Measurements. Electronic spectra were measured in chloroform by a Shimadzu MPS-5000 spectrophotometer. Magnetic susceptibilities were measured by the Faraday method in the temperature range 80—300 K. The apparatus was calibrated by the use of $[Nien_3]S_2O_3$.[11] Effective magnetic moments were calculated by the equation, $\mu_{eff} = 2.828(\chi_A \times T)^{1/2}$, where χ_A is the magnetic susceptibility per copper atom corrected for the diamagnetism of the constituting atoms by the use of Pascal's constants.[12] ESR spectra were measured in chloroform at liquid nitrogen temperature (frozen solution) with a JES-FE3X ESR instrument. Cyclic voltammograms were recorded on a Yanagimoto P-1000 voltammetric analyzer in dichloromethane containing 0.1 M† tetrabutylammonium perchlorate as the supporting electrolyte. A three-electrode cell with a glassy carbon as the working electrode, a platinum coil as the auxiliary electrode, and a saturated calomel as the reference electrode was used for the measurements. All the potentials were corrected for liquid junction potential by the use of ferrocene as an internal standard.[13,14]

Results and Discussion

By the reaction of 2,3-dicyano-2,3-butanediol and ammonia two isomers of 2,3-dicyano-2,3-butanediamine were obtained; one is liquid and the other is solid.

† 1 M=1 mol dm^{-3}.

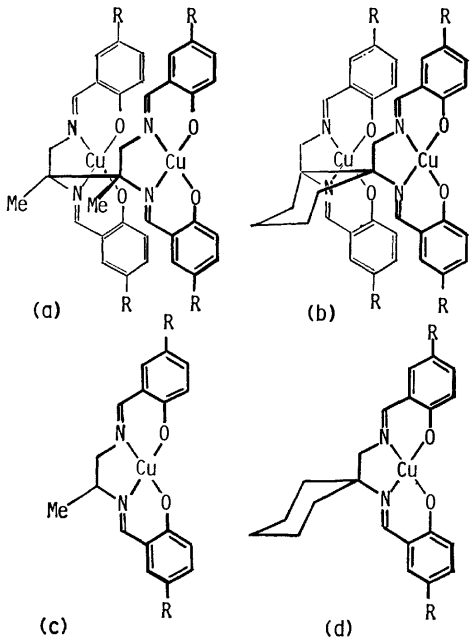

Fig. 1. Chemical structures of (a)Cu_2(R-sata), (b)Cu_2-(R-sacta), (c)Cu(R-salpn), and (d)Cu(R-sacda).

Similarly ammonolysis of 1,2-dicyano-1,2-cyclohexanediol gave two isomers (liquid and solid) of 1,2-dicyano-1,2-cyclohexanediamine. The presence of two isomers can be attributed to the fact that these diamino dinitriles are diastereomeric and exist as a mixture of *dl*- and *meso*-isomers. In this study, the solid diamino dinitriles were reduced to prepare 2,3-dimethyl-1,2,3,4-butanetetramine and 1,2-bis(aminomethyl)-1,2-cyclohexanediamine. However, we have not yet determined whether the tetramines are the *meso*- or the *dl*-isomer. In Fig. 1 the structures of Cu_2(R-sata) and Cu_2(R-sacta) of the *meso*-tetramines are shown.

The half of Cu_2(R-sata) corresponds to *N,N'*-bis(R-salicylidene)-1,2-propanediaminatocopper(II), Cu(R-salpn), which is hence adopted as the reference complex to Cu_2(R-sata). As the reference complex to Cu_2(R-sacta), we adopted the complexes Cu(R-sacda) of 1-(R-salicylideneamino)-1-(R-salicylideneaminomethyl)cyclohexane (H_2(R-sacda)), taking into account the steric characteristics of cyclohexane ring. The structures of Cu(R-salpn) and Cu(R-sacda) are also given in Fig. 1.

Table 2. Effective magnetic moments and Weiss constants of complexes

	μ_{eff}/BM(T/K)		θ/K
Cu_2(sata)	1.94(86.3)	1.87(295.6)	8
Cu_2(5-Me-sata)	1.90(87.4)	1.85(293.2)	3
Cu_2(5-Bu^t-sata)	1.86(86.9)	1.84(297.8)	≈0
Cu_2(sacta)	2.02(87.4)	1.87(296.1)	17
Cu_2(5-Me-sacta)	1.94(86.3)	1.84(295.4)	10
Cu_2(5-Bu^t-sacta)	1.88(88.5)	1.86(295.6)	≈0

Magnetic susceptibilities of Cu_2(R-sata) and Cu_2(R-sacta) were measured on solid samples in the temperature range from liquid nitrogen temperature to room temperature. The effective magnetic moments at room temperature and near liquid nitrogen temperature are given in Table 2. Magnetic moments of Cu_2(5-Bu^t-sata) and Cu_2(5-Bu^t-sacta) are almost independent of temperature. On the other hand, the moments of Cu_2(sata), Cu_2(5-Me-sata), Cu_2(sacta), and Cu_2(5-Me-sacta) increase with lowering of temperature. The χ_A *vs.* T^{-1} plotts for these complexes revealed that they obey the Curie-Weiss law, $\chi_A = C/(T-\theta)$. The Weiss constants thus determined are given in Table 2. Positive Weiss constants for Cu_2(R-sata) (R=H, 5-Me) and Cu_2(R-sacta) (R=H, 5-Me) imply the operation of an intramolecular, ferromagnetic spin-exchange interaction. This magnetic behavior resembles that of dimeric *N*,*N*′-disalicylideneethylenediaminatocopper(II), [Cu(salen)]$_2$.[15] Weiss constants for Cu_2(R-sacta) are larger than those of the corresponding Cu_2(R-sata). It is likely that two copper(II) ions are held in close distance in Cu_2(sacta) and Cu_2(5-Me-sacta) because of the steric requirement of cyclohexane ring, while two CuN_2O_2 planes of Cu_2(R-sata) can rotate about the C(2)–C(3) axis of the tetramine moiety. The temperature-independence of the magnetic moments of Cu_2(5-Bu^t-sata) and Cu_2(5-Bu^t-sacta) suggests that access of the copper(II) ions is sterically hindered by the bulky *t*-butyl group.

ESR spectra of Cu_2(R-sata) and Cu_2(R-sacta) were measured on frozen solutions in chloroform at liquid nitrogen temperature. The spectra of Cu_2(5-Me-sata), Cu_2(5-Bu^t-sata) and Cu_2(5-Bu^t-sacta) showed a tetragonal pattern with $A_\parallel \approx 190$G (1 G=1×10^{-4} T) and resemble the spectra of Cu(R-salpn) and Cu(R-sacda). This implies that metal-metal interaction is very weak in these complexes in chloroform solution. On the other hand, ESR spectra of Cu_2(sata), Cu_2(sacta), and Cu_2(5-Me-sacta) were characterized by a seven-lined hyperfine structure ($A_\parallel \approx 85$ G) centered around 3200 G. In Fig. 2 the ESR spectrum of Cu_2(sata) is shown as an example. It is evident that in these three complexes two copper(II) ions ferromagnetically couple to produce the $s=1$ ground state. The ESR spectral features of Cu_2(sata), Cu_2(sacta), and Cu_2(5-Me-sacta) resemble that of dimeric Cu(salen), which has been demonstrated to have a face-to-face structure[16] and displays a seven-lined hyperfine structure in ESR spectrum based on the $s=1$ ground state.[15]

Electronic spectra of Cu_2(R-sata) and Cu_2(R-sacta) were measured in chloroform. Electronic spectra of

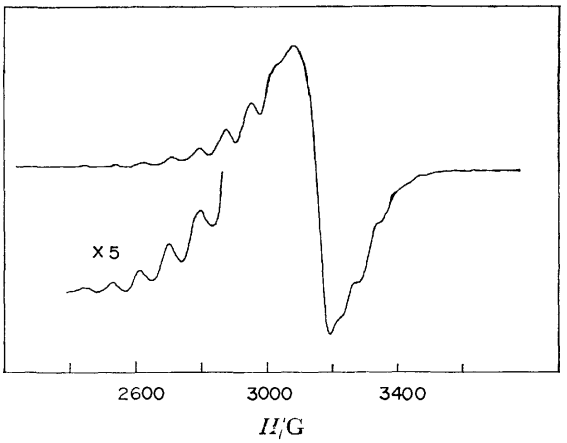

Fig. 2. ESR spectrum of Cu_2(sata) in chloroform at liquid nitrogen temperature.

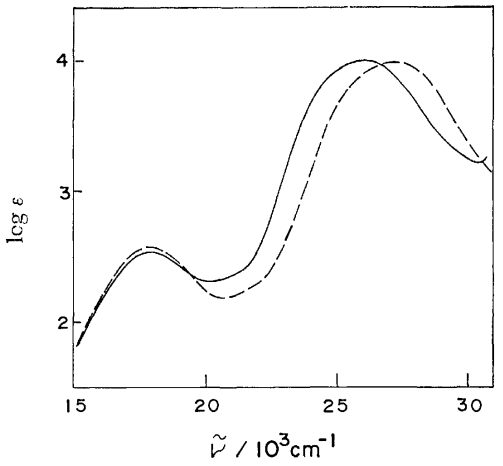

Fig. 3. Electronic spectra of (——) Cu_2(sata) and (– – –) Cu(salpn) in chloroform.

Cu_2(sata) and Cu(salpn) are given in Fig. 3. Absorption bands near 18×10^3 cm^{-1} is assigned to the d-d transition,[17–19] while the band around 26×10^3 cm^{-1} has been assigned to the π-π^* transition which involves the π-orbital functions of the azomethine group.[17,18] Table 3 includes the wavenumbers and the extinction coefficients of the d-d and the π-π^* transition bands of the binuclear complexes together with those of the mononuclear complexes as the reference. There is no substantial change in the frequency and the intensity of the d-d band between the binuclear and the corresponding mononuclear complexes. This clearly indicates that the configurations around the metal in Cu_2(R-sata) and Cu_2(R-sacta) are practically the same as those of Cu(R-salpn) and Cu(R-sacda), respectively. We presume that the configuration around the metal for Cu_2(R-sata) and Cu_2(R-sacta) is of planar, four-coordination as demonstrated for Cu(salen).[20]

The π-π^* transition frequencies of H_4(R-sata), H_4(R-sacta), H_2(R-salpn), and H_2(R-sacda) are almost the same and appear near 31×10^3 cm^{-1} (*e.g.*, 31.1×10^3 for H_4(sata), 31.0×10^3 for H_4(sacta), 31.3×10^3 for H_2(salpn), and 31.1×10^{3}cm^{-1} for H_2(sacda)). The π-π^* band shifts to lower wavenumber when the

	−1.51	−1.28	230	−1.40					
Cu_2(5-Bu^t-sacta)	−1.52	−1.28	240	−1.40	Cu(5-Bu^t-sacda)	−1.52	−1.38	160	−1.44

All potentials are corrected by the use of ferrocene as an internal standard and given in V (or mV) *vs.* NHE. Approximate redox potentials ($E'_{1/2}$) are given by the mean of E_{pc} and E_{pa}.

ligand coordinates to copper(II) ion. It is noteworthy that the band frequency for Cu_2(sata), Cu_2(sacta), and Cu_2(5-Me-sacta) are lower than those of Cu(salpn), Cu(sacda), and Cu(5-Me-sacda), respectively. The shift is more than 1,100 cm^{-1} (see Table 2). The red shift of the π-π* transition for these complexes suggests the stacking of the two CuN_2O_2 chromophores interacting through the π-bonding systems of the ligand. The π-π* transitions for Cu_2(5-Me-sata), Cu_2(5-Bu^t-sata), and Cu_2(5-Bu^t-sacta) are practically the same in wavenumber as that of the corresponding mononuclear complexes.

Electrochemical properties of Cu_2(R-sata), Cu_2(R-sacta), Cu(R-salpn), and Cu(R-sacda) were studied by means of cyclic voltammetry. Cathodic peak (E_{pc}), anodic peak (E_{pa}), peak separation (ΔE_p), and approximate redox potential ($E'_{1/2}$) given by the mean of the E_{pc} and E_{pa} are shown in Table 4. All waves observed are quasi-reversible or irreversible judging from the peak separations and the wave shapes. Each cyclic voltammogram of Cu_2(5-Me-sata), Cu_2(5-Bu^t-sata), and Cu_2(5-Bu^t-sacta) involves only one redox couple attributable to the process Cu(II,II)/Cu(I,I). Each redox potential is essentially the same as that of the corresponding mononuclear copper(II) complex. There is no interaction between the CuN_2O_2 chromophores of these complexes as demonstrated on the basis of ESR and visible spectra, and hence the two metal ions are reduced at an identical potential to copper(I) ion.

Cyclic voltammograms of Cu_2(sata), Cu_2(sacta), and Cu_2(5-Me-sacta) were characterized by two redox couples, a typical example being shown in Fig. 4. This separation is much larger than 0.036 V expected from the statistical effect.[21] The electrochemical behavior

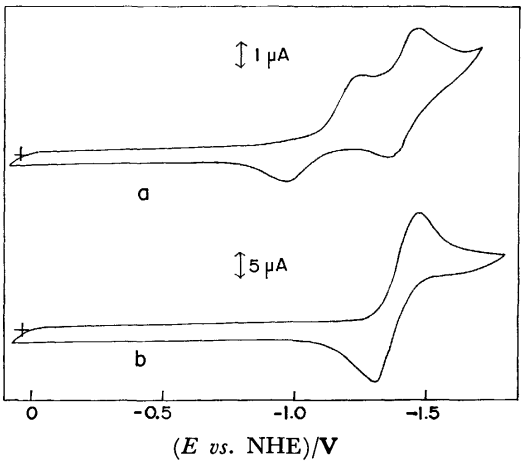

Fig. 4. Cyclic voltammograms of (a) Cu_2(sata) and (b) Cu(salpn) in dichloromethane (scan rate: 40 mV/s).

of this kind has usually been interpreted in terms of the stepwise redox-process, Cu(II,II)⇌Cu(II,I)⇌Cu(I,I).[2,5] Each of the first redox potentials for Cu_2(sata), Cu_2(sacta), and Cu_2(5-Me-sacta) is higher than that of the corresponding mononuclear complex. This may be ascribed to the stabilization of the Cu(II, I) state effected by the electron-delocalization over the molecule through the ligand π-system.

The second potential for these complexes well corresponds to the potential of the corresponding mononuclear complex. Thus, we tentatively assigned the second redox wave to the two-electron transfer from Cu(II,II) to Cu(I,I), although theoretical analysis[22] is impossible because of the irreversible process. Occurrence of the Cu(II,II)/Cu(I,I) and the Cu(II,II)/

Cu(II, I) processes is not clear at present. One plausible explanation is that an equilibrium exists between the stacked and the non-stacked forms at ambient temperature, and the latter form is reduced to the Cu(I, I) species at practically the same potential as that of the reference mononuclear complex.

The difference between the first and the second redox potentials, $E'_{1/2}$, is 0.17 V for Cu_2(sata), 0.31 V for Cu_2(sacta), and 0.26 V for Cu_2(5-Me-sacta). It is likely that the geometrical fixation of the CuN_2O_2 planes in the cases of Cu_2(sacta) and Cu_2(5-Me-sacta) owing to the cyclohexane ring brings about a considerable stabilization of the Cu(II,I) state compared with the case of Cu_2(sata), whose two chromophores can be remote from each other because of the free rotation around the C(2)–C(3) bond of the tetramine. Further, it seems that the stacking of the CuN_2O_2 planes may be sterically hindered by the substituent on the ring, since $E'_{1/2}$ decreases in the general trend R=H>5-Me>5-Bu^t and any indications of the stabilization of the Cu(II,I) state were not recognized in the cases of Cu_2(5-Bu^t-sata) and Cu_2(5-Bu^t-sacta).

The magnetic, spectral, and electrochemical characteristics found for the present complexes are particularily interesting in connection with the "dimeric bacteriochlorophyll", whose cation radical shows an ESR spectrum of a narrow line-width[23] and is reduced at a high potential compared with monomeric bacteriochlorophyll *in vitro*.[24]

Pyrolytic Sulfurization Gas Chromatography. XI. An Improved Apparatus and Procedure for Practical Use

Tadashi HARA* and Fujio OKUI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received December 10, 1981)

With the objectives of reducing the time necessary for an analysis and of improving the precision and accuracy of the analysis value, the isothermal gas-chromatographic optimum conditions were investigated and established. By the present method, the time necessary for an analysis is reduced to 25 min, from 35 min under the previous conditions, and both precision and accuracy are further improved together with an improvement of the calculation method of the calculation factors used in the calculation of the atomic ratio between C, H, O, and N. Thus many standard samples, including some liquid ones which are newly examined in this study, can be analyzed within an absolute error of about ±0.2%.

In order to establish a new elemental analysis method by which several elements can be simultaneously determined, pyrolytic sulfurization gas chromatography (PSGC) was originated[1] and has been investigated[2-9] fundamentally by the present authors to provide a simultaneous determination of the atomic ratio between C, H, O, and N in an organic compound. It has been successfully applied to an ordinaly organic compound,[1] a metal organic chelate compound,[3] a polymer,[5] and an organic halogen compound.[7,8]

The present study also intended to reduce the time necessary for an analysis and to improve both precision and accuracy of the analytical values. According to the PSGC, the reaction products from the pyrolytic sulfurization of a sample were restricted to nitrogen (N_2), carbon dioxide(CO_2), hydrogen sulfide(H_2S), calbonyl sulfide(COS), and carbon disulfide(CS_2). The additional products, water(H_2O) and sulfur dioxide (SO_2), were obtained only in the case of the atomic ratio C/O<1 in a sample. These products were separated and determined under the programmed gas-chromatographic conditions in the previous study.[2] According to this procedure, the next sample could not be applied until the column temperature went down at 85 °C and this led to an increase of the total analysis time. In the present study which aimed at the minimization of the total analysis time, the isothermal gas-chromatographic conditions were examined and optimum column conditions were obtained by combining a 150 cm Porapak QS column with a 50 cm Chromosorb 104 column in series and by interposing a six-way cock at a proper position of the column so as to reduce the retention time of CS_2. The present study reduced the net analysis time by gas chromatography to about 8 min, from about 18 min under the previous conditions. Thus the total time(including reaction time, standing time, and so on) necessary for an analysis is also reduced to about 25 min from about 35 min. Moreover, both precision and accuracy are also improved, together with the improvement of the calculation method of the calculation factors used in the calculation of the atomic ratio between C, H, O, and N. Thus many standard samples, including liquid ones which are newly examined in this study, can be analyzed within an absolute error of about ±0.2%.

Experimental

Reagents. All of the reagents used as the analytical samples were of reagent grade for elemental analysis except for cyanoguanidine, which was of reagent grade for melting point standard.

Apparatus. An analyzer used in the present study is shown in Fig. 1. It consists of a Shimadzu GC 4B gas chromatograph mounted with two six-way cocks in the column oven and a sampler similar to that in the previous work.[1] The gas chromatograph was operated under the following conditions: Columns a 45 cm stainless steel column C_1 packed with Porapak QS(80—100 mesh), a 105 cm stainless steel column C_2 with Porapak QS(80—100 mesh), and a 50 cm stainless steel column C_3 with Chromosorb 104 (80—100 mesh); the insides of the stainless steel columns were treated preliminarily by coating with water glass; column temperature 85 °C; flow rate of He as a carrier gas 50 cm³/min.

A high-frequency induction furnace was used for the pyrolytic sulfurization reaction under the same conditions as in the previous work.[9]

Procedure. The quartz ampule containing 0.3—0.5 mg of sample and 5 mg of S was prepared and treated for 1 min by the high-frequency induction furnace as in the previous study.[9] After standing for 3 min in the furnace, the ampule was inserted into the sampler. Replacing the inside of the sampler with He for 5 min, the sampler was connected with the gas chromatograph by operating the

six-way cock D_1. After 5 min, the time necessary for the stabilization of the base line in a gas chromatogram, the ampule was broken with a vice B and the evolved gases were subjected to gas-chromatographic analysis. After 4.5 min, the separation column was shortened to only a 45 cm Porapak QS column by operating the six-way cock D_2. On the basis of the data obtained by a digital integrator, the atomic ratio between C, H, O, and N in a sample was calculated by the use of calculation factors of the products.

Results and Discussion

Gas-chromatographic Separation of the Reaction Products under the Isothermal Conditions. According to the PSGC, the gaseous products of the pyrolytic sulfurization reaction were limited as follows: N_2, CO_2, H_2S, COS, H_2O, SO_2, and CS_2. Then, an investigation was undertaken to separate them under the isothermal gas-chromatographic conditions, instead of the programmed ones in the previous studies. Porapak Q, Porapak QS, Chromosorb 104, silica gel, Carbon molecular sieve B, and Molecular sieve 13X were chosen as representative gas-chromatographic packings to separate the above gaseous products. Each packing was investigated to determine the elution behavior of the products under the following standard conditions: Column length 100 cm, flow rate of He as a carrier gas 30 cm³/min, and column temperature 100 °C. All of the above-mentioned products were found to elute within 1 h when Porapak Q, Porapak QS, and Chromosorb 104, respectively, were used as a column packing. As can be seen from the retention time of each product in Table 1, H_2S cannot be separated from H_2O by Porapak Q or Porapak QS nor from COS by Chromosorb 104. It was suggested that the optimum column conditions to separate the seven kinds of products would be obtained by the combination of Porapak Q with Chromosorb 104(Q-104 type) or by that of Porapak QS with Chromosorb 104(QS-104 type) in series. Therefore, an examination was undertaken to separate the products by the above combination columns, and optimum conditions to separate them were obtained. Since two kinds of optimum conditions, however, indicated fairly large retention times for CS_2, the column was shortened by interposing the six-way cock at a proper position of the column so as to reduce the retention time of CS_2. Thus, the following optimum column conditions were obtained: (Q-104 type) first column a 50 cm Porapak Q(80—100 mesh) column, second column a 100 cm Porapak Q(80—100 mesh) column, third column a 45 cm Chromosorb 104(80—100 mesh) column, column temperature 90 °C, and flow rate of He 50 cm³/min. (QS-104 type) first column a 45 cm Porapak QS(80—100 mesh) column, second column a 105 cm Porapak QS (80—100 mesh) column, third column a 50 cm Chromosorb 104 (80—100 mesh) column, column temperature 85 °C, and flow rate of He 50 cm³/min. The six-way cock was interposed between the first column and the second column in each type. Typical chromatograms under the above-mentioned conditions are shown in Fig. 2. As can be seen from Fig. 2, the separation of the products is achieved

Table 1. The retention time of the products under the standard column conditions

Column packing	Retention time/min						
	N_2	CO_2	H_2S	COS	H_2O	SO_2	CS_2

under the isothermal gas-chromatographic conditions, and moreover the elution time of the products is reduced from 13 min under the previous conditions to 8 min under the present conditions.

Reproducibility of the Analytical Values. The reproducibility of the PSGC was examined using N_2, CO_2, H_2S, COS, and CS_2 obtained from alanine, since the atomic ratio of C/O in alanine was more than 1 and neither H_2O nor SO_2 was produced. The two sets of column conditions were compared with the previous column conditions by analyzing 10 samples of alanine and by estimating the coefficient of variation(C.V.) in the ratio of the individual peak area (Table 2). Table 2 shows that QS-104 type has the best reproducibility of the analytical values. Therefore, QS-104 type was employed in the present study.

Calculation Factor. In the PSGC, the atomic ratio between C, H, O, and N was calculated by using both the factors obtained by analyzing the standard compounds preliminarily and the peak areas of the individual product obtained from the sample. Judging from the meaning of the above factors, the term "calculation factor" is hereafter adopted instead of "correction factor" used in the previous papers.

The calculation factors of $N_2(K(N_2))$ and $CS_2(K(CS_2))$ were obtained by solving the following equations on the basis of the analytical data of cyanoguanidine:

$$\left(\frac{N}{H}\right)=\frac{2K(N_2)A(N_2)}{2K(H_2S)A(H_2S)}, \quad (1)$$

$$\left(\frac{C}{H}\right)=\frac{K(CS_2)A(CS_2)}{2K(H_2S)A(H_2S)}. \quad (2)$$

Here $A(X)$ is the peak area of X and $K(H_2S)$ is 1, as in the previous papers. The calculation actors of $CO_2(K(CO_2))$ and COS (K(COS)) were o tained by solving the following simultaneous equations on the basis of the analytical data of sucrose:

$$\left(\frac{O}{H}\right)=\frac{2K(CO_2)A(CO_2)+K(COS)A(COS)}{2K(H_2S)A(H_2S)}, \quad (3)$$

$$\left(\frac{C}{H}\right)=\frac{K(CO_2)A(CO_2)+K(COS)A(COS)+K(CS_2)A(CS_2)}{2K(H_2S)A(H_2S)}. \quad (4)$$

However, the values of $K(CO_2)$ and K(COS) obtained by Eqs. 3 and 4 were accompanied with the fluctuation of the value of $K(CS_2)$ in Eq. 4. Therefore an equation which is free from $K(CS_2)$ was necessary for an improvement of the values of $K(CO_2)$ and K(COS). In the present study, K(COS) was obtained from Eq. 5, which was obtained by neglecting $2K(CO_2)A(CO_2)$ in Eq. 3, by the use of the analytical data of 8-quinolinol in which the amount of CO_2 was negligibly small.

$$\left(\frac{O}{H}\right)=\frac{K(COS)A(COS)}{2K(H_2S)A(H_2S)} \quad (5)$$

Then $K(CO_2)$ was calculated by Eq. 3 by the use of the analytical data of sucrose. Table 3 shows the fluctuation of $K(CO_2)$ and K(COS) in the present and in the previous procedures. The values of C.V. in Table 3 indicate that the present procedure is superior to the previous one.

Analysis of Various Organic Compounds. Various organic compounds were analyzed by the present procedure (Table 4). Judging from the results in Table 4, both precision and accuracy were superior to those in the previous procedure.

Analysis of Liquid Samples. Liquid samples were newly analyzed in the following manner. A liquid sample was taken in a quartz capillary tube (0.5 mm i.d., 2 mm long) by the capillary action; 5 mg of S were inserted in the quartz tube which was closed at one end, and the inside of the quartz tube was replaced with He as in the previous study.[1] Ten minutes later, the stream of He was stopped, and the other end of the quartz tube was sealed. Each ampule thus obtained was analyzed by the present procedure. Analytical results of liquid samples are shown in Table 5. It shows that high boiling point liquid organic compounds can be analyzed with satisfactory results by the PSGC.

A Potentiometric Study on Mixed Ligand Cadmium(II) Complexes with 2-Pyridinecarboxylic Acid and 2-Aminoalkanoic Acids

Haruo Matsui* and Hitoshi Ohtaki†

Government Industrial Research Institute, Nagoya, Hirate-cho, Kita-ku, Nagoya 462

† *Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227*

(Received December 21, 1981)

Formation constants of cadmium(II) complexes with 2-pyridinecarboxylic acid (Hpic) were determined in aqueous solutions containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium at 25 °C by potentiometric titrations. On the basis of the formation constants of the complexes thus determined and those of the 2-aminoalkanoate complexes previously obtained, formation constants of mixed ligand cadmium(II) complexes CdL(pic) were determined, where L^- denotes a 2-aminoalkanoate ion such as glycinate (gly^-), α-alaninate (ala^-), 2-aminobutanoate (but^-), 2-aminopentanoate (pen^-), or 2-aminohexanoate (hex^-) ion. The formation constants $\log \beta_{111} = \log \{[CdL(pic)]/([Cd^{2+}][L^-][pic^-])\}$ of the 1:1:1 mixed ligand cadmium(II) complexes are: Cd(gly)(pic), 8.88; Cd(ala)(pic), 8.47; Cd(but)(pic), 8.42; Cd(pen)(pic), 8.73; and Cd(hex)(pic), 8.76. The equilibrium constant of the reaction between $Cd(gly)^+$ and pic^- was larger than that between $Cd(pic)^+$ and gly^-, and much larger than the equilibrium constants between CdL^+ and L'^- previously studied, where L^- and L'^- are 2-aminoalkanoate anions.

Formation equilibria of mixed ligand cadmium(II) complexes with various aliphatic 2-aminoalkanoic acids were studied in the previous work.[1] In the present investigation we examined the formation of mixed ligand cadmium(II) complexes containing aliphatic amino acids and 2-pyridinecarboxylic acid (Hpic) which can form five-membered chelate rings with the central cadmium(II) ion. 2-Quinolinecarboxylic acid (Hquin) was also used as another aromatic amino acid-like ligand, but the formation constant of neither $Cd(quin)_2$ nor CdL(quin) complex (L^-=2-aminoalkanoate ion) could be determined because of the formation of precipitates in solutions at an early stage of titrations.

Experimental

Reagents. 2-Pyridinecarboxylic acid was obtained from Wako Pure Chemicals Ind., Osaka, and used without further purification. Other reagents such as cadmium(II) perchlorate, lithium perchlorate, and lithium hydroxide were prepared and purified by the methods described in the previous paper.[1] Glycine (Hgly), α-alanine (Hala), 2-aminobutanoic acid (Hbut), 2-aminopentanoic acid (Hpen), and 2-aminohexanoic acid (Hhex) were used after analysis and purification by the previous method.[1]

Method of Measurements. Glass electrode, a pH meter and cells used were the same as those employed in the previous study.[1] Lithium perchlorate was used as an inert ionic medium (3 mol dm^{-3}).

The ratio of the total concentration of 2-pyridinecarboxylic acid (Hpic) to that of cadmium(II) ions (C^t_{pic}/C^t_{Cd}) was kept 5. When the mixed ligand systems were examined, the composition of the solution containing 2-pyridinecarboxylic acid, a 2-aminoalkanoic acid (HL), and cadmium(II) ion was kept 2.5:2.5:1, independent of the total concentrations of the species.

The method of emf measurements was essentially the same as that employed in the preceding work.[1] All the measurements were carried out at 25.00 °C±0.02 °C in a liquid paraffin bath under a nitrogen atmosphere.

Results and Discussion

The formation constants of the 1:1 and 1:2 complexes of cadmium(II) ion with 2-pyridinecarboxylic acid are given in Table 1, together with the acid dissociation constants (pK_1 and pK_2) of the ligand. The values were compared with those determined in other media.[2-4]

The formation constants of cadmium(II) complexes with 2-quinolinecarboxylic acid were determined under the same experimental conditions, but the formation constant (K_{12}) of the 1:2 complex was not determinable, because white precipitates were formed in solutions at an early stage of titrations. The acid dissociation constants of 2-quinolinecarboxylic acid were determined to be pK_1=2.17 and pK_2=5.58. The value

Table 1. Formation constants of cadmium(II) complex with 2-pyridinecarboxylic acid at 25 °C

Ligand	Medium (mol dm^{-3})	pK_1	pK_2	$\log K_{11}$	$\log K_{12}$	$\log \beta_2$	Ref.

	0.1 $NaNO_3$	1.60	5.54	4.36	3.18	7.54	2
	0	1.03	5.33	4.79	3.46	8.25	3
	0.5 $NaNO_3$	0.87	5.18	4.18	3.43	7.61	4

a) Standard deviations are ±0.02.

of $\log K_{11}$ for the 1:1 complex of cadmium(II) ion with 2-quinolinecarboxylic acid was 4.88, which was much larger than the literature value (4.12) at zero ionic concentration.[5]

Formation constants of mixed ligand cadmium(II) complexes with 2-pyridinecarboxylic acid were determined by the same procedure as described in the previous paper.[1] Typical titration curves are shown in Fig. 1, which were obtained in the Cd(II)–α-alanine–2-pyridinecarboxylic acid system. The solid lines in Fig. 1 were drawn by using calculated values of the degree of neutralization of the total ligands X (X_{calcd}) by the following equation:

$$X_{\text{calcd}} = \frac{C_{\text{L}}^{\text{t}} + K_{\text{i}}[\text{H}^+]^{-1} - [\text{H}^+] - \sum_p \sum_q \sum_r \sum_s q\beta_{pqrs}[\text{Cd}^{2+}]^p[\text{H}^+]^q[\text{L}^-]^r[\text{L}'^-]^s}{C_{\text{L}}^{\text{t}}}, \quad (1)$$

where K_{i} represents the autoprotolysis constant of water in the 3 mol dm^{-3} $LiClO_4$ aqueous solution at 25 °C ($10^{-13.87}$ mol^{2}dm^{-6} [6]). Since the only 1:1:1 type of mixed ligand complexes without protons has been found under the present experimental conditions (*i.e.*, $p=1$, $q=0$, and $r=s=1$), the formation constant of the mixed ligand complex will be denoted as β_{111}. The results obtained are summarized in Table 2 with values of F_{m}, F'_{m}, and b, which are indices of deviation of the formation constant of the mixed ligand complex from the statistical values defined by the following equations:

$$\left.\begin{aligned} &\text{CdL}_2 + \text{CdL}'_2 = 2\text{CdLL}' \\ &2\log\beta_{111} = \log\beta_{120} + \log\beta_{102} + \log F_{\text{m}} \end{aligned}\right\}, \quad (2)$$

$$\left.\begin{aligned} &\text{CdL}^+ + \text{CdL}'^+ = \text{CdLL}' + \text{Cd}^{2+} \\ &\log\beta_{111} = \log\beta_{110} + \log\beta_{101} + \log F'_{\text{m}} \end{aligned}\right\}, \quad (3)$$

$$\left.\begin{aligned} &\log F_{\text{m}} = 2\log F'_{\text{m}} + b \\ &b = \log\{(K_{110}\cdot K_{101})/(K_{120}\cdot K_{102})\} \end{aligned}\right\}. \quad (4)$$

It is well known that mixed ligand complexes which contain a ligand having a pyridine ring as one component are strongly stabilized.[7] The present results show the trend with the indication of large $\log F_{\text{m}}$ values compared with the statistical value of 0.6 and positive values of $\log F'_{\text{m}}$. The b values obtained in the present systems were much larger than those reported in the previous systems containing only 2-aminoalkanoate anions as ligands.[1]

The largest formation constant was obtained for the Cd(gly)(pic) complex. The degree of stabilization of mixed ligand 1:1:1 complex by coordination of the second ligand to the 1:1 complex can be indicated by the K_{12}^{m} value which is defined by the following equation:

$$\log K_{12}^{\text{m}} = \log\beta_{111} - \log K_{11}. \quad (5)$$

The $\log K_{12}^{\text{m}}$ values thus calculated are summarized in Table 3, together with those obtained for the mixed ligand cadmium(II) complexes with only 2-aminoalkanoate ions found in the previous work.[1] It is obvious that the coordination of a 2-pyridinecarboxylate anion to a 2-aminoalkanoatocadmium(II) complex remarkably stabilizes the 1:1:1 mixed ligand complex, because of a large coordination ability of the pyridine ring by electron-withdrawing from the central metal ion. However, it should be noted that the formation constant K_{12}^{m} between the 2-pyridinecarboxylatocadmium(II) complex and a 2-aminoalkanoate ion (*i.e.*, $\text{Cd(pic)}^+ + \text{L}^- = \text{CdL(pic)}$) was larger than that of the reaction between 2-aminoalkanoatocadmium(II) complex (CdL^+) and another 2-aminoalkanoate ion L'^- ($\text{L}^- \neq \text{L}'^-$) (see Table 3). The result indicates that the pyridine ring in the coordination sphere of the complex enhances the interaction between the central cadmium(II) ion and the entering 2-aminoalkanoate ion. It must be noted that the 2-pyridinecarboxylate anion coordinated to the central cadmium(II) ion does not significantly stabilize the interaction between the 2-pyridinecarboxyl-

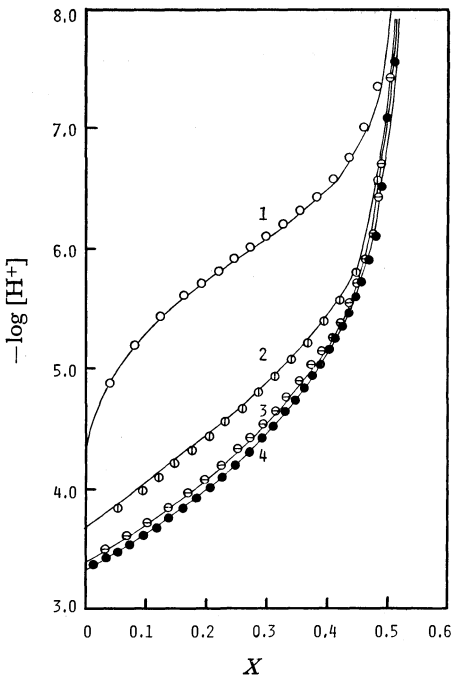

Fig. 1. Typical titration curves of cadmium(II)–α-alanine-2-pyridinecarboxylic acid mixed solutions. Curve 1 (○), C_{Cd}(mmol dm^{-3})=0, C_{ala}(mmol dm^{-3})=10.11, C_{pic}(mmol dm^{-3})=10.31; 2 (◑), 2.156, 5.409, 5.420; 3 (⊖), 6.565, 16.36, 16.39; 4 (●), 11.01, 27.44, 27.49. Solid lines represent calculated titration curves by using values listed in Tables 1 and 3 and Eq. 1.

TABLE 2. FORMATION CONSTANTS OF MIXED LIGAND COMPLEXES OF CADMIUM(II) ION AND F_{m}, F'_{m}, AND b VALUES IN 3 mol dm^{-3} $LiClO_4$ AT 25 °C

$Cd(hex)^+$	5.02	3.69[b]	3.50	3.46	3.57	*3.29*

a) Values underlined are $\log K_{12}$ of the bis(2-pyridinecarboxylato)- and bis(2-aminoalkanoato)cadmium(II) complexes. b) Values obtained from Ref. 1.

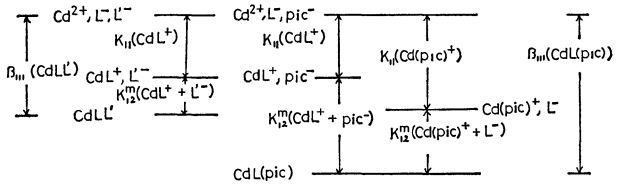

Fig. 2. A diagram showing relationships among the values of β_{111}, K_{11}, and K_{12}^{m}. Note that the magnitude of the K_{12}^{m} values are in the order $(CdL^+ + pic^-) > (Cd(pic)^+ + L^-) > (CdL^+ + L'^-)$.

atocadmium(II) complex and the second 2-pyridinecarboxylate ion (*i.e.*, $Cd(pic)^+ + pic^- = Cd(pic)_2$).

The values of K_{12}^{m} of the reaction, $CdL^+ + pic^- = CdL(pic)$, are larger than K_{12}^{m} value of the reaction, $Cd(pic)^+ + L^- = CdL(pic)$ (Fig. 2), the fact, no doubt, indicating a large affinity of pic^- compared with L^- to a cadmium(II) ion. The K_{12}^{m} values of the reaction, $Cd(pic)^+ + L^- = CdL(pic)$, are larger than those of the reaction, $CdL'^+ + L^- = CdLL'$. The result is explainable in terms of a large electron-withdrawing effect of the pyridine ring within pic^- which leads to a decrease in the electron density at the cadmium atom of the $Cd(pic)^+$ complex. The lowered electron density at the cadmium atom of the $Cd(pic)^+$ complex allows to transfer electron pairs from an entering second 2-aminoalkanoate ion. Therefore, a stronger electron donation from the second ligand of the 2-aminoalkanoate ion to the $Cd(pic)^+$ complex in comparison with the reaction between CdL^+ and L'^- can be done to form a strong σ-bonding between them. Thus, the K_{12}^{m} value of the CdL(pic) complex becomes larger than that of the CdLL′ complex.

(Received December 28, 1981)

Reactions of bis(trifluoroacetylacetonato)palladium(II), [Pd(tfac)$_2$], with tertiary phosphines followed by pyridine or its derivatives afforded a series of the [Pd(tfac(2—)-*C,O*)LL']-type complexes which contain a C,O-chelating trifluoroacetylacetonate dianion and a couple of tertiary phosphine and/or heterocyclic nitrogen base ligands (L and L'). Their structures in solution were studied by ^{1}H, ^{13}C, ^{19}F, and ^{31}P NMR spectroscopy and the molecular structure in a crystal of [Pd(tfac(2—)-*C,O*)(PPh_3)(2,6-Me_2-py)]·C_6H_6 containing triphenylphosphine and 2,6-dimethylpyridine as L and L' was determined by means of X-ray diffraction.

β-Dicarbonyl compounds are very popular ligands[1] and widely used as chelating monoanions.[2] In recent years the reactions of bis(β-diketonato)palladium(II) and -platinum(II) with a variety of nitrogen bases[3] and tertiary phosphines[3a,4] have been extensively studied to demonstrate transformation of the chelating β-diketonate anion into the central-carbon-bonded[5] and other bonding states. The η-allylic complexes of monoanions of ethyl acetoacetate[6] and acetylacetone[7] were also shown to react with Lewis bases to afford the terminal-carbon-bonded complexes.[7,8]

In the course of these studies, four novel coordination modes of β-diketonate dianions have been found: η-allylic coordination of the acetylacetonate dianion to palladium(II)[9] and platinum(II)[10] and of the dianion of ethyl acetoacetate to palladium(II),[9] C,O-chelation of the trifluoroacetylacetonate dianion to platinum(II),[11] bridging of the acetylacetonate dianion between palladium(II) and another metal *via* the terminal carbon and two oxygen atoms,[12] and another type of bridging by dianions of acetylacetone and ethyl acetoacetate, η^3-bonding to palladium and O,O'-chelating another metal atom.[13]

This paper reports the preparation and NMR characterization of C,O-chelates of the trifluoroacetylacetonate dianion with palladium(II) and also the crystal and molecular structure of one complex containing triphenylphosphine and 2,6-dimethylpyridine as ancillary ligands.

Experimental

Preparation of Complexes. Bis(trifluoroacetylacetonato)-palladium(II), [Pd(tfac)$_2$] (**1**) was prepared by the method reported in a previous paper.[14] Tris(*o*-tolyl)phosphine, P(*o*-tolyl)$_3$, was recrystallized from ethanol. Triphenylphosphine, PPh_3, and nitrogen bases were used as supplied without further purification.

*Trifluoroacetylacetonato(2—)bis(triphenylphosphine)palladium(II)–Diethyl Ether (1/1), [Pd(tfac(2—)-C,O)(PPh_3)$_2$]·Et_2O (**2**):* A dichloromethane solution (0.5 cm^3) of 1,8-bis(dimethylamino)naphthalene (21 mg, 0.10 mmol) was added to a solution of **1** (41 mg, 0.099 mmol) and triphenylphosphine (52 mg, 0.20 mmol) in the same solvent and the mixture was left to stand at room temperature for one day. Diethyl ether (8 cm^3) and hexane (8 cm^3) were added to the solution and the mixture was kept in a refrigerator overnight to deposit yellow needles, which were filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 58 mg (68%). Inclusion of one molecule of diethyl ether per palladium was confirmed by ^{1}H NMR spectroscopy.

*[Pd(tfac(2—)-C,O)(PPh_3)(py)] (**3**):* Pyridine (0.5 cm^3, 6 mmol) was added to a dichloromethane solution (5 cm^3) containing **1** (75 mg, 0.18 mmol) and triphenylphosphine (96 mg, 0.37 mmol) and the mixture was kept to stand at room temperature for one day. The solution was concentrated to 2 cm^3 by evaporation under reduced pressure and diethyl ether was added to the concentrate. Yellow plates deposited after standing for one day at room temperature were filtered, washed with diethyl ether, and dried *in vacuo*. On being washed with diethyl ether, yellow plates lost the solvent of crystallization (dichloromethane), turning opaque. The yield was 60 mg (56%).

*[Pd(tfac(2—)-C,O)(PPh_3)(4-Me_2N-py)]·1/2CH_2Cl_2 (**4**):* 4-(Dimethylamino)pyridine (31 mg, 0.25 mmol) was added to a solution of **1** (103 mg, 0.250 mmol) and triphenylphosphine (131 mg, 0.499 mmol) in benzene (5 cm^3) and the mixture was left to stand at room temperature overnight to precipitate yellow needles, which were filtered, washed with a mixture (1:2 by volume) of dichloromethane and hexane, and dried *in vacuo*. The yield was 91 mg (57%). Recrystallization from dichloromethane–hexane gave yellow needles which contain a half molecule of dichloromethane per palladium.

*[Pd(tfac(2—)-C,O)(PPh_3)(2,6-Me_2-py)] (**5**):* 2,6-Dimethylpyridine (3 cm^3, 26 mmol) was added to a solution of **1** (805 mg, 1.95 mmol) and triphenylphosphine (1045 mg, 3.98 mmol) in dichloromethane (25 cm^3) and the mixture was stirred for 3 h. The solution was concentrated to 5 cm^3 by evaporation under reduced pressure and diethyl ether was added to the concentrate to precipitate yellow crystals (1142 mg) in a 91% yield, which were recrystallized from dichloromethane–hexane or benzene. In the former case, yellow plates deposited lost the solvent of crystallization (probably dichloromethane) and turned opaque on being washed with diethyl ether. In the latter case the benzene solvate (**5'**) was obtained, which was submitted for X-ray analysis.

*[Pd(tfac(2—)-C,O){P(o-tolyl)$_3$}(2,6-Me_2-py)] (**6**):* 2,6-

Dimethylpyridine (2 cm³, 17 mmol) was added to a solution of [Pd(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}][4b] (215 mg, 0.300 mmol) in dichloromethane (10 cm³) and the mixture was stirred for 5 h. Addition of diethyl ether to the solution precipitated yellow fuzzy crystals, which were filtered and dried *in vacuo*. The yield was 78 mg (39%).

[Pd(tfac(2−)-C,O){P(o-tolyl)$_3$}(4-Me$_2$N-py)] (7): Yellow crystals of **7** were prepared in a manner similar to **6**. The yield was as low as 5% because of formation of [Pd(4-Me$_2$N-py)$_4$](tfac)$_2$ as a by-product.

[Pd(tfac(2−)-C,O)(2,9-Me$_2$-phen)] (12): Complex **1** (823 mg, 1.99 mmol) was allowed to react with 2,9-dimethyl-1,10-phenanthroline–water (1/2) (416 mg, 1.91 mmol) in dichloromethane (30 cm³) at room temperature for 4 h. The solvent was removed under reduced pressure and the residue was dissolved in acetone (5 cm³). Diethyl ether (10 cm³) was added to the solution and the mixture was kept in a refrigerator overnight to deposit yellow cubes, which were filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 600 mg (65%).

[Pd(tfac(2−)-C,O)(4-Me$_2$N-py)$_2$] (9): Complex **12** (234 mg, 0.501 mmol) and 4-(dimethylamino)pyridine (183 mg, 1.50 mmol) were dissolved in dichloromethane (5 cm³) and the mixture was left to stand for 1.5 h. On addition of hexane to the solution, yellow needles appeared immediately. After being kept in a refrigerator overnight, the crystals were filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 210 mg (83%).

[Pd(tfac(2−)-C,O)(py)$_2$] (8): Yellow needles of **8** were obtained in a 50% yield in the same way as above. This complex dissolves in dichloromethane and acetone but a yellow precipitate deposits promptly, which has not been characterized.

[Pd(tfac(2−)-C,O)(bpy)] (10): When a dichloromethane solution (2 cm³) of 2,2′-bipyridine (156 mg, 1.00 mmol) was added to a solution of **1** (413 mg, 1.00 mmol) in the same solvent (10 cm³), an orange-red crystalline solid appeared, which was filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 170 mg (41%). Recrystallization was performed from a mixture (1:1 by volume) of chloroform and methanol, the product containing one half molecule of chloroform per palladium. Alternatively, a suspension of [Pd(tfac)(bpy)](tfac)[3c] (100 mg, 0.176 mmol) in dichloromethane (5 cm³) was stirred at 40 °C for 40 min to result in a clear solution, which was cooled spontaneously to room temperature to deposit a yellow precipitate of **10** (27 mg) in a 37% yield.

[Pd(tfac(2−)-C,O)(phen)] (11): Compound **11** was obtained in a 30% yield by the reaction of **1** with 1,10-phenanthroline in a manner similar to **10**.

Measurements. IR spectra were recorded in Nujol mull on a Hitachi 295 infrared spectrophotometer. NMR spectra were measured with JEOL FX60Q (for ^{1}H, ^{13}C, and ^{31}P) and FX90Q (for ^{19}F) spectrometers. The molecular weight was determined by vapor pressure osmometry with an instrument manufactured by Knauer in West Berlin, West Germany.

X-Ray Diffraction: Crystal Data. [Pd(tfac(2−)-*C,O*)(PPh$_3$)(2,6-Me$_2$-py)]·(C$_6$H$_6$) (**5′**), C$_{30}$H$_{24}$O$_2$NF$_3$PPd·C$_6$H$_6$, F. W. 703.0, monoclinic, P2$_1$/c, a=10.035(2), b=17.941(6), c=18.903(5) Å, β=103.25(2)°, V=3312.6(16) Å^3, D_m=1.40 (flotation), D_c=1.41 g cm^{-3} for Z=4, μ(Mo $K\alpha$)=6.51 cm^{-1}.

The crystal was sealed in a thin-walled glass capillary tube, since it was rather unstable in air. The unit-cell parameters and reflection intensities of **5′** were measured on a Rigaku automated, four-circle diffractometer with graphite monochromatized Mo $K\alpha$ radiation (λ=0.71069 Å). Intensity data were collected by the θ-2θ scan technique. The scan rate was 4° min^{-1} and the scan width was $\Delta(2\theta)$=(2.0+0.7 tan θ)°. The background intensities were measured for 7.5 s at both ends of a scan. Four standard reflections (0, 10, 0, 500, 066, and 555) were measured at regular intervals to monitor crystal stability and orientation, and the intensities of these reflections remained constant throughout the data collection. Usual Lorentz and polarization corrections were made, but no absorption correction was carried out. A total of 6001 (5180 non-zero) reflections was measured (sin $\theta/\lambda \leqq 0.6$).

Solution and Refinement of the Crystal Structure of 5′. The structure was solved by the heavy atom method. Approximate coordinates of the palladium atom were obtained from a three-dimensional Patterson function. Subsequent Fourier synthesis revealed locations of all the non-hydrogen atoms. The existence of the solvated benzene molecule was also discovered. Including the carbon atoms of the crystalline benzene molecule, the structure was refined anisotropically by the block-diagonal least-squares procedure (*HBLS* **V**).[15] The function minimized was $\sum w(|F_o|-|F_c|)^2$. Hydrogen atoms except those of terminal methyl groups and solvated benzene molecule were located by the difference Fourier synthesis, and refined isotropically. The final R is 0.045 for non-zero (0.063 for all) reflections. The weighting schemes used at the final stage were $w=\{\sigma_{cs}^2(F_o)+0.0292|F_o|+0.0010|F_o|^2\}^{-1}$ for $|F_o|>0$ and $w=0.0504$ for $|F_o|=0$; σ_{cs} is the standard deviation obtained by the counting statics. The atomic scattering factors used for non-hydrogen atoms were taken from International Tables for X-Ray Crystallography[16] and those for hydrogen atoms from Stewart and co-workers.[17] Computations were done on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University. The final atomic coordinates with equivalent temperature factors[18] are given in Table 1.†††

Results and Discussion

Characterization of the Trifluoroacetylacetonate(2−) Complexes. The analytical data for the newly prepared complexes given in Table 2 conform to their proposed formulae, [Pd(tfac(2−)-*C,O*)LL′]. The molecular weight of complex **5** was determined in dichloromethane at 25 °C to be 616 in good agreement with the calculated value 627. In accord with the proposed structure, all complexes show the ν(C=O) bands in 1620—1600-cm^{-1} region, complex **5**, for instance, having a very strong band at 1615 cm^{-1}.

Table 3 presents the ^{1}H NMR spectra in CDCl$_3$. The spectrum of each complex is composed of signals assignable to CH$_2$, CH, L, and L′ protons. The methine proton of tfac dianion resonates in the 5.13—5.28-ppm region, the chemical shift being rather insensitive to natures of the ancillary ligands. On the other hand, the chemical shifts and multiplicities of the methylene signals clearly show dependence on natures of the neutral ligands L and L′, spanning a wider range of 2.54—3.14 ppm. Thus the signal for the methylene protons of **2** appears as a doublet of doublets due to couplings to both the trans and cis phosphorus atoms, ^3J(P-H) being 9.$_5$ and 5.$_9$ Hz,

††† Tables of anisotropic thermal parameters and observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8234).

a) Chemical shifts in ppm from internal Me_4Si. Signals are singlets except those marked with d(doublet), dd(doublet of doublets), and c(complex). Figures in parentheses and brackets give ^3J(CH–CH) and ^3J(P–H) in Hz, respectively. b) In a mixture (1:1 by volume) of $CDCl_3$ and CD_3OD at 50 °C.

respectively. The signal pattern closely resembles that of [Pt(tfac(2−)-*C,O*)(PPh_3)$_2$][11] except the ^{195}Pt satellites. The methylene protons of **4**, **5**, and **6** resonate as a doublet with smaller ^3J(P–H) values, indicating that the phosphine ligand lies on the position cis to the methylene in each of these complexes.

In the case of complexes containing the same kind of neutral ligands (L=L′), two sets of signals from L should be observed since the chelating tfac(2−) ligand is unsymmetric. In fact complex **9** shows two kinds of signals assignable to NMe_2 and pyridine-CH protons. However, complex **12** exhibits no splitting in signals from ring-CH and Me protons, suggesting some kind of fluxional motion (coordination-site exchange).

The ^{13}C NMR data are listed in Table 4. The methylene carbon of **2** resonates as a doublet owing to coupling to the trans ^{31}P, ^2J(P–C) being 70 Hz. Coupling to the cis ^{31}P is not detected contrary to the case of the corresponding platinum(II) complex in which couplings to both ^{31}P atoms were observed (72 and 4 Hz).[11] Complexes **4**, **5**, and **6** exhibit methylene doublets with ^2J(P–C) of 4—5 Hz in accordance with the proposed *cis*(CH_2, P) structure. The $\underline{C}F_3\underline{C}O$ carbons of these complexes also couple to ^{31}P, conforming with their positions trans to ^{31}P.

Complexes **2** and **9** exhibit two sets of signals attributable to PPh_3 and 4-Me_2N-py carbons, reflecting unsymmetry of the tfac(2−) chelate. In the case of **12** at room temperature, the methyl carbons of 2,9-Me_2-phen appear as two broad signals, while the ring carbons show one set of rather broad signals. The methyl signals merge at higher temperatures to a broad singlet at 52 °C and signals of the ring carbons are sharpened, indicating equivalence of two halves of the phen molecule. The tfac(2−) carbons are invariably sharp at these temperatures, suggesting that the coordination-site exchange occurs in an intramolecular fashion rapidly on the NMR time scale. Self catalysis by virtue of coordination of a neighboring molecule *via* the carbonyl oxygen of tfac(2−) as was observed for [Pd(acac)(6-chloro-3 or 4-pyridyl)(PPh_3)][19] is not a plausible mechanism for the present case, since a free ligand such as pyridine, triphenylphosphine, and tris(*o*-tolyl)phosphine added to a solution of **12** showed no promoting effect. No evidence to support mechanism *via* a three-coordinate[20] or a nonplanar four-coordinate[21] intermediate as proposed for some complexes has been obtained in the present case. The exact nature of the fluxional motion of **12** is not clear at the present stage of investigation.

The ^{19}F NMR spectrum of **5** shows a broad signal with the half-height width of 2.6 Hz at 72.60 ppm upfield from external $CFCl_3$. The broadness may be caused by coupling to the phosphorus atom situated at the trans position, since the ^{19}F signal from [Pt(tfac(2−)-*C,O*)(PPh_3)$_2$] appears as a doublet owing to coupling to ^{31}P with ^5J(P–F)=1.1 Hz.[11] Figure 1 shows the ^{31}P{^{1}H} NMR spectra of **2** and **5** in $CDCl_3$. Complex **5** exhibits a quartet at 37.2$_0$ ppm downfield from external H_3PO_4 with ^5J(P–F)=0.9 Hz in accord with the proposed trans arrangement. Complex **2** shows an AB quartet (^2J(P–P)=35.7 Hz), reflecting nonequivalence of the two phosphorus atoms. The broad signal at 38.5$_8$ ppm is assigned to P^2 trans to O, since the chemical shift is close to that observed for **5** and the broadening is thought to be caused by coupling to the ^{19}F atoms. The sharp doublet at 22.8$_4$ is thus assigned to P^1 trans to C. It may be worth noting that the relative positions of the P^1 and P^2 signals are reverse of those for [Pt(tfac(2−)-*C,O*)(PPh_3)$_2$].[11]

Formation of the Trifluoroacetylacetonato(2−) Complexes. In a previous paper[11] [Pt(tfac)$_2$] was reported to react with a Lewis base (L) such as triphenylphosphine, tris(*p*-chlorophenyl)phosphine, and triphenylarsine at room temperature to afford a C,O- chelate of the trifluoroacetylacetonate dianion, [Pt(tfac(2−)-

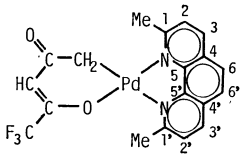

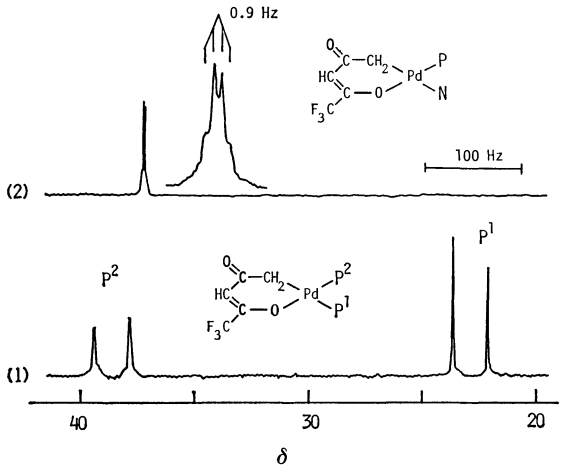

Fig. 1. $^{31}P\{^1H\}$ NMR spectra at 24.2 MHz of [Pd(tfac(2−)-*C,O*)$(PPh_3)_2$] (**2**) (curve 1) and [Pd(tfac-(2−)-*C,O*)(PPh_3)(2,6-Me_2-py)] (**5**) (curve 2) in $CDCl_3$ with H_3PO_4 as an external reference.

C,O)L_2]. The ^1H NMR monitoring revealed that when [Pt(tfac)$_2$] was mixed with a twice molar amount of triphenylphosphine in $CDCl_3$, [Pt(tfac)$(PPh_3)_2$](tfac) was produced at first, which was then converted gradually into [Pt(tfac(2−)-*C,O*)$(PPh_3)_2$].[4b] The tfac anion in the outer sphere of the salt-like compound was supposed to have abstracted a proton from the methyl group of the chelating tfac anion.

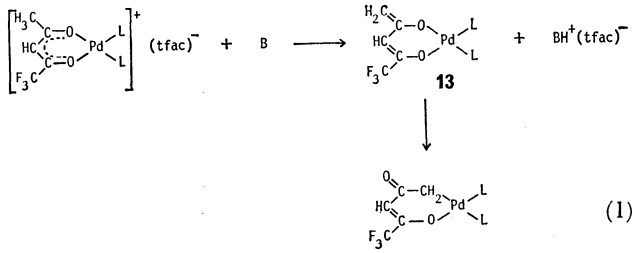
The reaction of [Pd(tfac)$_2$] with twice molar triphenylphosphine in $CDCl_3$ was also confirmed by ^1H NMR spectroscopy to form [Pd(tfac)$(PPh_3)_2$]-(tfac).[4b] Contrary to the platinum(II) case, however, the palladium(II) complex is stable and deprotonation of the chelating tfac does not occur spontaneously, although exchange of tfac anions in the inner and outer spheres is rapid on the NMR time scale.[4b] As was described in the Experimental section, addition of a powerful and noncoordinating base, 1,8-bis(dimethylamino)naphthalene ("proton sponge") to the solution of [Pd(tfac)$(PPh_3)_2$](tfac) in dichloromethane was effective for deprotonation of the chelating tfac to give rise to **2**. Employment of pyridine, 4-(dimethylamino)pyridine, and 2,6-dimethylpyridine as a base effected substitution of one phosphine molecule besides deprotonation of the chelating tfac to

result in **3**, **4**, and **5**, respectively. The reaction of $[Pd(tfac)_2]$ with tris(*o*-tolyl)phosphine produces [Pd(tfac)(tfac-*O*){P(*o*-tolyl)$_3$}] reversibly,[4b,22] which also reacts with pyridine derivative (L) to afford **6** and **7**. The latter reactions are also supposed to proceed *via* intermediates of the type [Pd(tfac){P(*o*-tolyl)$_3$}L](tfac).

$[Pd(tfac)_2]$ reacts readily with an equimolar amount of 2,2′-bipyridine in benzene at room temperature to afford [Pd(tfac)(bpy)](tfac).[3c] When the product is isolated and dissolved in hot dichloromethane, the salt-like complex is converted into **10**. Therefore the reactions of $[Pd(tfac)_2]$ with 2,2′-bipyridine, 1,10-phenanthroline, and 2,9-dimethyl-1,10-phenanthroline in dichloromethane to afford complexes **10**, **11**, and **12** are supposed to proceed *via* similar intermediary salt-like complexes. It is interesting that the bidentate base in **12** is easily displaced by pyridine and its derivatives to give **8** and **9**, for instance. These ligand substitution reactions are convenient for synthesis of **8** and related complexes, since the direct reactions between $[Pd(tfac)_2]$ and pyridines attain the following equilibria[3c] and do not give rise to **8** and the like.

$$[Pd(tfac)_2] \overset{py}{\rightleftharpoons} [Pd(tfac)(tfac\text{-}C^3)py] \overset{py}{\rightleftharpoons} [Pd(py)_4](tfac)_2$$

Deprotonation of the chelating tfac monoanion by a base (or tfac itself) might produce a dienediolate complex **13** as an intermediate. Such a dienediolate



(1)

bonding of acetylacetonate dianion was found in $[(\eta\text{-}C_5H_5)(CO)_2Mn\{PPh(C_5H_6O_2)\}]$[23] and $[(CO)_5M\{PPh(C_5H_6O_2)\}]$ (M=Cr and W).[24] However, complex **13** seems to be unstable in the case of Pd(II) and Pt(II) compounds, transforming into the C,O-chelate. It should be recalled that deprotonation of $[PdCl(CH_2COCH_2COCH_3)(NN)]$ produced mainly the η^3 complex of acac dianion, [Pd(acac(2−)-*C*^{1}—*C*^{3})(NN)], accompanied by a 20—25% amount of [Pd(acac(2−)-*C*,*O*)(NN)] depending on the nature of NN (2,2′-bipyridine, 4,4′-dimethyl-2,2′-bipyridine, and 1,10-phenanthroline), whereas $[PdCl(CH_2COCH_2COOC_2H_5)(bpy)]$ gave solely the trihapto complex.[9] These results reflect the tendencies of the three β-dicarbonyl compounds in the keto-enol tautomerization equilibria. Ethyl acetoacetate, which prefers the keto tautomer,[25] forms the η^3-C^1—C^3 complex of its dianion. On the other hand, trifluoroacetylacetone exists almost totally as the enol tautomer[25] and its dianion forms C,O-chelates. Each of the tfac(2−)-C,O-chelates reported in this paper is not contaminated with the trihapto complex. Acetylacetone shows the intermediate behavior.

The fact must be added that $[Pd(tfac)(PPh_3)_2]ClO_4$[26] does not undergo the reaction with nitrogen bases to afford the tfac(2−) chelate. Some kind of cooperation of the tfac anion in the outer sphere might be necessary for deprotonation of the chelating tfac by a nitrogen base. On the other hand the reactions of $[Pd(tfac)(PCy_3)_2](tfac)$,[4b] where PCy_3 abbreviates tricyclohexylphosphine, with nitrogen bases did not afford the tfac(2−) chelate. Trials to prepare [Pd(tfac(2−)-*C*,*O*)$(PR_3)_2$] complexes by the reactions of $[Pd(tfac)_2]$ with trialkylphosphines such as PEt_3 were not successful either. Stronger basicities and/or larger steric demands of PCy_3 and PEt_3 than PPh_3 might be unfavorable for the deprotonation. Although the mechanism is not clear at present, it is worth noting that deprotonation of the chelating tfac anion (Eq. 1) occurs easily under very mild conditions, since dianions of β-dicarbonyl compounds are usually prepared under more severe conditions.[27]

To our knowledge, the first example of the reported β-dik(2−) C,O-chelates is bis(acetylacetonato(2−)-*C*,*O*)selenium(IV). This compound was claimed in patents to have been prepared by the reaction between selenium(IV) oxide and acetylacetone[28] and was used as a brightener in a copper plating bath.[29] The acac(2−) chelates of palladium(II) [Pd(acac(2−)-*C*,*O*)(NN)] could not be isolated either, but characterized only by ^{1}H NMR spectra in solution.[9] On the other hand, the corresponding tfac(2−)-C,O chelates of platinum(II) and palladium(II) were isolated as pure compounds to allow full characterization by NMR spectroscopy, and fortunately single crystals of **5′** suitable for X-ray analysis were obtained.

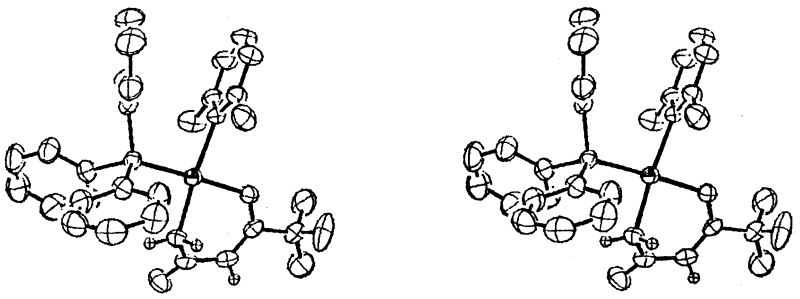


Fig. 2. A stereoscopic view of [Pd(tfac(2−)-*C*,*O*)(PPh_3)(2,6-Me_2-py)] (**5**) molecule. Non-hydrogen atoms are represented by thermal ellipsoids at 50% probability level. Hydrogen atoms attached only to the α- and γ-carbon atoms of the tfac(2−) dianion are drawn as spheres with the radius of 0.1 Å.

Molecular and Crystal Structure of [Pd(tfac(2−)-C,O)(PPh$_3$)(2,6-Me$_2$-py)]·C$_6$H$_6$ (5′). A stereoscopic drawing (*ORTEP* II)[30] of the **5** molecule is depicted in Fig. 2. Selected bond lengths and bond angles are listed in Table 5. Numbering scheme of atoms in **5** is given in Fig. 3.

The remarkable feature of the structure of **5** molecule is that the palladium atom is C,O-chelated by the tfac(2−) dianion as was expected from the spectroscopic studies (Figs. 2 and 3). The coordination around the palladium atom is essentially square-planar: the Pd atom shows the maximum deviation from the mean plane [0.034(2) Å]. The tfac(2−) dianion is not planar. Two locally planar parts are formed by the C(1), C(2), C(3), and O(2) atoms and by the C(3), C(4), C(5), and O(1) atoms. The dihedral angle between these planes is 29.3(2)°. The tfac(2−) dianion makes a distorted six-membered ring with a central palladium atom. The C(1) atom bonded to the palladium has a distorted sp^3 geometry, bond angles around the C(1) being 112.2(3), 114(3), 97(3), 109(3), 110(3), and 114(4)°. The Pd–C(1) bond length [2.051(4) Å] is consistent with the expected Pd(II)–C(sp^3) bond length and is equal to that (trans to N) in [PdCl(CH$_2$COCH$_2$COOCH$_2$Ph)(py)$_2$] [2.051(8) Å].[8b] The Pd–C(1) length is also equal to that in [(acac)PdCH$_2$COOH(PPh$_3$)][2.063(4) Å],[31] but shorter than those in [(PPh$_3$)$_2$Pd{(CH$_2$C=O)$_2$O}][2.124(11) and 2.141(13) Å].[32] The Pd–O(1) bond length [2.075(3) Å] seems to be equal to those in [(PPh$_3$)Pd(acac)-(acac-*C*^{3})][2.048(10) and 2.062(10) Å][5a] and that in a C,O-chelate, [Pd(C$_2$H$_2$O$_2$)(PPh$_3$)(py)][2.093(11) Å].[33] The Pd–N bond length [2.165(3) Å] is slightly longer than those in [PdCl(CH$_2$COCH$_2$COOCH$_2$Ph)-(py)$_2$][2.120(6) and 2.027(6) Å],[8b] and also longer than those in [{Pd(acac)(NHEt$_2$)$_2$}$^+$(acac)$^-$][both 2.044(3) Å],[34] whereas the Pd–N bond length in [Pd-(C$_2$H$_2$O$_2$)(PPh$_3$)(py)][2.144(12) Å] seems equal to that in the present complex **5′**. The 2,6-Me$_2$-py ring plane stands approximately normal to the coordination plane, the dihedral angle between these planes being 83.80(15)°.

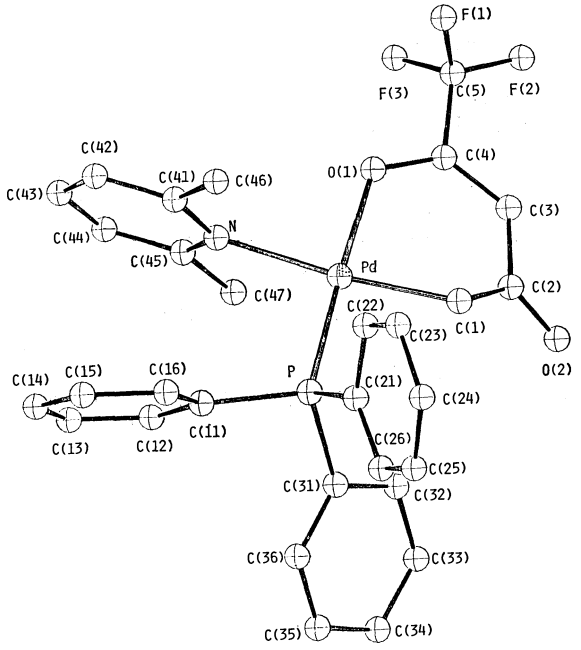

Fig. 3. The numbering scheme of non-hydrogen atoms of the **5** molecule.

Table 6. Intermolecular atomic constants[*l*/Å] less than 3.5 Å with estimated standard deviations in parentheses

F(1)···C(1)[a]	3.457(6)	
F(1)···C(22)[a]	3.365(7)	Key: a, 1−*x*, −*y*, −*z*,
C(24)···C(47)[b]	3.460(9)	b, *x*, 0.5−*y*, −0.5+*z*,
C(B3)···F(3)[c]	3.482(10)	c, −*x*, 0.5−*y*, 0.5−*z*,
C(B1)···F(2)[d]	3.406(9)	d, 1−*x*, 0.5+*y*, 0.5−*z*.

Complex **5′** forms the crystal structure shown in Fig. 4 (*ORTEP* II)[30] Intermolecular atomic contacts less than 3.5 Å are listed in Table 6. Close contacts are mainly involved between the fluorine atoms of the CF$_3$ group in one molecule and the carbon atoms in the neighboring molecules. The closest distance is F(1) (*x*, *y*, *z*)···C(22) (1−*x*, *y*, −*z*) [3.365(7) Å].

We wish to thank Mr. Junichi Gohda for elemental analyses and Mr. Tetsu Hinomoto of JEOL, Ltd. for ^{19}F NMR measurements. S. K. is grateful to the Ministry of Education, Science and Culture for Grant-in-Aid for Scientific Research, No. 243014.

Solute-Solvent Interactions in Ion Pair Extraction of Tetraalkylammonium Iodides. II. The Effect of Hydration of Iodide in Organic Solvents on the Extraction Constant

Kazuaki Ito, Etsuro Iwamoto, and Yuroku Yamamoto*

Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730

(Received January 21, 1982)

Solubilities of tetraalkylammonium iodides Et_4NI, Pr_4NI, and Bu_4NI in nitrobenzene, in water, and in their mutually saturated solvents, and of Pr_4NI in 1,1-dichloroethane and in its water saturated solvent were measured at 25 °C. Conductances of Et_4NI, Pr_4NI, and Bu_4NI in nitrobenzene and Bu_4NI in 1,1-dichloroethane, 1,2-dichloroethane, and dichloromethane have also been measured at 25 °C. A small amount of water in organic solvents increases the solubilities of the salts roughly twice those in pure solvents and decreases the association constants around 15% while a small amount of organic solvent in water gives a slight effect. Effects of mutual saturation of water and organic solvent on extraction equilibria of R_4NI were discussed in terms of the selective hydration of the iodide.

In the preceding paper,[1] we have investigated the extraction equilibria of tetraalkylammonium iodides (R_4NI) between water and eight organic solvents, and proposed a new treatment of "ionic" and "neutral" extraction constants. The results indicated that the influences of the solvents on the extractability of R_4NI can be interpreted in terms of the following properties; the dielectric constant for the ionic part, the solubility parameter for the neutral, and the hydrogen bonding for both.

The ion pair extraction is primarily concerned with the distribution of salts between water and an immiscible organic phase, but both water and organic solvent molecules are slightly soluble in each other. In addition, water is coextracted into the organic phase[2–6] with ion pairs, and organic solvent molecules are salted-in in the aqueous phase.[7,8] However, little is known concerning to what degree the mutual saturation of solvents contributes to the ion pair extraction equilibria.

The purpose of this paper is to investigate interactions between ion pairs and a minute quantity of water in an organic solvent or of organic solvent in aqueous phase by solubility and conductivity measurements and to clarify their effects on the process of ion pair extraction in connection with solvent effects on extractability of R_4NI.

Experimental

The purification of the solvents, {nitrobenzene (NB), 1,1-dichloroethane (1,1-DCE), 1,2-dichloroethane (1,2-DCE), and dichloromethane (DCM)} and of tetraalkylammonium iodides, R_4NI (R=Et, *n*-Pr, and *n*-Bu) and the distribution ratio measurements were the same as those reported previously.[1] The distribution ratio was calculated using the expression, D=[specific activity (cpm ml^{-1}) of radionuclide ^{131}I in organic phase]/[specific activity (cpm ml^{-1}) in aqueous phase].

The conductivity bridge and cell used have been described previously.[1] Anhydrous organic solutions were prepared in a dry box filled with dry nitrogen gas under slight pressure.

Solubility measurements were carried out as follows; (1) saturated solutions of the salts in pure water and organic solvents (*ca.* 40 ml) were prepared by vigorously agitating the solvents with an excess of the salts for at least 2 d in a thermostated water bath (25±0.05 °C). (2) Saturated solutions of the salts in organic solvents equilibrated with water (and vice versa) were prepared with an excess of both the salts and water (and of both the salts and organic solvents). An aliquot (*ca.* 1 ml) of the saturated aqueous solution was passed through a sintered-glass filter and weighed. Solubilities were determined by potentiometric titration of the iodide ion with silver nitrate. Salts in organic solvents were back-extracted into water for the titration; the salt-saturated organic solutions (*ca.* 1 ml) were shaken with water (*ca.* 50 ml) and the organic phase was separated from the aqueous phase by filtration (Toyo filter paper No. 5B). This procedure was repeated several times to back-extract the salt completely. The aqueous filtrates were combined, followed by titration. Measurements were usually continued for 1 week although the solubility equilibria were obtained in at least 2 d. Preliminary measurements confirmed that the back-extraction was completely carried out even in the nitrobenzene solution of Bu_4NI for which the solubility in water is very small compared with those of Pr_4NI and Et_4NI.

Water solubilities in organic solvents were determined coulometrically with a Hiranuma AQ-3 aquacounter. Nitrobenzene solubilities in water were determined by spectrophotometry at 252 nm after extraction into cyclohexane.[8a] Densities were obtained by an Anton Paar Model DMA O2D digital density meter at 25±0.01 °C.

Results

The solubilities of Et_4NI, Pr_4NI, and Bu_4NI at 25 °C are given in Table 1. A small amount of water in nitrobenzene increases the solubilities of R_4NI largely, while a small amount of nitrobenzene in water affects hardly. The increase in solubility of R_4NI in nitrobenzene corresponds to the salting-in of water by R_4NI. It was found that Pr_4NI (0.476 mol dm^{-3}) in nitrobenzene increases the solubility of water from 0.168 to 0.620 mol dm^{-3} and Pr_4NI (0.561 mol dm^{-3}) in water increases the solubility of nitrobenzene from 0.0156 to 0.0231 mol dm^{-3}. For the water–1,1-DCE system, a small amount of water increases also the solubility of Pr_4NI. Our value for Pr_4NI in dry 1,1-dichloroethane (1.96×10^{-2} mol dm^{-3}) agrees with the value (2.04×10^{-2} mol dm^{-3}) obtained by Abraham *et al.*[9] The solid phase in equilibrium with the saturated solution was checked by chemical analysis and differential thermal analysis, and no solvate was found.

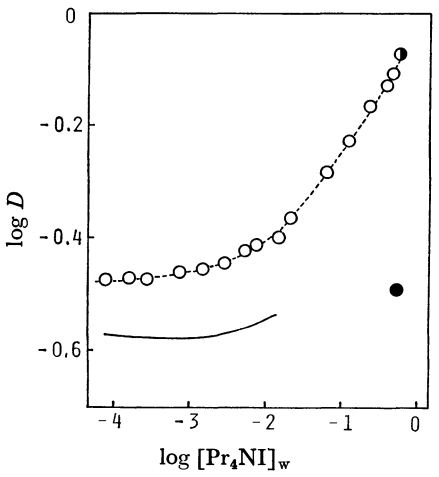

Fig. 1. Concentration dependence of distribution ratio for Pr_4NI in the water–nitrobenzene system at 25 °C. Solid line is the curve calculated from the extraction constants in Table 4. ◑: Solubility ratio for the mutually saturated solvent system, ●: solubility ratio for the pure solvent system.

Distribution ratios of Pr_4NI for the nitrobenzene–water extraction system were determined as a function of the salt concentration (Fig. 1). The distribution ratio increases with increasing the salt concentration and the solubility ratio (D=0.848) of Pr_4NI for mutually equilibrated solvents falls on the extended line. This also provides another evidence that no solvate is found.

The ionic association constant, K_a and the limiting conductance, Λ_0 of R_4NI were determined by the method of Shedlovsky.[10] The calculation was carried out using the conductances of the salts covering from 2×10^{-3} to 2×10^{-5} mol dm^{-3}. Shown in Table 2 are the ionic association constants of R_4NI in water-free and water-saturated organic solvents at 25 °C. The results indicated that the association constants in water-free solvents are larger by 10—15% than those in water-saturated solvents.

Discussion

Organic Phase. The quantity of water coextracted increases linearly with increasing salt concentration,[2-4] although the degree of dissociation of ion-pair changes markedly.[1] Pr_4NI,[3b] Bu_4NI,[4] $[Fe(phen)_3]I_2$,[2a] and $[Fe(bpy)_3]I_2$,[2a] coextract 0.98, 0.91, 1.1, and 1.1 mol of water per iodide ion into nitrobenzene, respectively, while Bu_4NBPh_4 does not coextract any water molecules. Similarly, in this study the values of 1.0, 0.95, and 1.1 mol of water per iodide ion were obtained in the saturated solutions of Et_4NI, Pr_4NI, and Bu_4NI, respectively. The value of 1.0 does not mean that the iodide anion in nitrobenzene carry exactly one water molecule, but more likely represents a distribution of the species involving hydrated and nonhydrated iodide anions and ion pairs.

The hydration of iodide anions (the ionic part) and ion pairs (the neutral part) is represented by the following equilibria,

$$I^-\cdot(m-1)H_2O + H_2O \rightleftharpoons I^-\cdot mH_2O$$

$$R_4NI\cdot(n-1)H_2O + H_2O \rightleftharpoons R_4NI\cdot nH_2O$$

with the corresponding formation constants,

$$K_m^- = [I^-\cdot mH_2O]/[I^-\cdot(m-1)H_2O]\,[H_2O], \quad (1)$$

$$K_n^p = [R_4NI\cdot nH_2O]/[R_4NI\cdot(n-1)H_2O]\,[H_2O]. \quad (2)$$

The hydration constants (K_1^-=3.45 mol dm^{-3}, K_2^-=2.60, and K_3^-=1.37) were determined from the dependence of the c.t.t.s. spectra between I^- and nitro-

benzene in the visible region on water contents in nitrobenzene solution of Pr_4NI.[11]

A small amount of protic solvent such as methanol significantly decreases the degree of ionic association for halide salts in low dielectric solvents.[12] The solubilities of water in the organic solvents used here are so small (below 0.02 mol fraction) that the water effects on dielectric constants are considered to be negligeble.[13] The change in the association constant by adding a small amount of water in organic solvents, thus, can be attributed to the hydration of the iodide anion.

The ionic association constant in organic solvents containing water is written by using Eqs. 1 and 2,

$$K_a = ([R_4NI]/[R_4N^+][I^-]f_\pm^2)(1+\sum^{n} K_1^p K_2^p \cdots K_n^p [H_2O]^n)/$$
$$(1+\sum^{m} K_1^- K_2^- \cdots K_m^- [H_2O]^m). \quad (3)$$

The first parenthesis on the right hand side in Eq. 3 is K_a°, the ionic association constant in pure organic solvent. The ratio of K_a° to K_a yields the relation,

$$(K_a^\circ/K_a) = (1+\sum^{m} K_1^- K_2^- \cdots K_m^- [H_2O]^m)/$$
$$(1+\sum^{n} K_1^p K_2^p \cdots K_n^p [H_2O]^n). \quad (4)$$

If the affinity of water for the iodide anion is greater than that for the iodide ion pair, the extent of ion pair association decreases in the presence of water. A small amount of water in nitrobenzene decreases the association constants of R_4NI by about 10% and the cation dependence is small (Table 2). This reveals that the hydration constants of the ion pairs are almost constant and are slightly less than that of the iodide anion. It has been reported that cation effects[14] were not observed in the formation phenol–halide anion complexes for a variety of quaternary ammonium salts in solvents of low dielectric constant such as dichloromethane in which salts are extensively ionic-associative. Ion pair formation between tetraalkylammonium cations and halide anions is almost electrostatic and has very modest geometrical requirements compared to mono-, di, and trialkylammonium salts which bear the sites for complex formation due to hydrogen bond.[14,15] So the hydration of the iodide ion pair is not so much different from that of the iodide anion. All the association constants of Bu_4NI in anhydrous NB, 1,2-DCE, 1,1-DCE, and DCM are about 15% greater than those in water-saturated solvents. The result that the value of K_a°/K_a is almost constant among the organic solvents would be partly because there is no specific interactions between the iodide and the solvents.

Aqueous Phase. The solubility of salts in water equilibrated with organic solvents is governed by the overall effect of mutual interactions among the three components (ion, water, and organic solvent) and can be examined from the view point of salting effects. Tetraalkylammonium salts increase the solubility of nitrobenzene in water although alkali metal halides such as NaBr do not.[8a] The salting-in by R_4N^+ is controlled mainly by the water structural effects through hydrophobic interactions which are decreased in the order, $Am_4N^+ > Bu_4N^+ > Pr_4N^+ > Et_4N^+$.[8a] Pr_4NI and Bu_4NI in the salt-saturated solutions increase solubilities of nitrobenzene with 48% and 9.6% in comparison with those in pure water, respectively (Table 3). The salting-in coefficient of Bu_4NI is reasonably larger (negative value) than that of Bu_4NBr (-0.513).[8a] Salting-in effects on benzene by aliphatic ions such as Bu_4N^+ were found to be weaker than those of aromatic ions such as Ph_4P^+ and BPh_4^- since van der Waals forces are less effective for aliphatic ions than for aromatic ions.[8b] Thus, the weaker interaction between R_4N^+ and nitrobenzene does not so much contribute to the solubility of R_4NI in aqueous phase.

Table 3. The salting-in of nitrobenzene by R_4NI in the salt-saturated aqueous solution at 25 °C

	Solubility		k_s[a]
	Nitrobenzene S/mol dm^{-3}	Salt C_s/mol dm^{-3}	
(Pure water)	0.0156[b]	—	—
n-Pr_4NI	0.0231	0.561	−0.304
n-Bu_4NI	0.0171	0.0684	−0.583

a) Salting effect coefficient $k_s = 1/C_s \times \log(S^\circ/S)$, where S° and S are the solubility of nitrobenzene in water and in a salt solution, respectively. b) From Ref. 8a.

Extraction Constant. In the extraction of tetraalkylammonium iodides the equilibrium is represented as

$$R_4N_w^+ + I_w^- + R_4NI_w \rightleftharpoons R_4N_o^+ + I_o^- + R_4NI_o,$$

where the subscripts w and o designate the aqueous and organic phases, respectively. The fraction of triple ions is so small that the triple ion term can be disregarded.[1] The extraction constant for the ionic species is

$$K_i = [R_4N^+]_o[I^-]_o f_{\pm o}^2/[R_4N^+]_w[I^-]_w f_{\pm w}^2 \quad (5)$$

for the associated species

$$K_n = [R_4NI]_o/[R_4NI]_w, \quad (6)$$

$$K_n' = [R_4NI]_o/[R_4N^+]_w[I^-]_w f_{\pm w}^2. \quad (7)$$

When the association constant of all the salts in water is taken as unity, we get the relation $K_n = K_n'$ since $[R_4NI]_w = [R_4N^+]_w[I^-]_w f_{\pm w}^2$ where $f_\pm$ is the mean ionic activity coefficient. The activity coefficient of ion pair is taken as unity. As mentioned above, since water and organic solvents are salted in by R_4NI for the solvent extraction system, the transfer free energy of R_4NI is different from that of the ion pair from one pure solvent to another pure solvent. The tetraalkylammonium cations are essentially non-hydrated in organic solvents and the solubilities of R_4NI in water equilibrated with organic solvents are almost the same as those in water, so Eqs. 5 and 6 can be rewritten upon introduction of Eqs. 1 and 2.

$$K_i'' = K_i \times (1+\sum^{m} K_1^- K_2^- \cdots K_m^- [H_2O]_o^m) \quad (8)$$

$$K_n'' = K_n \times (1+\sum^{n} K_1^p K_2^p \cdots K_n^p [H_2O]_o^n) \quad (9)$$

The extraction constants K_i'' and K_n'' for Pr_4NI in the water–nitrobenzene system were obtained at each concentration from the association constants (Table 2)

Table 4. Extraction constants of n-Pr_4NI for nitrobenzene–water system at 25 °C

b) From Ref. 1.

and distribution ratios (Fig. 1). Activity coefficients of Pr_4NI in aqueous phase, which were reported by Lindenbaum and Boyd,[16] were converted to molarity scale from molality scale. Activity coefficients of ions in nitrobenzene were calculated by using the extended Debye-Hückel equation with a value for $\mathring{a}$ of 6 Å. The satisfactory constancy of extraction constants was also observed up to *ca.* 0.02 mol dm^{-3} in nitrobenzene phase as for Bu_4NI in the NB, 1,1-DCE, 1,2-DCE, and DCM systems,[1] showing that the parenthesis terms in Eqs. 8 and 9 are constant. The deviation from the constancy of extraction constants at higher concentration may be attributed to higher aggregates for the solvent extaction system and to the change in water activity in addition to the inadequate application of the Debye-Hückel equation to such concentrated nitrobenzene solutions. The extraction constants K_i and K_n for Pr_4NI in the pure solvent system, which were calculated in a similar way, are also given in Table 4. For this pure solvent system these extraction constants may be almost constant over a wider concentration range because no hydrates and triple ions are formed in nitrobenzene.[1] So imaginary distribution ratios of Pr_4NI in pure solvent system were calculated at any concentration to reproduce the extraction constants obtained and are shown in Fig. 1. This result shows that at an initial salt concentration of 1.0×10^{-3} mol dm^{-3} the hydration of the iodide in nitrobenzene increases the distribution ratio by 31% (from 0.263 for pure case to 0.345 for the mutual saturation case).

For nitrobenzene system the parenthesis terms in Eqs. 8 and 9 are 1.6 and 1.5, respectively, which were calculated using K_a°/K_a (=1.1) from Eq. 4, the hydration constants of the iodide ion, water solubility, and the self-association constant of water (1.054 mol^{-1} dm^3) in nitrobenzene.[17] These values and the extraction constants for the pure solvent system give $K_i''=1.3 \times 10^{-1}$ in Eq. 8 and $K_n''=4.2$ in Eq. 9 which are in good agreement with those obtained from the distribution ratio at the initial concentration 1.0×10^{-3} mol dm^{-3} (Table 4). The hydration for Pr_4NI in the nitrobenzene system thus decreases ΔG_i and ΔG_n by *ca.* 1.5 kJ mol^{-1} which is less than the methylene group contribution 2.6 kJ mol^{-1}.[1] Furthermore, as is seen from the hydration effects on the association constants (Table 2), the decrease in ΔG_i and ΔG_n by the hydration does not seem to depend so much on the organic solvents used.

Our conclusion is that the mutual saturation in both phases affects the extraction equilibria of tetraalkylammonium iodides. Especially the role of a small amount of water which is salted-in in organic solvents is marked but does not depend on the solvents.

Dehydrooligopeptides. III. Synthesis of (*Z,Z*)- and (*Z,E*)-Geometric Isomers of Dehydrodipeptides and Their Base-catalyzed Transformation to the Hydantoin Derivatives[1)]

(Received July 28, 1981)

N-Benzyloxycarbonyl (Cbz)-(*Z,E*)-dehydrodipeptides, comprised of both (*Z*)- and (*E*)-α-dehydroamino acid residues, were first synthesized by dehydrochlorination of Cbz-(*Z*)-dehydrodipeptides containing an erythro-3-chloro-2-aminobutanoate moiety. Base-catalyzed transformation of the individual Cbz-(*Z, Z*)- and (*Z, E*)-dehydrodipeptides was carried out to give the corresponding new hydantoin derivatives. The NMR spectroscopic differences between the geometric isomers of both dehydrodipeptides and their hydantoin derivatives were elucidated.

In the previous papers,[1-3)] we reported some useful synthetic methods for the currently interesting dehydropeptides which contain more than one α-dehydroamino acid (DHA) or ΔAA[4)] residue. The syntheses of the dehydrodipeptides (DHP), which consist of a (*Z*)-DHA and an α-amino acid (AA) or two (*Z*)-DHAs, were performed by the coupling of (*Z*)-DHA with AA, by the coupling between two (*Z*)-DHAs, or by the base-catalyzed β-elimination of (*Z*)-DHP including a serine (Ser) or a threonine (Thr) residue.

Although the preparation of (*E*)-geometric DHA has been reported,[5)] dehydropeptide containing (*E*)-DHA residue has not yet been synthesized and few studies on the reactivity of ordinary DHP have been undertaken. Here, we will report on the first synthesis of *N*-benzyloxycarbonyl (Cbz)-(*Z,E*)-DHP, composed of (*Z*)-ΔAA-(*E*)-ΔAA sequence, by dehydrochlorination of erythro-3-chloro-2-aminobutanoate [But(Cl)] moiety in (*Z*)-DHP and base-catalyzed transformations of both (*Z,Z*)- and (*Z,E*)-DHP to the corresponding new (*E*)- and (*Z*)-hydantoin derivatives. After the isomerization of the (*E*)-hydantoin derivative to the (*Z*)-isomer, the NMR spectroscopic differences between the (*E*)- and (*Z*)-isomers of both DHPs and the hydantoin derivatives were unambiguously characterized.

Results and Discussion

(Z,E)-Dehydrodipeptides. According to the method which we previously reported,[3)] Cbz-(*Z*)-ΔAA-(*Z*)-ΔAA-OMe [(*Z,Z*)-**6**: **b**, R=C_2H_5; **c**, R=*n*-C_3H_7; **e**, R=C_6H_5], except for **6a** (R=CH_3) and **6d** (R=*i*-C_3H_7),[1)] was prepared by the triethylamine-catalyzed elimination of Cbz-(*Z*)-ΔAA-Thr(Mes)-OMe, derived by the coupling of Cbz-(*Z*)-ΔAA-OH with Thr-OMe, followed by the mesylation of the dipeptide (**4**) obtained with methanesulfonyl (mesyl) chloride. On the other hand, Cbz-(*Z*)-ΔAA-(*E*)-ΔAA-OMe [(*Z,E*)-**7a—e**] was also obtained by the similar base-catalyzed β-elimination of Cbz-(*Z*)-ΔAA-But(Cl)-OMe (**5**) as follows. According to the dicyclohexylcarbodiimide (DCC) method,[1)] the coupling of Cbz-(*Z*)-DHA (**1**) with methyl erythro-3-chloro-2-aminobutanoate (**3**)[6)] as an amine component in CH_2Cl_2 at room temperature for 24 h gave the expected (*Z*)-dehydrodipeptide (**5**) as colorless needles in *ca.* a 64% yield. The subsequent β-elimination of **5** with triethylamine occurred stereoselectively to give the desired (*Z,E*)-isomer of DHP (**7**) in a fairly good yield.

In the IR spectral data of **6** and **7**, the characteristic differences between the (*Z,Z*)- and (*Z,E*)-isomers could not be recognized. In the spectrum of **6**, the absorption bands of NH (3375—3280 cm^{-1}), the ester carbonyl (1734—1718 cm^{-1}), the secondary amide (1700—1670 and 1648—1620 cm^{-1}), and the carbon-carbon double bond (1665—1638 cm^{-1} region) functions all appeared. On the other hand, from comparison with the IR spectrum of **6**, the appearances of a similar pattern of bands due to NH (3300—3250 cm^{-1}), the ester carbonyl (1725—1714 cm^{-1}), the secondary amide (1680—1663 and 1640—1623 cm^{-1}), and the C=C bond (1655—1623 cm^{-1} region) functions indicate clearly the formation of the dehydrodipeptide (**7**) structure.

As mentioned above, although the IR spectra of **6** and **7** are similar, in the NMR spectrum of **7**, the chemical shifts of *C*-terminus alone were found to be considerably different from those of **6**. Therefore, it is supposed that the two compounds **6** and **7** are geometrically isomeric.

From the NMR spectral data, the disappearance of the characteristic methine proton signals coupled as double-doublet in the δ 4.81—4.90 (J=4.0—4.2 and 8.2—8.5 Hz) region in the *C*-terminus of **5** (Table 1) and the appearance of olefinic proton signals in the δ 7.24—7.03 region of **7** (Table 2) indicate unambiguously the formation of a DHA moiety in the *C*-terminus of **7**. In particular, both the olefinic [at δ 6.80—7.24 (q, J=7.5 Hz)] and the methyl protons (at δ 2.04—2.08 region) in the *C*-terminus of **7** resonate at a lower magnetic field than those of **6** [at δ 1.72—1.77 (q, J=7.2 Hz) and 6.77—6.82 regions], whereas the γ-alkyl and β-olefinic protons of *N*-terminus of **6** and **7** resonate at almost the same magnetic fields, in the δ 1.73—2.80 and 6.30—7.24 regions respectively. Hence, it was found that the olefin moiety newly formed in **7** was consistent with an (*E*)-geometric structure.

From the above results, in the NMR spectrum of DHP, the chemical shifts of γ-alkyl and β-olefinic protons of (*Z*)-configurational DHA residue were found

to resonate at higher magnetic fields than those of the (*E*)-DHA residue, as in the case of the differences between (*Z*)- and (*E*)-DHA derivatives.[7]

The melting points, physical constants, and spectral data of **5**, **6**, and **7** are summarized in Tables 1 and 2.

Hydantoin Derivatives. Recently, Srinivasan *et al.*[8] commented that, in the case of *N*,*N*-diacyl DHA, *e.g.*, alkyl 2-(phthalimido)crotonate, the protons of alkyl group in the γ-position of (*E*)-isomer shift to a lower magnetic field than that of (*Z*)-isomer, contrary to the *N*-free and *N*-monoacyl DHAs. They claimed that this is a reliable criterion for the confirmation of the geometric structure of DHA.

In order to further explain the differences of the chemical shifts of γ-alkyl protons between the *N*-monoacyl and *N*,*N*-diacyl DHAs and to study whether we can generalize the above criterion or not, compounds **6** and **7** were converted individually into the corresponding (*E*)- and (*Z*)-2-(hydantoin-3-yl)crotonate derivatives, which were the expected *N*,*N*-diacyl DHA structures. Instead of triethylamine,[9] sodium methoxide was used for the treatment of **6** to give colorless crystals. These were identified as methyl (*Z*)-2-[(*Z*)-5-alkylidenehydantoin-3-yl]crotonate (**8**) in *ca.* a 90% yield. In addition, instead of sodium methoxide, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) and potassium *t*-butoxide as a stronger base was also used in this reaction to give **8** in a fairly good yield.

On the other hand, the treatment of **7** with the same base as used above was worked up similarly to give the (*E*)-isomer of **8**, methyl (*E*)-2-[(*Z*)-5-alkylidenehydantoin-3-yl]crotonate (**9**), as a colorless syrup or crystals in *ca.* a 76% yield.

Furthermore, it was found that the direct transformation of **4** and **5** with a strong base such as DBU to the hydantoin derivatives also occurred to give **8** and **9** in high yields respectively, *via* the β-elimination and then cyclization reactions. During the prolonged treatment of **7** with the base, **9** was initially

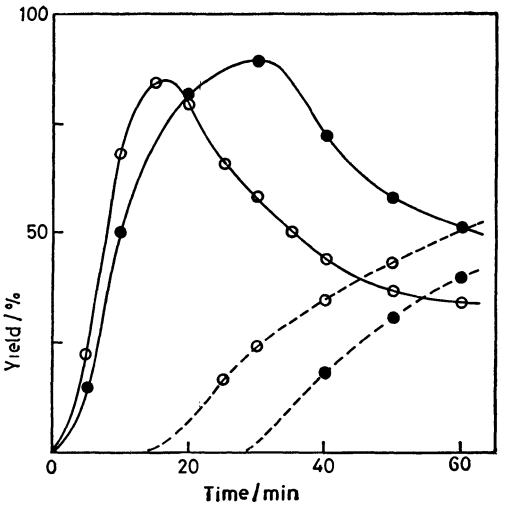

Fig. 1. Yields of **8e** and **9e** *vs.* reaction time and base concentration at room temperature.
8e (——), **9e** (- - -), 0.5 M-DBU (●), 1.0 M-DBU (○).

formed and then isomerization of only the (*E*)-crotonate moiety in **9** gradually occurred to give **8** almost quantitatively. For example, the successive conversion of **7e** to **9e** and **9e** to **8e** for various reaction times and base concentrations were examined in detail. The results are depicted by the curves in Fig. 1. The reaction of **7e** with 0.5 M-DBU (1 M=1 mol dm^{-3}) in $CHCl_3$ at room temperature gave the following results. The formation of **9e** first reached a maximum (*ca.* 90%) yield after 30 min. Then the quantity of **9e** decreased gradually with the isomerization of **9e** to **8e** and the yield of **8e** reached a maximum (*ca.* 80%) after 2 more h. Similarly, when 1.0 M-DBU was employed, the formation of **9e** attained rapidly to the maximum (*ca.* 80%) yield after 15 min; the yield of **8e** thus formed was found to reach its maximum (*ca.* 80%) within 2 h. These results suggested

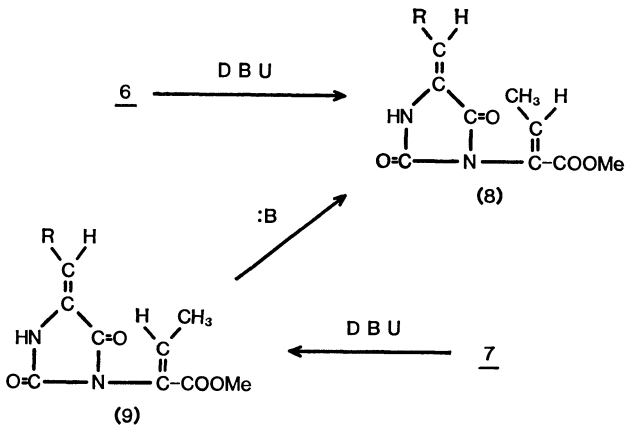
a) Colorless fibers from isopropyl alcohol. b) Colorless needles from CCl_4–isopropyl alcohol. c) Colorless needles from CCl_4–ethanol. d) Broad singlet.

to us that the higher the concentration of DBU or the other similar strong base was, the faster **7** transformed to **8** *via* **9**. In consequence, the expected (*Z*)- and (*E*)-2-(hydantoin-3-yl)crotonate [(*Z*,*Z*)-**8** and (*Z*,*E*)-**9**] were prepared readily as the *N*,*N*-diacyl DHA or enamine in high yields.

