrease with $|\Delta E|$. Rhem and Weller,[5,6] however, reported that such a decrease in the reaction rate was not observed in the abnormal region. Although their experimental results are significant, the electron transfer rate in the abnormal region could not be quantitatively discussed because of the diffusion limit of their reactions. The electrochemical electron transfer rate in the abnormal region has not been studied with metal electrode, because the electrons are distributed over a wide energy range in a metal. On the other hand, a tunnel electrode has an electron distribution in a definite and narrow energy range, so that the observed current directly reflects on the transition probability of electron with the semiconductor Fermi level. Therefore, the tunnel electrode is especially a useful tool for the measurement of electron transfer rate in the abnormal region.[7] The tunnel electrode has another advantage that the tunneling probability is usually not so high that the current may not be limited by diffusion even in a high overvoltage region.

In the present work, a theory for the cathodic tunnel current is derived and, by measuring the cathodic tunnel current at a highly doped tin oxide electrode, the electron transfer mechanism of Ce^{4+} at high overvoltage is discussed.

Theoretical

The cathodic and anodic current density at n-type tunnel electrode are respectively given by[8]

$$i_c = -ed\Omega C_{ox}\int W_c(E)\rho_{sc}(E)f(E)\mathrm{d}E, \quad (1)$$

and

$$i_a = ed\Omega C_{red}\int W_a(E)\rho_{sc}(E)[1-f(E)]\mathrm{d}E, \quad (2)$$

where W_c and W_a are respectively the transition probability for cathodic and anodic processes, $\rho_{sc}(E)$ is the state density in the semiconductor bulk, $f(E)$ is the Fermi distribution function, C_{ox} and C_{red} are respectively the concentration of the oxidant and that of reductant, d is the distance from the electrode surface, at which the transition probability is the greatest, E denotes the energy of transferring electron, e is the elementary charge, and Ω is the volume of the electrode.

The transition probability, $W_c(E)$, can be derived from the adiabatic perturbation theory considering the vibration in the first coordination sphere and given by[9-11]

$$W_c(E) = \frac{2\pi}{\hbar}|\langle\psi_f|V_{int}|\psi_i\rangle|^2\rho_{red}(E), \quad (3)$$

where ρ_{red} corresponds to the state density which is given by,[9-11]

$$\rho_{red}(E) = \left(\frac{1}{4\pi kT\lambda_s}\right)^{1/2} \times \sum_{m=-\infty}^{\infty}\exp\left[-(E-E^\circ_{redox}-\lambda_s-m\hbar\omega_c)^2/4kT\lambda_s\right] \times \exp\left[-Z_c\cosh\left(\frac{\hbar\omega_c}{2kT}\right)+\frac{m\hbar\omega_c}{kT}\right]I_m(Z_c), \quad (4)$$

where $Z_c=(1/2)\Delta_c^2\ \mathrm{cosec}\ (\hbar\omega_c/2kT)$, $I_m(Z_c)=(Z_c/2)_m\times\sum_{k=0}^{\infty}(Z_c/2)^{2k}/[k!\times(m+k)!]$, ψ_f denotes the unperturbed electronic wave function for the final state where an electron is located at an ion in solvent, ψ_i denotes the unperturbed electronic wave function for the initial state where an electron is located in semiconductor, V_{int} is the electronic interaction causing electron transfer, $\hbar\omega_c$ is the vibrational energy of the first coordination sphere, λ_s represents the rearrangement energy of solvent, E°_{redox} is the electronic energy corresponding to the standard redox potential, V°, and Δ_c is the difference between the equilibrium normal

coordinates of the vibration in the first coordination sphere in the initial state and those in the final state.

Similarly, the transition probability for anodic current, $W_a(E)$, is given by[9-11]

$$W_a(E) = \frac{2\pi}{\hbar}|\langle\phi_f|V_{int}|\phi_i\rangle|^2\rho_{ox}(E), \quad (5)$$

where

$$\rho_{ox}(E) = \left(\frac{1}{4\pi kT\lambda_s}\right)^{1/2} \times \sum_{m=-\infty}^{\infty} \exp\left[-(E^\circ_{redox}-E-\lambda_s-m\hbar\omega_c)^2/4kT\lambda_s\right] \times \exp\left[-Z_c\cosh\left(\frac{\hbar\omega_c}{2kT}\right)+\frac{m\hbar\omega_c}{2kT}\right]I_m(Z_c). \quad (6)$$

The square of the matrix element $|\langle\phi_f|V_{int}|\phi_i\rangle|^2$ can be rewritten as[12]

$$|\langle\phi_i|V_{int}|\phi_f\rangle|^2 = Pr|\langle\phi_f|V'_{int}|\phi'_i\rangle|^2, \quad (7)$$

where Pr represents the tunneling probability through the space charge layer, and $\langle\phi_f|V'_{int}|\phi'_i\rangle$ denotes approximately the matrix element causing electron transfer through the Helmholtz layer.

The tunneling probability Pr was calculated with the WKB approximation, assuming the Schottky type barrier and the two band model[13] for the energy-complex momentum relationship in the forbidden gap. In the case of a semiconductor with wide gap energy, the probability for the direct tunneling through the space charge layer is given by[14]

$$Pr = C_1\exp\left[-\frac{2}{\hbar}\left(\frac{m^*\varepsilon_{sc}}{n}\right)^{1/2}\phi_{sc}\right], \quad (8)$$

where m^* is the effective mass, ε_{sc} is the permittivity of semiconductor, ϕ_{sc} denotes the band bending, n is the electron density in the semiconductor bulk,[15] and C_1 is slowly varying function of the band bending, *etc.* With the decrease of carrier density, the probability for the direct tunneling decrease quickly, and thus the indirect tunneling *via* trapping states in the space charge layer becomes important. If the indirect tunneling occurs *via* one trapping state, the tunneling probability for this process is given by[14]

$$Pr = C_2\exp\left[-\frac{1}{\hbar}\left(\frac{m^*\varepsilon_{sc}}{n}\right)^{1/2}\phi_{sc}\right], \quad (9)$$

where C_2 is slowly varying function of the band bending, *etc.*

Figure 1 shows the energy relationship at a semiconductor/electrolyte interface. We consider then a highly doped SnO_2 electrode as an example. In the case of parabolic model for $\rho_{sc}(E)$, the Fermi level of SnO_2 with $n=10^{19}$ cm^{-3}, $m^*=0.22\,m$ and $\varepsilon_{sc}=10\,\varepsilon_0$ is located at 0.07 eV above the bottom of conduction band, and electrons are distributed in a narrow energy range near the Fermi level. Thus, if the tunneling through the space charge layer is dominant, $\rho_{sc}(E)f(E)$ can be approximated by

$$\rho_{sc}(E)f(E) = n\delta(E+eV), \quad (10)$$

where n is the carrier density, V is the electrode potential, and δ is the Dirac δ function. The validity of this approximation will be discussed later.

Substituting Eq. 10 and the relation of $E_{redox}=-eV^\circ$ into Eq. 1, the cathodic current density is written as

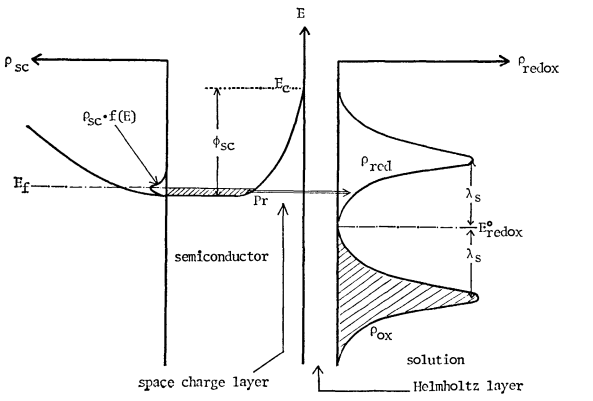

Fig. 1. Schematic representation of electron transfer under more positive potential than flat band potential at a highly doped semiconductor/electrolyte interface.

$$i_c = -edn\Omega C_{ox} \times \frac{2\pi}{\hbar}|\langle\phi_f|V'_{int}|\phi'_i\rangle|^2 \times Pr \times \rho_{red}(-eV), \quad (11)$$

where

$$\rho_{red}(-eV) = \left(\frac{1}{4\pi KT\lambda_s}\right)^{1/2} \times \sum_{m=-\infty}^{\infty} \exp\left[-(-eV+eV^\circ-\lambda_s-m\hbar\omega_c)^2/4kT\lambda_s\right] \times \exp\left[-Z_c\cosh\left(\hbar\omega_c/2kT\right)+m\hbar\omega_c/2kT\right]I_m(Z_c). \quad (12)$$

Equation 11 indicates that the magnitude of tunnel current directl reflects the transition probability at semiconductor Fermi level which can be defined by the electrode potential. On the other hand, the integral in Eq. 2 cannot be removed by the use of Eq. 10; the anodic current at an n-type semiconductor tunnel electrode contains all the electron transfer processes at various energy levels. Then, it is difficult to determine the transition probability from the experimental anodic tunnel current. In the present work, only the cathodic tunnel current at tunnel n-type semiconductor electrode is discussed.

The band bending, ϕ_{sc}, at more positive potential than the flat band potential is a function of the electrode potential, V, as follows:[3]

$$\phi_{sc}^{1/2} = \frac{1}{2}[-K+(K^2+4V-4V_{fb})^{1/2}]. \quad (13)$$

Here,

$$K = \frac{d_H}{\varepsilon_H}(2\varepsilon_{sc}nq)^{1/2}, \quad (14)$$

where V_{fb} is the flat band potential, d_H is the thickness of the Helmholtz layer, and ε_H is the permittivity of the Helmholtz layer. Then, the transfer coefficient, α, is given by

$$\alpha \equiv -\frac{kT}{e}\frac{\partial\ln(-i_c)}{\partial V} = \alpha_T + \alpha_\rho, \quad (15)$$

where $\alpha_T\equiv(-kT/e)(\partial\ln Pr/\partial V)$ is the transfer coefficient due to the tunneling through the space charge layer and is given by

$$\alpha_T \equiv \frac{kT}{e}\frac{2}{\hbar}\left(\frac{m^*\varepsilon_{sc}}{n}\right)^{1/2}\{1-K(K^2+4V-4V_{fb})^{-1/2}\}, \quad (16)$$

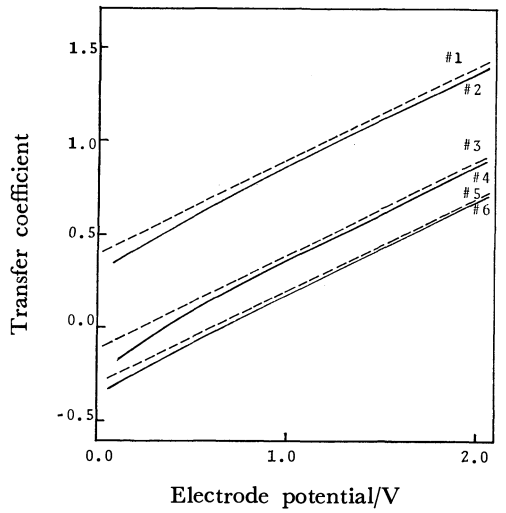

Fig. 2. Relationship between transfer coefficient and electrode potential in high temperature limiting case (T=300 K, λ_s=0.6 eV, $\hbar\omega_c$=0.002 eV, Δ_c=20, λ_c=0.4 eV, $V°$=2.0 V, V_{fb}=0.0 V, $\varepsilon_{sc}=10\varepsilon_o$, m^*=0.2 m, $\varepsilon_H=6\varepsilon_o$, d_H=0.3 nm). #1 and #2: $n=5\times10^{18}$ cm^{-3}, #3 and #4: $n=2.7\times10^{19}$ cm^{-3}, #5 and #6: $n=1.0\times10^{20}$ cm^{-3}. Solid lines are α-V curves considering potential drop across the Helmholtz layer, ϕ_H. Broken lines are α-V curves neglecting ϕ_H.

for the direct tunneling, and

$$\alpha_T \equiv \frac{kT}{e}\frac{1}{\hbar}\left(\frac{m^*\varepsilon_{sc}}{n}\right)^{1/2}\{1-K(K^2+4V-4V_{fb})^{-1/2}\}, \quad (17)$$

for the indirect tunneling with one trapping state, and $\alpha_\rho \equiv (-KT/e)(\partial \ln \rho_{red}/\partial V)$ is the transfer coefficient depending on the state density for acceptor state.

In case of $\hbar\omega_c \ll kT$, the transfer coefficient α_ρ is written as[16]

$$\alpha_\rho = \frac{eV-eV°+\lambda_s+(1/2)\hbar\omega_c\Delta_c^2}{2(\lambda_s+(1/2)\hbar\omega_c\Delta_c^2)}. \quad (18)$$

In case of $\hbar\omega_c \gg kT$, the transfer coefficient α_ρ in the normal region, *i.e.* $V > V°-\lambda_s/e$, is given by

$$\alpha_\rho = \frac{eV-eV°+\lambda_s}{2\lambda_s}, \quad (19)$$

while in the abnormal region, *i.e.* $V < V°-\lambda_s/e$,

$$\alpha_\rho = -\frac{kT}{e}\frac{\partial \ln}{\partial V}\left\{\sum_{m=0}^{\infty}\exp\left[-\frac{(-eV+eV°-\lambda_s-m\hbar\omega_c)^2}{4kT\lambda_s}\right]\times\frac{1}{m!}\left(\frac{\Delta_c^2}{2}\right)^m\right\}, \quad (20)$$

and it oscillates with the period, $V_p=\hbar\omega_c/e$, when the electrode potential is swept. In the intermediate case, *i.e.* $\hbar\omega_c \approx kT$,[9]

$$\alpha_\rho = \frac{e(V-V°)+\lambda_s}{2\lambda_s}+\frac{kT}{\lambda_s}\frac{\Delta_c^2}{2}\frac{\hbar\omega_c}{2kT}\operatorname{cosech}\left(\frac{\hbar\omega_c}{2kT}\right)\times\sinh\left[\frac{\hbar\omega_c(-eV+eV°)}{2kT\lambda_s}\right] \quad (21)$$

Broken lines in Figs. 2, 3, and 4 show the α-V curves neglecting the potential drop across the Helmholtz layer for $\hbar\omega_c \ll KT$, $\hbar\omega_c \gg KT$, and $\hbar\omega_c \approx KT$, respectively. In the high temperature limiting case, the slope of α-V curves is $(2\lambda_s+\hbar\omega_c\Delta_c^2)^{-1}$, and

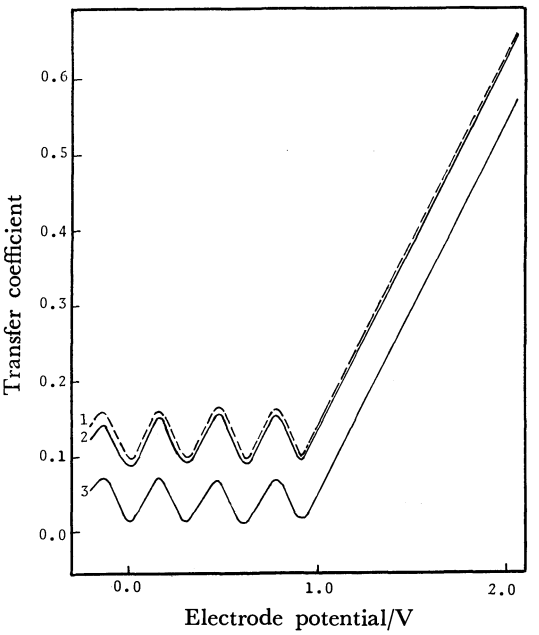

Fig. 3. Relationship between transfer coefficient and electrode potential in low temperature limiting case (T=30 K, $\hbar\omega_c$=0.3 eV, λ_s=1.0 eV, $\varepsilon_H=6\varepsilon_o$, d_H=0.3 nm, $\Delta_c=2^{1/2}$, $V°$=2.0 V). Curves of 1 and 2 are α-V curves at semiconductor with V_{fb}=0.0 V, m^*=0.1 m, $\varepsilon_{sc}=5\varepsilon_o$, and $n=10^{19}$ cm^{-3} in case of neglecting ϕ_H and that in case of considering ϕ_H, respectively. Curve 3 corresponds to α_T=0.

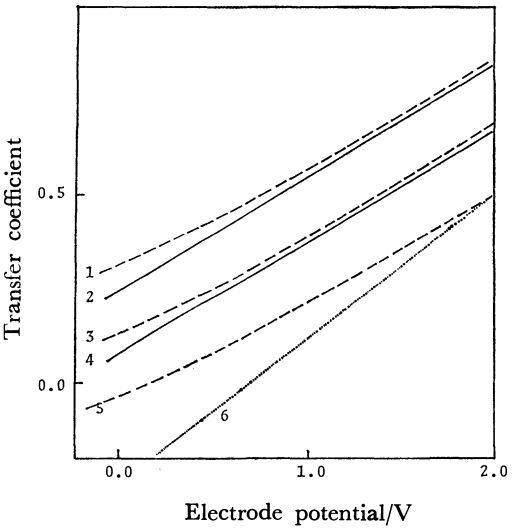

Fig. 4. Relationship between transfer coefficient and electrode potential in intermediate case (T=300 K, $\hbar\omega_c$=0.06 eV, λ_s=0.6 eV, m^*=0.2 m, $\varepsilon_{sc}=10\varepsilon_o$, Δ_c=2, V_{fb}=0.0 V, $V°$=2.0 V).
1 and 2: $n=2.7\times10^{19}$ cm^{-3}, 3 and 4: $n=1.0\times10^{20}$ cm^{-3}, 5: α_T=0.0. Dotted line is α-V curve neglecting ϕ_H and change of Δ_c (Δ_c=0). Broken lines are α-V curves neglecting ϕ_H. Solid lines are α-V curves considering ϕ_H.

there is not difference in α-V curve between the normal and abnormal regions. In the low temperature limiting case, electron transfer is accompanied by the nuclear tunneling in the first coordination sphere. Then, the slope of α-V curves in the normal region

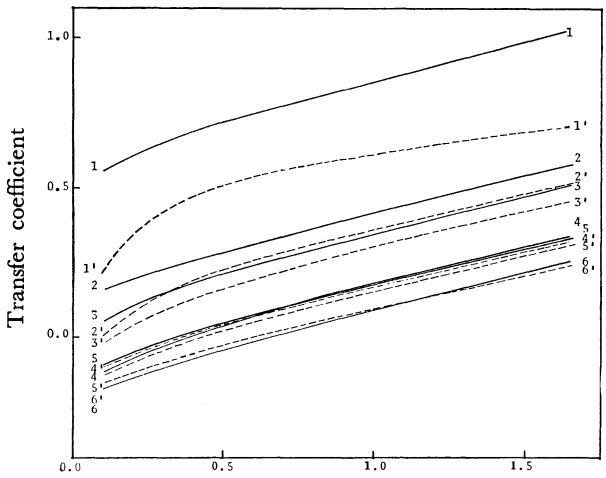

Fig. 5. Relationship between transfer coefficient and electrode potential ($T=300\,K$, $\lambda_s=1.0$ eV, $\lambda_c=1.0$ eV, $\lambda_c=1.0$ eV, $\hbar\omega_c=0.002$ eV, $\Delta_c=22.3$, $V^\circ=3.0$ V, $V_{fb}=0.0$ V, $\varepsilon_{sc}=10\varepsilon_o$, $m^*=0.2\,m$). Solid lines are α-V curves calculated with Eq. 10. Broken lines are α-V curves calculated without Eq. 10. 1,1′,3,3′,5,5′: direct tunneling; 2,2′,4,4′,6,6′: indirect tunneling. 1,1′,2,2′: $n=5\times10^{18}$ cm^{-3}; 3,3′,4,4′: $n=2.7\times10^{19}$ cm^{-3}; 5,5′,6,6′: $n=1.0\times10^{20}$ cm^{-3}.

is $(2\lambda_s)^{-1}$ because both the initial vibrational state and the final state are the ground states, while α-V curves in the abnormal region oscillate with the period, $\hbar\omega_c$, because of the significant contribution of an excited vibrational state in the final state. In the intermediate case, the nuclear tunneling in the first coordination sphere occurs to some extent, and the slope of α-V curves in small overvoltage region is approximately $(2\lambda_s)^{-1}$.

The solid lines in Figs. 2, 3, and 4 show the α-V curves considering the potential drop across the Helmholtz layer. In determing the rearrangement energy of solvent from the α-V curve, the effect of the potential drop across the Helmholtz layer on the transfer coefficient is not significant, except for the region near the flat band potential.

Here we consider the validity of the approximation in Eq. 10. Figure 5 shows the α-V curves corresponding to the high temperature limiting case. The broken lines in Fig. 5 are α-V curves calculated numerically without using the approximation given in Eq. 10. The α-V curves calculated with Eq. 10 are also shown by solid lines in Fig. 5. The good agreement between the solid lines of 3 to 6 and the broken lines of 3′ to 6′ indicates that the approximation of Eq. 10 is reasonable under the condition, $n\geqq2.7\times10^{19}$ cm^{-3}, $m^*=0.2\,m$, and $\varepsilon_{sc}=10\,\varepsilon_o$, at room temperature. However, the broken line (1′) deviates from the solid line (1). This deviation is interpreted in terms of a considerable contribution of the thermal excitation in the total current. This result means that the approximation given by Eq. 10 is no longer applicable when the carrier concentration is less than 5×10^{18} cm^{-3} at room temperature.

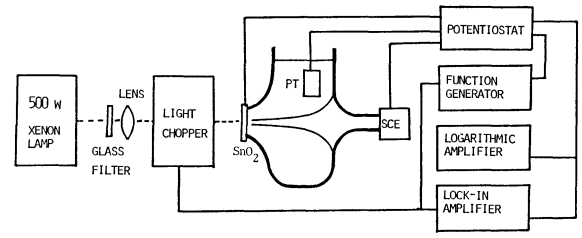

Fig. 6. Diagram of the experimental setup.

Experimental

Tin oxide coated glasses supplied from Matsuzaki Vacuum Co. and those from Asahi Glass Co. were made by the spray and vacuum evaporation methods, respectively. The former tin oxide layer has been doped with Sb and the latter has a high density O_2-vacancy. The surface area of each electrode was about 0.8 cm^2. The thickness of the SnO_2 layer was measured by a surface roughness meter. Ceric sulfate of commercially available reagent grade was used without further purification. The experimental setup is shown in Fig. 6. A saturated calomel electrode and a large area platinum disk electrode were used as the reference electrode and the counter electrode, respectively. In order to determine the flat band potential at various pH values, photocurrents by the band gap excitation were measured with a chopped light and a lock-in amplifier. Buffered solutions of pH 3, 5, and 7 were prepared with 0.2 M (1 M=1 mol dm^{-3}) citric acid and sodium dihydrogenphosphate. Differential capacitance measurements were made by modulating the electrode potential with a 10 mV sine wave of 120—1000 Hz and by balancing the bridge. The transfer coefficient was obtained by using a logarithmic amplifier and a lock-in amplifier by modulating the electrode potential with a 0.2 mV square wave of 2 Hz. The steady state current was measured with the potential sweep rate of 2 mV/s.

Results and Discussion

The Measurement of the Properties of Tin Oxide Electrode. Figure 7 shows the relation between differential capacitance per unit area, C, and the electrode potential. As seen in Fig. 7, the plots of C^{-2} *vs.* applied potential show good linearity. This result indicates that the spatial distribution of the dopant in SnO_2 electrode is uniform, and that the depletion layer is formed under the anodic polarization. A frequency dependence in the capacitance was observed as shown in Fig. 7, but this may be interpreted in terms of the CR dispersion at the semiconductor/electrolyte interface[1] and the structural irregularity of the electrode surface.[17] The slopes of the plots in Fig. 7 should be proportional to N_D^{-1}, but the accurate carrier density could not be obtained from Fig. 7 without the knowledge of the surface factor.

The carrier density was determined directly by the Hall effect measurement. The carrier density of the SnO_2 electrodes thus obtained was in the range from 2.7×10^{19} to 3×10^{20} cm^{-3}. The large carrier density shows that the distribution of the carrier of those electrodes is degenerate. The surface factor was determined by comparing the carrier density obtained from the Hall effect with that from the slope of Mott-Schottky plot in Fig. 7.

TABLE 1. PROPERTIES OF TUNNEL SnO_2 ELECTRODES

Electrode #	Thickness[a] Å	Apparent carrier[b] concentration cm^{-3}	Carrier[c] concentration n cm^{-3}	Surface factor	Flat band[d] potential V_{fb} *vs.* SCE V
1	1450	4.5×10^{21}	3.1×10^{20}	3.8	0.20
2	3000	3.7×10^{22}	1.0×10^{20}	19.2	0.22
3	400	1.0×10^{21}	2.7×10^{19}	6.0	0.24

a) Thickness of the SnO_2 layers measured by Dr. R. Kimura of the Institute of Molecular Science in Japan. b) Values obtained from Mott-Schottky plot at 120 Hz. c) Values obtained from Hall effect. d) Values obtained at pH=0.3.

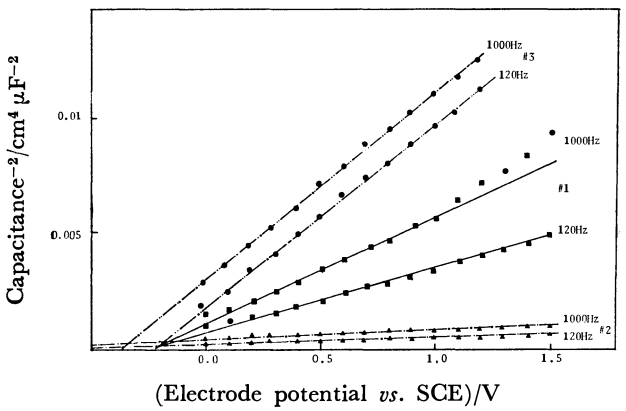

Fig. 7. Mott-Schottky plots for SnO_2 electrodes in a 0.25 M H_2SO_4.

The flat band potential, V_{fb}, of the SnO_2 electrode was determined from the onset potential of the anodic photocurrent[18] corresponding to O_2 evolution. The onset potential thus obtained agrees with the literature value.[19]

In Table 1 are listed the thickness of the tin oxide layer, the apparent carrier density from the slope of Mott-Schottky plot, the carrier density by the Hall effect, the surface factor and the flat band potential. The thickness of the electrode #3 is rather thin but is thicker than that of the depletion layer, *e.g.* 64 Å at 1.2 V *vs.* SCE. Table 1 also shows that the flat band potential shifts more negative with the increase of the carrier density, *i.e.* the Fermi level moves upper with the carrier density. The Fermi energy calculated by the parabolic model with $m^*=0.22m^{20}$ lies above the bottom of the conduction band, E_c: for the electrode #1; $E_F=E_c+0.66$ eV, #2; $E_c+0.39$ eV, and #3; $E_c+0.16$ eV. The difference among the above mentioned Fermi levels of these electrodes is significantly larger than the difference among the flat band potentials shown in Table 1. The discrepancy between the Fermi level thus calculated and the measured one has been often observed in the study of the tunnel diode,[21] and it was interpreted in terms of impurity band model.[22] Thus, the impurity band is formed in the SnO_2 electrode in this work. When the donor is O_2-vacancy or Sb, the relation between the donor density N_D and the donor ionization energy E_D for SnO_2 crystal has been given as[20]

$$E_D = 0.15 - 8.7\times10^{-8}N_D^{1/3} \quad [\text{eV}] \qquad (22)$$

The above relation means that the donor ionization energy approaches zero at a donor density of 5.5×10^{18} cm^{-3}. Since the carrier density of SnO_2 used in this work is larger than 10^{19} cm^{-3}, the shallow donor impurity band has been merged near the bottom of conduction band.

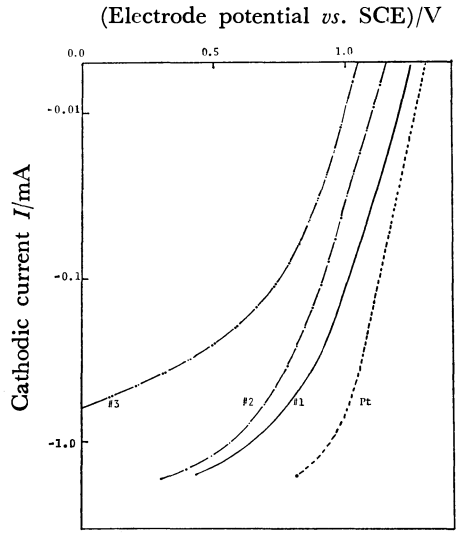

Fig. 8. Plots of cathodic tunnel current for the system of highly doped SnO_2–Ce^{4+} in a 0.25 M H_2SO_4 aqueous solution against electrode potential. #1: $n=3.1\times10^{20}$ cm^{-3}, #2: $n=1.0\times10^{20}$ cm^{-3}, #3: $n=2.7\times10^{19}$ cm^{-3}.

Cathodic Tunnel Current for Highly Doped SnO_2/Ce^{4+}. The steady state tunnel current was measured for Ce^{4+} which has very positive standard redox potential; $V^\circ(Ce^{4+/3+})=1.3$ V *vs.* SCE. In order to extend the potential region where the current is controlled by the electron transfer rate, a concentrated Ce^{4+} solution (0.5 M) was used. Figure 8 shows the curves of the cathodic current *vs.* electrode potential (*i-V*) for Ce^{4+} at SnO_2 electrodes in a 0.25 M H_2SO_4 aqueous solution. An *i-V* curve at a Pt electrode was also shown in Fig. 8 for comparison. As shown in Fig. 8 the magnitude of the current increases with the carrier density in SnO_2. The diffusion limited current is observed in the large current density region. In order to study the electron transfer mechanism in high overvoltage region, it is not suitable to use a too heavily doped semiconductor electrode because the current tends to become diffusion limited. However, a high carrier density is needed to ignore the thermal excitation current.

In Fig. 9 experimental values of the transfer coefficient, $\alpha(V)$, are plotted against electrode potential.

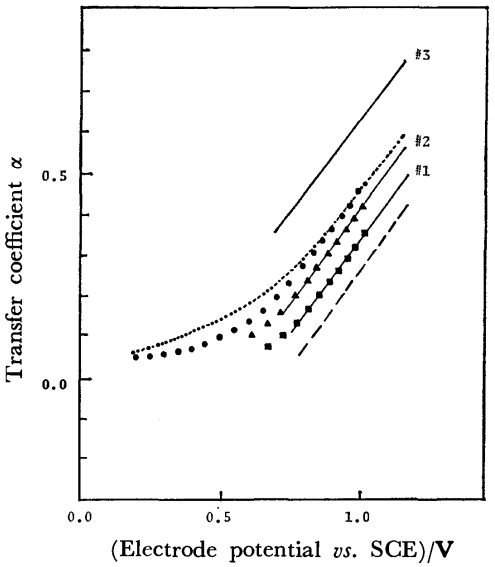

Fig. 9. Curves of transfer coefficient vs. electrode potential for 0.5 M Ce^{4+} at tunnel SnO_2 electrodes in a 0.25 M H_2SO_4 aqueous solution.
■,▲,●: Experimental values, ■ corresponds to #1, ▲ to #2 and ● to #3; solid lines: theoretical curves calculated with $m^*=0.21\,m$, $\lambda_s=0.65$ eV, and $V^\circ=1.3$ *vs.* SCE, broken line: solvent term, $1/2+e(V-V^\circ)/\lambda_s$, dotted line: theoretical curve for indirect tunneling at the electrode #3. #1: $n=3.1\times10^{20}$ cm^{-3}, #2: $n=1.0\times10^{20}$ cm^{-3}, #3: $n=2.7\times10^{19}$ cm^{-3}.

Since the amplitude of the modulation in obtaining α was such small value as 0.2 mV, higher order differential terms were negligible, and the pretty accurate values for $\partial \ln i/\partial V$ could be obtained. It seems from Fig. 8 that one can get constant values for the transfer coefficient in the potential range more positive than 1.0 V. However, in such region where the potential becomes near the equilibrium electrode potential, the contribution of the anodic process to the total current becomes so large that the effect of the anodic process on the transfer coefficient can not be neglected. Under such condition, α-V curve deviates from the theoretical one.

The plots in Fig. 9 show linearity in the potential region, $V>0.65$ V *vs.* SCE, and the slopes of these plots are almost same for three electrode. The plots shift with the carrier density of SnO_2 electrode. The slope of an α-V curve begins to change near $V=0.6$: the slope of an experimental α-V curve in the potential region, $V<0.6$, is much smaller. As mentioned in theoretical part, this α-V relationship implies that the electron transfer of Ce^{4+} corresponds to the intermediate case at room temperature. Thus, the rearrangement energy $\lambda_s=0.65$ eV for Ce^{4+} was determined from the slope of α-V in the small overvoltage region.

The rearrangement energy, λ_s, for Ce^{4+} or Ce^{3+} has been estimated by various methods. For instance, $\lambda_s=2.06$ eV[23] was determined from the electron transfer rate constant at a metal electrode by assuming the adiabatic electron transfer. Memming and Möller[19] estimated $\lambda_s=1.75$ eV by analyzing the anodic tunnel current at SnO_2. However, the Marcus theory[24] using the ion radius of Ce^{4+}, $R=3.77$ Å, has given $\lambda_s=0.5$ eV,[25] and the above values of λ_s seems too large. The overestimation of λ_s value determined from an electron transfer rate at a metal electrode is attributed to the break-down of the adiabatic electron transfer approximation: Ce^{4+} is so powerful oxidant that even a noble metal electrode is covered with a thin oxide layer in the potential region where the rates are measured. The electron transfer rate is mainly governed by the tunneling probability through the thin oxide film,[26] and the assumption of adiabatic electron transfer is not longer applied in this case. In addition, the nonadiabatic behaviour would be expected for the reduction of Ce^{4+} because the 4f orbitals involved in the reduction are strongly shielded by the 5s and 5p orbitals and the matrix element in Eq. 11 is expected to be very small.[27] In fact, the nonadiabatic electron transfer was found in the homogeneous redox reaction of $Eu^{2+/3+}$ in which 4*f* electron takes part in the electron transfer.[28]

The large λ_s-value reported by Memming and Möller[19] seems to be attributed to the complicated electron transfer mechanism of the anodic tunnel current at SnO_2 electrode: They calculated the anodic tunnel current by assuming the state density ρ_{ox} to be Gaussian function including the rearrangement energy, λ_s, as the parameter, and they determined the λ_s value by comparing the experimental tunnel i-V curve with the calculated one. In their calculation, however, they neglected the factors which might affect the tunnel i-V characteristics, that is, the indirect tunneling process, the excited vibrational states in the first coordination sphere, and the potential dependence of the state density in the conduction band, and the tunnel i-V characteristics were interpreted only in terms of the change in the rearrangement energy. Then, λ_s value thus estimated includes the rearrangement energy of the vibration in the first coordination sphere $(1/2)\hbar\omega_c\Delta_c^2$ as well as the contribution of the outersphere.

Three solid lines in Fig. 9 are the theoretical α-V curves, each of which is the sum of α_T in Eq. 16 and $\alpha_\rho=(eV-eV_0+0.65)/(2\times0.65)$. Two lines for the electrode #1 and #2 fit well will the experimental values, while for the electrode #3, the theoretical α-V curve does not fit with the experimental one. The small α_T for the electrode #3 indicates that the indirect tunneling process becomes significant in the tunneling through the space charge layer as expected in Eq. 17.

According to the values of standard redox potential for $Ce^{4+/3+}$, $V^\circ=1.3$ V *vs.* SCE and $\lambda_s=0.65$ eV for the cerium ion in an aqueous solution, the potential region more positive than 0.65 V *vs.* SCE corresponds to the normal region, and the region less than 0.65 V corresponds to the abnormal region. Linear relationship of α-V in the normal region leads to the Gaussian function for the acceptor state density, ρ_{red}. The dotted line in Fig. 9 was calculated with $\hbar\omega_c=400$ cm^{-1}, $\Delta_c=2.6$ by assuming the indirect tunneling (two step process). Those values of $\hbar\omega_c$ and Δ_c are typical ones[29] for the hydrated ions. Therefore, the small slope of α-V in the abnormal region is explained

by the contribution of the excited vibrational state in the first coordination sphere. If the λ_s-value is estimated formally from the potential dependence of the tunnel cathodic current in this abnormal region, one may obtain a unreasonably large value.[30]

Conclusion

The tunnel electrode appeared to be the very useful tool to study the electron transfer rate at high overvoltage. The λ_s-value of 0.65 eV for Ce^{4+} proved that this electron transfer process is nonadiabatic. Large electron transfer rate in the abnormal region could be explained by the significant contribution of the excited vibrational state in the first coordination sphere. The small tunnel transfer coefficient at SnO_2 #3 ($n = 2.7 \times 10^{19}$ cm^{-3}) implied that, in this case, the tunneling through the space charge layer involved the indirect tunneling *via* trapping states in the space charge layer.

Temperature Effect on the Hydrophobic Hydration in Aqueous Solution of Nonpolar Molecule by Monte Carlo Calculation

Susumu Okazaki, Hidekazu Touhara, Koichiro Nakanishi,* and Nobuatsu Watanabe

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, 606

(Received March 13, 1982)

Monte Carlo calculations have been carried out for pure water and aqueous solution of Lennard-Jones particle at infinite dilution between 273.15 K and 353.15 K in order to examine temperature effect on the hydrophobic hydration. It is found that internal energy of mixing ΔU due to the introduction of the solute into water becomes less negative monotonously with increasing temperature. It is in good correspondence with the tendency obtained from solubility measurement, and represents that heat capacity of mixing ΔC_v is positive. Furthermore the dissolution proceeds no longer exothermically at 353.15 K, where water behaves as a normal solvent. Several structural and energetical distribution functions have been calculated for the deep understanding of these observations.

In a previous paper,[1] it was shown that the energetic stabilization and free energy increase due to the hydrophobic hydration in dilute aqueous solution of methane can be reproduced by Monte Carlo (MC) calculations adopting the ST-2 model[2] for water and Lennard-Jones (LJ) potential for methane. The MC calculation was later extended to other LJ solutes having larger sizes and the size effect in hydrophobic hydration has been clarified.[3] In principle, the energetic stabilization can be directly evaluated by calorimetry; however extremely low solubility of nonpolar solutes in water prevents the establishment of accurate and reliable value for the energy change from ordinary laboratory experiments. Thus, we are at present forced to rely on the information from the temperature dependence of solubility. The solubility of nonpolar gas into water decreases with increasing temperature, and this anomaly is not observed in other solute and solvent systems.[4] It must be related to the temperature dependence of the hydrophobic hydration.

Computer experiment may be more favourable in studying these phenomena of the hydrophobic hydration. Although many MC or MD (molecular dynamics) studies have been reported recently for aqueous solution of nonpolar solute,[5] no extensive calculation has been hitherto made on the temperature effect in hydrophobic hydration. We will present here MC results for aqueous methane solutions at 273.15, 333.15, and 353.15 K. Temperature effect on hydrophobic hydration will be discussed based upon these calculations together with the results in the previous calculation at 298.15 K.[1]

Model and Method of Computation

The model and method of computation used here are the same as those in preceding papers.[1,3] They are summarized briefly as follows.

Monte Carlo calculations have been carried out with the ordinary Metropolis method[6] in NVT-ensemble where $N=64$ (64 water molecules or 63 water molecules+one LJ particle whose potential parameters are those of methane), $T=273.15$, 333.15, and 353.15 K, and $V=18.02$, 18.32, and 18.54 $cm^3\ mol^{-1}$ at the above three temperatures, respectively. The volume of each system is determined from the molar volume of pure water at each temperature, no correction being made for the volume change due to the introduction of the solute. The total number of configurations generated is $(5-9)\times10^5$ for pure water and $(6-12)\times10^5$ for methane solutions.

Table 1. Internal energy and internal energy of mixing at each temperature for aqueous solution of methane. The standard state of the solute is assumed to be ideal gas

		T/K			
		273.15	298.15	333.15	353.15
U/kJ mol^{-1}	Pure	−38.5	−35.1	−31.7	−30.4
	Soln	−40.2	−36.1	−32.1	−29.1
ΔU/kJ mol^{-1}		−2.3	−1.5	−0.9	0.9

Results and Discussion

The convergence characteristics of the system to an equilibrium state are the most important problem in the MC calculation. This has been already discussed in detail elsewhere[3] and enough convergence has been also confirmed for the present systems.

Internal Energies. The internal energies U of

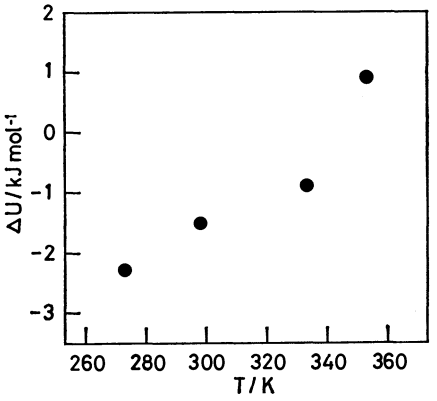

Fig. 2. Internal energies of mixing ΔU of aqueous solution of methane as a function of temperature. The standard state of the solute is assumed to be ideal gas.

both pure water and aqueous methane solution have been calculated as a function of temperature and the results are given in Table 1.

First the temperature dependence of U for pure water shown in Fig. 1 is examined. This kind of calculation has already been carried out with the MD method by Stillinger and Rahman[2] in a wide range of temperature, and their results are also given in the figure. The present calculations are concerned with a narrower temperature range in detail and the results are in good agreement with those obtained by Stillinger and Rahman.[2] Although U increases with increasing temperature as expected, the U *vs.* T curve is convex upward, which means that the heat capacity C_v decreases with increasing temperature. This result coincides with experimental observation.[7] The C_v value evaluated from the present result of the temperature gradient is 80 J K^{-1} mol^{-1} at 298.15 K. The agreement with the experimental value (75 J K^{-1} mol^{-1})[7] is reasonable in view of the present status of computer experiment.

It must be noted here that the fluctuation of internal energies for pure water and the solution at 273.15 K is so large that the values are less reliable than those at higher temperatures. This uncertainty in the present calculation is unavoidable. It may be caused by the continuous phase transition from liquid state to ice in computer experiment owing to the restriction of initial phase condition. Then the thermodynamic properties and distribution functions at 273.15 K are limited only to the comparison with those at other temperatures. For this reason, we present here only the results of internal energy at 273.15 K, and do not discuss the distribution functions in detail.

In Table 1 are given the internal energies of mixing ΔU,

$$\Delta U = U_{\text{soln}} - (x_{\text{water}}U_{\text{water}} + x_{\text{solute}}U_{\text{solute}}),$$

where the reference state of the solute is an ideal gas state and x refers to mole fraction. The ΔU *vs.* T relation is plotted in Fig. 2. Except at 353.15 K, the dissolution proceeds exothermically which is evidence for hydrophobic hydration.

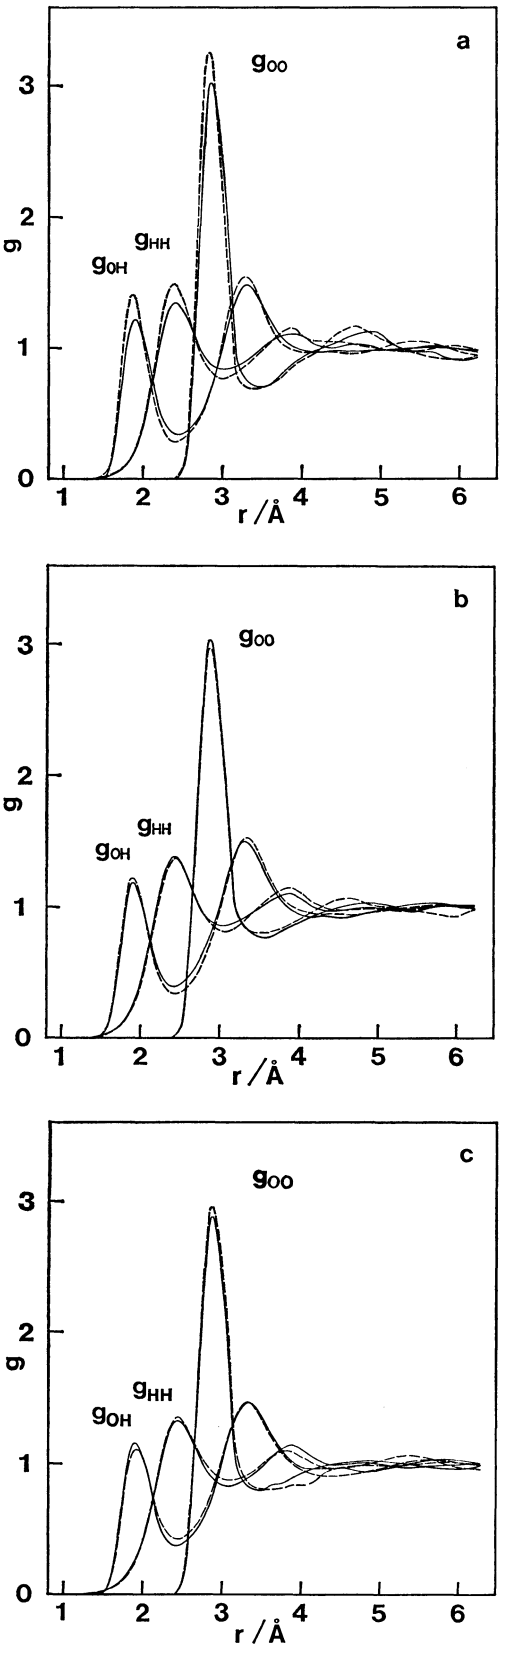

Fig. 3. Atom-atom pair correlation functions, g_{OO}, g_{OH}, and g_{HH} at (a) 298.15 K, (b) 333.15 K, (c) 353.15 K.
Solid line: pure water, broken line: aqueous solution of methane.

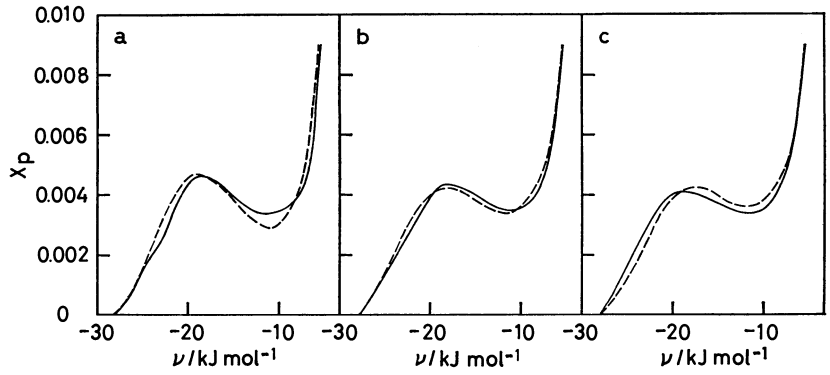

Fig. 4. Pair interaction distribution function x_p at (a) 298.15 K, (b) 333.15 K, and (c) 353.15 K.
Solid line: pure water, broken line: aqueous solution of methane.

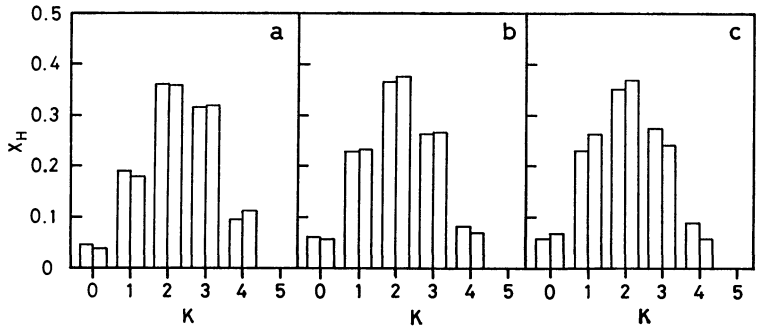

Fig. 5. Hydrogen bonding number distribution function x_H for $\nu_H = -16$ kJ mol^{-1} at (a) 298.15 K, (b) 333.15 K, and (c) 353.15 K.
Left: pure water, right: aqueous solution of methane.

The solubilities of nonpolar molecules in water decrease regularly as temperature increases; then the change in partial molar enthalpies $\Delta\bar{H}^\circ$ associated with dissolution is negative and its absolute values become smaller as temperature increases.[4] The temperature dependence of ΔU obtained from the present MC calculations is in good accordance with that of $\Delta\bar{H}^\circ$. From the positive slope of the internal energy of mixing it becomes clear that the heat capacity of mixing is positive.

Radial Distribution Functions. In order to explore the behaviour of ΔU which reflects hydrophobic hydration in aqueous solutions, we have calculated various distribution functions. In the first place, atom-atom radial distribution functions, g_{OO}, g_{OH}, and g_{HH} are presented and discussed in this subsection. Figure 3 shows the three rdf's as a function of temperature. Among these rdf's, g_{OH} is very important in discussing the structuration of water near the solute because higher positional correlation between oxygen and hydrogen atoms corresponds to stronger hydrogen bonding and is evidence for structuration of water molecules around a nonpolar solute. As is clearly seen in Fig. 3, the height of the first peak of g_{OH} for aqueous solution of methane is much larger than that for pure water only at 298.15 K. At 333.15 K, the correlation is still higher in the case of aqueous solution, though the difference becomes smaller. However, the reverse of this order is observed at 353.15 K, where the correlation is smaller for the aqueous solution. This suggests that water behaves as a normal solvent at this temperature.

Other Distribution Functions. The results of radial distribution functions presented above show a good correspondence with the internal energy of mixing ΔU for the solution at each temperature. It is now interesting to examine the temperature dependence of other distribution functions, such as hydrogen bonding number distribution function (HBNDF) and pair interaction distribution function (PIDF). The former function represents fractions of water molecules which make hydrogen bondings with other K water molecules and the latter function represents fraction of molecular pair which interacts with each other by ν kJ mol^{-1}. The detailed definitions are given elsewhere.[3,8] The results for PIDF are shown in Fig. 4, whereas those for HBNDF are plotted in Fig.5.

We first discuss the PIDF results. It is seen from Fig. 4 that the peak at about -20 kJ mol^{-1} indicates the hydrogen bonding. With the increase in temperature, the peak of PIDF gradually shifts to higher energy direction both for pure water and aqueous solution. The value of ν at the peak for aqueous solution is lower than that for pure water at 298.15 K and 333.15 K. This is the region where the structuration of water due to nonpolar solute takes place significantly. On the contrary, the peak for aqueous solution shifts slightly to higher energy compared with that for pure water at 353.15 K. At this rather higher temperature, most of water molecules seem to behave

as an ordinary molecular liquid, though a considerable number of hydrogen-bonded species are still retained.

The above picture can be further confirmed by the information from HBNDF which counts the number of hydrogen bonds in the system. Although we have calculated the distribution functions with different criteria for the hydrogen bonding strength, it is enough for the present purpose to give only the HBNDF at $v_H = -16$ kJ mol^{-1}. Figure 5 clearly shows that the number of water molecules with the hydrogen bonding number $K=3$ or 4 in pure water at 353.15 K is evidently larger than that in aqueous solution at the same temperature, indicating overall decrease in hydrogen bonding structure by the introduction of the solute molecule. On the other hand, the fractions of molecules with $K=3$ and especially $K=4$ for aqueous solution are larger than those in pure water at 298.15 K. The fractions for $K=1$, 2, and 3 in aqueous solution are slightly larger than those in pure water at 333.15 K.[9] These are also in the same situation with other distribution functions.

The mole fraction of the nonpolar solute in the present systems is as large as 0.015, which is much more concentrated than that in the gas solubility equilibrium of methane and related compounds in water. In spite of this different situation, one can depict a fairly consistent picture on the temperature effect on the hydrophobic hydration as below.

1) The value for internal energy of mixing ΔU is negative except at 353.15 K.

2) The heat capacity of mixing ΔC_v is positive at all temperatures.

3) Radial distribution function and other distribution functions show that the structuration of water due to apolar solute is significant at 298.15 K and 333.15 K. These are in good correspondence to those observed in solubility measurements of nonpolar molecule in water.

4) At 353.15 K, unique structural properties of water are lost and the introduction of nonpolar solute is energetically unfavourable.

The authors thank the Computer Center, Institute for Molecular Science and the Data Processing Center, Kyoto University for the use of the facilities, HITAC M-200H and FACOM M200, respectively.

9) It must be noted that the negative ΔU value at 273.15 K is not due to the increase in the number of hydrogen bonds with larger interaction energy, but due to the enhancement of smaller dipole-dipole interactions. Thus energetical stabilization at 273.15 K is quite different from those at higher temperatures. However, the statistical error in the calculation for 273.15 K is so large that we cannot reach a final conclusion here.

Observation of Spin Sublevel Excitation Spectra. An Application to Vibrational Analysis of T←S Absorption

Kazuhiko SUGA,† Nobuyuki NISHI,†† and Minoru KINOSHITA*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received April 9, 1982)

A new application of the $T_1 \leftarrow S_0$ excitation spectroscopy is presented by which absorptions to one or two of the three spin sublevels can be measured separately. This method has been applied to the $T_1 \leftarrow S_0$ excitation of crystalline 1,2,4,5-tetrachlorobenzene and 9*H*-xanthen-9-one at 1.4 K. The vibrational structures of the excitation spectra are analyzed in view of the spin selectivity observed.

The photoexcitation spectroscopy has achieved a considerable success in studying absorptions of aromatic compounds at low temperatures. In particular, the method using phosphorescence for detection has been applied successfully to observation of $T_1 \leftarrow S_0$ absorptions in crystalline aromatic compounds. In this case, triplet excitons in a crystal are formed by direct $T_1 \leftarrow S_0$ absorption and then the triplet excitation is transferred to guest or trap molecules having a lower T_1 energy, from which emission originates.

Since $T_1 \leftarrow S_0$ absorption requires anisotropic spin-orbit interactions, the absorption cross sections of the individual spin sublevels in a particular vibronic level are quite different from one another, resulting in formation of the state of spin alignment of triplet excitons in the crystal. It is well established that the triplet-triplet energy transfer occurs through the exchange mechanism[1] and that the spin angular momentum is conserved during energy transfer.[2] Consequently, at very low temperature, where the spin-lattice relaxation is negligible, the high degree of spin alignment in the excitons can be replicated on the guest or trap molecules in accordance with the relative orientation of the principal spin axes.

Then, if the spin alignment thus prepared in the guest or trap molecules is analyzed by applying the MIDP (microwave induced delayed phosphorescence) method to the trap emission, the spin selectivity in the $T_1 \leftarrow S_0$ excitation processes may be inferred. In fact, this technique has been developed previously[3] and applied successfully to the analyses of the spectra of *p*-chloroaniline,[4] pyrazine,[5] triphenylene,[6] and *p*-dichlorobenzene.[7]

In the present paper, a new method is described by which the $T_1 \leftarrow S_0$ spin sublevel excitation spectra can be obtained. This method is applied to neat crystals of 1,2,4,5-tetrachlorobenzene (TCB) and 9*H*-xanthen-9-one (xanthone) for the purpose of analyzing the vibrational structures of the $T_1 \leftarrow S_0$ absorptions. For successful application of this technique, some requirements have to be satisfied by the system selected. These conditions will be first described below.

Description of the Method

Excitation spectroscopy provides information on excited states through the properties of the monitored emission. Therefore, when the emission which originates predominantly from one of the spin sublevels of the trap is monitored, the resulting spectrum would reflect the absorption cross section of the corresponding spin sublevel in the triplet state of the crystal to be examined, provided that the spin alignment produced in the triplet excitons by direct $T_1 \leftarrow S_0$ excitation is almost exactly replicated on the trap molecules. This is the essential point of the method presented in this paper. To populate the spin sublevels of the excitons in proportion to the absorption cross sections of the individual spin sublevels, it may be appropriate to use the pulse excitation method.

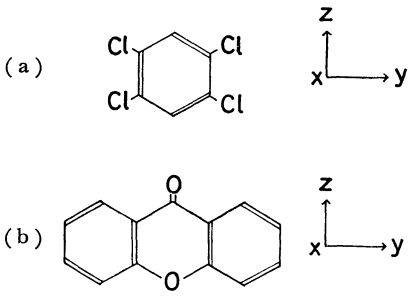

Fig. 1. Molecular structure and choice of the axis system; (a) 1,2,4,5-tetrachlorobenzene and (b) 9*H*-xanthen-9-one.

The spin alignment produced by T←S excitation plays a crucial role in this method; it should be maintained throughout the experiment which involves the processes of vibrational relaxation, energy transfer, trapping, and emission from the trap molecules. The first three processes are usually fast compared with the spin-lattice relaxation process at very low temperature. Therefore, molecules having a relatively short lifetime, such as halogenated aromatics and aromatic carbonyls, may be chosen as a trap to minimize the spin-lattice relaxation effect.

Another requirement to be satisfied by the trap molecules is that the individual spin sublevels should contribute quite differently to an emission band which is energetically resolvable for monitoring. Most of the compounds having a symmetry of C_{2v} or higher are known to fulfill this requirement and may be used as a trap.

In addition, the trap molecules should enter into the crystal in such a way that the orientation of the principal spin axes of the trap relative to that of the triplet excitons can be inferred. The simplest case is an experiment on the system in which the directions

† Present address: Technical Research Center, Nippon Mining Co., Ltd., Niiso-Minami, Toda, Saitama 335.

†† Present address: Institute for Molecular Science, Myodaiji, Okazaki, Aichi 444.

of the spin axes of the trap triplet state are, at least approximately, coincident with those of the excitonic triplet state. In such a system, the populations of the spin sublevels in the emitting trap molecules are almost exactly proportional to the absorption cross sections of the spin sublevels in the excitons pumped by pulse excitation ($N_i \propto P_i$). Accordingly, the intensity of the phosphorescence to a selected vibrational band, ν, is given by $I(\nu)=c\Sigma k_i^r(\nu)P_i$, where the sum is taken over the spin sublevels(i), $k_i^r(\nu)$ refers to the relative radiative decay rates to ν, P_i is the relative absorption cross sections of the individual spin sublevels, and c is a proportional constant which also corrects for the sensitivity of the detection system. On the basis of the values of $k_i^r(\nu)$, the values of P_i may be determined by observing the intensities of the emission to different vibrational bands. In an ideal case where the vibrational band having contribution only from one of the spin sublevels could be selected for monitoring, an absorption spectrum of that spin sublevel would be obtained. In a real system, however, contributions from the other two sublevels would not be eliminated completely, but the following examples demonstrate the usefulness of the method.

Experimental

1,2,4,5-Tetrachlorobenzene (TCB) was purified by recrystallization and vacuum sublimation, followed by extensive zone-refining. 9*H*-Xanthen-9-one (xanthone) was recrystallized and then zone-refined. Single crystals were grown by the standard Bridgman technique.

Excitation of the crystals was performed with a Molectron DL-200 tunable dye laser equipped with a Molectron UV-1000 1 MW N_2 laser. Phosphorescence was monitored at right angle to excitation path through a Spex 1700 III 3/4 m monochromator. A PAR 162 boxcar integrator was used to acquire the average emission intensity for 2 ms. Other equipment for optical experiments was essentially the same as reported in the previous paper.[8]

1,2,4,5-Tetrachlorobenzene

A TCB crystal is triclinic below 188 K and belongs to the space group $P_{\bar{1}}$ with two molecules in a unit cell.[9] The molecules in the translationally inequivalent lattice sites are interchanged by the action of inversion so that the molecular axes of these two are parallel. Therefore, the principal spin axes of the excitons are coincident with those of the molecule. The selection rules for the isolated molecule are expected to hold for the excitons.

The translationally equivalent molecules stack nearly plane-to-plane along the a axis with the out-of-plane molecular axis almost parallel to the a axis. Because of this card pack array of the molecules, together with the small value of the *a* lattice constant relative to the *b* and *c* lattice constants, the exchange interaction for the π,π^* triplet state is largest along the a axis. In fact, the Davydov splitting, which is a measure of the interchain interaction, has been estimated to be about 1 MHz, that is orders of magnitude less than the intrachain matrix element of 0.35 cm^{-1}.[10] All these lead to the conclusion that the exciton migration in this system is essentially one-dimensional along the a axis and probably coherent at liquid helium temperatures. The manifestation of this nature has been discussed in great detail in the literature.[11]

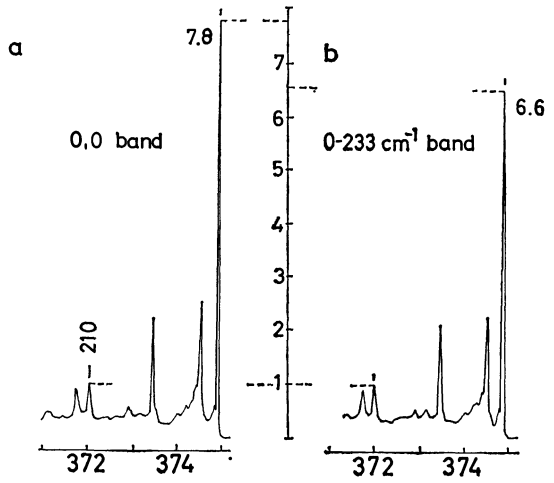

Fig. 2. The $T_1 \leftarrow S_0$ phosphorescence excitation spectra of the TCB neat crystal at 1.4 K, monitored (a) at the 0,0 band and (b) at the 0−233 cm^{-1} band of the Y trap emission.

In addition to the exciton, TCB crystals show phosphorescence from traps with the origin at 26626 cm^{-1} (Y trap).[12] Francis and Harris[13] have reported that the electron spin transitions associated with the excitons are also observed by monitoring the Y trap emission. This evidently results from the spin selectivity of the exciton-trap interaction and, furthermore, indicates that the spin alignment in the excitons is transferred, for the most part, with electronic energy to the molecules in the Y trap site.

Figure 2 shows the excitation spectra of the TCB crystal at 1.4 K obtained by separately monitoring the 0,0 band and 0−233 cm^{-1} band in the phosphorescence emission from the Y trap. There is a significant difference between the two spectra. The intensity of the 0+210 cm^{-1} band relative to the intensity of the origin band is larger in the spectrum monitored at the 0−233 cm^{-1} band than that at the 0,0 band. Since the emission of the Y trap originates mainly from the y sublevel at the 0,0 band and, on the other hand, predominantly from the z sublevel at the 0−233 cm^{-1} band,[14] this difference can be attributed to the difference in the populations of the y and z sublevels. As mentioned above, the spin alignment in the excitons can be replicated on the Y trap without serious population rearrangement. Therefore, the observed results above indicate that the absorption to the 0+210 cm^{-1} band occurs in the y sublevel in preference to the z sublevel, whereas the situation is opposite for the origin band.

A number of studies[14,15] on the phosphorescence of TCB have revealed that besides the vibronic bands due to the a_g modes, only the band due to the C–Cl out-of-plane bending mode of b_{2g} appears strongly in the phosphorescence spectrum and that the main mech-

a) Taken from Ref. 18; data for the trap named site I in the neat crystal.

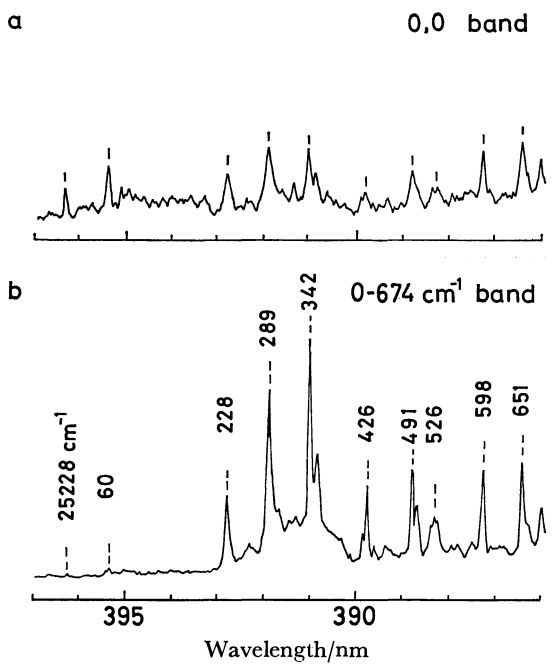

Fig. 3. The $T_1 \leftarrow S_0$ phosphorescence excitation spectra of the xanthone neat crystal at 1.4 K, monitored (a) at the 0,0 band and (b) at the 0−670 cm^{-1} band of the trap emission of site I.

anisms for the radiative decay are those listed in Table 1. A similar situation can be expected to hold for the absorption processes. Accordingly, the 0+210 cm^{-1} band can be assigned as being due to the C−Cl out-of-plane bending mode of b_{2g}, corresponding to that of 233 cm^{-1} in the ground state.

9*H*-Xanthen-9-one

A xanthone crystal is orthorhombic with four molecules in a unit cell.[16] The translationally equivalent molecules stack plane-to-plane along the a axis, with the out-of-plane molecular axis almost parallel to the a axis. The *a* lattice constant is small (4.894 Å) compared with the *b*(13.651 Å) and *c*(14.127 Å) lattice constants. The exciton motion in this system is therefore considered to be essentially one-dimensional along the a axis. No Davydov splitting has been resolved in the $T_1 \leftarrow S_0$ absorption, implying that the interaction between linear molecular chains is small. Therefore, the spin alignment of the excitons created by direct $T_1 \leftarrow S_0$ excitation is assumed to be appreciably preserved during the exciton migration. In addition, since the molecules in the trap sites have the orientations close to those in the host lattice, the populations of the spin sublevels of the trap molecules populated by the excitation trapping are considered to be just a replica of those of the excitons.

The $T_1 \leftarrow S_0$ absorption of the xanthone crystal was studied at 1.4 K by phosphorescence excitation method with short pulses. Some of the vibronic bands are found to behave in quite different ways from the 0,0 band as the wavelength for monitoring is changed. Figure 3 compares, as an example, the spectra obtained by monitoring the emission from the trap, named as site I, at the 0,0 band and 0−670 cm^{-1} band. These two bands have been reported to differ largely in the radiative activity of the z sublevel, whereas the x and y sublevels make similar contributions.[17,18] The remarkable difference between the two spectra can be attributed to the change in the relative population of the z sublevel of the site I trap as the wavelength of the excitation is changed. Furthermore, this indicates that both the spin-lattice relaxation and population rearrangement according to the relative orientation of the spin axes of donor and acceptor molecules have a little effect during the energy transfer process and is in good agreement with the expectation mentioned above that the excitation transfer may occur essentially in a one-dimensional manner.

Accordingly, the observed results imply that for excitation to the vibronic bands in the triplet manifold, such as 0+228, 0+289, and 0+342 cm^{-1}, the z sublevel has preferable activity whereas the y sublevel is

probably most active for the 0,0 band excitation. The y and z sublevels have been reported to gain the activity in the $T_1 \rightarrow S_0$ radiative decay through the mechanisms listed in Table 2, and similar mechanisms are expected to play a role in the $T_1 \leftarrow S_0$ absorption process. In fact, the experimental finding that the absorption cross section of the y sublevel is larger than that of the z sublevel in the case of the 0,0 band excitation is consistent with this expectation, and also the vibronic bands such as 0+228, 0+289, and 0+342 cm^{-1} can be assigned as being due to the b_1 species in view of the intensity behavior. In addition, the vibronic bands probably due to the a_2 modes such as 0+670 cm^{-1} are found to appear with considerable intensity at upward of 600 cm^{-1} from the origin, although the bands involving a_2 species appear with little intensity in the phosphorescence spectrum. This is a consequence of the increased importance of the vibronic coupling with intermediate $^3A_2$ (n,π^*) state resulting from the reduction of energy separation.

The Group Coordinate Force Field of Oxymethylene and Thiomethylene Chain Molecules

Hiroatsu MATSUURA* and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received May 12, 1982)

Force field was systematically determined in terms of the group symmetry coordinates for series of $CH_3(OCH_2)_mOCH_3$ ($m=1$—3), the polymer $(-OCH_2-)_n$, and their deuterated derivatives, and of $CH_3(SCH_2)_mSCH_3$, $(-SCH_2-)_n$, and their deuterated derivatives. Twenty-five force constants for the oxymethylene molecules and twenty-two force constants for the thiomethylene molecules were adjusted by using 178 and 126 observed wavenumbers, respectively. The force constants obtained were compared with those for related molecules. The results of the normal coordinate treatment on the polymers were discussed in comparison with the results in previous works.

The intramolecular force field is one of the essential factors that characterize the properties of a molecule. The data concerning the force field are, therefore, of great importance in various fields of chemistry and physics, and the accumulation of such data is highly desired. In fact, systematic researches to establish the molecular force constants have been initiated by Shimanouchi *et al.* and the results so far obtained have been compiled as standard reference data.[1-3] The force constants thus published include those for unbranched chain molecules of alkanes, dialkyl ethers, dialkyl sulfides,[1] fluoroalkanes, chloroalkanes, bromoalkanes, and iodoalkanes.[2]

The force constants in these studies have been expressed in terms of the symmetry coordinates of the atomic groups constituting the molecule. This type of force field, called the group coordinate force field (GCFF)[3] or the local symmetry force field, has been proved to be suitable for describing the intramolecular potential of such classes of molecules as those mentioned above.

Having established the force field for dialkyl ethers ROR′, where R and R′ are alkyl groups,[1] and studied closely a conformational stability of dimethoxymethane $CH_2OCH_2OCH_3$,[4] it seems timely to work thoroughly on the GCFF for a series of $CH_3(OCH_2)_mOCH_3$ and the polymer $(-OCH_2-)_n$. In the present work, therefore, the force constants in the GCFF were derived for the oxymethylene chain molecules and the sulfur analogues, namely the thiomethylene chain molecules. The force constants determined and the results of the normal coordinate calculations are reported in the present paper.

Normal Coordinate Treatment

The force constants in the GCFF were calculated for the oxymethylene and thiomethylene chain molecules by means of the normal coordinate treatment.[5] The calculations were carried out by using a computer program MVIB[3] which has been developed for treating vibrations of chain molecules.

Molecules Treated. The calculations were performed on the following molecules; the oxymethylene series: $CH_3OCH_2OCH_3$ *gauche-gauche* form (to be abbreviated as G_2), $CH_3OCD_2OCH_3$ G_2, $CD_3OCH_2OCD_3$ G_2, $CD_3OCD_2OCD_3$ G_2, $CH_3(OCH_2)_2OCH_3$ G_4, $CH_3(OCH_2)_3OCH_3$ G_6, $(-OCH_2-)_n$ G_∞, and $(-OCD_2-)_n$ G_∞, and the thiomethylene series: $CH_3SCH_2SCH_3$ G_2, $CH_3SCD_2SCH_3$ G_2, $CH_3(SCH_2)_2SCH_3$ G_4, $CH_3(SCH_2)_3SCH_3$ G_6, $(-SCH_2-)_n$ G_∞, and $(-SCD_2-)_n$ G_∞. The observed infrared and Raman wavenumbers were taken from the literature: $CH_3OCH_2OCH_3$,[4,6] $CH_3OCD_2OCH_3$,[6] $CD_3OCH_2OCD_3$,[6] $CD_3OCD_2OCD_3$,[6] $CH_3(OCH_2)_2OCH_3$,[7] $CH_3(OCH_2)_3OCH_3$,[7] $(-OCH_2-)_n$,[8-10] $(-OCD_2-)_n$,[8-10] $CH_3SCH_2SCH_3$,[11] $CH_3SCD_2SCH_3$,[12] $CH_3(SCH_2)_2SCH_3$,[11] $CH_3(SCH_2)_3SCH_3$,[11] $(-SCH_2-)_n$,[13] and $(-SCD_2-)_n$.[14]

Table 1. Atomic masses for the oxymethylene and thiomethylene molecules

Atom	Atomic mass[a]/u
Hydrogen, protium	1.007825
Hydrogen, deuterium	2.014102
Carbon	12.011[b]
Oxygen	15.9994[b]
Sulfur	32.06[b]

a) Atomic mass in units of unified atomic mass unit. $1\ u \approx 1.660531 \times 10^{-27}$ kg. b) Isotope-abundance weighted atomic mass.

Atomic Masses and Structural Parameters. The values of the atomic masses and the structural parameters used in the normal coordinate treatment are listed in Tables 1 and 2. Isotope-abundance weighted atomic masses were used for carbon, oxygen, and sulfur, since the experimental vibrational wavenumbers were not resolved into components of individual isotopic species except for hydrogen under the spectral resolution utilized.

The structural parameters for the polymers are based on the results of the X-ray diffraction analyses,[15,16] and are in conformity with the 9/5 helix for poly(oxymethylene) and the 17/9 helix for poly(thiomethylene). Some of the structural parameters were recalculated by making use of equations for helix parameters.[17] The geometries of the oligomer molecules, $CH_3(OCH_2)_mOCH_3$ and $CH_3(SCH_2)_mSCH_3$ ($m=1-3$), were deduced from those of related molecules.[18]

Group Symmetry Coordinates. The symmetry coordinates in the methyl group, $CH_3(O)$ or $CH_3(S)$, and the methylene group, $(O)CH_2(O)$ or $(S)CH_2(S)$,

were constructed in accordance with the group symmetry of C_{3v} and C_{2v}, respectively. General expressions to give the group symmetry coordinates with arbitrary valence angles have been formulated.[3] The coordinates and their signs were thus defined on the basis of these formulations, with the structural parameters given in Table 2. The group coordinates for the molecules treated in this work are similar to those for ROR′ and RSR′ molecules[1] with different coefficients only for the CH_2 scissoring, CH_2 wagging, and OCO or SCS deformation coordinates. Full details of the coordinate definition are found in Table 1 of Ref. 3.

Force Constants. The force constants in the GCFF are given in terms of the group symmetry coordinates given above and are classified into intragroup force constants and intergroup force constants.[1-3] The intragroup force constants for the terminal methyl group and the intergroup force constants between the methyl group and the adjoining oxygen or sulfur atom were constrained to those determined previously for CH_3OR or CH_3SR[1] and were not adjusted further in the present work. Other force constants were refined by the least-squares method in order that the calculated wavenumbers of normal vibrations agreed more closely with the observed ones. In the course of the refinement calculations, some of the force constants were found to be ill-determined with large errors. Such force constants were eventually assumed to be equiv-

a) Potential-energy distributions (P.E.D.) calculated in this work are given in parentheses following the symmetry coordinates; 1: CH_2 symmetrical stretching, 2: CH_2 scissoring, 3: CH_2 antisymmetrical stretching, 4: CH_2 rocking, 5: CH_2 wagging, 6: CH_2 twisting, D: OCO deformation, B: COC bending, S: C-O stretching, and T: C-O torsion. b) Ref. 7. c) Ref. 19. d) Ref. 8.

alent to those for similar atomic groups so that the remaining constants converged properly. The calculations also revealed that the interaction force constants between the coordinates belonging to the second-neighboring atomic groups were required for satisfactory fitting of the observed and calculated wavenumbers. These constants include the interactions between the CH_2 rocking and CH_2 rocking coordinates, CH_2 wagging and CH_2 wagging, *etc.* of the neighboring methylene groups with an oxygen or sulfur atom in between, and the interaction between the COC (or CSC) bending and COC (or CSC) bending coordinates of the neighboring COC (or CSC) groups. The constants associated with the CH_2 symmetrical and antisymmetrical stretching coordinates were not refined in the present study.

A full list of the force constants finally determined for the oxymethylene and thiomethylene chain molecules, together with the calculated results for all the molecules treated, has been deposited with the Chemical Society of Japan (Document No. 8247). In Tables 3 and 4, some important force constants are compared with those for related molecules. The calculated wavenumbers and assignments are given in this article only for the polymers.

Results and Discussion

In the present study, twenty-five force constants in the GCFF were determined for the oxymethylene chain molecules from 178 observed wavenumbers and twenty-two force constants for the thiomethylene chain molecules from 126 observed wavenumbers. The calculations with these force constants gave overall root-mean-square deviations of 9.6 and 8.2 cm^{-1}, respectively, for the oxymethylene and thiomethylene molecules, between the observed and calculated wavenumbers.

Table 3 shows that the values of the diagonal force constants for the $(X)CH_2(Y)$ group increase systematically in going from $(CH_2)CH_2(CH_2)$ to $(CH_2)CH_2(O)$ and $(O)CH_2(O)$. For the sulfides in Table 4, on the other hand, the values of the CH_2 scissoring, CH_2 wagging, and CH_2 twisting force constants decrease in going from $(CH_2)CH_2(CH_2)$ to $(CH_2)CH_2(S)$ and $(S)CH_2(S)$, but the value of only the CH_2 rocking constant increases. The CH_2–O stretching constant for the $(O)CH_2$–$O(CH_2)$ group (4.67 mdyn $Å^{-1}$) is found to be considerably smaller than that for the $(CH_2)CH_2$–$O(CH_2)$ group (5.04 mdyn $Å^{-1}$). This contrasts with the essentially same value (2.96 mdyn $Å^{-1}$) of the CH_2–S stretching constant for the $(S)CH_2$–$S(CH_2)$ and $(CH_2)CH_2$–$S(CH_2)$ groups.

The calculated results for poly(oxymethylene) and poly(oxymethylene-d_2) are given in Tables 5 and 6 in comparison with those reported previously.[7,8,19] The agreement between the observed and calculated wavenumbers is less satisfactory in the earlier studies. The nature of the normal modes is represented by the potential-energy distributions (P.E.D.).† The P.E.D.'s for the undeuterated species is almost the same among the studies, but some of the P.E.D.'s for the deuterated species differ considerably from one another. For example, the vibration at 1156 cm^{-1} (e_1) is assigned in this work to the CD_2 rocking, but was assigned to the CD_2 wagging and CD_2 scissoring,[7] to the C–O stretching and CD_2 scissoring,[19] or to the C–O stretching and CD_2 wagging,[8] and the vibration at 1078 cm^{-1} (e_1) is assigned in this work to the CD_2 wagging and C–O stretching, but was assigned to the CD_2 rocking,[7] to the CD_2 rocking and C–O stretching,[19] or to the CD_2 scissoring and C–O stretching.[8] We believe that the present assignment based on the systematic treatment is more likely than the previous ones.

The assignment of the observed bands of poly(thiomethylene) and poly(thiomethylene-d_2) is now estab-

† The potential-energy distribution, as defined by (P.E.D.)$_{ji} = 100 \times L_{ji}^2 f_{jj}/\lambda_i$,[3] may exceed 100 because of neglecting the contribution of off-diagonal force constants. This effect is particularly enhanced for polymers.

a) Potential-energy distributions (P.E.D.) are given in parentheses following the symmetry coordinates; 1: CH_2 symmetrical stretching, 2: CH_2 scissoring, 3: CH_2 antisymmetrical stretching, 4: CH_2 rocking, 5: CH_2 wagging, 6: CH_2 twisting, D: SCS deformation, B: CSC bending, S: C–S stretching, and T: C–S torsion.

lished, as given in Table 7, in the light of the force field determined in the present work. The vibrational assignment of this polymer was first made by Hendra *et al.*,[13] who acknowledged, however, that their assignment based on empirical basis was very tentative. The normal coordinate treatment of poly(thiomethylene) and the deuterated derivative has been reported by Ohsaku.[14] His calculation is unfortunately erroneous as evidenced by the unlikely number of normal vibrations belonging to each symmetry species.

The group coordinate force field derived in this work for the $-OCH_2O-$ and $-SCH_2S-$ groups may be applied to other molecules consisting of similar atomic groups. The accumulation of the force constants for various types of atomic groups will eventually make possible the calculation of normal vibrational wavenumbers and modes of a large number of molecules.

The authors wish to thank Mr. Tomoya Takuwa for his assistance in the computational work. Numerical computations were carried out with a HITAC M-200H computing system at Hiroshima University.

The Structure and Properties of the Triaquahexakis(methylthioacetato)-dineodymium(III) Polymer, $[Nd_2(C_3H_5SO_2)_6(H_2O)_3]_n$, and the Same-ligand Complexes of Lanthanoid Elements

Satoshi KONDO, Mamoru SHIMOI, Akira OUCHI,* and Toshio TAKEUCHI†

Department of Chemistry, College of General Education, The University of Tokyo, Komaba 3-8-1, Meguro-ku, Tokyo 153

† *Department of General Sciences, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102*

(Received August 25, 1981)

The crystal and molecular structure of the title complex has been determined by the X-ray diffraction method. The crystal was triclinic, space group $P\bar{1}$, $a=12.80(1)$, $b=16.65(1)$, $c=8.659(9)$ Å, $\alpha=104.6(1)$, $\beta=93.7(2)$, $\gamma=107.5(1)°$, $Z=2$, $D_x=1.892(3)$, $D_m=1.91(2)$ Mg m^{-3}, μ(Mo $K\alpha$)$=3.45$ mm^{-1}, and the final R value was 0.051 for 3577 reflections. The coordination number of both neodymium atoms is nine, although the coordinated atoms around one neodymium atom are arrayed in a tri-capped trigonal prism, and those around the other neodymium atom, in a mono-capped tetragonal antiprism. The neodymium atoms are arrayed on a linear chain bridged by the ligand; however, no metal-metal interaction is observed. The corresponding complexes of cerium(III), praseodymium(III), and europium(III) form isomorphous crystals with the title complex, but the complex of lanthanum(III) has the formula of $ML_3\cdot 4.5H_2O$ (HL=(methylthio)acetic acid), and the complexes of dysprosium(III) and ytterbium(III), $ML_3\cdot 2H_2O$.

Many synthetic works were already published about the (alkylthio)acetato** complexes of 3d elements,[1-11] and we have already reported about these structures.[12-15] According to our results, in general, one oxygen atom as well as a sulfur atom are coordinated with the central metal atom, thus forming a five-membered chelate ring. However, in the case of bis(isopropylthioacetato)copper(II) dihydrate, two oxygen atoms of a carboxyl group of the ligand are coordinated to separate metal atoms.[14] In the case of the bis(propylthioacetato)cobalt(II) hexamer, there are two kinds of ligands acting in different modes of coordination.[15] Although no structural analysis was done, in the case of bis(alkylthioacetato)triphenylantimony(III) the ligand is expected to be coordinated to the metal atom by only one oxygen atom.[11]

The methylthioacetato complexes of lanthanoid elements now obtained were found to have the formula of $ML_3\cdot nH_2O$ (where HL=methylthioacetic acid, and $n=4.5$, 1.5, or 2 for their hydrated complexes). The lanthanoid elements generally show a high coordination number, and the sulfur atom of a ligand is hardly coordinated at all to the metal because of its "hard" character. Consequently, it is not probable that the five-membered chelate ring found in the 3d element complexes exists also in the lanthanoid complexes. On the other hand, a linear polymer structure has been reported for some carboxylato complexes of 4f and 5f metals, such as cerium(III) acetate[16] and uranium(IV) acetate.[17] Therefore, for the alkylthioacetato complexes of lanthanoid elements, too, such a type of interesting polymerized structure was expected. Thus, we have attempted to determine their crystal and molecular structure by means of X-ray diffraction. The methylthioacetato complexes of other lanthanoid elements were also obtained and were compared with the titled complex with regard to their analytical, spectral, and thermochemical properties, as well as their X-ray powder patterns in order to classify them.

** The parentheses in the name of the ligand are neglected hereafter.

Experimental

Synthesis of Triaquahexakis(methylthioacetato)dineodymium(III), $[Nd_2(CH_3SCH_2CO_2)_6(H_2O)_3]_n$. The ligand was obtained by means of a slight modification of the method of Larsson;[18] a condensation reaction between dimethyl sulfate (in place of methyl iodide) and mercaptoacetic acid in the presence of sodium hydroxide in an aqueous solution. The aqueous solutions of sodium methylthioacetate (2.4 g (19 mmol) in 5 cm^3 of water) and of neodymium(III) chloride hexahydrate (2.0 g (5.5 mmol) in 5 cm^3 of water) were mixed and the mixture was left standing for one day or more at 6 °C. The first crop of the product was thus obtained; the yield was 1.1 g (41%). The filtered mother liquor was concentrated to 5 cm^3 and then left standing; a second crop which was almost as pure as the first one was also obtained; the total yield was 1.8 g (66%). The complex could be recrystallized from water, although the crystal appeared slowly, and the yield was low because of its fairly high solubility. The crystals thus obtained were submitted to the X-ray diffraction after being checked by means of their Weissenberg photograph. Found: Nd, 29.76; C, 22.08; H, 3.69%. Calcd for $Nd_2C_{18}H_{36}S_6O_{15}$: Nd, 29.64; C, 22.21; H, 3.73%.

Syntheses and Analyses of the Methylthioacetato Complexes of Lanthanoid Elements. These complexes were obtained in almost the same way as the neodymium complex. Among them, the cerium(III), praseodymium(III), and europium(III) complexes have the same type of chemical formula, $ML_3\cdot 1.5H_2O$ (HL=methylthioacetic acid). 1) Cerium(III) complex, Found: Ce, 28.78; C, 22.30; H, 3.67%. Calcd for $CeC_9H_{18}O_{7.5}S_3$: Ce, 29.04; C, 22.42; H, 3.76%. 2) Praseodymium(III) complex, Found: Pr, 29.15; C, 22.24; H, 3.70%. Calcd for $PrC_9H_{18}O_{7.5}S_3$: Pr, 29.15; C, 22.37; H, 3.75%. 3) Europium(III) complex, Found: Eu, 30.73; C, 21.80; H, 3.63%. Calcd for $EuC_9H_{18}O_{7.5}S_3$: Eu, 30.74; C, 21.87; H, 3.67%. The lanthanum(III) complex of the ligand has the chemical formula of $ML_3\cdot 4.5H_2O$. Found: La, 25.67; C, 19.81; H, 4.17%. Calcd for $LaC_9H_{24}O_{10.5}S_3$: La, 25.95; C, 20.19; H, 4.52%. The dysprosium(III) and ytterbium(III) complexes have the chemical formula of $ML_3\cdot$

$2H_2O$. 1) Dysprosium(III) complex, Found: Dy, 31.61; C, 21.02; H, 3.68%. Calcd for $DyC_9H_{18}O_8S_3$: Dy, 31.62; C, 21.03; H, 3.73%. 2) Ytterbium(III) complex, Found: Yb, 33.01; C, 20.54; H, 3.57%. Calcd for $YbC_9H_{18}O_8S_3$: Yb, 32.99; C, 20.61; H, 3.65%.

X-Ray Measurements. *X-Ray Powder Pattern*: Their X-ray powder patterns were obtained by the use of the diffractometer, Model DX-GO-F JEOL, using Cu $K\alpha$ radiation, in the range from 6° to 30° in 2θ.

Single-crystal X-Ray Analysis: Almost all single crystals of the title complex obtained were thin-plate ones; the crystal grew poorly in the a axis direction. As it was brittle, a crystal of 0.3 mm × 0.2 mm × 0.3 mm was used for the measurement, without any reshaping process.

The crystallographic data are: $Nd_2C_{18}H_{36}O_{15}S_6$, F.W.= 973.34, triclinic, space group $P\bar{1}$, $Z=2$, $a=12.80(1)$, $b=16.65(1)$, $c=8.659(9)$ Å $\alpha=104.6(1)$, $\beta=93.7(2)$, $\gamma=107.5(1)$°, $D_x=1.892(3)$, $D_m=1.91(2)$ Mg m^{-3}, μ(Mo $K\alpha$)=3.45 mm^{-1}.

The reflections with 2θ less than 55° were collected on a Philips PW 1100 automated four-circle diffractometer with Mo $K\alpha$ radiation, the θ-2θ scan technique being employed. We used 3577 independent reflections with $|F_o|>3\sigma(|F_o|)$ for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction.

All the calculations were carried out on a HITAC M-200H computer at The Computer Center of The University of Tokyo, using the local version of the UNICS program.[19] The atomic-scattering factors were taken from the tables.[20]

Structure Determination. The structure was solved by the heavy-atom method. The positions of neodymium atoms were deduced from a three-dimensional Patterson map, while all the other non-hydrogen atoms were located by means of successive Fourier syntheses. Their positional and thermal parameters were refined by the block-diagonal least-squares method. The positions of 20 hydrogen atoms were obtained from a difference Fourier synthesis and were also refined. The position of a sulfur atom, S(4), was divided into two, and the probability of the occupancy of each position was approximately assigned from the Fourier map and refined by the full-matrix procedure with regard to the positions of the atoms of the ligand. The final values are 46.7 and 53.3% respectively. Although it is not necessary to divide the position of the methyl carbon atom of each ligand, it has a relatively large amplitude of thermal vibration, just as in the case of some ligands in the hexamer of the propylthioacetato complex of cobalt(II).[15] In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value obtained was 0.051.[21]

Other Measurements. The magnetic moments of the solid samples were measured using a Gouy balance at 25 °C.

The simultaneous thermogravimetric (TG) and differential thermal analysis (DTA) were carried out with a Rigaku Denki "Thermoflex" M-8075 using a sample weighing about 10 mg in each operation, at the heating rate of 10 °C min^{-1} in air, using α-alumina as the reference.

The infrared spectra of the samples were obtained by means of a JASCO 403G infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull.

Results and Discussion

The crystal structure of the triaquahexakis(methylthioacetato)dineodymium(III) polymer will now be summarized. The final atomic parameters are listed in Table 1,[22] while the interatomic distances as well as the bond angles are tabulated in Table 2. A projection of the structure along the c axis is shown in Fig. 1, and a perspective drawing of the complex around Nd(1) and Nd(2), together with the numbering scheme of neodymium, oxygen, and carbon atoms, is presented in Fig. 2.

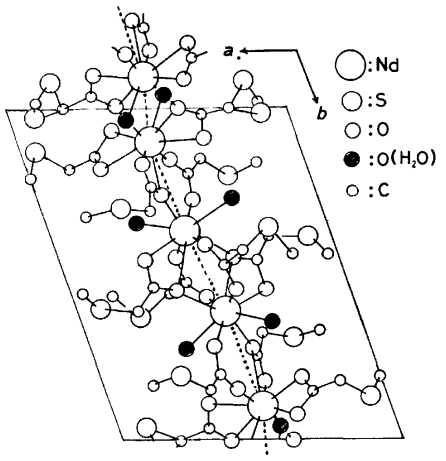

Fig. 1. Crystal packing diagram of $[Nd_2(CH_3SCH_2CO_2)_6(H_2O)_3]_n$ projected along c.

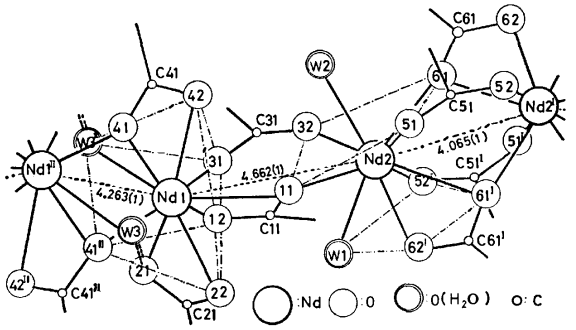

Fig. 2. A perspective drawing of $[Nd_2(CH_3SCH_2CO_2)_6(H_2O)_3]_n$, and the numbering scheme of neodymium, oxygen, and carboxyl carbon atoms. Each coordination polyhedron around neodymium atom is shown by —·—.

The crystal consists of the linear polymer of $[Nd(CH_3SCH_2CO_2)_3(H_2O)$–$Nd(CH_3SCH_2CO_2)_3(H_2O)_2]_n$, nearly parallel to the b axis. Each chain is connected with a hydrogen bond between O(W3) atom and the O(21) atom of the neighbouring chain in the c axis direction. No other bonds were observed between chains except for van der Waals interactions. As is shown in Fig. 1, the coordination number of both the neodymium atoms in the complex is nine. Their coordination polyhedrons are, however, different from each other; that around Nd(1) is a distorted tri-capped trigonal prism, while that around Nd(2) is, rather, a mono-capped tetragonal antiprism, as is shown by the —·— line in Fig. 2. Each water molecule is coordinated to one of the neodymium atoms, and, as is shown above, one of them forms a hydrogen bond with the carboxyl oxygen atom of a neighbouring chain. Each methylthioacetato ligand is coordinated to neodymium atoms through the oxygen

Table 1. Final atomic coordinates ($\times 10^4$ for non-hydrogen atoms, and $\times 10^3$ for hydrogen atoms), equivalent isotropic (for non-hydrogen atoms), and isotropic temperature factors (for hydrogen atoms), with estimated standard deviations in parentheses

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=(4/3)(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{12}ab\cos\gamma+B_{13}ac\cos\beta+B_{23}bc\cos\alpha)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

**** The probability of the occupancy of each position was 46.7% for S(4A) and 53.3% for S(4B).

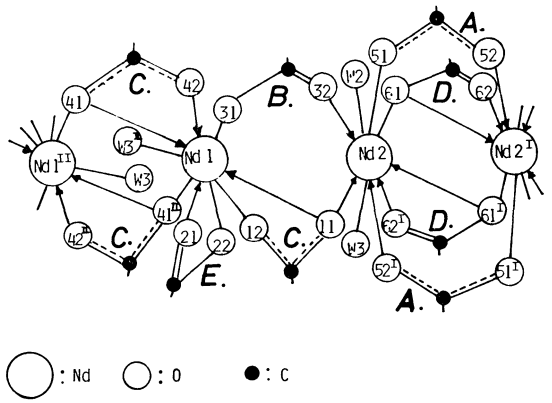

Fig. 3. Schematic presentation of the bonding modes of ligands. The mode of each carboxyl group is presented by *A*—*E*. The Nd–O bond without arrow mark is the shortest one of those from the carboxyl group.

atoms, not through its sulfur atom. As is shown in Fig. 3, there are five kinds of ligands, as considered in terms of their coordination modes; they are tentatively named *A*—*E*-mode ligands.