In the IR spectrum of **8** and **9**, the appearances of absorption bands of NH (3430—3230 cm^{-1}), ester carbonyl (1736—1715 cm^{-1}), carbon-carbon double bond (1660—1640 cm^{-1}), in particular, the characteristic hydantoin carbonyl bands (1778—1760 and 1720—1673 cm^{-1} regions) at higher wavenumber indicate the formation of the hydantoin ring and the presence of a crotonate moiety. Moreover, from the NMR spectral data of **8** and **9**, the disappearance of NH proton in peptide bonding at δ 6.72—7.20 and that of benzyl protons at about δ 7.20—7.34 (phenyl) and 5.06—5.14 (methylene) in **6** and **7** support the occurrence of a ring closure for hydantoin formation,[9] after the elimination of benzyl alcohol from **6** and **7**. In addition, we have compared the NMR spectrum of **8** with that of **9**. The olefinic proton of the crotonate moiety in (*Z*)-isomer (**8**) resonates at lower magnetic field (at δ 7.34—7.45) than that of (*E*)-isomer (**9**; at δ 6.44—6.52): $\Delta\delta$ *ca.* 0.9. But γ-methyl protons of (*Z*)-isomer shift at higher field (at δ 1.84—1.87) than that of (*E*)-isomer (at δ 2.23—2.28), $\Delta\delta$ *ca.* 0.4, whereas the chemical shifts of β- and γ-protons of the alkylidene group in the hydantoin rings of both **8** and **9** are similar (at δ 5.78—6.84 and δ 1.88—2.64 regions).

These facts are consistent with the Srinivasan comment. Consequently, the criterion became reliable for the confirmational assignment of the geometric structures for *N*-monoacyl and *N*,*N*-diacyl DHAs.

The yields, physical constants, and NMR spectral data of **8** and **9** are summarized in Table 3.



Scheme 2.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co. Ltd.), using tetramethylsilane as the internal standard.

Materials. Compounds **3** and **4** were prepared according to the methods reported previously by Kinoshita and Umezawa[6] and by us.[7]

Preparation of **5**. First the hydrochloride of **3** (20 mmol) and triethylamine (20 mmol) in dry CH_2Cl_2 (20 ml) were stirred below 0 °C for 10 min. Into the resulting solution we stirred successively **1** (20 mmol) and DCC (20 mmol), portion by portion; stirring was continued at room temperature for 24 h and the *N*,*N*′-dicyclohexylurea which separated out was filtered off. Into the reaction solution was added CH_2Cl_2 (30 ml); the resulting solution was washed once with successive 1 M HCl, saturated aqueous $NaHCO_3$, and water and then dried over anhydrous Na_2SO_4. Removal of CH_2Cl_2 gave a syrupy residue, which was purified on a silica-gel column using a mixture of benzene and ethyl acetate (4:1 v/v) to give **5** as colorless crystals. See Table 1.

Preparation of **6**. According to the method reported previously,[1,10] compound **4** was subjected to the mesylation, followed by the elimination. Into a solution of **4** (4 mmol) and mesyl chloride (5 mmol) in dry CH_2Cl_2 (20 ml) we stirred triethylamine (12 mmol), drop by drop, at 0—2 °C for 1 h; stirring was continued at room temperature for 12 h. Into the reaction solution was added CH_2Cl_2 (20 ml); the resulting solution was worked up as above. The reaction solution thus obtained was concentrated under reduced pressure to give a crude syrupy substance: this was then purified on a silica-gel column using a mixture of benzene and ethyl acetate (3:1 v/v) as the eluent to give **6** as a colorless syrup or crystals. See Table 2.

Preparation of **7**. Into a solution of **5** (10 mmol) in dry CH_2Cl_2 (15 ml) we stirred triethylamine (30 mmol), drop by drop, under cooling for 2 h; stirring was continued at room temperature for 15 h. Dichloromethane (20 ml) was added to the reaction solution and the resulting solution was washed twice with 1 M HCl, once with saturated aqueous $NaHCO_3$, and three times with water, and finally dried over anhydrous Na_2SO_4. Evaporation of CH_2Cl_2 gave a syrupy residue; this was purified on a silica-gel column using a mixture of benzene and ethyl acetate (4:1 v/v) as the eluent to give **7** as a colorless syrup or crystals. See Table 2.

Preparation of **8**. Into a solution of **6** (10 mmol) in dry $CHCl_3$ (15 ml) we stirred DBU (10 ml) at room temperature for 3 h. To the reaction solution was added $CHCl_3$ (15 ml); this was then washed with 2 M HCl and three times with water and then dried over anhydrous Na_2SO_4. After removal of $CHCl_3$ and the small amount of benzyl alcohol formed as a by-product under reduced pressure, the residual syrup was purified on a silica-gel column using a mixture of benzene and ethyl acetate (4:1 v/v) as the eluent to give **8** as colorless crystals. See Table 3.

Preparation of **9**. Into a solution of **7** (10 mmol) in $CHCl_3$ (15 ml) we stirred some DBU (5 ml) at room temperature for half an hour. The reaction solution was acidified weakly with 1 M HCl. $CHCl_3$ (15 ml) was added and the resulting solution was worked up as the case of **8** mentioned above, to give **9** as a colorless syrup or crystals. See Table 3.

Isomerization of **9** *to* **8**. *From* **9**: A solution of **9** (10 mmol) in $CHCl_3$ (15 ml) in the presence of triethylamine (10 mmol) was stirred at room temperature for 3 d. The reaction solution was washed once with 2 M HCl and three times with water and then dried over anhydrous Na_2SO_4. Removal of $CHCl_3$ gave **8** quantitatively.

A similar isomerization of **9** to **8** was accomplished completely within only 10 h, by using DBU, sodium methoxide,

or potassium *t*-butoxide, instead of triethylamine.

From ***5*** via ***9***: Into a solution of **5** (20 mmol) in methanol (15 ml) we stirred sodium methoxide (12 mmol), drop by drop, below 0 °C; stirring was continued at room temperature for 6 h. After removal of methanol, the residual syrup thus obtained was dissolved in ethyl acetate (40 ml). The resulting solution was washed twice with 1 M HCl and three times with water and finally dried over anhydrous Na_2SO_4. Evaporation of the solvent under reduced pressure gave a residual substance, which was worked up as the case of **6** to give **8** in *ca.* an 85% yield.

Preferential Introduction of a Pyridylmethyl Group into Sulfonamides as an Approach to an Intramolecular Transimination[1)]

Masaaki IWATA* and Hiroyoshi KUZUHARA
The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received September 21, 1981)

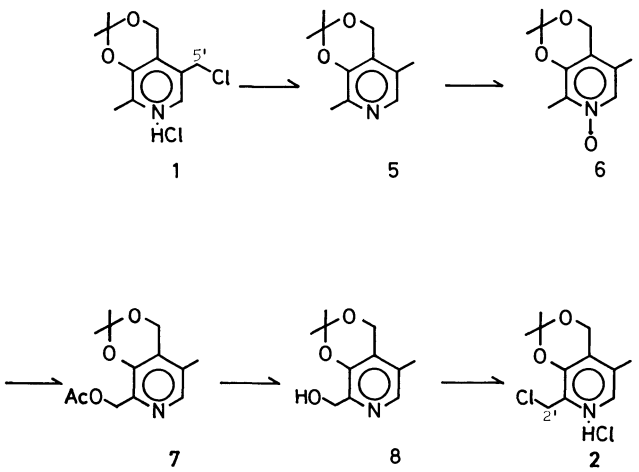
N,N'-Bis(*p*-tolylsulfonyl)-α,ω-alkanediamine disodium salts ($n=3$, 4, 5, 6, 7, 8, 9, 10) were subjected to monopyridylmethylation by the reaction with 5'-deoxy-5'-chloro- or 5'-deoxy-2'-chloro-3,4'-*O*-isopropylidenepyridoxine hydrochloride, accompanied by the corresponding bispyridylmethylation. Monopyridylmethylation became remarkable for longer methylene chains of the diamine. Thus, introduction of an amino group protected by a sulfonyl group at the end of either the C_2- or the C_5-side chains of pyridoxine derivatives was achieved.

Catalysis of coenzyme pyridoxal phosphate in the enzyme system has been belived to be initiated through transimination of the coenzyme originally bound to an ε-amino group of a lysine residue of the enzyme to the amino group of a substrate amino acid.[2)] The transimination of the coenzyme provides several orders faster rate acceleration of the coenzyme catalysis in the enzymic reaction, compared with the catalysis of the direct imine formation of the coenzyme with a substrate.[3)] The biologically inherent properties of the coenzyme process have become kinetically well understood[3)] and the essential part of the chemical process has been successfully applied to a solution of synthetic problem in several cases.[4)] The present work was started, expecting that if a suitable three-dimensional disposition of a primary amino group were introduced into pyridoxal molecule, then the catalytic potency would be remarkably increased through intramolecular transimination. In this context, Fisher and Metzler studied a cyclic imine derivative of pyridoxal,[5)] demonstrating that the imine is catalytically inactive, due to the formation of the stable six-membered ring; its electronic absorption spectrum is strikingly similar to those of pyridoxal phosphate-containing enzymes.

The development of a general method for the synthesis of diaza(2,5)pyridinophanes[6)] by the reaction of dichloropyridoxine derivative with *N,N'*-bis(*p*-tolylsulfonyl)-α,ω-alkanediamine disodium salts (**4**) encouraged us to examine systematically the possibility of the molecular construction of a "intramolecular transimination model" system by the use of 2'- or 5'-position of pyridoxal where the substituent is dispensable for catalysis in the nonenzymic system.[7)] The coupling method was expected to be equally applicable to the reaction of a monochloropyridoxine derivative with the alkanediamine disodium salt, even though the reaction will be accompanied by complete alkylation on two nucleophilic sites of the disodium salt. Therefore, the syntheses of 5'-deoxy-5'-chloro- and 5'-deoxy-2'-chloro-3,4'-*O*-isopropylidenepyridoxine, **1** and **2** respectively, were first examined; these were then subjected to a coupling reaction with **4**.

Results and Discussion

5'-Deoxy-5'-chloro-3,4'-*O*-isopropylidenepyridoxine hydrochloride (**1**) was synthesized by the known method[8)] from pyridoxine hydrochloride. For the synthesis of 5'-deoxy-2'-chloro-3,4'-*O*-isopropylidenepyridoxine hydrochloride (**2**), **1** was used as a starting material; neutralization of **1** followed by catalytic hydrogenation afforded 5'-deoxy-3,4'-*O*-isopropylidenepyridoxine (**5**) (92% yield). This was then oxidized to 5'-deoxy-3,4'-*O*-isopropylidenepyridoxine 1-oxide (**6**) with *m*-chloroperbenzoic acid (87% yield). The *N*-oxide was converted to 5'-deoxy-2'-acetoxy-3,4'-*O*-isopropylidenepyridoxine (**7**) in acetic anhydride–chloroform in 91% yield. Treatment of **7** with sodium methoxide afforded 5'-deoxy-2'-hydroxy-3,4'-*O*-isopropylidenepyridoxine (**8**) in 90% yield. This was subjected to chlorination with thionyl chloride to give **2** in 95% yield (Scheme 1).



Scheme 1.

Utilizing a newly developed method,[6)] normalized reaction conditions were set up for the coupling reaction of monochloropyridoxine derivative hydrochloride with **4**, using *N,N'*-bis(*p*-tolylsulfonyl)-1,6-hexanediamine disodium salt (**4d**) as a representative counterpart; to a stirred suspension of **4d** in *N,N*-dimethylformaminde (DMF), which was prepared by the reaction of **3d** with sodium ethoxide, a solution of **1** or **2** in DMF[9)] was added dropwise (Scheme 2). Two products were detected on TLC; these were chromatographed to give *N*-[2,2,8-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-5-ylmethyl]-*N,N'*-bis(*p*-tolylsulfonyl)-1,6-hexanediamine (**9d**) and *N,N'*-bis[2,2,8-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-5-ylmethyl]-*N,N'*-bis(*p*-tolylsulfonyl)-1,6-hexanediamine (**10d**), when **1** was used. On the other hand, when **2** was used, detected and isolated products were *N*-[2,2,5-trimethyl-4*H*-[1,3]-dioxino[4,5-*c*]pyridin-8-ylmethyl]-*N,N'*-bis(*p*-tolylsul-

fonyl)-1,6-hexanediamine (**11d**) and *N*,*N*′-bis[2,2,5-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-8-ylmethyl]-*N*,*N*′-bis(*p*-tolylsulfonyl)-1,6-hexanediamine (**12d**). All other series of reactions were carried out as similarly as possible to those of **4d**. The results obtained are summarized in Tables 1 and 2. They demonstrate several features of the pyridylmethylation reaction; total yield of products lies in the range from 62 to 72% for **1**, and from 47 to 60% for **2**. It is quite interesting, however, to note that the ratio of the yield of **9** to that of **10** clearly increases as the methylene chain becomes longer (Table 1). A similar trend is obvious for the ratio of the yield of **11** to that of **12** as well (Table 2).

Table 3. ^{1}H NMR spectra of pyridoxine derivatives **6**, **7**, and **8**[a]

	R	X	$H^{2'}$	$H^{4'}$	$H^{5'}$	H^{6}	$C(\underline{CH_3})_2$
6	H	O	2.40	4.74	2.11	7.82	1.59
7	OAc	—	5.18	4.74	2.14	7.97	1.58
8	OH	—	4.71	4.79	2.18	7.97	1.60

a) Chemical shift in δ, in $CDCl_3$.

The ratio was not linearly correlated with the methylene chain length. The qualitative change in the ratios is interpreted as follows: in the shorter methylene chains ($n=3$—5), one pyridylmethyl group bound to one end of the diamine brings another pyridylmethyl group toward the other end of the diamine through an inductive effect such as stacking between the two aromatic rings. When the methylene chain becomes longer (more than seven), it is difficult for such an inductive effect to occur and, thus, the reaction favors monopyridylmethylation over bispyridylmethylation. Decreases in yields of **10** or **12** compared to increases in those of **9** or **11** without reduction in total yield as the chain length becomes longer, support the interpretation as well. Furthermore, a comparison of both ratios suggests that such a definite interactive distance between the aromatic rings will be longer in 5′-chloro derivatives (**1**) than in 2′-chloro derivatives (**2**) at the reactive points, probably due to spatial substituent interaction. In other words, monopyridylmethylation is more likely to occur in 2′-chloro derivatives (**2**) than in 5′-chloro derivatives (**1**).

^{1}H NMR spectral data are summarized in Table 3 for **6**, **7**, and **8**, Fig. 1 for **9** and **10**, and Fig. 2 for **11** and **12**, in which chemical shifts are correlated with the chain length. Although it is difficult to distinguish the effects of intermolecular and/or intramolecular interactions on the chemical shift changes, certain features are noteworthy. In general, it is seen that proton chemical shifts move to lower field as the methylene chain becomes longer. A linear correlation is apparent for C_6–H, pyr–$^{4'}C\underline{H_2}$–O, pyr–$^{5'}C\underline{H_2}$–N, and $C(C\underline{H_3})_2$ in **9**, and for pyr–$^{5'}C\underline{H_2}$–N, $C_6\underline{H}$, pyr–$^{4'}C\underline{H_2}$–O, ^{5}C–N–$C\underline{H_2}$–C, and $C(C\underline{H_3})_2$ in **10**

in the order of the slope magnitude, respectively, in contrast to nonlinear correlation of –NHTs, $^{5'}C$–N–CH_2–C (triplet), and HN–CH_2–C (quartet) in **9**, and the other –CH_2– in **9** and **10**. A constant chemical shift is shown for C_2–CH_3 and –$SO_2C_6H_4$–CH_3 in both **9** and **10**. As for **11** and **12**, no proton chemical shift in **11** is linearly correlated with the chain length except for the constant signals of C_5–CH_3 and –$SO_2C_6H_4$–CH_3, although pyr–$^{2'}CH_2$–N, C_6–H, $C(CH_3)_2$, and pyr–$^{4'}CH_2$–O in **12** have a linear correlation in the order of slope magnitude.

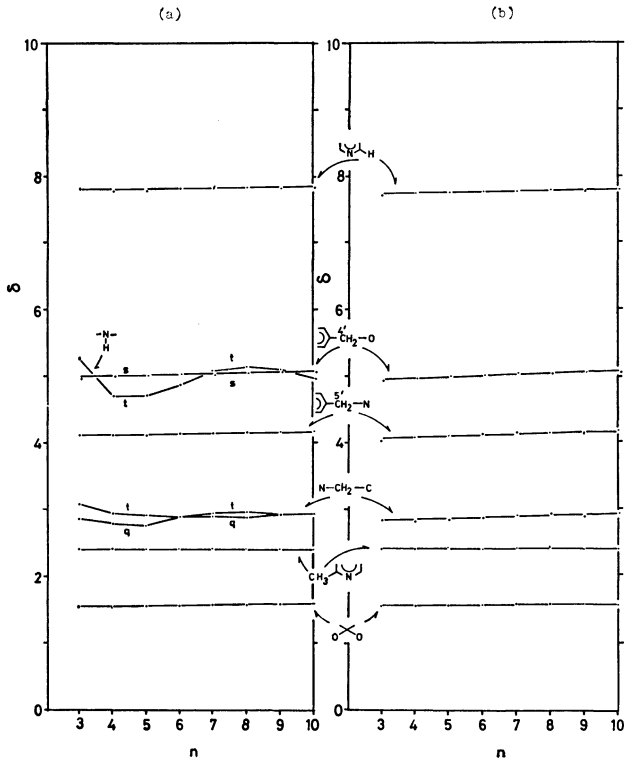

Fig. 1. Correlation of chemical shifts with the methylene chain length in ^1H NMR spectra of (a) **9** and (b) **10**, in $CDCl_3$.

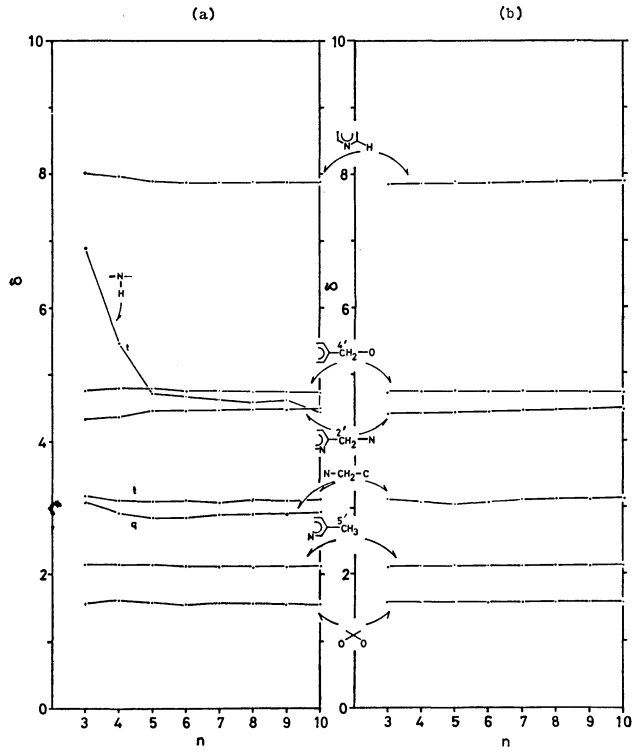

Fig. 2. Correlation of chemical shifts with the methylene chain length in ^1H NMR spectra of (a) **11** and (b) **12**, in $CDCl_3$.

The drastic chemical shift change for amino proton (triplet) and methylene protons (quartet) contiguous to the amino proton in both **9** and **11** suggests that intermolecular and/or intramolecular interaction is involved in the molecule through N–H···N or N–H···O hydrogen-bonding. It is very significant that the change becomes rather little when the methylene chain becomes longer than around six.

Experimental

The ^1H NMR spectra were recorded on a Varian HA-100D apparatus, with TMS as the internal standard in chloroform-*d*; the chemical shift and coupling constant are presented in ppm and Hz, respectively. Merck silica gel 60 (Art. 7734, 0.063—0.20 mm) was used for the column chromatography and Wakogel B-5 FM (Wako pure and Chem. Co., Ltd.) for the thin layer chromatography (TLC), in which products were visualized in an iodine-vapor bath. DMF was dried over molecular sieve (type-4A) and the supernatant was used directly for the reaction. The uncorrected mp were measured in a bilayered cover glass (18 m/m) with a micro melting point apparatus (Yanagimoto Seisakusho, serial No. 2647). For column chromatography and TLC analysis, benzene–ethyl acetate (3:2 v/v) (solvent A) was used as an eluent. 5′-Deoxy-5′-chloro-3,4′-*O*-isopropylidenepyridoxine hydrochloride (**1**) was prepared by a known method[8] from pyridoxine hydrochloride.

Preparation of 5′-Deoxy-3,4′-O-isopropylidenepyridoxine 1-Oxide (6). To 10.21 g (0.053 mol) of 5′-deoxy-3,4′-*O*-isopropylidenepyridoxine (**5**), which was prepared by the known method[8] from pyridoxine hydrochloride, in 150 ml of chloroform, 10.94 g (1.2 mol equiv. as 85% purity) of *m*-chloroperbenzoic acid was added at ambient temperature. After the mixture was stirred for *ca.* 3 h, it was neutralized with 2.55 g of sodium hydroxide and then extracted with chloroform. The extract was washed with water, dried over $MgSO_4$, and then evaporated to dryness to give a colorless powder; this was recryst. from acetone–diisopropyl ether to afford 9.67 g of **6** (87% yield); mp 157—158 °C. Found: C, 63.07; H, 7.27; N, 6.69%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14, H, 7.23; N, 6.69%.

Preparation of 5′-Deoxy-2′-acetoxy-3,4′-O-isopropylidenepyridoxine (7). The mixture of 9.67 g of **6** in 20 ml of acetic anhydride and 30 ml of chloroform was refluxed for 2 h in an oil-bath. Solvents were evaporated under reduced pressure and the residue was chromatographed on a silica gel (250 g) column eluted with solvent A to give 10.58 g of **7** (91% yield) as a viscous liquid; R_f 0.43 (solvent A). Found: C, 61.97; H, 6.70; N, 5.50%. Calcd for $C_{13}H_{17}O_4N$: C, 62.14; H, 6.82; N, 5.57%.

Preparation of 5′-Deoxy-2′-hydroxy-3,4′-O-isopropylidenepyridoxine (8). To sodium methoxide in 200 ml of methanol, prepared by addition of 0.97 g of metal sodium, 10.08 g of **7** in 50 ml of methanol was added dropwise and the mixture was stirred for 1 h at ambient temperature; the reaction was completed instantly, monitored on TLC (R_f 0.3 (solvent

A)). The mixture was neutralized with the occasional addition of pieces of solid carbon dioxide, and then evaporated to dryness. The residue was triturated several times with chloroform and filtered through Celite (No. 545). The filtrate was evaporated to dryness and the residue was recrystallized from benzene (minor)–hexane (major) to give 7.51 g of **8** (89% yield), as colorless crystals; mp 125—126 °C. Found: C, 63.22; H, 7.16; N, 6.62%. Calcd for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%. IR (KBr disk): *v* 3180, 2990, 1600, 1570, 1450, 1405, 1387, 1377, 1350, 1292, 1280, 1270, 1252, 1196, 1140, 1050, 935, 855, 770, 732, 670, and 570 cm^{-1} as relatively strong characteristic bands.

Preparation of 5′-Deoxy-2′-chloro-3,4′-O-isopropylidenepyridoxine Hydrochloride (2). To a stirred suspension of 2 g of **8** in 40 ml of benzene, 0.7 ml (1 mol equiv.) of thionyl chloride in 10 ml of benzene was added dropwise at ambient temperature, resulting in an immediate clear solution and then in a precipitate. The precipitation was promoted by addition of 50 ml of dry diethyl ether. The colorless precipitate was collected by filtration, washed several times with dry diethyl ether, and then recryst. from acetone to give 2.39 g of **2** (95% yield) as colorless crystals; mp 140 °C (starts to become brown) and at 148 °C (darkening). Found: C, 50.13; H, 5.68; N, 5.36; Cl, 26.30%. Calcd for $C_{11}H_{15}O_2NCl_2$: C, 50.01; H, 5.72; N, 5.30; Cl, 26.85%. IR (KBr disk): *v* 3060, 3010, 2970, 2320, 2025, 1552, 1480, 1465, 1445, 1420, 1385, 1370, 1310, 1278, 1260, 1204, 1125, 1078, 1060, 867, 831, 770, 651, 582, and 560 cm^{-1} as relatively strong characteristic bands.

Preparation of N,N′-*Bis(*p-*tolylsulfonyl)-α,ω-alkanediamines (3) (n=3, 4, 5, 6, 7, 8, 9, 10).* To a α,ω-alkanediamine in pyridine, three molar equivalents of *p*-toluenesulfonyl chloride were added and the mixture was stirred at 80—90 °C for 0.5—1 h. The mixture was poured into water; after cooling, a precipitate resulted. This was collected by filtration and recryst. from ethanol. All the elemental analyses for C, H, N, and S (omitted) were coincident with those calculated. Mp 134—136 °C (**3a**), 125—126 °C (**3b**), 137—138 °C (**3c**), 155—156 °C (**3d**), 144.5—145.5 °C (**3e**), 151—152 °C (**3f**), 93.5—94 °C (**3g**), and 128—129 °C (**3h**).

Preparation of N,N′-*Bis(*p-*tolylsulfonyl)-α,ω-alkanediamine Disodium Salts (4) (n=3, 4, 5, 6, 7, 8, 9, 10) and Its Reaction with 1 and 2.* To a stirred sodium ethoxide solution, prepared by addition of three gram-atom equivalents of metal sodium to ethanol (*e.g.*, 30 ml), one molar equivalent of **3** (*e.g.*, 0.5 g) was added. The mixture was refluxed for 1 h, followed by complete evaporation of ethanol under reduced pressure. DMF (*e.g.*, 50 ml) was readded to the resulting powder (**4**); to this a solution[9] of one molar equivalent of **1** or **2** in DMF (*e.g.*, 15 ml) was added dropwise with stirring at around 90 °C over the period of 2—3 h. After cooling, the brown mixture was poured into water (*e.g.*, 700 ml). Precipitation was promoted by addition of sodium chloride (*e.g.*, 10 g) (salting out effect). The precipitate was collected by filtration. Thus, by silica gel chromatography of the precipitate eluted with solvent A, the following were isolated: *N*-[2,2,8-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-5-ylmethyl]-*N*,*N*′-bis(*p*-tolylsulfonyl)-α,ω-alkanediamine (**9**) and *N*,*N*′-bis[2,2,8-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-5-ylmethyl]-*N*,*N*′-bis(*p*-tolylsulfonyl)-α,ω-alkanediamine (**10**) prepared from **1**, or *N*-[2,2,5-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-8-ylmethyl]-*N*,*N*′-bis(*p*-tolylsulfonyl)-α,ω-alkanediamine (**11**) and *N*,*N*′-bis[2,2,5-trimethyl-4*H*-[1,3]dioxino[4,5-*c*]pyridin-8-ylmethyl]-*N*,*N*′-bis(*p*-tolylsulfonyl)-α,ω-alkanediamine (**12**) prepared from **2**.

The Reaction of 2,4,6-Triphenyl-1,3,5-thiadiazin-1-ium Salt with Active Methylene Compounds

Isao SHIBUYA

National Chemical Laboratory for Industry, Yatabe, Tsukuba-gun, Ibaraki 305

(Received September 28, 1981)

The reaction of 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium tetrafluoroborate with several active methylene compounds was studied. Nitromethane and nitroethane gave 2*H*-1,3,5-thiadiazines. The compounds possessing a benzoyl group reacted with this salt to give 5-substituted 2,4,6-triphenylpyrimidines, while those possessing a carbamoyl group afforded 5-substituted 4-hydroxy-2,6-diphenylpyrimidines or 4(3*H*)-pyrimidinone. On the other hand, malononitrile and ethyl cyanoacetate gave 5-substituted 4-mercapto-2,6-diphenylpyrimidines, with the liberation of benzonitrile. It was thus found that 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium tetrafluoroborate reacts with active methylene compounds in fashions similar to that of 2,4,6-triphenyl-1,3-thiazin-1-ium salt.

2,4,6-Triphenylpyrylium salt (**1**) and its *S*-analog (**2**) usually react with active methylenes in a similar way to give 1-substituted 2,4,6-triphenylbenzenes;[1,2] however, 2,4,6-triphenyl-1,3-oxazin-1-ium salt (**3**) and its *S*-analong (**4**) reacted with them in the different manners to afford various pyridines and other derivatives.[3,4] 2,4,6-Triphenyl-1,3,5-oxadiazin-1-ium salt (**5**) reacts with them in ways similar to **3** and produces several pyrimidines.[5,6] The *S*-analog of **5**, 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium salt (**6**), has been synthesized recently,[7] but its behavior toward nucleophiles has not yet been checked. In this report, the reaction of **6** with active methylenes was investigated; the reactivity of these heteroaromatic cation compounds (**1**—**6**) with them was also discussed.

Results and Discussion

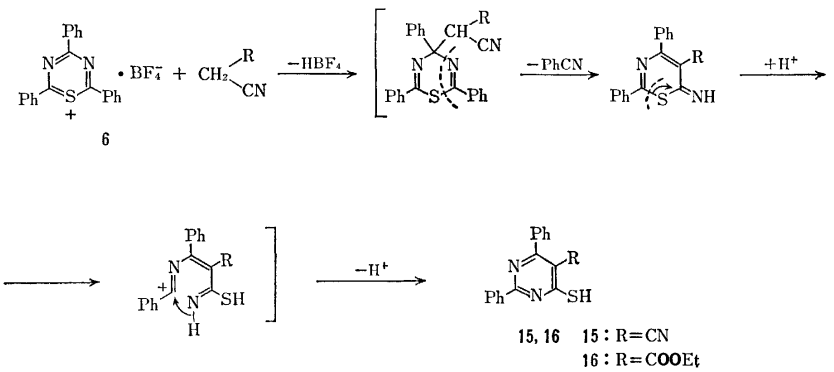
The starting material, 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium tetrafluoroborate (**6**), was obtained by treating 4*H*-1,3,5-thiadiazine with triphenylcarbenium tetrafluoroborate.[7]

When **6** was treated with nitromethane and nitroethane under mild conditions, **7** and **8** were afforded in 62 and 53% yields respectively. The analytical data showed that both the products were adducts of the thiadiazin-1-ium cation and the carbanions given by each active methylene. Their IR spectra closely resembled each other and had no absorption assignable to N–H or S–H stretching. Moreover their UV spectra were almost the same (λ_{max}=252 nm, ε=34000). Therefore, for **7** and **8**, two probable structures, 2*H*- and 4*H*-1,3,5-thiadiazines, can be supposed. According to the MS data, the presence of the fragments at 135 *m/e* of **7** and 149 *m/e* of **8**, assigned to $PhCSCH_2^+$ and $[PhCSCHCH_3]^+$ respectively, strongly suggests that **7** and **8** are 2*H*-1,3,5-thiadiazine derivatives. It was thus confirmed that **7** and **8** are 2-nitromethyl- and 2-(1-nitroethyl)-2,4,6-triphenyl-2*H*-1,3,5-thiadiazine. This reaction mode is found in the reaction of **4** with nitromethane, nitroethane, and diethyl malonate; however, it is not found in that of the corresponding *O*-analogs, **3** and **5**.

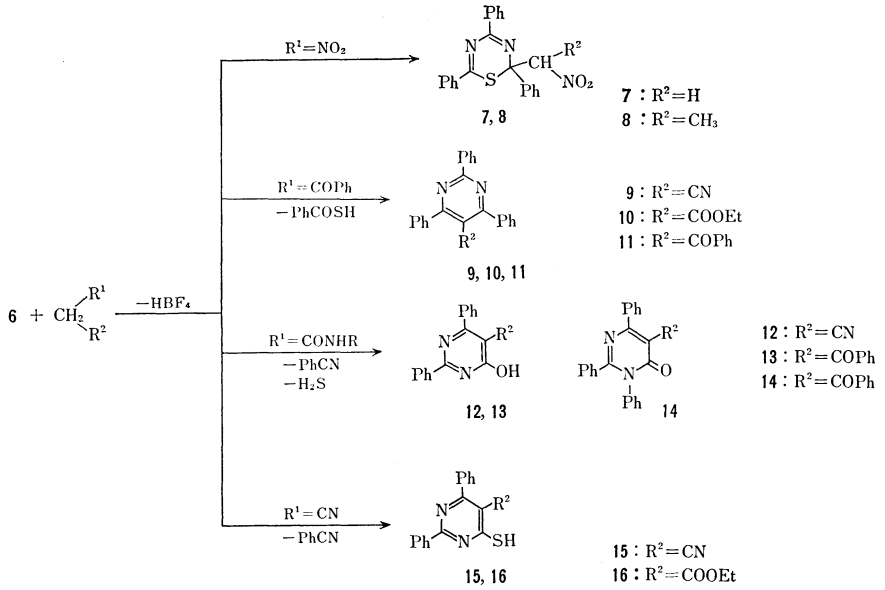
Benzoylacetonitrile, ethyl benzoylacetate, and dibenzoylmethane were treated with **6** to give 5-cyano-, 5-ethoxycarbonyl-, and 5-benzoyl-2,4,6-triphenylpyrimidine (**9**, **10**, and **11**) in 85, 39, and 43% yields respectively. These reagents react also with **5** to give the respective common products; consequently, they appear to behave in the same fashion toward **5** and **6**. This reaction mode can also be found among the reactions of **1**—**6** with active methylenes; especially, the compounds possessing a benzoyl group are apt to obey this mode to afford 1-substituted 2,4,6-triphenylbenzenes, 3-substituted 2,4,6-triphenylpyridines, and 5-substituted 2,4,6-triphenylpyrimidines.[1-4,6]

Cyanoacetamide, benzoylacetamide, and benzoylacetanilide reacted with **6** to give 5-cyano- and 5-benzoyl-4-hydroxy-2,6-diphenylpyrimidines (**12**, **13**), and 5-benzoyl-2,3,6-triphenyl-4(3*H*)-pyrimidinone (**14**) in 73, 46, and 60% yields respectively. This reaction mode is commonly known in the reactions of **3**—**6** with the compounds possessing a carbamoyl group.

Malononitrile reacted with **6** to give a yellow powder,



Scheme 1.



Scheme 2.

15, with the escape of benzonitrile, while ethyl cyanoacetate afforded yellow needles, **16**. Both **15** and **16** were weakly acidic. In their MS spectra the M^+ values were observed at 289 and 336 *m/e*, and a common peak at 264 *m/e*, assignable to $[M+1-CN]^+$ and $[M+1-COOC_2H_5]^+$ respectively, was present. Their UV spectra were similar to one another. Their IR spectra also resembled each other; that of **16** had absorptions assigned to an ester group (1728, 1257 cm^{-1}), but no absorption assigned to a cyano group. These facts suggested that they have the same skeletal structure, and that a cyano group of the reagents participates in this reaction. **15** was obtained by an alternative method as follows: 4-Chloro-5-cyano-2,6-diphenylpyrimidine was treated with hydrogen sulfide in triethylamine–benzene. It was thus concluded that **15** is 5-cyano-4-mercapto-2,6-diphenylpyrimidine; consequently, **16** is 5-ethoxycarbonyl-4-mercapto-2,6-diphenylpyrimidine. For the formation of **15** and **16**, a probable reaction course could be speculated about; it is shown in Scheme 1. This recyclization process into pyrimidine can be regarded as the same as the reaction of *N*-acyl imidoyl chloride with malononitrile.[8]

From all the results described above, the reaction of 2,4,6-triphenyl-1,3,5-thiadiazin-1-ium tetrafluoroborate with active methylenes could be deduced to be as is summarized in Scheme 2.

It is proved that the reaction manner of **6** toward active methylenes is more similar to that of **4** rather than to that of **5**; in addition, these heteroaromatic cations (**1**—**6**), treated with active methylenes, are useful materials for synthesizing benzenes, pyridines, pyrimidines, and other derivatives.

Experimental

2-Nitromethyl- or 2-(1-Nitroethyl)-2H-1,3,5-thiadiazine (7,8). Into a solution of nitromethane or nitroethane (1.5 mmol) and triethylamine (0.3 ml) in chloroform (3 ml), **6** (0.42 g, 1.0 mmol) was stirred at room temperature, after which the mixture was allowed to stand for 5 d. The solvent was distilled out under reduced pressure, and the residue was washed with dilute hydrochloric acid and recrystallized from acetonitrile to give **7** (0.24 g, 62%) or **8** (0.21 g, 53%). Their data are shown below.

7: Mp 166 °C; IR (KBr) 1645, 1555, 1448, 1372, 1224, and 917 cm^{-1}; UV_{max} (EtOH) 252 nm (ε 34000); ^{13}C NMR ($CDCl_3$), δ 82.69 (–C–), 86.02 ($-CH_2NO_2$), 127.21—132.69, 136.66, 137.89, 139.96, and 157.54; ^1H NMR ($CDCl_3$), δ 5.25 (s, $-CH_2NO_2$), 7.24—8.18 (m, arom H); MS, *m/e* (%), 327 (10.4, $[M-CH_2NO_2]^+$), 236 (18.5), 206 (14.6), 135 (36.2 $[PhCSCH_2]^+$), 121 (100, $PhCS^+$), and 103 (63.1, $PhCN^+$). Found: C, 68.41; H, 4.40; N, 10.88; S, 8.39%. Calcd for $C_{22}H_{17}N_3SO_2$; C, 68.20 H, 4.42 N, 10.84; S, 8.28%.

8: Mp 164 °C; IR (KBr), 1651, 1551, 1448, 1382, 1214, and 903 cm^{-1}; UV_{max} (EtOH), 252 nm (ε 34000); ^{13}C NMR ($CDCl_3$) δ 14.47 ($-CH_3$), 84.42 (–C–), 92.15 (>$CHNO_2$), 126.64—132.12, 136.16, 136.41, 139.35, and 156.71; ^1H NMR ($CDCl_3$) δ 1.71 (*d*, >CH–C$\underline{H}_3$), 5.54 (*q*, >C$\underline{H}$–CH_3), 7.24—8.18 (*m*, arom H); MS *m/e* (%), 355 (0.5, $[M-NO_2]^+$), 327 (13.7, $[M-CHNO_2CH_3]^+$), 149 (10.0, $[PhCSCHCH_3]^+$), 121 (100), and 103 (10.3). Found: C, 68.79; H, 4.75; N, 10.51; S, 8.04%. Calcd for $C_{25}H_{19}N_3SO_2$: C, 68.81; H, 4.77; N, 10.47; S, 7.98%.

5-Cyano-, 5-Ethoxycarbonyl-, or 5-Benzoyl-2,4,6-triphenylpyrimidine (9, 10, 11). Into a solution of benzoylacetonitrile, ethyl benzoylacetate, or dibenzoylmethane (1.5 mmol) in 1.0 mol dm^{-3} of MeOH–MeONa (3 ml), **6** (0.42 g, 1.0 mmol) was added; the mixture was stirred at room temperature for 10 min and then refluxed for 1 h. The reaction mixture was poured into dilute hydrochloric acid. The resulting precipitate was collected by filtration and recrystallized from acetonitrile or methanol to give **9** (0.28 g, 84%), **10** (0.15 g, 39%), or **11** (0.18 g, 43%). Their mp and IR spectra agreed with those of authentic samples.[6]

5-Cyano- or 5-Benzoyl-4-hydroxy-2,6-diphenylpyrimidine (12,13), and 5-Benzoyl-2,3,6-triphenyl-4(3H)-pyrimidinone (14). Cyanoacetamide, benzoylacetamide, and benzoylacetanilide (1.5 mmol) were treated with **6** (1.0 mmol), as in the preparation of **9**—**11**. The resulting precipitate was dissolved

in DMF and reprecipitated by the addition of ether to give **12** (0.20 g, 73%), **13** (0.16 g, 46%), and **14** (0.26 g, 60%) respectively. The IR spectra of **12** and **13** were completely superimposed on those of authentic samples.[6] The data of **14** are as below.

14: Mp 243 °C; IR, 1667, 1651, 1535, and 1492 cm^{-1}; UV_{max} (CH_2Cl_2) 252 nm (ε 30900), 315 (sh, ε 9500); ^1H NMR ($CDCl_3$) δ 7.27—8.00 (*m*, arom H); MS *m/e* (%), 428 (28.0, M^+), 400 (15.5, $[M-CO]^+$), 180 (87.6, $[PhC{\equiv}NPh]^+$), 105 (25.7, $PhCO^+$), and 77 (100, Ph^+). Found: C, 81.30; H, 4.67; N, 6.53%. Calcd for $C_{29}H_{20}N_2O_2$: C, 81.29; H, 4.70; N, 6.54%.

*5-Cyano- or 5-Ethoxycarbonyl-4-mercapto-2,6-diphenylpyrimidine (**15**, **16**).* Malononitrile or ethyl cyanoacetate (1.5 mmol) was treated with **6** (1.0 mmol), as in the preparation of **9**—**11**. The resulting precipitation was recrystallized from acetonitrile to give **15** (0.23 g, 80%) or **16** (0.18 g, 54%). Their data are shown below.

15: Mp 250 °C (decomp), IR (KBr), 3176, 3060, 2230, 1545, 1495, and 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ 7.45—8.16 (m, arom H), 8.51 (s, SH); UV_{max} (CH_2Cl_2), 283 (ε 26500), 307 (sh, ε 23000), 393 (ε 5000); MS *m/e* (%), 289 (55.6, M^+), 264 (22.8, $[M+1-CN]^+$), 186 (79.0), 153 (44.3), and 135 (100). Found: C, 70.32; H, 3.81; N, 14.47; S, 11.37%. Calcd for $C_{17}H_{11}N_3S$: C, 70.57; H, 3.83; N, 14.52; S, 11.08%.

16: Mp 182 °C; IR (KBr), 2963, 1728, 1546, 1491, 1257, and 1230 cm^{-1}; UV_{max} (CH_2Cl_2), 271 (ε 25200), 303 (sh, ε 17500), 388 (ε 7100); ^1H NMR ($CDCl_3$) δ 7.45—8.16 (m, arom H), 8.51 (s, SH); MS *m/e* (%), 336 (25.2, M^+), 307 (57.0, $[M-C_2H_5]^+$), 292 (20.5, $[M-CO_2]^+$), 290 (30.1, $[M-C_2H_5OH]^+$), 264 (43.3, $[M+1-COOC_2H_5]^+$), 158 (39.3), and 128 (100). Found: C, 67.64; H, 4.70; N, 8.19; S, 9.75%. Calcd for $C_{19}H_{16}N_2SO_2$: C, 67.84; H, 4.79; N, 8.32; S, 9.53%.

*Conversion of 4-Chloro-5-cyano-2,6-diphenylpyrimidine into **15**.* 4-Chloro-5-cyano-2,6-diphenylpyrimidine (0.20 g) was added to a solution saturated with hydrogen sulfide in benzene–triethylamine (2:1, 15 ml), after which the mixture was distilled under reduced pressure, the residue was washed with dilute hydrochloric acid and dissolved with 1 mol dm^{-3} of MeOH–MeONa (5 ml). The solution was filtered to separate an insoluble substance and acidified with hydrochloric acid to produce a yellow powder. The powder was recrystallized from acetonitrile to give **15** (0.15 g, 76%). The mp and the IR spectrum agreed with those of **15** obtained from **6**.

(Received October 2, 1981)

The oxidation of alkyl aryl ketones by *t*-butyl hydroperoxide under basic conditions gave products which resulted from the fission of the carbon-carbon bond between carbonyl carbon and alkyl carbon. The reaction was investigated using chiral alkyl aryl ketones. On the basis of the results, a probable reaction mechanism is proposed.

Oxidation of alkyl aryl ketones by peracids under acidic conditions, *i.e.*, Baeyer-Villiger oxidation, is well documented.[1] On the contrary, oxidation of alkyl aryl ketones by hydroperoxides under basic conditions has not been so familiar to chemists, although it has some mechanistically attractive features in its reaction. Some of the reactions have been investigated by one of the present authors(K.M.) and a tentative reaction mechanism has been proposed, but detailed investigations remained to be done.[2] Oxidation of alkyl aryl ketones by *t*-butyl hydroperoxide under basic conditions gave carbon-carbon fission products between $C_{carbonyl}$–C_{alkyl}, but none of those resulted from fission between $C_{carbonyl}$–C_{aryl} without dependency on the structure of alkyl groups (see Eq. 1). In this

$$\text{Aryl–}\overset{\overset{O}{\|}}{C}\text{–Alkyl} + t\text{-BuOO}^- \longrightarrow \text{Aryl–}\overset{\overset{O}{\|}}{C}\text{–O}^- + \text{Oxidation Products of Alkyl Groups} + t\text{-BuO}^- \quad (1)$$

work we reinvestigated the reaction using chiral alkyl aryl ketones, and proposed the most probable reaction mechanism.

Results and Discussion

Oxidation of Chiral Alkyl Aryl Ketones. Chiral alkyl aryl ketones **1**, **4**, and **7** were subjected to the reaction, and the optical rotations of the alcohols resulting from the alkyl groups were examined. Addition of 18-crown-6 in a reacting mixture was a new device of our present oxidation conditions; this was done to make the reacting mixture homogeneous.[2]

Oxidation of (*S*)-(−)-2-ethyl-2,4-dimethyl-1-phenyl-1-pentanone (**1**) by *t*-butyl hydroperoxide anion afforded benzoic acid and (*S*)-(−)-3,5-dimethyl-3-hexanol (**2**) of 100% optical purity, $[\alpha]_{5805}^{25}$ −3.5°, and ester (**3**). The optical purity and the absolute configuration of the isolated 3,5-dimethyl-3-hexanol was confirmed by the literature.[3,4] Thus, alkyl aryl ketone reacted with retention of the configuration of the alkyl group.

An analogous result was obtained in the reaction with (*R*)-(−)-2-methyl-1,2-diphenyl-1-butanone (**4**). The specific optical rotation of 2-phenyl-2-butanol (**5**) isolated from the reacting mixture showed the value $[\alpha]_{5805}^{16}$ +18.9°, optical purity 93%. Correlation of the absolute configurations between (−)-**4** and (+)-**5** has been independently reported by D. J. Cram *et al.*[5] and S. Mitsui.[6] Thus, 2-phenyl-2-butanol (**5**) obtained in this reaction has an *R*-configuration, indicating unambiguously retention of its configuration in the alkyl group in the course of the reaction. Minor but distinctive amounts of 1-methyl-1-phenylpropyl benzoate (**6**) was also obtained in this reaction.

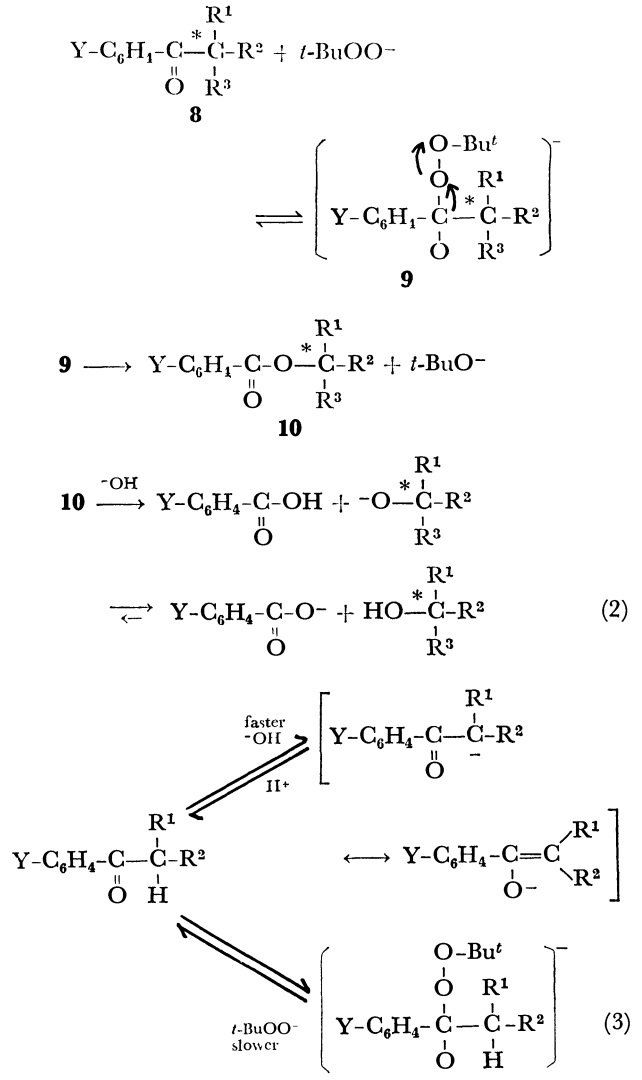
Fig. 1.

From the results of the above two reactions we can conclude that the reaction of alkyl aryl ketone proceeds with retention of the configuration around the alkyl carbon adjacent to the carbonyl carbon. However, chiral alkyl aryl ketone, in which the alkyl group has enolizable hydrogen, lost its chirality in the course of the reaction. This is exemplified in the reaction of chiral 2-methyl-1-phenyl-1-octanone (**7**). The reaction of chiral **7** under similar conditions gave a mixture of benzoic acid, 2-octanone, *t*-butyl alcohol, and some recovered **7**. 2-Octanol was not detected in the reacting mixture, but its oxidation product, 2-octanone, was found in a reasonable yield (25%). Though diagnosis from 2-octanol was not achieved, the recovered **7** showed no optical rotation, indicating complete loss of the chirality in the course of the reaction, presumably *via* enolization.[7]

In conclusion, oxidation of alkyl aryl ketones by *t*-butyl hydroperoxide anion may be formulated best as shown in Eq. 2. Thus, the previously proposed reaction mechanism including an attack of *t*-butyl hy-

** 1 mmHg≈133.322 Pa.

droperoxide anion on carbonyl carbon and subsequent back-side attack of hydroxide anion on alkyl carbon[2] should be revised as described here. When one of R^1–R^3 was hydrogen, alkyl aryl ketone could be enolized to lose its chirality before attack by hydroperoxide anion. That the enolization of ketone occurred more quickly than the attack of hydroperoxide anion is suggested by the experimental results of the reaction of (−)-**7**.



Comparison of our Reaction with the Baeyer-Villiger Reaction. The characteristics of our reaction and the Baeyer-Villiger reaction are illustrated in Table 1.

In the Baeyer-Villiger reaction, methyl and ethyl phenyl ketones (Rec. No. 1 and 2) gave preferentially carbon-carbon fission products between carbonyl carbon and phenyl carbon, whereas isopropyl and *t*-butyl phenyl ketones (Rec. No. 3 and 4) gave preferentially carbon-carbon fission products between carbonyl carbon and alkyl carbon. On the contrary, in our reaction all alkyl phenyl ketones gave carbon-carbon bond cleavage products between carbonyl carbon and alkyl carbon.

Thus, it is clear now that by choosing suitable reaction conditions of the peroxide oxidation one can attain a selective carbon-carbon bond cleavage of alkyl aryl ketones.

Experimental

All melting and boiling points are uncorrected. The infrared spectra were measured on a Hitachi 215 grating infrared spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL JNM-MH 100 spectrometer. Gas chromatography was carried out with a Hitachi gas chromatograph, Model 163. The optical rotations were measured on a Union high sensitivity polarimeter PM-70. Elemental analyses were carried out at the Analytical Center of Kyoto University.

t-Butyl Hydroperoxide. This peroxide was prepared by the literature method:[8] bp 38—39 °C/19 mmHg; lit:[8] bp 33—34 °C/17 mmHg.

*Preparation of 2-Ethyl-2,4-dimethyl-1-phenyl-1-pentanone (**1**).* This procedure is a modification of that employed by D. J. Cram.[5] A mixture of 2-ethyl-2,4-dimethylpentanoic acid (**11**, 57 mmol) prepared from 2,4-dimethylpentanoic acid by the procedure of P. E. Pfeffer *et al.*[9] and thionyl chloride (75 mmol) was allowed to stand overnight at room temperature, the excess thionyl chloride being evaporated under vacuum. Two successive portions of anhydrous benzene

Table 1. Comparison of Baeyer-Villiger reaction with the present reaction

Reaction No.	Ketone	Baeyer-Villiger reaction[a]			Present reaction[b]

3	Ph-C(=O)-Pr^i	7	75	18	40	60
4	Ph-C(=O)-Bu^t	0	76	24	40	60

Reaction conditions: a) ketone: 2 mmol; *m*-chloroperbenzoic acid: 2.4 mmol; solvent: $CHCl_3$(12 ml); temp: 28 °C; reaction time: 7 d. b) Ketone: 2 mmol; *t*-BuOOH: 6 mmol; KOH: 7 mmol; 18-crown-6: 0.8 mmol; solvent: C_6H_6(20 ml); temp: 70 °C; reaction time: 1 h.

were added and evaporated under vacuum. The residual oil consisted of 2-ethyl-2,4-dimethylpentanoyl chloride was used for the next step without further purification. To a hot benzene solution of diphenylcadmium prepared in the usual way[10] was added the above residual oil. The reaction mixture was held at reflux for 30 min and worked up in the usual manner to give **1** (72%): bp 143—147 °C/15 mmHg; NMR (CCl_4) δ=7.70—7.50 (2H, m), 7.40—7.10 (3H, m), 2.10—1.30 (5H, m), 1.20 (3H, s), 1.00—0.65 (9H, m); IR (CCl_4) 1670 cm^{-1} (C=O).

Found: C, 82.68; H, 10.21%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

Optical resolution of **11** with the aid of burcine to the procedure of W. v. E. Doering and K. B. Wiberg[11] was unsuccessful, but we have accomplished this using quinine by the following procedures. A mixture of **11** (29 g) and quinine (50 g) was dissolved in 66%-ethanol by heating. The solution was allowed to stand in a refrigerator, and then filtered to give colorless crystals. These were recrystallized fifteen times from 66%-ethanol to give a quinine salt (9 g): mp 97.5—98.5 °C. The salt was suspended in dilute sulfuric acid and extracted with ether. The etherial extract was washed with dilute sulfuric acid, dried over sodium sulfate, and then the solvent was removed. The residual oil was purified by distillation to give (−)-**11** (2.5 g): bp 138—140 °C/20 mmHg; $[\alpha]_{5805}^{25}$ −22.7° (*c* 5.15, 99%-EtOH); lit[11] for (+)-**11**: bp 124—125 °C/12 mmHg; $[\alpha]_D^{25}$ +21.42° (*c* 10.3, 95%-EtOH).

The active (−)-**1** was prepared in 85% over-all yield from (−)-**11** by use of the above procedure: $[\alpha]_{5805}^{25}$ −11.8° (*c* 4.02, 99%-EtOH). The IR and NMR spectra of this ketone were identical with those of (±)-**1**.

Preparation of 2-Methyl-1,2-diphenyl-1-butanone (4). This ketone was prepared from 2-methyl-2-phenylbutanoic acid by the procedure given in the literature:[5,12] bp 139—140 °C/2 mmHg; lit:[5] bp 144—145 °C/2.5 mmHg.

Optically active (−)-**4** was prepared from (−)-2-methyl-2-phenylbutanoic acid: $[\alpha]_{5805}^{20}$ −32.1° (*c* 4.04, C_6H_6); mp 87—88 °C; lit:[12] $[\alpha]_D^{23}$ −30° (*c* 4.5, C_6H_6); mp 86—87 °C. After employing the above procedure to the synthesis of **4**, we obtained the active **4**: $[\alpha]_{5805}^{20}$ −69.7° (*c* 3.8, C_6H_6); lit:[5] $[\alpha]_D^{25}$ −63.7° (neat).

Preparation of 2-Methyl-1-phenyl-1-octanone (7). Ketone **7** was prepared in a yield of 84% by the Friedel-Crafts reaction of a mixture of 2-methyloctanoyl chloride (63 mmol), anhydrous aluminium chloride (75 mmol), and dry benzene: bp 130—131 °C/2 mmHg; lit:[13] bp 100 °C/0.01 mmHg.

Resolution of the 2-methyloctanoic acid was achieved in the following way. A mixture of 2-methyloctanoic acid (8.5 g) and cinchonidine (16 g) was dissolved in 95%-acetone by heating, and then allowed to stand in a refrigerator. The precipitated salts were collected by filtration and then repeatedly recrystallized using the same solvent until the optical rotation of the acid showed a very slight increase (twelve times). The salt was then decomposed in the usual manner to give (−)-2-methyloctanoic acid (745 mg): $[\alpha]_{5805}^{20}$ −20.0° (*c* 1.8, C_6H_6); lit[14] for (+)-isomer: $[M]_D^{20}$ +26° ($[\alpha]_D^{25}$ +16.45°).

Optically active (−)-**7** was prepared from (−)-2-methyloctanoic acid. After the above procedure similar to the synthesis of **7** was employed, we obtained the active **7**: $[\alpha]_{5805}^{20}$ −29.7° (*c* 2.9, C_6H_6); lit:[13] $[\alpha]_D$ −21.5° (*c* 5, Et_2O), $[\alpha]_D$ 24.5°.

General Procedure for Oxidation of the Ketone with t-Butyl Hydroperoxide. Powdered analytical grade potassium hydroxide (5 mmol) was suspended in benzene (10 ml). After the air in the reaction vessel was expelled completely with dry nitrogen gas and the temperature of the oil bath reached 80 °C, a benzene solution (5 ml) of ketone (2 mmol) was added to the reaction mixture; then a benzene solution (5 ml) of *t*-butyl hydroperoxide (4 mmol) and 18-crown-6 (5 mmol) was added sequentially with an injector. The reacting mixture was stirred at 80 °C for 3 h and cooled in an ice-water bath. Ether (10 ml) was added to the reacting mixture and the resulting carboxylic acid was extracted with water (10 ml) and twice with aqueous sodium hydrogencarbonate solution (10 ml). The combined aqueous layer was acidified with dilute sulfuric acid and then extracted twice with ether (10 ml). The amount of acid extracted was determined by gas chromatography after methylating with diazomethane. The unreacted ketone and the neutral products in the residual organic layer were determined by gas chromatography and then isolated by column chromatography on silica gel for analyses.

Oxidation of (±)-1. The resulting mixture consisted of benzoic acid (44%), recovered ketone (47%), 3,5-dimethyl-3-hexanol (**2**, 32%): bp 72—73 °C/50 mmHg; lit:[15] bp 152—153 °C, and 1-ethyl-1,3-dimethylbutyl benzoate (**3**, 9%): bp 153 °C/28 mmHg (slightly dec); NMR (CCl_4) δ=7.88 (2H, dd, J=8 and 2 Hz), 7.46—7.10 (3H, m), 2.10—1.64 (5H, m), 1.51 (3H, s), 1.04—0.80 (9H, m); IR (CCl_4) 1710 (ester C=O) and 1275 cm^{-1} (C–O–C).

Found: C, 76.84; H, 9.67%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

The specific rotation of **2** produced in the oxidation of (−)-**1** was as follows: $[\alpha]_{5805}^{25}$ −3.5° (*c* 5.36, 99%-EtOH); lit:[15] $[\alpha]_D^{25}$ −3.5° (*c* 8.5, 95%-EtOH).

Oxidation of (±)-4. Oxidation was done at 50 °C and the reaction products were analyzed as usual. The resulting mixture consisted of benzoic acid (65%), recovered ketone (20%), 2-phenyl-2-butanol (**5**, 13%): bp 111 °C/25 mmHg; lit:[16] bp 90—91 °C/14 mmHg, and 1-methyl-1-phenylpropyl benzoate (**6**, 9%): viscous oil; NMR (CCl_4) δ=7.98 (2H, dd, J=8 and 2 Hz), 7.50—7.10 (8H, m), 2.40—2.00 (2H, m), 1.92 (3H, s), 0.84 (3H, t, J=7 Hz); IR (CCl_4) 1720 (ester C=O) and 1270 cm^{-1} (C–O–C).

Found: C, 80.13; H, 7.21%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

The specific rotation of **5** produced from oxidation of (−)-**4** was as follows: $[\alpha]_{5805}^{16}$ +18.9° (*c* 2.16, C_6H_6); lit:[16] $[\alpha]_D^{22}$ +17.45° (neat).

Oxidation of (±)-7. The resulting mixture consisted of benzoic acid (41%), heptanoic acid (4%), hexanoic acid (4%), recovered ketone (57%), and 2-octanone (25%). 2-Octanol was not detected in the mixture.

Rapid Peptide Synthesis in Liquid Phase. Preparation of Angiotensin II and Delta-sleep-inducing Peptide by the "Hold-in-Solution" Method[1,2]

Sukekatsu NOZAKI* and Ichiro MURAMATSU†

Department of Microbiology, Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02

† *Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171*

(Received October 3, 1981)

A new technique for rapid peptide synthesis has been demonstrated by the preparation of a protected angiotensin II, Z–Asp(OBzl)–Arg(NO_2)–Val–Tyr(Bzl)–Ile–His(Bzl)–Pro–Phe–OBzl (**1**), and a protected delta-sleep-inducing peptide, Z–Trp–Ala–Gly–Gly–Asp(OBzl)–Ala–Ser(Bzl)–Gly–Glu(OBzl)–OBzl (**2**). Elongation of the peptide chain was carried out in 1,2-dichloroethane by repeating the following series of operations: acylation of a benzyl ester of amino acid or peptide with Boc-amino acid by 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride and 1-hydroxybenzotriazole; washing of the organic layer; acidolysis of the α-amino protector; neutralization; and washing. Throughout the synthesis, the growing peptides were held in the organic layer without being isolated. The protected peptides, **1** and **2**, were obtained in overall yields of 78% and 53% based on their *C*-terminal amino acid esters, and were then hydrogenated to give angiotensin II and delta-sleep-inducing peptide, respectively, thus demonstrating the usefulness of this method for rapid peptide synthesis.

The liquid phase method for peptide synthesis is superior to the solid phase method especially with respect to variety of synthetic routes available and facility for purification of the intermediates. The former method, however, usually involves a considerable amount of time-consuming work; hence various attempts have been made to reduce the time required.[3] The present paper describes a new technique, tentatively named the "hold-in-solution" method, for rapid peptide synthesis in the liquid phase, in which a water-containing environment can be tolerated throughout the entire procedure for peptide elongation. Essentially, this method consists of a series of operations, the series being repeated in as many cycles as necessary to obtain the desired elongation (Fig. 1). The details of the operations, designated herein as (A), (B), (C), (D), and (E), are as follows: (A) Acylation of an amino acid benzyl ester with a Boc-amino acid by using 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (WSCD·HCl)[4] and 1-hydroxybenzotriazole (HOBt)[5] as the coupling reagents in a water-immiscible organic solvent, 1,2-dichloroethane (DCE). The coupling reaction is carried out at room temperature. Completion of the acylation is easily detected by disappearance of the amine component on TLC. Excess amounts (usually 2 mol equivalents per mole of the amine component) of a Boc-amino acid, HOBt, and WSCD·HCl are used for the acylation. (B) Successive washing of the reaction mixture with 0.1 M (1 M = 1 mol dm^{-3}) HCl, water, 0.5 M Na_2CO_3, and water. Complete removal of the excess Boc-amino acid is sometimes difficult by the washing but is not necessary in this step. (C) Acidolysis of the α-amino protector by HCl in dioxane (concentration of HCl in the mixture; 1.7—2.2 M. 0 °C, 0.5 h). In this step the excess Boc-amino acid is converted to the free amino acid, which is easily removed from the organic layer in the following steps. (D) Neutralization of the mixture by 2 M Na_2CO_3 below 0 °C. (E) Removal of the aqueous layer and washing of the organic layer with water, 0.5 M Na_2CO_3, and water in that order. All the treatments are carried out in a single vessel. When a mixture emulsifies, the two layers are separated by centrifugation.

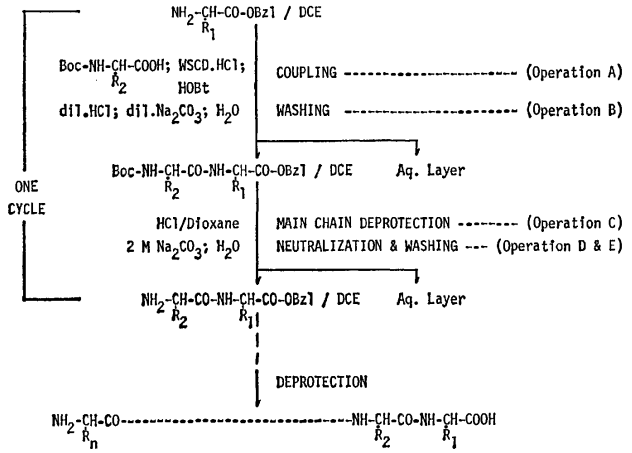

Fig. 1. Scheme of the synthesis of an oilgopeptide by the "hold-in-solution" method.

By repeating the series of operations through two or more cycles, a peptide chain can be elongated stepwise. During the preparation, the intermediate peptide is held in the organic layer without being isolated. It is desirable for best results that the *N*-terminal free peptide have low solubility in the aqueous layer.

by a one-hour coupling reaction of Boc–Val–OH and H–Ile–OBzl, both of which are rather less reactive because of the steric hindrance of their bulky side chains, in several solvent systems. Without the additives, the coupling yield was low even in the anhydrous solvents. The presence of water further lowered the yield. Addition of HOBt markedly improved the yield in the water-containing solvents as well as in the anhydrous media. It is interesting that the use of other additives, *N*-hydroxysuccinimide (HOSu)[6] and *N*-hydroxy-5-norbornene-2,3-dicarboximide (HONb),[7] rather lowered the yield in the anhydrous solvents. In the water-containing systems, they improved the yield but the effect was not as significant as that of HOBt. Thus, peptide elongation with sufficient yield is possible in water-containing media by addition of HOBt.

As a model peptide synthesis by this new method, preparation of a protected angiotensin II, Z–Asp(OBzl)–Arg(NO_2)–Val–Tyr(Bzl)–Ile–His(Bzl)–Pro–Phe–OBzl (**1**), and a protected delta-sleep-inducing peptide,[8] Z–Trp–Ala–Gly–Gly–Asp(OBzl)–Ala–Ser(Bzl)–Gly–Glu(OBzl)–OBzl (**2**), was carried out in DCE. Two equimolar amounts of the acylating reagents were used per mole of the amine components. Tables 2 and 3 show the amino acid ratios in the acid hydrolysates of the intermediate peptides held in the organic layer at the end of operation E of each cycle. Complete acylation was achieved in every coupling reaction This fact indicates that the acylation in this method proceeds more smoothly than that in the solid phase method employing the usual polystyrene resin as the support.[9] Centrifugation was required in operation E after introduction of valine at position 3 in the preparation of **1**, and of alanine at position 6 in the case of **2**. The protected peptides, **1** and **2**, were obtained in overall yields of 78% and 53%, respectively, based on their *C*-terminal esters. HPLC profiles of the products are shown in Fig. 2. After the catalytic hydrogenolysis of **1** and **2**, the free peptides were easily purified by partition chromatography on Sephadex[10] to give angiotensin II and DSIP, respectively. Homogeneities of the synthetic peptides were confirmed by HPLC analyses (Fig. 3).

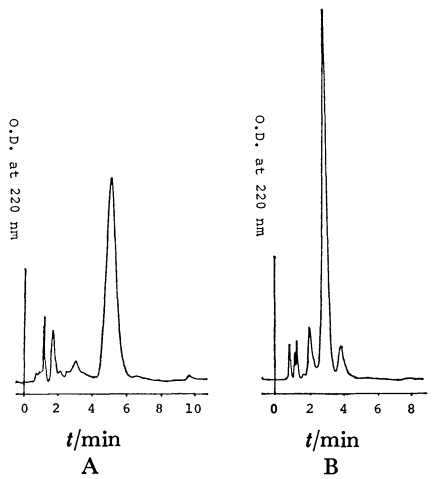

Fig. 2. HPLC profiles of (A) crude **1** ($MeOH/H_2O$, 8/1) and (B) crude **2** ($MeOH/H_2O$, 5/1).

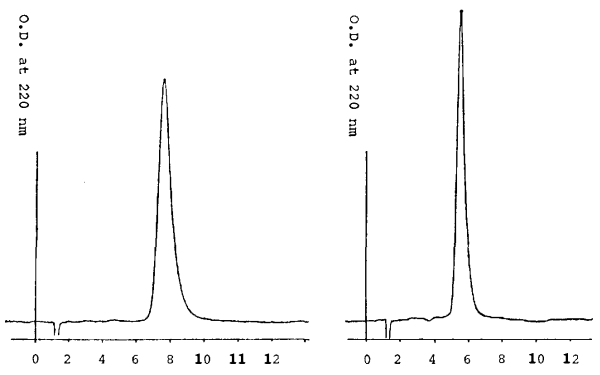

Fig. 3. HPLC profiles of (A) synthesized angiotensin II (MeOH/1% ammonium acetate, pH 6.90, 7/10) and (B) synthesized DSIP (MeOH/1% ammonium acetate, pH 6.90, 1/8).

Preparation of the octa- and nonapeptide demonstrated the utility of the new method for rapid synthesis of oligopeptides. The method has been applied successfully to the preparation of the fragment peptides which served as the building blocks in the construction of granuliberin R[11] and the active site of troponin I.[12]

Advantages of the "hold-in-solution" peptide synthesis are (1) that it is fast, (2) that it permits the intermediates to be characterized easily, and (3) that it does not require large excesses of the acylating reagents nor any special apparatus.

Experimental

The peptides were hydrolyzed in constantly boiling HCl (110 °C, 16 h) or in 3 M 2-mercaptoethanesulfonic acid (110 °C, 20 h). Amino acid analyses were carried out on a JLC-6AS automatic amino acid analyzer (JEOL). HPLC analyses were performed on a steel column (4 mm×250 mm) packed with LiChrosorb RP-18 (10 μm, Merck & Co.) and optical density at 220 nm was monitored at a flow rate of 1.83 ml/min. An authentic sample of angiotensin II was purchased from the Protein Research Foundation, Osaka, Japan.

Effect of Additives. Boc–Val–OH (0.5 mM, derived from the DCHA salt), H–Ile–OBzl tosylate (0.5 mM), triethylamine (0.5 mM), and an additive (0.5 mM) were dissolved in a solvent. To this solution, solid WSCD·HCl (0.5 mM) was added and the mixture was stirred for 1 h at room temperature. The solvent was removed *in vacuo*. The residue was dissolved in ethyl acetate (50 ml) and washed successively with 0.1 M HCl (10 ml×2), water (10 ml), 0.5 M Na_2CO_3 (20 ml), and water (10 ml×4). After removal of the solvent, the residue was dissolved in methanol/water (3/1) of a known volume (50—110 ml) and an aliquot of the solution (5—30 μl) was applied to HPLC (solvent: methanol/water, 3/1). The yield of the dipeptide was determined by use of the calibration curve of a standard solution of Boc–Val–Ile–OBzl (9.56 mg in 30 ml of methanol/water, 3/1).

Preparation of Angiotensin II. H–Phe–OBzl tosylate (222 mg, 0.5 mM), triethylamine (0.07 ml), Boc–Pro–OH (1.0 mM, 215 mg), and HOBt (135 mg, 1.0 mM) were dissolved in DCE (25 ml). WSCD·HCl (192 mg, 1.0 mM) in water (1 ml) was added to the solution and the mixture was stirred for 2 h at room temperature. The reaction mixture was washed successively with 0.1 M HCl (5 ml×3), water (5 ml), 0.5 M Na_2CO_3 (5 ml), and water (5 ml×4) below 10 °C. Each of the aqueous phases was removed by pipetting. To the organic layer, HCl in dioxane (7.2 M, 8 ml) was added at −10—0 °C and the mixture was stirred at 0 °C for 0.5 h, then chilled to −10 °C, and 2 M Na_2CO_3 (18 ml) was added to it. The aqueous layer was removed and the organic layer was washed successively with water (4 ml×2), 0.5 M Na_2CO_3 (4 ml), and water (4 ml×2). An aliquot (*ca.* 0.05 ml) of the organic layer was evaporated and the residue was hydrolyzed to determine the amino acid ratio (Table 2). In the second cycle, Boc–His(Bzl)–OH (345 mg, 1.0 mM) and HOBt (135 mg, 1.0 mM) were added to the organic layer followed by WSCD·HCl (192 mg, 1.0 mM) dissolved in water (1 ml). The mixture was stirred for 4.5 h, then otherwise subjected to the procedures described above for the first cycle. Further acylation was carried out successively by Boc–Ile–OH, Boc–Tyr(Bzl)–OH, Boc–Val–OH, Boc–Arg(NO_2)–OH, and Z–Asp(OBzl)–OH (1.0 mM each) using HOBt and WSCD·HCl (1.0 mM each) as the condensation reagents. The coupling reactions were carried out for 3 h to overnight. Oily Boc-amino acids, Boc–Ile–OH and Boc–Val–OH, were added as DCE solution (2 ml). Boc–Arg(NO_2)–OH was added as a DMF solution (2 ml). Centrifugation was required in operation E after addition of Boc–Val–OH. In the final acylation, the reaction mixture was diluted with DMF (10 ml) after addition of WSCD·HCl. After the acylation was completed, the mixture was further diluted with DCE (100 ml) and water (40 ml). The organic layer was separated and washed successively with 0.1 M HCl (10 ml×2), 0.5 M Na_2CO_3 (20 ml), and water (40 ml×2, 20 ml×3). The organic layer was concentrated to give an oil, which was then solidified by addition of ether. **1**: mp 169—178 °C decomp, 609 mg (78% based on H–Phe–OBzl tosylate). Calcd for $C_{86}H_{100}O_{16}N_{14}$: C, 65.14; H, 6.36; N, 12.37%. Found: C, 65.10; H, 6.43; N, 12.16%. R_f: 0.29 (Merck precoated silicagel plate, $CHCl_3$/MeOH, 95/5). A part of the product (200 mg) was hydrogenated in a mixture of DMF (30 ml), water (20 ml), and acetic acid (1 ml) for 42 h using Pd black. After removal of the catalyst and the solvent, a crude product was obtained. R_f: 0.54 (Avicel precoated cellulose plate, 1-butanol/pyridine/acetic acid/water, 16/10/3/12). Amino acid ratio in HCl–hydrolysate, Asp 1.07, Pro 1.04, Val 1.04, Ile, 0.92, Tyr 0.99, Phe 1.08, His 0.93, Arg 0.94. The product was purified by partition chromatography on a Sephadex G-25 column (1.6 cm×36 cm, 1-butanol/pyridine/acetic acid/water, 16/10/3/12). Fractions of 3 g each were collected and fractions 15—18 were combined and concentrated. The residue was applied to a Sephadex G-10 column (1.2 cm×24 cm) and eluted with 5% acetic acid. Fractions of 2 g each were collected and the desired peptide was recovered from fractions 5—9 by lyophilization: 94 mg; 63% from **1**. Amino acid ratio in HCl–hydrolysate (for 24 h): Asp 1.09, Pro 0.98, Val 1.02, Ile 0.91, Tyr 1.01, Phe 1.09, His 0.94, Arg 0.96. Calcd for $C_{50}H_{71}O_{12}N_{13}\cdot CH_3COOH\cdot 4H_2O$: C, 53.01; H, 7.10; N, 15.45%. Found: C, 53.24; H, 6.57; N, 15.14%. The biological activity (oxytocic activity on an isolated rat uterus) of the prepared peptide was the same as that of the authentic sample.

Preparation of DSIP. H–Glu(OBzl)–OBzl tosylate (250 mg, 0.5 mM) in DCE (25 ml) was acylated successively by Boc–Gly–OH, Boc–Ser(Bzl)–OH, Boc–Ala–OH, Boc–Asp(OBzl)–OH, Boc–Gly–OH, Boc–Gly–OH, Boc–Ala–OH, and Z–Trp–OH (1.0 mM each) using HOBt and WSCD·HCl

(1.0 mM each) as described above. The following reagents were used:

Operation B: 0.1 M HCl (5 ml×3), water (5 ml), 0.5 M Na_2CO_3 (5 ml), water (5 ml×4).

Operation C: 8.8 M HCl/dioxane (8 ml).

Operation D: 2 M Na_2CO_3 (18 ml).

Operation E: water (4 ml×2), 0.5 M Na_2CO_3 (4 ml), water (4 ml×4 to 6).

Centrifugation was required in operation E after introduction of Boc–Ala–OH at position 6 and in both operation B and E after introduction of Boc–Ala–OH at position 2. After the final acylation, the reaction mixture was washed with water (10 ml×3, the aqueous phases being separated by centrifugation). The organic layer was concentrated to give an oil, which was solidified in ether. The solid collected was dissolved in DMF, decolorized with charcoal, and reprecipitated by addition of ether. **2**: 284 mg. 53% based on H–Glu(OBzl)–OBzl tosylate. Mp 210—213 °C decomp. Calcd for $C_{71}H_{78}O_{17}N_{10}\cdot H_2O$: C, 62.26; H, 5.92; N, 10.29%. Found: C, 62.59; H, 5.88; N, 10.26%. Amino acid ratio in HCl–hydrolysate: Asp 1.10, Ser 0.93, Glu 1.07, Gly 2.96, Ala 1.94. In 2-mercaptoethanesulfonic acid–hydrolysate: Asp 1.12, Ser 0.96, Glu 1.10, Gly 2.90, Ala 1.92, Trp 0.73. A part of the product (166 mg) was hydrogenated for 7 h in DMF (60 ml) and water (20 ml) using Pd black. After the usual work-up, the crude product was applied to partition chromatography on a Sephadex G-25 column (1.6 cm×36 cm, 1-butanol/pyridine/acetic acid/water, 16/10/3/12). Fractions of 3 g each were collected and fractions 47—53 were combined, concentrated, and lyophilized from water (67 mg). The peptide was further applied to a Sephadex G-10 column (1.2 cm×26 cm), and eluted with water. Fractions of 1 g each were collected and fractions 12—19 were combined and lyophilized to give the desired peptide: 52 mg, 39% from **2**. R_f: 0.11 (silica gel, 1-butanol/acetic acid/water, 4/1/1). Calcd for $C_{35}H_{48}O_{15}N_{10}\cdot 4H_2O$: C, 45.65; H, 6.12; N, 15.20%. Found: C, 45.12; H, 5.58; N, 15.41%. Amino acid ratio in HCl-hydrolysate: Asp 1.01, Ser 0.92, Glu 1.09, Gly 2.96, Ala 2.01, Trp 0.85. In 2-mercaptoethanesulfonic acid–hydrolysate: Asp 0.91, Ser 0.97, Glu 1.08, Gly 2.99, Ala 2.06, Trp 0.98.

The authors are indebted to the Research Laboratory of Nihon Kayaku Co. Ltd. for the biological measurement and the Research Laboratory of Toyo Jozo Co. Ltd. for the elemental analyses. They also thank Dr. Yoshiaki Motoki for the amino acid analyses.

The Synthesis of Highly Strained Buttaflanes with Aromatic Rings

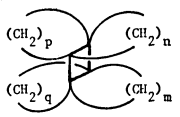
Koji KIMURA,* Hideki OHNO, Kiyoshi MORIKAWA, Yasuhiro HIRAMATSU, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

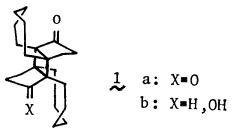
(Received October 8, 1981)

Dibenzo[4.4.2.2]buttaflanes, *syn*-13,14:15,16-dibenzopentacyclo[6.4.2.2^{2,7}.0^{1,8}.0^{2,7}]hexadeca-13,15-diene, and *syn*-13,14:15,16-dibenzohexacyclo[6.4.2.2^{2,7}.0^{1,8}.0^{2,7}.0^{3,12}]hexadeca-13,15-diene, were synthesized by the intramolecular photocycloaddition of the dibenzo[*a,e*]cyclooctene derivatives, *syn*-13,14:15,16-dibenzotricyclo[6.4.2.2^{2,7}]hexadeca-1,7,13,15-tetraene and *syn*-13,14:15,16-dibenzotetracyclo[6.4.2.2^{2,7}.0^{3,12}]hexadeca-1,7,13,15-tetraene, which had themselves been derived by the catalytic hydrogenation of the biphenylene photodimer, *syn*-13,14:15,16-dibenzotricyclo[6.4.2.2^{2,7}]hexadeca-1,3,5,7,9,11,13,15-octaene, and the pentacyclic compound, *syn*-13,14:15,16-dibenzopentacyclo[6.4.2.2^{2,7}.0^{3,12}.0^{4,11}]hexadeca-1,5,7,9,13,15-hexaene, respectively.

The synthesis of strained compounds showing unusual chemical and physical properties has been of considerable interest.[1] As a part of our studies of the synthesis of a novel polycarbocyclic ring system, we ourselves have previously reported the synthesis of buttaflane (**1**),[2] wherein two propellane units share a cyclobutane ring.[3] The present [6.3.6.3]buttaflane (**1a**)



[m.n.p.q]Buttaflane

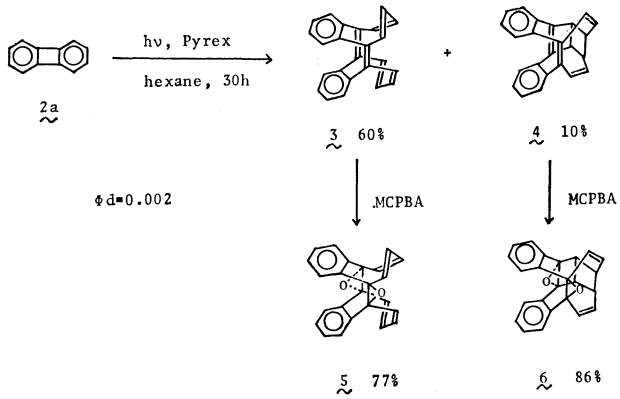


1 a: X=O
b: X=H,OH

[6.3.6.3]Buttaflane

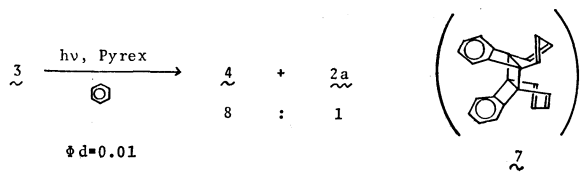
had its long bonds in the planar cyclobutane ring,[4] and, concerning anomalous chemical behavior, a remarkably large rate constant was observed in the chromium trioxide oxidation of **1b**.[5] These noteworthy aspects are considered to be due to the nonbonded interaction of hydrogens between alicyclic rings facing each other. Therefore, when aromatic rings facing each other are incorporated into a buttaflane framework, it is very interesting to see if this buttaflane exhibits some π-π interaction,[6] as do cyclophanes[7] or janusenes,[8] in association with the closeness of the two facing benzene rings. However, what was, to the best of our knowledge, the first attempt to synthesize buttaflane with aromatic rings facing each other was unsuccessful.[9] That is, the direct or sensitized photolysis of 9,9',10,10'-tetradehydrobi(9,10-anthrylene) (**18**) provided no evidence for the formation of tetrabenzo[2.2.2.2]buttaflane. In this connection, we wish now to report the synthesis of new highly strained buttaflanes with aromatic rings facing each other, and the related compounds.

In this successful approach to the synthesis of buttaflanes, we make use of the ready photodimerization of biphenylene (**2a**). On the irradiation of biphenylene (**2a**)[10] in hexane through a Pyrex filter for 30 h, a *syn*-photodimer (**3**), with the dibenzo[*a,e*]cyclooctene structure, was obtained in a 60% yield, along with the pentacyclic compound (**4**, 10%). In this photoreaction, no *anti*-photodimer was detected at all. This *syn*-photodimer (**3**) might be formed from the excimer of biphenylene (**2a**), though the emission of the excimer fluorescence could not be observed. The quantum yield for the disappearance of biphenylene (**2a**) was 0.002.



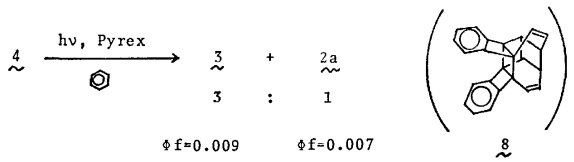
In 1968, Goldman *et al.* reported erroneously that the biphenylene photodimer was buttaflane (**7**) and also that the octahydrogenated biphenylene photodimer was buttaflane (**19**).[11] Afterward, as we were conducting our investigation, they corrected the structure of the octahydro dimer to correspond to ours (**9**) as a result of X-ray study,[12] and Nishida and Furusaki *et al.* reported independently, also as a result of X-ray analysis, that the biphenylene photodimer had the same structure as ours (**3**).[13] Significantly, in their photoreactions of biphenylene (**2a**), these two groups did not mention at all the formation of the pentacyclic compound (**4**), the intramolecular photocycloadduct of two peripheral double bonds of the biphenylene photodimer (**3**). In order to confirm the structures of **3** and **4**, epoxidation was examined. The epoxidation of **3** and **4** with *m*-chloroperbenzoic acid took place preferentially at two bridgehead double bonds to give the diepoxides, **5** and **6**, respectively.

Conceivably, the shortest way to the synthesis of buttaflanes is the intramolecular photocycloaddition of the respective two bridgehead double bonds of **3** and **4**. Unfortunately, the direct irradiation of **3** gave no buttaflane (**7**), but only biphenylene (**2a**) and the pentacyclic compound (**4**). The quantum yield for the disappearance of 3 was 0.01. A quenching experiment using 1,3-pentadiene and a sensitizing ex-

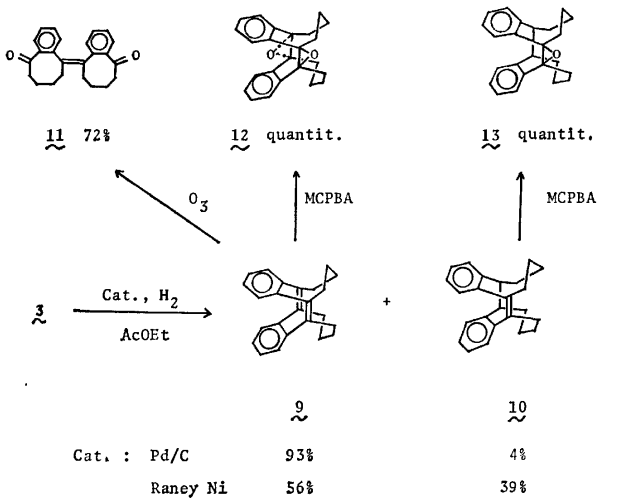


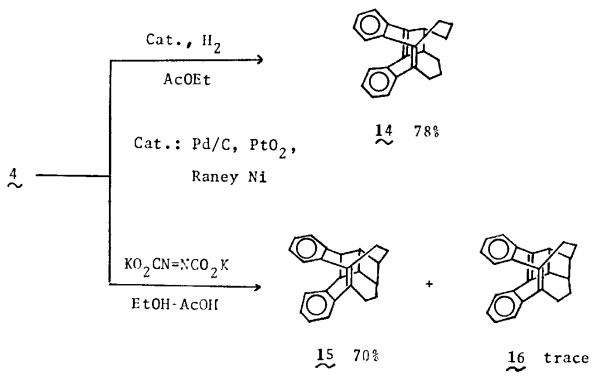
periment using acetone showed no effect on the formation of **4** and **2a**, indicating that this photoreaction proceeded *via* the singlet or unquenchable triplet state.

In the similar irradiation of **4**, cycloreversion took place to give **3** and **2a**, without any formation of buttaflane (**8**). The quantum yields for formation of **3** and **2a** were 0.009 and 0.007 respectively. These results obviously show that **2a**, **3**, and **4** are in a photostationary state. When **2a** was irradiated for 150 h, the ratio of **2a**, **3**, and **4** was 5:1:3. Moreover, the thermal cycloreversion of **4** to **3** also occurred above 180 °C.



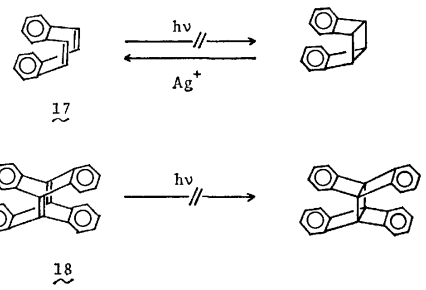
In the attempt at the one-step synthesis of buttaflanes (**7**) and (**8**) from **3** and **4**, some unfavorable reactions took place exclusively, as has been described above. Therefore, the selective hydrogenation of each peripheral double bond of **3** and **4** was attempted for the purpose of the photochemical synthesis of buttaflanes *via* **3** and **4**. The catalytic hydrogenation of **3** with Pd/C in ethyl acetate gave the desired octahydrogenated compound (**9**) retaining two bridgehead double bonds, along with a small amount of the decahydrogenated compound (**10**). In contrast, when Raney Ni was used as a catalyst, the decahydrogenated compound (**10**) was formed predominantly. The structure of dibutano-bridged dibenzo[*a*,*e*]cyclooctene (**9**) was confirmed by ozonolysis to give the diketone (**11**).[14] The epoxidation of **9** and **10** gave the corresponding diepoxide (**12**) and monoepoxide (**13**) quantitatively. On the other hand, the pentacyclic compound (**4**) was hydrogenated with Pd/C, Raney Ni, or PtO_2 to give the tetracyclic compound (**14**), accompanied by the reductive cleavage of one bond of the cyclobutane ring. In the case of the diimide reduction of **4** using potassium azodicarboxylate, the hexahydrogenated compound (**15**) was obtained in a 70% yield, together with a trace of a tetra-



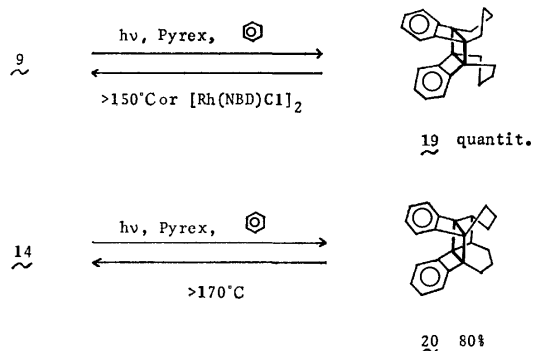


hydrogenated compound (**16**) retaining two bridgehead double bonds.

The photochemical behavior of dibenzo[*a*,*e*]cyclooctene derivatives (**9**) and (**14**), in which the central cyclooctatetraene ring takes a tub form and the two bridgehead double bonds are forced by their geometry to interact with each other, is of considerable interest in comparison with that of the fairly planar dibenzo[*a*,*e*]cyclooctene (**17**)[15] or similar tub-form compounds such as 9,9′,10,10′-tetradehydrobi(9,10-anthrylene) (**18**).[9]



When the dibenzo[*a*,*e*]cyclooctene derivative (**9**) was irradiated in benzene, the expected buttaflane with aromatic rings facing each other, *syn*-13,14:15,16-dibenzopentacyclo[6.4.2.2^{2,7}.0^{1,8}.0^{2,7}]hexadeca-13,15-diene (**19**), could be synthesized quantitatively. The crystals were orthorhombic. The ^{13}C NMR spectrum of **19** with C_{2v} symmetry had six signals, especially, the signal at δ 138.8 ppm due to a quaternary olefinic carbon of **9** was replaced by the signal at δ 49.3 ppm, based on the newly formed cyclobutane ring carbon. Similarly, the more highly strained cage buttaflane, *syn*-13,14:15,16-dibenzohexacyclo[6.4.2.2^{2,7}.0^{1,8}.0^{2,7}.0^{3,12}]hexadeca-13,15-diene (**20**), was synthesized in an



80% yield by the intramolecular photocycloaddition of **14**.

While it has been reported that the intramolecular [2+2]photocycloaddition of dibenzo[*a*,*e*]cyclooctene (**17**)[15] did not occur, the similar photocycloaddition of **9** and **14** to **19** and **20** took place excellently. This is probably because the two tetramethylene bridges between two bridgehead double bonds in **9** or **14** enforce the relatively small double-bond separations, as well as their parallel orientations,[13,16] which are preferable for photocycloaddition. On the other hand, the failure of the [2+2]photocycloaddition of the similar tub-form compound (**18**) may be attributed to the remarkable instability of the [2.2.2.2]buttaflane moiety of the supposed adduct.[17]

As expected, the tricyclo[4.2.0.0^{2,5}]octa-3,7-diene moiety in buttaflane (**19**) can be opened to **9** quantitatively by reaction with a catalytic amount of [Rh(NBD)Cl]$_2$(NBD=norbornadiene) or above 150 °C.[18] Similarly, the thermal cleavage of cage buttaflane (**20**) occurred to afford **14** almost quantitatively above 170 °C.

Attributable to the transannular π-π interaction, the aromatic ring protons of **19** and **20** in ^{1}H NMR appeared to show a somewhat high-field shift, and the electronic spectra of these compounds showed bathochromic and hyperchromic shifts. It is interesting that these interactions of **19**, **20**, and the cage compound (**21**)[19] successively decrease with an increase in the rigidity of the structure, as is shown by their UV spectra. An X-ray study of buttaflanes (**19**) and (**20**) will now be undertaken.

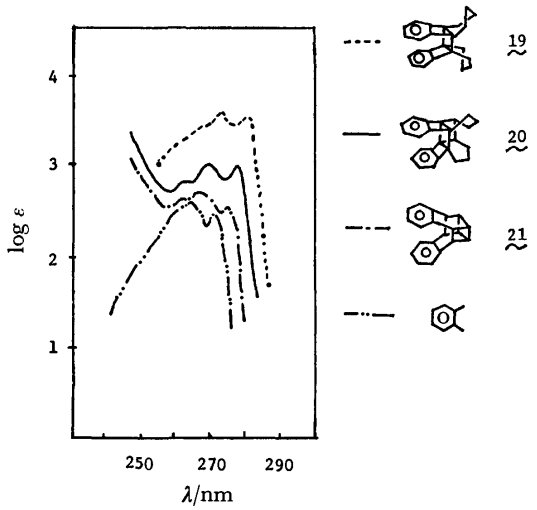


Fig. 1. UV spectra (in CH_3CN).

Experimental

The melting points are uncorrected. The infrared spectra were recorded on a JASCO IR-G spectrometer. The ^{1}H NMR and ^{13}C NMR spectra were obtained on JEOL JNM-PS-100 and JEOL JNM-FX60S spectrometers respectively, using $CDCl_3$ as the solvent and Me_4Si as the internal standard. The mass spectra were determined with a Hitachi RMU-6E spectrometer. The UV spectra were recorded on a Hitachi 356 spectrometer. Analytical GLC was carried out on a Hitachi 163 gas chromatograph, while preparative GLC separation was undertaken on a Varian Aerograph 90-P gas chromatograph.

Materials. The biphenylene (**2a**) was prepared according to the method of Friedman.[20] The 2-acetyl- (**2b**),[21] 2-methoxy- (**2c**),[22] and 2-cyanobiphenylenes (**2d**)[21] were prepared by a modification of the method of McOmie.

Photoreaction of Biphenylene (2a). A hexane solution of **2a** (0.04 mol dm^{-3}) was irradiated through a Pyrex filter at room temperature for 30 h using 500-W high-pressure mercury lamp. After the solvent had evaporated, the residue was chromatographed on silica gel with petroleum ether to elute biphenylene (**2a**), the pentacyclic compound (**4**, 10%), and the biphenylene photodimer (**3**, 60%), in this order (conv. 43%). When benzene, ether, or acetonitrile was used as the solvent, the yields of the biphenylene photodimer (**3**, 50—60%) and the pentacyclic compound (**4**, 8—15%) were somewhat similar to that of hexane (conv. 30—40%). Further irradiation gave rise to an increase in the formation of **4** and the decrease in that of **3**. After 150 h, the ratio of **2a**, **3**, and **4** was 5:1:3. In addition, when compounds **3** and **4** were allowed to stand for a long time on exposure to air, the diene moieties of **3** and **4** were easily oxidized. **3**; mp 247—252 °C decomp; Mass (*m/e*) 304 (M^+); UV (CH_3CN) λ 310 nm (ε, 1555); ^{1}H NMR ($CDCl_3$) δ 5.54—5.76 (m, 4H), 6.19—6.41 (m, 4H), 7.03 (s, 8H); ^{13}C NMR ($CDCl_3$) δ 124.0 (d), 125.0 (d), 127.1 (d), 134.6 (d), 140.4 (s), 141.2 (s); Found: C, 94.57; H, 5.27%. Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%. **4**; mp 178—179 °C; Mass (*m/e*) 304 (M^+); UV (CH_3CN) λ 276 nm (ε, 1094), 267 (1600); ^{1}H NMR ($CDCl_3$) δ 3.32—3.52 (m, 2H), 3.68—3.80 (m, 2H), 5.20—5.54 (m, 2H), 6.45 (d, 2H), 6.92—7.20 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 38.7 (d), 45.7 (d), 124.1 (d), 126.5 (d), 126.6 (d), 126.9 (d) 127.6 (d), 137.5 (s), 137.7 (s), 138.5 (d), 146.4 (s), 151.8 (s); Found: C, 94.83; H, 5.20%. Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%.

Photoreaction of 2-Acetyl-(2b) or 2-Methoxybiphenylene (2c). A hexane solution (4.2×10^{-3} mol dm^{-3}) of 2-acetyl-(**2b**) or 2-methoxybiphenylene (**2c**) was irradiated under conditions similar to those used for biphenylene (**2a**). After the removal of the solvent, the residue was chromatographed to recover unreacted 2-acetyl- or 2-methoxybiphenylene almost quantitatively.