The *A* and *B* ligands span two neodymium atoms through both the oxygen atoms of a carboxyl group. The C–O distances of *A* ligand are almost the same (C(51)–O(51)=1.256(14), C(51)–O(52)=1.258(14) Å), and the corresponding Nd–O distances are not much different (Nd(2)–O(51)=2.415(7), Nd(2)–O(52^{I})=2.456(9) Å). In the case of the *B* ligand, one C–O is longer than the other one (C(31)–O(31)=1.272(16), C(31)–O(32)=1.198(13) Å), while the Nd–O from the oxygen atom of the shorter C–O is longer than the other one (Nd(2)–O(32)=2.454(8), Nd(1)–O(31)=2.312(10) Å). The *C* and *D* ligands bridge two neodymium atoms by one oxygen atom, and, at the same time, the other oxygen atom of the ligand is coordinated to one of the bridged neodymium at-

oms. The two C–O distances of the *D* ligand are different from each other (C(61)–O(61)=1.289(13), C(61)–O(62)=1.236(12) Å); the difference is a little larger than those of *C* ligands (C(11)–O(11)=1.269(13), C(11)–O(12)=1.241(13) Å; C(41)–O(41)=1.247(14), C(41)–O(42)=1.265(13) Å). In the *D* ligand, the oxygen atom of the longer C–O, O(61), forms the bridge, and both the bridging Nd–O distances are a little shorter than the one-oxygen-atom-bridging Nd–O distances of the *C* ligands (Nd(2)–O(61)=2.405(8), and Nd(2^{I})–O(61)=2.633(8) Å, *vs.* Nd(2)–O(11)=2.513(8), Nd(1)–O(11)=2.691(7); Nd(1^{II})–O(41)=2.441(8), Nd(1)–O(41)=2.681(8) Å). The Nd–O distance of the non-bridged oxygen atom of the *D* ligand (Nd(2)–O(62^{I})=2.568(9) Å) is longer than the corresponding Nd–O distance of the *C* ligands (Nd(1)–O(12)=2.452(7), Nd(1)–O(42)=2.488(8) Å). The *E* ligand forms a four-membered chelate ring by being coordinated its two oxygen atoms to the same neodymium atom. Its two C–O distances are different from each other (C(21)–O(21)=1.236(11), C(21)–O(22)=1.294(13) Å).

Consequently, as is shown in Fig. 3, there are three kinds of bridging modes between neodymium atoms in a polymer chain; *i.e.* Nd(1^{II})···Nd(1) (4.236(1) Å), where two *C* bridges exist; Nd(1)···Nd(2) (4.662(1) Å), connected with one each of the *B* and *C* bridges, and Nd(2)···Nd(2^{I}) (4.065(1) Å), with two each of the *A* and *D* bridges. From these Nd···Nd distances, the *B* bridge is found to be weaker than the *C* one in the ability of bridging neodymium atoms, while Nd(2)···Nd(2^{I}) is the shortest because of the existence of four bridges between them. This type of complicated polymeric linear-chain structure, including many types of coordination modes of the ligands, has not previously known.

Each complex has a normal magnetic moment as the metal salt of each elements,[23] and no metal-metal interaction was found. The found magnetic moments of the methylthioacetato complexes of lanthanum(III), diamagnetic; and cerium(III) was 2.4_2; praseodymium(III), 3.5_8; neodymium(III), 3.5_4; europium(III), 3.3_8; dysprosium(III), 10.6_5; ytterbium(III), 4.4_4 BM,*** at 25 °C.

The powder X-ray diffraction patterns of synthesized methylthioacetato complexes of lanthanoid elements are shown in Fig. 4. They are divided into three groups according to their patterns; the grouping is the same as that when they are divided by their chemical composition: *i.e.*, Group 1 (lanthanum(III) complex $ML_3 \cdot 4.5H_2O$), Group 2 (cerium(III), praseodymium(III), neodymium(III) and europium(III) complexes; $ML_3 \cdot 1.5H_2O$), and Group 3 (dysprosium(III) and ytterbium(III) complexes; $ML_3 \cdot 2H_2O$). The same grouping was also observed with regard to their infrared absorption spectra, as well as with regard to TG and DTA, as will be shown later. The complexes belonging to the same group give similar powder X-ray diffraction patterns, and the intensity ratios of their main peaks are nearly the same. Therefore, they are found to be isomorphous with each other, and the structure given to the neodymium(III) complex can be expected to be the same as those of light lanthanoid elements, although exceptionally, lanthanum(III) makes a different type of hydrate. On the other hand, as Group 3 elements make the $ML_3 \cdot 2H_2O$ type of hydrated complexes, they are likely to be like those of heavy lanthanoid elements. In fact, this kind of difference in hydration number and this type of difference in structure between the complexes of light

Mass loss of TG was taken downwards, and the exothermal change of DTA was taken upwards.

and heavy lanthanoid elements are often observed; for example, the hydrated oxalates of the light lanthanoid metals are commonly decahydrates, while the heavy lanthanoid metals make stable hexa- or heptahydrates.[23]

The results of the simultaneous TG and DTA of these complexes, together with that of diaquabis(methylthioacetato)cobalt(II), are shown in Fig. 5. As is shown by Pattern 3 of the figure, the dehydration of the neodymium(III) complex is in one step, even in the each coordination mode of O(W1) and O(W2) is different from that of O(W3). It is characteristic that the dehydration occurs at a low temperature;

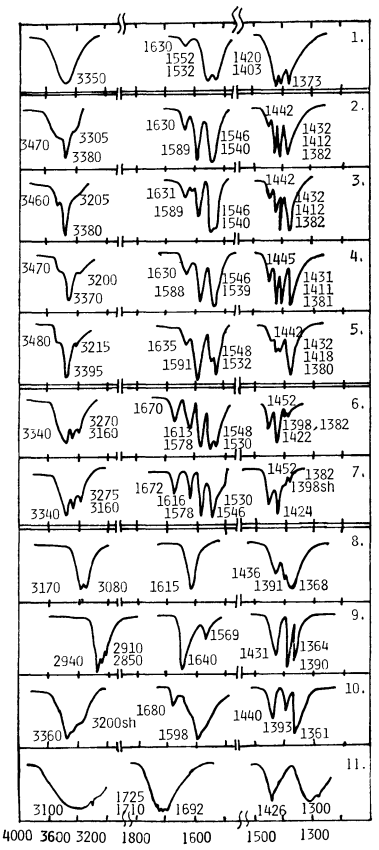

Fig. 6. Infrared absorption spectra of the methylthioacetato complexes and the related compounds.
1: $LaL_3 \cdot 4.5\ H_2O$, 2: $CeL_3 \cdot 1.5\ H_2O$, 3: $PrL_3 \cdot 1.5\ H_2O$, 4: $NdL_3 \cdot 1.5\ H_2O$, 5: $EuL_3 \cdot 1.5\ H_2O$, 6: $DyL_3 \cdot 2\ H_2O$, 7: $YbL_3 \cdot 2\ H_2O$, 8: $CoL_2 \cdot 2\ H_2O$, 9: bis(propylthioacetato)cobalt(II) hexamer–xylene, 10: bis(isopropylthioacetato)copper(II) dihydrate (violet isomer), 11: HL (HL=methylthioacetic acid).

lower than that of the corresponding hydrated complexes of cobalt(II) and of other 3d elements (*cf.* Pattern 6). A drastic mass loss due to the decomposition of the ligand occurs at about 200—300 °C, and the temperature is about the same as that of 3d-complexes.

The hydrated methylthioacetato complexes of the other Group 2 elements show almost the same TG and DTA patterns as are shown by Patterns 2 and 3 in the figure.

Although the general features of the TG and DTA curves of the other-group complexes are nearly the same, and although the low dehydration temperature is characteristic of all of them, there are some differences between them, as will be shown below. The lanthanum(III) complex (Group 1) gives two steps of dehydration, as is shown in Pattern 1 of the figure, and the Group 3 complexes give an endothermic peak of DTA, due to the isomerization and not the melting, between the dehydration and the ligand degradation temperatures, when the complexes are kept in the solid state (see Patterns 4 and 5).

Their infrared absorption spectra of the ν(OH), ν_{as}(COO), and ν_s(COO) regions are shown in Fig. 6, together with the maximum wave numbers of the peaks. The corresponding charts of some related com-

plexes and of methylthioacetic acid are also shown. These spectra, too, are divided into Groups 1, 2, and 3 in terms of their general features, as well as in terms of the wave numbers of the split peaks in the range, as is shown in the figure. This splitting of the peak of ν_{as}(COO) and of ν_{s}(COO) is probably due to the existence of multi-modes of the coordination of the carboxyl groups, although the assignment of each splitting peak is difficult. The ν_{as}(COO) peak of the methylthioacetato complexes of lanthanoid elements appears in rather a little lower wave number region than that of the common 3d-metal complexes.[24] This is probably due to the "hard" character of lanthanoid elements, which makes the coordination bond more ionic. The bridging of the carboxyl group in these complexes may be another reason.

The authors wish to thank Professor Yoichi Iitaka, Faculty of Pharmaceutical Sciences, the University of Tokyo, for the collection of the intensity data.

Simple Approximate Approaches for the Determination of Circular Dichroism Spectra in Multiple Scattering Systems

Yutaka TANIGUCHI* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 24, 1981)

A convenient method for the determination of CD spectra in multiple scattering systems is demonstrated. The formula of approximation, which gives the molar CD in terms of the values observable with commercial spectrometers by using a plate of opal glass, is presented based on some assumptions. The resulting solid-state CD spectrum of Λ-$[Co(en)_3]Br_3 \cdot H_2O$ is reported and compared with the solution CD spectrum.

Circular dichroism (CD) spectra have proved very useful in the studies of the structure of molecules. The measurements of CD spectra have recently been extended to the suspensions of particulate biological matters.[1,2] However, the CD spectra obtained are contributed by unequal scattering of left- and right-circularly polarized light, and this effect has not been well elucidated.

In the preceding paper[3] we demonstrated the method for determining the approximate molar CD in a multiple scattering system, a Nujol mull of cobalt(III) complex. In our method, the ellipticity (Θ) and the transmittance (T) are measured with conventional spectrometers by only setting a plate of opal glass on the unilluminated sides of a sample and a blank cell. The molar CD ($\Delta\varepsilon$) of a particulate sample is evaluated based on appropriate assumptions and approximations from the values of Θ and T by somewhat lengthy calculations. The resulting molar CD is well reproducible. The $\Delta\varepsilon$ of Λ-$[Co(en)_3]Br_3 \cdot H_2O$ obtained by our method at the peak position of the first absorption band is almost equal in magnitude to that in aqueous solution.

In order to obtain the CD spectrum in such a multiple scattering particulate system, lengthy calculating operations, which are inconvenient for rapid analysis of spectra, need to be carried out at every wavelength. In this paper a simple approximation method for such a CD spectrum will be described, and the resulting CD spectrum of solid-state Λ-$[Co(en)_3]Br_3 \cdot H_2O$ will be shown.

Calculation Methods

The variation of the intensity and polarization state of a light beam in a multiple scattering medium is written by the equation of radiative transfer in the vector form.[4] In the preceding paper the intensity of light transmitted through the plane-parallel scattering medium containing optically active particles has been analyzed by using the Kubelka-Munk model.[5] When the optical activity of the scatterers is weak, as is often the case with the d-d transition of cobalt(III) complexes, the transmittance constituents for the left (L) and right (R) circularly polarized light are approximately given by[3]

$$T_i = 4\beta_i(I_0)_i/[(1+\beta_i)^2 e^{\alpha_i l} - (1-\beta_i)^2 e^{-\alpha_i l}]I_0;\ i=L,R, \quad (1)$$

where

$$\alpha_i = [k_i(k_i+2s_i)]^{1/2}, \quad (2)$$

$$\beta_i = [k_i/(k_i+2s_i)]^{1/2}, \quad (3)$$

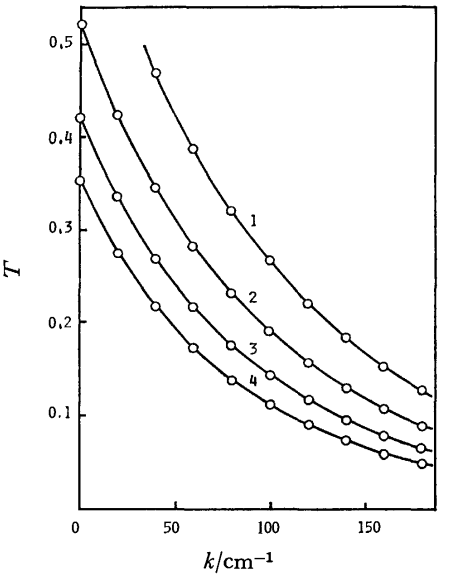

Fig. 1. Variation of T with k.
The value of s: (1) 50 cm^{-1}, (2) 100 cm^{-1}, (3) 150 cm^{-1}, and (4) 200 cm^{-1}.

and

$$I_0 = \Sigma_i(I_0)_i. \quad (4)$$

The letters k and s denote the absorption and scattering coefficients, respectively, l the path length, and I_0 the intensity of incident light. Hereinafter, l is always taken to be 9.15×10^{-3} cm (path length of our sample cell). Figure 1 shows the variation of T with k plotted when s remains constant.

The angular dependence of the scattering contribution to CD has been investigated by Bohren[6] and Gitter-Amir *et al.*[7] It has been shown that the difference between scattering of left- and right-circularly polarized light by optically active spheres is significant only in the forward scattering directions. The difference in scattering is negligible in the backward directions. In the Kubelka-Munk model, s is the back-scattering coefficient. It is, therefore, assumed in this study that the scattering coefficients s_L and s_R are equal, and hence their value is equal to that for natural light:

$$s_L = s_R = s. \quad (5)$$

In a conventional Grosjean-Legrand type CD instrument,[8] the polarization state of incident light varies with time alternately between left- and right-circular polarizations. As shown in the preceding paper,[3] the recorded ellipticity Θ in radians is related to the trans-

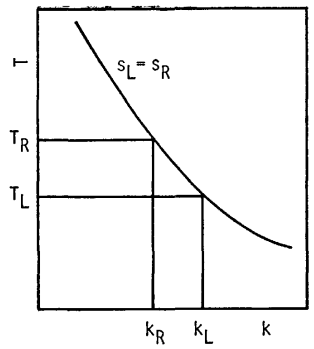

Fig. 2. Diagram showing the relation between ΔT and Δk in the case of $s_L = s_R$.

mittances for the periodical incidence of left- and right-circularly polarized light, T_L and T_R, by

$$\Theta = -(1/4)\Delta T/T, \tag{6}$$

where

$$\Delta T = T_L - T_R, \tag{7}$$

and

$$T = (T_L + T_R)/2. \tag{8}$$

Consequently, T_L and T_R are separately given by

$$T_L = (1-2\Theta)T, \tag{9}$$

and

$$T_R = (1+2\Theta)T. \tag{10}$$

Thus the values of T_L and T_R which are defined in the Kubelka-Munk model can be determined by measuring Θ and T with conventional spectrometers using a plate of opal glass.

Since the scattering coefficients s_L and s_R are considered equal in the Kubelka-Munk model, the T_L and T_R are given by the ordinates of two points on a certain k-T curve (see Fig. 2). Then the distance between the two points along the horizontal axis gives the experimental value of circular dichroism:

$$\Delta k = k_L - k_R. \tag{11}$$

The experimental value of ΔT being generally small, about the order of 10^{-3} in our measurements, the ratio $\Delta T/\Delta k$ approaches the differential coefficient dT/dk, *i.e.*, the slope of the k-T curve. In practice we may let

$$\Delta T/\Delta k = dT/dk. \tag{12}$$

Rearranging this equation we have

$$\Delta k = (dk/dT)\Delta T. \tag{13}$$

According to Eq. 6 we can rewrite Eq. 13 in the form

$$\Delta k = -4\Theta(dk/dT)T. \tag{14}$$

Thus, in order to obtain the CD spectrum, we must evaluate dk/dT for the set of T and s values found at every wavelength. But this is a big operation.

Now we consider the value of $(dk/dT)T$. In the Kubelka-Munk model, k, s, and T are associated with one another as has been represented by Eqs. 1—4. When s remains constant, log T is plotted against k in Fig. 3. Figure 3 shows these plots are approximately aligned in a straight line. In other words, the slopes of the plots are not exactly but nearly constant regardless of the value of k. Therefore, as a

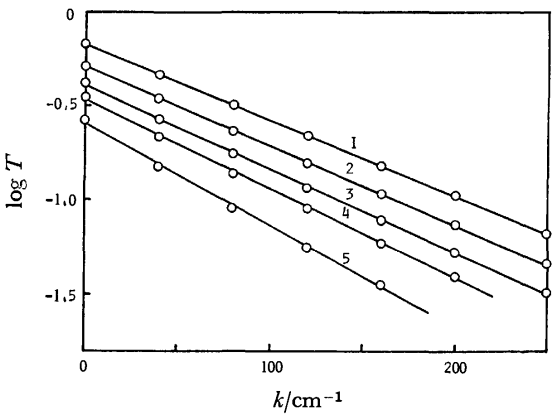

Fig. 3. Plots of log T against k.
The value of s: (1) 50 cm^{-1}, (2) 100 cm^{-1}, (3) 150 cm^{-1}, (4) 200 cm^{-1}, and (5) 300 cm^{-1}.

first approximation, we may let

$$\log T = Ak + B, \tag{15}$$

where A and B are constants.

Differentiating log T with respect to k, we have

$$(1/2.303T)(dT/dk) = A. \tag{16}$$

Rearranging this equation we have

$$(dk/dT)T = 1/2.303A. \tag{17}$$

Since A is a constant in the above approximation, the value of $(dk/dT)T$ can be considered constant, too.

It is also found from Fig. 3 that the slopes of the lines are not sensitive to their s values. In particular, when the values of s are not so different from each other, the slopes are nearly equal.

The scattering coefficient usually increases in magnitude with decreasing wavelength, but its variation should be small in the region of the d-d transitions of cobalt(III) complexes,[9] which we are now concerned about. Consequently, as a first approximation, the value of $(dk/dT)T$ can be taken as constant in such a region, though k, s, and T may vary with wavelength. In our studies a certain value of $(dk/dT)T$ associated with the first absorption maximum will be chosen for convenience.

In the preceding paper the molar CD of a microcrystalline sample has been determined based on the assumption that the molar absorbance is equal both in crystal and in solution in the region of d-d transitions. By using the molar absorbance ε(soln) and the absorption coefficient k at a peak position, which will be marked by asterisks, the molar CD in crystal is related to the experimentally determinable Δk as follows:

$$\Delta\varepsilon(\text{cryst}) = \varepsilon^*(\text{soln})\Delta k/k^*. \tag{18}$$

Substituting Eq. 14 in Eq. 18 we have

$$\Delta\varepsilon(\text{cryst}) = -4\Theta(dk/dT)_{s^*,T^*}T^*\varepsilon^*(\text{soln})/k^*, \tag{19}$$

where the subscripts s^* and T^* denote the restriction of (dk/dT) to the value for the case of $s=s^*$ and $T=T^*$. The values of Θ, ε^*(soln), and T^* are measurable by conventional instruments. Further, the values of k^* and $(dk/dT)_{s^*,T^*}$ can be calculated if s^* and T^* are fixed. Although s^* cannot be measured directly, but estimated from the data of transmittance

Table 1. Spectral properties of Λ-$[Co(en)_3]Br_3 \cdot H_2O$

Absorption (soln)		CD (soln)		Solid-state CD (Nujol mull)	
$\sigma/10^3$ cm^{-1}	log (ε/mol^{-1} dm^3 cm^{-1})	$\sigma/10^3$ cm^{-1}	$\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1}	$\sigma/10^3$ cm^{-1}	$\Delta\varepsilon$/mol^{-1} dm^3 cm^{-1}
21.5	1.95	20.4	+1.89	20.2	+1.83
		22.4	0	22.1	0
		23.3	−0.14	23.0	−0.26

29.6	1.91	28.8	+0.24	28.9	+0.24

in the wavelength region without absorption.[3] Thus the quantities other than Θ are fixed irrespective of wavelengths, and hence the CD curve can be readily obtained by only multiplying Θ by a definite value associating with an absorption maximum:

$$-4(dk/dT)_{s^*,T^*}T^*\varepsilon^*(\text{soln})/k^*. \quad (20)$$

Experimental

Materials. Λ-$[Co(en)_3]Br_3 \cdot H_2O$ was prepared by the method of Werner.[10] Commercial Nujol was used as the mulling agent.

Measurements. The principles and the validity of our measurements have been described in the preceding paper.[3] The transmittance and the absorbance were measured by a Shimadzu UV-200 spectrophotometer, and the ellipticity by a JASCO MOE-1 spectropolarimeter(detector: end-window photomultiplier tube, HTV-R376). Measurements on Nujol mulls were carried out by the opal glass technique,[11] where a plate of opal glass was placed just after the sample cell, and the diffused light penetrating behind the plate was detected by a photomultiplier.

A quartz cell with demountable window (path length 9.15×10^{-3} cm) was used in the measurements on mulls. A mull was prepared by grinding the complex salt (5—11 mg) and mixing it with Nujol (40—50 mg) in an agate mortar.

Since the intensity of light after passage of a plate of opal glass was very weakened in the wavelength region shorter than *ca.* 320 nm, the CD measurements were unable to be carried out in this region.

Results and Discussion

The CD spectra of Λ-$[Co(en)_3]Br_3 \cdot H_2O$ in Nujol and in water are shown in Fig. 4. Table 1 gives the intensities of $\Delta\varepsilon$ at peak positions. Both the CD curves are roughly similar in pattern and intensity. This shows the effects of molecular orientation and crystal anisotropy, which are usually observed in the single-crystal CD, are cancelled out in a randomly oriented particulate system, microcrystallines in Nujol. The solid-state CD spectrum obtained by our method is, therefore, regarded as an isotropic CD spectrum, and hence can be compared directly with a solution CD spectrum.

Figure 4 shows the solid-state CD spectrum is slightly changed in intensity compared to the solution CD spectrum. There are a decrease in the rotational strength, proportional to the area of a CD peak, of E_a band and an increase in that of A_2 band. These changes are similar to the changes well-known as the ion-pairing effects,[12] which are usually observed in

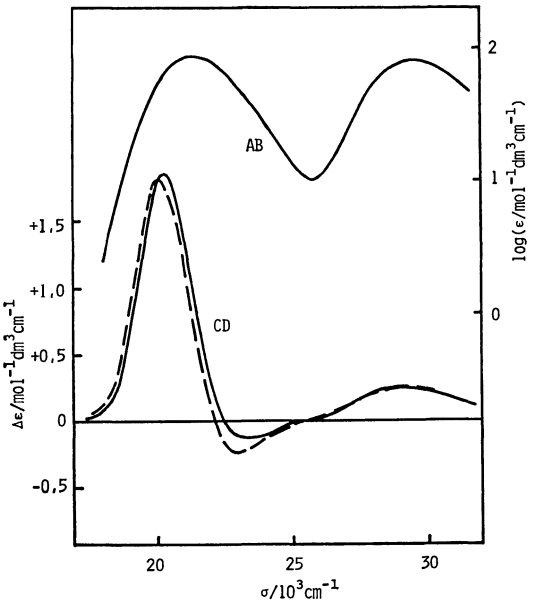

Fig. 4. Absorption (AB) and CD spectra of Λ-$[Co(en)_3]Br_3 \cdot H_2O$.
- - -: Nujol mull, ——: aqueous solution.

the CD spectrum of Λ-$[Co(en)_3]^{3+}$ on addition of anions. Thus the solid-state CD measurements may provide some significant informations regarding the ion-pairing effects.

Single-crystal CD spectra are generally attended by experimental difficulties owing to the crystal anisotropies.[13] Solid-state CD spectra are readily obtained by the KBr method, but there are some questions in the resulting CD spectra. Even if disks are clear, there may exist optical artifacts more or less by the effects of light scattering arising from optical fluctuation in disks. The counter ions of complex ions may be substituted by the matrix ion K^+ or Br^- in disks; so essential informations may not be obtained.

On the other hand, there is no fear of the exchange of counter ions in Nujol mulls. A Nujol mull method will give good results in this connection. Another advantage of our Nujol mull method is that the isotropic solid-state CD spectrum can be obtained by easy procedures of experimentation and calculation.

9) The scattering coefficient of a colored particle depends on the complex refractive index. When its absorption is weak, as is often the case with the d-d transition bands, the scattering coefficient is mainly governed by the real part of the complex refractive index. The variation of the real part should not be so large in the d-d absorption region because the normal dispersion of the real part is almost determined by far apart intense bands in the ultraviolet region. The anomalous dispersion should be small in the d-d absorption region, because the absorption in such a region is generally small. Therefore, we can suppose the scattering coefficient is not so changed in such a d-d absorption region.

Spectrophotometric Determination of Hexacyanoferrate(III) by Use of Coagulated Material Prepared from Finely Divided Anion and Cation Exchange Resins

Kin-ya Suzuki, Guee-deuk Park,** Kunio Ohzeki,* and Tomihito Kambara

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

***Division of Environmental Conservation, Graduate School of Environmental Science, Hokkaido University, Sapporo 060*

(Received November 2, 1981)

A simple and sensitive method for the determination of hexacyanoferrate(III) is described. This method is based on the preconcentration of hexacyanoferrate(III) ion on the coagulated material prepared from finely divided anion and cation exchange resins. The mixed resin is collected on a filter paper, forming a disk of thin layer. The hexacyanoferrate(III) fixed on the resin is converted to Turnbull's Blue by treating with iron(II) ammonium sulfate solution. The colored compound in the resin phase is determined by a densitometer equipped with a linearizer. The working range is 0.4—3.0 μmol dm^{-3} hexacyanoferrate(III). Among cations likely to be present, only copper(II) interferes, however, the interference is removed by the addition of EDTA. Hexacyanoferrate(II) ion shows the same coloration as hexacyanoferrate(III), and the total amount is determined when both ions are present.

Mutual coagulation takes place when a suspension of finely divided anion and cation exchanger is mixed with each other.[1] The resulting coagulated material is bulky and easily separated from the solution by filtration. By use of a cylindrical filter holder, a disk of thin layer of the mixed resin is prepared on a filter paper. Metal complexes with negative and/or positive charge are much more effectively fixed on the mixed resin than simple ions. When a colored complex is retained on the resin, the resulting thin layer is directly subjected to spectrophotometric analysis. In this manner, chromium(VI) was determined as the diphenylcarbazide compound,[2] and phosphate as the Molybdenum Blue complex,[3] both in ppb range.

The determination of hexacyanoferrate(III) is important in environmental analysis. Yogo *et al.*[4] reported a method in which hexacyanoferrate(II) and (III) were converted to the 1,10-phenanthroline complex and determined spectrophotometrically, in which, after adding mercury(II) heating was required for accelerating the ligand exchange reaction. In the present report, hexacyanoferrate(III) is selectively concentrated on the mixed resin and determined as Turnbull's Blue.

Experimental

Reagents. All chemicals used were of analytical reagent grade.

Standard hexacyanoferrate(III), 10^{-2} mol dm^{-3} solution was prepared by dissolving potassium salt in water.

Standard hexacyanoferrate(II), 10^{-2} mol dm^{-3} solution was also made by dissolving potassium hexacyanoferrate(II) trihydrate in water containing 0.05% of sodium carbonate.

Iron(II) ammonium sulfate, 0.5 mol dm^{-3} solution was prepared by dissolving Mohr's salt in water containing 0.06 mol dm^{-3} hydrochloric acid.

Sodium chloride, 1 mol dm^{-3} solution was used to adjust the ionic strength of sample solutions.

Ion exchange resin suspension. The ion exchangers used were macroreticular type Amberlyst 15 and A-27 (both Rohm and Haas Co.) in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively. The cation exchange resin suspension (CRS) and the anion exchange resin suspension (ARS) were prepared according to the method already reported.[1] The ion exchange capacities of CRS and ARS were determined by conductometric titration with the sodium hydroxide and silver nitrate solutions, respectively. The exchange capacities were 9.73 μequiv. ml^{-1} for CRS and 2.43 μequiv. mol^{-1} for ARS. When one part of CRS was mixed with two parts of ARS, both resins were almost completely coagulated.[1]

Apparatus. A Shimadzu Chromatoscanner CS-920 was used for absorption measurement. A Shimadzu UV-visible recording spectrophotometer, type UV-240, was used for measuring absorption spectra. A Toyo KG-25 filter holder was used for the preparation of thin layer of the mixed resin by filtration. Filter papers of No. 5A (Toyo Roshi) were used.

All experiments were carried out at room temperature.

Procedure. An aliquot of sample solution containing more than 20 nmol of hexacyanoferrate(III) is placed in a 100-ml beaker. A 5-ml portion of 1 mol dm^{-3} of sodium chloride is added for controlling the ionic strength and the volume is adjusted to 50 ml with water. A 3-ml portion of CRS and 6 ml of ARS are added. The mixture is stirred for 5 min by means of a magnetic stirrer. The resulting coagulated resins are collected on the filter paper by suction with a running water. A disk of thin layer of the mixed resin of 17 mm in diameter and about 0.3 mm in thickness is prepared. It is then dipped into the iron(II) ammonium sulfate solution for 1 h to develop the coloration. The wet filter paper holding the colored resin is placed on a white plastic plate fixed on the scanning board in the apparatus. The center of the disk of thin layer is exposed by a light beam, the section area is 1.44 mm^2. The board is periodically moved from side to side in a range of 24 mm wide, so that the absorbance of the thin layer is determined against the filter paper substrate. The absorbance is measured at 630 nm and the value is printed out automatically.

Another disk of resin is prepared without addition of hexacyanoferrate(III). The absorbance corresponding to the reagent blank including the resin matrices is also measured. The net absorbance of the complex in the resin phase is obtained as the difference.

Results and Discussion

Preparation of Thin Layer. During the course of stirring, hexacyanoferrate(III) ion is fixed on the anion

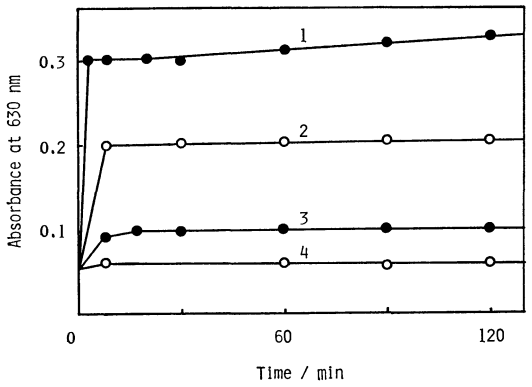

Fig. 1. Rate of color development at various concentrations of hexacyanoferrate(III).
(1): 2.0 μM, (2): 1.2 μM, (3): 0.4 μM, (4): blank. Sample volume: 50 ml.

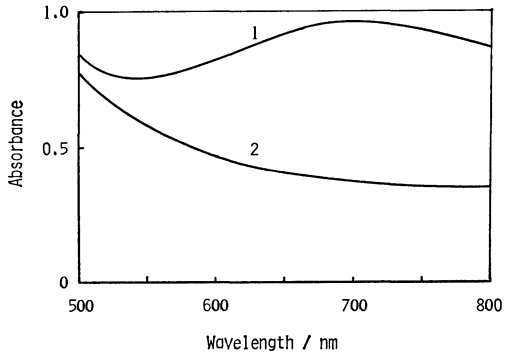

Fig. 2. Absorption spectra of the Turnbull's Blue on the thin layer of mixed resin prepared from 50 ml of solution.
(1): 2.0 μM of hexacyanoferrate(III), (2): blank, reference: wet filter paper.

exchanger and the latter is simultaneously combined with the cation exchanger, forming a coagulated material. The homogeneous dispersion of the mixed resin in the sample solution is essential for preparing the thin layer with a smooth surface. The degree of dispersion depends on the ionic strength of the sample solution. The finely dispersed mixed resin was obtained from the solution containing sodium chloride in 0.1—0.3 mol dm^{-3}. The average rate of filtration was about 30 ml min^{-1}. When sodium chloride was added too much, a long time was required for collecting the coagulated material.

Color Development. The color producing reagent used was 0.5 mol dm^{-3} of iron(II) ammonium sulfate. With decreasing concentration of the reagent, a longer dipping time was needed for the coloration of Turnbull's Blue. The dependence of coloration on the soaking time was examined with varying concentrations of hexacyanoferrate(III). A rapid coloration was found at the higher hexacyanoferrate(III) concentration, while at the lower concentration more than 20 min were necessary for obtaining a constant coloration (Fig. 1). The blue coloration was stable at least for 1.5 h in the iron(II) salt solution.

Absorption Measurement. The absorbance of Turnbull's Blue in the resin phase was determined by

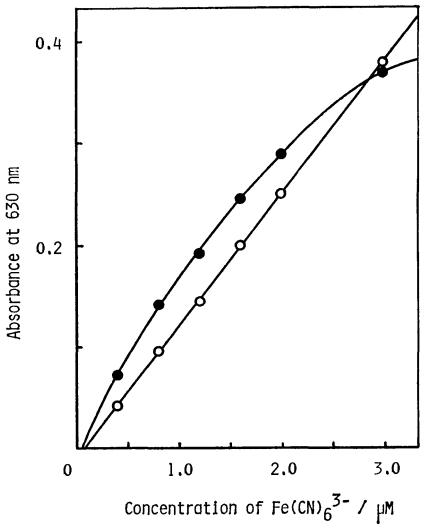

Fig. 3. Calibration curve.
○: Linearizer on, ●: linearizer off. Sample volume: 50 ml.

the densitometer at 630 nm, that is the upper limit of measurable wavelength of the apparatus. Since the complex has an absorption maximum at around 700 nm, higher sensitivity would be obtainable, if the measurement at the maximum wavelength is possible (Fig. 2).

Collection of Hexacyanoferrate(III). A trace amount of hexacyanoferrate(III) was effectively fixed on the mixed resin by stirring the sample mixture for 5 min, even in the presence of 0.3 mol dm^{-3} of sodium chloride. The recovery was considered to be quantitative, since the hexacyanoferrate(III) was not found in the filtrate. A 100-nmol portion of hexacyanoferrate(III) was quantitatively collected from 50—200 ml of sample solution.

Effect of pH. The pH of test solution was adjusted with the addition of hydrochloric acid or sodium hydroxide solution. A constant absorbance was obtained for the given amount of hexacyanoferrate(III) in the pH range of 1—12.

Calibration Curve. The calibration curve deviated from the linearity. By use of the linearizer a good linearity was obtained, however, the line did not go through the origin (Fig. 3). The relative standard deviation was 2.4% (n=6) for 1.2 μmol dm^{-3} of hexacyanoferrate(III).

Effect of Foreign Ions. Among the diverse ions studied, copper(II) interfered with the determination of 1 μmol dm^{-3} of hexacyanoferrate(III) even in the same concentration level (Table 1). When the concentration of foreign ions was 100 times hexacyanoferrate(III), copper(II), mercury(II), and zinc(II) gave negative error, while silver(I) a positive one. The interference from copper(II) was successfully eliminated by EDTA. The addition of EDTA was also effective for masking zinc(II), manganese(II), and lead(II) even in 1000 times concentration of hexacyanoferrate(III).

Effect of Hexacyanoferrate(II). As well known, hexacyanoferrate(II) combines with iron(III) to form

Table 1. Effct of foreign ions on the determination of hexacyanoferrate(III)[a]

the familiar Prussian Blue. The spectrophotometric determination of hexacyanoferrate(II) as the Prussian Bule was reported.[5,6] Galik and Vopravilova extracted the Prussian Blue into chloroform in the presence of a quaternary ammonium ion.[6]

Hexacyanoferrate(II) was found to be fixed on the mixed resin and showed a blue coloration as well as hexacyanoferrate(III); namely, the Prussian Blue and Turnbull's Blue are the same compound.[7] In the presence of hexacyanoferrate(II) and (III), the sum of them was determined (Table 2).

Table 2. Determination of hexacyanoferrate(II) and (III)

Spectroscopic Properties for High-pressure Polymorphs of Calcium and Strontium Metasilicates

Ken-ichi MACHIDA, Gin-ya ADACHI,* and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received November 4, 1981)

The IR spectra for the high-pressure polymorphs of alkaline-earth metasilicates, *viz.* α-$CaSiO_3$, δ-$CaSiO_3$, α-$SrSiO_3$, δ-$SrSiO_3$, and δ′-$SrSiO_3$, which consist of cyclic anions, $(Si_3O_9)^{6-}$ or $(Si_4O_{12})^{8-}$ rings, were studied over a range of 1200—400 cm^{-1}. These silicates gave absorption bands in wavenumbers of about 1050—820 cm^{-1}, 750—620 cm^{-1}, and below about 580 cm^{-1}, based on symmetrical and anti-symmetrical stretches of Si–O bonds and Si–O bending modes for tetrahedral SiO_4 units, and Ca–O or Sr–O stretches. Among them, the bands characteristic of the silicate anions with ring structure in the $SrSiO_3$ polymorphs were found to shift to lower wavenumber with transformation into the δ′ form. This suggests that the $(Si_4O_{12})^{8-}$ ring in δ′-$SrSiO_3$ is less flexible than the $(Si_3O_9)^{6-}$ ring in the α or δ form. The experimental result that the quenching temperature of δ′-$SrSiO_3$:Eu^{2+} phosphor is higher than that of the δ form supports this consideration.

For most of silicates, the structure elements in crystal lattices are tetrahedral SiO_4 units, which are either isolated or connected with one another by sharing oxygens. The infrared absorption (IR) spectra of those silicates result from the stretching and bending modes for the Si–O bonds of SiO_4 units.[1] Lazarev and coworkers[2] have estimated the structures of silicate anions from the measurements of IR spectra.

Alkaline-earth metasilicates show various polymorphisms under high-temperature and high-pressure.[3] For example, α- and β-$CaSiO_3$ (atmospheric high- and low-temperature forms) transform into δ-$CaSiO_3$ above 30 kbar and 900 °C.[4] The strontium metasilicate, α-$SrSiO_3$, also give high-pressure phases, δ- and δ′-$SrSiO_3$, at 34—120 kbar and 750—1400 °C.[5] Recently we have studied the luminescence properties for the high-pressure polymorphs of $CaSiO_3$:Eu^{2+} and $SrSiO_3$:Eu^{2+}, and their emission intensities have been found to increase when the host lattice transforms into the high-pressure phases.[6] Lattice vibrations of phosphors can be pointed out as one of quenching effects on luminescences.

In this paper, we study the IR spectra for the high-pressure polymorphs of $MSiO_3$ (M=Ca and Sr) and the temperature dependence for the luminescences of $SrSiO_3$:Eu^{2+} polymorphs.

Experimental

Sample Preparation. The preparation methods for the atmospheric and high-pressure phases of $MSiO_3$ and $MSiO_3$:Eu^{2+} are described in Ref. 6.

Optical Measurements. The IR spectra of samples were obtained with a Hitachi Perkin-Elmer 225 grating spectrophotometer covering the range of 1200—400 cm^{-1}. Dry air was circulated through the spectrometer to eliminate the interference from atmospheric moisture. The samples dispersed in potassium bromide were examined using the pressed disk technique, and the mixtures containing 1.0 wt% samples were generally employed. Ultraviolet luminescence spectra were obtained with a Shimadzu recording absolute spectrofluorophotometer according to the techniques described elsewhere.[7] The temperature dependence of luminescences was measured over the range between liquid N_2 temperature (77.4 K) and about 450 K in a stream of dry N_2 gas.

Results and Discussion

Silicate Anions. In Table 1, we show the silicate anions in the high-pressure polymorphs of $CaSiO_3$ and $SrSiO_3$. Among these polymorphs, α- and δ-$CaSiO_3$ correspond to α- and δ-$SrSiO_3$, and hence the α or δ forms of $CaSiO_3$ and $SrSiO_3$ are approximately or entirely isostructural with each other. However, the δ′ form is a characteristic phase of $SrSiO_3$ because δ′-$CaSiO_3$ has not been obtained. The crystal lattices consist of $(Si_3O_9)^{6-}$ rings for the α or δ form and $(Si_4O_{12})^{8-}$ rings for the δ′ form, respectively. The symmetries of these silicate anions are generally low.

In Fig. 1, we illustrate the silicate anions in $SrSiO_3$ polymorphs, of which the crystal structures have been reported in our previous papers.[5b,6] The $(Si_3O_9)^{6-}$ rings of the α form show the symmetry of twofold rotation around an axis of Si(1)–O(1) or Si(3)–O(6) and the $(Si_4O_{12})^{8-}$ rings have inversion centers, but

Table 1. Silicate anions in the high-pressure polymorphs of $MSiO_3$ (M=Ca and Sr)

Phase	Symmetry of crystal lattice[a)]	Silicate anion	Point group of anion	Ref.
α-$CaSiO_3$[b)]	Triclinic (P1 or $P\bar{1}$)	$(Si_3O_9)^{6-}$ ring	$\overline{\quad}$ (pseudo D_{3h})	8
δ-$CaSiO_3$	Triclinic ($P\bar{1}$)	$(Si_3O_9)^{6-}$ ring	C_1	9
α-$SrSiO_3$	Monoclinic (C2)	$(Si_3O_9)^{6-}$ ring	C_2 (pseudo D_{3h})	5b
δ-$SrSiO_3$	Triclinic ($P\bar{1}$)	$(Si_3O_9)^{6-}$ ring	C_1	6
δ′-$SrSiO_3$	Monoclinic ($P2_1/c$)	$(Si_4O_{12})^{8-}$ ring	Ci	6

a) The space groups of polymorphs are given in parentheses. b) The detailed structure analysis of this phase has not been performed, but α-$CaSiO_3$ is approximately isostructural with α-$SrSiO_3$.

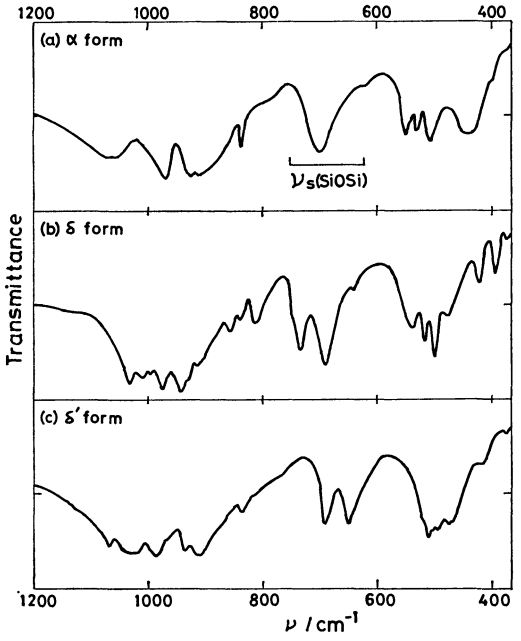

Fig. 3. IR spectra for the high-pressure polymorphs of $SrSiO_3$.

no symmetry element can be found out about the $(Si_3O_9)^{6-}$ rings of the δ form. Their point groups are C_2 (pseudo D_{3h}), C_1, and Ci for the α, δ, and δ′ forms, respectively. Consequently, the IR spectrum patterns of $CaSiO_3$ and $SrSiO_3$ polymorphs are expected to be very complex.

IR Spectra. For an isolated tetrahedral SiO_4 anions with a symmetry Td, there are four fundamental modes of vibrations, *viz.* a normally inactive symmetric stretch (800 cm^{-1}), an inactive doubly degenerate bend (500 cm^{-1}), a strongly active triply degenerate stretch (1050 cm^{-1}), and another active bending mode (625 cm^{-1}).[1)] When the SiO_4 units are connected with one another by sharing oxygens, the symmetric stretch of SiO_4 unit becomes an infrared active mode.

In Figs. 2 and 3, we show the IR spectra for the high-pressure polymorphs of $CaSiO_3$ and $SrSiO_3$, and in Table 2, their spectrum patterns are interpreted according to the assignments of some silicates attempted by Lazarev and co-workers.[2)] These metasilicates give strong absorptions over three regions around ≈580 cm^{-1}, 615—750 cm^{-1}, and 815—1070 cm^{-1}. The absorption bands of 815—1070 cm^{-1} are derived from $\nu_{as}(O^-SiO^-)$, $\nu_{as}(SiOSi)$, and $\nu_s(O^-SiO^-)$, where ν_{as} and ν_s correspond to the antisymmetric and symmetric stretching modes of SiO_4 unit, and $\nu(O^-SiO^-)$ and ν(SiOSi) represent the Si–O bonds of oxygens non-shared and shared with the other SiO_4 units, respectively. The bands below 580 cm^{-1} are responsible for the Si–O bending and Ca–O or Sr–O stretching modes. The group of bands in the regions of 615—750 cm^{-1} corresponds to the mode originated from the ν_s(SiOSi), which has been suggested to be a characteristic mode of the silicates containing cyclic anions by some workers.[10)] From the absorption bands around 615—750 cm^{-1}, consequently, we can obtain information for the ring structures of silicate anions in the high-pressure polymorphs of $CaSiO_3$ and $SrSiO_3$.

The IR spectrum patterns of δ-$CaSiO_3$ and δ-$SrSiO_3$, of which the crystal structures have been found to be entirely isostructural from the previous X-ray analyses,[6,9)] are closely similar to each other. For the α form, however, the spectrum profile around 615—750 cm^{-1} for $CaSiO_3$ somewhat differs from that of $SrSiO_3$. The former silicate consists of three bands: 616, 653, and 717 cm^{-1} whereas two bands: 622 and 705 cm^{-1} are observed on the latter silicate. This suggests that the shapes of $(Si_3O_9)^{6-}$ rings in α-$CaSiO_3$ and α-$SrSiO_3$

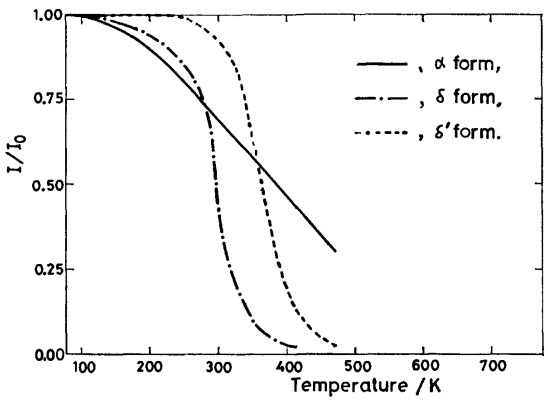

Fig. 4. Temperature dependences of the light output of $SrSiO_3$: Eu^{2+} (1 atom%) polymorphs.

are similar but their symmetries are distinct from each other. The symmetries of crystal structures are generally higher than those of structure elements, *e.g.* silicate anions, in crystal lattices. From Table 1, the symmetry for the $(Si_3O_9)^{6-}$ ring in α-$CaSiO_3$ is expected to be low compared with that for α-$SrSiO_3$, and possibly the silicate anion in α-$CaSiO_3$ does not show the symmetry of two-fold rotation. This must be confirmed if the detailed structure analysis of α-$CaSiO_3$ is performed.

For the δ' form, the IR spectrum profile responsible for the mode of ν_s(SiOSi) consists of two strong bands at about 648 and 690 cm^{-1}, which shift to longer wavenumber compared with the main absorption bands of α- or δ-$SrSiO_3$. This observation suggests that the ring of $(Si_4O_{12})^{8-}$ anion is less flexible than that of the $(Si_3O_9)^{6-}$ anion in α- or δ-$SrSiO_3$.

Luminescence Properties of $SrSiO_3$:Eu^{2+}. In Table 3, we summarize the luminescence properties of $SrSiO_3$: Eu^{2+} modifications. The polymorphs of $SrSiO_3$:Eu^{2+} give various emissions colored with blue or green,[6] and the emission intensity considerably increases when the host lattice has transformed into high-pressure phases. As one of quenching effects on luminescences, we can point out the lattice vibration of phosphors, and the luminescences are generally quenched when the temperature of phosphors is raised. The temperature dependences for the emission intensities of $SrSiO_3$: Eu^{2+} polymorphs are shown in Fig. 4. The shape of quenching curve observed on α-$SrSiO_3$:Eu^{2+} differs from those for the δ and δ' forms. Since the emission of the α form is very weak and the quenching curve is unreliable, however, we are possibly unable to obtain any information from this observation. The δ

and δ' forms give the shapes of quenching curves similar to each other, of which the results are reasonable and well reliable.

It is noticeable that the T_{50} value of δ'-$SrSiO_3$:Eu^{2+} (*ca.* 360 K) is higher than that of δ-$SrSiO_3$:Eu^{2+} (*ca.* 300 K). This means that, in δ'-$SrSiO_3$:Eu^{2+}, the quenching effect caused by the lattice vibration is to be smaller than that in the δ form. Since the silicate anions can be regarded as mainly taking part in the lattice vibration of the crystals, the $(Si_4O_{12})^{8-}$ ring in the δ' form must be hard to vibrate compared with the $(Si_3O_9)^{6-}$ ring in the δ form. This agrees with the information obtained form the IR spectrum measurements. Therefore, δ'-$SrSiO_3$:Eu^{2+}, which consists of the rigid $(Si_4O_{12})^{8-}$ rings give the relatively strong emission. The experimental result that the emission intensity of α-$SrSiO_3$:Eu^{2+} has been very weak is interpreted on the basis of a quenching effect *via* energy transfers between the neighboring Eu^{2+} ions.[6]

(Received November 11, 1981)

New nitrosyls, $[Fe(C_9H_6NO)_2(NO)]_2$($C_9H_6NO^-$=8-quinolinolate ion), $[Fe(C_{10}H_8NO)(NO)_2]$ ($C_{10}H_8NO^-$= 2-methyl-8-quinolinolate ion), and $[Fe(C_9H_5NOCl)_2(NO)(DMF)]$ ($C_9H_5NOCl^-$=5-chloro-8-quinolinolate ion) were isolated by the reaction of nitrogen monoxide with a mixture of iron(II) perchlorate and the corresponding quinolinol in methanol or methanol/DMF. They were characterized by IR, ^{57}Fe-Mössbauer, and magnetic measurements.

One of the present authors reported that $[Co(C_9H_6NO)_2(NO)]$ prepared by the reaction of nitrogen monoxide with a mixture of cobalt(II) chloride and 8-quinolinol in methanol, reacted further with nitrogen monoxide in dichloromethane at room temperature to precipitate $[NO][Co(C_9H_6NO)_2(NO_3)(NO_2)]$ with liberation of dinitrogen oxide. The reaction involved disproportionation of nitrogen monoxide and electrophilic attack by nitrogen monoxide on the coordinating nitrosyl group of the nitrosylcobalt complex.[1]

In this paper, we report the syntheses and characterization of some new nitrosyliron complexes containing 8-quinolinolate ion, and its derivatives, 2-methyl-, or 5-chloro-8-quinolinolate ion, and also examine whether the obtained nitrosyliron complexes react further with nitrogen monoxide, as reported for $[Co(C_9H_6NO)_2(NO)]$.

Experimental

Materials. The nitrosyl complexes were synthesized and manipulated under nitrogen atmosphere or in a vacuum line. Commercial iron(II) perchlorate hexahydrate was treated with zinc powder in methanol to reduce any iron (III) present and dried over Zeorum A-4(Toyo Soda Ind. Co., Ltd.) before using. Organic solvents were dried over anhyd calcium sulfate or Zeorum A-4, distilled or deoxygenated in nitrogen or argon stream, and then degassed in a reaction vessel by a repetitive freeze-pump-thaw cycle. Nitrogen monoxide was derived from the reaction of potassium nitrate with mercury and concd sulfuric acid.

Preparation. Two mmol of iron(II) perchlorate in methanol (40 cm^3) was brought into contact with 5 mmol of nitrogen monoxide, which resulted in an instant color change to dark brown. Four mmol of 8-quinolinol or 2-methyl-8-quinolinol in methanol or DMF (10 cm^3) was poured into the dark brown solution; it was then stirred at *ca.* 0 °C for 1 h to precipitate the nitrosyl complexes. In the case of using 5-chloro- or 5-nitro-8-quinolinol, DMF was used instead of methanol as a solvent because they are sparingly soluble in methanol. A mixture of the dark brown solution and 4 mmol of the quinolinol in DMF(10 cm^3) was stirred at *ca.* −20 °C for 1 h. The product was collected by filtration, washed with diethyl ether, dried under vacuum for a minute, and then stored in nitrogen atmosphere. The ^{15}NO-substituted complexes(^{15}N atom% in NO=99.4) were prepared by the use of ^{15}NO derived from $K^{15}NO_3$. The elementary analyses and the yields of the obtained nitrosyls are shown in Table 1. The C, H, N, and Cl contents were analyzed by the Organic Analysis Center of the Institute of Physical and Chemical Research. The content of the iron was obtained by colorimetric determination.[2]

Reaction of the Nitrosyl Complexes with Nitrogen Monoxide in Dichloromethane. Dichloromethane(20 cm^3) and 5 mmol of nitrogen monoxide were trapped into a reaction vessel containing *ca.* a half mmol of the nitrosyl complexes with the aid of liquid nitrogen. The frozen solution was melted and stirred at room temperature for several days. Gaseous materials in the reaction vessel were collected and identified by their IR bands. After the unreacted original nitrosyl had been filtered, the dichloromethane was removed from the filtrate at *ca.* −20 °C, and the residual product was characterized.

Measurements. The IR spectra in the solid state as Nujol and poly(chlorotrifluoroethylene) oil mulls, and of the dichloromethane solution were measured in the regions 200—4000 cm^{-1}, and 1500—2000 cm^{-1}, respectively. The gaseous materials were trapped into a calcium difluoride gas cell with the aid of liquid nitrogen, and identified on the basis of their IR bands.[3] The magnetic susceptibility at room temperature was measured by the Gouy method.

Table 1. Elementary analyses and yields of the nitrosyls

	Compound	Color	Yield/%		Fe(%)	C(%)	H(%)	N(%)	Cl(%)

**Partly presented at 43rd National Meeting of the Chemical Society of Japan, Tokyo, April 1981, Abstr., No. 3C02.

The magnetic susceptibility for $[Fe(C_9H_6NO)_2(NO)]_2$ was measured by the Faraday method in the temperature range from 83 K to room temperature. The apparatus was calibrated by $[Fe(H_2O)_6]SO_4\cdot(NH_4)_2SO_4$. The ^{57}Fe-Mössbauer spectra were measured at 80 K under vacuum by using a ^{57}Co(Pt) source moving in a constant acceleration mode. The isomer shift are relative to metallic iron foil.

Results and Discussion

It is very remarkable that different types of the nitrosyl complexes were isolated under the same preparative conditions. Nitrosyliron containing 5-nitro-8-quinolinolate ion could not be isolated under the present experimental conditions, dark green $[Fe(C_9H_5N_2O_3)_3]\cdot 1/2DMF$ being precipitated instead. Found: Fe, 8.3; C, 49.3; H, 2.8; N, 13.4%. Calcd: Fe, 8.5; C, 51.8; H, 2.8; N, 13.8%.

All the nitrosyls in the solid state were stable in nitrogen atmosphere, but compounds **1** and **2** were unstable at room temperature in a vacuum and nitrogen monoxide was liberated. The nitrosyls were also unstable in deoxygenated organic solvents such as dichloromethane, chloroform, acetone, THF, and DMSO, giving off nitrogen monoxide. Hence, they could not be recrystallized.

IR Spectra. *[Fe(C$_9$H$_5$NOCl)$_2$(NO)(DMF)] (1)*: Upon ^{15}NO-substitution, the IR bands at 1710(vs)[4] and 440(w) cm^{-1} shifted to 1679 and 434 cm^{-1}, respectively. The former was assigned to the N–O stretching vibration and the latter to one of the FeNO skeletal vibrations.[5] A shoulder band at 1655 cm^{-1} overlapping with the N–O stretching band was observed for both the ^{14}NO- and ^{15}NO-complexes, and was assigned to the C–O stretching vibration of DMF. It has been reported that the C–O stretching band at 1670 cm^{-1} for free DMF shifted to 1625—1650 cm^{-1} on coordination.[6,7] Thus, the DMF of the present nitrosyl seems to coordinate to the iron.

[Fe(C$_{10}$H$_8$NO)(NO)$_2$] (2): The IR bands at 1758 (vs), 1685(vs), 543(w), 519(s), 511(w), and 379(s) cm^{-1} shifted to 1722, 1649, 539, 515, 500, and 369 cm^{-1}, respectively, upon ^{15}NO-substitution, which suggests the presence of a $Fe(NO)_2$ skeleton. Although the wave numbers of the N–O stretching bands in the region 1760—1650 cm^{-1} shifted upwards by *ca.* 7 cm^{-1} at 80 K, relative intensity of the bands at room temperature did not change at 80 K.

Four-coordinate compounds containing a monopositive dinitrosyliron group such as the present nitrosyl have already been reported. $[N(PPh_3)_2][FeX_2(NO)_2]$ (X=Cl, Br, or I)[8] and $[Fe(L'H)(NO)_2]$ (L'=$^-$SCH$_2$-CH$_2$N(CH$_3$)CH$_2$CH$_2$CH$_2$N(CH$_3$)CH$_2$CH$_2$S$^-$)[9] show two N–O stretching bands in the region 1700—1780 cm^{-1} as observed for the present nitrosyl. X-Ray diffraction studies show that four-coordinate compounds with monopositive dinitrosyliron have flattened tetrahedral geometry with two equivalent nitrosyl groups, and the Fe–N–O angles are in the range 160—175°.[9,10] Thus, the present nitrosyl also is probably a pseudo-tetrahedral complex with almost linear Fe–N–O groups.

[Fe(C$_9$H$_6$NO)$_2$(NO)]$_2$ (3): Upon ^{15}NO-substitution, the IR bands at 1740(vs), 1667(vs), and 373(m) cm^{-1} shifted to 1711, 1643, and 362 cm^{-1}, respectively,

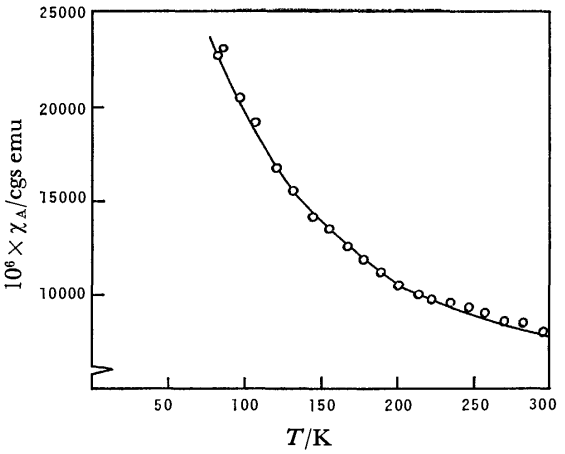

Fig. 1. Temperature dependence of atomic susceptibility of $[Fe(C_9H_6NO)_2(NO)]_2$.
The solid curve was calculated from Eq. 1 with $g=2.25\pm0.01$ and $-J=4.4\pm0.5$ cm^{-1}.

and the 540 cm^{-1} band(sh) also shifted and became concealed by the foot of the very strong band at 520 cm^{-1}, due to the coordinating 8-quinolinolate ions. The bands at 1740 and 1667 cm^{-1} could be assigned to the N–O stretching vibrations, and the bands at 540 and 373 cm^{-1} to the FeNO skeletal ones.

In the case of a dimer complex, $[Fe(TDBM)_2(NO)]_2$ (TDBM$^-$ = diphenylpropane-1-onate-3-thionate ion), where two of the iron atoms are bridged through the sulfur atoms of two TDBM and each iron atom has a coordination number of six, the N–O stretching vibrations are observed at 1675 and 1780 cm^{-1}.[11] For a spin-equilibrium complex, [Fe(salen)(NO)] (salen^{2-}= *N,N'*-disalicylideneethylenediaminate ion) with two N–O stretching bands, the relative intensity of the N–O bands changes with lowering temperature.[12,13] Geometry-equilibrium complexes, $[CoCl_2(NO)L_2]$ (L= phosphine derivatives) also show two N–O stretching bands; their relative intensity changes with temperature.[14,15]

On the other hand, the relative intensity of the N–O stretching bands for the present nitrosyl at 80 K was almost equal to that at room temperature although the bands shifted upwards by *ca.* 5 cm^{-1} at 80 K. The separation of the two bands is too large to be due to the solid state effect. The wave numbers of the two bands show that both nitrosyl groups are terminal.[16] Thus, the two N–O stretching bands suggest that the terminal nitrosyl groups are in different chemical environments.

Magnetism. According to the notation introduced by Enemark and Feltham,[17] both compounds, **1** and **3**, contain $\{Fe(NO)\}^7$, and compound **2** contains $\{Fe(NO)_2\}^9$; here the superscripts show the number of the *d*-electrons in the iron when the nitrosyl ligand is formally assumed to be NO$^+$.

The effective magnetic moment of compound **2** was 1.97 BM (at 292 K), which was comparable to that of $[N(PPh_3)_2][FeX_2(NO)_2]$ where the dinitrosyliron is the $\{Fe(NO)_2\}^9$ species.[8] The effective magnetic moments of compounds **1** and **3** were 4.21 (at 291 K) and 4.43 BM (at 285 K), respectively, and the values correspond to those observed for first row transition-

Table 2. Mössbauer parameters of the nitrosyls at 80 K

	Compound	δ[a,b) mm s^{-1}	ΔE_Q[b) mm s^{-1}	Γ_1[b) mm s^{-1}	Γ_2[b) mm s^{-1}
1	$[Fe(C_9H_5NOCl)_2(NO)(DMF)]$	0.68	1.32	0.49	0.36
2	$[Fe(C_{10}H_8NO)(NO)_2]$	0.47	0.88	0.28	0.30
3	$[Fe(C_9H_6NO)_2(NO)]_2$	0.45	0.69	0.48	0.49

a) The isomer shift is relative to metallic iron foil. b) The values are accurate within ± 0.03 mm s^{-1}. Γ_1, line width of a lower energy peak; Γ_2, line width of a higher energy peak.

metal ions with high-spin d^7 configurations.[18] The magnetic moment of compound **3** decreased gradually with lowering temperature from 4.4 (at 285 K) to 4.0 BM (at 83 K); this decrease suggests the presence of antiferromagnetic exchange interaction between the iron ions.[19] The temperature dependence of the magnetic susceptibility is shown in Fig. 1.

The molecular weight of compound **3** could not be measured because it is unstable in the examined organic solvents. The two N–O stretching bands of compound **3** can not deny the possibility that it is a dimer. Thus, by assuming that compound **3** was a binuclear complex containing two iron ions with $S=3/2$, the susceptibility data were fit to Eq. 1, which was reported by Earnshaw and Lewis:[20]

$$\chi_A = \frac{Ng^2\beta^2}{kT}\left[\frac{14+5\exp(-6J/kT)+\exp(-10J/kT)}{7+5\exp(-6J/kT)+3\exp(-10J/kT)+\exp(-12J/kT)}\right] + N\alpha. \quad (1)$$

$N\alpha$ was neglected in the fitting. The experimental data fit Eq. 1 with $g=2.25\pm0.01$ and the exchange integral, $-J=4.4\pm0.5$ cm^{-1}. The negative J suggests that there is some antiferromagnetic interaction between the two iron ions in the assumed binuclear complex, $[Fe(C_9H_6NO)_2(NO)]_2$.

The value of J for compound **3** was comparable to those reported for $[Fe(salen)Cl]_2$ and its analogs with a binuclear moiety, $Fe^{III}\langle O \rangle Fe^{III}$.[19] On the other hand, the value of $-J$ for $[Fe(salen)]_2O$ and its analogs containing a Fe^{III}-O-Fe^{III} system with an Fe–O–Fe angle of *ca.* 160° have been reported to be 87—100 cm^{-1}.[21] This value of J shows that the $Fe\langle O \rangle Fe$ system is less favorable for transmitting the exchange interaction than the Fe–O–Fe one. The formal oxidation number of the iron for compound **3** is considered to be +I as discussed later. There is no

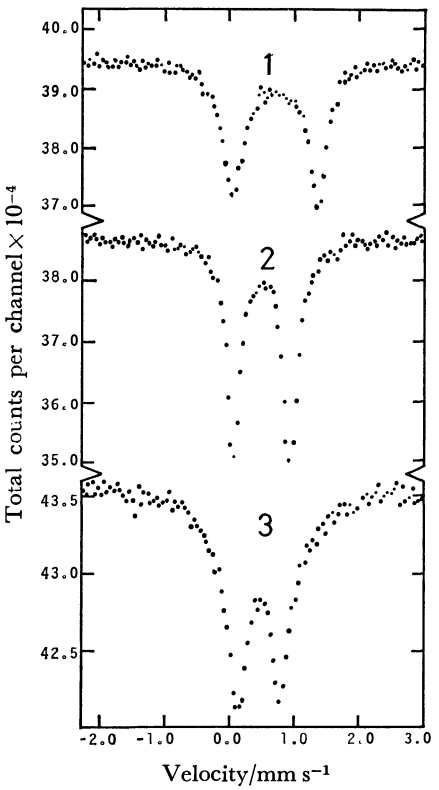

Fig. 3. Mössbauer spectra of the nitrosyls at 80 K.
1: $[Fe(C_9H_5NOCl)_2(NO)(DMF)]$, **2**: $[Fe(C_{10}H_8NO)(NO)_2]$, **3**: $[Fe(C_9H_6NO)_2(NO)]_2$.

data for the J value of the iron(I) complexes. Although the J value for the iron(I) complex can not be directly compared with those for the iron(III) complexes, the J value suggests the possibility that compound **3** is a dimer in which two of the iron atoms are bridged through the oxygen atoms of two 8-quinolinolate ions to form a $Fe^{I}\langle O \rangle Fe^{I}$ moiety. One of the possible structures for compound **3** is shown in Fig. 2.

^{57}Fe-Mössbauer Spectra. The Mössbauer spectra and the derived parameters of the nitrosyls are shown in Fig. 3 and Table 2, respectively. The spectrum of compound **2** consisted of a single and symmetrical doublet with line widths of *ca.* 0.3 mm s^{-1}, whereas that of compound **1** consisted of an unsymmetrical doublet with line widths of more than 0.3 mm s^{-1}. This suggests the presence of some impurity that may be derived from compound **1** which is not stable under these conditions. Compound **3** showed a symmetrical doublet but its line widths are broader than those of

compound **2**. The line broadening can be reasonably explained by supposing that compound **3** is a dimer, as shown in Fig. 2; the two sites of the irons are in very similar chemical environments, so the Mössbauer spectra are expected to be almost equal to each other. Such spectra are overlapped to give the line broadening.

Studies on the wave numbers of the N–O stretching vibration and its ^{15}N-isotopic shift for transition-metal nitrosyls indicate that the nitrosyl ligand of the present nitrosyls formally coordinates as NO^+ to the iron.[5] Thus, the formal oxidation number of the iron for both compounds **1** and **3** is +I, and that for compound **2** is −I. One might expect that the isomer shift observed for the iron compounds with such electronic structures are higher than those for high-spin iron(III) compounds (d^6, $S=2$). The isomer shift for $[Fe(H_2O)_5(NO)]SO_4$ (Fe^+, $S=3/2$) has been observed at *ca.* 1.3 mm s^{-1} at room temperature.[22] However, the isomer shifts for the present nitrosyls were observed in the region of those for Fe^{2+} ($S=0$), Fe^{3+} ($S=1/2$), or Fe^{3+} ($S=5/2$) ions.[23] The results can be explained as follows; strong π-acidity of NO^+ causes a decrease of the 3d-electron density of iron, and thus the isomer shifts for the nitrosyls decreases.[23] The smaller isomer shifts of compounds **1** and **3**, compared with that of $[Fe(H_2O)_5(NO)]SO_4$, indicate the increase in π-acceptor ability of the ligands in compounds **1** and **3**. The close values of the isomer shifts for compound **2** and compounds **1** and **3** may be due to strong π-back donation of two nitrosyl groups in compound **2**. The value of the isomer shift for compound **2** is comparable to those reported for dinitrosyliron compounds, $LYFe(NO)_2$ (L=$C_5H_{11}N$, Ph_3P, Ph_3As, or Ph_3Sb; Y=Br or I).[24]

The quadrupole splittings for the present nitrosyl compounds arise not only from the extra electrons in 3*d* orbitals, which can distort the symmetry of the total environment of iron atom, but also from the differences in strength of the π-acceptor of the ligands. Therefore, the larger quadrupole splitting for compound **1**, compared with that of compound **3**, indicates that the distortion from the octahedral symmetry in compound **1** is larger than that in compound **3**. Although compounds **1** and **3** seem to have the high-spin configuration from the magnetic results, the Mössbauer data shows the presence of strong π-back donation leading to low-spin configuration. This discrepancy seems worthy of further investigation.

. *Reaction of the Nitrosyl Complexes with Nitrogen Monoxide in Dichloromethane.* It has been reported that nitrogen monoxide disproportionates by reacting with transition-metal complexes to give nitrosyl nitrite and hyponitrito complexes, and that nitrosyl complexes with a NO^- group reacts with nitrogen monoxide to form nitro complexes with liberation of dinitrogen oxide.[1,25]

Compound **3** was stable in dichloromethane saturated with nitrogen monoxide, and the product from the filtrate was identified to be the original compound **3**. Compounds **1** and **2** decomposed to give unidentified products, but dinitrogen oxide could not be observed in the reaction vessel. Products from compounds **1** and **2** showed no N–O stretching bands assignable to $[NO]^+$, coordinating nitrosyl, nitrite or hyponitrite groups.

Thus, for all the present nitrosyl compounds, the disproportionation of nitrogen monoxide or the electrophilic attack by nitrogen monoxide on a coordinating nitrosyl group could not be observed. These facts are consistent with the idea that the present nitrosyls are formally NO^+-complexes.

The authors wish to express their thanks to Mr. Takashi Nagai of Rikkyo University for calculating the values of *g* and *J* from the magnetic data.

The present work was supported in part by a Grant-in-Aid for Scientific Research No. 564199 from the Ministry of Education, Science and Culture.

Copper(II) Complex of 2,2′-Bi-8-quinolinol

Youichi DEMURA,* Kazuyoshi HIRAKAWA,† and Ichiro MURASE

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

† *Department of Electronics, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

(Received April 23, 1982)

A copper(II) complex of 2,2′-bi-8-quinolinol was prepared. The structure has been determined by means of infrared and electronic spectra, magnetic susceptibility under temperature variation, and molecular weight measurement. It was found to be a binuclear chelate having a tetrahedral arrangement around each copper ion.

8-Quinolinol functions as a bidentate ligand and forms stable chelates with a variety of metal ions as well as copper(II). The high stability of the complexes is mainly attributable to the fixed planar ligand structure containing a phenolic oxygen and a heteroaromatic nitrogen atom. On the other hand, 2,2′-biquinoline is known as a specific ligand for copper(I), and this property is due to the steric fitness of the ligand structure together with the stabilization of low oxidation state by the α-diimine coordination. It is of interest to prepare the compound in which these two functions are combined in one molecule. We thus have synthesized 2,2′-bi-8-quinolinol (**1**) and examined its complex formation with transition metal ions, and well defined crystals have been obtained with copper(II). In this paper we will deal with the synthesis of the ligand and the copper complex, and will discuss its structure by means of electronic and infrared spectroscopy and of magnetic measurement at various temperature.

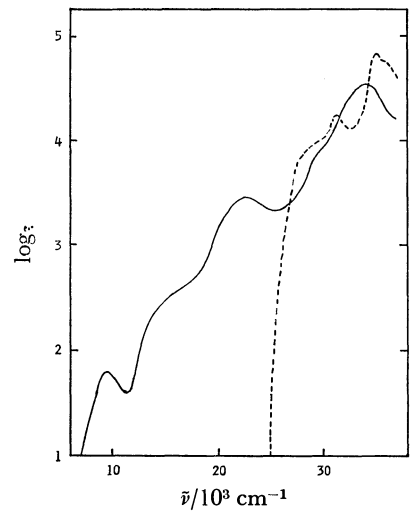

Fig. 1. Electronic spectrum of the free ligand (**1**) (- - -), and the Cu(II) complex (——).

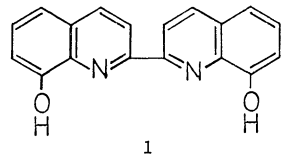
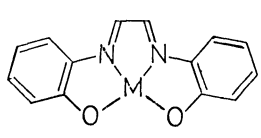
Results and Discussion

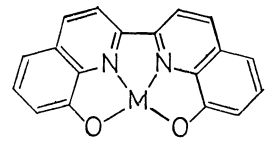
2,2′-Bi-8-quinolinol (**1**) was prepared in poor yield by the dimerization of 2-bromo-8-tosyloxyquinoline with palladium-calcium carbonate catalyst in the presence of hydrazine according to the method developed by Nakano.[1] The tosyl group was hydrolyzed simultaneously during the dimerization reaction.



1



2



3

1 is considered as a heterocyclic analogue of *N,N′*-bis(*o*-hydroxyphenyl)-1,2-ethanediimine[2] in which the azomethine linkages are incorporated into heteroaromatic rings. *N,N′*-Bis(*o*-hydroxyphenyl)-1,2-ethanediimine functions as a planar quadridentate ligand and forms deep blue chelates **2** with copper(II) and other transition metal ions. Provided that **1** forms a copper chelate in the similar manner as shown in **3**, a molecular model reveals that the Cu–N and Cu–O distances are about 0.2 nm and 0.3 nm respectively, unless the quinoline moieties bend towards the central metal ion. The Cu–O distance will be too long to achieve stable coordination as compared with those in bis(8-quinolinolato)copper(II) in which the Cu–N and the Cu–O distances are 0.19 nm and 0.21 nm respectively.[3]

The copper(II) complex is deep brown fine crystals and the elemental analysis agrees with the metal-ligand ratio of 1:1. However, the molecular weight determined in chloroform was 708 and it is very close to the calculated value as a dimer (700).

The infrared spectral pattern in KBr resembles that of bis(8-quinolinolato)copper(II) in many respects, especially showing a sharp absorption at 1105 cm^{-1} which is characteristic for a C–O stretching vibration in metal 8-quinolinolates.[4] No absorption is observed for the OH stretching which appears as a sharp band at 3350 cm^{-1} in the free ligand. The electronic spectrum in chloroform exhibits an absorption maximum at 34000 cm^{-1}(ε=35500), 22200(ε=2900), 14300(ε=300), and 9300(ε=90) as seen in Fig. 1. The spectral pattern is quite different from those usually associated with bivalent copper in square-planar arrangements. Similar spectrum has been observed for bis(2,2′-biquinoline)copper(II) perchlorate, which exhibited d-d transition at 19230 cm^{-1}(ε=950), 13300(ε=170), and 9300

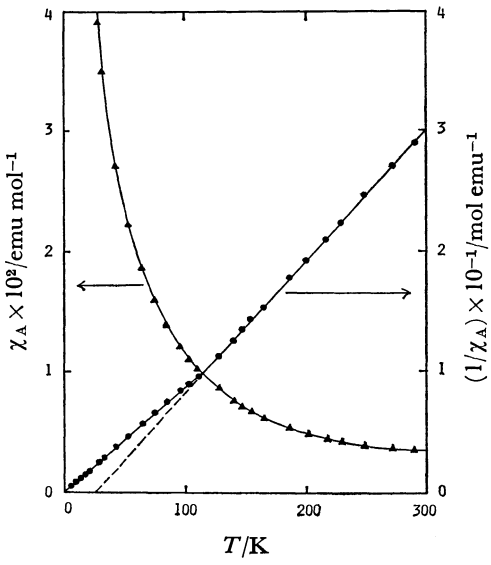


Fig. 2. Temperature variation of molar and inverse magnetic susceptibilities of the complex. The diamagnetic correction was -3.11×10^{-4}.

(ε=90) in nitrobenzene.[5] {2,2'-[1,1'-Biphenyl-2,2'-diyldinitrilomethylidyne]bisphenolato}copper(II) also showed absorptions at 20800 cm^{-1}(ε=790), 15200(ε=340), and 11500(ε=50).[6] These complexes have been assumed to have a pseudo tetrahedral structure and the latter was confirmed by X-ray crystallography.[7]

The variation of the magnetic susceptibility under temperature change is shown in Fig. 2. The susceptibility obeys Curie-Weiss' law in the temperature range 118—290.8 K with a value of θ=20.5 K, while it obeys Curie's law between 5.7—118 K. This temperature dependence of χ_A suggests that the copper(II) ions are not magnetically isolated but under some magnetic interaction. Provided a binuclear structure exists, the χ_A is given as the Bleaney-Bowers' equation,[8]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N_\alpha,$$

where N is the Avogadro constant, β the Bohr magneton, k the Boltzman constant, T the temperature, J the exchange integral, and the N_α the temperature-independent paramagnetism. The experimental $|J|$/K value which fits this equation best is 200 K below 118 K, and 120 K at higher temperature, where N_α is 1×10^{-4} emu/mol. The μ_{eff} values for one copper ion are 2.02 BM(290.8 K), 2.15(118.3 K), and 2.29 (5.7 K). The room temperature value is slightly lower than that (2.2 BM) predicted for copper(II) in a tetrahedral environment.[9] However, distortion can appreciably lower it, if low symmetry ligand fields produced are large compared to the spin-orbit coupling, and similar values (1.9—2.0 BM) have been reported for bis(2,2'-biquinoline)copper(II).[5]

Judging from the dimeric molecular weight, the electronic spectrum, and the magnetic evidence, the copper(II) complex prepared is binuclear and the ligands are tetrahedrally arranged around the copper ions. A molecular model can be sketched as shown in Fig. 3. Here one quinolinol plane is nearly perpendicular to the other in one biquinolinol molecule,

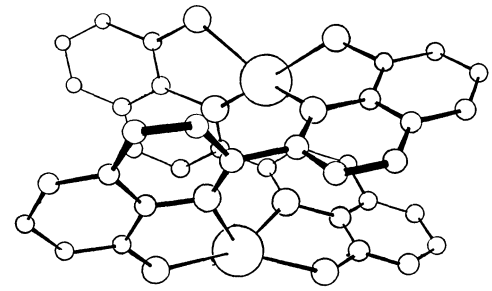

Fig. 3. Probable structure of the complex.

and each quinolinol moiety is individually coordinated to each of the two copper ions. The data obtained so far support the proposed structure, though the definite conclusion must wait for X-ray crystallography.

Experimental

2-Bromo-8-tosyloxyquinoline. A mixture of 8-tosyloxy-2(1*H*)-quinolinone (22.5 g) and phosphoryl bromide (50 g) in 40 cm^3 chloroform was refluxed with stirring in an oil bath at 110 °C for 4 h. The reaction mixture was poured into crashed ice and the water layer was neutralized with 5% aqueous sodium hydrogencarbonate. The chloroform layer was collected and the aqueous layer was extracted twice with 150 cm^3 of chloroform. The combined extracts were dried over anhydrous sodium sulfate and the solvent was removed by distillation. The crude residual product was recrystallized from ethanol and 24 g of the compound were obtained as colorless crystals, mp 133 °C, yield 80%.

Found: C, 50.55; H, 3.19; N, 3.70%. Calcd for $C_{16}H_{12}BrNO_3S$: C, 50.80; H, 3.18; N, 3.70%.

2,2'-Bi-8-quinolinol. 2-Bromo-8-tosyloxyquinoline (5 g) was dissolved in 200 cm^3 of methanol containing 5% potassium hydroxide and 3 g of 2% palladium on calcium carbonate was added. The mixture was heated at 50 °C and to this was added dropwise with stirring 6 cm^3 of hydrazine hydrate in 50 cm^3 methanol. The addition took 4 h and 3 g of the catalyst was newly added after 2 h during the reaction. After the addition of hydrazine, the reaction mixture was further heated at 80 °C for 1 h. The catalyst was filtered off and the mixture was treated with 500 cm^3 of hot 5% potassium hydroxide–methanol solution. The filtrate and the extract were combined and acidified with concentrated hydrochloric acid. Methanol was removed under reduced pressure and the residue was neutralized with aqueous sodium hydrogencarbonate. The resulting white precipitate was collected by filtration and boiled with 500 cm^3 of chloroform. The chloroform was removed from the extracts under reduced pressure and the residue was recrystallized from dioxane. The compound crystallized as colorless plates, mp 264 °C, yield 0.5 g.

Found: C, 74.78; H, 4.18; N, 9.76%. Calcd for $C_{18}H_{12}N_2O_2$: C, 75.01; H, 4.16; N, 9.72%.

Copper(II) Complex. 2,2'-Bi-8-quinolinol (0.1 g) was dissolved in minimum amount of hot dioxane and to this was added copper acetate monohydrate (0.065 g) in a dioxane–ethanol mixture (1:1). The mixture was heated on a water bath for 10 minutes and the resulting deep brown needles were collected by filtration and washed with methanol and dried at 100 °C under vacuum. The complex can be recrystallized from pyridine, but it is pure enough without recrystallization.

Found: C, 61.75; H, 2.87; N, 7.87; Cu, 18.22%. Calcd

for $C_{18}H_{10}N_2O_2Cu$: C, 61.80; H, 2.88; N, 8.01; Cu, 18.16%.

Measurements. Molecular weight was determined by vaper pressure equilibrium method with a Hitachi Osmometer Type-115 using chloroform as a solvent. Infrared spectra were recorded in KBr disks with a Hitachi EPI-S2, and electronic spectra were taken with a Hitachi EPS-3T spectrophotometer. The magnetic moments were measured bv means of a recording magnetometer especially designed by Hirakawa *et al.*[10]

Studies of the Cobalt(III) Complexes of 8-Amino-3,6-diazaoctanate Ion. IV.[1] Preparations and Some Properties of [Co(ADAO)XY] Type Complexes: XY=Cl(NH_3), Cl(py), (H_2O)(py), Cl(H_2O), (NO_2)(H_2O), and Cl(NO_2)

Kiyokatsu WATANABE

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received January 14, 1982)

The following new cobalt(III) complexes containing the 8-amino-3,6-diazaoctanate ion (adao[2]) have been isolated: two isomers of *β-mer(N)-trans(Cl,*O_{adao})-[Co(adao)(Cl)(NH_3)]ClO_4, two isomers of *β-mer(N)-trans(Cl,* O_{adao})-[Co(adao)(Cl)(py)]ClO_4, *β-mer(N)-trans(O)*-[Co(adao)(H_2O)(py)]ClO_4·bcs,[2] *β-mer(N)-trans(Cl,*O_{adao})-[Co(adao)(Cl)(H_2O)]ClO_4, *β-fac(N)*-[Co(adao)(Cl)(H_2O)]ClO_4, *β-mer(N)-cis(O)*-[Co(adao)(NO_2)(H_2O)]ClO_4, and *β-fac(N)*-[Co(adao)(Cl)(NO_2)]. The geometrical structures have been determined on the basis of the absorption spectra, the proton NMR spectra, and the consideration of their preparative processes.

In the case of [Co(adao)XY] type complex, in which two different unidentate ligands (X and Y) occupy the residual two coordination sites, seven geometrical isomers, two *α*, two *β-mer(N)*, two *β-fac(N)*, and *trans*,[3] are possible, as shown in Fig. 1. The isolation of [Co(adao)XY] type complex has not been performed so far. It is necessary to isolate the complexes of [Co(adao)XY] type for the establishment of the stereochemistry of adao-Co(III) complex. In a previous paper,[1] it was reported that the deep crimson [Co(adao)(Cl)(H_2O)]ClO_4 was used as the starting material for the preparation of [Co(adao)X_2] type complexes. However, the structure of the deep crimson aquachloro isomer could not be decided yet. For its structural determination, it is essential to isolate many various kinds of [Co(adao)XY] isomers as well as the other aquachloro isomers.

In addition, two kinds of *β-mer(N)* racemic isomers with different configurations of the adao's secondary amine (*s*-N) were isolated in some complexes of [Co(adao)X_2] type (X=NO_2^- and Cl^-), as was described in the previous paper.[1] When the configurations of *s*-N in [Co(adao)XY] type complexes are considered, twelve kinds of racemic isomers are possible: namely, two *α*, four *β-mer(N)*, *four β-fac(N)*, and two *trans* ones. As an example, the *s*-N configurations of *Λ-β-mer(N)*-[Co(adao)XY] are shown in Fig. 2. Thus, the following four *β-mer(N)* racemic isomers are able to exist: *trans*(X,O_{adao})-($R_{N_1^s}S_{N_2^p},S_{N_1^s}R_{N_2^p}$), *trans*($X,O_{adao}$)-($R_{N_1^s}$-$R_{N_2^p},S_{N_1^s}S_{N_2^p}$), *cis*($X,O_{adao}$)-($R_{N_1^s}S_{N_2^p},S_{N_1^s}S_{N_2^p}$), *cis*($X,O_{adao}$)-($R_{N_1^s}R_{N_2^p},S_{N_1^s}S_{N_2^p}$).[4-6] Therefore, the isolations of isomers with the different *s*-N configurations are attempted also in [Co(adao)XY] type complex.

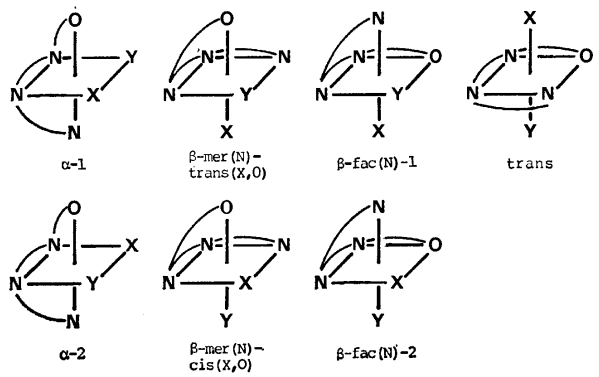

Fig. 1. The possible geometrical isomers of [Co(adao)-XY] type complex.

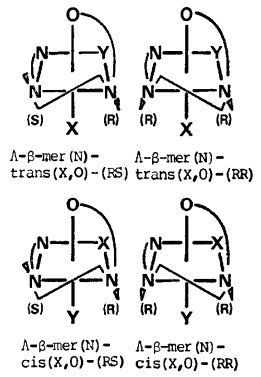

Fig. 2. The possible isomers of *Λ-β-mer(N)*-[Co(adao)-XY] under consideration of *s*-N configurations.

Experimental

Preparations of Complexes. *(1) β*-mer(N)-[*Co(adao)(Cl)(*H_2O*)*]ClO_4: The crude [Co(adao)Cl_2] (50 g)[1] was suspended in 400 cm^3 of 1 M (1 M=1 mol dm^{-3}) $HClO_4$, and the suspension was heated at about 65 °C in a water bath. The gray starting materials began to dissolve, at the same time the deep crimson crystals appeared. After the reaction mixture was allowed to stand at 65 °C for 20 min, it was cooled in an ice bath, and then filtered. The crystals were washed with a mixture of ethanol and ether (1:1). Upon recrystallization from 0.1 M $HClO_4$, *β-mer(N)*-[Co(adao)-Cl)(H_2O)]ClO_4 precipitated as deep crimson crystals. Yield, 40 g.

Found: C, 19.32; H, 4.35; N, 11.28%. Calcd for [Co(adao)(Cl)(H_2O)]ClO_4=$CoC_6H_{16}N_3O_7Cl_2$: C, 19,37; H, 4.33; N, 11.29%.

(2) β-fac(N)-[*Co(adao)(Cl)(*H_2O*)*]ClO_4: Method A, from the crude *β-fac(N)*-[Co(adao)Cl_2]; The reserved filtrate, which was obtained in the preparation of the crude [Co(adao)Cl_2] as described in the previous paper,[1] was concentrated on a water bath with the aid of an air stream, whereupon the brown material appeared. After the product was cooled, the brown material was filtered off. The procedures of concentration and removal were repeated two or three times. When the last deep blue filtrate obtained was further evaporated with the same method mentioned

above, tarry material was obtained. To this tarry material, ethanol (≈100 cm³) was added. When the mixture was stirred with a glass rod, the spherical oily material was sedimented. The blue supernatant solution was decanted. When the oily material was washed two times with 50 cm³ portions of ethanol by decantation, it changed to a crystalline material. These crystals were collected on a filter, and then washed with ethanol. Yield, 3 g. Although recrystallization was repeated, it was found that the blue crystals were not composed of pure *β-fac(N)*-dichloro isomer. This blue crystal will be named as the "crude *β-fac(N)*-[Co(adao)-Cl_2]" in the subsequent part.

The crude *β-fac(N)*-[Co(adao)Cl_2] (3 g) was suspended in 10 cm³ of water, and then 5 cm³ of 2 M $HClO_4$ was added to the suspension. The mixture was concentrated on a water bath with the aid of an air stream. Furthermore, 10 cm³ of water and 5 cm³ of 2 M $HClO_4$ were added to this concentrated product, and then the mixture was concentrated by the method mentioned above. When the treatment was repeated two or three times, pink red crystals began to appear. These crystals were dissolved in about 10 cm³ of water, and the solution was filtered once. The filtrate was concentrated by the same method until the crystals appeared. The pink red crystals were separated by filtration, and then washed with ethanol and ether. Yield, 0.15 g.

Found: C, 18.46; H, 4.49; N, 10.83%. Calcd for [Co(adao)(Cl)(H_2O)]$ClO_4 \cdot H_2O = CoC_6H_{18}N_3O_8Cl_2$: C, 18.48; H, 4.65; N, 10.77%.

Method B, from *β-fac(N)*-[Co(adao)(Cl)(NO_2)]; To the suspension of *β-fac(N)*-[Co(adao)(Cl)(NO_2)] (0.3 g) in 5 cm³ of water (whose preparative method will be described in the following procedure (*6*)) was added 1 cm³ of 1 M $HClO_4$ drop by drop. The suspension was concentrated to dryness on a water bath under an air stream. After the product was allowed to stand at room temperature for some time, 5 cm³ of water and 2 cm³ of 1 M $HClO_4$ were added to the product, and then the mixture was concentrated to dryness again. This treatment was repeated once more to force the aquation of the starting material to completion. The product was dissolved in 10 cm³ of water, and then filtered. The filtrate was evaporated until pink red crystals began to deposit out. After cooling, the crystals were collected on a filter, and then washed with ethanol and ether. Yield, 0.25 g. The identity of this crystal and the pink red isomer obtained in the Method A was checked by the absorption spectra.

Method C, the chromatographic separation of the product obtained from the crude *β-fac(N)*-[Co(adao)Cl_2]; The crude *β-fac(N)*-[Co(adao)Cl_2] (3 g) was suspended in 10 cm³ of water, and then 5 cm³ of 2 M $HClO_4$ was added. The mixture was treated with the method described in the Method A. After the violet precipitate obtained was removed by filtration, the filtrate was diluted with 10 cm³ of water. To the diluted solution was added ethanol, whereupon pink red crystals were deposited. After the removal of these crystals by filtration, the filtrate obtained was poured into a column (ϕ 50 mm × l 400 mm) containing a gel ion-exchange (SP-Sephadex C-25, Na^+ form). The column was swept with water, and then the adsorbed band at top of the column was eluted with an aqueous sodium perchlorate solution. By elution with 0.01—0.06 M $NaClO_4$, the adsorbed band was progressively separated into six bands, which were deep crimson (I), pink red (II), red (III), violet red (IV), red (V), and red (VI), in the order of elution. From their absorption spectra, it was found that these eluates contained the following isomers. Of the earlier two eluates, (I) consisted of *β-mer(N)*-[Co(adao)(Cl)(H_2O)]$^+$, and (II), *β-fac(N)*-[Co(adao)(Cl)(H_2O)]$^+$. In the case of the middle two eluates, it was certain that (III) was composed of *β-mer(N)*-[Co(adao)(H_2O)$_2$]$^{2+}$, although the structure of the isomer contained in (IV) could not be determined. Each of the latter two eluates ((V) and (VI)) consisted of an isomer with the dimeric structure. For the isolation of *β-fac(N)*-[Co(adao)(Cl)(H_2O)]ClO_4, (II) (≈3 dm³), which was eluted with 0.01 M $NaClO_4$, was concentrated to about 5 cm³ in a rotary evaporator below 40 °C. This concentrated solution was allowed to stand overnight in a refrigerator, whereupon the pink red needles were precipitated. After filtration, these were washed with ethanol, and then with ether. Yield, 0.1 g.

It was found that the visible absorption spectrum of the isolated isomer is identical to that of the pink red one in Method A or B.

(3) *β*-mer(N)-trans(Cl,O_{adao})-[*Co(adao)(Cl)(NH_3)*]ClO_4: To the suspension of *β-mer(N)*-[Co(adao)(Cl)(H_2O)]ClO_4 (3.8 g) in 20 cm³ of water was added 2 cm³ of 14% ammonia, and then the mixture was heated at 75 °C for 3 h with stirring. After cooling, deposited crystals were filtered off. The filtrate was evaporated at 50 °C with the aid of an air stream until the pale brown crystals began to appear. The product was cooled and filtered. The crystals collected on a filter were washed with ethanol and ether. Yield, 0.5 g. The filtrate which was obtained in this stage was reserved for the isolation of another isomer.

Recrystallization of the pale brown crystals was carried out by the method of fractional extraction with hot (≈75 °C) 0.1 M $HClO_4$ as follows. The first and the second extracts were cooled in an ice bath, whereupon the pale brown crystals with enough purity deposited out. They were washed with ethanol and ether. The total yield was about 0.3 g.

When the reserved filtrate (≈5 cm³) was further evaporated, reddish brown crystals deposited out. After cooling, they were collected on a filter, and then washed with ethanol. Yield, 1.5 g. They were recrystallized by a method similar to that described above. The total yield was about 0.2 g.

Found: C, 19.35; H, 4.70; N, 15.45% for the pale brown isomer; C, 19.10; H, 4.70; N, 15.57% for the reddish brown one. Calcd for [Co(adao)(Cl)(NH_3)]$ClO_4 = CoC_6H_{17}N_4O_6Cl_2$: C, 19.42; H, 4.62; N, 15.10%.

The reaction in the presence of active charcoal was also carried out. However, only one reddish brown isomer could be isolated together with *β-mer(N)*-[Co(adao)(NH_3)$_2$](ClO_4)$_2$.[7]

(4) *β*-mer(N)-trans(Cl,O_{adao})-[*Co(adao)(Cl)(py)*]ClO_4: To the suspension of *β-mer(N)*-[Co(adao)(Cl)(H_2O)]ClO_4 (1.9 g) in 10 cm³ of water was added 1 cm³ of pyridine, and then the mixture was stirred at ≈80 °C for 2 h. After that, the product was cooled in an ice bath, whereupon reddish brown needles precipitated. The crystals were separated by filtration, and then washed with ethanol. The yield of first precipitate was about 0.9 g.

When the filtrate was concentrated furthermore at 40 °C, massive crystals with a dull reddish brown color began to deposit out. After cooling, they were filtered and washed with ethanol. The yield of second precipitate was about 0.4 g.

Recrystallization was carried out by the fractional extraction as follows; the first precipitate was extracted with three 3 cm³ portions of hot (≈75 °C) 0.1 M $HClO_4$. Of these three extracts, the first and second extracts gave the pure reddish brown needles. The total yield was about 0.15 g. The second precipitate was extracted with five 2 cm³ portions of hot 0.1 M $HClO_4$. All these extracts

gave pure dull reddish brown massive crystals. The total yield was about 0.3 g.

Found: C, 30.33; H, 4.71; N, 13.39% for the reddish brown isomer; C, 30.09; H, 4.65; N, 13.40% for the dull reddish brown one. Calcd for $[Co(adao)(Cl)(py)]ClO_4$= $CoC_{11}H_{19}N_4O_6Cl_2$: C, 30.50; H, 4.42; N, 12.94%.

(5) β-mer(N)-trans(O)-*[Co(adao)(H_2O)(py)]ClO_4·bcs·$2H_2O$*:*[2] The author's carbonato complex (3 g)[8] was suspended in 15 cm³ of water. After 3.5 cm³ of 6 M $HClO_4$ was added to the suspension, pyridine (3.5 cm³) and active charcoal (0.5 g) were added in this order. The mixture was heated at 55 °C for 7 h with mechanical stirring. After the charcoal was separated on a filter, it was washed with two 10 cm³ portions of hot water (≈80 °C). The washings and filtrate were combined, and the combined solution was evaporated to about 25 cm³ at 55 °C in an air stream. After cooling, the first precipitate was filtered off. The filtrate was evaporated again, and then the second precipitate was also removed. On further concentrating, the third precipitate began to appear. After cooling, the precipitate was collected on a filter, and then washed with an ethanol–ether mixture (1:1). Yield, 0.7 g.

The above procedure was repeated three times to get enough crude *trans(O)*-aquapyridine complex deposited as the third precipitate. This crude complex (≈2 g) was dissolved in 20 cm³ of water, and then 10 cm³ of solution containing NH_4bcs (1.3 g)[2] was added to it. After the mixture was heated at 55 °C for 5 min, it was allowed to stand for about 6 h at room temperature. Brown orange crystals deposited out. They were collected on a filter, and then washed with a ethanol–ether (1:1) and with ether. Yield, 0.18 g. The filtrate was kept overnight in a refrigerator, whereupon the same crystals were obtained. Yield, 0.36 g.

Upon recrystallization from 3 cm³ of hot water (≈70 °C) containing the crude diastereoisomer (0.25 g), the pure brown orange crystals were precipitated. Yield, 0.1 g.

Found: C, 33.12; H, 5.18; N, 7.40%. Calcd for $[Co(adao)(H_2O)(py)]ClO_4$·bcs·$2H_2O$ = $CoC_{21}H_{39}N_4O_{13}ClBrS$: C, 33.11; H, 5.16; N, 7.35%.

(6) β-fac(N)-*[Co(adao)(Cl)(NO_2)]*: To the solution of *β-fac(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$·$H_2O$ (0.1 g) dissolved in 20 cm³ of water was added $NaNO_2$ (0.1 g), and then the mixture was heated at 75 °C for 15 min, whereupon orange crystals began to deposit gradually. After the heating was continued for 10 min more to achieve the complete reaction, the product was cooled. The crystals precipitated were separated by filtration, and then washed with ethanol and with ether. Yield, 0.05 g.

Found: C, 24.25; H, 4.44; N, 18.92%. Calcd for $[Co(adao)(Cl)(NO_2)]$= $CoC_6H_{14}N_4O_4Cl$: C, 23.98; H, 4.70; N, 18.64%.

(7) β-mer(N)-cis(O)-*[Co(adao)(NO_2)(H_2O)]ClO_4*:* The sparingly soluble *β-mer(N)*-$[Co(adao)(NO_2)_2]$ (1.3 g), of which preparative procedure was reported in the previous paper,[1] was covered with 5 cm³ of 2 M $HClO_4$, and then the mixture was heated at about 80 °C on a water bath. When the mixture was heated for 5 min, the starting material began to dissolve, and soon orange crystals began to appear. It was heated for 15 min more to complete the reaction, and then cooled. The crystals were filtered, then washed with ethanol and with ether. Yield, 1.1 g.

They were recrystallized from 5 cm³ of hot water (≈80 °C) by fractional extraction. The first and second extracts gave the pure crystals. The total yield was 0.6 g.

Although the reaction of Collman's dinitro complex[3] and $HClO_4$ afforded also the same isomer, the yield is lower than that in the reaction using this sparingly soluble *β-mer(N)*-dinitro isomer[1] as the starting material.

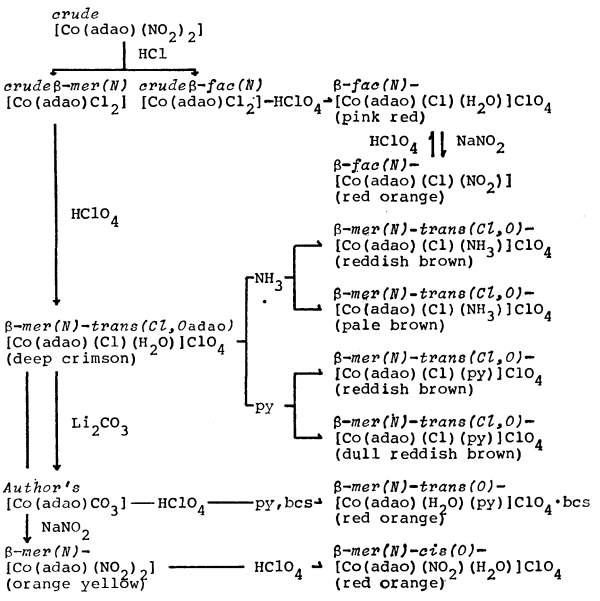

Fig. 3. The preparation scheme of [Co(adao)XY].

Found: C, 18.42; H, 4.47; N, 14.55%. Calcd for $[Co(adao)(NO_2)(H_2O)]ClO_4$= $CoC_6H_{16}N_4O_9Cl$: C, 18.84; H, 4.22; N, 14.64%.

Analyses. The carbon, hydrogen, and nitrogen in the isolated complexes were analyzed at the Microanalysis Center of Osaka University.

Measurements. The visible and ultraviolet absorption spectra were measured with a Shimadzu UV-200 Recording Spectrophotometer using 1 cm or 10 cm silica cells. The IR spectra were recorded with a JASCO IRA-1 Spectrophotometer by a Nujol mull method. The proton NMR spectra were recorded with a Varian XL-100 Spectrometer or a JEOL JNM-4H-100 Spectrometer in deuterium oxide, with *t*-butyl alcohol as the internal reference.

Results and Discussion

Preparative Remarks. As seen in Fig. 3, which shows the preparative scheme of [Co(adao)XY], the two aquachloro isomers with an deep crimson color or a pink red one were mainly used as the starting materials. The deep crimson isomer was isolated from crude *β-mer(N)*-$[Co(adao)Cl_2]$ by the treatment with 1 M $HClO_4$ (*1*), and the pink red one was precipitated from the last blue filtrate containing the crude *β-fac(N)*-dichloro isomer (Method A in *2*) or the *β-fac(N)*-$[Co(adao)(Cl)(NO_2)]$ (Method B in *2*) by using 6 M $HClO_4$ as the selective precipitant or reactant. Similar substitution reactions to that of the crude *β-mer(N)*-$[Co(adao)Cl_2]$ and 1 M $HClO_4$ were observed in the synthesizing reactions of *β-mer(N)-trans(O)*-$[Co(adao)(H_2O)(py)]ClO_4$·bcs (*5*) and *β-mer(N)-cis(O)*-$[Co(adao)(NO_2)(H_2O)]ClO_4$ (*7*). These facts suggest that in the substitution reaction of *β-mer(N)* isomer, the dissociation rates for the two unidentate ligands which are situated in the different coordination sites are different: that is, the unidentate ligand occupying the *cis* site to the "O_{adao}" is more dissociative than the other unidentate ligand occupying the *trans* site.

a) Measured in 0.1 M $HClO_4$. b) Measured in 0.1 M HCl. c) Nitro specific band.

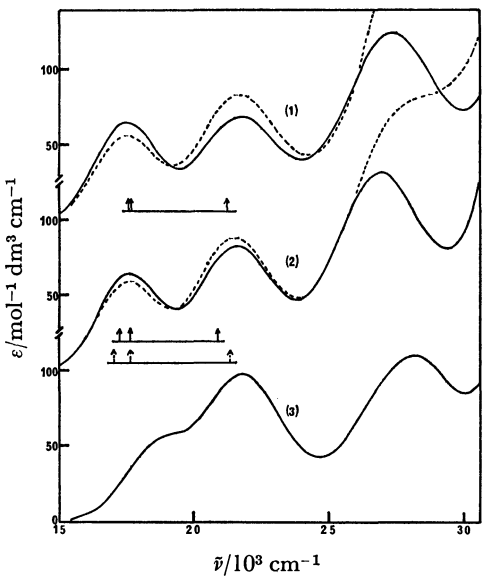

Fig. 4. The absorption spectra of [Co(adao)XY] type complexes and the predicted first band components.
(1): *β-mer(N)-trans(Cl,O_{adao})*-[Co(adao)(Cl)(NH_3)]ClO_4.
——: Reddish brown, - - -: pale brown. a) $\delta(N)=+330$ cm^{-1}, $\delta(O)=-3800$ cm^{-1}, and $\delta(Cl)=-10070$ cm^{-1} are used in the case of solid arrows.
(2): *β-mer(N)-trans(Cl,O_{adao})*-[Co(adao)(Cl)(py)]ClO_4.
——: Reddish brown, - - -: dull reddish brown. b) $\delta(N)=+330$ cm^{-1}, $\delta(O)=-3800$ cm^{-1} are used in the case of solid arrows, and $\delta(N_{adao})=+970$ cm^{-1}, $\delta(O_{adao})=-5190$ cm^{-1}, in the case of dotted arrows.
(3): *β-mer(N)-trans(O)*-[Co(adao)(H_2O)(py)]ClO_4·bcs.
——: Brown orange.

Furthermore, it was recognized that under only the mild reaction conditions, pairs of isomers with the different *s*-N configuration can be isolated in *β-mer(N)-trans(Cl,O_{adao})*-[Co(adao)(Cl)(NH_3)]ClO_4 and *β-mer(N)-trans(Cl,O_{adao})*-[Co(adao)(Cl)(py)]ClO_4, respectively.

The Structures of [Co(adao)(Cl)(NH_3)]ClO_4. As mentioned in procedure (*3*), the reddish brown and pale brown isomers were isolated. Their elemental analyses corresponded well to the composition of [Co(adao)(Cl)(NH_3)]ClO_4. Although there are small differences between their absorption spectra, which are shown in Fig. 4, the spectra show a similar pattern in the region of their first absorption bands. Namely, the positions of two split components are located at 17500 cm^{-1} and 21730 cm^{-1} for the reddish brown isomer, and at 17540 cm^{-1} and 21670 cm^{-1} for the pale brown one (Table 1).

When the following shift parameters, $\delta(N)=+330$ cm^{-1},[9] $\delta(O)=-3800$ cm^{-1},[9] $\delta(Cl)=-10070$ cm^{-1},[10] and $\delta(NH_3)=0$,[9] which were used in the previous paper,[1] are used, the first band components of *β-mer(N)-trans(Cl,O_{adao})*-[Co(adao)(Cl)(NH_3)]$^+$ can be predicted as is shown with the solid arrows in Fig. 4. These predicted components fit approximately to the observed first band maxima. Therefore, the reddish brown and pale brown isomers can be assigned to the *β-mer(N)-trans(Cl,O_{adao})* structure.

However, it is recognized from Fig. 4 that the observed higher wave number components (21730 cm^{-1} for the reddish brown and 21670 cm^{-1} for the pale brown) are located at the higher wave number than the predicted highest one (21220 cm^{-1}). These discrepancies suggest that the practical $\delta(N_{adao})$ in [Co(adao)(Cl)(NH_3)]ClO_4 is larger than $\delta(N)=+330$ cm^{-1} which was used in the above calculation. In order to estimate new adao shift parameter values ($\delta(N_{adao})$ and $\delta(O_{adao})$), the following calculations are made by using the mean value of the corresponding observed split band's positions for two kinds of *β-mer(N)-trans(Cl,O_{adao})*-[Co(adao)(Cl)(NH_3)]ClO_4. In the higher wave number component, the following equa-

tion is written:

$$3/4\,\delta(N_{adao}) + 1/4\,\delta(NH_3) = 21700 - 20970 = +730\ (cm^{-1}) \quad (1)$$

When it is assumed that the lower wave number maximum is observed as the mean of two lower wave number component positions, the following equation also holds.

$$1/2[\{2/4\,\delta(N_{adao}) + 1/4\,\delta(O_{adao}) + 1/4\,\delta(Cl)\} + \{1/4\,\delta(N_{adao}) + 1/4\,\delta(NH_3) + 1/4\,\delta(O_{adao}) + 1/4\,\delta(Cl)\}] = 3/8\,\delta(N_{adao}) + 1/8\,\delta(NH_3) + 1/4\,\delta(O_{adao}) + 1/4\,\delta(Cl) = 17520 - 20970 = -3450\ (cm^{-1}) \quad (2)$$

Because $\delta(NH_3)=0$,[9] the value of $\delta(N_{adao})$ is obtained as $+970\ cm^{-1}$ from Eq. 1. Substituting this value into Eq. 2, the value of $\delta(O_{adao})$ is also obtained as $-5190\ cm^{-1}$. Here, the value of $\delta(Cl)=-10070\ cm^{-1}$ [10] is used.

The Structures of [Co(adao)(Cl)(py)]ClO$_4$. In the case of [Co(adao)(Cl)(py)]ClO$_4$, two isomers with a reddish brown color and dull reddish brown one were isolated. Their absorption spectra are shown in Fig. 4. From their marked splitting patterns, these two isomers are assigned as taking the *β-mer(N)-trans(Cl, O$_{adao}$)* structure.

In Fig. 4, two sets of the predicted first band components of *β-mer(N)-trans(Cl,O$_{adao}$)*-[Co(adao)(Cl)(py)]-ClO$_4$ are represented with the solid arrows and the dotted arrows. The former is predicted by using the following shift parameters: $\delta(N)=+330\ cm^{-1}$, $\delta(O)=-3800\ cm^{-1}$, $\delta(Cl)=-10070\ cm^{-1}$, and $\delta(py)=-1300\ cm^{-1}$ (estimated from *trans*-[CoCl$_2$(py)$_4$]$^+$ [11]). The latter is predicted by the use of new adao shift parameters, $\delta(N_{adao})=+970\ cm^{-1}$, and $\delta(O_{adao})=-5190\ cm^{-1}$. When their predicted first band components are compared with the observed ones, better correspondence is observed between the latter predicted pattern and the observed one. Then, it is attempted to estimate the value of $\delta(py)$ in [Co(adao)(Cl)(py)]ClO$_4$ by using the following equation:

$$3/4\,\delta(N_{adao}) + 1/4\,\delta(py) = 21530 - 20970 = +580\ (cm^{-1}) \quad (3)$$

Substituting the value of $\delta(N_{adao})=+970\ cm^{-1}$ into Eq. (3), $\delta(py)$ is obtained as $-670\ cm^{-1}$.

The Structure of [Co(adao)(H$_2$O)(py)]ClO$_4$·bcs·2H$_2$O. By the use of NH$_4$bcs, this complex could be obtained as the crystalline form for the first time. The measurement of its circular dichroism spectrum suggests that the complex is an optically active one. Its IR spectrum in a Nujol mull shows a band due to bcs$^-$ at 1760 cm^{-1} and a strong broad band due to ClO$_4^-$ around 1100 cm^{-1}.

The first absorption band of brown orange isomer exhibits a sub-peak at the lower wave number side ($\approx$18900 cm^{-1}) of major peak (21790 cm^{-1}), as seen in Fig. 4 and Table 1. From this large splitting pattern, the isomer can be identified as the *trans(O)* one.[12,13] It is found from Fig. 1 that the coordinated adao in the *trans(O)* isomer takes necessarily the *β-mer(N)* coordination mode, and hence [Co(adao)(H$_2$O)-(py)]ClO$_4$·bcs is assigned to the *β-mer(N)-trans(O)* structure. It is an interesting behavior that the intensity of the higher wave number split component is stronger than that of the lower wave number one, which is thought to consist of two components.

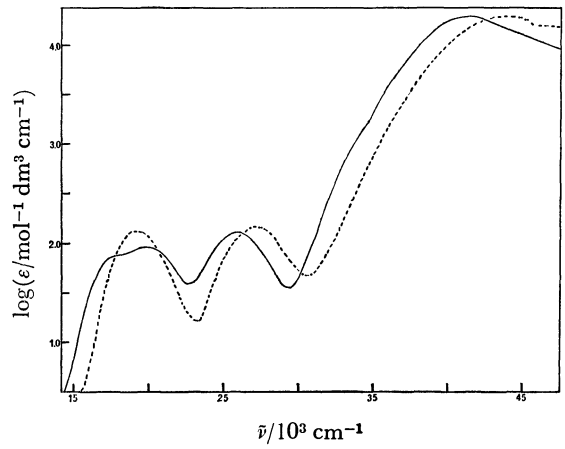

Fig. 5. The absorption spectra of [Co(adao)(Cl)-(H$_2$O)]ClO$_4$.
——: *β-mer(N)*-[Co(adao)(Cl)(H$_2$O)]ClO$_4$ (deep crimson), - - -: *β-fac(N)*-[Co(adao)(Cl)(H$_2$O)]ClO$_4$ (pink red).

In order to estimate the shift parameter of aqua ligand ($\delta(H_2O)$), new shift parameters, $\delta(N_{adao})=+970\ cm^{-1}$, $\delta(O_{adao})=-5190\ cm^{-1}$, and $\delta(py)=-670\ cm^{-1}$, are used. Then, the value of $\delta(H_2O)$ is obtained as $-4210\ cm^{-1}$.

The Structures of [Co(adao)(Cl)(H$_2$O)]ClO$_4$. For the aquachloro complex, two isomers, deep crimson and pink red isomers, were isolated. The elemental analyses of these isomers showed the following compositions: [Co(adao)(Cl)(H$_2$O)]ClO$_4$ for the deep crimson isomer, [Co(adao)(Cl)(H$_2$O)]ClO$_4$·H$_2$O for the pink red one. As seen in Fig. 5 and Table 1, the deep crimson isomer shows the first band with two split components ($\approx$17200 cm^{-1} and 19830 cm^{-1}); the intensity of the higher wave number component is stronger than that of the lower wave number one. The pink red isomer shows the first band without splitting (19140 cm^{-1}). The second absorption maximum of the deep crimson isomer is located at a lower wave number (25830 cm^{-1}) than that of the pink red isomer (27030 cm^{-1}).

When the configuration of *s*-N is ignored, seven geometrical isomers are possible in the complex of [Co-(adao)(Cl)(H$_2$O)]$^+$ (in Fig. 1). In order to predict the first split components for these seven geometrical isomers, the new estimated shift parameters, $\delta(N_{adao})=+970\ cm^{-1}$, $\delta(O_{adao})=-5190\ cm^{-1}$, $\delta(H_2O)=-4210\ cm^{-1}$, which were mentioned above, and $\delta(Cl)=-10070\ cm^{-1}$,[10] are used. In Fig. 6, their predicted components are shown with the solid arrows together with the absorption spectrum of deep crimson isomer.

When the predicted split patterns are compared with the observed first band of deep crimson isomer, the predicted split patterns of three structures, *β-mer(N)-trans(Cl,O$_{adao}$)*, *β-mer(N)-cis(Cl,O$_{adao}$)*, and *trans*, agree with the split pattern of the observed first band. Among the three possible structures, the best coinci-

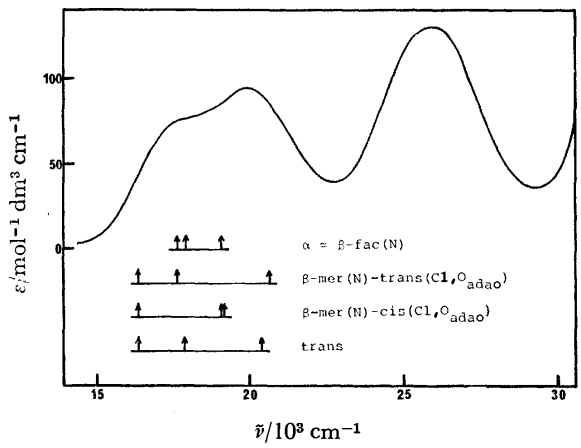

Fig. 6. The absorption spectrum of deep crimson [Co(adao)(Cl)(H_2O)]ClO_4 and the predicted first band components (solid arrows) for the possible geometrical isomers of [Co(adao)(Cl)(H_2O)]$^+$.

dence is observed between the predicted first band components of *trans* structure and the observed first band. However, the possibility of a *trans* structure is excluded, because it was already found that the treatment of this deep crimson isomer with hydrochloric acid gave only *β-mer(N)*-[Co(adao)Cl_2], as was reported in the previous paper.[1] Furthermore, as is shown in Fig. 7, the proton NMR spectrum of deep crimson isomer shows one AB quartet in the range of 2.09 ppm to 3.18 ppm, although the two resonances at the lower field split into two doublets. The value of $\delta_{AB}(=\delta_A-\delta_B)$ is about 0.7 ppm (J_{AB}=18 Hz). As was reported in the previous papers,[1,7,8] this observation of AB quartet pattern due to the adao glycinate ring protons suggests that the deep crimson isomer takes the α or the *β-mer(N)* structure. From the consideration of these proton NMR and absorption spectral patterns, the coordination mode of deep crimson isomer is assigned to the *β-mer(N)* one.

As was mentioned above, the reaction of deep crimson *β-mer(N)*-[Co(adao)(Cl)(H_2O)]ClO_4 and ammonia or pyridine gave *β-mer(N)-trans(Cl,*O_{adao}*)*-[Co(adao)(Cl)(NH_3)]ClO_4 or *β-mer(N)-trans(Cl,*O_{adao}*)*-[Co(adao)(Cl)(py)]ClO_4. These facts indicate that the chloro ligand in the deep crimson isomer occupies the *trans* position to "O_{adao}." Thus, it can be concluded that the structure of deep crimson isomer is the *β-mer(N)-trans(Cl,*O_{adao}*)* one.

In Fig. 5, the absorption spectrum of pink red isomer is shown. From the narrow first absorption band shape, it is recognized that the pink red isomer takes the α or the *β-fac(N)* structure. The proton NMR spectrum of the pink red isomer is shown in Fig. 7. The proton NMR spectrum shows the strong doublet peaks at 1.64 ppm and 1.69 ppm, due to the adao glycinate ring protons. These resonance peaks are located at higher field than those of *β-fac(N)*-[Co(adao)CO_3] (located at 2.73 ppm and 2.41 ppm) and *β-fac(N)*-[Co(adao)mal] (located at 2.35 ppm and 2.29 ppm).[8] In the proton NMR studies of [Co(Hedta)X]$^{n-}$ (X= NO_2^- and H_2O),[14-16] [Co(edta)en]$^-$,[17] and [Co(H_2dtpa)NO_2]$^-$,[18] the resonance peaks of the unco-

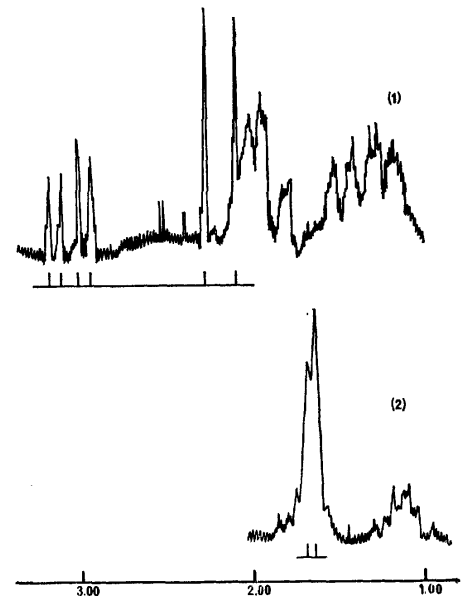

Fig. 7. The proton NMR spectra of [Co(adao)(Cl)(H_2O)]ClO_4.
(1): *β-mer(N)*-[Co(adao)(Cl)(H_2O)]ClO_4 (deep crimson), (2): *β-fac(N)*-[Co(adao)(Cl)(H_2O)]ClO_4 (pink red).

ordinated glycinate ring protons are observed as the singlet or AB quartet pattern in the field region lower than 2.0 ppm. Therefore, some doubts as to whether the adao glycinate ring in the pink red isomer is coordinated to the Co(III) ion or not, still remain.

To clarify the above doubts, a few preparations using the pink red isomer had been achieved as were described in procedure (*5*) and the previous paper.[1] Their isolated complexes have the compositions of [Co(adao)(Cl)(NO_2)] and [Co(adao)Cl_2]. From the facts, it is inferred that the adao glycinate ring is coordinated to the Co(III) ion. As the other experiment, the chromatographic separation was also performed (Method C in *2*). The chromatographic behavior of pink red isomer was similar to that of *β-mer(N)*-[Co(adao)(Cl)(H_2O)]ClO_4. This fact suggests that the pink red isomer is an univalent cation and that the adao glycinate ring is not free. Then, the pink red isomer is tentatively assigned to the *β-fac(N)* structure. However, it is difficult to decide the position of the chloro ligand in the pink red isomer.

The Structure of [Co(adao)(NO_2)(H_2O)]ClO_4.
The reaction of orange yellow *β-mer(N)*-[Co(adao)(NO_2)$_2$][1] and $HClO_4$ gave [Co(adao)(NO_2)(H_2O)]ClO_4. The reaction of α-[Co(adao)(NO_2)$_2$][1] and $HClO_4$ was attempted, but no crystalline complex could be obtained. In Fig. 8, the absorption spectrum of [Co(adao)(NO_2)(H_2O)]ClO_4 is shown.

The proton NMR spectrum of [Co(adao)(NO_2)(H_2O)]ClO_4 shows one AB quartet pattern at 2.01, 2.19, 2.81, and 2.99 ppm. From this observation, the adao coordination mode is the α or the *β-mer(N)* one. The reaction of α-[Co(adao)(NO_2)$_2$] and $HClO_4$ gave no crystals. The structure can thus be assigned to the *β-mer(N)* one. For *β-mer(N)*-[Co(adao)(NO_2)-

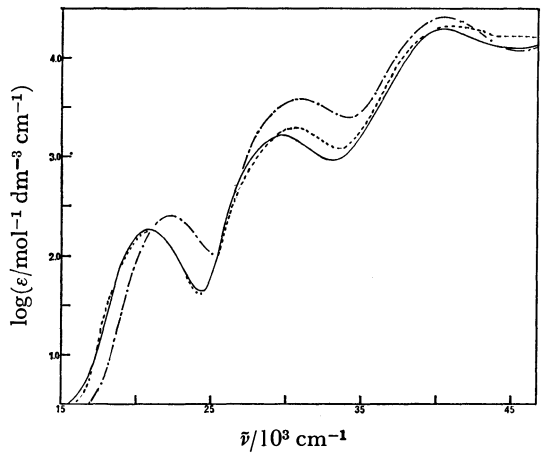

Fig. 8. The absorption spectra of $[Co(adao)(NO_2)(H_2O)]ClO_4$ and $[Co(adao)(Cl)(NO_2)]$.
——: *β-mer(N)*-$[Co(adao)(NO_2)(H_2O)]ClO_4$ (red orange), – – –: *β-fac(N)*-$[Co(adao)(Cl)(NO_2)]$ (red orange), —·—: *β-mer(N)*-$[Co(adao)(NO_2)_2]$ (orange yellow).

$(H_2O)]ClO_4$, the *cis(O)* and *trans(O)* isomers are possible. When $[Co(adao)(NO_2)(H_2O)]ClO_4$ is regarded as a complex of $[CoN_4O_2]$ type, the *trans(O)* isomer shows the more split first absorption band than that of the *cis(O)* one.[12,13] Because the isolated aquanitro isomer exhibits the first absorption band with no remarkable splitting, it is concluded that $[Co(adao)(NO_2)(H_2O)]ClO_4$ takes the *β-mer(N)-cis(O)* structure. The production of *β-mer(N)-cis(O)*-$[Co(adao)(NO_2)(H_2O)]ClO_4$ by the treatment of $[Co(adao)(NO_2)_2]$ with $HClO_4$ indicates that the reactivities of two nitro ligands in *β-mer(N)*-$[Co(adao)(NO_2)_2]$ are different.

The Structure of [Co(adao)(Cl)(NO₂)]. As was mentioned in (*5*), $[Co(adao)(Cl)(NO_2)]$ was obtained as the slightly soluble crystal from *β-fac(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$ by the treatment with $NaNO_2$. Table 1 (ε=2000 for the chloronitro complex and ε=1652 for the aquanitro one) shows that the isolated complex contains one coordinated nitro ligand. It is also observed that its first absorption maximum is located at a similar wave number region to that of *β-mer(N)-cis(O)*-$[Co(adao)(NO_2)(H_2O)]ClO_4$. The similar absorption band shifts to the higher wave number side are observed as an anomalous absorption spectral behavior also in the other *β-fac(N)* complexes.

Furthermore, it was found that the treatment of $[Co(adao)(Cl)(NO_2)]$ with $HClO_4$ gave *β-fac(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$. The fact suggests that the reaction of *β-fac(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$ and $NaNO_2$ proceeds with the configurational retention of adao. This retention reaction supports that the isolated chloronitro isomer takes the *β-fac(N)* structure.

Summary. From the successful isolations of two isomers of *β-mer(N)-trans(Cl,O*$_{adao}$*)*-$[Co(adao)(Cl)(NH_3)]ClO_4$, reddish brown, pale brown, and two isomers of *β-mer(N)-trans(Cl,O*$_{adao}$*)*-$[Co(adao)(Cl)(py)]ClO_4$, reddish brown, dull reddish brown, the existence of two kinds of *β-mer(N)* isomers with the different *s*-N configurations was proved.

By using their definitive split first band maxima, furthermore, the shift parameters of the adao ligating atoms were estimated as $\delta(N_{adao})=+970\ cm^{-1}$ and $\delta(O_{adao})=-5190\ cm^{-1}$ at present. The pyridine shift parameter ($\delta(py)=-670\ cm^{-1}$) and the aqua one ($\delta(H_2O)=-4210\ cm^{-1}$) could also be calculated. On the basis of the absorption band components predicted by the use of these shift parameters and the considerations of the preparative results, the deep crimson $[Co(adao)(Cl)(H_2O)]ClO_4$ could be assigned to the *β-mer(N)-trans(Cl,O*$_{adao}$*)* structure.

Besides the one kind of isolated *β-fac(N)*-$[Co(adao)Cl_2]$,[1] it was also found that the respective *β-fac(N)* isomers can be isolated in $[Co(adao)(Cl)(H_2O)]ClO_4$ and $[Co(adao)(Cl)(NO_2)]$.

The author is sincerely grateful to Professor Yoichi Shimura of Osaka University for the guidance of this work. He also thanks Professor Kashiro Kuroda of Ehime University for his continuing interest and encouragement during the work.

Oxidative Synthesis, Optical Resolution, and Characterization of Mixed Sulfenato and Sulfinato Cobalt(III) Complexes

Masakazu KITA,* Kazuaki YAMANARI, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 20, 1982)

Twelve new mixed sulfenato and sulfinato cobalt(III) complexes were prepared via successive H_2O_2 oxidation of $[Co(SCH_2CH_2NH_2)_3]$, $[Co\{SCH_2CH(COOCH_3)NH_2\}_3]$, and related complexes. These oxidation products, $[Co(sulfenato\text{-}N,S)_n(sulfinato\text{-}N,S)_{3-n}]$ ($n=3$, 2, 1, and 0), were optically resolved by means of column chromatography or preferential crystallization of a diastereomeric molecular compound with *d*-tartaric acid. The mixed sulfenato and sulfinato complexes show characteristic variation of absorption spectra with the change of "*n*" in $[Co(sulfenato\text{-}N,S)_n(sulfinato\text{-}N,S)_{3-n}]$ ($n=3$, 2, 1, and 0). It is concluded that the (*R*) configuration of the sulfenato group is more stable than the (*S*) one in the *fac*(*S*)-*Λ*-$[Co(sulfenato\text{-}N,S)_n(sulfinato\text{-}N,S)_{3-n}]$.

Owing to the high nucleophilicity of the thiolato sulfur atom coordinated to cobalt(III) ion, the reaction of the thiolato complex with other metal ion, Co^{3+}, Zn^{2+}, Ag^+, *etc.*,[1] or with carbonium ion, CH_3^+, $C_2H_5^+$, $C_6H_5CH_2^+$, *etc.*,[2] yielded easily μ-thiolato or thioether complex, respectively. Furthermore, it has been reported that the successive oxidation of the thiolato cobalt(III) complex generates several sulfur-bonded sulfenato and sulfinato complexes.[3] These complexes are of interest in connection with their kinetic and spectrochemical behaviors. However, no optically active sulfenato or sulfinato complex except $[Co\{S(O)CH_2CH(COOH)NH_2\}(en)_2]^{2+}$ has been reported so far and consequently their stereochemical aspects have not been investigated systematically.

Present study is concerned with the preparation and optical resolution of mixed sulfenato and sulfinato complexes, $[Co(sulfenato\text{-}N,S)_n(sulfinato\text{-}N,S)_{3-n}]$ ($n=3$, 2, 1, and 0), and related complexes. These optically active complexes were obtained by means of three methods, preferential crystallization of a diastereomeric molecular compound, column chromatography, and stereospecific substitution reaction. The complexes were identified from their visible and ultraviolet absorption, circular dichroism (CD), and ^{13}C NMR spectra, and their spectrochemical and stereochemical features were discussed. A preliminary report has been presented.[4]

Abbreviations used for ligands are as follows: Haet, 2-aminoethanethiol $HSCH_2CH_2NH_2$; Haese, 2-aminoethanesulfenic acid $HS(O)CH_2CH_2NH_2$; Haesi, 2-aminoethanesulfinic acid $HS(O)_2CH_2CH_2NH_2$; L-Hcym, L-cysteine methyl ester $HSCH_2CH(COOCH_3)NH_2$; L-cyme, (*R*)-2-amino-2-(methoxycarbonyl)ethanesulfenic acid $HS(O)CH_2CH(COOCH_3)NH_2$; L-Hcymi, (*R*)-2-amino-2-(methoxycarbonyl)ethanesulfinic acid $HS(O)_2CH_2CH(COOCH_3)NH_2$; L-$H_2$cys, L-cysteine $HSCH_2CH(COOH)NH_2$; L-H_2cyse, (*R*)-2-amino-3-sulfenopropanoic acid $HS(O)CH_2CH(COOH)NH_2$; L-H_2cysi, (*R*)-2-amino-3-sulfinopropanoic acid $HS(O)_2CH_2CH(COOH)NH_2$; L-H_2pene, (*R*)-2-amino-3-methyl-3-sulfenobutanoic acid $HS(O)C(CH_3)_2CH(COOH)NH_2$; en, ethylenediamine $NH_2CH_2CH_2NH_2$; *d*-H_2tart, *d*-tartaric acid *d*-$C_4H_6O_6$.

Experimental

Preparation, Separation, and Optical Resolution of Complexes.

(1) $[Co(aese)_n(aesi)_{3-n}]$ *(n=3, 2, 1, and 0)*: To a solution of 3.5 g (30 mmol) of 2-aminoethanethiol hydrochloride in 30 cm^3 of water was gradually added 3.6 g (10 mmol) of $Na_3[Co(CO_3)_3]\cdot 3H_2O$ and the mixture was stirred at 95 °C for 1 h. The blue-green curdy precipitate of $[Co(aet)_3]$ was filtered and washed with water. A stoichiometric amount (21 mmol) of 2.86% aqueous H_2O_2 was added dropwise to suspension of 2.0 g (7 mmol) of $[Co(aet)_3]$ in 25 cm^3 of water with stirring below 5 °C, leading to an orange-red solution instantly. This solution was filtered in order to remove a little amount of unreacted $[Co(aet)_3]$. On addition of acetone (200 cm^3) and ether (200 cm^3) to the filtrate, an orange precipitate was obtained. This was dissolved in a small amount of water, adsorbed on a column (2 cm × 100 cm) of anion-exchange resin (QAE-Sephadex A-25, *d*-tartrate form) and eluted with water. Five colored bands, orange(I), orange(II), orange(III), yellow orange(**IV**), and orange yellow(**V**), were eluted in this order. Bands, II, III, and **IV**, were major products, and I and **V** minor ones. At this stage each of the bands was partially resolved: the earlier eluted fractions of band II, III, **IV**, or **V** showed negative CD at the longest wavelength region of the first d-d absorption band.

The oxidation of eluate II or III by diluted H_2O_2 (*ca.* 2%) produced bands **IV** and V which were separated by column chromatography. Similarly, eluate **IV** generated band **V** and a new yellow band **VI**, and eluate **V** did single band **VI**. The sparingly soluble yellow complex **VI** could also be obtained *via* oxidation of eluate II, III, **IV**, or **V** by an excess 30% H_2O_2. These results indicate that the oxidation process is stepwise in a series of II (or III)→**IV**→**V**→**VI**.

Each eluate was concentrated in a vacuum rotatory evaporator at *ca.* 8 °C to yield the precipitate. The precipitate was collected by filtration and washed with acetone and ether. But the precipitate could not be isolated from eluate I because of the low yield and very hygroscopic property. Complex II partially isomerized into complex III during the crystallization, which was identified by column chromatographic treatment and ^{13}C NMR spectra. It was confirmed from the absorption measurement and the following elemental analyses that complexes II (and III), **IV**, **V**, and **VI** correspond to $n=3$, 2, 1, and 0 of $[Co(aese)_n(aesi)_{3-n}]$, respectively.

Found for II: C, 21.08; H, 5.56; N, 12.25%. Calcd for $[Co(aese)_3]\cdot 0.5H_2O = C_6H_{19}N_3O_{3.5}S_3Co$: C, 20.93; H, 5.56; N, 12.20%. Found for III: C, 19.08; H, 6.12; N, 11.22%. Calcd for $[Co(aese)_3]\cdot 2.5H_2O = C_6H_{23}N_3O_{5.5}S_3Co$: C, 18.94; H, 6.09; N, 11.22%. Found for **IV**: C, 18.39; H, 5.62; N, 10.79%. Calcd for $[Co(aese)_2(aesi)]\cdot 2H_2O = C_6H_{22}N_3O_6S_3Co$: C, 18.61; H, 5.72; N, 10.48%. Found

for **V**: C, 18.50; H, 5.17; N, 10.84%. Calcd for [Co(aese)(aesi)$_2$]·H_2O=$C_6H_{20}N_3O_6S_3Co$: C, 18.70; H, 5.23; N, 10.90%. Found for VI: C, 18.80; H, 4.80; N, 10.90%. Calcd for [Co(aesi)$_3$]=$C_6H_{18}N_3O_6S_3Co$: C, 18.80; H, 4.73; N, 10.96%.

(2) Molecular Compound of III with d-*Tartaric Acid,* d-$C_4H_6O_6$·$(+)^{CD}_{500}$-[*Co(aese)*$_3$]·H_2O *and Its Derivatives*: The optical resolution of III was achieved using *d*-tartaric acid as a resolving agent. Racemate III, [Co(aese)$_3$]·2.5H_2O (1.0 g, 2.76 mmol), was dissolved in an ethanol–water (2:1) mixture and then *d*-H_2tart (0.42 g, 2.76 mmol) was added to the solution. After a few minutes, an orange-red diastereomeric molecular compound, *d*-H_2tart·$(+)^{CD}_{500}$-[Co(aese)$_3$]·H_2O began to deposit as needle-like crystals. The crystals were filtered and washed with ethanol. Found: C, 23.72; H, 5.22; N, 8.35%. Calcd for *d*-H_2tart·$(+)^{CD}_{500}$-[Co(aese)$_3$]·H_2O=$C_{10}H_{26}N_3O_{10}S_3Co$: C, 23.86; H, 5.21; N, 8.35%.

The diastereomeric molecular compound was converted into $(+)^{CD}_{500}$-[Co(aese)$_3$] by treating with an equimolar amount of $Ca(OH)_2$.

Optically pure complexes corresponding to IV, V, and **VI** were prepared by the oxidation of $(+)^{CD}_{500}$-[Co(aese)$_3$]. The CD spectra were measured with the eluates and their concentrations were calculated from the optical densities referring to those of the corresponding racemates. The oxidation products of $(+)^{CD}_{500}$-II were same as those of $(+)^{CD}_{500}$-III.

(3) Partial Resolution of [*Co(aet)*$_3$]: A solution of 1.0 g (2.0 mmol) of *Λ*-[Co(en)$_3$]Br_3·H_2O in 20 cm^3 of water was added to a solution of 0.5 g (6.5 mmol) of 2-aminoethanethiol and of 0.5 g (12 mmol) of sodium hydroxide in 20 cm^3 of water. The mixture was stirred at 70 °C. After a few minutes, the precipitate of [Co(aet)$_3$] which shows optical activity began to deposit. This was filtered and washed with water. Its oxidative derivatives, II, III, **IV**, **V** and **VI**, were obtained according to the same procedure mentioned above and separated by the column chromatography using anion-exchange resin (QAE-Sephadex A-25, Cl^- form). These oxidation products showed positive CD at the longest wavelength region of the first d-d transition band. Their $\Delta\varepsilon$ values were 13.0% compared with those of optically pure complexes $(+)^{CD}_{500}$-III, $(+)^{CD}_{485}$-**IV**, $(+)^{CD}_{468}$-**V**, and $(+)^{CD}_{440}$-**VI**, respectively, which were obtained from the previous two methods. This enantiomer ratio (+)/(−)=1.30 was used to the calculation of the optical purity of $(+)^{CD}_{500}$-II resolved by column chromatography, which was approximately optically pure.

(4) [*Co(*L*-cym)*$_3$]: The procedure employed for this preparation was analogous to that of [Co(aet)$_3$]. To a solution of 8.0 g (47 mmol) of L-cysteine methyl ester hydrochloride in 70 cm^3 of water was gradually added 5.6 g (15.6 mmol) of Na_3[Co(CO_3)$_3$]·3H_2O, and the mixture was stirred at 95 °C for an hour. The blue-green curdy precipitate of [Co(L-cym)$_3$] was filtered and washed with water. Found: C, 29.89; H, 5.32; N, 8.76%. Calcd for [Co(L-cym)$_3$]·H_2O=$C_{12}H_{26}N_3O_7S_3Co$: C, 30.06; H, 5.47; N, 8.76%.

(5) [*Co(*L*-cyme)*$_n$*(*L*-cymi)*$_{3-n}$] (n=*3, 2, 1, and 0*): These complexes were prepared *via* H_2O_2 oxidation of [Co(L-cym)$_3$] and isolated by the analogous column chromatographic technique used for [Co(aese)$_n$(aesi)$_{3-n}$] (*n*=3, 2, 1, and 0).

To a suspension of 2.0 g (4.2 mmol) of [Co(L-cym)$_3$]·H_2O in 30 cm^3 of water was added 20 cm^3 (12.6 mmol) of 6.43% aqueous H_2O_2 with stirring below 5 °C, leading to an orange-red solution. On addition of acetone and ether, an orange precipitate appeared. This was dissolved in a small amount of water, adsorbed on a column (QAE-Sephadex A-25, *d*-tartrate form) and eluted with water. Four colored bands, orange (II′, major), orange (III′, minor), yellow-orange (**IV′**, major), and orange-yellow (V′, minor), were eluted in this order. Each band was composed of single optical isomer. Therefore, this system showed the high stereoselectivity as well as that of tris(L-cysteinato-*N*,*S*)cobaltate(III) (3−).[6] Some yellow-orange bands remained on the column, which seem to be partially hydrolyzed products because of their negative charges. The absorption and CD spectra of bands II′, III′, **IV′**, and V′ correspond to *n*=3, 3, 2, and 1 of [Co(L-cyme)$_n$(L-cymi)$_{3-n}$], respectively. The insoluble yellow complex [Co(L-cymi)$_3$] (**VI′**) was prepared by oxidation of [Co(L-cym)$_3$] with excess 30% H_2O_2. After concentrating each eluate, a small amount of acetone and ether was added to the solution, and the precipitate was filtered off. Complex II′ as well as **II** partially changed into complex III′ during the crystallization, though the other eluates showed no isomerization. Found for II′: C, 26.48; H, 4.98; N, 7.37%. Calcd for [Co(L-cyme)$_3$]·2H_2O=$C_{12}H_{28}N_3O_{11}S_3Co$: C, 26.42; H, 5.17; N, 7.70%. Found for III′: C, 26.98; H, 4.88; N, 7.89%. Calcd for [Co(L-cyme)$_3$]·1.5H_2O=$C_{12}H_{27}N_3O_{9.5}S_3Co$: C, 26.87; H, 5.07; N, 7.83%. Found for **IV′**: C, 26.01; H, 4.78; N, 7.56%. Calcd for [Co(L-cyme)$_2$(L-cymi)]·1.5H_2O=$C_{12}H_{27}N_3O_{11.5}S_3Co$: C, 26.09; H, 4.93; N, 7.61%. Found for **V′**: C, 26.00; H, 4.61; N, 7.56%. Calcd for [Co(L-cyme)(L-cymi)$_2$]·0.5H_2O=$C_{12}H_{25}N_3O_{11.5}S_3Co$: C, 26.18; H, 4.58; N, 7.63%. Found for **VI′**: C, 25.78; H, 4.72; N, 7.52%. Calcd for [Co(L-cymi)$_3$]=$C_{12}H_{24}N_3O_{12}S_3Co$: C, 25.86; H, 4.34; N, 7.54%.

The complex [Co(L-cymi)$_3$] (**VI′**) was easily hydrolyzed in diluted sodium hydroxide solution (0.1 mol dm^{-3}) and the resulting complex had high solubility. The CD and absorption spectra of this hydrolyzed complex were quite similar to those of [Co(L-cysi)$_3$]$^{3-}$.

*(5) Λ-(*R*)- and Λ-(*S*)-*[*Co(aese)(en)*$_2$]$^{2+}$: *Λ*-[Co(aet)(en)$_2$](ClO_4)$_2$ was obtained according to the procedure previously reported.[5] The stoichiometric oxidation of the *Λ*-complex gave an orange solution. After addition of 2-propanol to the solution, an orange precipitate appeared, which showed almost the same CD spectrum as that of *Λ*-(*R*) isomer in [Co(L-cyse)(en)$_2$]$^+$. The filtrate contained *Λ*-(*S*) isomer predominantly. The concentrations of solutions used for CD spectral measurement were determined from the optical densities referring to that of the racemate.

(6) Na_3[*Co(*L*-cysi)*$_3$]: This compound was prepared *via* oxidation of green Na_3[Co(L-cys)$_3$] with excess 30% H_2O_2. The procedure forms the only one isomer stereoselectively.[6] Found: C, 13.63; H, 4.56; N, 5.31%. Calcd for Na_3[Co(L-cysi)$_3$]·11H_2O=$C_9H_{37}N_3O_{23}S_3CoNa_3$: C, 13.87; H, 4.78; N, 5.31%.

(7) K[*Co(aesi)*$_2$*(*L*-cysi)*]: The solution of 2-aminoethanethiol, L-cysteine, and KOH (2:1:4) was added to the solution of $[Co(NH_3)_6]Cl_3$ (a stoichiometric amount). The mixture was heated until no further evolution of ammonia could be detected. Then an excess of 30% H_2O_2 was added to the reaction mixture. After the column chromatography, the desired complex was obtained. Found: C, 16.07; H, 4.29; N, 7.93%. Calcd for K[Co(aesi)$_2$(L-cysi)]=$C_7H_{23}N_3O_{11}S_3CoK$: C, 16.18; H, 4.46; N, 8.07%.

Measurements. The visible and ultraviolet absorption spectra were measured on a Shimadzu UV-200 and a Hitachi 330 spectrophotometers. The CD spectra were recorded on a JASCO MOE-1 spectropolarimeter. The absorption and CD measurements of the complexes were made in aqueous solutions at ambient temperature. The ^{13}C NMR spectra were measured with a Varian XL-100-15 NMR spec-

trometer in D_2O containing dioxane as an internal standard.

Results and Discussion

Optical Resolution. So far only a limited number of neutral complexes have been optically resolved, where the available methods were stereoselective decomposition by bacteria,[7] circular dichromatic excitation,[8] and column chromatography,[9] no preferential crystallization of a diastereomer having been applied. In the present study, three techniques were applied effectively to the optical resolution of neutral complexes $[Co(aese)_n(aesi)_{3-n}]$ (n=3, 2, 1, and 0). The first method is a modification of column chromatography; the anion-exchange resin (QAE-Sephadex A-25) was used as *d*-tartrate form and the eluting solvent was water. In the course of separation, all eluates contain no salt advantageously. The second method is the preferential crystallization of a diastereomeric molecular compound *d*-H_2tart·$(+)^{CD}_{500}$-$[Co(aese)_3]\cdot H_2O$ (molecular compound of III). This is the first case of optical resolution of a neutral complex *via* diastereomer formation. The composition and structure of this diastereomeric molecular compound has been confirmed by the single crystal X-ray structure analysis.[10] The third method is the substitution reaction with partial retention of configuration (see Experimental).

Geometrical Isomerism. The unsymmetrical nature of bidentate ligands such as 2-aminoethanethiol, L-cysteine methyl ester, and L-cysteine leads to the possibility of two geometrical isomers, *fac*(*S*) and *mer*-(*S*), for the tris(bidentate)cobalt(III) complexes of $[Co(N)_3(S)_3]$ type. It has been shown by the investigations of trinuclear derivatives of $[Co(aet)_3]$[1a] that the complex exists only in the *fac*(*S*) form. The visible and ultraviolet absorption spectra of the present starting thiolato complexes $[Co(aet)_3]$, $[Co(L\text{-}cym)_3]$, and $[Co(L\text{-}cys)_3]^{3-}$ are quite similar as shown in Fig. 1. Furthermore, the ^{13}C NMR spectra of their oxidation products, which have a C_3 symmetry, suggest that the starting complexes have *fac*(*S*) geometry. The energy difference between the two isomers, *fac* and *mer*, has been discussed by Burdett, who concluded that the most stable geometry will be *fac* for a low spin d^6 configuration such as $[Co(CN)_3(H_2O)_3]$, $[Cr(CO)_3(PH_3)_3]$, and $[M(CO)_3(P_4S_3)_3]$ (M=Cr and Mo).[11] A similar trend is also found in the tris(bidentate-*N*,*S*)cobalt(III) complexes.

Characterization of $[Co(aese)_n(aesi)_{3-n}]$ *(n=3, 2, 1, and 0).* Table 1 shows the absorption spectral data of the complexes. The absorption spectra of the complexes containing thiolato groups exhibit a characteristic weak band at *ca.* 17000 cm^{-1}.[12] All the oxidation products did not show this band and therefore contain no thiolato group. The intense absorption bands appeared in the near-ultraviolet region (*ca.* 32000—37000 cm^{-1}) indicate that the coordination of sulfur-containing ligands occurs through the sulfur atoms.[3] Complexes II and III, both of which are the precursors of complexes IV, V, and VI in the oxidation reaction, gave the same absorption spectra (Fig. 2). Since the most intense band at *ca.* 27000 cm^{-1} is due to the sulfenato groups,[3] the two complexes

$[Co(L\text{-}cysi)_3]^{3-}$	26.4(2.90), 32.5(4.43), 35.3(4.25)[sh]

a) Wave numbers are given in 10^3 cm^{-1} unit, log ε (in parentheses) in mol^{-1} dm^3 cm^{-1}, and sh means a shoulder. b) The absorption confficient of the complex could not be determined. c) Obtained by diffuse reflection method in 15000—25000 cm^{-1}. d) 0.1 mol dm^{-3} NaOH solution.

can be identified to the diastereomers of $[Co(aese)_3]$. The gradual decrease in molar extinction coefficients at 27000 cm^{-1} along a series of II (or III)→IV→V just corresponds to the decrease in the number of sulfenato groups. Complex VI does not exhibit the 27000 cm^{-1} band and therefore no sulfenato group exists in this complex. The assignments are well supported by the oxidation reaction scheme (Scheme 1). Thus, complexes II (and III), IV, V, and VI correspond to n=3, 2, 1, and 0 of $[Co(aese)_n(aesi)_{3-n}]$, respectively.

The CD spectra of complexes II, III, IV, V, and VI are shown in Figs. 3 and 4 and Table 2. The

complexes containing sulfenato groups should have two CD contributions, one from the configurational chirality based on the skew pair of chelate rings (Δ or Λ) and the other from the chirality based on the asymmetric sulfur donor atoms of sulfenato groups (*S* or *R*). The oxidation of Λ-[Co(aet)(en)$_2$]$^{2+}$ produced two sulfenato diastereomers Λ-(*R*) and Λ-(*S*), whose absorption and CD spectra are shown in Fig. 5. Both complexes showed a positive CD band at the longest wavelength region of the first d-d absorption band, whereas the almost enantiomeric CD patterns appeared in the remaining regions. Similar results have been reported for the oxidation products of Λ-[Co(L-cyse)(en)$_2$]$^+$;[3c] the configurational chirality dominates the CD band at the longest wavelength region of the first d-d absorption band but the CD bands at remaining regions depend on the chirality of sulfenato group. The complexes of $(+)^{CD}_{500}$-II, $(+)^{CD}_{500}$-III, $(+)^{CD}_{485}$-IV, $(+)^{CD}_{468}$-V, and $(+)^{CD}_{440}$-VI are tentatively assigned to the Λ-configuration on the basis of the sign of the longest wavelength CD band (Figs. 3 and 4). The absolute configuration of sulfur center can be characterized on the basis of the CD sign in the sulfenato absorption band region at *ca.* 27000 cm^{-1}; the (*R*) and (*S*) configurations correspond to a negative and a positive band, respectively. The ^{13}C NMR spectrum of complex III showed only two resonances and that complex II six resonances (Fig. 6 and Table 3). Therefore, the *fac*(*S*)-Λ-(*R*,*R*,*R*) configuration can be assigned for Λ-III and the *fac*(*S*)-Λ-(*R*,*R*,*S*) one for Λ-II. The fact that the oxidation of the com-

TABLE 2. CD DATA OF THE COMPLEXES

[Co(L-cysi)$_3$]$^{3-}$	22.7(−3.16), 25.6(+3.48), 31.8(+17.98), 35.7(−17.20), 41.3(+7.59)

a) Wave numbers are given in 10^3 cm^{-1} unit, $\Delta\varepsilon$ (in parentheses) in mol^{-1} dm^3 cm^{-1}, and sh means a shoulder. b) 0.1 mol dm^{-3} NaOH solution.

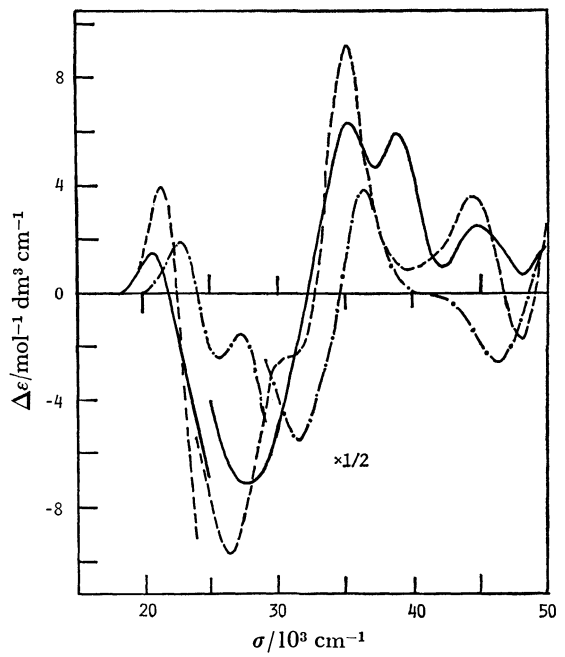

Fig. 4. CD spectra of the complexes $(+)^{CD}_{485}$-IV (——), $(+)^{CD}_{468}$-V (- - -), and $(+)^{CD}_{440}$-VI (—·—).

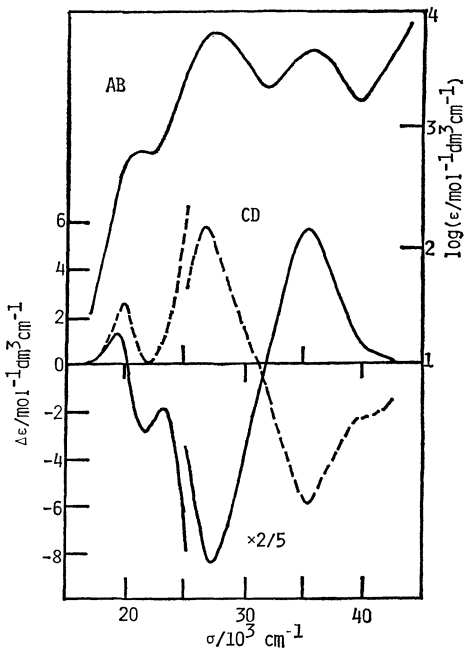

Fig. 5. Absorption and CD spectra of Λ-(*R*)-[Co(aese)-(en)$_2$]$^{2+}$ (——) and Λ-(*S*)-[Co(aese)(en)$_2$]$^{2+}$ (- - -).

plexes Λ-(*R,R,S*)-II and Λ-(*R,R,R*)-III generated the same products leads to an unequivocal assignment of complexes IV and V; $(+)^{CD}_{485}$-IV and $(+)^{CD}_{468}$-V have Λ-(*R,R*) and Λ-(*R*) configurations, respectively. This assignment is consistent with the result of the X-ray single crystal structure analysis of *d*-H$_2$tart·$(+)^{CD}_{500}$-[Co(aese)$_3$]·H$_2$O in which the cobalt(III) complex III has the *fac*(*S*)-Λ-(*R,R,R*) structure.[10]

[*Co*(L-*cyme*)$_n$(L-*cymi*)$_{3-n}$] (n=*3, 2, 1, and 0*). The absorption and CD spectra of complexes II′, III′, IV′, V′, and VI′ (Figs. 7 and 8, and Tables 1 and 2) are similar to those of $(-)^{CD}_{500}$-[Co(aese)$_3$] (II), $(-)^{CD}_{500}$-[Co(aese)$_3$] (III), $(-)^{CD}_{485}$-[Co(aese)$_2$(aesi)] (IV), $(-)^{CD}_{468}$-[Co(aese)(aesi)$_2$] (V), and $(-)^{CD}_{440}$-[Co(aesi)$_3$] (VI), respectively. Furthermore, complex III′ exhibited only four ^{13}C NMR resonances (Table 3), which indicate that complex III′ has the *fac*(*S*)-Λ-(*S,S,S*) structure with C_3 symmetry. The stepwise oxidation scheme of this system is entirely similar to Scheme 1. The assignment of structure is as follows; Λ-(*R,S,S*)-[Co(L-cyme)$_3$] for II′, Λ-(*S,S,S*)-[Co(L-cyme)$_3$] for III′, Λ-(*S,S*)-[Co(L-cyme)$_2$(L-cymi)] for IV′, Λ-(*S*)-[Co(L-

$[Co(aese)_3]$ (III)	42.17, 52.07
$[Co(L\text{-}cyme)_3]$ (III′)	53.58, 54.34, 55.47, 173.55

a) In D_2O containing *ca.* 80 mg of dioxane (δ=67.40) as an internal standard.

cyme)(L-cymi)$_2$] for V′, and Δ-[Co(L-cymi)$_3$] for VI′. Assuming that the ester group $-COOCH_3$ in L-cym$^-$, L-cyme$^-$, or L-cymi$^-$ ligand takes an equatorial orientation, the chelate ring conformations of Δ- and Λ-complexes become $(lel)_3$ and $(ob)_3$, respectively. Because no Λ-isomer was detected in this [Co(L-cyme)$_n$-(L-cymi)$_{3-n}$] system, the experimental result means that the Δ-$(lel)_3$ conformation is of primary importance to the stability of these complexes.

$[Co(L\text{-}cysi)_3]^{3-}$ and $[Co(aesi)_2(L\text{-}cysi)]^-$ Complexes. The absorption and CD spectra of the complexes, $(-)^{CD}_{440}$-[Co(aesi)$_3$], $(-)^{CD}_{440}$-[Co(L-cysi)$_3$]$^{3-}$, and $(-)^{CD}_{440}$-[Co(aesi)$_2$(L-cysi)]$^-$, are shown in Fig. 9, and Tables 1 and 2. These three complexes and $(-)^{CD}_{440}$-[Co(L-cymi)$_3$] show quite similar absorption and CD spectra to one another. Since $(-)^{CD}_{440}$-[Co(aesi)$_3$] and $(-)^{CD}_{440}$-[Co(L-cymi)$_3$] complexes were assigned to the *fac*(*S*)-Δ structure as described above, two remaining complexes can be assigned reasonably to the same *fac*(*S*)-Δ configuration. The geometry of [Co(L-cysi)$_3$]$^{3-}$ assigned from ^{13}C NMR spectrum[13)] is identical with the present results. Thus, it is concluded that the *ac*(*S*) geometry is preferentially formed for the [Co(N)$_3$(S)$_3$] type complexes and Δ-configuration is significantly stable for the complexes containing L-cysteine or its derivatives.

Stereoselectivity of Chiral Sulfenato Sulfur Atoms. The $R \rightleftarrows S$ interconversion of sulfenato group was reported in diluted solution of Λ-(*R*)- or Λ-(*S*)-[Co(L-cyse-*N*,*S*)(en)$_2$]$^+$ complex and the equilibrium ratio *S*/*R* became 3.[3c)] The result was explained as fol-

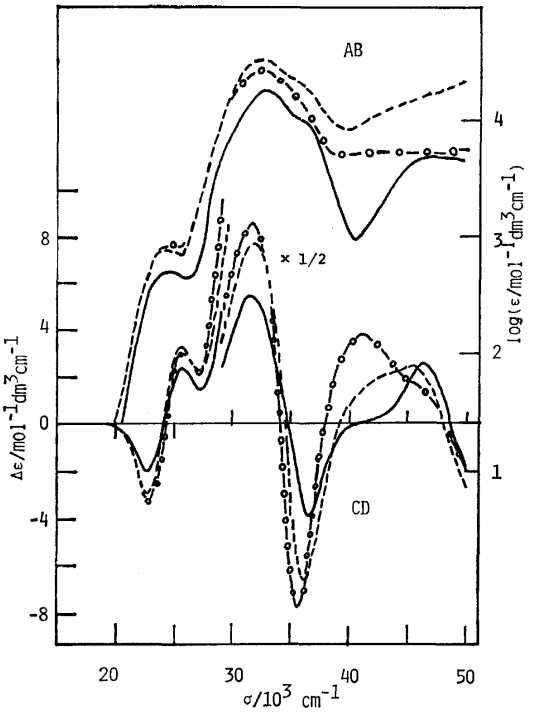

Fig. 9. Absorption and CD spectra of the tris(sulfinato) complexes $(-)^{CD}_{440}$-**VI** (——), $[Co(aesi)_2(L\text{-}cysi)]^-$ (- - -), and $[Co(L\text{-}cysi)_3]^{3-}$ (—○—).

lows; the cobalt–sulfur bond breaking and re-forming occurred to produce the (*S*) configuration, which has lesser steric hindrance toward the ethylenediamine chelate ring because of an equatorial orientation of carboxylate than the (*R*) one. Present systems also showed such interconversions. Complexes II and II′ partially isomerized into complexes III and III′, respectively, during the crystallization in a vacuum rotary evaporator at *ca.* 8 °C. This fact was confirmed by ^{13}C NMR spectra. The spectrum of crystallized complex II was identical to that of a mixture of complexes II and III (Fig. 6 and Table 3). This result was supported by the chromatographic separation. The isomerization of *Δ*-(*R*,*R*,*S*) configuration into *Δ*-(*R*,*R*,*R*) one occurs easily but the reverse does not. Similarily, the crystallized complex II′ was a mixture of complexes II′ and III′, this fact being detected by the ^{13}C NMR spectra (Table 3) and chromatographic separation. The isomerization of *Δ*-(*R*,*S*,*S*) configuration into *Δ*-(*S*,*S*,*S*) one takes place but its reverse change does not occur. Other complexes, *Δ*-(*R*,*R*)-$[Co(aese)_2(aesi)]$, *Δ*-(*R*)-$[Co(aese)_2(aesi)]$, *Δ*-(*S*,*S*)-$[Co(L\text{-}cyme)_2(L\text{-}cymi)]$, and *Δ*-(*S*)-$[Co(L\text{-}cyme)(L\text{-}cymi)_2]$, showed no change even after crystallization.

Figure 10 shows the view of *fac*(*S*)-*Δ*-$[Co(L\text{-}cym)_3]$ projected down the threefold axis. There are six lone pairs on the three sulfur donor atoms, they being divided into two groups, three axial and three equatorial. In the first oxidation process from *fac*(*S*)-$[Co(L\text{-}cym)_3]$ to *fac*(*S*)-$[Co(L\text{-}cyme)(L\text{-}cym)_2]$, the (*R*) and (*S*) configurations will be formed. In the second and third oxidation steps of the remaining sulfur atoms for (*R*)-$[Co(L\text{-}cyme)(L\text{-}cym)_2]$, however, oxygen atom

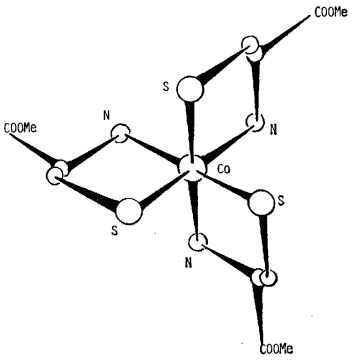

Fig. 10. A perspective view of the *fac*(*S*)-*Δ*-(*lel*)$_3$-$[Co(L\text{-}cym)_3]$ projected down the threefold axis of the complex, the axial or equatorial group on sulfur lone pairs denotes parallel or perpendicular one to the C_3 axis, respectively.

will take preferentially the equatorial position rather than the axial one to avoid the steric interaction with the first sulfenato oxygen. Consequently the (*R*,*S*,*S*) and (*S*,*S*,*S*) configurations will be formed. The consideration agrees with the fact that no *Δ*-(*R*,*R*,*S*) and *Δ*-(*R*,*R*,*R*) isomers occurred in *Δ*-$[Co(L\text{-}cyme)_3]$. The isomerization from *Δ*-(*R*,*S*,*S*) (II′) to *Δ*-(*S*,*S*,*S*) (III′) can be also explained; in the *Δ*-(*S*,*S*,*S*) isomer, all sulfenato oxygens occupy the equatorial positions and the mutual repulsion among them will be weak as compared with *Δ*-(*R*,*S*,*S*) isomer. This argument apparently conflicts with the experimental result that the yield of II′ is significantly higher than that of III′. However, the formation ratio does not reflect the relative stability because the equilibrium state was not realized in our experiment owing to very short reaction time. A similar argument can be also applied to *fac*(*S*)-*Δ*-$[Co(aese)_3]$, in which the *Δ*-(*R*,*R*,*R*) configuration becomes the most stable species.

It has been shown that the oxidation of $[Co(L\text{-}cyse)(en)_2]^+$ or $[Co(L\text{-}pene)(en)_2]^+$ complex proceeds approximately 10^3 times slower than that of the corresponding thiolato complex.[3c] In the present systems of $[Co(L\text{-}cym)_3]$ and $[Co(aet)_3]$, significant amounts of $[Co(L\text{-}cyme)_2(L\text{-}cymi)]$ (*ca.* 50%) and $[Co(aese)_2(aesi)]$ (*ca.* 30%) were nevertheless derived by the very short reaction time, further oxidation products, V′ and VI′ or V and VI, being in small yields. Product IV or IV′ is regarded as the superimposed one of II and III or II′ and III′, respectively. Four oxygen atoms occupy three equatorial and one axial positions and two axial positions remain unoccupied in both complexes. Therefore, the steric hindrance in IV (or IV′) is not largely different from that in II and III (or II′ and III′). On the other hand, complexes V and VI (or V′ and VI′) require the further oxygen attack to the remaining axial positions. Such a process seems to have a large energy barrier.

Effect of Protolytic Behavior of Ligands on Formation Rates of Mono-complexes of Nickel(II) Ion with 2,2′-Bipyridine and 1,10-Phenanthroline in Aqueous Solution

Isao Ando, Shigeyoshi Nishijima,† Kikujiro Ujimoto, and Hirondo Kurihara*

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma 11, Jonan-ku, Fukuoka 814-01

(Received January 22, 1982)

The mono-complex formation of nickel(II) ion with 2,2′-bipyridine(bpy) and 1,10-phenanthroline (phen) was studied in aqueous solution by means of a stopped-flow method. The apparent complex formation rates of the Ni(II)–bpy and Ni(II)–phen complexes depended on the pH of the solution. The rate constants of the mono-complex formation with the ligand in the free base form, k_f, and that with the monoprotonated ligand, k_{fh}, were evaluated from the rate-[H$^+$] profiles in the region of high hydrogen ion concentration where the pseudo-equilibrium of acid dissociation of the ligands was attained during the complex formation. The rate constants determined for the Ni(II)–phen were $k_f=(2.6\pm0.3)\times10^3$ mol^{-1} dm^3 s^{-1} and $k_{fh}=2.4\pm0.3$ mol^{-1} dm^3 s^{-1}, which are practically the same as those reported elsewhere. On the other hand, the rate constants for the Ni(II)–bpy were $k_f=(5.3\pm1.2)\times10^3$ mol^{-1} dm^3 s^{-1} and $k_{fh}=5.0\pm2.6$ mol^{-1} dm^3 s^{-1}, which are quite different from the values reported by other researchers. The validity of the present data was discussed in terms of slow proton-transfer reactions of the ligands.

Nickel(II) ion is one of the ions suitable for kinetic studies on complex formation because it has the slowest rate among metal ions which form labile octahedral complexes. In addition, the behavior of this nickel(II) ion is representative. Therefore, the complex formation reactions of nickel(II) ion have been investigated in detail by many workers.[1–17]

Cassatte *et al.*[18] studied the complex formation of nickel(II) ion with a number of ligands involving 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen). They reported that both the monoprotonated form and the free base form of the ligands take part in the complex formation and that the rate constant with the former is much smaller than that with the latter because of the shielding effect on the reaction site by a proton. The rate constants with the ligand in the two forms were evaluated separately from the rate-[H$^+$] profiles which were obtained by kinetic measurements of apparent rates at various pH, assuming that the pseudo-equilibrium between the two forms of the ligand is attained throughout the complex formation.[18–22]

On the other hand, we have recently found that ligands such as bpy and phen undergo an unexpectedly slow reaction with respect to the proton-transfer process.[23,24] This fact suggests that in the complex formation with bpy and phen there is a region of hydrogen ion concentration where the pseudo-equilibrium of acid dissociation of the ligands is no longer maintained and hence the proton-transfer process of the ligands is a rate-determining step. The rate constants evaluated from the kinetic data in such a hydrogen ion concentration range should be erroneous.

Therefore, this study was undertaken in order to confirm that the rate-determining step interchanges depending on hydrogen ion concentration for the mono-complex formation of nickel(II) ion with bpy and phen. The rate constants of the complex formation were determined in the region of hydrogen ion concentration where the pseudo-equilibrium of acid dissociation holds during the reaction.

Theoretical

With a ligand of weak acids such as bpy and phen, the mono-complex formation of nickel(II) ion in aqueous solution is thought to proceed through both reaction paths, 1 and 2:[18]

$$Ni^{2+} + L \xrightarrow{\text{(rate f)}} NiL^{2+}, \quad (1)$$

$$Ni^{2+} + HL^+ \xrightarrow{\text{(rate fh)}} NiL^{2+} + H^+, \quad (2)$$

where L and HL$^+$ represent the free base form and the monoprotonated form of the ligand, respectively, and (rate f) and (rate fh) denote the rates of the Reactions 1 and 2, respectively. Assuming that the diprotonated species of the ligand, H_2L^{2+}, is negligible and that the equilibrium between HL$^+$ and L,

$$HL^+ \overset{K_2}{\rightleftharpoons} L + H^+, \quad (3)$$

holds in the whole course of the complex formation, the acid dissociation constant, K_2, can be introduced into a rate expression. Since the backward reactions of Eqs. 1 and 2 can be ignored in the early stage of the reaction, the formation rate of the mono-complex is expressed by

$$\begin{aligned} d[NiL^{2+}]/dt &= (k_f[L]+k_{fh}[HL^+])[Ni^{2+}] \\ &= \{(k_f+k_{fh}[H^+]/K_2)/(1+[H^+]/K_2)\}[Ni^{2+}][L'], \end{aligned} \quad (4)$$

where k_f and k_{fh} denote the rate constants of the Reactions 1 and 2, respectively, and [L′] designates the analytical concentration of the ligand. Consequently, the apparent second order rate constant, k_{obsd}, can be correlated with k_f and k_{fh} by

$$k_{obsd}(1+[H^+]/K_2) = k_f + k_{fh}[H^+]/K_2. \quad (5)$$

As long as the equilibrium of Eq. 3 holds during the complex formation, the k_f and k_{fh} values can be evaluated from the k_{obsd} values at various hydrogen ion concentrations according to Eq. 5.

† Present address: Atom Chemical Paint Co. Ltd., Funado, Itabashi-ku, Tokyo 174.

However, Eq. 5 is not applicable when the deprotonation rate of HL^+, (rate dp), or the protonation rate of L, (rate p), in Reaction 3 is slower than the (rate f) or the (rate fh), that is, when the pseudo-equilibrium between HL^+ and L does not hold in progress of Reactions 1 and 2. Namely, the requirement for the applicability of Eq. 5 is

$$\text{(rate dp)} > \text{(rate f) and (rate p)} > \text{(rate fh)}. \quad (6)$$

These four rates for the mono-complex formation in acidic solution are given by

$$\text{(rate f)} = k_f[Ni^{2+}][L], \quad (7)$$

$$\text{(rate fh)} = k_{fh}[Ni^{2+}][HL^+], \quad (8)$$

$$\text{(rate dp)} = k_{dp}[HL^+], \quad (9)$$

and

$$\text{(rate p)} = k_p[H^+][L], \quad (10)$$

where k_{dp} and k_p are the rate constants of the forward and the backward reaction of Eq. 3, respectively. The contribution of hydroxide ion is negligibly small in acidic solution.[23,24] The (rate fh), (rate dp), and (rate p) decrease and the (rate f) increases with lowering hydrogen ion concentration. Therefore, the pseudo-equilibrium of the ligand holds in adequately high hydrogen ion concentration, but it might fail at lower hydrogen ion concentration.

Experimental

Materials and Sample Solutions. Nickel(II) perchlorate was synthesized with nickel(II) carbonate and perchloric acid in the usual way. 2,2′-Bipyridine was purchased from Wako Pure Chemical Ind. and 1,10-phenanthroline monohydrate from Nakarai Chemicals; these ligands were used without further purification. All other chemicals were of guaranteed reagent grade and used without further purification, unless otherwise noted.

The stock solution of nickel(II) ion was prepared by dissolving nickel(II) perchlorate in deionized-distilled water. The concentration was determined by a chelate titration with edta. The stock solution of bpy or phen was prepared by dissolving a weighed amount of it in water. These stock solutions were diluted appropriately for kinetic measurements. The ionic strength of the solution was adjusted to 0.20 mol dm^{-3} with sodium perchlorate except for the case of evaluating the effect of ionic strength on the formation rate constant of the Ni(II)–bpy complex.

Kinetic Measurements. The rates of the complex formation were measured by means of a Union RA-1300 stopped-flow spectrophotometer at 25.0 °C. In order to determine the formation rate of a mono-complex, the concentration of nickel(II) ion to be mixed in the stopped-flow apparatus was one hundred or more times that of the ligand. The pH values of both the nickel(II) ion and ligand solutions to be mixed were adjusted to be the same within the 0.05 pH unit with perchloric acid. The change in absorbance of the mixture was followed at the wavelength at which the absorbance change accompanied by the complex formation was most marked. The optimum wavelength varied slightly depending on the pH of the solution in the vicinity of 314 nm for bpy and 277 nm for phen, respectively.

Both of the nickel(II) ion and ligand solutions were thermally equilibrated at 25.0 °C in separate reservoirs of the stopped-flow apparatus. Equal volumes of them were mixed instantaneously by a pressure-drive device. The change in absorbance of the mixture at the optimum wavelength was stored in a high speed memory unit and displayed on an X-Y recorder as a function of time. The pseudo-first order rate constant was determined from the first order plot of the concentration of mono-complex, $[NiL^{2+}]$, against time. The apparent rate constant of the second order, k_{obsd}, was obtained by dividing the pseudo-first order rate constant by the concentration of nickel(II) ion existing in large excess.

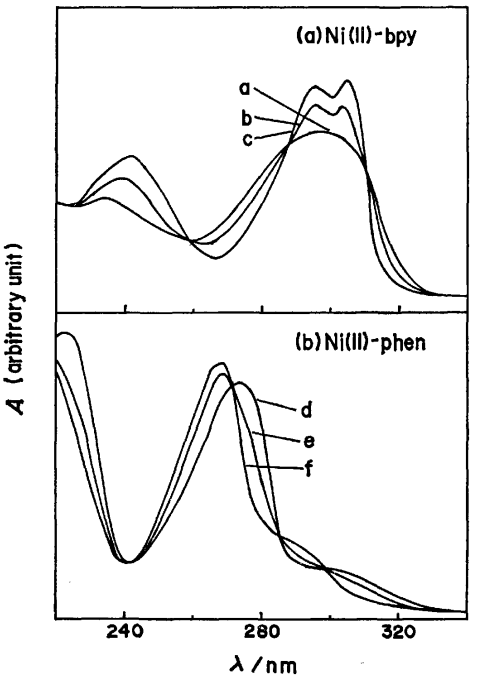

Fig. 1. Rapid scanning spectra of mono-complex of nickel(II) ion with bpy or phen at 25.0 °C. The pHs are 3.99 for the Ni(II)–bpy complex and 1.90 for the Ni(II)–phen complex. Times after mixing: a, 0—10 ms; b, 1.9—2.0 s; c, 7.9—8.0 s; d, 0—10 ms; e, 4.9—5.0 s; f, 10—20 s.

Results and Discussion

Figure 1 shows a typical example of the spectral change of the mixed solution of nickel(II) ion and bpy or phen, measured by a rapid scanning technique during the complex formation. The spectra of c and f in Fig. 1 were identical with those of the mixed solutions at equilibrium which contain nickel(II) ions in large excess to the respective ligands. This indicates that only the mono-complex formation of nickel(II) ion with bpy or phen can be followed spectrophotometrically under the experimental conditions.

The apparent second order rate constant for the Ni(II)–bpy complex formation tended to decrease slightly with the increasing ionic strength from 0.1 to 1.0 mol dm^{-3}. The k_{obsd} values for the Ni(II)–bpy and the Ni(II)–phen complex formations were almost independent of the concentration of nickel(II) ion, as can be seen in Figs. 2 and 3. In contrast to the insensitiveness to the ionic strength and the concentration of nickel(II) ion, the k_{obsd} values varied significantly depending on the pH of the solutions and increased markedly with increasing pH.

Figures 4 and 5 show the plots of $k_{obsd}(1+[H^+]/K_2)$

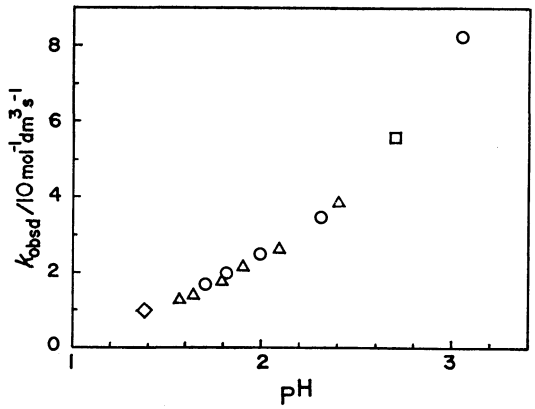

Fig. 2. pH dependence of k_{obsd} values for the Ni(II)–bpy complex. [Ni^{2+}]: □, 5.28×10^{-3}; ○, 9.26×10^{-3}; ◇, 1.06×10^{-2}; △, 2.11×10^{-2} mol dm^{-3}; [bpy]: 5.00×10^{-5} mol dm^{-3}. Temperature: 25.0 °C.

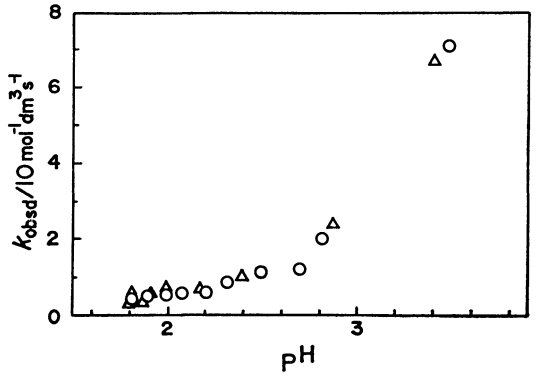

Fig. 3. pH dependence of k_{obsd} values for the Ni(II)–phen complex. [Ni^{2+}]: ○, 5.28×10^{-3}; △, 2.40×10^{-2} mol dm^{-3}; [phen]: 2.50×10^{-5} mol dm^{-3}. Temperature: 25.0 °C.

against $[H^+]/K_2$. For the Ni(II)–bpy system, the plot seems to consist of two straight lines: one in the region of high hydrogen ion concentration, the other in that of low concentration. The boundary of the two regions somewhat changes depending on the concentration of nickel(II) ion. On the other hand, the plot for the Ni(II)–phen system consists approximately of one straight line under the present experimental conditions.

As mentioned in Theoretical, it was assumed in this study that the ligands exist as the monoprotonated form and/or as the free base form. However, if bpy and phen exist partly as a diprotonated species in the range of high hydrogen ion concentration, the rates of the complex formation shall be reduced because of the unreactivity of H_2L^{2+}. Based on the pK_1 values of H_2L^{2+}, 1.5 for bpy and 1.9 for phen, reported by Condike and Martell,[25] the amount of H_2L^{2+} cannot be ignored in the acidic region. Other workers, however, reported the pK_1 values of −0.2——0.5 for bpy[26-30] and −0.9——1.7 for phen.[30-33] Hence, we also determined the pK_1 value of bpy by a spectrophotometric method under the present experimental conditions and obtained the value of −0.35. This pK_1 value, different from that of Condike and Martell, indicates that the H_2L^{2+} species of bpy is

negligible in the pH region of this study (pH 1.5—5.0). The H_2L^{2+} of phen can be also neglected, because of its pK_1 values of −0.9——1.7 given in the literature.

Consequently, it is concluded that the pseudo-equilibrium of the proton transfer on bpy holds in the region represented by the straight line in the higher hydrogen ion concentration in Fig. 4. The pseudo-equilibrium may fail in hydrogen ion concentrations lower than the cross point of the two straight lines. On the other hand, the pseudo-equilibrium of proton transfer on phen is established in the whole region of hydrogen ion concentration in Fig. 5. Table 1 lists the k_f and k_{fh} values obtained from the intercept and the slope of the linear plot in the high hydrogen ion concentration in Fig. 4 and from those in Fig. 5 by the least-squares method, together with the literature values.

In order to add support to the validity of k_f and k_{fh} determined in the present study, the establishment of the pseudo-equilibria of acid dissociation of the

ligands were confirmed as follows. The rates of the processes 1 to 3 at $t=0$ were calculated as functions of hydrogen ion concentration according to Eqs. 7 to 10 by use of the k_f and k_{fh} values in this study, the k_{dp} values of bpy and phen in the previous papers,[23,24] and the initial concentrations of the species participating in the reaction. An example of the results is shown in Fig. 6. The $(\text{rate p})_0$ is identical with the $(\text{rate dp})_0$ at $t=0$. Then the $(\text{rate p})_0$ is greater than the $(\text{rate fh})_0$ over the whole range of hydrogen ion concentration investigated. Accordingly, the inequality 6 is satisfied at $t=0$, in the high hydrogen ion concentration where the $(\text{rate dp})_0$ is larger than the $(\text{rate f})_0$. At $t>0$, the (rate p) and (rate dp) values will no longer be identical with each other, owing to the difference in the magnitude between the $(\text{rate f})_0$ and $(\text{rate fh})_0$. The (rate p) and (rate dp) values, however, do not presumably vary so much that the inequality 6 will also fail in the high hydrogen ion concentration. Consequently, the requirement 6 may be satisfied in the hydrogen ion concentrations higher than that at the cross point of the (rate f) and (rate dp) curves. For the Ni(II)–bpy system, the hydrogen ion concentrations at the cross points, $[H^+]_{cp}$, were calculated to be 4.0×10^{-3} mol dm^{-3} at $[Ni^{2+}]=9.26\times10^{-3}$ mol dm^{-3} and 9.2×10^{-3} mol dm^{-3} at $[Ni^{2+}]=2.11\times10^{-2}$ mol dm^{-3}. These values agree approximately with 8.2×10^{-3} mol dm^{-3} at $[Ni^{2+}]=9.26\times10^{-3}$ mol dm^{-3} and 1.2×10^{-2} mol dm^{-3} at $[Ni^{2+}]=2.11\times10^{-2}$ mol dm^{-3}, which were obtained from the critical points deviating from the straight line in the high hydrogen ion concentration in Fig. 4. For the Ni(II)–phen system, the $[H^+]_{cp}$ values were calculated to be 5.4×10^{-4} mol dm^{-3} at $[Ni^{2+}]=5.28\times10^{-3}$ mol dm^{-3} and 2.4×10^{-3} mol dm^{-3} at $[Ni^{2+}]=2.40\times10^{-2}$ mol dm^{-3}. However, no critical point was observed in Fig. 5. Since the $[H^+]_{cp}$ values calculated for the Ni(II)–phen system are small relative to the hydrogen ion concentration investigated, it is likely that the inequality 6 holds in all the hydrogen ion concentration region in Fig. 5. When the pseudo-equilibrium of acid dissociation of ligands is attained, Eqs. 7 and 9 give the following expression with respect to $[H^+]_{cp}$:

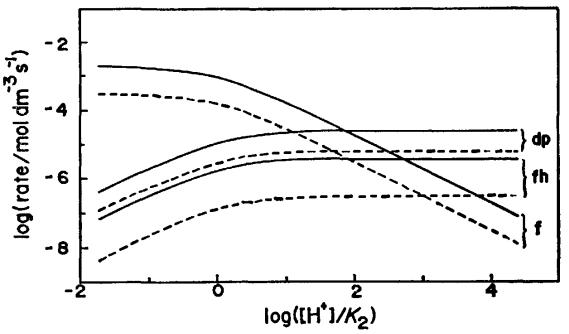

Fig. 6. Relationship between initial rates and $[H^+]/K_2$ at 25.0 °C.
Curve f, (rate f); curve fh, (rate fh); curve dp, (rate dp). Solid lines: for the Ni(II)–bpy complex, $[Ni^{2+}]=9.26\times10^{-3}$, $[bpy]=5.00\times10^{-5}$ mol dm^{-3}; broken lines: for the Ni(II)–phen complex, $[Ni^{2+}]=5.28\times10^{-3}$, $[phen]=2.50\times10^{-5}$ mol dm^{-3}.

$$[H^+]_{cp} = k_f K_2 [Ni^{2+}]/k_{dp}, \quad (11)$$

because the (rate f) is equal to the (rate dp) at the hydrogen ion concentration of $[H^+]_{cp}$. The $[H^+]_{cp}$ value obtained from the plot in Fig. 4 for the Ni(II)–bpy system increased with the increasing nickel(II) ion concentration, in agreement with the prediction of Eq. 11. The appearance of two regions in Fig. 4 can thus be interpreted in terms of the pseudo-equilibrium of acid dissociation of the ligand.

As can be seen in Table 1, the rate constants for the Ni(II)–phen complex obtained in this study agree well with the literature values.[11,16,18,19] In contrast, the k_f and k_{fh} values for the Ni(II)–bpy complex are considerably different from those reported by other workers.[9,11,16,18] This discrepancy is probably attributable to the fact that all the previous data were obtained under the conditions where the pseudo-equilibrium of acid dissociation of bpy failed during the mono-complex formation. Accordingly, it is concluded that the careful examination for the rate-determining step is necessary to evaluate the rate constant of the complex formation especially with ligands showing slow protolytic properties.

The authors wish to thank Professor S. Kida and Associate Professor H. Okawa of Kyushu University for valuable discussions.

Electron Transfer Activation in the Oxidative Addition of Iodine to Rhodium(I) Complexes

Shunichi Fukuzumi, Nobuaki Nishizawa, and Toshio Tanaka*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 5, 1982)

The kinetics of the oxidative addition of iodine to the following isocyaniderhodium(I) monomers and dimers in MeCN has been examined; $[Rh(RNC)_4]^+$, $[Rh(RNC)_2(PPh_3)_2]^+$, $[Rh_2(dppm)_2(RNC)_4]^{2+}$, and $[Rh_2(dicp)_4]^{2+}$ (R=alkyl, aryl; dppm=bis(diphenylphosphino)methane; dicp=1,3-diisocyanopropane). The reaction proceeds *via* two consecutive steps which consist of the formation of the initial adduct followed by the intramolecular isomerization to yield the final *trans*-adduct. The kinetic results for the first step of the oxidative addition reactions suggest that there exist three kinds of intermediates formed between the Rh(I) complex and iodine with 1:1, 1:2, and 2:1 stoichiometry prior to the formation of the initial adduct. This mechanism coincides with that for the electron transfer reactions between the Rh(I) complexes and inorganic oxidants such as $[Fe(N\text{-}N)_3]^{3+}$ (N-N=1,10-phenanthroline and 2,2′-bipyridine). The values of the rate constants for the first step of the oxidative addition of iodine to dppm- or dicp-bridged Rh(I) dimers are found to agree with those for the electron transfer reactions between the same reactants by using linear free energy relationships. The possibility of electron transfer activation as the rate determining step in the oxidative addition to Rh(I) complexes is discussed.

Coordinatively unsaturated d^8 metal complexes are converted into octahedral d^6 metal complexes by the oxidative addition of polar or highly polarizable addenda such as alkyl halides RX and halogens X_2.[1,2] Despite extensive studies on the mechanism of the oxidative additions from the importance of their key role in various metal catalyzed processes,[1-3] there has been no simple generalization to predict the reactivities of the metal complexes. Such a situation in organo-transition metal chemistry is in a marked contrast to organic reaction systems, where reactivities of organic substrates have been summarized as a number of linear free energy relationships such as the Taft σ^* constant in electrophilic additions of X_2 to olefins and the Brown σ^+ constant in electrophilic aromatic substitutions with X_2.[4] These constants represent donor properties of substituents of the organic substrates, providing quantitative prediction on the change of reactivities of the substrates with different substituents.[5]

Our aim in this study is to understand the change of the reactivities of d^8 metal complexes in the oxidative addition reactions in terms of the donor properties of d^8 metal complexes with various ligands. The system we chose for study is the oxidative addition of iodine to Rh(I) (d^8) complexes.[6,7] Rhodium(I) complexes were selected since we have previously reported the electrochemistry of Rh(I) complexes as well as the electron transfer reactions with inorganic oxidants[8,9] which revealed the donor properties of the Rh(I) complexes. Thus, the kinetic study on the oxidative addition reactions of the same series of Rh(I) complexes with iodine allows the direct comparison of the reactivities as well as the mechanisms for the oxidative addition reactions with those for the electron transfer reactions of the Rh(I) complexes.