Photoreaction of 2-Cyanobiphenylene (2d). A hexane solution of 2-cyanobiphenylene (**2d**) (3.5×10^{-3} mol dm^{-3}) was irradiated for 50 h. After the removal of the solvent, the residue was chromatographed to give the photodimer (**3d**, 24%) and some polymeric compounds (conv. 35%). This photodimer (**3d**) was labile and readily reacted with atmospheric oxygen to give a new substance in a deuteriochloroform solution. This compound was found to have four oxygens, but the structure had not yet been determined. **3d**; mp 215—220 °C decomp; IR 2200 cm^{-1}; Mass (*m/e*) 354 (M^+); UV (CH_3CN) no maximum, but the end absorption is at 390 nm; ^{1}H NMR ($CDCl_3$) δ 5.64—5.84 (m, 4H), 6.22—6.56 (m, 4H), 7.02—7.45 (m, 6H); ^{13}C NMR ($CDCl_3$) δ 146.8, 147.6 (quaternary olefinic carbon).

Photoreaction of Biphenylene Dimer (3). A degassed benzene solution of the biphenylene dimer (**3**) (1.5×10^{-3} mol dm^{-3}) was irradiated in a sealed Pyrex tube at room temperature for 5 h. After the removal of the benzene, the residue was chromatographed on silica gel. Elution with petroleum ether afforded biphenylene (**2a**, 11%) and the pentacyclic compound (**4**, 88%) (conv. 91%).

Photoreaction of Pentacyclic Compound (4). The irradiation of a degassed benzene solution of **4** (1.5×10^{-3} mol dm^{-3}) in a sealed Pyrex tube for 3 h gave no buttaflane (**8**), but biphenylene (**2a**, 23%) and the biphenylene photodimer

(**3**, 69%) (conv. 36%).

Epoxidation of ***3***. To a dichloromethane solution (50 ml) of **3** (1 mmol) was added *m*-chloroperbenzoic acid (2.2 mmol) in dichloromethane (30 ml). The mixture was stirred at 20 °C for 48 h. The excess peracid was then destroyed by the addition of 10% sodium sulfite. The reaction mixture was washed with a 5% sodium hydrogencarbonate solution to extract the *m*-chlorobenzoic acid, followed by washing with water and finally with a saturated sodium chloride solution. The organic layer was dried and stripped of the solvent. The residue was chromatographed on silica gel with petroleum ether/ether (10/1) to give the diepoxide (**5**) in a 77% yield. **5**; mp 255—257 °C decomp; Mass (*m/e*) 336 (M^+); UV (CH_3CN) λ 275 nm (ε, 2447), 248 (4404); ^1H NMR ($CDCl_3$) δ 5.80 (s, 8H), 7.06—7.25 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 68.3 (s), 124.4 (d), 125.0 (d), 128.3 (d), 134.1 (d), 134.3 (s); Found: C, 85.60; H, 4.56%. Calcd for $C_{24}H_{16}O_2$: C, 85.69; H, 4.79%.

Epoxidation of ***4***. The procedure described above was carried out to give the diepoxide (**6**) in an 86% yield. **6**; mp 234—236 °C decomp; Mass (*m/e*) 336 (M^+); UV (CH_3CN) λ 269 nm (ε, 315), 263 (396), 257 (360); ^1H NMR ($CDCl_3$) δ 3.36—3.52 (m, 2H), 3.76—3.96 (m, 2H), 5.24—5.42 (m, 2H), 6.32 (d, 2H), 7.04—7.44 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 39.7 (d), 47.9 (d), 67.7 (s), 69.4 (s), 124.9 (d), 125.2 (d), 127.8 (d), 128.8 (d), 129.0 (d), 131.2 (d), 135.4 (s), 138.4 (s); Found: C, 85.62; H, 4.62%. Calcd for $C_{24}H_{16}O_2$: C, 85.69; H, 4.79%.

Catalytic Reduction of ***3***. A suspension of **3** (2 mmol) and Pd/C in ethyl acetate (30 ml) was reduced at room temperature during 3 d. After the removal of the catalyst and the solvent, the residue was chromatographed on silica gel. Elution with petroleum ether gave the octahydrogenated compound (**9**, 93%) and the decahydrogenated compound (**10**, 4%). In contrast, when Raney Ni (W7) was used as the catalyst, **10** was obtained in a 39% yield, along with **9** in a 56% yield. **9**; mp 182.5—183.5 °C; Mass (*m/e*) 312 (M^+); UV (CH_3CN) λ 276 nm (ε, 788), 268 (1089); ^1H NMR ($CDCl_3$) δ 1.30—1.92 (m, 8H), 1.95—2.41 (m, 4H), 2.55—2.87 (m, 4H), 6.68—6.95 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 28.4 (t), 33.3 (t), 124.5 (d), 126.2 (d), 138.8 (s), 145.0 (s); Found: C, 92.10; H, 7.88%. Calcd for $C_{24}H_{24}$: C, 92.26; H, 7.74%. **10**; mp 182—183 °C; Mass(*m/e*) 314 (M^+); ^1H NMR ($CDCl_3$) δ 1.0—2.28 (m, 10H), 2.28—2.65 (m, 4H), 2.70—3.20 (m, 2H), 3.51—3.76 (m, 2H), 6.62—7.05 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 25.6 (t), 26.6 (t), 32.2 (t), 32.6 (t), 48.7 (d), 125.8 (d), 126.1 (d), 126.2 (d), 126.5 (d), 129.4 (s), 137.4 (s), 144.4 (s); Found: C, 91.57; H, 8.15%. Calcd for $C_{24}H_{26}$: C, 91.67; H, 8.33%.

Epoxidation of ***9***. The procedure described above was carried out to give the diepoxide (**12**) quantitatively. **12**; mp 219—222 °C decomp; Mass (*m/e*) 344 (M^+); UV (CH_3CN) λ 276 nm (ε, 147), 266 (178), 263 (184); ^1H NMR ($CDCl_3$) δ 1.20—2.43 (m, 16H), 6.96—7.20 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 24.1 (t), 35.4 (t), 69.6 (s), 125.5 (d), 127.7 (d), 138.2 (s); Found: C, 83.38; H, 6.97%. Calcd for $C_{24}H_{24}O_2$: C, 83.69; H, 7.02%.

Epoxidation of ***10***. A dichloromethane solution of *m*-chloroperbenzoic acid (1.2 mmol) was added to a dichloromethane solution of **10** (1 mmol). A monoepoxide (**13**) was thus obtained quantitatively. **13**; mp 180—181 °C; Mass (*m/e*) 330 (M^+); UV (CH_3CN) λ 274 nm (ε, 493), 266 (578), 261 (548); ^1H NMR ($CDCl_3$) δ 1.21—2.64 (m, 16H), 3.33—3.62 (m, 2H), 6.63—7.16 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 22.9 (t), 25.6 (t), 32.0 (t), 32.3 (t), 49.6 (d), 72.6 (s), 126.0 (d), 126.3 (d), 127.0 (d), 129.7 (d), 140.5 (s), 141.5 (s); Found: C, 86.90; H, 7.93%. Calcd for $C_{24}H_{26}O$: C, 87.23; H, 7.93%.

Ozonolysis of ***9***. Ozone was passed through a solution of **9** (1 mmol) in ethyl acetate (30 ml) for 30 min at −78 °C. The ozonide residue was then reduced with Pd/C at room temperature for 24 h. After the subsequent removal of the catalyst and solvent, the residue was chromatographed on silica gel with petroleum ether/ether (7/3) to give the diketone (**11**) in a 72% yield. **11**; mp 171—172 °C; Mass (*m/e*) 344 (M^+); ^1H NMR ($CDCl_3$) δ 1.52—2.08 (m, 8H), 2.80 (t, 4H), 3.30 (t, 4H), 6.52—6.68 (m, 2H), 6.95—7.25 (m, 4H), 7.82—8.05 (m, 2H); Found: C, 83.69; H, 6.99%. Calcd for $C_{24}H_{24}O_2$: C, 83.69; H, 7.02%.

Catalytic Reduction of ***4***. Using Pd/C, Raney-Ni (W7), or PtO_2 as a catalyst, the tetracyclic compound (**14**) was obtained in a 78, 76, or 73% yield respectively. **14**; mp 162—166 °C decomp; Mass (*m/e*) 310 (M^+); UV (CH_3CN) λ 273 nm (ε, 679), 266 (931); ^1H NMR ($CDCl_3$) δ 1.85—2.47 (m, 6H), 2.55—3.15 (m, 6H), 3.63—3.78 (m, 2H), 6.75—7.10 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 33.1 (t), 34.6 (t), 39.5 (t), 48.3 (d), 126.1 (d), 126.2 (d), 127.9 (d), 130.0 (d), 138.1 (s), 139.2 (s), 143.3 (s), 144.9 (s); Found: C, 92.73; H, 7.10%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%.

Diimide Reduction of ***4***. A solution of **4** (0.35 mmol) in 30 ml of dry methanol containing potassium azodicarboxylate (4.7 mmol) was treated, drop by drop, under nitrogen at −78 °C with glacial acetic acid (1 ml). After the completion of the addition, the mixture was stirred for 2 h at −78 °C and for 24 h at room temperature. The mixture was then diluted with water and extracted with dichloromethane. The combined organic layers were washed with a 10% aqueous sodium hydrogencarbonate solution and water prior to drying and concentration. The subsequent chromatography of the residue on silica gel with petroleum ether afforded **15** in a 70% yield. **15**; mp 137—140 °C decomp; Mass (*m/e*) 310 (M^+); UV (CH_3CN) λ 275 nm (ε, 1010), 248 (3480); ^1H NMR ($CDCl_3$) δ 1.50—1.89 (m, 4H), 1.90—2.21 (m, 4H), 3.38—3.62 (m, 2H), 3.64—3.95 (m, 2H), 4.20—4.42 (m, 2H), 6.92—7.16 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 24.0 (t), 24.5 (t), 41.8 (d), 44.5 (d), 52.2 (d), 126.2 (d), 126.2 (d), 126.9 (d), 131.8 (d), 138.9 (s), 142.3 (s), 147.4 (s); Found: C, 92.75; H, 7.12%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%.

*Synthesis of Buttaflane (****19****).* A 90-ml degassed benzene solution of **9** (1 mmol) in a sealed Pyrex tube was irradiated at room temperature for 100 h using a 500-W high-pressure mercury lamp. After the removal of the solvent, the GLC of the residue revealed only one peak with the same retention time as that of **9** because the buttaflane (**19**) was cyclореversed thermally, but ^{13}C NMR showed a new signal at δ 49 ppm based on a cyclobutane ring carbon of buttaflane (**19**). A mixture of buttaflane (**19**) and unreacted **9** was chromatographed on silica gel or silver nitrate-impregnated silica gel, but the two components could not be completely separated. Therefore, the mixture in ethyl acetate was ozonized for 15 min at −78 °C. The workup was analogous to that of the ozonolysis of **9**. Elution with petroleum ether gave buttaflane (**19**, 66%), and elution with petroleum ether/ether (7/3) gave the diketone (**11**, 25%) as the ozonization product of the unreacted **9**. **19**; mp 179—183 °C decomp; Mass (*m/e*) 312 (M^+); UV (CH_3CN) λ 278 nm (ε, 3203), 271 (3503), 265 (2588); ^1H NMR ($CDCl_3$) δ 1.35—1.64 (m, 8H), 1.96—2.25 (m, 8H), 6.44—6.76 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 22.2 (t), 25.0 (t), 49.3 (s), 121.2 (d), 126.5 (d), 150.1 (s); Found: C, 92.10; H, 7.69%. Calcd for $C_{24}H_{24}$: C, 92.26; H, 7.74%.

*Synthesis of Cage Buttaflane (****20****).* A 30-ml degassed benzene solution of **14** (0.5 mmol) in a sealed Pyrex tube

was irradiated for 50 h. After the removal of the solvent, the residue was chromatographed on silica gel. The subsequent elution of petroleum ether gave cage buttaflane (**20**) in an 80% yield. **20**; mp 204—208 °C decomp; Mass (*m/e*) 310 (M^+); UV (CH_3CN) λ 276 nm (ε, 1040), 268 (1095), 261 (889); ^1H NMR ($CDCl_3$) δ 1.24 (d, 2H), 1.84—3.40 (m, 10H), 3.44—3.56 (m, 2H), 6.52—6.96 (m, 8H); ^{13}C NMR ($CDCl_3$) δ 24.9 (t), 25.5 (t), 30.5 (t), 41.6 (s), 42.4 (d), 50.8 (s), 124.8 (d), 124.9 (d), 126.3 (d), 126.9 (d), 140.3 (s), 144.2 (s); Found: C, 92.72; H, 7.15%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%.

Thermal Reaction of ***4***. The heating of a sealed Pyrex tube containing 10 mg of **4** at 180 °C for 20 min gave **3** quantitatively. In the case of 100 °C or 150 °C, no cycloreversion of **4** to **3** occurred.

*Thermal Reaction of Buttaflane (****19****)*. The heating of a sealed Pyrex tube containing 10 mg of **19** at 150 °C for 30 min gave **9** quantitatively.

*Thermal Reaction of Cage Buttaflane (****20****)*. The heating of a sealed Pyrex tube containing 10 mg of **20** at 170 °C for 2 h gave **14** almost quantitatively.

*Catalytic Reaction of Buttaflane (****19****) with [Rh(NBD)Cl]$_2$*. A catalytic amount of $[Rh(NBD)Cl]_2$ and **19** (20 mg) in 5 ml of $CDCl_3$ was allowed to stand at room temperature in a sealed Pyrex tube for 5 d. ^{13}C NMR showed clearly that the cycloreversion of **19** to **9** occurred quantitatively.

Quenching with 1,3-Pentadiene. Five samples were prepared each containing 10 ml of a degassed benzene solution of **3** (0.1 mmol). Four samples also contained 1,3-pentadiene (0.05, 0.10, 0.50, or 1.00 mol dm^{-3}). All the sealed samples were irradiated for 2 h. 1,3-Pentadiene exhibited no quenching effect on the formation of **4** and **2a** in any case.

Quantum Yield Measurement. The quantum yields were measured by the method using potassium ferrioxalate as the actinometer.[23]

Nucleophilic Reaction upon Electron-deficient Pyridone Derivatives. IV. Ring Transformation of 1-Substituted 3,5-Dinitro-2-pyridones with Ketones in the Presence of Amines

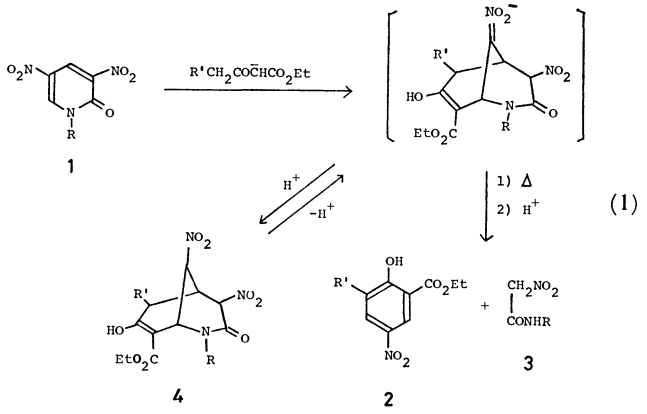
Eizo MATSUMURA,† Yasuo TOHDA,* and Masahiro ARIGA

Department of Chemistry, Osaka Kyoiku University, Minamikawahori-cho 4-88, Tennoji-ku, Osaka 543

(Received October 9, 1981)

Ring transformation of 1-substituted 3,5-dinitro-2-pyridones with 1,3-disubstituted acetones in the presence of secondary or primary amines gave *p*-nitroaniline derivatives and *N*-substituted 2-nitroacetamide. Two types of enamine intermediates, 2-azabicyclo[3.3.1]nonene derivatives and *N*-substituted 2-(5-amino-2-nitro-2,4-cyclohexadienyl)-2-nitroacetamides were isolated and characterized. The course of the base-catalyzed reaction is interpreted.

Recently we reported the ring transformation of 1-substituted 3,5-dinitro-2-pyridones (**1**) into *p*-nitrophenol derivatives (**2**) and 2-nitroacetamide derivatives (**3**) by treatment with monosodium salts of β-keto esters. In the case of the reaction of 3,5-dinitro-1-(2-pyridyl)-2-pyridone (**1b**), 2-oxo-2*H*-pyrido[1,2-*b*]-[1,2,4]triazine 4-oxide (**3b**) was isolated as the dehydration product of *N*-(2-pyridyl)-2-nitroacetamide (**3**, R=2-pyridyl). The course of these reactions was elucidated by the isolation of bicyclo intermediates (**4**) (Eq. 1).[1] The similar ring transformations of 1,3,5-

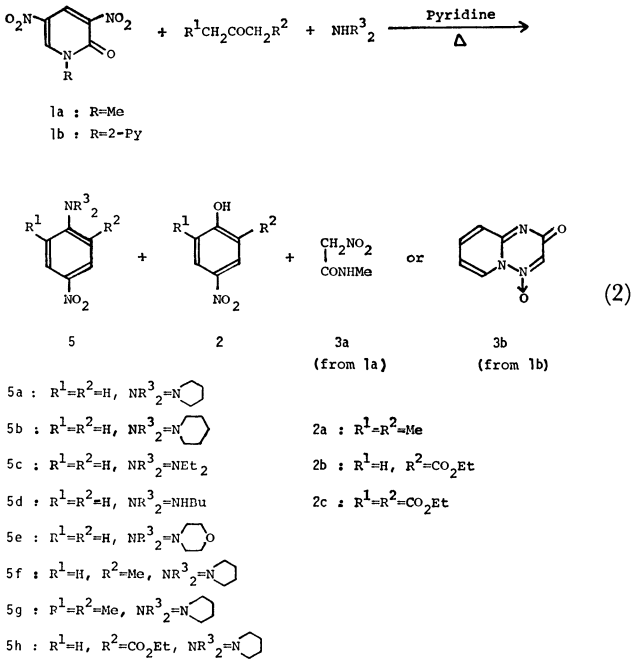


(1)

triazine[2,3] and 5-substituted uracils[4] into other six-membered aromatic systems have been studied by using sodium salts of β-keto esters or other 1,3-ambident nucleophiles. However these reactions were postulated to take place *via* open-chain intermediates rather than via such bicyclo intermediates. Another example of a similar ring transformation has been reported for 1,3,5-trinitrobenzene, which reacts with acetone and diethylamine to form *N*,*N*-diethyl-*p*-nitroaniline.[5] In this case, Strauss suggested the presence of a bicyclo[3.3.1]nonane derivative.[6] He also showed the generation of such meta-bridged compounds by the reaction of 1,3,5-trinitrobenzene with various 1,3-ambident nucleophiles.[7] In this paper, we wish to report on the reactions of 1-substituted 3,5-dinitro-2-pyridones (**1**) with 1,3-disubstituted acetones in the presence of secondary or primary amines.

Results and Discussion

Treatment of *N*-substituted 3,5-dinitro-2-pyridones (**1a**: R=Me, **1b**: R=2-pyridyl) with ketones, $R^1CH_2COCH_2R^2$ ($R^1=R^2=H$; $R^1=H$, $R^2=Me$; $R^1=R^2=Me$; $R^1=H$, $R^2=CO_2Et$; $R^1=R^2=CO_2Et$), in the presence of secondary or primary amines in pyridine at 80 °C for 5 h gave *p*-nitroaniline derivatives (**5a**—**h**) or *p*-nitrophenol derivatives (**2a**—**c**). The results are summarized in Eq. 2 and Table 1. Under



(2)

the reduced amount of pyrrolidine, *N*-methyl-2-nitroacetamide (**3a**) was obtained as the residual moiety of the substrate, **1a**, in poor yield (Table 1, run 6′). This fact suggests that excess of the amines in the reaction mixtures may decompose the acetamide produced (**3a**) under such conditions. In the case of the reaction of **1b**, 2-oxo-2*H*-pyrido[1,2-*b*][1,2,4]triazine 4-oxide (**3b**)[1] was isolated as the dehydration product of *N*-(2-pyridyl)-2-nitroacetamide (**3**, R=2-pyridyl).

In the presence of pyrrolidine, ketones such as acetone, 2-butanone, or 3-pentanone as well as ethyl acetoacetate (EAA) gave the corresponding *p*-nitroaniline derivatives (**5**) in good yields. The experimental data for a number of the ring transformations make it clear that the yields of **5** depend not only on the bulkiness of the ketones but also on the basicity

† Emeritus professor of Osaka Kyoiku University.

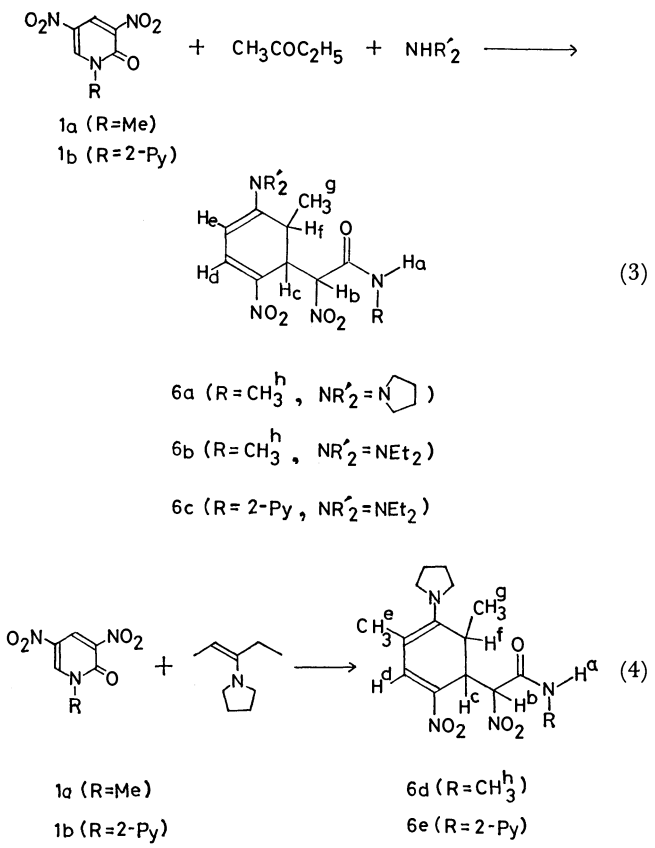
1a=1-Methyl-3,5-dinitro-2-pyridone, **1b**=3,5-dinitro-1-(2-pyridyl)-2-pyridone, **2a**=2,6-dimethyl-4-nitrophenol, **2b**=ethyl 5-nitrosalicylate, **2c**=diethyl 2-hydroxy-5-nitroisophthalate, **3a**=*N*-methyl-2-nitroacetamide, **3b**=2-oxo-2*H*-pyrido[1,2-*b*][1,2,4]triazine 4-oxide, **5a**=1-nitro-4-(1-pyrrolidinyl)benzene, **5b**=1-nitro-4-piperidinobenzene, **5c**=1-diethylamino-4-nitrobenzene, **5d**=1-butylamino-4-nitrobenezen, **5e**=1-morpholino-4-nitrobenzene, **5f**=2-methyl-4-nitro-1-(1-pyrrolidinyl)benzene, **5g**=1,3-dimethyl-5-nitro-2-(1-pyrrolidinyl)benzene, **5h**=ethyl 5-nitro-2-(1-pyrrolidinyl)benzoate, EAA=ethyl acetoacetate, DOPD=diethyl 3-oxopentanedioate.

of the amines. Thus easy formation of enamines can be postulated to take place in a series of reactions involving an initial nucleophilic attack of the amino group to the carbonyl carbon atom of the ketones. On the other hand, the treatment of **1a** or **1b** with highly acidic ketones such as diethyl 3-oxopentanedioate (DOPD) in the presence of the amines yields diethyl 2-hydroxy-5-nitroisophthalate (**2c**) quantitatively. The formation of the 4-nitrophenol suggests that the amines play a role of an acceptor of the proton of the acidic ketone to form the enolate ion. The reaction of the enolate ion with **1a** or **1b** follows essentially the identical course with that of diethyl 2-sodio-3-oxopentanedioate as shown in Eq. 1.[1] The reactivity of EAA was found to be intermediate between DOPD and the other dialkyl ketones. The treatment of **1a** with EAA in the presence of diethylamine only gave the phenol (**2b**) in 14% yield. The lower yield of the phenol can be attributed to the lower acidity of EAA, while the treatment of **1a** with EAA in the presence of pyrrolidine gave the *p*-nitroaniline derivative (**5h**) in 85% yield. This indicates that the basicity of the pyrrolidine is sufficient to bring about the formation of the enamine from EAA.

In order to isolate the intermediates, the reactions of **1a** or **1b** with ketones in the presence of secondary amines were carried out under somewhat milder conditions. When **1a** was treated with 2-butanone and pyrrolidine in pyridine at 70 °C for 1 h, **6a** was obtained as deep red crystals in 55% yield. The analytical data of **6a** were consistent with the formula, $C_{14}H_{20}N_4O_5$. The IR spectra had a carbonyl band at 1676 cm^{-1} and an N–H stretching band at 3270 cm^{-1}, which were attributable to a secondary amide group. The ^{1}H-NMR spectra also showed signals due to an *N*-methyl amide moiety at δ 2.44 (NCH_3, d, J=4 Hz) and 8.52 (N–H, m), and showed two doublets at δ 4.83 (J=8.5 Hz) and 7.71 (J=8.5 Hz), corresponding to two vicinal olefinic protons. The NMR spectra also showed a doublet of methyl protons at δ 1.16 (J=7 Hz). On the basis of these data, **6a** was assigned to be *N*-methyl-2-[6-methyl-2-nitro-5-

(1-pyrrolidinyl)-2,4-cyclohexadienyl]-2-nitroacetamide. The presence of a highly polarized 1-amino-4-nitro-1,3-butadiene system in the molecule was also suggested by very intense absorption at 497 nm (ε= 4.78×10^4) (Fig. 1). Similar cyclohexadiene intermediates (**6b** and **6c**) were also isolated by the reaction of **1a** or **1b** with 2-butanone and diethylamine (Eq. 3). Furthermore, reactions of **1a** or **1b** with 3-(pyrrolidinyl)-2-pentene gave similar enamine adducts, **6d** or **6e** (Eq. 4). The NMR, IR, and electronic spectra of **6** are summarized in Tables 2, 3, and Fig. 1.



The intermediate, **6a**, on heating at 80 °C for 5 h in pyridine, afforded a mixture, which was separated by column chromatography on silica gel to give the final products, **5f** and **3a** in 78 and 47% yields, respectively. The intermediate, **6d**, was also converted into **5g** in 55% yield under the same reaction conditions (Eq. 5). Only by standing for 24 h in DMSO-d_6 at 35 °C, **6e** was completely converted into **5g**. These facts reveal that the cyclohexadiene derivatives (**6**) are one of the intermediates of the ring transformation.

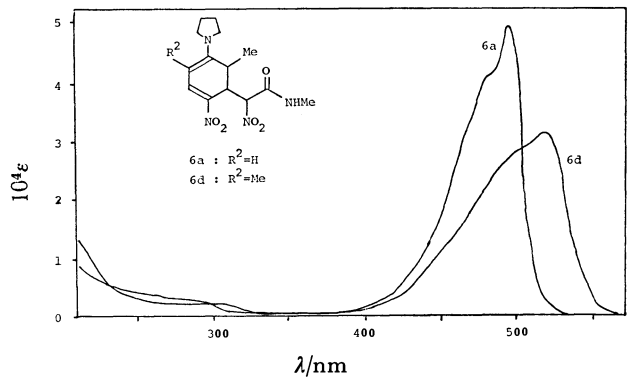


Fig. 1. Electronic spectra of the intermediate, **6a** and **6d**, in methanol.

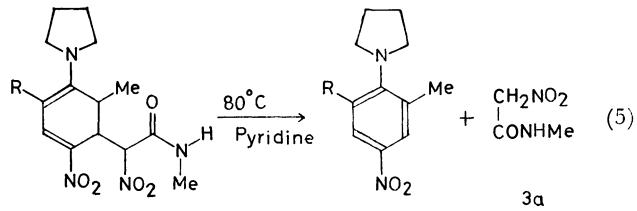
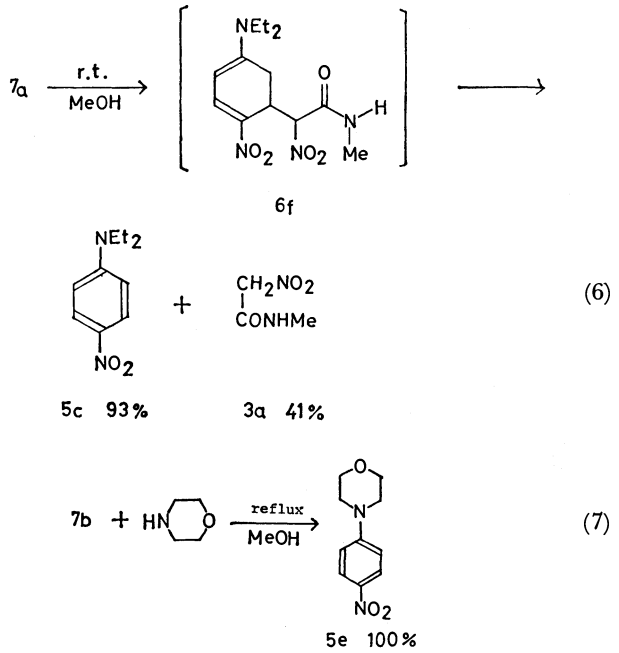
a) In Nujol. b) In methanol.



(5)

When **1a** was treated with diethylamine in acetone at room temperature, another type of intermediate, **7a**, was obtained in quantitative yield. The analytical data indicate that **7a** consists of **1a**, diethylamine, and an enamine derived from acetone and diethylamine in molar ratio 1:1:1. Similar treatment of **1a** with morpholine in acetone gave **7b** in quantitative yield. The analytical data of **7b** is composed of each one molecule of **1a**, morpholine, and an enamine derived from acetone and morpholine, and a half molecule of water. In a similar experiment using pyrrolidine as the amine component, the analogue of **7a** or **7b** was not afforded. However the final product, **5a**, was obtained from this reaction mixture.

When a methanol solution of **7a** was allowed to stand at room temperature, spontaneous decomposition occurred, **5c** and **3a** being obtained as the final products in 93 and 41% yields, respectively (Eq. 6). Under similar conditions, the contraction of **7b** did not occurred. However, on boiling with excess morpholine in methanol, **7b** afforded **5e** in quantitative yield (Eq. 7).



(6)

(7)

Figure 2 shows a change in the electronic spectrum of **7a** in methanol at room temperature. The intensity of the band at 310 nm decreases and that at 400 nm increases. It could be reasonably explained that the absorption at 300 nm corresponds to the diethylammonium salt of *N*-methyl-2-nitroacetamide (**3a**) and

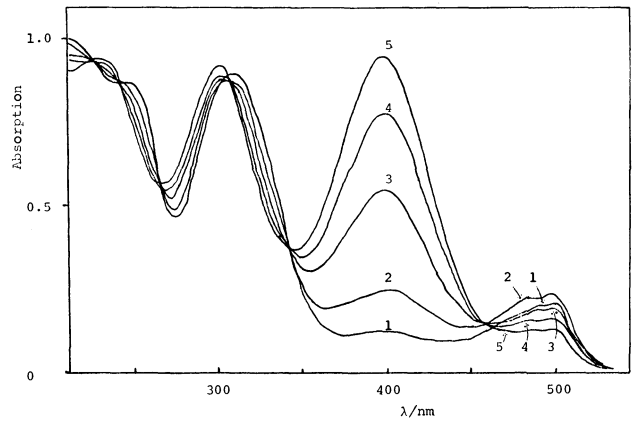


Fig. 2. Changes in electronic spectra of **7a** in methanol (8.34×10^{-5} mol/l) after (1) 3 min, (2) 18 min, (3) 52 min, (4) 82 min, and (5) 110 min at 20 °C.

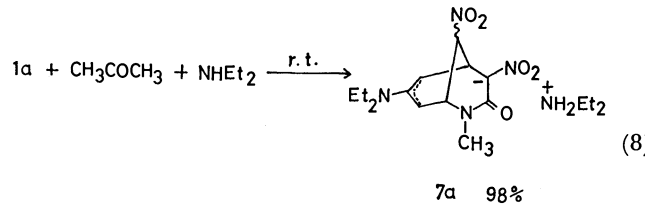
that of 400 nm corresponds to 1-diethylamino-4-nitrobenzene (**5c**), because the authentic samples of **3a** and **5c** showed strong absorption maxima at 295 and 400 nm, respectively. An absorption band at about 500 nm indicates formation and subsequent decomposition of a transient species, which could be identified as the cyclohexadiene intermediate, 2-(5-diethylamino-2-nitro-2,4-cyclohexadienyl)-*N*-methyl-2-nitroacetamide (**6f**), by comparing the absorption band at 500 nm (Fig. 2) with that of the similar intermediates, **6a**—**c** (Fig. 1).

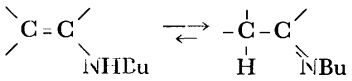
The ^{1}H-NMR spectra of **7a** showed an olefinic proton at δ 4.6 (a broad doublet, $J=3$ Hz). The IR spectra showed a C=C band at 1628 cm^{-1}, and the UV spectra showed an absorption at 248 nm ($\varepsilon=11400$). These data indicate the presence of an enamine moiety in **7a**. Broad absorptions at 2800—2300 cm^{-1} imply that **7a** is a diethylammonium salt. Since the diethylammonium salt of *N*-methyl-2-nitroacetamide absorbs UV light at 295 nm, the absorption of **7a** at 310 nm suggests the presence of a salt of the 2-nitroacetamide moiety. On the basis of these spectral data, as well as the elemental analysis and the chemical behavior shown in Eq. 6, the structure of diethylammonium 7-diethylamino-2-methyl-4,9-dinitro-3-oxo-2-azabicyclo[3.3.1]non-6(or 7)-en-4-ide was assigned to **7a** (Eq. 8).



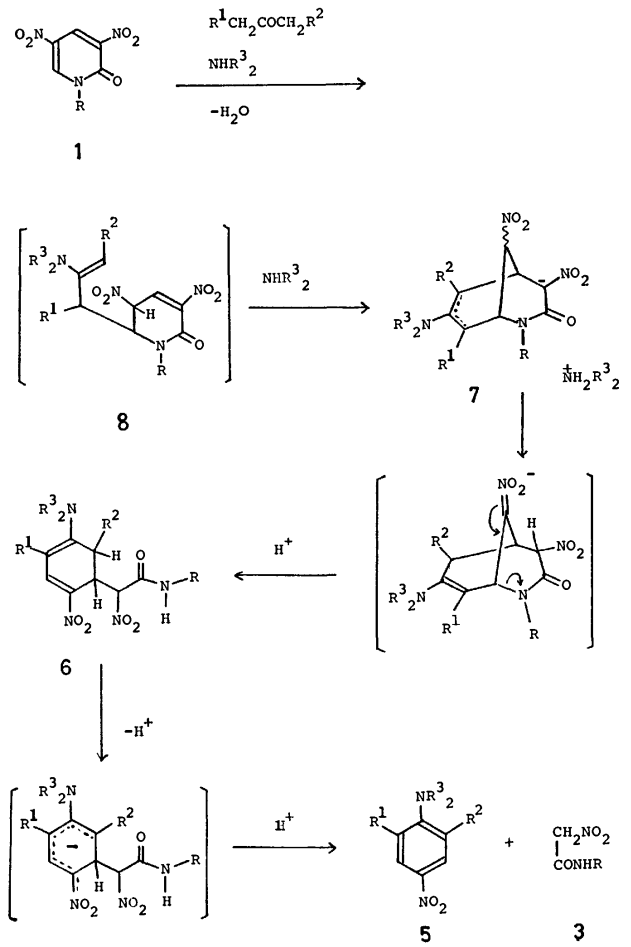
(8)

From these results, a possible process which occurs during the treatment of *N*-substituted 3,5-dinitro-2-pyridones (**1**) with the dialkyl ketones in the presence of the amines may start with the reaction of the ketones with the secondary amines to form an intermediate enamine. Usually the reaction of primary amines with aldehydes or ketones affords products which primarily contain imines (Schiff bases) rather than the enamine tautomers. Thus, in the initial reaction of

acetone and butylamine, the enamine may be a minor tautomer.



The amino olefinic component in the enamine as well as the enolate ion component in the β-keto ester anions has an electron-donating trend. Both the HOMO and the LUMO of these olefins are raised in energy relative to the HOMO and the LUMO of ethylene. The HOMO of enamine is the one which has the coefficient on the β-carbon atom larger than the α-carbon atom. On the other hand, the 1,3-dinitro-1,3-butadiene component of *N*-substituted 3,5-dinitro-2-pyridones has an electron-withdrawing trend, and the conjugation with the nitro group lowers both the energy of the HOMO and the LUMO relative to those of butadiene. The LUMO of the diene component is the one which has the largest coefficient on the C_6 atom of the 2-pyridone nucleus. By using the data given by Houk,[8] we can predict, as a favorable pathway, that the nucleophilic attack of the β-carbon of the enamine (HOMO) at the C_6 atom of the pyridone nucleus (LUMO of 1,3-dinitro-1,3-butadiene system) may lead to an adduct, **8**, as shown in Scheme 1. In this adduct, the intramolecular interaction between the β′-carbon of the enamine component and C_4 of the pyridone moiety would lead to the bicyclo adduct (**7**).



Scheme 1.

As described above, an excess amount of morpholine promotes the conversion of the intermediate, **7b**, to the final product, **5e** (Eq. 7). This suggests that the fission of the C_1–N_2 bond of the 2-azabicyclo[3.3.1]-nonene intermediate (**7**) is a base-catalyzed step. The transformation of **6** to **5** and **3** may also occur via base-catalyzed C–C bond fission. When the proton on C_6 of the intermediate, **6**, is removed by base, the heterolysis between C_6 and C_α in the deprotonated Meisenheimer-type species may lead to the final products. In the case of **6a—e**, the intermediates may be stabilized by the electron-donating character of the methyl group at C_6 and the deprotonation from this carbon atom may be more difficult than that in the case of **6f** which does not have any substituents at C_6.

From these results, it is concluded that the ring transformation of the 3,5-dinitro-2-pyridones to the *p*-nitroanilines is strongly promoted by the secondary or primary amines in each step.

Experimental

^{1}H-NMR spectra were measured using a Hitachi R-20 B spectrometer with TMS as an internal reference. UV spectra were recorded using a Hitachi EPS-3 spectrophotometer. Mass spectra were recorded with a JMS-D100 mass spectrophotometer. IR spectra were collected with a Hitachi 225 Grating IR spectrophotometer. All the melting points were uncorrected.

*Reaction of 1-Methyl-3,5-dinitro-2-pyridone (**1a**) with Dialkyl Ketones and Amines.* In a typical procedure, 0.21 g of pyrrolidine in 5 ml of pyridne was added slowly at 0 °C to a solution of 0.20 g of 1-methyl-3,5-dinitro-2-pyridone (**1a**) and 0.86 g of 3-pentanone in 5 ml of pyridine. Then the mixture was heated at 80 °C for 5 h. The solvent was removed under reduced pressure and the residual oil was column-chromatographed on silica gel (Wakogel C-300) and eluted with benzene. From the first elute, 0.13 g (58%) of 1,3-dimethyl-5-nitro-2-(1-pyrrolidinyl)benzene (**5g**) was obtained. The second elute gave 0.02 g (11%) of 2,6-dimethyl-4-nitrophenol (**2a**).

*1,3-Dimethyl-5-nitro-2-(1-pyrrolidinyl) benzene (**5g**)*: Yellow prisms (from hexane); mp 93—93.5 °C. NMR (CCl_4): δ 2.0 (4H, m), 2.28 (6H, s), 3.2 (4H, m), 7.73 (2H, s). Found: C, 65.83; H, 7.27; N, 12.70%. Calcd for $C_{12}H_{16}N_2O_2$: C, 65.43; 7.32; N, 12.70%.

*2,6-Dimethyl-4-nitrophenol (**2a**)*: Pale yellow needles (from hexane–benzene); mp 168—169 °C. NMR ($CDCl_3$): δ 2.28 (6H, s), 7.79 (2H, s). Found: C, 57.43; H, 5.28; N, 8.44%. Calcd for $C_8H_9NO_3$: C, 57.48; H, 5.43; N, 8.38%.

From the similar treatment of **1a** with other dialkyl ketones and amines, following compounds were obtained.

*1-Nitro-4-(1-pyrrolidinyl)benzene (**5a**)*: Yellow plates (from hexane); mp 167 °C. NMR ($CDCl_3$): δ 2.03 (4H, m), 3.34 (4H, m), 6.38 (2H, d, J=10 Hz), 8.00 (2H, d, J=10 Hz). Found: C, 62.77; H, 6.52; N, 14.58%. Calcd for $C_{10}H_{12}N_2O_2$: C, 62.48; H, 6.29; N, 14.58%.

*1-Nitro-4-piperidinobenzene (**5b**)*: Yellow plates (from hexane); mp 99.5—100 °C. NMR (CCl_4): δ 1.7 (6H, m), 3.3 (4H, m), 6.73 (2H, d, J=9.5 Hz), 8.01 (2H, d, J=9.5 Hz). Found: C, 64.36; H, 7.05; N, 13.72%. Calcd for $C_{11}H_{14}N_2O_2$: C, 64.06; H, 6.86; N, 13.58%.

*1-Diethylamino-4-nitrobenzene (**5c**)*: Yellow needles (from hexane); mp 73—74 °C. NMR (CCl_4): δ 1.19 (6H, t,

J=7 Hz), 3.41 (4H, q, J=7 Hz), 6.45 (2H, d, J=10 Hz), 7.90 (2H, d, J=10 Hz). Found: C, 61.61; H, 7.09; N, 14.20%. Calcd for $C_{10}H_{14}N_2O_2$: C, 61.83; H, 7.27; N, 14.42%.

*1-Butylamino-4-nitrobenzene (**5d**)*: Yellow needles (from hexane); mp 56 °C. NMR (CCl_4): δ 1.05 (3H, t, J=6 Hz), 1.5 (4H, m), 3.15 (2H, t, J=8 Hz), 4.65 (1H, m), 6.47 (2H, d, J=9 Hz), 7.99 (2H, d, J=9 Hz). Found: C, 62.01; H, 7.48; N, 14.59%. Calcd for $C_{10}H_{14}N_2O_2$: C, 61.83; H, 7.27; N, 14.42%.

*1-Morpholino-4-nitrobenzene (**5e**)*: Yellow needles (from hexane); mp 149.5—150 °C. NMR ($CDCl_3$): δ 3.33 (4H, m), 3.86 (4H, m), 6.79 (2H, d, J=10 Hz), 8.09 (2H, d, J=10 Hz). Found: C, 57.92; H, 6.06; N, 13.23%. Calcd for $C_{10}H_{12}N_2O_3$: C, 57.68; H, 5.81; N, 13.46%.

*2-Methyl-4-nitro-1-(1-pyrrolidinyl) benzene (**5f**)*: Yellow plates (from hexane); mp 100—100.5 °C. NMR (CCl_4): δ 1.96 (4H, m), 2.36 (3H, s), 3.40 (4H, m), 6.49 (1H, d, J=10 Hz), 7.7 (2H, m). Found: C, 63.90; H, 6.92; N, 13.64%. Calcd for $C_{11}H_{14}N_2O_2$: C, 64.06; H, 6.84; N, 13.58%.

*Reaction of 1-Methyl-3,5-dinitro-2-pyridone (**1a**) with Equimolar Amount of 2-Butanone and Pyrrolidine.* To a solution of 0.199 g of **1a** and 0.072 g of 2-butanone in 5 ml of pyridine 0.071 g of pyrrolidine in 5 ml of pyridine was added at 0 °C. The solution was heated at 80 °C for 5 h. The solvent was distilled off and the residual oil was dissolved in a minimum amount of tetrahydrofuran; then ether was added to the solution until it turned to cloudy. After 0.062 g (19%) of red precipitate (**6a**) was filtered off, the solvent was removed and the residue was column-chromatographed on silica gel. From a benzene elute, 0.109 g (53%) of 2-methyl-4-nitro-1-(1-pyrrolidinyl)benzene (**5f**) was obtained and 0.009 g (8%) of *N*-methyl-2-nitroacetamide (**3a**) was obtained from an ether elute; mp 75—75.5 °C; colorless needles (from i-Pr_2O).

*Reaction of 1-Methyl-3,5-dinitro-2-pyridone (**1a**) with Ethyl Acetoacetate and Diethylamine.* To a solution of 0.20 g of **1a** and 0.39 g of ethyl acetoacetate in 5 ml of pyridine, 0.38 g of diethylamine in 5 ml of pyridine was added slowly at 0°C. The mixture was heated at 80 °C for 5 h and the pyridine removed *in vacuo*. The residue was neutralized to pH 3—4 with dil. hydrochloric acid and extracted with chloroform. After the extract had been dried over anhydrous sodium sulfate, the chloroform was distilled off and the residue was column-chromatographed on silica gel. From a benzene elute, 0.060 g (14%) of ethyl 5-nitrosalicylate (**2b**) was obtained; mp 57.5—58.5 °C, colorless needles (from hexane).

The similar treatment of 0.40 g of **1a** with 1.21 g of DOPD and 0.43 g of pyrrolidine gave 0.54 g (98%) of diethyl 2-hydroxy-5-nitroisophthalate (**2c**); colorless needles (from hexane); mp 58—59 °C.

*Reaction of 1-Methyl-3,5-dinitro-2-pyridone (**1a**) with Ethyl Acetoacetate and Pyrrolidine.* To a solution of 0.40 g of **1a** and 0.78 g of ethyl acetoacetate in 10 ml of pyridine was added 0.71 g of pyrrolidine in 10 ml of pyridine at 0 °C. The mixture was heated at 80 °C for 5 h and the solvent was removed *in vacuo*. To the residue was added 20 ml of 10% sodium hydroxide and the mixture was extracted with chloroform. After the extract had been dried over anhydrous sodium sulfate, the chloroform was distilled off and the residual oil was column-chromatographed on silica gel. A benzene elute gave 0.45 g (85%) of ethyl 5-nitro-2-(1-pyrrolidinyl)benzoate (**5h**): yellow needles (from diisopropyl ether–diethyl ether); mp 128.5—129 °C. NMR ($CDCl_3$): δ 1.40 (3H, t, J=6.6 Hz), 2.0 (4H, m), 3.3 (4H, m), 4.36 (2H, q, J=6.6 Hz), 6.67 (1H, d, J=9 Hz), 8.07 (1H, dd, J=9 and 3 Hz), 8.42 (1H, d, J=3 Hz). Found: C, 59.08; H, 5.94; N, 10.70%. Calcd for $C_{13}H_{16}N_2O_4$: C, 59.08; H, 6.10; N, 10.60%. The water layer was acidified with 6 M (1 M=1 mol dm^{-3}) hydrochloric acid to pH 1—2 and then extracted with chloroform but the organic layer failed to give ethyl 5-nitrosalicylate (**2b**) or *N*-methyl-2-nitroacetamide (**3a**) after the usual work up.

*Reaction of 3,5-Dinitro-1-(2-pyridyl)-2-pyridone (**1b**) with Acetone and Piperidine.* To a solution of 0.54 g of **1b** in 20 ml of acetone was added 0.51 g of piperidine at 0 °C. After the mixture had been refluxed gently for 5 h, the acetone was removed under reduced pressure. The residual oil was washed with *ca.* 20 ml of chloroform. After insoluble solids had been filtered off, the organic layer was concentrated to a few milliliters and column-chromatographed on silica gel. A benzene elute gave 0.39 g (94%) of 1-nitro-4-piperidinobenzene (**5b**). A methanol elute and the chloroform-insoluble solids were combined together and recrystallized from water to give 0.08 g (25%) of 2-oxo-2*H*-pyrido-[1,2-*b*][1,2,4]triazine 4-oxide (**3b**); yellow needles; dec 210 °C.

*Reaction of 3,5-Dinitro-1-(2-pyridyl)-2-pyridone (**1b**) with DOPD and Piperidine.* To a solution of 0.54 g of **1b** and 1.21 g of DOPD in 15 ml of pyridine was added 0.51 g of piperidine in 5 ml of pyridine at 0 °C. The mixture was heated at 60 °C for 5 h and the pyridine was removed *in vacuo*. To this mixture 50 ml of chloroform and 20 ml of 1 M hydrochloric acid was added. Insoluble solids were filtered off and the organic layer was dried over anhydrous sodium sulfate. The organic layer was concentrated to a few milliliters and column-chromatographed on silica gel. A benzene elute gave 0.51 g (94%) of diethyl 2-hydroxy-5-nitroisophthalate (**2c**). A methanol elute and the chloroform-insoluble solids were combined and recrystallized from water to give 0.36 g (88%) of **3b**.

*Reaction of 1-Methyl-3,5-dinitro-2-pyridone (**1a**) with 3-(1-Pyrrolidinyl)-2-pentene.* To a solution of 0.20 g of **1a** in 5 ml of pyridine at 0 °C was added 0.42 g of 3-(1-pyrrolidinyl)-2-pentene in 5 ml of pyridine. The deep red solution was heated at 80 °C for 5 h. After the usual work up, 0.144 g (66%) of **5g** was obtained.

*Isolation of the Cyclohexadiene Intermediates (**6**).* *N*-Methyl-2-[6-methyl-2-nitro-5-(1-pyrrolidinyl)-2,4-cyclohexadienyl]-2-nitroacetamide (**6a**): To a mixture of 0.40 g of **1a** and 5 ml of 2-butanone in 10 ml of pyridine was added 0.43 g of pyrrolidine at 0 °C. The solution was heated at 70 °C for 1 h, and then the solvent was removed *in vacuo*. The residual oil was washed with water and crystallized from tetrahydrofuran–ether to give 0.37 g (55%) of **6a**; wine-red prisms; decomp 154—155 °C. Found: C, 51.95; H, 6.34; N, 17.44%. Calcd for $C_{14}H_{20}N_4O_5$: C, 51.84; H, 6.22; N, 17.28%.

*N-Methyl-2-(5-diethylamino-5-methyl-2-nitro-2,4-cyclohexadienyl)-2-nitroacetamide (**6b**)*: The treatment of 0.40 g of **1a** with 0.46 g of diethylamine and 5 ml of 2-butanone in 10 ml of pyridine at 70 °C for 2 h gave 0.30 g (43%) of **6b**; wine-red prisms (from methanol-ether); decomp 138—138.5 °C. Found: C, 51.49; H, 6.70; N, 17.18%. Calcd for $C_{14}H_{22}N_4O_5$: C, 51.52; H, 6.80; N, 17.17%.

*N-(2-Pyridyl)-2-(5-diethylamino-6-methyl-2-nitro-2,4-cyclohexadienyl)-2-nitroacetamide (**6c**)*: A treatment of 0.26 g of **1b** with 1.44 g of 2-butanone and 0.22 g of diethylamine in 10 ml of pyridine at 50 °C for 5 h gave 0.06 g (15%) of **6c**; wine-red prisms (from chloroform); decomp 135—136 °C. Found: C, 55.26; H, 6.23; N, 17.61%. Calcd for $C_{18}H_{23}N_5O_5$: C, 55.52; H, 5.95; N, 17.99%.

N-Methyl-2-[4,6-dimethyl-2-nitro-5-(1-pyrrolidinyl)-2,4-cyclo-

*hexadienyl]-2-nitroacetamide (**6d**)*: To a solution of 0.40 g of **1a** in 10 ml of pyridine was added 0.42 g of 3-(1-pyrrolidinyl)-2-pentene in 10 ml of pyridine at 0 °C. The solution immediately turned purple; it was heated at 70 °C for 1 h. After the pyridine was removed *in vacuo*, the residual oil was washed with ether and crystallized from tetrahydrofuran–ether to give 0.26 g (38%) of **6d**; purple prisms; decomp 156—157 °C. Found: C, 53.02; H, 6.67; N, 16.77%. Calcd for $C_{15}H_{22}N_4O_5$: C, 53.24; H, 6.55; N, 16.56%.

*N-(2-Pyridyl)-2-[4,6-dimethyl-2-nitro-5-(1-pyrrolidinyl)-2,4-cyclohexadienyl]-2-nitroacetamide (**6e**)*: Treatment of 0.26 g of **1b** with 0.21 g of 3-(1-pyrrolidinyl)-2-pentene in 10 ml of pyridine at 45 °C for 2 h gave 0.08 g (20%) of **6e**; purple prisms (from methanol–ether); decomp 156—157 °C. Found: C, 56.68; H, 5.62; N, 17.17%. Calcd for $C_{19}H_{23}N_5O_5$: C, 56.85; H, 5.78; N, 17.45%.

*Conversion of N-Methyl-2-[6-methyl-2-nitro-5-(1-pyrrolidinyl)-2,4-cyclohexadienyl]-2-nitroacetamide (**6a**) into 2-Methyl-4-nitro-1-(1-pyrrolidinyl)benzene (**5f**) and N-Methyl-2-nitroacetamide (**3a**)*. A solution of 0.324 g of **6a** and 0.71 g of pyrrolidine in 20 ml of pyridine was heated at 80 °C for 5 h. The solvent was removed *in vacuo*. When the residual solids were washed with a small portion of chloroform, 0.04 g of **6a** was recovered. The chloroform solution was concentrated and column-chromatographed on silica gel. A benzene elute gave 0.16 g (78%) of 2-methyl-4-nitro-1-(1-pyrrolidinyl)-benzene (**5f**) and an ether elute gave 0.055 g (47%) of *N*-methyl-2-nitroacetamide (**3a**).

*Isolation of the Bicyclo Intermediates (**7**)*. To a solution of 0.20 g of **1a** in 10 ml of acetone, 0.44 g of diethylamine was added slowly at 0 °C. After standing several hours at room temperature, yellow crystals began to precipitete. The crystals were collected by filtration and washed with acetone to give 0.76 g (98%) of **7a**; yellow prisms; decomp 122.5 °C. Found: C, 52.69; H, 8.38; N, 17.89%. Calcd for $C_{17}H_{31}N_5O_5$: C, 52.96, H, 8.11, N, 18.17%. IR (Nujol): 2740 cm^{-1} (ν_{N^+-H}), 1625 cm^{-1} ($\nu_{C=C}$ and $\nu_{C=O}$), 1540 cm^{-1} (ν_{NO_2}). NMR ($CDCl_3$): δ 0.97 ($NCH_2C\underline{H}_3$, 6H, t, J=7 Hz), 1.22 ($NC\underline{H}_2CH_3$, 6H, t, J=7 Hz), 2.2—3.3 ($\approx$11H, m), 2.90 (N–CH_3, 3H, s), 4.2—4.5 (2H, m), 4.6 (a broad doublet, J=3 Hz), 8.1—9.0 (N^+H_2, 2H, m). UV (MeOH): 250 nm (ε=9620), 309 nm (ε=9620).

Similarly **7b** was obtained in 96% yield; pale yellow prisms; decomp 139—140 °C. Found: C, 48.83; H, 6.48; N, 16.56%. Calcd for $C_{17}H_{28}N_5O_{7.5}$: C, 48.34; H, 6.68; N, 16.58%. IR: 2750, 2690, and 2530 cm^{-1} (ν_{N^+-H}), 1628 cm^{-1} ($\nu_{C=C}$ and $\nu_{C=O}$), 1548 cm^{-1} (ν_{NO_2}). NMR ($CDCl_3$): δ 2.3—3.3 (10H, m), 2.94 (N–CH_3, 3H, s), 3.5—4.0 (8H, m), 4.2—4.5 (2H, m), 4.5—4.9 (2H, m), 6.4—7.0 (N^+H_2, 2H, m). UV (MeOH): 314 nm (ε=12400).

*Conversion of **7a** into 1-Diethylamino-4-nitrobenzene (**5c**) and N-Methyl-2-nitroacetamide (**3a**)*. A solution of 0.39 g of **7a** in 50 ml of methanol was allowed to stand for 24 h at room temperature. The solvent was removed *in vacuo* and the residue was dissolved in 10 ml of chloroform and chromatographed on silica gel. A benzene elute gave 0.18 g (93%) of 1-diethylamino-4-nitrobenzene (**5c**). An ether elute gave 0.048 g (41%) of *N*-methyl-2-nitroacetamide (**3a**).

*Conversion of **7b** into 1-Morpholino-4-nitrobenzene (**5e**)*. When a solution of 0.42 g of **7b** in 50 ml of methanol was refluxed for 3 h, **7b** was recovered quantitatively. To the solution was added 0.87 g of morpholine and then refluxed for 3 h to give 1-morpholino-4-nitrobenzene (**5e**) quantitatively after the usual work up.

(Received October 9, 1981)

3-Substituted 2-oxo crown ethers and a novel dioxo crown ether with a point symmetry were synthesized by the cyclization of the corresponding substituted oligoethylene glycol monocarboxymethyl ethers using benzenesulfonyl chloride in the presence of alkali metal carbonates. The reaction mechanism was discussed. Their stability constants toward sodium and potassium cations were determined and the relation between their structures and complexing properties was discussed.

Since crown ethers were first synthesized by Pedersen, several thousand publications concerning these compounds and their derivatives have appeared.[1,2] Among them, attention has recently been denoted to the oxo crown compounds,[3,4] since some of these were shown to have a different complexing tendency towards cations than normal crown ethers. They may be considered as model compounds of natural macrocyclic antibiotics such as valinomycin and nonactin,[5,6] and those having the pyridine ring as mimics of enzymes such as NADH.[7,8]

A large number of oxo crown compounds have been synthesized and their properties investigated by Bradshaw,[9–17] Vögtle,[18–20] and Kellogg,[7,8,21,22] but most of these compounds were prepared through either the reaction between diacids and dihalides (ditosylates) of oligoethylene glycols, or the reaction between di(acid chloride)s and oligoethylene glycols; thus, the oxo crown compounds so far synthesized are mainly restricted to di- and tetraesters with limited kinds of substituents.

On the other hand, there are a few reports on the synthesis of monooxo crown ethers with rather special structure. Kellogg[23] prepared monooxo benzocrown ethers starting from salicylic acid, Cs_2CO_3 and oligoethylene glycol dibromides, while Newkome and coworkers[24,25] have synthesized pyridine macrocyclic lactones from 2-chloronicotinoyl chloride and oligoethylene glycol.

In the previous communications,[26,27] we have reported the synthesis of unsubstituted 2-oxo crown ethers *via* the intramolecular cyclization of monocarboxymethylated oligoethylene glycols. Here we describe the extension of this new method to the synthesis of monooxo crown ethers with substituents and a novel symmetrical dioxo crown ether. The characteristics of the complexing ability of monooxo crown ethers toward alkali metal cations were also examined in comparison with normal crown ethers and dioxo crown ethers.

Experimental

The ^{1}H NMR spectra were taken at 100 MHz on a JEOL-JNM-PS 100 spectrometer using tetramethylsilane as the internal standard. The infrared spectra were obtained on a Hitachi 260-10 spectrometer. The mass spectra were measured with a Hitachi RMU-6E mass spectrometer at an ionization potential of 70 eV. The GLC analyses were performed on a Shimadzu GC-3BF using a 2 m×3 mm column packed with 10% Silicone SE-30 on 60—80 mesh Celite 545. Stability constants were determined by potentiometry using an ion-selective electrode at 25 °C in methanol according to the literature.[28] Toko Na^+ 1100 and Toko K^+ 1200 were used as ion-selective electrodes for Na^+ and K^+ respectively. The emf was measured with a Beckmann 4500 digital pH meter.

General Procedure for Preparation of 2-Oxo Crown Ethers (4). In an appropriate oligoethylene glycol (**2**), one eighth molar amount of alkali metal was dissolved at 90—100 °C. To this solution, one eighth molar amount of alkali metal salt of a halo fatty acid (**1**) was added; the mixture was then stirred at 80—90 °C for 4—5 h. In some cases, where a halo acid was used in place of its salt, one quarter molar amount of alkali metal was used. The excess **2** was distilled off from the reaction mixture under reduced pressure, the residue was then dissolved in 2-propanol and the insoluble matter (alkali metal halide) was removed by filtration. The solvent was evaporated to give the intermediate **3**. One quarter molar amount of pulverized alkali metal carbonate was suspended together with **3** in dioxane. To this suspension, one eighth molar amount of benzenesulfonyl chloride in dioxane was added over a 2—3 h period at 65—70 °C, and the mixture was stirred for another 3 h. The insoluble salt was removed by filtration and the solvent was distilled off under reduced pressure. The residue was submitted to pyrolytic distillation using a Kugelrohr apparatus to give **4** as a distillate. Further purification of **4** was accomplished through redistillation or silicic acid column chromatography.

2-Oxo-15-crown-5 (4a). The sodium salt of tetraethylene glycol carboxymethyl ether (**3**, n=2, R^1, R^2=H), which was prepared according to the general procedure mentioned above from tetraethylene glycol (97.9 g, 0.504 mol), sodium metal (2.90 g, 0.126 mol), and bromoacetic acid (8.76 g, 0.063 mol), was treated with benzenesulfonyl chloride (11.1 g, 0.063 mol) and sodium carbonate (13.4 g, 0.126 mol) in dioxane (200 ml+50 ml) to give sodium cation complex of **4a**. The complex was destructively distilled and purified by redistillation to give a pale yellow oil. 2-Oxo-18-crown-6 (**4b**) was obtained according to a similar procedure. Spectral and analytical data have already been reported in the previous communication.[26]

2-Oxo-21-crown-7 (4c). A pale yellow oil; bp 134—137 °C/0.04 Torr (1 Torr=133.322 Pa) (Kugelrohr apparatus); n_D^{20} 1.4665; IR (neat) 2880(s), 1760—1740(s), 1455(m), 1350(m), 1290(m), 1250(m), 1200(m), 1135(s), 1040(w), 1000(w), 945(m), 850(w) cm^{-1}; ^{1}H NMR (CCl_4) δ 3.50—3.70 (m, 22H, OCH_2CH_2O), 4.12 (s, 2H, OCH_2COO), 4.16—4.28 (m, 2H, $COOCH_2CH_2O$); mass spectrum, *m/e* (relative intensity) 322 (M^+), 103(45), 102(23), 89(35),

87(34), 86(28), 73(28), 59(25), 58(27), 45(100), 44(29), 43(50), 42(21). Found: C, 51.82; H, 8.38%. Calcd for $C_{14}H_{26}O_8$: C, 52.16; H, 8.13%.

*3-Methyl-2-oxo-15-crown-5 (**4d**).* A pale yellow oil; IR (neat) 1730—1750 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 1.30 (d, 3H), 3.52—3.72 (m, 14H), 3.88—4.40 (m, 3H); mass spectrum, *m/e* 248 (M^+). Found: C, 52.89; H, 8.31%. Calcd for $C_{11}H_{20}O_6$: C, 53.22; H, 8.12%.

*3,3-Dimethyl-2-oxo-15-crown-5 (**4e**).* A pale yellow oil; IR (neat) 1720—1740 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 1.35 (s, 6H), 3.30—3.74 (m, 14H), 4.18 (t, 2H); mass spectrum, *m/e* 262 (M^+). Found: C, 54.66; H, 8.69%. Calcd for $C_{12}H_{22}O_6$; C, 54.95; H, 8.45%.

*3-Ethyl-2-oxo-15-crown-5 (**4f**).* A pale yellow oil; IR (neat) 1720—1740 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 0.92 (t, 3H), 1.68 (m, 2H), 3.55—3.78 (m, 14H), 3.85 (t, 1H), 4.00—4.40 (m, 2H); mass spectrum, *m/e* 262 (M^+). Found: C, 54.69; H, 8.76%. Calcd for $C_{12}H_{22}O_6$: C, 54.95; H, 8.45%.

*3-Hexyl-2-oxo-15-crown-5 (**4g**).* A pale yellow oil; IR (neat) 1720—1750 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 0.88 (t, 3H), 1.20—1.50 (m, 8H), 1.50—1.76 (m, 2H), 3.50—3.76 (m, 14H), 3.85 (t, 1H), 4.00—4.40 (m, 2H); mass spectrum, *m/e* 318 (M^+). Found: C, 60.20; H, 9.71%. Calcd for $C_{16}H_{30}O_6$: C, 60.35; H, 9.50%.

*3-Phenyl-2-oxo-15-crown-5 (**4h**).* A pale yellow oil; IR (neat) 1730—1750 ($\nu_{C=O}$), 730, 700 cm^{-1}; ^1H NMR (CCl_4) δ 3.50—3.78 (m, 14H), 3.92—4.40 (m, 2H), 4.98 (s, 1H), 7.15—7.45 (m, 5H); mass spectrum, *m/e* 310 (M^+). Found: C, 61.74; H, 7.29%. Calcd for $C_{16}H_{22}O_6$: C, 61.92; H, 7.15%.

*3-Methyl-2-oxo-18-crown-6 (**4i**).* A pale yellow oil; IR (neat) 1730—1745 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 1.34 (d, 3H), 3.55—3.76 (m, 18H), 3.92—4.32 (m, 3H); mass spectrum, *m/e* 292 (M^+). Found: C, 53.20; H, 8.46%. Calcd for $C_{13}H_{24}O_7$: C, 53.41; H, 8.28%.

*3,3-Dimethyl-2-oxo-18-crown-6 (**4j**).* A pale yellow oil; IR (neat) 1730—1745 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 1.36 (s, 6H), 3.36—3.80 (m, 18H), 4.20 (t, 2H); mass spectrum, *m/e* 306 (M^+). Found: C, 54.55; H, 8.80%. Calcd for $C_{14}H_{26}O_7$: C, 54.89; H, 8.55%.

*3-Ethyl-2-oxo-18-crown-6 (**4k**).* A pale yellow oil; IR (neat) 1720—1740 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 0.92 (t, 3H), 1.68 (m, 2H), 3.55—3.80 (m, 18H), 3.90 (t, 1H), 4.15—4.35 (m, 2H); mass spectrum, *m/e* 306 (M^+). Found: C, 54.82; H, 8.81%. Calcd for $C_{14}H_{26}O_7$: C, 54.89; H, 8.55%.

*3-Hexyl-2-oxo-18-crown-6 (**4l**).* A pale yellow oil; IR (neat) 1730—1750 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 0.88 (t, 3H), 1.20—1.48 (m, 8H), 1.50—1.76 (m, 2H), 3.50—3.76 (m, 18H), 3.88 (t, 1H), 4.10—4.28 (m, 2H); mass spectrum, *m/e* 362 (M^+). Found: C, 59.36; H, 9.71%. Calcd for $C_{18}H_{34}O_7$: C, 59.65; H, 9.45%.

*3-Phenyl-2-oxo-18-crown-6 (**4m**).* A pale yellow oil; IR (neat) 1740—1760 ($\nu_{C=O}$), 740, 700 cm^{-1}; ^1H NMR (CCl_4) δ 3.56—3.70 (m, 18H), 3.90—4.40 (m, 2H), 5.06 (s, 1H), 7.16—7.48 (m, 5H); mass spectrum, *m/e* 354 (M^+). Found: C, 60.70; H, 7.59%. Calcd for $C_{18}H_{26}O_7$: C, 61.00; H, 7.40%.

*3-Methyl-2-oxo-21-crown-7 (**4n**).* A pale yellow oil; IR (neat) 1730—1750 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 1.32 (d, 3H), 3.55—3.75 (m, 22H), 4.05 (quartet, 1H), 4.24 (t, 2H); mass spectrum, *m/e* 336 (M^+). Found: C, 53.19; H, 8.50%. Calcd for $C_{15}H_{28}O_8$: C, 53.56; H, 8.39%.

*3,3-Dimethyl-2-oxo-21-crown-7 (**4o**).* A pale yellow oil; IR (neat) 1720—1740 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 1.35 (s, 6H), 3.40—3.72 (m, 22H), 4.20 (t, 2H); mass spectrum, *m/e* 350 (M^+). Found: C, 54.77; H, 8.80%. Calcd for $C_{16}H_{30}O_8$: C, 54.84; H, 8.63%.

*3-Ethyl-2-oxo-21-crown-7 (**4p**).* A pale yellow oil; IR (neat) 1730—1750 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 0.95 (t, 3H), 1.68 (m, 2H), 3.50—3.80 (m, 22H), 3.88 (t, 1H), 4.18—4.30 (m, 2H); mass spectrum, *m/e* 350 (M^+). Found: C, 55.00; H, 8.81%. Calcd for $C_{16}H_{30}O_8$: C, 54.84; H, 8.63%.

*3-Hexyl-2-oxo-21-crown-7 (**4q**).* A pale yellow oil; IR (neat) 1730—1760 cm^{-1} ($\nu_{C=O}$); ^1H NMR (CCl_4) δ 0.88 (t, 3H), 1.20—1.40 (m, 8H), 1.50—1.70 (m, 2H), 3.50—3.85 (m, 22H), 3.90 (t, 1H), 4.15—4.28 (m, 2H); mass spectrum, *m/e* 406 (M^+). Found: C, 58.72; H, 9.53%. Calcd for $C_{20}H_{38}O_8$: C, 59.09; H, 9.42%.

*3-Phenyl-2-oxo-21-crown-7 (**4r**).* A pale yellow oil; IR (neat) 1720—1760 ($\nu_{C=O}$), 730, 700 cm^{-1}; ^1H NMR (CCl_4) δ 3.50—3.72 (m, 22H), 4.10—4.28 (m, 2H), 5.00 (s 1H), 7.15—7.30 (m, 3H), 7.32—7.45 (m, 2H); mass spectrum, *m/e* 398 (M^+). Found: C, 59.93; H, 7.68%. Calcd for $C_{20}H_{30}O_8$: C, 60.29; H, 7.59%.

*2,11-Dioxo-18-crown-6 (**5**).* Metallic sodium (9.2 g, 0.4 mol) was dissolved in diethylene glycol (170 g, 1.60 mol) and bromoacetic acid (27.8 g, 0.2 mol) was added to the resultant solution at 90—100 °C; the mixture was then stirred at 95—100 °C for 5 h. The excess diethylene glycol was removed *in vacuo*. Methanol (200 ml) was added to the distillation residue and the sodium bromide was removed by filtration. On evaporation of the methanol from the filtrate, the sodium salt of diethylene glycol carboxymethyl ether (**3s**) was obtained. The intermediate was suspended in dioxane (250 ml) and sodium carbonate (31.8 g, 0.3 mol) and benzenesulfonyl chloride (35.3 g, 0.2 mol) in dioxane (60 ml) was added dropwise to the mixture at 65—70 °C for 4 h under stirring and the mixture was stirred for another 3 h. The resultant mixture was cooled to room temperature, and the insoluble matter was removed by filtration. The filtrate was evaporated under reduced pressure to give a brown solid. The crude product was pyrolized in a Kugelrohr apparatus under reduced pressure and recrystallized from acetone to give a white solid (10.5 g, 18%). Mp 115.0—116.0 °C; IR (KBr) 2930—2850(s), 1750 (s, $\nu_{C=O}$), 1450(m), 1405(m), 1350(m), 1215(s), 1125(s), 1030(m), 940(m), 860 cm^{-1} (m); ^1H NMR ($CDCl_3$) δ 3.65—3.88 (m, 12H), 4.28—4.45 (m, 8H); mass spectrum, *m/e* (relative intensity) 292 (M^+, 10), 249(7), 248(8), 147(29), 103(100), 102(65), 86(66), 73(25), 45(66). Found: C, 49.34; H, 6.90%. Calcd for $C_{12}H_{20}O_8$: C, 49.31; H, 6.93%.

Reaction of Tetraethylene Glycol with the Mixture of Acetic Acid and Benzenesulfonyl Chloride in the Presence of Sodium Carbonate. To a stirred suspension of 3.88 g (0.02 mol) of tetraethylene glycol and 8.48 g (0.08 mol) of sodium carbonate in 80 ml of dioxane, a mixture of 2.40 g (0.04 mol) of acetic acid and 10.71 g (0.06 mol) of benzenesulfonyl chloride in 20 ml of dioxane was added over a 1-h period at 60 °C. The reaction was followed by GLC and the peak corresponding to the desired ester was observed soon after the addition of the reagents. The mixture was then stirred at 60 °C for 30 h. The resultant mixture was cooled to room temperature and insoluble matter was removed by filtration. The solvent was evaporated under reduced pressure. Water (100 ml) was added to the residue and the mixture was extracted with dichloromethane (50 ml). The dichloromethane solution was concentrated to give 5.54 g of a slightly yellow liquid. The crude product was distilled under reduced pressure to give 3.42 g (61%) of tetraethylene glycol diacetate as a colorless liquid. Bp 163 °C/0.03 Torr (Kugelrohr apparatus); IR (neat) 2960(m), 2880(s), 1735(s), 1460(m), 1380(s), 1245(s), 1130(s), 1060(s), 960(m), 855(w)

cm^{-1}; ^1H NMR ($CDCl_3$) δ 2.05 (s, 6H), 3.52—3.80 (s+m, 12H), 4.20 (t, 4H).

Reaction of Tetraethylene Glycol Ditosylate with Acetic Acid in the Presence of Sodium Carbonate. A suspended mixture of 2.60 g (5.17×10^{-3} mol) of tetraethylene glycol ditosylate, 0.95 g (0.0158 mol) of acetic acid, and 1.65 g (0.0156 mol) of sodium carbonate in 25 ml of dioxane was stirred at 60 °C for 30 h. The required ester was not detected by GLC anlysis.

Results and Discussion

The alkali metal salts of oligoethylene glycol monocarboxymethyl ethers and their alkyl derivatives(**3**) were prepared from 2-halo carboxylic acids(**1**) and the appropriate oligoethylene glycols(**2**) through the Williamson ether synthesis, and successively cyclized to 2-oxo crown ethers (**4**) by the treatment with benzenesulfonyl chloride in dioxane in the presence of alkali metal carbonates (scheme 1). The results of synthesis of **4** are summarized in Tables 1 and 2.

The yields of unsubstituted 2-oxo crown ethers were not influenced significantly by the difference in the halogen atom (Table 1). However, the kind of alkali metal cation was observed to effect the yield considerably. Thus yields of both 2-oxo-15- and 2-oxo-18-crown ethers in the reactions with sodium carbonate were better than those with potassium carbonate, while for 2-oxo-21-crown-7 potassium carbonate gave good yields compared with sodium carbonate. A caesium base had been used to improve the yields in esterification and the related reactions instead of more common alkali metal bases,[29] and the effect of a change in the alkali metal cation on the yields in the synthesis of 2-oxo crown ethers was examined in this study. Although the general trend of the effect of the caesium cation was not clearly observed, the partial replacement of sodium carbonate by this cation gave somewhat improved yield in the case of **4a** as shown in Table 1.

In spite of the difference in the substituent group, the yields of 3-monosubstituted-2-oxo-15-, 18-, and 21-crown ethers were approximately 20, 40, and 25% respectively. In addition, it is noteworthy that the temperature used for pyrolytic distillation of the reaction products under reduced pressure in a Kugelrohr apparatus were almost constant for the crown ethers with the same ring size; the distillation conditions were as follows: 160 °C/0.03 Torr for 15-crown, 175 °C/0.02 Torr for 18-crown, and 190 °C/0.02 Torr for 21-crown ethers. This finding suggests that above-cited conditions correspond to the decomposition temperature of the complex with the alkali metal cation.

On the other hand, the sodium salt of diethylene glycol monocarboxymethyl ether(**3s**) was submitted

to the bimolecular esterification with each other followed by intramolecular cyclization in the presence of an effective template ion to give 2,11-dioxo-18-crown-6(**5**); this is a novel type of dioxo crown ethers possessing a point symmetry.

The postulated reaction mechanism of the cyclization to monooxo crown ethers was offered in Scheme 3. Two possible routes of cyclization (route **A** and **B**) can be conceived: differing in the first reaction site with the benzenesulfonyl chloride. Brewster *et al.* reported that the lactone formation reaction of *trans*-2-hydroxycyclohexaneacetic acid using *p*-toluenesulfonyl chloride in the presence of pyridine proceeded without losing its geometrical configuration.[30] This can be explained by assuming the first formation of a mixed acid anhydride. In addition, two model reactions under conditions similar to the case of 2-oxo crown ethers were carried out to clarify the mechanism. One was the reaction of oligoethylene glycol with acetic acid using benzenesulfonyl chloride in the presence of sodium carbonate in dioxane; the other was the reaction of oligoethylene glycol ditosylate with acetic acid in the presence of sodium carbonate in dioxane. Only the former reaction could give the required product, and from all these results route **A** seems to be probable in this case.

Finally, the complexing ability of the synthesized oxo crown ethers toward sodium and potassium cations was examined according to the method using ion selective electrode in methanol at 25 °C,[28] and compared with that of dioxo and normal crown ethers (Table 3).

The increase of the number of ester group was observed drastically to decrease the complexing ability toward alkali metal cations as expected from the decrease of the electron-donating ability of coordination sites. In general, monooxo crown ethers were concluded to be intermediate in properties between normal crown ethers and dioxo crown ethers.

As for the effect of the substituent, the introduction of alkyl substituent(s) on an oxo crown ring slightly reduced their complexing ability; a phenyl substituent does not affect the complexing ability as indicated by the fact that 3-phenyl-2-oxo-18-crown-6(**4m**) showed almost the comparable stability constant to that of unsubstituted 2-oxo-18-crown-6(**4b**).

On the other hand, the difference in the position of the ester groups of dioxo crown ethers does not seem to influence the complexing ability.

Table 3. Stability constant of oxo crown ethers

The Preparation of Optically Pure 3-Hydroxyalkanoic Acid. The Enantioface-differentiating Hydrogenation of the C=O Double Bond with Modified Raney Nickel. XXXVII.

Masaaki NAKAHATA, Motomasa IMAIDA, Hiroshi OZAKI, Tadao HARADA, and Akira TAI*

Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka 565

(Received November 28, 1981)

The enantioface-differentiating hydrogenation of methyl 3-oxoalkanoate ($CH_3(CH_2)_nCOCH_2COOCH_3$, n=0, 6, 8, 10, 12) over the (*R,R*)-tartaric acid–NaBr–modified Raney nickel catalyst ((*R,R*)-TA–NaBr–MRNi) gave methyl (*R*)-3-hydroxyalkanoate ($CH_3(CH_2)_nCH(OH)CH_2COOCH_3$, n=0, 6, 8, 10, 12) in an average optical yield of 85%. After the methyl ester had been converted to dicyclohexylammonium salt of 3-hydroxyalkanoic acid, the salt was recrystallized three times from acetonitrile and then treated with acid to give optically pure (*R*)-3-hydroxyalkanoic acid ($CH_3(CH_2)_nCH(OH)CH_2COOH$, n=0, 6, 8, 10, 12) in a reasonable yield. From the hydrogenation product with (*S,S*)-TA–NaBr–MRNi, optically pure (*S*)-3-hydroxyalkanoic acid was obtained by the same process as above.

Optically active 3-hydroxyalkanoic acids (**1**) and their derivatives exist widely in the biological system. For example, 3-hydroxydecanoic acid is a sprouting regulatory substance secreted by the leaf-cutting ant (*A sexdens*)[1] and is also a component of depsipeptide "Serataniolide,"[2] 3-hydroxytetradecanoic acid is a major fatty acid comprising "lipid-A in endotoxin,"[3] the choline ester of 3-acetoxyhexadecanoic acid is a fish toxin "pahutoxine,"[4] and 3-hydroxyoctadecanoic acid is a component of emposatilin, an antitumor reagent.[5]

Although various methods of synthesizing these important 3-hydroxyalkanoic acids have been proposed,[6–8] no practical ways for the preparation of these optically pure compounds have been reported. As has been briefly reported in a preliminary communication,[9] the present method consists of the enantioface-differentiating hydrogenation of the methyl 3-oxoalkanoate over an asymmetrically modified nickel and the preferential crystallization of an optically pure substance from the hydrogenation products. In this paper, the preparations of optically pure acids of carbon numbers from 10 to 16 in the practical scale will be reported.

Results and Discussion

The preparation of optically pure 3-hydroxyalkanoic acid (**1**) was carried out by the process outlined in Scheme 1.

Since the catalytic hydrogenation with the nickel catalyst is sensitive to the impurities of the substrate, one of the essential factors in the present process is the development of a suitable method to synthesize methyl 3-oxoalkanoate (**5**). Among the previously reported methods[10–13] here examined, a modification of the method of Oikawa and his co-workers[10] (Scheme 1) gave the best results with respect to the practical-scale preparation of chemically pure **5**. The isolation and purification of the intermediate (**4**) before the decarboxylation was necessary to obtain long-chain methyl 3-oxoalkanoate (**5**) in a high purity. The average yield of **4** was 70%, based on **3**.

The catalyst (TA–NaBr–MRNi) employed for the enantioface-differentiating hydrogenation of **5** to methyl 3-hydroxyalkanoate (**6**) was prepared by soaking the Raney nickel catalyst in an aqueous solution of tartaric acid (TA) and NaBr at 100 °C.[14]

a) Recovery after 6 recrystallizations.

The hydrogenations of **5** to **6** proceeded smoothly under an initial hydrogen pressure of 100 kg/cm² at 100 °C; they produced quantitative chemical yields and an optical yield of more than 83%. The saponification of **6** gave **1** in an averaged isolation yield of 95%, based on **5**. The results are listed in Table 1. In all cases, the use of (*R*,*R*)-TA–NaBr–MRNi gave (*R*)-**1** in excess. It is advantageous that the natural type of (*R*)-**1** can, incidentally, be obtained by the use of common (*R*,*R*)-TA as a modifying reagent.

The isolation of optically pure **1** from the reaction product (85% e.e.) was achieved by the preferential crystallization method.

To ascertain the most effective derivatives of **1** for the preferential crystallization, various ammonium salts of **1a** (C_{16} acid) were prepared and the efficiencies of resolution were examined. The results are listed in Table 2. Among the ammonium salts of **1** examined, the dicyclohexylammonium salt (**7**) gave the best result. An optically pure substance was obtained in a yield of 70% by three successive recrystallizations from acetonitrile.

The method was also effectively applicable to the resolution of **1b** to **1e** as is shown in Table 3.

The advantage of the present procedure is that optically pure 3-hydroxyalkanoic acid with various alkyl chain lengths is easily obtained by a simple unit process: catalytic hydrogenation and recrystallization. Furthermore, the preparation of TA–NaBr–MRNi is very simple, and the cost of the catalyst is negligible.

Experimental

The ^{1}H-NMR and IR spectra were taken with a JEOL FX-100 spectrometer and a Shimadzu IR 27G spectrometer respectively. The optical rotation was measured with a Perkin Elmer 241 Polarimeter. The GLC was carried out with a Shimadzu 6A-PF Gas Chromatography, using a 3 m-5 mm o.d. glass column packed with 2% Silicone OV-17 on Chromosorb W (OV-17).

All the chemicals except those described below were obtained from commercial sources and were used without further purification.

Substrate. Methyl 3-Oxohexadecanoate (5a): Tetradecanoyl chloride (**2a**) (217 g, 0.88 mol) was added, drop by drop, into a solution of 2,2-dimethyl-1,3-dioxane-4,6-dione (**3**) (115 g, 0.8 mol) and pyridine (128 g) in 1000 ml of CH_2Cl_2 at 5 °C. The reaction mixture was then stirred for 1 h at room temperature. The mixture was washed with three 200-ml portions of 10% HCl and a 200-ml portion of water successively, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The residue was dissolved in 200 ml of methanol and kept overnight at −20 °C. The crystalline intermediate, **4**, precipitated was collected by filtration and washed with a small portion of cold methanol. The resulting substance was dissolved in 1000 ml of methanol and subjected to decarboxylation under reflux for 5 h. After the evaporation of the solvent from the reaction product, the residue was crystallized from 100 ml of methanol at −20 °C. The separation of the crystals by filtration at −20 °C gave 170 g of **5a** in a yield of 75% based on **3**; mp 41 °C. Calcd for $C_{17}H_{32}O_3$: C, 71.78; H, 11.34%. Found C, 71.50; H, 11.57%. IR, (KBr disk) 2950, 1735, 1695 cm^{-1}. ^{1}H-NMR ($CDCl_3$); δ 0.89 (t, 3H, $-C\underline{H}_3$), 1.25 (m, 22H, $-(C\underline{H}_2)_n$), 2.55 (t, 2H, $-C\underline{H}_2-\overset{\overset{O}{\|}}{C}-$), 3.42 (s, 2H, $-CO-C\underline{H}_2-CO$), 3.72 (s, 3H, $-OC\underline{H}_3$).

Methyl 3-Oxotetradecanoate (5b) and Methyl 3-Oxododecanoate (5c): These substances were prepared by the same procedure as that used for **5a**, except for the use of dodecanoyl chloride (**2b**) and decanoyl chloride (**2c**) respectively, instead of tetradecanoyl chloride (**2a**), as starting materials.

From 193 g (0.88 mol) of **2b** and 115 g of **3** (0.8 mol), 147 g of **5b** were obtained. (Yield 72% based on **3**). Mp 30 °C. Calcd for $C_{15}H_{18}O_3$: C, 70.27; H, 11.01%. Found: C, 70.20; H, 11.21%.

From 167.6 g (0.88 mol) of **2c** and 115 g of **3**, 123 g of **5c** was obtained. The final purification was performed by vacuum distillation instead of crystallization. Bp 127 °C/3 mmHg.** Calcd for $C_{13}H_{24}O_3$: C, 68.38; H, 10.59%. Found: C, 67.80; H, 10.66%. The IR and ^{1}H-NMR spectra of these samples consisted of structures of **5b** and **5c**.

Methyl 3-Oxodecanoate (5d): Octanoyl chloride (**2d**) (162 g, 0.88 mol) and **3** (115 g, 0.8 mol) were subjected to the reaction under the same conditions as those described before. The resulting crude intermediate (**4**) in CH_2Cl_2 was washed three 200-ml portions of 10% HCl and three 200-ml portions of water, and then concentrated under reduced pressure. The residue was dissolved in 800 ml of methanol, and the mixture was refluxed for 5 h. After the evaporation of the methanol from the reaction mixture, the residue was dissolved in 400 ml of benzene, washed successively with two 100-ml portions of a 10% aqueous K_2CO_3 solution and two 100-ml portions of water, and dried over Na_2SO_4. The solvent was evaporated, and the residue was distilled under reduced pressure to give 83 g of **5d**. Bp 112 °C/3 mmHg, Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%. Found: C, 66.10; H, 10.07%. The ^{1}H-NMR and IR spectra of the sample consisted of the structure of **5d**.

Catalyst. (R,R)-TA–NaBr–MRNi: Into an alkaline solution (4.5 g of NaOH in 20 ml of H_2O) was added 1.9 g of the Raney nickel alloy (Ni:Al=42:58, Kawaken Fine Chemicals Co.) portion by portion. The resulting suspension was kept for 1 h at 100 °C, after which the supernatant was removed by decantation. The resulting Raney nickel catalyst (RNi) was washed 15 times with 30-ml portions of deionized water. (*R*,*R*)-TA (1 g) and NaBr (10 g) were dissolved in 100 ml of deionized water, and the pH of the solution was adjusted to 3.2 with 1 M NaOH solution. To the solution heated in a boiling-water bath was then added the Raney nickel previously prepared; the mixture was kept for 1 h with occasional stirring at 100 °C. After the removal of the supernatant by decantation, the residual catalyst was washed with a 10-ml portion of water, two 50-ml portions of methanol, and a 25-ml portion of methyl propionate, and then stored in 25-ml of methyl propionate. By the same process, (*S*,*S*)-TA–NaBr–MRNi was prepared by the use of (*S*,*S*)-TA.

3-Hydroxyalkanoic Acid 1a (or 1b, 1c, 1d). In an autoclave (100-ml capacity) were placed 10 g of **5a** (or **5b**, **5c**, **5d**), 30 ml of methyl propionate, 0.1 ml of acetic acid, and TA–NaBr–MRNi prepared from 1.9 g of the Raney alloy. Hydrogenation was carried out at an initial H_2-pressure of 100 kg/cm² at 100 °C until no more consumption of H_2 was observed. After the subsequent evacuation of H_2, the reaction product was dissolved in 50 ml of ether and filtered to separate the catalyst. The filtrate was washed with a 30-ml portion of 10% aqueous Na_2CO_3 and con-

** 1 mmHg≈133.322 Pa.

centrated under reduced pressure to give crude **6a** (or **6b**, **6c**, **6d**). A 100-mg portion of crude **6a** (or **6b**, **6c**, **6d**) was purified on preparative TLC as the sample for NMR and IR analysis. The GLC (OV-17) of each purified sample showed a single peak. The retention times of the samples were 31.2 min (**6a**, 160 °C), 11.4 min (**6b**, 160 °C), 12.0 min (**6c**, 110 °C), and 4.2 min (**6d**, 100 °C). The IR and ^{1}H-NMR spectra of **6a** were as follows: IR (KBr disk), 3390, 2950, 1739, 1700; NMR ($CDCl_3$) δ 0.90 (t, 3H, $-C\underline{H}_3$), 1.30 (m, 24H, $-(C\underline{H}_2)_n-$), 2.50 (m, 2H, $-C\underline{H}(OH)-C\underline{H}_2-C(=O)-$), 3.72 (s, 3H, $-OC\underline{H}_3$), 4.00 (m, 1H, $-C\underline{H}(OH)-$). The spectra of **6b**, **6c**, **6d** were almost the same as those of **6a** and were consistent with their structures.

The optical purity of each sample as determined by ^{1}H-NMR in the presence of Eu(hfmc)$_3$, is listed in Table 1. The difference in the chemical shift for the methyl proton of $-C(=O)-OC\underline{H}_3$ (singlet) of (*S*)- and (*R*)-**6** was 6—10 Hz when the spectra were measured with a solution of **6** (10 mg) and Eu(hfmc)$_3$ (15 mg) in 400 μl of $CDCl_3$. The saponification of the major part of crude **6a** (or **6b**, **6c**, **6d**) with NaOH and subsequent acid treatment gave crude **1a** (or **1b**, **1c**, **1d**). The yields are listed in Table 1.

Preferential Crystallizations of Various Ammonium Salts of 1a. Cyclohexyl-, benzyl-, phenyl-, dicyclohexyl-, and hexylammonium salts of **1a** (85% e.e., $[\alpha]_D^{20}$ −10.7 (*c*=1, $CHCl_3$)) were prepared from 5.5 g of **1a** and a 1.1-mol equivalent of the amine. Each ammonium salt was dissolved in a minimum amount of boiling acetonitrile and crystallized at room temperature. The amounts of acetonitrile used are listed in Table 2. After three recrystallizations, the salt was acidified with 10% aqueous HCl and the liberated **1a** was extracted with ether. After drying over Na_2SO_4, the extract was concentrated to the crystals. The optical rotation of **1a** liberated from each recrystallized salt is listed in Table 2.

Optically Pure 3-Hydroxyalkanoic Acid 1a (or 1b, 1c, 1d). Crude **1a** (or **1b**, **1c**, **1d**) obtained by the hydrogenation was converted to dicyclohexylammonium salt. Three recrystallizations of the salt from a minimum amount of acetonitrile gave the optically pure salt of **1a** (or **1b**, **1c**, **1d**). The optical purity of the starting material, the amount of acetonitrile used for recrystallization, and the recovery of optically active salt as crystals are listed in Table 3.

Optically active **1a** (or **1b**, **1c**, **1d**) was obtained by the acid treatment of the salt as described above. The analytical data of the products are listed in Table 4.

A 100-mg portion of each acid was converted to the methyl ester with diazomethane and purified by preparative TLC. The optical purity of each purified sample as determined by ^{1}H-NMR, is listed in Table 3.

The authors are grateful to professors Yoshiharu Izumi, Tetsuo Shiba, and Shoichi Kusumoto, Osaka University for their helpful suggestions. This research was supported by a Scientific Research Grant-in-Aid from the Ministry of Education, Science, and Culture.

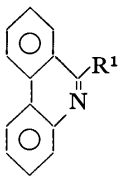
The Photocycloaddition of 6-Substituted Phenanthridines to Electron-rich Olefins

Shigeru FUTAMURA, Hiroyuki OHTA,* and Yoshio KAMIYA
Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received December 1, 1981)

The photocycloaddition reaction of 6-substituted phenanthridines and electron-rich olefins, such as *trans*-anethole and phenyl vinyl ether, is described. This reaction proceeds from the $^1(\pi,\pi^*)$ states of 6-substituted phenanthridines *via* the exciplex to give azocine and/or azetidine derivatives in ethanol.

Photocycloaddition between multiple bonds seems to be common and many papers have been reported in this area.[1] However, the intermolecular photocycloaddition reactions of the carbon-nitrogen double bond are documented only for the cyclic imines, which are classified into two groups. One of them is the system where the carbon-nitrogen double bond is conjugated with the imino[2] or the carbonyl group,[3,4] while the other one is the system where a hetero atom, such as nitrogen,[4] oxygen,[5] and sulfur,[6] is attached to the imino linkage.

Our concern has been concentrated on the photochemical behavior of phenanthridine, and we have already reported its luminescence phenomena and photoesterification reaction.[7] Phenanthridine(**1**), which is isoelectronic to phenanthrene, can also be expected to undergo photocycloaddition reactions with olefins similar to phenanthrene derivatives.[8] We have probed the photochemical reactivity of **1** with olefins and wish now to present some novel photocycloaddition reactions of **1** with electron-rich olefins(**2a—c**).[9]



1a: $R^1=CH_3$
1b: $R^1=CN$

Experimental

Materials. **1a** and **1b** were synthesized according to the literature.[10,11] **1a**: mp 78.4—79.0 °C; NMR (δ) 7.46—8.51 (m, 8H), 2.94 (s, 3H); IR (cm^{-1}) 1615, 751, 720; UV (EtOH, nm) 254.5 (ε=36000), 329.6 (ε=3900), 344.5 (ε=3900). **1b**: mp 136—137 °C; NMR (δ) 7.57—8.82 (m, 8H); IR (cm^{-1}) 2220, 1608, 758, 722; UV (EtOH, nm) 257.0 (ε=28000), 351.2 (ε=2500), 367.9 (ε=2200).

Benzene was purified by the conventional method and was finally distilled. The following solvent and quenchers (reagent special grade) were used without further purification: ethanol, *N,N*-dimethylaniline, *trans*-anethole (**2a**), pyrrole, 1-methyl-pyrrole, triethylamine, β-methylstyrene, quinoline, 2,3-dimethyl-2-butene, furan, γ-picoline, *trans*-1,3-pentadiene, acrylonitrile, and pyridine.

The benzophenone and benzhydrol were recrystallized from hexane–benzene and ethanol respectively; benzophenone, mp 48.5—48.7 °C, benzhydrol, mp 68.9—69.2 °C.

cis-Anethole (**2b**) was prepared by Michler's ketone (10^{-2} M†)-sensitized isomerization of **2a** (10^{-1} M). The subsequent separation of **2b** from **2a** by column chromatography (silica gel, hexane) gave pure **2b** in a 50% yield. **2b**: colorless oil; NMR (δ) 1.86 (dd, 3H), 3.74 (s, 3H), 5.80 (m, 1H), 6.38 (dd, 1H), 6.82 (d, 2H), 7.25 (d, 2H); IR (cm^{-1}) 2870, 1609, 1510, 1250, 1178, 1038, 845.

Phenyl vinyl ether was synthesized according to the literature.[12] Its IR and NMR spectra were superimposable on those of an authentic sample.

Instrumental. The GC analyses were done on a Shimadzu GC-6A-FID apparatus equipped with a column of 5% OV 17 on chromosorb p. The products were analyzed on a Waters liquid chromatograph, Model 440, equipped with a column of μ-PORASIL. Photocycloadducts were also isolated by HPLC. The IR spectra were taken either on a JASCO Model IR-G Spectrophotometer or on a Shimadzu IR-420 Infrared Spectrophotometer. The NMR spectra were obtained either on a JEOL JNM-PMX (60 MHz) or on a Varian EM 360A NMR Spectrometer (60 MHz), using Me_4Si as the internal standard. The UV spectra were recorded on a JASCO NEW-UV-210A Digital Double-beam Spectrophotometer. The fluorescence and phosphorescence spectra were taken either on a Hitachi MPF 4A or on a Shimadzu RF-502A Fluorescence Spectrophotometer. The melting points were measured by means of a Yazawa Hot Plate and are uncorrected.

Irradiations. Irradiations on a preparative scale were carried out with Pyrex-filtered light from a 400-W high-pressure mercury lamp (Riko) under the continuous bubbling of nitrogen in an immersion apparatus at the temperature of running water. The samples for kinetic studies and the controlled experiments were irradiated using a merry-go-round mounted on an optical bench. The light source was a 200-W super-high-pressure mercury arc, and light at 366 nm was selected through a Shimadzu-Bausch-Lomb monochromator.

*Irradiations of **1** and **2**.* **1** (10^{-2} M) was irradiated in benzene or ethanol (200 ml) in the presence of **2** (10^{-1} M). The reaction mixtures were separated by means of column chromatography (Florisil, hexane–ether), and the products were purified by preparative HPLC. The products were identified by means of IR and NMR.

*Quenching of the Photocycloaddition Reaction of **1** to **2**.* A 10 ml ethanol solution of **1** (10^{-2} M) with **2** (10^{-1} M) was irradiated in the absence or presence of a quencher, such as acrylonitrile and *trans*-1,3-pentadiene (10^{-1} M). The reactions were then monitored by means of HPLC.

*Quantum Yield for the Formation of **3ba**.* Benzophenone-benzhydrol actinometry was used ($\lambda_{irrad.}$=366 nm).[13] The reactions were monitored by means of HPLC.

Results and Discussion

*Quenching of **1a** Fluorescence.* **1a** fluoresces only in hydroxyl solvents, such as ethanol and benzene–acetic acid.[7]

† 1 M=1 mol dm^{-3}.

Figure 1 shows that the **1a** fluorescence is attenuated by **2a** in ethanol, accompanied by the growing-in of a new emission at a longer wavelength. The **1a** fluorescence is also quenched by other electron-rich olefins and amines at almost the diffusion-controlled rate, and a new emission is observed similarly in the cases of triethylamine, pyrrole, 1-methylpyrrole, β-methylstyrene, and 2,3-dimethyl-2-butene. Figure 2 shows the correlation of the log k_q for **1a** with the ionization potential of the quencher(IP_Q).

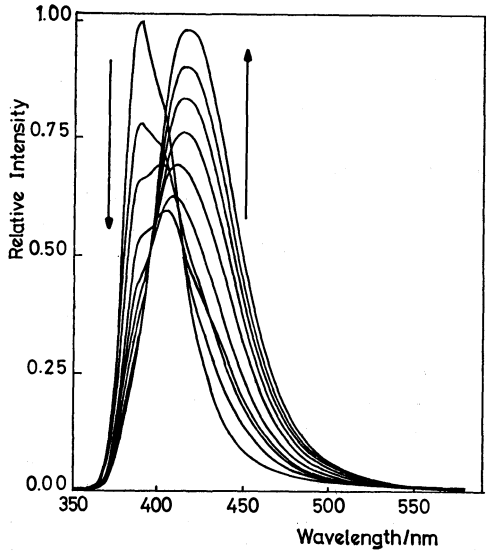


Fig. 1. Quenching of **1a** fluorescence by **2a** in ethanol at room temperature: concentration of **1a**=1.60×10^{-2} M, excitation wavelength=353.1 nm, K_{SV}=18.1 M^{-1}.