Experimental

Materials. Tetrakis(isocyanide)- and bis(isocyanide)-bis(triphenylphosphine)rhodium(I) perchlorates used in this study were prepared as described previously ($[Rh(RNC)_4]^+$: R=*p*-MeC_6H_4, 2,4,6-$Me_3C_6H_2$, Ph, $PhCH_2$, *t*-Bu, C_6H_{11}; $[Rh(RNC)_2(PPh_3)_2]^+$:R=*p*-$MeOC_6H_4$, 2,4,6-$Me_3C_6H_2$).[8,10] Ligand-bridged complexes of Rh(I) dimer of the $[Rh_2(dppm)_2(RNC)_4](ClO_4)_2$ (dppm=bis(diphenylphosphino)-methane; R=Ph, *p*-$MeOC_6H_4$, *t*-Bu, $PhCH_2$)[11] were prepared by the addition of dppm to a solution of the corresponding $[Rh(RNC)_4](ClO_4)$ in acetone by the procedure analogous to the literature.[7a,9] Another ligand-bridged complex of Rh(I) dimer, $[Rh_2(dicp)_4]Cl_2$ (dicp=1,3-diisocyanopropane),[12] was prepared by the reaction of dicp with [Rh(cyclooctadiene)Cl]$_2$[13] in chloroform. Since the chloride salt formed in the reaction is sparingly soluble in acetonitrile, the tetraphenylborate salt which is soluble in acetonitrile was prepared by methathesis in methanol. Iodine was sublimed three times prior to use. Acetonitrile used as a solvent for kinetic and electrochemical measurements was purified by a standard procedure.[14]

Kinetic Measurements. Acetonitrile solutions of the Rh(I) complexes as well as those of iodine were freshly prepared before use. The reactions of Rh(I) complexes with iodine were carried out at 298 K in the presence of a large excess of either Rh(I) complexes or iodine. Rates of the reactions were measured by monitoring the change of the absorbance (at 360 nm) due to the reaction by using a Union RA-103 stopped-flow spectrophotometer. The ionic strength of the reaction medium was adjusted to 0.1 with *n*-Bu_4NClO_4. The change of the absorbance at 360 nm was expressed as two consecutive pseudo-first-order steps with significantly different half-lives, *e.g.*, the half-life of the first step was 1.2×10^3 times shorter than the second step for the reaction of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ (2.43×10^{-4} mol dm^{-3}) with iodine (2.72×10^{-3} mol dm^{-3}) in MeCN at 298 K. The two steps were then well separated by changing the monitoring time scale; the first and the second steps were monitored for 50 ms—1 s and 200—1000 s, respectively. The pseudo-first-order rate constants $k^{(1)}$ and $k^{(2)}$ for the first and the second steps were determined from Eqs. 2 and 3, respectively, by the least squares curve fit, using a microcomputer Union System 77;

$$A^{(1)} = A_\infty^{(1)} + (A_0^{(1)} - A_\infty^{(1)}) \exp(-k^{(1)}t) \quad (2)$$

$$A^{(2)} = A_\infty^{(2)} + (A_0^{(2)} - A_\infty^{(2)}) \exp(-k^{(2)}t) \quad (3)$$

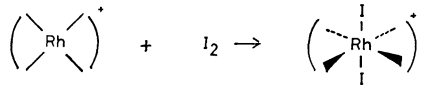
where $A^{(1)}$ and $A^{(2)}$ are the absorbances at 360 nm for the first and second steps, respectively, in the two different time scales, $A_0^{(1)}$ and $A_0^{(2)}$ are the initial absorbances, and $A_\infty^{(1)}$ and $A_\infty^{(2)}$ are the final absorbances due to the products in the first and second steps, respectively. It should be noted that $A_\infty^{(1)}=A_0^{(2)}$. It was confirmed that the pseudo-

first-order rate constants $k^{(1)}$ and $k^{(2)}$ were independent of the monitoring wavelengths in the range 340—450 nm.

Cyclic Voltammetry. The cyclic voltammograms (CV) of Rh(I) complexes were obtained as described previously.[9] The CV of iodine in MeCN containing 0.1 mol dm^{-3} *n*-Bu_4NClO_4 as a supporting electrolyte was measured on a Hokuto Denko Model HA-301 potentiostat/galvanostat at 298 K, using a platinum microelectrode and a Ag/Ag^+ ($AgNO_3$ 0.1 mol dm^{-3}) reference electrode. A reversible CV wave was observed at $E_{1/2}=0.34$ V *vs.* Ag/Ag^+ with the peak separation of 0.1 V, which corresponds to the two electron processes; $I_2 \overset{2e}{\rightleftharpoons} 2I^-$.

Results and Discussion

Kinetics and Mechanism of Oxidative Addition of Rh(I) Complexes with Iodine. The final products of the oxidative addition of I_2 to Rh(I) complexes have well been established as the *trans*-adducts (Eq. 4).[6,7] Typical decay curves of the absorbance at 360 nm



(4)

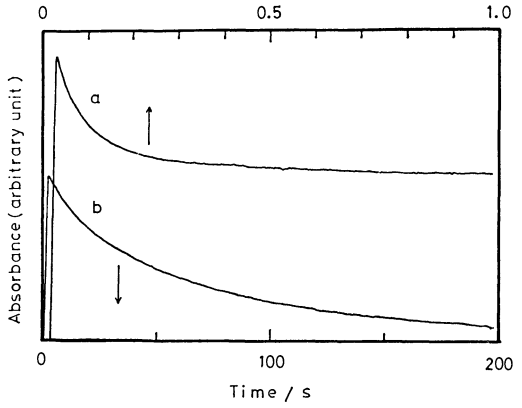


Fig. 1. Decay curves of the absorbance at 360 nm for the reaction of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ (2.4×10^{-4} mol dm^{-3}) with I_2 (2.7×10^{-3} mol dm^{-3}) in MeCN containing 0.1 mol dm^{-3} *n*-Bu_4NClO_4 at 298 K; a) monitored for 1 s, b) monitored for 200 s.

Table 1. Observed rate constants for the two consecutive steps for the reactions of Rh(I) complexes with excess I_2 in MeCN at 298 K

$[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ (mol dm^{-3})	I_2 (mol dm^{-3})	$k^{(1)}$ / s^{-1}	$k^{(2)}$ / s^{-1}

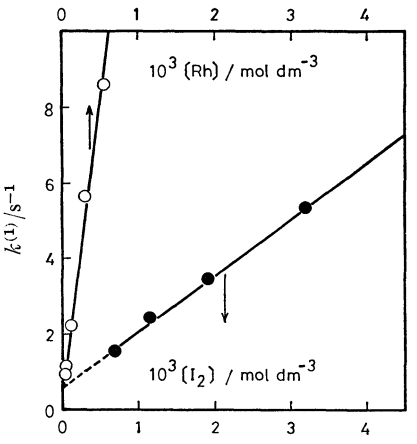

Fig. 2. Kinetics of the oxidative addition of $[Rh(PhCH_2NC)_4]^+$ with I_2; the pseudo-first-order rate constant $k^{(1)}$ for the first step as a function of large excess I_2 (●) or $[Rh(PhCH_2NC)_4]^+$ (○) in MeCN at 298 K.

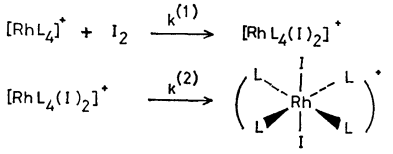
after mixing $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ and excess I_2 in MeCN at 298 K are shown in Fig. 1, which indicates that the reaction proceeds *via* two consecutive pseudo-first-order steps with different half-lives of 44 ms and 53 s. The reaction rates in the two steps differ from each other sufficiently to allow the determination of both rate constants separately. As shown in Table 1, the pseudo-first-order rate constant $k^{(2)}$ for the second step is independent of the I_2 concentration, while $k^{(1)}$ for the first step varies with the I_2 concentration. Thus, the second step is suggested as an intramolecular process. Since the final product is the *trans*-adduct, the two consecutive steps may consist of the formation of the initial *cis*-adduct followed by the isomerization to the *trans*-adduct (Eqs. 5 and 6). Such an intramolecular *cis-trans* isomerization has



been reported also for transition metal complexes of $[Rh(I)_2(dtc)L_2]$ (dtc=S_2CNMe_2, L=2,4,6-$Me_3C_6H_2$-NC),[6a] $[Cr(CO)_4(C(OMe)Me)(PR_3)]$ (R=C_2H_5, C_6H_{11}),[15] $[Ru(CO)_4(SiCl_3)_2]$,[16] and $[Os(CO)_4$-$(SiMe_3)_2]$.[16]

On the other hand, the pseudo-first-order rate constant $k^{(1)}$ for the first step is linearly dependent on the I_2 concentration as shown in Fig. 2. Thus, the first step may involve a bimolecular process. However, the $k^{(1)}$ values in the presence of large excess Rh(I) complex differ significantly from those in the presence of large excess I_2 when they are compared at the same concentrations as seen in Fig. 2, where the reaction of $[Rh(PhCH_2NC)_4]^+$ with I_2 is illustrated as a typical example. Such different $k^{(1)}$ values suggest that the reactive species are different, depending upon the conditions where either I_2 or the Rh(I) complex is present in large excess. Since the extrapolated $k^{(1)}$ values to the zero concentration in both cases, *i.e.*, the intercepts in Fig. 2, are the same,

Scheme 1.

it is suggested that there exist three kinds of intermediates, one of which is common for both cases. Thus, the kinetics for the first step may best be interpreted by assuming three kinds of complexes formed between the Rh(I) cation and I_2 with 1:1, 1:2, and 2:1 stoichiometry (Scheme 1). According to Scheme 1, the pseudo-first-order rate constants $k_I^{(1)}$ and $k_{Rh}^{(1)}$ for the first step are expressed by Eqs. 10 and 11 in the presence of excess I_2 and $[RhL_4]^+$, respectively, when a steady state approximation is applied to the three complexes with 1:1, 1:2, and 2:1 mole ratios. When $K_1[I_2]$, $K_1[Rh] \gg 1$ and $K_2[I_2]$, $K_3[Rh] \ll 1$, Eqs. 10 and 11 are reduced to Eqs. 12 and 13, respectively.

$$k_I^{(1)} = \frac{k_1K_1[I_2] + k_2K_1K_2[I_2]^2}{1 + K_1[I_2] + K_1K_2[I_2]^2} \quad (10)$$

$$k_{Rh}^{(1)} = \frac{k_1K_1[Rh] + k_3K_1K_3[Rh]^2}{1 + K_1[Rh] + K_1K_3[Rh]^2} \quad (11)$$

Thus, the intercept of the plots of $k_I^{(1)}$ *vs.* $[I_2]$ and $k_{Rh}^{(1)}$ *vs.* [Rh] in Fig. 2 gives the k_1 value and the slopes of $k_I^{(1)}$ and $k_{Rh}^{(1)}$ yield the k_2K_2 and k_3K_3 values, respectively. The same kinetic formulation as Eq. 12 was applied to dppm- and dicp-bridged Rh(I)

$$k_I^{(1)} = k_1 + k_2K_2[I_2] \quad (12)$$

$$k_{Rh}^{(1)} = k_1 + k_3K_3[Rh] \quad (13)$$

dimers, $[Rh_2(dppm)_2(RNC)_4]^{2+}$ and $[Rh_2(dicp)_4]^{2+}$, as well as other $[RhL_4]^+$ monomers. The k_1 and k_2K_2 values for reactions of these complexes in the presence of excess I_2 are listed in Table 2.

Mechanistic Comparison for Reactions of Rh(I) Complexes between the Oxidative Addition of Iodine and the Electron Transfer with Inorganic Oxidants. The Rh(I) complexes employed in this study are readily oxidized by inorganic oxidants such as $[Fe(N\text{-}N)_3]^{3+}$ (N-N= 1,10-phenanthroline and 2,2′-bipyridine) and $[Co(bpy)_3]^{3+}$ (bpy=2,2′-bipyridine) (Eq. 14);[8,9]

$$[RhL_4]^+ + Ox \longrightarrow [RhL_4]^{2+} + Ox^- \quad (14)$$

where Ox represents the inorganic oxidants. Based on the kinetic study the following scheme has previously been presented for the electron transfer reactions between the Rh(I) complexes and inorganic oxidants;[8,9]

$$[RhL_4]^+ + Ox \overset{K_1'}{\rightleftharpoons} ([RhL_4]^+\ Ox) \xrightarrow[e.t.]{k_1'} \quad (15)$$

$$([RhL_4]^+\ Ox) + Ox \overset{K_2'}{\rightleftharpoons} ([RhL_4]^+\ 2Ox) \xrightarrow[e.t.]{k_2'} \quad (16)$$

$$([RhL_4]^+\ Ox) + [RhL_4]^+ \overset{K_3'}{\rightleftharpoons} (2[RhL_4]^+\ Ox) \xrightarrow[e.t.]{k_3'} \quad (17)$$

Scheme 2.

where e.t. represents the electron transfer reaction in Eq. 14. It is noteworthy that Scheme 1 for the oxidative addition of Rh(I) complexes with I_2 is equivalent to Scheme 2 for the electron transfer reactions of the same Rh(I) complexes with inorganic oxidants, as characterized by three kinds of complexes formed between the Rh(I) cation and I_2 or Ox with 1:1, 1:2, and 2:1 stoichiometry. Such complex formation may occur through the d_{z^2} HOMO orbital of the Rh(I) complex[17] since a given Rh(I) complex can interact with I_2, Ox, or another Rh(I) complex at both sides of the square-planar Rh(I) complex. The

a) The E^{p}_{ox} values of Rh(I) complexes and the E^{0}_{red} values of inorganic oxidants were taken from Refs. 9 and 8, respectively.

kinetic formulation for the electron transfer reactions (Eqs. 18 and 19)[8] also is equivalent to that for the first step for the oxidative addition reactions (Eqs. 12 and 13);

$$k'_{Ox} = k'_1 + k'_2K'_2[Ox] \quad (18)$$

$$k'_{Rh} = k'_1 + k'_3K'_3[Rh] \quad (19)$$

where k'_{Ox} and k'_{Rh} are the pseudo-first-order rate constants in the presence of excess oxidant and Rh(I) complex, respectively. The k'_1 and $k'_2K'_2$ values for the electron transfer reactions of the Rh(I) complexes with the inorganic oxidants have been determined previously from the intercepts and the slopes of the plots between k'_{Ox} and [Ox] by the same manner as described above,[8] and relisted in Table 2 for comparison.

In addition to the similarity in the reaction scheme between the oxidative addition (Scheme 1) and the electron transfer reactions (Scheme 2), there can be seen similarities in the reactivity patterns of the Rh(I) complexes as well. In both oxidative additions and electron transfer reactions, the k_1 and k_2K_2 values as well as the k'_1 and $k'_2K'_2$ values for ligand bridged Rh(I) dimers $[Rh_2(dppm)_2(RNC)_4]^{2+}$ and $[Rh_2(dicp)_4]^{2+}$ are significantly larger than those for Rh(I) monomers $[Rh(RNC)_4]^+$. Moreover, the rate constants for Rh(I) monomers as well as Rh(I) dimers are approximately constant in both reactions, independent of the ligands. Such similarities in the reactivity patterns of Rh(I) complexes as well as the reaction scheme between the oxidative additions and the electron transfer reactions indicate that the activation process for the oxidative addition is analogous to that for the electron transfer shown in Eq. 20,

$$([RhL_4]^+ I_2) \xrightarrow{e.t.} ([RhL_4]^{2+} I_2^-)^* \quad (20)$$

where the double dagger represents the activated complex. Attachment of electron to I_2 is known to cause the dissociation of the I–I bond since the ground state energy of I_2 is 1.5 eV higher than the dissociation limit for I_2^- (Eq. 21).[18] Thus, electron transfer from

$$I_2 \xrightarrow{e} I\cdot + I^- \quad (21)$$

$[RhL_4]^+$ to I_2 would result in the facile dissociation of I–I bond, followed by the geminate recombination between the $[RhL_4]^{2+}$ and I· radicals to yield the adduct as the first step (Eq. 22). In the next section,

$$([RhL_4]^{2+}I_2^-)^* \longrightarrow [RhL_4(I)_2]^+ \quad (22)$$

the rate constants for the oxidative additions of Rh(I) complexes with I_2 are compared with those of the posturated electron transfer reactions (Eq. 20) in a quantitative manner with the aid of linear free energy relationships.

Quantitative Comparison of Rate Constants between the Oxidative Additions and the Electron Transfer Reactions of Rh(I) Complexes. Previously, we have established a linear free energy relationship (LFER) for the electron transfer reactions of Rh(I) complexes with inorganic oxidants (Eq. 14), which can be expressed as Eq. 23,[9,19]

$$\log k'_1 = -8.6(E^{p}_{ox}-E^{0}_{red}) + \text{Const.} \quad (23)$$

where k'_1 stands for the rate constant (Eq. 15), E^{p}_{ox} is the anodic current peak potential in the cyclic voltammogram of the Rh(I) complex at a constant sweep rate (100 mV s^{-1}), and E^{0}_{red} is the standard reduction potential of the oxidant. Thus, the rate constant for the electron transfer reaction from the Rh(I) complex to I_2 (Eq. 20) may be evaluated by substituting the reduction potential of I_2 into Eq. 23. The reduction potential may be approximated by the $E_{1/2}$ value of I_2 obtained in the Experimental section, since the peak separation (0.1 V) is close to that for one electron reversible process (0.06 V).[20,21] The $E^{p}_{ox}-E^{0}_{red}$ values for the redox pairs between the Rh(I) complexes and I_2 as well as the representative inorganic oxidants are listed in Table 3.

The plot of Eq. 23 is shown by open circles in Fig. 3a, where the plot of the log k_1 values for the oxidative additions of Rh(I) complexes with I_2 against the $E^{p}_{ox}-E^{0}_{red}$ values (Table 3) also is given by closed circles. The log k_1 values for the Rh(I) dimers (Nos. 9, 11—13) agree well with the solid line which represents the rate constant when electron transfer reactions between the cationic Rh(I) complexes and I_2 would occur (Eq. 20). The k_2K_2 values for the same

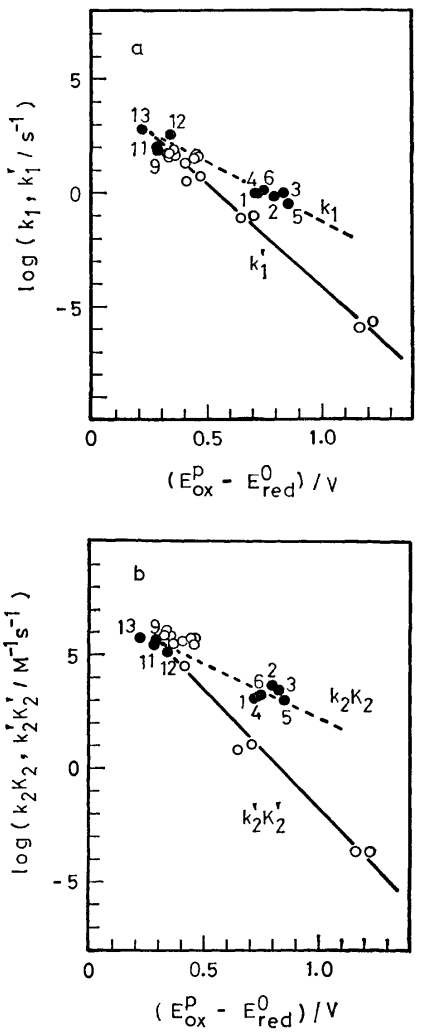

Fig. 3. Linear free energy relationships between logarithm of the rate constants ($\log(k_1, k_1')$ (a) and $\log(k_2K_2, k_2'K_2')$ (b)) and $E^p_{ox}-E^0_{red}$ for the reactions of Rh(I) complexes with I_2 (k_1, k_2K_2) and inorganic oxidants (k_1', $k_2'K_2'$); numbers refer to compounds in Table 2.

Rh(I) dimers also are in agreement with those for the electron transfer rate constant $k_2'K_2'$ drawn by the solid line in Fig. 3b, which barrs fortuitous coincidences. Such agreement of the absolute values of k_1 as well as k_2K_2 for the oxidative additions of I_2 to the Rh(I) dimers with those for the electron transfer reactions strongly suggests that the activation process in the first step of the oxidative additions is electron transfer from the Rh(I) complexes to I_2 as shown in Eq. 20.

The k_1 and k_2K_2 values decrease with increasing the $E^p_{ox}-E^0_{red}$ values as shown by the dotted lines in Figs. 3a and 3b. The differences between the Rh(I) dimers (Nos. 9, 11—13) and the Rh(I) monomers (Nos. 1—6) are remarkable both in k_1 and in k_2K_2. These values for the Rh(I) monomers, however, lie somewhat above the solid lines which represent the electron transfer rate constants. Accordingly the slopes of the linear free energy relationships for the oxidative additions are smaller than those for the electron transfer reactions. The linear free energy relationships in Figs. 3a and 3b themselves are not a definitive proof for the occurrence of complete electron transfer in the activation process of the oxidative addition reactions of I_2 to the Rh(I) complexes since the reaction *via* an intermediate with greater or lesser charge-transfer character is expected to show similar trends.[22,23] The description of the activation process as the complete electron transfer in Eq. 20, however, enables us to evaluate the rate constants for the oxidative additions of the Rh(I) dimers with I_2 as the rate constants for the electron transfer reactions in the same systems as shown in Figs. 3a and 3b. Since the solid lines in Figs. 3a and 3b represent the electron transfer rate constants, the larger rate constants for the oxidative additions of the Rh(I) monomers with I_2 than expected from the solid lines in Figs. 3a and 3b may be regarded as arising from the stronger interaction of the Rh(I) monomers with I_2 in the transition state of electron transfer in Eq. 20 than that with the inorganic oxidants.

A similar electron transfer mechanism has been presented by Tsou and Kochi[24] for the oxidative addition of aryl halides to tetrakis(triethylphosphine)-nickel, in which the second-order rate constant ($\log k$) were linearly related to the polarographic $E_{1/2}$ values of aryl halides. Our study has shown that there exists a mechanistic similarity between the oxidative addition of Rh(I) complexes with I_2 and the electron transfer reactions with inorganic oxidants $[Fe(N\text{-}N)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$, and that the absolute values of the rate constants for the oxidative additions can be approximated by the rate constants for the electron transfer reactions from the Rh(I) complexes to I_2. The generalization of the electron transfer mechanism for the oxidative additions of Rh(I) complexes with I_2 described above or its utility to predict the rate constants for oxidative additions of other metal complexes with different substrates remains to be elaborated in further studies.

Cyclic Voltammetry of Rh(I) Complexes and the Oligomers. A Correlation between the Anodic Peak Potentials and the Rate Constants for the Electron Transfer Reactions with Inorganic Oxidants

Shunichi Fukuzumi, Nobuaki Nishizawa, and Toshio Tanaka*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 5, 1982)

The cyclic voltammogram of a CH_3CN solution of $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ exhibits three anodic current peaks which correspond to the oxidations of the monomer, the dimer, and the trimer, with no cathodic wave on the reverse scan. The anodic peak potentials E^p_{ox} in such irreversible cyclic voltammograms were determined for various Rh(I) monomers and the oligomers such as $[Rh(RNC)_4]^+$, $[Rh_2(RNC)_8]^{2+}$, $[Rh_2(dppm)_2(RNC)_4]^{2+}$, $[Rh_2(dicp)_4]^{2+}$, $[Rh_3(RNC)_{12}]^{3+}$, and $[Rh_4(dicp)_8]^{4+}$ (R=*p*-$MeOC_6H_4$ and Ph, *etc*; dppm=bis(diphenylphosphino)methane, dicp=1,3-diisocyanopropane). The anodic peak potentials E^p_{ox} vary mainly with the degree of oligomerization of the Rh(I) complexes, decreasing in the order monomer>dimer>trimer>tetramer, in parallel with the energies of the highest occupied molecular orbitals E_{HOMO}. It has been found that the E^p_{ox} values are linearly correlated with logarithm of the rate constants for the electron transfer reactions with inorganic oxidants such as $[Fe(bpy)_3]^{3+}$ and $[Co(bpy)_3]^{3+}$ (bpy=2,2′-bipyridine) in the context of the Marcus theory as expected when the standard oxidation potentials E^0_{ox} would be used. It is thus suggested that the anodic peak potentials of the Rh(I) complexes in the irreversible system can be used as the standard oxidation potentials as far as the relative values are concerned.

Recently, Rh(I) complex oligomers such as $[Rh_2(dicp)_4]^{2+}$ (dicp=1,3-diisocyanopropane) have merited a special attention since Gray *et al.*[1] discovered that $[Rh_2(dicp)_4]^{2+}$ dissolved in 12 mol dm^{-3} aqueous HCl solution produces H_2 upon irradiation of visible light. It seems to be of importance to know the redox properties of the Rh(I) complexes in order to delineate the mechanism as well as to improve the efficacy of the system. However, the redox properties of Rh(I) complexes have scarcely been known in contrast with other conventional systems of photosensitized hydrogen production such as utilizing $[Ru(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine)[2-4] whose redox properties have well been established.[5]

Previously, we have reported the kinetic study on the electron transfer reactions of tetrakis(isocyanide)-rhodium(I) and the oligomers, $[(RhL_4^+)_n]$ (n=1—3), with inorganic oxidants such as $[Fe(N\text{-}N)_3]^{3+}$ (N-N= 2,2′-bipyridine, 1,10-phenanthroline, and related ligands) and $[Co(bpy)_3]^{3+}$,[6] in which $[(RhL_4^+)_n]$ were found to undergo irreversible oxidation by these oxidants. In such irreversible systems, the thermodynamic redox properties of $[(RhL_4^+)_n]$ such as the redox potentials E^0 cannot be obtained directly. It seems, however, to be possible to relate the dynamic properties of $[(RhL_4^+)_n]$ in the redox reactions to the redox potential by utilizing the linear free energy relationship (LFER).

In the present study, we wish to report the relation between the dynamic properties of various Rh(I) complexes including $[Rh_2(dicp)_4]^{2+}$ in the electrochemical oxidation, obtained as the anodic peak potentials of the cyclic voltammograms (E^p_{ox}), and the standard oxidation potentials of the complexes (E^0_{ox}), by comparing the E^p_{ox} values with the electron transfer rate constants for the reactions with inorganic oxidants (k_1) reported previously.[6] It will be shown that the anodic peak potentials (E^p_{ox}) provide useful informations on the differences between the redox properties of the Rh(I) monomers and the oligomers.

Experimental

Materials. Preparations of tetrakis(isocyanide)rhodium(I) perchlorates used in this study were described previously.[6,7] Bis(diphenylphosphino)methane (dppm) was prepared according to the literature.[8] dppm-Bridged Rh(I) dimers of the $[Rh_2(dppm)_2(RNC)_4]^{2+}$ type (R=Ph, *p*-$MeOC_6H_4$, *t*-Bu, $PhCH_2$) were prepared by adding a stoichiometric amount of dppm to a solution of appropriate $[Rh(RNC)_4](ClO_4)$ in acetone by the procedure analogous to the preparation of $[Rh_2(dppm)_2(n\text{-}BuNC)_4]^{2+}$.[9] The product was collected by filtration and purified by recrystallization from acetone/ethanol, followed by drying in a vacuum. The elemental analysis was performed for a representative compound, $[Rh_2(dppm)_2(p\text{-}MeOC_6H_4NC)_4](ClO_4)_2$. Found: C, 57.25; H, 4.56; N, 3.23%. Calcd for $Rh_2C_{82}H_{72}N_4P_4Cl_2O_{12}$: C, 57.73; H, 4.25; N, 3.28%. 1,3-Diisocyanopropane (dicp) was prepared from 1,3-propanediamine, chloroform, and 50% aqueous sodium hydroxide by the procedure analogous to the preparation of phenyl isocyanide,[10] and the product was purified by vacuum distillation. The dicp-bridged Rh(I) dimer, $[Rh_2(dicp)_4]Cl_2$, was prepared by the reaction of dicp with $[Rh(cyclooctadiene)Cl]_2$[11] in chloroform according to the literature.[12] The tetraphenylborate salt, $[Rh_2(dicp)_4](BPh_4)_2$, was obtained by the addition of $NaBPh_4$ to a methanol solution of $[Rh_2(dicp)_4]Cl_2$. Tetrabutylammonium perchlorate used as a supporting electrolyte was prepared by the reaction of tetrabutylammonium bromide with perchloric acid, and purified by recrystallization from ethanol. Acetonitrile used as a solvent for electrochemical and kinetic experiments was purified by the standard method.[13]

Cyclic Voltammetry. Cyclic voltammetry measurements were performed on a Hokuto Denko Model HA-301 potentiostat/galvanostat at 298 K in CH_3CN containing 0.1 mol dm^{-3} $n\text{-}Bu_4NClO_4$ as a supporting electrolyte, using a platinum microelectrode and a standard NaCl calomel reference electrode (SCE) or a Ag/Ag^+ reference electrode ($Ag/AgNO_3$ 0.1 mol dm^{-3}). The electrochemical cell was constructed according to the literature.[14] The platinum microelectrode was routinely cleaned by soaking it in concentrated nitric acid, followed by repeated rinsing with water

and then acetone, and drying at 353 K prior to use. Two cm^3 of a CH_3CN solution of Rh(I) complexes (1.0×10^{-3}—1.0×10^{-2} mol dm^{-3}) was introduced into the cell and flashed with nitrogen prior to the measurements. The anodic peak potentials, E^p_{ox}, observed at the same sweep rate of 100 mV s^{-1} for the Rh(I) complexes employed in this study were always reproducible to within 50 mV. No aging of the electrode was observed on a week to week basis. There were no complications on the electrode arising from the deposition of the oxidized Rh(II) species for most Rh(I) complexes so that the repeated scans did not affect the appearance of the voltammograms. For some Rh(I) dimer complexes such as $[Rh_2(dicp)_4]^{2+}$ and $[Rh_2(dppm)_2(t\text{-BuNC})_4]^{2+}$, the anodic peak current decreased with repeating the scan, but the anodic peak potentials in the first scan were reproducible. The cyclic voltammetry of $[Rh_2(dicp)_4]^{2+}$ was measured in a methanol solution of the chloride salt containing 0.04 mol dm^{-3} KCl or 0.1 mol dm^{-3} LiCl, since the salt was not soluble enough in CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4. The anodic peak potential of each Rh(I) complex in CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 *vs.* Ag/Ag^+ ($Ag/AgNO_3$ 0.1 mol dm^{-3}) was 0.34 V lower than that *vs.* SCE. The same difference between the redox potentials of ferrocene used as a reference compound *vs.* Ag/Ag^+ and SCE was always observed in accordance with the literature.[15]

Kinetic Measurements of Electron Transfer Reactions. The measurements of rates of the electron transfer reactions between Rh(I) complexes and $[Fe(N\text{-}N)_3]^{3+}$ were described previously.[6] Rates of the electron transfer reactions between dppm-bridged Rh(I) complexes, $[Rh_2(dppm)_2(RNC)_4]^{2+}$, and $[Co(bpy)_3]^{3+}$ in CH_3CN were measured at 298 K by monitoring the decay of the absorbances due to the Rh(I) dimers (λ_{max} listed in Table 1) in the presence of large excess $[Co(bpy)_3]^{3+}$ (2.19×10^{-3}—1.22×10^{-2} mol dm^{-3}), by using a Union SM-401 spectrophotometer. A mixing apparatus (Model MX-7, Union Giken) was used to ensure the fast and complete mixing of the two sample solutions. The ionic strength of the reaction medium was adjusted to 0.1 with n-Bu_4NClO_4.

Results

Cyclic Voltammetry of Rh(I) Complexes. The cyclic voltammograms (CV) of three representative Rh(I) complexes, $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$, $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$, and $[Rh_2(dppm)_2(PhNC)_4]^{2+}$, are illustrated in Fig. 1, which shows anodic waves with current maxima but no cathodic wave on the reverse scan, as confirmed by changing the sweep rates in the range 20 mV s^{-1} to 1000 mV s^{-1}. The anodic oxidation of the Rh(I) complexes is thus irreversible, indicating that the follow-up chemical reactions are fast on the time scale of the CV experiments.

The CV of $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ shows three distinct anodic current peaks in the range 0.2—1.2 V *vs.* Ag/Ag^+ (Fig. 1a), which correspond to the fact that the $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ cation oligomerizes in CH_3CN to exist as an equilibrium mixture with the dimer $[Rh_2(p\text{-}MeOC_6H_4NC)_8]^{2+}$ and the trimer $[Rh_3(p\text{-}MeOC_6H_4NC)_{12}]^{3+}$, as shown in Eqs. 1 and 2,[6,16]

$$2[RhL_4]^+ \overset{K_D}{\rightleftharpoons} [Rh_2L_8]^{2+} \quad (1)$$

$$[Rh_2L_8]^{2+} + [RhL_4]^+ \overset{K_T}{\rightleftharpoons} [Rh_3L_{12}]^{3+} \quad (2)$$

where L represents p-$MeOC_6H_4NC$. Similar multi-

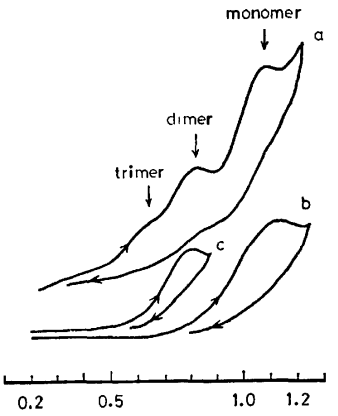

Fig. 1. Cyclic voltammograms of representative Rh(I) complexes in CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4; (a) $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ 2.1×10^{-2} mol dm^{-3}, (b) $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ 1.0×10^{-3} mol dm^{-3}, (c) $[Rh_2(dppm)_2(PhNC)_4]^{2+}$ 5.1×10^{-3} mol dm^{-3}.

CV peaks were observed for $[Rh(p\text{-}MeC_6H_4NC)_4]^+$ and $[Rh(PhNC)_4]^+$ which also are known to oligomerize in CH_3CN.[6,17] On the other hand, $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ does not oligomerize appreciably because of the steric effect of the bulky ligand,[6] and there exists only the monomer as the predominant species in CH_3CN, *e.g.*, 99.9% monomer in 2.21×10^{-3} mol dm^{-3} where the CV was measured. Indeed, the CV of $[Rh(2,4,6\text{-}Me_3C_6H_2NC)_4]^+$ shows a single anodic current peak at 1.14 V (Fig. 1b) which is nearly the same as the position of the third anodic peak for $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$. Similar single CV peaks were observed for $[Rh(C_6H_{11}NC)_4]^+$, $[Rh(2,6\text{-}Me_2C_6H_3NC)_4]^+$, $[Rh(t\text{-BuNC})_4]^+$, and $[Rh(PhCH_2NC)_4]^+$ which do not oligomerize appreciably either.[6] dppm-Bridged Rh(I) dimers of the $[Rh_2(dppm)_2(RNC)_4]^{2+}$ type (R=Ph, $PhCH_2$, t-Bu) do not oligomerize in CH_3CN either.[9] In accordance with this, the CV of $[Rh_2(dppm)_2(PhNC)_4]^{2+}$ exhibits a single anodic wave due to the oxidation of the dimer with a current maximum at 0.68 V (Fig. 1c) which corresponds to the second anodic peak of $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$.

Based on the above results, the three anodic current peaks at 1.03, 0.79, and 0.56 V for the CV of $[Rh(p\text{-}MeOC_6H_4NC)_4]^+$ can be assigned to the oxidation of the monomer, the dimer, and the trimer, respectively. Anodic peak potentials E^p_{ox} of Rh(I) complexes determined at the same sweep rate (100 mV s^{-1}) are listed in Table 1. The peak potentials E^p_{ox} of the Rh(I) monomers (Nos. 1—8) are approximately constant, independent of the nature of isocyanide ligands. Those values of the Rh(I) dimers present in CH_3CN solutions of $[RhL_4]^+$ (Nos. 9—11) also are constant at 0.76 ± 0.03 V, but smaller by about 0.3 V than the Rh(I) monomers. Moreover, the E^p_{ox} values (Nos. 12—15) are slightly smaller than those of the Rh(I) dimers whose ligands are not bridged. The $[Rh_2(dicp)_4]^{2+}$ cation partly oligomerizes to form the tetramer in methanol (Eq. 3). The formation of the

$$2[Rh_2(dicp)_4]^{2+} \overset{K_D}{\rightleftharpoons} [Rh_4(dicp)_8]^{4+} \quad (3)$$

16	$[Rh_3(p\text{-}MeOC_6H_4NC)_{12}]^{3+}$ Tetramer	0.56±0.02	710	1.75
17	$[Rh_4(dicp)_8]^{4+}$	0.25±0.04[b]	778[b]	1.59[b]

a) Measured at the sweep rate of 100 mV s^{-1} in CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K unless otherwise noted. b) Measured in methanol containing 0.04 mol dm^{-3} KCl.

tetramer, $[Rh_4(dicp)_8]^{4+}$, is characterized by the appearance of a new absorption band at 778 nm in the high concentrations in addition to absorption bands at 318, 342, and 559 nm observed in the low concentrations. The anodic current peak which is assignable to the tetramer appears at the smallest potential (No. 17) among the Rh(I) complexes in Table 1. Thus, the E^{p}_{ox} values for the Rh(I) monomers and the oligomers in Table 1 are concluded to increase in the order tetramer < trimer < dimer(bridged) < dimer(not bridged) < monomer.

Electron Transfer Reactions of Rh(I) Complexes with Inorganic Oxidants. The kinetics of the oxidation of Rh(I) monomers, $[Rh(RNC)_4]^+$, with inorganic oxidants such as $[Fe(N\text{-}N)_3]^{3+}$ (Eq. 4) were examined earlier,[6]

$$[RhL_4]^+ + [Fe(N\text{-}N)_3]^{3+} \longrightarrow [RhL_4]^{2+} + [Fe(N\text{-}N)_3]^{2+} \quad (4)$$

where N-N=2,2′-bipyridine, 1,10-phenanthroline, and substituted 1,10-phenanthrolines. The kinetic results in the presence of excess oxidants were best interpreted by the scheme,[6]

$$[RhL_4]^+ + Ox \overset{K_1}{\rightleftharpoons} ([RhL_4]^+\ Ox) \xrightarrow{k_1} \text{e. t.} \quad (5)$$

$$([RhL_4]^+\ Ox) + Ox \overset{K_2}{\rightleftharpoons} ([RhL_4]^+\ 2Ox) \xrightarrow{k_2} \text{e. t.} \quad (6)$$

Scheme

where Ox and e.t. represent the inorganic oxidants and the electron transfer reactions as the rate determining step, respectively. In order to compare the reactivity of Rh(I) dimers with Rh(I) monomers, the electron transfer reactions of $[Rh_2(dppm)_2(RNC)_4]^{2+}$ with $[Co(bpy)_3]^{3+}$ were examined kinetically in CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K. The reactions were followed by monitoring the decay of the absorbance due to $[Rh_2(dppm)_2(RNC)_4]^{2+}$ (λ_{max} in Table 1).[18] The reactions obey pseudo-first-order kinetics in the presence of excess $[Co(bpy)_3]^{3+}$. According to the Scheme the pseudo-first-order rate constant k_{Co} is expressed as

$$k_{Co} = \frac{k_1K_1[Co] + k_2K_1K_2[Co]^2}{1 + K_1[Co] + K_1K_2[Co]^2} \quad (7)$$

When $K_1[Co] \gg 1$ and $K_2[Co] \ll 1$, Eq. 7 is reduced to Eq. 8.

$$k_{Co} = k_1 + k_2K_2[Co] \quad (8)$$

The plots of k_{Co} *vs.* [Co] are given in Fig. 2, which shows linear relations, in accordance with Eq. 8. The intramolecular electron transfer rate constant k_1 in Eq. 5 can thus be obtained from the extrapolated intercepts in Fig. 2 (compare with Eq. 8). The plot of k_{Fe} *vs.* [Fe] for the electron transfer reaction of $[Rh(PhCH_2NC)_4]^+$ with $[Fe(N\text{-}N)_3]^{3+}$ also is shown in Fig. 2 for comparison. The k_1 values for the reactions of Rh(I) complexes with $[Co(bpy)_3]^{3+}$ as well as $[Fe(N\text{-}N)_3]^{3+}$ are listed in Table 2, which gives the difference between the anodic peak potentials of Rh(I) complexes, E^{p}_{ox}, (Table 1) and the reduction potentials of the oxidants, E^{0}_{red},[6] as well for comparison. It can be seen that the electron transfer rate constants k_1 vary significantly from 1.0×10^{-6} to 1.2×10^{2} s^{-1}, approximately in parallel with the $E^{p}_{ox} - E^{0}_{red}$ values.

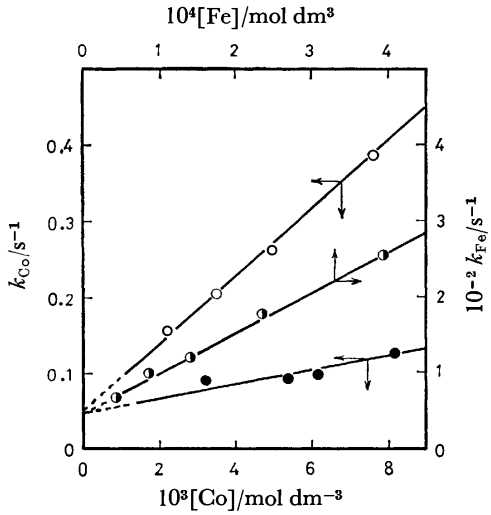

Fig. 2. Pseudo-first-order rate constants k_{Co} and k_{Fe} as a function of [Co] or [Fe] for the oxidations of $[Rh_2(dppm)_2(p\text{-}MeOC_6H_4NC)_4]^{2+}$ (○) and $[Rh_2(dppm)_2(PhCH_2NC)_4]^{2+}$ (●) with $[Co(bpy)_3]^{3+}$ and of $[Rh(PhCH_2NC)_4]^+$ (◑) with $[Fe(bpy)_3]^{3+}$, respectively, in CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K.

a) In CH_3CN containing 0.1 mol dm^{-3} n-Bu_4NClO_4 at 298 K. b) Numbers refer to compounds in Table 1. c) The E^0_{red} values are taken from Ref. 6. d) From Ref. 6 unless otherwise noted. e) This study.

reversible systems, an anodic current peak potential of CV is thermodynamically determined and the corresponding cathodic peak is observed in the reverse scan with the peak separation of 59 mV, irrespective of the sweep rate.[19] Thus, the redox potential E^0 is experimentally determined as $(E^p_{ox}+E^p_{red})/2$. When the oxidized species is unstable, however, the CV becomes irreversible since the oxidized species no longer exists on the electrode owing to the facile chemical reactions. Under such circumstances, the redox potential cannot be determined, and the anodic peak potential is dependent on a number of factors such as the electron transfer rate constant on the electrode, the reverse electron transfer rate constant, the sweep rate of the CV, and the rate constants of the follow-up chemical reactions. Recently, Klingler and Kochi[20] have, however, demonstrated that under the conditions where the follow-up chemical reactions are much faster than the reverse electron transfer, the anodic peak potential becomes independent of the follow-up chemical reactions since the forward electron transfer is the rate determining step. The anodic peak potential E^p_{ox} is then expressed in terms of the oxidation potential E^0_{ox}, the transfer coefficient β, and the electron transfer rate constants $k(E^p_{ox})$ and $k(E^0_{ox})$ at the peak potential and the oxidation potential, respectively,[20,21]

$$E^p_{ox} = E^0_{ox} + \frac{RT}{\beta F}\ln\frac{k(E^p_{ox})}{k(E^0_{ox})} \quad (9)$$

where $k(E^p_{ox})$ (in units of cm s^{-1}) is a function of the sweep rate v (in V s^{-1}) as given by Eq. 10,[19]

$$k(E^p_{ox}) = 2.18(D\beta Fv/RT)^{1/2} \quad (10)$$

where D (in cm^2 s^{-1}) is the diffusion coefficient and the other notations are conventional. It should be noted that the diffusion coefficient D is nearly constant irrespective of metal complexes.[20] Thus, if β and $k(E^0_{ox})$ are constant, the peak potential E^p_{ox} is linearly related to the standard oxidation potential E^0_{ox} with the slope of unity at a constant sweep rate as given by Eq. 11. Under such conditions, the peak potential

$$E^p_{ox} = E^0_{ox} + \text{Const.} \quad (11)$$

E^p_{ox} can be used as the thermodynamically defined oxidation potential E^0_{ox} as far as the relative values are concerned. In order to examine whether Eq. 11 is applicable to the anodic oxidation of Rh(I) complexes, the irreversibility of the CV wave is discussed in the following section.

Irreversibility in Oxidation of Rh(I) Complexes. The CV of Rh(I) complexes in Fig. 1 clearly demonstrates that the anodic oxidation of Rh(I) complexes is irreversible since no cathodic wave is observed in the reverse scan at the sweep rate as high as 1000 mV s^{-1}. The oxidized Rh(I) complexes, *i.e.*, Rh(II) species have well been regarded as radicals,[6,22] and dimerize rapidly (Eq. 12). An additional support for the irreversibility

$$2[RhL_4]^{2+} \xrightarrow{\text{fast}} [Rh_2L_8]^{4+} \quad (12)$$

in the anodic oxidation of Rh(I) complexes is given by the sweep rate dependence of the anodic peak potential E^p_{ox}. By combining Eqs. 9 and 10, one obtains Eq. 13 which shows that E^p_{ox} depends on the sweep rate v,[20]

$$E^p_{ox} = \frac{2.3RT}{2\beta F}\log v + \text{Const.} \quad (13)$$

where

$$\text{Const.} = E^0_{ox} + \frac{2.3RT}{\beta F}\log\frac{2.18D\beta F}{k(E^0_{ox})RT} \quad (14)$$

In Fig. 3, the E^p_{ox} values for some representative Rh(I) complexes are plotted against logarithm of the sweep rates. A linear correlation is obtained for each

Fig. 3. Rh(I) complex in accordance with Eq. 13. The slopes in Fig. 3 are almost the same for the present Rh(I) complexes, as 95±10 mV per decade, and are significantly larger than those of partially reversible electron transfer between the limits of 0 and 30 mV per decade.[19] Such large slopes may be characteristic of totally irreversible processes. Thus, from Eq. 13 the transfer coefficient β is obtained as 0.31±0.04 for the Rh(I) complexes studied here. The same β value was obtained from the analysis of the half-width of the CV wave in Fig. 1 by the use of Eq. 15 as well,[19]

$$E^p_{ox} - E^{p/2}_{ox} = 1.857\ (RT/\beta F) \qquad (15)$$

where $E^{p/2}_{ox}$ represents the electrode potential at the half peak current.

A Linear Free Energy Relationship (LFER) in the Irreversible Oxidation of Rh(I) Complexes. The foregoing section has established the conditions to use the E^p_{ox} values as the relative E^0_{ox} values (Eq. 11), such as the total irreversibility and the constant transfer coefficient β. In order to test the validity of Eq. 11 for the oxidation of Rh(I) complexes independently, the E^p_{ox} values have been compared with the electron transfer rate constants k_1 for the chemical oxidations of the Rh(I) complexes with inorganic oxidants by the following manner. Previously, the intramolecular electron transfer rate constants k_1 for reactions of a given Rh(I) complex with a series of inorganic oxidants whose reduction is reversible have been related to the reduction potentials of the oxidants by Eq. 16,[6] which accords with the Marcus relation (Eq. 17),[23]

$$\log k_1 = 8.5E^0_{red} + \text{Const.} \qquad (16)$$

$$\log k_1 = -8.5\Delta G^0 + \text{Const.} \qquad (17)$$

where ΔG^0 is the standard free energy change of electron transfer reactions given by $E^0_{ox}-E^0_{red}$ (in V). If Eq. 11 can be applied to the oxidations of Rh(I) complexes, the E^0_{ox} values which cannot be determined directly may be substituted by the experimentally accessible values of E^p_{ox}, and Eq. 17 is rewritten as Eq. 18. The relation of Eq. 18 is tested by plotting

$$\log k_1 = -8.5\ (E^p_{ox}-E^0_{red}) + \text{Const.} \qquad (18)$$

the log k_1 values for the oxidations of Rh(I) complexes with the inorganic oxidants against the $(E^p_{ox}-E^0_{red})$ values by taking the data in Table 2, as shown in Fig. 4. There is seen an excellent agreement between the experimental plot in Fig. 4 and the relation in Eq. 18 (the slope is −8.6 with the correlation coefficient ρ=0.98), which strongly supports the validity of Eq. 11. Thus, the LFER in Fig. 4 underscores the utility of the anodic peak potentials E^p_{ox} at a constant sweep rate for obtaining the relative oxidation potentials E^0_{ox} of Rh(I) complexes.

Variation of HOMO with Rh(I) Oligomerization. The E^p_{ox} values of Rh(I) complexes vary with the Rh(I) oligomerization (Table 1). Such variations of the E^p_{ox} value must reflect the change of the energy of the highest occupied molecular orbital (HOMO) from which electron is removed upon oxidation since the E^p_{ox} values are related to the standard oxidation potentials E^0_{ox} as discussed in the foregoing section. The variation of the E^p_{ox} values with the Rh(I) oligomerization may be understood by comparing the E^p_{ox} values with the electronic transition energies of the Rh(I) complexes which also reflect the HOMO energies, with the aid of the MO diagram of Rh(I) monomers and the oligomers shown in Fig. 5.[16] The HOMO energy, E^{HOMO}_n (n=1—4), increases with oligomerization, resulting in decrease of the transition energy in the order $h\nu_1 > h\nu_2 > h\nu_3 > h\nu_4$. Thus, the approximate relation between $h\nu_n$ and E^{HOMO}_n is given by Eq. 19 derived from the energy diagram (Fig. 5),

$$h\nu_n = -2E^{HOMO}_n + \text{Const.} \qquad (19)$$

where Const. is $h\nu_1+2E^{HOMO}_1$. The E^{HOMO}_n value is related to the oxidation potential E^0_{ox} by Eq. 20,[24]

$$E^{HOMO}_n = -E^0_{ox} + \Delta G^s - C' \qquad (20)$$

where ΔG^s is the free energy change of solvation in solutions, and C′ is a constant which includes the potential of the reference electrode on the absolute scale together with the liquid junction potential.[25] When

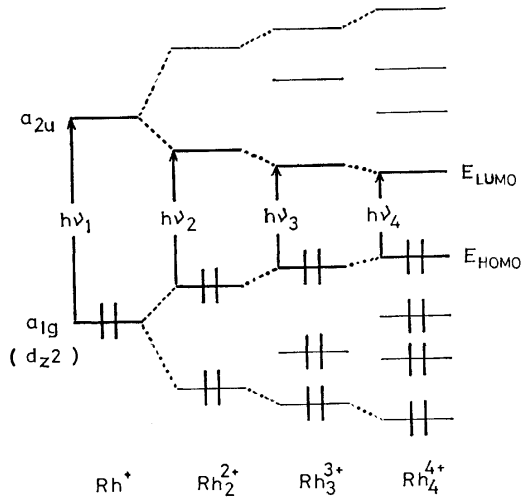

Fig. 5. MO diagram of the Rh(I) monomer and the oligomers.

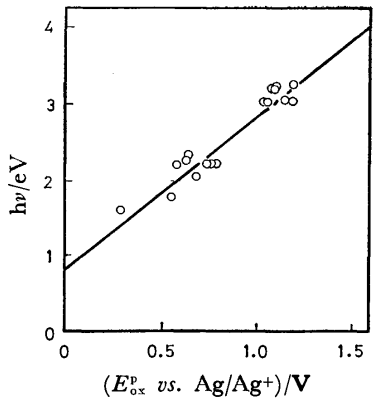

Fig. 6. Correlation between the electronic transition energies $h\nu$ of Rh(I) complexes and the anodic peak potentials E^{p}_{ox}.

ΔG^{s} is assumed as constant in the homologous series of Rh(I) complexes, Eq. 19 is rewritten by Eq. 21. Then, the relation between $h\nu_n$ and the anodic peak potential E^{p}_{ox} is obtained as Eq. 22, by substituting Eq. 11 into Eq. 21. The validity of Eq. 22 is confirmed from the plot between $h\nu$ and E^{p}_{ox} as shown in Fig. 6. Thus, the correlation between $h\nu$ and E^{p}_{ox} gives an additional support for the conclusion that the anodic peak potential E^{p}_{ox} can be taken as the relative thermodynamic quantity for the oxidation of Rh(I) complexes, E^{0}_{ox}, which cannot otherwise be obtained directly.

$$h\nu_n = 2E^{0}_{ox} + \text{Const.} \quad (21)$$

$$h\nu_n = 2E^{p}_{ox} + \text{Const.} \quad (22)$$

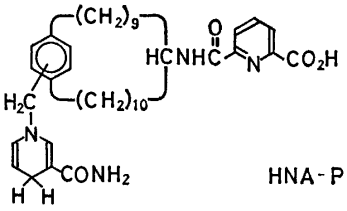
Macrocyclic Enzyme Model System. Kinetic Activity of [20]Paracyclophane Bearing 1,4-Dihydronicotinamide and 2-Pyridinecarboxylic Acid Moieties as Effected by Zinc Ion†

Yukito Murakami,* Yasuhiro Aoyama,†† and Jun-ichi Kikuchi
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

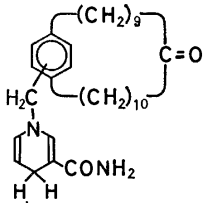
(Received March 1, 1982)

As regards the effect of zinc(II) ion on the reduction of hexachloroacetone, the kinetic activity of a [20]paracyclophane (PCP) bearing 1,4-dihydronicotinamide (HNA) and 2-pyridinecarboxylic acid (Py) moieties, HNA–PCP–Py, has been investigated as an alcohol dehydrogenase model in reference to that of PCP–HNA in the light of their metal-coordination behavior. The reduction ability of PCP–HNA was significantly lowered as it underwent complex formation with zinc. On the other hand, HNA–PCP–Py showed an apparent rate maximum in a relatively lower concentration range of $ZnCl_2$. The kinetic behavior was analyzed on the basis of the formation of two kinds of zinc complexes of HNA–PCP–Py: the 1:1 complex $\left(\begin{matrix}\text{Py}\\ \text{PCP}\\ \text{HNA}\end{matrix}\!\!>\!\text{Zn}^{\text{II}}\right)$, in which both Py and HNA moieties are simultaneously coordinated to the same zinc ion, showed a decreased reactivity relative to metal-free HNA–PCP–Py; while the 2:1 complex (HNA–PCP–Py–Zn^{II}–Py–PCP–HNA), in which HNA is free from metal-coordination, exercised a much enhanced activity, 7 times as reactive as metal-free HNA–PCP–Py. A plausible reaction mechanism for the enhanced reactivity has been discussed.

The NAD-dependent alcohol dehydrogenase contains zinc ion as an essential cofactor, and catalyzes the conversion of carbonyl compounds into alcohols and the reversed process. Such interconversion reactions are coupled with oxidation-reduction of the coenzyme. It is generally realized that direct coordination of the enzyme-bound zinc ion to an incorporated substrate promotes the hydrogen transfer between the coenzyme and the substrate,[1–3] and that there is no direct metal–coenzyme interaction in the enzyme active site.[3–5] In line with the participation of zinc ion in the enzyme system, metal ions have been observed to catalyze the reduction of *chelating* carbonyl substrates by simple NADH models[6–15] along with detailed kinetic analysis for relevant systems.[7,8,14] Recently, we have pointed out that a good alcohol dehydrogenase model needs to exhibit such a substrate–zinc interaction that arises from an enforced proximity effect even if the substrate has no or least intrinsic capability of coordination with zinc ion.[16] This situation can be attained if the dihydronicotinamide and the zinc ion are placed in an appropriate and fixed orientation owing to some rigid framework. Along this line, we have prepared a macrocyclic enzyme model involving both dihydronicotinamide and 2-pyridinecarboxylic acid moieties, the latter being an intramolecular zinc-binding site, and clarified its zinc-coordination behavior.[16] In the present work, we assessed the reactivities of zinc complexes of the [20]paracyclophane-based alcohol dehydrogenase model (HNA–PCP–Py) in the reduction of a simple carbonyl substrate in relation to that of a related compound having only a dihydronicotinamide moiety, PCP–HNA, in the light of their metal-coordination behavior.



HNA-PCP-Py



PCP-HNA

Experimental

Melting points were measured using capillary tubes with a Yamato MP-1 melting point apparatus (oil-bath type). Infrared spectra and ^1H NMR spectra were taken on a JASCO IR-E spectrophotometer and a Hitachi R-20 spectrometer, respectively. Electronic absorption spectra were obtained with a Union Giken SM-401 high-sensitivity spectrophotometer.

Materials. 1-[10(11)-(2-Carboxy-6-pyridylcarbonylamino)[20]paracyclophan-22-ylmethyl]-1,4-dihydronicotinamide (HNA–PCP–Py) and 1-[10(11)-oxo[20]paracyclophan-22-ylmethyl]-1,4-dihydronicotinamide (PCP–HNA) were prepared as described previously.[16] 1-Benzyl-1,4-dihydronicotinamide (BNAH) was prepared according to the published procedure.[17] Dichloromethane was fractionally distilled and stored over 4 Å molecular sieve. Hexachloroacetone was distilled (bp 110 °C/5.3×10^3 Pa) and zinc chloride of the highest quality was fused just before use.

Reduction of Hexachloroacetone with BNAH. A solution of BNAH (0.80 g, 3.7 mmol) and hexachloroacetone (1.0 g, 3.7 mmol) in dichloromethane (25 ml) was placed in a stoppered reaction vessel protected from room light, stirred for 9 h, and allowed to stand for 42 h at room temperature.

† Contribution No. 660 from this Department.

†† Present address: Department of Material Science and Technology, Technological University of Nagaoka, Nagaoka, Niigata 949-54.

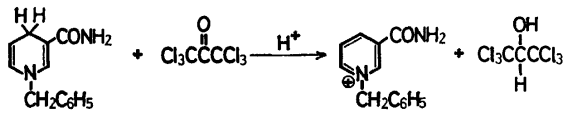
Dilute hydrochloric acid (3%, 10 ml) was added to the solution, and the mixture was extracted with refluxing hexane (450 ml) for 7 h. The solvent was removed *in vacuo* and an oily residue was sublimed at 80 °C/1.1 × 10^4 Pa to recover colorless needles of 1,1,1,3,3,3-hexachloro-2-propanol (282 mg, 28%), mp 88.0—88.5 °C (lit,[18] 86—87 °C); IR spectrum being identical with that of the authentic sample obtained by LAH reduction of hexachloroacetone.[18]

The reaction behavior was monitored by ^{1}H NMR spectroscopy. Hexachloroacetone (30 μl, 2.0 × 10^{-4} mol) was added to a solution of BNAH (31 mg, 1.4 × 10^{-4} mol) in deuteriochloroform (300 μl), containing 5% toluene as an internal reference, in an NMR tube. After the reaction mixture was allowed to stand at room temperature for 1 h, ^{1}H NMR signals attributable to BNAH disappeared completely on one hand and a proton signal referred to the 2-proton of the alkoxide product (4.90 ppm downfield from Me_4Si) was observed to appear on the other. The latter signal was shifted to 4.81 ppm upon addition of deuterium oxide (30 μl). The signal intensity indicated quantitative formation of the alcohol.

Kinetic Measurements. A 30-μl sample of a stock solution of hexachloroacetone (1.0 mol dm^{-3}) in dichloromethane was injected into a reaction medium [dichloromethane–methanol (100:1 v/v), 3 ml], containing either PCP–HNA or HNA–PCP–Py (1.0 × 10^{-4} mol dm^{-3}) and an appropriate amount of $ZnCl_2$, placed in a thermostated cell (at 25.0 ± 0.1 °C) set in the spectrophotometer. The absorption intensity at 370 nm, characteristic of the dihydronicotinamide moiety, was measured to pursue the progress of reaction. An apparent first-order rate constant was obtained from the slope of the first-order plot for an early stage of the reaction. Control experiments indicated that no reaction took place in the absence of the carbonyl substrate. Hexachloroacetone having a broad absorption band at around 300 nm was independently shown to be practically free from spontaneous decomposition in dichloromethane–methanol (100:1 v/v), while underwent rapid decomposition (ketalization) in methanol. Kinetic measurements in methanol were not carried out due to such reason.

Results and Discussion

Hexachloroacetone is one of the activated carbonyl compounds which can be reduced with 1,4-dihydronicotinamides.[19,20] The reaction of hexachloroacetone with 1-benzyl-1,4-dihydronicotinamide in dichloromethane afforded 1,1,1,3,3,3-hexachloro-2-propanol quantitatively with concomitant formation of the oxidized nicotinamide salt, as shown below.



The reaction between the present cyclophane-1,4-dihydronicotinamide (PCP–HNA or HNA–PCP–Py, 1.0 × 10^{-4} mol dm^{-3}) and hexachloroacetone (1.0 × 10^{-2} mol dm^{-3}) in dichloromethane–methanol (100:1 v/v) was investigated kinetically both in the presence and absence of $ZnCl_2$. At lower concentrations of the zinc salt, the addition of water and/or methanol to the C_5–C_6 double bond of the dihydronicotinamide moiety also took place, leading to the formation of a solvolyzed product having an absorption maximum at around 290 nm. Since the solvolyzed product was not detected in the absence of the carbonyl substrate, it must be derived from the nicotinamide–substrate radical pair which was formed through one-electron transfer from the dihydronicotinamide moiety to the substrate.[21,22] The absorption maximum characteristic of the metal-free 1,4-dihydronicotinamide moiety appeared at 354.5 nm and shifted to somewhat longer wavelength as $ZnCl_2$ was added. Thus, the decrease in absorbance at 370 nm was measured to determine the reaction rate. The initial rate constants for reactions with PCP–HNA and HNA–PCP–Py are plotted in Fig. 1 against the total concentration of $ZnCl_2$. As described previously for the coordination equilibrium involving PCP–HNA and zinc ion,[16] the sole existing species in the concentration range of $[Zn^{II}] > 1 \times 10^{-3}$ mol dm^{-3} is a Zn^{II} complex at a 1:1 molar ratio of ligand to metal (PCP–HNA–Zn^{II}) and both the metal-free species and the zinc complex are present at the intermediate zinc

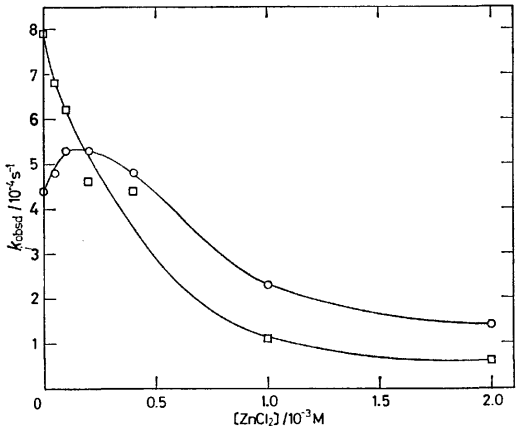


Fig. 1. Correlations between total concentration of $ZnCl_2$ and apparent first-order rate constant for reduction of hexachloroacetone (1.0 × 10^{-2} mol dm^{-3}) with HNA–PCP–Py (○) (1.0 × 10^{-4} mol dm^{-3}) and PCP–HNA (□) (1.0 × 10^{-4} mol dm^{-3}) in dichloromethane–methanol (100:1 v/v) at 25.0 °C.

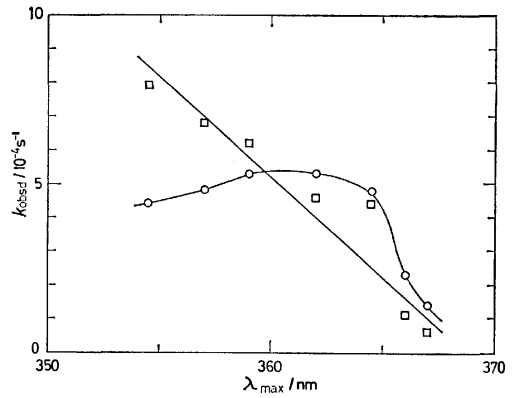

Fig. 2. Correlations between λ_{max} of the dihydronicotinamide moiety and rate constant for reduction of hexachloroacetone (1.0 × 10^{-2} mol dm^{-3}) in the presence of the same varying amounts of $ZnCl_2$: HNA–PCP–Py (○), 1.0 × 10^{-4} mol dm^{-3}; PCP–HNA (□), 1.0 × 10^{-4} mol dm^{-3}; in dichloromethane–methanol (100:1 v/v) at 25.0 °C.

Table 1. Specific first-order rate constants for reactions of dihydronicotinamide species with hexachloroacetone (1.0×10^{-2} mol dm^{-3}) at 25.0 °C

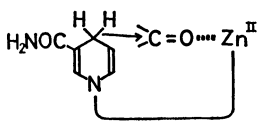
Dihydronicotinamide	Medium	k/s^{-1}
PCP-HNA	CH_2Cl_2-CH_3OH (100 : 1 v/v)	7.9×10^{-4}
PCP-HNA-Zn^{II}	CH_2Cl_2-CH_3OH (100 : 1 v/v)	0.6×10^{-4}
HNA-PCP-Py	CH_2Cl_2-CH_3OH (100 : 1 v/v)	4.4×10^{-4}
	CH_2Cl_2	2.9×10^{-4}
PCP$\langle^{Py}_{HNA}\rangle Zn^{II}$	CH_2Cl_2-CH_3OH (100 : 1 v/v)	1.4×10^{-4}
HNA-PCP-Py-Zn^{II}-Py-PCP-HNA	CH_2Cl_2-CH_3OH (100 : 1 v/v)	3×10^{-3}
	CH_2Cl_2	2×10^{-3}

concentration range. The rate constant for the reaction with PCP–HNA monotonously decreases as the concentration of zinc ion is raised until it levels off beyond $[Zn^{II}]>1\times10^{-3}$ mol dm^{-3}. It is apparent that PCP–HNA–Zn^{II} has a reduced reactivity (by a factor of 13) compared with PCP–HNA. A nearly linear correlation between rate constant and λ_{max} of the PCP–HNA species obtained by changing the zinc concentration (Fig. 2) also indicates that the formation of the zinc complex with the dihydronicotinamide moiety of PCP–HNA is responsible for the diminished rate, and the medium effect has no direct concern. Whatever the mechanistic details may be,[13,23-31] the reduction with dihydronicotinamide is an electron-donating process and the deactivation of PCP–HNA upon complex formation with Zn^{II} is readily understood on this basis.[20]

As for the HNA–PCP–Py system, the most remarkable aspect is that the rate constant reaches a maximum and then falls down as the concentration of $ZnCl_2$ increases (Fig. 1). This overall feature is completely reproducible in several sets of kinetic runs. The observed correlation of rate with $ZnCl_2$ concentration may be understood on the following basis: at least two kinds of zinc complexes are present in the reaction system to control the rate, the major one with a diminished (relative to HNA–PCP–Py) reactivity and the minor one with an enhanced reactivity. Figure 2 shows another aspect of the reaction behavior. In spite of an increase in the fraction of dihydronicotinamide–Zn^{II} species as the Zn^{II} concentration increases to a certain extent, the expected reduction in rate is compensated by contribution of rate-enhancement brought about by the active zinc species. In the light of the coordination behavior,[16] the major deactivated species and the minor activated one are referred to the 1:1 complex (PCP$\langle^{Py}_{HNA}\rangle Zn^{II}$), in which both Py and HNA moieties are simultaneously coordinated to the same zinc ion, and the 2:1 complex (HNA–PCP–Py–Zn^{II}–Py–PCP–HNA), in which HNA is free from metal-coordination, respectively. Consistent with this view, the highest reactivity is attained (Fig. 1) when the 2:1 complex reaches its maximum concentration at $[ZnCl_2]\cong1\times10^{-4}$ mol dm^{-3}. The rate constant at $[ZnCl_2]=2.0\times10^{-3}$ mol dm^{-3} may represent the specific reactivity of PCP$\langle^{Py}_{HNA}\rangle Zn^{II}$. The specific rate constant for the 2:1 complex, HNA–PCP–Py–Zn^{II}–Py–PCP–HNA, was calculated so that the observed rate–$[ZnCl_2]$ profile can be best reproduced by summation of rate contributions of the metal-free species (specific rate constant 4.4×10^{-4} s^{-1}), the 1:1 complex (specific rate constant 1.4×10^{-4} s^{-1}), and the 2:1 complex on the basis of their respective populations: a value of 3×10^{-3} s^{-1} (per HNA–PCP–Py unit) was obtained, larger by factor of 7 than that for the metal-free HNA–PCP–Py. The kinetic behavior of HNA–PCP–Py (5.1×10^{-5} mol dm^{-3}) was also investigated in dry dichloromethane, in which the addition reaction of water and/or methanol to dihydronicotinamide was not detected. The rate–$[ZnCl_2]$ profile, showing again a maximum at relatively lower concentration of zinc, was analyzed in a manner as described above under the assumption that the coordination behavior of HNA–PCP–Py in dichloromethane is the same as that in dichloromethane–methanol (100:1 v/v); the reactivity of HNA–PCP–Py–Zn^{II}–Py–PCP–HNA (per HNA–PCP–Py unit), 2×10^{-3} s^{-1}, 7 times as large as that of HNA–PCP–Py (2.9×10^{-4} s^{-1}). The specific rate constants for reduction of hexachloroacetone are summarized in Table 1.

The rate enhancement by HNA–PCP–Py–Zn^{II}–Py–PCP–HNA, even though not extremely large, should not be underestimated in reference to the more marked rate enhancement brought about by Zn^{II} in reduction of 2-pyridinecarbaldehyde,[6-12] its Schiff base,[12] 1,10-phenanthroline-2-carbaldehyde,[13] and pyridoxal phosphate[15] with dihydronicotinamide and its derivatives. These substrates are *specific* because, by virtue of their metal-chelating abilities, they readily form zinc complexes which are undoubtedly more susceptible to reduction with dihydronicotinamides. Not being limited to the nicotinamide chemistry, many investigators working on the metal-ion catalysis often choose *specific* substrates so as to be suited for given catalysts, which then undergo chelation with such substrates. However, we rather take a different approach; a catalyst should be chosen so as to be effective for a given *non-specific* substrate. It is generally realized that the role of zinc ion in the reduction of a carbonyl compound with alcohol dehydrogenase is to polarize the carbonyl group through metal-coordination and consequently facilitate the hydride transfer (in a formal sense) from the 1,4-dihydronicotinamide moiety of coenzyme NADH to the carbonyl carbon.[1-3] Hexachloroacetone, an electron-deficient carbonyl compound, may have the least tendency to coordinate to a metal ion. On the basis of these considerations, the ultimate goal of the present study has been to clarify whether or

not the zinc ion accelerates the reduction of hexachloroacetone, a *non-specific* substrate as regards the metal-coordination tendency, by a reaction mechanism schematically shown in **1**. The acceleration effect pro-



1

vided by the zinc ion, involved in the 2:1 complex (HNA–PCP–Py–Zn^{II}–Py–PCP–HNA), is the first successful example along this line, to the best of our knowledge. As for the overall rate effect provided by the zinc ion on the present reaction, the major complex formed with HNA–PCP–Py ($PCP\langle^{Py}_{HNA}\rangle Zn^{II}$) reduced the reactivity of HNA–PCP–Py itself. In order to improve this situation, a ligand for coordination with the zinc ion must have significantly larger metal-binding ability than the dihydronicotinamide moiety. Furthermore, dihydronicotinamide and ligand moieties need to be constrained in a certain limited space so that the cooperation of the former and the zinc ion bound to the latter toward a substrate molecule is geometrically possible under the condition: the zinc-binding with the ligand should not result ultimately in metal-bridging between the dihydronicotinamide and ligand moieties.

† *Department of Chemistry, Vanderbilt University, Nashville, Tennessee 37235, U. S. A.*

(Received November 24, 1981)

A preferential exchange of chlorines and bridging oxygens between phosphorus(III and V) chlorides and diarsenic trioxide was studied by adding diarsenic trioxide into phosphorus chlorides and then heating the mixtures at 50—60 °C with vigorous stirring under dried nitrogen (phosphorus(III) chlorides) or dried air (phosphorus(V) chlorides). ^{31}P NMR study showed that the exchange of chlorines and oxygens occurred between diarsenic trioxide and phosphorus trichloride, phosphoryl chloride, diethylphosphinic chloride, tetramethylphosphorodiamidic chloride, or diethylphosphinothioic chloride and that P–O–P bonds were formed in the products.

Diphosphorus trioxide is conventionally prepared by burning phosphorus under a reduced supply of oxygen. It is not easy to obtain pure diphosphorus trioxide by this method. One of us (J. R. Van Wazer) has pointed out the possibility of the exchange reaction of oxygen and halogen atoms for several pairs of different atoms. Among these exchange reactions, the enthalpy of the exchange between P–Cl and As–O bonds is the largest one, about 75 kJ/bond.[1] Therefore, we studied the exchange of oxygen and chlorine between diarsenic trioxide and several phosphorus(III and V) chlorides to investigate the formation of the P–O–P bond from the P–Cl bond.

Experimental

Materials. The diarsenic trioxide used in this study was purchased from J. T. Baker Chemical Co. and was ground for about 30 min by a miller, MIXER/MILL, made by Spex Co. Phosphorus trichloride, phosphoryl chloride, and carbon disulfide were Fisher Scientific Co. reagent grade. Phosphorus trichloride and phosphoryl chloride were distilled. Carbon disulfide was dried with calcium chloride and then distilled. Phenylphosphorous dichloride, diethylphosphinic chloride, diphenyl phosphorochloridate, tetramethylphosphorodiamidic chloride, and dimethylphosphinothioic chloride were purchased from Aldrich Chemical Co. and were used without any other purification. They were checked by ^{31}P NMR and gave the correct spectra.

^{31}P NMR Measurement. ^{31}P NMR measurements were carried out on Varian XL-100 spectrometer at 40.48 MHz. The chemical shifts in the phosphorus spectra are reported with respect to 85% phosphoric acid. In all cases, positive shifts were measured upfield.

Procedure. Diarsenic trioxide was added into a large excess of phosphorus(III) chloride in a three-necked round bottom flask under a stream of dried nitrogen. The mixtures were heated at 50—60 °C with vigorous stirring by using a hot-plate magnetic stirrer. The reaction mixtures were withdrawn at hourly intervals and analyzed for phosphorus compounds by the ^{31}P NMR instrument without any other solvent. The mixtures of diarsenic trioxide and a large excess of phosphorus(V) chloride were also reacted under dried air at 50—60 °C in the same way as that of the reaction of phosphorus(III) chloride. The progress of the reaction of the mixtures was checked by the same way as used for the reactions of phosphorus(III) chloride. The ^{31}P NMR analysis of the solid product in the system of phosphoryl chloride and diarsenic trioxide was also made by dissolving it in cold water.

Results and Discussion

As_2O_3–PCl_3 System. Typical NMR spectra of the reaction mixture are shown in Fig. 1. In the early stage of the reaction, the mixture gave a peak of PCl_3 at −220 ppm and unknown peaks at −183 and −193 ppm. The peak height of these unknown peaks did not change much with the passage of reaction time. Finally, the mixture gave a narrow peak of diphosphorus trioxide at −113 ppm and an unknown peak at −133 ppm. The intensity of these peaks increased as the reaction proceeded. The peak height of diphosphorus trioxide had a maximum; after

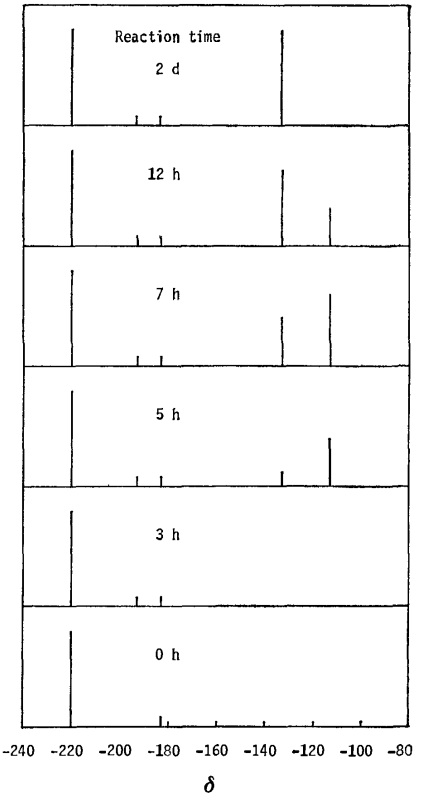

Fig. 1. ^{31}P NMR spectra of the reaction mixture of the As_2O_3–PCl_3 system.

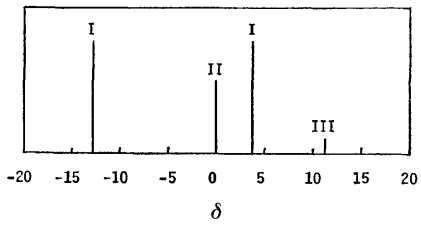

Fig. 2. ^{31}P NMR spectrum of the aqueous solution of the solid product of the As_2O_3–PCl_3 system.

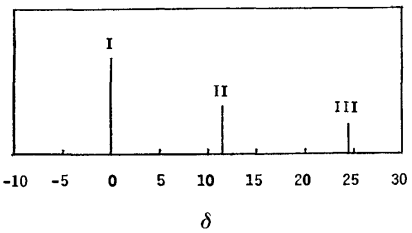

Fig. 3. ^{31}P NMR spectrum of the aqueous solution of the solid product of the As_2O_3–$POCl_3$ system.
I: Orthophosphoric acid, II: diphosphoric acid, III: *cyclo*-tetraphosphoric acid.

the maximum, it decreased gradually and finally disappeared. At this step of the reaction, the mixture gave a peak of phosphorus trichloride and unknown peaks at −133, −183, and −193 ppm. It was necessary to stir the reaction mixture vigorously to increase the rate of reaction. If the reaction mixture was stirred gently, it would take a much longer time to finish the reaction. When the reaction was stopped at the stage of maximum height of the ^{31}P NMR peak corresponding to diphosphorus trioxide, the reaction mixture contained a white precipitate. This precipitate was separated from the phosphorus trichloride solution by filtration and washed with phosphorus trichloride in a dry bag under nitrogen. Diphosphorus trioxide was obtained by a reduced distillation (667 Pa, 40 °C) of the phosphorus trichloride solution by using a trap cooled by Dry Ice–methanol; it had a melting point of around 23 °C and gave a narrow sharp ^{31}P NMR peak at −113 ppm. The yield of diphosphorus trioxide was about 35% relative to the amount of diarsenic trioxide used in this experiment. The liquid product in the trap gave boiling points of 75 and 130 °C at atmospheric pressure. The compound with a boiling point of 75 °C is unreacted phosphorus trichloride and that with a boiling point of 130 °C is arsenic trichloride. When the white precipitate was dissolved in cold water, a reddish brown precipitate was produced. The precipitate was filtered; the ^{31}P NMR spectrum of the filtrate is shown in Fig. 2. These peaks are due to phosphonic acid and ortho- and diphosphoric acids. The reddish brown precipitate was soluble in nitric acid and the solution gave the peak of phosphoric acid. So it could be concluded that the reddish brown precipitate is red phosphorus containing some phosphorus suboxides. Accordingly, the white precipitate mentioned above must be diphosphorus tetraoxide. Diphosphorus trioxide is oxidized very easily with oxygen, and the produced diphosphorus trioxide seems to be oxidized by slight amounts of oxygen in the reaction apparatus. It was difficult to prevent oxidation in the reaction apparatus used in this experiment. According to above results, one can write the following chemical equation for this reaction system:

$$4PCl_3 + 2As_2O_3 \xrightarrow{(N_2)} P_4O_6 + 4AsCl_3.$$
$$\downarrow (O_2)$$
$$P_4O_8$$

Diphosphorus trioxide was extracted from diphosphorus tetraoxide with carbon disulfide by mixing the tetraoxide with carbon disulfide and stirring the mixture under nitrogen. It took a long time to extract (a few days). The peak at −133 ppm seems to be due to diphosphorus trioxide, since one peak of diphosphorus trioxide shifts easily from −113 ppm to −133 ppm in arsenic trichloride. Diphosphorus trioxide gives the same peak at −133 ppm in phosphorus trichloride and the change is very slow.[2)]

As_2O_3–$C_6H_5PCl_2$ System. The reaction mixture was brown in the initial stage of the reaction. The reaction mixture did not give any peak other than that of phenylphosphonous dichloride. The reaction was stopped at the reaction time of 15 h and the brownish solid product was separated by filtration. The solid product was insoluble in any solvent, so it was impossible to study the phosphorus compounds contained in the solid product by the ^{31}P NMR instrument.

As_2O_3–$POCl_3$ System. The reaction mixture did not show any ^{31}P NMR spectrum other than that of phosphoryl chloride at any reaction time. At the reaction time of 50 h, the reaction mixture was cooled and the ashy solid product was filtered in a dry bag. The solid product was insoluble in any solvent. When the product was dissolved in water, the aqueous solution gave the spectrum shown in Fig. 3. The aqueous solution of diphosphorus pentaoxide gives the same spectrum and diphosphorus pentaoxide is insoluble in any solvent. So the ashy solid product must be diphosphorus pentaoxide. The liquid part of the reaction mixture was distilled at atmospheric pressure. It gave products with boiling points of 108 and 130 °C; these are unreacted phosphoryl chloride and arsenic trichloride. Therefore, the following equation can be written for this reaction system:

$$4POCl_3 + 2As_2O_3 \longrightarrow P_4O_{10} + 4AsCl_3.$$

As_2O_3–$(C_2H_5)_2POCl$ System. Diarsenic trioxide was soluble in diethylphosphinic chloride. The dissolution reaction is highly exothermic. So diarsenic trioxide was added carefully to diethylphosphinic chloride; the temperature of the mixture did not go beyond 60 °C. About 3 g of diarsenic trioxide was dissolved completely in 12 cm^3 of diethylphosphinic chloride. The reaction system seemed to reach equilibrium in less than 1 h, because the ^{31}P NMR spectrum of the reaction mixture gave the same spectrum at any reaction time longer than 1 h. The ^{31}P NMR spectrum

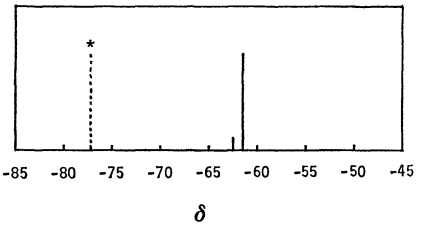

Fig. 4. Proton decoupled ^{31}P NMR spectrum of the reaction mixture of the As_2O_3–$(C_2H_5)_2POCl$ system at a reaction time of 1 h.
*: Diethylphosphinic chloride.

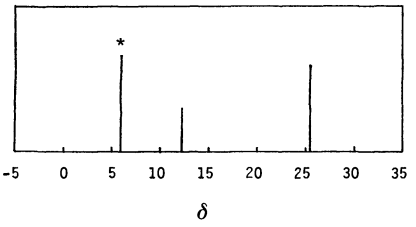

Fig. 5. ^{31}P NMR spectrum of the reaction mixture of the As_2O_3–$(C_6H_5O)_2POCl$ system at a reaction time of 15 h.
*: Diphenyl phosphorochloridate.

of the reaction mixture at the reaction time of 1 h is shown in Fig. 4. The mixture gave a strong peak at −61.5 ppm. This peak seems to be due to diethylphosphinic anhydride, $(C_2H_5)_2\overset{O}{P}O\overset{O}{P}(C_2H_5)_2$. There are no ^{31}P NMR data about diethylphosphinic anhydride, but P(α) of $(C_2H_5)_2\overset{O}{\underset{\alpha}{P}}O\overset{S}{\underset{\beta}{P}}(C_2H_5)_2$ gives a ^{31}P NMR peak at −60 ppm.[3] Accordingly, a preferential exchange of oxygen and chlorine between diarsenic trioxide and diethylphosphinic chloride seems to take place in this reaction system. Another new peak at −62.5 ppm could not be identified. Arsenic trichloride was not obtained by distillation of the reaction mixture.

As_2O_3–$(C_6H_5O)_2POCl$ System. Diarsenic trioxide does not dissolve in diphenyl phosphorochloridate. As is shown in Fig. 5, the reaction mixture gave two new peaks at 12.2 and 25.6 ppm other than that of diphenyl phosphorochloridate. The intensity of the new peaks increased with reaction time. Tetraphenyl diphosphate, $(C_6H_5O)_2\overset{O}{P}O\overset{O}{P}(C_6H_5O)_2$, gives a ^{31}P NMR peak at 23.3 ppm,[3] so the new peaks do not come from tetraphenyl diphosphate. There are no ^{31}P NMR data for these new peaks.

As_2O_3–$[(CH_3)_2N]_2POCl$ System. Diarsenic trioxide did not dissolve in tetramethylphosphorodiamidic chloride. The reaction mixture gradually changed into an ashy color with the elapse of reaction time. The ^{31}P NMR spectrum of the reaction mixture is shown in Fig. 6 and a strong new peak appears at −11 ppm. The height of the new peak increased as the reaction proceeded. The data listed in Ref. 3 show that octamethyldiphosphoramide, $[(CH_3)_2N]_2\overset{O}{P}O\overset{O}{P}[(CH_3)_2N]_2$, gives a ^{31}P NMR peak at −11 ppm. It can be concluded that the exchange of oxygen and chlorine between diarsenic trioxide and tetramethylphosphorodiamidic chloride occurs in this reaction system. We could not find from where the other weak new peaks come. Arsenic trichloride was not obtained by distillation of the reaction mixture.

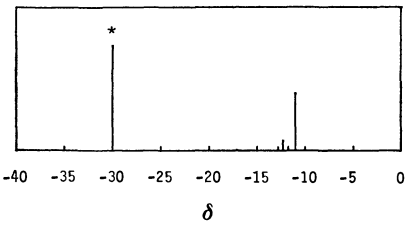

Fig. 6. Proton decoupled ^{31}P NMR spectrum of the reaction mixture of the As_2O_3–$[(CH_3)_2N]_2POCl$ system at a reaction time of 18 h.
*: Tetramethylphosphorodiamidic chloride.

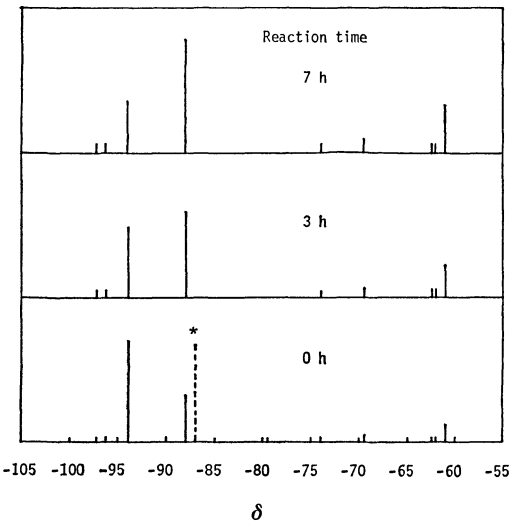

Fig. 7. Proton decoupled ^{31}P NMR spectrum of the reaction mixture of the As_2O_3–$(CH_3)_2PSCl$ system.
*: Dimethylphosphinothioic chloride.

As_2O_3–$(CH_3)_2PSCl$ System. Diarsenic trioxide dissolves in dimethylphosphinothioic chloride and the reaction is highly exothermic. Diarsenic trioxide was added into dimethylphosphinothioic chloride so slowly that the temperature of the mixture did not go beyond 60 °C. As is shown in Fig. 7, just after mixing, the mixture gave two strong new peaks at −94 and −88 ppm and several weak peaks in the region below −95 ppm and the region between −61 and −80 ppm. The peak at −94 ppm decreased and the peak at −88 ppm increased as the reaction proceeded. There are no ^{31}P NMR data about dimethylphosphinothioic anhydride, but the data in Ref. 3 give these results:

$$(C_6H_5)_2PSCl \longrightarrow (C_6H_5)_2\overset{S}{P}O\overset{S}{P}(C_6H_5)_2$$
$$-79.5 \text{ ppm} \qquad -79.3 \text{ ppm}$$

$$(CH_3)(C_2H_5)PSCl \longrightarrow (CH_3)(C_2H_6)\overset{O}{\underset{\alpha}{P}}O\overset{S}{\underset{\beta}{P}}(CH_3)(C_2H_5)$$
$$-98 \text{ ppm} \qquad P(\beta): -98.1 \text{ ppm}$$

$$(C_2H_5)_2PSCl \longrightarrow (C_2H_5)_2\overset{\alpha}{P}O\overset{\beta}{P}(C_2H_5)_2 \quad (O\ S)$$

-109 ppm P(β): -107 ppm

The result of this reaction system is

$$(CH_3)_2PSCl \longrightarrow \text{Product.}$$

-87 ppm -88 ppm

The new peak at -88 ppm may come from dimethylphosphinothioic anhydride, $(CH_3)_2\overset{S}{P}O\overset{S}{P}(CH_3)_2$. The other new peaks could not be identified. Arsenic trichloride was not obtained by distillation of the reaction mixture.

Substitution of Cyano Group by Hydroxyalkyl Group and of Ring Hydrogen by Alkoxyl Group in UV-Irradiation of 2-Pyridinecarbonitrile in Alcohols

Akira SUGIMORI,* Toshikazu FURIHATA, Shigeyuki MIKAYAMA, Makiko YOSHIDA, and Yasuo NAKANISHI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102

(Received August 12, 1981)

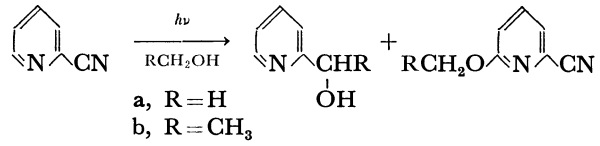
The UV-irradiation of 2-pyridinecarbonitrile(**1**) in methanol and in ethanol brings about the replacement of the cyano group by the hydroxyalkyl groups and the replacement of the ring hydrogen by the alkoxyl group. Free base-form of **1** in ethanol undergoes exclusively photo-hydroxyethylation, while the pyridinium form of **1** in ethanol undergoes both photo-hydroxyethylation *via* a singlet excited state and -ethoxylation *via* a singlet-excited state complex, which is quenched by the electron transfer from the aromatic hydrocarbons to the excited complex.

Photochemical reactions of aromatic carbonitriles have been extensively investigated, especially from the viewpoint of the photoreactions *via* charge transfer complexes either in the ground state or in the excited state.[1,2] Concerning the photoreactions of quinolinecarbonitriles in alcohols, Hata *et al.* reported the substitution of the cyano group by the hydroxyalkyl groups derived from the solvent alcohols.[3] A similar photosubstitution has been reported for 4-pyridinecarbonitrile–triethylamine system.[4] Most of the reported photoreactions of aromatic and heteroaromatic nitriles are the substitution of CN in radical processes.

Another photoreactivity is expected for pyridinecarbonitriles: As a member of pyridinecarboxylic acid derivatives,[5,6] they are expected to undergo ionic type reactions. The main concern of our present study is to clarify in the photoreactions of pyridinecarbonitriles whether ionic processes similar to those of pyridinecarboxylic esters occur actually in parallel with radical processes or not and further what kinds of excited states are responsible for photoreactions.[7]

Results and Discussion

The UV-irradiation of 2-pyridinecarbonitrile (**1**) in alcohols brings about the replacement of the cyano group by the hydroxyalkyl group and the replacement of the ring hydrogen by the alkoxyl group (Table 1).



a, R=H
b, R=CH_3

1 **2** **3**

The former reaction is similar to that reported for quinolinecarbonitriles[3] and the latter to that reported for 2-pyridinecarboxylic ester.[6]

A detailed study was done mainly on the **1**–ethanol system. Which of the reactions is dominant is dependent on the reaction conditions: 1) the presence or the absence of the added acids, 2) the nature of the added acids, and 3) the concentration of **1**. Additives (quenchers) affect photo-ethoxylation and -hydroxyethylation differently.

Table 1 and Fig. 1 show the effect of sulfuric acid

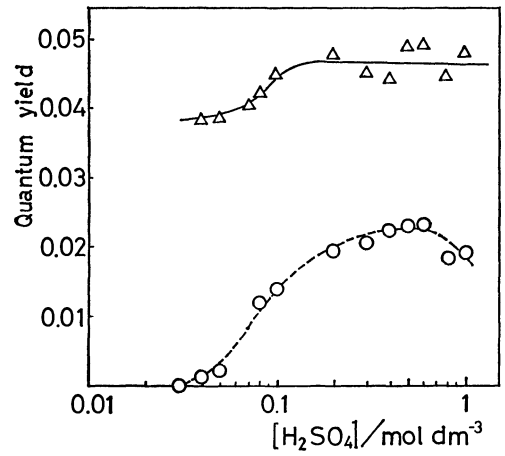


Fig. 1. Dependence of photo-hydroxyethylation and -ethoxylation of **1** on the concentration of sulfuric acid.
[**1**]=0.04 mol dm^{-3}, —△—: **2b**, --○--: **3b**.

on the photoreaction. In the absence of sulfuric acid, hydroxyethylation occurs exclusively. However, ethoxylation becomes significant as the concentration of sulfuric acid increases.

Like the photo-methoxylation of methyl 2-pyridinecarboxylate[6] and 2-pyridinecarboxylic acid,[8] the photo-ethoxylation of 2-pyridinecarbonitrile shows a remarkable concentration dependence (Fig. 2). Such behavior, *i.e.*, that alkoxylation is efficient at higher concentrations of the substrates, is an important common feature of 2-pyridinecarboxylic acid derivatives. A kinetic analysis for photo-methoxylation of methyl 2-pyridinecarboxylate shows that the concentration dependence is due to the formation of an excimer which undergoes alkoxylation.[6] A similar mechanism can be applied to the photo-ethoxylation of **1**.

An attempt to obtain direct evidence for the existence of an excimer by means of emission spectral measurement was unsuccessful because no fluorescence from **1** was observed either in lower or higher concentration of **1**.

In order to identify the excited species responsible for hydroxyethylation and ethoxylation, the effects of *trans*-1,3-pentadiene, anthracene, naphthalene, fluorene, and azulene were analyzed. Because some additives

absorb the 254 nm light competitively with the substrate, the effects of the additives were analyzed by means of an index, A, the relative quantum yield calculated on the basis of the light absorbed by the substrate:

$$A = Y/L$$

$$Y = \frac{\text{Yield in the presence of additive}}{\text{Yield in the absence of additive}}$$

$$L = \frac{\varepsilon_1 c_1}{\varepsilon_1 c_1 + \varepsilon_Q c_Q},$$

where ε_1 and ε_Q are the molar absorption coefficients of **1** and the additive at 254 nm, respectively. Symbols c_1 and c_Q are the concentrations of **1** and the additive. A^{-1} corresponds to ϕ_0/ϕ for the Stern-Volmer equation in the quenching experiment (ϕ_0, quantum yield in the absence of a quencher; ϕ, quantum yield in the presence of a quencher).

trans-1,3-Pentadiene, an effective triplet quencher, (E_T=244 kJ/mol[9]), inhibits neither the photo-hydroxyethylation nor the photo-ethoxylation (Fig. 3). However, the quenching by fluorene (Fig. 4) shows a different feature from that by *trans*-1,3-pentadiene. Fluorene, the triplet energy of which is higher (E_T for fluorene, 284 kJ/mol[9]) than that of *trans*-1,3-pentadiene, inhibits photo-ethoxylation of **1**. On the other hand, fluorene exhibits no quenching during the photo-hydroxyethylation.