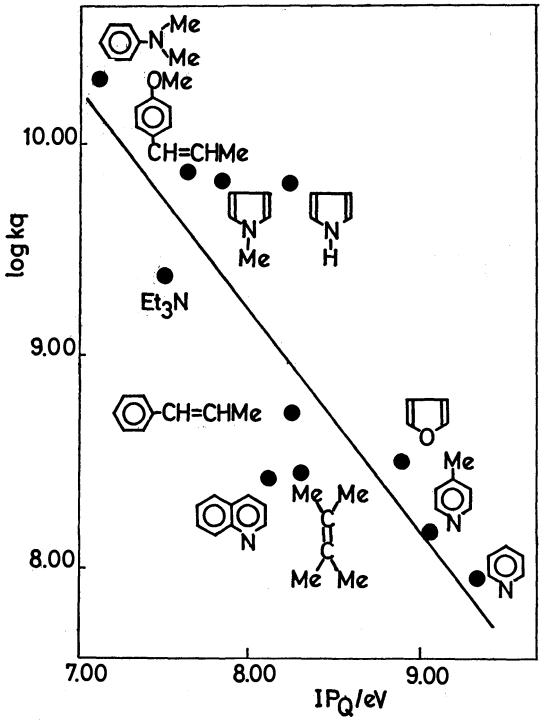

Fig. 2. Correlation of log k_q for **1a** with IP_Q; in EtOH under air, at room temperature.

The new emission is indicative of exciplex formation, and the good correlation of log k_q with IP_Q suggests that charge-transfer interaction is dominant in the above systems. Although it is generally accepted that exciplexes dissociate into radical ion pairs in a polar solvent and that exciplex emission is weak, in these cases a fairly strong exciplex emission is observed, even in a polar hydroxyl solvent.

*Photocycloaddition of **1a** with **2a** in Ethanol.* The azocine derivative **4aa** was afforded in a 56% yield, instead of the expected azetidine derivative, **3aa**. It is noteworthy that **5** was obtained in a 40% yield. **5** probably arises from the radical cation **2a**$^+$ *via* the *anti*-Markownikov addition of ethanol. This fact indirectly supports the exciplex formation, followed by its dissociation into radical ions.[14] In changing the solvent from ethanol to methanol or 2-propanol, the corresponding *anti*-Markownikov adducts were obtained. The yields were in the order of: methanol≅ethanol≧2-propanol. Although only 30% of the isomerization from **2a** to **2b** occurs on the direct irradiation of **2a**, 74% of the recovered anethole is *cis* in this reaction. It is known that exciplex formation often enhances intersystem crossing;[15] the observed fact suggests the presence of such a path for the collapse of the exciplex, which leads to the photoiso-

Scheme 1. Photochemical reactions of **1** with **2** in ethanol.

Table 1. Photocycloaddition reactions of **1** with **2** in ethanol

Substrate	Olefin	Irradiation time/h	Products (yield/%)
1a	**2a**	29	**2b** (37) **4aa** (56) **5** (40)
1a	**2b**	30	
1b	**2a**	5	**2b** (47) **3ba** (16) **4ba** (84)
1b	**2b**	6	
1b	**2c**	26	**4bc** (42) **6** (5)

merization from **2a** to **2b**.[16,17]

*Photocycloaddition of **1b** with **2a** in Ethanol.* **1b** reacted much faster than **1a** to give **3ba** and **4ba** in 16 and 84% yields respectively. The formation of both **3ba** and **4ba** greatly intrigued us as to the reaction course by which **4** is formed. In this reaction, 52% of the anethole was **2b**. However, no **5** was obtained.

*Photocycloaddition of **1** with **2b** in Ethanol.* As has been described above, no incorporation of **2b** into the photocycloadducts was observed, though a considerable amount of **2b** was accumulated after the photocycloaddition reaction of **1a** or **1b** with **2a**. Thus, **1a** or **1b** was irradiated in the presence of **2b**, but no photocycloadduct was obtained in either case. The unreactive nature of **2b** toward the excited state of **1** is ascribable to the following facts. (1) The non-emissive (**1**–**2b**) exciplex collapses to the ground states much faster than the (**1**–**2a**) exciplex, partly because of its instability caused by its less efficient resonance stabilization between the two molecules, and (2) the exciplex substitution might be occurring, as in the case of (9-cyanophenanthrene–**2b**) exciplex.[18] The quenching rate of S_1 of **1b** by **2b** ($k_q = 6.6 \times 10^9$ M^{-1} s^{-1}) is slower than the quenching by **2a** ($k_q = 1.7 \times 10^{10}$ M^{-1} s^{-1}), and the (**1b**–**2b**)* + **2a** → (**1b**–**2a**)* + **2b** reaction would be exothermic.

*Photocycloaddition of **1b** with **2c** in Ethanol.* **1b** was irradiated in the presence of **2c** to give **4bc** and **6** in 42 and 5% yields respectively. It has been reported that the radical cation of **2c** reacts with **2c** to give cyclobutane dimers,[19] but in our study no such compounds were obtained.

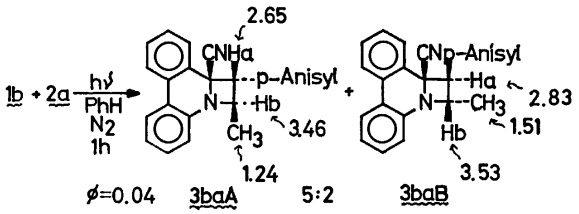
Table 2 summarizes the spectroscopic data of the products.

*Photocycloaddition of **1a** with **2a** in Benzene.* Even on the prolonged irradiation of **1a** and **2a** in benzene (99 h), no **3** was afforded, and **1** was recovered quantitatively, but a **2a** dimer[20] and **2b** were obtained in 49 and 32% yields respectively. These facts indicate that no photocycloaddition reaction between excited **1a** and **2a** proceeded.

*Photocycloaddition of **1b** with **2a** in Benzene.* A stereoisomeric mixture of **3** was obtained in a 52% yield on the irradiation of **1b** with **2a** in benzene for 1 h. The quantum yield for the formation of **3ba** was 0.04. This value is around a tenth as large as that for the formation of the cycloadduct between 9-cyanophenanthrene and **2a**.[18]

***3** as Precursor for **4**.* The irradiation of **3** in ethanol for 1 h gave **4** in a 50% yield, and its original stereochemistry was retained. This fact shows that **3** is the precursor for the formation of **4**.

Exciplex as Intermediate. Exciplexes have been postulated as intermediates in the photocycloaddition reactions of phenanthrene[21–23] or 9-cyanophenanthrene[18,24] by simultaneous observations of exciplex emission and photocycloadduct formation. Recently,



Scheme 3. Photocycloaddition reaction of **1b** with **2a** in benzene.

Caldwell *et al.* have, by a kinetic study together with the spectroscopic evidence, established the exciplex as the intermediate in the photocycloaddition reaction of 9-cyanophenanthrene to **2a**.[18]

The (**1b**–**2a**) exciplex emission was quenched by acrylonitrile, which did not attenuate the **1b*** fluorescence. Acrylonitrile (10^{-1} M) also quenched the product formation in the photocycloaddition reaction of **1b** and **2a**, while the triplet quencher, *trans*-1,3-pentadiene did not suppress the formation of the photocycloadducts. These facts indicate that the singlet exciplex is the intermediate in this photocycloaddition reaction.

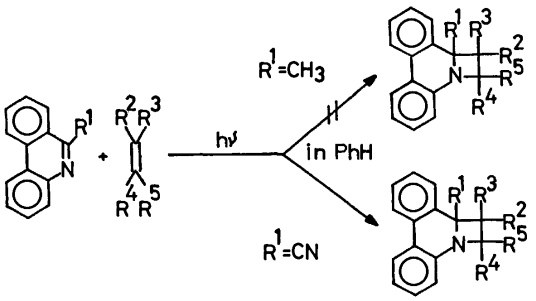
Stereochemistry of 3 and 4. LC analysis and NMR spectroscopy revealed that this photocycloaddition reaction proceeds regiospecifically, but that stereospecificity is low. **4b** was given as a mixture of the stereoisomers. The molar ratio of **A** to **B** is 4:3 in **4ba** and 8:5 in **4bc**. The less sterically hindered **A** predominated over **B**, and the above ratio reflects the ratio of **3**, which is the precursor of **4**. In fact, **3ba** was obtained as a mixture of the stereoisomers in a 5:2 (**3baA**: **3baB**) ratio in benzene. As Scheme 3 shows, the Hb proton of **3baA** appeared at a higher field than that of **3baB**. This is due to the diamagnetic anisotropy of the cyano group, which is *trans* to the Hb proton.[18b] The stereochemical assignment of **4** was based on the fact that the methyl protons(R^5) of the cycloadduct absorb at a magnetic field lower than 1 ppm.[25] This fact indicates that the methyl group (R^5) is *trans* to the aromatic ring.

The reason for the low stereospecificity even *via* the exciplex intermediate is not yet certain. We presume that the oriented structures of the exciplexes in these cases are not bound tightly; also the exciplexes may have two different structural orientations. The lack of any incorporation of **2b** into **3** or **4** suggests that the photodimerization from **2a** to **2b** competes with the photocycloaddition of **1** to **2a** and that the collapse of the exciplex to a biradical which gives a random stereoisomeric mixture of the adducts is unfavorable.

Solvent Effect. As Scheme 5 shows, a clear solvent effect is observed in this reaction. This may be ascribed to the different nature of the S_1 of **1** depending on the solvent. Table 3 clearly shows that the photocycloaddition reaction is governed by the nature of the S_1 of **1**. In ethanol, the emissive S_1 of **1** is of (π,π^*) and can undergo photocycloaddition with **2**. In benzene, the S_1 of **1a** is non-emissive, and its lifetime is considered to be shorter than in ethanol. The unreactive nature of **1a** in benzene may be ascribable to the (n,π^*) character of the S_1 of **1a**, whose short lifetime may be anticipated to be attributable to its non-emissiveness. That would be why **1a** is unreactive toward **2** in benzene. On the other hand, the S_1 of **1b** is of (π,π^*) even in benzene.[7] The simultaneous fluorescence emission and cycloadduct formation in this case support the above explanation.

Scheme 6 shows a plausible reaction scheme of the observed reaction.

In conclusion, we have found the novel photocycloaddition reaction of **1** with **2a** and **2c**. This reaction proceeds from the $^1(\pi,\pi^*)$ state of **1** to give **4** *via* **3**. The exciplex is considered to be the intermediate of **3**. The above reaction is affected by the solvent and by the structure of olefin.



R^2=*p*-Methoxyphenyl, $R^3=R^4=H$, $R^5=CH_3$

Scheme 5. Solvent effect on photocycloaddition of **1** with **2a**.

Applications of Homogeneous Water-gas Shift Reaction. IV. Hydrocarbonylation and Dimerization of Methyl Acrylate with CO and H_2O

Kazuhisa MURATA* and Akio MATSUDA

National Chemical Laboratory For Industry, Tsukuba Research Center, Yatabe, Tsukuba, Ibaraki 305

(Received December 2, 1981)

Hydrocarbonylation of methyl acrylate with CO and H_2O forms dimethyl 4-oxopimelate in 94% yield based on H_2O, the $Co_2(CO)_8$-1,2-bis(diphenylphosphino)ethane (diphos) catalyst system being used as in the case of ethylene or propylene. Increasing temperature tends to promote the dimerization and/or hydrodimerization of methyl acrylate to give 1,3-bis(methoxycarbonyl)-1-butene and/or dimethyl 2-methylglutarate. Effects of CO pressure and H_2O concentration on the hydrocarbonylation and dimerization were examined at 135 and 165 °C. Catalytically active intermediates for the hydrocarbonylation take part in the dimerization of methyl acrylate.

In connection with the synthesis of dialkyl 4-oxopimelate under oxo conditions using transition metal catalyst,[1] only one case is known, where a cobalt-catalyzed hydroesterification of methyl acrylate in the presence of pyridine produces the ketone as a minor product.[2]

Recently, we have described a homogeneous catalysis of hydrocarbonylation of ethylene or propylene with CO and H_2O where the $Co_2(CO)_8$–phosphine system is a catalyst precursor and symmetrical ketones are selectively produced.[3,4]

In the present paper, the applicability of this method to selective synthesis of dimethyl 4-oxopimelate from methyl acrylate is first tested, then an unexpected dimerization of the olefin under identical conditions is described, and finally a possible scheme effective for both hydrocarbonylation and dimerization is discussed in connection with catalytically active intermediates.

Experimental

Materials. Methyl acrylate, acrylonitrile, and H_2O were distilled before use. 1,2-Bis(diphenylphosphino)ethane (diphos) and the solvent were used without further purification. $Co_2(CO)_8$ was prepared by the conventional method.

Reaction Procedure. The hydrocarbonylation (dimerization) reaction was carried out in a 300 cm^3 stainless-steel autoclave. A reaction vessel containing $Co_2(CO)_8$, diphos, H_2O, substrate, and solvent was placed in the autoclave, and after sealing, CO was introduced. The vessel was kept heated with stirring at a reaction temperature for a certain period and then cooled down to room temperature. Liquid products formed were analyzed at 180 °C with a gas chromatograph equipped with an FID using a 4-m squalane column.

Results and Discussion

Typical Examples of Hydrocarbonylation with CO and H_2O. As shown in Table 1, dimethyl 4-oxopimelate[5] was formed in 94% yield based on H_2O when the reaction was carried out in dioxane with an initial CO pressure of 100 kg/cm^2 at 135 °C (Run 6). However, the yield drastically decreased as the methyl acrylate (MA): $Co_2(CO)_8$ ratio was decreased (Runs 4—6). The effectiveness of polar ether solvents for increasing the yield is in the order dioxane > 1,2-dimethoxyethane > THF (Runs 1—3). The use of H_2 as hydrogen donor resulted also in decrease in the yield and methyl 4-oxobutyrate was predominantly produced (Runs 7 and 8). These features of catalytic

$$2CH_2{=}CH\text{-}COOMe + 2CO + H_2O \longrightarrow CO(CH_2CH_2COOMe)_2 + CO_2 \quad (1)$$

behavior are similar to those observed for the hydrocarbonylation of ethylene[3] or propylene.[4] No detectable amounts of other isomers (n-to-iso or iso-to-iso ketone) were formed under these condition. Hydrogenation of MA to methyl propionate occurred (see Table 1, last column). Thus, the $Co_2(CO)_8$–diphos

$$CH_2{=}CH\text{-}COOMe + 2CO + H_2O \longrightarrow OHC\text{-}CH_2CH_2COOMe + CO_2 \quad (2)$$

complex, which is effective for the hydrocarbonylation of ethylene or propylene, was also found to be an active and selective catalyst for the reaction of MA with CO and H_2O to give dimethyl 4-oxopimelate.

$$CH_2{=}CH\text{-}COOMe + CO + H_2O \longrightarrow CH_3CH_2COOMe + CO_2 \quad (3)$$

It has been found that under the conditions employed, dimerization and/or hydrodimerization[6] of MA occur to give 1,3-bis(methoxycarbonyl)-1-butene (unsaturated head-to-tail dimer, UD) and dimethyl 2-methylglutarate (saturated dimer, SD) as identified by ^{13}C NMR and IR spectal analysis,[7] whereas no trace of dimethyl adipate (saturated head-to-head dimer) is formed; thus this is the first example of cobalt-catalyzed dimerization of MA with CO and H_2O.

$$2CH_2{=}CHCOOMe \longrightarrow CH_3CH(COOMe)CH{=}CHCOOMe \quad (4)$$

$$2CH_2{=}CHCOOMe + CO + H_2O \longrightarrow CH_3CH(COOMe)CH_2CH_2COOMe + CO_2 \quad (5)$$

Effect of Temperature. Effects of reaction parameters on product yields were examined by allowing the reaction of MA with $Co_2(CO)_8$ in a 100:2 molar ratio to proceed in dioxane for 4 h using the $Co_2(CO)_8$–diphos catalyst system.

Temperature dependence at 100 kg/cm^2 CO pressure is illustrated in Fig. 1. The yield of dimethyl 4-oxopimelate increased with an increase in tempera-

ture between 120 and 150 °C but decreased thereafter. Considerable amounts of dimers UD and SD as well as methyl propionate were formed at high reaction temperature. In order to examine catalytic properties of dimerization as well as hydrocarbonylation, two reaction temperatures 135 and 165 °C were adopted for varying parameters such as time course, P_{CO}, and P_{H_2O} in the experiments to be described below.

Time Course of Product Formation. As shown in Fig. 2, there was an induction period, similar in trend to those observed for the hydrocarbonylation of ethylene[3] and propylene.[4] Two dimers UD and SD were also formed with the same induction period with the ketone.

Effect of CO Pressure. As illustrated in Fig. 3a (135 °C), the yield of dimethyl 4-oxopimelate is slightyl dependent on CO pressure over the range from 50 to 130 kg/cm². Lowering the pressure reduces the yield because it induces partial decomposition of $Co_2(CO)_8$. At 165 °C, the yield incerased with the increase in CO pressure (Fig. 3b). On the contrary, yields of the two dimers UD and SD as well as methyl propionate decreased with the increase in CO pressure (Fig. 3b).

Effect of H_2O Concentration. The results are shown in Fig. 4a; the yield of the ketone increased with in-

creasing H_2O concentration in the range 30—180 mmol but leveled off thereafter. At 165 °C, the yield increased initially as the H_2O concentration increased from 10 to 60 mmol, but a further increase in H_2O concentration resulted in decrease in the yield (Fig. 4b). The formation of dimer UD showed a H_2O dependence similar to that of the ketone formation, while the formation of dimer SD was steadily accelerated with increase in H_2O concentration. The hydrogenation of MA to methyl propionate was favored at higher H_2O concentrations.

Catalytically Active Intermediates and a Possible Reaction Scheme. Since the hydrocarbonylation of MA with CO and H_2O selectively produces dimethyl 4-oxopimelate (Table 1), catalytically active intermediates responsible for this reaction may be $HCo(CO)_m(diphos)_n$, as in the case of ethylene[3] and propylene.[4] In fact, induction period was observed for the reaction (Fig. 2) and their catalytic characteristics are similar, especially at 135 °C (Figs. 1a, 3a, and 4a).

Dimerization and/or hydrodimerization, by which dimers UD and/or SD were produced from MA, occurred under the conditions described above (Table 1). It seems likely that the intermediates $HCo(CO)_m$-$(diphos)_n$ catalyze the hydrocarbonylation as well as the dimerization. In fact, there was an induction period for the formation of two dimers UD and SD (Fig. 2). Also, a support for the contention was furnished by an experiment in which a catalyst solution, consisting of $Co_2(CO)_8$, diphos, H_2O, and dioxane, and active in the water-gas shift reaction, was prepared at 165 °C[8] and, in the absence of gaseous CO, a stoichiometric reaction of the solution with MA occurred even at room temperature to give both dimethyl 4-oxopimelate and the two dimers UD and

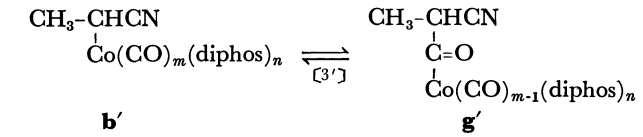
SD.[9,10]

Considering the scheme previously mentioned for the hydrocarbonylation of ethylene,[3] a possible scheme is proposed as Scheme 1, where [2- and 1-(methoxycarbonyl)ethyl]cobalt complexes **c** and **b**,[11] formed by the reaction of $HCo(CO)_m(diphos)_n$ with MA followed by hydride addition, are assumed to be other key imtermediates for the production of the ketone and two dimers; unlike the hydrocarbonylation of ethylene, CO insertion into **b** to yield [2-(methoxycarbonyl)-propionyl]cobalt complex, **g**, would occur very slightly because **g** is a β-dicarbonyl-type complex which is thermally unstable.[12] This is in agreement with the absence of n-to-iso or iso-to-iso ketone as well as methyl 2-methyl-3-oxopropionate (Table 1). At low reaction temperatures, a direct formation of **c** (step [14]) would predominantly occur because the higher selectivity for the ketone is achieved in 135 °C reactions (Table 1);[13] rapid CO insertion followed by MA addition to **d** gives complex **e** and the reaction of **a** with **e** forms dimethyl 4-oxopimelate (Table 1).[14]

Further addition of MA to [1-(methoxycarbonyl)-ethyl]cobalt complex **b** gives [1,3-bis(methoxycarbonyl)butyl]cobalt complex **h**, which undergoes β-elimination to yield 1,3-bis(methoxycarbonyl)-1-butene (dimer UD) and cobalt hydride complex **a**. The reaction of complex **h** with **a** affords dimethyl 2-methylglutarate (dimer SD) and dimeric cobalt complex **f**. Since there was no detectable amount of dimethyl adipate, CO insertion into [2-(methoxycarbonyl)ethyl]-cobalt complex **c** would be rapid and smooth.[15]

Steps [11] and [12] account for the formation of methyl 4-oxo butyrate and methyl propionate, respectively. The resulting complex **f** is converted into **a** by the water-gas shift reaction pathway [13] again, as described in the preceding paper.[3]

To obtain additional information about the catalytically active intermediate **b**, hydrocarbonylation of acrylonitrile was carried out under the same conditions with MA.



b' **g'**

In this case, we expect that CO insertion into (1-cyanoethyl)cobalt complex **b'** (step [3']) can occur to give (2-cyanopropionyl)cobalt complex **g'** and successively give n-to-iso and/or iso-to-iso ketones as well as n-to-n ketone. Satisfactory data are shown in Table 2, through a considerable amount of propionitrile was formed. It is worth noting that there were no detectable amounts of such dimers as 1,3-dicyano-1-butene and 2-methyl glutaronitrile.

Some attempts were tried in vain to isolate complexes **b** and **c** and identify them spectroscopically. Therefore, Scheme 1 needs to be considered as one of some probable schemes for the hydrocarbonylation and dimerization of methyl acrylate with CO and H_2O.

Soc.*, **92**, 7078 (1970):

12) I. Ogata and T. Asakawa, *Kogyo Kagaku Zasshi*, **74**, 1640 (1971).

13) The isomerization of **c** to **b** ([4]) and the successive MA addition ([8]) would considerably occur as temperature rises; this may be responsible partially for the fact that higher temperatures favor the formation of two dimers UD and SD (Fig. 1).

14) There is an alternative route: acyl complex **d** reacts with alkyl complex **c** to yield the ketone and dimeric cobalt complex **f**.

15) MA addition to **c** to give [1,4-bis(methoxycarbonyl)-butyl]cobalt complex **h'** may not be ruled out:

$$\underset{\mathbf{c}}{CH_2XCH_2Co(CO)_m(diphos)_n} \underset{CH_2=CHX}{\rightleftharpoons} \underset{\mathbf{h'}}{CH_2XCH_2CH_2CHXCo(CO)_m(diphos)_n}.$$

However, this step would occur to a lesser extent, because no traces of 1,4-bis(methoxycarbonyl)-1-butene or dimethyl adipate were detected.

Kinetics and Mechanism of Decompositions of *N*-Methyl-*N'*-aryl-*N*-nitrosoureas and Related Compounds in Aqueous Buffer Solution

Kitaro YOSHIDA* and Kazuyuki YANO

Department of Chemistry, Saitama Medical School, 981 Kawakado, Moroyama, Iruma-gun, Saitama 350-04

(Received December 4, 1981)

The decomposition reactions of *N*-methyl-*N'*-aryl-*N*-nitrosoureas (**1**) and of *N,N'*-dimethyl-*N'*-aryl-*N*-nitrosoureas (**2**) were studied kinetically in phosphate buffer solution. All nitrosoureas **1** were easily hydrolyzed even under neutral conditions and the rates of hydrolysis were found to be proportional to the hydroxide ion concentration over pH range 5.4—7.6. General base catalysis by buffer components was negligible. The reaction was subjected to the elimination mechanism in which an abstraction of the ureido proton was involved as an initial step. On the other hand, nitrosoureas **2** had no significant reactivity under the same conditions.

N-alkyl-*N*-nitrosoureas are unstable and are readily hydrolyzed to produce alkanediazohydroxides, which are thought to be active alkylating agents toward genetic material in biological systems.[1] The simplest member of this class of compounds is *N*-methyl-*N*-nitrosourea (MNU). This is known to act as a powerful carcinogen and mutagen without need of enzymatic hydroxylation and its chemical and biological aspects have been well documented.[2]

In earlier work, we synthesized two families of substituted MNU, namely, *N*-methyl-*N'*-aryl-*N*-nitrosoureas (**1a—1c**, **1e**, **1g**) and *N,N'*-dimethyl-*N'*-aryl-*N*-nitrosoureas (**2**), and their mutagenic activities on *S. Typhimurium* TA 1535 were investigated.[3] All *N'*-monosubstituted derivatives (**1**) exhibited the higher mutagenisity than that of MNU, whereas no respectable activity was found for *N',N'*-disubstituted ones (**2**). The study showed that the presence of the proton on *N'* is significant to the mutagenic activity and also that this activity is influenced by the electronic effect of the para substituent X on the phenyl group. The structural and electrostatic natures of these nitrosoureas are thus important factors that govern their biological efficiency. However, the mode of decomposition as well as the intrinsic stability under physiological conditions have been left unclear. Therefore, we undertook a systematic degradation study of these nitrosoureas in neutral aqueous solution and elucidated their hydrolytic mechanism.

Results and Discussion

The decomposition reactions of **1** and **2** were conducted in 0.1 M (1 M=1 mol dm^{-3}) phosphate buffer solution at constant ionic strength. The reaction was followed by monitoring the decrease of UV absorption of the substrate. The observed pseudo-first order rate constants (k) at pH 6.95 are summarized in Table 1.

Table 1 indicates the following features: (a) All *N'*-monosubstituted derivatives (**1**) that contain the labile proton on *N'* were rapidly decomposed even under neutral conditions ($t_{1/2}$=7—19 min at 36.8 °C). On the contrary, *N',N'*-disubstituted derivatives (**2**) in which the proton was replaced by methyl group were markedly stable up to pH 7.6 (see Experimental).

This blocking effect by *N'*-methyl substituent under chemical hydrolytic conditions appears to be correlated with our previous finding in the mutagenic study.[3] (b) The decomposition rates within the series of **1** were in order of the substituent effect of X. Plot of log k against σ gave a positive slope ($\rho=0.65$, $r=0.991$,[4] 36.8 °C) which indicates that decreasing in the electron density at nitrogen atom (*N'*) results in increasing the decomposition rate of **1**.

It is clearly shown that the decomposition rate of every nitrosourea **1** depends on the hydroxide ion concentration (Table 2). The pH-rate profile exhibited positive slopes of exactly 0.94±0.02 over pH range 5.4—7.6 (Fig. 1). This indicates that the reaction can be described in a first order with respect to the hydroxide ion term.[5] Further, changing the buffer concentration at constant pH gave little effect on the observed rate (Table 3). Therefore, general base catalysis by hydrogenphosphate dianion is negligible in comparison with the specific base catalysis.[5]

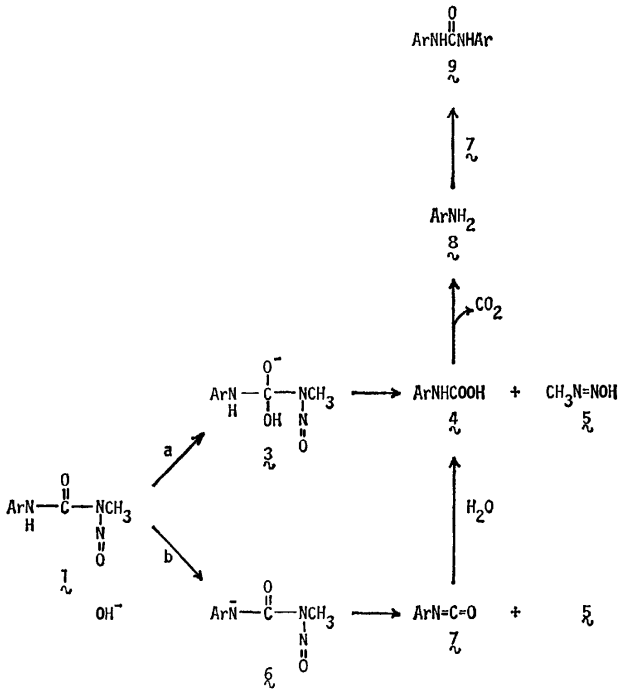
a) **1c** $=1.64\times 10^{-4}$ M, $\mu=0.5$.



On the basis of these kinetic results, two possible mechanisms could be proposed to the aqueous decomposition of **1** as shown in the above scheme. One involves hydroxide ion attack on the carbonyl carbon of **1** to form tetrahedral intermediate **3** (or *via* direct S_N2 displacement), followed by the decomposition of **3** to give arylcarbamic acid **4** and methanediazohydroxide **5** ($B_{AC}2$ type mechanism, path a). The other involves an initial abstraction of the ureido proton by hydroxide ion to produce anion **6** which

releases aryl isocyanate **7** and **5** (E1cB type mechanism, path b). The aryl isocyanate is very reactive in water.[6] Accordingly, **4** may be formed again with this reaction mechanism. Thus, both types of mechanism can represent the same set of products.

The only different feature that distinguishes these two mechanisms is the presence of aryl isocyanate intermediate **7** along the reaction path b. Although **7** is not isolable from aqueous solution, this can be effectively trapped by aniline **8**[6a,7] which is formed from **4**. Degradation of **1c** in 0.1 M phosphate buffer under several pH conditions yielded *N,N'*-diphenylurea **9** as a major product. Undoubtedly, this is a striking evidence of the formation of the aryl isocyanate in the course of the reaction, indicating the occurrence of path b.

Generally, Arrhenius parameters are used to distinguish E1cB from $B_{AC}2$, where the former should show a considerably more positive entropy of activation than the latter.[8] The entropies of activation of **1** were 15—22 e.u. (see Table 1). There was no discernible difference in the kinetic behavior of each compound. Such a value is too large to be assigned to $B_{AC}2$ mechanism.[8b,8c] Consequently, the E1cB pathway is favored. Further, the effect of substituent X on the decomposition rate is relatively small ($\rho=0.65$), showing a close similarity to that reported for the ester hydrolysis involving an isocyanate intermediate ($XC_6H_4NHCOOC_6H_5$, $\rho=0.64$).[9]

Thus, the experimental results listed above are consistent with an interpretation that nitrosoureas **1** first react by the abstraction of the α proton to produce anion **6** and that the nucleophilic attack to the carbonyl group is excluded as possible mechanism. The presence of the isocyanate intermediate during the reaction of **1** may be of interest from the viewpoint of their carbamoylating abilities toward many nucleophiles in cellular environment.[10]

Snyder and Stock reported the aqueous decomposition of *N,N'*-dimethyl-*N*-nitrosourea (DMNU) in basic solution.[2d] This aliphatic nitrosourea represented evidence that the key reaction occurred with carbonyl group as a reaction site. In our neutral conditions, DMNU showed much lower reactivity ($k=6.40\times10^{-6}$ s^{-1}, pH 6.95, $\mu=0.222$, 36.8 °C) than those of **1**. The great increase of the decomposition rate from the aliphatic compound to the aromatic ones ($k_{1c}/k_{DMNU}=128$) can be interpreted in terms of the inductive effect of the aryl group of **1**.[11] The electron-withdrawing effect of the aryl substituent might more stabilize the negative charge on nitrogen (*N'*) and this facilitates the elimination process of **1**.

Our present observation provides the fact that, as in the cases of other reported alkylnitrosoureas,[1d,2d,5] the aqueous decomposition rate of **1** thoroughly depends on the hydroxide ion concentration around neutral pH. Owing to the absence of a labile proton on *N'*, disubstituted derivatives **2** are inert under neutral conditions. This stability of **2** in chemical process appears to limit their mutagenic potency.

Experimental

All melting points were uncorrected. IR spectra were recorded on a Shimadzu IR 400 spectrometer and UV spectra with a Shimadzu UV 200 spectrometer. NMR spectra were taken in acetone-d_6 solutions using a Hitachi R-24 (60 MHz) instrument and chemical shifts are given in δ with TMS as an internal standard. Microanalyses were performed in the microanalytical laboratory of the Institute of Physical and Chemical Research, Wako-shi, Saitama. pH was measured with a Toa-denpa HM-5A pH meter. Doubly distilled water was used for kinetics and buffer reagents were of commercial special grade.

N-Methyl-*N'*-arylureas were synthesized by the condensation reactions[12] of *p*- or *m*-substituted anilines with methyl isocyanate in quantitative yield. *N,N'*-Dimethyl-*N'*-arylureas were prepared from corresponding *N*-methylanilines. The ureas were purified by recrystallization from acetone and were used for subsequent nitrosation reactions. A typical procedure of the nitrosation was as follows.

*N-Methyl-N'-(p-methoxyphenyl)-N-nitrosourea (**1a**)*: To a stirred solution of *N*-methyl-*N'*-(*p*-methoxyphenyl)urea (900 mg, 5 mmol) in acetic acid (10 ml) and acetic anhydride (50 ml) was added sodium nitrite (518 mg, 7.5 mmol) in small portions at 0 °C. The resulting solution was allowed to stand in a refrigerator overnight. The mixture was poured onto ice and extracted with ether three times. The etheral solution was washed with cold 5% sodium hydrogencarbonate solution, dried ($MgSO_4$), and evaporated to give crude product, which was recrystallized from ether–hexane to yield **1a** (355 mg, 34%): mp 97.0—98.0 °C (decomp). Kinetics. The ionic strength of the buffer solution was adjusted with sodium chloride.[14] Thirty microliters of a stock solution of nitrosourea **1** (*ca.* 1.4×10^{-2} M in anhydrous methanol) was added by a microsyringe to 3 ml of the appropriate buffer solution in a thermostatted (±0.3 °C) UV cell. The final methanol concentration was 1% by volume. The disappearence of the characteristic absorption of the substrate (**1a**, 278; **1b**, 270; **1c**, 264; **1d**, 278; **1e**, 268; **1f**, 262; **1g**, 219 nm) was followed at intervals. The infinity reading was obtained after at least eight half lives had elapsed. For all the substrates, the kinetic plots showed good first order behavior up to 90% of the overall reaction. The stabilities of *N',N'*-disubstituted derivatives (**2**) were checked at pH 7.60 and at 36.8 °C. No spectral changes were observed for 52 h and 110 min for **2a** and **2b**, respectively.

Decomposition Products. Nitrosourea **1c** (50 mg) in 5 ml of ether was added to 300 ml of 0.1 M phosphate buffer solution (pH 7.20). The resulting suspension was allowed to stir for 140 min at 37 °C. The mixture was extracted with ether and evaporated to yield essentially pure *N,N'*-diphenylurea **9** [17 mg (57%), mp 238—239 °C, λ_{max} (H_2O) 252 nm]. Similar result was also obtained at pH 5.82 (37 °C, 43 h). An authentic sample of *N,N'*-diphenylurea (carbanilide) was prepared by the reaction of aniline with phenyl isocyanate [mp 238—240 °C,[15] λ_{max} (H_2O) 252 nm].

The authors wish to thank Professor K. Nagamatsu in this laboratory for his encouragement during this work.

Photosensitized *cis-trans* Isomerization of β-Alkylstyrenes

Tatsuo ARAI,* Hirochika SAKURAGI, and Katsumi TOKUMARU
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received December 7, 1981)

Triplet sensitized isomerization of a series of β-alkylstyrenes has been investigated with the use of various sensitizers. Among the olefins employed β-*t*-butyl- and β-*t*-pentylstyrene were found to give remarkably high ratios of the *cis*-isomers (>80%) at the photostationary state. This fact is reasonably attributed to lower rate constants for energy transfer from the triplet sensitizers to the *cis*-isomers than to the *trans*-isomers.

The mechanism of triplet sensitized *cis-trans* isomerization of aromatic olefins has extensively been investigated.[1,2] However, the isomerization of β-alkylstyrenes has scarcely been learned.[3-8] This paper describes the triplet sensitized isomerization of a series of β-alkylstyrenes, that is, β-methyl- (**1**), β-ethyl- (**2**), β-isopropyl- (**3**), β-*t*-butyl- (**4**), and β-*t*-pentylstyrene (**5**)[9] with the use of triplet sensitizers with different triplet energies. Particularly, it was found that β-*t*-butyl- and β-*t*-pentylstyrenes exhibited remarkably high *cis*-isomer ratios at the photostationary state irrespective of the triplet energies of the sensitizers employed. This fact is reasonably attributed to inefficient energy transfer from the triplet sensitizers to the *cis*-isomers of these olefins as described below.[10]

Results and Discussion

Photostationary State Isomer Ratios. Isomeric β-alkylstyrenes, β-methyl-, β-ethyl-, β-isopropyl-, β-*t*-butyl- and β-*t*-pentylstyrene, were irradiated in the presence of sensitizers of various triplet energies in benzene at 26 °C for 2—24 h under degassed conditions with 366-nm light and the resulting photostationary ratios of the *cis*- and *trans*-isomers were accurately determined by GLPC. The pure *cis*- and *trans*-isomers were irradiated in the presence of the sensitizers of higher triplet energies. However, with the sensitizers of lower triplet energies like fluoranthene, benzil, and benz[*a*]anthracene, the irradiation was carried out for mixtures of the *cis*- and *trans*-isomers with compositions close to the photostationary state isomer ratios because of their lower efficiencies for the energy transfer to the olefins. The photostationary state isomer ratios extrapolated to infinite dilution with respect to sensitizer concentration are summarized in Table 1. Figure 1 shows the plots of the photostationary state compositions of these olefins against the triplet energies of the sensitizers employed. As this figure indicates, among the olefins examined, β-methyl-, β-ethyl-, and β-isopropylstyrene show quite similar profiles to that of stilbene[11,12] and confirm a strong similarity in mechanism of the photosensitized isomerization between these three alkylstyrenes and stilbene. On the other hand, β-*t*-butyl- and β-*t*-pentylstyrene exhibit

quite different profiles from the above olefins; the *cis*-isomer ratios are remarkably high for all sensitizers employed. From the profiles in Fig. 1, the triplet excitation energies of the olefins can be estimated to be *ca.* 62 kcal mol^{-1} for the *cis*-isomers and *ca.* 56 kcal mol^{-1} for the *trans*-isomers of β-methyl-, β-ethyl-, and β-isopropylstyrene, and *ca.* 70 kcal mol^{-1} for the *cis*-isomers and *ca.* 60 kcal mol^{-1} for the *trans*-isomers of β-*t*-butyl- and β-*t*-pentylstyrene according to the well known method.[12]

The present photosensitized isomerization is assumed, by analogy with the isomerization of stilbene,[11] to proceed simply through the following processes,

$$S \xrightarrow{h\nu} {}^1S^* \xrightarrow{\Phi_{isc}} {}^3S^* \quad (1)$$

$${}^3S^* \longrightarrow S \quad (2)$$

$${}^3S^* + t \xrightarrow{k_{st}} S + {}^3t^* \quad (3)$$

$${}^3S^* + c \xrightarrow{k_{sc}} S + {}^3c^* \quad (4)$$

$${}^3c^* \longrightarrow {}^3p^* \quad (5)$$

$${}^3t^* \longrightarrow {}^3p^* \quad (6)$$

$${}^3p^* \xrightarrow{k_d} \alpha t + (1-\alpha)c, \quad (7)$$

where S stands for a sensitizer, t, c, and p mean transoid, cisoid, and twisted species, respectively, and α is the decay ratio from the twisted triplets to the *trans*-isomers of the olefins.

Based on the above scheme, the photostationary state composition, $([t]/[c])_{pss}$, is expressed by Eq. 8 and the quantum yields of *trans*-to-*cis* and *cis*-to-*trans* isomerization, $\Phi_{t\to c}$ and $\Phi_{c\to t}$, by Eqs. 9 and 10, respectively.

$$([t]/[c])_{pss} = \frac{k_{sc}}{k_{st}} \frac{\alpha}{1-\alpha} \quad (8)$$

$$\Phi_{t\to c} = \Phi_{isc}(1-\alpha) \quad (9)$$

$$\Phi_{c\to t} = \Phi_{isc}\alpha \quad (10)$$

Equation 8 suggests that the observed high ratios of the *cis*-isomers at the photostationary state of the β-*t*-alkylstyrenes might originate from the following possibilities: (1) The triplet state sensitizer, $^3S^*$, would undergo faster excitation transfer to the *trans*-isomers than to the *cis*-isomers ($k_{st}>k_{sc}$), and/or (2) the twisted triplet states, $^3p^*$, of the olefins would decay more efficiently to the *cis*-isomer than to the *trans*-isomer ($1-\alpha>\alpha$). In order to examine these possibilities attempts were made to determine the rate constants for the energy transfer and the quantum yields for the isomerization.

Rate Constants for Energy Transfer. Determination of the rate constants for triplet excitation transfer to the representative olefins, *cis*- and *trans*-β-methylstyrenes, and β-*t*-butylstyrenes, was undertaken for typical triplet sensitizers, benzophenone and chrysene, at ambient temperature. The rate constants for quenching of phosphorescence of benzophenone with these olefins were measured in carbon tetrachloride with the single photon counting technique, and quenching rate of the triplet-triplet absorption of chrysene with the olefins were determined in cyclohexane by the flash photolysis technique. The measured rate constants are summarized in Table 2.

Table 2. Rate constants for quenching of excited triplet sensitizers by β-alkylstyrenes in benzene[a]

Sensitizer	Olefin	k_{st}/l mol^{-1} s^{-1}	k_{sc}/l mol^{-1} s^{-1}
Chrysene	PhCH=CHMe	5.4×10^7	8.8×10^6
	PhCH=CHBu^t	1.1×10^7	6.2×10^5
Benzophenone	PhCH=CHMe	1.95×10^9	1.21×10^9
	PhCH=CHBu^t	1.21×10^9	1.25×10^8

a) At ambient temperature.

As Table 2 indicates, in the case of β-methylstyrenes, triplet benzophenone (E_T=68.6 kcal mol^{-1})[13] transfers excitation energy to both *cis*- and *trans*-isomers with nearly diffusion-controlled rate constants, but slightly less efficiently to the *cis*-isomer; however, the excitation transfer from triplet chrysene (E_T=56.6 kcal mol^{-1})[13] is much slower than the diffusion-controlled rate and the rate constant for the *cis*-isomer is six times smaller than to the *trans*-isomer. As for the excitation transfer to β-*t*-butylstyrenes, even when benzophenone was used as a sensitizer, the rate constant for the *cis*-isomer is about ten times lower than that for the *trans*-isomer. The magnitude of the rate constants is in good agreement with the aforementioned estimate of the triplet excitation energies of the olefins and suggests that the remarkably high composition of the *cis*-isomer of the β-*t*-alkylstyrenes at the photostationary state is mostly due to the smaller energy transfer rate constants from the triplet sensitizers to the *cis*-isomers.

Furthermore, the results in Table 2 indicate that the rate constants of the energy transfer are governed not only by the *exo*- and *endo*-thermicity of the processes but also by the steric effects exerted from the crowded olefins on approach to the triplet sensitizers. Thus, triplet benzophenone undergoes energy transfer to *cis*-β-methylstyrene about 1.6 times more slowly than to its *trans*-isomer. From the results of photoelectron spectroscopy, *cis*-β-methylstyrene is presumed to take a conformation where its benzene ring is twisted about 20° from the C=C molecular plane.[14] Therefore, the slower rate of energy transfer to the *cis*-isomer might be caused by the steric effect exerted by its twisted conformation to prevent the approach of the triplet sensitizer.[15] Also, the energy transfer rate from triplet benzophenone to *trans*-β-*t*-butylstyrene is about 1.6 times lower than to *trans*-β-methylstyrene. *trans*-β-*t*-Butylstyrene takes a planar conformation similar to that of *trans*-β-methylstyrene.[14] Accordingly, the triplet excitation energy of *trans*-β-*t*-butylstyrene will be close to that of *trans*-β-methylstyrene, 59.8 kcal mol^{-1} as reported by Lamola and Hammond[8] or less as suggested by the profile in Fig. 1. These results clearly indicate that in the energy transfer from triplet benzophenone the presence of the bulky *t*-butyl group in β-*t*-butylstyrene exerts steric hindrance to reduce the rate for accepting triplet energy as compared to the case of *trans*-β-methylstyrene. Herkstroeter, Jones, and Hammond showed the steric effect exerted in energy transfer from triplet states of sterically hindered benzophenones to stilbene.[16] The

Table 3. Quantum yield of isomerization of β-*t*-butylstyrene[a)]

Sensitizer	Sensitizer concn / mol l^{-1}	Olefin concn / mol l^{-1}	$\Phi_{t\to c}/\Phi_{isc}$	$\Phi_{c\to t}/\Phi_{isc}$

		∞		0.24[b)]

a) In benzene at 26 °C. b) Quantum yield extrapolated to infinite olefin concentration.

present results provide an example of steric effects brought about by triplet energy acceptors on the energy transfer process.

The energy transfer rate from triplet benzophenone to *cis*-β-*t*-butylstyrene is about ten times lower than that to *trans*-β-*t*-butylstyrene. *cis*-β-*t*-Butylstyrene is presumed by PES to take a conformation where its benzene ring is twisted about 70° from the C=C molecular plane.[14] The highly twisted conformation will increase its triplet excitation energy to make the energy transfer from triplet benzophenone endothermic and will sterically hinder the approach of the triplet sensitizer.

Quantum Yields. Table 3 summarizes typical results of the quantum yields for the isomerization of β-*t*-butylstyrenes using benzophenone and 2-acetylnaphthalene as sensitizers. Both sensitizers give nearly the same value, 0.5±0.05, for $\Phi_{t\to c}/\Phi_{isc}$, which means that the energy transfer effectively takes place from the triplets of both sensitizers to the *trans*-isomer. The above value is in good agreement with the results of β-methylstyrene with various sensitizers reported by Caldwell.[3] The value for $\Phi_{c\to t}/\Phi_{isc}$ is nearly 0.25 in benzophenone sensitization almost irrespective of the olefin concentration. However, in 2-acetylnaphthalene sensitization, the value tends to increase with the olefin concentration, and leads to 0.24 by extrapolation to infinite olefin concentration, which agrees well with the above value for benzophenone sensitization. However, the value for $\Phi_{c\to t}/\Phi_{isc}$ thus obtained remains still nearly half of $\Phi_{t\to c}/\Phi_{isc}$.

This quantum inefficiency in the *cis*-to-*trans* process would result from formation of a *cis*-olefin-sensitizer exciplex followed by its decay to the *cis*-olefin as suggested by Caldwell[3,17] in the sensitized isomerization of β-methylstyrene with low energy sensitizers.

Effects of Sensitizer Concentration, Azulene, and Oxygen. Quenching of excited states with a number of species including ground-state sensitizers, azulene, and oxygen can serve to explore triplet energy surfaces of olefins as investigated on stilbene.[18,19]

These processes are expressed by Eqs. 11—14, where Az stands for azulene. The quenching of the *trans* triplet, $^3t^*$, by azulene might be an energy transfer process, and the quenching of $^3t^*$ by oxygen, if it takes place, should be energy transfer, but the quenching of the twisted triplet, $^3p^*$, by oxygen might be enhancement of the intersystem crossing from $^3p^*$ to a ground state with twisted geometry and this quenching cannot affect the photostationary state isomer ratios. Reactions 11, 12, and 14 were inferred to occur actually for stilbene.[18,19]

$$^3t^* + S \xrightarrow{k_{ts}} t + {}^3S^* \quad (11)$$

$$^3t^* + Az \xrightarrow{k_{az}} t + {}^3Az^* \quad (12)$$

$$^3t^* + O_2 \xrightarrow{k_{ot}} t + O_2 \quad (13)$$

$$^3p^* + O_2 \xrightarrow{k_{op}} \alpha t + (1-\alpha)c + O_2 \quad (14)$$

In the present investigation, attempts were done to examine the effects of azulene, oxygen, and sensitizer concentration on the photostationary isomer ratios in benzophenone-sensitized isomerization of β-methyl- and β-*t*-butylstyrene. However, no measurable effect was observed. This fact agrees with a previous result that azulene did not affect the photostationary isomer ratios in benzophenone-sensitized isomerization of β-methylstyrene.[20] The above results for the β-alkylstyrenes are in contrast with the results of stilbene, for which azulene and the sensitizer concentration are effective to change the photostationary isomer ratio.[18] Therefore, for β-alkylstyrenes, Reactions 11, 12, and 13 are unimportant, although Reaction 14 might be operative. The present results suggest that the *trans* as well as *cis* triplets of the β-alkylstyrenes are alive in too short lifetimes to be quenched by azulene, sensitizer, or oxygen, and undergo rapid relaxation into the twisted triplets which are incapable of being quenched by azulene. This mechanism is in contrast with the *trans* triplets of stilbene.[18]

Experimental

The NMR spectra and UV spectra were recorded on a JEOL JNM-MH-100 spectrometer and a Hitachi 200-20 spectrophotometer, respectively. Gas-liquid chromatographic analysis was performed on a Shimadzu GC-4CM-PF gas chromatograph equipped with an FID and a Hitachi K53 gas chromatograph equipped with a TCD was used for preparative purposes.

Materials. Isomeric β-methyl- (**1**), β-ethyl- (**2**), and β-*t*-butylstyrenes (**4**), were prepared as described previously.[13] A mixture of *cis*- and *trans*-β-isopropylstyrene (**3**) was prepared from 2-methylpropanal and benzyltriphenylphosphonium bromide according to literature.[21] Pure *cis*- and *trans*-**3** were separated by GLPC (polyethylene glycol 20 M (10%)). A mixture of *cis*- and *trans*-β-*t*-pentylstyrene (**5**) was similarly prepared. Pure *cis*- and *trans*-**5** were separated by column chromatography. Their structures were identified by NMR spectroscopy. The purity of all the samples was more than 99% as determined by GLPC (polyethylene glycol 20 M (5%)). These olefins were distilled under reduced pressure before use.

cis-**5**, bp 80—82 °C/12 Torr (1 Torr=133.322 Pa); NMR (CCl_4): δ 0.82 (t, J=6.0 Hz, 3H, C=C–C–C–CH_3), 0.88 (s, 6H, C=C–C(CH_3)$_2$–), 1.31 (q, J=6.0 Hz, 2H, C=C–C–CH_2–), 5.40 (d, J=12.6 Hz, 1H, Ph–C=CH–), 6.40 (d, J=12.6 Hz, 1H, PhCH=C–), 7.09 (m, 5H, aromatic H); Found: C, 89.73; H, 10.50%. Calcd for $C_{13}H_{18}$: C, 89.58; H, 10.41%.

trans-**5**, bp 84—86 °C/12 Torr; NMR (CCl_4): δ 0.85 (t, J=7.0 Hz, 3H, C=C–C–C–CH_3), 1.07 (s, 6H, C=C–C–(CH_3)$_2$–), 1.51 (q, J=7.0 Hz, 2H, C=C–C–CH_2–), 6.08 (d,

J=16.0 Hz, 1H, PhC=CH–), 6.23 (d, J=16.0 Hz, 1H, Ph–CH=C–), 7.25 (m, 5H, aromatic H). Found: C, 89.54; H, 10.49%. Calcd for $C_{13}H_{18}$: C, 89.58; H, 10.41%.

Benzene was purified by distillation. Aromatic hydrocarbons used as sensitizers were purified by column chromatography and recrystallization. Acetophenone and 3'-methoxyacetophenone were purified by distillation. Other aromatic ketones were purified by recrystallization.

Determination of the Photostationary State Isomer Ratios on Irradiation of 366-nm Light. Benzene solutions (3 ml) of a desired concentration of a sensitizer and *cis-* and *trans-β*-alkylstyrenes in Pyrex tubes were degassed using freeze-thaw cycles under about 10^{-5} Torr, and irradiated for 2—24 h by a 1 kW high pressure mercury lamp immersed in a Pyrex cooling well and further surrounded by Toshiba UV-D36B glass filters using a merry-go-round type Riko RH400-10W rotary photochemical reactor. The glass filters were used for isolation of the 366-nm line. The isomer ratios of *cis-* and *trans-β*-alkylstyrenes were determined by GLPC analysis. The following columns were used for quantitative analysis: polyethylene glycol 20 M (5%), Thermon 1000 (5%), and Silicone XF-1150 (5%).

Quantum Yield Measurements Using 366-nm Light. Benzene solutions of either a pure *cis* or *trans* substrate and a sensitizer in Pyrex tubes were degassed by freeze-thaw cycles and were irradiated in parallel with a 400 W high pressure mercury lamp surrounded by Toshiba UV-D36B glass filters using a merry-go-round type reactor. Light intensity was determined by benzophenone-benzhydrol actinometry using the method of Moore and Ketchum.[21] After being irradiated for 10 min the tubes containing the actinometry solutions were opened, and the contents were diluted with benzene and analyzed by UV spectroscopy. The total period of irradiation was adjusted so that usually 2—8% of an isomer was converted and the conversion was determined quantitatively by GLPC analysis.

Measurements of Photostationary State Isomer Ratios in the Presence of Azulene and/or Oxygen. Benzene solutions containing benzophenone (0.1 mol l^{-1}) and a *cis-* or *trans-β*-alkylstyrene and varying amounts of azulene (0.01—0.03 mol l^{-1}) in Pyrex tubes were degassed, aerated, or saturated with oxygen and irradiated for 2 h by a 1 kW high pressure mercury lamp surrounded by Toshiba UV-D36B glass filters using a merry-go-round type reactor. The isomer ratios of *cis-* and *trans-β*-alkylstyrenes were determined by GLPC analysis.

Rate Constants for Energy Transfer from Triplet Benzophenone to β-Alkylstyrenes. Phosphorescence lifetimes of benzophenone (1.1×10^{-3} mol l^{-1}) were measured in carbon tetrachloride at ambient temperature using a single photon counting apparatus, an Applied Photophysics SP-3X system, in the absence and in the presence of varying concentrations of *cis-* and *trans-β*-methyl- and *β-t*-butylstyrenes. The solutions were deaerated by bubbling with argon for more than 30 min. The phosphorescence lifetime of benzophenone monitored at 452 nm in this solvent in the absence of quenchers was 23 μs and the lifetime was diminished by addition of the quenchers. The energy transfer rate constants were calculated from these experiments.

Rate Constants for Energy Transfer from Triplet Chrysene to β-Alkylstyrenes. Rate constants for energy transfer from triplet chrysene to *cis-* and *trans-β*-methyl- and *β-t*-butylstyrenes were obtained by the measurements of lifetimes of the triplet-triplet absorption of chrysene monitored at 570 nm on a conventional flash photolysis apparatus (Applied Photophysics).

††† *School of Medicine, Kinki University, Sayama-cho, Osaka 589*

(Received December 7, 1981)

Three new bitter diterpenoids, shikokianoic acid, shikokianal acetate, and 16,17-epoxyshikokianal acetate, have been isolated from the leaves of *Rabdosia shikokiana* (Makino) Hara. Their structures were established on the basis of spectral and chemical evidence.

In the previous paper,[1] we reported the structures of three *ent*-kaurenoids, rabdosianin A, B, and C, isolated from *Rabdosia shikokiana* (Makino) Hara. Our continuing search for bitter principles in this plant has now led to the isolation of three new diterpenoids, designated as shikokianoic acid, shikokianal, and 16,17-epoxyshikokianal, the last two as their acetates. The present paper deals with the structural elucidation of these new compounds.

Shikokianoic acid (**1**), $C_{24}H_{32}O_9$, mp 134—135 °C, $[\alpha]_D^{20}$ +3° (*c* 0.35, $CHCl_3$), was isolated as colorless flakes in 0.005% yield from the ether extract of the dried leaves by extensive column chromatography. It showed IR absorptions indicative of hydroxyl (3620, 3520) and carboxyl (3200—2500, and 1702 cm^{-1}) groups, and formed a triacetate (**2**), $C_{26}H_{34}O_{10}$, mp 144—145 °C, on acetylation with pyridine–acetic anhydride and a methyl ester (**3**), $C_{25}H_{34}O_9$, mp 224—226 °C, by treatment with diazomethane. The 400 MHz ^1H NMR spectrum showed signals due to two tertiary methyl groups at δ 1.00 and 1.22, two acetyl groups at δ 2.02 and 2.22, one methine proton on an oxygenated carbon atom at δ 3.94 (ddd, J=11.3, 9.2, and 8.4 Hz), one oxygenated methyl group at δ 4.62 and 5.00 (each d, J=12.7 Hz), two methine protons attached to carbon atoms bearing an acetoxyl group at δ 5.13 (dd, J=8.1 and 8.1 Hz) and 5.54 (dd, J=2.7 and 2.5 Hz), and one terminal methylene group at δ 5.00 (dd, J=2.5 and 0.8 Hz) and 5.21 (dd, J=2.7 and 0.8 Hz). In addition, extensive ^1H NMDR studies, summarized in Table 1, revealed the presence of the partial structures (**A**) and (**B**), the latter showing the following long-range couplings: $J_{H_{13},H_{17a}}=J_{H_{13},H_{17b}}=0.8$ Hz, $J_{H_{15},H_{17a}}=2.5$ Hz, and

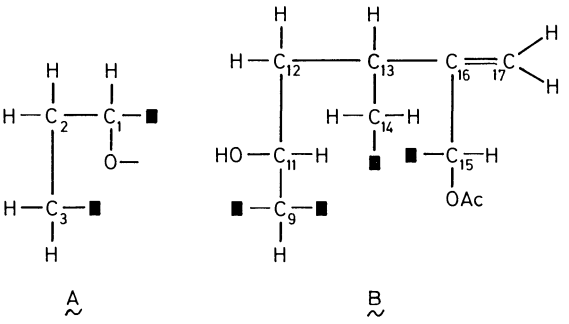
a) The spectra were measured at 100.61 MHz in $CDCl_3$ solutions and the shifts are given in ppm (δ) relative to the internal TMS. Assignments were made by off-resonance and selective proton-noise decoupling techniques. b) These assignments may be interchanged.

$J_{H_{15},H_{17b}}$=2.7 Hz. The ^{13}C NMR data (Table 2) showed the presence of one lactonic and one carboxylic carbon atoms (δ 173.4 and 173.9) along with four methylene groups, three methine groups, three oxygen-bearing methine groups, and three quaternary carbon atoms.

The spectral data and the analogy with the congeners isolated from *Rabdosia* species[1,2] suggested a B-seco-*ent*-kaurene type structure for shikokianoic acid, in which the partial structure (**A**) would form the A-ring and (**B**) the C- and D-rings. In the ^1H NMR spectrum of **3**, the chemical shifts of 18- and 19-methyl signals (δ 0.91 and 1.19) and the splitting pattern of the signal due to the methine proton on an oxygenated carbon atom in A-ring (dd, J=9.1 and 6.7 Hz) revealed that the location of the oxy linkage in A-ring is $C_{1\alpha}$ in analogy with isodonal (**4**).[2a,3] The β-configuration of the secondary hydroxyl group at C_{11} in **1** was evident from the coupling pattern and the large J values of H_{11} signal (ddd, $J_{H_9,H_{11}}$=11.3 Hz, $J_{H_{11},H_{12\alpha}}$=8.4 Hz, and $J_{H_{11},H_{12\beta}}$=9.2 Hz). The corresponding signal of shikodonin (**5**),[2b] in which the hydroxyl group at C_{11} is α-oriented, appeared as a doublet of doublets ($J_{H_9,H_{11}}$=6.0 Hz and $J_{H_{11},H_{12\alpha}}$=15.0 Hz).

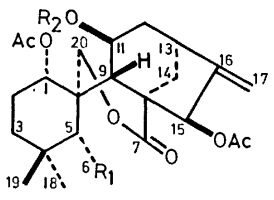


A B

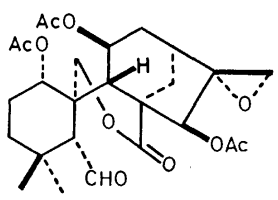
The treatment of **2** with diazomethane gave a methyl ester (**6**), $C_{27}H_{36}O_{10}$, mp 216—218 °C. The catalytic hydrogenation of **6** yielded a dihydro compound (**7**), $C_{27}H_{38}O_{10}$, mp 245—248 °C, as the major product. It is well known that the hydrogenation of the C_{16} double bond in such a skeleton occurs from the less hindered α-side and, hence, the newly introduced secondary methyl group must be β-oriented.[4] The ^1H NMR spectrum of **7** showed a signal of H_{15} as a doublet at δ 5.08 (J=10.5 Hz), the large J value of which defined the configuration of the acetoxyl group at C_{15} as β.[4] Of the positions of the carboxyl group in **1**, C_6 and C_7, possible from biogenetic considerations, the latter is rejected by the IR spectrum of **1** which did not show the presence of a γ-lactone but of a δ-lactone (1738 cm^{-1}). If the carboxyl group was settled on C_7 position, a γ-lactone should be formed at C_6–C_1 or C_6–C_{20}.

The position of closure of the lactone ring remained to be assigned and this was done by the scrutiny of ^1H NMR data and the study of the nuclear Overhauser effect (NOE). The preceding discussion limited this to C_7–C_1 and C_7–C_{20}. The signals of H_1 and H_5 in **2** were shifted upfield, as compared with those of **1**, and the degree of the shift of both signals was identical [δ(**2**)−δ(**1**)=−0.47 ppm]. This fact suggested that the hydroxyl group in **1** is situated at equal distances from both H_1 and H_5. In addition, irradiation at the resonance of H_{11} under NOE condition did not lead to a significant change in signal intensity of H_5, while irradiation at the resonance of H_1 produced a clear and reproducible enhancement of the intensity of H_{11} (11%) and H_5 (4%) signals. This fact revealed that H_{11} is disposed across H_1 from H_5. These observations, combined with the examination of the model, can be satisfied only by the closure of the lactone ring at C_7–C_{20}. From the evidence outlined above, we proposed the structure **1** for shikokianoic acid.

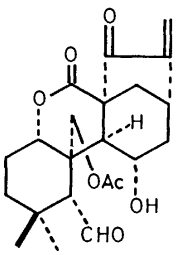
Shikokianal acetate (**8**), $C_{26}H_{34}O_9$, mp 192—194 °C, $[\alpha]_D^{20}$ +89° (*c* 0.26, $CHCl_3$), was isolated in 0.021% as white needles by the acetylation of a crude fraction and exhibited spectral data quite similar to those of **1**, except for the following observations. The IR spectrum did not show the presence of the hydroxyl and carboxyl groups present in **1** and, instead, showed the presence of a formyl group at 2740 and 1718 cm^{-1}. The ^1H NMR spectrum contained the signals of three acetoxyl groups, one more than those of **1**, and a grouping $-\underset{|}{C}H-CHO$ [δ 3.19 and 9.99 (each d, J=



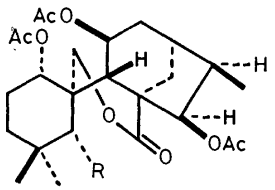
1 R_1 = COOH, R_2 = H
2 R_1 = COOH, R_2 = Ac
3 R_1 = COOMe, R_2 = H
6 R_1 = COOMe, R_2 = Ac
8 R_1 = CHO, R_2 = Ac



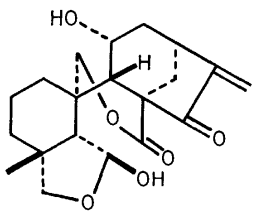
10



4



7 R = COOMe
9 R = CHO



5

2.7 Hz)], the latter suggesting the location of the formyl group at C_6.[2a] These facts and the pertinent ^{13}C NMR data (Table 2) suggest that **8** has a structure close to that of **1**, in which the carboxyl and hydroxyl groups in **1** are displaced by the formyl and acetoxyl groups, respectively. This was confirmed by the chemical correlation of **8** with **1**. The catalytic hydrogenation of **8** gave a dihydro compound (**9**), $C_{26}H_{36}O_9$, mp 210—212 °C. The oxidation of **9** with Jones' reagent, followed by methylation with diazomethane, yielded a methyl ester (**7**), which was found to be identical with the compound derived from **1** as described above. Consequently, shikokianal acetate must be represented by structure **8**.

16,17-Epoxyshikokianal acetate (**10**), $C_{26}H_{34}O_{10}$, mp 205—206.5 °C, $[\alpha]_D^{20}$ +66° (*c* 0.32, $CHCl_3$), was isolated in 0.002% yield as colorless flakes by the acetylation of a crude fraction near shikokianal, the natural precursor of **8**. The spectral data suggested that the relationship of **8** to **10** was that of a olefin to the corresponding epoxide. In particular, the ^1H NMR spectrum of **10** contained signals due to a methylene group in an epoxide ring at δ 2.77 and 2.93 (each d, J=4.6 Hz) and lacked signals of an exocyclic methylene group, while the ^{13}C NMR spectrum contained two signals attributable to an epoxide moiety at δ 70.5 (s) and 48.8 (t). The structure of **10** was confirmed by its correlation with **8**. Thus, the treatment of **8** with *m*-chloroperbenzoic acid gave an epoxide, which was identical with **10** in all respects. This conversion also determines the configuration at C_{16} in **10**. Since the epoxidation of C_{16} double bond in such a compound is assumed to occur on the less hindered side of the molecule, the introduced oxygen atom must be α-oriented. Therefore, structure **10** is assigned to 16,17-epoxyshikokianal acetate. **10** is the first compound of *Rabdosia* diterpenoids which has an epoxide functionality at C_{16}–C_{17}.

Experimental

For general experimental details see Ref. 1.

Isolation. The ether extract (210 g)[1] of the dried leaves of *Rabdosia shikokiana* (Makino) Hara was subjected to chromatography over silicic acid (1.50 kg) eluting with $CHCl_3$–MeOH mixtures, with MeOH increasing from 0 to 10%. Elution with 5% MeOH in $CHCl_3$ gave a fraction (26.7 g) which was rechromatographed over silicic acid (900 g), using 50% ethyl acetate in petroleum ether, to yield a mixture of shikokianal and 16,17-epoxyshikokianal (7.10 g), and a fraction of shikokianoic acid (**1**) (718 mg). The former mixture was treated with acetic anhydride (30 ml) and pyridine (30 ml) at room temperature for 4 d and then worked up in the usual way. The resulting precipitates (3.10 g) were chromatographed over silicic acid (100 g), with ether as eluent, to give shikokianal acetate (**8**) (1.15 g) and 16,17-epoxyshikokianal acetate (**10**) (285 mg).

Shikokianoic Acid (1). The crude fraction was recrystallized from petroleum ether–ethyl acetate to give colorless flakes (262 mg), mp 134—135 °C, $[\alpha]_D^{20}$ +3° (*c* 0.35, $CHCl_3$); IR (nujol) 3620, 3520, 3200—2500, 1740, 1702, 1620, 1240, and 898 cm^{-1}; ^1H NMR (see Table 1); ^{13}C NMR (see Table 2); MS *m/e* 464 (M^+), 446 (M^+-H_2O), 422, 404 (M^+—AcOH), 386 (M^+-H_2O–AcOH), 362, and 344 (M^+—2AcOH). Found: C, 59.53; H, 6.99%. Calcd for $C_{24}H_{32}O_9\cdot H_2O$: C, 59.74; H, 7.10%.

Shikokianal Acetate (8). The crude material was recrystallized from EtOH to yield white needles (970 mg), mp 192—194 °C, $[\alpha]_D^{20}$ +89° (*c* 0.26, $CHCl_3$); IR (Nujol) 2740, 1760, 1740, 1718, 1660, 1240, and 915 cm^{-1}; ^1H NMR (see Table 1); ^{13}C NMR (see Table 2); MS *m/e* 490 (M^+), 448, 430 (M^+—AcOH), 388, 374, 370 (M^+—2AcOH), 360, 346, 328, 310 (M^+—3AcOH), and 300. Found: C, 63.33; H, 6.94%. Calcd for $C_{26}H_{34}O_9$: C, 63.66; H, 6.99%.

16,17-Epoxyshikokianal Acetate (10). The crude substance was recrystallized from ether-CH_2Cl_2 to afford colorless flakes (186 mg), mp 205—206.5 °C, $[\alpha]_D^{20}$ +66° (*c* 0.32, $CHCl_3$); IR (Nujol) 2755, 1745, 1730, 1720, 1230, and 908 cm^{-1}; ^1H NMR (see Table 1); ^{13}C NMR (see Table 2). Found: C, 61.46; H, 6.68%. Calcd for $C_{26}H_{34}O_{10}$: C, 61.65; H, 6.77%.

Acetylation of 1. A solution of **1** (30 mg) in acetic anhydride (1 ml) and pyridine (1 ml) was allowed to stand at room temperature for 2 d and then worked up in the usual way to give white precipitates (27 mg) which were subsequently recrystallized from ether–petroleum ether to yield a triacetate (**2**) as colorless needles (20 mg), mp 144—145 °C; IR (Nujol) 3200—2500, 1750, 1720, and 1220 cm^{-1}; ^1H NMR δ 1.03 and 1.16 (3H each, s, 18- and 19-Me), 2.04, 2.11, and 2.24 (3H each, s, 3Ac), 2.74 (1H, d, J=11.6 Hz, H_9), 3.20 (1H, s, H_5), 4.66 (1H, dd, J=11.0 and 4.3 Hz, H_1), 4.88 (1H, ddd, J=11.6, 8.5, and 8.5 Hz, H_{11}), 4.90 and 4.94 (1H each, d, J=12.8 Hz, H_{20}), 5.00 (1H, dd, J=2.4 and 1.2 Hz, H_{17a}), 5.21 (1H, dd, J=2.8 and 1.2 Hz, H_{17b}), and 5.58 (1H, dd, J=2.8 and 2.4 Hz, H_{15}). Found: C, 59.84; H, 6.81%. Calcd for $C_{26}H_{34}O_{10}\cdot 3/4H_2O$: C, 60.05; H, 6.88%.

Methylation of ***1***. A solution of **1** (60 mg) in ether (3 ml) was treated with ethereal diazomethane solution in the usual manner and the residue was recrystallized from ether–petroleum ether to give a methyl ester (**3**) as colorless plates (42 mg), mp 224—226 °C; IR ($CHCl_3$) 3580, 1735, 1220, and 902 cm^{-1}; ^1H NMR δ 0.91 and 1.19 (3H each, s, 18- and 19-Me), 2.02 and 2.27 (3H each, s, 2Ac), 2.22 (1H, dd, J=11.6 and 1.2 Hz, H_9), 3.72 (3H, s, OMe), 3.73 (1H, s, H_5), 3.84 (1H, ddd, J=11.6, 9.5, and 7.9 Hz, H_{11}), 4.69 (1H, dd, J=12.8 and 1.2 Hz, H_{20a}), 4.96 (1H, br s, H_{17a}), 4.98 (1H, d, J=12.8 Hz, H_{20b}), 5.14 (1H, dd, J=2.8 and 1.2 Hz, H_{17b}), 5.16 (1H, dd, J=9.1 and 6.7 Hz, H_1), and 5.54 (1H, dd, J=2.8 and 2.4 Hz, H_{15}). Found: C, 62.82; H, 7.19%. Calcd for $C_{25}H_{34}O_9$: C, 62.75; H, 7.16%.

Methylation of ***2***. A solution of **2** (35 mg) in ether (2 ml) was treated with ethereal diazomethane solution as described above and the product was recrystallized from ether–petroleum ether to yield a methyl ester (**6**) as colorless plates (34 mg), mp 216—218 °C; IR (Nujol) 1755, 1725, 1220, and 910 cm^{-1}. Found: C, 62.37; H, 6.82%. Calcd for $C_{27}H_{36}O_{10}$: C, 62.29; H, 6.97%.

Hydrogenation of ***6***. A mixture of **6** (34 mg) and 10% Pd–C (30 mg) in EtOH (3 ml) was stirred under a hydrogen atmosphere at room temperature for 12 h. The catalyst was removed by filtration and the filtrate was evaporated. The residue was recrystallized from ether–petroleum ether to give a dihydro compound (**7**) as white needles (26 mg), mp 245—248 °C; IR (Nujol) 1745, 1730, and 1225 cm^{-1}; ^1H NMR δ 0.83 (3H, d, J=7.6 Hz, 17-Me), 0.93 and 1.15 (3H each, s, 18- and 19-Me), 2.02, 2.13 ,and 2.25 (3H each, s, 3Ac), 2.60 (1H, d, J=11.9 Hz, H_9), 2.69 (1H, ddq, J= 10.5, 7.6, and 7.3 Hz, H_{16}), 3.19 (1H, s, H_5), 3.75 (3H, s, OMe), 4.64 (1H, dd, J=10.8 and 4.3 Hz, H_1), 4.82 (1H, ddd, J=11.9, 8.9, and 7.8 Hz, H_{11}), 4.93 and 5.01 (1H each, d, J=13.0 Hz, H_{20}), and 5.08 (1H, d, J=10.5 Hz, H_{15}). Found: C, 62.06; H, 7.40%. Calcd for $C_{27}H_{38}O_{10}$: C, 62.05; H, 7.33%.

Hydrogenation of ***8***. A mixture of **8** (52 mg) and 10% Pd–C (50 mg) in EtOH (5 ml) was treated under a hydrogen atmosphere as described above and the residue was recrystallized from EtOH to afford a dihydro compound (**9**) as colorless plates (35 mg), mp 210—212 °C; IR (Nujol) 1755, 1740, 1725, 1715, and 1225 cm^{-1}; ^1H NMR δ 0.83 (3H, d, J=7.5 Hz, 17-Me), 1.07 and 1.09 (3H each, s, 18- and 19-Me), 1.95, 2.07, and 2.21 (3H each, s, 3Ac), 5.07 (1H, d, J=10.2 Hz, H_{15}), and 9.93 (1H, d, J=2.2 Hz, H_6). Found: C, 63.32; H, 7.26%. Calcd for $C_{26}H_{36}O_9$: C, 63.40; H, 7.37%.

Conversion of ***9*** *into* ***7***. To a solution of **9** (30 mg) in acetone (2 ml) were added two drops of Jones' reagent with ice cooling. The mixture was stirred for 5 h at 0 °C, then worked up by dilution with water (20 ml), and extracted with ethyl acetate. The organic layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. The amorphous residue was dissolved in ether (3 ml) and treated with ethereal diazomethane solution as described above. The product was recrystallized from ether–petroleum ether to give a methyl ester (18 mg) which was identified by mixed mp, IR, and ^1H NMR comparison with **7**.

Epoxidation of ***8***. A mixture of **8** (100 mg) and *m*-$ClC_6H_4CO_3H$ (40 mg) in dichloromethane (3 ml) was stirred at room temperature for 42 h under nitrogen atmosphere. The reaction mixture was worked up in the usual way and the product was chromatographed over silicic acid (8 g) with ether as eluent to yield an epoxide (46 mg) which was found to be identical with **10** in all respects.

We are grateful to Mr. Hideo Mori, Laboratories of Natural Products Chemistry, Otsuka Pharmaceutical Co. Ltd., for recording the mass spectra.

Bis(2,4-pentanedionato)phenylchromium(III). Preparation and Reactions with Organic Carbonyl Compounds and Alcohols

Takashi Ito,*,† Tsukasa Ono, Kazunori Maruyama, and Akio Yamamoto*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received December 21, 1981)

A phenylchromium complex $CrPh(acac)_2$ (**1**) (acac=2,4-pentanedionato ligand) was prepared from $Cr(acac)_3$ and $AlPh_3 \cdot Et_2O$. Complex **1** reacts with acetone to give benzene, 2-phenyl-2-propanol, and mesityl oxide and is converted into a hydroxo complex $[Cr(OH)(acac)_2]_2$. The mechanism involving the insertion of the carbonyl group of acetone into the Ph–Cr bond giving an alkoxo intermediate is proposed. Reactions of **1** with esters proceed similarly to give diphenylmethanol derivatives and alkoxochromium complexes. Complex **1** reacts with ROH to give benzene and alkoxo complexes $[Cr(OR)(acac)_2]_n$ (n=1 or 2) which were characterized by means of IR spectra, elemental analyses, molecular weight measurements, magnetic susceptibilities, and chemical reactions. The reactions of **1** with β-dicarbonyl compounds yield corresponding mixed chelate complexes $Cr(\beta\text{-dic})(acac)_2$, where β-dic=diethyl malonato and 1-ethoxy-1,3-butanedionato ligands.

A number of organochromium(III) complexes having σ-alkyl or aryl bond have been prepared by treatment of chromium(III) halides with alkyl(aryl)ating agents such as Grignard reagents, organolithium and aluminium compounds.[1] Most monoalkyl or monoaryl organochromium(III) complexes thus prepared such as $CrRCl_2(thf)_n$[2,3] and its phenyl analog, $CrPhCl_2(thf)_3$[4] (thf=tetrahydrofuran), contain halogen ligands. In the course of our studies on preparation of phenyl complexes of various transition metals using triphenylaluminium as arylating agents,[5–9] we found that a new, halogen-free, monophenylchromium complex $CrPh(acac)_2$ (**1**) was prepared from the system consisted of tris(2,4-pentanedionato)chromium(III), $Cr(acac)_3$ (acac stands for 2,4-pentanedionato ligand), $AlPh_3 \cdot Et_2O$, and tetrahydrofuran. Although extensive studies have been made on the systems consisted of alkyl- and arylaluminium compounds and $Cr(acac)_3$ with special reference to its catalytic behavior towards olefin and diene polymerization,[10] no characterizable compound has been isolated from the system. Sartori and Costa[11] suggested formation of an adduct between $Cr(acac)_3$ and $AlPh_3$ in a benzene solution through IR and ESR spectroscopic studies and conductivity measurements, but the characterization is not unequivocal. The only reasonably well established organochromium(III) complex so far isolated starting from $Cr(acac)_3$ is $CrBr(\eta\text{-}C_5H_5)(acac)$, which was prepared from $Cr(acac)_3$ and $Mg(C_5H_5)Br$.[12]

Although phenylchromium(III) complex of the type $CrPhCl_2(thf)_3$ has been known,[4] the study of its reactions is limited only to the oxidation with $HgCl_2$ and I_2.[1] In view of the importance of the species possessing carbon to transition metal σ-bond in a catalytic C–C bond formation reaction, we studied the reactions of the organic carbonyl compounds with phenylchromium complexes $CrPh(acac)_2$ (**1**) and $CrPhCl_2(thf)_3$. The reactions of **1** with some organic compounds having an active hydrogen such as alcohols and β-dicarbonyl compounds were also investigated to shed light on the mechanism of the reactions of the carbonyl compounds. A part of the present study has been communicated elsewhere.[13]

† Present address: Department of Materials Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240.

Results and Discussion

Preparation and Characterization of Bis(2,4-pentanedionato)phenylchromium(III). Kurras has reported that treatment of chromium(III) chloride with triphenylaluminium etherate in tetrahydrofuran at room temperature afforded yellow-green dichlorophenyltris(tetrahydrofuran)chromium(III).[4] In contrast, when tris(2,4-pentanedionato)chromium(III) was similarly treated with $AlPh_3 \cdot Et_2O$ in tetrahydrofuran, no apparent reaction occurred at room temperature. However, on heating the system at 80 °C, a wine red solution resulted, from which brilliant red crystals deposited on allowing it to stand at −78 °C for 1 d. The crystals which appear to be $CrPh(acac)_2(thf)$ as judged from the IR spectrum, easily released the solvated tetrahydrofuran molecule and turned into an orange powder of $CrPh(acac)_2$ (**1**) on drying *in vacuo* at room temperature for 1 h (Eq. 1).

$$Cr(acac)_3 + AlPh_3 \cdot Et_2O \xrightarrow[80°C]{\text{tetrahydrofuran}} \underset{\text{red crystals}}{CrPh(acac)_2(thf)} \xrightarrow{\text{drying } in\ vacuo} \underset{\text{orange powder}}{CrPh(acac)_2\ \mathbf{1}} \quad (1)$$

A triphenylaluminium adduct of $Cr(acac)_3$, in which $AlPh_3$ was assumed to be attached to one of two oxygen of the acac ligands, has been claimed to exist in the reaction mixture consisted of $Cr(acac)_3$ and $AlPh_3$ in benzene at room temperature.[11] The higher temperature employed in the present system might have transformed this unstable adduct to the more stable phenylchromium complex **1**. A qualitative test with the use of aluminon and alizarin indicated the absence of aluminium in the product. In contrast to the arylation of $CrCl_3$ with aryl Grignard reagents, which afforded triarylchromium as well as mono- and diaryl derivatives,[1] phenylation of $Cr(acac)_3$ with $AlPh_3 \cdot Et_2O$ yielded the monophenyl derivative exclusively, as in the case of analogous alkylation with aluminium alkyls.[2,3] Addition of an equimolar amount of triphenylphosphine or tricyclohexylphosphine to the system did not alter the reaction course and the phenyl complex **1** was isolated exlusively in

each case.

Complex **1** which is hardly soluble in diethyl ether and toluene can be recrystallized from tetrahydrofuran and is fairly inert to dry air in the solid state and even in solution. The magnetic moment of 3.52 BM, which is somewhat lower than the spin-only value of 3.88 BM for high spin Cr(III) complexes, was observed for complex **1**. Complex **1** decomposed *in vacuo* at 160—165 °C. The IR spectrum of **1** was very close to that of the parent $Cr(acac)_3$ except that there exist some additional bands due to the phenyl group at 3050 m (assignable to ν(C–H)), 675s, 695s, and 725s (π(C–H)), and 455 cm^{-1} (ν(Cr–C)). The characteristic absorptions of the acac ligand of **1** were observed as very strong bands at 1585, 1560, 1510, 1380, and 1345 cm^{-1}.

$CrPh(acac)_2$ (**1**) reacted with anhydrous HCl in diethyl ether to give benzene exclusively (91% of the calculated amount). The reaction of **1** with methyl iodide, allyl bromide, and acetyl chloride gave benzene (46—64%) and biphenyl. The yields of cross coupling products such as toluene, allylbenzene, or acetophenone, respectively, were very low (*ca.* 2%), indicating that the electrophilic attack of organic halogen compounds to the phenylchromium complex hardly occurred, unlike the similar reaction with phenylnickel(II) complex where certain amounts of cross coupled products have been obtained.[6] Although stable η^6-arene–chromium complexes such as $Cr(\eta^6\text{-}C_6H_6)_2$ are well known,[1,14] and formation of some η^6-arene–chromium complexes has been observed in the reaction of $CrCl_3$ with phenylmagnesium halides,[15] complex **1** is thought to have the phenyl-chromium σ-bond as is supported by the results of its reactions with organic carbonyl compounds (*vide infra*).

Reactions of $CrPh(acac)_2$ (1) with Organic Carbonyl Compounds. An orange-red heterogeneous mixture of phenylchromium complex **1** and rigorously dried acetone turned to a clear deep green solution on stirring at room temperature for 2 h. A GLC analysis of the resulting solution showed the formation of benzene, 2-phenyl-2-propanol, and 4-methyl-3-penten-2-one (mesityl oxide) in the yield listed in Table 1. Working up the system afforded a crystalline powder which was characterized as hydroxochromium complex $[Cr(OH)(acac)_2]_2$ **2** (0.84 mol/l) on the basis of IR spectrum, elemental analysis, and molecular weight measurement (*vide post*).

$$CrPh(acac)_2 + (CH_3)_2C{=}O \longrightarrow \underset{\mathbf{1}}{} PhH + Ph(Me)_2COH + Me_2C{=}CHCOMe + \underset{\mathbf{2}}{[Cr(OH)(acac)_2]_2} \quad (2)$$

The result indicates that two types of reactions, namely, protonation of the phenyl ligand and the insertion of the carbonyl group into the phenyl-chromium bond followed by protonation are taking place simultaneously in the present system. The result is in contrast to that of similar reactions of diphenylmanganese complex with acetone which afforded only benzene to give (2-oxopropyl)manganese complex indicating that protonation of the phenyl ligand with an active hydrogen of acetone was taking place exclusively.[8] On the other hand $Cr(acac)_3$ did not react with acetone upon heating under reflux for 2 h.

Formation of the hydroxochromium complex **2** and mesityl oxide indicates direct or indirect involvement of water in the reaction and it was suspected that the protonation was caused by water formed in the reaction giving mesityl oxide from 4-hydroxy-4-methyl-2-pentanone (diacetone alcohol), the dimerization product of acetone. However, kinetic examination of the reaction as represented by Fig. 1 excludes the water as the direct proton source for giving benzene and 2-phenyl-2-propanol. Figure 1 indicates that benzene and 2-phenyl-2-propanol are formed simultaneously without any induction period. If water produced by dehydration of the diacetone alcohol is acting as the proton source, the water would be produced concomitant with mesityl oxide. It is observed, however, that the sum of benzene and 2-phenyl-2-propanol far exceeds the amount of mesityl oxide at any moment in the reaction course supporting that the dehydration of diacetone alcohol yielding mesityl oxide does not provide a sufficient amount of water to liberate benzene and 2-phenyl-2-propanol. Furthermore, addition of 2 mol of water per mol of **1** to the system

Table 1. Reactions of $CrPh(acac)_2$ **1** with organic carbonyl compounds[a]

a) Reactions were carried out under N_2 or *in vacuo* at room temperature unless otherwise stated. b) $[Cr(OH)(acac)_2]_2$ **2** was isolated from the reaction system (see text). c) $[Cr(OEt)(acac)_2]_2$ **4b** was isolated from the reaction system (see text). d) Reactions were carried out *in vacuo* at 80 °C. e) $Cr(OPh)(acac)_2$ **4i** was isolated from the reaction system (see text). f) The similar results were obtained when the reactions were carried out in the absence of solvent, diethyl ether.

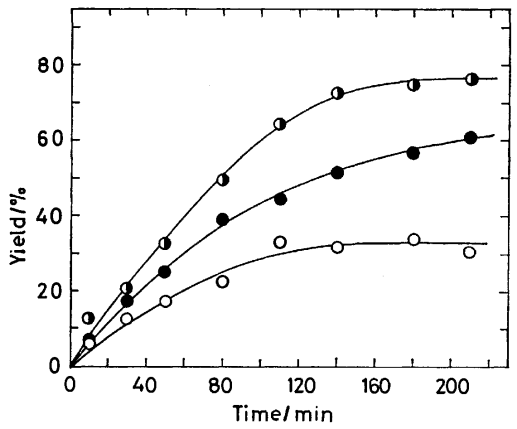

Fig. 1. Time dependence of the yields of benzene (○), mesityl oxide (●) and 2-phenyl-2-propanol (◑) in the reaction of $CrPh(acac)_2$ **1** with excess amount of acetone at 8 °C (Eq. 2).

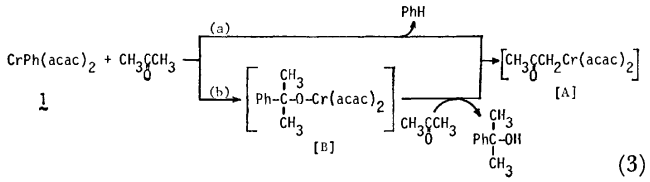
did not affect the yields of benzene and the alcohol, but inhibited the formation of mesityl oxide. Figure 1 shows also that the yield of mesityl oxide still increased after *ca.* 150 min when more than 95% of the phenyl complex had been consumed as reflected by leveling off of the yields of benzene and 2-phenyl-2-propanol.

These results support that the phenyl complex **1** is more susceptible to acetone than to water. Benzene and 2-phenyl-2-propanol are considered to be formed by the following parallel reactions of **1** with acetone:



(3)

Since evidence supporting the formation of the 2-oxopropyl transition metal complex [**A**] was previously obtained for the diphenylmanganese complex on its treatment with acetone, it is likely that a similar complex may be produced in the present case by the reaction of **1** with acetone (route a). On the other hand, insertion of the carbonyl group of acetone into the Ph–Cr bond would produce the intermediate alkoxo complex [**B**] which may further react with acetone liberating 2-phenyl-2-propanol and [**A**].

The assumed intermediate [**A**], if present, must be quite susceptible to protonation to give mesityl oxide and the hydroxo complex **2**. The exact route to produce **2** and mesityl oxide remains unclarified. Mesityl oxide may be simply formed by an aldol condensation of acetone together with water, which further attacks the intermediate [**A**] to give **2**.

However, since the reaction to form mesityl oxide and **2** proceeds very readily at room temperature in the present system and the formation of mesityl oxide is inhibited by addition of water, it is certainly reasonable to assume the intervention of a chromium complex such as [**A**] which promotes the reaction to produce mesityl oxide and is susceptible to the attack of water. A possible route is given below where the second acetone insertion into the C–Cr bond of the intermediate [**A**] is assumed.

$$[CH_3\overset{\overset{O}{\|}}{C}CH_2Cr(acac)_2] + CH_3\overset{\overset{O}{\|}}{C}CH_3 \longrightarrow$$

[**A**]

$$[CH_3\overset{\overset{O}{\|}}{C}CH_2\overset{\overset{CH_3}{|}}{C}-O-Cr(acac)_2] \qquad (4)$$
$$\qquad\qquad\quad CH_3$$

[**C**]

The intermediate [**C**] may interact further with acetone to release diacetone alcohol with regeneration of [**A**].

$$[CH_3\overset{\overset{O}{\|}}{C}CH_2\overset{\overset{CH_3}{|}}{C}-O-Cr(acac)_2] + CH_3\overset{\overset{O}{\|}}{C}CH_3 \longrightarrow$$
$$\qquad\qquad\quad CH_3$$

[**C**]

$$[A] + CH_3\overset{\overset{O}{\|}}{C}CH_2\overset{\overset{CH_3}{|}}{C}CH_3 \qquad (5)$$
$$\qquad\qquad\quad OH$$

The diacetone alcohol thus produced may be dehydrated to liberate mesityl oxide and water which may readily attack [**A**] to produce the hydroxochromium complex **2**.

$$CH_3\overset{\overset{O}{\|}}{C}CH_2Cr(acac)_2 + H_2O \longrightarrow$$

[**A**]

$$\frac{1}{2}[Cr(OH)(acac)_2]_2 + CH_3\overset{\overset{O}{\|}}{C}CH_3 \qquad (6)$$

2

Acetophenone reacted with **1** in the essentially similar fashion as did acetone to give 1,1-diphenylethanol and 1,3-diphenyl-2-buten-1-one together with benzene and the hydroxochromium complex **2** (Table 1). The reaction paths can be accounted for similarly to the reaction of **1** with acetone. In contrast, benzophenone, bearing no hydrogen attached to the carbon atom α to the carbonyl group, did not yield benzene, but gave triphenylmethanol on reaction with **1** in diethyl ether. The proton source for producing triphenylmethanol was not clarified.

Acetaldehyde reacted with **1** affording mainly the insertion product of the aldehyde into the Ph–Cr bond accompanied by formation of only a trace amount of benzene (Table 1). The formation of 1-phenylethanol (81%) and acetophenone suggests the concurrent occurrence of protonation and β-hydrogen abstraction of the intermediate 1-phenylethoxochromium complex [**D**].

$$CrPh(acac)_2 + MeCHO \longrightarrow$$

1

$$\left[\begin{array}{l} CH_3 \\ PhC-O-Cr(acac)_2 \\ H \end{array}\right] \longrightarrow \begin{array}{l} \overset{\overset{CH_3}{|}}{Ph-C-OH} \\ \qquad H \end{array} \qquad (7)$$
$$\qquad\qquad\qquad\qquad\quad \longrightarrow PhC\overset{\overset{O}{\|}}{C}H_3$$

D

It is noted that crotonaldehyde was formed in greater than the stoichiometric amount. A chromium complex may be promoting the aldol condensation of acetaldehyde in a manner similar to that of acetone dimerization with repetition of processes expressed by Eqs. 4 and 5. A concomitant formation of polymeric products, possibly due to the aldol condensation reaction, prohibited the isolation of the chromium complex from the reaction system.

The reaction of propionaldehyde with **1** proceeded more slowly than that of acetaldehyde to give the products shown in Table 1. In addition to the products listed in Table 1, biphenyl (0.13 mol/mol of complex) was formed, but the mechanism of its formation is not clear.

Benzaldehyde carrying no acidic hydrogen α to the carbonyl group, did not give diphenylmethanol but yielded benzophenone almost exclusively as a result of the β-H abstraction from an alkoxo intermediate which can be produced by benzaldehyde insertion into the Cr–Ph bond of **1** (Table 1).

$$\underset{\mathbf{1}}{CrPh(acac)_2} + PhCHO \xrightarrow{\text{insertion}} [Ph\text{-}\underset{H}{\overset{Ph}{C}}\text{-}O\text{-}Cr(acac)_2]$$

$$\xrightarrow{\beta\text{-H abstraction}} PhC(Ph)=O + [HCr(acac)_2] \qquad (8)$$

This reaction system accompanied the formation of benzyl benzoate, the Tishtchenko type dimerization product. There are a few precedents of the Tishtchenko type reactions promoted by transition metal complexes.[8,16,17]

Ethyl and phenyl acetates reacted with $CrPh(acac)_2$ only at elevated temperatures accompanying a color change from orange-red to deep green (Table 1). Ethoxo- and phenoxochromium complexes, $[Cr(OEt)(acac)_2]_2$ and $Cr(OPh)(acac)_2$, were isolated from the reaction systems. They were characterized by comparison with the ethoxo and phenoxo complexes prepared by the independent reactions of **1** with ethanol and phenol, respectively. Isolation of the alkoxochromium complexes strongly supports that the reactions proceed by the insertion of the carbonyl group of the esters into the Cr–Ph bond followed by the alkoxo group elimination as generally assumed for the reactions of Grignard reagents with carboxylic esters. Higher yields of benzene than 1,1-diphenylethanol in these reactions suggest a facile protonation of the phenyl complex with esters or acetophenone as the proton source at the elevated temperature.

$$\underset{\mathbf{1}}{CrPh(acac)_2} + MeC(=O)OR \longrightarrow Ph\text{-}\underset{OR}{\overset{Me}{C}}\text{-}O\text{-}Cr(acac)_2$$

$$\longrightarrow Ph\text{-}\overset{Me}{C}=O + \frac{1}{2}[Cr(OR)(acac)_2]_2 \qquad (9)$$

For comparing the reactivity of the phenylchromium acetylacetonate with other phenylchromium complexes reactions of $CrPhCl_2(thf)_3$ (**3**) with some ketones and aldehydes were examined. The results are shown in Table 2. Although benzophenone and benzaldehyde afforded similar products to those of $CrPh(acac)_2$ (**1**), the reactions of acetone and acetaldehyde with **3** gave different results from those with **1**. Thus, the yields of aldol condensates such as mesityl oxide and crotonaldehyde which were formed in relatively high yields in the case of **1** decreased, whereas considerable amounts of olefins such as α-methylstyrene and styrene were produced. Since aldol condensation is known to be accelerated by the base and the dehydration of alcohol to give olefin is catalyzed by the acid, the present results seem to reflect a stronger acidic nature of complex **3** than **1**.

The formation of 2-phenyl-2-propanol in the reaction of acetone with **3** indicates the acetone insertion into the Ph–Cr bond in **3** giving $Ph(Me)_2C\text{-}O\text{-}Cr$ species which may be protonated by acetone to give the tertiary alcohol.

$$\underset{\mathbf{3}}{CrPhCl_2(thf)_3} + MeC(=O)Me \longrightarrow [Ph\text{-}\underset{Me}{\overset{Me}{C}}\text{-}O\text{-}CrCl_2]$$

$$\xrightarrow{H^+} Ph\text{-}\underset{Me}{\overset{Me}{C}}\text{-}OH \qquad (10)$$

Dehydration of the alcohol thus formed promoted

Table 2. Reactions of $CrPhCl_2(thf)_3$ **3** with organic carbonyl compounds[a]

Compound	Reaction time (Solvent)	Products (mol/mol of **3**)				
		Alcohol	Dimer	Ketone	Olefin	PhX

PhCHO	1 d (Et_2O)		$PhCOOCH_2Ph$ (Trace)	PhCOPh (0.88)		PhPh (0.06)

a) Reactions were carried out under N_2 at room temperature. b) Three moles of tetrahydrofuran per mole of complex were found to be present in the reaction mixture. c) After the measurement of the yields of reaction products, phenol was added to the system. The figures placed after the arrows indicate the yields after treatment with phenol.

by acid gives α-methylstyrene. In the reaction of acetone with the phenylchromium chloride liberation of HCl is also likely. The acid thus formed may also act as the dehydration agent.

A quite similar reaction sequence as discussed above may be also operative in the reaction of **3** with acetaldehyde. The assumption that the alcohol is a precursor for the olefin formation in the system utilizing complex **3** was further confirmed by the following experiment. After the completion of the reaction between **3** and acetone, a weak acid such as phenol was introduced to the system, and the reaction mixture was stirred for 1 h at room temperature. This resulted in the appreciable increase in the yield of α-methylstyrene at the expense of the alcohol (see footnote c in Table 2).

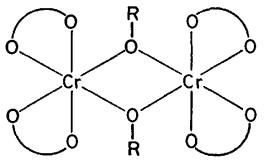
*Reactions of CrPh(acac)$_2$ (**1**) with Alcohols.* In view of the possible intermediacy of alkoxochromium species in the reactions of phenyl complex **1** with organic carbonyl compounds, isolation of alkoxochromium complexes *via* direct reactions of alcohols with phenyl complex **1** was attempted.

Complex **1** readily reacted with an excess of various kinds of alcohols at room temperature to give a series of green alkoxochromium complexes **4** accompanied by release of quantitative amounts of benzene.

$$\underset{\mathbf{1}}{\mathrm{CrPh(acac)_2}} + \mathrm{ROH} \longrightarrow \frac{1}{n}\underset{\mathbf{4}}{[\mathrm{Cr(OR)(acac)_2}]_n} + \mathrm{PhH} \quad (n=1 \text{ and } 2) \qquad (11)$$

Although the homoleptic chromium alkoxides such as Cr(OR)$_n$ has been known,[18] complexes containing both the alkoxo- and β-diketonato ligands of the type [Cr(OR)(β-dik)$_2$]$_n$ have been prepared only recently by the reactions of alcohols with Cr(3-halo-2,4-pentanedione)$_2$[19,20] or of β-diketones with chromium trialkoxides under refluxing conditions.[21] The former method has a limitation that only such 2,4-pentanedionato derivatives that carries strong electronegative substituent can be replaced by alcohol, whilst the latter is inconvenient for getting complexes with an extensive series of alkoxo ligands. The present method shown in Eq. 11, albeit indirect, has an advantage that the reaction readily proceeds under mild conditions to give complexes with a variety of alkoxo ligands.

Table 3 lists analytical results of the alkoxo complexes thus obtained. Most alkoxo complexes are soluble in organic solvents such as hexane and toluene from which they were recrystallized to give green crystals. Molecular weight measurement by cryoscopy in benzene reveals that the alkoxo complexes are dimeric in solution in accordance with the observation by Mahendra *et al.*[21] and by Kasuga *et al.*[19] for [Cr(OR)(3-bromo-2,4-pentanedione)$_2$]$_2$. Alkoxo-bridged dimeric structure in the solid state has been demonstrated for the last complex by an X-ray crystal structure analysis.[20] By analogy, most alkoxo complexes prepared in the present study may have the structure as shown below:



where O⌒O represents acac ligands. The phenoxo complex Cr(OPh)(acac)$_2$ was found to be monomeric in benzene. The presence of the phenoxo group may serve to make the phenoxo oxygen less basic for formation of the bridge structure. A steric reason may be also contributing here.

Assignment of their IR bands was performed by comparing them with those of the parent complex **1**, tris(2,4-pentanedionato)chromium(III), and some other related compounds.[19,22,23] For example, methoxo complex [Cr(OCH$_3$)(acac)$_2$]$_2$ (**4a**) showed, in addi-

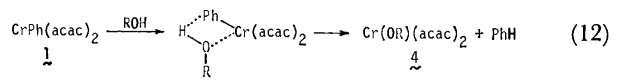
a) Reactions were carried out under N_2 at room temperature without solvent for **4a**—**d** and in Et_2O and tetrahydrofuran for **4e**—**4j**, and **4k** and **2**, respectively. b) Calcd values in parentheses. c) Not measured. d) Band assignable to ν(O-H) (see text).

tion to the bands due to the acac ligand, several bands assignable to the methoxo ligand: 2925m and 2820m (ν(C–H)), 1083s (ν(C–O)), 600s, 548s, and 453s cm^{-1} (bands due to Cr–O bond). In the case of the phenoxo complex, Cr(OPh)(acac)$_2$ (**4i**), the bands arising from the phenoxo group were 3050m (ν(C–H)), 1485s (ν(C–C)), 1232s (ν(C–O)), 767s (π(C–H)), 685s (δ(C–C)), and 600s and 480s cm^{-1} (bands due to Cr–O bond). The fairly distinctive C–O stretching bands of the alkoxo ligands are listed in Table 3.

In accordance with the observation by Mahendra *et al.*,[21] magnetic moments of the present alkoxo complexes were found to be in the region of 3.35 to 3.63 BM which are less than the value of 3.88 BM calculated for the spin only system of Cr(III), suggesting occurrence of the antiferromagnetism due to super exchange through bridging alkoxo ligands.[22]

The formation of the alkoxo complexes may be explained by considering nucleophilic attack of alcohol to a vacant site of the metal center of phenylchromium complex **1** followed by formation of Cr–O bond.



(12)

The necessity of a vacant site on the metal center was demonstrated by the following additional experiment. The orange phenylchromium complex **1**, on treatment with γ-picoline in tetrahydrofuran at room temperature, turned to a yellow adduct, CrPh(acac)$_2$(γ-picoline) (**5**), which was characterized on the basis of IR spectrum and elemental analysis. In contrast to the high reactivity of **1** toward alcohol as described above, coordinatively saturated complex **5** did not react with ethanol in tetrahydrofuran at room temperature, but reacted at 80 °C to give the alkoxo complex [Cr(OEt)(acac)$_2$]$_2$ liberating quantitative amounts of benzene and γ-picoline. This result implies that dissociation of γ-picoline ligand is a prerequisite for complex **5** to be attacked by alcohol according to Eq. 12.

The reaction of **1** with ethylene glycol in tetrahydrofuran at room temperature afforded a deep purple solution, from which a pale purple powder was obtained on working up. On treatment with hot toluene, the purple powder turned to a green powder **4k** which showed a strong IR band at 3490 cm^{-1} assignable to ν(OH). In view of the fact that the rest of the IR absorptions are quite similar to those of the other alkoxo complexes **4** and that the elemental analysis excludes the binuclear structure with a bridging $-OCH_2CH_2O-$ group, complex **4k** is tentatively formulated as a 2-hydroxyethoxo complex [Cr(OCH_2CH_2OH)(acac)$_2$]$_2$. The structure of the pale purple precursor which has no ν(OH) band is not certain.

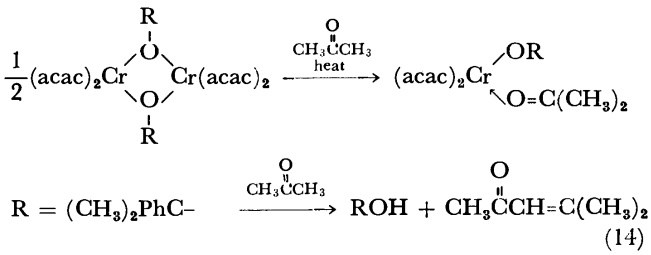
Reactions of Alkoxochromium Complexes. Alkoxobis(2,4-pentanedionato)chromium(III) complexes **4a**, **4b**, **4d**, **4i**, and **4j** reacted with acetyl chloride to give quantitvatie amounts of corresponding esters. Since the reaction takes place readily at ambient conditions, it may be applicable to the rest of the alkoxo complexes listed in Table 3 which were not examined.

$$[Cr(OR)(acac)_2]_n + \text{excess MeCOCl} \xrightarrow{\mathbf{4}} n\ \text{MeCOOR} + \text{"complex"} \quad (13)$$

All the reaction products thus obtained showed the identical IR bands with those of the reaction products between **1** and HCl (*vide supra*), at 2790m, 1695s, 1170m, and 1050m cm^{-1} in addition to those of the acac ligand. The complex is tentatively assigned to $CrCl_n(acac)_m$. The reaction of acetyl chloride with the alkoxo complex, [Cr(OCH_2CH_2OH)(acac)$_2$]$_2$ (**4k**), derived from ethylene glycol afforded diester, ethylene glycol diacetate, the yield of which was one mol per Cr atom.

The alkoxo complexes **4** were found to be chemically inert to most reagents other than acetyl chloride. Thus, in contrast to trialkoxochromium(III) complexes, Cr(OR)$_3$, which reportedly react with isocyanate to give insertion product, $Cr(OR)_{3-n}\{N(Ph)COOR\}_n$,[24] complex **4b** did not react with excess phenyl isocyanate in toluene at room temperature. Methyl iodide and phenyl acetate did not react with **4b** even on heating at 80 °C. Only a trace amount of anisole was detected in the reaction of the phenoxo complex **4i** with methyl iodide at room temperature. When the ethoxo complex **4b** in toluene was stirred at room temperature in the presence of equimolar amount of phenol for 9 h, only 2% of ethanol per **4b** was formed, indicating that the alkoxo exchange reaction of **4** with more acidic alcohol proceeds very slowly. Neither CO_2 (4 atm, 80 °C) nor CO (1 atm, room temperature) reacted with **4b** in toluene solution or in ethanol suspension.

It is rather surprising that even the alkoxo complex **4h**, derived according to Eq. 12 from **1** and 2-phenyl-2-propanol, which was thought to be a possible reaction intermediate between **1** and acetone as shown in Eq. 3, was found to be inert to further reaction with acetone at room temperature. Heating **4h** in acetone under reflux yielded only a small amount of mesityl oxide and 2-phenyl-2-propanol. The result conflicts with the mechanism presented for the reaction between the phenyl complex **1** and acetone in which mesityl oxide was formed by room temperature *via* a postulated alkoxo intermediate **4h**. Tentatively, we elucidate this inconsistency by supposing a significant difference in the reactivity of **4h** toward acetone between monomeric and dimeric forms. As shown in the preceding section, most alkoxochromium complexes once isolated were found to be dimeric in solution, which are chemically inert. On the other hand, the pentacoordinated alkoxo intermediate [**B**] in Eq. 3 formed *in situ* by the reaction of phenyl complex **1** and excess acetone may exist as a monomer, since excess acetone, behaving as a Lewis base, may occupy the vacant coordination site of chromium which is necessary for the dimerization of alkoxide. The monomeric alkoxide may have a potential to react further with excess acetone. The formation of 2-phenyl-2-propanol and mesityl oxide by the reaction of **4h** with acetone at refluxing temperature suggests that the dissociation of dimeric alkoxide may take place at the elevated temperature in the presence of acetone.



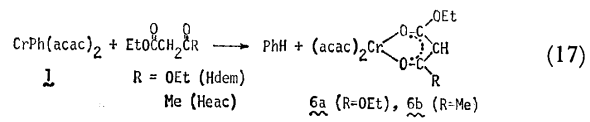
$$R = (CH_3)_2PhC- \xrightarrow{CH_3\overset{O}{\overset{\|}{C}}CH_3} ROH + CH_3\overset{O}{\overset{\|}{C}}CH{=}C(CH_3)_2 \quad (14)$$

Reaction of CrPh(acac)$_2$ (1) with Water. Complex **1** reacted slowly with an excess of water in the tetrahydrofuran solution at room temperature to afford benzene quantitatively and give purple crystals which were analyzed as dimeric hydroxo complex **2** on the basis of IR spectrum, elemental analysis, and magnetic susceptibility as well as molecular weight measurements. The analytical results are included in Table 3. IR spectrum of **2** showed a characteristically

$$\underset{\mathbf{1}}{2\,CrPh(acac)_2} + 2\,H_2O \xrightarrow[\text{room temp}]{\text{tetrahydrofuran}} 2\,PhH + \underset{\mathbf{2}}{[Cr(OH)(acac)_2]_2} \quad (15)$$

sharp ν(OH) band at 3635 cm^{-1} and bridging δ(OH) band at 820 cm^{-1}.[23] These bands shifted to 2665 (ν(OD)/ν(OH)=1.37) and 620 cm^{-1} (δ(CD)/δ(OH)=1.32), respectively in the deuterio analog [Cr(OD)(acac)$_2$]$_2$, which was similarly prepared from **1** according to Eq. 15 using D_2O in place of H_2O. The binuclear complexes bridged with the hydroxo group(s) have been reported for Cu,[25] Fe,[26] Co,[26] Ru,[27] and Pt,[28] as well as Cr(III) of the type [(L-L)$_2$Cr(OH)]$_2$X$_4$ (L-L=2,2'-bipyridine and 1,10-phenanthroline) and K$_4$[(C$_2$O$_4$)$_2$Cr(OH)]$_2$.[26]

Reactions of CrPh(acac)$_2$ (1) with β-Dicarbonyl Compounds. Phenyl complex **1** reacted with β-dicarbonyl compounds such as diethyl malonate (Hdem) and ethyl acetoacetate (Heac) at room temperature to give corresponding mixed chelate complexes **6** with accompanying release of quantitative amounts of benzene. Purple needles of **6a** had IR absorptions at



1620, 1143, and 1076 cm^{-1} assignable to the ester groups of dem ligand in addition to the bands due to acac ligands. Similarly, the IR bands due to the ester group in eac ligand in **6b** were observed at 1610, 1090, and 1058 cm^{-1}. Replacement of metal alkyls with nucleophiles such as β-dicarbonyl anion to give chelate complex has been reported for methylcopper and dimethylnickel complexes.[29] It has also been reported that Pt(acac){CH(COCH$_3$)$_2$}(PPh$_3$) reacted with dimethyl malonate (Hdmm) and Heac to replace central carbon bonded acac ligand {CH(COCH$_3$)$_2$} with dmm and eac which were also bonded to Pt through their central carbon atoms.[30] Absence of the ester carbonyl bands above 1700 cm^{-1} in the IR spectra of **6a** and **6b** indicates that dem and eac ligands are not attached unidentately through central carbon atom but chelated through two oxygens.

Experimental

Most reactions and manipulations were carried out either under dry, oxygen-free nitrogen or argon, or *in vacuo* using Schlenk-type flasks.

Solvents were dried, purified in the usual manner, and stored under an atmosphere of nitrogen. Commercial acetone was dried by Drierite, distilled under nitrogen, and stored with added molecular sieve 3A. Acetone thus purified was found to contain less than 1.5×10^{-3} M of water on the basis of GLC analysis. Acetaldehyde was dried over molecular sieve 3A, distilled under nitrogen, and stored in the presence of molecular sieve 3A. The other ketones, aldehydes, and esters were purified appropriately. Methanol was dried with Drierite, distilled under nitrogen, and distilled again over calcium hydride *in vacuo*. Commercial phenol, 2-phenyl-2-propanol, 1-phenylethanol, and *p*-methoxyphenol were used without further purification. Other alcohols were dried over anhydrous sodium sulfate. Acetyl chloride was distilled and stored under nitrogen in the presence of molecular sieve 3A. AlPh$_3$·Et$_2$O was prepared from PhMgBr and AlCl$_3$ according to the reported method.[31] Tris(2,4-pentanedionato)chromium(III) (Tokyo Kasei Industrial Co.) was used as purchased without further purification. CrPhCl$_2$(thf)$_3$ (**3**) was prepared by the literature method.[4]

Infrared spectra were recorded on a Hitachi model 295 spectrometer using KBr disks prepared under inert atmosphere. The magnetic susceptibility was measured by Gouy method using Shimadzu MB-100 apparatus at 23 °C and the diamagnetic corrections for the coordinated ligands were made on the basis of the Pascal's constants.[32] Molecular weight was measured cryoscopically in benzene solution. The organic products formed in the reactions were quantitatively analyzed by GLC using internal standard. GLC was recorded on a Shimadzu GC-3BT or GC-6A gas chromatography using SDC-550, SDC-410, and/or PEG-20M columns and helium as a carrier gas. Micro analyses (C and H) were carried out by Mr. T. Saito of our laboratory using Yanagimoto CHN Autocorder Type MT-2. Analysis of the chromium content was performed by a colorimetric method using diphenylcarbazide as a color-producing agent.[33]

Preparation of CrPh(acac)$_2$ (1). Tris(2,4-pentanedionato)-chromium(III) (2.8 g, 8.0 mmol) and AlPh$_3$·Et$_2$O (2.9 g, 8.4 mmol) in 20 cm^3 of tetrahydrofuran was heated under reflux for 8 h. The original deep purple solution changed to wine red in the initial 1 h. On allowing to stand the solution at −78 °C overnight, brilliant red crystals deposited, which were filtered, washed with tetrahydrofuran, and dried *in vacuo*. Orange powdery CrPh(acac)$_2$ thus obtained weighed 1.64 g (yield, 63% based on Cr(acac)$_3$ used) and was crystallized from hot tetrahydrofuran. Found: C, 58.4; H, 6.0%. Calcd for C$_{16}$H$_{19}$O$_4$Cr: C, 58.7, H, 5.9%.

Reaction of CrPh(acac)$_2$ (1) with Acetone. To a flask containing CrPh(acac)$_2$ (0.406 g, 1.24 mmol), 3 cm^3 of acetone was added by means of a trap-to-trap method. On stirring the mixture at room temperature for 2 h a dark green solution resulted, the GLC analysis of which using toluene as an internal reference showed the formation of benzene (0.335 mmol), 3-phenyl-2-propanol (0.880 mmol), 4-methyl-3-penten-2-one (mesityl oxide) (0.446 mmol), and 2,6-dimethyl-2,5-heptadien-4-one (0.062 mmol). Volatile liquid materials were evaporated from the solution to leave a dark colored solid. The resulting solid was successively washed at −10 °C with diethyl ether and hexane to give

a purple powder which was analyzed as $[Cr(OH)(acac)_2]_2$ (0.279 g, 84% based on **1** used).

The time-course of the yields of the organic products in the reaction of **1** and acetone (Fig. 1) was followed by submitting the aliquot of the reaction mixture maintained at 8 °C to GLC analysis at regular intervals.

The reactions of **1** with other ketones, aldehydes, and esters were carried out essentially in a similar fashion as described above, except that in some experiments diethyl ether was used as solvent and the reaction mixture was heated appropriately as shown in Table 1.

Reaction of $CrPhCl_2(thf)_3$ (3) with Acetone. Acetone (2 cm³) was condensed into a flask containing 0.114 g (0.273 mmol) of $CrPhCl_2(thf)_3$ by the trap-to-trap method. On stirring the mixture at room temperature for 10 min, a purple solution resulted. After being stirred overnight, the solution was analyzed by means of GLC to confirm the presence of benzene (0.016 mmol), styrene (0.109 mmol), 2-phenyl-2-propanol (0.147 mmol), mesityl oxide (0.007 mmol), and tetrahydrofuran (0.811 mmol). Addition of phenol to the solution changed the product distribution to benzene (0.046 mmol), styrene (0.261 mmol), 2-phenyl-2-propanol (0.005 mmol), and mesityl oxide (0.045 mmol) (Table 2).

The reactions of **3** and benzophenone, acetaldehyde, and benzaldehyde were carried out similarly except that diethyl ether was used as solvent.

Reaction of $CrPh(acac)_2$ (1) with Alcohols. Since the method is general the reaction of **1** with methanol is described as a representative example, and reaction conditions, yields, and analytical data are listed in Table 3.

To the flask containing 1.127 g (3.44 mmol) of **1** was added 5 cm³ of methanol by the trap-to-trap method. After being stirred at room temperature for 6 h, the volatile liquid was evaporated off *in vacuo* to leave 0.834 g (86%) of a green powder of $[Cr(OMe)(acac)_2]_2$ **4a**. The powder was crystallized from 8 cm³ of hot toluene.

In the reaction with less volatile alcohols, solvents such as diethyl ether and tetrahydrofuran were employed and freshly distilled alcohols were added to the mixture using a syringe (see Table 3).

Reactions of the Alkoxo Complexes (4) with Acetyl Chloride. To the flask containing 44.4 mg (0.079 mmol) of $[Cr(OMe)(acac)_2]_2$ (**4a**) and 2 cm³ of toluene, *ca.* 0.5 cm³ of acetyl chloride was added by means of the trap-to-trap method. After being stirred at room temperature for 30 min, the solution was analyzed by GLC using benzene as an internal reference to reveal the formation of 0.131 mmol (0.83 mol/Cr) of methyl acetate.

Similarly carried out were the reactions of acetyl chloride with $[Cr(OEt)(acac)_2]_2$ (**4b**) (the yield of ester was 0.99 mol/Cr), $[Cr(O\text{-}i\text{-}Pr)(acac)_2]_2$ (**4d**) (1.00 mol/Cr), $Cr(OPh)(acac)_2$ (**4i**) (0.97 mol/Cr), $[Cr(OC_6H_4\text{-}p\text{-}OMe)(acac)_2]_2$ (**4j**) (1.00 mol/Cr), and $[Cr(OCH_2CH_2OH)(acac)_2]_2$ (**4k**) (1.00 mol/Cr).

Reaction of $CrPh(acac)_2$ with Water. Stirring the mixture of 0.725 g (2.20 mmol) of $CrPh(acac)_2$ (**1**), 5 cm³ of tetrahydrofuran, and 0.2 cm³ (11.1 mmol) of water at room temperature for 2.5 h afforded a purple solution. Evaporating off the volatile liquid gave 0.529 g (90%) of a purple powder which was crystallized from hot toluene. The product was analyzed as $[Cr(OH)(acac)_2]_2$ (**2**) on the basis of IR spectrum, elemental analysis, and molecular weight measurement (Table 3). GLC analysis of the volatile liquid showed the formation of benzene in the yield of 1 mol per mol of complex.

Reaction of $CrPh(acac)_2$ (1) with Diethyl Malonate. To the flask containing 0.726 g (2.21 mmol) of $CrPh(acac)_2$ (**1**), 3 cm³ of diethyl malonate was condensed under high vacuum. The mixture was stirred at room temperature for 2 d and a reddish orange suspension turned to purple solution. GLC analysis of the resulting solution indicated the formation of 1.00 mol of benzene per mol of **1**. Evaporating off the volatile liquid from the system gave a purple solid of $Cr(dem)(acac)_2$ (**6b**) (0.448 g, yield 50% on the basis of **1**). The solid was recrystallized from toluene–hexane to give purple crystals. Found: C, 48.9; H, 5.9; Cr, 12.5%. Calcd for $C_{17}H_{25}O_8Cr$: C, 49.9; H, 6.2; Cr, 12.7%.

Reaction of **1** with ethyl acetoacetate to give $Cr(eac)(acac)_2$ (**6a**) was carried out similarly.

Stereospecific Synthesis of (2*Z*,4*E*,6*E*)-3,7,11-Trimethyl-2,4,6,10-dodecatetraene [*trans*(C_{10})-Allofarnesene]

Norio Miyaura, Hiroshi Suginome,* and Akira Suzuki†

Organic Synthesis Division, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

† *Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received December 24, 1981)

The stereospecific synthesis of the title acyclic sesquiterpene, isolated from *Perilla frutscens* f. viridis Makino (Japanese name, Aojiso) by the palladium-catalyzed cross-coupling of 2-(4,8-dimethyl-1,3,7-nonatrienyl)-1,3,2-benzodioxaborole with (*Z*)-2-bromo-2-butene, is described. The benzodioxaborole was prepared by the hydroboration of 4,8-dimethyl-3,7-nonadien-1-yne, newly prepared *via* three steps from geranial, with 1,3,2-benzodioxaborole.

Two isomers, **1** and **2** of α-farnesene were isolated from *Perilla frutscens* Makino (Japanese name, Aojiso) by Sakai and Hirose, who called them *trans*(C_{10})-allofarnesene and *cis*(C_{10})-allofarnesene and assigned the structures, (2*Z*,4*E*,6*E*)-3,7,11-trimethyl-2,4,6,10-dodecatetraene and its (2*E*,4*E*,6*E*)-isomer.[1]

In this paper, a stereospecific synthesis of (2*Z*,4*E*,6*E*)-3,7,11-trimethyl-2,4,6,10-dodecatetraene (**1**) corresponding to *trans*(C_{10})-allofarnesene by the palladium-catalyzed cross-coupling of 2-(4,8-dimethyl-1,3,7-nonatrienyl)-1,3,2-benzodioxaborole (**7**) with (*Z*)-2-bromo-2-butene[2] is described. The synthesis is based on the method developed by us and reported in previous papers.[3,4]

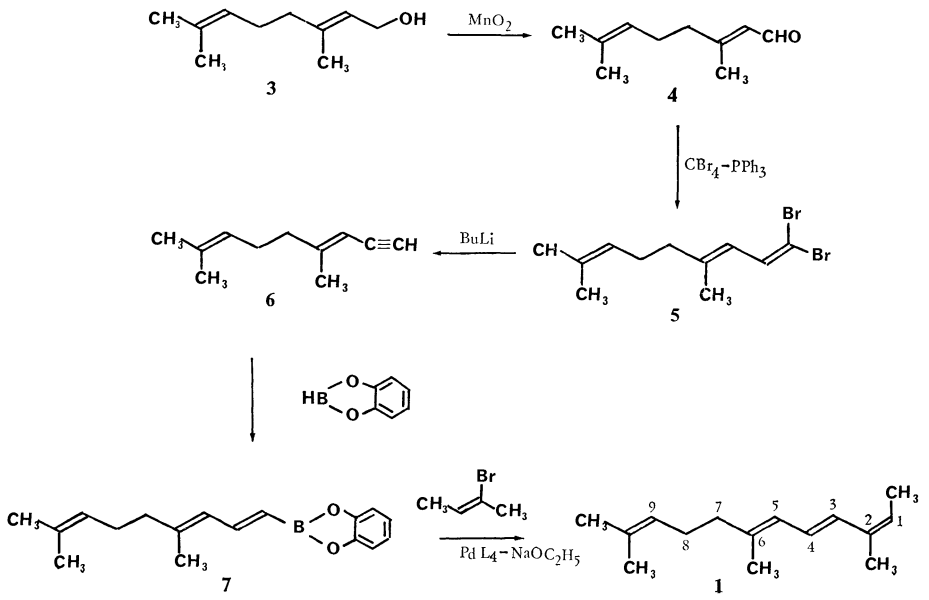
The alkenylborane, **7** required for the coupling reaction was prepared *via* three steps from geranial (**4**), itself previously prepared by the oxidation of geraniol (**3**) with active manganese dioxide.[5,6]

Thus, the reaction of geranial (**4**) with carbon tetrabromide and triphenylphosphine in dichloromethane in the presence of zinc, according to the method developed by Corey and Fuchs,[7] gave dibromide (**5**) in a 95% yield. Analysis by GC indicated that the geometry of geranial (**4**) was retained in dibromide, **5**, the ratio of (3*E*)- and (3*Z*)-isomer being 98:2. 4,8-Dimethyl-3,7-nonadien-1-yne (**6**) was prepared in a 90% yield by the reaction of dibromide, **5**, with butyllithium in hexane. The ratio of (3*E*)- and (3*Z*)-isomers in the product, **6**, was found by GC analysis to be 98:2.

The reaction of **6** with 1,3,2-benzodioxaborole[8] at 70 °C in an atmosphere of nitrogen gave 2-(4,8-dimethyl-1,3,7-nonatrienyl)-1,3,2-benzodioxaborole (**7**) as a viscous oil in a 72% yield. The ^{1}H NMR spectrum of borole, **7**, indicated that it was nearly a single isomer. It was found, however, that it gradually decomposed when exposed to air.

A mixture of borole **7** and (*Z*)-2-bromo-2-butene[2] in benzene containing $Pd(PPh_3)_4$[9] and sodium ethoxide was heated under reflux for 2 h in an atmosphere of nitrogen. The subsequent distillation of the product by Kugelrohr gave (2*Z*,4*E*,6*E*)-3,7,11-trimethyl-2,4,6,10-dodecatetraene (**1**) [*trans*(C_{10}) allofarnesene] in a 51% isolated yield. It was found that the use of THF as the solvent in this coupling considerably lowered the yield (29%) of **1** as well as the stereoselectivity of the coupling, the ratio of the (2*Z*,4*E*,6*E*) and (2*E*,4*E*,6*E*) isomers in the product being 32:68.[10]

The 200 MHz ^{1}H NMR spectrum of the synthetic *trans*(C_{10}) allofarnesene (**2**) thus obtained gave, for the



Scheme 1.

first time, well-resolved signals for all the olefinic protons and the methyl groups; their assignments are described in the Experimental section.

Experimental

The IR spectra were recorded on a Hitachi-Perkin Elmer Model 125 spectrometer. The ^{1}H-NMR spectra of all compounds with the exception of synthetic farnesene were determined with a Hitachi R-22 spectrometer (90 MHz) (solvent $CDCl_3$: TMS as the internal reference). The ^{1}H-NMR spectra of the synthetic farnesene was recorded with a JEOL JNM-FX-200 spectrometer (200 MHz). The mass spectra of **5** and **6** were determined with a JEOL JMS-D 300 spectrometer (70 eV) in the Faculty of Agriculture. Specimens for analysis were prepared by distillation with Kugelrohr (Shibata GTO-250 R). The bp shows the oven temperature of Kugelrohr. THF was distilled from benzophenone ketyl.

Geranial (4). This aldehyde was prepared by a procedure reported by Corey *et al.*[6] An analysis by VPC (10% Silicone OV-17 on Uniport B, 2m) indicated that this geranial contained 2% of neral (citral-b).

Preparation of (3E)-1,1-Dibromo-4,8-dimethyl-1,3,7-nonatriene (5). A mixture of PPh_3 (13.2 g, 50 mmol), CBr_4 (16.6 g, 50 mmol), and Zn powder (3.9 g, 60 mmol) in dry CH_2Cl_2 (250 ml) was stirred at room temperature for 48 h under an atmosphere of N_2. To this solution, we then added geranial (3.1 g, 20.5 mmol) in CH_2Cl_2 (10 ml) at 0 °C over a period of 15 min; the solution was stirred at that temperature for 1 h, after which the stirring was continued for another hour at room temperature. To the reaction mixture, we added hexane (500 ml) and colorless crystals and a viscous tarry material thus precipitated were removed by filtration. The removal of the solvent gave a mixture of products. This mixture was extracted with hexane (200 ml). The removal of the solid by filtration from the hexane solution and evaporation of the solvent gave a pale brown oil which was distilled with Kugelrohr to give dibromide, **5** (6.0 g, 95%); bp 80—85 °C(0.05 mmHg**). (Found: *m/z* 305.9643. Calcd for $C_{11}H_{16}Br_2$: M, 305.9621); MS *m/z* (rel intensity) 310 (M^++4, 0.2), 308 (M^++2, 0.4), 306 (M^+, 0.3), and 69 [$(CH_3)_2C{=}CH{-}CH_2^+$, 100]; n_D^{20}=1.5579; IR, (KBr disk), 1625, 1070, 845, and 775 cm^{-1}; ^{1}H NMR 1.60 (3H, s, 8-methyl), 1.68 (3H, s, 8-methyl), 1.74 (3H, s, 4-methyl), 2.08—2.12 (4H, m, 5 and 6-methylenes), 5.13 (1H, broad s, 7H), 5.90 (1H, broad d, J=10 Hz, 3-H), and 7.16 (1H, d, J=10 Hz, 2-H).

Preparation of 4,8-Dimethyl-3,7-nonadien-1-yne (6). To a solution of **5** (5.4 g, 17.5 mmol) in dry THF (30 ml) kept at −78 °C, was added dropwise BuLi in hexane (1.5 mol dm^{-3} solution, 28 ml, 42 mmol) over a period of 20 min; the solution was then stirred for 1 h at that temperature. The bath temperature was then gradually raised up to room temperature over the period of 1 h. After the solution had been further stirred for 1 h at room temperature, a saturated solution of NH_4Cl (5 ml) was added. The aqueous layer was separated and extracted with petroleum ether. The combined extracts were washed with saturated brine and with water and dried over anhydrous $MgSO_4$. The distillation of the product by Kugelrohr gave 4,8-dimethyl-3,7-nonadien-1-yne (**6**) (2.35 g, 90%); bp 75 °C (15 mmHg). (Found: *m/z* 148.1223. Calcd for $C_{11}H_{16}$: M, 148.1250); MS *m/z* (rel intensity) 148 (M^+, 0.4), 133 (M^+-CH_3, 8), and 69 [$(CH_3)_2C{=}CH{-}CH_2^+$, 100] n_D^{20}=1.4838; IR (film), 3296(C≡CH), 2104(C≡C), and 1632 cm^{-1}; ^{1}H NMR, 1.60 (3H, s, 8-methyl), 1.68 (3H, s, 8-methyl), 1.91 (3H, s, 4-methyl), 1.09—2.13 (4H, m, 5- and 6-methylene), 3.02 (1H, t, J=2 Hz, 1-H), 5.11 (1H, broad s, 7-H), and 5.32 (1H, broad s, 3-H).

2-(4,8-Dimethyl-1,3,7-nonatrienyl)-1,3,2-benzodioxaborole (7). A mixture of **7** (0.45 g, 3.0 mmol) and 1,3,2-benzodioxaborole (0.33 ml, 3.0 mmol) was heated at 70 °C for 3 h under an atmosphere of N_2: Distillation by using Kugelrohr gave trienylborane, **7**, as a viscous oil, bp 130 °C (0.05 mmHg) (0.58 g, 72%). A shorter reaction time (1 h) resulted in a lower yield (37%) of the borane. This borane was used immediately for the next step. This trienylborane has been found to decompose gradually when it is exposed to air, but it can be stored in an atmosphere of N_2 in a refrigerator. ^{1}H NMR, 1.63 and 1.70 (each 3H, s, *gem*-dimethyl), 1.94 (3H, s, 6-methyl), 2.15—2.20 (4H, m, 4- and 5-methylenes), 5.17 (1H, broad s, 3-H), 5.80 (1H, d, J=18 Hz, 9-H), 6.14 (1H, broad d, J=11 Hz, 7-H), 7.07—7.34 (4H, m, aromatic protons), and 7.73 (1H, dd, J=18 and 11 Hz).

(Z)-2-Bromo-2-butene. This bromide was prepared in an 80% yield according to the method reported by Bordwell and Landis.[2] It showed bp of 44 °C(160 mmHg) [lit,[2] bp 83.5—84.0 °C]. The isomeric purity of the product was found to be 99% by GC analysis (Hitachi K-53 instruments, SVS capillary column, 0.25 mm×45 m, Ucon Oil LB-550X). This bromide was immediately used for the next step, since it is gradually isomerized during storage in a refrigerator. After one-week storage, the isomeric purity went down to *Z*/*E* 91:9.

Synthesis of trans*(C$_{10}$)-Allofarnesene (1).* A mixture of $Pd(PPh_3)_4$ (0.033 g, 0.029 mmol), 2-(4,8-dimethyl-1,3,7-nonatrienyl)-1,3,2-benzodioxaborole (0.348 g, 1.43 mmol), and (*Z*)-2-bromo-2-butene (0.23 g, 1.7 mmol) in benzene (5 ml) containing 2 M-NaOEt†† in EtOH (2 ml) was heated under reflux for 2 h in an atmosphere of N_2. The unreacted borane was then removed by oxidizing with 3 M-NaOH (1 ml) and 30% H_2O_2 (0.3 ml) for 1 h at room temperature. The reaction mixture was extracted with 1:1 benzene–hexane, and the solution was washed with saturated brine and dried over anhydrous $MgSO_4$. Distillation of the product by Kugelrohr gave 0.15 g (51%) of *trans*(C$_{10}$)-allofarnesene (**1**); bp 70 °C(0.08 mmHg). It had n_D^{20}=1.5371. IR (KBr disk), 3040, 1640, and 955 cm^{-1}. ^{1}H NMR, (200 MHz), δ 1.61,††† 1.69,††† 1.80,††† and 1.85††† (each 3H, s, *gem*-dimethyl, 3-methyl, and 7-methyl groups), 1.74 (3H, d, J=7 Hz, protons on C_1), 2.10 (4H, broad s, C_8 and C_9 methylene protons), 5.11 (1H, broad s, 10-H), 5.41 (1H, q, J=7 Hz, 2-H), 5.97†† (1H, d, J=10 Hz, 6-H), 6.57 (1H, d, J=15 Hz, 4-H), 6.42 (1H, dd, J=10 and 15 Hz, 5-H). UV, λ_{max} (C_2H_5OH) 270 nm (inflection, ε 33700), 280 (ε 39500), and 291 (ε 33000); MS, *m/z* 204 (M^+). The yield of *trans*(C$_{10}$)-allofarnesene in this coupling, examined by GLC (Hitachi 163 instrument with a 2 m in 15% Ucon Oil HB-2000 on Uniport B column and with tetradecane as the internal standard), was 89% (1.27 mmol), accompanied by 6% (0.086 mmol) of *cis* (C$_{10}$)-allofarnesene.

10) The observed lower stereoselectivity, when THF was used as the solvent, is probably due to the partial isomerization of (*Z*)-2-bromo-2-butene to its (*E*)-isomer before the coupling. The rate of the oxidative addition of the (*E*)-isomer to Pd(0) would probably be faster than that of the (*Z*)-isomer, since we observed that, in the cross-coupling reaction of a 1:1 mixture of (*E*) and (*Z*)-isomers of styryl bromide with (*E*)-1-hexenyl-1,3,2-benzodioxaborole catalyzed by $Pd(PPh_3)_4$, the rate of the disappearance of (*E*)-styryl bromide was some 10 times faster than that of the (*Z*)-isomer (unpublished results).

Methylation of a Benzene Ring as a Chemical Signal. Marked Changes in the Pattern of Temperature Dependence of the Selectivity in Oxidation of a Pair of Associating Thiols

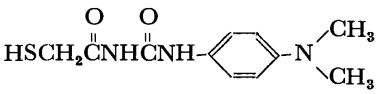
(Received December 26, 1981)

Temperature dependence of the selectivity [the ratio of an unsymmetrical disulfide to symmetrical one] has been studied in oxidation of a pair of associating thiols, each with the recognition site [$C_6H_4N(CH_3)_2$ and R^1], with O_2 in 80% (v/v) acetonitrile–20% water in the range of −10 to 70 °C. The selectivity for $R^1=C_6H_4CH_3$ shows a minimum at 35 °C, whereas for $R^1=C_6H_5$ the selectivity exhibits a maximum at 35 °C; for $R^1=C_6H_4C_2H_5$ plots of the selectivity against temperature shows a sigmoid-like curve. The selectivity in oxidation of a pair of non-associating thiols, 2-(dimethylamino)ethanethiol and a para-substituted benzenethiol, remains practically unaltered with temperature in the same solvent. Though thiol-disulfide exchange reaction proceeds slowly below 35 °C, the selectivity in the exchange differs entirely from that in the oxidation. It has been found that changes in hydrophobicity with R^1 and temperature cannot explain dramatic alterations in the selectivity with R^1 and temperature.

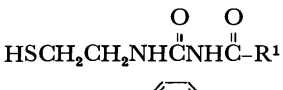
Highly specific molecular recognition underlies living systems. Proteins such as restriction endonucleases[1] and modification methylases[1] can recognize the methyl group. The enzyme-catalyzed methylation of DNA,[2] proteins,[3] and phospholipids[4] is among the biological control mechanisms,[5] and has been investigated extensively: (1) methylation of nucleotide bases (5-methylcytosine and N^6-methyladenine) lying within the recognition sequence serves to protect the cell's own DNA from being degraded by its restriction endonucleases,[6] (2) methylation, for example, of cytosine is involved in gene regulation and differentiation,[7] (3) most eukaryotic, but not bacterial, messenger RNAs contain a methylated guanosine (7-methylguanosine) —— the "cap" —— at their 5′-ends,[8] and (4) methylation of protein-carboxyl groups (*e.g.*, γ-carboxyl group(s) of glutamic acid residue(s)) is associated with the control of chemotactic behavior and with signal transduction in both prokaryotes and eukaryotes.[9]

It is striking that biological systems make use of quite a "simple" chemical modification, *methylation*, in their control mechanisms as described above. In spite of biological significance, the problem of methylation has not so far been examined from a chemical point of view of, for example, what influence the methylation exercises on chemical events as well as of how noncovalent weak interactions are altered upon methylation. We report here that the methylation of a benzene ring remote from the reaction site radically alters the pattern of temperature dependence of the selectivity in oxidation of a pair of associating thiols.

In this study we used two reaction systems: the associating system (system A) and non-associating system (system N). These two systems are structurally related to each other except for the ability to associate. System A consists of a pair of thiols (**1** and **2**)[10] which can associate mainly through intermolecular hydrogen bonding.[11] Thiols **1** and **2** each have the three sites —— thereaction site (SH group) where model reaction takes place, the binding site (–CNHCNH–, acylurea bond) that can participate in intermolecular hydrogen bonding,[11] and the recognition site [$C_6H_4N(CH_3)_2$ or R^1] that can participate in the selective recognition. System A is further divided into system A_p (**1** and **2p**), system A_t (**1** and **2t**), system A_e (**1** and **2e**), and system A_a (**1** and **2a**). System N is made up of a pair of thiols, 2-(dimethylamino)ethanethiol (**3**) and a para-substituted benzenethiol (**4**); this system is also divided into system N_p (**3** and **4p**) and system N_t (**3** and **4t**).

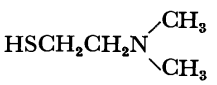


1

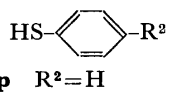


2p $R^1=$

2t $R^1=$ 
2e $R^1=$ 
2a $R^1=C_nH_{2n+1}$



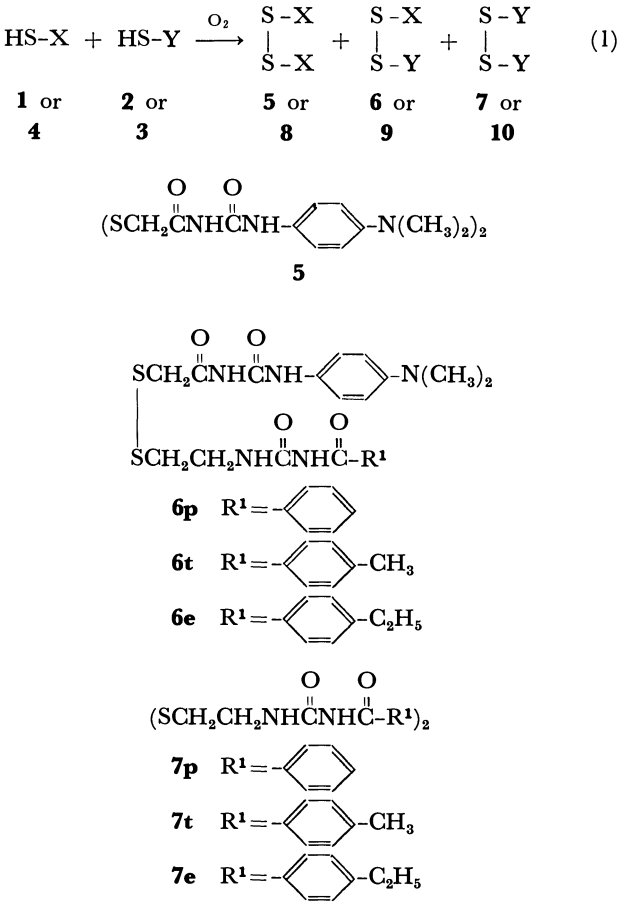
3



4p $R^2=H$
4t $R^2=CH_3$

As a model reaction, oxidation of system A or N with oxygen was chosen. Oxidation of system A gives three disulfides, two symmetrical disulfides (**5** and **7**) and an unsymmetrical disulfide (**6**) as shown in Eq.

1; similarly, oxidation of system N gives the corresponding three disulfides (**8**—**10**) (Eq. 1). The determination of the products in the case of oxidation of system A was made according to our method[12] which took advantage of separation by thin-layer chromatography (TLC) and UV absorption due to the moiety $-HNC_6H_4N(CH_3)_2$.[13] The selectivity (R) —— a measure of *molecular recognition* —— in this oxidation is represented by the ratio of the yield of **6** (or **9**) to that of **5** (or **8**) [R=**6**/**5** for system A or **9**/**8** for system N].[13,14]



Results

Selectivity in Oxidation of a Pair of Thiols. The temperature dependence of the selectivity (R) in oxidation of system A was examined in 80% (v/v) acetonitrile–20% water within the temperature range from −10 to 70 °C. The results are shown in Table 1 and Fig. 1: (1) each of the three curves for systems A_p, A_t, and A_e shows considerable symmetry around 35 °C; (2) the selectivity for all the three systems increases in going from 0 to −10 °C; (3) even at 70 °C the R values do not approach 2 (the statistically expected value[15]) for this type of reaction) except in the case of system A_p, this result contrasting sharply with the fact[16] that for system A_a where R^1=*i*-C_5H_{11} and *n*-C_5H_{11} the R values at 70 °C were 2.9 and 2.3, respectively.

Control experiments were performed at 20, 35, and 70 °C using oxidation of system N. The R values were found to vary only slightly (*i.e.*, from 1.6 to 1.8) in both systems N_p and N_t within this temperature

a) The time required for the oxidation was 1.5 h for 70 °C, 3 h for 35 °C, and 50 to 70 h for 0 °C. b) Yields are calculated in such a way that (1) when **1** and **2** are converted exclusively to **5** and **7**, respectively, the yields of **5** and **7** are both 50% and (2) when **1** and **2** are converted exclusively to **6**, the yield of **6** is 100%.

range.

Selectivity in Thiol-Disulfide Exchange Reaction. We studied thiol-disulfide exchange reaction, known to take place generally as shown in Eqs. 2 and 3,[17] in order to elucidate whether or not the exchange affects the experimental results illustrated in Fig. 1. The exchange was carried out mainly between thiol **2** and disulfide **5** at 0, 35, and 70 °C for the same time as with the corresponding oxidation. Since resulting thiol **1** (Eqs. 2 and 3) could not be separated from disulfide **5** by TLC in the solvent required to separate the three disulfides **5**—**7** from one another, **1** was converted to the corresponding sulfide having the carbamoyl group (**11**), by treatment with iodoacetamide and Et_3N (Eq. 4),[18] so as to be determined by the method[12] described above.

$$\underset{\mathbf{2}}{\text{HS-Y}} + \underset{\mathbf{5}}{\text{XS-SX}} \rightleftharpoons \underset{\mathbf{6}}{\text{XS-SY}} + \underset{\mathbf{1}}{\text{HS-X}} \quad (2)$$

$$\underset{\mathbf{2}}{\text{HS-Y}} + \underset{\mathbf{6}}{\text{XS-SY}} \rightleftharpoons \underset{\mathbf{7}}{\text{YS-SY}} + \underset{\mathbf{1}}{\text{HS-X}} \quad (3)$$

$$\underset{\mathbf{1}}{\text{HS-X}} + \text{ICH}_2\overset{\overset{\text{O}}{\|}}{\text{C}}\text{NH}_2 \xrightarrow[-\text{Et}_3\text{N}\cdot\text{HI}]{\text{Et}_3\text{N}} \underset{\mathbf{11}}{\text{XSCH}_2\overset{\overset{\text{O}}{\|}}{\text{C}}\text{NH}_2} \quad (4)$$

In Table 2 are listed the experimental data: (1) at 0 °C the exchange reaction is slow in all cases; (2) at 35 °C the exchange proceeds to some extent except in the case of **2t** and **5**; (3) at 70 °C the reaction is fast; (4) the rate of the reaction increases progressively with increasing temperature as exemplified by the yield of **5**.

The exchange was also performed between thiol **1** and disulfide **7** for the same time as with the corresponding oxidation (Table 2). In view of the results with the exchange between **2** and **5**, the reaction temperature to be examined was limited to 35 and 70 °C, and disulfide **7** to **7p** and **7t**. As a result, 75 to 94% of **1** was found to remain unreacted in all cases. From the data shown in Tables 1 and 2, it has been demonstrated that the selectivity in the exchange differs entirely from the selectivity in the oxidation.

Further, we examined disulfide-disulfide exchange reaction between **5** and **7t** at 35.0 °C in the presence of Et_3N, but in the absence of a thiol, for 3 h (Eq. 5). The exchange proved not to occur practically, as

$$\underset{\mathbf{5}}{\text{XS-SX}} + \underset{\mathbf{7t}}{\text{YS-SY}} \rightleftharpoons 2\,\underset{\mathbf{6t}}{\text{XS-SY}} \quad (5)$$

indicated by the observation that recovery of **5** was 92% with the yield of **6t** being <1%; this agrees well with the generally accepted view.[17a]

Physicochemical Properties of the Associating Thiols. The degree to which molecules self-associate in solution can be represented, for example, by the "degree of association" (f): the f value for the solute is obtained by dividing the stoichiometric mole fraction of the solute by the effective mole fraction of the solute.[19] The data (in benzene at 36.0 °C) in Table 3 exhibit that thiols **1** and **2** are similar in f values to each other and that f values for **2** increase with increasing number of the carbon atoms introduced at the para position of its benzene ring.

The solubilities of **1** and **2** in aqueous acetonitrile, the same solvent as in the oxidation, in the range of 20 to 50 °C are illustrated in Fig. 2 and partly in Table 3 for comparison with the melting points of **1** and **2**. Figure 2 shows that (1) the solubility increases with increasing temperature for each thiol, (2) the solubility of **2** increases in the order **2t**<**2e**<**2p** at all temperatures studied, and (3) **1** is approximately equal in solubility to **2t** at all temperatures. There exists an empirical rule that solubilities decrease with increasing melting-points for a series of homologs.[20]

Table 2. Yields of **5**, **6**, and **11** and the selectivity in thiol-disulfide exchange reaction[a]

Temp/°C	Reactant	Yield[b]/%			Selectivity (**6**/**5**)
		5	**6**	**11**

a) The exchange reaction time was the same as with the oxidation; see footnote a in Table 1. b) The yields of **5** and **6** are calculated as in Table 1. The yield of **11** is calculated in such a way that when **5** is converted exclusively to **1**, the yield of **11** is 100%.

Table 3. Physicochemical properties of thiols **1** and **2**

Thiol	f[a]	Solubility[b] (35 °C)	Mp[c] θ_m/°C	Chemical shift[d] H^α (or H^γ)	Chemical shift[d] H^β (or H^δ)
1	1.31	3.06	173	9.50	10.17
2p	1.30	13.4	148	8.73	8.85
2t	1.33	3.15	187	8.58	9.02
2e	1.41	5.36	165	8.56	8.92

a) The values at 36.0 °C and 0.010 M (1 M = 1 mol dm^{-3}) in benzene. For the definition, see the text. b) Expressed in mmol per 100 g of 80% (v/v) CH_3CN-20% H_2O. c) Obtained from the DTA curves. d) The chemical shifts for the individual thiols in $CDCl_3$ at 34 °C and 0.020 M. The values are in ppm downfield from TMS. Greek letters (α, β, γ, and δ) indicate assignments as given in Fig. 4. When **1** and **2** were mixed together in equimolar amounts (0.010 M each) in $CDCl_3$ at 34 °C, the chemical shifts of the NH^α proton were 9.39, 9.36, and 9.38 ppm for systems A_p, A_t, and A_e, respectively, those of the NH^γ proton being 8.67, 8.58, and 8.58 ppm for systems A_p, A_t, and A_e, respectively.

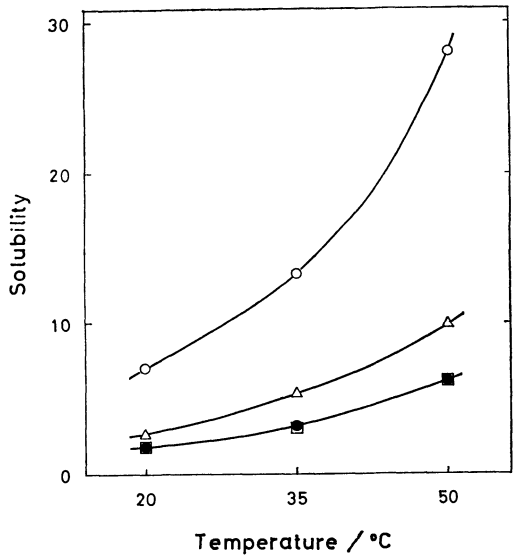

Fig. 2. Temperature dependence of the solubility for **1** and **2**. The solubilities are expressed in mmol/100 g of 80% (v/v) CH_3CN–20% H_2O.
□: **1**, ○: **2p**, ●: **2t**, △: **2e**.

The data in Table 3 show that this rule holds true for thiol **2**.

Using surface tension measurement, we have examined whether or not system A forms micelles in aqueous acetonitrile. As a result, it has been found that in 80% (v/v) acetonitrile–20% water surface tension for systems A_p, A_t, and A_e all remains constant (32.0±0.2 dyn/cm) over the concentration range of 1.3×10^{-6} to 1.0×10^{-2} M.[21]

Figure 3 provides the temperature dependence of the NH proton chemical shifts for system A in $CDCl_3$. The results shown in Fig. 3 reveal that the chemical shifts are more sensitive to temperature for the NH^{α} and NH^{γ} protons (Fig. 4), each participating in intermolecular hydrogen bond, than for the NH^{β} and NH^{δ} protons (Fig. 4), each participating in intramolecular hydrogen bond. Furthermore, chemical shift changes with the structure of R^1 proved to be larger for the NH^{γ} proton than for the NH^{α} proton.

Discussion

The most striking feature of the results reported above is the radical changes in temperature-selectivity profiles from one pattern to another around 35 °C —— from a maximum-having curve to minimum-having one (or to sigmoid-like one) —— on methylation (or ethylation) of the benzene ring in **2** at the para position.[22] This observation would imply that methylation of a benzene ring can function as a *chemical signal* (*or information*) in an associating system. In what follows, we would like to discuss some factors which have the possibility of affecting the temperature dependence of the selectivity on methylation and ethylation.

Intermolecular Association. Table 3 clarifies that **1** and **2** associate strongly with themselves in benzene. In Fig. 4 are given the association patterns[23] of three dimers, two homodimers (**12** and **14**) and a heterodimer (**13**), the association patterns being assigned mainly on the basis of the NMR results (Fig. 3) as in our previous work.[11] Moreover, our study

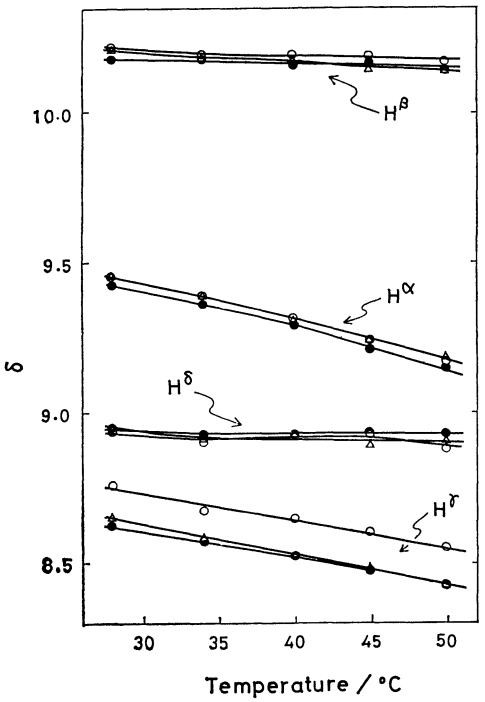

Fig. 3. Temperature dependence of the NH proton chemical shifts for a 1:1 mixture of **1** and **2** (0.010 M each) in $CDCl_3$ at 34 °C.

Fig. 4. Association patterns of three dimers **12**—**14**.

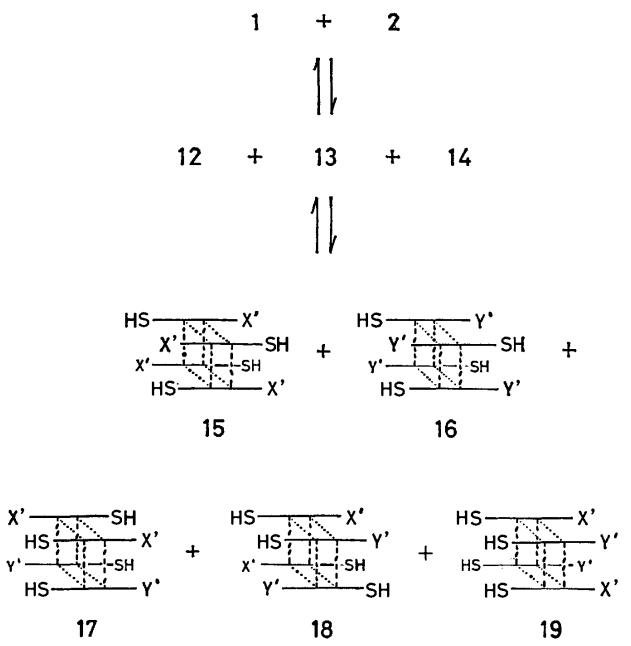

Fig. 5. Association schemes of tetramers **15**—**19** formed by dimerization of dimers **12**—**14**.
·····: Hydrogen bond responsible for stabilization of dimers, ----: noncovalent weak interactions responsible for stabilization of tetramers. The symbols X′ and Y′ represent $C_6H_4N(CH_3)_2$ and R^1, respectively.

has indicated that dimers **12**—**14** would dimerize to form tetramers (Fig. 5) —— two homotetramers (**15** and **16**) and three heterotetramers (**17**—**19**)[23,24] —— in equilibrium with dimers **12**—**14** and monomers (**1** and **2**) and that oxidation of system A_a proceeds through these tetramers **15**—**19**. Since the f value of 1.41 for **2a** ($R^1=i$-C_5H_{11}) is similar to those for **2p**, **2t**, and **2e** under the same conditions as in Table 3, it seems reasonable to assume that oxidation of systems A_p, A_t, and A_e proceeds also through tetramers **15**—**19**. There is substantial evidence for the presence of tetramers[25] and for their participation in biological reactions.[11]

Simple thiols are reported to be capable of forming very weak hydrogen bonds with themselves.[26] However, considering that f values even for the amide derivatives of **2** (**20**) which can form a single hydrogen bond are less than 1.05 in benzene at 36.0 °C and 0.010 M,[27] it is probably fair to say that thiols **3** and **4** are present mainly as monomers in dilute solutions.[26]

$$HSCH_2CH_2NHC(=O)-R^3$$

20

The selectivity remained approximately constant, when oxidation of system N was performed at 20, 35, and 70 °C. This finding together with the data in Fig. 1 demonstrates the importance of intermolecular association in molecular recognition, in agreement with our previous conclusion.[16]

Seeman *et al.* studied how the base pairs in double helical nucleic acids could be recognized by proteins, and concluded that using two hydrogen bonds, fidelity of base pair recognition might be achieved, whereas a single hydrogen bond was inadequate for uniquely identifying any particular base pair.[28]

Possibility of Micelle Formation in Aqueous Acetonitrile. It is recognized that when the concentration of a surfactant in an aqueous solution is increased, surface tension is initially reduced with its concentration, for example, to *ca.* 25 dyn/cm,[29] and then kept approximately constant beyond the critical micelle concentration (cmc).[30] In contrast, surface tension of system A in aqueous acetonitrile did not alter over the concentration range of 1.3×10^{-6} to 1.0×10^{-2} M, the latter corresponding to the concentration of a nearly saturated solution. This result clearly demonstrates that no micelle formation occurs for system A in the same solvent as in the oxidation.

Solubility Differences and Heterogeneity of Reactions. System A was homogeneous at higher temperatures in 80% (v/v) CH_3CN–20% H_2O under argon in the presence of a catalytic amount of Et_3N: system A_p was completely soluble above 40 °C, and systems A_t and A_e above 50 °C. Accordingly, differential solubilities of **1** and **2** at lower temperatures may influence the selectivity in oxidation of system A in such a way that the larger the solubility differences between **1** and **2** are, the smaller the R values become. Since solubility differences between **1** and **2** vary monotonously with temperature, the temperature dependence of solubility differences between **1** and **2** has no appreciable correlation with that of the selectivity for system A (Figs. 1 and 2).

Rys reported the mixing effects on the product distribution in competitive consecutive or parallel reactions.[31] This problem was not examined directly in the present case. However, if diffusion effects influence the selectivity, the temperature-selectivity profiles for systems A_p, A_t, and A_e all should become similar in pattern to one another as temperature increases. As is clear from Fig. 1, this does not hold true, suggesting that the selectivity would not be disguised by diffusion effects.

Exchange Reactions. It is generally accepted that thiol-disulfide exchange reaction occurs easily if a base is present and that the rate of the exchange increases with temperature.[17c] In contrast, in this study thiol-disulfide exchange has been found to take place to a small extent below 35 °C (Table 2), and no appreciable disulfide-disulfide exchange has occurred. It seems probable, therefore, that the exchange reactions have not so great influence on the selectivity in the oxidation of system A at least below 35 °C, judging from the fact that (1) there is a remarkable difference in the selectivity between the exchange and the oxidation (Tables 1 and 2) and (2) the amount of the thiols which can participate in thiol-disulfide exchange is reduced as the oxidation proceeds.

Hydrophobic Interaction.[32] The strength of hydrophobic interaction (hydrophobicity)[33] appears to increase with increasing surface area[34] of the nonpolar group removed from contact with water:[35] The $\Delta G°$ value for the transfer of solute from the pure liquid to aqueous solution increases in the order benzene (4.61 kcal/mol) < toluene (5.33 kcal/mol) < ethylben-

zene (6.07 kcal/mol).[36] Furthermore, hydrophobicity represented by ΔG° for the transfer is known to increase progressively with temperature.[36]

The temperature dependence of R described above was investigated in acetonitrile containing a given amount (20% (v/v)) of water. In addition, using acetonitrile with varying amounts (10 to 50% (v/v)) of water as solvents, oxidation of system A_p was performed similarly at 35.0 °C; R values were plotted against the volume percent of water. As a result, R values were found to show a maximum at 20% of water.[37] If hydrophobic interaction is responsible for the selectivity changes with temperature on methylation and ethylation, the R values for all of systems A_p, A_t, and A_e should vary progressively with volume percent of water and with temperature because of progressive increment of hydrophobicity with these two factors. This does not coincide with the experimental results. These arguments indicate that marked changes in the selectivity with temperature on methylation and ethylation (Fig. 1) cannot be interpreted at all in terms of hydrophobic interaction.

Evidence is now presented to force reexamination of the concept of hydrophobic interaction.[38-40] Lawaczeck and Wagner[38] pointed out that this interaction, though consistent with the behavior of proteins or nonpolar amino acids, failed to account for the thermodynamic data in the nucleic acid field —— the large positive entropy values obtained for nucleic acid melting and for transfer of nucleobases from organic solvents to water. Cramer III[39] showed that hydrophobic interaction was incompatible with relationships between the structures of various nonpolar solutes and their solvation energies by water and 1-octanol. Moreover, based on adhesion and surface free energy data to indicate that the forces between hydrocarbons and water in contact with each other are attractive and not repulsive, Hildebrand[40] has argued against the use of the word "hydrophobic" to describe the relative lack of attraction between water and nonpolar substances.

Three-dimensional Shape-specific Weak Interactions. We have recently suggested that weak interactions specific for three-dimensional shape of nonpolar groups are responsible for selective molecular recognition in oxidation of system A_a.[41] This type of interactions are assumed to possess the following features: (1) they have energies smaller than that for hydrogen bond, (2) they are made up of individual interactions between groups, between a group and an atom, or between atoms, and (3) they can reflect three-dimensional shape of nonpolar groups such as alkyl groups.[42]

The data in Fig. 3 indicate that there is inappreciable difference in the pattern of temperature dependence of the NH^α proton chemical shifts on methylation and ethylation. Hence it seems difficult to consider that specific weak interactions[43] are reflected in the NH^α proton resonance.

Abraham reported that the major contribution to the hydrophobic CH_2 free-energy increment ($\Delta G^\circ =$ 0.54 kcal/mol at 298 K) was an enthalpic effect ($\Delta H^\circ =$ 0.46 kcal/mol) and not an entropic effect ($-T\Delta S^\circ =$ 0.08 kcal/mol), by dissecting the gas→water CH_2 contribution into a favorable normal solvent effect and a true (unfavorable) hydrophobic effect.[44] Abraham's conclusion stimulates our view that the selectivity changes on methylation are better to understand by three-dimensional shape-specific weak interactions rather than by hydrophobic interaction.

Conclusion

The pattern of temperature dependence of the selectivity in oxidation of a pair of associating thiols varies radically from a maximum-having curve to a minimum-having one (or to a sigmoid-like one) upon methylation (or ethylation) of a benzene ring remote from the reaction site. This is not the case with the oxidation of a pair of non-associating thiols. These experimental results would mean that methylation of a benzene ring can function as a *chemical signal* in an associating system.

Further, any of the factors discussed in this work —— solubility differences, exchange reactions, hydrophobic interaction, and three-dimensional shape-specific weak interactions —— alone cannot, at present, satisfactorily explain the dramatic alterations in the selectivity with temperature on methylation and ethylation.

Experimental

Determination of Physicochemical Properties of Thiols and Disulfides. Melting points were obtained from the DTA (Differential Thermal Analysis) curves recorded with a Shimadzu DT-20B thermal analysis apparatus. The samples were finely powdered, diluted with fine-grained quarz wool in the specimen holder, and heated in a stream of nitrogen with a heating rate of 10 °C/min.

The effective mole fraction of the solute required to calculate the degree of association (f) was determined on a Hitachi Perkin-Elmer 115 molecular weight apparatus using a differential vapor pressure method at 36.0 °C and 0.010 M in benzene.

The solubility was measured gravimetrically by evaporating a saturated solution of **1** or **2** to dryness under reduced pressure. The saturated solution of **1** or **2** was prepared by vigorous stirring of the two-phase mixture for 8 h in a well-stirred water bath held at constant temperatures controlled to ±0.1 °C. Further stirring caused no increase in solubility. Separate experiments containing different ratios of residual solid solute to solvent yielded the same equilibrium solubility. The solubility recorded for a given temperature is the mean value of at least four measurements which did not deviated more than 4%.

Surface tension for three systems A_p, A_t, and A_e was measured on a Kyowa surface tensiometer CBVP-A3 using a counter balance and vertical plate method in 80% (v/v) CH_3CN–20% H_2O at 25 °C. The concentrations of each thiol employed for this measurement were 1.3×10^{-6}, 2.6×10^{-5}, 5.2×10^{-4}, and 1.0×10^{-2} M; the concentration of 0.010 M corresponds to that of a nearly saturated solution of system A. The uncertainty in surface tension is ±0.2 dyn/cm.

^1H NMR spectra were measured on a Hitachi R-20B spectrometer at 60 MHz. The chemical shifts for the NH protons shown in Fig. 3 were measured precisely by the sideband method with the aid of a frequency counter. The uncertainty in chemical shifts is ±0.01 ppm.

Materials. Acetonitrile was dried and purified by dis-

tillation from calcium hydride and phosphorus pentaoxide, and stored over molecular sieves. Water was distilled after deionization. Precoated TLC plates (silica gel 60 F_{254}) were purchased from Merck Darmstadt.

Thiol **1** was prepared as described before[45] and had the following properties (the melting point and NH proton chemical shifts are listed in Table 3): R_f 0.69 [silica, Et_2O-$EtCO_2H$-MeOH (30:3:1) and Et_2O-$EtCO_2H$-MeOH-AcOEt (60:6:1:1)]; NMR ($CDCl_3$) δ=2.10 (1H, t, J=9.0 Hz, SH), 2.94 (6H, s, $N(CH_3)_2$), 3.38 (2H, d, J=9.0 Hz, $HSCH_2$), 6.6—7.6 (4H, m, ArH). Found: C, 52.45; H, 6.10; N, 16.64; S, 12.69%; M^+, 253.

Thiol **3** was prepared by reaction of its hydrochloride (Tokyo Kasei Kogyo Co., Ltd.) with an excess of tetraethylenepentamine and purified by distillation (bp 57—58 °C (80 mmHg**)); satisfactory spectral data were used to support the assignment of **3**. Thiol **4** was obtained from Tokyo Kasei Kogyo Co., Ltd. and purified by distillation before use. Thiol **20** was synthesized as reported before.[27]

Preparation of Thiol 2. Freshly sublimated cysteamine (10 mmol) was dissolved in 35 ml of tetrahydrofuran (THF) under argon by heating. This solution was cooled to 0 °C. To the cold solution was added an acyl isocyanate (10.5 mmol) at 0 °C under argon with stirring. The reaction mixture was stirred for 2 h at room temperature under argon, evaporated to dryness, and recrystallized from benzene for **2p** and from acetonitrile for **2t** and **2e**. Thiol **2** had the following properties (the melting points and NH proton chemical shifts are listed in Table 3).

2p: NMR ($CDCl_3$) δ=1.44 (1H, t, J=7.6 Hz, SH), 2.72 (2H, m, $HNCH_2$), 3.54 (2H, m, CH_2SH), 7.2—8.3 (5H, m, ArH). Found: C, 53.78; H, 5.42; N, 12.44; S, 14.28%; M^+, 224. Calcd for $C_{10}H_{12}N_2O_2S$: C, 53.57; H, 5.39; N, 12.50; S, 14.27%; M, 224.

2t: NMR ($CDCl_3$) δ=1.44 (1H, t, J=8.6 Hz, SH), 2.44 (3H, s, $ArCH_3$), 2.74 (2H, m, $HNCH_2$), 3.56 (2H, m, CH_2SH), 7.2—8.1 (4H, m, ArH). Found: C, 55.28; H, 5.82; N, 11.82; S, 13.17%; M^+, 238. Calcd for $C_{11}H_{14}N_2O_2S$: C, 55.45; H, 5.92; N, 11.76; S, 13.43%; M, 238.

2e: NMR ($CDCl_3$) δ=1.26 (3H, t, J=7.5 Hz, CH_3), 1.45 (1H, t, J=8.0 Hz, SH), 2.5—2.9 (4H, m, CH_2NH and CH_2CH_3), 3.56 (2H, m, $HSCH_2$), 7.1—8.1 (4H, m, ArH). Found: C, 57.24; H, 6.42; N, 11.16; S, 12.72%; M^+, 252. Calcd for $C_{12}H_{16}N_2O_2S$: C, 57.13; H, 6.39; N, 11.11; S, 12.69%; M, 252.

Preparation of Disulfides. Symmetrical disulfides **5** and **8** were easily obtained by treatment with O_2 in the presence of Et_3N in CH_3CN at room temperature; disulfide **5** was recrystallized from CH_3CN-DMF. Satisfactory spectral data were used to support the assignment of disulfides **5**—**10**. Unsymmetrical disulfides **6** and **9** were prepared as described before,[46] recrystallized from CH_3CN for **6**, and had the following properties (NMR spectra of **5** and **6** were measured in Me_2SO-d_6 at 34 °C and 0.040 M).

5: Mp 210 °C; R_f 0.67 (silica, Et_2O-$EtCO_2H$-MeOH, 30:3:1) or 0.70 (silica, Et_2O-$EtCO_2H$-MeOH-AcOEt, 60:6:1:1); NMR δ=2.89 (12H, s, $N(CH_3)_2$), 3.81 (4H, s, SCH_2CO), 6.5—7.5 (8H, m, ArH), 10.02 (2H, s, NH^α), 10.65 (2H, s, NH^β). Found: C, 52.09; H, 5.58; N, 16.67; S, 12.95%. Calcd for $C_{22}H_{28}N_6O_4S_2$: C, 52.37; H, 5.59; N, 16.66; S, 12.69%.

6p: Mp 187 °C; R_f 0.83 (silica, Et_2O-$EtCO_2H$-MeOH-AcOEt, 60:6:1:1); NMR δ=2.7—3.8 (4H, m, SCH_2CH_2N), 2.84 (6H, s, $N(CH_3)_2$), 3.72 (2H, s, SCH_2CO), 6.5—8.3 (8H, m, ArH), 8.88 (1H, t, J=6 Hz, NH^δ), 10.03 (1H, s, NH^α), 10.68 (2H, s, NH^β and NH^γ). Found: C, 52.89; H, 5.33; N, 14.60; S, 13.54%. Calcd for $C_{21}H_{25}N_5O_4S_2$: C, 53.04; H, 5.31; N, 14.73; S, 13.48%.

6t: Mp 192 °C; R_f 0.84 (silica, Et_2O-$EtCO_2H$-MeOH, 30:3:1); NMR δ=2.37 (3H, s, $ArCH_3$), 2.83 (6H, s, $N(CH_3)_2$), 2.6—3.8 (4H, m, SCH_2CH_2N), 3.72 (2H, s, SCH_2CO), 6.5—8.1 (8H, m, ArH), 8.89 (1H, t, J=6 Hz, NH^δ), 10.04 (1H, s, NH^α), 10.60 (1H, s, NH^β), 10.67 (1H, s, NH^γ). Found: C, 54.15; H, 5.58; N, 14.47; S, 13.07%. Calcd for $C_{22}H_{27}N_5O_4S_2$: C, 53.97; H, 5.56; N, 14.30; S, 13.10%.

6e: Mp 195 °C; R_f 0.81 (silica, Et_2O-$EtCO_2H$-MeOH, 30:3:1); NMR δ=1.19 (3H, t, J=7.5 Hz, $ArCH_2CH_3$), 2.6—3.8 (6H, m, SCH_2CH_2N and $ArCH_2$), 2.82 (6H, s, $N(CH_3)_2$), 3.71 (2H, s, SCH_2CO), 6.5—8.1 (8H, m, ArH), 8.89 (1H, t, J=6 Hz, NH^δ), 10.03 (1H, s, NH^α), 10.60 (1H, s, NH^β), 10.64 (1H, s, NH^γ). Found: C, 54.68; H, 5.77; N, 13.83; S, 12.53%. Calcd for $C_{23}H_{29}N_5O_4S_2$: C, 54.86; H, 5.81; N, 13.91; S, 12.71%.

*2-(Dimethylamino)ethyl Phenyl Disulfide (**9p**)*: Oil; R_f 0.38 (silica, n-C_6H_{14}-EtOH, 17:2); NMR ($CDCl_3$) δ=2.20 (6H, s, $N(CH_3)_2$), 2.4—3.0 (4H, m, SCH_2CH_2N), 6.8—7.8 (5H, m, ArH); M^+, 213.

*2-(Dimethylamino)ethyl p-Tolyl Disulfide (**9t**)*: Oil; R_f 0.39 (silica, n-C_6H_{14}-EtOH, 17:2); NMR ($CDCl_3$) δ=2.18 (6H, s, $N(CH_3)_2$), 2.28 (3H, s, $ArCH_3$), 2.3—2.9 (4H, m, SCH_2CH_2N), 6.8—7.8 (4H, m, ArH); M^+, 227.

*Preparation of Sulfide (**11**).* To a mixture of iodoacetamide (10 mmol) and Et_3N (11 mmol) in 100 ml of CH_3CN was added **1** (10 mmol) with stirring at 0 °C under argon. Stirring was continued for 1 h at room temperature. The reaction mixture was evaporated to dryness, washed with water, dried under reduced pressure over phosphorus pentaoxide, recrystallized from CH_3CN to give a pale yellow crystal, and had the following properties (NMR spectra were measured in Me_2SO-d_6 at 34 °C and 0.040 M): mp 195 °C; R_f 0.40 (silica, Et_2O-$EtCO_2H$-MeOH, 30:3:1) or 0.37 (silica, Et_2O-$EtCO_2H$-MeOH-AcOEt, 60:6:1:1); NMR δ=2.84 (6H, s, $N(CH_3)_2$), 3.24 (2H, s, SCH_2CONH), 3.45 (2H, s, SCH_2CONH_2), 6.5—7.5 (6H, m, $CONH_2$ and ArH), 10.06 (1H, s, NH^α), 10.58 (1H, s, NH^β). Found: C, 50.41; H, 5.87; N, 18.31; S, 10.55%. Calcd for $C_{13}H_{18}N_4O_3S$: C, 50.31; H, 5.85; N, 18.06; S, 10.31%.

Oxidation of a Pair of Thiols. A mixture of **1** (0.50 mmol) and **2** (0.50 mmol) [or of **3** (0.50 mmol) and **4** (0.50 mmol)] in 12.5 ml of 80% (v/v) CH_3CN-20% H_2O was stirred vigorously under oxygen for 15 min in a well-stirred water bath (for 20 to 70 °C) or methanol bath (for −10 and 0 °C) which was thermostated to ±0.1 °C for 20 to 50 °C and to ±0.5 °C for −10, 0, and 70 °C. To this mixture was added Et_3N (0.05 mmol), and vigorous stirring was continued for the time required to complete the oxidation. When the oxidation was completed, the reaction mixture was evaporated to dryness. In the case of the oxidation of system A, the yields of **5** and **6** were determined by the use of their absorption at 310 nm (ε=20300 for **5**, 10300 for **6p**, 10500 for **6t**, and 10400 for **6e** in 90% (v/v) THF-10% H_2O) after separation by TLC [2 mm×1.2 cm×5 cm E. Merck precoated silica gel plates (60 F_{254}), Et_2O-$EtCO_2H$-MeOH (30:3:1) for systems A_t and A_e or Et_2O-$EtCO_2H$-MeOH-AcOEt (60:6:1:1) for system A_p] followed by elution with 90% (v/v) THF-10% H_2O.[12] The yield shown in Table 1 represents the mean value of four or more measurements, and was reproducible to <3% average deviation from the mean. With oxidation of system N, the yields of **8** and **9** were determined gravimetrically after

** 1 mmHg≈133.322 Pa.

separation by preparative TLC [1 mm×20 cm×20 cm silica gel plates (E. Merck 60 PF_{254}), n-C_6H_{14}–EtOH (17:2)] followed by elution with CH_2Cl_2 for **8** and with CH_3CN for **9**.

Thiol-Disulfide Exchange Reaction. A mixture of **2** (0.50 mmol) and **5** (0.25 mmol) was stirred in 12.5 ml of 80% (v/v) CH_3CN–20% H_2O vigorously under argon for 15 min in a well-stirred water bath or methanol bath which was thermostated as in the oxidation. To this mixture was added Et_3N (0.05 mmol), and vigorous stirring was continued for the same time as with the corresponding oxidation under argon. To this mixture were added iodoacetamide (0.55 mmol) and Et_3N (0.55 mmol). After vigorous stirring for 10 min at 35 and 70 °C or for 20 min at 0 °C, the resulting mixture was evaporated to dryness. The yields of **5**, **6**, and **11** (ε=10300 at 310 nm in 90% (v/v) THF–10% H_2O) were determined as described with the oxidation. The yield of the corresponding sulfide derived from **2** could not be determined by the method[12] because of its small molar extinction coefficient (ε=*ca.* 30 in 90% (v/v) THF–10% H_2O at 310 nm). Similarly, the exchange reaction between **1** and **7** was carried out. The yield shown in Table 2 represents the mean value of four or more measurements, and was reproducible to <3% average deviation from the mean.

Disulfide-Disulfide Exchange Reaction. A mixture of **5** (0.25 mmol) and **7t** (0.25 mmol) was stirred vigorously in 12.5 ml of 80% (v/v) CH_3CN–20% H_2O for 15 min in a well-stirred water bath held at 35.0 °C controlled to ±0.1 °C. To this mixture was added Et_3N (0.025 mmol), and vigorous stirring was continued for 3 h. The resulting reaction mixture was evaporated to dryness, and the yields of **5** and **6t** were determined as described above.

We thank Professor Yoshio Sasada, Dr. Motohiro Nishio, and Dr. Yuji Ohashi for their helpful discussions and reading the manuscript. We are grateful to Mrs. Yukiko Takeda, Mr. Tomoji Murata, Mr. Koji Kobinata, Mr. Shigeru Miyamoto, and Mr. Kazuhiro Furumoto for their valuable assistance.

18) This nucleophilic substitution (Eq. 4) is known to proceed very rapidly, and extensively used in protein chemistry: A. Fontana and C. Toniolo, "Detection and Determination of Thiols," in "The Chemistry of the Thiol Group," ed by S. Patai, Wiley, London (1974), Part 1, Chap. 5.
19) If a single multimer species in equilibrium with monomer is assumed to be dimer, f values range from 1.0 to 2.0: M. Davies and D. K. Thomas, *J. Phys. Chem.*, **60**, 763 (1956).
20) J. H. Hildebrand, E. T. Ellefson, and C. W. Beebe, *J. Am. Chem. Soc.*, **39**, 2301 (1917).
21) Surface tension is reported to be 71.97 for water (25 °C) and 29.3 for CH_3CN (20 °C): "Lange's Handbook of Chemistry," 11th ed, ed by J. A. Dean, McGraw-Hill, New York (1973), Section 10.
22) Similar, but less dramatic, variations in temperature-selectivity profiles were observed in oxidation of system A_a: a plot of R in 80% (v/v) CH_3CN–20% H_2O against temperature showed a peak of maximum selectivity (R=21) at 35 °C for R^1=i-C_5H_{11}, whereas for R^1=n-C_5H_{11} the R values altered progressively over a wide range (0.13 to 2.3).[16]
23) We have recently prepared a great variety of solid 1:1 complexes between a pair of acylurea bond-containing compounds (analogs of **1** and **2**) each with the *p*-(dimethylamino)phenyl or *p*-nitrophenyl group as one of the two substituents. X-Ray crystallographic studies of the two complexes and **1** have indicated that (1) they have the same pattern of hydrogen bonding as in Fig. 4 and (2) the packing modes of the four molecules in the unit cells of the complexes and of **1** are analogous to the association schemes of heterotetramer **18** and homotetramer **15**, respectively (Y. Ohashi, A. Uchida, and Y. Sasada, private communication). These observations encourage our view that there exist tetramers **15**—**19** in solution (Fig. 5).
24) Among many possibilities, five tetramers were chosen so that (1) the ratio of **1** to **2** in heterotetramers might be 1:1 and (2) the stabilization of tetramers might become strongest.[11]
25) Tetramer formation is shown for methanol in the gas (W. Weltner, Jr., and K. S. Pitzer, *J. Am. Chem. Soc.*, **73**, 2606 (1951)); the important multimer species of both methanethiol and ethanethiol in argon matrices at low concentrations at 20 K is the open chain dimer and cyclic tetramer, the latter being particularly stable for ethanethiol (A. J. Barnes, H. E. Hallam, and J. D. R. Howells, *J. Chem. Soc., Faraday Trans. 2*, **68**, 737 (1972)). For the other examples, see Ref. 11.

Syntheses of 2-Amino-3,4-dimethyl-3*H*-imidazo[4,5-*f*]quinoline and Its Related Compounds

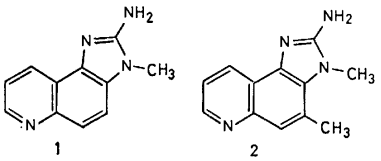
Hiroshi KASAI* and Susumu NISHIMURA

Biology Division, National Cancer Center Research Institute, Tsukiji 5-1-1, Chuo-ku, Tokyo 104

(Received February 3, 1982)

The strongly mutagenic compound, 2-amino-3,4-dimethyl-3*H*-imidazo[4,5-*f*]quinoline (Me-IQ), isolated from broiled sardines was synthesized from 6-amino-7-methylquinoline. Several structurally related compounds were also synthesized to clarify the structure-activity relationship. Some of them also showed strong mutagenic activity towards *Salmonella typhimurium* TA98.

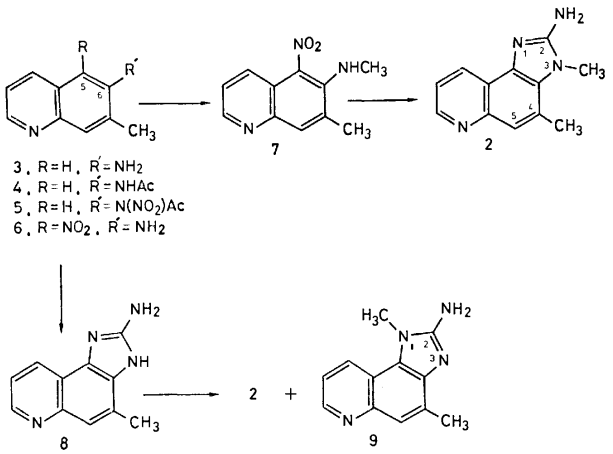
We previously isolated two new potent mutagens from broiled fish (sardine) and identified them as 2-amino-3-methyl-3*H*-imidazo[4,5-*f*]quinoline (IQ, compound **1**)[1-4] and 2-amino-3,4-dimethyl-3*H*-imidazo-[4,5-*f*]quinoline (Me-IQ, compound **2**).[5] They are strongly mutagenic, especially towards *Salmonella typhimurium* TA98.[2,5] For final structure assignment of Me-IQ and for studies on structure-activity relationship of 2-aminoimidazo[4,5-*f*]quinoline derivatives, we synthesized compound **2** and its related compounds from 6-aminoquinoline derivatives. In this paper, we describe detailed data on syntheses of these new imidazo[4,5-*f*]quinoline derivatives. A preliminary account of this work has been published.[2,5]



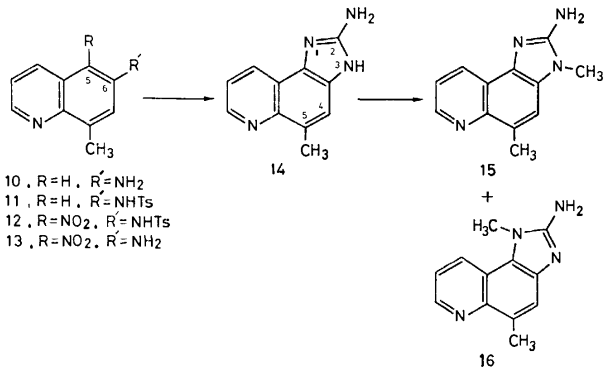
1 2

Results and Discussion

Compound **2** was synthesized from 6-amino-7-methylquinoline (**3**) as shown in Scheme 1. Compound **3** prepared by the method of Huisgen[6] was converted to the 6-acetamido derivative **4**. Nitration of compound **4** with KNO_3–H_2SO_4 mixture gave an *N*-nitro derivative **5**. Acid hydrolysis of compound **5** gave the 5-nitro derivative **6** with migration of the nitro group on nitrogen to the neighboring 5-C position of the quinoline nucleus. Compound **6** was treated with sodium hydride in *N*,*N*-dimethylformamide and methylated with methyl iodide to afford the *N*-methyl derivative **7**. Compound **7** was then reduced to the 6-methylamino-5-amino derivative with Fe/HCl mixture and the neutralized reaction mixture was treated with cyanogen bromide to afford compound **2**. Compound **2** was also prepared by methylation of compound **8**, which was obtained from compound **6**. In the latter reaction, the 1-methyl isomer, compound **9**, was also produced.



Scheme 1.



Scheme 2.

Compound **15** was synthesized from 6-amino-8-methylquinoline (**10**) as shown in Scheme 2. This method is practically the same as that reported for the synthesis of compound **1**.[2] Namely, the tosyl derivative **11**, prepared from compound **10**,[7] was converted to the nitro derivative **12** by treatment with 61% HNO_3. Compound **12** was then hydrolyzed with concentrated H_2SO_4, resulting in formation of 6-amino-5-nitro-8-methylquinoline (**13**). Compound **13** was converted to the diamine derivative by reduction with Fe/HCl mixture. The reaction mixture was neutralized, and then treated with cyanogen bromide to yield the cyclized derivative **14**. The 3-methyl derivative **15** was finally obtained as a major product by heating the tetramethylammonium salt of compound **14** in vacuum.[2,3,8] In this reaction 1-methyl derivative **16** was also obtained as a minor product.

The mass, UV, and ^{1}H-NMR spectra of compound **2**, isolated from broiled fish were exactly the same as those of the synthetic compound **2**, but different from those of compounds **9**, **15**, and **16**. Therefore, compound **2** was unambiguously identified as 2-amino-3,4-dimethyl-3*H*-imidazo[4,5-*f*]quinoline (**2**). Compounds **2**, **9**, **15**, and **16** showed strong mutagenic activity towards the *S. typhimurium* TA98 strain by

metabolic activation with microsomal enzymes. However compounds **8** and **14** showed almost no mutagenic activity.[9] Quantitative measurements of compounds **1** and **2** in various cooked foods by G.C.-mass spectrometry are in progress in this laboratory.

Experimental

Spectral Measurements. ^{1}H-NMR (270 MHz) spectra were recorded in a Bruker WH 270 spectrometer at 23 °C in $CDCl_3$ or CD_3OD. Chemical shifts were measured relative to the residual $CHCl_3$ signal (δ 7.25) or CHD_2OD signal (δ 3.40). Mass spectra were obtained by a Varian MAT-44 instrument. UV spectra were obtained using a Shimadzu UV-300 spectrophotometer.

6-Acetamido-7-methylquinoline (4). 6-Amino-7-methylquinoline (**3**)[6] (130 mg) was dissolved in acetic anhydride (1 ml) and the solution was allowed to stand at room temperature for 10 min. Then, cold water (6 ml) was added, and the solution was adjusted to pH 10 by adding NaOH solution. The product was extracted with ethyl acetate (3×10 ml) and crystallized from ethanol. Yield, 110 mg; mp 176—177 °C; MS: 200 (M^+), 158 (M^+−Ac).

6-(N-Nitroacetamido)-7-methylquinoline (5). Compound **4** (1.2 g) was dissolved in concentrated H_2SO_4 (5 ml), and KNO_3 (1.5 g) was added with vigorous stirring at 0 °C. Stirring was continued for 30 min at room temperature and then the reaction mixture was poured onto ice, neutralized with NaOH solution and extracted with ethyl acetate. The crude product was purified on a column of silica gel (3 cm×50 cm) with methanol–chloroform (3:97, v/v) as solvent. Compound **5** was crystallized from methanol. Yield, 500 mg; mp 240—242 °C; MS: 245 (M^+), 203 (M^+−Ac), 199 (M^+−NO_2): NMR ($CDCl_3$): δ=8.96 (1H, dd, J=4.2, 1.5 Hz, 2-H), 8.20 (1H, dd, J=8.6, 1.5 Hz, 4-H), 8.18 (1H, s, 8-H), 7.67 (1H, br s, 5-H), 7.51 (1H, dd, J=8.6, 4.2 Hz, 3-H), 2.52 (3H, s, 7-Me), 2.25 (3H, s, Ac).

6-Amino-7-methyl-5-nitroquinoline (6). Compound **5** (500 mg) was suspended in concentrated H_2SO_4 (2 ml) and heated at 70 °C for 30 min. The reaction mixture was poured onto ice and neutralized with NH_4OH. The precipitate was collected by filtration, washed with a small amount of water and dried. The crude product was crystallized from ethanol. Yield, 360 mg; mp 171—172 °C; MS: 203 (M^+), 157 (M^+−NO_2); NMR ($CDCl_3$): δ=8.98 (1H, ddd, J=8.8, 1.3, 1.0 Hz, 4-H), 8.68 (1H, dd, J=4.2, 1.3 Hz, 2-H), 7.95 (1H, dd, J=1.0, 0.8 Hz, 8-H), 7.46 (1H, dd, J=8.8, 4.2 Hz, 3-H), 6.72 (2H, br s, NH_2), 2.44 (3H, d, J=0.8 Hz, Me).

7-Methyl-6-methylamino-5-nitroquinoline (7). Compound **6** (27 mg) was dissolved in *N*,*N*-dimethylformamide (0.2 ml). Sodium hydride (7.8 mg, 50% oil suspension) was added and the reaction mixture was stirred for 30 min at room temperature. Then methyl iodide (10 μl) was added during 1 h and stirring was continued for 1 h at room temperature. After cold water (1 ml) was added, the reaction mixture was neutralized with NaOH solution and the product was extracted with ethyl acetate (3×1.5 ml). The crude product thus obtained was purified on a column of silica gel (1 cm×30 cm) with methanol–chloroform (5:95, v/v) as solvent. Yield, 4.3 mg; powder; MS: 217 (M^+), 170 (M^+−H−NO_2), 156 (M^+−NO_2−Me); NMR ($CDCl_3$): δ=8.69 (1H, dd, J=4.3, 1.5 Hz, 2-H), 8.18 (1H, ddd, J=8.6, 1.5, 0.7 Hz, 4-H), 7.86 (1H, dd, J=0.7, 0.7 Hz, 8-H), 7.40 (1H, dd, J=8.6, 4.3 Hz, 3-H), 5.17 (1H, d, J=5.5 Hz, NH), 3.00 (3H, d, J=5.5 Hz, N–Me), 2.47 (3H, d, J=0.7 Hz, 7-C–Me).

*2-Amino-3,4-dimethyl-3*H*-imidazo[4,5-f]quinoline (2).* Compound **7** (4 mg) was dissolved in concentrated HCl (0.1 ml) and reduced by adding Fe powder (10 mg). After 20 min, the reaction mixture was filtered and washed with water. The filtrate was neutralized with KOH solution, aqueous BrCN (12 mg, 0.2 ml) was added during 3 h with stirring, and stirring was coninued for 4 h. The reaction mixture was made alkaline with KOH solution and extracted with ethyl acetate (5×1 ml). The crude product thus obtained was purified by HPLC [Shimadzu LC-3A; μBondapak C_{18} (Waters); 30% methanol–0.04% formic acid]. Yield, 2.2 mg; mp 295—297 °C; MS: 212 (M^+), 197 (M^+−H−HCN); UV (MeOH): $\lambda(\varepsilon)$=219 (29000), 265 (48000), and 332 nm (4000); NMR ($CDCl_3$): δ=8.80 (1H, dd, J=4.2, 1.7 Hz, 7-H), 8.66 (1H, ddd, J=8.3, 1.7, 0.7 Hz 9-H), 7.53 (1H, dd, J=0.9, 0.7 Hz, 5-H), 7.36 (1H, dd, J=8.3, 4.2 Hz, 8-H), 4.51 (2H, br s, NH_2), 3.88 (3H, s, N–Me), 2.83 (3H, d, J=0.9 Hz, 4-C–Me), NOE (N–Me→4-C–Me) 3%±1%.

*2-Amino-4-methyl-3*H*-imidazo[4,5-f]quinoline (8).* Compound **6** (100 mg) was dissolved in concentrated HCl (1.5 ml) and reduced by adding Fe powder (200 mg). The reaction mixture was filtered and washed with water. The filtrate was neutralized with KOH solution, and aqueous BrCN (300 mg, 6 ml) was added during 1 h with stirring. Stirring was further continued for 2 h. Then the solution was made alkaline with KOH solution, and the crude product was extracted with ethyl acetate (5×100 ml). The ethyl acetate layer was evaporated to dryness, and the residue was fractionated on a column of silica gel (1.5 cm×30 cm) with methanol–chloroform (15:85, v/v) as solvent to isolate compound **8**. Yield, 36 mg; mp 280—290 °C (decomp): MS: 198 (M^+), 170 (M^+−H−HCN); NMR (CD_3OD): δ=8.81 (1H, dd, J=4.5, 1.6 Hz, 7-H), 8.73 (1H, ddd, J=8.4, 1.6, 0.8 Hz, 9-H), 7.67 (1H, dd, J=1.0, 0.8 Hz, 5-H), 7.60 (1H, dd, J=8.4, 4.5 Hz, 8-H), 2.74 (3H, d, J=1.0 Hz, Me).

*2-Amino-1,4-dimethyl-1*H*-imidazo[4,5-f]quinoline (9).* Compound **8** (16 mg) was dissolved in dimethyl sulfoxide (0.45 ml) and methylated with methyl iodide (20 μl) in the presence of K_2CO_3 (32 mg). The reaction was continued for 1 h at room temperature. In this reaction, compounds **2** and **9** were produced in approximately equal proportions. Compound **9** was separated from compound **2** by HPLC using the same conditions as those described above for purification of synthetic compound **2**. Yield, 3.5 mg; powder; MS: 212 (M^+), 197 (M^+−Me), 184 (M^+−H−HCN); NMR ($CDCl_3$): δ=8.81 (1H, d, J=4.0 Hz, 7-H), 8.54 (1H, d, J=8.5 Hz, 9-H), 7.76 (1H, s, 5-H), 7.39 (1H, dd, J=8.5, 4.0 Hz, 8-H), 5.98 (2H, br s, NH_2,), 4.02 (3H, s, N–Me), 2.72 (3H, s, 4-C–Me), NOE (N–Me→9-H)17%± 4%. UV (MeOH): $\lambda(\varepsilon)$=216 (26600), 276 (46500), and 344 nm (2400).

*8-Methyl-6-(*p*-tolylsulfonylamino) quinoline (11).* 6-Amino-8-methylquinoline (**10**)[7] (10 g), *p*-toluenesulfonyl chloride (12.1 g), and potassium acetate (6.2 g) were suspended in ethanol (200 ml) and refluxed for 2.5 h. The hot mixture was then filtered, and the filtrate was evaporated to dryness. The crude product was purified on a column of silica gel (5 cm×60 cm) with chloroform as solvent. Yield, 19 g; oil; MS: 312 (M^+), 248 (M^+−SO_2); NMR ($CDCl_3$): δ=8.84 (1H, dd, J=4.3, 1.7 Hz, 2-H), 8.01 (1H, dd, J=8.3, 1.7 Hz, 4-H), 7.73 (2H, d, J=8.1 Hz, tosyl-H_o), 7.42 (1H, d, J=2.4 Hz, 5-H), 7.35 (1H, dd, J=8.3, 4.3 Hz, 3-H), 7.29 (1H, dd, J=2.4, 0.9 Hz, 7-H), 7.18 (2H, d, J=8.1 Hz, tosyl-H_m), 2.67 (3H, d, J=0.9 Hz, 8-Me), 2.31 (3H, s, tosyl-Me).

8-Methyl-5-nitro-6-(p-tolylsulfonylamino) quinoline (12). Compound **11** (18.5 g) was nitrated with 61% HNO_3 (6.9 ml) at 70—80 °C for 1 h. The solution was poured onto ice, and the solid material formed was collected by filtration. The crude product was purified by crystallization from ethanol. Yield 16.6 g; mp 204—205 °C; MS: 357 (M^+), 246 ($M^+-SO_2-NO_2-H$); NMR ($CDCl_3$): δ=9.05 (1H, dd, J=4.4, 1.5 Hz, 2-H), 8.61 (1H, dd, J=8.9, 1.5 Hz, 4-H), 8.11 (1H, d, J=0.8 Hz, 7-H), 7.70 (2H, d, J=8.2 Hz, tosyl-H_o), 7.67 (1H, dd, J=8.9, 4.4 Hz, 3-H), 7.25 (2H, d, J=8.2 Hz, tosyl-H_m), 2.87 (3H, d, J=0.8 Hz, 8-Me), 2.37 (3H, s, tosyl-Me).

6-Amino-8-methyl-5-nitroquinoline (13). Compound **12** (16 g) was suspended in concentrated H_2SO_4 (20 ml) and heated for 1 h at 95 °C. The hydrolyzate was neutralized with NH_4OH. The precipitate was collected by filtration and dried. The crude product was purified by crystallization from toluene and then recrystallized from ethanol. Yield, 3 g; mp 161—162 °C; MS: 203 (M^+), 157 (M^+-NO_2); NMR ($CDCl_3$): δ=9.15 (1H, dd, J=8.8, 1.7 Hz, 4-H), 8.70 (1H, dd, J=4.2, 1.7 Hz, 2-H), 7.50 (1H, dd, J=8.8, 4.2 Hz, 3-H), 6.99 (1H, d, J=1.0 Hz, 7-H), 6.67 (2H, br s, NH_2), 2.71 (3H, d, J=1.0 Hz, Me).

2-Amino-5-methyl-3H-imidazo[4,5-f]quinoline (14). Compound **14** was synthesized and purified by the procedure used for preparation of compound **8**. Yield, 15%; mp 246—248 °C (decomp); MS: 198 (M^+), 170 ($M^+-H-HCN$); NMR ($CDCl_3$): δ=8.88 (1H, dd, J=4.1, 1.7 Hz, 7-H), 8.61 (1H, dd, J=8.4, 1.7 Hz, 9-H), 7.53 (1H, d, J=0.7 Hz, 4-H), 7.43 (1H, dd, J=8.4, 4.1 Hz, 8-H), 4.59 (2H, br s, NH_2), 2.84 (3H, d, J=0.7 Hz, Me).

2-Amino-3,5-dimethyl-3H-imidazo[4,5-f]quinoline (15) and 2-Amino-1,5-dimethyl-1H-imidazo[4,5-f]quinoline (16). An aqueous solution of compound **14** (135 mg) and tetramethylammonium hydroxide (62.3 mg) was lyophilized in a sublimation apparatus and heated slowly to 200 °C under vacuum pressure (3 mmHg†). At this temperature the sublimate began to collect on the condenser. The crude product thus obtained was purified on a column of silica gel (3 cm × 30 cm) with methanol–chloroform (10:90, v/v) as solvent. Compound **15** was crystallized from aqueous ethanol. Yield, 34 mg; mp >300 °C; MS: 212 (M^+), 184 (M^+), UV (MeOH): $\lambda(\varepsilon)$=213 (24900), 265 (45600), 354 nm (3600). NMR ($CDCl_3$): δ=8.91 (1H, d, J=4.0 Hz, 7-H), 8.67 (1H, d, J=8.2 Hz, 9-H), 7.48 (1H, dd, J=8.2, 4.0 Hz, 8-H), 7.44 (1H, s, 4-H), 6.07 (2H, br s, NH_2), 3.67 (3H, s, N–Me), 2.87 (3H, s, C–Me).

During purification by the silica gel column chromatography, compound **16** was also obtained as a minor component. Yield, 3 mg; powder; MS: 212 (M^+), 197 (M^+-Me), 184 ($M^+-H-HCN$); NMR ($CDCl_3$): δ=8.85 (1H, dd, J=4.2, 1.6 Hz, 7-H), 8.56 (1H, dd, J=8.6, 1.6 Hz, 9-H), 7.74 (1H, d, J=0.7 Hz, 4-H), 7.41 (1H, dd, J=8.6, 4.6 Hz, 8-H), 4.50 (2H, br s, NH_2), 4.00 (3H, s, N–Me), 2.84 (3H, d, J=0.7 Hz, C–Me).