This characteristic of the quenching by fluorene is common for those by aromatic hydrocarbons, as are shown in the Stern-Volmer plots for the quenching by anthracene (Fig. 5), naphthalene (Fig. 6), and benzene (Fig. 7). Even benzene, which can be used as

a triplet sensitizer because of its high triplet energy (E_T=347 kJ/mol[9]), inhibits the photo-ethoxylation of **1**. In contrast with the photo-ethoxylation, photo-hydroxyethylation is independent on the quenchers.

These facts indicate that: 1) the substitution of the cyano group by the hydroxyethyl group is ascribed to a singlet excited state and 2) the substitution of the ring hydrogen by the ethoxyl group is ascribed not to a triplet excited state but to a certain singlet excited state. This singlet excited state should be different from the one which gives the hydroxyethylated product.

When the fact that the photo-ethoxylation has a significant concentration dependence is taken into consideration, the quenching of the photo-ethoxylation by aromatic hydrocarbons can be explained by the quench-

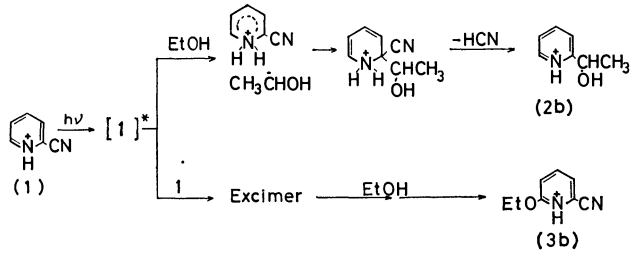
ing of an excimer *via* the electron transfer mechanism proposed by Caldwell *et al.*[10]

The efficiencies for the quenching ($k_q\tau$ values obtained from the Stern-Volmer plots) of photo-ethoxylation by aromatic hydrocarbons correlate well with the ionization potentials of aromatic hydrocarbons[11] (Fig. 8). The lower the ionization potential, the higher the $k_q\tau$ value (k_q, rate constant for bimolecular quenching; τ, lifetime of the excited species). This shows that the excimer, which gives an ethoxylation product in the absence of quenchers, is quenched *via* the electron transfer from the quenchers. Alkoxylation is considered to involve a nucleophilic attack of alcohol to the electron-deficient moiety of the excited species. Therefore, the inhibition of ethoxylation by electron-rich aromatic hydrocarbons is reasonable. A similar quenching of photo-methoxylation by anthracene and benzene was observed for methyl 2-pyridinecarboxylate.[6]

Photo-ethoxylation is depressed by HCl (Fig. 9). A similar effect of HCl (or LiCl) on photo-methoxylation of 2-pyridinecarboxylic ester has been observed.[6] As in the case of 2-pyridinecarboxylic ester, the depression of photo-ethoxylation by HCl can be explained by the electron transfer from chloride ion to an electron-deficient excimer.

The conclusion that the hydroxyethylation occurs *via* a singlet excited state of **1** is similar to that reported by Hata *et al.* for the photo-hydroxyalkylation of quinolinecarbonitriles.[3] The mechanism proposed by Hata *et al.* can be applied to the corresponding reaction of 2-pyridinecarbonitrile.

The photoreactions of 2-pyridinecarbonitrile in acidic ethanolic solutions are summarized in Scheme 1.



Scheme 1.

Experimental

Materials. 2-Pyridinecarbonitrile (**1**) supplied by Yuki Gosei Yakuhin Co. was purified by vacuum distillation; mp 28—29 °C. Commercial naphthalene was purified by recrystallization; mp 80.5—81.5 °C. Commercial anthracene (analytical standard reagent of BDH Chemicals Co.), fluorene (zone-refined U.P. grade reagent of Tokyo Kasei Co.), and *trans*-1,3-pentadiene (GR grade reagent of Wako Junyaku Co.) were used without further purification.

UV-Irradiation. The alcoholic solutions containing **1**, sulfuric or hydrochloric acid, and the additive if necessary, were deaerated by bubbling nitrogen or argon for 40 min before irradiation. For the quenching experiment with *trans*-1,3-pentadiene or benzene, the quencher was added after the deaeration of the substrate solutions in order to avoid the evaporation of the quenchers during the bubbling of inert gas.

The solutions were irradiated with a low pressure mercury lamp in a merry-go-round type photoreactor. For the normalization, standard and sample solutions were irradiated at the same time.

Isolation and Identification of Photo-products. After the irradiation the solution was concentrated under reduced pressure. The solution was neutralized with sodium carbonate and the products were extracted with dichloromethane. The products were separated by means of TLC (plate, GF_{254} (Type 60) of E. Merck Co.; developing solvent, ethyl acetate–dichloromethane 1:1 for the reaction products in methanol, hexane–dichloromethane–diethyl ether 2:20:3 for the reaction products in ethanol).

2-Pyridylmethanol (**2a**) was identified by the accordance of its spectral properties with those of the commercially available authentic specimen. 1-(2-Pyridyl)ethanol (**2b**) was identified by the accordance of its spectral and gas-chromatographic properties with those of the authentic sample prepared by the hydrogenation of 2-acetylpyridine over Raney nickel catalyst.

6-Methoxy-2-pyridinecarbonitrile (**3a**): mp 58.0—58.5 °C; IR (KBr disk) 3000, 2950, 2915, 2850, 2225 (C≡N), 1603, 1465, 1130, and 1030 cm^{-1}; NMR (CCl_4) δ=7.60 (1H, dd, J=8.4 and 7.4 Hz, H at 4-position), 7.16 (1H, dd, J=7.4 and 1.2 Hz, H at 3- or 5-position), 6.84 (1H, dd, J=8.4 and 1.2 Hz, H at 3- or 5-position), and 3.88 (3H, s, CH_3). Found: C, 61.6; H, 4.4; N, 20.4%. Calcd for $C_7H_6N_2O$: C, 62.7; H, 4.5; N, 20.9%.

6-Ethoxy-2-pyridinecarbonitrile (**3b**): mp 67.0—69.0 °C; IR (KBr disk) 3050, 2970, 2900, 2840, 2210 (C≡N), 1600, 1450, 1330, 1270, 1030, and 800 cm^{-1}; NMR ($CDCl_3$) δ=7.66 (1H, dd, J=8 and 6 Hz, H at 4-position), 7.21 (1H, dd, J=6 and 1 Hz, H at 3- or 5-position), 6.86 (1H, dd, J=8 and 1 Hz, H at 3- or 5-position), 4.34 (2H, q, J=7 Hz, CH_2), and 1.30 (3H, t, J=7 Hz, CH_3). Found: C, 64.9; H, 5.6; N, 19.4%. Calcd for $C_8H_8N_2O$: C, 64.9; H, 5.4; N, 18.9%.

Quantitative Analysis of Photoproducts. After the irradiation the reaction mixture was concentrated under reduced pressure and was neutralized with sodium hydroxide and/or sodium hydrogencarbonate. The products were extracted repeatedly with dichloromethane and submitted to GLC analysis (column, 2 m column of Triton QS 11 (15%) on Uniport B (60/80 mesh); column temperature, 160 °C).

Actinometry. Actinometry was performed with a potassium trioxalatoferrate(III) actinometer.[12]

Spectral Measurements. NMR spectra were recorded on a Hitachi R 22 NMR spectrometer (90 MHz), and IR spectra were recorded on a Hitachi 260-50 IR spectrometer.

Reaction of 1-Ethyl-3-methyl-4-imidazoline-2-thione with Methyl Iodide. Kinetic and Thermodynamic Aspects

Tetsuya YAMADA, Yasuhiko KONDO,* and Shigekazu KUSABAYASHI

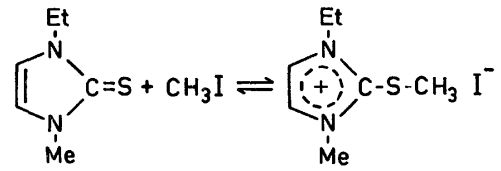
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received August 29, 1981)

The reaction of 1-ethyl-3-methyl-4-imidazoline-2-thione with methyl iodide followed simple second order kinetics in polar solvents, whereas in less polar solvents the reverse process made a significant contribution to the overall rate. The solvent effects on the forward rate constant were linearly related to those on the rate of the reaction of tetramethylthiourea with methyl iodide. A plot of ΔV_0^* *vs.* $\Delta \overline{V}^\circ$ was linear with a slope of 0.33. From the volume changes and enthalpy changes measured, three transition state indices, $(\Delta_2 V^*/\Delta_2 \overline{V}^\circ)$, n_T and α were determined in acetonitrile, *ca.* 0.33, 0.32, and 0.41, respectively.

Much effort has recently been devoted to the rationalisation of solvent effects on kinetic and thermodynamic phenomena,[1-6] and it seems to have been commonly accepted that since the observed phenomena often result from combinations of various solvent characteristics, multiple parameter analysis is indispensable for such rationalisation. From another point of view, the relationships between kinetic and thermodynamic effects, especially those recently developed,[7-10] can be regarded as providing a theoretical basis for the characterisation of a solution reaction on terms of a transition state index.

As part of our continuing program to study any given process by as many different methods as possible, we analyse the reaction of 1-ethyl-3-methyl-4-imidazoline-2-thione (EMImdT) with methyl iodide which have a convenient rate,[11] from both kinetic and thermodynamic aspects, and then compare the results with those so far obtained for the reactions of the following thione derivatives with methyl iodide; 1,3-dimethyl imidazolidine-2-thione (DMIT),[12] *N,N,N',N'*-tetramethyl-thiourea (TMTU),[13] 3-isopropyl-4-methyl-4-thiazoline-2-thione (TT).[14]



Experimental

Materials. 1,3-Dimethyl-4-imidazoline-2-thione, prepared as described,[15] was recrystallized three times from benzene and was then dried over phosphorus pentaoxide. 1-Ethyl-3-methyl-4-imidazoline-2-thione, prepared from *N*-methylimidazole and ethyl iodide by the same procedure as described,[15] was recrystallized three times from ether–pentane mixture and was dried over phosphorus pentaoxide (Found: C, 50.54; H, 7.09; N, 19.61; S, 22.59%. Calcd for $C_6H_{10}N_2S$: C, 50.67; H, 7.09; N, 19.70; S, 22.54%). 1,3-Dimethyl-2-methylthioimidazolium iodide, prepared by refluxing the corresponding thione with methyl iodide in acetonitrile was recrystallized twice from methanol–ether mixture, and was dried *in vacuo* over phosphorus pentaoxide at 65 °C. (Found: C, 26.75; H, 4.12; N, 10.28%. Calcd for $C_6H_{11}IN_2S$: C, 26.68; H, 4.10; N, 10.37%). 1-Ethyl-3-methyl-2-methylthioimidazolium iodide, prepared by refluxing the corresponding thione and methyl iodide in ether, was recrystallized twice from methanol–ether mixture and was dried *in vacuo* over phosphorus pentaoxide at 65 °C (Found: C, 29.66; H, 4.62; N, 9.90%. Calcd for $C_7H_{13}IN_2S$: C, 29.59; H, 4.61; N, 9.86%).

Solvents were purified as described elsewhere.[14,16] Kinetic measurements and density measurements (at 2.5×10^{-2} mol dm^{-3}) were performed as described elsewhere.[14,16]

Heat of Reaction Measurements. The heat of reaction was measured at 25° C with a Tokyo Riko MPC-11 calorimeter used as a conduction type vessel. A methyl iodide solution (5.5×10^{-2} mol dm^{-3}) in acetonitrile or in propylene carbonate (25 cm^3) and 1-ethyl-3-methyl-4-imidazoline-2-thione solution (0.1165 g in 1.2 cm^3 of the respective solvent) sealed in an ampoule were placed in the calorimeter cell. After thermal equilibration, the ampoule was broken, with stirring, and the temperature was recorded on a chart over 20 h. Calibration was achieved by introducing a measured quantity of electrical energy. Two to three determinations yielded a heat of reaction ΔH_r in acetonitrile of -59.8 ± 2 (kJ mol^{-1}) and in propylene carbonate of -51.9 ± 0.8 (kJ mol^{-1}).

Heat of solution Measurements. Heats of solution were measured at 25.0 °C with a twin isothermal calorimeter (Tokyo Riko TIC-2D) at 1.2×10^{-2} mol dm^{-3} for salts, 2.5×10^{-2} mol dm^{-3} for thione derivatives, and 1.3×10^{-1} mol dm^{-3} for methyl iodide. The experimental error was estimated to be *ca.* 1% from duplicate or triplicate runs.

Results and Discussion

Rate Laws. In polar solvents the reaction of 1-ethyl-3-methyl-4-imidazoline-2-thione with methyl iodide followed second order kinetics as expected,[11,14] *i.e.*, first order in both EMImdT and methyl iodide. In cyclohexanone an equilibrium was eventually reached. In bromobenzene the precipitation of the produced salt started at the point marked by an arrow in Fig. 1. In benzene the salt precipitated from the beginning of the reaction and the reaction was treated by second order kinetics. For a comprehensive treatment of the kinetic data which were measured in homogeneous phase, the scheme was postulated, and data have been treated, as described elsewhere.[13,14] The subscript, *e*, denotes the concentration at equilibrium.

$$\underset{a-x}{\text{EMImdT}} + \underset{b-x}{\text{MeI}^-} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \underset{x_{fl}}{\text{MEMImdT}^+} + \underset{x_{fl}}{\text{I}^-} \rightleftharpoons \underset{x_{ip}}{\text{MEMImdT}^+\text{I}^-}$$

$$2\,\underset{x_{ip}}{\text{MEMImdT}^+\text{I}^-} \rightleftharpoons \underset{x_q}{(\text{MEMImdT}^+\text{I}^-)_2}$$

Scheme 1.

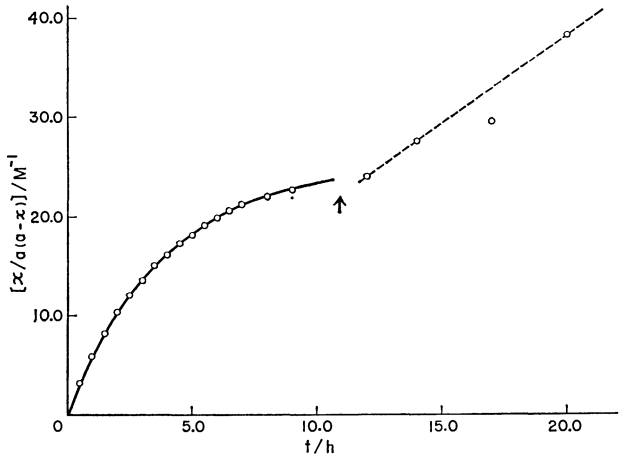


Fig. 1. Plots of $x/a(a-x)$ *vs.* t in bromobenzene at 30 °C.
○: Experimental, ——: calculated with $K_{obsd}=770$ $(dm^3mol^{-1})^{3/2}$ and $k_f=2.21\times10^{-3}$ $(dm^3\,mol^{-1}\,s^{-1})$. The arrow in the plots indicates the position where the precipitation of the salt started.

$$dx/dt = k_f(a-x)(b-x) - k_r x_{fl}^2 \quad (1)$$

$$K = k_f/k_r \quad (2)$$

$$K_{ip} = x_{ip}/x_{fl}^2 \quad (3)$$

$$K_q = x_q/x_{ip}^2 \quad (4)$$

$$x = x_{fl} + x_{ip} + 2x_q$$
$$= x_{fl} + K_{ip}x_{fl}^2 + 2K_qK_{ip}^2x_{fl}^4 \quad (5)$$

$$k_f(a-x_e)(b-x_e) = k_r x_{fl,e}^2 \quad (6)$$

In cyclohexanone the stoichiometric equilibrium constant, K_{sto}, determined analytically is rearranged to Eq. 8. From the set of x_e and K_{sto} values the equations were solved simultaneously to give $K=0.274$, $K_{ip}=1.25\times10^3$ dm³ mol⁻¹, $K_q=8.84$ dm³ mol⁻¹ (Fig. 2). The forward rate constant, k_f was calculated from Eq. 9 by the procedure described.[13,14]

$$K_{sto} = x_e^2/\{(a-x_e)(b-x_e)\} \quad (7)$$

$$(K_{sto}/K)^{1/2}$$
$$= 1 + K_{ip}(Kx_e^2/K_{sto})^{1/2} + 2K_qK_{ip}^2(Kx_e^2/K_{sto})^{3/2} \quad (8)$$

$$\int_0^x \frac{dx}{(a-x)(b-x)-x_{fl}^2/K} = \int_0^t k_f dt \quad (9)$$

In bromobenzene the assumption, $x_q \gg x_{fl}$ and x_{ip} seems plausible[12,13] and under the conditions the observed equilibrium constant as defined by the left hand side of Eq. 10 leads to the right hand side of Eq. 10. The forward rate constant, k_f was obtained

$$K_{obsd} \equiv x_e^{1/2}/[(a-x_e)(b-x_e)] = K(2K_qK_{ip}^2)^{1/2} \quad (10)$$

by performing the integration as described,[13,14] and the comparison of the experimental sets of x *vs.* t data

$$\int_0^x \frac{dx}{(a-x)(b-x)-K_{obsd}^{-1}x^{1/2}} = \int_0^t k_f dt \quad (11)$$

with the theoretical values calculated on the basis of the Scheme indicates fair agreement (Fig. 1). The kinetically determined equilibrium constant, $K_{obsd}=770$ $(dm^3\,mol^{-1})^{3/2}$ is in a comparable range with those observed previously (18.0—4400 $(dm^3\,mol^{-1})^{3/2}$),[12-14] though the value could not be verified analytically because of the precipitation of the produced salt.

Solvent Effects on the Rate Constants, k_f. The rate constants, k_f for the present reaction are summarized in Table 1, where k_x values calculated from the rate constant, k_f, and the molar volume of the solvent, V_s, expressed in dm³ mol⁻¹ by the equation, $k_x = k_f V_s^{-1}$ are also given.

There is a linear free energy relationship between the values of $\log k_x$ for the present reaction and the reaction of *N*,*N*,*N*′,*N*′-tetramethylthiourea with methyl iodide. (Fig. 3). The slope is 0.97.

In Table 2, typical values of the kinetic and thermodynamic data are summarized for comparison, where the reaction of TMTU with methyl iodide is taken as a standard reaction for comparison of the solvent effect.

The solvent effects on the rates of these ion forming reactions have been taken as giving the measure of the position of the transition state along the reaction coordinate, and were sometimes invoked as criteria for or against the operation of the reactivity-selectivity principles.[7-10] As far as these reactions are concerned, the first two reactions which proceed faster, have a larger sensitivity to solvent changes. In contrast to this observation, with respect to structural variations there seems to be some kind of correlation between kinetic and thermodynamic quantities, *i.e.*, a larger rate constant accompanies a larger equilibrium constant, and the activation enthalpy decreases with decreasing reaction enthalpy. Considering these trends, the interpretation of solvent effects on kinetics and thermodynamics needs deeper insights into the molecular processes operating in solution.

Activation Volumes and Volume Changes of Reaction. Activation volumes, ΔV_0^* and their pressure derivatives were determined by the least-squares method after expanding the rate constant into a power series of the pressure, Eqs. 12—14.

$$\ln k_p = \ln k_0 + Bp + Cp^2 \quad (12)$$

$$\Delta V_0^* = -1\ BRT \quad (13)$$

$$(\partial\Delta V^*/\partial p)_0 = -2\ CRT \quad (14)$$

The apparent molal volumes of the solutes, ϕ_v and the overall volume change in the reaction, $\Delta\phi_v$ are summarized in Table 3.

The volume behavior observed for the present reaction confirms the trends mentioned previously,[12] first, that molal volumes of thione derivatives and of ionic products are always larger in propylene carbonate than in acetonitrile and second, that the reaction in acetonitrile gives larger negative volume changes than in propylene carbonate, on activation as well as on reaction.

Recently, on the basis of the X-ray structural analysis[17] a polar structure with a partial negative charge on sulfur atom has been postulated for 1,3-dimethyl-4-imidazoline-2-thione. The apparent molal volume has also been measured for the compound for comparison. The molal volume difference of 7.7 cm³ mol⁻¹ between 1,3-dimethyl-4-imidazoline-2-thione (DMImdT) and 1,3-dimethylimidazolidine-2-thione (114.1 cm³ mol⁻¹ in acetonitrile[12]) would largely be ascribed to the molal volumes of two hydrogen atoms bonded to the ethylenic linkage of dimethylimidazolidine-2-thione. The estimation developed by Edwards and Bondi which relates the molal volumes to van der Waals volumes and surface areas,[18,19] gives 6.7 cm³ mol⁻¹ for the difference and this supports the above views. The methylene group contribution as deduced from molal volumes of two thione derivatives EMImdT and DMImdT, 18.2 cm³ mol⁻¹ agrees also with their estimation.[19] Thus, at this point, it is indeterminable to what extent the polarity of the solute manifests itself on the molal volume determined in dilute solution.

A fairly nice linear relationship, Eq. 15 exists be-

TABLE 4. ENTHALPY CHANGE OF SOLUTION, ΔH_s, AND OF REACTION, ΔH_r, AND ACTIVATION ENTHALPIES, ΔH^*

Solvents	ΔH_s/kJ mol^{-1} (25.0 °C)			ΔH_r	ΔH^*
	EMImdT	MeI	MEMImdT+I$^-$	kJ mol^{-1}	kJ mol^{-1}
Propylene carbonate	17.7	3.30	26.4	−51.9	53.5

N,*N*-Dimethylacetamide	12.3	0.23	15.9	—	55.6
Methanol	22.0	2.59	38.4	—	—
N,*N*-Dimethylacetamide	17.8[a]	0.23	11.7[b]		
Methanol	26.6[a]	2.59	31.0[b]		

a) DMIT. b) MDMIT+I$^-$.

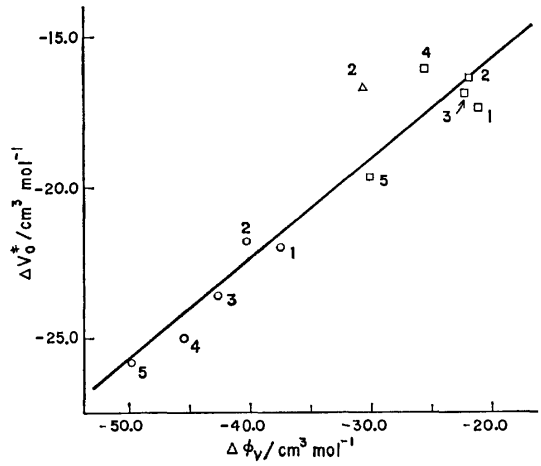

Fig. 4. Plots of ΔV_0^* *vs.* $\Delta\phi_v$.
Solvents: ○: acetonitrile, □: propylene carbonate, △: *N*,*N*-dimethylacetamide. Reactions: 1: TMTU+MeI, 2: EMImdT+MeI, 3: DMIT+MeI, 4: TT+MeI, 5: pyridine+MeI.

tween activation volumes and the overall volume changes of reactions studied by the authors, surprisingly including pyridine—methyl iodide reaction (Fig. 4). However, the possibility should be kept in mind

$$\Delta V_0^* = 0.33\Delta\phi_v - 9.2/\text{cm}^3\,\text{mol}^{-1} \quad (15)$$

that the linear relationship might be an artifact, since the points determined in propylene carbonate suggest a different trend from that obtained from the data in acetonitrile, though the regression line passes through the averaged point; also the point in dimethylacetamide largely deviates from the regression line. In the same vein as proposed previously,[12,13] the slope can be equated to the charge development index at the transition state, and the Eq. 16 can be derived,

$$\frac{\Delta V_0^* - \Delta_1 V^*}{\Delta\overline{V}^\circ - \Delta_1\overline{V}^\circ} = 0.33 \quad (16)$$

where the suffix, 1 indicates the structural volume changes on activation as well as on reaction. The combination of Eqs. 15 and 16 yields Eq. 17. In

$$\Delta_1 V^* - 0.33\Delta_1\overline{V}^\circ = -9.2/\text{cm}^3\,\text{mol}^{-1} \quad (17)$$

these derivations the apparent molal volumes were equated to the partial molal volumes ($\Delta\phi_v = \Delta\overline{V}^\circ$), taking into account the experimental conditions.

The structural volume changes have been estimated on various grounds, that is, for $\Delta_1 V^*$ they range from −6.5 to −11.7 cm^3 mol^{-1} [13,20-22] and for $\Delta_1\overline{V}^\circ$ from −4 to 0 cm^3 mol^{-1}.[13,14,20] Equation 17 does not give any preference to the respective set of values but serves as the criteria for the consistency of a given estimation. Considering these estimated values and also the relation (17), the set of central values, presumably the most plausible values, are taken as −10.1 and −2.8 cm^3 mol^{-1} for $\Delta_1\overline{V}^*$ and $\Delta_1 V^\circ$. The derived value, −10.1 cm^3 mol^{-1} for $\Delta_1 V^*$ is in fair agreement with the value, −10.7 cm^3 mol^{-1} estimated on completely different grounds.[21]

Enthalpy Measurements. Various enthalpies are summarized in Table 4. Throughout the two series of reactions, *i.e.*, DMIT with methyl iodide[12] and EMImdT with methyl iodide, the activation enthalpy has larger values in acetonitrile than in propylene carbonate, while the reaction enthalpy has larger negative values in acetonitrile than in propylene carbonate. With respect to structural variations there is observed some kind of relation between kinetics and thermodynamics as expected from the reactivity—selectivity pattern. In this regard also, the interpretation of the solvent effects on rates needs deeper insights. As a candidate, at least the cavity effect[23-25] would have to be invoked, though its' evaluation seems to present various problems.[23-25] On activation, as well as on reaction, reactants lose their volumes, *i.e.*, $\Delta_1 V^*$ and $\Delta_1\overline{V}^\circ$, and the work required to make a cavity in solution would differently affect activation enthalpies and reaction enthalpies. For rationalizing solvent effects on rates and on equilibria these would have to be evaluated on some basis. Abraham's way of taking an ion-pair as a final product[26] would provide one method for avoiding the complexity due to the cavity effect.

The thione derivatives as well as their methyl iodide salts give rise to characteristic transfer enthalpies. This might be ascribed to the polarity difference between the two thione derivatives DMIT and EMImdT, which could not be detected by the molal volume measurements. However, because of cancellations between reactants and products, a linear relation holds between the transfer reaction enthalpies, enthalpies of transfer from acetonitrile to other solvents of reaction, $\Delta H_{r,t} = \Delta H_{r,S} - \Delta H_{r,AN}$, of the two series (Fig. 5), and the slope of the plot, 0.86 is quite close to the ratio of the slopes of the linear free energy relationships

Table 5. Transition state indices for the reaction of 1-ethyl-3-methyl-4-imidazoline-2-thione with methyl iodide (30 °C)

Solvents	Slope	n_T	α
Acetonitrile	0.33	0.32	0.41
Propylene carbonate	0.33	0.34	0.42

as mentioned above, *i.e.*, (0.79/0.97)=0.82. This suggests that with respect to solvent variations, some sort of relation is operating between kinetics and thermodynamics as inferred from reactivity—selectivity pattern, though its direct proof would require much more effort.

Transition State Indices. Three kinds of transition state indices are compared in Table 5. The first is the charge development parameter which is defined as the slope of the plot of ΔV_0^* *vs.* $\Delta\overline{V}^\circ$. The second index has been calculated from the equation,

$$n_T = \frac{E_a}{(2E_a - \Delta E)} \tag{18}$$

where E_a and ΔE stand for the activation energy and the enthalpy change of the reaction.[8,9] The third index has been calculated by applying Marcus equations following the procedure as described by Albery and Kreevoy.[27,28] In the latter two calculations the activation enthalpy and the enthalpy change of the reaction have been directly substituted into these equations. Thus, judging from the experimental conditions, these indices would refer to the dissociated pair of ions as the final state.

$$\Delta G^* = \Delta G_0^* + (1/2)\Delta G^\circ + \Delta G^{\circ 2}/16\Delta G_0^* \tag{19}$$

$$\alpha = (1/2)(1+\Delta G^\circ/4\Delta G_0^*) \tag{20}$$

Recently Arnett *et al.*,[29] performed a complete kinetic and thermodynamic dissection of alkyl transfers. The Brönsted type plots gave linear relations and the slopes amount to 0.26 for the free energy correlation and to 0.23 for enthalpy correlation. On the other hand, the direct substitution of their enthalpies into Eq. 18, and Eqs. 19 and 20, and averaging afterwards lead to 0.30 and 0.39 for n_T and α. On the other hand Albery[30] calculated α ranging from 0.45 to 0.49 on the basis of the activation free energies and reaction free energies determined by Arnett *et al.*[29] Theoretical considerations demand the coincidence between the slope of the Brönsted type plots and the direct theoretical calculations as performed above.[10] In this regard for the Menschutkin reactions, n_T values indicate rather self-consistency. A similar situation holds for the present case, since n_T values obtained for the present reaction as well as for the previous reactions,[12-14] indicate close proximity to the charge development parameter as obtained from the volume correlation.

Here, again it should be pointed out that so far as we are concerned with a structurally related series of compounds, for a volume change correlation such as Fig. 4, structural volume changes, $\Delta_1 V^*$ and $\Delta_1\overline{V}^\circ$, could reasonably be assumed to be constant over the series. In contrast, for regular Brönsted type correlations such as ΔH^* *vs.* ΔH° or ΔG^* *vs.* ΔG°, the slope consists of two contributions, *i.e.*, a structural term and a solvational term accompanying structural variations. Thus the dissection of the slope into its constituent terms would be desirable for a more consistent comparison of the two types of slopes.

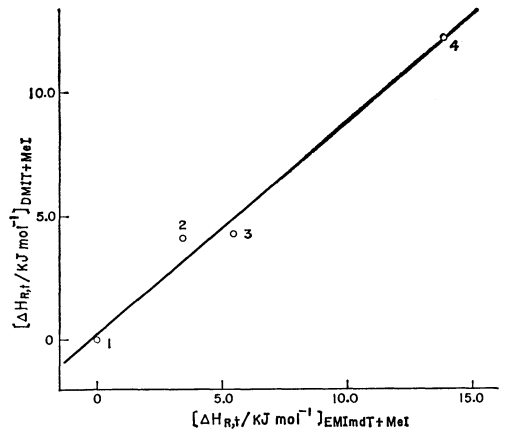

Fig. 5. Empirical correlations for the transfer reaction enthalpies (25 °C).
1: Acetonitrile, 2: *N,N*-dimethylacetamide, 3: propylene carbonate, 4: methanol.

The authors acknowledge their thanks to Dr. M. H. Abraham, University of Surrey, and Prof. T. Asano, Oita University for helpful discussions.

(Received October 23, 1981)

Diphenylphosphine and diphenylphosphinite derivatives of sugars such as methyl 6-deoxy-4-*C*-(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-talopyranoside, methyl 4-*O*-(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-rhamnopyranoside, methyl 4-*C*,4-*O*-(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-talopyranoside, 6-deoxy-6-*C*-(diphenylphosphino)-1,2:3,5-di-*O*-isopropylidene-α-D-glucofuranose, and 6-*O*-(diphenylphosphino)-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose were synthesized by the reaction of diphenylphosphine-sodium dihydrobis(2-methoxyethoxy)aluminate (SDMA) and/or diphenylphosphinous chloride–triethylamine with sugar derivatives. Homogeneous asymmetric hydrogenations of several prochiral olefins (α-acetylaminocinnamic acid, methyl α-acetylaminocinnamate, α-benzoylaminocinnamic acid, itaconic acid, and tiglic acid) were carried out using rhodium(I) catalysts with the tervalent chiral phosphorus derivatives of sugars. The highest optical yield for all the five substrates was obtained when di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and 6-*O*-(diphenylphosphino)-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose were used. The advantages of this method are the simplicity in the synthesis of the chiral phosphorus compound and the comparatively high optical yield in the asymmetric hydrogenation of olefins.

Homogeneous catalytic hydrogenation of olefins had been widely investigated since Wilkinson's works on chlorotris(triphenylphosphine)rhodium(I) were published.[1] The chirality of phosphine ligands of the reported rhodium catalysts appeared either on a phosphorus atom or on a carbon atom of the ligands. Various diphosphine ligands were often used for the asymmetric hydrogenation and they gave efficient results.[2] Monophosphines such as neomenthyldiphenylphosphine were used as the ligand of catalysts for asymmetric hydrogenation; these results, especially for monophosphines having a chiral center on the carbon atom,[3,4] were not always satisfactory.

Monosaccharides have several chiral carbon atoms in their skeletons; their applications to homogeneous asymmetric hydrogenation of prochiral materials are found in only a few papers. Iwami reported the asymmetric hydrogenation of olefins by rhodium complex with the ligand of 6-deoxy-6-(diphenylphosphino) derivative of galactose and 2-deoxy-2-(diphenylphosphino) derivative of altrose giving reduction products in optical yields of 2—39%.[5] Cullen and Sugi obtained an enantiomeric excess of 60—91% in the enantioselective hydrogenation of α-acetylaminoacrylic acid by rhodium catalyst having 2,3-bis(diphosphinite) derivative of glucopyranoside.[6,7] Recent studies on the efficiency of various tervalent diphosphorus derivatives of glucose and idose revealed that the ligand afforded up to 56% of enantiomeric excess *N*-acetylphenylalanine with *R* configuration in the hydrogenation.[8]

Our work on syntheses of carbohydrates having a phosphorus atom in the hemiacetal ring[9,10] suggested that we investigate the utility of chirality in the phosphorus-sugar skeleton as a chiral ligand. This paper deals with the synthesis of carbohydrates having a phosphorus-carbon linkage and the efficient application for asymmetric hydrogenation of olefins as a ligand of rhodium catalysts.

Results and Discussion

Synthesis of Chiral Phosphorus Ligands from Carbohydrates. Methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**1**) was oxidized with phosphorus pentaoxide in dimethyl sulfoxide–pyridine to give methyl 6-deoxy-2,3-*O*-isopropylidene-α-L-*lyxo*-hexopyranosid-4-ulose (**2**) in 75% yield.[11] The reaction of glucosid-4-ulose **2** with diphenylphosphine in the presence of triethylamine under nitrogen atmosphere afforded methyl 6-deoxy-4-*C*-(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-talopyranoside (**3**) in 13% yield.[12] The analogous reaction of glycosid-4-ulose **2** with diphenylphosphine oxide gave the corresponding 4-*C*-(diphenylphosphinyl) derivative of α-L-talopyranoside **4** in quantitative yield.

The reaction of compound **1** with diphenylphosphinous chloride in the presence of triethylamine under nitrogen atmosphere gave methyl 4-*O*-(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**5**) in 97% yield. The analogous reaction of compound **3** with diphenylphosphinous chloride gave methyl 4-*C*,4-*O*-bis(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-talopyranoside (**6**) in 54% yield.

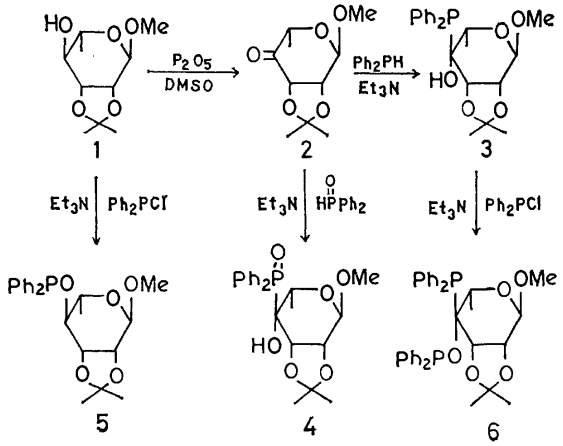

TABLE 1. HYDROGENATION OF OLEFINS WITH $RhCl(C_8H_{14})_2$-COMPOUND **3**

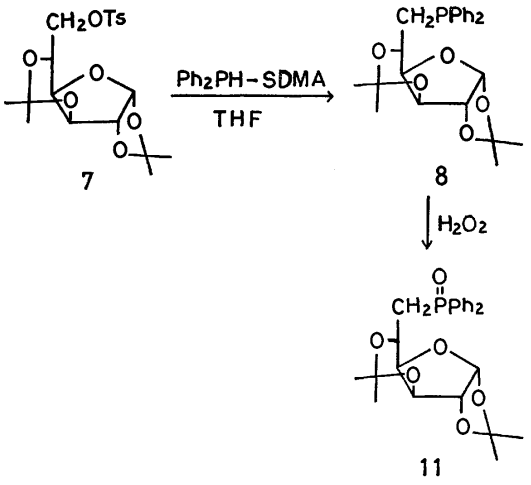
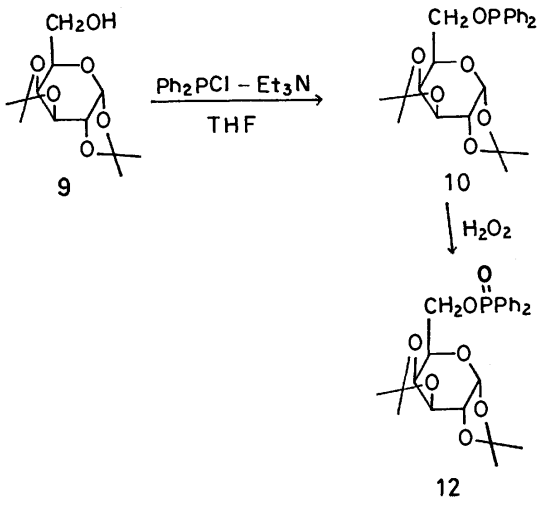
Substrate[a]	Ratio of substrate to Rh (I)	Solvent[b]	Temp °C	Time h	H_2 Pressure atm
α-Acetamidocinnamic acid	40[c]	EtOH	r. t.	48	1
	40[c]	EtOH	50	120	1
	100[d]	Benzene–EtOH (1:1)	50	12	50
Itaconic acid	100[d]	MeOH	50	120	1

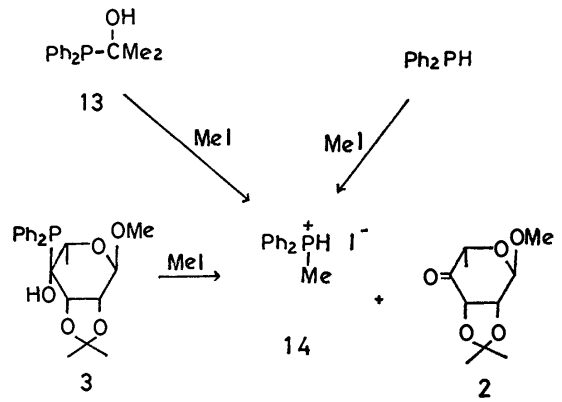
a) 10 mmol of the substrate was used. b) 15 ml of the solvent was used. c) 1 mmol of compound **3** and 1.5 mmol of triethylamine was used. d) 0.5 mmol of compound **3** and 0.6 mmol of triethylamine was used.

The reaction of 1,2:3,5-di-*O*-isopropylidene-6-*O*-(*p*-tolylsulfonyl)-α-D-glucofuranose (**7**) with diphenylphosphine in the presence of SDMA gave 6-deoxy-6-*C*-(diphenylphosphino)-1,2:3,5-di-*O*-isopropylidene-α-D-glucofuranose (**8**) in 90% yield. The reaction of 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**9**) with diphenylphosphinous chloride in the presence of triethylamine in tetrahydrofuran gave the corresponding phosphinite, 6-*O*-(diphenylphosphino)-1,2:3,4-di-*O*-isopropyridene-α-D-galactopyranose (**10**), in 46% yield. Oxidation of compounds **8** and **10** with hydrogen peroxide gave the oxides **11** and **12**. These tervalent phosphorus compounds were used as chiral ligands of rhodium catalysts.





Asymmetric Hydrogenation of Prochiral Olefins. Asymmetric hydrogenations of α-acetylaminocinnamic acid and itaconic acid were carried out using compound **3** as a chiral ligand for chlorobis(cyclooctene)-rhodium(I) complex. The hydrogenation under the conditions shown in Table 1 afforded almost none of the corresponding products. This result shows that the ligand cannot contribute to the hydrogenation. The hydrogenation of α-acetylaminocinnamic acid in benzene–ethanol (1:1) under 50 atm. of hydrogen by chlorobis(cyclooctene)rhodium(I) and (1-hydroxy-1-methylethyl)diphenylphosphine (**13**) catalyst was also unsuccessful. The reaction of compound **3** with methyl iodide gave methyldiphenylphosphonium iodide (**14**) and glycosid-4-ulose **2**, instead of the methiodide of compound **3**. The same result was observed when compound **13** was treated with methyl iodide; the reaction product was compound **14**.



These findings suggest that the adducts of diphenylphosphine, *i.e.*, compounds **3** and **13**, are not so stable as to make complexes with the rhodium compound.

The asymmetric hydrogenation of α-acetylaminocinnamic acid by chlorobis(cyclooctene)rhodium(I) in the presence of compound **5** or **6** as a chiral ligand gave *N*-acetylphenylalanine with *R* configuration as a major product (Table 2). The dissociation of diphenylphosphine observed in adduct **3** should be depressed in making a rhodium complex with compound **6**.

The asymmetric hydrogenation of prochiral olefins in the presence of di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and compound **8** gave the results summarized in Table 3. The same procedure using the rhodium complex and compound **10** for the prochiral olefins gave good results, as shown in Table 4. Table 5 summarizes the observed optical yield given by di-

Table 2. Asymmetric hydrogenation of α-acetamidicinnamic acid[a] with $RhCl(C_8H_{14})_2$-compound **5** or **6**

Phosphorus compound[b]	Ratio of substrate to Rh (I)	Temp °C	Time h	Conversion %	Optical yield/% (Configuration)
5	100	r. t.	24	100	13 (*R*)
6	100	r. t.	48	100	4.7(*R*)

a) 10 mmol of the acid, 40 ml of benzene-ethanol (1:1), and 0.6 mmol of triethylamine were used. b) 0.4 mmol of compound **5** and 0.1 mmol of compound **6** were used.

Table 3. Asymmetric hydrogenation of prochiral olefins with $Rh_2Cl_2(C_8H_{12})_2$-compound **8**[a]

Substrate	Reaction time h	Product	Chemical yield/%	$[\alpha]_D^{14}$/° (Solvent)	Optical yield/% (Configuration)
α-Acetylamino-cinnamic acid	24	*N*-Acetylphenylalanine ethyl ester	99	−1.3 (*c* 1.3, EtOH)	9 (*R*)
Methyl α-acetyl-aminocinnamate	24	*N*-Acetylphenylalanine methyl ester	99	−0.4 (*c* 1.0, MeOH)	2 (*R*)
α-Benzoylamino-cinnamic acid	24	*N*-Benzoylphenylalanine ethyl ester	72	−0.8 (*c* 1.0, MeOH)	2 (*S*)
Itaconic acid	24	Methylsuccinic acid	96	+2.4 (*c* 1.3, EtOH)	14 (*R*)
Tiglic acid	24	2-Methylbutyric acid	98	−0.3 (*c* 2.0, EtOH)	2 (*R*)

a) The ratios of substrate to Rh(I) complex and of compound **8** to Rh(I) complex were 25:1 and 4:1, respectively. All hydrogenations were carried out in 10 ml of benzene-ethanol (1:1) in the presence of 0.2 ml of triethylamine at room temperature under atmospheric pressure of hydrogen.

Table 4. Asymmetric hydrogenation of prochiral olefins with $Rh_2Cl_2(C_8H_{12})_2$-compound **10**[a]

Substrate	Reaction time h	Product	Chemical yield/%	$[\alpha]_D^{14}$/° (Solvent)	Optical yield/% (Configuration)
α-Acetylamino-cinnamic acid	24	*N*-Acetylphenylalanine ethyl ester	99	−8.9 (*c* 1.2, EtOH)	67 (*R*)
Methyl α-acetyl-aminocinnamate	24	*N*-Acetylphenylalanine methyl ester	99	−6.6 (*c* 2.2, MeOH)	29 (*R*)
α-Benzoylamino-cinnamic acid	24	*N*-Benzoylphenylalanine ethyl ester	85	−12.8 (*c* 1.0, MeOH)	32 (*S*)
Itaconic acid	24	Methylsuccinic acid	99	−8.4 (*c* 1.0, EtOH)	49 (*S*)
Tiglic acid	24	2-Methylbutyric acid	99	−11.9 (*c* 2.8, EtOH)	62 (*R*)

a) The ratios of substate to Rh(I) complex and of compound **10** to Rh(I) complex were 25:1 and 4:1, respectively. All hydrogenations were carried out in 10 ml of benzene-ethanol (1:1) in the presence of 0.2 ml of triethylamine at room temperature under atmospheric pressure of hydrogen.

μ-chloro-bis(cyclooctadiene)dirhodium(I) and chloro-bis(cyclooctene)rhodium(I) with compound **10** as the ligand.

These results indicate that efficiency of chiral phosphinite **10** is good enough for the asymmetric hydrogenation of prochiral olefins, since the reported enantiomeric excess of *N*-acetylphenylalanine is up to 56% in the homogeneous asymmetric hydrogenation of α-acetylaminocinnamic acid by a rhodium catalyst using chiral ligands of 5,6-bis(diphenylphosphino) derivatives of glucose and idose.[8] This procedure seems to be a simple and efficient way for the asymmetric hydrogenation of prochiral olefins, compared with the other methods reported in the literature,[8,13] owing to the convenience in the ligand synthesis and to comparably high optical yields.

Experimental

Measurements. Melting and boiling points were uncorrected. ^{1}H-NMR spectra were measured on Hitachi-Perkin-Elmer R-24 (60 MHz) spectrometer with tetramethylsilane as an internal standard, and IR spectra on a Japan Spectroscopic Co. Ltd. A-3 infrared spectrophotometer. Optical rotations were measured on Japan Spectroscopic Co. Ltd. DIP-4 digital polarimeter.

Materials. The following materials were synthesized according to reported methods: α-acetylaminocinnamic acid,[14] α-benzoylaminocinnamic acid,[15] methyl α-acetylam-

TABLE 5. ASYMMETRIC HYDROGENATION OF PROCHIRAL OLEFINS WITH $Rh_2Cl_2(C_8H_{12})_2$- OR $RhCl(C_8H_{14})_2$-COMPOUND **10**[a]

Rh(I) Complex	Substrate	Reaction time / h	Product	Chemical yield/%	$[\alpha]_D^{17}$/° (Solvent)	Optical yield/% (Configuration)
$Rh_2Cl_2(C_8H_{12})_2$	α-Acetylamino-cinnamic acid	96	*N*-Acetylphenyl-alanine ethyl ester	78	−3.3 (*c* 0.9, EtOH)	25 (*R*)
	Itaconic acid	96	Methylsuccinic acid	100	−3.8 (*c* 1.8, EtOH)	22 (*S*)
	Tiglic acid	120	2-Methylbutyric acid	100	−2.8 (*c* 1.6, EtOH)	15 (*R*)
$RhCl(C_8H_{14})_2$	α-Acetylamino-cinnamic acid	216	*N*-Acetylphenyl-alanine ethyl ester	88	−0.7 (*c* 1.1, EtOH)	6 (*R*)
	Itaconic acid	216	Methylsuccinic acid	100	−2.3 (*c* 1.6, EtOH)	14 (*S*)
	Tiglic acid	216	2-Methylbutyric acid	100	−1.0 (*c* 1.4, EtOH)	5 (*R*)

a) The ratios of substrate to Rh(I) complex and of compound **10** to Rh(I) complex were 100:1 and 4:1, respectively. All hydrogenations were carried out in 10 ml of benzene-ethanol (1:1) in the presence of 0.2 ml of triethylamine at room temperature under under atmospheric pressure of hydrogene.

inocinnamate,[16] diphenylphosphine (bp 108.5—113 °C/2 mmHg[17]),[18] diphenylphosphinous chloride (bp 110 °C/0.5 mmHg),[19] chlorobis(cyclooctene)rhodium(I),[20] di-μ-chlorobis(cyclooctadiene)dirhodium(I),[21] methyl 2,3-*O*-isopropylidene-α-L-rhamnopyranoside (**1**),[12] 1,2-*O*-isopropylidene-6-*O*-(*p*-tolylsulfonyl)-α-D-glucofuranose (**7**) (mp 108 °C),[22] 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**9**),[23] (1-hydroxy-1-methylethyl)diphenylphosphine (13) (mp 140 °C).[24]

Methyl 6-Deoxy-2,3-O-isopropylidene-α-L-lyxo-hexopyranosid-4-ulose (2). Compound **1** (8.2 g) was oxidized with phosphorus pentaoxide (20.5 g) at room temperature for 4 d. The work-up, with addition of water and extraction with chloroform, gave compound **2** in 75% yield,[12] $[\alpha]_D^{15}$ −110° (*c* 0.7, EtOH). Mass spectrum, *m/e*, 216 (M^+).

Found: C, 55.08; H, 7.46%. Calcd for $C_{10}H_{16}O_5$: C, 55.55; H, 7.46%.

Addition of Diphenylphosphine to Compound 2. Addition of diphenylphosphine (0.30 g) to glycosid-4-ulose **2** (0.30 g) in the presence of triethylamine under nitrogen atmosphere at room temperature for 2 days gave methyl 6-deoxy-4-*C*-(diphenylphosphino)-2,3-*O*-isopropylidene-α-L-talopyranoside (**3**) (0.080 g) in 13% yield, mp 100—101.5 °C, $[\alpha]_D^{16}$ −97° (*c* 0.71, EtOH). ^{1}H-NMR ($CDCl_3$) δ 0.98, 1.30 (2×s, 6H, CMe_2), 1.36 (d, *J*=6.6 Hz, C_5–Me), 3.35 (s, 3H, C_1–OMe), 4.0—4.9 (m, 5H, C_1–, C_2–, C_3–, C_4–OH), 7.05—8.0 (m, 10H, Ph); IR ν_{max}^{KBr} 3200 cm^{-1} (OH); mass spectrum, *m/e*, 402 (M^+). Oxidation of compound **3** gave the oxide (compound **4**).

Found: C, 62.80; H, 6.31%. Calcd for $C_{22}H_{27}O_6P$: C, 63.15; H, 6.50%.

Addition of Diphenylphosphine Oxide to Compound 2. Addition of diphenylphosphine oxide (0.10 g) to glycosid-4-ulose **2** (0.10 g) in the presence of triethylamine under nitrogen flow at room temperature for 3 h gave a crystalline adduct **4**. Recrystallization of the product from methanol-ether gave 0.18 g of pure methyl 6-deoxy-4-*C*-(diphenylphosphinyl)-2,3-*O*-isopropylidene-α-L-talopyranoside (**4**), mp 117—118.5 °C, $[\alpha]_D^{25}$ −132° (*c* 1.0, $CHCl_3$). ^{1}H-NMR ($CDCl_3$) δ 1.00 (d, *J*=12 Hz, 3H, C_5–Me), 1.05, 1.31 (2×s, 6H, CMe_2), 3.45 (s, 3H, C_1–OMe), 3.96—5.0 (m, 5H, C_1–, C_2–, C_3–, C_5–H, C_4–OH), 7.0—8.5 (m, 10H, Ph); IR ν_{max}^{KBr} 3150 cm^{-1} (OH); mass spectrum, *m/e*, 418 (M^+).

Found: C, 63.06; H, 6.76%. Calcd for $C_{22}H_{27}O_6P$: C, 63.15; H, 6.50%.

Methyl 4-O-(Diphenylphosphino)-2,3-O-isopropylidene-α-L-rhamnopyranoside (5). Reaction of compound **1** (0.10 g) with diphenylphosphinous chloride (0.10 g) in triethylamine (4 ml) under nitrogen atmosphere at room temperature for 24 h, followed by work-up by adding water and extraction with chloroform, gave compound **5** (0.189 g) in 97% yield, $[\alpha]_D^{20}$ −8.3° (*c* 2.0, EtOH). ^{1}H-NMR ($CDCl_3$) δ 1.25 (d, *J*=6.0 Hz, 3H, C_5–Me), 1.30, 1.50 (2×s, 6H, CMe_2), 3.35 (s, 3H, C_1–OMe), 3.50—4.90 (m, 5H, C_1–, C_2–, C_3–, C_4–, C_5–H), 7.0—8.0 (m, 10H, Ph); mass spectrum, *m/e*, 402 (M^+).

Found: C, 65.52; H, 6.99%. Calcd for $C_{22}H_{27}O_5P$: C, 65.66; H, 6.76%.

Methyl 4-C,4-O-(Diphenylphosphino)-2,3-O-isopropylidene-α-L-talopyranoside (6). Reaction of compound **3** (0.080 g) with diphenylphosphinous chloride (0.050 g) in triethylamine (4 ml) at room temperature for 24 h, followed by purification by liquid chromatography, gave compound **6** (0.062 g) in 54% yield, $[\alpha]_D^{15}$ −28° (*c* 1.0, EtOH). ^{1}H-NMR ($CDCl_3$) δ 1.21 (d, *J*=13.6 Hz, 3H, C_5–Me), 1.21, 1.48 (2×s, 6H, CMe_2), 3.44 (s, 3H, C_1–OMe), 2.95—5.0 (m, 4H, C_1–, C_2–, C_3–, C_5–H), 7.0—8.5 (m, 20H, Ph); mass spectrum, *m/e*, 586.

The oxidation of compound **6** with hydrogen peroxide gave the dioxide, mp 104—106 °C, mass spectrum, *m/e*, 618 (M^+).

Found: C, 65.84; H, 6.33%. Calcd for $C_{34}H_{36}O_7P_2$: C, 66.01; H, 5.87%.

6-Deoxy-6-C-(diphenylphosphino)-1,2:3,5-di-O-isopropylidene-α-D-glucofuranose (8). Addition of compound **7** (1.5 g) in tetrahydrofuran (10 ml) to a mixture of diphenylphosphine (1.0 g) and SDMA (2.0 g) in tetrahydrofuran at room temperature, followed by refluxing for 4 h, gave compound **8**. Work-up by addition of water and neutralization, followed by filtration, concentration *in vacuo*, and isolation by liquid chromatography, gave 1.4 g of pure compound **8** (90% yield), $[\alpha]_D^{16}$ +2.1° (*c* 1.0, EtOH). ^{1}H-NMR ($CDCl_3$) δ 1.06, 1.26, 1.31, 1.45 (4×s, 12H, CMe_2), 2.02 (d, *J*=13.0 Hz, 2H, C_6–, $C_{6'}$–H), 3.3—5.0 (m, 4H, C_2–, C_3–, C_4–, C_5–H), 5.92 (d, 1H, *J*=4.0 Hz, C_1–H), 7.15—7.90 (m, 10H, Ph); mass spectrum, *m/e*, 428 (M^+)

Found: C, 67.35; H, 6.87%. Calcd for $C_{24}H_{29}O_5P$: C, 67.28; H, 6.82%.

*6-O-(Diphenylphosphino)-1,2:3,4-di-O-isopropylidene-α-D-galactopyranose (**10**).* Reaction of compound **9** (5.4 g) with diphenylphosphinous chloride (6.8 g) in the presence of triethylamine (13 ml) at room temperature for 24 h under nitrogen atmosphere, followed by filtration, concentration, and purification by liquid chromatography, gave compound **10** (4.1 g, 46% yield), $[\alpha]_D^{16}$ +47.0° (*c* 1.18, EtOH). ^{1}H-NMR ($CDCl_3$) δ 1.32, 1.42, 1.46 (4×s, 12H, CMe_2), 3.76—4.76 (m, 6H, C_2–, C_3–, C_4–, C_5–, C_6–, C_6'–H), 5.56 (d, *J*=5.0 Hz, 1H, C_1–H), 7.16—7.72 (m, 10H, Ph); mass spectrum, *m/e*, 444 (M^+).

Found: C, 64.35; H, 6.70%. Calcd for $C_{24}H_{29}O_6P$: C, 64.86; H, 6.58%.

*Asymmetric Hydrogenation of α-Acetylaminocinnamic Acid with Di-μ-chloro-bis(cyclooctadiene)dirhodium(I) and Compound **10**.* Asymmetric hydrogenation of α-acetylaminocinnamic acid (500 mg) in anhydrous benzene (5 ml)–absolute ethanol (5 ml) was carried out using di-μ-chloro-bis(cyclooctadiene)-dirhodium (I) (35 mg) and compound **10** (211 mg) as the catalyst in the presence of triethylamine (0.2 ml) under atmospheric pressure of hydrogen at room temperature for 24 h. Removal of the catalyst by passing a column peacked with ion exchange resine Dowex 50W (H^+), followed by decolorization with activated charcoal and removal of the solvent *in vacuo*, gave *N*-acetylphenylalanine ethyl ester (100% conversion). The identification of the product was performed by ^{1}H-NMR, whose spectrum was as follows: ($CDCl_3$) δ 1.21 (t, *J*=7.0 Hz, 3H, $OCH_2C\underline{H}_3$), 1.95 (s, 3H, Ac), 3.09 (d, *J*=6.0 Hz, 2H, $C\underline{H}_2Ph$), 4.15 (q, *J*=7.5 Hz, 2H, $OC\underline{H}_2CH_3$), 4.85 (dd, *J*=6.0 Hz, 1H, CH), 6.46 (bd, *J*=7.5 Hz, NH), 7.05—7.40 (m, 5H, Ph). The product had $[\alpha]_D^{16}$ −8.82° (*c* 1.2, EtOH) which showed 67% optical yield of the *R* configuration.

The asymmetric hydrogenation of methyl α-acetylaminocinnamate, *N*-benzoylaminocinnamic acid, itaconic acid, and tiglic acid were performed in a similar fashion. The optical yields of the products were calculated based on the reported values of optical rotation for *N*-acetyl-(*S*)-phenylalanine,[25] *N*-acetyl-(*S*)-phenylalanine ethyl ester,[26] *N*-acetyl-(*S*)-phenylalanine methyl ester,[26] *N*-benzoyl-(*R*)-phenylalanine ethyl ester,[27] (*R*)-methylsuccinic acid,[5] and (*S*)-2-methylbutyric acid.[28]

*Reaction of 6-Deoxy-4-C-(diphenylphosphino)-2,3-O-isopropylidene-α-L-talopyranoside (**3**) with Methyl Iodide.* Reaction of compound **3** (0.10 g) with an excess amount of methyl iodide in anhydrous ether (10 ml) under nitrogen atmosphere gave methyldiphenylphosphonium iodide (**14**) and glycosid-4-ulose **2** in 80% yield.

*Oxidation of Compound **10** with Hydrogen Peroxide.* Oxidation of compound **10** with 38% hydrogen peroxide (0.11 g) at room temperature, followed by work-up by treatment with sodium thiosulfate and extraction with chloroform, gave 6-*O*-(diphenylphosphinyl)-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**12**) in 75% yield, mp 115—116 °C, $[\alpha]_D^{15}$ −40° (*c* 0.6, EtOH). ^{1}H-NMR δ 1.26, 1.33, 1.50 (4×s, 12H, CMe_2), 3.8—4.9 (m, 6H, C_2–, C_3–, C_4–, C_5–, C_6–, C_6'–H), 5.60 (d, *J*=8.0 Hz, 1H, C_1–H), 7.2—8.1 (m, 10H, Ph); mass spectrum, *m/e*, 460 (M^+).

Found: C, 62.80; H, 6.45%. Calcd for $C_{24}H_{29}O_7P$: C, 62.60; H, 6.35%.

*Oxidation of Compound **8**.* Oxidation of compound **8** in a similar way as described above gave 6-deoxy-6-*C*-(diphenylphosphinyl)-1,2:3,5-di-*O*-isopropylidene-α-D-glucofuranose (**11**), $[\alpha]_D^{16}$ +1.8° (*c* 1.2, EtOH), ^{1}H-NMR ($CDCl_3$) δ 1.16, 1.23, 1.40 (4×s, 12H, CMe_2), 2.02—2.75 (m, 2H, C_6–, C_6'–H), 3.25—4.46 (m, 3H, C_3–, C_4–, C_5–H), 4.50 (d, *J*=5.1 Hz, 1H, C_2–H), 5.89 (d, *J*=5.1 Hz, 1H, C_1–H), 6.80—7.93 (m, 10H, Ph); mass spectrum, *m/e*, 444 (M^+).

Found: C, 64.94; H, 6.40%. Calcd for $C_{24}H_{29}O_6P$: C, 64.86; H, 6.58%.

Synthesis of 4,7-Indolequinones by Photoinduced Reaction of Azidoquinones

Tadashi KOZUKA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 30, 1981)

Various azidoquinones were prepared from methyl 3-substituted 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate. Irradiation of these azidoquinones gave methyl 3-substituted 6-methyl-4,7-dioxoindole-2-carboxylates, a model of mitomycin analogs, in a moderate yield.

Recently, the author found that *p*-benzoquinones having an ester group in the α position of alkyl side chains have a high reactivity toward γ-hydrogen abstraction reaction to give the rearranged product, *i.e.*, methyl 3-substituted 2,3-dihydro-5-hydroxybenzofuran-2-carboxylate derivatives **1**, in fairly good yields.[1] In this paper, as a further extension of these reactions, the present author reports a reaction of the corresponding azidoquinone **4** derived from the dihydrobenzofuran **1**. The investigations of the photolysis of azidoquinones have been centered on the exploitation of a new general synthetic method of 4,7-indolequinones, which are related to some natural products.[2] Pharmacologically interesting functionalized 4,7-indolequinones **5a**—**i** were obtained by photoinduced cyclization of the corresponding azidoquinones **4a**—**i** having a suitable side chain.

In general, the intramolecular cyclization of ortho-substituted aryl azide could be one of the most important synthetic routes to five-memberd nitrogen heterocycles.[3] However, research studies on simple alkyl-substituted azidoquinones so far reported have revealed that the reactions of azidoquinones were highly dependent upon the reaction conditions (acidic or thermal), and rearrangement products[4] or ring contraction products[5] were the major components of the reactions.[6] On the contrary, in the photoreaction of functionalized alkylazidoquinones as described in the following text, it was found that an intramolecular photoinduced cyclization reaction occurs without any difficulties to give 4,7-indolequinone derivatives **5**.

Results and Discussion

Preparation of Azidoquinones. All of the azidoquinones **4** were usually obtained from methyl 3-substituted 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylates **1**[1] by the subsequent reaction (Scheme 1). The dihydrobenzofuran **1** was treated with bromine in chloroform to give methyl 3-substituted 4-bromo-2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate **2**. Oxidation of this bromide **2** with ceric ammonium nitrate (CAN) in an aqueous acetonitrile[7] afforded bromoquinone **3**, which was reacted with sodium azide[8] in an aqueous methanol to provide azidoquinone **4** in an excellent overall yield from **1**. The structures of bromodihydrobenzofuran **2**, bromoquinone **3**, and azidoquinone **4** were identified on the basis of its spectroscopic properties (Table 2).

Table 1. Photoinduced formation of 4,7-indolequinone **5** from azidoquinone **4**

Entry	Azidoquinone	R	Product	Yield/%[a]
1	**4a**	H	**5a**	42
2	**4b**	Me	**5b**	62
3	**4c**	Et	**5c**	61
4	**4d**	$(CH_2)_2CH_3$	**5d**	60
5	**4e**	CO_2Me	**5e**	40
6	**4f**	$(CH_2)_2CO_2Me$	**5f**	64
7	**4g**	$(CH_2)_3NPht$	**5g**	56
8	**4h**	$(CH_2)_3NHCOCF_3$	**5h**	42
9	**4i**	$CH_2OCO_2C_6H_5$	**5i**	37

a) Reported yields are for isolated, purified products.

Irradiation of Azidoquinones. On irradiation of a solution of azidoquinone **4** (1 mmol) in methanol with a high pressure Hg arc lamp (300 W), the orange yellow color of the solution rapidly turned purple red with the evolution of nitrogen, and then gradually changed to dark yellow. The photochemical reaction was complete in several hours (2—5 h) at room temperature and gave methyl 3-substituted 6-methyl-4,7-dioxoindole-2-carboxylate **5** in a good yield after purification by column chromatography (Table 1). Methanol was the best solvent for the photochemical reaction. Although the same product was taken in benzene, hexane, and chloroform, the yield of the 4,7-indolequinone **5** was rather poor.

The salient feature of this result indicated that the formation of functionalized 4,7-indolequinones **5e**—**i** easily occures on irradiation of azidoquinone **4e**—**i** having various functional groups (ester, amide, imide, and protected alcohol) in the alkyl side chain.

The structures of the irradiation product **5** were established by their IR and ^1H NMR spectra and by their chemical reactions (Experimental). For ex-

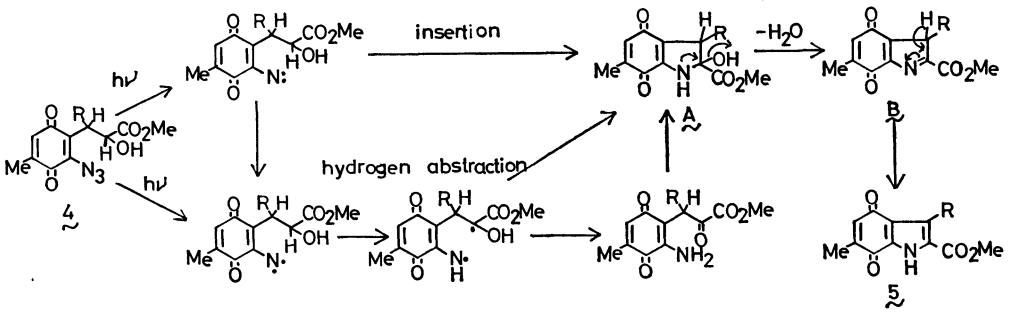
a) ^{1}H NMR spectra were run on a 100 MHz instrument. b) ABX type: 3.29(dd, J=7.2 and 16 Hz, 1H); 3.53(dd, J=10 and 16 Hz, 1H). c) Chemical shifts and coupling constants were not determined due to overlap with the signal of other protons.



Scheme 2.

ample, evidence for the presence of N–H bond in photoproduct **5** was shown by the fact that the reaction of **5b** with 1 equiv of potassium *t*-butoxide,[9] followed by addition of the excess methyl iodide, gave methyl 1,3,6-trimethyl-4,7-dioxoindole-2-carboxylate **6a** in an excellent yield (90%). Additional evidence for the presence of the quinone ring in the product **5** was obtained by reduction-acetylation[10] of **5f** to methyl 4,7-diacetoxy-5-methylindole-2-carboxylate derivative **7** in an 80% yield. The structure of **5f** was further supported by the Thiele oxidation[11] to methyl 4,5,7-triacetoxy-6-methylindole 2-carboxylate **8**.

Thermal cyclization of azidoquinone **4** in benzene or toluene gave indolequinone **5** in a low yield (5—10%). The yield of **5** decreased further when **4** was heated in a high boiling solvent (xylene or decalin), and tars were obtained.

The photochemical conversion from **4** to **5** can be rationalized as proceeding *via* nitrene[12] (Scheme 2), but it is not clear whether the cyclization step takes place by direct intramolecular insertion of the singlet nitrene into a C–H bond or by intramolecular 1,5-hydrogen abstraction of the triplet nitrene.

The evidence for the reaction pathway outlined in Scheme 2 was obtained by studying UV spectra analysis during irradiation of **4b**. Irradiation of **4b** in methanol caused a rapid change in the absorption spectrum. The absorption maximum at 405 nm (**4b**) was shifted initially to 510 nm (**A** or **B**), but finally moved 346 nm (**5b**). That is to be expected for the intermediate corresponding to **A** or **B**.

In summary, these photochemical ring formations from the azidoquinone under mild conditions allow the facile synthesis of highly functionalized 4,7-indolequinones which have mitosane ring systems.

Experimental

Melting points were measured on a Yanagimoto micro melting point apparatus and are uncorrected. Infrared spectra were run on a JASCO IRA-1 spectrophotometer. Nuclear magnetic resonance spectra were obtained with JEOL PS-100 spectrometer with tetramethylsilane as an internal standard and the chemical shifts are recorded in δ values. Mass spectra were measured with Hitachi M-52 instrument (20 eV). Column chromatography was performed using Wako reagent grade silica gel (200 mesh). Preparative thin layer chromatography was performed using Merck silica gel F-254. Elemental analyses were performed by the Microanalytical Laboratory of Kyoto University. UV irradiations were carried out in a Pyrex tube at room temperature with an Eikosha 300 W high pressure Hg lamp.

Preparation of Starting Materials. All of the compounds **1a**—**i** described below were prepared according to the previously reported methods.[1] Methyl 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate (**1a**), methyl 2,3-dihydro-5-hydroxy-3,6-dimethylbenzofuran-2-carboxylate (**1b**), methyl 3-ethyl-2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate (**1c**), methyl 2,3-dihydro-5-hydroxy-6-methyl-3-propylbenzofuran-2-carboxylate (**1d**), dimethyl 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2,3-dicarboxylate (**1e**), methyl 2,3-dihydro-5-hydroxy-3-[2-(methoxycarbonyl)ethyl]-6-methylbenzofuran-2-carboxylate (**1f**), methyl 2,3-dihydro-5-hydroxy-3-[3-(phthalimido)propyl]-6-methylbenzofuran-2-carboxylate (**1g**), methyl 2,3-dihydro-5-hydroxy-6-methyl-3-[3-trifluoroacetamido)propyl]benzofuran-2-carboxylate (**1h**), and methyl 2,3-dihydro-5-hydroxy-3-(phenoxycarbonyloxymethyl)benzofuran-2-carboxylate (**1i**).

Methyl 4-Bromo-2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate (2a). (General Procedure for Bromination). To a well-stirred solution of **1a** (389 mg, 1.87 mmol) in chloroform (20 ml) at 0 °C was added dropwise (30 min) 1 M (1 M=1 mol dm^{-3}) bromine in chloroform (2 ml). After stirring for 30 min, the reaction mixture was treated with a diluted solution of sodium thiosulfate. The organic layer was washed twice with water, dried over $MgSO_4$, evaporated, and chromatographed (silica gel, benzene solvent) to give **2a** (484 mg, 90%): Mp 81.5—82.5 °C (dichloromethane–petroleum ether); IR (KBr): 3350 and 1740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.25 (s, 3H), 3.29 (dd, J=7.2 and 16 Hz, 1H), 3.53 (dd, J=10 and 16 Hz, 1H), 3.81 (s, 3H), 3.92 (bs, 1H), 5.18 (dd, J=7.2 and 10 Hz, 1H), and 6.62 (s, 1H); Found: C, 45.81; H, 3.94; Br, 28.17%. Calcd for $C_{11}H_{11}O_4Br$: C, 46.01; H, 3.86; Br, 27.83%.

Methyl 4-Bromo-2,3-dihydro-5-hydroxy-3,6-dimethylbenzofuran-2-carboxylate (2b). Reaction of **1b** (641 mg, 2.88 mmol) with bromine by the method described above gave **2b** (702 mg, 81%): Mp 70—73 °C (dichloromethane–petroleum ether); IR (KBr): 3420 and 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.46 (d, J=7 Hz, 3H), 2.23 (s, 3H), 3.72 (s, 3H), 3.62 (m, 1H), 4.68 (d, J=4 Hz, 1H), 5.14 (s, 1H), and 6.62 (s, 1H); Found: C, 47.62; H, 4.43; Br, 26.77%. Calcd for $C_{12}H_{13}O_4Br$: C, 47.86; H, 4.35; Br, 26.54%.

Methyl 4-Bromo-3-ethyl-2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate (2c). Reaction of **1c** (236 mg, 1 mmol) with bromine gave **2c** (230 mg, 73%): Mp 80—81 °C (petroleum ether); IR (KBr): 3460 and 1740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.96 (t, J=7 Hz, 3H), 1.66 (m, 2H), 2.26 (s, 3H), 3.52 (m, 1H), 3.78 (s, 3H), 4.85 (d, J=3.2 Hz, 1H), 5.17 (s, 1H), and 6.67 (s, 1H); Found: C, 49.26; H, 4.92; Br, 25.29%. Calcd for $C_{13}H_{15}O_4Br$: C, 49.54; H, 4.80; Br, 25.36%.

*Methyl 4-Bromo-2,3-dihydro-5-hydroxy-6-methyl-3-propylbenzofuran-2-carboxylate (**2d**).* Bromination of **1d** (250 mg, 1 mmol) gave **2d** as an oil (263 mg, 80%). IR (neat): 3460 and 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.96 (t, J=7 Hz, 3H), 1.20—2.20 (m, 4H), 2.25 (s, 3H), 3.52 (m, 1H), 3.76 (s, 3H), 4.85 (d, J=3.2 Hz, 1H), 5.16 (s, 1H), and 6.64 (s, 1H). Found: C, 50.94; H, 5.40%. Calcd for $C_{14}H_{17}O_4Br$: C, 51.08; H, 5.21%.

*Dimethyl 4-Bromo-2,3-dihydro-5-hydroxy-6-methylbenzofuran-2,3-dicarboxylate (**2e**).* A solution of **1e** (476 mg, 1.79 mmol) in chloroform was treated with bromine to give **2e** (405 mg, 66%): Mp 182—185 °C (methanol–petroleum ether); IR (KBr): 3340 and 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.27 (s, 3H), 3.80 (s, 3H), 3.82 (s, 3H), 4.40 (d, J=4.6 Hz, 1H), 5.22 (s, 1H), 5.35 (d, J=4.6 Hz, 1H), and 6.71 (s, 1H). Found: C, 45.10; H, 3.94%. Calcd for $C_{13}H_{13}O_6Br$: C, 45.24; H, 3.80%.

*Methyl 4-Bromo-2,3-dihydro-5-hydroxy-3-[2-(methoxycarbonyl)ethyl]-6-methylbenzofuran-2-carboxylate (**2f**).* Reaction of **1f** (589 mg, 2 mmol) with bromine afforded **2f** (642 mg, 86%): Mp 91—92 °C (petroleum ether–dichloromethane); IR (KBr): 3470, 1745, and 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.90—2.51 (m, 4H), 2.26 (s, 3H), 3.52—3.88 (m, 1H), 3.66 (s, 3H), 3.75 (s, 3H), 4.83 (d, J=3.3 Hz, 1H), 5.23 (s, 1H), and 6.64 (s, 1H). Found: C, 47.97; H, 4.76; Br, 21.59%. Calcd for $C_{15}H_{17}O_6Br$: C, 48.27; H, 4.59; Br, 21.41%.

*Methyl 4-Bromo-2,3-dihydro-5-hydroxy-3-[3-(phthalimido)propyl]-6-methylbenzofuran-2-carboxylate (**2g**).* Reaction of **1g** (395 mg, 1 mmol) with bromine gave **2g** (337 mg, 71%): Mp 153—154 °C (methanol–dichloromethane); IR (KBr): 3490, 1765, and 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.60—2.20 (m, 4H), 2.24 (s, 3H), 3.50—3.90 (m, 3H), 3.77 (s, 3H), 4.86 (d, J=3.5 Hz, 1H), 5.19 (s, 1H), 6.65 (s, 1H), and 7.66—7.90 (m, 4H). Found: C, 55.44, H, 4.17; N, 2.83; Br, 17.07%. Calcd for $C_{22}H_{20}O_6NBr$: C, 55.71; H, 4.25; N, 2.95; Br, 16.85%.

*Methyl 4-Bromo-2,3-dihydro-5-hydroxy-6-methyl-3-[3-(trifluoroacetamido)propyl]benzofuran-2-carboxylate (**2h**).* Prepared from **1h** (860 mg, 2.38 mmol) and bromine; (628 mg, 60%): Mp 93—94 °C (petroleum ether–dichloromethane); IR (KBr): 3420, 3290, 1735, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$)δ: 1.45—2.20 (m, 4H), 2.25 (m, 3H), 3.40 (t, J= 7 Hz, 2H), 3.54 (m, 1H), 3.75 (s, 3H), 4.78 (d, J=3 Hz, 1H), 5.13 (s, 1H), 6.41 (bs, 1H), and 6.61 (s, 1H). Found: C, 43.50; H, 3.87; N, 3.30%. Calcd for $C_{16}H_{17}O_5NBr$: C, 43.65; H, 3.89; N, 3.18%.

*Methyl 4-Bromo-2,3-dihydro-5-hydroxy-6-methyl-3-(phenoxycarbonyloxymethyl)benzofuran-2-carboxylate (**2i**).* Treatment of **1i** (117 mg, 0.327 mmol) with bromine afforded **2i** (140 mg, 98%): Mp 103—104 °C (petroleum ether–dichloromethane); IR (KBr): 3470, 1760, and 1590 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.27 (s, 3H), 3.79 (s, 3H), 4.02 (m, 1H), 4.31 (dd, J= 8.2 and 11 Hz, 1H), 4.72 (dd, J=3.8 and 11 Hz, 1H), 5.18 (d, J=3.2 Hz, 1H), 5.19 (s, 1H), 6.71 (s, 1H), and 7.20—7.44 (m, 5H). Found: C, 52.24; H, 4.09%. Calcd for $C_{19}H_{17}O_7Br$: C, 52.19; H, 3.92%.

*Methyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxypropionate (**3a**).* (General Procedure for Oxidation). To a solution of **2a** (287 mg, 1 mmol) in 70% aq acetonitrile (10 ml) at 0 °C was added dropwise over 15 min a solution of ceric ammonium nitrate (CAN)[7] (1.21 g, 2.2 mmol) in water (5 ml). The mixture was stirred for 15 min and then poured into water (100 ml). The aq suspension was extracted with chloroform (3×20 ml) and the organic phases were washed with water (3×20 ml), dried, passed through a short pad of silica gel using chloroform, and evaporated to give **3a** (220 mg, 98%): Mp 77—78 °C (dichloromethane–petroleum ether); IR (KBr): 3480, 1735, 1660, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.11 (d, J=1.6 Hz, 3H), 2.83 (d, J=7 Hz, 1H), 3.10 (d, J=7 Hz, 2H), 3.78 (s, 3H), 4.43 (q, J=7 Hz, 1H), and 6.61 (q, J=1.6 Hz, 1H). Found: C, 43.78; H, 3.69; Br, 26.60%. Calcd for $C_{11}H_{11}O_5Br$: C, 43.58; H, 3.66; Br, 26.37%.

*Methyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxybutyrate (**3b**).* (CAN Oxidation of **2b**): (86%); mp 116—118 °C (hexane–dichloromethane); IR (KBr): 3470, 1740, 1675, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.32 (d, J=7 Hz, 3H), 2.12 (d, J=1.6 Hz, 3H), 3.39 (bd, J=8 Hz, 1H), 3.53—3.80 (m, 1H), 3.80 (s, 3H), 4.64 (t, J=8 Hz, 1H), and 6.62 (q, J=1.6 Hz, 1H). Found: C, 45.53; H, 4.16; Br, 25.43%. Calcd for $C_{12}H_{13}O_5Br$: C, 45.44; H, 4.13; Br, 25.19%.

*Methyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxypentanoate (**3c**).* (CAN Oxidation of **2c**): (88%); IR (neat): 3460, 1740, 1670, and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.90 (t, J=7 Hz, 3H), 1.70—1.92 (m, 2H), 2.12 (d, J=1.6 Hz, 3H), 3.61 (m, 1H), 3.70 (d, J=10 Hz, 1H), 3.74 (s, 3H), 4.56 (dd, J=7.5 and 10 Hz, 1H), and 6.63 (q, J=1.6 Hz, 1H). Found: C, 47.10; H, 4.66; Br, 24.38%. Calcd for $C_{13}H_{15}O_5Br$: C, 47.15; H, 4.57; Br, 24.13%.

*Methyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxyhexanoate (**3d**).* (CAN Oxidation of **2d**): (90%); mp 82—83 °C (petroleum ether); IR (KBr): 3460, 1735, 1670, and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.90 (t, J=7 Hz, 3H), 1.28 (m, 2H), 1.77 (m, 2H), 2.16 (d, J=1.6 Hz, 3H), 3.74 (s, 3H and m, 2H), 4.55 (dd, J=7.5 and 10 Hz, 1H), and 6.63 (q, J=1.6 Hz, 1H). Found: C, 48.51; H, 5.01; Br, 23.43%. Calcd for $C_{14}H_{17}O_5Br$: C, 48.71; H, 4.96; Br, 23.15%.

*Dimethyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxysuccinate (**3e**).* (CAN Oxidation of **2e**): (96%); IR (neat): 3460, 1735, 1670, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.13 (d, J=1.6 Hz, 3H), 3.39 (d, J=8 Hz, 1H), 3.70 (s, 3H), 3.76 (s, 3H), 4.55 (d, J=6 Hz, 1H), 4.84 (dd, J=6 and 8 Hz, 1H), and 6.65 (q, J=1.6 Hz, 1H). Found: C, 43.02; H, 3.75%. Calcd for $C_{13}H_{13}O_7Br$: C, 43.23; H, 3.63%.

*Dimethyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxyhexanedioate (**3f**).* (CAN Oxidation of **2f**): (92%); mp 91—92 °C (hexane–dichloromethane); IR (KBr): 3440, 1735, 1725, 1665, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.13 (d, J=1.6 Hz, 3H), 2.13—2.46 (m, 4H), 3.64 (s, 3H), 3.75 (s, 3H and m, 2H), 4.57 (dd, J=8 and 10 Hz, 1H), and 6.64 (q, J=1.6 Hz, 1H). Found: C, 46.55; H, 4.44; Br, 20.68%. Calcd for $C_{15}H_{17}O_7Br$: C, 46.29; H, 4.40; Br, 20.53%.

*Methyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxy-6-phthalimidohexanoate (**3g**).* (CAN Oxidation of **2g**): (89%); mp 153—155 °C (dichloromethane–petroleum ether); IR (KBr): 3460, 3400, 1770, 1735, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.40—2.10 (m, 4H), 2.10 (d, J=1.6 Hz, 3H), 3.62—3.76 (m, 2H), 3.72 (s, 3H), 4.52 (dd, J= 8 and 10 Hz, 1H), 6.60 (q, J=1.6 Hz, 1H), and 7.69—7.82 (m, 4H). Found: C, 53.67; H, 4.34; N, 2.76%. Calcd for $C_{22}H_{20}O_7NBr$: C, 53.89; H, 4.11; N, 2.86%.

*Methyl 6-Trifluoroacetamido-3-(2-bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxyhexanoate (**3h**).* (CAN Oxidation of **2h**): (42%); mp 124—125 °C (dichloromethane–petroleum ether); IR (KBr): 3450, 3330, 1750, 1700, and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.30—2.10 (m, 4H), 2.12 (d, J=1.6 Hz, 3H), 3.35 (q, J=7 Hz, 2H), 3.73 (s, 3H and m, 1H), 4.54 (dd, J=4 and 5 Hz, 1H), and 6.60 (q, J=1.6 Hz, 1H). Found: C, 41.83; H, 3.82; N, 3.03; Br, 17.78%.

Calcd for $C_{16}H_{17}O_6NF_3Br$: C, 42.12; H, 3.76; N, 3.07; Br, 17.52%.

*Methyl 3-(2-Bromo-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxy-4-(phenoxycarbonyloxy)butyrate (**3i**).* (CAN Oxidation of **2i**): (80%); IR (neat): 3460, 1750, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.12 (d, J=1.6 Hz, 3H), 3.59 (d, J=8 Hz, 1H), 3.79 (s, 3H), 4.12 (m, 1H), 4.44—4.85 (m, 2H and m, 1H), 6.65 (q, J=1.6 Hz, 1H), and 7.05—7.51 (m, 5H). Found: C, 50.19; H, 5.97%. Calcd for $C_{19}H_{17}O_8Br$: C, 50.35; H, 5.84%.

*Methyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxypropionate (**4a**).* (General Procedure for Azidoquinone Formation). To a solution of **3a** (303 mg, 1 mmol) in methanol (10 ml) at 0 °C was added sodium azide (78 mg, 1.2 mmol) in water (2 ml). The resulting mixture gradually became red. After stirring for 1 h at room temperature, the solvent was removed under reduced pressure at a temperature below 40 °C, water (50 ml) was added and the mixture was extracted with chloroform (3×25 ml). The combined chloroform extracts were washed with water (3×25 ml), dried ($MgSO_4$), evaporated, and chromatographed (silica gel, chloroform solvent) to give **4a** (238 mg, 90%). IR (neat): 3460, 2120, 1735, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.07 (d, J=1.6 Hz, 3H), 2.87 (d, J=7 Hz, 2H), 2.96 (bs, 1H), 3.80 (s, 3H), 4.36 (t, J=7 Hz, 1H), and 6.61 (q, J=1.6 Hz, 1H). Anal.[13]

Compounds **4b**—**i** were prepared from the corresponding **3b**—**i** by the same procedure. The spectral data of these compounds are given below.

*Methyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxybutyrate (**4b**).* (Oil, 90%); IR (neat): 3440, 2110, 1735, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.24 (d, J=7 Hz, 3H), 2.07 (d, J=1.6 Hz, 3H), 3.49 (m, 1H), 3.74 (s, 3H and m, 1H), 4.46 (d, J=8 Hz, 1H), and 6.55 (q, J=1.6 Hz, 1H). Anal.[13]

*Methyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxypentanoate (**4c**).* (Oil, 98%); IR (neat): 3440, 2110, 1740, 1670, and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.84 (t, J=7 Hz, 3H), 1.74 (m, 2H), 2.07 (d, J=1.6 Hz, 3H), 3.34 (dt, J=8 and 7.5 Hz, 1H), 3.72 (s, 3H), 3.94 (bs, 1H), 4.47 (t, J=8 Hz, 1H), and 6.60 (q, J=1.6 Hz, 1H). Anal.[13]

*Methyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxyhexanoate (**4d**).* (88%); mp 93—94 °C (petroleum ether); IR (KBr): 3460, 2120, 2100, 1735, 1670, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.88 (t, J=7 Hz, 3H), 1.22 (m, 2H), 1.73 (m, 2H), 2.05 (d, J=1.6 Hz, 3H), 3.43 (m, 1H), 3.72 (s, 3H), 3.78 (d, J=9.5 Hz, 1H), 4.45 (dd, J=7 and 9.5 Hz, 1H), and 6.55 (q, J=1.6 Hz, 1H). Found: C, 54.60; H, 5.64%. Calcd for $C_{14}H_{17}O_5N_3$: C, 54.72; H, 5.58%.

*Dimethyl 3-(2-Azido-5-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxysuccinate (**4e**).* (Oil, 88%); IR (neat): 3460, 2120, 1735, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.10 (d, J=1.6 Hz, 3H), 3.38 (bd, J=7 Hz, 1H), 3.70 (s, 3H), 3.76 (s, 3H), 4.32 (d, J=5.5 Hz, 1H), 4.83 (dd, J=5.5 and 7 Hz, 1H), and 6.59 (q, J=1.6 Hz, 1H). Anal.[13]

*Dimethyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxyhexanedioate (**4f**).* (Oil, 80%); IR (neat): 3440, 2110, 2095, 1745, 1730, 1670, and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.13 (d, J=1.6 Hz, 3H), 2.13—2.46 (m, 4H), 3.64 (s, 3H), 3.75 (s, 3H and m, 2H), 4.57 (dd, J=8 and 10 Hz, 1H), and 6.64 (q, J=1.6 Hz, 1H). Found: C, 51.11; H, 4.75%. Calcd for $C_{15}H_{17}O_7N_3$: C, 51.28; H, 4.88%.

*Methyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxy-6-phthalimidohexanoate (**4g**).* (71%); mp 117—120 °C (petroleum ether–dichloromethane); IR (KBr): 3460, 2110, 2100, 1770, 1735, 1705, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.30—2.07 (m, 4H), 2.07 (d, J=1.6 Hz, 3H), 3.32—3.80 (m, 2H and m, 2H), 3.70 (s, 3H), 4.44 (m, 1H), 6.51 (q, J=1.6 Hz, 1H), and 7.60—7.80 (m, 4H). Anal.[13]

*Methyl 3-(2-Azido-4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-6-trifluoroacetamido-2-hydroxyhexanoate (**4h**).* (Oil, 85%); IR ($CHCl_3$): 3430, 2110, 1720, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.30—2.00 (m, 4H), 2.09 (d, J=1.6 Hz, 3H), 3.34 (m, 2H), 3.67 (m, 1H), 3.73 (s, 3H), 3.92 (bd, J=10 Hz, 1H), 4.45 (dd, J=7 and 10 Hz, 1H), 6.55 (q, J=1.6 Hz, 1H), and 6.95 (bs, 1H). Anal.[13]

*Methyl 3-(2-Azido-5-methyl-3,6-dioxo-1,4-cyclohexadienyl)-2-hydroxy-4-(phenoxycarbonyloxy)butyrate (**4i**).* (Oil, 68%); IR (neat): 3440, 2120, 1750, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.10 (d, J=1.6 Hz, 3H), 3.81 (s, 3H and m, 1H), 4.35—4.82 (m, 3H), 6.61 (q, J=1.6 Hz, 1H), and 7.09—7.53 (m, 5H). Anal.[13]

*Irradiation of **4a**.* (General Photochemical Procedure for 4,7-Indolequinone Formation). A solution of **4a** (265 mg, 1 mmol) in methanol (200 ml) was purged with nitrogen for 15 min and irradiated in a Pyrex tube for 5 h with a 300-W high pressure Hg lamp. After removal of the solvent, the crude residue was chromatographed on silica gel using chloroform to give methyl 6-methyl-4,7-dioxoindole-2-carboxylate (**5a**) (92 mg, 42%): Mp 249—250 °C (methanol–dichloromethane); IR (KBr): 3260, 1710, and 1660 cm^{-1}; ^1H NMR (DMSO-d_6) δ: 2.02 (d, J=1.6 Hz, 3H), 3.82 (s, 3H), 6.55 (q, J=1.6 Hz, 1H), 6.97 (s, 1H), and 13.49 (bs, 1H); MS, *m/e* (rel intensity), 219 (M^+, 92), 187 (82), 159 (78), 151 (48), and 131 (100). Found: C, 60.01; H, 4.32; N, 6.25%. Calcd for $C_{11}H_9O_4N$: C, 60.27; H, 4.14; N, 6.39%.

Physical properties of the other photoproducts **5b**—**i** are given below.

*Methyl 3,6-Dimethyl-4,7-dioxoindole-2-carboxylate (**5b**) from **4b**.* (62%); mp 275—277 °C (decomp); IR (KBr): 3250, 1700, and 1655 cm^{-1}; ^1H NMR (DMSO-d_6) δ: 2.01 (d, J=1.6 Hz, 3H), 2.47 (s, 3H), 3.81 (s, 3H), 6.50 (q, J=1.6 Hz, 1H), and 13.10 (bs, 1H). Found: C, 62.02; H, 4.77; N, 5.94%. Calcd for $C_{12}H_{11}O_4N$: C, 61.80; H, 4.75; N, 6.01%.

*Methyl 3-Ethyl-6-methyl-4,7-dioxoindole-2-carboxylate (**5c**) from **4c**.* (61%); mp 221—222 °C; IR (KBr): 3250, 1695, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.17 (t, J=7.5 Hz, 3H), 2.08 (d, J=1.6 Hz, 3H), 3.09 (q, J=7.5 Hz, 2H), 3.95 (s, 3H), 6.49 (q, J=1.6 Hz, 1H), and 9.97 (bs, 1H). Found: C, 63.30; H, 5.42; N, 5.64%. Calcd for $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30; N, 5.67%.

*Methyl 6-Methyl-4,7-dioxo-3-propylindole-2-carboxylate (**5d**) from **4d**.* (60%); mp 183—184 °C; IR (KBr): 3260, 1695, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.95 (t, J=7.5 Hz, 3H), 1.61 (m, 2H), 2.08 (d, J=1.6 Hz, 3H), 3.07 (t, J=7.5 Hz, 2H), 3.94 (s, 3H), 6.47 (q, J=1.6 Hz, 1H), and 9.92 (bs, 1H); MS, *m/e* (rel intensity), 261 (M^+, 7), 260 (40), 229 (91), and 201 (100). Found: C, 64.45; H, 5.83; N, 5.26%. Calcd for $C_{14}H_{15}O_4N$: C, 64.36; H, 5.79; N, 5.36%.

*Dimethyl 6-Methyl-4,7-dioxoindole-2,3-dicarboxylate (**5e**) from **4e**.* (40%); mp 200—201 °C; IR (KBr): 3220, 1735, 1695, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.13 (d, J=1.6 Hz, 3H), 3.96 (s, 3H), 4.00 (s, 3H), 6.57 (q, J=1.6 Hz, 1H), and 8.70 (bs, 1H). Found: C, 56.54; H, 4.18; N, 4.91%. Calcd for $C_{13}H_{11}O_6N$: C, 56.32; H, 4.00; N, 5.05%.

*Methyl 3-[2-(Methoxycarbonyl)ethyl]-6-methyl-4,7-dioxoindole-2-carboxylate (**5f**) from **4f**.* (64%); mp 195—196 °C; IR (KBr): 3260, 1740, 1700, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.10 (d, J=1.6 Hz, 3H), 2.65 (t, J=7 Hz, 2H), 3.43 (t, J=7 Hz, 2H), 3.69 (s, 3H), 3.97 (s, 3H), 6.53 (q, J=1.6 Hz, 1H), and 10.15 (bs, 1H); MS, *m/e* (rel intensity),

305 (M^+, 8), 273 (35), 245 (94), and 213 (100). Found: C, 58.89; H, 4.77; N, 4.39%. Calcd for $C_{15}H_{15}O_6N$: C, 59.01; H, 4.95; N, 4.59%.