† 1 mmHg≈133.322 Pa.

We wish to thank Dr. S. Yokoyama, the University of Tokyo, for measurements of NMR spectra and Dr. Yamaizumi of our institute for measurements of Mass spectra.

(Received October 2, 1981)

An alkaloid extracted from a small evergreen tree, *Annona montata*, was identified as 1-(2-amino-4-pyrimidinyl)-β-carboline monohydrate by the X-ray method. The crystal data are; $a=20.699$, $b=4.453$, $c=15.720$ Å, and $\beta=112.16°$; space group, $P2_1/c$; $Z=4$. The structure was solved by the direct method and refined by the least-squares method to the final R value of 0.109 for 1451 independent reflections. The water molecule is connected to four nitrogen atoms by hydrogen bonds. Two of them are in different groups; one is in the five-membered ring of the β-carboline skelton, and the other is in the pyridine of the β-carboline skelton. The fifth hydrogen bond connects two nitrogen atoms, one of which is in the amino group, and the other, in the pyrimidine skelton.

As a part of studies of Formosan folk-medicines, the constituents of small evergreen tree, *Annona montana* Macf., have been investigated by several workers. Yang *et al.*[1] isolated seven species of alkaloids from this plant. The present report will describe the molecular and crystal structure of one of them, annomurine, which has thus been designated by us. This substance was identified as 1-(2-amino-4-pyrimidinyl)-β-carboline by this work.

Experimental

The EtOH extract of the stem bark was triturated with 3% AcOH, and the filtrate was shaken with $CHCl_3$ to separate a $CHCl_3$-soluble fraction and an aqueous fraction. Crystals were obtained from the $CHCl_3$-soluble fraction in the form of light yellow plates. They were recrystallized by slow evaporation from an aqueous solution of MeOH. The result of the structure analysis showed that they were monohydrates.

The cell dimensions were determined by the least-squares method using various sets of high-angle reflections on a diffractometer. The crystal data are given in Table 1. The crystal (0.31, 0.03, 1.86 mm) was mounted on a four-circle diffractometer (Rigaku AFC III), with Mo $K\alpha$ ($\lambda=0.7107$ Å) from a graphite monochromator. The intensities were collected for the independent 1759 reflections within $2\theta<60°$, using the ω-2θ scan technique with a scanning speed of 4° min^{-1} in 2θ, while 344 reflections with $|F_o|<3\sigma(F)$ were designated as unobserved. Corrections for the background and the Lorentz-polarization factor were made, but not for the absorption or the extinction.

Table 1. Crystallographic data for 1-(2-amino-4-pyrimidinyl)-β-carboline monohydrate

$C_{15}H_{11}N_5\cdot H_2O$, space group $P2_1/c$, $Mr=279.2$	
$a=20.699(7)$ Å	$D_m=1.396$ g cm^{-3} (flotation; $CHCl_3/CH_3C_6H_5$)
$b=4.453(2)$ Å	$D_x=1.439$ g cm^{-3} ($Z=4$)
$c=15.720(5)$ Å	μ (Mo $K\alpha$) $=0.856$ cm^{-1}
$\beta=112.16(2)°$	
$V=1341.8$ Å^3	

All the numerical calculations were carried out on a NEAC 2200 MODEL 575 computer at the Computing Center of the National Defense Academy with programs of the Universal Crystallographic Computing System.[2] The phase problem was solved without difficulty by the use of MULTAN.[3] The initial residual index was 0.44 for the trial structure. The structure was refined by a block-diagonal least-squares procedure. Five cycles of refinement reduced the R value to 0.201. Further refinements were made using anisotropic thermal parameters for the non-hydrogen atoms, together with isotropic B values of the hydrogen atoms, which were fixed assuming the angle of 120° for each carbon atom and a bond length of 1.09 Å for each C–H bond. The hydrogen positions of water were deduced from a difference Fourier synthesis. The R value at this stage was 0.109. The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[4] The final atomic coordinates, together with B_{eq}, are given in Table 2.†††

Discussion

The R value did not decrease to less than 0.109, partly because attempts to obtain good-shaped single crystals suitable for X-ray analysis were not successful.

The mean standard deviations are 0.02 Å for the interatomic distance and 0.9° for the angle. These values may be sufficient to discuss the molecular geometry and the packing of the molecules in the unit cell, especially the role the hydrogen bonds play in the crystal.

Configuration of the Molecule. The numbering scheme of the nonhydrogen atoms and four molecular planes (A, B, C, D) is presented in Fig. 1.[5] The numbering scheme of the hydrogen atoms is shown in Table 2. The mean atomic deviations were ±0.007 Å for the A plane, ±0.005 Å for B, ±0.007 Å for C, and ±0.014 Å for D. The dihedral angle between A and B is 1.1°, while that between B and C is 1.0°. The value of the indole nucleus is 2.1°.[6] The two six-membered rings (A and C) make an angle of 1.9°.

** A preliminary report was presented at the 42nd National Meeting of the Chemical Society of Japan, Sendai, September 1980.

††† The complete tables of the anisotropic thermal parameters, the F_o-F_c data, and the torsion angles are deposited as Document No. 8226 at the Office of the Editor of the Bulletin, the Chemical Society of Japan.

Bond Lengths and Bond Angles. The average C–C bond length in the benzene ring is 1.396 Å. The C(5)–C(6) bond (1.362 Å) is significantly shorter than the average value. These results compare well with those found in indole.[6] The C(11)–C(13) bond (1.421 Å) is longer than the standard aromatic C–C bond of 1.395 Å.[8] The mean C–N distance in the five-

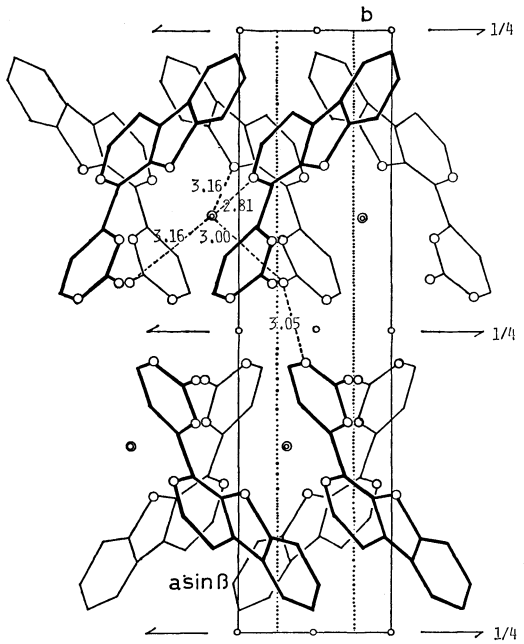

Fig. 2. Packing of the molecules viewed down c. Hydrogen bonds are shown by broken lines with their lengths in Å.

membered ring is 1.381 Å, and the C–C distance is 1.416 Å. The mean bond distances in the pyridine ring are 1.396 Å for C–C and 1.346 Å for C–N. As for the pyrimidine ring, the mean C–N distance is 1.335 Å. The angles at the nitrogen atoms are less than 120° by about 4°, in agreement with the values in similar heterocyclic systems. The angles at the carbon atoms are all greater than 120° [that at C(16) considerably so], with the exception of that at C(19), which is only 115.9°. These results compare well with those found in the structure of pyrimidine.[9]

Environment of the Molecule. Five types of hydrogen bonds can be seen in the structure. The first hydrogen bond connects N(20) with O(21) at a distance of 3.00 Å. The second (3.16 Å) connects N(9) with O(21). The third (2.81 Å) is the O(21)–N′(2) bond, in which N′(2) is equivalent to N(2). The fourth (3.16 Å) connects N″(20), which is equivalent to N(20), with O(21). The fifth hydrogen bond connects N(20) with N‴(17) at a distance of 3.05 Å.

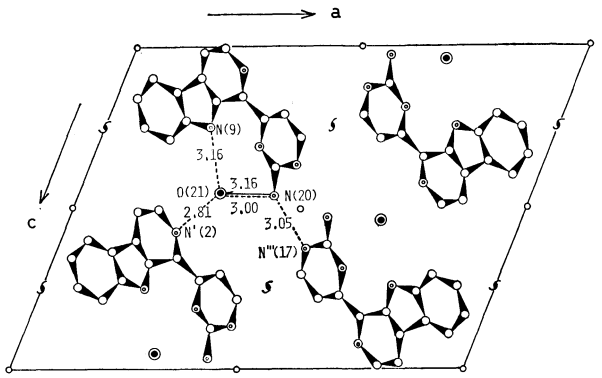

Fig. 3. The packing of the molecules in a unit cell seen along the b axis.

These hydrogen bonds are shown in Figs. 2 and 3.

We wish to thank Mr. Toshio Sato for giving us a chance to cooperate in this work; Professor Daihei Oda, Mr. Osamu Moriya, and Mr. Shigeru Hasegawa for their valuable suggestions, and Dr. Teruo Noguchi and Mr. Jun Ito for plotting the thermal ellipsoids. We also wish to thank Mr. Kazumasa Maruyama for help with the calculations.

The Effect of Quaternary Phosphonium Halides on the Temperature of the Maximum Density of Water

Katsuko TAKAIZUMI* and Toshiki WAKABAYASHI

The College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received November 10, 1981)

The shifts in the temperature of the maximum density(tmd) of water produced by quaternary phosphonium halides, $(n\text{-Bu})_{4-n}Ph_nPX$($n$=0—4), were measured dilatometrically, and the Despretz constants, K_D, were determined. The K_D, which is positive when the tmd is lowered by a solute, increases nearly linearly with increasing n from 1.16 kK for $(n\text{-Bu})_3PhPCl$ to 1.57 kK for Ph_4PCl, while the K_D for Bu_4PCl, 0.933 kK, is considerably lower than that to be expected from those for other members. Since the standard partial molal volumes of the cations have been found to be nearly the same, the variation in K_D with n would originate from the difference in ion-water interaction between the cations. Some estimation was made for the contribution of the structural effect of the cations on the solvent water (K_{st}). The K_{st} is largely negative for the Bu_4P^+ ion, indicating that the cation is a structure maker. The K_{st} becomes less negative as n increases, indicating that the structure-making ability decreases with an increase in n.

The shifts in the temperature of the maximum density (tmd) of water produced by solutes contain information about the structural influence of the solutes on the solvent water. With nonelectrolytes as solutes, Franks and Watson[1] showed that the shifts (ΔT) are divided into two terms. One(ΔT_v) is dependent upon the size and expansibility of the solute in its pure liquid state, as derived by Wada and Umeda,[2] and it serves always to depress the tmd. The other(ΔT_{st}) is identified with the structural influence of the solute on the solvent water, positive for structure makers and negative for structure breakers. Some alcohols and amines[1,2] elevate the tmd at low concentrations.

On the other hand, the negative shifts alone have been found with electrolytes, including alkali metal halides and tetraalkylammonium halides. Darnell and Greyson[3] noticed, by comparing the tmd's of aqueous solutions of alkali metal halides with common ions, that the stronger the structure-breaking ability of the uncommon ions, the lower the tmd. They found, however, that tetraalkylammonium halides(R_4NX) depress the tmd; this effect becomes greater as the size of the alkyl group increases, contrary to our expectation that tmd would be raised as the size of the alkyl group increases because the structure-making ability of these groups increases with the alkyl-group size.[4] A similar trend was also found in D_2O as the solvent.[5] Darnell and Greyson interpreted their observation as showing that, at least in the neighborhood of the tmd, ion sizes play a more important role in influencing the water structure than the structure-making or structure-breaking properties of the ions which are observed at room temperature, and that, at low temperatures, R_4N^+ ions disrupt the water structure because of the incompatibility of the structure of the solvent.

However, this interpretation seems inconsistent with some facts which indicate that the lower the temperature, the greater is the structure-making ability of R_4N^+ ions, as found in the studies of the near-infrared spectra of Bu_4NBr and in the H_2O–D_2O mixture at 5 °C,[6] the NMR chemical shifts of the water proton in aqueous solution of R_4NX,[7] and the temperature dependence of the cationic partial molal heat capacities of R_4N^+ ions in water.[8] In order to discuss the influence of hydrophobic salts on the water structure, the extraction of ΔT_{st} from ΔT is essential. This is generally very difficult, however, because in this case we must be concerned with the volumetric properties of the salts in a hypothetical pure liquid state.

One way to approach the subject may be to examine the shifts produced by a series of salts which are nearly the same in their volumetric properties, but not in their interactions with water. Quaternary phosphonium salts, $(n\text{-Bu})_{4-n}Ph_nPX$($n$=0—4), satisfy this requirement comparatively well; their standard partial molal volumes[9] tend to approach one another as the temperature is lowered, and the structure-making ability decreases with n.

Experimental

Apparatus and Measurements. Measurements of the volume changes of aqueous solutions of $(n\text{-Bu})_{4-n}Ph_nPX$($n$=0—4) with the temperature were made in dilatometers of about 100-cm³ capacity, calibrated triply with conductivity-grade water, at 0.5 K intervals in the temperature range of 0.5—6 °C. The dilatometers were constructed of Pyrex tubing about 35 mm i.d. and capillary tubing about 0.5 mm i.d. with minimum graduations of 0.0005 cm³. The temperatures of the thermostat bath were controlled to within ±0.005 K. The temperatures of the bath were measured by a standard thermometer calibrated against a platinum-resistence thermometer (Leeds and Northrup).

The volume changes with the temperature were found to be approximately symmetrical near the tmd for all solutions. The tmd was obtained graphically from the temperature *vs.* volume curve, with a maximum error of ±0.05 K.

Materials. The tetraphenylphosphonium chloride was obtained from Merck. The other salts, $Bu_{4-n}Ph_nPCl$(n=0—3), were synthesized from the corresponding phosphines. The method of purifying the salts and their purity were similar to those reported previously[9]. The stock solutions were filtered through a Millipore-filter. The solutions for dilatometric measurement were prepared by the dilution of the stock solutions by weight, all weighings being vacuum-corrected.

Results and Discussion

The shifts, ΔT, in the tmd of water produced by

a) Standard deviation. b) Uncertainty expected in K_D.

$Bu_{4-n}Ph_nPX$(n=0—4, X=Cl, Br) are shown in Fig. 1 as a function of the solute mole fraction, x. As may be seen from the figure, the ΔT for each salt seems to be nearly a linear function of x.

The Despretz constants, K_D, defined by:

$$\Delta T = -K_D x, \tag{1}$$

were determined by the least-squares method. The K_D values thus obtained are summarized in Table 1.

Table 2 lists the densities, d, of the solutions and the apparent molal volumes, ϕ_v, for $Bu_{4-n}Ph_nPCl$ at 5 °C in the concentration range of 0.02—0.2 mol kg^{-1}. The ϕ_v were calculated by means of the equation:

$$\phi_v = \frac{1}{m}\left(\frac{1000+mM}{d} - \frac{1000}{d_o}\right), \tag{2}$$

where m is the molality of salt; M, the formula weight of the salts, and d_o, the density of water at 5 °C, which was taken as 0.999965 g cm^{-3}.[10] The standard partial molal volumes, ϕ_v°, and the B_v coefficients for ϕ_v for the phosphonium halides were determined by fitting

the ϕ_v data to Eq. 3 by the method of least squares;

$$\phi_v - A_v c^{1/2} = \phi_v^\circ + B_v c, \tag{3}$$

where A_v is the Debye-Hückel limiting slope and where the value at 5 °C was taken as 1.529 cm^3 $dm^{3/2}$ $mol^{-3/2}$.[11] The results are summarized in Table 3.

The ΔT for liquid nonelectrolytes can be expressed as:

$$\Delta T = T - T^* = \frac{-\alpha_2 V_2^\circ x}{2\alpha_1(1-x)V_1^*} + \frac{-1}{2\alpha_1(1-x)V_1^*}\frac{\partial \Delta V_x^M}{\partial T}, \quad (4)$$

where the T and T^* are the temperature of the maximum density of a solution and of pure water(3.98 °C) respectively; x is the mole fraction of the solute; α_2 the thermal expansion coefficient of the solute, and α_1, a coefficient in a quadratic equation of T expressing the molal volume of pure water around T^*($\alpha_1 = 7.80\times10^{-6}$ K^{-2}),[2] V_1^* and V_2° are the molal volume of pure water at T^* and that of the solute in the pure liquid state at T, and ΔV_x^M is the excess volume of mixing referred to a mixture of the solute mole fraction, x. For dilute solutions, Eq. 4 is reduced to:

$$\Delta T = -\left(\frac{\alpha_2 V_2^\circ}{2\alpha_1 V_1^*} + \frac{1}{2\alpha_1 V_1^*}\frac{\partial b}{\partial T}\right)x = -(K_v + K_{st})x, \quad (5)$$

under the assumption that $\Delta V_x^M = bx(1-x)$,[12] where b is a constant with regard to the mole fraction. Thus, the Despretz constant can be divided into the volume-dependent term, K_v, and the structural term, K_{st}. With electrolytes containing large organic ions, as in the present case, the K_v would contribute largely to K_D.

As may be seen from Table 1 and Fig. 2, K_D increases with an increase in the number of phenyl groups on the cations. The K_D(Bu_4PBr) is larger by about 70 K than K_D(Bu_4PCl), indicating that the anionic contribution of Br^- to K_D is larger than that of the Cl^- ion. This difference is comparable to that, 50 K,[3] found for a set, K_D(Et_4NBr) and K_D(Et_4NCl). The contribution of the Br^- (and also of Cl^-) ion to K_D's would be comparatively small, say around 5×10^2 K for the Br^- ion, which is the mean value of K_D for HBr and KBr.[20] Thus, it appears that the cationic contribution to K_D increases with an increase in n, from 5×10^2 K for the Bu_4P^+ ion to 1.1×10^3 K for the Ph_4P^+ ion, assuming that the volumetric properties, V_+° and α_+, of the cations are nearly the same, as is suggested by the equality in their standard partial molal volumes(Table 2). This point is discussed below more elaborately.

The $\overline{V}_+^\circ$ may be written as the sum of the contributions of several factors: the intrinsic volume of the cation, $\overline{V}_{in}$; the structural volume change associated with the shift of the H-bond equilibria of the solvent water in the presence of the ion, $\overline{V}_{st}$, and the packing effect of the ion in the cavities in water structures, $\overline{V}_c$. The electrostriction effect can be neglected here because of the large cationic sizes. $\overline{V}_{in}$ will decrease with an increase in n, as is suggested by the molal volume of benzene and liquid butane at 25 °C, 89.4 and 100 cm^3 mol^{-1} (extrapolated values from higher homologs) respectively. $\overline{V}_+^\circ$(Bu_4P^+) in methanol was estimated as 267, and that of the Ph_4P^+ ion, as 264 cm^3 mol^{-1},[13] where the structural effects are much lower than in water. Thus, the $\overline{V}_+^\circ$ values of the present cations are expected to decrease as n increases. The expansion coefficients of the cations would also decrease with n because the polarizability of the butyl group is expected to be smaller than that of the phenyl group, and hence the dispersion force would increase with n.[14] Thus, the conclusion is obtained that K_v decreases somewhat with an increase in n and that, therefore, K_{st} increases with n. Since it has been confirmed that, with a nonelectrolyte as a solute, $\partial\Delta V_x^M/\partial T$ and so $\partial b/\partial T$ are negative for structure-makers and positive for structure-breakers,[2] the phenyl group may be either a structure-breaker or a weaker structure-maker than the butyl group. This conclusion is in agreement with the information obtained from the studies of the viscosity,[15] the molal volume,[9] the molal heat capacity,[13] and the differential near-infrared spectra[16] for Bu_4PBr or Bu_4NBr and Ph_4PCl solutions.

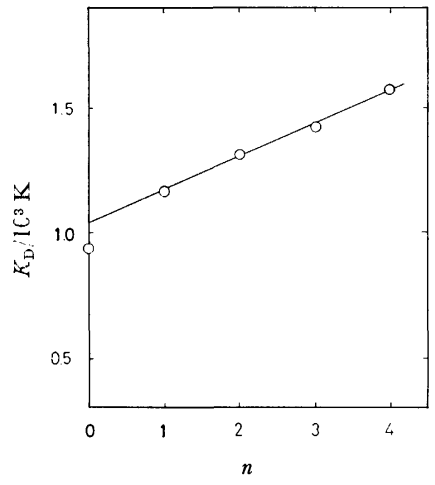

Fig. 2. Despretz constants(K_D) for $Bu_{4-n}Ph_nPCl$ as a function of n.

The estimation of K_{st} for the present cations is of interest and may be possible in the case of the Bu_4P^+ ion. Since Bu_4PBr is similar in molecular structure to Bu_4NBr, the K_{st} can be assumed to be nearly the same with these two salts, and we can obtain the following relation by subtracting K_D(Bu_4NBr) from K_D(Bu_4PBr):

$$K_D(Bu_4PBr) - K_D(Bu_4NBr) = \frac{\alpha_2}{2\alpha_1 V_1^*}(V_2^\circ(Bu_4PBr) - V_2^\circ(Bu_4NBr)), \quad (6)$$

where the thermal expansion coefficient, α_2, is assumed to be equal. From the equation, the value for α_2 is estimated by inserting the standard partial molal volumes, $\overline{V}_2^\circ$(5 °C), in place of V_2°. This approximation seems reasonable because $\overline{V}_{st}$ and $\overline{V}_c$ are expected to be equal for the two cations, and these contributions cancel each other out upon the subtraction. The value obtained for α_2 is 1.8×10^{-3} K^{-1}, with 310.0 and 295.15[8] cm^3 mol^{-1} at 5 °C for $\overline{V}_2^\circ$ of Bu_4PBr and Bu_4NBr respectively, and 888 K for K_D(Bu_4NBr).[5] The α_2 value is of the same order as those for C_5—C_9 alkanes,[14] and seems reasonable. From Eq. 5 with the α_2 value, we obtain 1.8 kK for K_v(Bu_4P^+), where $\overline{V}_+^\circ$(Bu_4P^+) is taken as 281.1 cm^3 mol^{-1}, which is obtained by subtracting $\overline{V}_-^\circ$(Br^-, 5°) 28.9 cm^3 mol^{-1},[9] from $\overline{V}_2^\circ$(Bu_4PBr, 5°). The estimation shows that K_{st} (Bu_4P^+) is largely negative, about −1.3 kK, indicating a strong structure-making ability of the cation, but overshadowed by the larger K_v(Bu_4P^+).

It is noticeable that the K_D for Bu_4PCl is considerably

smaller than that extrapolated from those for other members (Fig. 2). This would suggest the presence of a clathrate-like structure of Bu_4P^+ ion, which was proposed by Wen and Saito[17] for the hydration model for Bu_4N^+ and Pr_4N^+ ions. The cooperative nature in forming a hydrogen-bonded structure of water[18,19] may be responsible for the large increase in K_{st} value from the Bu_4P^+ to the Bu_3PhP^+ ion because of a different kind of water structure in the cosphere of the phenyl group. The aqueous-solution behavior of the Ph_4P^+ ion can, in comparison with that of the Bu_4P^+ ion, be characterized by the following: A low activation energy for viscous flow,[15,21] a low partial molal heat capacity,[13] a large molal expansibility with a negative temperature dependence,[9] a low negative value of B_v(Table 3) with a negative temperature dependence, in contrast with a positive dependence for Bu_4PBr,[9] *etc.* All these facts suggest that the water molecules in the phenyl-cosphere are less structured, and hence less hydrogen-bonded, than those in the butyl-group cospheres; in other words, the phenyl groups are hydrophilic rather than hydrophobic. This character of the phenyl groups would arise from delocalized charges on the phenyl groups[22] and the structure-breaking effect due to the poor fit of planar phenyl groups into the partly tetrahedral structure of water. The volumetric properties of the present salts, including a discussion of the B_v-coefficients, will be given in detail elsewhere.[23]

The approach attempted here seems promising for obtaining information, from the tmd data, about the structural influence of organic ions on the solvent water. The division of K_D for electrolytes into ionic contributions based on a sounder basis is required for a more comprehensive treatment of the tmd data. This will be one next subject.[24]

(Received January 26, 1982)

The surface pressure-area (π-A) curves for monolayers of cation-anion double long-chain salts, alkylammonium alkanesulfonates, were determined at the air-water interface by the Langmuir method. When the total chain length of cation and anion was constant, the transition pressure from the expanded to the condensed state in the monolayer was lowered as the chain length of cation elongated, and the lowest pressure at the transition point was observed in the case of the equal chain length of cation and anion. The lower the pressure at the transition point, the larger the value of the mean area per molecule at that point. The apparent molar entropy, enthalpy, and energy of transition from the expanded to the condensed phase were calculated from the temperature dependence of the transition pressure on the π-A curve. All the values calculated were negative. The magnitude in the changes of the apparent molar quantities was greatest when both a cationic and an anionic chain had the same length. These results were interpreted in terms of the orientation of double long-chain salt in the condensed state of monolayer. The increase in the chain length of cation and anion tends to increase the values of apparent molar quantity changes. The contributions of long-chain anion and cation to the phase transition of monolayer are not equivalent; the condensing effect of long-chain cation is larger than that of long-chain anion.

There are numerous studies on the adsorbed films from the mixture of cationic and anionic surfactant solutions at the air-water interfaces.[1-7] With respect to the mixed monolayers of cationic and anionic surfactants, a few studies have been reported.[8-12] Our previous investigation[13] has been made on the insoluble monolayers of double long-chain salts, which are composed of a long-chain cation and a long-chain anion, and has shown unique behavior with a series of alkyltrimethylammonium alkanesulfonates. The surface pressure-area curves of these salts exhibited the transition from an expanded to a condensed film, in such a manner as to depend upon the combination of the anion and cation chain-lengths. To elucidate this phenomenon in more detail, it is necessary to extend the study so as to include the double long-chain salts with a different polar group.

In the present study, alkylammonium alkanesulfonates were prepared, and the surface pressure of monolayers of these salts has been measured as a function of molecular area at various temperatures. The thermodynamic quantities on the phase transition from the expanded to the condensed state were determined.

Experimental

The double long-chain salts, that is, alkylammonium alkanesulfonates, were prepared by mixing equimolar solutions of alkylammonium chlorides and sodium alkanesulfonates (Tokyo Kasei Kogyo Co., Ltd.). The precipitates formed were purified by recrystallization from an acetone/ethanol mixture (3:1, v/v). In this study 16 salts of different hydrocarbon chain length shown in Table 1 were used. These salts are abbreviated as Cm–Cn, in which m is the number of carbon atoms in the cationic long chain and n is that in the anionic long chain. The purity of these salts was checked by elemental analyses, which gave correct results.

Table 1. Materials

Double long-chain salt		Abbreviation	
$C_mH_{2m+1}N^+H_3 \cdot C_nH_{2n+1}SO_3^-$		Cm–Cn	
m = 12, 14, 16, 18		(cationic long-chain)	
n = 12, 14, 16, 18		(anionic long-chain)	
Salt used for monolayers			
C12–C12	C12–C14	C12–C16	C12–C18
C14–C12	C14–C14	C14–C16	C14–C18
C16–C12	C16–C14	C16–C16	C16–C18
C18–C12	C18–C14	C18–C16	C18–C18

Each double long-chain salt was spread from a chloroform/methanol (4:1, v/v) mixture (both Merck, Uvasol) at the air-water interface. The substrate solution of 0.1 M (1 M = 1 mol dm^{-3}) sodium chloride was prepared by thrice-distilled water. Here the sodium chloride was roasted at 973 K to remove any surface active material.

The surface pressure was measured by an automatic Langmuir film balance, which was constructed in our laboratory, within an accuracy of ± 0.1 mN m^{-1}.[13] The temperature of the substrate was controlled within ± 0.1 K at the desired temperature by circulating thermostated water. The monolayer was compressed continuously with a constant velocity of 2.93×10^{-2} nm^2 molecule^{-1} min^{-1}.

Results and Discussion

The surface pressure-area (π-A) curve of C12–C12 was affected by the NaCl concentration of substrate, and showed a reasonable limiting area on the 4 M NaCl solution. Except for a C12–C12 system, the concentration of NaCl did not affect the π-A curves only if it is above 0.1 M; that is, the π-A curves coincide with each other. Considering this, the concentration of NaCl was held at 0.1 M except for the C12–C12 system.

The π-A curves of C12–C12, C14–C14, C16–C16, and C18–C18 salts, which have equal numbers of carbon atoms in the long-chain cation and anion, that is, m=n, are depicted in Fig. 1. The π-A curve of C12–C12 salt had a transition point from an expanded to a condensed state at 298.2 K under the high concentration of sodium chloride (4 M). The π-A curve of C14–C14 had also a transition point, while the curves of C16–C16 and C18–C18 exhibited only the condensed film. It is of interest to compare the monolayer of a double long-chain salt with that of the corresponding single long-chain salt, but the

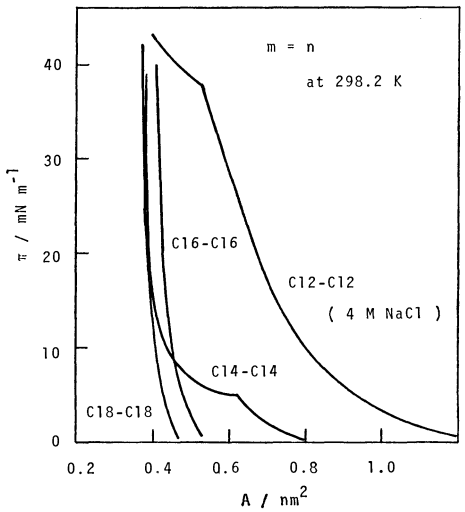

Fig. 1. The π-A curves of double long-chain salts on 0.1 M NaCl at 298.2 K. Except for C12–C12 on 4 M NaCl.

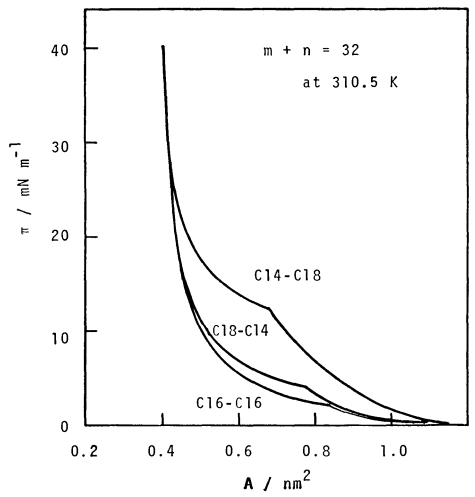

Fig. 2. The π-A curves in the case of total carbon number of long-chain cation and anion equal to 32. Substrate: 0.1 M NaCl at 310.5 K.

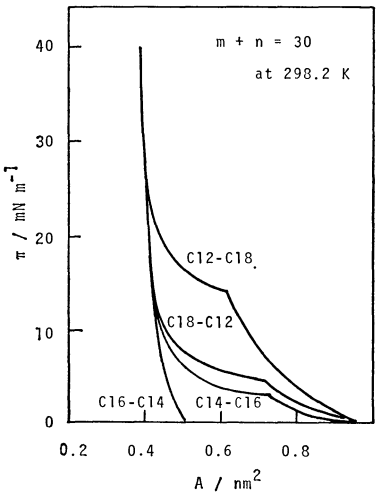

Fig. 3. The π-A curves in the case of total carbon number of long-chain cation and anion equal to 30. Substrate: 0.1 M NaCl at 298.2 K.

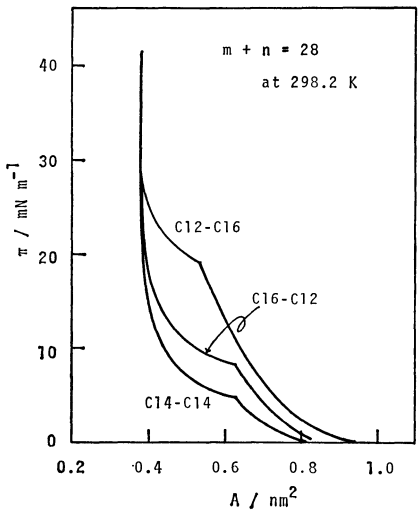

Fig. 4. The π-A curves in the case of total carbon number of long-chain cation and anion equal to 28. Substrate: 0.1 M NaCl at 298.2 K.

latter is soluble in water. So we compared the former with the monolayer of single long-chain fatty acid. For example, the π-A curve of tetradecanoic acid is of an expanded type, which has a transition from the expanded to the condensed state at 298.2 K. The π-A curve of C14–C14 in the present work has also a transition point under this condition. When the alkyl chain of double long-chain salt is longer, *i.e.*, m $(=n) \geq 16$, the monolayer shows only a condensed type film at 298.2 K. The same trend is shown for the monolayers of a single long-chain fatty acid. This result is different from the previous data of alkyltrimethylammonium alkanesulfonates.[13]

Figure 2 shows the π-A curves at 310.5 K for three double long-chain cation and anion when $m+n$ is equal to 32. At this temperature the C16–C16 salt shows phase transition and it has the lowest transition pressure among three compounds as seen in Fig. 2. It is noteworthy that in the case of the equal length of cation and anion, the condensing effect is most pronounced. This condensing effect seems to be due to the increase in the molecular interaction between the alkyl chains.

Figures 3—5 show the π-A curves for sets of double long-chain salts with the total carbon numbers of long-chain cation and anion, that is, $m+n$, equal to 30, 28, and 26, respectively. When the carbon number difference between a long-chain cation and anion is large as in the case of C12–C18 and C18–C12, the transition pressure is higher than that of C14–C16 and C16–C14. As is seen from Figs. 2—5, when the chain length of the cation is longer than that of the anion, the transition pressure is lower. The π-A curve of C16–C14, in this case, shows only a condensed type of film at 298.2 K. It can be concluded that when the chain length of the cation is longer than that of the anion, the monolayer is apt to be more condensed.

The π-A curves of alkylammonium alkanesulfonates studied in this paper, as shown in Figs. 1—5, show

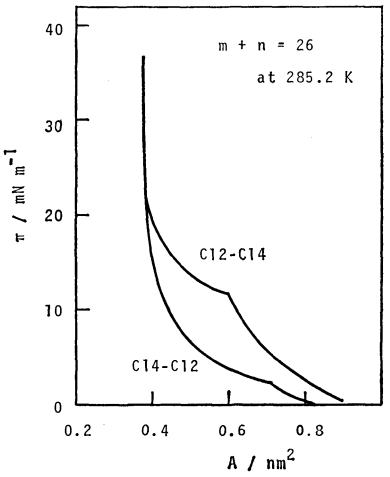

Fig. 5. The π-A curves in the case of total carbon number of long-chain cation and anion equal to 26. Substrate: 0.1 M NaCl at 285.2 K.

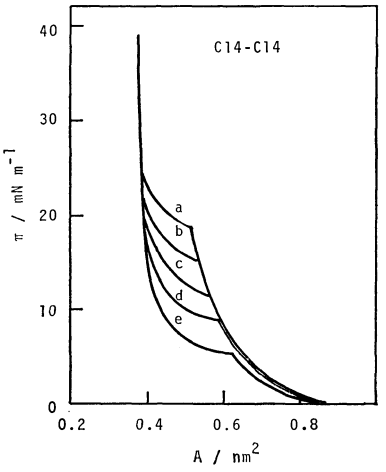

Fig. 6. Temperature dependence of π-A curves of C14–C14 salt. Substrate: 0.1 M NaCl. Temperature: (a) 308.4 K, (b) 306.4 K, (c) 303.2 K, (d) 300.9 K, (e) 298.2 K.

the same limiting area of about 0.4 nm². This value is in good agreement with twice area of corresponding single long-chain fatty acid.[17,19–21] The double long-chains of these salts are probably aligned perpendicular to the water surface when the film is fully compressed. We have reported previously the value of 0.6 nm² for alkyltrimethylammonium alkanesulfonate.[13] Corkill *et al.* reported also the value of 0.6 nm² for alkyltrimethylammonium alkyl sulfate.[8] The replacement of sulfate for sulfonate hardly causes the difference in the limiting area. It is evident, on the contrary, that the substitution of cationic ammonium group for trimethylammonium group leads to the appreciable increase in the limiting area. Compared with alkylammonium ion, the bulky head of alkyltrimethylammonium ion may be responsible for the larger limiting area in the π-A curve of the double long-chain salt containing alkyltrimethylammonium ion.

The studies of the temperature effect on the transition pressure in the monolayer are of much interest, since it provides us with thermodynamic information about the state of the monolayers. Figure 6 shows the π-A isotherms of C14–C14 at various temperatures. All the curves have break points, showing the phase transition from the expanded to the condensed state. As was expected, the transition pressure increased with an increase in the temperature. The π-A curves of other salts Cm–Cn with a transition pressure were also measured at various temperatures. In Fig. 7, the transition pressure (π^{eq}) is shown as a function of temperature for various double long-chain salts. The curves are almost linear. This figure includes the temperature effect of π^{eq} of tetradecanoic acid (C14 acid) in order to compare with that of double long-chain salts. The slopes of these lines were determined in order to calculate the apparent molar entropy change on the phase transition.

Exact thermodynamic equations for the multicomponent monolayers were recently derived by Motomura *et al.*[14–18] The thermodynamic quantities on the transition from the expanded to the condensed film can

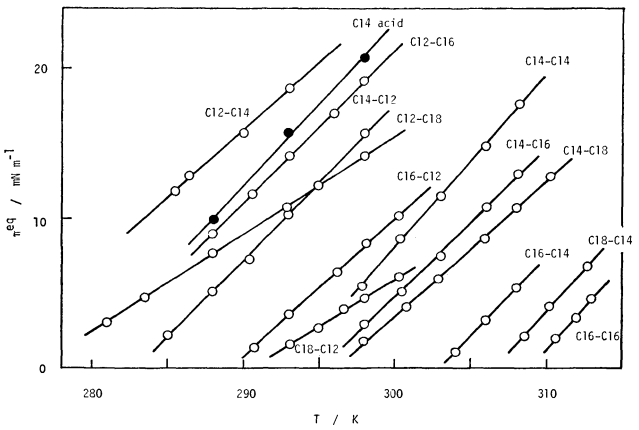

Fig. 7. Transition pressure (π^{eq}) as a function of temperature. Substrate: 0.1 M NaCl, C14 acid: tetradecanoic acid.

be determined by this thermodynamic treatment, which takes account of contribution of water in a monolayer. When a substance exists in the monolayer state, the apparent molar entropy change is evaluated by applying the relation

$$\Delta s^r = (a^c - a^e)\left[\left(\frac{\partial \pi^{eq}}{\partial T}\right)_p - \left(\frac{\partial \gamma^\circ}{\partial T}\right)_p\right], \quad (1)$$

which corresponds to Eq. 29 of Ref. 17. In this equation, Δs^r is the apparent molar entropy change, a^c and a^e are the molecular area (nm²) (superscripts c and e refer to the condensed and expanded state, respectively), π^{eq} is the transition pressure from the expanded to the condensed state, and γ° is the surface tension of pure water. a^c and a^e are estimated as follows. a^e is the area at the point where the film begins to change from the expanded to the condensed state. a^c is determined in the following way: when the point (π^{eq}, a^e) is shifted parallel to the area axis, it comes into contact with the elongated line of the π-A curve in the condensed state to the lower surface pressures. This point of intersection gives the a^c value. The right side of Eq. 1 is calculated numerically from

the results given in Figs. 6 and 7. Moreover, the apparent molar enthalpy change is calculated by the relation

$$\Delta h^r = T\Delta s^r. \quad (2)$$

Now the apparent molar energy change Δu^r is related to Δs^r by

$$\Delta u^r = -(\pi^{eq}-\gamma^\circ)(a^c-a^e) + T\Delta s^r, \quad (3)$$

which corresponds to Eq. 32 of Ref. 17. Thus we can determine Δu^r by use of the above experimental results.

The apparent molar quantity changes on the phase transition calculated by using these equations are given in Table 2. In Table 2, the column represents the cation chain length and the row represents the anion chain length. The element of any column or row shows the value of the apparent molar quantity change on the phase transition of the salt combined. It is seen from Table 2 that for the apparent molar enthalpy changes, all the values are negative as expected. That is, the transition from the expanded to the condensed state is exothermic. These values for the double long-chain salts may be expected to be close to twice the values for corresponding fatty acid. In the C14(+) system, however, the values were about four-fold that of tetradecanoic acid, ($\Delta h^r = -14$ kJ mol^{-1}),[17,19-21] Since the double long-chain salts of the type of alkylammonium alkanesulfonates are composed of a long-chain anion and a long-chain cation, the transition from the expanded to the condensed state causes the cohesion of alkyl chains as well as the formation of ionic pairs between ionic head groups. Therefore, the large exothermic change on the transition may be attributable to the combined effects of the cohesive interaction between the alkyl chains, and the electrostatic attraction between the charged head groups. Similar results are reflected upon the values of other apparent molar quantities, which are likely to be characteristic of the monolayers of these salts.

TABLE 2. THE APPARENT MOLAR QUANTITY CHANGES ON THE PHASE TRANSITION OF DOUBLE LONG-CHAIN SALTS $C_mH_{2m+1}N^+H_3 \cdot C_nH_{2n+1}SO_3^-$ AT 298.2 K

		99[c]	—	—

a) 285.5 K. b) 304.4 K. c) 310.4 K.
Thermodynamic quantities for tetradecanoic acid (C14 acid): $\Delta s^r = -0.47\times10^{-2}$ J K^{-1} mol^{-1}, $\Delta h^r = -14$ kJ mol^{-1}, $\Delta u^r = -17$ kJ mol^{-1}.

The longer the chain length of cation and anion, the larger the apparent molar entropy change (Δs^r) on the transition from the expanded to the condensed state. Holding the total carbon number of long-chain cation and anion constant, the salts with a small difference in the chain length or with the equal-chain-length cation and anion such as C14–C14, C16–C14, and C16–C16 tend to increase the value of the entropy change. The apparent molar enthalpy change (Δh^r) and the apparent molar energy change (Δu^r) follow similar trends.

In Fig. 8, the apparent molar entropy changes (Δs^r) are shown as a function of the carbon number of long-chain cation (m) or anion (n) when the total number ($m+n$) is equal to 28, 30, and 32 at a constant temperature. All the curves are convex upward. All the values of Δs^r are negative as mentioned before. In the case of total carbon number of long-chain cation and anion equal to 32 (the right side in Fig. 8), the magnitude of Δs^r for the C16–C16 salt is the greatest in three double long-chain salts. This means the C16–C16 salt has the most stable orientation in the condensed state of three salts. Similarly in the series of the salts with the total carbon number of long-chain cation and anion equal to 28, the magnitude of Δs^r is greatest for the C14–C14 salt. In the series of total carbon number of 30, the magnitude of Δs^r is the greatest for the C16–C14 salt. Con-

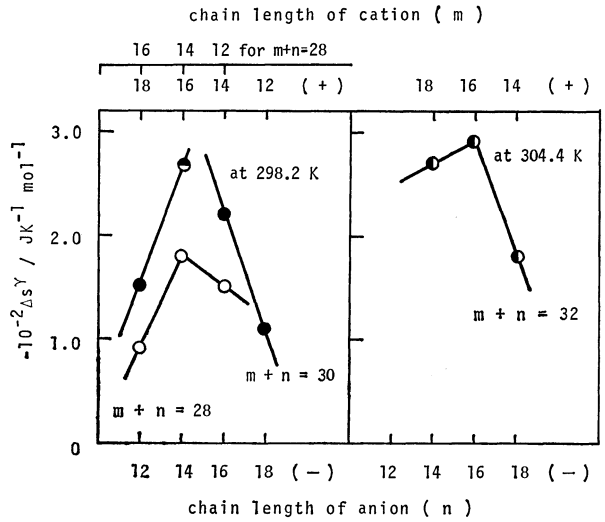

Fig. 8. The apparent molar entropy changes on the phase transition of double long-chain salts. m: cationic chain length, n: anionic chain length. ◓: C16–C14 salt at different temperature (304.4 K).

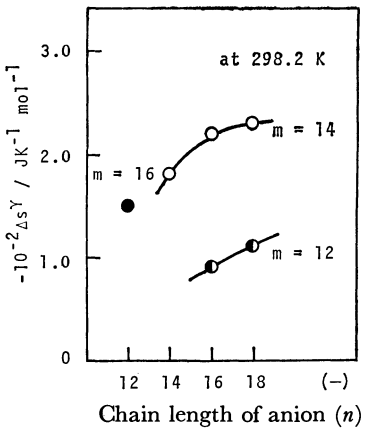

Fig. 9. Anionic chain length dependence of apparent molar entropy change at constant cationic chain length.

sidering above results, in the case of the total carbon number of long-chain cation and anion equal to 30, it is likely that the C15–C15 salt may have the most stable orientation in the condensed film. But the combination of odd carbon number was not treated in this study. This problem will be solved in the future. It is concluded from the above results that the change of apparent molar entropy on the transition tends to be greatest in its magnitude for the salts with the equal-chain-length cation and anion, and that the combination of the equal chain length of cation and anion makes the most stable arrangement in the monolayer of the condensed state.

Figure 9 shows the apparent molar entropy change as a function of the anion chain length at the constant length of the cationic chain. From Fig. 9, for the apparent molar entropy change (Δs^{γ}), it may be concluded that the contribution of long-chain cation and anion to the phase transition of monolayer is not equivalent, the contribution of long-chain cation being slightly larger than that of long-chain anion.

Corkill *et al.*[2] studied solution properties of double long-chain salts (alkyltrimethylammonium alkyl sulfates). They showed that C8–C12, C10–C10, and a mixture of C12 and C8 (all total carbon number 20) gave the same values of cmc or free energy of micelle formation, no difference being present between the contribution of long-chain cation and anion. It is evident that the results we obtained in the present study are characteristic of monolayer properties.

One of authors (O. S.) wants to express his deep gratitude to Dr. K. Motomura of the Department of Chemistry, Kyushu University, for many valuable and most stimulating discussions during this work and would like to thank Prof. I. Murase of College of General Education, Kyushu University for help with purification of starting materials.

This work has been financially supported in part by a Grant No. 574178 of the Ministry of Education, Science and Culture for Scientific Research of Japan.

High Performance Liquid Chromatography Using Polymer Gels for Direct Analyses and Characterizations of Soluble Organic Pollutants in Water

Kohei URANO,* Hiroyuki FURUUNE, and Koji HAYASHI

Department of Safety and Environmental Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama 240

(Received October 9, 1981)

The optimum conditions in HPLC separations using columns packed with polymer gels were investigated for analyzing and characterizing directly various organic pollutants in water without complicated pretreatment. Experimental results showed that polystyrene gel column was unsuitable for direct analyses of water samples. Direct analyses of various organic compounds in water could be achieved on polyacrylester and polyhydroxystyrene columns by using 0.02 mol L^{-1} phosphoric acid and acetonitrile (85:15) as a mobile phase. At 40 °C, these systems of column and mobile phase gave values of height equivalent to a theoretical plate ranging from approximately 0.10 to 0.25 mm and retention times ranging from approximately 8 to 60 min for various compounds in water. Separation characteristics of these polymer column systems were discussed by taking into account solubilities, functional groups, aromaticities, or molecular weights of organic compounds in water. Furthermore, several wastewaters and their treated waters were directly analyzed for examples.

The conventionally used indices of organic pollution of water are biochemical oxygen demand (BOD), chemical oxygen demand (COD), and concentrations of several toxic pollutants. However, fractionations, characterizations, and analyses of soluble organic pollutants by chromatographic methods such as gel chromatography (Gel C), gas chromatography (GC), and high performance liquid chromatography (HPLC) have recently been used for evaluating organic pollutions and treatment processes of organic wastewater.[1] Since actual water samples contain miscellaneous compounds, there are many cases that the compounds in water need not necessarily to be separated and analyzed completely and need only to be classified and characterized by molecular weight, aromaticity, functional group, or solubility in water. Furthermore, it is expected especially that direct analytical methods without complicated pretreatments such as extraction and reaction are developed for evaluation of water qualities. Columns and operating conditions for direct analyses of water samples should be applicable in the analysis of a wide range of compounds. In other words, there is necessary to select the optimum columns and operating conditions so that analyses of water samples can be achieved within a short time by a very simple operation.

In previous papers, the authors reported about the characteristics of Gel C using Sephadex gel[2] and a specific GC using steam as carrier gas[3,4] for direct analyses and/or characterizations of organic pollutants in water. The characteristics of UV detector for Gel C and HPLC were also reported in another paper.[5] In this study, the optimum conditions together with applicability of HPLC using columns packed with typical polymer gels were investigated for analyses and characterizations of soluble organic pollutants in water without complicated pretreatment. By this series of studies about chromatographic methods for direct analyses and/or characterizations of organic pollutants in water, water pollution with organic matter and water treatment processes will be estimated more exactly than by the conventional indices only.

Materials and Methods

Aqueous solutions of 48 organic compounds whose properties are shown in Table 1, wastewaters from an oil refinery and a dye factory, and their treated waters by adsorption with activated carbon were used as samples in this study. The equipment used in this study consisted of Nipponbunko HPLC Model A-1, two ultraviolet (UV) absorption detectors, a refractive index (RI) detector, and a three pen recorder. Three kinds of commercial packed columns of synthetic polymer gels, whose properties are shown in Table 2, were tested for direct analyses of the water samples. The water samples of 5—50 μL were injected directly, and the organic compounds were separated on the polymer gels by using various mobile phases and were detected with the UV detectors at wavelengthes of 220 nm and 275 nm and the RI detector. Retention time (t_R) and time of peak width (W_t) were obtained for the aqueous solution of organic compound, and height equivalent to a theoretical plate (HETP) was calculated by the following equation:

$$\mathrm{HETP} = L\,W_t^2/16t_R^2.$$

Here, L is the length of packed column. Better resolutions can be achieved by using systems of column and mobile phase showing smaller values of HETP. In this study, the optimum conditions which can be used for a wide range of organic compounds without complicated operations will be selected, and applicability of the column systems for analyses and/or characterizations of various organic pollutants in actual water samples will be discussed.

Results and Discussion

Characteristics of Polystyrene Gel Column. Mobile Phase: The most important factor in the direct analyses of organic compounds in water is selection of the optimum system of column and mobile phase liquid. The column of polystyrene gel (Jascopack HP 01) can be used with mobile phases of organic

solvents or mixtures of polar organic solvents containing less than 10% water. Retention times and the values of HETP of several organic compounds were obtained at 40 °C with mixtures of methanol and water as mobile phases. The changes of t_R and HETP of several benzene substitutes with water contents of the mobile phases are shown in Fig. 1, representatively. With methanol only, the retention times were too short for separation of various compounds, and the values of HETP were slightly large. The mixtures of methanol and water were better than methanol only, but the variations of t_R among compounds was not large enough to separate various compounds. In the case of using mixtures of phosphoric acid solution and methanol or acetonitrile as the mobile phases, the values of HETP were improved, but the variation of t_R among compounds was also not large enough. Thus, it was concluded that direct analyses of various organic compounds in water could not be achieved by using the column packed with polystyrene gel, and other polymer columns were studied.

Table 2. Packed columns of polymer gels employed[a]

Polymer	Commercial name	Column size	Limit pressure
Polystyrene	Jascopack HP-01	$4.6\phi\times250$ L	50 kg cm^{-2}
Polyacrylester	Shodex OH pak M614	$6.0\phi\times250$ L	15 kg cm^{-2}
Polyhydroxy-styrene	Shodex Ion pak C811	$8.0\phi\times500$ L	30 kg cm^{-2}

a) These columns can be used at a temperature lower than 60 °C and a flow rate lower than 1.5 mL min^{-1}.

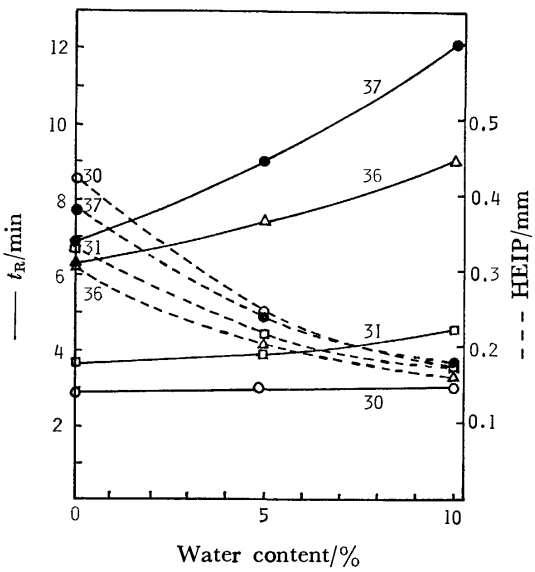

Fig. 1. Changes of retention time and HETP with water content in mobile phase for Jascopack HP 01.
1.0 mL min^{-1}, 40 °C.

Characteristics of Polyacrylester Gel Column. Mobile Phase: The column of polyacrylester gel (Shodex OH pak M614) can be used with the mobile phases of water or aqueous solutions containing less than 30% polar organic solvents. Retention times and the values of HETP for several typical organic compounds at 40 °C were obtained with various mobile phases of water, aqueous solution of phosphoric acid, or mixtures of aqueous solution of phosphoric acid and methanol or acetonitrile. The peaks showed tailing

or leading, and both values of t_R and HETP were large in the case of using water only. Though the values of HETP decreased by addition of phosphoric acid, t_R were still very long for several organic compounds. In the case of using mixture of aqueous solution of phosphoric acid and methanol, t_R was not satisfactorily decreased. The mixtures of 0.02 mol L^{-1} phosphoric acid with different contents of acetonitrile were tested as mobile phases at a flowrate of 0.57 mL min^{-1}. The changes of t_R for several benzene substitutes with the content of acetonitrile are shown in Fig. 2, representatively. From these results, the mixture of phosphoric acid solution and acetonitrile of 15% was thought to be better than the other mobile phases, because t_R was not too long, and variation of t_R among compounds was large enough to separate various compounds. Consequently, the mixture of 0.02 mol L^{-1} phosphoric acid and acetonitrile (85:15) was selected as a standard mobile phase of this column for the analyses of various organic compounds in water.

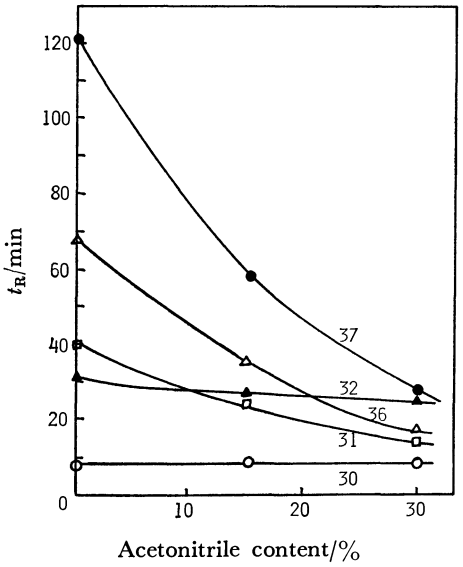

Fig. 2. Change of retention time with acetonitrile content in mobile phase for Shodex OH pak M614. 0.57 mL min^{-1}, 40 °C.

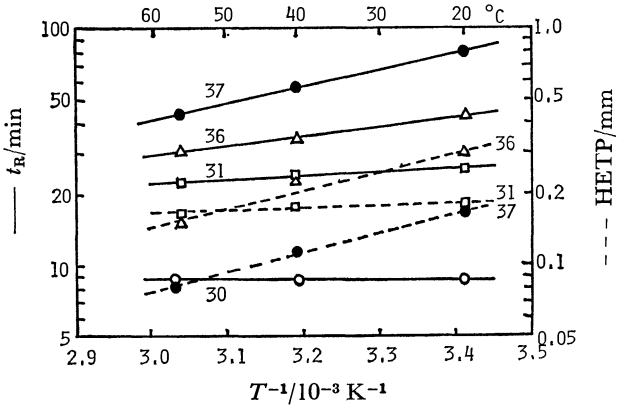

Fig. 3. Changes of retention time and HETP with temperature for Shodex OH pak M614. 0.02 mol L^{-1} H_3PO_4 and acetonitrile 15:85, 0.57 mL min^{-1}.

Influence of Column Temperature: Change of t_R and HETP with column temperature in the case of using the above standard mobile phase are representatively shown in Fig. 3 for several organic compounds. The values of HETP decreased with temperature, but the influence of temperature on the separation performance was small, because the apparent activation energies of separation were approximately 4 to 20 kJ mol^{-1}. Since the temperature higher than 40 °C made operation troublesome, 40 °C was chosen as a standard temperature in the following experiments.

Relation between Retention Times and Properties of Organic Compounds: Values of t_R and HETP for various organic compounds obtained using the standard mobile phase at a flowrate of 0.57 mL min^{-1} and 40 °C are shown in Table 3. The values of HETP for all the organic compounds were small ranging from approximately 0.13 mm to 0.25 mm.

The retention times of benzenesulfonate, ethylbenzenesulfonate, and naphthalenesulfonate were short, approximately 10 min, but those of alkylbenzenesulfonates in a synthetic detergent could be classified into 5 groups ranging from 20 to 60 min according to the number of alkyl carbons which ranged from 10 to 14 as shown in Fig. 4. The retention times of the aromatic compounds except the low molecular weight sulfonates exceeded 20 min. It was found that the retention times for hydrophobic aromatic compounds tend to be longer than those of hydrophilic compounds. The logarithmic relationships between the retention times and solubilities in water are shown in Fig. 5 for the aromatic compounds. These relationships could be shown by two lines for the two groups of the carboxylic acids and the others. The

Conditions are as in Fig. 4.

retention times for the carboxylic acids were slightly shorter than those of the other compounds, because they ionize partialy in the mobile phase. Consequently, the packed column of polyacrylester gel could be used for the direct analyses of various aromatic compounds in water. The retention time of an aromatic compound can, therefore, be predicted from its chemical structure and solubility, and conversely, the compound in an unknown sample can be characterized or identified from its retention time. Since the retention times of all the used aliphatic compounds, whose solubilities in water are larger than 10^{-1} mol L^{-1} were in the range from 10 to 18 min, separation was difficult when many kinds of aliphatic compounds coexist in water. However, the peaks for an unknown sample within 20 min could be characterized as the peaks of aliphatic compounds or the low molecular weight aromatic sulfonates.

Characteristics of Polyhydroxystyrene Gel Column.
Mobile Phase: Similar to the polyacrylester column, the column of poly(*p*-hydroxystyrene) gel (Shodex Ion pak C811) can be used with water or aqueous solutions

Flow rate: 1.0 mL min^{-1}, mobile phase: 0.02 mol L^{-1} phosphoric acid and acetonitrile (85:15), temp: 40 °C.

containing less than 30% polar organic solvents. Further, the retention times with water or phosphoric acid as mobile phase were also very long for several hydrophobic compounds. Thus as with the case of the polyacrylester column, the mixture of 0.02 mol L^{-1} phosphoric acid and acetonitrile (85:15) was used for mobile phase, and the results are shown in Table 4. By this mobile phase, most organic compounds eluted within 60 min at a flow rate of 1.0 mL min^{-1}. The values of HETP were in the range from 0.10 mm to 0.21 mm for many organic compounds. This values were slightly better than those of the polyacrylester column. But amines and amino acids were not eluted within 120 min at a flow rate of 1.0 mL min^{-1}, because these cationic compounds combined strongly with the anionic group of the gel. Conversely, the retention times of all the sulfonates including alkylbenzenesulfonates in detergent were short and approximately 8.5 min, because they completely ionize to anions in mobile phase. Therefore, the anionic resin could not be used for separation of cationic compounds such as amines and amino acids and strong anionic compounds such as sulfonates.

Relation between Retention Times and Properties of Organic Compounds: The values of t_R of the aromatic compounds except sulfonates exceeded 20 min, and it was found that t_R tend to decrease with solubilities in water similar to the case of the polyacrylester column. Changes of t_R for the aromatic compounds with their solubilities are shown in Fig. 6. These relationships could be shown by two lines for carboxylic acids and the other compounds as in the case of the polyacrylester column. The retention times of the carboxylic acids were shorter than those of the other compounds for

a same solubility, because they ionize partialy to anions in mobile phase. On the other hand, there were no clear relationships between t_R and solubilities in water for aliphatic compounds. Variations of t_R with molecular weight are shown in Fig. 7 for each group of aliphatic compounds. The values of t_R for all the aliphatic compounds increased with their molecular weight in the similar series of compounds, and t_R increased in the following order for the compounds which have the same number of alkyl carbons: alcohols > aldehydes > ketones ≃ esters > monocarboxylic acids > dicarboxylic acids. However, the retention times of sugars decreased with molecular weight by gel permeation function as shown in also Fig. 7, and raffinose was eluted at a very short time. Consequently, this column could not be used for separation of nonaromatic compounds with molecular weights exceeding 600.

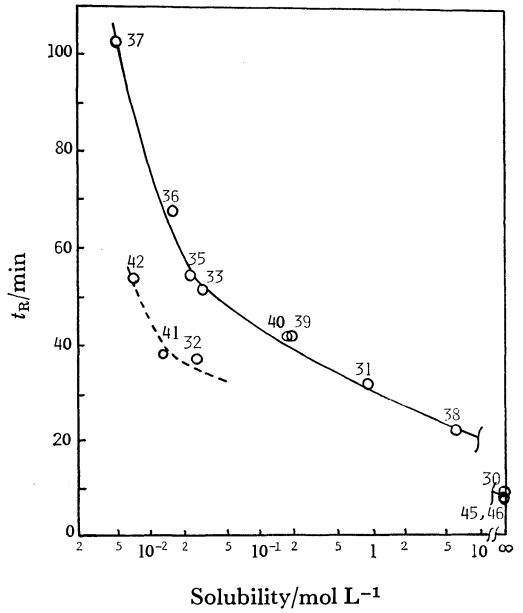

Fig. 6. Relationships between retention times and solubilities in water of aromatic compounds for Shodex Ion pak C811.
Flow rate; 1.0 mL min^{-1}, other conditions are as in Fig. 4.

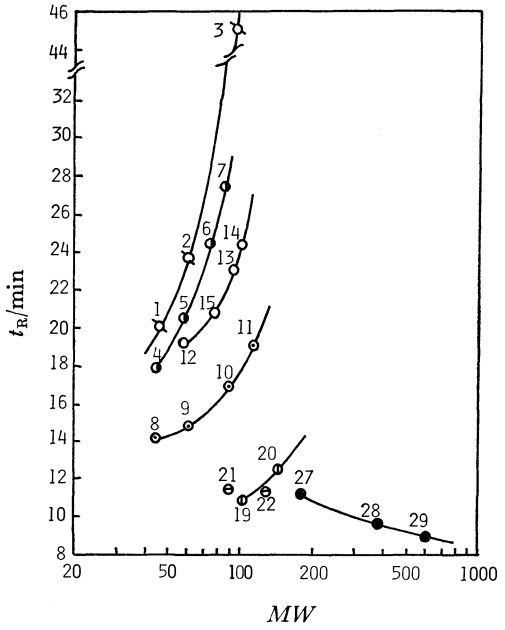

Fig. 7. Relationships between retention times and molecular weights of aliphatic compounds for Shodex Ion pak C811.
Conditions are as in Fig. 6.

From the foregoing results, the following conclusions were obtained:

(1) The column of polystyrene gel was unsuitable for direct analyses of water samples containing various organic compounds.

(2) The column of polyacrylester gel could be used for direct analyses of various organic compounds in water, but it was unsuitable for analyses of aliphatic compounds.

(3) The column of polyhydroxystyrene gel could be used for direct analyses of various aliphatic and aromatic compounds in water, but it could not be used for analyses of strong anionic compounds such as sulfonates, cationic compounds such as amines and amino acids, and nonaromatic compounds whose molecular weights exceed 600.

Application to Wastewater Analyses. For examples, raw and treated wastewaters from an oil refinery and a dye factory were directly analyzed after filtration with 0.45 μm membrane by the HPLC with Shodex OH pak M614 using the standard mobile phase at 40 °C. The chromatograms are representatively shown in Figs. 8 and 9. Eight peaks were found in the chromatogram of the raw wastewater from the oil refinery. The peaks 1—6 were characterized to be low molecular weight aliphatic compounds, and the peaks 7 and 8 were identified to be phenol, and *o*- and *m*-cresols respectively, the main pollutants in this wastewater, by their retention times, UV absorbances at two wave lengths,[5] and coloration with 4-aminoantipyrine. The chromatogram of its treated

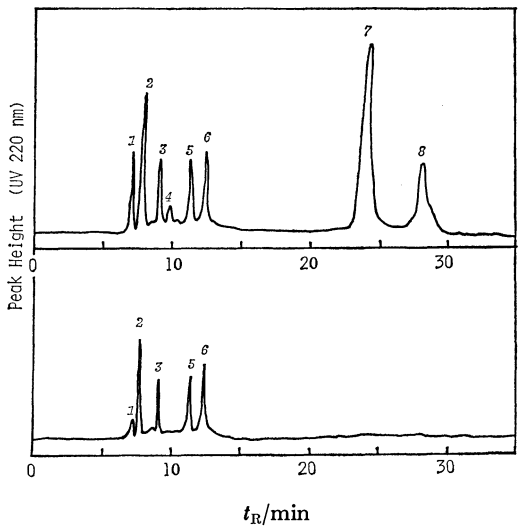

Fig. 8. Chromatograms of raw and treated wastewaters from an oil refinery by Shodex OH pak M614.
Conditions are as in Fig. 4.

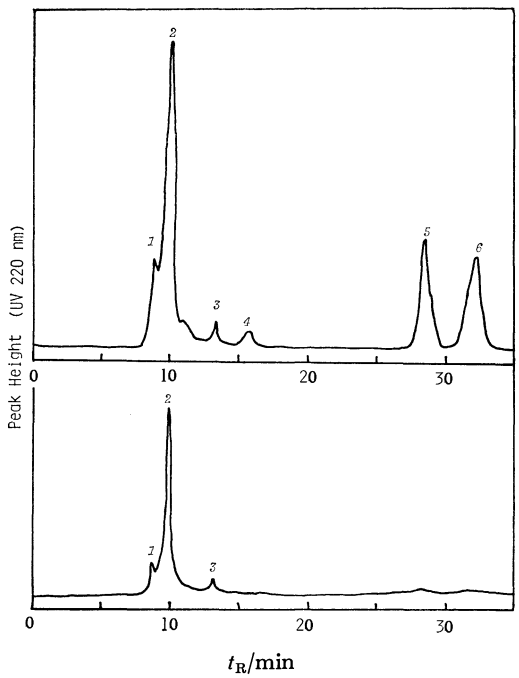

Fig. 9. Chromatograms of raw and treated wastewaters from a dye factory by Shodex OH pak M614. Conditions are as in Fig. 4.

water showed that phenol and cresols were completely removed by adsorption with activated carbon, but aliphatic compounds were only partially removed. On the other hand, six clear peaks were found in the chromatogram of the raw wastewater from the dye factory. The peaks 2—6 were identified to be naphthylaminedisulfonate, acetic acid, produced dye, cresols, and *m*-toluidine, respectively, and the peak 1 was assumed to be an aromatic sulfonate. The chromatogram of its treated water showed that dye, cresols, and toluidine were effectively removed by adsorption with activated carbon, but naphthylaminedisulfonate, acetic acid, and an unknown compound (peak 1) were only partially removed. As shown in these examples, the HPLC systems could be applied in direct analyses and characterizations of water containing various organic pollutants, and they are more superior than the conventional water quality tests in the evaluation of water quality and water treatment processes.

The Effect of the Vanadium Component on the Life of the WO_3–TiO_2 Catalyst Used for the Reduction of NO_x with NH_3

Shigeru Morikawa,* Kazumasa Takahashi, Junichi Mogi, and Satoru Kurita

Research Institute of Ishikawajima Harima Heavy Industries Co., Ltd., 3-15, Toyosu, Koto-ku, Tokyo 135-91

(Received November 6, 1981)

The 5000-h life test of the WO_3–TiO_2 catalyst for the reduction of NO_x with NH_3 has been investigated in real flue gases containing vanadium and SO_x on a pilot plant. When the present catalyst was used in a residual-oil-fired-boiler flue gas, steady activities over 90% of NO_x reduction were achieved for 5000 h at 400 °C (space velocity: 2700 h^{-1}). On the other hand, when the catalysts were taken out of the reactors at certain intervals and studied by means of a laboratory reactor, they were much more active than fresh catalyst at lower temperatures (250—350 °C). Also, the SO_2 oxidation efficiency increased with the reaction time. This activation was considered to be due to the vanadium component in the flue gas.

In many of the processes proposed hitherto, the selective reduction of NO_x with NH_3 on such catalyst systems as V_2O_5–TiO_2[1] and WO_3–TiO_2[2] has been considered to be the most promising process for removing NO_x from stationary sources. Furthermore, these catalysts are known to have an excellent activity and to be stable to SO_x; in particular, the WO_3–TiO_2 catalyst is thermally stable at 400 °C or higher temperatures and has a low oxidation activity from SO_2 to SO_3.

A mechanism for the reduction of NO_x with NH_3 in the presence of O_2 on the TiO_2–WO_3 catalyst was proposed by Imanari *et al.*[2] Kasaoka *et al.*,[3] reported the effect of the addition of WO_3 over V_2O_5 for activity on NO_x reduction with NH_3.

However, the life and effects of the vanadium component in real flue gas has not yet been reported with regard to the WO_3–TiO_2 catalyst. In this study, the life test for 5000 h as a pilot test has been investigated over WO_3–TiO_2 in connection with the reduction of NO with NH_3 using a Khafji residual-oil-fired-boiler flue gas. Also, catalysts were taken out of the reactor at certain intervals and their catalytic properties were examined by means of a X-ray photoelectron spectrometer.

Experimental

Catalyst Preparation. The 10 wt%WO_3–TiO_2 catalysts used in this study were prepared by impregnating TiO_2 (specific surface area: 70 m^2/g, mean pore radius: 320 Å, SO_4^{2-} content: 3.8%) in an aqueous solution of ammonium paratungstate ($5(NH_4)_2O12WO_3 \cdot 5H_2O$). After the impregnation, the catalysts were dried for 3 h at 120 °C and then calcined for 5 h at 550 °C in an air stream.

Activity Measurement. *Pilot-plant Test*: A life test was carried out with a pilot-plant test with an apparatus which consisted of a 150 mm-id reactor containing pellet catalysts (diam. 7 mmϕ). Activity measurements were carried out at 400 °C over the space velocity of 2700 h^{-1} using the combustion flue gas at a flow rate of 100 Nm^3/h from the Khafji residual-oil-fired-boiler (sulfur content: 5.2%, vanadium content: 220—230 ppm, NO_x: 95—105 ppm).

Laboratory scale Test: The reduction of NO with a model flue-exhaust gas consisting of NO, NH_3, H_2O, SO_2, and O_2 has also been studied over the WO_3–TiO_2 catalysts which were used in the pilot test. Activity measurements were carried out between 250 and 450 °C at a space velocity of 3500 h^{-1} using a conventional flow reactor made of a quartz tube reactor (length: 500 mm, dia.: 30 mm) under atmospheric pressure. A gas mixture consisting of 150 ppm of NO, 150 ppm of NH_3, 1000 ppm of SO_2, 5% of O_2, 8% of H_2O, and balance, N_2 was used as a standard feed. The analysis of NO and SO_2 was done with a chemiluminessence-type NO_x analyzer and a NDIR type SO_x analyzer respectively.

Measurements of Catalyst Property. The surface areas were measured by means of the BET method. An X-ray photoelectron spectrometer (Dupont-Shimadzu 650) was used to examine the surface properties of the catalysts. Mg $K\alpha$ (1253.6 eV) X-ray radiation was used as the excitation source. The measurements were conducted at room temperature under a vacuum of about 10^{-7} Torr (1 Torr≈ 133.322 Pa). The binding energies of the C (1 s) and Au ($4f_{7/2}$) electron peaks were used as the energy standards throughout the present work; they have taken to be 285.0 and 83.6 eV respectively.

Results and Discussion

Life Test of the WO_3–TiO_2 Catalyst for NO_x Removal. The life test of the 10% WO_3–TiO_2 catalyst on the reduction of NO with NH_3 was investigated in real flue gas containing 105 ppm of NO, 8% of H_2O, 4% of O_2, 10% of CO_2, 220—230 ppm of the vanadium component, and a 5.2% sulfur component at 400 °C over the space velocity, 2700 h^{-1}. The NH_3/NO inlet ratio was 1.0. Figure 1 shows the change in the conversion of NO with the reaction time. Steady activities over an NO_x reduction efficiency of 90% were achieved for 5000 h. Thus, the WO_3–TiO_2 catalyst was revealed to be highly resistant to the large amount of SO_x which was present in the residual oil and maintained a high activity for NO_x reduction. However, the color of the catalyst in a fresh catalyst changed from light yellow to green yellow over long periods of reaction time.

Figure 2 shows the results for the reduction of NO with NH_3 at 275—450 °C. In the pilot test, they were examined by means of a laboratory scale apparatus over the WO_3–TiO_2 catalysts used after 816 h, 1150 h, 2160 h, and 4800 h. Tests were conducted with simulated flue gas containing 8% of H_2O, 5% of O_2, 1000 ppm of SO_2, and 150 ppm of NO with 150 ppm of NH_3 (balance, N_2) over a space velocity

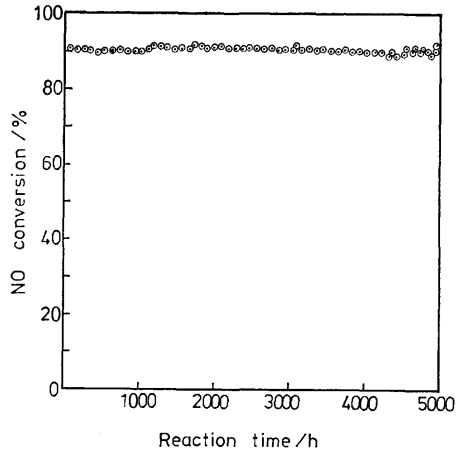

Fig. 1. Life test of WO_3–TiO_2 catalyst in real flue gas.
Reaction conditions: reaction temp; 400 °C, SV; 2700 h^{-1}. Composition of the flue gas: NO; 105 ppm, O_2; 4%, H_2O; 8%, CO_2; 10%, S component: 5.2%, vanadium component: 220—230 ppm

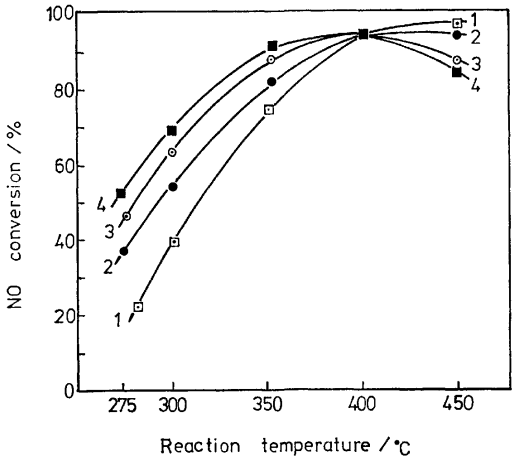

Fig. 2. Activity change in WO_3–TiO_2 catalyst with reaction time in simulated flue gas.
1: Fresh catalyst, 2: used for 1150 h, 3: used for 2160 h, 4: used for 4800 h. Reaction conditions: NO; 150 ppm, NH_3; 150 ppm, O_2; 5%, SO_2; 1000 ppm, H_2O; 8%, N_2; balance, SV; 3500 h^{-1}.

of 3500 h^{-1}. The conversion of NO was revealed to be 95% at the temperature of 400 °C, and the NO reduction efficiency did not change with the reaction time. This result fits well with that of the pilot test in Fig. 1. As shown in Fig. 2, however, the conversion of NO increased with the reaction time at 275—350 °C and decreased with the reaction time at 450 °C. In particular, the conversion of NO increased from 20 to 50% at 275 °C on a 4800-h catalyst. These observations suggest that catalysts were affected by the composition of real flue gas and changed in their surface properties. Although the present real flue gas contain a considerable amount of vanadium and sulfur components, as mentioned above, it may be supposed that such an increase in the NO reduction efficiency over a temperature range of 275—350 °C was due to the vanadium component accumulated on the catalyst, because the presence of the vanadium component is known to enhance the NO reduction efficiency at lower temperatures:[4] in contrast, SO_x is known to reduce the activities of the catalysts.[5]

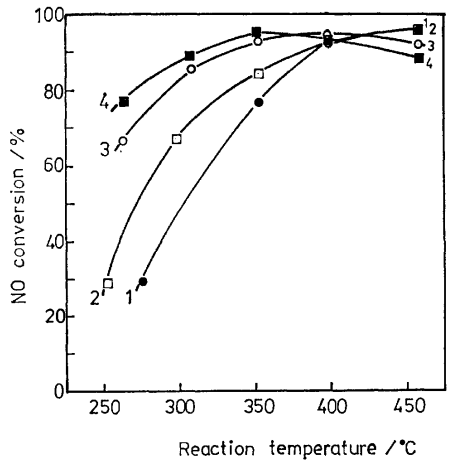

Fig. 3. Effect of amount of vanadium on activity for NO reduction.
Amounts of vanadium: 1; 0 wt%, 2; 0.5 wt%, 3; 1.5 wt% 4; 2.5 wt%. Reaction conditions are the same as for Fig. 2.

To clarify the effect of the vanadium component on NO_x reduction efficiency, we prepared the V_2O_5–WO_3–TiO_2 catalysts at various V_2O_5 concentrations and examined the activity, the conversion of NO *vs.* the reaction temperature. The results are shown in Fig. 3. The vanadium-loaded catalysts appear to be superior to the WO_3–TiO_2 catalyst in the NO reduction efficiency between 250 and 350 °C, and the increase in the amount of vanadium seems to be correlated with the activity, the 2.5 wt% V_2O_5–WO_3–TiO_2 catalyst in particular revealing the highest NO reduction efficiency. By contrast, at a high temperature (450 °C) the reduction efficiency decreased as the amount of vanadium loaded was increased. Similar behavior was seen on the V_2O_5–TiO_2 catalyst.[4] Furthermore, these results are in agreement with the experimental results obtained in Fig. 2. Thus, it was found that the conversion of NO in the reaction temperature range of 250—350 °C distinctly depends on the vanadium components.

Change in the Properties of the Catalyst. Next, surface analysis of the catalyst was conducted before and after use. Figure 4 shows the variations in the X-ray photoelectron spectra of the catalyst used in the NO reduction for V $2p_{3/2}$.

In Fig. 4, the V $2p_{3/2}$ peak was not observed on a fresh catalyst, but the intensity of the V $2p_{3/2}$ peak,[6] the binding energy being 517.2, increased with the reaction time, while the spectra of W $4f_{5/2}$, O_{1s}, and S_{2p} were almost unchanged with the reaction time, except for 4800 h. Each peak of the 4800-h catalyst was slightly shifted to the higher-binding-energy side.

Furthermore, to clarify the effect of catalytic properties, Table 1 shows the results of the analysis for dust components (K_2O, Na_2O), SO_4^{2-}, V_2O_5, WO_3, surface area (BET method), pore volume, surface

Table 1. Analytical results of WO_3–TiO_2 catalysts with the reaction time

Catalyst	$\frac{V\ 2p_{3/2}}{Au\ 4f_{7/2}}$	Surface area[1] / $m^2\ g^{-1}$ (Pore volume / $ml\ g^{-1}$)	Surface excess oxygen[2] / g equiv./g	Chemical analysis

Binding energies were referenced to C 1s of contaminant carbon (285.0 eV).

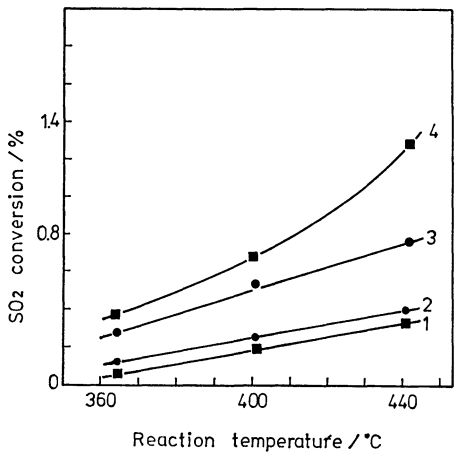

Fig. 5. Catalytic activity of WO_3–TiO_2 catalyst on SO_2 oxidation with reaction time in simulated flue gas.
1: Fresh catalyst, 2: used for 1150 h, 3: used for 2160 h, 4: used for 4800 h. Reaction conditions: NO; 150 ppm, $NO/NH_3=1$, H_2O; 8%, O_2; 5%, SO_2; 1000 ppm, SV; 3500 h^{-1}

excess oxygen by the KI method,[7] and the ratio of V $2p_{3/2}$/Au $4f_{7/2}$ over fresh, 816-h, 1150-h, 2160-h, and 4800-h catalysts. It may be seen that the surface area, pore volume, potassium and sodium as dust components, and WO_3 and SO_4^{2-} contents were almost unchanged with the reaction time. The activation of a catalyst at a lower temperature was not explained sufficiently only by the change in the surface area and the pore volume. However, the concentration of V_2O_5 and the ratio of intensities between V $2p_{3/2}$ and Au $4f_{5/2}$ (standard) in the 4800-h catalyst were two times than that of the 816-h catalyst. Similar behavior was seen in the amount of surface excess oxygen on the catalyst. Judging from the results shown in Table 1, no doubt the presence of vanadium influences this increase in NO reduction efficiency at lower temperatures.

On the other hand, a previous study[4] showed that the SO_2 oxidation was affected by the increase in vanadium concentration and enhanced by the amount of surface excess oxygen. Therefore, we examined the SO_2 oxidation over fresh and used catalysts at various temperatures. The results are shown in Fig. 5. The activity of the catalyst for SO_2 oxidation increased with an increase in the reaction time. At 365 °C, the SO_2 conversion in the 4800-h catalyst was four times that of the fresh catalyst. As is shown in Table 1, both the vanadium content and the surface excess oxygen increased with the reaction time, while the other dust components and the surface area were almost unchanged with the reaction time. Hence, it has been speculated that the increase in SO_2 conversion with the reaction time is mainly due to the vanadium accumulated on the catalyst and the amount of surface excess oxygen.

From our results, the following conclusions can be drawn. The NO reduction reached a constant value of 90%, and no change in efficiency was observed for 4500 h in real flue gases. Thus, the WO_3–TiO_2 catalyst performs well and maintains a high activity for NO reduction. However, when the WO_3–TiO_2 catalyst is used in flue gas containing a vanadium component such as Khafji residual oil, the NO reduction is not only increased at lower temperatures, but also the SO_2 oxidation is increased by accumulating vanadium on the surface of the catalyst. Therefore,

for practical purposes, if the WO_3–TiO_2 catalyst is used for NO_x reduction in a residual-oil-fired-boier flue gas, it may be necessary to retard the oxidation of SO_2 to SO_3 without affecting the high activity for NO_x reduction over WO_3–TiO_2 as well as over the V_2O_5–TiO_2 catalysts.[4)]

The details of the reaction mechanism of NO with NH_3 over the WO_3–TiO_2 catalyst will be reported later.

Lanthanoid Shift Reagents. Synthesis and Spectral Studies†

Khalid IFTIKHAR,* Mohammad SAYEED, and Naseer AHMAD
Department of Chemistry, Aligarh Muslim University, Aligarh-202001, U.P., ndia

(Received May 21, 1981)

The seven coordinate adducts of [Ln(fod)$_3$]chelates are described. The NMR spectra of diamagnetic and paramagnetic adducts have been discussed. The europium, praseodymium and ytterbium adducts have been scanned as potential shift reagents and these seven coordinate adducts produce large dipolar shifts in the proton magnetic resonances of organic moieties. The dipolar shift produced by [Eu(fod)$_3$(pz)] in the spectrum of benzyl alcohol is different from that reported. Some interelectronic and spectral parameters ($\bar{\beta}$, $b^{1/2}$, and δ) have been calculated. Ligand field parameter (T_λ) and oscillator strengths have been computed and discussed.

NMR spectra may usually be obtained from the complexes of paramagnetic lanthanoid ions with organic ligands.[1,2] Such spectra commonly show paramagnetic shifts, mainly of dipolar (pseudo-contact) origin. This principle has been applied by Hinckley[3] to weak association between tris(dipivaloylmethanato)-europium(III) and cholesterol (the complex being used as its bis(pyridine)adduct). Further investigations have established that (1) [Eu(dpm)$_3$], dpm=2,2,6,6-tetramethyl-3,5-heptanedione, itself (*i.e.*, without the pyridine molecules appended) is even better than the pyridine adduct[4] (pyridine tends to block coordination of substrate) (2) the analogous praseodymium compound, [Pr(dpm)$_3$], induces NMR shifts of opposite sign[5] and also much larger than those reported for [Eu(dpm)$_3$]. Selbin *et al.*[6] reported a series of analogous lanthanoid complexes with the same bulky β-keto enolate and their mixed ligand complexes with uni and bidentate ligands. Ahmad *et al.*[7] studied the temperature dependant shifts. It has been pointed[8] out that the mixed ligand adducts [Eu(dpm)$_3$-(bpy)] and [Eu(dpm)$_3$(phen)] (bpy=2,2′-bipyridyl and phen=1,10-phenanthroline) are inefficient in producing shifts. We have also shown[9] that our eight coordinate adduct, [Pr(fod)$_3$(phen)] (fod=6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato) does not produce dipolar shifts in the proton resonance of 1-butanol but it does not dissociate in solution as reported by Hinckley,[3] for eight coordinate complex. Recently[10–12] we have synthesized seven, eight and ten coordinate complexes of lanthanoid and studied their electronic spectra. During these investigations it has been found that as the coordination number increases the number of bands decrease and also the intensity of the hypersensitive bands increases.

The present paper deals with the synthesis and characterization of seven coordinate adducts of [Ln-(fod)$_3$] chelates with pyrazole (pz) and possible use of their europium, praseodymium, and ytterbium adducts as lanthanoid induced shift reagents. Covalency parameters[13–16] ($\bar{\beta}$ and δ), bonding parameter ($b^{1/2}$) have been calculated and discussed. Oscillator strength (P) have also been computed for some of the complexes[17–19]

Experimental

Rare earth oxides (Leico Chem., U.S.A.) were converted to corresponding chlorides. Hfod (Pierce Chem., U.S.A.), pyrazole, pz, (Fluka) and Xylenol Orange (BDH, England) were used in this study.

Synthesis. [Ln(fod)$_3$] chelates were synthesized by the method of Sievers *et al.*[20] with a slight modification. The adducts of all the lanthanoid with pyrazole were prepared as follows:

The pyrazole was refluxed in ethanol for 1 h; the solution of [Ln(fod)$_3$] chelates (in 1:1 ratio) was mixed with it. Finally the mixture was refluxed for 4 h on a water bath. The solvent of the resulting mixture was evaporated on a hot plate. The product thus, formed was crystallized from hexane by keeping it in the fridge for 30 d. Good crystals were obtained by recrystallization. Finally these were dried in vacuo over P_2O_5 for several days.

Methods. Carbon, hydrogen, and nitrogen contents of the complexes were estimated by microanalyses while the metals were estimated by complexometric titrations with edta using Xylenol Orange as the indicator. The IR spectra were recorded on a Perkin-Elmer model 621 spectrophotometer in the range 4000—200 cm^{-1}. A Beckman DU-2 spectrophotometer was used to obtain the optical spectra. The NMR spectra were recorded on a Varian A-60 NMR machine in carbon tetrachloride. The magnetic susceptibility was measured by Evans' NMR method[21] in methanol as well as in chloroform at the probe temperature. TGA and DTA studies were carried out at RRL Hyderabad, India.

Calculations

On complexation radial integrals of the valence orbital of the metal ion decrease. This phenomenon is known[13] as nephelauxetic effect and may be regarded as a measure of the covalency in a complex. Nephelauxetic ratio, $\bar{\beta}$, can be calculated from the relation

$$\bar{\beta} = \frac{1}{n}\sum_{n=1}^{n} \nu_{\mathrm{comp}}/\nu_{\mathrm{aq}}. \quad (1)$$

If the f orbitals are involved in covalent bond formation with the ligand the metal wave function can be expressed[14] as

$$<\phi_{4f}| = (1-b)^{1/2}<4f| - b^{1/2}<\phi_{\mathrm{ligand}}|, \quad (2)$$

where $b^{1/2}$ measures the amount of 4f-ligand mixing and is calculated from the relation[15]

$$b^{1/2} = \left[\frac{1}{2}(1-\bar{\beta})\right]^{1/2}. \quad (3)$$

The positive and negative values of $b^{1/2}$ for a complex, correspond to covalent and ionic characters respectively.

† Abstracted in part from the thesis submitted by K. Iftikhar to the Aligarh Muslim University for the degree of Doctor of Philosophy.

Sinha's covalency parameter, δ, is calculated from the relation[16]

$$\delta = \left[\frac{1-\bar{\beta}}{\bar{\beta}}\right]100. \quad (4)$$

The experimental values of the oscillator strength (P_{exptl}) of the absorption bands are calculated by performing Gaussian curve analyses of the curves and using the equation[19]

$$P_{\text{exptl}} = 4.31 \times 10^{-9}\left[\frac{9\eta}{(\eta^2+2)^2}\right]\int \varepsilon(\nu)\mathrm{d}\nu, \quad (5)$$

where η is the refractive index of the medium, ε is the molar extinction coefficient and ν is the energy of the transition in wave number.

The oscillator strengths (P_{calcd}) can be computed from an equation[17,18] derived from a theory in which the ligand field interaction with central ion causes a mixing of higher configuration of opposite parity into the $4f^n$ configuration giving rise to induced electric dipole transions.

$$P = \sum_{\lambda=2,4,6} T_\lambda \nu (f^n\psi_J||U^{(\lambda)}||f^n\psi'_{J'})^2(2J+1)^{-1}, \quad (6)$$

where ν is the energy of the transition, $\psi_J \rightarrow \psi'_{J'}$ and $U^{(\lambda)}$ is the unit tensor operator connecting the initial and final states *via* three phenomenological parameters $T_\lambda(\lambda=2, 4, \text{and } 6)$. The three T_λ parameters are related to the radial part of the $4f^n$ wave functions, the wave functions of the perturbing configurations, the refractive index of the medium and the ligand field parameters characterizing the environment of the ion. The three quantities, T_λ, can be treated as the parameters to be determined from the experimental oscillator strengths.

Results and Discussion

These adducts are well defined crystalline solids with sharp melting points. The melting points of pyrazole adducts are lower than those of imidazole adducts.[12] These are soluble in all organic solvents and are air stable. The molar conductances of these complexes in methanol (Table 1) showed their non-electrolytic behaviour.[22]

IR Spectra. The IR spectra of these adducts show the presence of coordinated pyrazole. The N–H frequency in pyrazole ligand appears as a broad band (2300—3500 cm^{-1}) because of intermolecular hydrogen bonding. It appears as a sharp band in the region 3000—2940 cm^{-1} in the adducts. The weak band found between 305 and 290 cm^{-1} in these adducts has been assigned to metal-nitrogen frequency. We have found the metal-nitrogen frequency in the same region (282—290 cm^{-1}) for imidazole adducts[12]

of $[Ln(fod)_3]$ chelates. The metal-oxygen frequency in $[Pr(fod)_3]$ and $[Sm(fod)_3]$ occurs at 390 cm^{-1}. These go up to 454 cm^{-1} and 450 cm^{-1} in the corresponding adducts. Thus the bands appearing between 445 and 460 cm^{-1} have been assigned to metal-oxygen frequency in these adducts. This is an observation in contrast to what is seen in imidazole[12] adducts.

The thermograms of the adducts of La, Eu, Gd, Tm, and Yb showed the same behaviour as reported for their respective chelates,[20] except in the temperature range of 200—220 °C in which pyrazole is eliminated. The total weight loss is consistent with the loss of pyrazole in this temperature range (Table 2). One sharp DTA peak is identified in all cases.

Thus, these adducts on the basis of their elemental analyses for carbon, hydrogen, nitrogen, and metals, molar conductance (Table 1), IR spectral and thermal studies have been assigned the general formula, $[Ln(fod)_3(pz)]$.

The magnetic moments (Table 1) of these adducts, when plotted against their increasing atomic number, showed the characteristic unequal double humped curve.

NMR Spectra. The NMR spectral data are summarized in Table 3. NMR signals of fod moiety of the adducts appear at 1.05—1.15 ppm for *t*-butyl protons and at 5.95—6.11 ppm for methine protons as sharp singlet (for diamagnetic adducts). It has been found that the signals due to *t*-butyl and methine protons have been shifted to higher fields as compared to their respective chelates.[20] Perhaps it is due to withdrawal of electron density from pyrazole, that the Ln^{3+} ions become more polarized and transfer some charge to diketonate ring, which can be very conveniently accommodated by the highly electronegative fluorine. Other signals can be assigned to those of the coordinated pyrazole.

Pyrazole is reported[23] to give two signals (one for H-4 and another for H-3 and H-5) with relative areas of 1 : 2. But we found all the three signals (for H-2, H-4, and H-3 and H-5) with relative areas of 1 : 1 : 2. The signals of the coordinated pyrazole are found to shift to the lower fields, except in the case of lanthanum in which the signals are slightly shifted to higher fields. This deshielding effect of pyrazole protons obviously suggests the coordination of pyrazole to metal ion.

Information concerning electron delocalization in lanthanoid complexes may be obtained from NMR studies of paramagnetic species, provided nuclear relaxation times are long enough to allow well-resolved spectra to be obtained. Paramagnetic lanthanoid complexes whose spectra have been recorded are few.[1,8] In the spectra of $[Pr(fod)_3(pz)]$ and $[Yb(fod)_3(pz)]$ the methine signal is not seen but the proton resonances of pyrazole show large chemical shifts as compared to their diamagnetic analogue. These shifts are due to pseudo-contact (dipolar) interaction as $\boldsymbol{g}$ tensor is anisotropic. If $\boldsymbol{g}$ is isotropic this interaction goes to zero. The dipolar shift is limited by the geometry of the complex species, as given by the expression[24]

$$\left(\frac{\Delta\nu}{\nu_0}\right) = -K_D f(\theta, r) f(g_\parallel, g_\perp),$$

or simply

$$\left(\frac{\Delta\nu}{\nu_0}\right) = -D\left(\frac{3\cos^2\theta - 1}{r^3}\right),$$

where all notations have their usual connotations.

One of the intents of this study was to examine praseodymium, europium and ytterbium adducts as potential shift reagents. $[Eu(fod)_3(pz)]$ added to a solution of 1-butanol show large chemical shifts (Fig. 1). The two methylene protons which resonate as a singlet get resolved into two individual signals. The substrate associates with the complex at the hydroxyl group and the induced shifts decrease rapidly with increasing distance of the protons from the hydroxyl group. When $[Pr(fod)_3(pz)]$ was used, it induced the 1-butanol spectrum to become first order and all peaks greatly shifted to high field (Fig. 3). On addition of $[Yb(fod)_3(pz)]$ the spectrum is amenable to a first order analysis and the magnitude of the induced shift is larger than the europium adduct, but with a little broadening and the coupling interactions of the nuclei having disappeared. This little broadening is due to long electron relaxation time of Yb(III) ion as compared to europium(III). In the above examples, the shifts of the hydroxyl protons are of course extremely large and have not been recorded, (See Tables 4—6).

In the normal ^1H NMR spectrum of benzyl alcohol

(CCl_4 solution) the aromatic protons resonate as a sharp singlet. Sanders and Williams[4] studied NMR spectrum of benzyl alcohol using [Eu(dpm)$_3$] and reported that the signals appear in order CH_2, *o*-protons, *m*-protons, and then *p*-proton (all lower field to TMS). Our studies gave a different result. [Eu-

Table 4. [Eu(fod)$_3$(pz)] shifts in ppm downfield

	H_α	H_β	H_γ	H_δ
1-Butanol	12.04	7.23	5.22	2.37
	CH_2	H_o	H_p	H_m

1-Butanol	−9.40	−5.90	−3.90	−2.06
	CH_2	H_o	H_p	H_m
Benzyl alcohol	−6.77	3.14	1.09	0.78

Negative sign indicate shifts upfield w.r.t. Me_4Si and positive shifts are downfield w.r.t. Me_4Si.

Table 6. [Yb(fod)$_3$(pz)] shifts in ppm downfield

	H_α	H_β	H_γ	H_δ
1-Butanol	28.67	27.82	17.82	8.92

(fod)$_3$(pz)] when added to a CCl_4 solution of benzyl alcohol resolved all the ring protons (Fig. 2) but in a different manner as reported.[4] The CH_2 protons appear at the lowest field as a sharp singlet, the next resonance is due to *o*-protons after this appear signal for *p*-proton and the *m*-protons appear at the last (all lower field to TMS). When [Pr(fod)$_3$(pz)] is used only CH_2 signal appears at higher field to TMS the other signals lie within the TMS envelope. The CH_2 proton resonance shows that the angle between the principal axis and line joining the paramagnetic ion and the proton inquestion is greater than 54.7° or 125.3°.

The NMR spectra of these adducts show no resonance for free pyrazole. Even on keeping the solutions for several days no change in signal line width or position is seen. This shows that coordinated pyrazole does not dissociate in solution as suggested by Hinckley[3] for pyridine.

Electronic Spectra. The electronic spectra of the complexes are recorded in ethanol. The intraligand

Hypersensitive transitions are enclosed in parentheses.

transitions occur in UV region and have not been discussed. The sharp line like f-f transitions originating within the $4f^n$ configuration of lanthanoid(III) ions are affected by the influence of the ligands on complexation. The shift of absorption bands to lower wave numbers (nephelauxetic effect) is usually of the order of a few percent[13] and is caused by a decrease in interelectronic repulsion parameter in the complexes.[25] A general red shift of the f-f transitions would be observed for these complexes as compared to the corresponding aqua ions. The $\bar{\beta}$ values for these complexes are presented in Table 7. The $\bar{\beta}$ values which are less than one show covalent nature of bonding between the metal and the ligand. The $\bar{\beta}$ value of Nd(III) complex is higher than the Pr-(III) complex but it is lower for Er(III) complex as compared to Nd(III) complex. This is in contrast to the general observation that the nephelauxetic effect is more pronounced in the beginning of the 4f group than in the later members. The bonding parameter, $b^{1/2}$ and Sinha's covalency parameter, δ are positive for these complexes indicating covalent bonding (Table 7). The greater the values of $b^{1/2}$ and δ the greater will be the degree of covalency. The $b^{1/2}$ and δ values of Nd(III) complex are less than those for Pr(III) complex showing decrease of covalency with increase of atomic number. The higher values of $b^{1/2}$ and δ for Er(III) complex than for Nd-(III) complex are surprising in view of the general observation and trend observed in case of $[Ln(fod)_3$-(im)] (im=imidazole) complexes.[12] The $[Ln(fod)_3$-(pz)] complexes are less covalent as compared to the corresponding $[Ln(fod)_3(im)]$[12] complexes since values of $b^{1/2}$ and δ are lower in the former case than in the later.