*Methyl 6-Methyl-4,7-dioxo-3-[3-(phthalimido)propyl]indole-2-carboxylate (**5g**) from **4g**.* (56%); mp 242—243 °C; IR (KBr): 3240, 1770, 1700, and 1650 cm $^{-1}$; H NMR (DMSO-d_6) δ: 1.90 (m, 2H), 1.99 (d, J=1.6 Hz, 3H), 3.03 (t, J=7 Hz, 2H), 3.61 (t, J=7 Hz, 2H), 3.76 (s, 3H), 6.48 (q, J=1.6 Hz, 1H), 7.83 (s, 4H), and 13.02 (bs, 1H); MS, *m/e* (rel intensity), 406 (M^+, 40), 373 (15), 329 (13), 233 (44), and 227 (100). Found: C, 64.93; H, 4.49; N, 6.85%. Calcd for $C_{22}H_{18}O_6N_2$: C, 65.02; H, 4.46; N, 6.89%.

*Methyl 6-Methyl-4,7-dioxo-3-[3-(trifluoroacetamido)propyl]indole-2-carboxylate (**5h**) from **4h**.* (42%); mp 241—242 °C; IR (KBr): 3240, 1700, and 1650 cm $^{-1}$; ^{1}H NMR (DMSO-d_6) δ: 1.79 (m, 2H), 2.04 (d, J=1.6 Hz, 3H), 3.13 (m, 4H), 3.86 (s, 3H), 6.43 (q, J=1.6 Hz, 1H), 8.85 (bs, 1H), and 12.74 (bs, 1H); MS, *m/e* (rel intensity), 372 (M^+, 5), 258 (75), 244 (19), and 227 (100). Found: C, 51.55; H, 4.28; N, 7.41%. Calcd for $C_{16}H_{15}O_5N_2F_3$: C, 51.16; H, 4.06; N, 7.53%.

*Methyl 6-Methyl-4,7-dioxo-3-(phenoxycarbonyloxymethyl)indole-2-carboxylate (**5i**) from **4i**.* (37%); mp 155—156 °C; IR (neat): 3240, 1760, 1700, and 1650 cm $^{-1}$; ^{1}H NMR ($CDCl_3$) δ: 2.10 (d, J=1.6 Hz, 3H), 3.98 (s, 3H), 5.70 (s, 2H), 6.53 (q, J=1.6 Hz, 1H), 7.10—7.40 (m, 5H), and 10.60 (bs, 1H). Found: C, 62.02; H, 4.18; N, 3.65%. Calcd for $C_{19}H_{15}O_7N$: C, 61.79; H, 4.09; N, 3.79%.

*Methyl 1,3,6-Trimethyl-4,7-dioxoindole-2-carboxylate (**6a**).* To a solution of **5b** (116 mg, 0.5 mmol) in dry DMSO (20 ml) at 20 °C was added under argon potassium *t*-butoxide (68 mg, 0.6 mmol). The resulting red solution was stirred for 10 min, and methyl iodide (156 μl, 2.5 mmol) was added. After stirring for 1 h at room temperature, the reaction mixture was poured into cold 0.1 M hydrochloric acid (100 ml) and the resulting suspension was extracted with chloroform (3×20 ml). The organic layer was washed with water and dried ($MgSO_4$). Removal of the solvent and chromatography gave **6a** (111 mg, 90%): Mp 141—143 °C; IR (KBr): 1705 and 1650 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.08 (d, J=1.6 Hz, 3H), 2.58 (s, 3H), 3.92 (s, 3H), 4.25 (s, 3H), and 6.45 (q, J=1.6 Hz, 1H); MS, *m/e* (rel intensity), 247 (M^+, 100). Found: C, 63.00; H, 5.41; N, 5.50%. Calcd for $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30; N, 5.67%.

*Methyl 1-Allyl-3,6-dimethyl-4,7-dioxoindole-2-carboxylate (**6b**).* Reaction of **5b** (116 mg, 0.5 mmol), potassium *t*-butoxide (75 mg, 0.67 mmol), and allyl bromide (0.5 ml, 5.76 mmol) in dry DMSO (20 ml) solution by the procedure described for the preparation of **6a** gave after chromatography **6b** (123 mg, 90%): Mp 144—145 °C; IR (KBr): 1700, 1650, and 1645 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.05 (d, J=1.6 Hz, 3H), 2.59 (s, 3H) 3.91 (s, 3H), 4.91—6.19 (m, 5H), and 6.46 (q, J=1.6 Hz, 1H); MS, *m/e* (rel intensity), 273 (M^+, 26), 258 (63), 215 (65), and 71 (100). Found: C, 65.82; H, 5.49; H, 4.89%. Calcd for $C_{15}H_{15}O_4N$: C, 65.92; H, 5.53; N, 5.13%.

*Methyl 4,7-Diacetoxy-3-[2-(methoxycarbonyl)ethyl]-6-methylindole-2-carboxylate (**7**).* A solution of **5f** (153 mg, 0.5 mmol) in ether was reduced with excess aq sodium dithionite[10] to give methyl 4,7-dihydroxy-3-[2-(methoxycarbonyl)-ethyl]-6-methylindole-2-carboxylate, which was acetylated with acetic anhydride (2 ml) in the presence of pyridine (0.1 ml) to afford **7** (156 mg, 80%); mp 171—172 °C (methanol–petroleum ether); IR (KBr): 3340, 1750, 1720, and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.24 (s, 3H), 2.40 (s, 6H), 2.58 (t, J=7 Hz, 2H), 3.38 (t, J=7 Hz, 2H), 3.68 (s, 3H), 3.92 (s, 3H), 6.70 (s, 1H), and 8.62 (bs, 1H). Found: C, 58.11; H, 5.38; N, 3.35%. Calcd for $C_{19}H_{21}O_8N$: C, 58.31; H, 5.41; N, 3.58%.

*Methyl 4,5,7-Triacetoxy-3-[2-(methoxycarbonyl)ethyl]-6-methylindole-2-carboxylate (**8**)* was prepared by the Thiele oxidation of **5f** (153 mg, 0.5 mmol) with acetic anhydride (5 ml) in the presence of conc H_2SO_4 (0.1 ml).[11] (79 mg, 35%); mp 238—239 °C (dichloromethane–petroleum ether); IR (KBr): 3350, 1770; 1750, 1735, and 1715 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.07 (s, 3H), 2.32 (s, 3H), 2.42 (s, 6H), 2.56 (t, J=8 Hz, 2H), 3.34 (t, J=8 Hz, 2H), 3.70 (s, 3H), 3.94 (s, 3H), and 8.75 (bs, 1H); MS, *m/e* (rel intensity), 449 (M^+, 5), 409 (23), 366 (48), 334 (21), 324 (49), and 292 (100). Found: C, 55.90; H, 5.29; N, 3.23%. Calcd for $C_{21}H_{23}O_{10}N$: C, 56.12; H, 5.16; N, 3.12%.

During this investigation the author became particularly indebted to Professor Kazuhiro Maruyama for his invaluable suggestions and continuous encouragement.

(Received November 28, 1981)

Sudachiin A was isolated from the green peels of *Citrus sudachi* Hort. *ex* Shirai. This structure was deduced to be sudachitin 4′-β-D-glucoside by means of its spectra and degradation; this was confirmed by the synthesis of the one from sudachitin 7-benzyl ether and α-acetobromoglucose *via* several steps. 4′,5,7-Trihydroxy-3′,6,8-trimethoxyflavone 7-glucoside (sudachitin 7-β-D-glucoside), which was isolated from *Sideritis leucantha* Cavanilles, was also synthesized from sudachitin and α-acetobromoglucose in a similar manner.

In continuous investigations of the constituents in green peels of *Citrus sudachi* Hort. *ex* Shirai, we have already reported the isolation of several flavonoids, sudachitin (**1**),[1,2] demethoxysudachitin (**2**),[3] dinatin (**3**),[4] xanthomicrol (**4**),[4] 4′,5,7-trihydroxy-3′,6-dimethoxyflavone (**5**),[4] and 7-methylsudachitin (**6**).[4] In a recent preliminary communication[5] we reported the structure elucidation of sudachiin A (sudachitin 4′-β-D-glucoside) (**7**), a new flavone glucoside isolated from the same source. Recently, 4′,5,7-trihydroxy-3′,6,8-trimethoxyflavone 7-glucoside (sudachitin 7-β-D-glucoside) (**8**), one of the isomers of sudachiin A (**7**), was isolated from a whole plant of *Sideritis leucantha* Cavanilles by F. Tomas and E. Ferreres.[6] In the present paper we will describe the details of the structure elucidation of sudachiin A (**7**) and the synthesis of **7** and its isomer (**8**).

The methanol concentrate, obtained from fresh green peels, was washed with ether and then extracted with ethyl acetate. The extract, dissolved in methanol, was allowed to stand in a refrigerator to give precipitates, which were then removed by filtration. The resulting solution was concentrated and fractionated by column chromatography over polyamide. The yellow fraction eluted with methanol was subjected to repeated chromatography over polyamide to give a glycoside, named sudachiin A.

Sudachiin A, yellow needles (mp 211—213 °C, $[\alpha]_D$ −37.4° (0.5% aq NaOH)), was analyzed for $C_{24}H_{26}O_{13}$ (mol wt 522) by means of elemental analysis and CI-MS (*m/z* 523 (MH^+)).[7] The glycoside, which was easily converted into a hexaacetate (**9**; mp 212—213 °C), was hydrolyzed with 5% sulfuric acid to sudachitin (4′,5,7-trihydroxy-3′,6,8-trimethoxyflavone) (**1**)[1,2,8] and D-glucose. In the UV spectrum of the glucoside, Band I (λ_{max} 337 nm) was shifted to 385 nm in the presence of sodium acetate, and its intensity was markedly lower than that of Band II[9] (Table 1). On the other hand, the exhaustive methylation of sudachiin A with diazomethane, followed by the hydrolysis of the resultant methyl ether, gave 4′-hydroxy-3′,5,6,7,8-pentamethoxyflavone (sudachitin 5,7-dimethyl ether) (**10**; mp 145—146 °C).[10] Judging from the above results, sudachiin A seemed to be sudachitin 4′-D-glucoside (4′,5,7-trihydroxy-3′,6,8-trimethoxyflavone 4′-D-glucoside (**7**).

The ^1H NMR spectrum of the hexaacetate (**9**) showed the presence of two phenolic acetoxyl groups (δ 2.43 and 2.48) in the flavone nucleus and four acetoxyl groups (δ 2.04 and 2.08, each 6H) in the sugar moiety (Table 2). The proton signals attributable to the sugar moiety at δ 4.1—4.3 and 5.0—5.4 were superimposable on those of cirsilineol 4′-tetra-*O*-acetyl-β-D-glucopyranoside.[11] Consequently, sudachiin A (**7**) was shown to be sudachitin 4′-β-D-glucopyranoside; the structure of **7** was further confirmed by the following synthesis.

Sudachitin (**1**) was partially benzylated with benzyl chloride, potassium iodide, and aqueous potassium hydroxide in acetone-*N*,*N*-dimethylformamide (DMF) to give two monobenzyl ethers, **11** (mp 159—160 °C) and **12** (mp 177—178 °C), and 7,4′-dibenzyl ether (**13**; mp 126—127 °C) of **1** (Table 2), in yields of 40, 2, and 8% respectively. Each Band I of the UV spectra for the monobenzyl ethers in ethanol underwent a bathochromic shift upon the addition of aluminum chloride and sodium acetate (Table 1). In the UV spectra for **11** and **12** in the presence of sodium acetate, the magnitude (71 nm) of the Band I shift of **11** is much larger than that (40 nm) of **12**; furthermore, the intensity for the Band I of **11** is markedly greater than that for the Band II of **11**. These facts show that the two hydroxyl groups on **11** are located at the 5- and 4′-positions.[4,9] Therefore, the monobenzyl ethers, **11** and **12**, are the 7- and 4′-benzyl ethers of **1** respectively. Sudachitin 7-benzyl ether (**11**) was easily condensed with α-acetobromoglucose to give an *O*-acetylglucoside (**14**; mp 156—157 °C), which was subsequently debenzylated to sudachitin 4′-*O*-acetylglucoside (**15**; mp 196—197 °C; $[\alpha]_D$ −22.5° ($CHCl_3$)) with 10% palladium on charcoal. The hydrolysis of **15** with 5% aqueous sodium hydroxide gave the desired 4′-β-D-glucopyranoside (**7**; mp 211—213 °C; $[\alpha]_D$ −39.2° (0.5% aq NaOH)). The synthetic glucoside and its hexaacetate were found to be identical with natural sudachiin A and its hexaacetate respectively on the basis of a mixed-melting point determination and by IR, UV, and ^1H NMR spectral comparisons.

Sudachitin 7-β-D-glucopyranoside (**8**), one of the isomers of sudachiin A, was synthesized from sudachitin (**1**) and α-acetobromoglucose *via* the corresponding *O*-acetylglucoside by the same method as that described

above. The direct condensation of **1** with α-acetobromoglucose gave sudachitin 7-β-D-tetra-*O*-acetylglucopyranoside (**16**; mp 156—157 °C; $[\alpha]_D$ +25.4° ($CHCl_3$)), which was then easily converted into a hexaacetate (**17**, mp 111—113 °C). The hydrolysis of **16** with 5% aqueous sodium hydroxide yielded the 7-β-D-glucopyranoside (**8**, mp 187—188 °C; $[\alpha]_D$ +58.9° (0.5% aq NaOH)). The spectral data of the synthetic 7-β-D-glucoside were superimposable on those of 4′,5,7-trihydroxy-3′,6,8-trimethoxyflavone 7-glucoside (**8**).[6)] The natural 7-glucoside (**8**) was shown to be sudachitin 7-β-D-glucopyranoside.

Experimental

All the melting points are uncorrected. The UV spectra were measured in ethanol with a Hitachi 215 spectrophotometer, and the ^1H NMR spectra were measured in $CDCl_3$ with a JEOL PS-100 spectrometer (100 MHz), with tetramethylsilane as the internal standard. The mass spectra were obtained using a Shimadzu LKB-9000B mass spectrometer equipped with a chemical-ionization source. The operating conditions were as follows; ion source temp: 230—250 °C; electron energy: 140 eV; reactant gas pressure (isobutane): 0.3 Torr (1 Torr≈133.322Pa); emission current: 250 μA. Polyamide (Wako polyamide C-200) was used for the column.

Isolation of Sudachiin A (7). Fresh green peels (8 kg) of *C. sudachi* collected at Tokushima Prefecture in August were extracted with methanol (*ca.* 20 l) for several days. The methanol solution was concentrated to *ca.* 2.5 l under reduced pressure below 30 °C. The concentrate was treated with hexane and then ether. The resulting water-soluble layer was concentrated to 1.5 l and then extracted thoroughly with ethyl acetate. The extract added to a small amount of methanol was allowed to stand in a refrigerator to give precipitates, which were then removed by filtration. The methanol solution was subjected to chromatographic purification on polyamide, using methanol as the eluent. The yellow eluate was repeatedly chromatographed on polyamide to yield **7** (0.96 g: 0.012%; mp 211—213 °C (yellow needles from methanol); $[\alpha]_D$ −37.4° (0.5% aq NaOH, c=0.31). CI-MS (*i*-C_4H_{10}): *m/z* 523 (MH^+, 0.5), 417 (2), 403 (4.5), 363 (7), 362 (14), 361 (AGL·H, 100), 360 (14), 163 (4.5), 145 (30), 127 (5.5). Found: C, 52.72; H, 5.15%. Calcd for $C_{24}H_{26}O_{13}\cdot 1.5H_2O$: C, 52.46; H, 5.32%.

Sudachiin A Hexaacetate (9). The glycoside (**7**) was converted into a hexaacetate (**9**) by an acetic anhydride-pyridine method. **9**; mp 212—213 °C (colorless needles from ethanol); $[\alpha]_D$ −21.6° ($CHCl_3$, c=0.31). Found: C, 55.88; H, 4.66%. Calcd for $C_{36}H_{38}O_{19}$: C, 55.81; H, 4.94%.

Hydrolysis of Sudachiin A (7). A suspended mixture of **7** (101 mg) in 5% aq sulfuric acid (20 ml) was heated on a steam bath for 2 h under nitrogen. The precipitates thus separated were collected and recrystallized from aq ethanol to give an aglycone; mp 239—240 °C (yellow needles). Its acetate: mp 167—168 °C (colorless needles from ethanol). The aglycone and its acetate were identical with authentic sudachitin (4′,5,7-trihydroxy-3′,6,8-trimethoxyflavone) (**1**) and its acetate previously reported[1,2,8)] respectively.

The aqueous solution remaining after the separation of the aglycone was neutralized with barium carbonate, filtered, and concentrated. The resulting syrupy compound was found to be identical with D-glucose by silica gel TLC. Its osazone: mp and mmp 200—202 °C.

4′-Hydroxy-3′,5,6,7,8-pentamethoxyflavone (10) from Sudachiin

* Overlapped with the benzyl aromatic protons.

A (7). A solution of **7** (206 mg) in ethanol was treated with an excess of diazomethane in ether. After standing at room temperature for 24 h, the mixture was evaporated under reduced pressure to dryness. The residue was heated at 100 °C with 5% sulfuric acid for 1 h, after which the mixture was worked up in the same manner as that described above to give precipitates, which were recrystallized from methanol as colorless needles **10** (83 mg); mp 145—146 °C. **10** was identical with the sample prepared by the method given in the literature.[10]

Partial Benzylation of Sudachitin (1). To a solution of **1** (1.5 g), benzyl chloride (0.8 g), and potassium iodide (0.83 g) in acetone–DMF (1:1) (60 ml), 1% aq potassium hydroxide (26 ml) was added. The reaction mixture was allowed to stand for 4 days at room temperature to give precipitates, which were then separated by filtration. Water was added to the filtrate, and the resulting precipitates were collected. The combined precipitates were recrystallized from methanol to recover sudachitin (**1**) (150 mg: 10%).

The mother liquor was evaporated, and the residue was chromatographed on silica gel with chloroform–ethyl acetate (5:1) to give three fractions. The first fraction was recrystallized from methanol–ethyl acetate to give sudachitin 4',7-dibenzyl ether as yellow needles (**13**) (188 mg: 8%); mp 126—127 °C. Found: C, 71.29; H, 5.45%. Calcd for $C_{32}H_{28}O_8$: C, 71.10; H, 5.22%.

The second fraction, which was a mixture of monobenzyl ethers, was separated into two components **11** and **12** by recrystallization from methanol–ethyl acetate and then by chromatography on silica gel with chloroform–ethyl acetate (5:1). Sudachitin 7-benzyl ether (**11**); yellow needles (755 mg: 40%), mp 159—160 °C. Found: C, 66.82; H, 4.99%. Calcd for $C_{25}H_{22}O_8$: C, 66.66; H, 4.92%.

Sudachitin 4'-benzyl ether (**12**); yellow needles (34 mg: 2%), mp 177—178 °C. Found: C, 66.46; H, 4.85%. Calcd for $C_{25}H_{22}O_8$: C, 66.66; H, 4.92%.

The third fraction was unchanged sudachitin (**1**) (250 mg: 17%).

7-Benzyloxy-4',5-dihydroxy-3',6,8-trimethoxyflavone 4'-Tetra-O-acetyl-β-D-glucopyranoside (14). To a solution of **11** (585 mg) and α-acetobromoglucose (1.1 g) in acetone–DMF (4:1) (25 ml), 2% aq potassium hydroxide (6 ml) was added. The mixture was allowed to stand in a refrigerator for 1 week to give an *O*-acetylglucoside as yellow crystals, which were separated by filtration. To the filtrate, water was added. The separated precipitates were collected and then chromatographed on silica gel, using chloroform–ethyl acetate (5:1), to give unchanged **11** (190 mg: 32%) and the *O*-acetylglucoside. The combined *O*-acetylglucoside was recrystallized from methanol to give **14** as pale yellow needles (450 mg: 44%); mp 156—157 °C. Found: C, 60.12; H, 5.23%. Calcd for $C_{39}H_{40}O_{17}$: C, 60.00; H, 5.16%.

Sudachitin 4'-Tetra-O-acetyl-β-D-glucopyranoside (15). *O*-Acetylglucoside (**14**) (241 mg) was hydrogenated over 10% palladium on charcoal (80 mg) in a mixture of ethyl acetate (15 ml) and methanol (7 ml) until the uptake of hydrogen ceased. The catalyst was filtered off, and then the solvent was removed under reduced pressure. The residue was recrystallized from aq ethanol to give **15** as pale yellow needles (190 mg: 90%); mp 196—197 °C; $[\alpha]_D$ −22.5° ($CHCl_3$, c=0.196). Found: C, 54.45; H, 4.99%. Calcd for $C_{32}H_{34}O_{17}\cdot H_2O$: C, 54.24; H, 5.12%.

Sudachitin 4'-β-D-Glucopyranoside Hexaacetate (Sudachiin A Hexaacetate) (9). Compound **15** was converted into the acetate **9** as colorless needles (mp 212—213 °C; undepressed on admixture with the natural sudachiin A hexaacetate.). The ^1H NMR spectrum of the acetate was also superimposable on that of the acetate of sudachiin A.

Sudachitin 4'-β-D-Glucopyranoside (Sudachiin A) (7). A solution of **15** (98 mg) in 5% aq sodium hydroxide was heated at 50—60 °C for 5 min. The reaction mixture was then cooled and acidified with acetic acid. The resulting precipitates were separated and recrystallized from aq methanol as pale yellow needles (67 mg: 85%); mp 211—213 °C; [α] −39.2° (0.5% aq NaOH, c=0.204). Found: C, 52.50; H, 5.50%. Calcd for $C_{24}H_{26}O_{13}\cdot 1.5H_2O$: C, 52.46; H, 5.32%.

The synthetic glucoside was identified with natural sudachiin A on the basis of a mixed-melting point determination and by IR and UV spectral comparisons.

Sudachitin 7-Tetra-O-acetyl-β-D-glucopyranoside (16). To a solution of **1** (1.035 g) and α-acetobromoglucose (2.0 g) in acetone–DMF (2:1) (50 ml), 2% aq potassium hydroxide (8.8 ml) was added. The mixture was allowed to stand in a refrigerator for 5 d, and then the solvent was removed under reduced pressure. The residue was diluted with water and extracted with ethyl acetate. The extract was washed with water and dried over sodium sulfate, and the solvent was evaporated under reduced pressure. The residue was chromatographed on polyamide (45 g), using methanol, to give **16** (710 mg: 36%), which was subsequently recrystallized from methanol; mp 156—157 °C (pale yellow needles); $[\alpha]_D$ +28.4° ($CHCl_3$, c=0.362). Found: C, 54.03; H, 5.42%. Calcd for $C_{32}H_{34}O_{17}\cdot H_2O$: C, 54.24; H, 5.12%.

Sudachitin 7-β-D-Glucopyranoside Hexaacetate (17). Compound **16** (70 mg) was acetylated by an acetic anhydride–pyridine method, and the acetate was chromatographed on silica gel with chloroform–ethyl acetate (5:1). The first fraction was dissolved in a small amount of methanol, and then water was added to give white precipitates (60 mg: 76%); mp 111—113 °C. Found: C, 55.52; H, 4.74%. Calcd for $C_{36}H_{38}O_{19}$: C, 55.81; H, 4.94%.

Sudachitin 7-β-D-Glucopyranoside (8). A solution of **16** (150 mg) in 5% aq sodium hydroxide was heated at 50—60 °C for 5 min. The reaction mixture was then cooled and acidified with acetic acid. The resulting semi-solids were separated and then chromatographed on silica gel, using ethyl methyl ketone (saturated water), to give **8** (91 mg: 80%), which was subsequently recrystallized from methanol; mp 187—188 °C (yellow needles, lit.[6] mp 185—187 °C); $[\alpha]_D$ +58.9 (0.5% aq NaOH, c=0.258). Found: C, 52.70; H, 5.53%. Calcd for $C_{24}H_{26}O_{13}\cdot 1.5H_2O$: C, 52.46; H, 5.32%.

The spectral data and mp of the synthetic glucoside were identical with those of natural 4',5,7-trihydroxy-3',6,8-trimethoxyflavone 7-glucoside.[6]

The authors wish to thank Professor Makoto Susuki, Meijo University, for the measurement of the CI-MS. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Department of Applied Chemistry, Technical College of Tokushima University, Minamijosanjima-cho, Tokushima 770

† *Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730*

(Received December 24, 1981)

5,6-Dihydroxy-3,4′,8-trimethoxyflavone, which was the proposed structure of the pigment occuring in *Conyza stricta*, was synthesized from 2,3,5,6-tetramethoxyacetophenone in six steps. The natural pigment was identical not with the synthesized flavone, but with 5,7-dihydroxy-3,4′,8-trimethoxyflavone, an isomer of the former.

Two new flavones (**A**) and (**B**) were isolated from *conyza stricta* by Sen *et al.*;[2] their structures were proposed to be 5,6-dihydroxy-3,4′,8-trimethoxyflavone (**1**) and 5,7-dihydroxy-3,3′,4′,5′,8-pentamethoxyflavone (**2**) on the basis of their spectroscopic data and degradation studies. The properties of natural flavone (**A**), however, did not agree with those of synthesized 5,6-dihydroxy-3,4′,8-trimethoxyflavone (**1**). A close inspection of the properties of natural flavone (**A**) and of the isomers of **1** indicated that those of the former were identical with those of 5,7-dihydroxy-3,4′,8-trimethoxyflavone (**3**),[3] an analogue of **2**. This paper will describe the synthesis of 5,6-dihydroxy-3,4′,8-trimethoxyflavone (**1**) and a revised structure, 5,7-dihydroxy-3,4′,8-trimethoxyflavone (**3**), for the natural flavone (**A**).

The outline of the synthesis was as follows. 2,3,5,6-Tetramethoxyacetophenone (**4**)[4] was brominated with copper(II) bromide, according to the method of Malik *et al.*;[5] then the resulting ω-bromo-2,3,5,6-tetramethoxyacetophenone (**5**) was converted into 2,3,5,6-tetramethoxy-ω-(*p*-methoxybenzoyloxy)acetophenone (**6**) with potassium *p*-methoxybenzoate in *N*,*N*-dimethylformamide. The benzoate (**6**) was demethylated with anhydrous aluminium chloride in acetonitrile to give 2-hydroxyacetophenone (**7**) in a good yield.

According to the Allan-Robinson method of flavone synthesis, the condensation of the 2-hydroxyacetophenone (**7**) with *p*-methoxybenzoic anhydride and potassium *p*-methoxybenzoate, followed by treatment with methanolic potassium hydroxide, gave 3-hydroxyflavone (**8**), which was easily converted into the acetate (**9**). The ^{1}H-NMR spectra for **8** and **9** showed a singlet peak corresponding to the C-7 proton at δ 6.87 and 6.90 respectively (Table 1). The methylation of the flavone (**8**) with dimethyl sulfate gave 3,4′,5,6,8-pentamethoxyflavone (**10**). The flavone (**10**) was demethylated with a 5—10%(w/v) anhydrous aluminium chloride–acetonitrile solution to give a 5-hydroxyflavone (**11**) in a quantitative yield. On the other hand, demethylation with an about 30%(w/v) anhydrous aluminium chloride–acetonitrile solution containing 0.5% (v/v) water at 70 °C for 48 h[1] gave the desired 5,6-dihydroxy-3,4′,8-trimethoxyflavone (**1**). The strontium chloride-coloration test of the flavone (**1**) indicated the presence of two hydroxyl groups adjacent to each other.[6] The ^{1}H-NMR data for the synthesized flavones are shown in Table 1. The chemical shifts of the C-7 proton on the flavones and their acetates appeared in the narrow range of δ 6.87—6.99, in contrast to those of the aromatic protons on the A ring of 5,7-dihydroxy-6- or 8-methoxyflavones and their acetates. The 3-methoxyflavone (**1**) and **11** showed also characteristic UV spectra, which failed to show Band II (Table 2).

The 5,6-dihydroxyflavone (**1**) and its diacetate (**13**) are not identical with the natural flavone (**A**) and its diacetate, which were sent us by Sen. However, the ^{1}H-NMR data of the natural flavone diacetate are similar to that of the synthesized (**13**), and the singlet peak at δ 6.89 can be attributed to the C-6 or C-8 proton on the acetate of 5,7-dihydroxy-3,4′,8-trimethoxyflavone (**3**)[3] or 5,6-dihydroxy-3,4′,7-trimethoxyflavone (**14**)[7] (Table 3). The results indicated that the structure of **A** is either **3** or **14**. Since the UV data of the natural flavone (**A**) are similar to those

of **13**, and not to those of **14**, the structure of **A** is preferable to that of **3** (Table 4). In conclusion, the natural flavone (**A**) is confirmed to be 5,7-dihydroxy-3,4′,8-trimethoxyflavone (**3**), analogous to **2**, on the basis of the following results: the melting points of the natural flavone (**A**) and its diacetate are undepressed on mixing with the synthesized (**3**) and its diacetate respectively (Table 5), and the UV and IR spectra of these natural flavones are also superimposable on each other.

These two substances, **2** and **3**, were also isolated from the same plant by Tandon *et al.* in 1977.[8]

Experimental

All the melting points were determined in glass capillaries and are uncorrected. The ^{1}H-NMR spectra were measured with a Hitachi R-24 spectrometer (60 MHz), using tetramethylsilane as the internal standard, and the chemical shifts are presented in terms of the δ values. The UV and IR spectra were taken on Hitachi 124 and 215 spectrophotometers.

*ω-Bromo-2,3,5,6-tetramethoxyacetophenone (**5**).* To a solution of 2,3,5,6-tetramethoxyacetophenone (**4**) (4 g) in chloroform–ethyl acetate (each 25 ml), copper(II) bromide (7.6 g) was added, after which the mixture was stirred for 24 h at room temperature. The precipitate was then filtered off, and the filtrate was concentrated under reduced pressure. The residue was dissolved in ether, washed with water, and dried. After the removal of the ether, the residue was recrystallized from ether–hexane to give pale yellow prisms; mp 91—93 °C; NMR ($CDCl_3$) δ 3.80, 3.88 (each 6H, s, OCH_3), 4.37 (2H, s, $-CH_2-$), 6.63 (1H, s, Arom. H); yield, 4 g (75%). Found: C, 45.28; H, 4.82%. Calcd for $C_{12}H_{15}O_5Br$: C, 45.16; H, 4.74%.

*2,3,5,6-Tetramethoxy-ω-(p-methoxybenzoyloxy)acetophenone (**6**).* A mixture of **5** (4 g) and potassium *p*-methoxybenzoate (5 g) in *N,N*-dimethylformamide (15—20 ml) was heated at 140—150 °C for 2 h. After the addition of water to the reaction mixture, the precipitate separated was collected, washed with water, and recrystallized from methanol to

give colorless prisms; mp 118—120 °C; NMR ($CDCl_3$) δ 3.80 (6H, s, OCH_3), 3.84 (9H, s, OCH_3), 5.22 (2H, s, $-CH_2-$), 6.61 (1H, s, Arom. H), 6.90, 8.04 (each 2H, d, J=9 Hz, Arom. H); yield, 3.69 g (81%). Found: C, 61.80; H, 5.83%. Calcd for $C_{20}H_{22}O_8$: C, 61.53; H, 5.68%.

2-Hydroxy-3,5,6-trimethoxy-ω-(p-methoxybenzoyloxy)acetophenone (7). To a solution of anhydrous aluminium chloride (12 g) in acetonitrile (40 ml), **6** (3.82 g) was added, and the mixture was heated at 60 °C for 3 h. The reaction mixture was then poured into a mixture of hydrochloric acid and ice under stirring. The precipitate was collected and recrystallized from methanol to give yellow prisms (2.50 g); mp 120—121 °C; NMR ($CDCl_3$) δ 3.86 (9H, s, OCH_3), 3.98 (3H, s, OCH_3), 5.49 (1H, s, Arom. H), 6.92, 8.08 (each 2H, d, J=9 Hz, Arom. H), 11.84 (1H, s, OH). The precipitate recovered (1 g) from the mother liquor of recrystallization was repeatedly demethylated by the above-described method; an additional 0.8 g of **7** was thus obtained; total yield, 3.3 g (90%). Found: C, 60.61; H, 5.42%. Calcd for $C_{19}H_{20}O_8$: C, 60.63; H, 5.36%.

3-Hydroxy-4',5,6,8-tetramethoxyflavone (8). A mixture of **7** (2.35 g), *p*-methoxybenzoic anhydride (10 g), and potassium *p*-methoxybenzoate (6.6 g) was heated at 170—180 °C under reduced pressure for 10 h. The mixture was then refluxed with a solution of potassium hydroxide (6.3 g) in 80% aqueous methanol (about 200 ml) under a nitrogen atmosphere for 30 min. The solvent was removed under reduced pressure, and water was added to the residue. The solution was saturated with carbon dioxide and then allowed to stand overnight in a refrigerator. The separated precipitate was collected and recrystallized from chloroform–methanol to give yellow prisms; mp 184—186 °C; yield, 0.67 g (30%). Found: C, 63.45; H, 5.04%. Calcd for $C_{19}H_{18}O_7$: C, 63.68; H, 5.06%.

Acetate (9): Colorless needles from methanol; mp 201—203 °C. Found: C, 62.74; H, 4.99%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%.

3,4',5,6,8-Pentamethoxyflavone (10). A mixture of **8** (500 mg), dimethyl sulfate (0.62 ml), and anhydrous potassium carbonate (1.2 g) in acetone (50 ml) was refluxed for 8 h. The reaction mixture was again refluxed for 30 min after the addition of water; then a part of the acetone was evaporated off. The resulting precipitate was recrystallized from methanol to give pale yellow needles; mp 124—126 °C; yield, 490 mg (94%). Found: C, 64.33; H, 5.41%. Calcd for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41%.

5-Hydroxy-3,4',6,8-tetramethoxyflavone (11). To a solution of anhydrous aluminium chloride (0.52 g) in acetonitrile (10 ml), **10** (110 mg) was added, after which the mixture was heated at 60 °C for 1.5 h. After the addition of diluted hydrochloric acid, the mixture was heated on a steam-bath for 30 min and the acetonitrile was evaporated. The precipitate separated was recrystallized from methanol to give yellow needles; mp 163—164 °C; yield, 96 mg (91%). Found: C, 63.40; H, 5.01%. Calcd for $C_{19}H_{18}O_7$: C, 63.68; H, 5.06%.

Acetate (12): Colorless needles from methanol; mp 194—196 °C. Found: C, 62.68; H, 5.14%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%.

5,6-Dihydroxy-3,4',8-trimethoxyflavone (1). A mixture of **10** (180 mg) and anhydrous aluminium chloride (2 g) in 0.5% (v/v) aqueous acetonitrile (6 ml) was heated at 70

°C for 48 h, and after which the reaction mixture was treated by the method described for **11** to give a brownish-yellow precipitate. The precipitate was separated by preparative HPLC with a column packed with Hitachi gel #3019 using methanol, and then recrystallized from methanol to give orange-yellow needles; mp 183.5—184.5 °C; yield, 90 mg (54%). Found: C, 62.85; H, 4.72%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

*Diacetate (**13**)*: Colorless needles from methanol; mp 173—174 °C. Found: C, 61.45; H, 4.62%. Calcd for $C_{22}H_{20}O_9$: C, 61.68; H, 4.71%.

The authors are grateful to Dr. A. K. Sen, Indian Institute of Chemical Biology, for offering the samples of natural flavone and its acetate.

Photoinduced Ring-opening Reaction of 1-(2-Naphthoyl)aziridine in Various Halogenated Hydrocarbons

Sei-ichi NISHIMOTO, Tsukuru IZUKAWA, and Tsutomu KAGIYA*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 5, 1981)

The in-source photoreaction and the postreaction of 1-(2-naphthoyl)aziridine (NAz) in various halogenated hydrocarbons have been investigated at room temperature under deaerated conditions. Secondary amide such as *N*-(2-chloroethyl)-2-naphthamide (CENA) or *N*-(2-bromoethyl)-2-naphthamide (BENA) was obtained along with a rearranged product of 2-(2-naphthyl)-2-oxazoline (NOz). The initial rate of secondary amide formation increased with decreasing dissociation energy of the carbon–halogen bond of halogenated hydrocarbon. The yield of CENA in the postreaction was substantially equal to that of chloride ion formed *via* the photolyses of chlorinated hydrocarbons. The rearranged product of NOz was confirmed to undergo subsequently photochemical ring-opening reaction to afford CENA or BENA.

We previously reported the photoinduced ring-opening reaction of the aziridinyl group of 1-(2-naphthoyl)-aziridine (NAz) in deaerated solution to afford various secondary amides.[1] The structure of secondary amides obtained was dependent on solvent used for the photoreaction. In the case of chlorinated and brominated hydrocarbons, the formations of *N*-(2-chloroethyl)-2-naphthamide (CENA) and *N*-(2-bromoethyl)-2-naphthamide (BENA) were observed, respectively, accompanied by a rearranged product of 2-(2-naphthyl)-2-oxazoline (NOz).

In the present paper, the in-source photoreaction of NAz in a series of chlorinated and brominated hydrocarbons was investigated in further detail at room temperature under deaerated conditions. The dark reaction of NAz in preirradiated solvents was determined to clarify the influence of the photolysis of solvent. The behavior of NOz as an intermediate in the ring-opening of NAz to CENA or BENA is also described.

Experimental

IR spectra were recorded on a JASCO DS-403 spectrophotometer and ^{1}H NMR spectra on a JEOL PMX-60 spectrometer using tetramethylsilane as an internal standard, respectively. High speed liquid phase chromatography (HLPC) was carried out with a TOYO SODA HLC-802UR apparatus under the same column conditions as reported.[1] Colorimetry was performed with a Shimadzu UV-200S spectrophotometer.

Materials. 1-(2-Naphthoyl)aziridine (NAz) and 2-(2-naphthyl)-2-oxazoline (NOz) were prepared and purified as reported.[1] Dibromomethane was purified by distillation. *t*-Butyl chloride was passed through a silica-gel column, washed with ice water, dried with calcium chloride, and then fractionally distilled before use. The other halogenated hydrocarbons (spectroscopic or guaranteed grade) were used without further purification. Gaseous Cl_2 was prepared by the reaction of manganese dioxide (10 g) with concentrated hydrochloric acid (50 cm^3).[2]

Procedures. The in-source photoreaction of NAz in various halogenated hydrocarbons was carried out according to the same procedures as reported.[1]

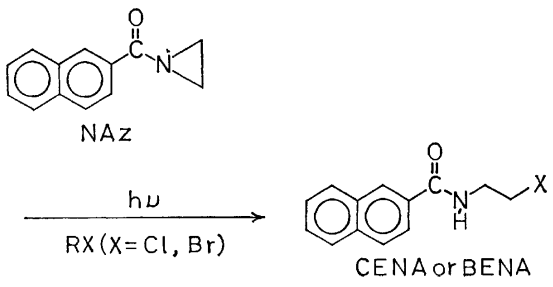
In the postreaction of NAz, each halogenated hydrocarbon (2 cm^3) was irradiated in advance at room temperature under deaerated conditions in a Vycor or Pyrex glass tube, using a merry-go-round apparatus equipped with a high-pressure mercury lamp (EIKOSHA 400 W). NAz was dissolved in the resulting halogenated hydrocarbon and permitted to stand for a specified time at room temperature in the dark. The photolytic product such as HCl or Cl_2 was extracted with water (10 cm^3) from 1 cm^3 aliquots of chlorinated hydrocarbons after preirradiation. Chloride ion derived from HCl and Cl_2 in aqueous solution was determined by Volhard titration using silver nitrate.[3] Similarly, both HBr and Br_2 was extracted with water (100 cm^3) from 0.1 cm^3 aliquots of brominated hydrocarbons after preirradiation. From 5 cm^3 aliquots of the aqueous solution thus obtained Br_2 was extracted with CCl_4 (45 cm^3) and was determined colorimetrically with diphenylcarbazone.[4] Bromide ion due to HBr in aqueous solution was determined by Volhard titration and colorimetry with diphenylcarbazone.[5]

The structures of CENA, BENA, and NOz were identified by comparing their spectral data with those of the authentic sample.[1] The product afforded by the reaction of NOz with HCl in $CHCl_3$ was assigned to 2-(2-naphthyl)-2-oxazolinium hydrochloride from the IR spectral data; IR ($CHCl_3$): 2450 (=$\overset{+}{N}$H), 1947 (C=$\overset{+}{N}$H), 1640 (C=$\overset{+}{N}$), 1239 (C–O), and 895 (ring) cm^{-1}.[6]

The conversion of NAz and the product yield were determined by the same method as reported.[1]

Results and Discussion

In-source Photoreaction of NAz in Various Halogenated Hydrocarbons. Solutions of NAz in various halogenated hydrocarbons (see Table 1) were irradiated with the UV light through a Vycor (>215 nm) or a Pyrex (>286 nm) glass tube under deaerated conditions. Inspection of Table 1 provides a general feature that *N*-(2-chloroethyl)-2-naphthamide (CENA) is a common photoproduct in chlorinated hydrocarbons and *N*-(2-bromoethyl)-2-naphthamide (BENA) in brominated hydrocarbons, respectively, irrespective of the irradiation wavelength.



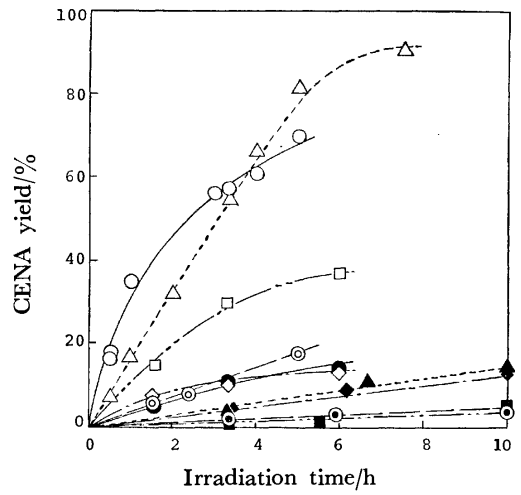


Fig. 1. Variation in CENA yield as a function of irradiation time in the in-source photoreaction of NAz. ——: CCl_4 (V:○, P:●), ----: $CHCl_3$ (V:△, P:▲), — —: CH_2Cl_2 (V:◎, P:⊙), ——: *t*-BuCl (V:◇, P:◆), ——: PhCl (V:□, P:■).

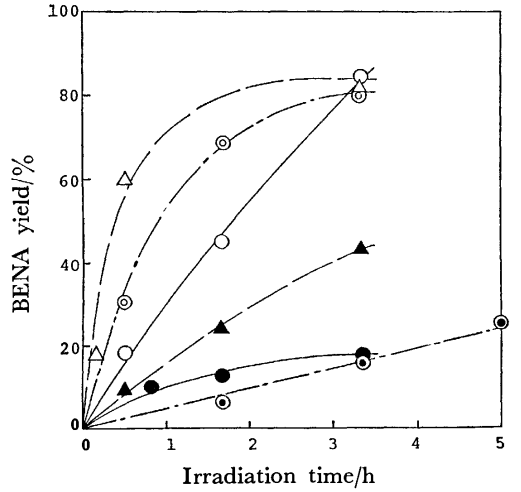

Fig. 2. Variation in BENA yield as a function of irradiation time in the in-source photoreaction of NAz. ——: CH_2Br_2 (V:○, P:●), — —: *n*-PrBr (V:△, P:▲), ——: PhBr (V:◎, P:⊙).

Variations in the CENA and BENA yields as a function of irradiation time are shown in Figs. 1 and 2, respectively. Table 1 summarizes the initial rate of the formation of halogen substituted secondary amide which was estimated from Figs. 1 and 2 by extrapolation. The initial rate in the Vycor system is larger than that in the Pyrex system by a factor of 3—76 in chlorinated hydrocarbons and 3—14 in brominated hydrocarbons, depending on the solvent structure. It can also be seen from Table 1 that the initial rate of CENA formation observed in a series of chloromethanes increases with increasing the number of substituted chlorine atom; $CCl_4 > CHCl_3 > CH_2Cl_2$. Comparing the initial rate of BENA formation with that of CENA formation observed in a couple of brominated and chlorinated hydrocarbons having mutually analogous structure, *e.g.*, CH_2Br_2/CH_2Cl_2 and PhBr/PhCl, the former was 6—33 times larger than the latter.

TABLE 1. IN-SOURCE PHOTOREACTION OF NAz IN VARIOUS HALOGENATED HYDROCARBONS[a]

Run	Solvent	Glass tube	$[NAz]_0$ / mmol dm^{-3}	Initial rate $\times 10^7$ / mol min^{-1}	
				CENA (BENA)[b]	NOz

a) Under the photoirradiation through a Vycor (V) or a Pyrex (P) glass tube at room temperature for 200 min. b) The value in parenthesis denotes the initial rate of BENA formation.

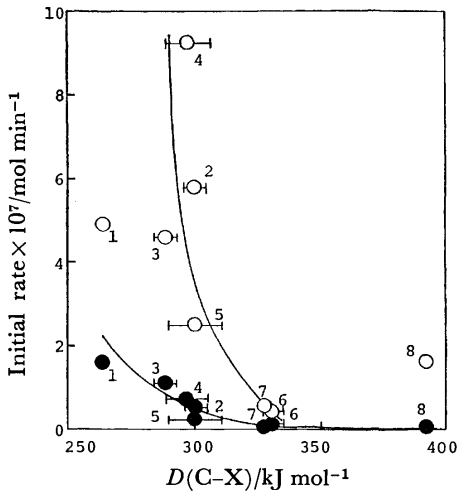

Fig. 3. Relationship between the initial rate of CENA or BENA formation and the carbon-halogen (C–X) bond-dissociation energy of halogenated hydrocarbon solvent for the Vycor (○) and Pyrex (●) systems. 1: CH_2Br_2, 2: CCl_4, 3: *n*-PrBr, 4: PhBr, 5: $CHCl_3$, 6: *t*-BuCl, 7: CH_2Cl_2, 8: PhCl.

As shown in Fig. 3, a fairly good correlation between the initial rate of secondary amide formation and the dissociation energy of the carbon-halogen bond D(C–X) of solvent[7] except for PhCl was obtained in each of the Vycor and Pyrex systems. Apparently, the decrease in the D(C–X) value tends to increase the initial rate of CENA or BENA formation. This seems to indicate that the photochemical ring-opening of NAz to CENA or BENA involves the radical decomposition of halogenated hydrocarbon solvent in its car-

bon-halogen bond.

The previous paper suggested that both the CENA and BENA formations are due to the dark reaction of NAz with the photolytic product of a halogenated hydrocarbon.[1)] Supposing that the D(C–X) value of a given halogenated hydrocarbon provides a measure of the reactivity for photodecomposition, the previous account may be consistent with a correlation observed in Fig. 3. Nevertheless, in view of a fact that most of the incident light (not less than 90%) is absorbed by NAz under the present conditions except for the cases in PhCl and PhBr, it seems likely that the reaction of NAz in the electronically excited state with halogenated hydrocarbon solvents also affords CENA or BENA.

Postreaction of NAz in Various Halogenated Hydrocarbons. In order to estimate the contribution from the ring-opening of NAz arising from the photolysis of halogenated hydrocarbon, the dark reaction of NAz was carried out in various halogenated hydrocarbons pre-irradiated through a Vycor or Pyrex glass tube under deaerated conditions. The product yields are summarized in Table 2.

It can be seen from Table 2 that the postreaction of NAz in chlorinated hydrocarbons affords CENA as a sole product. Analogous to gaseous HCl,[1)] Cl_2 was confirmed to afford CENA exclusively when bubbled into a solution of NAz in CCl_4. Furthermore, as shown in Fig. 4, the CENA yield in the Vycor systems is in fair agreement with the amount of chloride ions produced *via* photolyses of chlorinated hydrocarbons. These results indicate that the photolytic products of both HCl and Cl_2 are responsible for the ionic ring-opening of NAz to afford CENA.

In the postreactions in CH_2Br_2 and PhBr, the yield of NOz is comparable to that of BENA (Table 2). This is in contrast to the postreaction in *n*-PrBr in which only BENA is obtained. On irradiation through a Pyrex glass for 1 h, both bromide ion (53.3 mmol dm^{-3}) and Br_2 (5.6 mmol dm^{-3}) were detected in CH_2Br_2, whereas only bromide ion (55.4 mmol dm^{-3}) was produced in *n*-PrBr. A separate experiment indicated that NAz is converted almost quantitatively to BENA (94%) in the presence of an equimolar amount of aqueous HBr in CH_2Br_2, accompanied by a minor product of NOz (6%). On the other hand, although the overall conversion decreased considerably, the yield of NOz (5%) was comparable to that of BENA (6%) in the presence of aqueous Br_2 in CH_2Br_2. It seems therefore that a photolytic product of Br_2 is a possible species being responsible for the rearrangement of NAz to NOz.

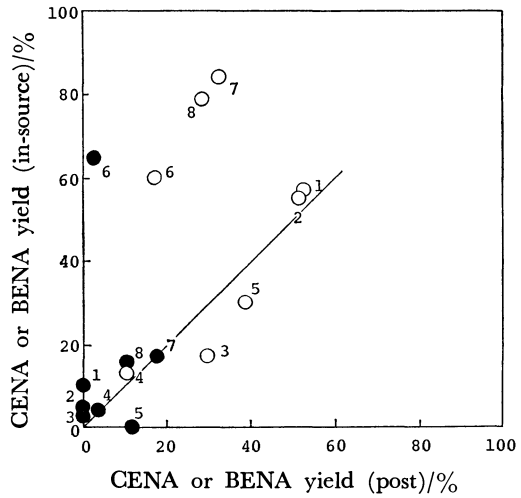

Fig. 5. Relationship between the CENA or BENA yield in the in-source photoreaction and that in the postreaction; (○) Vycor and (●) Pyrex systems.
1: CCl_4, 2: $CHCl_3$, 3: CH_2Cl_2, 4: *t*-BuCl, 5: PhCl, 6: *n*-PrBr, 7: CH_2Br_2, 8: PhBr.

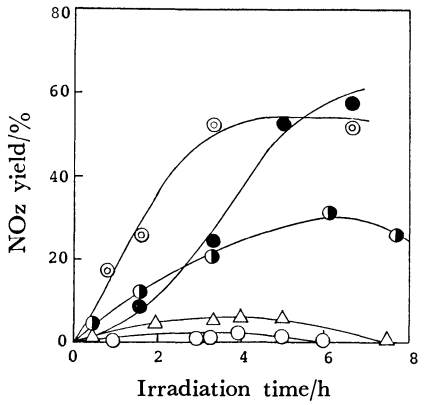

Fig. 6. Variation in NOz yield as a function of irradiation time in the in-soure photoreaction of NAz.
○: CCl_4 (V), △: $CHCl_3$ (V), ◎: CH_2Br_2 (P), ◑: *n*-PrBr (P), ●: PhBr (P).

In Fig. 5 the CENA or BENA yield at 200 min-irradiation in the in-source reaction system is plotted against that in the postreaction system. Under the irradiation through a Vycor glass tube, the stationary concentration of excited $CHCl_3$ in the absence of NAz (91 mmol dm^{-3}) was estimated to be at least 600-fold larger than that in the in-source photoreaction system because of the intense UV absorption by NAz. It follows that the apparent CENA yield in the postreaction system would provide a roughly 600-fold overestimation for the contribution from the photolysis of $CHCl_3$ to the CENA formation in the in-source photoreaction system. Taking into account such a circumstance, the apparent agreement between the CENA yields in the in-source photoreaction and postreaction in a series of chlorinated hydrocarbon solvents indicates that the photochemical CENA formation in source can be attributed almost exclusively to the reaction of excited NAz with solvent molecules. More explicitly, the BENA yield in the in-source photoreactions is seen to exceed considerably that in the postreactions

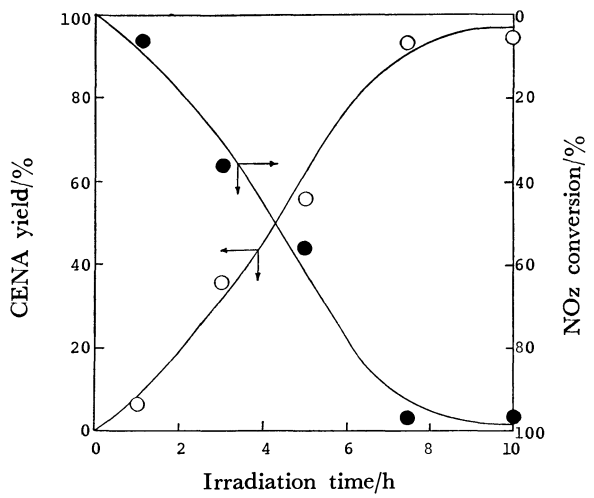

Fig. 7. Variation in NOz conversion (●) and CENA yield (○) as a function of irradiation time in the $CHCl_3$-Vycor in-source photoreaction system; $[NOz]_0$ = 91 mmol dm^{-3}.

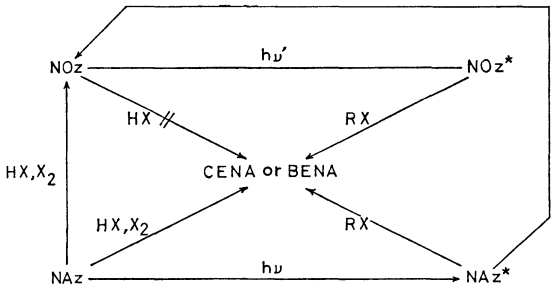
(Fig. 5).

In this connection, it can be presumed from Fig. 3 that NAz undergoes radical cleavage of the aziridine ring moiety in the electronically excited state to abstract halogen atom from halogenated hydrocarbon solvents. Such a halogen abstraction would be a rate-determining step in the photochemical CENA and BENA formations in source.

Photochemical Formation and Decomposition of NOz in Various Halogenated Hydrocarbons. It is remarkable in Table 1 that although BENA is afforded exclusively on irradiation of NAz in brominated hydrocarbons through a Vycor glass tube, the rearrangement of NAz to NOz occurs simultaneously in the Pyrex system. Such a formation of NOz was also observed in CCl_4 and $CHCl_3$ even in the Vycor system.

Figure 6 shows the variation in NOz yield as a function of irradiation time. The yields of NOz exceed 50% in CH_2Br_2 and PhBr on irradiation for 200 and 300 min, respectively, and 30% in *n*-PrBr for 360 min. The NOz formation was nevertheless no more observed in these solvents by the prolonged irradiation for over 20 h under the same conditions. During the irradiation for over 300 min in CCl_4 and $CHCl_3$, an analogous variation in the NOz yield with its maximum value of <6% was observed.

As can be seen from Fig. 7, NOz undergoes ring-opening reaction to afford CENA as a sole product on irradiation of a deaerated solution in $CHCl_3$ through a Vycor glass tube. Apparently, the photochemical behavior of NOz is very similar to that of NAz. It is however remarkable that the reactivity of NOz toward HCl is quite different from that of NAz. Thus the slow formation of 2-(2-naphthyl)-2-oxazolinium hydrochloride salt[4] was observed when gaseous HCl was bubbled through a solution of NOz in $CHCl_3$, whereas NAz reacts rapidly with HCl to afford CENA under the same conditions.[1] It follows that the photochemical CENA formation shown in Fig. 7 may be attributed to the reaction of excited NOz with $CHCl_3$.



Scheme 1.

In view of the results presented above, the following scheme may be drawn for the photochemical ring-opening reaction of NAz in halogenated hydrocarbons (RX). Although hydrogen halide (HX) and halogen molecule (X_2) derived from the solvent photolysis are highly reactive to NAz, the formation of such species in the in-source photoreaction system would be minor under conditions investigated.

Syntheses and Properties of Copolymers of Isopropenyl-1,3,5-triazines and Methacrylic Esters

Toshihiro SEO* and Toshio KAKURAI

Department of High Polymer Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 28, 1981)

Copolymerizations of 2-amino-4-(substituted amino)-6-isopropenyl-1,3,5-triazines (methacryloguanamine) with alkyl methacrylates using redox initiator gave polymers with high molecular weights in satisfactory yields. The monomer reactivity ratios and *Q*-*e* values were also determined. Softening and glass transition temperatures rose and specific gravity increased with the increase in the content of triazine units. The copolymers were slightly soluble in nonpolar solvents and readily soluble in polar solvents with a solubility parameter (δ) = 11—13. This polymer with aminotriazine groups showed high viscosity in acid solution and can be utillized as polyelectrolyte.

Polymers containing amino-1,3,5-triazine groups have been investigated as industrial materials and heat-stable polymers. Furthermore, the polymers with aminotriazine groups in the side or main chain are expected to have a variety of other properties, such as rigidity, intermolecular interaction, thermal stability and basicity.[1-3]

The polymerization of several vinyl- and isopropenyl-1,3,5-triazines and the copolymerization with styrene,[4] acrylic or methacrylic acid[1] have been studied previously. Recently isopropenyl-1,3,5-triazines were readily prepared in high yields from methacrylic active esters and biguanides.[5]

This paper describes the determination of copolymerization parameters of 2-amino-4-(substituted amino)-6-isopropenyl-1,3,5-triazines with methacrylic esters and a survey for synthetic conditions to obtain the desired polymers with high molecular weights. Physical and thermal properties of the polymers, *e.g.*, softening and glass transition temperature, specific gravity, solubilities and solution viscosities are also reported.

Experimental

Materials. The mono- and disubstituted biguanides were prepared by the method of Kono and Odo[6] or Cohn[7] from dicyanodiamide and the corresponding amines. Methacrylic esters and *N*,*N*-dimethylaniline were purified by the usual methods.

The initiator, α,α′-azobisisobutyronitrile (AIBN) or benzoyl peroxide (BPO) was a commercial material.

Dioxane was purified by drying with anhydrous magnesium sulfate, refluxing with sodium, and fractionally distilling. Dimethyl sulfoxide (DMSO) was fractionally distilled under reduced pressure in the presence of nitrogen after drying with calcium hydride.

All the other reagents were commercially available and were used after purification, if necessary.

2,4-Diamino-6-isopropenyl-1,3,5-triazine (AIPT): 9.2 g (0.165 mol) of potassium hydroxide dissolved in 90 ml of methanol was added dropwise to the solution of 22.7 g (0.165 mol) biguanide hydrochloride dissolved in 200 ml of methanol at 5—10 °C under stirring. The resulting potassium chloride was filtered off, then the filtrate was concentrated using vacuum evaporator at 30—40 °C. To the concentrate, dissolved in 120 ml of DMSO, was added phenyl methacrylate 24.3 g (0.15 mol). After the temperature was kept at 30 °C for 3 d, the reaction mixture was poured into 2 l of water. The crude product obtained was recrystallyzed from methanol–Methyl Cellosolve to afford colorless crystals, mp 247—248 °C (lit, 247—248 °C)[4] in 81.6% yield.

Other 2,4-substituted amino-6-isopropenyl-1,3,5-triazines were prepared by the procedure described before.[5]

2-Amino-4-anilino-6-isopropenyl-1,3,5-triazine (AAIPT) was recrystallyzed from methanol, mp 174—175 °C (lit, 174—175.5 °C).[4]

2-Amino-4-(*N*-methylanilino)-6-isopropenyl-1,3,5-triazine (NMeAIPT) was recrystallyzed from benzene, mp 117—118 °C (lit, 118—119 °C).[4]

2-Amino-4-dimethylamino-6-isopropenyl-1,3,5-triazine (DMAIPT) was recrystallyzed from methanol, mp 191—192 °C (lit, 191—192 °C).[4]

Procedure. All the polymerization experiments were carried out in a glass tube sealed under a vacuum. Methanol was used as a precipitant. The composition of the polymer was calculated from the carbon and nitrogen contents.

Measurement. Reduced and intrinsic viscosities were determined using an Ostwald and an Ubbelode viscometer, respectively. Number average molecular weights (Mn) were measured by osmometry in a benzene or toluene solution (high speed membrane osmometer Mechrolab 501). Gel permeation chromatography (GPC) was done on a Toyo Soda Model HLC 801A with tetrahydrofuran as the solvent. Ultraviolet absorption spectra were obtained with a Hitachi Model 139 spectrometer.

The softening temperature was measured with a Shimadzu Type MM-2 micro softening point determination apparatus. The glass transition temperature was determined by the same heat-expansion measurement as was reported before.[8] The specific gravity of a polymer film was measured by the suspension method in concentrated sodium chloride or sucrose solution.

Results and Discussion

Homopolymerization. As shown in Table 1, 2-amino-4-anilino-6-isopropenyl-1,3,5-triazine (AAIPT), whose ceiling temperature was about 170 °C,[9] gave only polymers with reduced viscosities of 0.3—0.4 dl/g when polymerized at 60 °C using AIBN. However, poly(AAIPT) with high molecular weight (reduced viscosities of 2—3 dl/g) formed during a short reaction time in satisfactory yields when the polymerizations were attained at 30 °C using redox initiator.

Homopolymers of 2,4-diamino-6-isopropenyl-1,3,5-triazine (AIPT) precipitated from a solution, and their viscosities, obtained using both redox initiator

and AIBN, were nearly equal.

Redox polymerizations of other 2-amino-4-(substituted amino) derivatives gave high polymers in 70—90% yields in 1—2 h polymerization period.

Copolymerization. Copolymerizations of AAIPT or AIPT with methacrylic esters such as methyl, ethyl, or butyl methacrylate (MMA, EMA, or BMA) were carried out as shown in Tables 2 and 3 respectively.

Copolymerizations of AAIPT with alkyl methacrylates using redox initiator gave polymers with high molecular weights (viscosities of 0.5—1.7 dl/g), whereas the viscosity of the polymer prepared using AIBN was 0.4 dl/g. Similarly, the redox polymerizations of AIPT with alkyl methacrylates gave high polymers with viscosities of 0.9—1.5 dl/g.

Next, the monomer reactivity ratios were determined by the method of Finemann and Ross or Mayo and Lewis; Q-e values are summarized in Table 4.

The r_1r_2 values for copolymerization of AIPT or AAIPT with methacrylic esters are larger than those with styrene. This suggests that copolymerizations of isopropenyl-1,3,5-triazines with methacrylic esters give a lower alternating tendency than that with styrene. Q values were 0.9—1.2. The negative e values for AIPT and the positive e values for AAIPT may be due to the presence of a strong electron-donating effect of two amino groups and a weaker conjugation of anilino group with double bond.[4]

a) St: Styrene ($Q_1=1.0$, $e_1=-0.8$), BMA: butyl methacrylate ($Q_1=0.74$, $e_1=0.39$), EMA: ethyl methacrylate ($Q_1=0.70$, $e_1=0.44$), MMA: methyl methacrylate ($Q_1=0.74$, $e_1=0.40$).

As shown in Table 5, viscosities in dioxane are different from those in benzene, and hence the affinities of triazine rings for solvent seem to influence to some extent the conformation of copolymers. $\bar{M}n$ of copolymers with viscosities of 1.6—1.7 dl/g and 0.6—1.0 dl/g were $(65$—$90)\times 10^4$ and $(10$—$40)\times 10^4$ respectively. The peak count number in GPC decreased with increasing $\bar{M}n$, as recognized generally.

In the UV spectra of copolymers given in Table 6, λ_{max} was assigned to triazine rings in analogy with the model compound; ε values decreased with increasing triazine content, which may show the presence of an interaction between aminotriazine groups.

The other absorption at about 259 nm for AAIPT–BMA copolymers probably indicates the existence of steric hindrance between triazine rings and butyl ester groups in side chain. This may be substantiated by the fact that λ_{max} of *o*-toluidino derivative shifted to a much lower wavelength compared with that of anilino derivative.

Properties. The previous reports[1,2] showed that various polymers containing vinyl-1,3,5-triazines (acryloguanamine) were prepared by the reaction of cyano groups in polymer side chain with dicyanodiamide and/or from polymers containing active ester groups as a pendant and biguanides; then their several properties were investigated. In this paper the thermal and physical properties of polymers containing isopropenyl-1,3,5-triazines (methacryloguanamine) were studied in detail.

As shown in Figs. 1—4, the glass transition temperature (T_g) of polymers was generally about 2/3—3/4 times the softening temperature (T_s). Ts of AIPT–BMA copolymers rose linearly with AIPT content and became above 300 °C at 60 mol% of triazine rings. Ts of AAIPT–BMA copolymers rose in proportion to AAIPT content, but became much lower

than that of polymers containing AIPT beyond 40 mol% of triazine rings.

For copolymers of isopropenyl-1,3,5-triazines and EMA, the content of AIPT or AAIPT influenced significantly on T_s or T_g. In the introduction of AIPT to poly(methyl methacrylate), T_s or T_g rose more remarkably than that of AAIPT. The effect of DMAIPT or NMeAIPT on T_s or T_g was approximately equal to that of AAIPT, as given in Fig. 4.

As a result, the introduction of triazine rings to a polymer as a pendant decreased the flexibility of the polymer chain. Specifically, the softening and glass transition points rose considerably with the increase in the content of triazine units. And interac-

tions between triazine rings with two amino groups were stronger than those between triazine rings with one amino or anilino group, and phenyl groups attached to the triazine rings may act as the external plasticizer.

Further, 40—60 °C rises in Ts occurred for each 10 mol% of introduction of methacryloguanamines to poly(methyl methacrylate), whereas about 100 °C rise occurred for that of acryloguanamines.[2] This suggests that the α-methyl group weakens the interaction between aminotriazine groups.

Next, as shown in Figs. 5 and 6, specific gravities of poly(AIPT) and poly(AAIPT) were 1.296 and 1.245 respectively, which were close to that of poly(vinyl alcohol)(1.2—1.3) and poly(vinyl chloride) (1.3—1.4).

The specific gravities of copolymers of AIPT and alkyl methacrylate increased from 1.07 to 1.30 with increasing AIPT content. Moreover, specific gravities of polymers containing AAIPT increased considerably with AAIPT content and came into agreement with that of poly(AAIPT) at 40—60 mol% of triazine rings. A similar relation may hold for the copolymer containing NMeAIPT or DMAIPT.

In addition, the polymer with less than 25 mol% of triazine rings formed a very transparent flexible hard film.

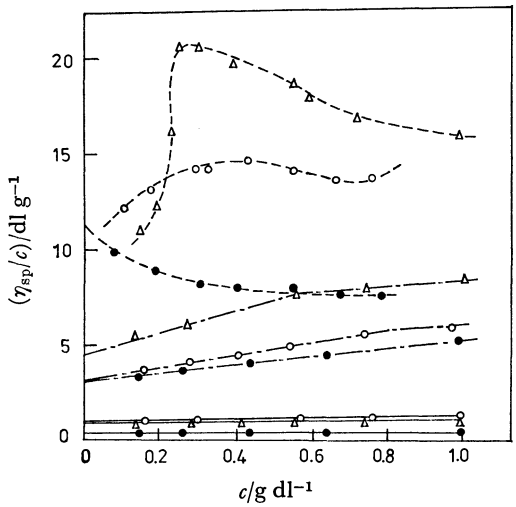

Fig. 7. The relationship between reduced viscosity and the concentration of copolymer of 2,4-diamino-6-isopropenyl-1,3,5-triazine (AIPT) and butyl methacrylate in various solvents.

Mole percent of AAIPT in copolymer; ○: 13.20, △: 26.43, ●: 35.40, ——: in dioxane, —·—: in HCOOH+0.1 mol dm^{-3} HCOONa, — — —: in HCOOH.

Since specific gravity is closely associated with index of refraction and dielectric constant, an introduction of aminotriazine rings to various polymers can be expected to improve their properties and produce materials useful industrially.

As given in Tables 7 and 8, the solubilities of copolymers of isopropenyl-1,3,5-triazines and alkyl methacrylates increased with increasing the number of carbon atoms of alkyl group.

Polymers containing below 20 mol% of AIPT were soluble in 2-propanol and polar solvents, but became insoluble in dioxane or DMF and soluble in only DMSO or organic acid at AIPT content of over 40 mol%. And even the introduction of 3 mol% of AIPT to poly(methyl acrylate) greatly decreased the solubilities, allowing effective interaction between aminotriazine groups in a very flexible polymer chain.

Further, polymers containing AAIPT were more readily soluble in organic solvents, with solubility parameter (δ)=10—13. Namely, polymers containing 40—50 mol% of AAIPT were soluble in dioxane and Methyl Cellosolve. Other polymers containing 4-(substituted amino) derivatives also exhibited similar solubilities as described above.

It was noteworthy that even copolymers with 10 mol% of triazine rings were soluble in organic acids. As shown in Figs. 7 and 8, the viscosities in formic acid were 10—20 times that in dioxane or Methyl Cellosolve; these increased with dilution and had a maximum value at a certain concentration. However, the viscosities decreased linearly in formic acid–sodium formate solution.

This result indicates that the basic aminotriazine rings have affinities for acid, and hence the protonation at the nitrogen atom of the triazine ring increased the intra- and intermolecular excluded volume effects in polymer solution. Thus, polymers having triazine rings as a pendant can be utilized as polyelectrolytes.[1]

In conclusion, the above-mentioned thermal and physical properties were markedly affected by the species and the number of substituted groups of triazine ring and the structure or composition of the polymer. Moreover, these effects were found to be based upon the rigidity of the basicity of triazine rings and their intra- and intermolecular interactions.

The knowledge obtained in this investigation can be available for the molecular design of polymer-containing heterocyclic rings with many nitrogen atoms.

The authors wish to thank Mr. T. Saito of Tokyo Institute of Technology for his elementary analyses. They are also grateful to Dr. Y. Yuki of Nagoya Institute of Technology for his helpful suggestions and are pleased to acknowledge the considerable assistance of Dr. T. Fukutomi of Tokyo Institute of Technology.

Studies on Chemical Synthesis of mRNAs. I. Synthesis and Properties of N^2-Tritylguanosine Derivatives and Application to Synthesis of pGpUpU

Tsujiaki HATA,* Noboru GOKITA, Nobuo SAKAIRI,† Kazuo YAMAGUCHI, Mitsuo SEKINE, and Yoshiharu ISHIDO†

Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received January 5, 1982)

Trityl (Tr), 4-methoxytrityl (MMTr), and 4,4′-dimethoxytrityl (DMTr) groups were introduced into the 2-amino group of 2′,3′,5′-tri-*O*-acetylguanosine by treatment with the corresponding trityl chlorides in pyridine to afford the N^2-tritylated guanosine derivatives in high yields. Similarly, the N^6-tritylated adenosine derivatives were synthesized. The stability of the three kinds of trityl groups under acidic conditions were described. The MMTr and Tr groups were found to be suitable for the protection of the 2-amino group of guanosine in oligonucleotide synthesis. An appropriately protected N^2-tritylguanosine 5′-phosphorodithioate derivative was synthesized and utilized for the synthesis of pGpUpU.

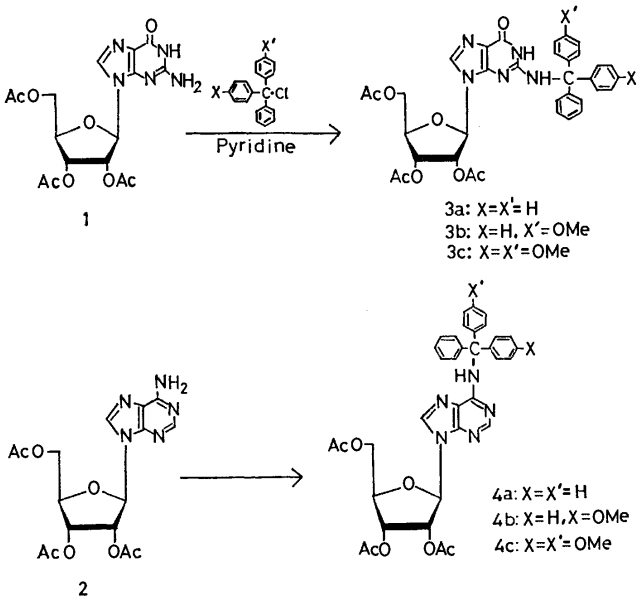
In 1975, Miura[1] discovered the so-called "cap" structure in the 5′-terminal region of cytoplasmic polyhedrosis virus mRNA which was represented as m^{7}G$^{5'}$pppAmpGpU···. Since then, the cap structure has been found from several viruses, eukaryotic cells, and mammarian cells.[2] The cap structure is now well recognized as the common structure of eukaryotic mRNAs. Therefore, much attention has been paid to the correlation between the structure and functions of mRNAs in peptide synthesis.[3]

In connection with our study on the chemical synthesis of 5′-terminal structures of eukaryotic mRNAs, especially, the common sequence of mosaic viruses represented as m^{7}G$^{5'}$pppGpUpU···, we wish to report here a basic study on the protection of the 2-amino group of guanosine and also describe the synthesis of pGpUpU.

Results and Discussion

Since 7-methylguanosine (m^{7}G), contained in the cap structure, is quite unstable under alkaline conditions and decomposes to a ring-opening product,[4] the chemical synthesis of capped oligoribonucleotides should be designed to perform under neutral and mildly acidic conditions. In general,[5] the amino groups of nucleoside bases were masked with acyl groups. Only a few have been reported of the acid labile protecting groups for the amino groups. Among them, Holy[6] reported the dimethylaminomethylene group as the protecting group of the 2-amino function of guanine moiety. However, this group is unstable under both acidic and alkaline conditions. On the other hand, 4,4′-dimethoxytrityl (DMTr) group has been used as the acid labile protecting group of the 2-amino group of guanosine by Khorana[7] and Shimidzu.[8] In this study, we tried to use the latter type of protecting groups since introduction of trityl groups enhanced the lipophilicity of the product and the groups could serve as the markers which were easily detected by spraying 10% perchloric acid solution on a chromatogram.

First, the three kinds of trityl groups (Tr, MMTr, and DMTr), were introduced to the 2-amino group of 2′,3′,5′-tri-*O*-acetylguanosine (**1**). In a similar manner, 2′,3′,5′-tri-*O*-acetyladenosine (**2**) was also tritylated. The conditions and results are summarized in Table 1. It was found that the tritylations of **2** proceeded more readily than those of **1**. All the products **3** and **4** could be isolated in pure form as the stable compounds. The N^2-tritylguanosine derivatives **3a—c** were proved to be less polar than the N^6-trityladenosine derivatives **4a—c** from their R_f values.



The stability of the Tr, MMTr, and DMTr groups introduced into **1** and **2** was examined. Compounds **3a—c** and **4a—c** were respectively stirred with silica gel (Wakogel C-200) in dichloromethane at room temperature for one day. The amounts of the detritylated compound **1** and **2** were estimated spectrophotometrically after thin layer chromatography. Table 4 shows that the adenosine derivatives are less stable than the guanosine derivatives on silica gel.

Similar results were obtained by treatment of **3a—c** and **4a—c** with 80% acetic acid as summarized in Table 5. Complete removal of each trityl group from **3** or **4** could be performed within one day at room

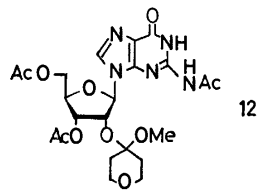
temperature except for **3a**. In the case of **3a**, the trityl group was removed completely at 100 °C for 10 min.

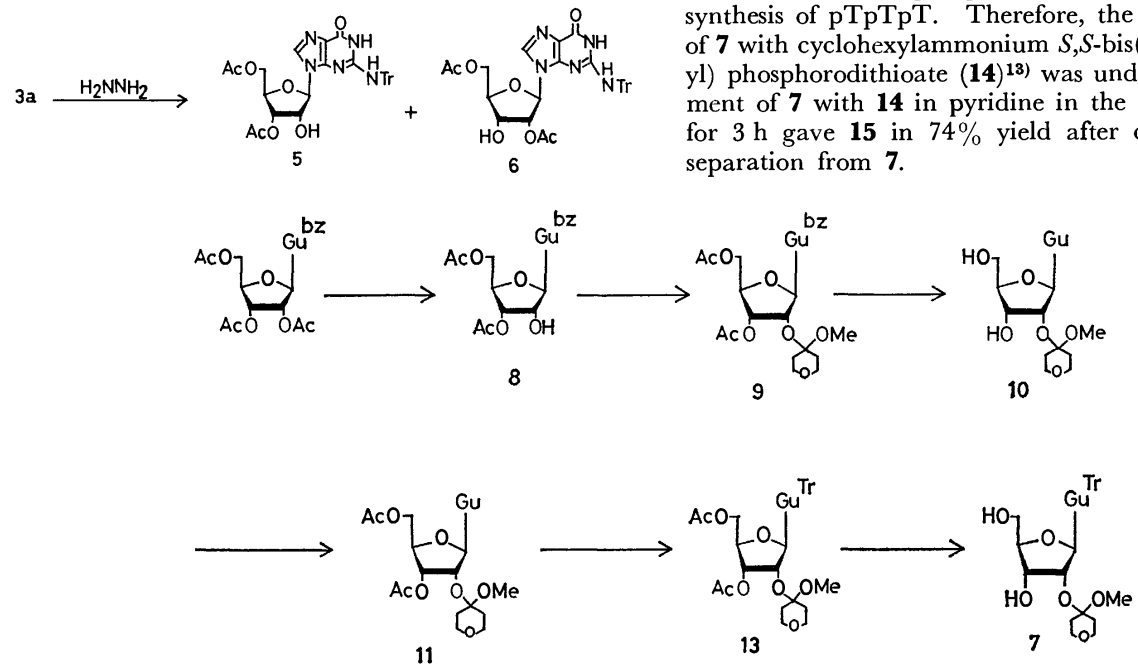
Recently, the 5′-terminal structure of brome mosaic virus mRNA has been determined by Kaesberg.[9] It was described as m^{7}G$^{5'}$ pppGpUpU···. From biological interest of the 5′-terminal structure of brome mosaic virus mRNA, we aimed to synthesize the terminal trimer pGpUpU utilizing the trityl group. In order to prepare a N^2-tritylguanosine derivative having the unmasked 2′-hydroxyl group as the starting material for the synthesis of pGpUpU, the selective deacetylation of **3a** by means of hydrazine hydrate was first examined to obtain 3′,5′-di-*O*-acetyl-N^2-tritylguanosine (**5**). However, **5** and the 2′,5′-diacetate (**6**) were not easily separated, and **5** could not be purified by recrystallization. Repeated chromatography was needed for the complete purification of **5**,[10] since the difference in R_f value between **5** and **6** was unappreciable. From the synthetic point of view this approach could not be applied to the preparation of **5** on a large scale. Therefore, the synthesis of a 2′-protected N^2-tritylguanosine derivative (**7**) was carried out by an alternative route outlined in Scheme 1.

We have chosen 4-methoxytetrahydropyranyl group[11] as the 2′-hydroxyl protecting group, since it could be removed under acidic conditions and had no chiral center in contrast with tetrahydropyranyl group. A convenient method for the synthesis of 3′,5′-di-*O*-acetyl-N^2-benzoylguanosine (**8**) has been reported recently.[12] The methoxytetrahydropyranylation of **8** gave the 2′-protected guanosine derivative (**9**) in 71% yield. Treatment of **9** with butylamine–methanol (1:1, v/v) gave 2′-(4-methoxytetrahydropyran-4-nyl)guanosine (**10**) in 76% yield. Acetylation of **10** with 20 equiv. of acetic anhydride in pyridine gave selectively the 3′,5′-di-*O*-acetylated derivative (**11**) in 90% yield. When more than 20 equiv. of acetic anhydride was used, N^2,$O^{3'}$,$O^{5'}$-triacetylated product (**12**) was formed to an appreciable extent. N^6-tritylation of **11** in pyridine at 100 °C for 1 h gave the fully protected guanosine derivative (**13**) in 87% yield. Deacylation of **13** by means of butylamine–methanol (1:1, v/v) gave **7** in 90% yield.

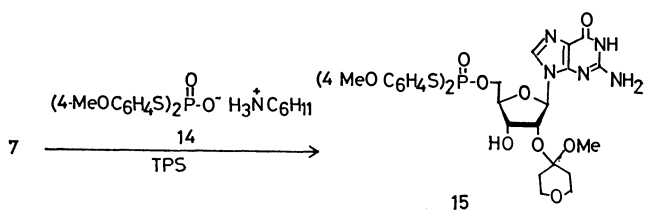


12

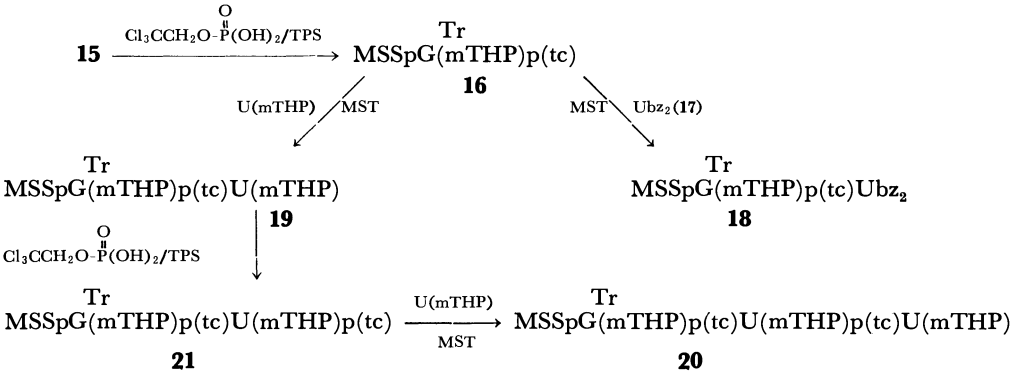
For the construction of the triphosphate bridge involved in the cap structure of the mRNA, a suitable protected phosphate group should be introduced into the 5′-hydroxyl group of **7**. In a previous paper,[13] we described the utility of 4-methoxyphenylthio group as the 5′-terminal phosphate protecting group in the synthesis of pTpTpT. Therefore, the phosphorylation of **7** with cyclohexylammonium *S*,*S*-bis(4-methoxyphenyl) phosphorodithioate (**14**)[13] was undertaken. Treatment of **7** with **14** in pyridine in the presence of TPS for 3 h gave **15** in 74% yield after chromatographic separation from **7**.



Scheme 1.



Next, the synthesis of the protected pGpUpU was performed according to Neilson's procedure.[14] Phosphorylation of **15** with 2,2,2-trichloroethyl dihydrogenphosphate was examined by using TPS, 1-(4-nitrophenylsulfonyl)-1*H*-1,2,4-triazole,[15] or dicyclohexylcarbodiimide (DCC). Among those condensing agents, TPS was found to be the most effective. When **15** was phosphorylated by using TPS, TLC of the reaction mixture showed more than 9 spots. However, the mixture was hydrolyzed with aqueous pyridine at room temperature for one day, the desired 3'-phosphorylated product (**16**) appeared as main spot on TLC. Subsequent coupling of **16** with 2',3'-di-*O*-benzoyluridine (**17**) in the presence of 1-(mesitylsulfonyl)-1*H*-1,2,4-triazole (MST)[15] gave the fully protected guanylyl(3'→5') uridine derivative (**18**) in 80% yield.

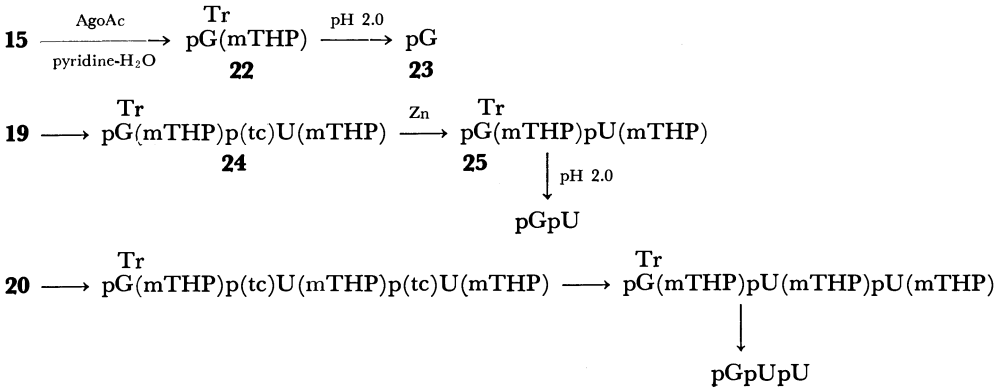


In a similar manner, the dinucleotide (**19**) was obtained in 60% yield from **16** and 2'-*O*-(4-methoxytetrahydropyranyl)uridine [U(mTHP)]. The trimer (**20**) was synthesized by a similar procedure: When a dinucleotide derivative obtained by the phosphorylation of **19** with 2,2,2-trichloroethyl phosphate in the presence of TPS was condensed with U(mTHP) by means of MST, the desired trinucleotide (**20**) was obtained in 54% yield.

During the coupling reactions by-products having blue fluorescence were detected on TLC. They appeared just on the desired products and decomposed to the starting material (**21**) and the desired product during workup. Since O^6-dialkoxyphosphinyl derivatives of **3a** has blue fluorescence,[16] the present by-products might be the O^6-phosphorylated derivatives concomitantly formed from the reaction of **18** or **20** with **16** or **21**.

Deprotection of the Protected Oligonucleotides. We first tested the deprotection of mononucleotide **15**. Treatment of **15** with silver acetate in pyridine–water (2:1, v/v) at room temperature for 24 h followed by chromatography on Whatman 3 MM papers gave 2'-*O*-(4-methoxytetrahydropyranyl)-N^2-tritylguanosine 5'-phosphate (**22**). Subsequent treatment of **22** with 0.01 M (1 M=1 mol dm^{-3}) HCl (pH 2.0) with vigorous stirring for 2 d gave guanosine 5'-phosphate (**23**). The overall yield of **23** from **15** was almost quantitative (99%).

The removal of the protecting groups from the dinucleotide **19** was carried out as follows. As described above, treatment of **19** with silver acetate[13] gave pG^{Tr}(mTHP)p(tc)U(mTHP) (**24**). The 2,2,2-trichloroethyl group was removed from **24** by treatment with zinc/acetylacetone according to the method reported by Adamiak.[17] Finally, the resulting product (**25**) was converted to pGpU in an overall yield of 50% by treatment with 0.01 M HCl for 2 d. Finally, in a similar manner, from the protected trinucleotide **20** pGpUpU was obtained in 41% yield. Both the dimer and the trimer were degraded by snake venom phosphodiesterase to give pG and pU in the theoretical ratios. Usually, 2,2,2-trichloroethyl group can also be removed by treatment with tetra-



butylammonium fluoride (TBAF). However, attempts to remove the 2,2,2-trichloroethyl group from **24** by means of TBAF were unsuccessful. This result was consistent with that reported by Ogilvie[18] that the presence of a charged phosphate one unit removed from the triester phosphate was sufficient to prevent removal of the internucleotidic phenyl group by TBAF. On the other hand, treatment of **19** with TBAF gave the 5'-terminal phosphorofluoridate derivative, FpG^{Tr}-(mTHP)pU(mTHP), which remained unchanged upon treatment with silver acetate in aqueous pyridine. The decrease of the yields of the deprotected oligomers might be mainly due to side reactions or adsorption of the nucleotidic substances on the zinc surface on the removal of the 2,2,2-trichloroethyl group, although the latter group was rapidly deprotected. While improvement of the yields in the coupling and deblocking processes remained as a problem to be investigated, the present approach provides oligomers with the acid labile protecting groups, which may be useful for the joining with the 'cap' part. Further extention of this wark is now in progress.

Experimental

Melting points were determined on a Thomas-Hoover apparatus and are uncorrected. ^{1}H NMR spectra were recorded at 100 MHz on a JEOL ST-100 spectrometer. UV spectra were obtained on a Hitachi 124 spectrophotometer.

Paper chromatography was performed by descending technique using Toyo Roshi No. 51 and Whatman 3 MM papers. The solvent systems used were Solvent I: isopropyl alcohol–concentrated aqueous ammonia–water (7:1:2, v/v/v); Solvent II: isopropyl alcohol–concentrated aqueous ammonia–water (6:1:3, v/v/v). Paper electrophoresis was carried out with an apparatus similar to that described by Markham and Smith.[19] The buffer used were Buffer I: 0.05 M phosphate (pH 8.0); Buffer II: 0.873 M acetic acid (50 ml)–morpholine (3.3 ml) (pH 3.5) solution (1 l).

Pyridine was distilled from *p*-toluenesulfonyl chloride and stored over calcium hydride. Dichloromethane (CH_2Cl_2) was distilled after being kept over P_4O_{10} for 1 d, redistilled from potassium carbonate, and stored over molecular sievers (3A). Dioxane (1 l) was purified by passing nitrogen gas into the refluxing mixture which contained concentrated hydrochloric acid (13 ml) and water (10 ml) followed by neutralization with potassium hydroxide, extraction, and distillation over sodium. 2',3',5'-Tri-*O*-acetylguanosine (**1**) and 2',3',5'-tri-*O*-acetyladenosine (**2**) were prepared according to the literature method.[20]

Snake venom phosphodiesterase (1 mg/1 ml) was purchased from Boehringer Mannheim GmbH.

Typical Procedure for the Synthesis of **3** *and* **4**. Compound **1** (1.02 g, 2.5 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry pyridine (25 ml) trityl chloride (1.12 g, 4 mmol) was added and the mixture was stirred at 100 °C for 2 h. The mixture was cooled to room temperature and ice (5 g) was added. After being kept for 30 min, the mixture was extracted with CH_2Cl_2 (3×30 ml). The combined organic extracts were dried over Na_2SO_4 and evaporated *in vacuo*. The residue was chromatographed on a column of silica gel using CH_2Cl_2–MeOH to give **3a** (1.49 g, 91%). The conditions and results are summarized in Table 1. Physical properties and elemental analysis of **3** and **4** are listed in Table 2.

3',5'-Di-O-acetyl-2'-O-(4-methoxytetrahydropyran-4-yl)-N^2-benzoylguanosine (**9**). To a solution of *p*-toluenesulfonic acid monohydrate (570 mg, 3 mmol) in dioxane (120 ml) was added **8** (5.64 g, 12 mmol). The mixture was stirred for 1 h, and then 5,6-dihydro-4-methoxy-2*H*-pyran (30 mmol)[11] was added. After 3 h, the resulting mixture was neutralized with 1 M methanolic sodium methoxide and evaporated to dryness. The residue was chromatographed on a column of silica gel (98:2—97:3 CH_2Cl_2–MeOH) to give **9** (5.61 g, 71%): Mp 129 °C; NMR ($CDCl_3$) δ 1.76 (4H, m, pyranyl ring protons), 2.06 (3H, s, $CH_3C(O)$), 2.16 (3H, s, $CH_3C(O)$), 2.56 (3H, s, CH_3–O), 3.63 (4H, m, pyranyl ring protons), 4.50 (3H, m, H-4' and 5'), 5.06 (1H, m, H-3'), 5.30 (1H, m, H-2'), 5.90 (1H, d, $J_{1',2'}$= 7.5 Hz, H-1'), 7.20—8.20 (6H, m, ArH and H-8). Found: C, 54.94; H, 5.35; N, 11.10%. Calcd for $C_{27}H_{31}O_{10}N_5 \cdot 1/2H_2O$: C, 54.56; H, 5.33; N, 11.78%.

2'-O-(4-Methoxytetrahydropyran-4-yl)guanosine (**10**). Compound **9** (7.51 g, 12.9 mmol) was dissolved in 1:1 butylamine–methanol (100 ml), and the solution was allowed to stand at room temperature. After 1 d, the solvent was evaporated *in vacuo*. The residue was washed with benzene and recrystallized from methanol to give **10** (3.91 g, 76%): Mp 226 °C (decomp); $UV^{H_2O}_{max}$ 252 nm (ε=14.4×10^3), $UV^{H_2O}_{min}$ 222 nm (ε=3×10^3), $UV^{H_2O}_{sh}$ 269 nm (ε=3×10^3); NMR ($CDCl_3$) δ 1.63 (4H, m, Pyranyl ring protons), 2.67 (3H, s, CH_3–O), 3.35 (4H, m, pyranyl ring protons), 3.58 (2H, m, H-5'), 3.94 (1H, m, H-4'), 4.07 (1H, m, H-3'), 4.70 (1H, dd, $J_{1',2'}$=7.4 Hz, $J_{2',3'}$=5 Hz, H-2'), 5.13 (2H, m, OH), 5.87 (1H, d, $J_{1',2'}$=7.4 Hz, H-1'), 6.45 (1H, br.s, NH_2), 7.98 (1H, s, H-8). Found: C, 48.05; H, 5.85; N, 17.68%. Calcd for $C_{16}H_{23}N_5O_7$: C, 48.36; H, 5.83; N, 17.62%.

3',5'-Di-O-acetyl-2'-O-(4-methoxytetrahydropyran-4-yl)guanosine (**11**). To a mixture of acetic anhydride (20 ml) and pyridine (23 ml) was added **10** (4.03 g, 10.2 mmol). The suspension was vigorously stirred at 60 °C for 2 h. The resulting homogeneous solution was cooled to room temperature. The crystalline precipitate was collected by filtration, washed with benzene, and recrystallized from methanol to give **11** (4.39 g, 90%): Mp 263 °C (decomp); $UV^{H_2O}_{max}$ 253 nm (ε=14.5×10^3), $UV^{H_2O}_{min}$ 222 nm (ε=2.9×10^3), $UV^{H_2O}_{sh}$ 270 nm (ε=10.4×10^3); NMR ($CDCl_3$) δ 2.06 (4H, m, pyranyl ring protons), 2.06 (3H, s, $CH_3C(O)$), 2.16 (3H, s, $CH_3C(O)$), 2.62 (3H, s, CH_3–O), 3.42 (4H, m, pyranyl ring protons), 4.30 (3H, br.s, H-4' and 5'), 5.11 (1H, dd, $J_{1',2'}$=7.6 Hz, $J_{2',3'}$=4.6 Hz, H-2'), 5.22 (1H, t, $J_{2',3'}$= 4.6 Hz, $J_{3',4'}$=4.6 Hz, H-3'), 5.90 (1H, d, $J_{1',2'}$=7.6 Hz, H-1'), 6.55 (1H, br.s, NH_2), 8.00 (1H, s, H-8). Found: C, 49.52; H, 5.74; N, 14.00%. Calcd for $C_{20}H_{27}N_5O_9$: C, 49.81; H, 5.65; N, 14.55%.