Another point of interest in these spectra are the intensities of the f-f transitions. Experimentally hypersensitivity refers to transitions having oscillator strengths which show a relatively large variability in oscillator strengths as the environment about the lanthanoid ion is changed. The large variability in oscillator strengths for the hypersensitive transitions is due to eigen perturbation.[26] Hypersensitivity can also be disccused from the theoretical point of view of Judd-Ofelt. According to this theory hypersensitivity is intimately associated with T_2 parameter of Eq. 6. Consequently only those transitions having relatively large values of $U^{(2)}$ matrix element should be called hypersensitive. Judd[27] has suggested that hypersensitivity may be due to symmetry of the crystal fields. Henrie[28] has shown that T_4 and T_6 appear to be primarily influenced by the symmetry of the complexes whereas T_2 seems to be correlated with the basicity of the ligand.

The oscillator strengths are listed in Table 9 and hypersensitive transitions classified by previous workers[28] are enclosed in parentheses. There is a good correlation between P_{exptl} and P_{calcd} showing that the intensity theory of Judd-Ofelt is applicable but poor correlation between P_{exptl} and P_{calcd} in case of Pr(III) complex strengthens the conclusion of the earlier workers[29,30] that this theory is not applicable to the complexes of Pr(III).

The transitions in Pr(III) and Er(III) complexes have values of $U^{(2)}$ which are significantly larger than either the $U^{(4)}$ or $U^{(6)}$ values and thus have oscillator strengths which are affected primarily by T_2 parameter.

In Nd(III) complex the magnitude of $U^{(2)}$ is not large enough to permic the effect of T_2 parameter to dominate instead T_4 and T_6 are more sensitive than T_2 and hence the observed oscillator strength is governed by these parameters. The oscillator strength of $^2H_{11/2}$ in Nd(III) complex shows a very large change as compared to the aqua ion. This change is larger than the change shown by hypersensitive transition (enclosed in parenthesis).

The oscillator strength of the hypersensitive transitions is related to the degree of covalency. As the covalency in the complex increases the oscillator strength of the hypersensitive transitions exhibits a corresponding increases. The oscillator strengths of the hypersensitive transitions of pyrazole complexes have lower values as compared to the corresponding imidazole complexes[12] since imidazole is more basic than pyrazole.

In the last we can say that pyrazole complexes, though less covalent, have superiority over imidazole complexes[12] since they can be used as potential shift reagents.

KI and MS thank the CSIR, New Delhi India, for the award of the research fellowships to them.

Synthesis of Naturally Occurring Prenylated Benzophenones. Vismiaphenone A, Vismiaphenone B, and Isovismiaphenone B

Ved Prakash PATHAK and Rajinder Nath KHANNA*
Department of Chemistry, University of Delhi, Delhi-110007, India
(Received August 13, 1981)

2,4,6-Trihydroxybenzophenone on prenylation with 2-methyl-3-buten-2-ol in the presence of $(C_2H_5)_2O\cdot BF_3$ yielded 2,4,6-trihydroxy-3,5-diprenylbenzophenone (**3**), 2,6-dihydroxy-4-prenyloxybenzophenone, 2,6-dihydroxy-3-prenyl-4-prenyloxybenzophenone, a benzodipyran and 6-benzoyl-5,7-dihydroxy-2,2-dimethyl-3-prenylchroman. **3** on reaction with 2 moles of *p*-toluenesulfonyl chloride followed by methylation and detosylation gave a naturally occurring benzophenone, vismiaphenone A (**12**). Cyclodehydrogenation of 6-hydroxy-3,5-diprenyl-2,4-ditosyloxybenzophenone gave 8-benzoyl-2,2-dimethyl-6-prenyl-5,7-ditosyloxy-2*H*-1-benzopyran, which on detosylation gave another naturally occurring benzophenone, isovismiaphenone B, while cyclodehydrogenation of **3** gave vismiaphenone B, another naturally occurring benzophenone. 2,4-Dihydroxy-6-methoxybenzophenone on similar treatment with 2-methyl-3-buten-2-ol afforded **12** directly.

Monache *et al.*[1] recently reported the isolation of new prenylated benzophenones *viz.* vismiaphenone A (**12**), vismiaphenone B (**8**) and isovismiaphenone B (**9**) from the fruits of *Vismia decipiens*. The structures were assigned on the basis of spectroscopic and degradative studies. In order to confirm the proposed structures, we report the syntheses of these benzophenones starting from 2,4,6-trihydroxybenzophenone.

2,4,6-Trihydroxybenzophenone (**1**) (prepared by the condensation[2] of 1,3,5-trimethoxybenzene[3] with benzoyl chloride followed by demethylation) on reaction with 2-methyl-3-buten-2-ol in the presence of $(C_2H_5)_2O\cdot BF_3$ in dioxane at 25—30 °C furnished six products on TLC (benzene:hexane, 2:1), which were separated by column chromatography on silica gel and designated as compounds **A**, **B**, **C**, **D**, **E**, and **F**.

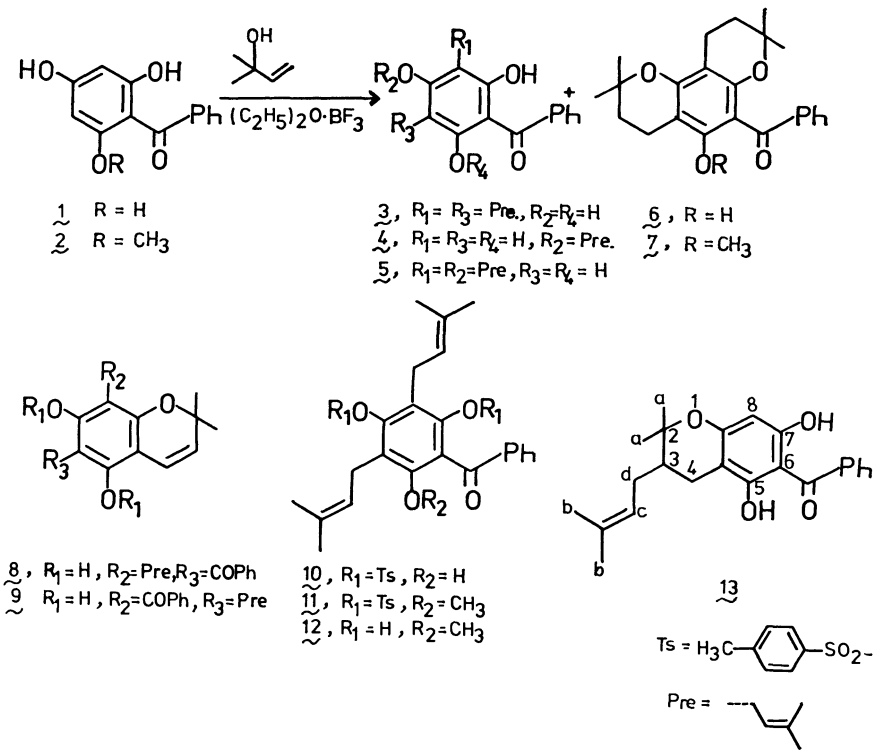
Compound **A** was obtained as yellow shining crystals, $C_{23}H_{26}O_4$, mp 94—95 °C. It exhibited positive iron(III) chloride reaction and negative Gibbs' reaction.[4] The infrared (IR) spectrum suggested the presence of hydroxyl groups (3350 and 3100 cm^{-1}) and carbonyl (1610 cm^{-1}) groups. Its ^1H NMR spectrum showed δ 7.33—7.65 (5H, m) due to the unsubstituted phenyl ring. It also indicated the presence of two prenyl groups [δ 1.77, 1.72 (6H, s each, $(CH_3)_2\times2$), 3.31 (4H, d, J=6.5 Hz, $-C\underline{H}_2-CH=\times2$), 5.2 (2H, t, J=6.5 Hz, $-CH_2-C\underline{H}=\times2$)] and three hydroxyl groups [δ 6.2 (1H), 8.85 (1H), 12.8 (1H) all exchangeable with deuterium]. Based on these data, compound **A** was assigned the structure 2,4,6-trihydroxy-3,5-diprenylbenzophenone (**3**), which was further confirmed by its acid cyclization to benzo[1,2-*b*:3,4-*b'*]dipyran (**6**). Compound **3** was also reported earlier by us[5] in poor yields by the reaction of **1** with prenyl bromide in the presence of sodium methoxide.

Compound **B** was obtained as light yellow needles, $C_{18}H_{18}O_4$, mp 121 °C. It exhibited positive Gibbs' reaction and indicated a hydroxyl (3250 cm^{-1}) and a carbonyl (1620 cm^{-1}) groups in IR spectrum. Its ^1H NMR spectrum showed a singlet at δ 6.08 integrating for two protons assigned to C_3–H and C_5–H and a multiplet at δ 7.4—7.78 assigned to unsubstituted phenyl ring. It also indicated the presence of a prenyloxyl group [δ 1.78, 1.84 (3H, s each $(CH_3)_2$), 4.57 (2H, d, J=7 Hz, $-C\underline{H}_2-CH=$), 5.5 (1H, t, J=7 Hz, $-CH_2-C\underline{H}=$)] and two hydroxyl groups [δ 8.98 (1H, s), 12.84 (1H, s), both exchangeable with deuterium]. On this basis compound **B** was assigned the structure as 2,6-dihydroxy-4-prenyloxybenzophenone (**4**).

Compound **C** was a brown oil, $C_{23}H_{26}O_4$, gave a positive iron(III) chloride reaction as well as Gibbs' reaction. ^1H NMR spectrum indicated the presence of one prenyloxyl group and one *C*-prenyl group [δ 4.18 (2H, d, J=6.5 Hz, $-C\underline{H}_2-CH=$), 3.38 (2H, d, J=7 Hz, $-C\underline{H}_2-CH=$), 5.3, 4.67 (1H, bt each, J=6.5 Hz, $-CH_2-C\underline{H}=\times2$), 1.74, 1.78, 1.64, 1.57 (3H, s each, $(CH_3)_2\times2$)]. It also showed the presence of an aromatic proton δ 5.95 (1H, s), an unsubstituted phenyl ring δ 7.36—7.71 (5H, m) and two hydroxyl groups at δ 10.8 (2H, s, C_2– and C_6–OH). It was assigned the structure as 2,6-dihydroxy-3-prenyl-4-prenyloxybenzophenone (**5**).

Compound **D** was obtained as white crystals, mp 176 °C, having molecular formula $C_{23}H_{26}O_4$. It exhibited positive iron(III) chloride reaction and the ^1H NMR spectrum revealed the presence of two 2,2-dimethylchroman units [δ 0.86, 0.38 (6H, s each, $(CH_3)_2\times2$), 1.27, 1.03 (2H, t each, J=7 Hz, $CH_2-C\underline{H}_2\times2$), 2.13, 1.93 (2H, t each, J=7 Hz, $C\underline{H}_2-CH_2\times2$)], unsubstituted phenyl ring δ 6.68—6.97 (5H, m) and a chelated hydroxyl δ 12.4 (1H, s). On the basis of these data, it was assigned 2,2,8,8-tetramethyl-2*H*,10*H*-benzo[1,2-*b*:3,4-*b'*] benzopyran structure (**6**), which was further confirmed by its methylation to give **7**, which corresponded to that derived from **12**.

Compound **E** was a light brown oil, $C_{23}H_{26}O_4$, exhibited positive iron(III) reaction. A positive Gibbs' test along with a singlet at δ 5.91 indicated that C_8–H *para* to C_5–OH is free and thus C_5 position of benzophenone must be linked to the $C_{10}H_{18}$ unit. It also showed in its ^1H NMR spectrum (i) two methyl groups attached to a saturated centre at δ 1.26, 1.44 (3H, s each), (ii) two methyl groups attached to an unsaturated centre, δ 1.63, 1.74 (3H, s each), (iii) a multiplet integrating for three protons at δ 2.0—2.41 assignable to two protons at C_d and one proton at C_3, (iv) C_4 protons at δ 2.79 (2H, dd, J=16 and 5 Hz) and a methine proton δ 5.11—5.36 (1H, m, H_c). Unsubstituted phenyl ring protons were indicated at their usual position at δ 7.36—7.77 (5H, m). Thus, on the above basis compound **E** was formulated as



6-benzoyl-5,7-dihydroxy-2,2-dimethyl-3-prenylchroman (**13**). Compound **E** seems to arise by the attack of an isopentenyl carbonium ion, generated from 2-methyl-3-buten-2-ol, on the prenyl unit of 5-prenylbenzophenone.[6] Compound **F** was unreacted starting benzophenone **1**. Oxidative cyclodehydrogenation of **3** with DDQ afforded **8**, whose spectral data were in complete agreement with those reported for the natural sample of vismiaphenone B. Ditosylation of **3** with 2 mol of *p*-toluenesulfonyl chloride gave 6-hydroxy-3,5-diprenyl-2,4-ditosyloxybenzophenone (**10**) which on methylation followed by detosylation furnished **12**, identical in all respects with the reported data for vismiaphenone A. Compound **12** was also prepared by the reaction of 2,4-dihydroxy-6-methoxybenzophenone (**2**) (prepared by ditosylation of **1** followed by methylation and detosylation) with 2-methyl-3-buten-2-ol under similar reaction conditions as in **1**. This reaction showed the presence of two minor and two major products on TLC. The two major products were characterized to be **3** and **12**, while the minor products could not be identified.

Oxidative cyclodehydrogenation of **10**, followed by detosylation furnished **9**, identical with isovismiaphenone B in all respects.

Experimental

All melting points are uncorrected. IR and UV spectra were recorded on a Perkin-Elmer IR spectrophotometer Model-621 (ν_{max} in cm^{-1}) in KBr and on Perkin-Elmer UV spectrophotometer Model-554 (λ_{max} in nm) in methanol respectively. ^1H NMR spectra were measured on Perkin-Elmer R-32 (90 MHz) spectrometer in $CDCl_3$ or CCl_4 using tetramethylsilane as an internal standard (s, singlet; d, doublet; t, triplet; m, multiplet; br, broad).

Reaction of 2-Methyl-3-buten-2-ol with 2,4,6-Trihydroxybenzophenone. **1** (10 g, 27.3 mmol) was dissolved in dry dioxane (50 ml) and stirred vigorously at 25—30 °C. $(C_2H_5)_2O \cdot BF_3$ (3 ml in 15 ml of dioxane) was added to the stirring solution in 1 h. The solution was stirred for 1 h more. Then 2-methyl-3-buten-2-ol (4.5 ml, 52.3 mmol, in 10 ml of dioxane) was added in 10 min and the solution stirred for another 4 h. The reaction mixture was left overnight and diluted with water. It was extracted with ethyl acetate (2×250 ml) and the organic phase was washed with 5% aqueous sodium hydrogencarbonate (100 ml) and water. It was dried (Na_2SO_4) and solvent evaporated. The resulting brownish liquid (8.5 ml) was chromatographed on silica gel. On elution with light petroleum (boiling range 60—80 °C) with the increasing amount of ethyl acetate, following compounds were separated.

*Compound **A** (3).* Obtained as yellow shining crystals (950 mg), (Found: C, 75.35; H, 7.20%. Calcd for $C_{23}H_{26}O_4$: C, 75.46; H, 7.06%). UV(qualitative) 254 and 311. IR: 3350 (br), 3100 (br), 1610, 1552, 1390, 1320, 1252, 1155, 1095 and 940.

*Compound **B** (4).* Crystallized from chloroform as light yellow needles (80 mg), (Found: C, 72.46; H, 6.10%. Calcd for $C_{18}H_{18}O_4$: C, 72.48; H, 6.04%). UV (qualitative) 248 and 308, IR: 3250(br), 2900, 1620, 1459, 1375, 1150, 1082, and 820.

*Compound **C** (5).* Obtained as brown oil (60 mg), (Found: C, 75.38; H, 7.14%. Calcd for $C_{23}H_{26}O_4$: C, 75.46; H, 7.06%). UV (qualitative) 248 and 308; IR: 3360, 3120, 1620, 1510, 1385, 1290, 1165, 1060, and 935.

*Compound **D** (6).* Crystallised from light petroleum–benzene mixture as white crystals (50 mg), (Found: C, 75.41; H, 7.16%. Calcd for $C_{23}H_{26}O_4$: C, 75.46; H, 7.06%); UV: 210 and 312; IR: 3390, 2910, 1585, 1440, 1418, 1330, 1318, 1291, 1271, 1250, 1228, 1150, 1110, and 952.

*Compound **E** (13).* Obtained as light brown oil (740 mg), (Found: C, 75.40; H, 7.12%. Calcd for $C_{23}H_{26}O_4$: C, 75.46; H, 7.06%). UV: 253 and 310; IR: 3320, 2920,

1620, 1585, 1424, 1300, 1167, 1120, 1078, and 920.

Compound F. Obtained as light yellow crystals and was characterized to be the unreacted benzophenone **1** (500 mg).

2,4-Dihydroxy-6-methoxy-3,5-diprenylbenzophenone (12). A mixture of **3** (200 mg, 0.55 mmol) and *p*-toluenesulfonyl chloride (280 mg, 1.47 mmol) was dissolved in dry acetone (5 ml) and the solution was refluxed with ignited potassium carbonate (300 mg) for 6 h. Dimethyl sulfate (0.2 ml, 1.6 mmol) and potassium carbonate (100 mg) were added and the reaction mixture was further refluxed for 12 h. Inorganic salts filtered and acetone evaporated. The residue was treated with 10% ethanolic potassium hydroxide (20 ml) for 2 h at 50—55 °C. The solution was cooled, diluted with water (200 ml), acidified with HCl and extracted with ether. The ethereal layer was washed with 5% sodium hydrogen carbonate solution (45 ml) followed by water (100 ml) and dried (Na_2SO_4). The solvent was evaporated and the residue on purification by column chromatography afforded **12** as a light yellow oil (35 mg), (Found C, 75.81; H, 7.46%). UV: 255 and 310. IR: 3410, 1620, 1602, 1582, 1442, 1375, 1320, 1175, 1150, 1002. ^{1}H NMR(CCl_4): δ 11.8 (1H, s, O<u>H</u> at C-2), 7.75—7.31(5H, m, phenyl ring protons), 6.2(1H, br s, O<u>H</u> at C-4), 5.2(2H, br t, J=7 Hz, CH_2–C<u>H</u>=×2), 3.3—3.44(4H, m, C<u>H</u>$_2$–CH=×2), 3.21(3H, s, OCH_3), 1.75, 1.76(6H, s each, $(CH_3)_2$×2).

8-Benzoyl-5,7-dihydroxy-2,2-dimethyl-6-prenyl-2H-1-benzopyran (9). A mixture of **3** (250 mg, 0.68 mmol), *p*-toluenesulfonyl chloride (350 mg, 1.84 mmol) and potassium carbonate (360 mg) was refluxed in dry acetone (7 ml) for 8 h. The potassium salts were filtered off and washed with hot acetone (50 ml). The filtrate and washing were mixed and the solvent evaporated. The residue on purification with column chromatography on silica gel gave **10** as waxy solid (180 mg), mp 57 °C, ^{1}H NMR(CCl_4): δ 13.18 (1H, chelated OH), 7.81 (4H, d, J=7 Hz, tosyl protons at C-3′ and C-5′×2), 7.28—7.49 (5H, m, phenyl protons), 7.14 (4H, d, J=7 Hz, tosyl protons at C-2′ and C-6′×2), 4.94—5.14 (2H, m), 3.12—3.36 (4H, m), 2.48, 2.39 (3H, s each, methyl protons of tosyl×2), 1.68, 1.56 (6H, s each, $(CH_3)_2$×2).

Compound **10** (120 mg, 0.17 mmol) was dissolved in benzene (5 ml), DDQ (150 mg, 0.66 mmol) was added and refluxed for 16 h. The reaction mixture was filtered through a short column of silica gel. Solvent evaporated and the residue was treated with 10% ethanolic KOH (15 ml) at 55—60 °C for 2 h. Solvent evaporated, residue was diluted with water, acidified and extracted with ether (50 ml). The ethereal layer was washed with water, dried (Na_2SO_4) and the solvent evaporated. The residue on purification with column chromatography on silica gel afforded **9** as light yellow solid (25 mg), mp 117—118 °C (lit,[1] mp 118—120 °C), (Found: C, 75.85; H, 6.68%). UV: 295 and 305; IR: 3390, 3350, 1643, 1615, 1592, 1575, 1175, 1130, and 880; ^{1}H NMR ($CDCl_3$): δ 12.9 (1H, s, OH at C-2), 7.3—7.55 (5H, m, phenyl ring protons), 6.4 (1H, d, J=9 Hz, proton at C-4), 6.2 (1H, s, OH at C-7), 5.3 (1H, d, J=9 Hz, proton at C-3), 4.9—5.15(1H, m, –C<u>H</u>=CH$(CH_3)_2$), 3.3(2H, J=7 Hz, –C<u>H</u>$_2$–CH=), 1.75, 0.85 (12H, s each, $(CH_3)_2$×2).

6-Benzoyl-5,7-dihydroxy-2,2-dimethyl-8-prenyl-2H-1-benzopyran (8). **3** (50 mg, 0.14 mmol) was dissolved in dry benzene (5 ml) and refluxed with DDQ (30 mg, 0.13 mmol) for 3 h. The reaction mixture filtered through a small column of silica gel. On evaporation of solvent, **8** was left as light yellow oil (15 mg), (Found: C, 75.82; H, 6.62%). UV: 280 and 319; IR: 3390, 3340, 1642, 1615, 1590, 1570, 1175, 1160, 1128, 1120, and 880; ^{1}H NMR ($CDCl_3$): δ 12.6(1H, s, OH), 8.9(1H, s, OH), 7.3—7.6(5H, m), 6.45 (1H, d, J=8 Hz, proton at C-4), 5.45(1H, d, J=8 Hz, proton at C-3), 5.0—5.21(1H, t, J=7 Hz, –CH_2–C<u>H</u>=), 3.31(2H, d, J=7 Hz, –C<u>H</u>$_2$–CH=), 1.77, 1.25(6H, s each, $(CH_3)_2$×2).

Cyclization of 3. Compound **3** (50 mg, 0.14 mmol) was dissolved in chloroform (5 ml) and trifluoroacetic acid (0.5 ml) was added to it and left overnight. Solvent evaporated and the residue dissolved in benzene (25 ml) and filtered through a small column of silica gel. On evaporation of solvent, **6** was obtained as white crystals (30 mg).

Methylation of 6. The mixture of **6** (20 mg, 0.06 mmol), dimethyl sulfate (0.1 ml) and potassium carbonate (50 mg) was refluxed in acetone (5 ml) for 10 h. On working up in the usual manner, **7** was obtained as white solid which crystallized from hexane as white crystals (15 mg), mp 144 °C (lit,[1] mp 145—146 °C). ^{1}H NMR (CCl_4): δ 7.55—7.72 (2H, m, phenyl ring protons), 7.14—7.38 (3H, m, phenyl ring protons), 3.52(3H, s, OCH_3), 2.56, 2.42(2H, t each, J=7 Hz, C<u>H</u>$_2$–CH_2×2), 1.65, 1.56(2H, t each, J=7 Hz, –CH_2–C<u>H</u>$_2$×2), 1.26, 0.96(6H, s each, $(CH_3)_2$×2).

Reaction of 2 with 2-Methyl-3-buten-2-ol. Compound **2** (800 mg, 3.3 mmol) was treated with 2-methyl-3-buten-2-ol (0.5 ml) in the presence of $(C_2H_5)_2O\cdot BF_3$ (0.2 ml) as mentioned in case of **1**. On working up a brown oil (750 mg) was obtained, which was chromatographed on silica gel. On elution with light petroleum, two main fractions were separated and were characterized to be **12** and **3** respectively.

One of the authors (VPP) is grateful to the CSIR (New Delhi) for the award of Senior Research Fellowship.

Studies on 2-Methyl- and 2-Phenyl-4-arylmethylene-2-imidazolin-5-ones and Related Compounds

Mahmoud Zarif Badr, Hassan Ahmed Hassan El-Sherief,* and Magda Ebeid Tadros

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(Received October 28, 1981)

Compounds 4-arylmethylene-2-methyl-2-oxazolin-5-ones and 4-arylmethylene-2-styryl-2-oxazolin-5-ones react with primary aromatic amines in the presence of anhydrous zinc chloride to give the corresponding 4-arylmethylene-2-methyl-2-imidazolin-5-ones and 4-arylmethylene-2-styryl-2-imidazolin-5-ones (**5**) respectively. Treatment of **5** with phosphorus pentasulfide gives the corresponding 2-imidazoline-5-thiones. Reaction of 4-arylmethylene-2-phenyl-2-oxazolin-5-ones with hydroxylamine hydrochloride gives the corresponding imidazolinones which was reacted with alkyl halides and acid chlorides to give the corresponding ethers and esters respectively. Structures of the resulting products have been characterized on the basis of elemental analysis, IR, and UV data.

It has been reported[1] that 4-benzylidene-2-methyl-2-oxazolin-5-one reacts with aniline to give 4-benzylidene-1-phenyl-2-methyl-2-imidazol-in-5-one. Recently,[2] under the influence of acetic acid and sodium acetate, 4-arylmethylene-2-phenyl-2-oxazolin-5-ones and primary amines have been reported to yield directly the corresponding imidazolin-5-ones.

The present investigation is mainly concerned with the study of the reaction of 4-arylmethylene-2-methyl-2-oxazlin-5-ones (**1**) and 4-arylmethylene-2-styryl-2-oxazolin-5-ones (**2**) with primary amines, under different conditions, and the study of their behavior with 4-arylmethylene-2-phenyl-2-oxazolin-5-ones (**7**).

1a and **1b** react with aniline in acetic acid and sodium acetate to give *N*-phenyl-2-acetamido-3-arylacrylamides (**3**), instead of the expected 2-imidazolin-5-ones. This can be explained by the fact that the stabilization of the imidazolinone ring by the 2-phenyl group is higher than by the 2-methyl group because the former has three double bonds in conjugation with the ring system than the later. However, when the reaction was carried out in the presence of anhydrous zinc chloride, the corresponding 4-arylmethylene-2-methyl-2-imidazolin-5-ones (**4a—h**) were obtained.

On the other hand, it was previously mentioned[3] that **2a** reacted with primary amines in a benzene solution to give the corresponding α-cinnamido-*N*-substituted cinnamamide. However, when the reaction was carried out in the presence of anhydrous zinc chloride or in acetic acid with sodium acetate gave the corresponding 4-arylmethylene-2-styryl-2-imidazolin-5-ones (**5a—n**). Also, **5a**, **5e**, **5f**, **5h**, **5l**, and **5n** were obtained either by refluxing a mixture of **1a** and **1b** with appropriate amine and aldehyde in acetic acid and sodium acetate or by heating a mixture of **4** and aldehyde in the presence of anhydrous zinc chloride.

Consequently, it can be suggested that transformation of **1** to **5** in acetic acid and sodium acetate must go through an intermediate (**2**) which simultaneously reacted with amines, under reaction condition used to the final products (**5**) according to Scheme 1.

The identity of the imidazolinones (**5**) obtained by any one of these methods was established by TLC (using a benzene–ethanol mixture in the ratio 19:1 respectively) and mixed melting-point determination.

The IR spectra of **2** showed a carbonyl frequency at 1800—1790 cm^{-1} and an unresolved band at 1640—1620 cm^{-1} (due to the C=N and CH=CH). The structural assignment for the products (**4** and **5**) was supported by the IR and UV spectra. The IR spectra of **4** and **5** showed a stretching frequency at 1715—1700 cm^{-1} characteristic of the C=O group and the other band at 1630—1620 cm^{-1} attributed to the C=N stretch in compound **4**, in addition to the unresolved band in compound **5** at 1650—1630 cm^{-1} (due to C=N and CH=CH).

The UV absorption spectra of **4** are characterized by a principal absorption band at 352—378 cm^{-1}, which assigned to n-π^* transition of the carbonyl group perturbed by intramolecular charge transfers from arylmethylene residue to the polarized carbonyl group. This was confirmed through the pronounced red shift to 378 nm observed in **4f** and **4h** which can be attributed to the donating character of the methoxyl group in the arylmethylene residue. The data obtained for **4** showed a hypsochromic shift of about 20—25 nm in comparison with 4-arylmethylene-2-phenyl-2-imidazolin-5-ones.[4]

The UV spectra of **5** were similar to those of **4** and exhibited a principal absorption band at 410—432 nm. The data obtained for **5** showed a bathochromic shift of about 55—60 nm and 30—40 nm when compared with that of **4** and 4-arylmethylene-2-phenyl-2-imidazolin-5-ones respectively.[4]

Treatment of **5a**, **5e**, **5h**, **5i**, and **5j** with phosphorus pentasulfide in dry pyridine produced the corresponding 4-arylmethylene-2-styryl-2-imidazoline-5-thione (**6a**, **6e**, **6h**, **6i**, and **6j**).

The IR spectra of **6** showed absorption bands within the range 1270—1258 cm^{-1} and 1660—1640 cm^{-1} which are characteristic for C=S and -C=N- groupings respectively. The UV spectra of **6a** and **6h** are characterized by two or three absorption bands. The far-UV band is located at longer wavelength than the corresponding one in **5**. This behavior is understandable in view of the higher energy level of the nonbounding electrons in sulfur as compared to the oxygen atom.[5]

Furthermore, the authors have also investigated the hitherto unknown reaction of 4-arylmethylene-2-phenyl-2-oxazolin-5-ones (**7a—c**) and hydroxylamine hydrochloride. Compounds **7a—c** react with hydroxyl-

Scheme 2.

amine hydrochloride in a methanol solution in the presence of sodium acetate to give 4-arylmethylene-2-phenyl-1-hydroxy-2-imidazolin-5-ones (**8a**—**c**) respectively.

The IR absorption spectra of the newly synthesized compounds showed absorption bands at 1710—1700 cm^{-1} and 3340—3330 cm^{-1}, which were assigned to the C=O and -OH stretching frequencies respectively, in addition to the -C=N- stretch appeared at 1640—1630 cm^{-1}. The ^1H NMR spectrum of **8c** in trifluoroacetic acid showed signals at 7.8 (S, 1H, -CH=C-), 7.4 (m, 5H, C=N-C_6H_5); 6.82 (m, 4H, C=C-C_6H_4) and 3.8 (S, 3H, -OCH_3) which are in good agreement with its structure.

Reaction of **8a**—**c** with alkyl halides, acid chlorides and sulfonyl chlorides in dry acetone in the presence of anhydrous potassium carbonate gave the corresponding ethers (**9a**, **9b**, **9e**, **9f**, **9m**, **9k**, and **9l**), esters (**9c**, **9g**, **9j**, and **9n**), and sulfonic esters (**9d**, **9h**, **9l**, and **9o**) respectively.

The IR spectra of compounds **9a**—**9o** showed an absorption band at 1715—1700 cm^{-1} attributed to the C-O group and another carbonyl, the ester group in compounds **9c**, **9g**, **9j**, and **9n** appeared at 1780—1770 cm^{-1}. The UV spectra of **8** and **9** were similar to those of 4-arylmethylene-2-phenyl-2-imidazolin-5-ones[4] and exhibited a principal absorption band at 385—406 nm.

The ^1H NMR spectrum of **9k** in trifluoroacetic acid showed signals at 7.8 (S, 1H, CH=C-), 7.44 (m, 5H, C=N-C_6H_5), 6.82 (m, 4H, C=C-C_6H_4) and 3.8 (S, 6H, C_6H_4-OCH_3 and N-OCH_3), which is in agreement with its structure.

Biological Screening Results. Compounds of the type **8a**—**c** and **9h**, **9k**, **9o** were tested *in vitro* for their biological activities on some microbes *viz. Bacillus megaterium* and *Staphylococcus albus* and fungi as *Aspergillus fumigatus* and *Penicillium nigricans*. The more active compounds against *Bacillus megaterium* was **9o**, against *Staphylococcus albus* were **8b** and **9o**; against *Aspergillus fumigatus* were **8a**, **9h**, **9k** and against *Penicillium nigricans* was **9k**.

Experimental

Melting points are uncorrected. IR spectra in KBr were recorded on a Perkin-Elmer infracord spectrophotometer. UV spectra were taken in ethanol on a Pye-Unicam SP 8000 spectrophotometer and ^1H NMR spectra were recorded on a Varian 60 MHz NMR instrument using TMS at the internal standard.

4-Arylmethylene-2-styryl-2-oxazolin-5-ones (2). A mixture of **1** (0.01 mol), appropriate aldehyde (0.012 mol) and anhydrous zinc chloride (0.001 mol) was fused together for 5 min. The cooled reaction mixture gave a yellow precipitate on adding ethanol, which recrystallized from the same solvent. The yield was about 80—85%.

N-Phenyl-2-acetamido-β-arylacrylamide (3). A mixture of **1** (0.01 mol), aniline (0.012 mol) and anhydrous sodium acetate (0.005 mol) in acetic acid (20 ml) was refluxed was refluxed for 3 h. The cooled reaction mixture was filtered off, then recrystallized from ethanol. The yield was about 85%.

4-Arylmethylene-2-methyl-2-imidazolin-5-ones (4). A mixture of **1** (0.01 mol), primary aromatic amine (0.012 mol) and anhydrous zinc chloride (0.001 mol) was fused together for 5 min. The yellow product was collected and crystallized from methanol. The yield was about 55—65%.

4-Arylmethylene-2-styryl-2-imidazolin-5-ones (5). A mixture of **1** (0.01 mol), appropriate aromatic amine (0.012 mol) and aromatic aldehyde (0.012 mol) in acetic acid (20 ml) containing freshly fused sodium acetate (0.005 mol) was refluxed for 3 h, the reaction mixture was cooled, then poured into water. The crude product was collected and crystallized from ethanol. The yield was about 70—75%.

The same products were obtained from **2** and the corresponding aromatic amine when the reaction was carried out either in the presence of anhydrous zinc chloride or in acetic acid solution containing freshly fused sodium acetate as describe above.

4-Arylmethylene-2-styryl-2-imidazoline-5-thiones (6). A mixture of **5a**, **5b**, **5h**, **5i**, and **5j** (0.003 mol) and phosphorus pentasulfide (0.0035 mol) was refluxed in anhydrous pyridine (25 ml) for 7 h. The solvent was evaporated under reduced pressure and the residue was treated with dilute acetic acid.

The product was filtered and crystallized from ethanol as reddish-brown crystals, yield about 55%.

Translational Energy Distribution of the Excited Hydrogen Atom (n=3) Obtained by Controlled Electron Impact on CH_4

Teiichiro OGAWA* and Junichi KURAWAKI

Department of Molecular Science and Technology, Kyushu University, Kasuga, Fukuoka 816

(Received November 5, 1981)

Synopsis. Dissociative excitation of CH_4 has been investigated through the analysis of the high resolution spectra of the Balmer-α line. Translational energy distribution of H*(n=3) obtained in e-CH_4 collisions has three distinct components and another indefinite component; their peaks lie at 3, 0—1 and 4, and 8—12 eV, respectively.

Translational energy distribution of a fragment produced in a collision process gives valuable information for the detailed analysis of the mechanism of dissociative excitation of the molecule. Translational energy distributions of ionic and metastable fragments have been obtained by mass-spectroscopic or time-of-flight techniques, whereas those of excited short-lived fragments have recently become possible by an analysis of the Doppler profiles of their emission spectra.[1]

We have recently reported the translational energy distribution of H*(n=4) from methane obtained in e-CH_4 collisions and their assignments together with discussion on the mechanism of dissociative excitation of methane.[2] The results on H*(n=3) will be described in this note.

Experimental

The apparatus consists of an electron-molecule collision chamber, a Fabry-Perot interferometer and a data acquisition system. The details were reported previously.[3]

Results and Discussion

Since the line shape of the Balmer line obtained in an electron-molecule collision process is determined by the Doppler effect, analysis of the line shape should clarify the kinetic behavior of the excited hydrogen atom produced. The high resolution spectra of the Balmer-α lines have been taken with the use of an interferometer. Typical results of H*(n=3) from CH_4 are shown in Fig. 1.

For a successful analysis of the line shape, it has to be determined without distortion due to such as insufficient resolution of the optical system or the effect of anisotropy.[3] The optical resolution used here was 0.029—0.032 Å, and distortion from this source should be negligible. The line shapes were measured from 55° and 90° with respect to the electron-beam. Since the line shapes show no obvious difference for the two angles (Fig. 1), the effect of anisotropy should be smaller than the experimental uncertainty. Thus, we assume that the effect of anisotropy is negligibly small for the analysis of the translational energy distribution.

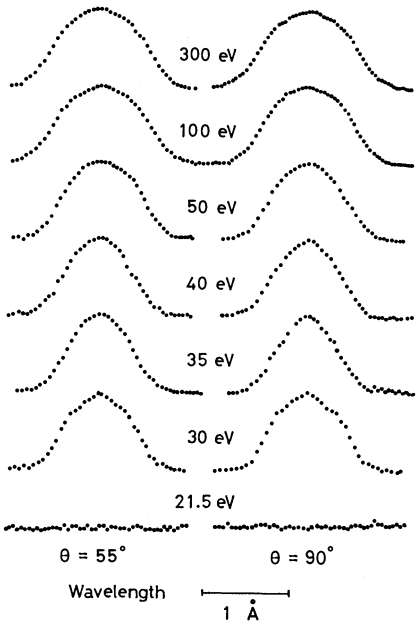

Fig. 1. High resolution spectra of Balmer-α line produced by controlled electron impact on CH_4. Electron energy: 21.5—300 eV, electron energy resolution: 1—2 eV, spectral resolution: 0.029—0.032 Å.

Ito *et al.* measured the Doppler profiles of the Balmer-α emission from methane with an etalon grating monochromator.[4] The observed linewidths of their measurement and of ours agree well within experimental uncertainties. They obtained the average translational energy from the halfwidth; however, the translational energy distribution calculated in this note contains more abundant and detailed information for the excitation process.

The differentiation of the line shape gives the translational energy distribution of the excited hydrogen atom;[3] the results are shown in Fig. 2. At an electron energy of 30 eV, the distribution has a peak at about 3 eV. As the electron energy increases, there appears a component with a peak at 0—1 eV. At higher electron energies, there is an intense peak at about 4 eV, and there seems to be another component in the 8—12 eV region. Thus, the translational energy distribution of H*(n=3) from methane has three distinct components and one indefinite component.

The translational energy distribution of H*(n=3) looks similar with those of H*(n=4),[2] H(HR),[5,6] and H^+.[7,8] Thus, the dissociative excitation of the short-lived and long-lived excited atoms and dissociative ionization proceed in similar processes. This finding is consistent with the core-ion model,[6] and justifies an

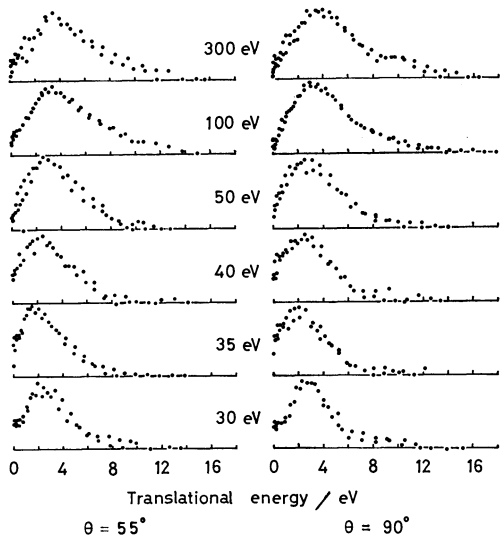

Fig. 2. Translational energy distribution of H*(n=3) produced by controlled electron impact on CH_4. Electron energy: 21.5—300 eV.

extension of this model to the formation of a low Rydberg atom.[2,4] Accordingly, we can conclude that the dissociative excitation of H*(n=3) proceeds through potential energy surfaces almost parallel to and reasonably close to that of the excited molecular ion core.

The component with the peak at 3 eV corresponds to component 1 of H*(n=4),[2] and the threshold of this component will be at about 21 eV. Thus, we can conclude that the formation of this component proceeds through excitation to Rydberg states converging to the $\tilde{A}^2A_1$ state of CH_4. The other components may be produced in a dissociative excitation through doubly excited Rydberg states converging to some excited ionic states or to some doubly ionized states.

The electron impact method has an distinct advantage for the investigation of molecular dissociation process, since optically-forbidden doubly excited states play important roles.

The authors thank Morihide Higo for discussion and Professor Nobuhiko Ishibashi for encouragement. The present study was partially supported by a Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture.

Efficiency of Noble Metal Electrodes for Zirconia Oxygen Sensors in Detecting Oxygen at Lower Temperatures

Tsuyoshi ARAKAWA,* Akira SAITO, and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565
(Received July 16, 1981)

Synopsis. Metal Au, Ag, or Pt was deposited as electrode on the closed end of a stabilized electrolyte tube in the ZrO_2 oxygen sensor, and emf of the cell, $O_2|m|ZrO_2$–$Y_2O_3|m|O_2'$ (m=Au, Ag, Pt) with P_{O_2}=8.8 and $P_{O_2'}$= 159 Torr (1 Torr=133.322 Pa), was measured as a function of temperature between 150 and 950 °C. For cells with Ag electrodes, a good agreement is found between theoretical and measured emf's at lower temperatures (*ca.* 340 °C).

Solid oxide electrolytes are in use for construction of oxygen sensors, high temperature fuel cells, and oxygen pumps.[1-3] However, for their practical use, for example, electrodes in the system of $O_2|$stabilized zirconia$|O_2'$ play an important part. In this connection, a number of studies have been made of the use of Pt electrodes on stabilized electrolyte,[4] but no reports have been published of the other noble metal electrodes. The object of the present work is to investigate the efficiency of noble metal electrodes for stabilized zirconia oxygen sensors in detecting oxygen at lower temperatures.

Experimental

The solid electrolytes used were impervious ZrO_2–Y_2O_3 (8 mol%), ZrO_2–CaO(11 mol%), and ZrO_2–MgO(15 mol%) tubes closed at one end. The electrolyte tube had an i.d. of 11 mm, an o.d. of 15 mm, and a length of 300 mm. Each noble metal was first deposited on both the inside and outside surfaces near the closed end of the electrolyte tube. One Pt electrode was prepared by applying a nonfluxed platinum paste consisting of submicron platinum powder suspended in a 5:1 mixture of ethanol and surface active agent. This was heated to 800 °C for 30 min in air and then 1200 °C for 1 h in an atmosphere of hydrogen. One Au electrode was prepared by brushing a nonfluxed gold paste onto the surface of the electrolyte, and then firing at 600 °C for 2 h in an atmosphere of hydrogen. Three Ag electrodes were prepared in three ways: (i) Silver paste was applied on the surface of the electrolyte and fired at 600 °C for 2 h in a stream of hydrogen. (ii) When a formaldehyde solution was added dropwise to a 20% silver nitrate solution to which an excess ammonia solution had been added, silver was deposited on the faces of stabilized zirconia. This procedure was repeated twice or three times. The faces were washed with distilled water, dried at 100 °C and then heated at 600 °C for 2 h in a stream of hydrogen. (iii) A thin film on the surface of electrolyte was prepared by evaporation of silver metal and then heated at 600 °C for 2 h in an atmosphere of hydrogen. As illustrated in Fig. 1, the electrolyte tube was placed inside a quartz tube closed at one end. The electrolyte tube and the quartz tube were connected to the brass heads and the assembly was tightly closed by o-ring. Each of the inner and outer electrodes was linked by a Pt wire to the output terminal. A Pt *vs.* Pt/13% Rh thermocouple was used to measure temperatures. The outside of the electrolyte tube was kept in 159 Torr O_2 and the inside was allowed to contain 8.8

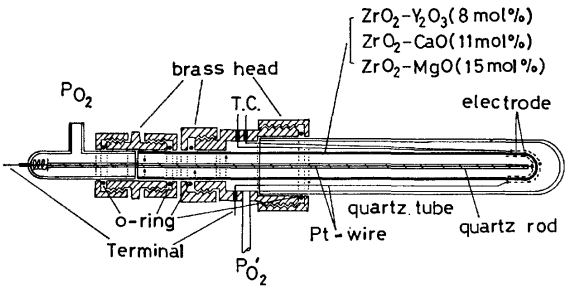

Fig. 1. Experimental cell assembly for evaluating the performance of the oxygen sensor.

Torr O_2. The effectiveness of these noble metal electrodes was determined by measuring the emf of the cell $O_2|m|Zr|m|O_2'$, where m is the metal electrode and Zr is the electrolyte as follows:

Cell number	Electrolyte (Zr)	Electrode (m)
1	ZrO_2–Y_2O_3	Pt
2	ZrO_2–Y_2O_3	Au
3	ZrO_2–Y_2O_3	Ag
4	ZrO_2–CaO	Ag
5	ZrO_2–MgO	Ag

In addition, the emf vs. relative oxygen-pressure ratio was determined by stepwise change of the inside oxygen partial pressure from 130 to 1 Torr, with the outside pressure kept 159 Torr. The emf was measured with a Takeda Riken electrometer. Measurements were carried out at 400—950 °C (Pt electrode) and 150—950 °C (Ag and Au electrodes).

Results and Discussion

In order to compare the abilities of the noble metal electrodes, each electrode prepared by applying the nonfluxed metal paste was tested, typical results being shown in Fig. 2. The solid line represents the theoretical emf as obtained from

$$E = \bar{t}_i \frac{RT}{4F} \ln \frac{P_{O_2'}}{P_{O_2}}, \quad (1)$$

where $\bar{t}_i$=1. All the noble metal electrodes, except the Au electrode (cell 2), were reversible in the measured temperature range, but the Ag electrode was deteriorated at temperatures over *ca.* 960 °C. With the cell $m|ZrO_2$–$Y_2O_3|m$, measurement of emf for the Ag electrode (cell 3) was possible from about 250 °C and a good agreement began around 340 °C to be found between the theoretical and measured emf's. Since the activity is in parallel with the temperature (T_g) at which the agreement between the theoretical and measured emf's begins, the sequence of activities for the noble metal electrodes is Ag>Au>Pt. Further, the emf-temperature curves for the other Ag electrodes

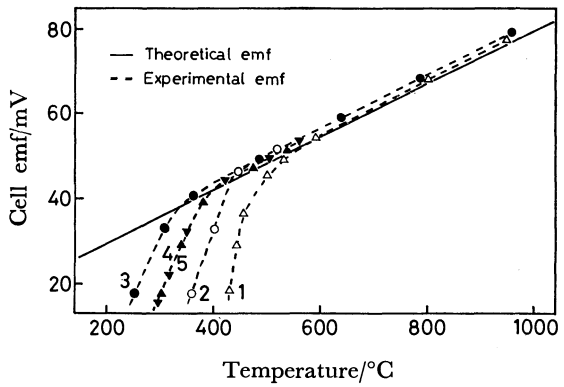

Fig. 2. Theoretical and experimental emf *vs.* temperature for the cell, where $P_{O_2}=8.8$ Torr and $P_{O_2'}=159$ Torr. The figures are cell number (see text).

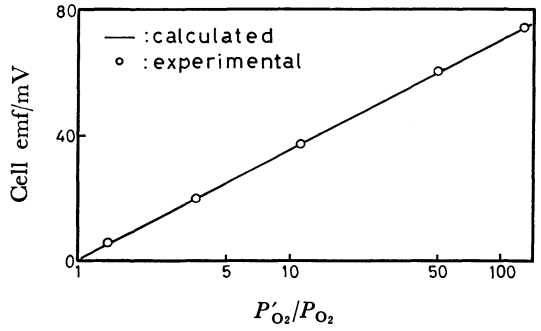

P'_{O_2}/P_{O_2}

Fig. 3. Dependence of emf on $P_{O_2}/P_{O_2'}$ for cell 4, $P_{O_2}|Ag|ZrO_2$–$Y_2O_3|Ag|P_{O_2'}$, where $P_{O_2'}=159$ Torr.

are similar to that for the Ag paste electrode, whereas for the other cells using Ag electrodes both cells 4 and 5 have T_g values slightly higher than that of cell 3. Thus it is concluded that electrodes greatly affect the detection of oxygen at lower temperatures and that the cells with Ag electrodes are better than those with the other electrodes.

In order to test the dependence of emf on $P_{O_2'}/P_{O_2}$, the emf of cell 3 was measured at 350 °C with P_{O_2} changed from 130 to 1 Torr. As shown in Fig. 3, the emf is proportional to $\ln P_{O_2'}/P_{O_2}$ and the slope is in good agreement with that calculated by using Eq. 1. Consequently, the cells with Ag electrodes may have the capability of detecting oxygen at lower temperatures, as described above.

Further, it is noted that for the cells with Ag or Pt (except Au) electrodes, T_g is close to the decomposition temperature, 300 or 560 °C, of the corresponding metal oxide Ag_2O or PtO, respectively.[5] In a potentiostatic experiment, Rickert and Steiner[6] found that for a cell $Fe(FeO)|electrolyte|Ag,O_2$ the oxygen moves from the silver electrode through the electrolyte to the opposite electrode, no product in the silver electrode being identified, whereas Belford and Alcock,[7] on the basis of findings obtained by using the galvanostatic technique, reported that, with respect to the diffusivity of oxygen through liquid tin, some evidence for limiting potential had been obtained at oxygen activities corresponding to those expected for unstable solid SnO. Thus it is concluded that cleavage of the metal-oxygen bond, which has been formed between the metal atom and the oxygen dissolved in the electrode, is an important process for the detection of oxygen at lower temperatures. Further physicochemical evidence shold be collected to support this result.

We thank the Ministry of Education of Japan for support of this work through a Grant-in-Aid for Scientific Research.

Concentration Dependence of Ketone Hydrogenation Catalyzed by Ru, Pd, and Pt. Evidence for Weak Ketone Adsorption on Pd Surface

Choi Sungbom† and Kazunori Tanaka*

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received October 13, 1981)

Synopsis. As the ketone (cyclohexanone, 4-heptanone) concentration in cyclohexane was increased, the hydrogenation rate saturated even below 0.05 mol dm^{-3} on Ru and Pt, but at a much higher concentration of around 0.5 mol dm^{-3} on Pd. This result suggests that ketone adsorption on Pd is weak in comparison with other platinum group metals.

Although palladium is an excellent catalyst for olefin hydrogenation, its activity for ketone (aliphatic and alicyclic) hydrogenation is notoriously low.[1] Breither *et al.*[2] regarded this poor activity as due to the unusual strength of ketone adsorption on Pd. On the contrary, Nishimura *et al.*[3] suggested that the attractive interaction of carbonyl with Pd surface is rather weak compared with other platinum group metals. Preliminary experiments in our laboratory[4] support Nishimura's view. To obtain further evidence for this view, we have carefully studied the concentration dependencies of ketone hydrogenation on Pd, and also on Pt and Ru for comparison. The substrate ketones chosen were cyclohexanone and 4-heptanone.

Experimental

Apparatus. The gas chromatograph was a Shimadzu GC-3BT instrument equipped with a thermocouple detector and a 10%-diglycerol column (3 mm i.d. × 3 m, 60—80 mesh supported on C-22 SK). The stainless steel autoclave used for catalyst pretreatment had a capacity of 100 ml. The glass reaction vessel used for kinetic studies has been described before.[5]

Materials. All chemicals were obtained commercially, and used without further purification: cyclohexane (Wako, guaranteed, stated purity 99.99%), cyclohexanone (Wako, guaranteed, 99.93%), 4-heptanone (Tokyo Kasei, extra pure, 99.83%). H_2 (in cylinder). Catalysts (Ru/SiO_2, Pd/Al_2O_3, Pd/SiO_2, Pt/Al_2O_3, Pt/SiO_2) were in the form of cylindrical pellets (Nippon Engelhard, 0.5-wt% metal loaded, 3.9 mmϕ × 4.0 mm long for the SiO_2-supported, 3.2 mmϕ × 3.7 mm long for the Al_2O_3-supported).

Kinetic Procedure. All catalyst samples were subjected immediately before use to a standard hydrogen-pretreatment procedure as follows. A small glass test tube, after being loaded with an appropriate number (1—10) of catalyst pellets and 10 ml of cyclohexane, was placed in the autoclave. The autoclave was charged with hydrogen, heated to 80 °C, and kept at that temperature for 30 min without stirring. During this 30-min pretreatment no significant decrease in hydrogen pressure (*ca.* 80 atm, 1 atm = 101.325 kPa) was observed.

Immediately after pretreatment, while still hot, the catalyst pellets were taken out of the autoclave and transferred to the glass reaction vessel pre-charged with the 5-ml cyclohexane solution of cyclohexanone or 4-heptanone that had already been flushed with hydrogen. Care was taken to minimize the air exposure time for the catalyst. The reaction vessel was connected to a hydrogen reservoir, and flushed with hydrogen one more time. The hydrogenation was started by shaking the reaction vessel vigorously at 30 °C in hydrogen at atmospheric pressure. During reaction the reaction mixture was sampled (usually 5 μl) at intervals, and analyzed by gas chromatography using helium as the carrier gas. The column temperature was set to 115 °C for the cyclohexanone systems and to 80 °C for the 4-heptanone systems.

† On leave from Jilin University, Changchun, People's Republic of China.

Results

Preliminary. The hydrogenation rate (V) increased in proportion to the catalyst weight, suggesting that it is not controlled by hydrogen dissolution into the bulk solution. The observed V values were reproducible to within 5%.

In the hydrogenation of 4-heptanone, no product peaks other than the corresponding alcohol were observed by gas chromatography. Also for the cyclohexanone system, hydrogenation to the corresponding alcohol was clean on all of the catalysts but Pd/Al_2O_3. On Pd/Al_2O_3 an unidentified side-product peak (retention time 23.5 min against 6.5 min for cyclohexanol) was detected, but its amount was always 0.1% or less in comparison with cyclohexanol.

Concentration Dependence. Figure 1 shows typical reaction profiles observed in Pd- and Pt-catalyzed hydrogenation. At the initial period of reaction, the ketone concentration (C_K) decreases linearly with time on Pt although on Pd a brief induction period precedes the linear region. The higher the initial C_K, the shorter was this induction period, with its complete disappearance for the 1 mol/dm^3 C_K. The reaction profile for Ru resembled that for Pt, with no induction period.

The values for V at various C_K levels were estimated from the initial linear region of the appropriate reaction profile, and are shown in Fig. 2. Most of the data points are the averages of duplicate experiments. Evidently, Pd-catalysis is distinguished from Pt- and

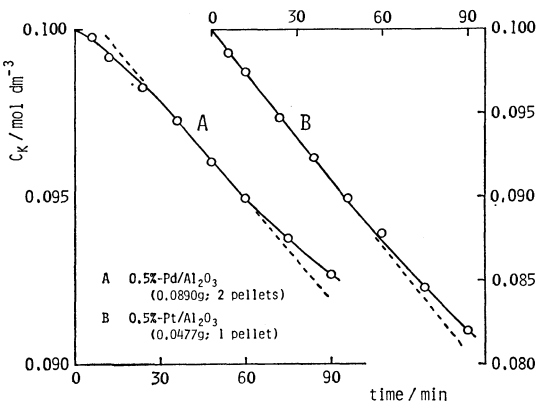

Fig. 1. Typical reaction profiles on Pd and Pt: plot of cyclohexanone concentration *vs.* time.

Table 1. Strength of ketone adsorption

Ketone	Catalyst	K_K / dm³ mol⁻¹	$\Delta G_K^\ddagger$ / kcal mol⁻¹	$\Delta G_K^\ddagger(M)^{a)} - \Delta G_K^\ddagger(Pd)$ / kcal mol⁻¹
4-Heptanone				
	Pt/Al_2O_3	66.9	−2.5	−1.3
	Pd/Al_2O_3	7.2	−1.2	
Cyclohexanone				
	Pt/Al_2O_3	50.5	−2.4	−0.4
	Pd/Al_2O_3	26.1	−2.0	
	Ru/SiO_2	186	−3.1	−1.6
	Pt/SiO_2	73.9	−2.6	−1.1
	Pd/SiO_2	12.2	−1.5	

a) Symbol (M) stands for a metal other than Pd.

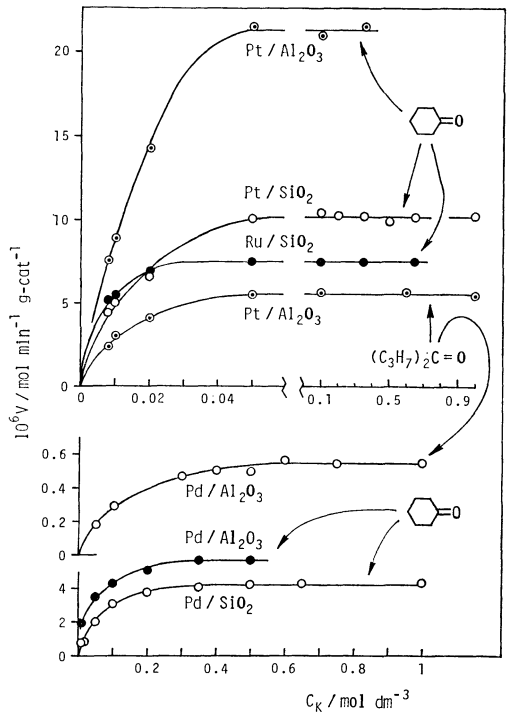

Fig. 2. Concentration dependence of ketone hydrogenation rate.

Ru-catalysis by the much slower increase in V with increasing C_K. This tendency is seen irrespective of the kind of catalyst support and reactant ketone, and therefore might be interpreted as due to the difference in ketone adsorption strength between Pd and the other metals.

Ketone Adsorption. All the plots in Fig. 2 have a long horizontal region, and there is no sign of rate decrease with increasing C_K at the higher C_K region. Rate V is thus given fairly well as a function of C_K:

$$V = kK_KC_K/(1+K_KC_K), \quad (1)$$

where k is the hydrogen pressure-dependent rate constant and K_K is the adsorption equilibrium constant of the substrate ketone. Rate expression (1) can be derived by assuming (a) the Langmuir isotherm for substrate ketone, (b) the neglect of alcohol adsorption, and (c) either the adsorption of hydrogen and ketone without mutual displacement or the hydrogenation of adsorbed ketone by a hydrogen source other than chemisorbed hydrogen. Item (b) is justified as far as the initial stage of reaction is concerned. Among examples of non-displacing hydrogen adsorption, in connection with item (c), might be hydrogen adsorption beneath the hydrocarbon ring or chain of the adsorbed ketone molecule. A small hydrogen atom or molecule might have access to this "shadow of ketone," but not another ketone molecule.

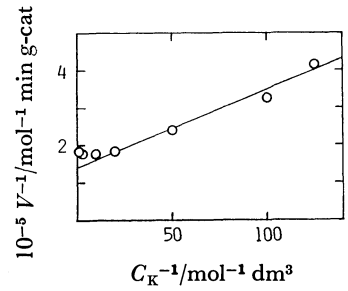

Fig. 3. Typical linear relationship due to Langmuir isotherm. 4-Heptanone on Pt/Al_2O_3.

Taking the reciprocal of both sides of Eq. (1), we have

$$\frac{1}{V} = \frac{1}{k} + \frac{1}{kK_KC_K}. \quad (2)$$

A typical linear relationship between $1/V$ and $1/C_K$ is shown in Fig. 3. The values of K_K were estimated from the slope and the intercept, and are listed in Table 1. Also included in Table 1 are the values for the standard free energy of ketone adsorption ($\Delta G_K^\ddagger$), which is calculated using the K_K values from

$$\Delta G_K^\ddagger = -RT\ln(K_KC^\ddagger) \quad (3)$$

where $C^\ddagger$ is a standard concentration. For the calculation of $\Delta G_K^\ddagger$, $C^\ddagger$ was set equal to 1 mol dm^{-3}, and T to 303 K. The $\Delta G_K^\ddagger$ data clearly indicate that ketone adsorption on Pd is weaker than on the other metals, as predicted in the Introduction.

There is a general rule proposed by Tanaka and Tamaru of Yokohama National University[6] for chemisorption of gases on metals. For many gases, according to this rule, the initial heat of chemisorption on various metals increases as the heat of formation of the highest oxide of the metal per metal atom ($-\Delta H_o^\ddagger$) is increased. Interestingly, in Table 1 the K_K values for cyclohexanone adsorption on the SiO_2-supported metals are in the sequence, Pd<Pt<Ru, which is parallel to the $-\Delta H_o^\ddagger$ sequence.

We thank Dr. Y. Takagi, Dr. S. Teratani, Dr. M. Kawai, and Mr. T. Chihara for a critical reading of the manuscript and their helpful comments.

The Formation of Anion Radicals in Glassy *N*-Propyl and *N*-Benzyldimethacryloylamines γ-Irradiated at 77 K

Toshiyuki KODAIRA,* Makoto TANIGUCHI, Hiroaki HASE, and Tomochika MATSUYAMA†

Department of Industrial Chemistry, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910

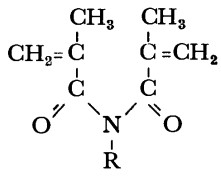
† *Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04*

(Received January 8, 1982)

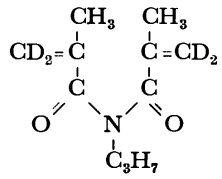
Synopsis. *N*-Propyl- and *N*-benzyldimethacryloylamines irradiated by γ-rays from ^{60}Co in their glassy state at 77 K yield anion radicals of their methacryloyl groups. These anion radicals afford a triplet with a coupling constant of 1.1 mT on measurement of the ESR and are bleached by a high-pressure mercury lamp at 77 K.

The primary effect of high-energy radiation is the excitation of the molecule, and ionization occurs subsequently. Electrons expelled are sometimes observed as trapped electrons in organic glasses, such as 2-methyltetrahydrofuran (MTHF)[1] and 3-methylpentane.[2] When electron-acceptors, for example, naphthalene or biphenyl, are added to organic glasses, the yield of the trapped electrons decreases and anion radicals of the solute electron-acceptors are formed through the reaction between the solute molecules and the electrons expelled from the solvent molecules.[3]

During the course of the studies of the solid-state cyclopolymerization of *N*-substituted dimethacryloylamines, *N*-propyl (DPA) and *N*-benzyl (DBA) derivatives were found to form a glassy state when they are quenched rapidly to the temperature of liquid nitrogen from above their melting points.[4] These results led us to ESR studies of these monomers in the glassy state, because the esters and amides of methacrylic acid trap electrons to form the anion radical of the methacryloyl group when they are exposed to ionizing radiation in such organic glasses as MTHF and 3-methylpentane.[5,6]



R=C_3H_7(DPA) or $CH_2C_6H_5$(DBA)



DPA-d_4

Experimental

DPA and DBA were synthesized as has been reported previously.[7,8] DPA deuterated at four methylene protons of methacryloyl groups(DPA-d_4) was prepared according to the procedure previously reported.[9] These monomers were dried over Drierite and distilled. The samples for ESR measurements were prepared in Suprasil tubes. The ESR spectra were recorded by means of a JEOL JES FE-1X X-Band spectrometer at a microwave power of 0.01 mW. The photobleach of the samples was carried out with a 100-watt high-pressure mercury lamp (Rikoh Scientific Industry Co., Ltd.) at a distance of 10 cm for 40 min at 77 K.

Results and Discussion

DPA and DBA subjected to γ-ray irradiation with a ^{60}Co source at 77 K in the dark afford the ESR spectra illustrated in Figs. 1a and 1d. After photobleaching, they changed to the spectral patterns depicted in Figs. 1c and 1f respectively. The 3-line spectra with a coupling constant of 1.1 mT were obtained by taking the difference between before and after the photobleaching of DPA and DBA irradiated at 77 K, as is shown in Figs. 1b and 1e. The spectra remaining after photobleaching at 77 K are mainly due to the 5-membered cyclic radical.[9] These results indicate that the active species which afford the 3-line spectra

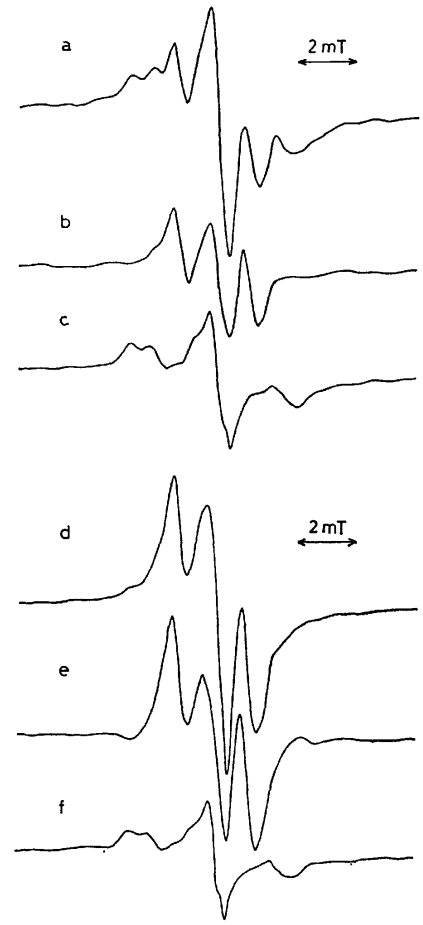


Fig. 1. ESR spectra of glassy DPA (a—c) and DBA (d—f) irradiated at 77 K for 2 h with a dose rate of 2.67×10^4 J/kg/h: (a,d) recorded at 77 K; (b,e) obtained by subtracting c from a and f from d, respectively; (c,f) measured at 77 K after photobleach.

with a coupling constant of 1.1 mT are formed on the γ-irradiation of glassy DPA and DBA at 77 K. The 3-line spectra with a separation of 1.1 mT observed on the ESR measurement of irradiated methacrylic acid derivatives in organic glasses have been ascribed to the anion radical of the methacryloyl groups.[5,6] The splitting was considered to be due to the methylene protons of the methacryloyl group, and the hyperfine splitting constant agreed well with the value obtained from theoretical calculations.[5] Accordingly, the triplets which disappeared during the photo-irradiation are attributable to the anion radicals of the methacryloyl groups of DPA and DBA.

To confirm the above identification, the ESR spectra of DPA-d_4 were measured. The spectrum illustrated by solid line in Fig. 2a was obtained when DPA-d_4 was γ-irradiated at 77 K. After photobleaching, it changed to the dotted spectrum depicted in Fig. 2a. The spectrum shown in Fig. 2b was obtained by subtracting the dotted line from the solid one. The large difference between the two spectra in Fig. 1b and Fig. 2b indicates that the methylene protons of the methacryloyl groups of DPA are responsible for the active species which yield the triplet with the coupling constant of 1.1 mT. In the case of DPA-d_4, a 5-line spectrum with an intensity ratio of 1:2:3:2:1 and with a coupling constant of about 0.17 mT should be observed if the photobleached spectrum is due to the anion radical of the methacryloyl group. The obtained spectrum (Fig. 2b) has a reasonable linewidth when we assume that it is a result of the line-broadening of the quintet. The 3-line spectra could not be detected when 14 mol% of CCl_4 known as a good electron-scavenger was added to the glasses of DPA and DBA. These results support the above conclusion that the triplets of 1.1 mT are due to the anion radicals of methacryloyl groups of DPA and DBA.

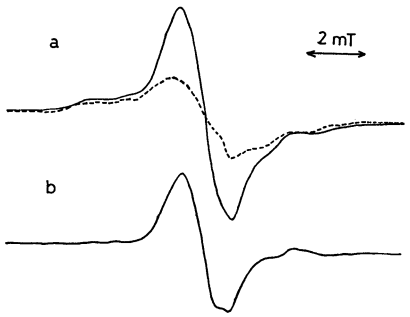

Fig. 2. ESR spectra of glassy DPA-d_4 irradiated at 77 K for 2 h with a dose rate of 2.67×10^4 J/kg/h: (a) solid line, recorded at 77 K; dotted line, measured at 77 K after photobleach; (b) obtained by subtracting dotted line from solid line in a.

When crystalline DPA and DBA were irradiated at 77 K, the anion radicals were not formed, and the main product was the 5-membered cyclic radical.[9]

A part of this work was done under the Visiting Researchers' Program of the Kyoto University Research Reactor Institute.

The MoO_3–SnO_2 Catalysts. Acid-Base Properties and Catalytic Activities for 2-Butanol Decomposition and 1-Butene Isomerization

Tuo JIN, Hideshi HATTORI, and Kozo TANABE*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 10, 1982)

Synopsis. Acidic and basic properties of MoO_3–SnO_2 catalysts with different compositions of MoO_3 were measured by adsorption of NH_3, CO_2, and acid-base indicators. Acidic property prevailed over basic property for all catalysts. Catalytic activities for 2-butanol dehydration and 1-butene isomerization correlated with the acidities measured under the reaction conditions.

A binary oxide of MoO_3–SnO_2 is known as a catalyst that promotes oxidation of propylene and of methanol.[1-3] Besides oxidation reactions, MoO_3–SnO_2 catalyzed acid-catalyzed reactions such as 1-butene isomerization.[4] Recently, MoO_3–SnO_2 was found to show a high activity for coal liquefaction.[5] Thus, the characterization of the surface property has become necessary.

Okamoto *et al.* studied the relationship between the structure of MoO_3–SnO_2 by XPS and the catalytic activity for 2-butanol decomposition.[6] They carried out the reaction in the presence of oxygen and proposed that the reaction proceeds by a Redox mechanism. Ai measured the acidity and found the correlation between the acidity and the catalytic activity for 1-butene isomerization, which was carried out in the presence of oxygen.[4]

In the present work, the acidic and basic properties of MoO_3–SnO_2 as well as the catalytic activities for 1-butene isomerization and 2-butanol decomposition in the absence of oxygen were studied, and the relationship between the properties and the activities is discussed.

Experimental

The MoO_3–SnO_2 was prepared by hydrolysis of mixed solution of ammonium molybdate ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$) and tin tetrachloride with ammonia water, the final pH being 8. The precipitate was aged over a water bath for 2 h, then washed with deionized water, dried at 120 °C for 24 h, and finally calcined at 500 °C for 2—3 h in air. The catalysts with different molar ratios of MoO_3 to SnO_2 were prepared from the different mixed solutions. The molar ratios were determined by fluorescence X-ray spectrometry. The MoO_3 was prepared from an aqueous solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ by precipitation with hydrochloric acid. The SnO_2 was prepared from an aqueous solution of $SnCl_4$ by precipitation with ammonia water. The precipitates were aged, washed, dried, and calcined as above. Acidic and basic strengths of the catalysts were qualitatively determined by use of indicators. A series of Hammett indicators were used for measurement of acidic strength. Bromothymol Blue ($pK_a=7.1$) and phenolphtalein ($pK_a=9$) were used for measurement of basic strength. The amounts of irreversible adsorption of NH_3 at 150 °C were measured by a pulse technique.[7,8] Prior to the measurement, a catalyst was pretreated under a He stream at 500 °C for 2 h or subsequently treated with 2-butanol in a He stream at 200 °C. The adsorption of CO_2 was measured volumetrically at 0 °C. The amount of irreversible adsorption of CO_2 was calculated as the difference in the amount between the first run and the second run which was carried out after outgassing at 0 °C for 30 min.

Reaction Procedures. A recirculation reactor (volume 280 ml) was employed with 0.5 g catalyst for carrying out the isomerization of 1-butene at 100 °C. Prior to the reaction, a catalyst was outgassed at 500 °C for 2 h. For the decomposition of 2-butanol, a microcatalytic pulse reactor was employed at 200 °C. A 10 μl of the reactant was injected in a He stream which flowed at a rate of 85 ml/min over 0.1 g catalyst.

Results and Discussion

The MoO_3–SnO_2 catalysts containing 10, 25, and 40% MoO_3 showed a fairly high acid strength of $H_0=-3.0$——5.6, and the catalysts containing 50, 70, and 90% MoO_3, the SnO_2 catalyst and the MoO_3 catalyst showed $H_0=+1.5$——3.0. As the content of MoO_3 in the binary oxide catalysts decreased, the acid sites became strong. The amounts of irreversible adsorption of NH_3 per unit surface area are plotted against the composition of catalyst in Fig. 1. For the catalysts which were pretreated only with a He stream at 500 °C, the amount of NH_3 adsorption exhibited a maximum at 50% of the MoO_3 content, though the amount was less than that for the MoO_3 catalyst. On subsequent treatment with 2-butanol at 200 °C, the amount of NH_3 adsorption decreased for the catalysts containing 25 and 50% MoO_3, and the plot of the amount *vs.* the MoO_3 content showed a monotonous increase with the increase in the MoO_3 content.

Okamoto *et al.* reported on the basis of XPS observation of the MoO_3–SnO_2 catalyst that Mo^{6+} ions in the catalyst containing a small amount of MoO_3 were easily reduced to Mo^{5+} ions which were stable toward further reduction. On the contrary, Mo^{6+} ions in the catalyst containing a large amount of MoO_3 were hardly reduced to Mo^{5+} ions under mild reduction conditions. However, once the Mo^{5+} ions were formed, the Mo^{5+} ions underwent further reduction

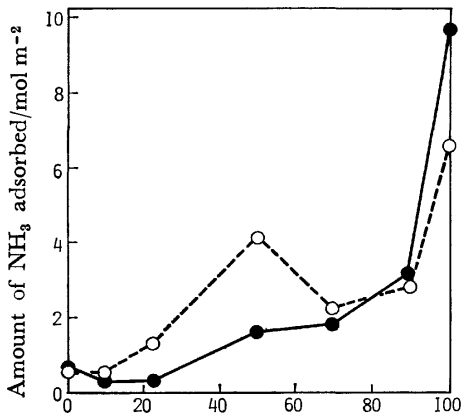

Fig. 1. Variation of the amount of NH_3 irreversibly adsorbed at 150 °C as a function of content of MoO_3 in catalyst.
--○--: Pretreated with a He stream at 500 °C,
—●—: subsequently pretreated with a 2-butanol at 200 °C.

to Mo^{4+} ions. This difference in reducibility with MoO_3 content seems to hold in the present case. It is assumed that the decrease in the amount of NH_3 adsorption on pretreatment with 2-butanol is caused by reduction of Mo^{6+} ions to Mo^{5+} ions for the catalysts containing small amounts of MoO_3. For the catalysts containing large amounts of MoO_3, Mo^{6+} ions persisted their oxidation states toward treatment with 2-butanol, and the amount of NH_3 adsorption did not change much.

Existence of weak basic sites ($H_-=7.1$—9) was observed for all the MoO_3–SnO_2 catalysts, but no basic sites were detected for the MoO_3 catalyst and the SnO_2 catalyst. The amounts of irreversible adsorption of CO_2 at 0 °C were 1.1—7.4 μmol/m², but all the adsorbed CO_2 were easily removed by evacuation at room temperature. This also indicates that basic sites on the catalysts are weak.

The rate of conversion of 1-butene to 2-butenes on unit surface area basis is plotted against the content of MoO_3 in Fig. 2. The catalysts containing 50 and 90% MoO_3 showed maximum activities. The variation of the activity for the isomerization with MoO_3 content correlated roughly with that of the amount of NH_3 adsorption on the catalysts pretreated with He except for MoO_3. This suggests that the active sites for the isomerization are acidic sites present on the MoO_3–SnO_2 catalysts. The higher activity of the catalysts containing 10 and 25% MoO_3 compared with SnO_2 catalyst is considered due to the higher acid strength. On the other hand, the higher activity of the catalyst containing 90% MoO_3 compared with the catalyst containing 50% MoO_3 is supposed to be due to a little cooperation of basic sites, since the acid strength of the former is lower than that of the latter. Since acid-catalyzed isomerization of 1-butene gives the cis/trans ratio in 2-butenes about 1 in most cases, the observed cis/trans ratios 0.9—1.5 also support that the acidic sites on the catalyst are acting mainly for the isomerization.

Degradation of activity for the reaction of 2-butanol with the pulse number was prominent for the catalyst

—●—: Total conversion, —△—: conversion to butenes, —□—: conversion to methyl ethyl ketone.

containing 10 and 50% MoO_3, while the activity did not decrease so much for the catalyst containing 90% MoO_3 and the MoO_3 catalyst. The variations of the conversions of 2-butanol to butenes and ethyl methyl ketone at the 5th pulse as a function of the composition of the catalysts are shown in Fig. 3. The conversion to butenes increased monotonously as the content of MoO_3 increased, and attained a maximum at the MoO_3 catalyst. Dehydrogenation to produce ethyl methyl ketone was minor reaction for all the catalysts. Only dehydration was observed on the MoO_3 catalyst. The variation of the conversion to butene with the composition of the catalyst correlated well with that of the amount of NH_3 adsorption on the catalyst pretreated with 2-butanol. During the reaction, a part of Mo^{6+} ions in the catalysts containing small amounts of MoO_3 may be reduced to Mo^{5+} ions. Prominent degradation of activity with increasing pulse number for the catalyst containing 10% and 50% MoO_3 supports the possibility of the reduction of Mo^{6+} ions and elimination of a part of the acidic sites.

Ai reported that the activities of MoO_3–SnO_2 for 1-butene isomerization and dehydration of isopropyl alcohol exhibited maxima at 30—60% of the MoO_3 content and that the activities correlated with the acidity. Taking into account that Ai carried out the reactions in the presence of oxygen, the present results are in accord with his results except for the MoO_3 catalyst. The reason for the discrepancy with MoO_3 is not certain.

Electrophoretic Behavior of Adenine, Adenosine, and Adenosine Nucleotides in Ion Exchange Cellulose Paper as a Support

Yoshinori KITAOKA

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04

(Received May 16, 1981)

Synopsis. Studies have been carried out on the effects of cationizable and anionizable groups of ion exchange cellulose papers on an electroosmotic flow over a range of pH=5—10 and on the electrophoretic migrations of adenine, adenosine, and adenosine nucleotides. The ionizable groups strongly affected the mobilities of adenosines.

An electrophoretic migration using a support is affected by many factors,[1,2] one of which is the chemical nature of the support. To improve the separability of the electrophoresis, many kinds of substances have been tried as a support. A filter paper having ionizable groups is one of them.

In this paper, we would like to report the electrophoretic behavior of adenine, adenosine, and adenosine 5′-mono, 5′-di-, 5′-tri-, and cyclic 3′,5′-monophosphates (AMP, ADP, ATP, and cAMP, respectively) in ion exchange cellulose papers at different pH-values. An electroosmotic flow is closely related to the ionic groups of a paper and affects the migration of a migrant. Thus, the flows in the papers were measured by movement of carbohydrates.

Reagents and Methods

Adenine and adenosine were purchased from Wako (Osaka, Japan), and the sodium salts of the nucleotides from Sigma (St. Louis, Mo., U.S.A.). Carbohydrates of guaranteed grade were used without further purification. Three different kinds of papers were used as a support: Toyoroshi No. 51A (=51A, pure cellulose paper), Whatman DEAE cellulose paper (=DE81, anion exchange cellulose paper), Whatman phosphate paper (=P81, cation exchange cellulose paper). Four kinds of supporting solutions were prepared; 0.1 M (1 M=1 mol dm^{-3}) NaCl solution (pH≈7.0, buffering capacity (β)=4.6×10^{-7}), citrate solution (pH=5.0, β=0.031, 0.1 M citric acid +0.2 M NaOH), phosphate solution (pH=7.0, β=0.027, 0.025 M Na_2HPO_4+0.025 M NaH_2PO_4) and glycine solution (pH=10, β=0.028, 0.06 M glycine+0.06 M NaCl+0.04 NaOH). The procedures and apparatus used were similar to those described previously.[3] A 5 μl volume of sample solution (5×10^{-2} M) was spotted at the position (see a footnote of Fig. 1) of a strip (1×40 cm) wetted with a supporting solution. It was then dipped in hexane in the migration chamber which was kept at constant temperature (*ca.* 25 °C). A d.c. voltage (1000 V per 30 cm) was applied for 30 min. The paper after migration was then dried and the position of adenines on the paper was detected under the irradiation of ultraviolet light (253 nm). The position of carbohydrates on the paper was detected an *o*-aminophenol solution.[4]

Results and Discussion

The movements of glucose, maltose, and maltotriose in three kinds of papers are shown in Fig. 1. The observed migrations are affected by capillary action, electroosmotic flow, and other physicochemical interactions in the system.[1,2] The differences of migration among spotting positions in a given paper are due to a capillary action, which is towards the center of a paper from both sides.[2,5] The movement due to the capillary action increases with increasing distances of the spotting position from the center of a paper.[1,2] The movement of carbohydrate spotted at the center is thought to be mainly due to an electroosmotic flow because the movement due to the capillary action is zero at the center. Three different carbohydrates showed similar movements in a given paper within experimental errors, showing that the effect of molecular weight on the capillary action and on the electroosmotic flow is small in this experimental range of molecular weight (mol wt: 180—504).

The movements of glucose spotted at the center of a paper dipped in four kinds of supporting solutions are shown in Fig. 2. The differences of migration among the pH-values in a given paper were small, while those among papers were large. The fact that the movement of glucose along with the supporting solution in DE81 paper was found in the anodic side of the paper indicates that the electroosmotic flow was towards the anode by the cationizable (diethylaminoethyl-) groups of the paper. The negative movements in 51A and P81 papers are due to an electroosmotic flow towards the cathode by the anionizable (–COOH and $-OPO_3H_2$, respectively) groups of the papers.

The observed migrations of adenine, adenosine, and adenosine nucleotides in three different papers are shown in Fig. 3. The largest migration of the nucleotides was seen in 51A paper, the next in DE81, and the smallest in P81.

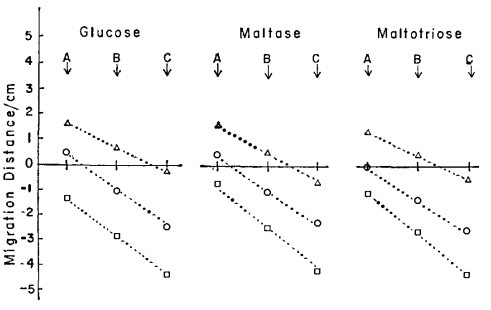

Fig. 1. Movements of carbohydrates at different spotting positions. Conditions: voltage gradient, 1000 V per 30 cm; migration time, 30 min; migration temperature, *ca.* 25 °C; supporting solution, 0.1 M NaCl. Spotting positions: A, 5 cm to the cathodic side from the center of the paper; B, the center of the paper; C, 5 cm to the anodic side from the center. Positive movement is towards the anode, negative movement towards the cathode. Supporting paper: △, DE81; ○, 51A; □, P81.

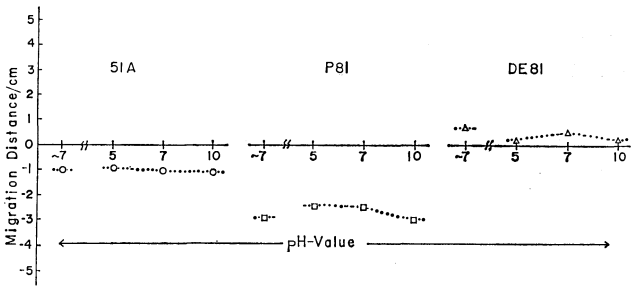

Fig. 2. Movements of glucose by different kinds of supporting solutions. Conditions: 1000 V per 30 cm; 30 min; *ca.* 25 °C. Supporting solutions: pH≈7.0, 0.1 M NaCl; pH=5.0, citrate solution; pH=7.0, phosphate solution; pH=10, glycine solution. Supporting papers: △, DE81; ○, 51A; □, P81.

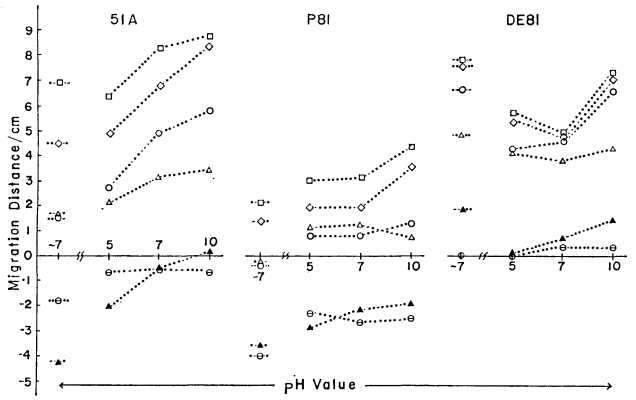

Fig. 3. Observed migrations of adenine, adenosine and adenosine nucleotides. Sample solutions: □, ATP; ◇, ADP; ○, AMP; △, cAMP; ⊖, adenosine; ▲, adenine. Conditions: 1000 V per 30 cm; 30 min; *ca.* 25 °C. Supporting solutions as in Fig. 2.

The migrations corrected for the electroosmotic flow shown in Fig. 2 are shown in Fig. 4. The migration of a weak acid or a weak base is very sensitive to the pH-value of a supporting solution.[6] When we dip a paper into a supporting solution, some ionizable groups in the paper will ionize. Thus, the pH-value of the supporting solution in the ion exchange paper becomes different from the initial pH-value. The pH change in the paper depends on the buffering capacity[7] of the supporting solution and the ion exchange capacity of the paper. The pH-value of the supporting solution in 51A paper will be not so different from the initial value because the number of ionizable (probably -COOH) groups in 51A is not sufficient to change

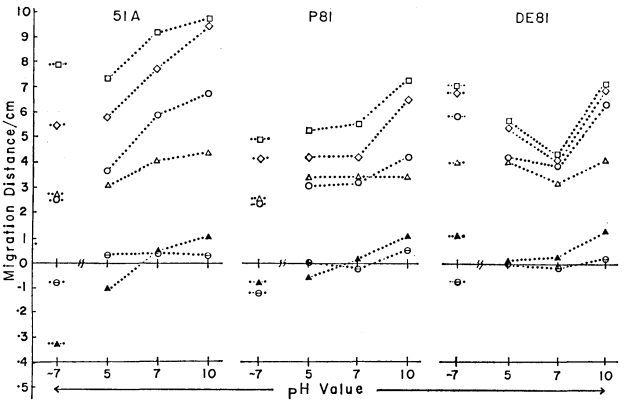

Fig. 4. Migrations corrected for electroosmotic flows. Electrophoretic conditions and symbols used are same as in Fig. 3.

the pH-value of the high buffering solution (approximately one carboxyl group per 500 glucose residues[1]). The increase[8] of the migrations due to the dissociation of the secondary-hydrogen of the phosphate group in the nucleotides is clearly observed at pH=7.0 in 51A (see Fig. 4). The migrations of the nucleotides on P81 or DE81 are strongly affected by ionizable groups of P81 or DE81 and the increase of migrations is not observed at pH=7.0. The migrations corrected for the electroosmotic flow on 51A are not identical with those on P81 or DE81. These results show that unestimated physicochemical interactions (mainly electrostatic forces) between the migrant and ionizable groups of the supporting paper are much involved in the migration of adenine, adenosine, and adenosine nucleotides, as well as an electroosmotic flow and/or a capillary action.

Studies of Lead-complex Formation in Sea Water by Anodic Stripping Methods

Ryuji NAKATA,*,† Satoshi OKAZAKI, and Taitiro FUJINAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

† *Department of Chemistry, Faculty of Education, Fukui University, Bunkyo, Fukui 910*

(Received November 30, 1981)

Synopsis. For the purpose of the determination and chemical speciation of trace lead in sea water by the use of an electrolytic concentration technique, the effects of the pH on the reduction potential of lead ions in the presence of various organic and inorganic ligands were investigated. In the pH range below *ca.* 5, the lead–chloro complex is dominant in sea water. Even in the presence of organic model ligands such as nitrilotriacetic acid (NTA), the electroactive species of lead was also its chloro complex when the sample solution was acidified enough below pH 2.

From the viewpoint of the electroanalytical studies of trace metals in natural waters, much attention has been paid not only to the total metal concentration, but also to the chemical speciation of the respective metals.[1] Particularly, for the direct identification of the metal complex in a very dilute solution *via* estimations of the ligand number and the complex stability constant, so-called "pseudo-polarography"[2,3] is one of the most promising methods; that is, the anodic stripping peak currents plotted as functions of the cathodic deposition potentials. The complexation of trace metals with organic ligands in natural waters has come to be of great interest in recent years.

We have developed an automatic coulopotentiographic analyzer system by utilizing several flow-electrolysis cells, and applied it to the analysis of trace lead and copper in sea water.[4] It was confirmed, by this method, that these metals at sub-ppb levels in sea water could be determined without any standards, and that the amounts of these metals determined depended remarkably upon the pH of the acidification of the sample sea water. This effect of pH seemed to be attributable to the distribution of the chemical species of these metals.

In this paper, we studied the relationships between the half-wave potential ($E^*_{1/2}$) of the pseudo-polarogram of lead and the pH of the solution in the presence of various organic and inorganic ligands in order to confirm the analytical conditions for the stripping coulopotentiographic determination of total lead and in order to clarify the distribution of chemical species of lead in sea water.

Experimental

Apparatus. The stripping voltammograms were recorded with a Yanagimoto voltammetric analyzer, model P-1000, and a National Pen-Recorder, model VP-654A. A three-electrode system was used; the working electrode was a hanging mercury drop electrode (Princeton Applied Research HMDE), and the potentials were controlled against an Ag/AgCl (saturated NaCl) reference electrode, with a platinum wire as an auxiliary electrode. During the pre-electrolysis stage, the sample solution was stirred for 5 min with a Yanagimoto magnetic stirrer, model MS-60, with a Teflon-covered stirring bar.

Reagents. The sodium perchlorate and humic acid were purified by the use of chelate or ion-exchange resins respectively. All the other chemicals used were of an analytical-reagent grade. Deionized water, after having been distilled from an all-quartz distillation apparatus, was used throughout for all the reagents. The sea-water sample was taken from the surface region of the Pacific Ocean off Wakayama and was filtered with conditioned 0.4 μm Nuclepore membrane filters.

Procedures. The pseudo-polarographic measurement consisted of the following stages, as usual: (1) to a 20 cm^3 base solution with adjusted pH in the electrolysis cell, we added 0.01 cm^3 of 1×10^{-4} mol dm^{-3} lead standard solution; (2) we passed nitrogen gas into the solution for 10 min (30 s for each subsequent run); (3) after renewing a mercury drop and setting the deposition potential, we pre-electrolyzed the solution for 5 min; (4) after stopping the stirrer and letting the solution equilibrate for 10 s, we recorded the anodic stripping voltammogram of lead ions at the scan-rate of 5 mV s^{-1}; (5) after changing the deposition potential, we repeated the procedures from Stage (2). Finally, each stripping current was plotted as a function of the corresponding deposition potential; that is, a pseudo-polarogram of lead was obtained. This pseudo-polarogram was then analyzed analogously to the classical d.c. polarogram, and its half-wave potential ($E^*_{1/2}$) was estimated.

Results and Discussion

In order to investigate the effects of the anions of the supporting electrolyte on the reduction potential of lead, the pseudo-polarogram of lead was measured in model solutions containing different supporting electrolytes at the ionic strength of 0.7, such as sodium perchlorate (ClO_4^- system), sodium chloride (Cl^- system), and sodium acetate plus acetic acid (CH_3COO^- system). Figure 1 shows the shift in $E^*_{1/2}$ with the pH of a lead solution containing a different supporting electrolyte. In the ClO_4^- system, the free lead ion is a dominant species in the pH range up to *ca.* 4. The negative shift of the half-wave potential with an increase in the pH is attributable to the formation of lead-hydroxy complexes. In the case of the Cl^- system, the lead ion preferentially forms chloro complexes ($K_1=10^{1.6}$, $K_2=10^{0.8}$) up to pH *ca.* 5, and then the half-wave potential shifts remarkably toward the negative side. The lead ion also forms weak complexes with the acetate anion in the pH range between 4 and 8 ($K_1=10^{2.4}$, $K_2=10^{1.5}$). The difference in the half-wave potentials between the Cl^- system and the CH_3COO^- system, −46 mV, was in good accordance with that calculated, *ca.* −44 mV, from the difference in the stability constants between the two complexes.

Figure 2 shows the shift in $E^*_{1/2}$ as a function of

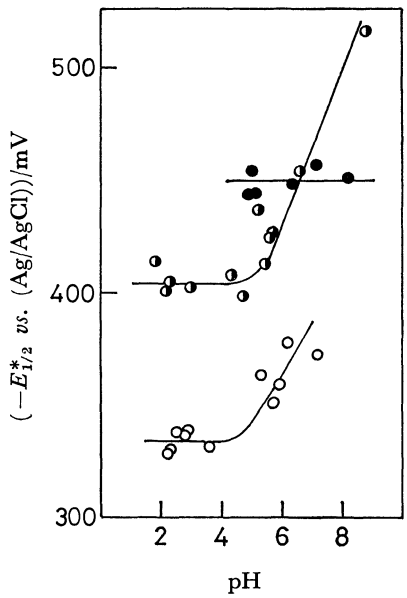

Fig. 1. Effect of pH on the $E^*_{1/2}$ values for the lead stripping peaks in model solutions (ionic strength= 0.7).
○: Sodium perchlorate, ◑: sodium chloride, ●: acetic acid+sodium acetate.

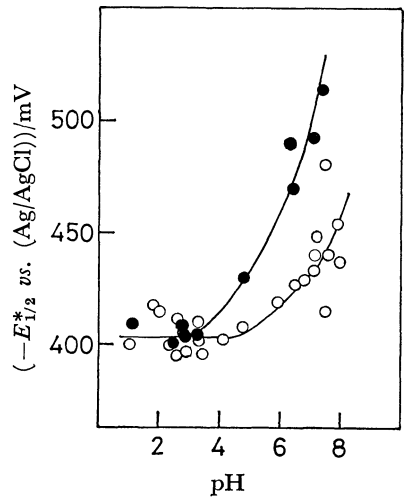

Fig. 2. Effect of pH on the $E^*_{1/2}$ values for the lead stripping peaks in sea water.
○: Sea water, ●: sea water with 5×10^{-5} mol dm^{-3} NTA.

the pH of sea water with or without the co-presence of the organic model ligand. The half-wave potential of lead in sea water was close to that in the Cl^- model system. However, the negative shift of the former was not so much as the latter at pH values greater than about 5. When the sea-water sample was pretreated with acetic acid, no notable shift of the half-wave potential was observed, not even in the presence of 0.1 mol dm^{-3} of acetic acid. For a detailed discussion of these phenomena, a more complicated metal complexation equilibrium should be taken into consideration for that complicated multicomponent system, sea water.

The complex-formation effects with organic ligands on the half-wave potential of lead were investigated in the same way using model ligands, such as NTA, cysteine, ethylenediaminetetraacetic acid (EDTA), and humic acid. As is shown in Fig. 2, in the co-presence of NTA, the electroactive species of lead also consisted of lead–chloro complexes when the pH of the sea-water sample was adjusted to below *ca.* 3. Cysteine behaves in a manner similar to NTA, while in the presence of EDTA, no definite stripping peak of lead was observed, not even by acidification to pH 3. Because of the stability constant of lead–EDTA ($K_1=10^{17.0}$), larger than those of lead–NTA ($K_1=10^{10.6}$) and lead–cysteine ($K_1=10^{13.2}$), this method is inapplicable to the study of lead–EDTA complexes.[5] However, the quantitative electrolysis of lead–EDTA can be performed by acidification with hydrochloric acid to pH 1.0. Concerning humic acid, the half-wave potential of lead was similar to that with NTA in a pH range up to *ca.* 3. In the higher pH range, however, no well-defined pseudo-polarogram of lead was obtained, though the stripping peaks were observed. The electrode process of lead reduction in the presence of humic acid seems to become rather complicated, as a result of the adsorption effect of humic acid on the electrode surface, *etc.*[6]

In conclusion, various chemical species of lead are distributed in sea water, and most of the organic and inorganic ligands of lead complexes can be replaced by chloride anions by acidification to pH 1.0. As a result, the pretreatment of the sea-water sample by acidification with hydrochloric acid to pH 1.0 is effective for the electrochemical determination of the total lead concentration in sea water at sub-ppb levels. For a quantitative discussion about metal complexation, it will be necessary also to take into account such effects as the reversibility of the electrode reaction and adsorption phenomena.

The present work was supported by the Nissan Science Foundation.

Salt Effects on the Intramolecular Cannizzaro Reaction of Phenylglyoxal. Specific Acceleration by Calcium Ion

Tadashi Okuyama,* Kazumasa Kimura, and Takayuki Fueno
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received June 30, 1981)

Synopsis. Effects of added salts on the rate of alkaline rearrangement of phenylglyoxal to mandelic acid were examined in aqueous solution at 30 °C. The reaction showed positive salt effects. Specific acceleration was found with some metal ions, the efficiency decreasing in the order $Ca^{2+}>Tl^{+}>Sr^{2+}>Ba^{2+}$.

The intramolecular Cannizzaro reaction of α-keto aldehydes in alkaline solutions to give α-hydroxy carboxylate ions has long been known and established to proceed through a 1,2-hydride shift.[1-4] The reaction has recently attracted renewed interest in relation to a formally similar reaction catalyzed by the glyoxalase system,[5-9] which involves zinc ion as a constituent essential for the enzymatic activity.[10] Enzyme-model reactions were found to be affected only very slightly by added magnesium ion in aqueous solutions.[7,8b] In the course of the studies on some model reactions of glyoxalase I involving metal ion catalysis,[11,12] we have found that Ca^{2+} and some other metal ions effectively accelerate the alkaline rearrangement of phenylglyoxal to mandelic acid (an intramolecular Cannizzaro reaction). The present communication describes results of the studies on such metal ion catalyses.

Experimental

Phenylglyoxal hydrate was prepared according to the literature.[11,13] Inorganic salts of reagent grade were used without further purification. Glass-distilled water was used throughout the work.

The Cannizzaro reaction was initiated by addition of 0.03 cm^3 of an aqueous stock solution of phenylglyoxal (typically 7×10^{-3} M (1 M=1 mol dm^{-3})) into 3 cm^3 of an alkaline solution which had been equilibrated at 30±0.1 °C in a stoppered quartz cuvette. Reactions were monitored by following the decrease in UV absorption of phenylglyoxal at 250 nm on a Shimadzu UV 200 spectrophotometer. Pseudo-first-order plots were linear over 3 lifetimes for all the runs.

Results and Discussion

At a constant ionic strength of 0.10 maintained with added KCl, the rates are dependent on [NaOH] in accord with Scheme I as reported previously:[5] $k_1=1.5\times10^{-4}$ s^{-1} and $k_2K_2=5.7\times10^{-2}$ M^{-1} s^{-1} using an assumed value of $K_1=250$ M^{-1}.[5]

With the alkaline concentration and ionic strength maintained at [NaOH]=0.01 M and μ=0.10, respectively, the effects of different salts on the rate were examined. The results are summarized in Table 1. While the alkali metal ions and anions show virtually no specific effect, Ca^{2+}, Tl^{+}, Sr^{2+}, and Ba^{2+} accelerate the reaction significantly. Of the various cations examined, Ca^{2+} is the most effective, showing a 13-fold acceleration at its concentration of 0.01 M.