3',5'-Di-O-acetyl-2'-O-(4-methoxytetrahydropyran-4-yl)-N^2-tritylguanosine (**13**). To a solution of **11** (482 mg, 1 mmol) in pyridine (10 ml) was added trityl chloride (557 mg, 2 mmol) and the mixture was kept at 80 °C for 6 h. After being cooled to room temperature, the mixture was poured onto crushed ice. The resulting aqueous mixture was extracted with dichloromethane (4×10 ml). The combined organic extracts were dried over anhydrous Na_2SO_4 and evaporated *in vacuo*. The residue was chromatographed on a column of silica gel (99:1 CH_2Cl_2–MeOH) to give crude **7** (610 mg, 87%): NMR ($CDCl_3$) δ 1.55 (4H, m, pyranyl ring protons), 2.10 (3H, s, $CH_3C(O)$), 2.19 (3H, s, $CH_3C(O)$), 2.50 (3H, s, CH_3–O), 3.51 (4H, m, pyranyl ring protons), 4.18 (3H, br.s, H-4' and 5'), 4.52 (1H, dd, $J_{1',2'}$=7.6 Hz, $J_{2',3'}$=6.0 Hz, H-2'), 5.16 (1H, d, $J_{2',3'}$= 6 Hz, H-3'), 5.40 (1H, d, $J_{1',2'}$=7.6 Hz, H-1'), 7.04—7.60

(15H, m, Tr), 7.99 (1H, s, H-8). Since **11** could not be purified by recrystallization and repeated chromatography, the crude material was used for the next reaction.

2'-O-(4-Methoxytetrahydropyran-4-yl)-N²-tritylguanosine (7). The crude **11** (96 mg, 0.137 mmol) was dissolved in 1:1 butylamine–methanol (80 ml) and the mixture was kept at room temperature for one day. The solvent was removed *in vacuo* and the residue chromatographed on a column of silica gel (97:3, CH_2Cl_2–MeOH) to give **7** (79 mg, 90%): Mp 168 °C; UV_{max}^{EtOH} 261 nm ($\varepsilon=16.4\times10^3$), UV_{min}^{EtOH} 238 nm ($\varepsilon=10.8\times10^3$), UV_{sh}^{EtOH} 275 nm ($\varepsilon=14.5\times10^3$); NMR ($CDCl_3$) δ 1.62 (4H, m, pyranyl ring protons), 2.62 (3H, s, $3H_3$–O), 3.10—3.95 (6H, m, pyranyl ring protons and H-5'), 4.05—4.29 (2H, m, H-3',4'), 4.84 (1H, dd, $J_{1',2'}=7.5$ Hz, $J_{2',3'}=5.4$ Hz, H-2'), 5.54 (1H, d, $J_{1',2'}=7.5$ Hz, H-1'), 7.26 (15H, m, Tr), 7.76 (1H, s, H-8). Found: C, 62.57; H, 5.73; N, 10.23%. Calcd for $C_{35}H_{37}N_5O_7$: C, 62.21; H, 6.21; N, 10.36%.

S,S-Bis(4-methoxyphenyl)-2'-O-(4-methoxytetrahydropyran-4-yl)-N²-tritylguanosine-5'-phosphorodithioate (15). To a solution of **7** (303 mg, 0.47 mmol) in dry pyridine (1 ml) was added **14** (230 mg, 0.52 mmol) and TPS (171 mg, 0.56 mmol), successively. After the solution was stirred for 3 h, 1:1 pyridine–water (2 ml) was added. The mixture was extracted with dichloromethane (4×2 ml). The combined organic extracts were dried over anhydrous Na_2SO_4 and evaporated to dryness. The residue was chromatographed on a column of silica gel (99:1 CH_2Cl_2–MeOH) to give **15** (335 mg, 74%) as a foam: UV_{max}^{EtOH} 256 nm ($\varepsilon=33.0\times10^3$), UV_{min}^{EtOH} 227 nm ($\varepsilon=28.0\times10^3$), UV_{sh}^{EtOH} 242 nm ($\varepsilon=29.7\times10^3$); NMR ($CDCl_3$) δ 1.60 (4H, m, pyranyl ring protons), 2.71 (3H, s, CH_3–O), 3.58 (4H, m, pyranyl ring protons), 3.71 (6H, s, CH_3–O), 4.11 (2H, m, H-5'), 4.22—4.58 (3H, m, H-2',3' and 4'), 5.37 (1H, d, $J_{1',2'}=5.7$ Hz, H-1'), 6.78 (4H, d, $J=9$ Hz, *m*-protons of CH_3O–C_6H_4–S), 7.08—7.52 (19H, m, Tr and *o*-protons of CH_3O–C_6H_4–S). Found: C, 58.69: H, 5.20; N, 6.94%. Calcd for $C_{49}H_{50}N_5O_{10}PS_2\cdot2H_2O$: C, 58.85; H, 5.44; N, 7.00%.

Synthesis of 18. A mixture of **15** (34 mg, 0.035 mmol) and 2,2,2-trichloroethyl dihydrogenphosphate (16.1 mg, 0.07 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (0.5 ml). TPS (43 mg, 0.14 mmol) was added and the mixture was stirred at room temperature. After 1 d, the mixture was treated with 1:1 pyridine–water (10 ml) overnight. The main spot of R_f 0.1 (CH_2Cl_2:MeOH, 12:1, v/v) was observed on silica gel plate. The mixture was extracted with CH_2Cl_2 (4×5 ml). The organic exeracts were combined washed water (2×5 ml), and evaporated to dryness. The residue was mixed with **17** (48 mg, 0.105 mmol) and rendered anhydrous by repeated coevaporation with dry pyridine. The mixture was dissolved in dry pyridine (0.5 ml) and 1-(*p*-nitrobenzenesulfonyl)-1*H*-1,2,4-triazole (NBST) (53 mg, 0.21 mmol) was added. The mixture was stirred at room temperature for 3 d and then pyridine–water (1:1, v/v) (2 ml) was added. After being kept for 30 min, the mixture was extracted with CH_2Cl_2 (4×5 ml). The organic extracts were combined, dried over Na_2SO_4, evaporated to dryness, and chromatographed on a column of silica gel (99:1→99:2 CH_2Cl_2–MeOH) to give **18** (45 mg, 80%): UV_{max}^{EtOH} 256 nm ($\varepsilon=19200$), UV_{max}^{EtOH} 233 nm ($\varepsilon=21600$), UV_{min}^{EtOH} 247 nm ($\varepsilon=16000$), UV_{min}^{EtOH} 221 nm ($\varepsilon=19500$); NMR ($CDCl_3$) δ 1.68 (4H, m, pyranyl ring protons), 2.60 (3H, s, OCH_3), 3.60 (4H, m, pyranyl ring protons), 3.76 (6H, s, CH_3O–C_6H_4), 4.60 (6H, m, H-4',5', of Ura and Guo), 4.72 (2H, d, $J=7.8$ Hz, Cl_3CCH_2O), 5.12 (1H, m, H-2' of Guo), 5.80 (3H, m, H-2',3' of Ura and H-3' of Guo), 6.06 (1H, d, $J_{1',2'}=7.4$ Hz, H-1' of Guo), 6.22 (1H, d, $J_{1',2'}=8$ Hz, H-1' of Ura), 6.82 (4H, d, $J=9$ Hz, *m*-protons of CH_3O–C_6H_4–S), 7.28 (25H, m, Tr, *o*-protons of CH_3O–C_6H_4–S, *m,p*-protons of benzoyl), 7.96 (4H, m, *o*-protons of benzoyl). Found: C, 54.25; H, 4.44; N, 6.18%. Calcd for $C_{74}H_{70}Cl_3N_7O_{20}P_2S_2\cdot H_2O$: C, 54.60; H, 4.46; N, 6.18%.

Synthesis of 19. A mixture of **15** (70 mg, 0.073 mmol) and 2,2,2-trichloroethyl dihydrogenphosphate (33.5 mg, 0.146 mmol) was rendered anhydrous as described above and dissolved in dry pyridine (1 ml). TPS (88 mg, 0.292 mmol) was added and the mixture was stirred at room temperature in the dark for 1 d. Then, the mixture was treated with 1:1 pyridine–water (10 ml) and the resulting solution was kept overnight. Extraction with CH_2Cl_2 (4×10 ml) followed by evaporation gave **16**, which was mixed with 2'-*O*-(4-methoxytetrahydropyran-4-yl)uridine (52 mg, 0.146 mmol).

The mixture was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (0.2 ml). 1-(Mesitylenesulfonyl)-1*H*-1,2,4-triazole (MST) (73 mg, 0.29 mmol) was added and the mixture was stirred continuously or 4 d. The usual workup gave **19** (66 mg, 60%): UV_{max}^{EtOH} 256 nm ($\varepsilon=45000$), UV_{min}^{EtOH} 227 nm ($\varepsilon=33000$), UV_{sh}^{EtOH} 243 nm ($\varepsilon=39000$); NMR ($CDCl_3$) δ 1.40—1.90 (8H, m, pyranyl ring protons), 2.59 (3H, s, CH_3O), 3.16 (3H, s, CH_3O), 3.60 (8H, m, pyranyl ring protons), 3.81 (6H, s, CH_3O–C_6H_4), 4.36 (8H, m, H-2', 3',4',5' of Ura and H-4',5' of Guo), 4.62 (2H, d, $J=7.8$ Hz, Cl_3CCH_2O), 4.76 (1H, m, H-2' of Guo), 5.00 (1H, m, H-3' of Guo), 5.41 (1H, d, $J_{1',2'}=8$ Hz, H-1' of Ura), 5.72 (1H, d, $J=8$ Hz, H-4 of Ura), 5.88 (1H, d, $J_{1',2'}=7.4$ Hz, H-1', of Guo), 6.88 (4H, d, $J=9$ Hz, *m*-protons of CH_3O–C_6H_4S–), 7.28 (20H, m, Tr, *o*-protons of CH_3O–C_6H_4S–, and H-5 of Ura). Found: C, 50.69; H, 4.86; N, 6.20. Calcd for $C_{66}H_{72}Cl_3N_7O_{20}P_2S_2\cdot2H_2O$: C, 51.08; H, 4.94; N, 6.32%.

Synthesis of 21. A mixture of **19** (104 mg, 0.069 mmol) and 2,2,2-trichloroethyl dihydrogenphosphate (31.4 mg, 0.137 mmol) was rendered anhydrous as described before and dissolved in dry pyridine (1 ml). TPS (83 mg, 0.274 mmol) was added and the mixture was stirred at room temperature for 1 d. The mixture was treated with 1:1 pyridine–water (10 ml) at room temperature overnight and then extracted with CH_2Cl_2 (4×5 ml). The organic extracts were combined, evaporated to dryness, and mixed with 2'-*O*-(4-methoxytetrahydropyran-4-yl)uridine (73.6 mg, 0.206 mmol). After being dried by coevaporation with dry pyridine several times, the mixture was treated with MST (103.4 mg, 0.412 mmol) in dry pyridine (0.2 ml) at room temperature for 5 d. The usual workup gave **21** (76 mg, 54%): UV_{max}^{EtOH} 257 nm ($\varepsilon=55000$); UV_{min}^{EtOH} 228 nm ($\varepsilon=33000$); NMR ($CDCl_3$) δ 1.40—1.98 (12H, m, pyranyl ring protons), 2.60 (3H, s, CH_3O of Guo), 3.10 (6H, s, CH_3O of Ura), 3.68 (12H, m, pyranyl ring protons), 3.80 (6H, s, CH_3O–C_6H_4), 4.40 (13H, m, H-2',3',4',5' of Guo), 4.64 (2H, d, $J=7.8$ Hz, Cl_3CCH_2O), 4.70 (2H, d, $J=7.8$ Hz, Cl_3CCH_2O), 5.04 (2H, m, H-2',3' of Guo), 5.48—6.12 (5H, m, H-1',4 of Ura and H-1' of Guo), 6.86 (4H, d, $J=9$ Hz, *m*-protons of $CH_3OC_6H_4S$–), 7.28 (20H, m, Tr *o*-protons of CH_3O–C_6H_4S–, and H-5 of the first Ura), 7.68 (1H, d, $J=8.2$ Hz, H-5 of the second Ura). Found: C, 47.15; H, 4.72, N, 6.25%. Calcd for $C_{83}H_{94}Cl_3N_9O_{30}P_3S_2\cdot2H_2O$: C, 47.39; H, 4.70; N, 6.00%.

Removal of Two 4-Methoxyphenylthio Groups from 15. To a solution of **15** (8.5 mg, 8.5 μmol) in 2:1 pyridine–water (1 ml) was added silver acetate (28 mg, 0.17 mmol). The solution was vigorously stirred at room temperature for 24 h. The resulting suspension was diluted with 2:1 pyridine–

water (10 ml) and bubbled by hydrogen sulfide at 0 °C until a clear supernatant solution had been obtained (*ca.* 5 min). The black precipitate was removed by centrifugation and the supernatant was passed through a column (1×2 cm) of Dowex 50 W×2 (pyridinium form). The column was washed with 1:5 pyridine–water (50 ml). The eluents were collected and concentrated to dryness. The residue was chromatographed on Whatman 3 MM papers (Solvent I). A band of R_f 0.44 was cut and eluted with 1:1 water–ethanol (200 ml) to give pG^{Tr}(mTHP) as ammonium salt (145 OD): UV_{max}^{EtOH} 256 nm, UV_{min}^{EtOH} 245 nm, UV_{sh}^{EtOH} 270 nm.

Complete Deprotection of pG^{Tr}(mTHP). The pG^{Tr}-(mTHP), (60 OD) obtained in the above experiment was concentrated to dryness and suspended in 0.01 M hydrochloric acid (pH 2.0) (5 ml). The heterogeneous mixture was vigorously stirred at room temperature for 2 d. The resulting emulsion was neutralized with pyridine (1 ml) and the solution was evaporated to dryness. The residue was analyzed by paper electrophoresis using Buffer I to give pG (48 OD) at 252.5 nm (λ_{max}), 99% from **15**, which was identified with the authentic sample.

*Removal of Bis(4-methoxyphenylthio) Group from **19**.* To a solution of **19** (9.3 mg, 6 μmol) in 2:1 pyridine–water (1 ml) was added silver acetate (20 mg, 0.12 mmol). The solution was worked up in the same manner as described in the case of **15**, which gave pG^{Tr}(mTHP)p(tc)U(mTHP) (**24**) (90 OD): R_f 0.4 (Solvent I); UV_{max}^{EtOH} 255 nm, UV_{min}^{EtOH} 228 nm.

*Removal of 2,2,2-Trichloroethyl Group from **24**.* The above-mentioned product (36 OD) was evaporated to dryness and dissolved in 1:2 *N,N*-dimethylformamide–water (0.6 ml). To the solution were added zinc power (3.1 mg, 48 μatom) and acetylacetone (0.06 ml). The resulting mixture was stirred vigorously at room temperature for 12 h. The mixture was diluted with 1:1 pyridine–water (10 ml) and passed through a column (1×3 cm) of Dowex 50 W×2 (pyridinium form). The column was washed with 1:1 pyridine–water (50 ml). The eluents were concentrated, applied to Whatman 3 MM papers, and chromatographed by using Solvent I. A band of R_f 0.27 was cut and eluted with 1:1 water–ethanol (200 ml) to give pG^{Tr}(mTHP)pU(mTHP) (**25**) (30 OD): $UV_{max}^{EtOH/H_2O\,(1:1)}$ 256 nm, $UV_{min}^{EtOH/H_2O\,(1:1)}$ 226 nm.

*Complete Deprotection of **25**.* Compound **25** (15 OD) obtained in the above experiment was evaporated to dryness and suspended in 0.01 M hydrochloric acid (pH 2.0) (2 ml). The suspension was stirred vigorously at room temperature for 2 d. The resulting emulsion was neutralized with pyridine (1 ml). The solution was concentrated, applied to Whatman 3 MM papers, and chromatographed (Solvent II) for 2 d to give pGpU (a band moved 2 cm from the origin, 12 OD) which was eluted with 0.05 M phosphate buffer (pH 7.0) (50 ml): $UV_{max}^{pH\,7.0*}$ 256 nm, $UV_{max}^{pH\,7.0*}$ 228 nm (*0.05 M phosphate buffer).

Enzyme Assay of pGpU. The dimer, pGpU (10 OD), obtained in the above experiment was incubated with snake venom phosphodiesterase (10 μg) in 0.1 M Tris–HCl buffer (pH 8.0, 0.12 ml) at 37 °C for 12 h. Then, the mixture was treated with pyridine (0.5 ml), applied to Toyo Roshi No. 51 A paper, and analyzed by paper electrophoresis (pH 3.5, 1500 **V**, 3 h), which showed the two bands of pG and pU eluted with water in the ratio of 0.89:1.00.

*Removal of Bis(4-methoxyphenylthio) Group from **20**.* To a solution of **20** (18.3 mg, 8.7 μmol) in 2:1 pyridine–water (0.5 ml) was added silver acetate (29 mg, 0.174 mmol). The solution was vigorously stirred at room temperature for 14 h. The same workup as described in the case of **15** gave pG^{Tr}(mTHP)p(tc)U(mTHP)p(tc)U(mTHP) (150 OD): R_f 0.41 (Solvent I) R_f 0.67 (Solvent D); UV_{max}^{EtOH} 250 nm.

Removal of 2,2,2-Trichloroethyl Group from pG^{Tr}(mTHP)p(tc)-U(mTHP)p(tc)U(mTHP). An aqueous ethanol solution of the product (60 OD) obtained above was evaporated and dissolved in 2:1 pyridine-*N,N*-dimethylacetamide (1 ml). To the solution was added zinc powder (9.2 mg, 0.14 mmol) and acetylacetone (0.1 ml). The resulting mixture was vigorously stirred at room temperature for 16 h. The same workup as described in the case of **24** gave a band of R_f 0.58 (Solvent II), which was eluted with 1:1 water–ethanol (100 ml) to give pG^{Tr}(mTHP)pU(mTHP)pU(mTHP) (30 OD): $UV_{max}^{EtOH\text{-}H_2O\,(1.1)}$ 252 nm.

Complete Deprotection of pG^{Tr}(mTHP)pU(mTHP)pU(mTHP). An aqueous ethanol solution of pG^{Tr}(mTHP)pU(mTHP) (30 OD) was evaporated to dryness and suspended in 0.01 M hydrochloric acid (3 ml). The suspension was vigorously stirred at room temperature for 4 d. The resulting emulsion was quenched with pyridine (1 ml). The solution was applied to Whatman 3 MM papers and chromatographed by using Solvent II to give pGpUpU (20 OD, *ca.* 40% from **20**): R_f 0.33 (Solvent II): $UV_{max}^{pH\,7.0}$ 255 nm, $UV_{max}^{pH\,7.0}$ 237 nm.

Enzyme Assay of pGpUpU. The trimer, pGpUpU (15 OD), was incubated with snake venom phosphodiestrase (15 μg) in 0.1 M Tris–HCl buffer (pH 8.0, 0.12 ml) at 37 °C for 12 h. Paper electrohoresis (Buffer II) showed the two bands corresponding to pG and pU, which was eluted in the ratio of 1.00:2.06.

Reactions of Alkanoyl Fluorides with *F*-Isopropyl and *F*-1-Chloroethyl Anions

Nobuo Ishikawa,* Kazuhiko Iwamoto, Tatsumi Ishiwata, and Tomoya Kitazume
Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received January 13, 1982)

Reactions between alkanoyl chlorides and *F*-propene or *F*-chloroethene with fluoride ion were investigated. While alkyl (*F*-isopropyl) ketones and 1-(*F*-isopropyl)alkenol esters were formed in the former case, 1-(*F*-1-chloroethyl)alkenol esters were exclusively obtained in the latter case. Reaction mechanisms are discussed.

Some sorts of perfluoroalkenes are readily attacked by a fluoride ion affording perfluoroalkyl anions, which are used as a versatile nucleophile. A number of reactions of *F*-tert-butyl anion (**2**), the most stable perfluoroalkyl anion formed from *F*-2-methylpropene (**1**) and a fluoride ion, have been widely investigated by I. L. Knunyants and his coworkers.[1]

$$\underset{\mathbf{1}}{(CF_3)_2C{=}CF_2} + F^- \longrightarrow \underset{\mathbf{2}}{(CF_3)_3\bar{C}} \xrightarrow{RX} (CF_3)_3C\text{–}R$$

F-Propene (**3**), a monomer which is handled much more safely than *F*-isobutene, also gives *F*-isopropyl anion (**4**) by the action of a fluoride ion in an aprotic solvent. This carbanion is trapped readily by strong electrophiles such as 2,4-dinitrofluorobenzene[2] and aroyl fluorides,[3,4] giving organic molecules carrying *F*-isopropyl group.

$$\underset{\mathbf{3}}{CF_3CF{=}CF_2} \xrightarrow{F^-} \underset{\mathbf{4}}{(CF_3)_2\bar{C}F} \begin{cases} \xrightarrow{ArC(O)F} ArC(O)CF(CF_3)_2 \\ \xrightarrow{2,4\text{-DNFB}} 2,4\text{-}(NO_2)_2C_6H_3CF(CF_3)_2 \end{cases}$$

Alkanoyl fluorides as an electrophile, however, react with *F*-isopropyl anion not to give a single product. The reaction accompanies *O*-acylation and is more complicated than that of aroyl fluorides.

Although *F*-chloroethene (**5**), on the other hand, is less susceptible to the attack of a fluoride ion than *F*-propene, it is known to give *F*-1-chloroethyl anion (**6**) at higher temperatures. Some 1-chlorotetrafluoroethylated products such as triazine derivatives were reported to be formed.[5] We now wish to reveal

$$\underset{\mathbf{5}}{ClFC{=}CF_2} + F^- \longrightarrow \underset{\mathbf{6}}{ClF\bar{C}\text{–}CF_3} \xrightarrow{sym\text{-}C_3N_3F_3} C_3N_3F_2(CClFCF_3)\ \textit{etc.}$$

the details of the reactions of alkanoyl fluorides with *F*-isopropyl and *F*-chloroethyl anions.

Results and Discussion

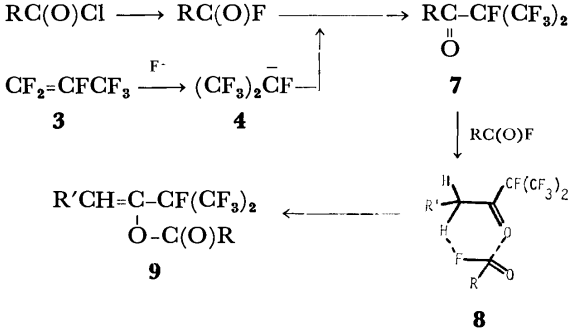
Reactions of F-*Propene with Alkanoyl Chlorides in the Presence of Fluoride Ion.* An earlier report[6] revealed that *F*-propene reacts with perfluoroalkanoyl fluorides in the presence of cesium fluoride affording *F*-alkyl isopropyl ketones.

$$\mathbf{3} \xrightarrow{CsF} \mathbf{4} \xrightarrow{R_fC(O)F} R_f\text{–}\overset{O}{\overset{\|}{C}}\text{–}CF(CF_3)_2$$

In our previous paper, it was reported that *F*-propene and an aroyl chloride in the presence of potassium fluoride in *N,N*-dimethylformamide gave aryl (*F*-isopropyl) ketones in a good yield.[3]

$$\mathbf{3} + ArC(O)Cl \xrightarrow{KF/DMF} ArC(O)CF(CF_3)_2$$

However, alkanoyl chlorides and *F*-propene in potassium fluoride-*N,N*-dimethylformamide system gave alkanoyl fluorides and *F*-propene oligomers[7] as main products. When the reaction was carried out in potassium fluoride–diglyme system, a mixture of an *F*-isopropyl ketone (**7**) and an enol ester (**9**) were obtained. The reactions were carried out at 120—130 °C, and potassium fluoride was used in excess, so that the chloride had been converted to the fluoride prior to the reaction with *F*-isopropyl anion **4**.



The enol ester **9** should be formed by the reaction of *F*-isopropyl ketone **7** with one more molecule of the alkanoyl fluoride. However, it was surprising to know that a nearly 1:1 mixture of **7** and **9** was always formed even by allowing a large excess amount of *F*-propene to react. This means that the formation of **9** from **5** undergoes as fast as the preceeding ketone formation. Another feature of this acylation was that the *O*-acylation giving **9** occurred exclusively and no *C*-acylated products were observed.

These facts can be explained by assuming a direct attack of acyl fluoride to the ketone **7**. Thus the α-hydrogen atoms of the alkyl group of **7** should be highly activated by the strong electron-withdrawing *F*-2-methylpropanoyl group, and they would readily accept the negative fluorine atom of the acyl fluoride. This H–F bond formation would assist the nucleophilic attack of the carbonyl oxygen of **7** to the carbonyl carbon of acyl fluoride to give *O*-acylated product **9**, through a six-membered cyclic transition state (**8**). The structures of enol esters **9** were elucidated from the ^1H and ^{19}F NMR spectral data (Table 1), though it was unable to determine whether these are in *E*-

or *Z*-form.

Reactions of F-*Chloroethene with Alkanoyl Chlorides in the Presence of Fluoride Ion.* The reaction of alkanoyl chlorides with *F*-chloroethene in the presence of potassium fluoride did not undergo smoothly as those with *F*-propene. This should be ascribed to the difficulty of formation of *F*-1-chloroethyl anion **6** compared with *F*-isopropyl anion **4**. Since the chlorine atom is less electronegative than trifluoromethyl group, the anion **6** should be less stable than **4**.

$$\underset{\mathbf{6}}{CF_3\bar{C}ClF} < \underset{\mathbf{4}}{CF_3\bar{C}FCF_3}$$

When cesium fluoride instead of potassium fluoride was used in the reaction, the corresponding enol esters (**10**) were obtained in good yields even at room temperatures (Table 2). Cesium fluoride is known as

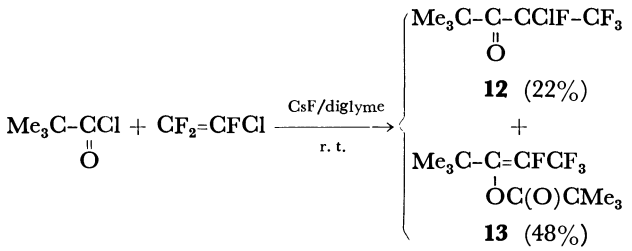
$$\underset{\mathbf{5}}{RC(=O)Cl} + CF_2{=}CClF \xrightarrow[\text{r. t.}]{\text{CsF/diglyme}} \underset{\mathbf{10}}{R'\text{-}CH{=}C(OC(O)R)\text{-}CClF\text{-}CF_3}$$

a stronger source for fluoride ions than potassium fluoride in an aprotic solvent.[8] Hence CsF accelerated the formation of *F*-chloroethyl anion **6** which reacted with an alkanoyl fluoride in a similar manner as *F*-isopropyl anion **4**. In this case, however, no formation of the *F*-chloroethyl ketone (**11**) was ob-

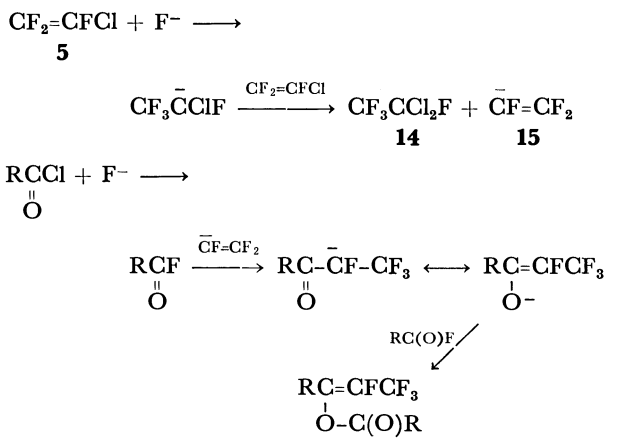
$$\underset{\mathbf{6}}{R\text{-}C(=O)\text{-}F} + CF_3\bar{C}ClF \xrightarrow[\text{slow}]{} \underset{\mathbf{11}}{R\text{-}C(=O)\text{-}CClF\text{-}CF_3} \xrightarrow[\text{fast}]{\text{RC(O)F}} \mathbf{10}$$

served. This should be ascribed to the much slower first-step reaction of *F*-chloroethyl anion with alkanoyl fluoride compared with the following *O*-acylation.

When 2,2-dimethylbutanoyl chloride, which has no α-hydrogen atoms, was allowed to react with *F*-chloroethene, a kind of enol ester(**13**) carrying no chlorine atom was formed together with *F*-chloroethyl ketone (**12**). Although the formation of **13** seemed to be



strange, it was rationalized by considering the formation of *F*-ethenyl anion(**15**) from *F*-chloroethene, followed by the addition of acyl fluoride.[5,9] Actually



we observed the formation of 1,1-dichlorotetrafluoroethane **14** when *F*-chloroethene (**5**) was treated in cesium fluoride–diglyme system and no oligomerization of **5** occurred.

Experimental

*Heptyl (F-Isopropyl) Ketone (**7**, R=n-C_7H_{15}) and 1-(F-Isopropyl)-1-hexenyl Octanoate (**9**, R=n-C_7H_{15}, R′=n-C_6H_{13}).* Into a mixture of octanoyl chloride (1.63 g, 10 ml), calcine-dried potassium fluoride (3.50 g, 60 mmol) and freshly dried diglyme (10 ml) in a pressure-vessel, liquefied *F*-propene (3.0 g, 20 ml) was introduced at −70 °C. The vessel was brought to room temperature, and heated for 2 h in an oil bath kept at 120—130 °C with magnetic stirring. The reaction mixture was poured onto water and an oily material was extracted with diethyl ether. After the solvent was removed, the residue was subjected to vacuum distillation. **7** (R=*n*-C_7H_{15}), bp 59—62 °C/12 mmHg, and **9** (R=*n*-C_7H_{15}, R′=*n*-C_6H_{13}), bp 150—152 °C/11 mmHg, were obtained in yields of 48 and 20%, respectively.

Other *F*-isopropyl ketones (**7**) and enol esters (**9**) were prepared in a similar manner.

*1-(F-1-Chloroethyl)-1-propenyl Propionate (**10**, R=Et, R′=Me).* Propionyl chloride (1.85 g, 20 mmol), calcine-dried cesium fluoride (7.5 g, 50 mmol) and freshly dried diglyme (20 ml) were put in a pressure-vessel, and liquefied chlorotrifluoroethene (4.8 g, 40 mmol) was introduced at −70 °C. The mixture was stirred for 48 h at room temperature, and worked up as described above. The enol ester **10** (R=Et, R′=Me), bp 68—70 °C/18 mmHg, was obtained in 83% yield.

Other enol esters **10** were prepared in a similar manner.

Reaction between 2,2-Dimethylpropionyl Chloride and F-Chloroethene with a Fluoride Ion. When 2,2-dimethylpropionyl chloride and *F*-chloroethene were allowed to react in a similar manner, following two products were obtained.

*t-Butyl (F-1-Chloroethyl) Ketone (**12**):* Bp 45—46 °C/46 mmHg, 22%. IR: 1730, 1745 cm^{-1} (C=O). ^{19}F NMR: δ 2 (d, CF_3), 57 (br, CF) ppm; J_{F-F}=5.6 Hz. ^1H NMR: δ 1.34 (d); J_{H-F}=1.7 Hz. Too much volatile to be analyzed.

*1-t-Butyl-2,3,3,3-tetrafluoro-1-propenyl 2,2-Dimethylpropionate (**13**):* Bp 67—68 °C/13 mmHg, 48%. IR: 1765 (C=O), 1690 (C=C) cm^{-1}. ^{19}F NMR: δ −9 (d, CF_3), 71 (m, F) ppm, J_{F-F}=1.7 Hz. ^1H NMR: δ 1.29 (s, 9H), 1.25 (d, 9H), J_{H-F}=1.7 Hz. Found: C, 53.72; H, 6.47%. Calcd for $C_{12}H_{18}F_4O_2$: C, 53.33; H, 6.67%.

(Received January 14, 1982)

Photosensitized oxidations of tryptophan (Trp), tryptamine, and their derivatives were investigated with a variety of sensitizers. Rose Bengal sensitized photooxidations proceed exclusively *via* Type II mechanism (singlet oxygen mechanism), whereas for thionine-sensitized photooxidations both Type I (nonsinglet oxygen mechanisms) and Type II mechanisms are operative under a given set of conditions. Rate constants of reaction, in units of 10^6 M^{-1} s^{-1}, were determined to be 3 for Trp, 4 for tryptophan methyl ester, 4 for N_b-acetyltryptophan methyl ester, 9 for tryptamine, and 7 for N_b-methoxycarbonyltryptamine in the Rose Bengal-sensitized photooxidations. These values are in good agreement with those obtained from reactions with chemically generated singlet oxygen. Quenching rate constants are somewhat larger than reaction rates constants, indicating that the quenching process is the major path for the interaction of singlet oxygen with these indolic substrates. Oxidation products in chemically generated singlet-oxygen reaction of Trp are compared with those obtained from dye-sensitized photooxidations.

Photooxidation of tryptophan (Trp) is of particular interest in connection with photodynamic degradation of Trp residues in proteins, and the possibility that the oxidation may represent a model for biological oxidation of Trp catalyzed dioxygenases. A number of reports on dye-sensitized photooxidation of Trp and related substrates have appeared in connection with photoproducts as well as mechanisms. The photooxidation of Trp gives many types of products, depending on experimental conditions such as wavelength of light, type and concentration of sensitizers, and solvents employed.[1] In earlier papers,[2] the photosensitized oxidation of Trp was shown to give a complex mixture of products, in which kynurenine and *N*-formylkynurenine (*N*-FK) were detected. Savige[3] reported that Methylene Bule (MB)-sensitized photooxidation of Trp in water gave *N*-FK and 3a-hydroxy-1,2,3,3a,8,8a-hexahydropyrrolo[2,3-*b*]indole-2-carboxylic acid (HPI). More recently, Nakagawa *et al.*[4] have reported isolation of 3a-hydroperoxy-1,2,3,3a,8,8a-hexahydropyrrole[2,3-*b*]indole-2-carboxylic acid (HPPI) as a primary product in Rose Bengal (RB)-sensitized photooxidation. This hydroperoxide (HPPI) decomposes to give *N*-FK and HPI under photolytic or thermolytic conditions.[4]

The mechanism of dye-sensitized photooxidation of Trp has long been a subject of controversy. Trp is reported to quench triplet states of sensitizers such as eosine and thionine under certain conditions.[5] A recent work[6] has demonstrated that the excited singlet states of RB and MB are also quenched by tryptamine and other indoles. These results may imply the importance of a nonsinglet oxygen (Type I[7]) mechanism involving interaction between photoexcited dyes and indoles in the sensitized photooxidation of Trp. In contrast to these reports, Nilsson *et al.*[8] pointed out that singlet oxygen ($^1O_2$) is involved in MB-sensitized photooxidation of Trp in aqueous methanol, and they have determined rate constants for the reaction (k_r) and quenching (k_q) of Trp with $^1O_2$. However, the rate constant of reaction, k_r, reported by Nilsson *et al.*[8] is approximately one order of magnitude smaller than the value obtained from the reaction of Trp with photophysically generated $^1O_2$ in D_2O (pD 8.4),[9] although the overall rate constant, k_r+k_q, has the same order of magnitude. Smith[10] showed that rate constants are highly dependent on the polarity of solvent. Furthermore, recent works[11,12] on photooxidations of Trp and tryptamine with hematoporphyrin sensitizer have shown that the reactions proceed *via* Type I mechanism, and that the singlet oxygen (Type II) mechanism is of minor importance even when reactions are carried out in the presence of micelles. These results apparently indicate that the dye-sensitized photooxidations of Trp and tryptamine are strongly dependent on reaction conditions, particularly on the type of sensitizer, solvent, and substrate concentration.

In this paper, the influence of conventional sensitizers such as RB and MB on the mechanism of sensitized photooxidation of Trp, tryptamine, and their derivatives has been examined as a model for photooxidation of Trp residues in a protein. Rate constants for the reaction and quenching of these substrates with $^1O_2$ in the RB-sensitized photooxidation have been compared with those obtained with chemically generated $^1O_2$. Oxidation products in both reactions were also examined.

Experimental

Materials. Rose Bengal (RB), Methylene Blue (MB), eosine, thionine, L-tryptophan (Trp, **1**), tryptophan methyl ester (**2**), and tryptamine (**4**) are commercially available. N_b-Acetyltryptophan methyl ester (**3**) and N_b-methoxycarbonyltryptamine (**5**) were prepared by the known methods. 3-(1,4-Epidioxy-4-methyl-1,4-dihydro-1-naphthyl)propionic acid (EP) was prepared by the published procedure.[13]

Procedure. A typical irradiation system consists of 10 ml of 1:1 MeOH–H_2O solution containing **1** (1.3×10^{-4} M) (1 M = 1 mol dm^{-3}), sensitizer (3.3×10^{-6} M), and varying amounts of sodium azide ($2—50\times10^{-3}$ M) in Pyrex reaction tubes. After the solutions were saturated with pure oxygen, the test tubes were sealed with jointed stoppers.

Table 1. Effects of azide ion and deuterated solvent on the rates of photooxidations of tryptophan derivatives with various sensitizers[a]

Sensitizer	1 (R = -C(H)(CO$_2$H)-NH$_2$)		2 (R = -C(H)(CO$_2$Me)-NH$_2$)		3 (R = -C(H)(CO$_2$Me)-NHCOMe)		4 (R = -CH$_2$NH$_2$)		5 (R = -CH$_2$NHCO$_2$Me)	
	I/%[b]	R_D/R_H[c]	I/%[b]	R_D/R_H[c]	I/%[b]	R_D/R_H[c]	I/%[b]	R_D/R_H[c]	I/%[b]	R_D/R_H[c]
Rose Bengal (RB)	100	9.6 (8.1)[d]	100	9.8 (8.7)[d]	100	10.2 (8.9)[d]	100	7.4	100	11.4 (9.5)[d]
Methylene Blue (MB)	90	9.0 (8.7)[d]	90	11.5 (9.1)[d]	90	9.5 (8.5)[d]	90	7.4	90	8.0 (6.5)[d]

a) In 1:1 MeOH-H_2O; [scns] = 3.3×10^{-6} M; [substrate] = 1.3×10^{-4} M. b) I denotes $(R_0-R_1)/R_0\times100$; R_0: the rate of photooxidation in the absence of NaN_3; R_1: the limiting rate of photooxidation in the presence of higher concentrations of NaN_3. c) The ratio of the photooxidation rates in 1:1 MeOD-D_2O *vs.* 1:1 MeOH-H_2O. d) The values in parentheses are for the higher concentrations of substrate; [substrate] = 3.7×10^{-3} M.

The samples were irradiated with a 500 W tungsten-bromine lamp operated at 40 V in a merry-go-round apparatus. Rates of photooxidation of **1** were followed by monitoring the decrease in the absorption maximum at 280 nm with a Nihon Bunko UV-1 spectrometer.

Measurement of Photooxidation Rates in MeOD-D_2O and in MeOH-H_2O. A comparison of photooxidation rates in 1:1 MeOD-D_2O and in 1:1 MeOH-H_2O was done in a merry-go-round apparatus under identical conditions. Rates of photooxidation were measured by the method described above.

Determination of Rate Constants. Rate constants for the reaction, k_r, and quenching, k_q, were measured by the direct disappearance method described by Foote and Ching[14] and by the competition technique. Solutions of various concentrations ($(0.3—3)\times10^{-4}$) of **1** containing RB (4×10^{-6} M) were irradiated. The concentrations of **1** before and after irradiation were determined from decrease in its absorption maximum. The relationship between the reciprocal of the amount of reacted **1** and the reciprocal of the initial concentration of **1** gives a straight line. From the slope and intercept, the sum, k_r+k_q, of reaction and quenching rate constants was obtained (within 10% error). Rate constants of the reactions were obtained from competition reactions. To a MeOH-H_2O solution of **1** containing RB was added a MeOH solution of diphenylisobenzofuran (DPBF), and the solution was irradiated as described above. Periodical change in concentration of **1** and DPBF was measured by decrease in the absorption maximum of **1** and in the fluorescence intensity of DPBF. Similar experiments were performed in order to determine in rate constant for **1** with $^1O_2$ generated from endoperoxide (EP). A solution of **1** (3.5 mM) and EP (25 mM) was warmed up to 35 °C with shaking. The rate constant was calculated from the disappearance of the peak area for **1** in high-performance liquid chromatography (HPLC, Waters, ALC/GPC 204, a Nucleosil $5C_{18}$ column, 90% aqueous methanol).

Quenching of Excited Singlet State of Dye. The fluorescence of dye was measured in the absence and presence of substrates **1**—**5** with a Nihon Bunko FP 550 at ambient temperature.

Results and Discussion

Participation of $^1O_2$ in the RB-sensitized photooxidation of **1**, **2**, **3**, **4**, and **5** was examined by the following experiments: (i) inhibition by azide ion, a well known singlet oxygen ($^1O_2$) quencher with a quenching rate constant of 10^8 M^{-1} s^{-1};[15] (ii) deuterium solvent effect on the rate of their photooxidations.[8]

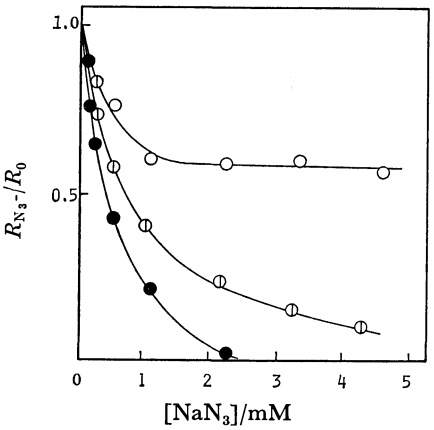

Fig. 1. Sodium azide inhibition of RB-(●), MB-(①), and thionine-(○) sensitized photooxidations of N_b-methoxycarbonyltryptamine (**5**) in methanol-water (1:1) at 25 °C as a function of sodium azide concentration.
[**5**] = 1.6×10^{-4} M; [sens] = 3.3×10^{-6} M.

Inhibition by Azide Ion. Reaction rate $R_{N_3^-}$ of RB-sensitized photooxidation of **5** in the presence of N_3^- was compared with that of control run, R_0. Ratio $R_{N_3^-}/R_0$ decreases with increasing concentration of N_3^- and the photooxidation was completely inhibited at concentration of 2.2 mM of N_3^-. In contrast, methylene blue (MB)- and thionine-sensitized photooxidations of **5** require much higher concentrations of N_3^- to exhibit the same extent of inhibition. In these cases, ratio $R_{N_3^-}/R_0$ decreases with increasing N_3^- concentration and reaches a constant value R_1 at higher concentrations of N_3^- (Fig. 1). By using this limiting value R_1, the extent I of contribution of $^1O_2$ process to overall reaction is calculated from the equation $I=(R_0-R_1)/R_0\times100$. Similar results have been obtained in the photooxidations of **1** and other indolic substrates **2**—**4** as summarized in Table 1. The data in Table 1 suggest that RB-sensitized photooxidations of

Table 2. Quenching of the fluorescence of dye sensitizers with tryptophan and tryptamine derivatives[a)]

Substrate	$k_q^s\tau/M^{-1}$ ($k_q^s/10^{-9}$ M^{-1} s^{-1})		
	Rose Bengal	Methylene Blue	Eosine

N_b-Methoxycarbonyl-tryptamine (**5**)	10 (15)	13	25.5 (0.79)

a) Opitical density of dye sensitizer is adjusted to 0.1 at the excitation wavelength.

1—**5** proceed exclusively *via* the $^1O_2$ (Type II) mechanism, whereas the lack of complete inhibition by N_3^- in MB- and thionine-sensitized photooxidations indicated a significant contribution of Type I process and/or the quenching of the sensitizer triplets by N_3^-.

Azide ion is known to quench not only $^1O_2$ but also triplet states of certain dye sensitizers. Quenching rate constants $k_q(N_3^-)$ for sensitizer triplets have been determined previously, *e.g.*, $k_q(N_3^-)=5\times10^5$ M^{-1} s^{-1} for MB[16)] and $k_q(N_3^-)=8\times10^5$ M^{-1} s^{-1} for eosine.[16)] These rate constants are much smaller than those for quenching of the triplet states of MB and eosine by oxygen, $k_q(O_2)=3\times10^9$ M^{-1} s^{-1} and $k_q(O_2)=1.1\times10^9$ M^{-1} s^{-1},[17)] respectively. Therefore, the interaction between triplet sensitizers and N_3^- may be negligibly small in MB- and eosine-sensitized photooxidations. On the other hand, sensitizer triplets can interact with substrates to result in hydrogen abstraction or electron transfer (D-R mechanism).[18)] In fact, Trp is known to quench triplet states of sensitizers with the following rate constants: $k_q^t=2\times10^9$ M^{-1} s^{-1} for MB,[8)] $k_q^t=8.4\times10^8$ M^{-1} s^{-1} for eosine,[5)] and $k_q^t=3.9\times10^9$ M^{-1} s^{-1} for thionine.[5)] These rate constants are comparable to the rates of quenching of the respective sensitizer triplets by oxygen. Thus, it seems probable that MB-, eosine-, and thionine-sensitized photooxidations may involve Type I process in which sensitizer triplets react directly with indolic substrates. The inhibitory effect of N_3^- (Table 1) and the deuterium solvent effect on the rate of photooxidation (*vide infra*) indicate that in MB- or eosine-sensitized photooxidation direct reaction of triplet sensitizer with Trp is a minor process with the major process being $^1O_2$ reaction. In thionine-sensitized photooxidation, however, Type I reaction involving the thionine triplet cannot be neglected as judged from the inhibitory effect of N_3^- as shown in Table 1.

In order to get information on the interaction between singlet dye sensitizers and indolic substrates, quenching of the fluorescence of sensitizers by **1**—**5** was examined in MeOH–H_2O. The value $k_q^s\tau$, which is obtained from the slope of Stern-Volmer plots, may be taken as a rough measure for the interaction between singlet state of sensitizer and substrate. From $k_q^s\tau$ values apparent rate constants for the quenching of singlet state of sensitizers were calculated from the known lifetimes of singlet of sensitizers, $\tau=3.2\times10^{-9}$ s for eosine[19)] and $\tau=6.5\times10^{-10}$ s for RB.[19)] As shown in Table 2, the apparent rate constants are close to a diffusion controlled limit. This result may imply that the interaction between the excited singlet state of sensitizer and substrate becomes more important when higher concentrations of substrate and/or sensitizer are used, as pointed out by Davidson and Trethewey.[6)]

Deuterium Solvent Effect on the Rate of Photooxidation. The lifetime of $^1O_2$ is known to be approximately 10 times as long in MeOD–D_2O as in MeOH–H_2O.[8)] Therefore, about tenfold increase in the rate of photooxidation might be expected for a pure $^1O_2$ reaction in going from protonated to deuterated solvent.[20)] However, this increase would be smaller if Type I mechanism becomes predominant or if the acceptor concentration is high enough to quench $^1O_2$ significantly. The results are shown in Table 1. The rates of RB-sensitized photooxidation of Trp and its derivatives **2** and **3** increase approximately tenfold at lower concentrations of substrates in going from MeOH–H_2O to MeOD–D_2O. The R_D/R_H value for the photooxidation of **4** was somewhat smaller than that expected from the inhibitory effect by N_3^- (Table 1), the reason remaining unknown. However, as will be discussed below, a kinetic treatment indicates that the photooxidation of **4** occurs exclusively *via* the $^1O_2$ mechanism. The deuterium solvent effect together with inhibition experiments clearly demonstrates that RB-sensitized photooxidations of **1**—**5** proceed by the $^1O_2$ mechanism.

For the thionine-sensitized photooxidation, both Type I and $^1O_2$ (Type II) processes are operative under our experimental conditions. The ratio (I) of $^1O_2$ process to overall reaction as obtained from the inhibition experiment is consistent with the R_D/R_H value, suggesting that the lack of complete inhibition by N_3^- in thionine-sensitized photooxidation is mainly due to the contribution of Type I process. It seems probable that the thionine triplet tends to increase the ratio of a free radical process by reacting with indolic substrates directly.[21)] In every case, at higher concentrations of substrates R_D/R_H values become smaller, suggesting an increasing contribution of Type I process at higher substrate concentrations (Table 1).

Determination of Rate Constants. Kinetic scheme for the RB-sensitized photooxidation can be written as

$$^1O_2 + A \xrightarrow{k_r} AO_2,$$
$$^1O_2 + A \xrightarrow{k_q} A + O_2,$$
$$^1O_2 \xrightarrow{k_d} O_2,$$

Scheme 1.

where A denotes substrate. An application of the steady-state approximation to $^1O_2$ gives the following expression for the rate of disappearance of A:[14)]

$$\frac{d[A]}{dt} = K\left(\frac{k_r[A]}{(k_r+k_q)[A]+k_d}\right)$$

Table 3. Rate constants of tryptophan, tryptamine, and their derivatives with singlet oxygen in methanol-water

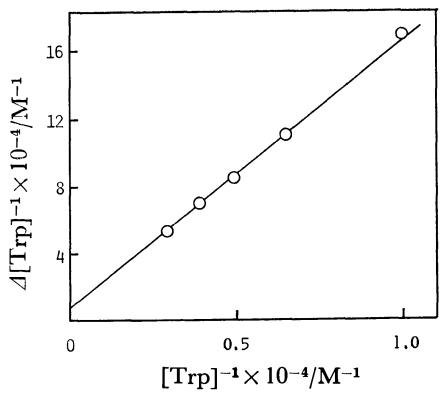

Fig. 2. Double reciprocal plot of tryptophan disappearance *vs.* tryptophan concentrations for the RB-sensitized photooxidation of tryptophan in methanol–water (1:1).
[sens]$=4\times10^{-6}$ M; [**1**]$=0.3$—3×10^{-4} M.

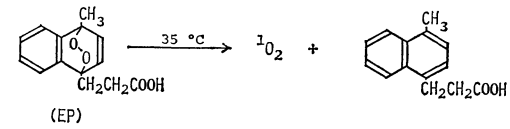
$$\Delta[A]^{-1} = (K\Delta t)^{-1}\left(\frac{k_r+k_q}{k_r}+\frac{k_d}{k_r}[A]^{-1}\right),$$

where K is the rate of $^1O_2$ formation. In fact, plots of $[Trp]^{-1}$ *vs.* $\Delta[Trp]^{-1}$ gave a linear relationship as shown in Fig. 2. For the RB-sensitized photooxidation of **4**, a straight line was also obtained, suggesting that only $^1O_2$ is participating in the reaction. From the slope and intercept, $k_d/(k_r+k_q)$ was obtained and the overall rate k_r+k_q was determined by using the literature k_d value[22] ($k_d=2.8\times10^5$ M^{-1} s^{-1}). In order to determine the absolute rate constants of k_r and k_q, a competition experiment between substrate and diphenylisobenzofuran (DPBF) was carried out. Disappearance rates of **1** and DPBF were determined from decrease in the absorption at 280 nm and in the fluoresence intensity at 477 nm, respectively. The kinetic equation for the competition reaction can be written as

$$\frac{k_r}{k_r^{DPBF}} = \frac{\log([A]_f/[A]_0)}{\log([DPBF]_f/[DPBF]_0)}.$$

The ratio k_r/k_r^{DPBF} obtained for **1** is 3.8×10^{-3}, and k_r was calculated to be 3×10^6 M^{-1} s^{-1} by using $k_r^{DPBF}=8\times10^8$ M^{-1} s^{-1} in 1:1 MeOH-H_2O.[8] The k_r value obtained is in fairly good agreement with that of Nilsson *et al.*[8] However, the rate constant k_r is approximately one order of magnitude smaller than that of Matheson and Lee,[9] although the quenching rate constants are comparable in both cases. The results together with the reported values are summarized in Table 3.

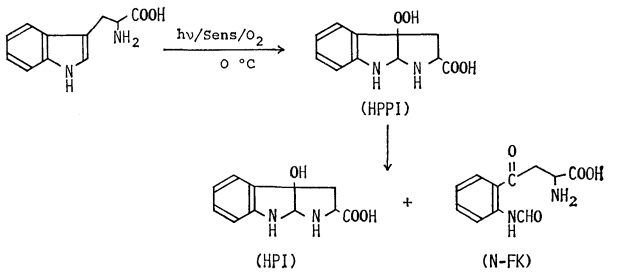
In view of the disagreement of our values with those obtained by Matheson and Lee,[9] we have performed a reaction with chemically generated $^1O_2$ from EP. It is noted that the thermolysis of EP results in nearly quantitative (>82%) production of $^1O_2$ at ambient



Scheme 2.

temperature.[13] The rate constant of reaction of **1** with chemically generated $^1O_2$ was in good agreement with the value obtained in the RB-sensitized photooxidation, whereas the quenching rate constant is somewhat larger than that obtained in the sensitized photooxidation (Table 3). A similar tendency was observed for **3** and **5**. The reason for this discrepancy is not clear. However, it is possible that the difference is due to difficulties in separating Type I and II processes kinetically. Thus substrates **1**—**5** quench $^1O_2$ with a somewhat higher rate than they react, as pointed out by Nilsson *et al.*[8] However, Matheson and Lee[9] reported a contradictory result, *i.e.*, that the main part of the interaction of $^1O_2$ with **1** is a chemical reaction.

Product Distribution. The dye-sensitized photooxidation of **1** is known to give (*N*-FK) and 3a-hydroxypyrrolidinoindole (HPI) *via* 3a-hydroperoxypyrro-



Scheme 3.

lidinoindole (HPPI)[4] (Scheme 3). The products of the reaction of chemically generated $^1O_2$ were compared with those for RB- and thionine-sensitized photooxidations. As already mentioned, the reaction mechanism is highly dependent on the type of sensitizer. The oxidation of **1** with RB proceeds exclusively by the $^1O_2$ mechanism, while with thionine it proceeds by a combination of $^1O_2$ and Type I mechanisms. Product ratio *N*-FK/HPI for the RB-sensitized photooxidation using a filter solution (aqueous $CaCl_2$–$CuCl_2$ solution, cutoff <550 nm) is the same as that obtained from the pure $^1O_2$ reaction (Table 4). However, when the photooxidation was carried out without filter, the yield of HPI decreased drastically. Savige[3] has reported that the photooxidation of **1** in water at 15—20 °C gives *N*-FK and HPI as the main product, while at temperatures above 20 °C it gives *N*-FK in improved yield but HPI in less yield, and that HPI is subjected to further photooxidation in the presence of MB. In fact, during the MB-sensitized photooxidation or direct irradiation (>290 nm) of HPI, at least 9 products were detected. Therefore, the low yield of HPI without filter solution may be due to its further photodecomposition by the action of shorter-wavelength light. Furthermore, the low yield of HPI in the thionine-sensitized photooxidation may be due to the co-occurrence of a free radical process (Type I mechanism). A similar result has been reported by Singh *et al.*,[23] who showed that product ratios *N*-FK/HPI in Sensitox II-sensitized photooxidation and in photophysically generated $^1O_2$ reaction are quite different from each other.

Although a number of interesting findings such as the formation of a tricyclic hydroperoxide like HPPI have been reported for the dye-sensitized photooxidation of indolic substrates including **1**,[1,4] the mechanism of the photooxidation has not yet be fully understood. The results described here demonstrate that the mechanisms of photooxidations of Trp, tryptamine, and their derivatives are strongly dependent on the type of sensitizers. The oxidation with RB sensitizer proceeds exclusively *via* the singlet oxygen process. However, if higher concentrations of substrates ($>10^{-3}$ M) were used, Type I process would become important. The oxidation with thionine sensitizer proceeds *via* a combination of Type I and II mechanisms even at lower concentrations of substrates. The rate constants of the reaction of $^1O_2$ with indolic substrates are somewhat smaller than those for the quenching reaction, indicating that the major part of the interaction of $^1O_2$ with Trp is the quenching process at least in aqueous methanol.

Table 4. Oxidation products of tryptophan under various conditions[a]

Reaction system	Experimental conditions	Product yield/%[b]	
		N-FK	HPI
EP	35 °C	23	42
Rose Bengal/O_2	>300 nm	30	1
	>550 nm[c]	23	44
Thionine/O_2	>300 nm	29	1
	>550 nm[c]	22	23

a) In 1:1 MeOH–H_2O. b) The yields were determined by HPLC analyses. c) Aqueous $CaCl_2$–$CuCl_2$ solution was used as a filter.

No variation in functional groups on side chains of Trp derivatives gives any significant effect on the rate of reaction with $^1O_2$ and on the extent of contribution of the $^1O_2$ mechanism under a given set of conditions. The product composition in the Rose Bengal-sensitized photooxidation of Trp under carefully controlled conditions is the same as that obtained in the reaction using chemically generated $^1O_2$. The present results suggest that the dye-sensitized photooxidation of tryptophan residues in a protein may porceed *via* a similar mechanism, and that the rate constant for the reaction of tryptophan residues with $^1O_2$ is of the same order of magnitude as that obtained for the present model compounds **1**—**5**.

A New and Convenient Synthetic Method for Cyclopropyl Phenyl Sulfides

Kazuhiko TANAKA,* Hideki UNEME, Shuichi MATSUI, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received January 20, 1982)

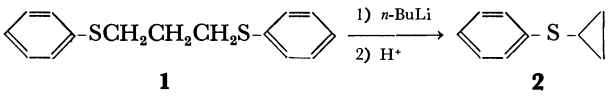
The reactions of a variety of 1,3-bis(phenylthio)propanes with butyllithium have been shown to produce cyclopropyl phenyl sulfides in good to high yields. A new and convenient *in situ* preparation of 1-lithiocyclopropyl phenyl sulfide can be readily carried out by treating 1,3-bis(phenylthio)propane with 2 equiv. of butyllithium at 0 °C in THF. The reaction with electrophiles proceeds in good yield. *O*-Aryl and *O*-alkyl *S*-cyclopropyl dithiocarbonates also can be prepared in good yields. 1,2-Bis(phenylthio)ethane was converted to phenyl vinyl sulfide on treatment with butyllithium, while 1,4-bis(phenylthio)butane was recovered unchanged by a similar treatment.

In 1973 Trost has reported that 1-lithiocyclopropyl phenyl sulfide, prepared by deprotonation of cyclopropyl phenyl sulfide is a useful reagent in the preparation of cyclobutanones and cyclobutenes.[1,2] Later, Miller and Cohen showed the transformations of 1-lithiocyclopropyl phenyl sulfide into useful synthetic intermediates such as γ-keto sulfides,[3] vinyl sulfides,[4] and 1-methoxycyclopropyl phenyl sulfide.[5] Cyclopropyl phenyl sulfide can be prepared by cyclization of 3-chloropropyl phenyl sulfide in liquid ammonia.[1a,6] Recently, Cohen has found the efficient method for conversion of 1,1,3-tris(phenylthio)propane into 1,1-bis(phenylthio)cyclopropane, which upon reductive lithiation with lithium naphthalenide affords lithiocyclopropane.[7a] In 1980 we reported preliminary results of one-step synthetic method for 1-lithiocyclopropyl phenyl sulfide utilizing readily available 1,3-bis(phenylthio)propane as the starting material.[8]

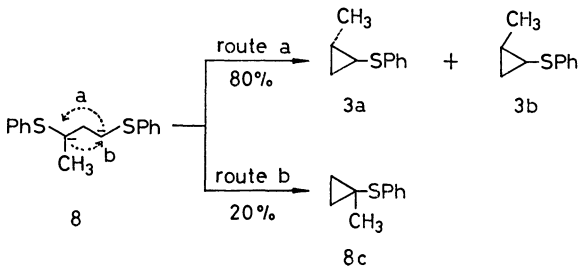
In this paper we investigated the scope and limitations of the new cyclization reaction as a viable route to various types of cyclopropyl phenyl sulfides.

Results and Discussion

Synthesis of Cyclopropyl Phenyl Sulfides. When 1 equiv. of butyllithium was added to THF solution of 1,3-bis(phenylthio)propane (**1**),[8,9] cyclopropyl phenyl sulfide (**2**)[1a] was obtained in 77% yield after quenching with aqueous ammonium chloride solution. The use of butyllithium in THF at −78 °C—0 °C for 3 h was found to be a convenient method for the synthesis of **2**. Additives such as hexamethylphosphoric triamide (HMPA) or *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) were found to have a negligible effect on yield of **2**. The possibility that various types of substituted 1,3-bis(phenylthio)propanes may be converted to the corresponding cyclopropanes by this method was further investigated. A variety of the alkyl-substituted 1,3-bis(phenylthio)propanes used in this study were prepared by the reported procedures.[1a,10–13] The cyclization of sulfides was efficiently carried out in addition of 1 equiv. of butyllithium at −78 °C—0 °C in THF in the presence of HMPA. Results are summarized in Table 1. The structures and stereochemistry of the substituted cyclopropyl phenyl sulfides



1 **2**

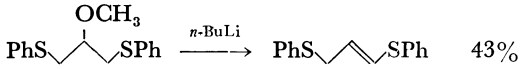


8 **3a** **3b** **8c**

Scheme 1.

were accomplished through the utilization of comparative spectroscopic data,[1] GLPC analyses, and authentic sample prepared from 1-lithiocyclopropyl phenyl sulfide. For example, GLPC analysis of cyclopropanes derived from sufide **3** showed a 9:1 mixture of **3a** and **3b** which was confirmed by comparison with the reported data.[1a] 1,3-Bis(phenylthio)butane (**8**) afforded three peaks, A, B, and C, in the ratio of 3:5:2. Peak A (retention time of 3.4 min) was shown to be 1-methylcyclopropyl phenyl sulfide (**8c**) by GLPC comparison with the authentic sample prepared from 1-lithiocyclopropyl phenyl sulfide and iodomethane.[1a,7c] Peak B (retention time of 4.3 min) and peak C (retention time of 5.7 min) were identified as trans-isomer (**3a**) and cis-isomer (**3b**) of 2-methylcyclopropyl phenyl sulfide by comparing the result from the reaction of sulfide **3**. These results clearly reflect the difference in acidity between C-1 hydrogen and C-3 hydrogen of sulfide **8** (Scheme 1).

Reaction of 2-methoxy-1,3-bis(phenylthio)propane (**12**) with 1 equiv. of butyllithium in THF gave only the elimination product **13**;[14] no cyclopropane could



12 **13**

be detected. An interesting change was observed with 2-hydroxy analogue **14**. Thus, reaction of 1,3-bis(phenylthio)-2-propanol (**14**) with 2 equiv. of butyllithium gave cyclopropanol **16** in good yield, most probably through a dianion intermediate **15**. The protection of OH group was readily carried out by adding 1-chloromethoxy-2-methoxyethane[15] or chlorotrimethylsilane into the reaction mixture (Scheme 2).

The mechanism of this facile ring closure has not been studied in detail, but it may be pictured in terms of an initial formation of the sulfur-stabilized carbanion

Table 1. Preparation of cyclopropyl sulfides from 1,3-bis(phenylthio)propanes

1,3-Bis(phenylthio)propanes	Products	Ratio	Yield/%

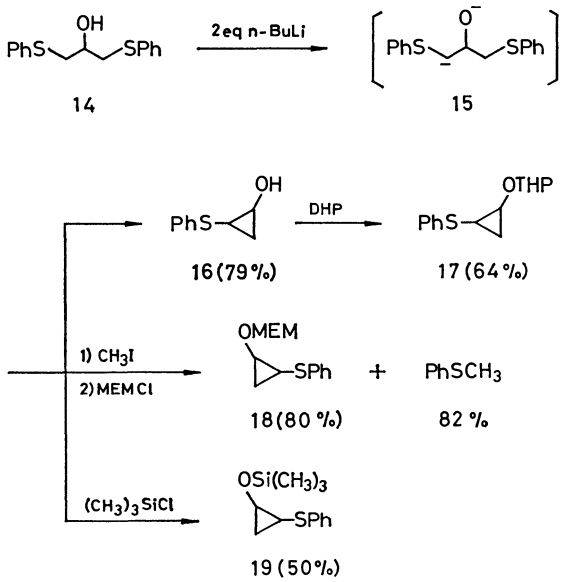
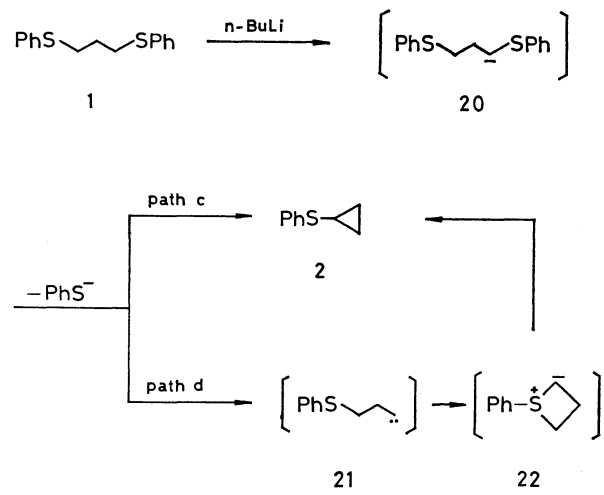
a) The trans/cis ratios of cyclopropyl sulfides were determined by ^{1}H-NMR and GLPC analyses. b) GLPC analyses showed three peaks. The first peak was presumed to be 1-alkylcyclopropyl phenyl sulfide by comparison of the data obtained from ^{1}H-NMR and GLPC.



Scheme 2.



Scheme 3.

20 followed by an intramolecular nucleophilic displacement of benzenethiolate anion (path c, Scheme 3).[7e] Recently, Cohen proposed a similar cyclization in the reaction of 1,1,3-tris(phenylthio)propane with methyllithium in the presence of TMEDA in THF.[7a] An alternative mechanism to that proposed would involve a carbene intermediate **21** which rearranges to a ylide **22** to give **2** (path d).[16] This pathway (d) is considered unlikely, however, since the reaction of 1,3-bis(phenylthio)propane (**1**) with butyllithium in the presence of excess of cyclohexane gave none of the addition product derived from the carbene **21**. Cyclopropyl phenyl sulfide (**2**) was formed as the only isolable product (59%).

In investigating the scope and limitations of this

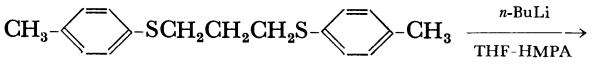
new cyclization, it was found that when the sulfides contain *p*-methyl or *p*-chloro substituent on benzene ring, the yields of cyclopropanes were decreased under the same reaction conditions cited above, possibly due to insolubility of these sulfides **23** and **25** in THF at a lower temperature. The use of 1.5—2.5 equiv. of HMPA as a co-solvent gave satisfactory results.



23

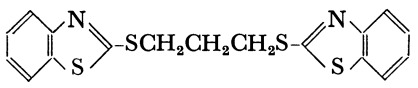
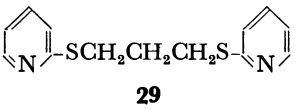
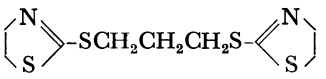
Attempts to cyclize the sulfides **28**—**30** using lithium diisopropylamide (LDA) or butyllithium in the presence of HMPA, however, were not successful due to the decomposition of sulfides under these reaction conditions.



28

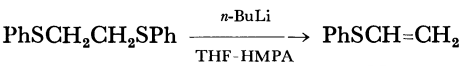


29



30

We briefly investigated the reaction of 1,2-bis(phenylthio)ethane (**31**)[17] or 1,4-bis(phenylthio)butane (**32**) with butyllithium in THF. Treatment of **31** in a mixture solvent of THF and HMPA afforded phenyl vinyl sulfide (**33**)[18] in 52% yield. However, the similar

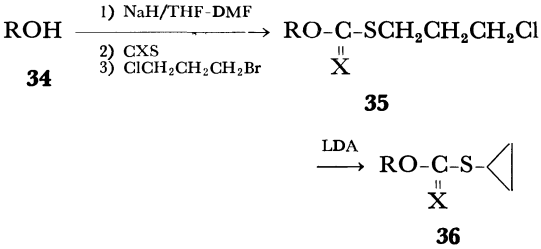


31 **33**

reaction of **31** in THF gave little of **33**; the Michael type addition of butyllithium to **33** took place. Treatment of **32** with butyllithium under various reaction conditions led to the recovery of the starting material **32**.

32

Next, we have developed a new method for the preparation of *S*-cyclopropyl thiocarbonate and dithiocarbonates. As outlined in Scheme 4, *S*-(3-chloropropyl) dithiocarbonates **35** were prepared from the corresponding alcohols and phenols **34**.[6,19] Treatment



Scheme 4.

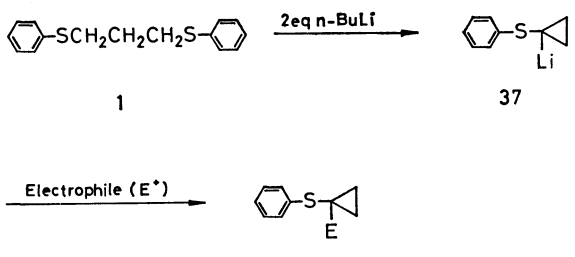
Table 3. Reactions of 1,3-bis(phenylthio)propane (**1**) and electrophiles in the presence of butyllithium

Electrophile[a]	Additive	Product (**38**)		Yield/%
4-Heptanone	—		(**38a**)	71
Benzaldehyde	—		(**38b**)	67
Cyclohexanone	—		(**38c**)	60
Acetone	—		(**38d**)	34
3-Pentanone	—		(**38e**)	69
3-Pentanone	CuI (10 mmol)		(**38e**)	85
Heptanal	CuI (10 mmol)		(**38f**)	59
2-Hexanone	CuI (10 mmol)		(**38g**)	65
D_2O	—		(**38h**)	65
CO_2	—		(**38i**)	55

a) The reaction was carried out by using 1,3-bis(phenylthio)propane (**1**) (10 mmol) and butyllithium (22 mmol) in THF.

of **35** in THF with 1.1 equiv. of LDA resulted in smooth cyclization to give *S*-cyclopropyl derivatives **36** in good to high yields as summarized in Table 2. The optically active *S*-cyclopropyl dithiocarbonates **36d** and **36e** could also be obtained by this procedure.

Direct Generation of 1-Lithiocyclopropyl Phenyl Sulfide. The finding that cyclopropyl phenyl sulfide (**2**) was formed on treatment of 1,3-bis(phenylthio)propane (**1**) with 1 equiv. of butyllithium suggested that it might be possible to trap 1-lithiocyclopropyl phenyl sulfide (**37**) with electrophiles in the reaction of **1** with 2 equiv. of butyllithium. Thus, treatment of sulfide **1** with 2 equiv. of butyllithium at 0 °C in THF gave a pale yellow solution of lithium reagent **37** after 3 h. Addition of 1 equiv. of 4-heptanone at −78 °C and allowing the reaction mixture to warm to room temperature resulted in the formation of the adduct **38a** in 51% yield. The yield of adduct was increased when 0.5 equiv. of 4-heptanone was added to the reaction mixture (71% yield). Results of one-pot reaction with a variety of electrophiles are summarized in Table 3. It was found that yields were improved when CuI was added to the reaction mixture to scavenge the thiolate anion as a copper(I) thiolate.



Experimental

General. All reactions involving organometallic species were run in flame-dried glasswares under an atmosphere of nitrogen or argon. ^{1}H-NMR spectra were determined in the indicated solvent on a JEOL Model PS-100 or a Hitachi Model R-24B spectrometer. Chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Infrared spectra were recorded on a Hitachi Model 215 spectrophotometer. GLPC analyses were performed on a Varian Aerograph Model 920 gas chromatograph using a 0.15 cm × 120 cm glass column (20% Silicone DC-550 on Celite 545). Mass spectra were recorded on a Hitachi Model M-52 mass spectrometer. Silica-gel columns for chromatography utilized Wakogel-200. Optical rotations were measured in 1-dm path length cell of 10 ml capacity using a JASCO Model DIP-181 polarimeter. Boiling points and melting points are uncorrected. All solvents and reagents were used as purchased unless otherwise specified. Aldehydes and ketones were purified by distillation. Tetrahydrofuran (THF) was dried by distillation from calcium hydride and subsequent distillation from lithium aluminium hydride under a nitrogen atmosphere, or distilled from sodium benzophenone ketyl under a nitrogen atmosphere. Diisopropylamine and *N,N,N',N'*-tetramethylethylenediamine were distilled from calcium hydride and stored over 4 Å molecular sieves. Hexamethylphosphoric triamide (HMPA) was distilled at 0.2—0.3 mmHg (1 mmHg ≈ 133.322 Pa) from calcium hydride and stored over 13 Å molecular sieves. Hexane and *N,N*-dimethyformamide were distilled from calcium hydride and stored over 4 Å molecular sieves. Elemental analyses were performed by the Microanalytical Laboratory, operated by the Institute for Chemical Research, Kyoto University.

1,3-Bis(phenylthio)propane (1). According to the method[8] previously described, sulfide **1** was prepared in 93% yield: bp 160—161 °C/0.2—0.3 mmHg; ^{1}H-NMR (CCl_4) δ 7.10 (m, 10H, C_6H_5S), 2.90 (t, J=7.5 Hz, 4H, CH_2S), 1.84 (q, J=7.5 Hz, 2H, CH_2).

Cyclopropyl Phenyl Sulfide (2). To a stirred solution of 2.60 g (10 mmol) of 1,3-bis(phenylthio)propane (**1**) in 20 ml of THF at −78 °C was added butyllithium (7.7 ml of a 1.5 M (1 M = 1 mol dm^{-3}) solution in hexane, 12 mmol). After it was stirred for 5 min, the cold bath was removed and the reaction mixture was stirred for 3 h in the ice bath. The reaction was quenched with saturated ammonium chloride solution (10 ml) and extracted four times with ether. The ether layers were combined, dried over anhydrous sodium sulfate, and evaporated to give a mixture of **2** and benzenethiol. Distillation under reduced pressure gave pure cyclopropyl phenyl sulfide (**2**):[1a,6] 1.15 g (77%); bp 89—90 °C/4.7 mmHg; IR (thin film) 3080, 3020, 1580, 1480, 1440, 1095, 1025 cm^{-1}; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m,

5H, SC_6H_5), 1.90—2.20 (m, 1H, CH), 0.80—1.00 (m, 2H), 0.50—0.80 (m, 2H). Found: C, 71.90; H, 6.83%. Calcd for $C_9H_{10}S$: C, 71.95; H, 6.71%. MS (20 eV) *m/e* 150 (M^+, 100).

Preparation of 1-(Phenylthio)-2-[(phenylthio)methyl]hexane (4): Diethyl 1,1-pentanedicarboxylate was prepared from diethyl malonate according to the literature.[10] Reduction of diethyl 1,1-pentanedicarboxylate (43.2 g, 0.2 mol) with lithium aluminium hydride (14.5 g, 0.38 mol) in dry ether under reflux gave 20.5 g (78%) of 2-(hydroxymethyl)-1-hexanol: bp 140—141 °C/18 mmHg. 1-Chloro-2-(chloromethyl)hexane was prepared from 2-(hydroxymethyl)-1-hexanol in 85% yield by the method of Trost:[1a] ^{1}H-NMR (CCl_4) δ 3.60 (m, 4H), 2.00 (m, 1H), 1.40 (m, 6H), 0.92 (m, 3H). To a stirred and cooled (ice-bath) solution prepared from Na (4.6 g, 0.2 mol) and methanol (150 ml) was added dropwise 22.1 g (0.2 mol) of benzenethiol. A solution of 12 g (0.07 mol) of 1-chloro-2-(chloromethyl)hexane in 10 ml of methanol was added dropwise. After being stirred at 0—5 °C for 1 h, the mixture was stirred at room temperature for 1 h, and then refluxed for 6 h. After evaporation of the solvent, the residue was diluted with ether, dried over anhydrous sodium sulfate, and concentrated. Distillation under reduced pressure gave 17.5 g (79%) of 1-(phenylthio)-2-[(phenylthio)methyl]hexane (**4**): bp 185—186 °C/0.8 mmHg; ^{1}H-NMR (CCl_4) δ 7.15 (m, 10H), 2.90 (m, 4H), 1.82 (m, 1H), 0.7—1.7 (m, 9H).

1-(Phenylthio)-2-[(phenylthio)methyl]dodecane (5): ^{1}H-NMR (CCl_4) δ 7.15 (m, 10H), 2.95 (m, 4H), 1.85 (m, 1H), 0.80—1.60 (m, 21H).

2-Cyclohexyl-1,3-bis(phenylthio)propane (6): ^{1}H-NMR (CCl_4) δ 7.10 (m, 10H), 2.95 (m, 4H), 0.60—2.00 (m, 12H).

1,3-Bis(phenylthio)butane (8): To a stirred and cooled (ice-bath) solution of 2.13 g (0.0926 mol) of Na in 300 ml of ethanol was added benzenethiol (10.2 g, 92.6 mmol) in 30 ml of ethanol. After an additional 30 min at 0 °C, a catalytic amount of sodium iodide was added, the cold bath was removed and the reaction mixture was refluxed for 10 h. Usual workup and distillation under reduced pressure gave pure sulfide **8** (8.42 g, 66%): bp 165—170 °C/0.6 mmHg; ^{1}H-NMR (CCl_4) δ 7.15 (m, 10H, C_6H_5S), 3.30 (q, J=7.1 Hz, 1H, CH), 3.00 (t, J=7.1 Hz, CH_2S), 1.80 (m, 2H, CH_2), 1.25 (d, J=7.1 Hz, 3H, CH_3).

Preparation of 1-(Phenylthio)-3-pentanol: According to Corey's procedure,[13] to a solution of 22 mmol of 1,4-diazabicyclo[2.2.2]octane (purified by sublimation) and 22 mmol of methyl phenyl sulfide in 40 ml of THF at 0 °C was added over 7 min 24 mmol of butyllithium. After stirring was continued at room temperature for 45 min, 20 mmol of 1,2-epoxybutane in 2 ml of THF was added dropwise at 0 °C. The reaction mixture was stirred for 45 h at room temperature and quenched with 20 ml of aqueous ammonium chloride solution. Usual workup gave 1-(phenylthio)-3-pentanol in 86% yield: bp 140—142 °C/3 mmHg; IR (thin film) 3370 (OH), 3050, 1575, 1480, 1435, 1020 cm^{-1}. ^{1}H-NMR (CCl_4) δ 6.90—7.30 (m, 5H, C_6H_5S), 3.40—3.70 (m, 1H, CH), 2.80—3.10 (m, 2H, SCH_2), 2.50—2.80 (m, 1H, OH), 1.20—1.80 (m, 4H), 0.88 (t, J=7 Hz, 3H, CH_3); MS (20 eV) *m/e* 196 (M^+, 85), 86 (100). Found: C, 67.26; H, 8.38%. Calcd for $C_{11}H_{16}OS$: C, 67.30; H, 8.22%.

In a similar way, 1-(phenylthio)-3-nonanol was obtained in 76% yield as white crystals after recrystallization from hexane: mp 45.0—45.7 °C; ^{1}H-NMR (CCl_4) δ 7.00—7.40 (m, 5H, C_6H_5S), 3.50—3.80 (m, 1H, CH), 2.90—3.10 (m, 2H, SCH_2), 1.98 (s, 1H, OH), 1.60—1.90 (m, 2H, CH_2), 1.24 (m, 10H), 0.86 (t, 3H, CH_3); MS (20 eV) *m/e* 252 (M^+, 45), 72 (100). Found: C, 71.17; H, 9.88%. Calcd for $C_{15}H_{24}OS$: C, 71.38; H, 9.58%.

1,3-Bis(phenylthio)pentane (**10**) was prepared from 1-(phenylthio)-3-pentanol: bp 184—187 °C/1.6 mmHg; ^{1}H-NMR (CCl_4) δ 7.00—7.40 (m, 10H, C_6H_5S), 2.90—3.20 (m, 3H), 1.40—1.90 (m, 4H, CH_2), 0.96 (t, J=7 Hz, 3H, CH_3); MS (20 eV) *m/e* 288 (M^+, 98), 123 (100).

1,3-Bis(phenylthio)nonane (**11**) was prepared from 1-(phenylthio)-3-nonanol: oil; ^{1}H-NMR (CCl_4) δ 7.00—7.40 (m, 10H, C_6H_5S), 2.90—3.30 (m, 3H), 1.10—2.00 (m, 12H), 0.85 (t, J=7 Hz, 3H, CH_3). MS (20 eV) *m/e* 344 (M^+, 100).

Reaction of 2-Methyl-1,3-bis(phenylthio)propane (3): To a solution of 10 mmol of sulfide **3** and 25 mmol of HMPA in 20 ml of THF at −78 °C was added over 10 min 12 mmol of butyllithium, and stirring was continued for 10 min. The cooling bath was removed, and the reaction mixture was stirred at 0 °C for 3 h. After quenching with 10 ml of saturated ammonium chloride solution, the mixture was acidified with 10% hydrochloric acid (50 ml) and extracted three times with ether. The combined extracts were washed twice with brine, dried over anhydrous sodium sulfate, and concentrated. Distillation under reduced pressure gave a mixture of cyclopropyl sulfides **3a** and **3b** of 9:1 ratio in 88% yield: bp 71—72 °C/0.8 mmHg; ^{1}H-NMR (CCl_4) δ 7.00—7.70 (m, 5H, C_6H_5S), 2.10—2.40 (m, 0.1H, SCH), 1.80—2.00 (m, 0.9H, SCH), 1.20—1.30 (m, 3H, CH_3), 0.20—1.20 (m, 3H); IR (thin film) 3060, 2950, 1580, 1480, 1440, 1090, 1025 cm^{-1}; MS (20 eV) *m/e* 164 (M^+, 100). Found: C, 73.50; H, 7.58%. Calcd for $C_{10}H_{12}S$: C, 73.12; H, 7.37%.

Reaction of 1-(Phenylthio)-2-[(phenylthio)methyl]hexane (4): Reaction of 10 mmol of sulfide **4** with 12 mmol of butyllithium in 20 ml of THF containing 20 mmol of HMPA gave a mixture of cyclopropyl sulfides **4a** and **4b**: bp 112—114 °C/1.7 mmHg; ^{1}H-NMR (CCl_4) δ 6.80—7.30 (m, 5H, C_6H_5S), 2.00—2.30 (m, 0.2H, CHS), 1.70—1.90 (m, 0.8H, SCH), 0.20—1.70 (m, 12H); IR (thin film) 3080, 2925, 1580, 1480, 1440, 1095, 1030 cm^{-1}; MS (20 eV) trans-isomer **4a** *m/e* 206 (M^+, 77), 55 (100); cis-isomer **4b** *m/e* 206 (M^+, 69), 142 (100). Found: C, 75.42; H, 9.02%. Calcd for $C_{13}H_{18}S$: C, 75.73; H, 8.74%.

Reaction of 1-(Phenylthio)-2-[(phenylthio)methyl]dodecane (5): Reaction of 10 mmol of sulfide **5** with 12 mmol of butyllithium in 20 ml of THF containing 20 mmol of HMPA gave a mixture of cyclopropyl sulfides **5a** and **5b**: bp 171—173 °C/1.6 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.30 (m, 5H, C_6H_5S), 2.10—2.40 (m, 0.13H, SCH), 1.70—1.90 (m, 0.87H, SCH), 0.60—1.60 (m, 24H); IR (thin film) 3060, 2920, 1580, 1475, 1435, 1090, 1020 cm^{-1}; MS (20 eV) trans-isomer **5a** *m/e* 290 (M^+, 82), 82 (100); cis-isomer **5b** *m/e* 290 (M^+, 63), 82 (100). Found: C, 78.63; H, 10.51%. Calcd for $C_{19}H_{30}S$: C, 78.62; H, 10.27%.

Reaction of 2-Cyclohexyl-1,3-bis(phenylthio)propane (6): Reaction of 10 mmol of sulfide **6** with 12 mmol of butyllithium in 20 ml of THF containing 20 mmol of HMPA gave a mixture of cyclopropyl sulfides **6a** and **6b**: bp 136—136.5 °C/1.1 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 0.50—2.00 (m, 15H); IR (thin film) 3070, 2920, 1580, 1480, 1450, 1440, 1090, 1025 cm^{-1}; MS (20 eV) trans-isomer *m/e* 232 (M^+, 81), 136 (100). Found: C, 77.81; H, 8.69%. Calcd for $C_{15}H_{20}S$: C, 77.59; H, 8.62%.

Reaction of 1,1-Bis[(phenylthio)methyl]cyclobutane (7): Reaction of 9.8 mmol of sulfide **7** with 12 mmol of butyllithium in 20 ml of THF containing 20 mmol of HMPA gave a 61% of 1-(phenylthio)spiro[2.3]hexane (**7a**): bp 83—84 °C/0.3 mmHg; IR (thin film) 3060, 2970, 1480, 1435, 1090, 1025 cm^{-1}; ^{1}H-NMR (CCl_4) δ 6.80—7.40 (m, 5H), 1.80—

2.50 (m, 6H), 0.78—1.80 (m, 2H), 0.50—0.78 (t, J=6 Hz, 1H). MS (20 eV) m/e 190 (M^+, 100). Found: C, 75.88; H, 7.67%. Calcd for $C_{12}H_{14}S$: C, 75.79; H, 7.37%.

Reaction of 1,3-Bis(phenylthio)butane (8): Reaction of sulfide **8** with 12 mmol of butyllithium in 20 ml of THF gave a mixture of cyclopropyl sulfides **3a**, **3b**, and **8c** (5:4:1) in 21% yield. A similar reaction of 10 mmol of sulfide **8** with 12 mmol of butyllithium in 20 ml of THF containing 25 mmol of HMPA gave a mixture of sulfides **3a**, **3b**, and **8c** (5:2:3) in 65% yield: bp 72—75 °C/2.2 mmHg; ^{1}H-NMR (CCl_4) δ 7.00—7.50 (m, 5H, C_6H_5S), 0.20—2.40 (m, 7H); IR (thin film) 3100, 1590, 1485, 1445, 1105, 1030 cm^{-1}; MS (20 eV) 1-methylcyclopropyl phenyl sulfide (**8c**): m/e 164 (M^+, 27), 131 (100); trans-isomer **3a**: m/e 164 (M^+, 100); cis-isomer **3b**: m/e 164 (M^+, 94), 110 (100). Found: C, 73.43; H, 7.60%. Calcd for $C_{10}H_{12}S$: C, 73.12; H, 7.37%.

Reaction of 1,3-Bis(phenylthio)hexane (9): Reaction of 10 mmol of sulfide **9** with 12 mmol of butyllithium in 20 ml of THF containing 20 mmol of HMPA gave a mixture of cyclopropyl sulfides **9a**, **9b**, and **9c**: bp 96—102.5 °C/2.8 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.30 (m, 5H, C_6H_5S), 0.20—2.40 (m, 11H); IR (thin film) 3060, 2950, 1580, 1475, 1435, 1090, 1020 cm^{-1}; MS (20 eV) 1-propylcyclopropyl phenyl sulfide (**9c**): MS (20 eV) m/e 192 (M^+, 63), 159 (100); 2-propylcyclopropyl phenyl sulfides (**9a** and **9b**) m/e 192 (M^+, 94), 149 (100). Found: C, 75.09; H, 8.42%. Calcd for $C_{12}H_{16}S$: C, 75.00; H, 8.33%.

Reaction of 1,3-Bis(phenylthio)pentane (10): Reaction of 10 mmol of sulfide **10** with 12 mmol of butyllithium in 20 ml of THF containing 25 mmol of HMPA gave a mixture of cyclopropyl sulfides **10a**, **10b**, and **10c** in 74% yield: bp 100—106 °C/3.9 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 0.30—2.40 (m, 9H); IR (thin film) 3070, 2960, 1580, 1480, 1435, 1090, 1025 cm^{-1}. Found: C, 74.23; H, 7.93%. Calcd for $C_{11}H_{14}S$: C, 74.10; H, 7.91%.

Reaction of 1,3-Bis(phenylthio)nonane (11): Reaction of 10 mmol of sulfide **11** with 12 mmol of butyllithium in 20 ml of THF containing 25 mmol of HMPA gave a mixture of cyclopropyl sulfides, **11a**, **11b**, and **11c**: bp 123—127 °C/0.9 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 0.30—2.40 (m, 17H); IR (thin film) 3060, 2920, 1580, 1470, 1435, 1090, 1020 cm^{-1}. Found: C, 77.10; H, 9.60%. Calcd for $C_{15}H_{22}S$: C, 76.86; H, 9.46%.

Preparation of 2-Methoxy-1,3-bis(phenylthio)propane (12): According to Corey's procedure,[14] sulfide **12** was prepared from 1,3-bis(phenylthio)-2-propanol (**14**) (*vide infra*) and iodomethane in 91% yield: bp 180—182 °C/0.7 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 10H, C_6H_5S), 3.20—3.50 (m, 1H, CH), 3.24 (s, 3H, OCH_3), 3.60 (d, J=6 Hz, 4H, CH_2); MS (20 eV) m/e 290 (M^+, 39), 135 (100).

Reaction of Sulfide 12 with Butyllithium: Reaction of 10 mmol of sulfide **12** with 12 mmol of butyllithium in THF containing 25 mmol of HMPA gave a mixture of 1,3-bis(phenylthio)propene (**13**) and sulfide **12**. Silica gel chromatography after distillation gave 1.12 g (43%) of **13** and 1.03 g (35%) of the starting material **12**. 1,3-Bis(phenylthio)propene (**13**): bp 192—198 °C/3.2 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 10H, C_6H_5S), 5.60—6.20 (m, 2H, CH=CH), 3.40—3.70 (m, 2H, CH_2); MS (20 eV) m/e 258 (M^+, 14), 149 (100). This compound had properties (NMR, MS, TLC) with those of an authentic sample prepared by tosylation of 1,3-bis(phenylthio)-2-propanol (**14**), followed by elimination with LDA in THF.

Preparation of 1,3-Bis(ohenylthio)-2-propanol (14): According to Corey's procedure,[14] to a solution of 0.6 mol of sodium benzenethiolate in methanol was added 0.3 mol (27.8 g) of 1-chloro-2,3-epoxypropane at room temperature. After stirring was continued for 1 h, the mixture was heated at 50—60 °C for 1 h. Usual workup gave 77.3 g (93%) of **14**: bp 187—188 °C/0.3 mmHg; ^{1}H-NMR (CCl_4) δ 7.00—7.40 (m, 10H, C_6H_5S), 3.60—3.90 (m, 1H, CH), 2.80—3.20 (m, 5H, OH and CH_2); IR (thin film) 3420 (OH) cm^{-1}; MS (20 eV) m/e 276 (M^+, 23), 110 (100).

Synthesis of 2-(Phenylthio)cyclopropanol (16): To a solution of 40 mmol (11.06 g) of 1,3-bis(phenylthio)-2-propanol (**14**) in 80 ml of THF at −78 °C was added over 36 min 88 mmol of butyllithium, and stirring was continued for 10 min at −78 °C and for 3 h at 0 °C. The mixture was quenched with 10 ml of aqueous ammonium chloride and was extracted with ether three times. The combined extracts were washed once with brine, dried over anhydrous sodium sulfate, and concentrated to give a crude product. Distillation under reduced pressure gave 5.23 g (79%) of **16**: bp 114—119 °C/0.8—0.9 mmHg; ^{1}H-NMR (CCl_4) δ 7.10—7.50 (m, 5H, C_6H_5S), 4.25 (brs, 1H, OH), 3.40—3.70 (m, 1H, CH), 2.10—2.30 (m, 1H, CHS), 0.60—1.30 (m, 2H, CH_2); IR (thin film) 3330 (OH), 3000, 1580, 1480, 1435, 1325, 1200, 1090, 1025 cm^{-1}. Found: C, 65.24; H, 5.99%. Calcd for $C_9H_{10}OS$: C, 65.02; H, 6.06%.

2-[2-(Phenylthio)cyclopropyloxy]tetrahydropyran (17): A mixture of 5.9 mmol (0.98 g) of cyclopropanol **16**, 7.1 mmol (0.60 g) of 3,4-dihydro-2*H*-pyran and a catalytic amount of *p*-toluenesulfonic acid monohydrate in dry dichloromethane was stirred at 0 °C for 18 h. Workup and column chromatography on silica gel gave 0.94 g (64%) of **17**: bp 135—141 °C/0.8—0.9 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 4.40—4.70 (m, 1H, OCH), 3.30—4.00 (m, 3H), 2.00—2.50 (m, 1H, SCH), 0.70—2.00 (m, 8H).

1-[(2-Methoxyethoxy)methoxy]-2-(phenylthio)cyclopropane (18): To a stirred solution of 40 mmol (11.04 g) of **14** in 120 ml of THF at −78 °C was added over 30 min 88 mmol of butyllithium. After completion of the addition, the reaction mixture was stirred at −78 °C for 10 min and at 0 °C for 3 h. The solution was then cooled to −78 °C, and treated with 60 mmol (8.50 g) of iodomethane and stirred at this temperature for 30 min and at 0 °C for 1 h. After the addition of 1-chloromethoxy-2-methoxyethane (5.48 g, 44 mmol), the reaction mixture was stirred at 0 °C for 15 h. Aqueous workup and distillation gave 4.08 g (82%) of methyl phenyl sulfide and 8.12 g (80%) of **18**: bp 146—151 °C/1.0—1.2 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 4.62 (s, 2H, OCH_2), 3.30—3.90 (m, 4H, CH_2), 3.28 (s, 3H, CH_3O), 2.20—2.50 (m, 1H, CHO), 0.70—1.60 (m, 3H); MS (20 eV) m/e 254 (M^+, 4) 59 (100).

1,3-Bis(4-methylphenylthio)propane (23): According to the procedure for the preparation of **1**, sulfide **23** was prepared by adding a solution of 0.101 mol (20.3 g) of 1,3-dibromopropane in 50 ml of ethanol to a solution of sodium 4-methylbenzenethiolate (0.201 mol) in ethanol (200 ml). The crude sulfide was purified by distillation to yield 27.14 g (94%) of **23**: bp 167—168 °C/0.2—0.5 mmHg; ^{1}H-NMR (CCl_4) δ 7.12 (d, J=9.2 Hz, 4H), 6.93 (d, J=9.2 Hz, 4H), 2.88 (t, J=7.7 Hz, 4H, CH_2S), 1.80 (q, J=7.7 Hz, 2H, CH_2).

In a similar way, 1,3-bis(4-chlorophenylthio)propane (**25**) was prepared in 80% yield: mp 40—41 °C (ethanol–acetone); ^{1}H-NMR (CCl_4) δ 7.61 (s, 8H), 2.94 (t, 4H, CH_2S), 1.87 (q, J=6.6 Hz, 2H).

1-Chloro-3-(4-chlorophenylthio)propane (27): Reaction of 0.05 mol of sodium 4-chlorobenzenethiolate with 0.06 mol of 1-bromo-3-chloropropane in ethanol gave **27** in 90% yield: bp 109—112 °C/0.3—0.4 mmHg; ^{1}H-NMR (CCl_4) δ 7.20 (m, 4H), 3.60 (t, J=7.5 Hz, 2H, CH_2Cl), 3.00 (t, J=7.5 Hz, 2H, CH_2S), 2.00 (q, J=7.5 Hz, 2H, CH_2).

Reaction of 19.2 mmol of sulfide **23** with 23 mmol of butyllithium in 50 ml of THF containing 28.7 mmol of HMPA at −78 °C for 30 min and at 0 °C for 3 h gave cyclopropyl 4-methylphenyl sulfide (**24**) in 50% yield: bp 84—86 °C/1.5 mmHg (lit,[6] bp 87 °C/2.3 mmHg); ^{1}H-NMR (CCl_4) δ 6.90—7.20 (m, 4H, C_6H_5S), 2.27 (s, 3H, CH_3), 1.90—2.20 (m, 1H, CH), 0.50—1.10 (m, 4H); IR (thin film) 3080, 3010, 1490, 1280, 1090, 1025 cm^{-1}. Found: C, 73.29; H, 7.64%. Calcd for $C_{10}H_{12}S$: C, 73.12; H, 7.37%.

Reaction of 10 mmol of sulfide **25** with 11 mmol of LDA in 20 ml of THF containing 24.7 mmol of HMPA at −78—0 °C for 3 h gave 4-chlorophenyl cyclopropyl sulfide (**26**) in 34%: bp 79—81 °C/0.4 mmHg; ^{1}H-NMR (CCl_4) δ 7.16 (s, 4H, C_6H_5S), 2.08 (m, 1H), 1.00 (m, 2H), 0.65 (m, 2H); IR (thin film) 3080, 3000, 1470, 1090, 1010, 810 cm^{-1}. Found: C, 58.79; H, 5.00%. Calcd for C_9H_9ClS: C, 58.53; H, 4.91%.

Reaction of 30 mmol of sulfide **27** with 31 mmol of LDA in THF at −78 °C to room temperature gave the same sulfide **26** in 46% yield.

*1,2-Bis(phenylthio)ethane (**31**)*: Mp 68—69 °C (lit,[17] mp 69 °C); ^{1}H-NMR (CCl_4) δ 7.20 (m, 10H, C_6H_5S), 3.00 (s, 4H, CH_2).

Reaction of 10 mmol of sulfide **31** with 22 mmol of butyllithium in 20 ml of THF containing 25 mmol of HMPA at −78 °C for 3 h gave phenyl vinyl sulfide (**33**) in 52% yield: bp 80 °C/16 mmHg; ^{1}H-NMR was agreement with the literature.[18]

Preparation of O-*(2,4,6-Tri-*t*-butylphenyl)* S-*(3-Chloropropyl) dithiocarbonate (**35a**)*: To a stirred suspension of 1.83 g of sodium hydride (50% mineral oil; washed with hexane three times) in 40 ml of THF was added 2,4,6-tri-*t*-butylphenol (10 g, 0.0381 mol) with ice-bath cooling. After the addition, the bath was removed and the reaction mixture was stirred for 1 h. Carbon disulfide (4.64 g, 0.061 mol) was then added and the stirring was continued for 1 h. The above reaction mixture was added to the solution of 6.00 g (0.381 mol) of 1-bromo-3-chloropropane in 20 ml of dry DMF at 0 °C. After the mixture was stirred for 4 h at room temperature, aqueous workup and recrystallization from methanol gave 11.9 g (75%) of **35a**: mp 47—49 °C. ^{1}H-NMR (CCl_4) δ 7.25 (s, 2H), 3.65 (t, J=7 Hz, 2H), 3.40 (t, J=7 Hz, 2H), 2.30 (m, 2H), 1.40 (s, 27H).

Analogous procedures were followed for the preparation of **35b**, **35c**, **35d**, and **35e**.

O-*(2,4,6-Tri-*t*-butylphenyl)* S-*(3-Chloropropyl) Thiocarbonate (**35b**)*: Mp 75—77 °C (MeOH); ^{1}H-NMR (CCl_4) δ 7.24 (s, 2H), 3.60 (t, J=6.9 Hz, 2H), 3.04 (t, J=6.9 Hz, 2H), 2.12 (m, 2H), 1.36 (m, 27H, CH_3).

O-*(4-*t*-Butylcyclohexyl)* S-*(3-Chloropropyl) Dithiocarbonate (**35c**)*: A viscous oil; ^{1}H-NMR (CCl_4) δ 5.34 (m, 1H), 3.60 (t, J=6.9 Hz, 2H, CH_2), 3.25 (t, J=6.9 Hz, 2H, CH_2), 2.05—2.40 (m, 4H), 0.80—2.05 (m, 16H).

O-L-*Menthyl* S-*(3-Chloropropyl) Dithiocarbonate (**35d**)*: A viscous oil; ^{1}H-NMR (CCl_4) δ 5.83 (m, 1H), 3.55 (t, J=6.9 Hz, 2H, CH_2), 3.20 (t, J=6.9 Hz, 2H, CH_2), 2.00—2.40 (m, 3H), 1.60—2.00 (m, 17H).

O-L-*Bornyl* S-*(3-Chloropropyl) Dithiocarbonate (**35e**)*: Bp 163—165 °C/2—3 mmHg. ^{1}H-NMR ($CDCl_3$) δ 5.45 (m, 1H), 3.60 (t, J=7 Hz, 2H, CH_2Cl), 3.25 (t, J=7 Hz, CH_2S), 2.60—0.80 (m, 18H).

Synthesis of O-*(2,4,6-Tri-*t*-butylphenyl)* S-*Cyclopropyl Dithiocarbonate (**36a**)*: To a stirred solution of 30 mmol (4.2 ml) of diisopropylamine in 40 ml of THF was added at −78 °C over 20 min 30 mmol of butyllithium. The solution was stirred at this temperature for 20 min, and treated dropwise with 28.7 mmol of **35a** in 20 ml of THF. After 3 h, the reaction mixture was allowed to warm to room temperature with stirring (4 h) and then quenched with 10 ml of aqueous ammonium chloride solution. The mixture was poured onto 50 ml of 10% hydrochloric acid and extracted with ether (4×50 ml). The ethereal extracts were washed with saturated sodium chloride solution, dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give pale yellow solid **36a**. The sample for analysis was prepared by repeated recrystallizations from methanol twice to give pale yellow crystals **36a** in 77% yield (8.40 g): mp 68—69 °C; ^{1}H-NMR (CCl_4) δ 7.20 (s, 2H), 2.40 (m, 1H), 1.35 (s, 27H, CH_3), 1.16 (m, 2H), 0.76 (m, 2H). Found: C, 69.62; H, 9.09%. Calcd for $C_{22}H_{34}OS_2$: C, 69.79; H, 9.05%.

Similar procedures to the above were used for cyclization.

O-*(2,4,6-Tri-*t*-butylphenyl)* S-*Cyclopropyl Thiocarbonate (**36b**)*: Mp 77—78 °C (MeOH); ^{1}H-NMR (CCl_4) δ 7.28 (s, 2H), 2.20 (m, 1H), 1.36 (m, 27H, CH_3), 1.04 (m, 2H), 0.68 (m, 2H). Found: C, 72.65; H, 9.57%. Calcd for $C_{22}H_{34}O_2S$: C, 72.88; H, 9.45%.

O-*(4-*t*-Butylcyclohexyl)* S-*Cyclopropyl Dithiocarbonate (**36c**)*: Mp 35—35.5 °C (EtOH); ^{1}H-NMR (CCl_4) δ 5.30 (m, 1H), 0.80—2.40 (m, 21H), 0.71 (m, 2H). Found: C, 61.65; H, 9.01%. Calcd for $C_{14}H_{24}OS_2$: C, 61.72; H, 8.88%.

O-L-*Menthyl* S-*Cyclopropyl Dithiocarbonate (**36d**)*: Mp 26—27 °C (EtOH); bp 117—120 °C/0.2 mmHg; ^{1}H-NMR (CCl_4) δ 5.40 (m, 1H), 2.30 (m, 2H), 0.50—2.10 (m, 21H); $[\alpha]_D^{25}$ −59.4° (*c* 1.47, $CHCl_3$). Found: C, 61.42; H, 9.08%. Calcd for $C_{14}H_{24}OS_2$: C, 61.72; H, 8.88%.

O-L-*Bornyl* S-*Cyclopropyl Dithiocarbonate (**36e**)*: Bp 119—125 °C/0.2 mmHg; ^{1}H-NMR ($CDCl_3$) δ 5.40 (m, 1H), 0.50—2.60 (m, 21H); $[\alpha]_D^{23}$ −17.6° (*c* 1.61, $CHCl_3$). Found: C, 62.51; H, 8.51%. Calcd for $C_{14}H_{22}OS_2$: C, 62.17; H, 8.20%.

*General Procedure for Addition of 1-Lithiocyclopropyl Phenyl Sulfide (**37**) to Carbonyl Compounds.* To a stirred solution of 1,3-bis(phenylthio)propane (**1**) (2.6 g, 10 mmol) in 20 ml of THF was added butyllithium (21 mmol) at −78 °C. After 5 min, the bath was removed and the mixture was stirred for 3 h at 0 °C. The resulting pale yellow solution was cooled to −78 °C, and the mixture of a carbonyl compound (10 mmol) in 3 ml of THF was added dropwise. After an additional 30 min at −78 °C, the solution was slowly warmed to room temperature. Saturated ammonium chloride solution (10 ml) was then added, and the reaction mixture was poured into 300 ml of water. The organic layer was removed, and the aqueous layer was extracted with ether (3×50 ml). The organics were combined, dried over anhydrous sodium sulfate and evaporated to give a crude adduct **38**. After chromatography on silica gel, eluted with hexane–benzene, a pure adduct **38** was obtained.

*Physical Properties of Adduct. 4-[1-(Phenylthio)cyclopropyl]-4-heptanol (**38a**)*: Bp 140 °C/0.9 mmHg; IR (thin film) 3530 (OH), 2970, 1585, 1480, 1440, 1025 cm^{-1}; ^{1}H-NMR (CCl_4) δ 7.10—7.50 (m, 5H, C_6H_5S), 0.70—1.80 (m, 19H); MS (20 eV) *m/e* 264 (M^+, 20), 117 (100). Found: C, 73.10; H, 9.49%. Calcd for $C_{16}H_{24}OS$: C, 72.68; H, 9.15%.

α-*[1-(Phenylthio)cyclopropyl]benzyl Alcohol (**38b**)*: IR (thin film) 3410 (OH), 2920, 1575, 1475, 1020 cm^{-1}; ^{1}H-NMR (CCl_4) δ 7.00—7.40 (m, 10H, C_6H_5), 4.63 (brs, 1H, CH), 2.64 (brs, 1H, OH), 0.80—1.21 (m, 4H); MS (20 eV) *m/e* 256 (M^+, 41), 150 (100). Found: C, 75.18; H, 6.50%. Calcd for $C_{16}H_{16}OS$: C, 74.96; H, 6.29%.

*1-[1-(Phenylthio)cyclopropyl]cyclohexanol (**38c**)*: IR (thin film) 3480 (OH), 2920, 1575, 1475, 1430, 1025 cm^{-1}; ^{1}H-NMR (CCl_4) δ 6.90—7.50 (m, 5H, C_6H_5S), 1.30—1.90 (m, 11H), 0.70—1.20 (m, 4H); MS (20 eV) *m/e* 248 (M^+, 20),

117 (100). Found: C, 72.62; H, 8.33%. Calcd for $C_{15}H_{20}OS$: C, 72.54; H, 8.12%.

2-[1-(Phenylthio)cyclopropyl]-2-propanol (38d): Bp 100 °C/0.9 mmHg; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 2.18 (brs, 1H, OH), 1.23 (s, 6H, CH_3), 0.80—1.20 (m, 4H); MS (20 eV) *m/e* 208 (M^+, 17), 59 (100). Found: C, 69.45; H, 8.05%. Calcd for $C_{12}H_{16}OS$: C, 69.19; H, 7.74%.

3-[1-(Phenylthio)cyclopropyl]-3-pentanol (38e): Bp 121 °C/0.6 mmHg; IR (thin film) 3490 (OH), 2960, 1580, 1475, 1430, 1025 cm^{-1}; ^{1}H-NMR (CCl_4) δ 7.10—7.60 (m, 5H, C_6H_5S), 1.40—1.90 (m, 4H), 0.70—1.40 (m, 11H); MS (20 eV) *m/e* 236 (M^+, 24), 117 (100). Found: C, 71.18; H, 8.82%. Calcd for $C_{14}H_{20}OS$: C, 71.14; H, 8.53%.

1-[1-(Phenthio)cyclopropyl]-1-heptanol (38f): Bp 151—152 °C/0.8 mmHg; IR (thin film) 3410 (OH), 2920, 1580, 1475, 1435, 1020 cm^{-1}; ^{1}H-NMR (CCl_4) δ 7.00—7.50 (m, 5H, C_6H_5S), 3.10—3.30 (m, 1H), 1.90—2.20 (m, 1H, OH), 0.70—1.80 (m, 17H); MS (20 eV) *m/e* 264 (M^+, 31), 117 (100). Found: C, 72.87; H, 9.30%. Calcd for $C_{16}H_{24}OS$: C, 72.68; H, 9.15%.

2-[1-(Phenylthio)cyclopropyl]-2-hexanol (38g): Bp 129 °C/0.6—0.7 mmHg; IR (thin film) 3495 (OH) cm^{-1}; ^{1}H-NMR (CCl_4) δ 6.90—7.40 (m, 5H, C_6H_5S), 0.70—1.80 (m, 17H); MS (20 eV) *m/e* 250 (M^+, 22), 117 (100). Found: C, 72.09; H, 9.19%. Calcd for $C_{15}H_{22}OS$: C, 71.95; H, 8.86%.

1-(Phenylthio)cyclopropanecarboxylic Acid (38i): ^{1}H-NMR (CCl_4) δ 9.80 (brs, 1H, COOH), 7.00—7.50 (m, 5H, C_6H_5S), 1.20—1.90 (m, 4H).[7c]

Alcoholysis Equilibria of Triethylalkoxysilanes Catalyzed by Iodine or Iodine Monobromide

Katsuko Ito and Takeshi Ibaraki*

Department of Natural Science, Osaka Women's University, Daisen-cho, Sakai, Osaka 590

(Received January 23, 1982)

The equilibrium constants K of alcoholysis of triethylalkoxysilanes were determined at 20 °C and 40 °C. Iodine monobromide was used to promote the reactions associated with the tertiary alkoxyl groups, while the other reactions proceeded in the presence of iodine. The K values of the reaction systems with ethoxyl or propoxyl—primary, secondary, and tertiary alkoxyl pairs were 1 or above, about 0.5, and about 0.05, respectively. These values reflect the extent of the binding abilities of the alkoxyl groups to silicon, which is in the expected order of primary>secondary>tertiary alkoxyl groups. A mechanism is postulated for the reaction which involves participation by the iodine or iodine monobromide.

Alcoholysis of alkoxysilanes had been carried out previously in the absence of catalyst,[1] but it was noted that under anhydrous conditions alkoxysilanes were generally quite stable and that non-catalytic alcoholysis proceeded only slowly.[2,7] Various acids and bases have been employed to catalyze such reactions,[2-11] as well as alkali metals.[2-4,9,10] Reaction mechanisms have been proposed in some of these cases,[2,7-9] but quantitative data concerning the equilibria of such reactions cannot be found in the literature, although a few kinetic studies have been reported.[8,11]

Alkoxyl-alkoxyl exchange reactions are promoted by iodine or interhalogen compounds such as iodine monobromide, and the equilibrium compositions of such systems can be ascertained by gas chromatography as described in the previous paper.[12] Thus, the iodine- or iodine monobromide-catalyzed reactions of triethylalkoxysilanes with various alcohols were examined, and the equilibrium constants at two different temperatures were determined. For reactions with tertiary alcohols, iodine monobromide was employed because of its superior catalytic activity, while iodine was used in the other cases.

Results and Discussion

Alcoholysis Equilibria of Triethylalkoxysilanes. Thirteen reaction systems with different OR–OR′ pairs were studied at 20.0 °C and 40.0 °C in the presence of iodine or iodine monobromide.

$$Et_3SiOR + R'OH \rightleftharpoons Et_3SiOR' + ROH$$

The equilibria were established from both forward and reverse directions. In most cases the compositions of the reaction mixtures became constant within a few hours. Equilibrium constants, K, for these reactions are summarized in Table 1. The K values are close to unity when both alkoxyl groups have about the same binding ability to silicon and both alcohols have similar reactivity. The reaction systems with ethoxyl–methoxyl, propoxyl and butoxyl, and propoxyl–butoxyl pairs seem to correspond to such cases, as the K values are 1.00—1.12. (entries 1—3,13 in Table 1)

In the reaction systems with ethoxyl–isobutoxyl, pentyloxyl, and isopentyloxyl pairs, K values somewhat larger than unity were observed. (entries 4,7,8) Corresponding free-energy changes for these reactions are −0.62—−1.02 kJ, which suggest that the products are slightly more stable than reactants.

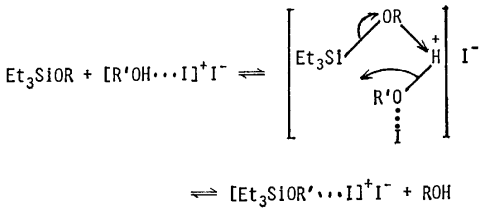
The K values of reaction systems associated with secondary alkoxyl groups are considerably less than unity (entries 5,9,10,12), so that the reverse reactions are spontaneous. Therefore, the alkoxyl groups with a side chain in the α-carbon appear to be attached more loosely to silicon than are the primary alkoxyl groups.

Since tertiary alcohols react slowly with triethylethoxysilane, iodine monobromide was used to accelerate the reactions. The K values observed for these reactions were small, about 0.05. (entries 6,11) These small values may be attributed to the steric hindrance of tertiary alkoxyl groups in the triethylalkoxysilanes.

The equilibrium constants determined at 20 °C and 40 °C were virtually the same, as shown in Table 1, so that the enthalpy changes in these reactions appear to be very small.

Proposed Reaction Mechanism. For the base-catalyzed alcoholysis of alkoxysilanes, some mechanisms with five- or six-coordinate intermediates have been proposed.[2,8,9] However, in the case of iodine- or iodine monobromide-catalyzed alcoholysis, a mechanism *via* a four-centered transition state as given below seems to be most suitable.

Iodine or iodine monobromide forms charge transfer complexes with alcohols,[13] and also with alkoxysilanes,[12] and hence the dative form of the complexes, *e.g.* $[R'OH\cdots I]^+I^-$ or $[Et_3SiOR\cdots I]^+I^-$, may be regarded as the reaction intermediate. In addition, alkoxysilane–alcohol complexing has been suggested,[14] so that the four-centered transition states are still more readily formed. The following mechanism may be derived.



or

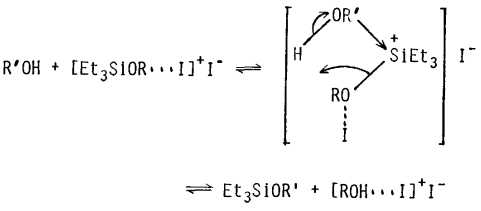
a) Mean value of equilibrium constants of both forward and reverse reactions.



Experimental

General Procedure. In a reaction vessel (volume about 5 cm^3) with a sealing-cap, measured amounts of triethylalkoxysilane and alcohol were placed. Molar ratios of alkoxysilanes to alcohols in the reaction mixtures were in the range of 1:0.5 to 1:6. I_2 or IBr was added to the reaction mixtures as the solution in each alcohol. The reaction was promoted using about 0.001 (mole fraction) of catalyst.

Each reaction mixture thus prepared was divided into two or three parts and maintained in a thermostat set at (20.0±0.1) °C or (40.0±0.1) °C. One of them was used to monitor the time course of the reaction until the composition became constant. The others were then used to determine the equilibrium composition.

Analysis. Analyses were performed by means of GLPC using a Shimadzu model GC-4B gas chromatograph with a thermal conductivity detector. The stationary phases of the packings used in this investigation were as follows:

PEG 4000+SPAN 80 (entries 1,8 in Table 1), SPAN 80 (entries 2,4,5,7,13), PEG 1000+DOP-B (entry 3), PEG 4000 (entry 6), PEG 6000 (entries 9,10), PEG 1000 (entry 11), SPAN 80+PEG 6000 (entry 12).

Reagents. Triethylmethoxysilane and triethylethoxysilane were prepared by the reaction of tetramethoxysilane or tetraethoxysilane with ethylmagnesium bromide. The other triethylalkoxysilanes were prepared by iodine or iodine monobromide-catalyzed alcoholysis of triethylethoxysilane. After the resulting ethanol and excess alcohol had been removed by distillation, each triethylalkoxysilane was obtained by fractional distillation. These triethylalkoxysilanes were purified by repeated fractional distillation, and the following compounds were prepared.

Et_3SiOMe, Et_3SiOEt, Et_3SiOPr^n, Et_3SiOPr^i, Et_3SiOBu^n, Et_3SiOBu^i, Et_3SiOBu^s, Et_3SiOBu^t, $Et_3SiOC_5H_{11}{}^n$, $Et_3SiOC_5H_{11}{}^i$, $Et_3SiOC_5H_{11}{}^t$, $Et_3SiOCHMePr^n$: bp 205.1 °C; n_D^{20} 1.4243; ^{13}C NMR (neat) δ=4.78 (t, 3C), 6.22 (q, 3C), 13.58 (q), 18.48 (t), 23.31 (q), 41.96 (t), 67.63 (d). Found: C, 65.04; H, 13.25%. Calcd for $C_{11}H_{26}SiO$: C, 65.27; H, 12.95%. $Et_3SiOCHEt_2$: bp 206.2 °C; n_D^{20} 1.4272; ^{13}C NMR (neat) δ=4.88 (t, 3C), 6.27 (q, 3C), 8.83 (q, 2C), 28.94 (t, 2C), 74.12 (d). Found: C, 65.08; H, 13.25%. Calcd: C, 65.27; H, 12.95%.

The last two alkoxysilanes are unreported compounds, while the boiling points and refractive indices of the others were virtually identical with the reported values.[4]

The alcohols were purified by fractional distillation. Methanol, ethanol, 1- and 2-propanol were previously freed from water by refluxing with magnesium or magnesium activated with iodine. *t*-Butyl alcohol was repeatedly recrystallized after distillation.[15]

Iodine was purified by repeated sublimation with calcium oxide and potassium iodide. Iodine monobromide was prepared and purified by recrystallization.[12]

The authors wish to thank professor Makoto Kumada of Kyoto University and Dr. Kenzo Hirayama for their kind advice and encouragement. We also would

like to thank professor Toshiyuki Shono of Osaka University and his co-workers for the elemental analyses and for the NMR spectral data.

Alkylation of Benzothiazolines and the Stevens Rearrangement of the Resulting 2,3,3-Trisubstituted Benzothiazolinium Salts

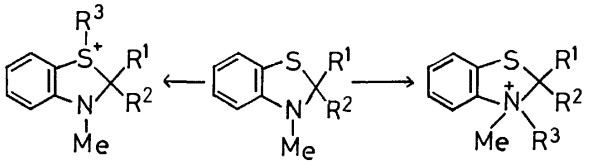
Kin-ya Akiba,† Yoshio Ohara, and Naoki Inamoto*
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received January 26, 1982)

Alkylation of 2-substituted 3-methyl- or 3-ethylbenzothiazolines with Meerwein reagents gave 2-substituted 3,3-dialkylbenzothiazolinium tetrafluoroborates (**3**). The configuration of two alkyl groups on the nitrogen was assigned by NMR spectra and NOE measurement. In the Stevens rearrangement of **3** with lithium diisopropylamide ethyl group showed a much larger migratory aptitude (Et:Me≧20:1) than methyl group irrespective of the configuration of **3**, and cyclic ammonium ylide with planar π-type carbanion was proposed as an intermediate. **3** suffered nucleophilic attack at the ring sulfur atom by butyllithium to afford a ring-opened ammonium ylide, which collapses to a radical pair to give unusual Stevens rearrangement product, where *o*-alkylthiophenyl group migrated selectively in preference to alkyl group, because of stabilization by participation of *o*-alkylthio group.

In an alkylation of a compound containing two hetero atoms such as sulfur and nitrogen, the position of alkylation is dependent on the structure of the compound and the kind of alkylating reagent.

For example, dimorpholino sulfide undergoes *S*-ethylation with triethyloxonium tetrafluoroborate, while it gives *N,N*-dimethylmorpholinium salt with methyl iodide.[1] 1-Pyrrolidinyl *p*-tolyl sulfoxide undergoes *O*-methylation with methyl trifluoromethanesulfonate,[2] and *S*-methyl-*S*-phenylsulfoximine[3] and 2-anilino-3-methylthio-1,4-naphthoquinone[4] *N*- and *S*-methylations with trimethyloxonium tetrafluoroborate, respectively.

In the benzothiazolines (**1**), it is also possible in their alkylation to give thionia (**2**) or azonia compound (**3**), but **3** was obtained in alkylation with Meerwein reagents.[5] Independently, Hori *et al.*[6] reported that **1** suffers *N*-methylation both with trimethyloxonium tetrafluoroborate (**4a**) and methyl iodide, but 2,2,3-trimethylbenzothiazoline *S*-methylation with methyl iodide.



2 1 3

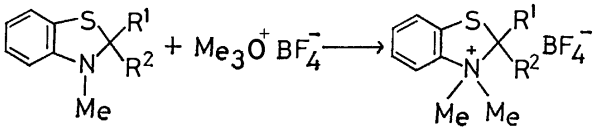
Moreover, it is well known that the quaternary ammonium salts undergo Stevens rearrangement[7] with bases *via* ammonium ylide[8] stereospecifically[9] in intramolecular manner.[10] Because of observation of CIDNP,[11] it is generally accepted that Stevens rearrangement involves a radical pair which recombines in a solvent cage. On the other hand, Dewar[12] have suggested that concerted S_Ni type mechanism, which is forbidden according to the Woodward-Hoffmann rule, is energetically not so unfavorable in gas phase based on the MINDO/3 calculation.

Therefore, we carried out the Stevens rearrangement of **3** (R^1=H, R^3≠Me) of a definite configuration with lithium diisopropylamide (LDA) or butyllithium in order to investigate the steric course and the migratory aptitude.[13]

This paper describes on alkylation of **1**, the structure of the resulting salts (**3**), and their Stevens rearrangement in detail.

Results and Discussion

Methylation of 3-Methylbenzothiazolines (1). Methylation of **1** with **4a** gave 3,3-dimethylbenzothiazolinium salts (**3**). The results are shown in Table 1.



1 4a 3

The structure of **3** was easily determined by NMR. The salts (**3a—e**), where the 2-position is asymmetric, show two methyl signals with an equal intensity at δ 3.1 and 3.7 ppm region. Although these two signals may be assigned to *S*- and *N*-methyl groups of the thionia compound (**2**), they should be assigned to the dimethylammonio group because no spectral change could be observed by addition of excess trifluoroacetic acid (TFA) to **3c** and **3e**. The conclusion was confirmed by the fact that **3f** and **3g** which bear the same two substituents at 2-C show a single methyl peak and no spectral change could be also observed by addition of excess TFA.

The chemical shifts of the lower field methyl of **3a—e** are almost constant (δ 3.7). On the other hand, these of the higher field methyl are constant for **3a—d** (δ 3.12), but a distinct shift to lower field is observed for **3e** (R^2=Me). Hence, it can be concluded that the lower field methyl is assigned to lie *syn* to 2-C–H and the higher field methyl *syn* to 2-C–R. The assignement was supported by NOE measurement (*vide infra*).

From the filtrate in the recrystallization of **3c** obtained by the reaction of **1c** with **4a**, *N*-methyl-*o*-methylthioaniline (10%) and its hydrotetrafluoroborate

† Present address: Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730.

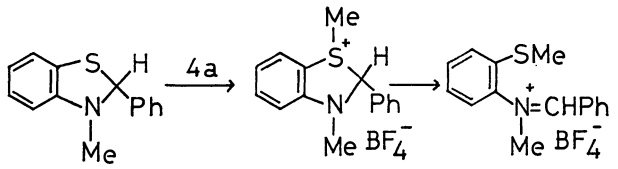
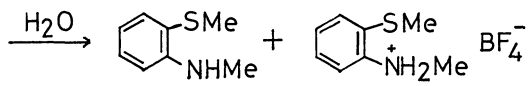
3g	Me	Me	72	177—178.5	—	3.53

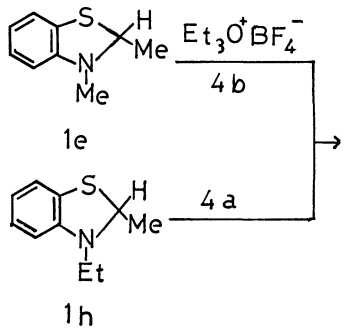
(4.5%) were isolated. These products are probably due to decomposition of *S*-methylated product, because Hori *et al.*[6] have reported isolation of **X** type salt in the methylation of **1g** ($R^1=R^2=Me$) with methyl iodide.

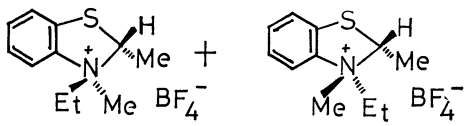


1c X



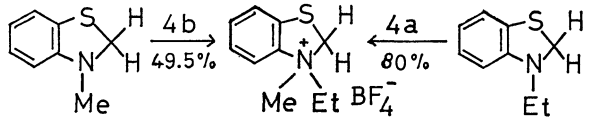
Alkylation of 3-Alkylbenzothiazolines. Ethylation of 2,3-dimethylbenzothiazoline (**1e**) with triethyloxonium tetrafluoroborate (**4b**) gave a diastereomeric mixture of **5A** and **5B** (**5A**/**5B**=*ca.* 10) in 61% yield, and methylation of 3-ethyl-2-methylbenzothiazoline (**1h**) with **4a** gave a mixture of the same salts (**5A**/**5B**=*ca.* 2) in 43% yield. The pure isomer **5A** could be isolated by repeated recrystallizations of the reaction mixture from **1e**.





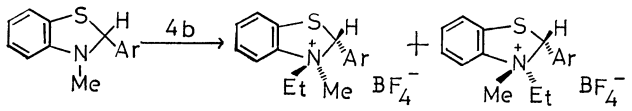
5A 5B

The salt (**6**) obtained by ethylation of 3-methylbenzothiazoline (**1f**) showed identical NMR spectrum with that obtained by methylation of 3-ethyl derivative (**1i**), confirming the structure **6**.



1f 6 1i

Ethylation of **1a—d** with **4b** gave a mixture of **7A** and **7B**. The results are summarized in Table 2.



1a-d 7A 7B

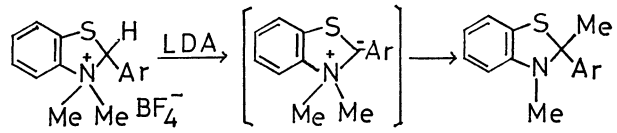
Since in these cases purification of the salts by recrystallization was considerably difficult, the isolated yields were relatively low. But pure **A** type of isomers could be isolated in the cases of **7c** and **7d** by repeated recrystallizations.

Methylations of 3-ethyl-2-phenyl-(**1j**), 2,2-diethyl-3-methyl-(**1k**), 2,3-dimethyl-2-phenyl-(**1l**), and 2-t-butyl-3-phenylbenzothiazolines (**1m**) with **4a** gave only tarry materials which may be decomposition products *via* *S*-methylation, but further identification was not done.

On the other hand, reaction of **1c** with benzyl chloride in the presence of silver perchlorate gave 3-methyl-2-phenylbenzothiazolium perchlorate (**8**), which was also obtained in the reaction with only silver perchlorate.

Determination of Stereochemistry by NOE Measurement. In order to confirm the stereochemistry of **3** and **5**, the NOE measurement was performed. In the NMR spectra of **3c**, **3e**, and **5A**, the increase of intensities of 2-H was observed on irradiation of the alkyl groups on the nitrogen atom resonating at lower field, while little change was observed on irradiation of the substituent resonating at higher field as shown in Table 3, supporting the before-mentioned conclusion.

Reactions of 3a—d and 7 with LDA. Reactions of **3a—d** with LDA in ether or tetrahydrofuran (THF) at −50 °C gave 2-aryl-2,3-dimethylbenzothiazolines (**9a—d**) as product due to Stevens rearrangement through a cyclic ammonium ylide (**10**). The results are summarized in Table 4.



3a-d 10 9a-d

Table 2. Ethylation products (**7A** and **7B**) from **1a—d**

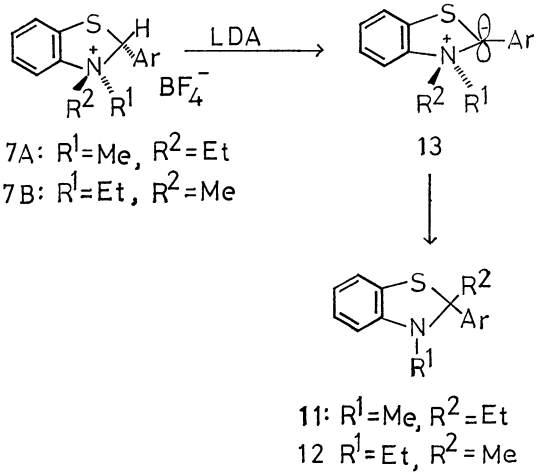
Salt	Irradiated group (δ)	Relative intensity of C_2-H/%
3c	3.71 (*N*-Me)	128±1
	3.11 (*N*-Me)	99±1
3e	3.73 (*N*-Me)	140±2
	3.35 (*N*-Me)	111±2
	1.86 (2-Me)	98±1
5A	3.8—4.3 (*N*-CH_2)	120±2
	3.41 (*N*-Me)	105±1
	1.78 (2-Me)	97±1

The salts (**3**) where the 2-substituent is an alkyl group was mostly recovered under the same conditions, probably because of much lower acidity of the 2-H.

The salts (**7A** and **7B**) should be very suitable models to study the stereochemical relation between the migratory group and the carbanion of the ylide, if the anion retains sp^3 type. If the migration occurs *via* concerted S_Ni type mechanism, **7A** and **7B** should give 2-aryl-2-ethyl-3-methyl-(**11**) and 2-aryl-3-ethyl-2-methylbenzothiazolines (**12**), respectively.



As was expected, reactions of pure **7cA** and **7dA** with LDA gave only **11** in 22 (in ether) and 33% (in THF) yields, respectively, and no **12** could be detected by NMR and GLC. However, a similar reaction of a 1:1 mixture of **7aA** and **7aB** or **7bA** and **7bB** in THF gave also only the corresponding **11** in 54 and 30% yields, respectively, being inconsistent with concerted S_Ni type mechanism. These facts indicate that ethyl group migrates exclusively irrespective of the stereochemistry of the starting salt.

In order to realize these phenomena, it is necessary to invoke not only a planar carbanion (**13**) conjugated with the aryl group as the intermediate, because inversion of sp^3 type carbanion is known to be slow enough to retain its configuration,[14] but also a preferential migration of ethyl group than methyl group.

Furthermore, in order to examine the difference of the migratory aptitudes of ethyl and methyl groups in general, benzylethylmethylphenylammonium tetrafluoroborate (**14**) was allowed to react with butyllithium to give **15**—**17** whose yields were estimated by GLC as shown below.

	14	**15**	**16**	**17**	**18**
in Et_2O		34%	6%	20%	—
in THF		35%	6%	12%	—

The compounds, **15** and **16**, are products due to decomposition of ylides resulting by deprotonation of the ethyl and the methyl groups, respectively, and **17** is the product resulting from the migration of the ethyl group. The product **18** due to methyl migration could not be detected.

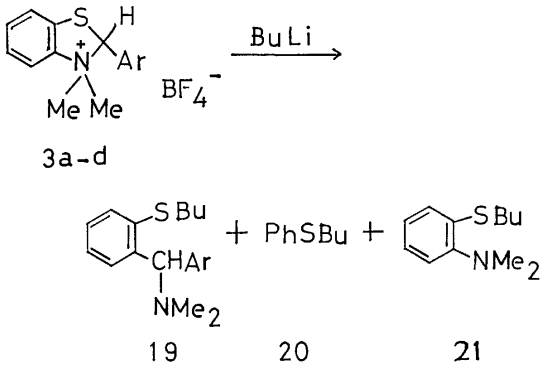
Judged from the sensitivity of glc, the ratio of migratory aptitude of ethyl group to that of methyl group is estimated to be more than 20. This value is nearly consistent with that for Wittig rearrangement (Et/Me=39)[15] which is generally accepted to proceed by radical pair mechanism as in Stevens rearrangement. Therefore, the remarkable difference between the migratory aptitudes of the ethyl and the methyl groups

Table 4. Yields of Stevens rearrangement products

3	Ar	With LDA		With BuLi		
		9(in Et_2O)/%	**9**(in THF)/%	**19**/%	**20**/%	**21**/%
a	*p*-$MeOC_6H_4$	14	20	33	12	8
b	*p*-MeC_6H_4		47	27		
c	C_6H_5	45	41	38	14	6
d	*p*-ClC_6H_4	59	62	13		

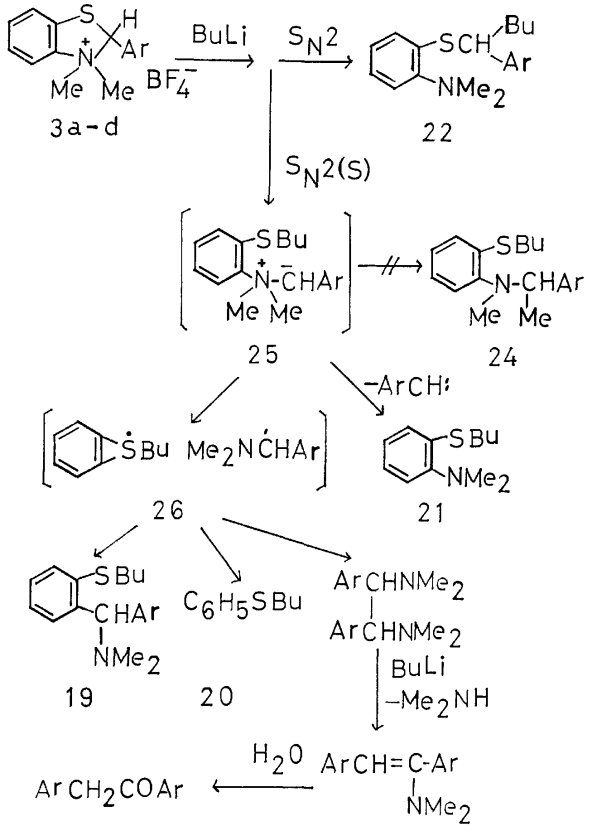
should be attributed to the radical stability in the radical pair during Stevens rearrangement.[16]

Reactions of 3a—d with Butyllithium. Reactions of **3a—d** with butyllithium in ether at −50 °C followed quite different course and gave butyl *o*-(α-dimethylaminobenzyl)phenyl sulfide derivatives (**19**) together with butyl phenyl sulfide (**20**) and *o*-butylthio-*N,N*-dimethylaniline (**21**). The results were shown in Table 4. The structure of **19** was determined by unequivocal synthesis of **19c** (see Experimental).



In the case of **3a**, *o*-[1-(*p*-methoxyphenyl)pentylthio]-*N,N*-dimethylaniline (**22**) (4%) was also obtained, and in the case of **3c**, *o*-butylthio-*N*-methylaniline (**23**) (6%) and benzyl phenyl ketone (3%) were also obtained.

A plausible reaction scheme is depicted as shown in Scheme 1.

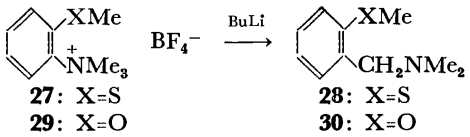


Scheme 1.

The normal product (**9**) derived from cyclic ammonium ylide (**10**) could not be obtained at all in contrast with the reaction with LDA. Formation of **19** can be rationalized by the formation of a ring-opened ammonium ylide (**25**) which then collapses to a radical pair (**26**) or decomposes to give **21** and arylcarbene. The radical pair (**26**) recombines to give **19** and also can afford **20** as an escape product. The starting salt (**3a—d**) is also attacked by butyllithium at the 2-position to a small extent to give **22**.

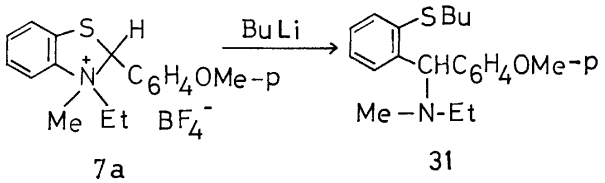
The most interesting point is that the product is not **24** but **19**, although an expected Stevens rearrangement product is **24**, because of higher migratory aptitude of alkyl groups than that of aryl groups in Stevens rearrangement.[7] However, **19** is the product due to migration of *o*-butylthiophenyl group.

The reason for this unusual aryl migration can be ascribed to participation of the adjacent sulfur atom in stabilizing the aryl radical as shown in **26**. This possibility was supported by reference reaction of trimethyl[*o*-(methylthio)phenyl]ammonium tetrafluoroborate (**27**) to give *N,N*-dimethyl-*o*-(methylthio)benzylamine (**28**) due to aryl migration as a major product (22%) under the same conditions, while *o*-methoxyphenyltrimethylammonium salt (**29**) did not give **30** under the same conditions.



A similar attack on the divalent sulfur atom by butyllithium has been reported in the reactions of 1-methyl-2-nitrosoimino-1,2-dihydrobenzothiazole[17] and diphenylphosphinodithioate esters.[18]

A similar reaction of **7a** gave **31** as a mian product (11%).



When there is no aryl group at 2-C, a similar reaction gave a complicated mixture and product such as **19** was not obtained.

Experimental

All the melting and boiling points are not corrected. IR spectra were measured with a Hitachi EPI-G2 spectrophotometer, ^{1}H NMR spectra with Hitachi R-24B and R-20B spectrometers using TMS as an internal standard, and MS and high-resolution MS (HMS) with Hitachi RMU-6L and JEOL D-300 mass spectrometers at 70 V, respectively.

Materials. Trimethyl-(**4a**)[19] and triethyloxonium tetrafluoroborates (**4b**),[20] 2,2,3-trimethyl-(**1g**),[21] 2,3-dimethyl-2-phenyl-(**1l**=**9c**),[22] and 2-*t*-butyl-3-phenylbenzothiazolines (**1m**)[23] were prepared according to the reported methods.

Syntheses of Benzothiazolines (1) by Grignard Reaction.[24] *General Procedure*: To a suspension of 3-methyl-(**32a**),[25] 3-ethyl-(**32b**),[21] or 3-methyl-2-methylthiobenzothiazolium io-

dide (**32c**)[22] (0.1 mmol) in ether (90—120 ml) was added dropwise an appropriate Grignard reagent (0.11—0.12 mmol) in ether (90—200 ml), filtered through a tube with glass wool, under nitrogen at −40 °C. The mixture was stirred at room temp for several hours and then refluxed for 0.5 h. The reaction mixture was washed with aq NH_4Cl and the ethereal layer was dried ($MgSO_4$). The solvent was evaporated *in vacuo* and the residue was recrystallized from ethanol, distilled, or purified by column chromatography (CC) (SiO_2, C_6H_6).

*2-(p-Methoxyphenyl)-3-methylbenzothiazoline (**1a**)*: 34% yield from **32a**, pale yellow crystals, mp 106.5—108.5 °C; NMR ($CDCl_3$): δ 2.58 (s, 3H), 3.79 (s, 3H), 5.94 (s, 1H), and 6.25—7.75 (m, 8H). Found: C, 69.87; H, 5.60; N, 5.52%. Calcd for $C_{15}H_{15}NOS$: C, 70.00; H, 5.87; N, 5.44%.

*3-Methyl-2-p-tolylbenzothiazoline (**1b**)*: 68% yield from **32a**, pale yellow crystals, mp 86—89 °C; NMR ($CDCl_3$) : δ 2.37 (s, 3H), 2.64 (s, 3H), 5.99 (s, 1H), and 6.3—7.6 (m, 8H). Found: C, 74.90; H, 6.11; N, 5.82%. Calcd for $C_{15}H_{15}NS$: C, 74.65; H, 6.26; N, 5.80%.

*3-Methyl-2-phenylbenzothiazoline (**1c**)*: 72% yield from **32a**, pale yellow crystals, mp 112—114 °C (lit,[25] 112—113 °C).

*2-(p-Chlorophenyl)-3-methylbenzothiazoline (**1d**)*: 55% yield from **32a**, colorless crystals, mp 77—79 °C; NMR ($CDCl_3$): δ 2.65 (s, 3H), 5.99 (s, 1H), and 6.35—7.7 (m, 8H). Found: C, 64.01; H, 4.80; N, 5.25%. Calcd for $C_{14}H_{12}NSCl$: C, 64.24; H, 4.62; N, 5.35%.

*2,3-Dimethylbenzothiazoline (**1e**)*: 67% yield from **32a**, pale yellow oil, bp 69 °C/0.2 mmHg (1 mmHg=133.322 Pa) (lit,[21] 120—121 °C/10 mmHg).

*3-Ethyl-2-methylbenzothiazoline (**1h**)*: 27% yield from **32b**, yellow oil, bp 95 °C/0.2 mmHg; NMR ($CDCl_3$): δ 1.15 (t, J=6 Hz, 3H), 1.53 (d, J=6 Hz, 3H), 3.21 (br q, J=7 Hz, 2H), 5.23 (q, J=6 Hz, 1H), and 6.2—7.2 (m, 4H). Found: C, 67.27; H, 7.25; N, 7.71%. Calcd for $C_{10}H_{13}NS$: C, 67.00; H, 7.31; N, 7.81%.

*3-Ethyl-2-phenylbenzothiazoline (**1j**)*: 33% yield from **32b**, yellow oil, bp 120 °C/0.25 mmHg; NMR ($CDCl_3$): δ 1.02 (t, J=7 Hz, 3H), 3.11 (m, 2H), 6.22 (s, 1H), and 6.3—7.7 (m, 9H). Found: C, 74.50; H, 6.42; N, 5.63%. Calcd for $C_{15}H_{15}NS$: C, 74.65; H, 6.26; N, 5.80%.

*2,2-Diethyl-3-methylbenzothiazoline (**1k**)*: 83% yield from **32c**, yellow oil;[26] NMR ($CDCl_3$): δ 0.95 (t, J=7 Hz, 6H), 1.82 (br q, J=7 Hz, 4H), 2.65 (s, 3H), and 6.0—7.1 (m, 4H).

*3-Methylbenzothiazoline (**1f**).* To **32a** (3.31 g, 11.9 mmol) in THF (80 ml), $NaBH_4$ (487 mg, 12.9 mmol) was added portionwise at −10 °C. The solution was stirred for 2 h at room temp, and usual work-up gave yellow oil (0.724 g, 40%); bp 90 °C/0.1 mmHg (lit,[25] 133 °C/11 mmHg).

*3-Ethylbenzothiazoline (**1i**)* was prepared from **32b** by a similar method to that of **1f** as pale yellow oil in 65% yield; bp 81 °C/0.1 mmHg; NMR ($CDCl_3$): δ 1.28 (t, J=7 Hz, 3H), 3.18 (q, J=7 Hz, 2H), 4.65 (s, 2H), and 6.3—7.1 (m, 4H). Found: C, 65.63; H, 6.60; N, 8.34%. Calcd for $C_9H_{11}NS$: C, 65.41; H, 6.60; N, 8.34%.

*Alkylations of **1** with Meerwein Reagents (**4**). General Procedure*: To **1** (7 mmol) in CH_2Cl_2 (20—30 ml) was added a slightly excess of **4a** or **4b**. After stirring at room temp for several hours, the reaction was quenched with a few ml of ethanol. The solvent was evaporated *in vacuo*, the residue was washed well with dry ether, and recrystallized to give colorless crystals unless otherwise noticed. The NMR spectra were determined in DMSO-d_6.

Methylation: **3a**: yield 69%, mp 165—167 °C (decomp) (from CH_2Cl_2–Et_2O); NMR: δ 3.12 (s, 3H), 3.65 (s, 3H), 3.87 (s, 3H), 6.94 (s, 1H), and 7.0—8.1 (m, 8H). Found: C, 53.31; H, 5.10; N, 3.73%. Calcd for $C_{16}H_{18}BF_4NOS$: C, 53.50; H, 5.05; N, 3.90%.

3b: pale yellow crystals, yield 59%, mp 195—197 °C (decomp) (from MeOH–Et_2O); NMR: δ 2.42 (s, 3H), 3.10 (s, 3H), 3.66 (s, 3H), 6.94 (s, 1H), and 7.2—8.1 (m, 8H). Found: C, 55.38; H, 5.16; N, 3.99%. Calcd for $C_{16}H_{18}BF_4NS$: C, 56.00; H, 5.29; N, 4.08%.

3c: yield 69%, mp 178.5—180.5 °C (decomp) (from MeOH–Et_2O); NMR: δ 3.11 (s, 3H), 3.71 (s, 3H), 6.99 (s, 1H), and 7.4—8.1 (m, 9H). Found: C, 54.50; H, 5.00; N, 4.11%. Calcd for $C_{15}H_{16}BF_4NS$: C, 54.73; H, 4.90; N, 4.26%. After collection of **3c**, the filtrate and washings were evaporated to be subjected to CC (SiO_2, CH_2Cl_2). *N*-Methyl-*o*-methylthioaniline[6] (IR (neat): 3360 cm^{-1} (NH); NMR ($CDCl_3$): δ 2.17 (s, 3H), 2.70 (s, 3H), 4.76 (br s, 1H), 6.3—6.8, and 6.95—7.45 (m, 4H)) and its hydrotetrafluoroborate (NMR: δ 2.47 (s, 3H), 2.97 (s, 3H), 7.0—7.7 (m, 4H), and 8.01 (br s, 2H)) were obtained in 10 and 4.5% yields, respectively. The NMR spectrum of the latter was in agreement with that of authentic sample obtained from *N*-methyl-*o*-methylthioaniline and tetrafluoroboric acid.

3d: yield 70%, mp 196—197 °C (decomp) (from EtOH–Et_2O); NMR: δ 3.17 (s, 3H), 3.71 (s, 3H), 7.00 (s, 1H), and 7.4—8.1 (m, 8H). Found: C, 49.65; H, 4.05; N, 3.59%. Calcd for $C_{15}H_{15}BClF_4NS$: C, 49.55; H, 4.16; N, 3.85%.

3e: yield 66%, mp 117.5—119.0 °C (decomp) (from CH_2Cl_2–Et_2O); NMR: δ 1.86 (d, J=7 Hz, 3H), 3.35 (s, 3H), 3.73 (s, 3H), 5.81 (q, J=7 Hz, 1H), and 7.3—8.0 (m, 4H). Found: C, 45.24; H, 5.42; N, 5.24%. Calcd for $C_{10}H_{14}BF_4NS$: C, 44.97; H, 5.28; N, 5.24%.

3f: yield 77%, mp 172—173.5 °C (decomp) (from EtOH–Et_2O); NMR: δ 3.62 (s, 6H), 5.34 (s, 2H), and 7.3—8.0 (m, 4H). Found: C, 42.55; H, 4.69; N, 5.71%. Calcd for $C_9H_{12}BF_4NS$: C, 42.72; H, 4.78; N, 5.53%.

3g: yield 71.5%, mp 177—178.5 °C (decomp) (from CH_2Cl_2); NMR: δ 1.95 (s, 6H), 3.55 (s, 6H), and 7.4—8.1 (m, 4H). Found: C, 47.22; H, 5.84; N, 5.27%. Calcd for $C_{11}H_{16}BF_4NS$: C, 47.00; H, 5.74; N, 4.98%.

5 (from **1h**): recryst from EtOH–Et_2O, yield 43% (**5A**/**5B**=*ca.* 2) (see below).

6 (from **1i**): recryst from EtOH–Et_2O, yield 80% (see below).

Ethylation: **5** (from **1e**): yield 61% (**5A**/**5B**=*ca.* 10); NMR: **5A**: δ 1.24 (t, J=7 Hz, 3H), 1.78 (d, J=7.5 Hz, 3H), 3.41 (s, 3H), 3.8—4.3 (m, 2H), 5.81 (q, J=7.5 Hz, 1H), and 7.3—8.0 (m, 4H); **5B**: δ 1.15 (t, J=7 Hz, 3H), 1.91 (d, J=7.5 Hz, 3H), 3.65 (s, 3H), 3.8—4.3 (m, 2H), *ca.* 5.9 (q, J=7.5 Hz, 1H), and 7.3—8.3 (m, 4H). Pure **5A**: mp 160—161.5 °C (decomp) (three times from CH_2Cl_2). Found: C, 47.12; H, 6.01; N, 5.25%. Calcd for $C_{11}H_{16}BF_4NS$: C, 47.00; H, 5.74; N, 4.98%.

6 (from **1f**): yield 49.5%, mp 93.5—95.0 °C (decomp) (from EtOH–Et_2O); NMR: δ 1.40 (t, J=7 Hz, 3H), 3.62 (s, 3H), 4.02 (dq, J=7 Hz and 2 Hz, 2H), 5.31 (s, 2H), and 7.2—7.9 (m, 4H). Found: C, 44.98; H, 5.23; N, 5.32%. Calcd for $C_{10}H_{14}BF_4NS$: C, 44.97; H, 5.28; N, 5.24%.

7aA+**7aB**: pale yellow crystals, yield 39%, mp 145.5—149.5 °C (from CH_2Cl_2–Et_2O) (**A**/**B**=*ca.* 1); NMR: **7aA**: δ 1.42 (t, J=7 Hz, 3H), 3.10 (s, 3H), 3.5—4.2 (m, 2H), 6.86 (s, 1H), and 6.95—8.0 (m, 8H); **7aB**: δ 1.09 (t, J=7 Hz, 3H), 3.53 (s, 3H), 3.5—4.5 (m, 2H), and 6.95—8.0 (m, 9H). Found (mixture): C, 54.65; H, 5.48; N, 3.71%. Calcd for $C_{17}H_{20}BF_4NOS$: C, 54.71; H, 5.40; N, 3.75%.

7bA+**7bB**: pale yellow crystals, yield 37%, mp 158—161 °C (**A**/**B**=*ca.* 1); NMR: **7bA**: δ 1.46 (t, J=7 Hz, 3H),

3.11 (s, 3H), 3.5—4.5 (m, 2H), 6.80 (s, 1H), and 7.2—8.0 (m, 8H); **7bB**: δ 1.13 (t, J=7 Hz, 3H), 3.57 (s, 3H), 3.5—4.5 (m, 2H), 7.07 (s, 1H), and 7.2—8.0 (m, 8H). Found (mixture): C, 57.43; H, 5.86; N, 4.09%. Calcd for $C_{17}H_{20}BF_4NS$: C, 57.16; H, 5.64; N, 3.92%.

7cA+**7cB**: yield 34% (**A**/**B**=*ca.* 10); NMR: **7cA**: δ 1.43 (t, J=7 Hz, 3H), 3.12 (s, 3H), 3.5—4.5 (m, 2H), 6.93 (s, 1H), and 7.4—8.0 (m, 9H); **7cB**: δ 1.08 (t, J=7 Hz, 3H), 3.57 (s, 3H), 3.5—4.5 (m, 2H), 7.17 (s, 1H), and 7.4—8.0 (m, 9H). Pure **7cA**: mp 144—145 °C (decomp) (three times from EtOH-Et_2O). Found: C, 55.76; H, 5.42; N, 3.91%. Calcd for $C_{16}H_{18}BF_4NS$: C, 56.00; H, 5.29; N, 4.08%.

7dA+**7dB**: pale yellow crystals (from CH_2Cl_2-Et_2O) (**A**/**B**=*ca.* 10), yield 35%; NMR: **7dA**: δ 1.42 (t, J=7 Hz, 3H), 3.17 (s, 3H), 3.7—4.6 (m, 2H), 6.89 (s, 1H), and 7.3—8.0 (m, 8H); **7dB**: δ 1.09 (t, J=7 Hz, 3H), 3.58 (s, 3H), 3.7—4.6 (m, 2H), 7.17 (s, 1H), and 7.3—8.0 (m, 8H). Pure **7dA**: mp 139—141 °C (three times from CH_2Cl_2-Et_2O). Found: C, 51.00; H, 4.38; N, 4.00%. Calcd for $C_{16}H_{17}BClF_4NS$: C, 50.89; H, 4.54; N, 3.71%.

Reaction of ***1c*** *with Silver Perchlorate.* 3-Methyl-2-phenylbenzothiazoline (**1c**) (1.1 g, 4.87 mmol) was subjected to the reaction with $AgClO_4$ (1.01 g, 4.89 mmol) in CH_2Cl_2 (20 ml) and $MeNO_2$ (10 ml). After usual work-up, recrystallization from MeOH gave **8** quantitatively, mp 219—223 °C (lit,[27] 219—220 °C).

Reactions of ***3a—d*** *and* ***7*** *with LDA. General Procedure*: To a suspension of the salt (**3a—d** and **7**) (1 mmol) in THF (5 ml) or ether (20 ml) at −40 °C was added LDA (1.1—2 mmol) in THF (5 ml) or ether (5 ml) under nitrogen. The mixture was stirred for 0.5 h at this temp, for 1.5 h at room temp, and then slightly heated. After removal of the solvent *in vacuo* and addition of water, the reaction mixture was extracted with ether. The ethereal layer was dried ($MgSO_4$) and evaporated to be subjected to dry column chromatography (DCC) (**9a**: SiO_2, CCl_4-CH_2Cl_2 (4:1); **9b**: SiO_2, CCl_4-CH_2Cl_2 (10:1); **9c**: SiO_2, CCl_4; **9d**: SiO_2, CCl_4-CH_2Cl_2 (3:1); **11a** and **11b**: SiO_2, hexane-Et_2O (3:1); **11c**: SiO_2, hexane-Et_2O (10:1); **11d**: SiO_2, CCl_4). The results were shown in Table 4 and in the text. These products were identified by a comparison of NMR spectra with authentic samples prepared independently (see below).

Independent Syntheses of ***9***, ***11***, *and* ***12***. *General Procedure*: To a suspension of 2-aryl-3-ethyl- or -3-methylbenzothiazolium perchlorate[27] (5 mmol) in ether (25—70 ml) at −40 °C was added an ethereal solution of Grignard reagent (8.5—10 mmol) under nitrogen. The mixture was stirred for several hours at room temp. After usual work-up, the residue was subjected to DCC (SiO_2, C_6H_6) to give **9** (as colorless crystals), **11** (as yellow viscous oil), and **12**.

9a: yield 68%, mp 58.5—59.5 °C (from EtOH); NMR ($CDCl_3$): δ 1.90 (s, 3H), 2.49 (s, 3H), 3.68 (s, 3H), and 6.1—7.6 (m, 8H). Found: C, 70.58; H, 6.47; N, 5.22%. Calcd for $C_{16}H_{17}NOS$: C, 70.81; H, 6.31; N, 5.16%.

9b: yield 61%, mp 104—105 °C (from EtOH); NMR ($CDCl_3$): δ 1.92 (s, 3H), 2.30 (s, 3H), 2.54 (s, 3H), and 6.1—7.6 (m, 8H). Found: C, 75.04; H, 6.65; N, 5.38%. Calcd for $C_{16}H_{17}NS$: C, 75.25; H, 6.71; N, 5.48%.

9d: yield 84%, mp 95.5—96.5 °C (from EtOH-hexane); NMR ($CDCl_3$): δ 1.95 (s, 3H), 2.55 (s, 3H), and 6.15—7.65 (m, 8H). Found: C, 65.27; H, 5.03; N, 5.25%. Calcd for $C_{15}H_{14}ClNS$: C, 65.32; H, 5.12; N, 5.08%.

11a: yield 68%; NMR ($CDCl_3$): δ 1.05 (t, J=7 Hz, 3H), 2.29 (q, J=7 Hz, 2H), 2.57 (s, 3H), 3.73 (s, 3H), and 6.1—7.6 (m, 8H); HMS: Found: *m/e* 285.1187. Calcd for $C_{17}H_{19}NOS$: 285.1187.

11b: yield 97%; NMR ($CDCl_3$): δ 1.08 (t, J=7 Hz, 3H), 2.32 (s, 3H), 2.33 (q, J=7 Hz, 2H), 2.62 (s, 3H), and 6.15—7.55 (m, 8H). Found: C, 75.73; H, 7.11; N, 5.28%. Calcd for $C_{17}H_{19}NS$: C, 75.79; H, 7.11; N, 5.20%.

11c: yield 77.5%; NMR ($CDCl_3$): δ 1.10 (t, J=7 Hz, 3H), 2.33 (q, J=7 Hz, 2H), 2.61 (s, 3H), and 6.1—7.65 (m, 9H). HMS: *m/e* 255.1109. Calcd for $C_{16}H_{17}NS$: 255.1082.

11d: yield 95%, bp 164 °C/0.1 mmHg; NMR ($CDCl_3$): δ 1.05 (t, J=7 Hz, 3H), 2.26 (q, J=7 Hz, 2H), and 6.1—7.6 (m, 8H). Found: C, 66.05; H, 5.42; N, 5.03%. Calcd for $C_{16}H_{16}ClNS$: C, 66.31; H, 5.56; N, 4.83%.

12a: colorless crystals, yield 92%, mp 78—79 °C (from EtOH-hexane); NMR ($CDCl_3$): δ 1.05 (t, J=7 Hz, 3H), 1.96 (s, 3H), 2.94 (q, J=7 Hz, 2H), 3.68 (s, 3H), and 6.1—7.7 (m, 8H). Found: C, 71.61; H, 7.00; N, 5.00%. Calcd for $C_{17}H_{19}NOS$: C, 71.54; H, 6.71; N, 4.91%.

12b: yellow viscous oil, yield 78%; NMR ($CDCl_3$): δ 1.11 (t, J=7 Hz, 3H), 2.04 (s, 3H), 3.04 (q, J=7 Hz, 2H), and 6.25—7.75 (m, 9H). Found: C, 75.12; H, 6.72; N, 5.46%. Calcd for $C_{16}H_{17}NS$: C, 75.25; H, 6.71; N, 5.48%.

Reactions of ***3a—d*** *and* ***7*** *with Butyllithium. General Procedure*: To a suspension of the salt (**3a—d** and **7**) (2 mmol) in ether (20 ml) under nitrogen at −60 °C was added butyllithium (2.2—2.4 mmol) and the mixture was stirred for 5 h at room temp. After usual work-up, the residue was subjected to DCC and/or TLC.

Reaction of ***3a***: DCC (SiO_2, CH_2Cl_2) afforded two fractions, R_f 0.1—0.2 and 0.5—0.9. TLC (SiO_2, Et_2O) of the former gave pale yellow viscous oil (**19a**) in 32% yield. TLC (SiO_2, hexane-C_6H_6 (1:1)) of the latter fraction gave **20** (12%), **21** (8%), and **22** (4%) as pale yellow oils. **19a**: NMR ($CDCl_3$): δ 0.91 (br t, J=7 Hz, 3H), 1.2—1.8 (m, 4H), 2.19 (s, 6H), 2.65—3.0 (br t, J=7 Hz, 2H), 3.70 (s, 3H), 4.72 (s, 1H), and 6.65—7.9 (m, 8H); MS: *m/e* 329 (M^+, 40%), 314 (M^+−Me, 100), 285 (M^+−NMe_2, 37), 272 (M^+−Bu, 49), and 164 ($Me_2\overset{+}{N}CH$–C_6H_4OMe, 77). **20**: NMR ($CDCl_3$): δ 0.90 (br t, J=7 Hz, 3H), 1.1—1.9 (m, 4H), 2.90 (br t, J=7 Hz, 2H), and 7.0—7.5 (m, 5H). **21**: NMR ($CDCl_3$): δ 0.91 (br t, J=7 Hz, 3H), 1.2—1.9 (m, 4H), 2.7—3.1 (br t, J=7 Hz, 2H), 2.76 (s, 6H), and 6.8—7.4 (m, 4H); MS: *m/e* 209 (M^+, 62%), 153 (M^+−Bu+H, 100), 152 (M^+−Bu, 46), 137 (56), 136 (54), and 120 (M^+−SBu, 32). **22**: NMR ($CDCl_3$): δ 0.83 (br t, J=7 Hz, 3H), 1.1—1.5 (m, 4H), 1.7—2.2 (m, 2H), 2.77 (s, 6H), 3.76 (s, 3H), 4.33 (t, J=7.5 Hz, 1H), and 6.7—7.4 (m, 8H); MS: *m/e* 329 (M^+, 4%), 209 (M^+−$Me_2NC_6H_4$, 58), 177 ($MeOC_6H_4\overset{+}{C}HBu$, 23), and 153 ($Me_2NC_6H_4SH^+$, 100).

Reaction of ***3b***: DCC (SiO_2, CH_2Cl_2) gave pale yellow viscous oil (**19b**) (27%); NMR ($CDCl_3$): δ 0.90 (br t, J=7 Hz, 3H), 1.1—1.9 (m, 4H), 2.18 (s, 6H), 2.23 (s, 3H), 2.7—3.0 (br t, J=7 Hz, 2H), 4.73 (s, 1H), and 6.9—7.9 (m, 8H).

Reaction of ***3c***: DCC (SiO_2, CCl_4-CH_2Cl_2 (2:1)) gave **19c** (38%), benzyl phenyl ketone (3%) (by IR and NMR), and a fraction of R_f 0.8—0.9, the latter of which was subjected again to TLC (SiO_2, C_6H_6-hexane (2:1)) to give **20** (14%), **21** (6%), and **23** (6%). **19c**: mp 42—43 °C; NMR ($CDCl_3$): δ 0.91 (br t, J=7 Hz, 3H), 1.2—1.9 (m, 4H), 2.22 (s, 6H), 2.86 (br t, J=7 Hz, 2H), 4.87 (s, 1H), and 7.0—8.0 (m, 9H); MS: *m/e* 299 (M^+, 74%), 284 (M^+−Me, 100), 242 (M^+−Bu, 54), and 211 (M^+−SBu+H, 55). Found: C, 76.49; H, 8.47; N, 4.65; S, 10.67%. Calcd for $C_{19}H_{25}NS$: C, 76.20; H, 8.41; N, 4.68; S, 10.71%. **23**: NMR ($CDCl_3$): δ 0.88 (br t, J=7 Hz, 3H), 1.1—1.8 (m, 4H), 2.6—3.0 (m, 2H), 2.89 (s, 3H), 5.1 (br s, 1H), and 6.5—7.6 (m, 4H); IR (neat): 3370 cm^{-1} (NH).

*Reaction of **3d***: DCC (SiO_2, CH_2Cl_2) gave **19d** (13%) as pale yellow viscous oil; NMR ($CDCl_3$): δ 0.75—1.1 (m, 3H), 1.2—1.8 (m, 4H), 2.19 (s, 6H), 2.7—3.0 (m, 2H), 4.79 (s, 1H), and 7.0—7.9 (m, 8H).

*Reaction of **7a***: TLC (SiO_2, CH_2Cl_2) gave **31** (11%) as pale yellow oil; NMR ($CDCl_3$): δ 0.96 (br t, J=7 Hz, 3H), 1.03 (t, J=7 Hz, 3H), 1.3—1.8 (m, 4H), 2.16 (s, 3H), 2.47 (q, J=7 Hz, 2H), 2.7—3.0 (m, 2H), 3.74 (s, 3H), 4.98 (s, 1H), and 6.7—7.9 (m, 8H). HMS: Found: *m/e* 343.1962. Calcd for $C_{21}H_{29}NOS$: 343.1968.

*Reaction of **14** with Butyllithium.* *N*-Benzyl-*N*-ethylaniline (5.70 g, 27.0 mmol) was methylated with **4a** (4.38 g, 29.6 mmol) in CH_2Cl_2 (30 ml). After addition of ether, the resulting precipitates were recrystallized from CH_2Cl_2–Et_2O to give **14** (5.82 g, 69%); NMR (DMSO-d_6): δ 1.09 (t, J=7 Hz, 3H), 3.37 (s, 3H), 4.08 (m, 2H), 5.00 (br d, J=2.5 Hz, 2H), and 6.8—7.8 (m, 10H). To **14** (1.06 g, 3.39 mmol) in THF (25 ml) was added BuLi (3.8 mmol) under nitrogen at −50 °C. The products extracted with ether was a mixture of **15** (35%), **16** (6%), and **17** (12%) by glc (column, OV-1, 170 °C). In ether (15 ml), the products were a mixture of **15** (34%), **16** (6%), and **17** (20%).

*Preparation of N-(α-Ethylbenzyl)-N-methylaniline (**17**).* *N*-Benzylideneaniline (5.31 g, 29.3 mmol) in ether (15 ml) was added to EtMgI (31.3 mmol) in ether (50 ml). The mixture was refluxed for 1.5 h and poured into ice and concd HCl (100 ml). After usual work-up, DCC (SiO_2, hexane–CH_2Cl_2 (1.7:1)) of the residue gave *N*-(α-ethylbenzyl)aniline (2.15 g, 35%). The product (2.05 g, 9.70 mmol) was methylated by **4a** (2.10 g, 14.2 mmol) in CH_2Cl_2 (20 ml) under reflux for 1 h. After addition of ether, the resulting precipitates were dissolved in CH_2Cl_2 followed by deprotonation with Et_3N (4.1 ml, 29 mmol). Usual work-up gave **17**, 1.76 g, 80.5% yield, bp 118 °C/0.05 mmHg; NMR ($CDCl_3$): δ 0.97 (t, J=7 Hz, 3H), 1.96 (m, 2H), 2.62 (s, 3H), 4.79 (br t, J=7 Hz, 1H), and 6.5—7.3 (m, 10H). Found: C, 85.20; H, 8.61; N, 6.31%. Calcd for $C_{16}H_{19}N$: C, 85.28; H, 8.50; N, 6.22%.

*Preparation of N-Ethyl-N-(α-methylbenzyl)aniline (**18**).* *N*-(α-Methylbenzyl)aniline (42% yield) was prepared from *N*-benzylideneaniline and MeMgI and ethylated with **4b** in a similar manner to that of **17** to afford **18** in 88% yield, bp 115 °C/0.07 mmHg; NMR ($CDCl_3$): δ 1.04 (t, J=7 Hz, 3H), 1.54 (d, J=7 Hz, 3H), 3.19 (q, J=7 Hz, 2H), 5.04 (br q, J=7 Hz, 1H), and 6.5—7.4 (m, 10H). Found: C, 85.17; H, 8.76; N, 6.03%. Calcd for $C_{16}H_{19}N$: C, 85.28; H, 8.50; N, 6.22%.

*Reaction of **27** with Butyllithium.* To trimethyl[*o*-(methylthio)phenyl]ammonium tetrafluoroborate (**27**)[28] (298 mg, 1.11 mmol) in ether (15 ml) was added BuLi (1.40 mmol). A similar treatment to that of **7** and submission to TLC (SiO_2, hexane–Et_2O (5:1)) gave **28**, 44.7 mg, 22% yield; NMR ($CDCl_3$): δ 2.25 (s, 6H), 2.42 (s, 3H), 3.45 (s, 2H), and 6.8—7.3 (m, 4H).

*Independent Synthesis of **19c**.* *o*-Butylthioaniline was prepared from sodium *o*-aminobenzenethiolate and BuBr in 82.5% yield, bp 87 °C/0.4 mmHg. The aniline was converted into *o*-bromophenyl butyl sulfide by Sandmeyer reaction in 40% yield. The sulfide (1.30 g, 5.32 mmol) was treated with BuLi (5.25 mmol) in ether (10 ml). Benzaldehyde (0.537 g, 5.06 mmol) in ether (10 ml) was added to this solution at −15 °C and the mixture was stirred for 14 h at room temp. After usual work-up, submission to DCC (SiO_2, CCl_4) gave α-(*o*-butylphenyl)benzyl alcohol, 1.26 g, 92% yield. This alcohol (1.17 g, 4.29 mmol) was treated with $SOCl_2$ (0.36 ml) in pyridine (0.39 ml) and ether (15 ml) by a similar method to that described in the literature.[29] Distillation gave butyl *o*-(α-chlorobenzyl)phenyl sulfide, 1.06 g, 85% yield; NMR ($CDCl_3$): δ 0.7—1.0 (m, 3H), 1.2—1.8 (m, 4H), 2.82 (br t, J=7 Hz, 2H), 6.78 (s, 1H), and 7.0—7.6 (m, 9H); MS: *m/e* 290 (M^+). Butyl *o*-(α-chlorobenzyl)-phenyl sulfide (0.85 g, 2.92 mmol) in ether (10 ml) was added at −60 °C to Me_2NLi (6.16 mmol) in ether (15 ml). After stirring for 2 h at room temp and then washing with water, the ethereal layer was subjected to DCC (SiO_2, CCl_4–CH_2Cl_2 (3:1)) to afford **19c** (671 mg, 77%); bp *ca.* 120 °C/0.1 mmHg. The spectral data were in agreement with those of reaction product.

(Received February 4, 1982)

Tetronolide is an aglycone moiety of novel antitumor antibiotics tetrocarcins. The space group of the crystal is $P2_12_12_1$ with $a=20.138(3)$, $b=22.680(3)$, $c=7.848(1)$ Å and $Z=4$. The structure was solved by direct methods and refined by the block-diagonal least-squares using 3577 independent reflexions. The final R value was 0.085. It is established that tetronolide is [1R-(1R*,3R*,4R*,4aR*,6aR*,7E,10R*,11E,12aS*,13R*,16aR*,20aR*,20bS*)]-1,2,3,4,4a,6a,9,10,12a,13,16,20,20a,20b-tetradecahydro-4,10,13,21-tetrahydroxy-1,3,7,11,20a-pentamethyl-18,20-dioxo-18*H*-16a,19-metheno-16a*H*-benzo[*b*]naphth[2,1-*j*]oxacyclotetradecin-15-carbaldehyde or its enantiomer.

Tetronolide (**1**) is an aglycone moiety of novel antitumor antibiotics tetrocarcins,[1,2] which are produced by *Micromonospora chalcea KY11091*. The structure of tetronolide could not be determined by the ordinary spectroscopic and chemical methods.[3] Therefore X-ray analysis of tetronolide was undertaken. It has been revealed that the molecule contains a peculiar skeleton; chlorothricolide (**2**)[4] is the only compound which possesses the similar molecular skeleton.[5] The preliminary results have already been published.[6]

Experimental and Structure Determination

Prismatic crystals of the title compound were obtained from an ethyl acetate solution containing a trace amount of methanol. A $0.22\times0.22\times0.65$ mm^3 crystal was used for data collection on a Rigaku four-circle automated diffractometer with Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Preliminary unit cell dimensions and space group were obtained from photographs. The space group was assigned to be $P2_12_12_1$ from systematic absences ($h00$ for odd h, $0k0$ for odd k, $00l$ for odd l). Accurate cell dimensions were determined by the least-squares calculation with 2θ values of 16 high-angle reflexions measured on the diffractometer. Crystal data are as follows: $C_{32}H_{40}O_8$; M. W.=552.664; $P2_12_12_1$; $Z=4$; $a=20.138(3)$, $b=22.680(3)$, $c=7.848(1)$ Å; $D_x=1.19$ g cm^{-3}; μ(Mo $K\alpha$)$=3.65$ cm^{-1}. All independent reflexions within the range $2\theta\leqq55°$ were collected by use of the ω-2θ scan mode with a scanning rate $4°(2\theta)$ min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Periodic checks of the intensity values of three standard reflexions showed no significant X-ray damage or crystal decay. Any corrections for absorption or extinction were not applied. A total of 3655 independent reflexions were obtained, of which 3577 ($|F_o|>3.0\sigma(|F_o|)$) were used for the structure determination.

The phases of 260 reflexions with $|E_o|\geqq1.67$ were assigned with MULTAN 78.[7] The best set of phases was employed to calculate an E map, which gave the appropriate peaks for all non-hydrogen atoms. The structural parameters were refined by the block-diagonal least-squares methods with the modified HBLS program. All of the hydrogen atoms were located from difference syntheses. In addition to the hydrogen atoms many peaks with height of about 0.3 eÅ^{-3} appeared on the difference map. Most of them were located between the molecules, of which six were regarded to correspond to solvent molecules of ethyl acetate, and their atomic parameters were successfully refined isotropically with the occupancy of 0.2. The weighting system applied was $w=1/(\sigma^2(F_o)+(0.015F_o)^2)$. The final R value is 0.085. Atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[8] The final positional and thermal parameters are given in Table 1.**

Results and Discussion

Bond Lengths and Angles. The atomic numbering and ring names are shown in Fig. 1. The stereoscopic drawing of the tetronolide molecule is given in Fig. 2. Absolute configuration was not determined. Bond lengths and angles are tabulated in Table 2. The C–C bonds around the ring B are short, *i.e.*, C(30)–C(32)=1.48(1), C(2)–C(32)=1.42(1), C(1)–C(2)=1.49(1), and C(2)–C(3)=1.41(1) Å. This indicates that the π electrons are delocalized extensively through-

** The tables of the observed and calculated structure factors, the anisotropic thermal parameters of non-hydrogen atoms, the atomic parameters of hydrogen atoms and the solvent molecule, and torsional angles in the molecule are kept as Document No. 8241 at the Chemical Society of Japan.

Table 1. Final atomic parameters with their estimated standard deviations, multiplied by 10^4 for C and O atoms

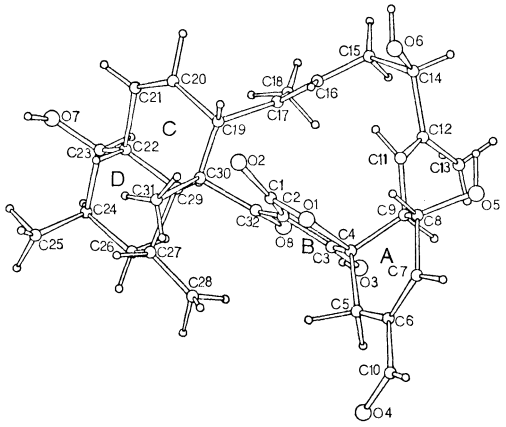

Fig. 1. The numbering system of tetronolide.

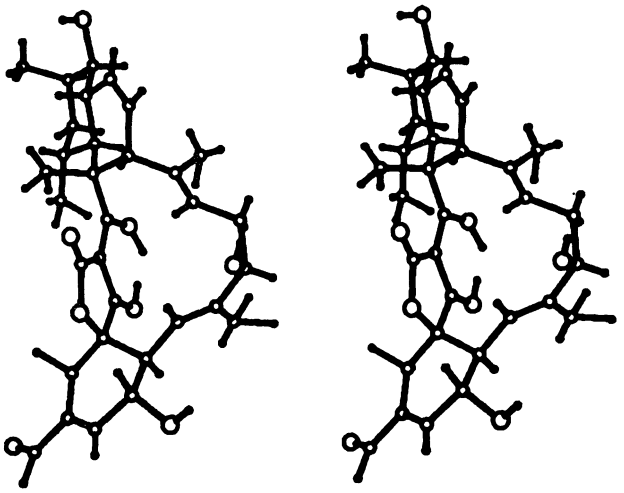

Fig. 2. Stereoscopic drawing of tetronolide.
The figure and Fig. 4 were drawn by TSD:XTAL, which is a computer-graphics interactive modeling program for a NOVA 3 computer.[9]

out this part. There is an intramolecular hydrogen bond between the O(3) and O(8) atoms. The bond lengths of C(3)–O(3) and C(32)–O(8) (1.250 and 1.267 Å, respectively) show that both of these bonds are intermediate of carbonyl and hydroxyl C–O bonds. Moreover the elctron density which corresponds to the two hydrogen atoms bonded to O(3) and O(8) atoms appeared on the difference map. These facts indicate that there are two tautomeric fomrs as $-\overset{\overset{O\cdots HO}{\|}}{C}-C=\overset{|}{C}-$ and $-\overset{|}{C}=C-\overset{\overset{OH\cdots O}{|}}{\underset{\|}{C}}-$. The geometry of the hydrogen bond is as follows: O(3)···O(8)=2.528(7), H(O(3))···O(8)=1.81(3), H(O(8))···O(3)=1.81(3) Å, ∠O(3)–H···O(8)=139(3), and ∠O(3)···H–O(8)=138(3)°.

In chlorothricolide (**2**) containing a closely related skeleton,[4] there is a similar but much weaker intramolecular C=O···H–O hydrogen bond; the O···O distance averaged over the two independent molecules of **2** in asymmetric unit is 2.95 Å.

The C(19)–C(30) distance is remarkably long (1.60 Å) and the corresponding C–C distance in **2** is also long (the average distance is 1.58 Å).

Of the two intramolecular short contacts, the contact between the C(28) atom and the O(8) atom is of perticular interest; the C(28)···O(8), HAC(28)···O(8) and HBC(28)···O(8) distances are 2.83(1), 2.35(7), and 2.56(9) Å, respectively. These values indicate that the C(28) methyl group is so sterically hindered by the O(8) atom that the rotation of the methyl group may be considerably restricted. On the other hand, the C(31) methyl group also contacts with the O(2) carbonyl oxygen atom. The geometry, the C-

(31)···O(2) distance of 2.793 Å and the C(31)-H···O(2) angle of 145°, indicates that this contact is a hydrogen bond. Since a similar methyl group in **2** is trans to the carbonyl oxygen atom, there is no possibility for such an intramolecular hydrogen bond.

Some exo- and endocyclic bond angles of the γ-lactone ring are distorted. The C(1)-C(2)-C(32), O(2)-C(1)-C(2), and C(2)-C(3)-O(3) angles are 133.7, 132.1, and 126.7°, respectively. The corresponding bond angles in chlorothricolide are also large (the average values are 135.9, 126.8, and 133.0°). Such distortion of the bond angles may be explained by the planar geometry of ring B with O(3), C(32), and O(8) atoms caused by the extensive delocalization of the π electrons.

The O(1)-C(4)-C(3) angle of 101.1(6)° at the spiro group in tetronolide is small (the corresponding averaged value of 102.8° in **2** is also small).

Although the C(19)-C(30)-C(32) angle of 101.4(6)° is remarkably small in tetronolide, but the corresponding value 107.3° in **2** is within the expected region.

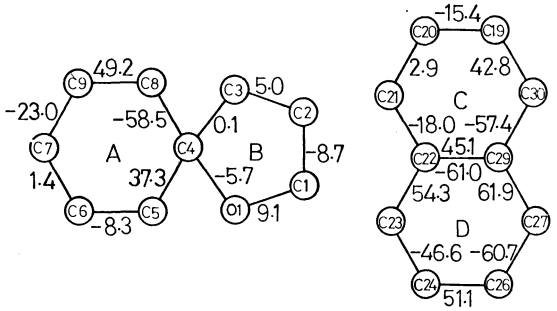

Fig. 3. Torsional angles in the rings, τ/°.

Other bond lengths and angles are normal.

Conformation. The thirteen-membered ring, two cyclohexene rings, and the cyclohexane ring take the crown, the half-chair, and the chair conformation, respectively. The γ-lactone ring is in the envelope con-

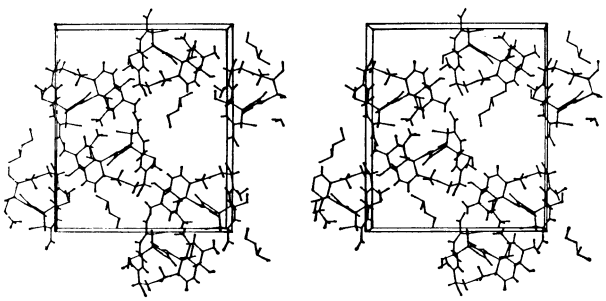

Fig. 4. Crystal structure viewed along the c axis. The vertical and holizontal axes denote b and a axes.

formation. The ring torsional angles in each ring are shown in Fig. 3. The conformational characteristics as a whole is similar to that of **2**. Ring A is more flattened than C. In the cyclohexane ring C(27) and C(29) are puckered, and C(23) and C(24) are flattened. Rings C and D are fused in the *trans*-decalin type.

Crystal Structure. The crystal structure viewed along the c axis is shown in Fig. 4. The molecules are connected by the two intermolecular hydrogen bonds and form the helical chain along the a axis. The geometry of the hydrogen bonds are $O(5)^{I}\cdots O(7)^{II}=2.865(8)$ Å, $\angle O(5)\text{-}H^{I}\cdots O(7)^{II}=172(3)°$; $O(7)^{II}\cdots O(6)^{I}=3.127(8)$ Å, $\angle O(7)\text{-}H^{II}\cdots O(6)^{I}=166(3)°$. Symmetry codes I and II denote (x,y,z) and $(0.5+x,\ 0.5-y,\ 1.0-z)$, respectively. The helical chains are stacked mainly by van der Waals interactions. There are large cavities between the helical chains, and the ethyl acetate molecule is located in the cavity. As mentioned in the experimental section many fragments corresponding to the low but significant electron density still remained at the final stage of the refinement. The fact indicates that much more solvent molecules must exist in the crystal.

Thermodynamic Properties for the Adduct Formation of Some Shift Reagents with Aniline

Hideo Kojima, Hiroshi Nonaka, and Minoru Hirota*
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240
(Received February 6, 1982)

Equilibrium constants, enthalpies, and entropies of formation of the shift reagent-substrate adducts were determined by the measurement of infrared spectra. Aniline was employed as substrate in most cases since its NH stretching absorption bands (ν_{as}) does not overlap with those of the adducts and suitable to estimate the amount of its free species quantitatively. A series of $Ln(dpm)_3$ and $Ln(fod)_3$ (where Ln=Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, and Yb) were used as shift reagents. The formation constants (K_1 and K_2), as well as ΔH, decrease in the increasing order of the atomic numbers of the central lanthanoid ions. The results were compared with those on some bis(β-diketonato) complexes of transition metal ions and discussed.

Since the discovery by Hinckley,[1] various lanthanoid shift reagents have been widely employed to expand the chemical shift range of NMR spectrum without remarkable broadening of the signals. Quite a few examples[2—5] of their application have been reported, and many new shift reagents, including Ag compounds[6] for aromatic substrates, have been prepared and used both to resolve the overlapping signals and to determine the stereochemistry of many complex organic compounds by use of the steric factor in the McConnell-Robertson equation.[7,8] However, the properties of the shift reagent-substrate complexes have not been known very thoroughly. Thus, the shift reagent-substrate complexes were studied quantitatively by the measurement of infrared spectra of the complexes in solution in order to determine their formation equilibrium constants and to estimate the enthalpies and the entropies of their formation.[9]

Theoretical

In general, 1:1 and 1:2 complexes RS and RS_2 are formed when the lanthanoid shift reagent (R) is added to the solution of the substrate (S). These reactions and their formation constants are expressed by the following equations. When the infrared X–H

$$R + S \rightleftharpoons RS \qquad K_1 = \frac{[RS]}{[R][S]} \tag{1}$$

$$RS + S \rightleftharpoons RS_2 \qquad K_2 = \frac{[RS_2]}{[RS][S]} \tag{2}$$

stretching bands are selected as key bands, addition of the shift reagent to the solution of substrate gives rise to new absorption band(s) in addition to the absorption band(s) due to the free species of the substrate, hereby accompanying a decrease in the intensity of the free band. The new bands are assigned to the complexed species RS and/or RS_2. If the measurements are carried out under conditions in which the Lambert-Beer law is valid, the concentration of the free substrate [S] is obtained from the intensity of the band assigned to the free substrate and its molar absorptivity ε_f, which can be determined easily by the measurement on the substrate alone in the same solvent. From the concentration of the free substrate [S] obtained by the infrared measurement, concentrations of the complexed substrate S_b and the free shift reagent [R] are derived by Eqs. 3 and 4, respectively.

$$S_b = (S_t - [S]) \tag{3}$$

$$[R] = R_t - (S_t - [S])/n \tag{4}$$

In these equations, S_t and R_t are stoichiometrical total concentrations of the substrate and the shift reagent, respectively, and n is the number of substrate molecules complexed to a shift reagent molecule.

When the second reaction to form 1:2 adduct is negligible, the first equilibrium constant K_1 is given by Eq. 5. Dissociation constant $K_D(=1/K)$ of the

$$K_1 = \frac{[S]\{nR_t - (S_t - [S])\}}{S_t - [S]} \tag{5}$$

shift reagent-substrate complex RS_n is then given by Eq. 6, by assuming that n molecules of substrate are coordinating to one molecule of the monomeric shift

$$\frac{S_t - [S]}{R_t \times [S]} = \frac{n}{K_D} - \frac{S_t - [S]}{K_D \times R_t} \tag{6}$$

reagent. Equation 6 is often called the Scatchard equation and is used to calculate K_D and n. When $(S_t - [S])/R_t[S]$ values are plotted against $(S_t - [S])/R_t$ values, both K_D and n are obtained from the slope and the intercept of the straight line calculated as the least squares of the plots. Another evidence for the stoichiometry of the complex is obtained when isosbestic points were observed with the concentration dependent spectra. The appearance of isosbestic points excludes the possibility of the coexistence of the 1:1 and 1:2 complexed species in the same solution. Thus the number of the coordinating substrate (n) can be determined by the Scatchard plot (Eq. 6).

When RS and RS_2 are present together in the same solution (apparently $1<n<2$), the following equation (Eq. 7), derived from Eqs. 1 and 2, is useful in evaluating the equilibrium constants K_1 and K_2.[10] The plot

$$\frac{[S]^3 + (2R_t - S_t)[S]^2}{S_t - [S]} = \frac{1}{K_2} \times \frac{(S_t - [S] + R_t)[S]}{S_t - [S]} + \frac{1}{K_1 K_2} \tag{7}$$

of $\{[S]^3 + (2R_t - S_t)[S]^2\}/(S_t - [S])$ (ordinate) *vs.* $(S_t - [S] - R_t)[S]/(S_t - [S])$ (abscissa) gives the K_1 and K_2 values from its slope and intercept.

In this way, the equilibrium constants are evaluated at various temperatures, the enthalpies and the entropies of formation of the complexes (RS and RS_2) being obtained from the $\log K$ *vs.* $1/T$ plots.

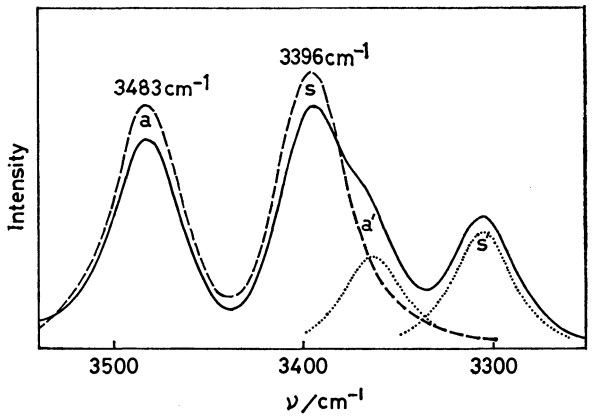

Fig. 1. NH Stretching bands of aniline in CCl_4 in the presence (——) and in the absence (----) of $Pr(dpm)_3$. Symmetric (s') and asymmetric (a') NH_2 stretching bands of the complexed species appear in the low frequency region. These bands are separated by the band shape analysis and illustrated by the dotted line (·····). The letters a and s denote asymmetric and symmetric stretching bands of the free species, respectively.

$$\ln K = -\frac{\Delta H}{R} \times \frac{1}{T} + \frac{\Delta S}{R} \qquad (8)$$

In this investigation, tris(dipivaloylmethanato)- or tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)lanthanoid(III)'s were used as the shift reagents (R) and anilines as the substrates (S). The equilibrium constants were estimated by measuring the intensities of the N–H stretching absorption bands of the free species of aniline as a measure of [S].