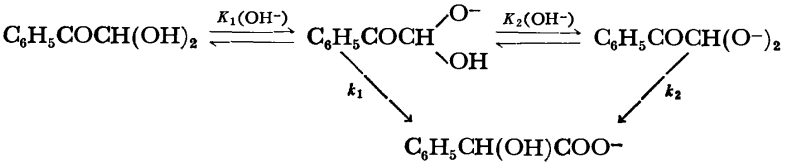
Table 1. Effects of added salts on the rate of rearrangement of phenylglyoxal[a]

Salt	$10^4 k_{obsd}/s^{-1}$
KCl	6.10
KNO_3	6.20
NaCl	6.15
$KCl+CaCl_2$[b]	81.3
$KCl+SrCl_2$[b]	16.4
$KCl+BaCl_2$[b]	11.1
KNO_3+TlNO_3[b]	21.4

a) [NaOH]=0.01 M, μ=0.10, 30 °C. b) The concentration of a second salt was 0.01 M.

When [NaOH] was kept constant at 0.01 M, the rate increased linearly with [$CaCl_2$] as is shown in Fig. 1. The slope is greater at lower ionic strength: 0.71 M^{-1} s^{-1} at μ=0.10 and 0.44 M^{-1} s^{-1} at μ=0.50. The effect of Ca^{2+} is thus largely dependent on the ionic strength. Figure 2 illustrates some details of such a dependence of the Ca^{2+} catalysis on μ. As is apparent from Fig. 2, the salt effect is positive in the absence of Ca^{2+} but is negative in the presence of Ca^{2+} ([$CaCl_2$]=0.001 M). In effect, the apparent catalytic efficiency of Ca^{2+} is the greater, the smaller the ionic strength. Addition of Ca^{2+} at a concentration as low as 10^{-3} M accelerates the reaction nearly 5-fold at the extrapolated zero ionic strength while it enhances the rate only by a factor less than 1.2 at ionic strengths greater than 0.5.

The marked catalytic effects of non-transition metal ions like Ca^{2+} found here may closely be related to the earlier observations of Pfeil *et al.*[14] They found that TlOH, $Ba(OH)_2$, and $Sr(OH)_2$ are much better catalysts for the benzilic acid rearrangement than alkali metal hydroxides in aqueous dioxane. They have not examined effects of $Ca(OH)_2$.[15] A univalent ion Tl^{+} also significantly accelerates the present reaction. Since the benzilic acid rearrangement takes place essentially in the same way as does the present



Scheme 1.

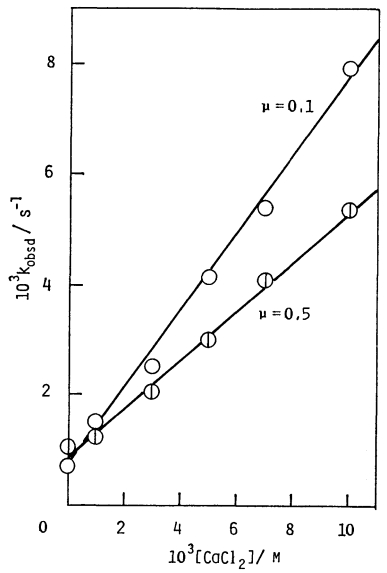


Fig. 1. Effects of $[CaCl_2]$ on the rate of rearrangement of phenylglyoxal in alkaline solution ([NaOH]=0.01 M) at μ=0.10 (○) and μ=0.50 (◐). Ionic strength was adjusted with KCl.

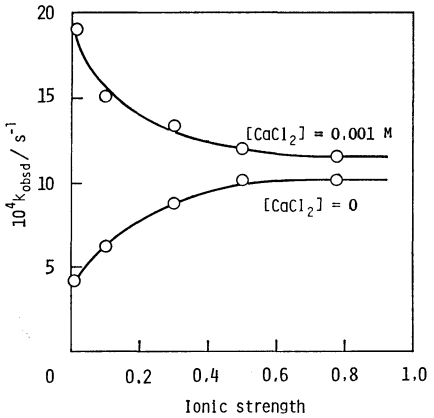

Fig. 2. Effects of ionic strength on the rate of rearrangement of phenylglyoxal in alkaline solution ([NaOH]=0.01 M) in the absence and in the presence of Ca^{2+} ($[CaCl_2]$=0.001 M) at 30 °C. Ionic strength was increased by the addition of KCl.

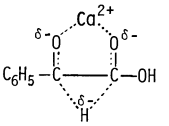
reaction,[17] the mechanisms of these catalytic actions of metal ions must be similar to each other.

The observed positive salt effect on the rearrangement of phenylglyoxal is not unexpected for a reaction of charged species.[4] The specific effects of Ca^{2+} may be accounted for by its influence either on the equilibrium constants, K_1 and/or K_2, or on the rate constants, k_1 and/or k_2. In any case, the transition state



for the hydride shift must be stabilized by the formation of a Ca^{2+} chelate. Added potassium ion may compete with Ca^{2+} to interact with the ionized phenylglyoxal hydrate, thus greatly interfering with the transition-state chelation of Ca^{2+}. This would be a possible reason for the negative salt effects on the Ca^{2+} ion-catalyzed rearrangement. Stability constants for some metal chelations are also known to depend strongly on the ionic strength.[18]

The Synthesis and Reactions of 2,6-Dimethyl-4-silaspiro[3.4]oct-6-ene

Daiyo Terunuma,* Noriyuki Shibuya, and Hiroyuki Nohira
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Urawa, Saitama 338

(Received September 9, 1981)

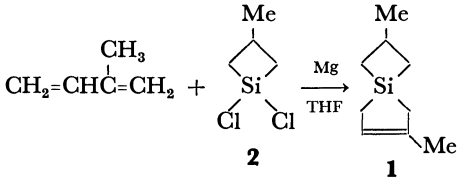
Synopsis. A new silaspiro compound, *i.e.*, 2,6-dimethyl-4-silaspiro[3.4]oct-6-ene, was synthesized by treating 1,1-dichloro-3-methyl-1-silacyclobutane with isoprene in the presence of magnesium in tetrahydrofuran. The reactions of the silaspiro compound with $LiAlH_4$, H_2PtCl_6, dimethyl acetylenedicarboxylate in the presence of $PdCl_2(PPh_3)_2$, and the Simmons-Smith agent were investigated.

A number of reports on the preparations and the reactions of silacyclobutanes have appeared.[1] However, a little work has been done on the synthesis of four-membered spiro compound which contains silicon atom in the ring.[2]

In the course of our studies of the synthesis and reactions of silacyclic compounds,[3b] a new silaspiro compound, *i.e.*, 2,6-dimethyl-4-silaspiro[3.4]oct-6-ene (**1**), was obtained. Being interested in the point that **1** contains two kinds of functional groups, double bond and silicon containing four-membered ring, in the molecule, we carried out some investigations concerning the reactivity of **1**.

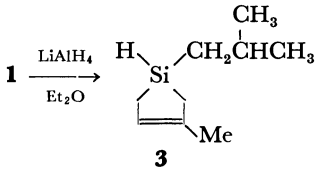
Results and Discussion

2,6-Dimethyl-4-silaspiro[3.4]oct-6-ene (**1**) was obtained in 59% yield by treating 1,1-dichloro-3-methyl-1-silacyclobutane (**2**) with an equimolar amount of isoprene in the presence of Mg in THF[3a] (Scheme 1).



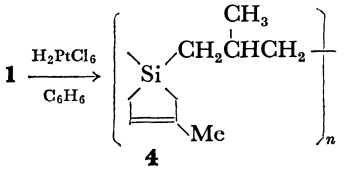
Scheme 1.

The reaction of **1** with $LiAlH_4$ gave the four-membered ring opening product, *i.e.*, 1-isobutyl-3-methyl-1-silacyclopent-3-ene (**3**), in 24% yield (Scheme 2).



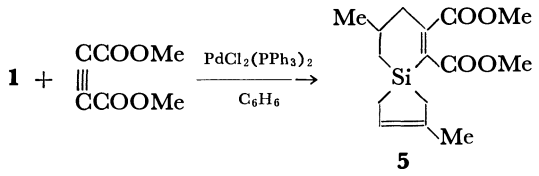
Scheme 2.

Polymerization of **1** was carried out in the presence of a small amount of H_2PtCl_6 in benzene. A solid polymer (**4**) ([η]=0.26 in benzene at 25 °C) was obtained in 74% yield. It was found that only the four-membered ring opening polymerization occurred and the five membered ring remained intact in the polymer, by comparing the IR and NMR spectra of **4** with those of **3**, and with those of the polymer obtained from 1,1,3-trimethyl-1-silacyclobutane (Scheme 3).



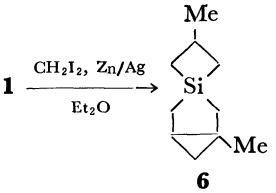
Scheme 3.

In the presence of a catalytic amount of $PdCl_2(PPh_3)_2$, the reaction of **1** with dimethyl acetylenedicarboxylate in benzene was carried out.[4] Another spiro compound, *i.e.*, 2,9-dimethyl-6,7-bis(methoxycarbonyl)-5-silaspiro[4.5]deca-2,6-diene (**5**), was obtained in 85% yield (Scheme 4).



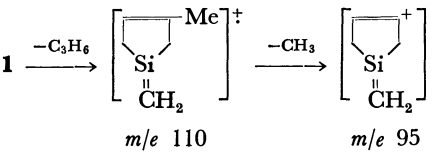
Scheme 4.

The reaction of **1** with the Simmons-Smith reagent in ether gave 1,3′-dimethylspiro[3-silabicyclo[3.1.0]hexane-3,1′-silacyclobutane] (**6**) in 47% yield. No methylene insertion product to the silicon-carbon or carbon-hydrogen bond of the four-membered ring was found in the reaction mixture (Scheme 5).



Scheme 5.

It is interesting that the silylene type fragment appears as the base peak in the case of 5-silaspiro[4.4]nona-2,7-diene,[5] whereas the silaethylene type fragment (*m/e* 110) is the base peak in the mass spectrum of **1**. Another silaethylene type fragment (*m/e* 95, relative intensity 71%) is also found in the spectrum of **1** (Scheme 6).



Scheme 6.

Experimental

The IR spectra were determined with a JASCO IR-A2 spectrometer. The NMR spectra were determined at 60

MHz with a Varian A-60D spectrometer in CCl_4 using TMS as the internal standard. Mass spectra were recorded on a JEOL-01SG instrument. The analytical GLC was carried out with a Shimadzu GC-5A chromatograph[1.5 m, 5% OV-1 on Chromosorb W(80—100 mesh)].

Preparation of 2,6-Dimethyl-4-silaspiro[3.4]oct-6-ene (1). In a flask Mg(5.5 g, 0.26 mol) was placed. A solution of isoprene (14.4 g, 0.21 mol) and **2**(29.5 g, 0.19 mol) in THF(85 ml) was added to the flask. The mixture was refluxed for 27 h with stirring. Water(150 ml) was added to the reaction mixture at 0 °C. The organic layer was washed three times with water, dried with Na_2SO_4. Subsequent evaporation and distillation gave **1** in 59%(17.1 g) yield. Bp 91—92 °C/38 Torr(1 Torr=133.322 Pa). n_D^{20} 1.5011. IR(neat) 1640, 1150, 1130, 950 cm^{-1}. NMR (δ) 0.6—1.2(m, 4, Si–CH_2), 1.16(d, 3, CH_3), 1.3—1.65(m, 4, Si–CH_2–C=), 1.75(broad s, 3, =C–CH_3), 2.1—2.8(m, 1, CH), 5.5(broad s, 1, =CH). Mass(*m/e*) 152(M^+), 124, 111, 110(base peak), 109, 96, 95, 83, 82, 81, 74, 69, 68, 67, 59, 55, 53, 31, 29. Found: C, 70.59; H, 10.61%. Calcd for $C_9H_{16}Si$: C, 70.97; H, 10.59%.

Reaction of 1 with $LiAlH_4$. A solution of **1**(1.0 g, 6.6 mmol) in ether(5 ml) was added to a suspension of $LiAlH_4$ (1.0 g, 0.026 mol) in ether(7 ml) with stirring. The reaction mixture was refluxed for 4 h. Saturated aqueous Na_2SO_4(about 20 ml) was added to the mixture with external cooling. Usual workup of the solution gave **3** in 24% (0.24 g) yield. Bp 90—92 °C/25 Torr. IR(neat) 2100, 1640 cm^{-1}. NMR(δ) 0.52(m, 2, Si–CH_2), 0.97(d, 6, C–CH_3), 1.3—1.6(m, 4, Si–CH_2–C=), 1.6—1.8(m, 3, CH_3), 2.1—2.3 (m, 1, CH), 4.2(m, 1, Si–H), 5.46(m, 1, =CH). Mass(*m/e*) 154(M^+), 149, 126, 112, 98, 97(base peak), 83, 71, 70, 69, 67, 59, 55, 45, 43, 31. Found: C, 69.70; H, 11.55%. Calcd for $C_9H_{18}Si$: C, 70.05; H, 11.76%.

Polymerization of 1. A solution of **1**(0.50 g, 3.3 mmol) in benzene(10 ml) was refluxed for 3 h in the presence of a small amount of H_2PtCl_6. The mixture was poured into methanol(250 ml). The polymer precipitated was collected, dried in a desiccator. Thus, **4** was obtained in 74%(0.37 g) yield. IR(KBr) 1640 cm^{-1}. NMR(δ) 0.5—0.7(m, 4, Si–CH_2), 0.97(d, 3, CH_3), 1.3—1.6(m, 4, Si–CH_2–C=), 1.6—1.8(m, 3, CH_3), 2.0—2.9(m, 1, CH), 5.5(m, 1, =CH).

Reaction of 1 with Dimethyl Acetylenedicarboxylate in the Presence of $PdCl_2(PPh_3)_2$. A solution of **1** (1.0 g, 6.6 mmol), $PdCl_2(PPh_3)_2$ (0.063 g, 0.065 mmol), and dimethyl acetylenedicarboxylate (1.0 g, 7.0 mmol) in benzene(16 ml) was refluxed for 2 h with stirring. Water was added to the reaction mixture. Usual workup of the organic layer gave **5** in 83%(1.6 g) yield. Bp 144—147 °C/3 Torr. n_D^{20} 1.5153. IR(neat) 1720, 1640, 1600 cm^{-1}. NMR(δ) 0.8—1.2(m, 2, Si–CH_2), 1.1(d, 3, CH_3), 1.25—1.6(m, 4, Si–CH_2–C=), 1.75 (m, 3, =C–CH_3), 1.9—2.2(m, 2, CH_2), 2.3—2.5(m, 1, CH), 3.62, 3.70(two singlets, 6, $COOCH_3$), 5.45(broad s, 1, =CH). Mass(*m/e*) 294(M^+), 279, 263, 262(base peak), 245, 228, 219, 218, 204, 190, 182, 162, 152, 126, 125, 57. Found: C, 61.06; H, 7.99%. Calcd for $C_{15}H_{22}O_4Si$: C, 61.20; H, 7.53%.

Reaction of 1 with the Simmons-Smith Reagent. Diiodomethane (4.0 g, 0.015 mol) was added slowly to the suspension of Zn–Ag couple(0.98 g, 0.015 mol) in dry ether (9 ml) at room temperature. The mixture was stirred for 1 h, and then **1**(1.0 g, 6.6 mmol) was added to the mixture. After the mixture was refluxed for 20 h with stirring, dil HCl was added to the mixture with cooling. Usual workup of the organic solution, gave **6** in 47%(0.52 g) yield. Bp 98—100 °C/20 Torr. IR(neat) 1130, 950 cm^{-1}. NMR(δ) −0.23(t, 1, C–H in cyclopropane ring), 0.2—0.45(m, 1, C–H in cyclopropane ring), 0.5—1.25(m, 8, Si–CH_2), 1.12 (d, 3, CH_3), 1.18(s, 3, CH_3), 1.2—1.4(m, 1, CH), 2.0—2.8 (m, 1, C–H in cyclobutane). Mass(*m/e*) 166(M^+), 138, 124, 109, 96(base peak), 83, 69, 55, 43. Found: C, 72.01; H, 10.80%. Calcd for $C_{10}H_{18}Si$: C, 72.21; H, 10.91%.

A Convenient Synthesis of 2-Deuterio-1,3-benzodithiolylium Salts. Useful Synthon for the Preparation of One-carbon Homologated 1-Deuterio Aldehydes

Juzo NAKAYAMA

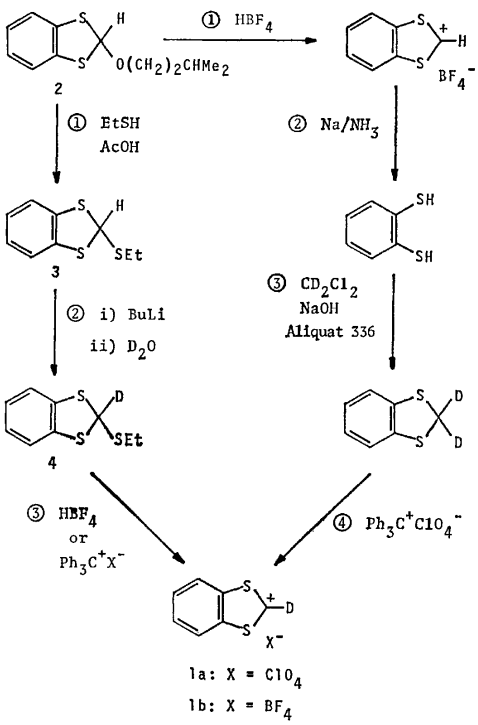
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338

(Received October 8, 1981)

Synopsis. 2-Deuterio-1,3-benzodithiolylium salt, a useful synthon for preparation of one-carbon homologated 1-deuterio aldehydes, can be prepared in excellent overall yield in three steps starting from easily accessible 2-isopentoxy-1,3-benzodithiole.

Very recently Degani *et al.*[1] have shown that 2-deuterio-1,3-benzodithiolylium perchlorate (**1a**) is a useful synthon for preparation of one-carbon homologated 1-deuterio aldehydes; it reacts with Grignard reagents yielding 2-alkyl- or 2-aryl-2-deuterio-1,3-benzodithioles, which in turn can be hydrolyzed to the corresponding 1-deuterio aldehydes. However, the reported method for the preparation of **1a** is not so favorable since it requires even four steps, though starting from easily accessible 2-isopentyloxy-1,3-benzodithiole (**2**),[2,3] and expensive CD_2Cl_2 (Scheme 1).

We wish to report a simple three-step synthesis of 2-deuterio-1,3-benzodithiolylium salts (**1**) from **2**. In the new method, 2-ethylthio-1,3-benzodithiole (**3**), readily obtainable from **2** and ethanethiol,[4] is deuterated[5] and the resulting 2-deuterio-2-ethylthio-1,3-benzodithiole (**4**) is converted to 2-deuterio-1,3-benzodithiolylium tetrafluoroborate (**1b**) by treatment with tetrafluoroboric acid in 79% overall yield.[6] The isotopic purity of **1b** is over 98%; the small loss of isotopic purity observed may result from a deuterium-hydrogen exchange reaction of the 1,3-benzodithiolylium ion.[7]



Scheme 1.

More isotopically pure **1** can be obtained by treatment of **4** with a trityl salt in aprotic medium, where no deuterium-hydrogen exchange reaction occurs. Thus treatment of **4** with trityl perchlorate in acetonitrile gives isotopically pure **1a** and ethyl trityl sulfide in excellent yield. In a similar way, isotopically pure **1b** can be prepared from **4** and trityl tetrafluoroborate in good yield.[8]

Accordingly, the procedure developed here, which requires neither the laborious ring-cleavage step on the dithiole skeleton (Birch reduction) nor any expensive reagents, is far more convenient than that reported by Degani *et al.*[1]

Experimental

Caution. 1,3-Benzodithiolylium perchlorate explodes violently at its melting point; see *Tetrahedron Lett.*, **22**, pp. i—ii, 1981. The fluoroborate salt is nonexplosive and chemically behaves similarly to the perchlorate salt, and therefore the use of **1b** instead of **1a** should highly be recommended.

2-Ethylthio-1,3-benzodithiole (3). A mixture of **2**[3] (24.0 g; 0.1 mol) and ethanethiol (25 ml; 0.34 mol) in acetic acid (300 ml) was allowed to stand at room temperature overnight and then diluted with ice–water (1000 ml). The resulting crystalline white solid was collected and washed with 40% aqueous methanol (150 ml). The material was thoroughly dried to give **3** of sufficient purity (20.6 g, 96%): mp 45—46 °C (lit,[4] mp 50—51 °C).

2-Deuterio-2-ethylthio-1,3-benzodithiole (4). To a stirred solution of **3** (20.5 g; 95 mmol) in dry tetrahydrofuran (420 ml) was added dropwise a 15% solution of butyllithium in hexane (90 ml; 120 mmol) at −73 °C under nitrogen. The mixture was stirred for 2 h and then 6 ml of deuterium oxide (E. Merck, D content>99.75%) dissolved in dry tetrahydrofuran (40 ml) was added at −73 °C. After being stirred for 1 h at −73 °C, the mixture was gradually warmed to room temperature and evaporated. The residue was partitioned between ether (300 ml) and water (200 ml). The ether layer was washed with water and dried. The ether was removed to leave 20.1 g (97%) of **4** which is sufficiently pure for the preparation of **1** and used without further purification (no absorption due to the proton at C-2 could be detected by ^{1}H NMR analysis).

2-Deuterio-1,3-benzodithiolylium Tetrafluoroborate (1b). To a stirred and ice-cooled solution of **4** (20.1 g; 93 mmol) in acetic anhydride (250 ml) was added dropwise 42% tetrafluoroboric acid (40 g; 0.19 mol) over a period of 0.6 h. After completion of the addition, ether (300 ml) was added to the mixture to precipitate the product completely. The precipitate was collected by filtration and washed with ether to give 19.0 g (85%) of **1b**, mp 148—149 °C [lit,[6] mp of the unlabeled compound, mp 150—150.5 °C (decomp)]: IR (KBr) 2300 and 2250 (C-D) and 1000—1100 cm^{-1} (BF_4^-); ^{1}H NMR (CF_3CO_2D) δ=8.0—8.4 and 8.6—9.0 (4H, AA'BB') (the content of the unlabeled compound was estimated to be less than 2% from the very weak

absorption due to the proton at C-2 of the unlabeled compound which appears at $\delta=11.53$).[9]

2-Deuterio-1,3-benzodithiolylium Salts (1) from 4 and Trityl Salts. **4** (2.15 g; 10 mmol) was added to a stirred suspension of trityl perchlorate (3.60 g; 10.5 mmol) in dry acetonitrile (20 ml) cooled at −10 °C. The mixture was gradually warmed to room temperature, stirred for 0.5 h, and diluted with dry ether (50 ml). The solid prepcipitate was collected and washed with ether to give 2.28 g (90%) of isotopically pure **1a** in white crystal, which will explode at 185 °C (lit,[1] explosion point 182 °C). From the filtrate, 2.80 g (92%) of ethyl trityl sulfide, mp 117—118 °C, was obtained.

A similar treatment of **4** (10 mmol) with trityl tetrafluoroborate (10.5 mmol) in acetonitrile gave **1b** in 80% yield.

The Stereoselective Diels-Alder Reaction of Bicyclo[3.2.0]nona-3,6-dien-2-one with Several Dienes

Hitoshi TAKESHITA,* Toshihide HATSUI, Isao SHIMOODA, and Hiroaki MAMETSUKA

Research Institute of Industrial Science, Kyushu University, Sakamoto, Kasuga, Fukuoka 816

(Received November 7, 1981)

Synopsis. The *endo-cis* adducts were selectively obtained by the Diels-Alder reaction of several dienes with bicyclo[3.2.2]nona-3,6-dien-2-one, prepared from tropone and ethylene. This selective formation from the bicyclic dienophile, the isolated C=C and ethano C–C bonds of which are situated in similar sterical environments within the molecule, was supported by an Extended Hückel calculation.

Recently, we have prepared a series of Diels-Alder adducts (**A**) of tropones with spiro[2.4]hepta-4,6-diene (**1**)[1] in connection with studying the cyclopropane effect on the singlet-oxygen oxidation of dispiro[cyclopropane-1,3′-tricyclo[5.2.1.0^{2,6}]deca-4′,8′-diene-10′,1″-cyclopropane],[2] a Diels-Alder dimer of **1**. During the studies, we have noticed the formation of 1:2 adducts (**B** and **C**), in which the geometry of the adducts was always *endo-cis* form with respects to the isolated double bond of the intermediate 1:1 adducts. Although Alder's classical rule for the stereochemistry of the adducts predicts the *endo-cis* adduct formation due to a maximal overlapping of the π-electron systems of the reacting molecules,[3] the previous discussions were restricted to the conjugated system, and only a few examples of stereoselective Diels-Alder addition controlled by an unconjugated π-electron system have been known.[4,5] It is known that the two π-electron systems of **A** show a transannular conjugation effect in the UV spectroscopy,[6] and this delocalization in the **A** may be reflected in the HOMO–LUMO interaction to favor the observed selective reaction. Thus, we thought it might be worthwhile to evaluate the role of this delocalized π-system in the selective 1:2 adduct formation on the sterically unhindered dienophile. With this in mind, we have made a study with bicyclo[3.2.2]nona-3,6-dien-2-one (**2**), the Diels-Alder adduct of tropone (**3**) with ethylene (**4**).[7] The isolated C=C and the ethano C–C of 2 are located in the same geometrical position with found to the α,β-unsaturated keto group of the reaction site.

When a mixture of **2** and **1** was heated in a sealed tube at 130 °C for 180 h, only one adduct (**5**) was obtained after the silica-gel chromatography of the reaction mixture. The NMR spectrum[8] of **5** clearly indicated the stereochemistry of the adduct, *endo-cis*, on the basis of the high-field shift for particular proton signals on the isolated double bond in an order of 1 ppm upon suffering a strong anisotropic effect of the other double bond. Similarly, the reaction of **2** with cyclopentadiene (**6**) also gave a sole 1:1 product (**7**), a colorless oil, which revealed an NMR spectrum very similar with that of **5**, suggesting the same stereochemistry. In this case, a small amount of 1:2 adduct (**8**) was obtained. In addition, cyclohexadiene (**9**) also gave a single product (**10**) by the reaction with **2**. The NMR features of **10** confirmed it to be an analogue of the other adducts in this series.

Parallel with the other experiments, we have carried out Extended Hückel MO calculations of the electronic structure of the ground-state geometry of **2**, which was figured out by inspecting the Dreiding Stereomodel; the stabilization energies of the HOMO level of **6**, as a representative diene, and the LUMO level of **2** for both *cis-cisoid* and *cis-transoid* geometries were calculated by the method of Herndon and Hall,[9] but the figures, $\Delta E_{cis}=7.7$ kJ/mol, and $\Delta E_{trans}=4.6$ kJ/mol, are too small for any definite conclusion to be drawn therefrom. The index for each carbon was also small, as is depicted in Fig. 1, but the signs are in accord with the adducts actually isolated.

As a whole, the Diels-Alder reaction of **2** with dienes proceeded with complete stereospecificity, and there is no isomer in any detectable quantity. It is clear now that the norbornene-type C=C of **2**, which prohibits,

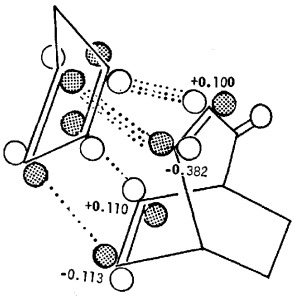

Fig. 1.

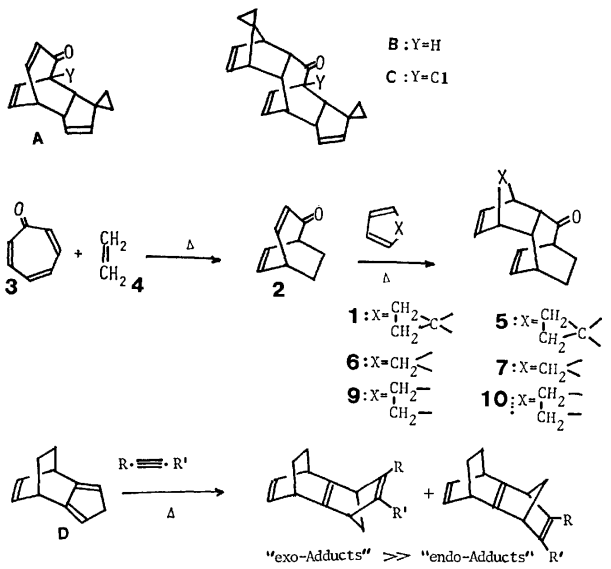

Scheme 1.

on structural grounds, full overlapping with the approaching diene, has determined the course of the product formation. On the contrary, a recent paper of Paquette *et al.*[4] described a somewhat inferior stereoselective adduct formation between a diene (**D**), with structural properties similar to those of **2**, and several acetylenic dienophiles. This seems to be attributable to the difference in the geometry of one component of the addends; linear acetylenic dienophiles can hardly interact with the isolated C=C of **D**.

Experimental

*Diels-Alder Reaction of **3** with **4**.* *Preparation of **2**:*[7] A toluene solution (100 cm³) of **3** (3 g) was placed in an autoclave, gaseous ethylene was introduced under *ca.* 30 atm, and the mixture was heated for 1.5 h at 225 °C. Then, the mixture was worked up in an ordinary manner. The product, purified on a silica-gel column, was **2** (2.93 g, 77%), which showed NMR spectral data identical with those previously reported.

*Diels-Alder Reaction of **2** with **1**.* A mixture of benzene (1 cm³), **2** (150 mg), **1** (1 cm³), and hydroquinone (20 mg) was heated in a sealed tube for 180 h at 130 °C. The mixture was then purified on a silica-gel column with hexane–ethyl acetate (9:1) to give a colorless oil, **5** (45 mg, 58%) [Found: *m/e*, 226.1354 (M^+). Calcd for $C_{16}H_{18}O$: 226.1358. δ: 0.15—0.60 (4H, m), 1.35—2.75 (8H, m), 3.13 (2H, m), 5.32 (1H, t, J=8 Hz), 5.88 (1H, dd, J=6, 3 Hz), 6.09 (1H, dd, J=6, 3 Hz), and 6.12 (1H, t, J=8 Hz). $\nu_{C=O}$: 1685 cm^{-1}], together with the recovered **2** (102 mg, 68%).

*Addition Reaction of **2** with **6**.* A mixture of benzene (1 cm³), **2** (150 mg), **6** (1 cm³), and hydroquinone (50 mg) was heated similarly in a sealed tube at 180 °C for 20 h. The mixture was then purified on a silica-gel column and then further by high pressure liquid chromatography to give **7** (31 mg, 20%) as colorless needles (mp 64—66 °C) [Found: *m/e*, 200.1210 (M^+). Calcd for $C_{14}H_{16}O$: 200.1201. δ: 1.20 (1H, dm, J=9 Hz), 1.34 (1H, dm, J=9 Hz), 1.4—2.0 (4H, m), 2.45 (1H, dt, J=9.5, 3 Hz), 2.57 (1H, m), 2.72 (1H, m), 3.01 (1H, dd, J=9.5, 4 Hz), 3.11 (1H, ddm, J=7.5, 4 Hz), 3.33 (1H, m), 5.31 (1H, ddm, J=8.5, 7.5 Hz), 5.85 (1H, dd, J=6, 3 Hz), 5.95 (1H, dd, J=6, 3 Hz), and 6.08 (1H, ddm, J=8.5, 8 Hz). $\nu_{C=O}$: 1690 cm^{-1}], recovered **2** (46 mg, 31%), and a colorless oil (**8**) [Found: *m/e*, 266.1680 (M^+). Calcd for $C_{19}H_{22}O$: 266.1671. $\nu_{C=O}$: 1685 cm^{-1}], 29 mg (16%).

*Addition Reaction of **2** with **9**.* A mixture of benzene (2 cm³), **2** (550 mg), **9** (2.2 g), and hydroquinone (5 mg) was heated in a sealed tube at 150 °C for 86 h. The mixture was then chromatographed on a silica-gel column with hexane–ethyl acetate (9:1) to give **10** (295 mg, 86%), colorless needles (mp 111—112 °C from benzene) [Found: C, 83.20; H, 8.62%. Calcd for $C_{15}H_{18}O$: C, 83.12; H, 8.97%. δ: 1.1—2.0 (8H, m), 2.24 (1H, dd, J=9.5, 3 Hz), 2.2—2.5 (2H, m), 2.79 (1H, dd, J=9.5, 3 Hz), 3.0—3.3 (2H, m), 5.49 (1H, ddd, J=8, 6, 1.5 Hz), 6.15 (1H, m), and 6.20 (1H, t, J=8 Hz). $\nu_{C=O}$: 1670 cm^{-1}].

The Condensation of Isatin with *o*-Phenylenediamine

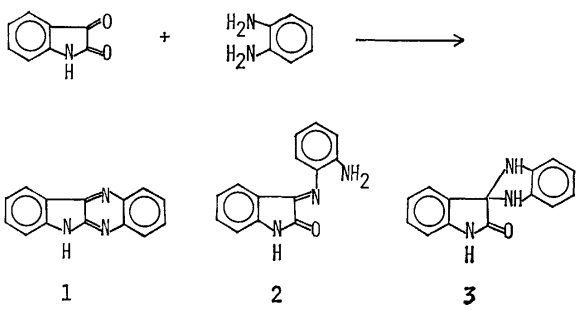
Kazuma NIUME,* Shigeru KUROSAWA, Fujio TODA,
Masaki HASEGAWA, and Yoshio IWAKURA†
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 11, 1981)

Synopsis. The condensation of isatin with *o*-phenylenediamine has been studied in various kinds of solvents. The reaction gave pure indolo[2,3-*b*]quinoxaline (**1**) in acidic solvents, while it gave a mixture containing at least two out three compounds, **1**, an anil and a spiro compound, in neutral or basic organic solvents. The anil and spiro compounds were converted to **1** in the presence of acid or by heating them above their melting points. The mechanism of the formation of these compounds and the conversion could be explained by the presence of the intermediate of the adduct formed between the amino groups of *o*-phenylenediamine and the β-carbonyl of isatin.

o-Phenylenediamine reacts with both carbonyl groups of isatin to form indolo[2,3-*b*]quinoxaline (**1**) in acetic acid.[1,2] It has been reported that spiro compounds were obtained by the reaction of a variety of isatin with aromatic *o*-diamines.[3,4] However, the formation of an anil compound has not been reported. In the present study, it was found that reaction of isatin with *o*-phenylenediamine gave **1**, anil **2**, and spiro **3** compounds, depending upon the reaction conditions. The present paper is also concerned with the conversion of the anil and spiro compounds to **1**.

Results and Discussion

o-Phenylenediamine was allowed to react with isatin in various kinds of solvents (Scheme 1).



Scheme 1.

When the reaction was carried out in acidic solvents, **1** was obtained exclusively. When polar amide solvents, such as *N*,*N*-dimethylacetamide (DMA) and *N*-methyl-2-pyrrolidone (NMP), were used, the spiro compound (**3**) was obtained in a high yield. The anil compound (**2**) was prepared at a low reaction temperature. The reaction conditions and the yields of the products are summarized in Table 1.

The IR spectra of **3** show characteristic absorptions around 1710 cm^{-1}, they are in good agreement with those observed in the similar spiro compounds prepared by Popp.[3] The carbonyl absorption of **2** was found at 1670 cm^{-1}. Figure 1 shows the infrared spectra of these compounds.

Table 1. The reaction of isatin with *o*-phenylenediamine

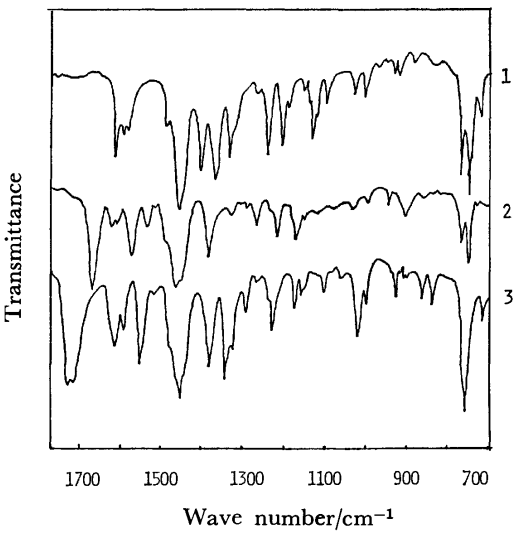

Fig. 1. Infrared spectra of **1**, **2**, and **3**.

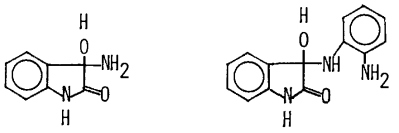
As may be seen in Table 1, the reaction gave a mixture containing at least two products out of **1**, **2**, and **3** in neutral or basic organic solvents, while that gave **1** exclusively in acidic solvents. It is well known that ammonia reacts with the β-carbonyl of isatin at a low temperature to give the adduct **4**.[5] The analogous intermediate, **5**, would offer a reasonable explanation of the formation of **1**, **2**, and **3** in the organic solvents. The initial reaction of the amino group with the α-carbonyl of the intermediate, **5**, followed by the removal of two molecules of water would give **1**. The

† Present address: Department of Inductrial Chemistry, Faculty of Engineering, Seikei University, Kichijyoji-kita, Musashino Tokyo 180.



4 5

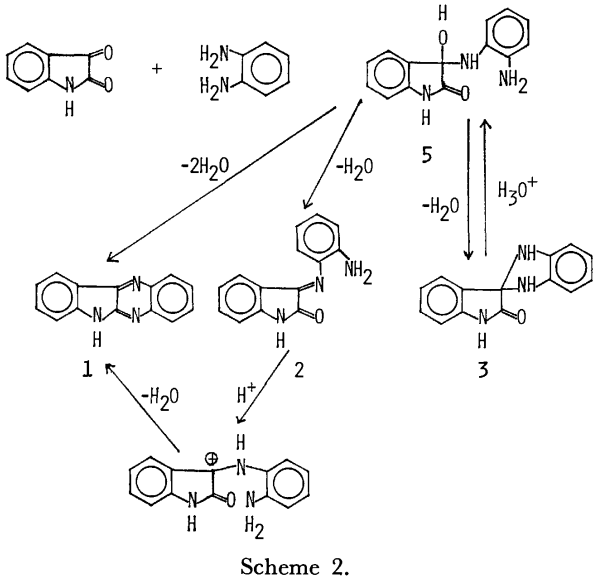
removal of one molecule of water from **5** appears to give **2**. The nucleophilic attack of the amino group on the β-carbon would lead to the formation of **3**.

Under acidic conditions, the reaction gave **1** exclusively, as has been mentioned previously, and **2** was easily converted to **1** by heating it in acetic acid, acetic anhydride, and polyphosphoric acid (PPA). The facile conversion in the presence of acid is accounted for by the *syn-anti* isomerism of the Schiff base. Apparently, **2** takes the *anti* form preferably, but it would be required to isomerize to the *syn* form, which provides the geometry necessary for the cyclodehydration. Under acidic conditions, the C–N double bond is protonated and the *anti-syn* interconversion is facilitated *via* the conjugated acid of the Schiff base.

In contrast to **2**, **3** was recovered unchanged after heating in acetic anhydride, formic acid, and PPA. However, it was easily converted to **1** by heating it in dilute hydrochloric acid. These results show that the conversion of **3** to **1** also proceeded *via* the intermediate, **5**, which was formed by the hydrolysis of the midazoline ring.

The formation of **1**, **2**, and **3**, and the rearrangements are summarized in Scheme 2.

It was also found out that **2** and **3** were rearranged into **1** by heating. The conversion of **2** proceeded very



Scheme 2.

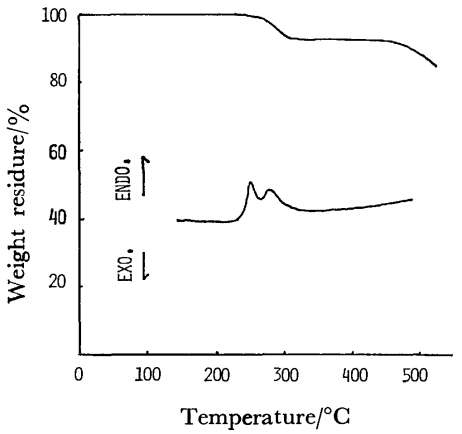


Fig. 2. TG-DSC for the conversion of **2** under nitrogen.

rapidly above its melting point. Figure 2 shows the TG-DSC curves for **2**. The conversion of **3** is a dehydration reaction involving the C–N bond cleavage, and the reaction proceeds slowly upon heating at a higher temperature than 280 °C.

Experimental

3-(o-Aminophenylimino)indolin-2-one (2). A 1.47 g (0.01 mol) of isatin and 1.08 g (0.01 mole) of *o*-phenylenediamine were dissolved in 70 ml of benzene. The solution was refluxed for 7 h and then allowed to stand at room temperature overnight to give orange needles, which were subsequently collected by filtration and washed with water. The spectrum of the crude product indicated the presence of small quantity of **1**. Recrystallization from methanol gave 1.85 g (78%) of **2** as orange needles; mp 249.5—250 °C. Found: C, 70.15; H, 4.87; N, 17.61%. Calcd for $C_{14}H_{11}N_{13}$-O: C, 70.87; H, 4.67; N, 17.71%.

1,3-Dihydrospiro[benzimidazole-2(3H),3'-indolin]-2'-one (3). A solution of a 1.47 g (0.01 mol) of isatin and 1.08 g (0.01 mol) of *o*-phenylenediamine in 40 ml of NMP was heated at 200 °C for 5 h. After cooling, the solution was poured into 500 ml of water to give a yellow precipitate, which was collected by filtration, washed with water, and dried. The IR spectrum of the crude product indicated the presence of a trace of **1**. Recrystallization from methanol gave 2.3 g (96%) of **3** as yellow crystals; mp 285—287 °C. Found: C, 70.87; H, 4.71; N, 17.62%. Calcd for $C_{14}H_{11}$-N_3O: C, 70.87; H, 4.67; N, 17.71%.

Synthesis of a 6-Methylpyridoxine Hydrochloride Derivative as an Electrophilic Precursor for Pyridoxal-like Functionalization

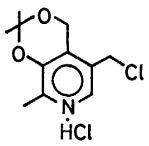
Masaaki IWATA* and Hiroyoshi KUZUHARA

The Institute of Physical and Chemical Research, Wako, Saitama 351

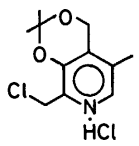
(Received November 11, 1981)

Synopsis. Through a key step of regioselective rearrangement of 5′-*O*-acetyl-3,4′-*O*-isopropylidene-6-methylpyridoxine 1-oxide, stable 5′-deoxy-2′,5′-dichloro-3,4′-*O*-isopropylidene-6-methylpyridoxine hydrochloride, which is expected to be a strong electrophile in an HCl free form, was synthesized from DL-alanine in good yield.

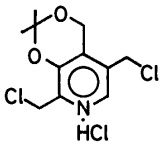
In relation to our systematic studies on the utilization of 2′- and/or 5′-chloropyridoxine derivatives as the electrophilic precursors for pyridoxal-like functionalization, the synthesis and electrophilic reactivity to thiols and sulfonamides have been successfully exemplified in the cases of 5′-deoxy-5′-chloro-3,4′-*O*-isopropylidenepyridoxine hydrochloride (**1**),[1] 5′-deoxy-2′-chloro-3,4′-*O*-isopropylidenepyridoxine hydrochloride (**2**),[1] and 5′-deoxy-2′,5′-dichloro-3,4′-*O*-isopropylidenepyridoxine hydrochloride (**3**).[2] Here we describe a synthetic method of 5′-deoxy-2′,5′-dichloro-3,4′-*O*-isopropylidene-6-methylpyridoxine hydrochloride (**4**) as an alternative precursor, required for completion of our present project. This method was characterized by novel regioselective isopropylidenation of **5** and regioselective rearrangement of an intermediate *N*-oxide (**8**).



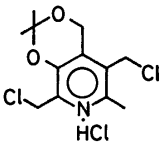
1



2

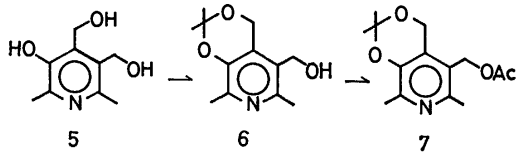


3

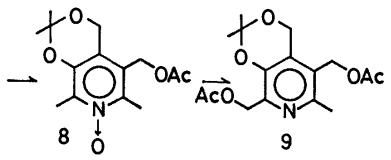


4

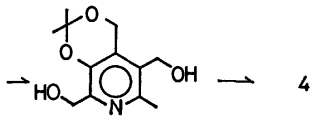
Synthesis began with 6-methylpyridoxine (**5**), which was prepared in good yield by the method previously reported.[3] Treatment of **5** with acetone saturated with hydrogen chloride gave 3,4′-*O*-isopropylidene-6-methylpyridoxine hydrochloride regioselectively, which was neutralized to yield the corresponding HCl free form (**6**). The usual acetylation of **6** with acetic anhydride and pyridine afforded 5′-*O*-acetyl-3,4′-*O*-isopropylidene-6-methylpyridoxine (**7**), which was, then,



5 6 7



8 9



10 4

oxidized with *m*-chloroperbenzoic acid to give 5′-*O*-acetyl-3,4′-*O*-isopropylidene-6-methylpyridoxine 1-oxide (**8**). Rearrangement of **8** with acetic anhydride in chloroform regioselectively gave 2′-acetoxy-5′-*O*-acetyl-3,4′-*O*-isopropylidene-6-methylpyridoxine (**9**). Compound **9** was successfully deacetylated by treatment with sodium methoxide in methanol followed by neutralization with solid carbon dioxide and extraction with ethyl acetate to afford 2′-hydroxy-3,4′-*O*-isopropylidene-6-methylpyridoxine (**10**). This was successfully chlorinated with thionyl chloride in benzene to yield **4**.

The regioselectivity in isopropylidenation of **5** is due probably to the concentration of hydrogen chloride as was established in the previous report.[4] As reported by Traynelis and Pacini[5a] and others,[5b,c] the rearrangement of pyridine 1-oxide with acetic anhydride occurs intramolecularly through a rate-controlling conversion of 1-acetoxy-2-methylpyridinium ion to an anhydrobase by proton abstraction. Therefore, facility of proton release from either methyl group at C_2 or C_6 in **8** determines the product. Since C_6-methyl protons always appear at lower field in ^{1}H NMR spectra (Table 1) than C_2-methyl protons and are interacting with a neighboring acetyl carbonyl group at C_5, release of a proton from C_6-methyl group seems less favorable than that from a C_2-methyl group.

TABLE 1. ^{1}H NMR SPECTRAL DATA OF 6-METHYLPYRIDOXINE DERIVATIVES
(δ ppm, IN $CDCl_3$ AT AMBIENT TEMPERATURE)

Compound	$C(CH_3)_2$	$-COCH_3$	C_2-CH_3	C_6-CH_3	$5'CH_2-O$	$4'CH_2-O$	$2'CH_2-O$

9	1.54	a)	—	2.55	5.01	4.95	5.18
10	1.53	—	—	2.55	4.63	4.99	4.63

a) $5'C-O-COCH_3$ at 2.07 and $2'C-O-COCH_3$ at 2.12 ppm.

Utilization of **4** as a precursor for an electrophilic construction unit will be reported elsewhere.

Experimental

The ^{1}H NMR spectra were recorded on a Japan Electron Optics Laboratory JEOL FX-400 apparatus with TMS as the internal standard in chloroform-*d* and the chemical shift was represented by δ. IR spectra were recorded on a Shimadzu IR-27 instrument. Merck silica gel 60 (Art. 7734, 0.063—0.20 mm) was used for the column chromatography and Wakogel B-5 FM (Wako Pure Chem. Co., Ltd.) for the thin layer chromatography (TLC), in which product spots were visualized in an iodine-vapor bath. The mp are uncorrected, measured in a bilayered cover glass (18 m/m) with micro melting point apparatus (Yanagimoto Seisakusho, serial No. 2647). Solvent system:benzene:ethyl acetate, 3:2 v/v (solvent A) and 9:1 v/v (solvent B). 6-Methylpyridoxine (**5**) was prepared by the method described in Ref. 3, in good yield from DL-alanine and dimethyl maleate.

Preparation of 3,4'-O-Isopropylidene-6-methylpyridoxine (6). A suspended mixture of 10.34 g of **5** in 200 ml of dry acetone was saturated with hydrogen chloride while being stirred and cooled in an ice-bath. Then, the flask was allowed to stand in a refrigerator overnight. After 500 ml of diethyl ether was mixed and stirred into the flask, the resulting colorless precipitate (hydrochloride) was collected by filtration. The hydrochloride of **6** dissolved in a minimum amount of water was neutralized by portional addition of sodium hydrogencarbonate saturated in water followed by extraction with chloroform to give 10 g of **6** as a colorless liquid, which spontaneously crystalized; mp 141.5—143 °C. Found: C, 64.09; H, 7.63; N, 5.93%. Calcd for $C_{12}H_{17}O_3N$: C, 64.55; H, 7.68; N, 6.27%. ^{1}H NMR data are listed in Table 1. IR (KBr disk) ν 3180, 3000, 2940, 1601, 1440, 1386, 1375, 1280, 1245, 1200, 1146, 1104, 1069, 1040, 1024, 996, 983, 875, 867, 795, 703, 676, 564, 530, and 497 cm^{-1} as characteristic bands.

Preparation of 5'-O-Acetyl-3,4'-O-isopropylidene-6-methylpyridoxine (7). To a solution of 3.077 g of **6** in 15 ml of pyridine, 15 ml of acetic anhydride was added all at once while being stirred. After subsequent stirring at the ambient temperature for 1 h, the mixture was poured into water (*ca.* 200 ml) and, then, extracted with chloroform, which was dried over $MgSO_4$ and filtered through Celite (No. 545). The solvent was removed under reduced pressure and the residue was chromatographed on a silica gel (200 g) column, eluted with solvent A, to give 3.29 g of **7** (90% yield); colorless liquid, R_f 0.7 (solvent A). Found: C, 63.61; H, 7.10; N, 5.18%. Calcd for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%. ^{1}H NMR data are listed in Table 1. IR (KRS neat) $\nu_{C=O}$ 1738 cm^{-1}.

Preparation of 5'-O-Acetyl-3,4'-O-isopropylidene-6-methylpyridoxine 1-Oxide (8). To 0.37 g of **7** in 10 ml of chloroform, 0.283 g of 85% pure *m*-chloroperbenzoic acid was added portion by portion at the ambient temperature. The reaction was monitored by TLC until **7** disappeared. The reaction mixture was neutralized by addition of sodium acetate after addition of 10 ml of water. After the usual work-up, 0.34 g (87% yield) of **8** was obtained by chromatography (solvent A) as a colorless liquid; R_f 0.2 (solvent A). ^{1}H NMR data are listed in Table 1. IR (KRS neat) $\nu_{C=O}$ 1740; ν 1560, 1490, 1375, 1300, 1220, 1130, 1070, 1025, 878, 828, and 581 cm^{-1} as characteristic bands. Found: C, 59.24; H, 6.64; N, 4.64%. Calcd for $C_{14}H_{19}O_5N$: C, 59.77; H, 6.81; N, 4.98%.

Preparation of 2'-Acetoxy-5'-O-acetyl-3,4'-O-isopropylidene-6-methylpyridoxine (9). A solution of 0.3 g of **8** in 2 ml of acetic anhydride and 5 ml of chloroform was heated at 50 °C for 20 min. After removal of solvents under reduced pressure, the residue was chromatographed on a silica gel (20 g) column, eluted with solvent A, to afford 0.304 g (88% yield) of **9** as colorless liquid; R_f 0.7 (solvent A). Found: C, 59.43; H, 6.48; N, 4.14%. Calcd for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55; N, 4.33%. ^{1}H NMR data are summarized in Table 1. IR (KRS neat) ν 1740, 1440, 1378, 1282, 1220, 1145, 1112, 1025, 965, 870, 792, and 605 cm^{-1} as characteristic bands.

Preparation of 2'-Hydroxy-3,4'-O-isopropylidene-6-methylpyridoxine (10). To a sodium methoxide solution, which was prepared by addition of 0.05 g of metal sodium to 10 ml of methanol, 0.266 g of **9** in 5 ml of methanol was added dropwise. The reaction was completed immediately. The mixture was neutralized by portional addition of pieces of solid carbon dioxide. After removal of the solvent, the residue was triturated with ethyl acetate followed by filtration through Celite (No. 545). The filtrate was evaporated under reduced pressure followed by recrystallization from ethanol to give 0.15 g (76% yield) of **10**; colorless plates, mp 168.5—170 °C. Found: C, 60.30; H, 7.25; N, 5.76%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.85%. ^{1}H NMR data are listed in Table 1. IR (KBr disk) ν 3320, 3050, 2990, 2940, 2880, 2760, 1595, 1570, 1430, 1382, 1370, 1280, 1265, 1202, 1140, 1105, 1040, 1015, 1002, 990, 958, 940, 872, 800, 743, 676, 655, 635, 597, 535, and 490 cm^{-1} as characteristic bands. R_f 0.5 ($CHCl_3$: methanol 9:1 v/v).

Preparation of 5'-Deoxy-2',5'-dichloro-3,4'-O-isopropylidene-6-methylpyridoxine Hydrochloride (4). To a suspended mixture of 2.33 g of **10** in 40 ml of benzene, 1.41 ml of thionyl chloride in 10 ml of benzene was added dropwise, resulting in coagulation and, then, a transparent solution without color change. After stirred for 30 min at ambient temperature, 50 ml of diethyl ether was added for precipitation. The precipitate was collected by filtration and washed several times with diethyl ether to give 2.643 g (87% yield) of **4.** A part of the product was recrystallized from acetone for analytical use; colorless crystals, mp 143 °C (browning with melt) —150 °C (decomposed with evolving gas) and —162 °C (complete melt and decomposition with browning and resulting in viscous liquid). Found: C, 46.29; H, 5.22; N, 4.48; Cl, 34.02%. Calcd for $C_{12}H_{16}O_2NCl_3$: C, 46.10; H, 5.16; N, 4.48; Cl, 34.02%. IR (KBr disk) ν 3020, 2960, 2350, 1960, 1632, 1540, 1470, 1430, 1417, 1377, 1365, 1312, 1285, 1253, 1204, 1135, 1110, 1075, 1050, 1010, 990, 980, 967, 943, 925, 912, 850, 838, 736, 721, 649, 618, 552, 492, and 425 cm^{-1} as characteristic bands.

The authors are grateful to Dr. Haruo Homma and his staff in this Institute for elemental analyses.

The Disproportionation of *cis*-Bicyclo[4.3.0]nona-3,7-diene Catalyzed by $Fe(CO)_5$ and $Cp_2Fe_2(CO)_4$

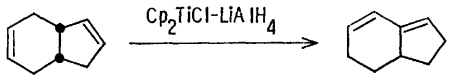
(Received November 12, 1981)

Synopsis. *cis*-Bicyclo[4.3.0]nona-3,7-diene (**1**) was catalytically disproportionated by the use of $Fe(CO)_5$ and $Cp_2Fe_2(CO)_4$ to bicyclo[4.3.0]non-1(6)-ene (**3**) and indan (**4**). However, the same reaction catalyzed by the use of other metal carbonyls gave merely small amounts of **3** and **4**, while those using Pd– and Rh–carbons yielded only **4** and the starting material, **1**, respectively.

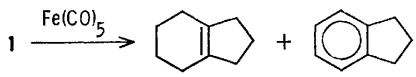
A variety of double-bond migration reactions of olefins and dienes catalyzed by transition-metal complexes are well known.[1] Nonconjugated dienes are usually converted into conjugated dienes with $Fe(CO)_5$, and the resulting 1,3-dienes form metal carbonyl complexes.[2] Recently, Tureček has reported a titanocene-catalyzed isomerization of *cis*-bicyclo[4.3.0]nona-3,7-diene (**1**) to bicyclo[4.3.0]nona-2,9-diene (**2**) (Eq. 1).[3]



(1)

1 **2**

However, the reaction of **1** catalyzed by $Fe(CO)_5$ gave bicyclo[4.3.0]non-1(6)-ene (**3**) and indan (**4**) (Eq. 2). In this communication, we wish to report the disproportionation reaction of **1** catalyzed by several iron complexes.



(2)

3 **4**

The reaction of **1** with a catalytic amount of $Fe(CO)_5$ at 230 °C for 4 h gave approximately equal amounts of **3** (40%) and **4** (39%), as well as, an oligomer (7%) containing a small amount of tetracarbonylbis(η^5-4,5,6,7-tetrahydroindenyl)diiron (**5**) (3%).[4]

Figure 1 shows some typical plots of the time conversion curves of **1**, **3**, and **4**. Since about the same amounts of **3** and **4** were obtained in all stages of the reaction, **1** should be disproportionally converted to **3** and **4**. The complex **5** was formed in much larger quantities in the early stage of the reactions. The stoichiometric reaction of **1** and $Fe(CO)_5$ gave **5**, in a yield of 35—40%, in addition to **3** and **4**.[5]

It is interesting to clarify whether the **5** complex is one of the products or a precursor of the disproportionation products. Thus, the reaction of **1** with **5** or tetracarbonylbis(η^5-cyclopentadienyl)diiron (**6**), which is structurally analogous to **5**, as a catalyst, was studied under similar conditions. The results are summarized in Table 1.

The reaction catalyzed by **5** gave **3** and **4** in a fashion similar to that found in the case of $Fe(CO)_5$, although the reaction rate was only about half as great. However, **5** was not recovered after the reaction because of the decomposition. Similarly, the **6** complex also promoted the disproportionation of **1** to give **3** and **4**. The reaction rate was slightly faster than that by $Fe(CO)_5$, and almost all of the **6** was recovered unchanged. Thus, **6** was found to be an excellent catalyst for the disproportionation of **1**.

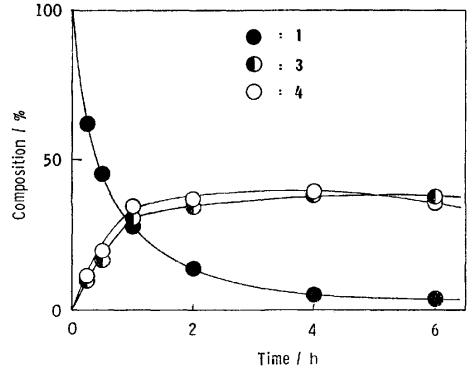


Fig. 1. Disproportionation of 1 catalyzed by $Fe(CO)_5$. **1**/$Fe(CO)_5$=10/1 (molar ratio), 230 °C

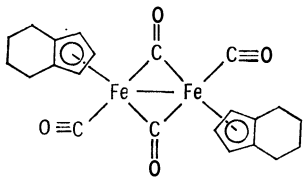
TABLE 1. DISPROPORTIONATION OF **1** BY VARIOUS IRON COMPLEXES[a]

Catalyst	Composition/%[b]			
	1	**3**	**4**	Oligomers
$Fe(CO)_5$	11.2	39.8	38.5	10.5[c]
5	44.5	23.6	22.8	9.1
6	6.2	44.2	42.8	6.8

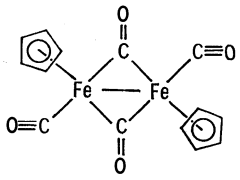
a) The reactions were carried out on 100-mmol scale with **1**/catalyst (molar ratio **1**/$Fe(CO)_5$=10/1, **1**/**5**=20/1, **1**/**6**=20/1) at 230 °C for 4 h in an autoclave. b) Estimated on the basis of the **1** used. c) A small amount of **5** was present.

Sufficient evidence has not been provided to establish a detailed reaction pathway for the disproportionation of **1**. However, it may be noted that the first step in the disproportionation is the hydrogen-migration reaction of **1** to a conjugated diene, followed by a reaction with $Fe(CO)_5$ to give diene iron tricarbonyl complexes, such as **7**, **8**, or **9**, which are not isolated. Then, the iron atom abstracts an allylic hydrogen, yielding a π-allyl-hydro-iron complex (**10**),[6] which seems to be an essential intermediate for the disproportionation of **1**, followed by intra- or intermolecular hydrogen transfer with other organic or iron species to produce **3** and **4**.

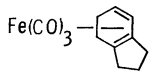
The disproportionation of **1** catalyzed by **5** and **6** is probably initiated by the homolytic cleavage of **5**



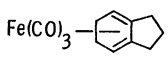
5



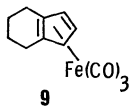
6



7



8

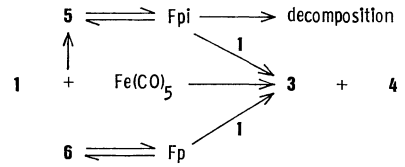


9

π-C_9H_{11}-$FeH(CO)_3$

10

and **6** to dicarbonyl(η^5-3,4,5,6-tetrahydroindenyl)iron (Fpi), and dicarbonyl(η^5-cyclopentadienyl)iron (Fp) fragments,[7] which then react with **1** to yield a diene iron complex. Subsequently, the reaction proceeds through a path analogous to that followed by $Fe(CO)_5$ to produce **3** and **4**. The outline of the disproportionation catalyzed by iron complexes is presented in Scheme 1.



Scheme 1. Outline of Disproportionation of **1** Catalyzed by **5** and **6**.

The difference in catalytic activity between **5** and **6** may be due to the ease of their homolytic cleavage and the stability of the resulting Fpi and Fp moieties in the course of the reaction.

The same reaction catalyzed by several metal carbonyls, such as Cr, Mn, Mo, and $Cp_2Mo_2(CO)_6$, gave only small amounts of **3** and **4**. No disproportionation product was obtained by the reaction of **1** catalyzed by Pd- and Rh-carbons, which are typical hydrogenation catalysts; *i.e.*, the dehydrogenated product, **4**, was exclusively produced by Pd, and the starting material, **1**, was recovered only by the use of Rh-carbon.

Experimental

The melting points are uncorrected. The IR spectra were taken with a JASCO-A202 spectrometer. The ^{1}H-NMR and ^{13}C-NMR spectra were recorded with a JEOL PMX-60 and a JNM-PS-100 FT-NMR spectrometer respectively. The mass spectra were measured with a JEOL-01SG apparatus. The GLC analyses were carried out on a Yanagimoto G1800 apparatus.

Materials. *cis*-Bicyclo[4.3.0]nona-3,7-diene (**1**) was prepared by a procedure reported previously.[8]

Tetracarbonylbis(η^5-cyclopentadienyl)diiron (**6**) was prepared accordingly to the King method.[9]

Tetracarbonylbis(η^5-4,5,6,7-tetrahydroindenyl)diiron (**5**) was prepared as follows: *cis*-Bicyclo[4.3.0]nona-3,7-diene **1** (12.0 g, 100 mmol) was allowed to react with $Fe(CO)_5$ (19.6 g, 100 mmol) in an autoclave at 230 °C for 4 h. After the filtration of the reaction mixture, the filtrate was dissolved in dichloromethane (200 dm^3). The crystals which separated out were collected and recrystallized from a solution of dichloromethane and hexane (1:9); ^{13}C-NMR ($CDCl_3$) δ 22.1(t), 22.6(t), 83.4(d), 89.2(d), 104.1(s), 214.0(s), 217.2(s); IR (KBr) 634, 831, 1432, 1754, 1951, 2920 cm^{-1}; MS *m/e* 462 (M^+), 175, 171 (base peak), 115, 91; Found: C, 57.11; H, 4.79%. Calcd for $C_{22}H_{22}O_4Fe_2$: C, 57.18; H, 4.80%.

Disproportionation Catalyzed by $Fe(CO)_5$. A mixture of **1** (12.0 g, 100 mmol) and a catalytic amount of $Fe(CO)_5$ (1.96 g, 10 mmol) was heated in an autoclave under a nitrogen atmosphere at 230 °C for 1—6 h. The reaction mixture was then poured into hexane to separate the **5**. After the removal of **5** and the solvent, bicyclo[4.3.0]non-1(6)-ene, **3** and **4**, were isolated; **3**, ^{1}H-NMR (CCl_4) δ 1.66 (m, 4H), 1.76 (m, 2H), 1.92 (m, 4H), 2.13—2.16 (m, 4H); ^{13}C-NMR ($CDCl_3$) δ 21.9(t), 23.4(t), 26.6(t), 36.3(t), 134.1(s); **4**, ^{1}H-NMR (CCl_4) δ 1.82 (q, 2H), 2.54 (t, 4H), 6.34 (s, 4H); ^{13}C-NMR ($CDCl_3$) δ 25.3(t), 32.8(t), 124.2(d), 125.9-(d), 143.9(s).

Compound **3** was hydrogenated on Pd-carbon to *cis*-perhydroindene, which was also formed by the hydrogenation of **1**.

*Disproportionation Catalyzed by **5** and **6**.* The reaction was performed by the above procedure.

Optical Resolution of 2-(Anilinomethyl)pyrrolidine

Kazuhiko SAIGO,*,† Jun TANAKA, and Hiroyuki NOHIRA
Department of Applied Chemistry, Faculty of Engineering Saitama University, 255 Shimo-ohkubo, Urawa 338
(Received February 3, 1982)

Synopsis. (±)-2-(Anilinomethyl)pyrrolidine, prepared from (±)-5-oxopyrrolidine-2-carboxylic acid, was effectively resolved into a pair of the enantiomers by fractional crystallization of its mandelic acid salt. Moreover, the preferential crystallization of its *p*-hydroxybenzoic acid salt was found to give both enantiomers in high optical purities by alternate seeding.

Optically active 2-(anilinomethyl)pyrrolidine is widely used as an effective chiral source for asymmetric inductions.[1] The diamine has been prepared from optically active proline[1a] or glutamic acid[2] maintaining the asymmetric center. The methods have a problem in total yield, chemical purity and/or optical purity, especially in the case of the preparation in a large scale, since they involve multiple reaction steps or drastic reaction conditions. In this paper, we wish to report a convenient and practical method for the preparation of a pair of the enantiomers of 2-(anilinomethyl)pyrrolidine.

(±)-(Anilinomethyl)pyrrolidine ((±)-**1**) was easily prepared by the reaction of commercially available (±)-5-oxopyrrolidine-2-carboxylic acid and aniline according to the procedure in the literature, followed by the reduction with $LiAlH_4$. After several examinations of a suitable resolving agent for the resolution of (±)-**1**, it was found that the effective fractional crystallization was achieved by utilizing optically active mandelic acid (**2**) to give almost optically pure (+)- and (−)-**1** over 65% yields without recrystallization. Moreover, the efficiency of the resolution was found to unchange by reducing the amount of **2** to 0.8 equimolar amount because there is great difference in the solubilities of the diastereomeric pair and **1** is very soluble in the solvent used.

Next, to find out the derivative of **1** resolvable by preferential crystallization which gives more conveniently both enantiomers, salts of **1** with achiral carboxylic acids such as acetic, cinnamic, phthalic, *cis*-cyclohexanedicarboxylic, benzoic, *p*-nitrobenzoic, *p*-chlorobenzoic, and *p*-hydroxybenzoic acids were prepared. Among these salts, *p*-hydroxybenzoic acid salt (**3**) was found to be deposited as conglomerate, which can be resolved by preferential crystallization.

Actually, 1.73 g of (+)-**3** was obtained in 94% optical purity by seeding of optically pure (+)-**3** to the supersaturated solution of (±)-**3** and (±)-**1**·(±)-lactic acid salt, which is readily soluble in the solvent employed and plays as a kind of buffer to decrease the concentration change of 2-(anilinomethyl)pyrrolidinium ion during the crystallization. Alternate seeding of (−)- or (+)-**3** to the supersaturated solution in a similar magnitude gave (−)- or (+)-**3** in 93—98% optical purity. The initial part of the preferential crystallization is shown in Table 1.

Experimental

Melting points were determined on a Laboratory Devices Mel-Temp apparatus and are uncorrected. The values of specific rotation were measured on a JASCO DIP-181 digital polarimeter.

Materials. 5-Oxopyrrolidine-2-carboxanilide was prepared in 82% yield from 0.5 ml of (±)-5-oxopyrrolidine-2-carboxylic acid and 320 ml of aniline according to the method described in the literature,[3] and half the amount of aniline used was able to be recovered after the reaction period. The reaction of 0.36 mol of the anilide with 2.5 molar amounts of $LiAlH_4$ in THF gave (±)-**1** in 89% yield.

The optically pure diastereomeric salts ((+)-**1**·(+)-**2** and (−)-**1**·(−)-**2**) for seeds were prepared by the method described below in one-fourth scale without seeding, followed by recrystallizations from 99% methanol for three times: mp 172—173 °C; $[\alpha]_{435}^{18}$ + and −185.0° (*c* 1.00, 99% MeOH).

Found: N, 8.64%; 8.53%. Calcd for $C_{19}H_{24}N_2O_3$: N, 8.53%.

Racemic and optically active **3** were obtained in 83—88% yields from equimolar amounts of *p*-hydroxybenzoic acid and (±)-, (+)-, and (−)-**1**, respectively, followed by recrystallization from 95% ethanol.

Racemic form: mp 160—162 °C.

Found: N, 8.96%. Calcd for $C_{18}H_{22}N_2O_3$: N, 8.91%.

Optically active forms: mp 176—177 °C, $[\alpha]_{435}^{18.5}$ + and −82.0° (*c* 1.00, 99% MeOH).

Found: N, 9.00%, 8.82%. Calcd for $C_{18}H_{22}N_2O_3$: N, 8.91%.

Fractional Crystallization of ***1*****·****2*** *Salt.* To a gently refluxing solution of (±)-**1** (35.25 g, 0.200 mol) in 99% methanol (300 ml) was added a solution of (+)-**2** (24.32 g, 0.160 mol) in 99% methanol (100 ml) in a period of 15 min. The solution was seeded with crystals of (+)-**1**·(+)-**2** salt (50 mg), stood for 40 min at room temperature, and cooled with an ice bath for 2.5 h. The precipitates appeared were collected by filtration, washed with a small amount of 99% methanol, and dried over P_2O_5 to yield 23.74 g (72%) of (+)-**1**·(+)-**2** salt: mp 172.5—173.5 °C; $[\alpha]_{435}^{14.5}$ +184.5° (*c* 0.99, 99% MeOH). The suspension of the salt in benzene (170 ml) was treated with 1 M NaOH solution (110 ml) to decompose the salt. After separation of the organic layer, the aq. solution was extracted with benzene (2×100 ml). The organic layer and the extracts were combined, dried with K_2CO_3, and concentrated under reduced pressure. Distillation of the oil remained gave 11.89 g (67% total yield) of (+)-**1**: bp 134—135 °C/80 Pa; $[\alpha]_{589}^{20}$ +19.3° (*c* 0.98, abs. EtOH).

The minus enriched diamine recovered from the mother liquor (21.70 g, 0.123 mol) in 99% methanol (200 ml) was similarly reacted with (−)-**2** (18.70 g, 0.123 mol) in 99% methanol (100 ml), and the solution was seeded with (−)-**1**·(−)-**2** salt (50 mg) to give 25.54 g (78%) of (−)-**1**·(−)-**2** salt: mp 172—173 °C; $[\alpha]_{435}^{15}$ −184.0° (*c* 0.96, 99% MeOH). The similar treatment of the salt with 1 M NaOH solution gave 12.66 g (72% total yield) of (−)-**1**: bp 133—134 °C/80 Pa; $[\alpha]_{589}^{18}$ −19.2° (*c* 1.07, abs. EtOH).

GLC analysis of the products, (+)- and (−)-**1**, gave no peak other than one arising from **1**. No rise of the specific rotations of (+)-**1**·(+)-**2** and (−)-**1**·(−)-**2** salts ($[\alpha]_{435}$ + and −185.0°) used as seeds was observed by recrystallizations for more three times, and the specific rotations at 589 nm in abs. ethanol of (+)- and (−)-**1** liberated from the salts were + and −19.3°, respectively, which were considered to be maximal values of the specific rotations. Based on the data, the chemical and optical purities of (+)- and (−)-**1** obtained here were considered to be over 99%.

The resolving agents used, (+)- and (−)-**2**, were satisfactorily recovered over 93% yield without racemization from the corresponding aq. solution by acidification with aq. HCl solution, followed by extraction with ether.

Preferential Crystallization of ***3****.* A refluxed clear solution of (±)-**3** (11.62 g) and (±)-**1**·(±)-lactic acid (12.78 g) in 95% ethanol (60 ml) was allowed to cool at about 40 °C, seeded with (+)-**3** (20 mg), and stood for 2 h at around 6 °C. The precipitates appeared were collected by filtration, washed with a small amount of 95% ethanol, and dried over P_2O_5 to give 1.73 g of (+)-**3** (94% optical purity). Successively, (±)-**3** (2.50 g) was added to the filtrate and dissolved at an elevated temperature. The solution was similarly cooled, seeded with (−)-**3** (20 mg), and stood at 6 °C for 2 h to yield 3.50 g of (−)-**3** (93% optical purity). The process was repeated in a similar manner supplying 4.50 g of (±)-**3** in each run to give 4.0—4.8 g of optically active **3** in 93—98% optical purity. The initial six runs is shown in Table 1. The crystals having the same sign of optical rotation were combined and recrystallized from 95% ethanol, giving almost optical pure (+)- or (−)-**3** in 86—90% yield. For examples, recrystallization of 10.30 g of (+)-**3** (95% optical purity on the average) from 95% ethanol (85 ml) gave almost optically pure (+)-**3**: 9.02 g (88%); $[\alpha]_{435}^{15}$ +81.7° (*c* 1.01, 99% MeOH); >99% optical purity. Suspension of the salt in benzene (60 ml) was treated with 3 M NaOH solution (120 ml). After separation of the organic layer, the aq solution was extracted with benzene (2×50 ml). The organic layer and the extracts were combined, dried with K_2CO_3, and concentrated under reduced pressure. Bulb to bulb distillation of the crude product gave 4.21 g (94%) of (+)-**1**: bp 150 °C (bath temperature)/106 Pa; $[\alpha]_{589}^{19}$ +19.2° (*c* 1.45, abs. EtOH); >99% chemical and optical purities.

Similarly, recrystallization of 12.19 g of (−)-**3** (95% optical purity on the average) gave almost optically pure (−)-**3**: 10.56 g (87%); $[\alpha]_{435}^{18.5}$ −81.8° (*c* 1.02, 99% MeOH). Decomposition of the salt, followed by distillation gave 5.01 g (93%) of (−)-**1**: $[\alpha]_{589}^{19}$ −19.3° (*c* 1.39, abs. EtOH); >99% chemical and optical purities.

The authors thank Yamakawa Chemical Industrial Co. Ltd. for a gift of optically active mandelic acid.

A Cyclization of Humulene by Means of a Mercuric Salt in Aceto- and Benzonitrile

Kiyoharu HAYANO, Haruhisa SHIRAHAMA,* and Takeshi MATSUMOTO*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 12, 1982)

Synopsis. Humulene was converted to 3,6-secoprotoilludane derivatives by treatment with mercury(II) trifluoroacetate in aceto- and benzonitrile.

For the purpose of accomplishing a biogenetically patterned chemical cyclization of humulene (**1**)[1] to illudoids and hirsutanoids,[2] mercury(II) salt induced cyclization of humulene had been examined. The key reaction, C(2)–C(9) bond formation, was previously achieved[1b,c] by using mercury(II) acetate in aqueous acetic acid or mercury(II) nitrate in aqueous tetrahydrofuran to give ethereal 3,6-secoprotoilludane derivatives **2**, **3**, and **4** (Fig. 1). The cyclization did not, however, proceed further to form the protoilludane or a hirsutane skeleton. Clearly, the formation of the ethereal products became favourable because of the presence of the cosolvent water. If the reaction was performed in a neat, polar aprotic solvent, further cyclized, tricyclic skeletons could be obtained. We report here the results of mercury induced cyclization of humulene in anhydrous nitriles.

Humulene was treated with more than 2 equivalents of mercury(II) trifluoroacetate in dry acetonitrile at room temperature and a product was demercurated with sodium borohydride and subsequently acetylated. Chromatographic purification gave a crystalline compound **5** in 60% yield. The mercuration-demercuration in benzonitrile was also carried out in the same manner without subsequent acetylation, and a crystalline mass **6** was obtained in 66% yield.

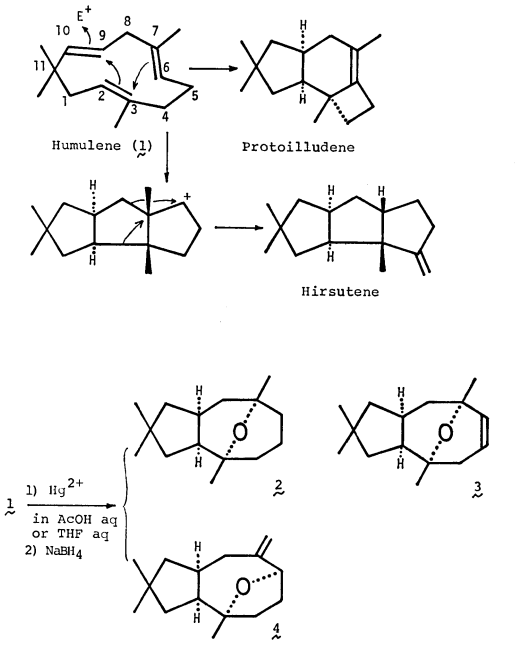

Fig. 1. Biosynthetic and chemical conversions of humulene.

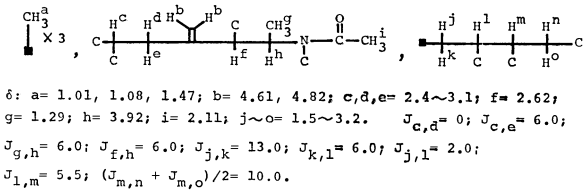
The high resolution mass sepctra of the products showed that a solvent molecule had been added to a molecule of each substrate and in the case of **5** 1 mol of hydrogen was further incorporated in the product. ^{1}H NMR studies on the product **5** including extensive decoupling experiments in the presence of a shift reagent revealed the existence of partial structures depicted in Fig. 2. Taking into consideration the possible combination of these fragments, together with probable reaction courses, we deduced 3,6-secoprotoilludane structure **5** for the product. LIS-values[3] [11(CH_3CO), 11(2-H), 9.9(14-CH_3), 9(10-H), 7(6-H), 5.8(18-CH_3), 1.6(CH_2=)] supported the proposed structure and moreover indicated that 2-H, 6-H, 10-H are placed near the *N*-acetyl group. The conclusive reaction course[4] and stereostructure **7** were shown in Fig. 3.

^{13}C NMR spectrum of the product in benzonitrile was reminiscent of that of a previously obtained 3,6-secoprotoilludane derivative **4**,[1c] except for the peaks due to the phenyl group, in multiplicities and in part in chemical shifts. ^{1}H NMR spectral data were in conformity with the formula **6**. In contrast to the case of acetonitrile, compound **6** was not reduced by $NaBH_4$, probably because of the resonance and steric effects in the conjugated C=N double bond.

In conclusion, it was shown that the reaction of mercuric salt with humulene in anhydrous nitriles is



δ: a= 1.01, 1.08, 1.47; b= 4.61, 4.82; c,d,e= 2.4~3.1; f= 2.62; g= 1.29; h= 3.92; i= 2.11; j~o= 1.5~3.2. $J_{c,d}$= 0; $J_{c,e}$= 6.0; $J_{g,h}$= 6.0; $J_{f,h}$= 6.0; $J_{j,k}$= 13.0; $J_{k,l}$= 6.0; $J_{j,l}$= 2.0; $J_{l,m}$= 5.5; $(J_{m,n} + J_{m,o})/2$= 10.0.

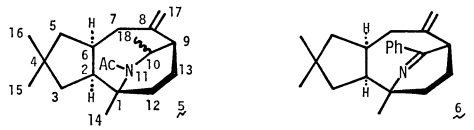


Fig. 2. Partial structures deduced from NMR studies. Chemical shifts (δ) and coupling constants (Hz) were shown.

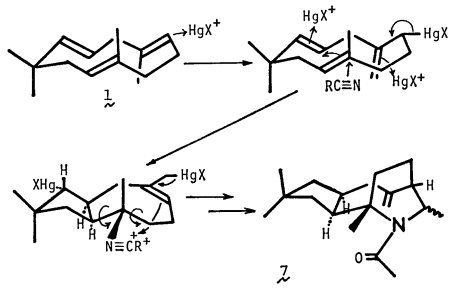

Fig. 3. Reaction course[4,5] in nitriles.

quite similar to that in the aqueous solvents, but the two reactions are different in that in the former solvents a new C–C bond is formed at C-6, and a C–N bond rather than a C–O bond is formed at C-3.

Experimental

All melting points were uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded on a HITACHI R20B (60 MHz) and a JEOL JNM FX-100 (25 MHz) instrument using TMS as an internal standard respectively. High resolution mass spectra were measured on a JEOL JMS D-300 mass spectrometer.

11-Acetyl-1,4,4,10-tetramethyl-8-methylene-11-azatricyclo[7.2.2.0^{2,6}]tridecane (5). To a stirred solution of $Hg(OCOCF_3)_2$ (1.88 g, 4.4 mmol) in CH_3CN(15 ml) was added 300 mg (1.47 mmol) of humulene at room temperature under argon and the mixture was stirred for 2 h. The solvent was removed *in vacuo* and the residue was dissolved in 10 ml of THF–H_2O (1:1). The solution was made alkaline (3 mol dm^{-3} NaOH) and $NaBH_4$ (300 mg, 7.89 mmol) was added by portions at 0 °C and the mixture was stirred for 3 h at room temperature. After evaporation of the THF *in vacuo*, the solution was extracted with ether three times. The combined extracts were washed with water, dried and concentrated to give a pasty mass which was subjected to acetylation (Ac_2O–pyridine, 20 °C, 12 h). Usual workup followed by chromatographic purification (silica-gel column, 10% AcOEt–C_6H_6) afforded a crystalline product **5** (254 mg, 60%): mp 102—103 °C; ^{1}H NMR ($CDCl_3$) δ=1.01, 1.08 (each 3H, s), 1.29 (3H, d, J=6), 1.47, 2.11 (each 3H, s), 3.92 (1H, quintet, J=6), 4.61, 4.82 (each 1H, t, J=1.5). Found: m/z 289.2408. Calcd for $C_{19}H_{31}NO$: M, 289.2407.

1,4,4-Trimethyl-8-methylene-10-phenyl-11-azatricyclo[7.2.2.0^{2,6}]-tridec-10-ene (6). Humulene (100 mg, 0.44 mmol) was treated with $Hg(OCOCF_3)_2$ (427 mg, 1 mmol) and PhCN (5 ml) in the same manner as above. After evaporation of the polar solvent the residue was dissolved in 3 ml of a mixture of volatile solvent (THF, MeOH, H_2O/1:1:1). The solution was made alkaline (3 mol dm^{-3} NaOH) and $NaBH_4$ (150 mg, 3.9 mmol) was added by portions at 0 °C and the whole was stirred for 2 h at room temperature. The organic solvent was removed *in vacuo* and the residue was extracted with $CHCl_3$ three times. The combined extracts were washed with water, dried and concentrated to give a pasty mass which was throughly made free from PhCN under reduced pressure. The solid obtained was crystallized from hexane to give a pure product **6** (230 mg, 66%): mp 83—85 °C; ^{1}H NMR ($CDCl_3$) δ=1.01, 1.09, 1.39 (each 3H, s), 3.72 (1H, t, J=4), 4.7 (2H, bs), 7.0—8.0 (5H, m); ^{13}C NMR ($CDCl_3$) δ=24.2(t), 24.4(t), 31.7(q), 32.4(q), 35.1-(q), 36.8(s), 40.2(t), 40.7(d), 41.3(t), 42.4(d), 50.5(t), 53.6 (d), 58.1(s), 113.8(t), 126.6(d×2), 128.1(d×2), 129.0(d), 140.6(s), 144.5(s), 168.2(s). Found: m/z 307.2300. Calcd for $C_{22}H_{29}N$: M, 307.2302.

A Convenient Method for the Preparation of *S*-Esters of Thio Analogs of Malonic Acid

Tsuneo IMAMOTO,* Masahito KODERA, and Masataka YOKOYAMA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 260

(Received February 12, 1982)

Synopsis. 2-Carboxyethanethioic *S*-esters ($RSCOCH_2COOH$) and propanebis(thioic) *S,S'*-diesters ($RSCOCH_2COSR$) were easily prepared in high yields by the direct condensation of malonic acid with thiols in the presence of ethyl polyphosphate (PPE).

In the previous paper[1] we reported that various thiocarboxylic *S*-esters were easily prepared by the direct condensation of carboxylic acids with thiols in the presence of ethyl polyphosphate (PPE).[2] The method compares favorably with others reported hitherto, in terms of simplicity, efficiency, generality, and in particular, the applicability to acid and/or base sensitive compounds such as penicillin G.

On the other hand, 2-carboxyethanethioic *S*-esters and propanebis(thioic) *S,S'*-diesters have been noticed as the useful intermediates for organic synthesis. The former esters are closely related to malonyl *S*-CoA and, in fact, undergo decarboxylative *C*-acylation under virtually natural conditions.[3,4] The latter ones are used for the synthesis of ethanol derivatives[5] and heterocycles.[6] We report herein a facile method for the preparation of these compounds from malonic acid and thiols using PPE as the condensation reagent.

When a thiol was treated with large excess of malonic acid[7] in PPE containing chloroform and tetrahydrofuran (THF), the condensation proceeded smoothly at room temperature without decarboxylation, and the corresponding 2-carboxyethanethioic *S*-esters (**1a—h**)

$$CH_2(COOH)_2 + RSH \xrightarrow[\text{in } CHCl_3\text{-THF}]{\text{PPE}} RSCOCH_2COOH \quad \mathbf{1a—h}$$

were produced in high yields. The results are summarized in Table 1. Since malonic acid is inexpensive, its use in excess detracts little from the utility of this process.

Next, we tried to prepare propanebis(thioic) *S,S'*-diesters. This was easily achieved by the treatment of malonic acid with two equivalents of thiols in PPE at room temperature. All the cases examined afforded

$$CH_2(COOH)_2 + 2\,RSH \xrightarrow{\text{PPE}} CH_2(COSR)_2 \quad \mathbf{2a—g}$$

the expected *S,S'*-diesters (**2a—g**) in excellent yields. The results are listed in Table 2. It is noted that sterically crowded *S,S'*-bis(2,4,6-trimethylphenyl) propanebis(thioate) (**2d**) was also prepared in a satisfactory yield.

We believe the present method has the superior attributes of high yields, ease of operation, and attractive economics.[8,9]

tra were recorded on a Hitachi 215 spectrophotometer. Products were identified by NMR and IR spectra together with elemental analyses.

Materials. PPE was prepared according to the method described in the Ref. 2. *o*-Methoxybenzenethiol[10] and 2,4,6-trimethylbenzenethiol[11] were synthesized by the methods described in the literatures. Other thiols were purchased from Tokyo Kasei Kogyo, Co., Ltd. and used without further purification.

*General Procedure for the Preparation of 2-Carboxyethanethioic S-Esters (**1a—h**).* A thiol (0.025 mol) was added to a stirred mixture of finely powdered malonic acid (10.4 g, 0.10 mol), PPE (15 g), purified chloroform (60 ml), and THF (10 ml).[12] After stirring for 30 h at room temperature, the reaction mixture was diluted with ether (200 ml) and treated successively with saturated aqueous $NaHCO_3$ solution (150 ml, 100 ml, and 50 ml). The combined aqueous extracts were acidified to pH 1—2 with 10% hydrochloric acid and extracted with chloroform (100 ml×2). The extracts were dried over Na_2SO_4 and concentrated by a rotary evaporator. The residue was purified by filtration through a column packed with silica gel (*ca.* 70 g) with benzene–ethyl acetate (1:1) as the eluent. Crystalline products were further purified by recrystallization.

*General Procedure for the Preparation of Propanebis(thioic) S,S'-Diesters (**2a—g**).* A mixture of malonic acid (10.4 g, 0.10 mol) and a thiol (0.20 mol) was stirred with PPE (30 g) at room temperature for 20 h. The reaction mixture was treated with saturated aqueous $NaHCO_3$ solution (600 ml) and the product was extracted into ether (150 ml×2). The combined extracts were washed with aqueous $NaHCO_3$ solution and dried (Na_2SO_4). The solvent was evaporated and the residue was filtered through a column packed with silica gel (*ca.* 70 g) with benzene. Evaporation of the solvent *in vacuo* afforded practically pure product, which was further purified by recrystallization or distillation under reduced pressure (Kugelrohr apparatus).

X-Ray Microanalysis of Uranium on Fibrous Amidoxime-type Adsorbent

Takao KITAMURA,* Koji SAKANE, and Shunsaku KATOH
Government Industrial Research Institute, Shikoku 2-3-3 Hananomiyacho, Takamatsu 761
(Received July 29, 1981)

Synopsis. The adsorption process for uranium from sea water was studied by X-ray microanalysis on polyacrylamidoxime fiber, whose functional group was found to distribute uniformly. Uniform distribution of uranium was observed on cross sections of the adsorbents, which had contacted with sea water for 14 and 55 d. It was deduced that intrafiber diffusion of uranium is not the rate determining step in adsorption.

Recently much higher interest is around on the organic polymer adsorbents because of their high adsorption rate and versatile possibilities in organic synthesis.[1-4] Among these adsorbents the ones with amidoxime functional groups have the highest adsorption rate for uranium from sea water.

Improvement of adsorptive properties for practical application necessitates knowledges about uranium adsorption process from sea water, which hitherto were not obtained from direct analysis of distribution of adsorbed uranium. In this note, distributions of functional groups and uranium were measured by X-ray microanalysis of copper(II) and uranium, respectively, and the uranium adsorption process is briefly discussed.

Experimental

Adsorbent. Adsorbent was obtained by reacting commercially available acrylic fiber of *ca.* 15 μm diam. with hydroxylamine by the usual method to form amidoxime functional groups.[5] Then the fiber was treated for 24 h with a 1 M (1 M=1 mol dm^{-3}) NaOH solution for conditioning. The amount of the functional group in the adsorbent was determined from copper(II) ion adsorption capacity.[6] Adsorption of copper(II) ion was carried out by shaking 0.1 g of the adsorbent for 3 d at 25 °C in a solution of 0.05 M $CuCl_2$ (25 cm^3), which is buffered to pH 4.5 with CH_3COOH–CH_3COONa.

Uranium Adsorption. Uranium was adsorbed from filtered natural sea water in columns of 2.5 cm inner diam. and 20 cm length at linear flow rate of 20 cm min^{-1} for 55 d. The uranium content in the adsorbent was determined by fluorometry on an Aloka fluorimeter FMT-3B after desorption with diluted HCl solution.[6]

X-Ray Microanalysis. Apparatus used was JEOL JXM-50A scanning electron microscope-X-ray microanalyser. Crystals used for resolution of spectra were pentaerithritol for U $M\alpha$, and lithium fluoride for Cu $K\alpha$. Standard samples for Cu and U analyses were the cross sections of wires supplied by JEOL.

Sample Preparation for X-Ray Microanalysis. Fibrous adsorbent was buried in an acrylic resin. After hardening the cylindrical resin of 5 mm diam. was cut to 5 mm height. Electrical contact of the specimen was attained by coating vacuum-evaporated aluminum, which was found to serve more satisfactorily than gold and platinum in minimizing X-ray absorption and preventing charging of the specimen. In some cases one end of the fiber was buried in a resorcinol resin, the other end being razored and coated with aluminum.

Results and Discussion

Characterization of Adsorbent. Secondary electron image of the adsorbent in Fig. 1 shows a smooth surface and existence of a notch in the direction of axis. This notch gave a typical shape of the cross section for most of the fibers as in Figs. 2—4. Amount of the functional group of the fiber was determined to be 2.6 mmol g^{-1}. Distribution of the functional group was measured on a cross section of the adsorbent by measuring Cu $K\alpha$ radiation of adsorbed copper(II). Figure 2 shows the secondary electron image and Cu $K\alpha$ micrography across a section. The image was observed under the same electron beam conditions with that for X-ray measurement, *i.e.*, at high electron beam intensity of 2×10^{-8} A and accelerating voltage of 25 kV, which were necessary to measure characteristic X-rays of elements at rather low concentration. This resulted in low resolution of the secondary electron image, which in turn reflects approximately the resolution of the line profile. Constant counting rate of Cu $K\alpha$

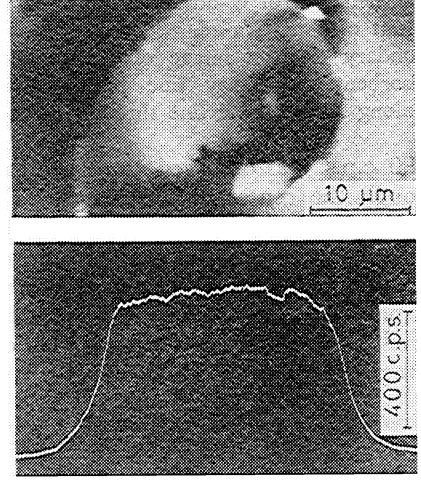

Fig. 2. Distribution of Cu(II) adsorbed from a buffered solution.
a: Secondary electron image of a cross section of the adsorbent, b: X-ray line profile analysis of Cu $K\alpha$ along a horizontal line through the center.

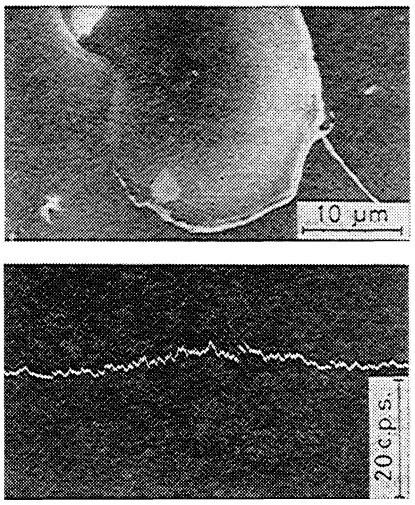

Fig. 3. Distribution of U adsorbed from sea water to an amount of 2 mg-U/g-ad.
a: Secondary electron image of a cross section of the adsorbent, b: X-ray line profile analysis of U *Mα* along a horizontal line through the center.

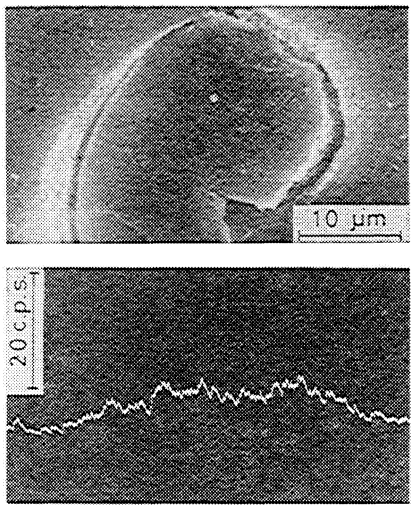

Fig. 4. Distribution of U adsorbed from sea water to an amount of 5 mg-U/g-ad.
a: Secondary electron image of a cross section of the adsorbent, b: X-ray line profile analysis of U *Mα* along a horizontal line through the center.

of about 490 c.p.s. was observed along the line, which passed through the center of the image. This result shows a uniform distribution of copper(II), hence the uniform formation of functional group in the adsorbent. The counting rate of Cu *Kα* of the standard sample was 7500 c.p.s. under the same conditions. The concentration of Cu(II) in the adsorbent was calculated to be 165 mg g^{-1}, giving correction factor[7] G of 2.5. This rather large G value can be attributed to the effect of absorption of electron and X-ray by coating materials.

Microanalysis of Uranium. The adsorbents at two different durations of uranium adsorption *i.e.* 14 and 55 d were examined. The former contained 2 mg g^{-1} and the latter 5 mg g^{-1} of uranium. Figure 3 shows a secondary electron image and U *Mα* X-ray line analysis of a cross section of the adsorbent after 55 d adsorption. Although the observed line is a little scattered, the counting rate around the center is nearly as high as that around the edge of the section. From the results observed above, it is found that the distribution of uranium in the fiber is approximately uniform. A similar observation with lower counting rate was made with adsorbents after 14 d adsorption as in Fig. 4. The above results of apparently uniform distribution of uranium for the two adsorbents at different durations of adsorption suggest that a boundary layer of adsorbed uranium does not exist, and intrafiber diffusion of uranium is not the rate determining step in adsorption from sea water.

For 0.3 mm diam. particle of hydrous titanium oxide adsorbent,[8] uranium-adsorbed layer of 0.03 mm thickness was calculated from the curve of adsorption rate, whereas the layer was not detected with the fibrous adsorbent, that is, the whole volume of the adsorbent was effective for uranium adsorption. The rate of uranium adsorption was 2 mg g^{-1} in 14 d with the fibrous adsorbent, whereas the rate with the hydrous titanium oxide adsorbent was 0.18 mg g^{-1} in 20 d.[8] These two characteristics of high adsorption rate and high effectivity can be denoted as the advantages of the fibrous amidoxime-type adsorbent for adsorption of uranium from sea water.

In-vitro Clot Forming Properties of Polyelectrolyte Complexes of [2-(Diethylamino)ethyl]dextran Hydrochloride with Poly(sodium-L-glutamate) and of Sodium Carboxymethyldextran with Chitosan

Yasuo KIKUCHI* and Tsutomu TAKEBAYASHI
Faculty of Engineering, Oita University, 700-Dannoharu, Oita 870

(Received August 31, 1981)

Synopsis. Polyelectrolyte complexes prepared at higher hydrogen ion concentrations may form clots in higher quantities than those prepared at lower hydrogen ion concentrations, irrespective of the content of anticoagulant reagents. This difference is attributable to the difference in molecular structure of polyelectrolyte complexes, especially to the presence of carboxyl groups.

We have reported[1,2] on novel chemical reactions, structures and properties of polyelectrolyte complexes (PEC) and their *in-vitro* clot formation and we have also reported[3] that different characters of blood coagulation are attributable to the difference in molecular structure among PECs, with an emphasis on the fact that formation of sulfo or carboxyl groups in PECs plays an important role in increasing the quantity of clot. This note deals mainly with attractive results of clot formation *in-vitro* by PECs of [2-(diethylamino)-ethyl]dextran hydrochloride with poly(sodium-L-glutamate),[4] and by carboxyl-containning PECs of sodium carboxymethyldextran of low molecular weight (about 5000) with chitosan.

Experimental

Chitosan (Tokyo Kasei Co., nitrogen content 7.89%, intrinsic viscosity 1.50 dl/g in 1 M (1 M=1 mol dm^{-3}) NaCl of pH 3.0 at 30 °C), sodium carboxymethyldextran (CMD) (Meito Sangyo Co., degree of substitution 1.38 mol/A.G.U., molecular weight about 5000), poly(sodium-L-glutamate) (PSLG), and [2-(diethylamino)ethyl]dextran hydrochloride (EA) were used. Properties of PSLG and EA are given in a previous paper.[4] When the pH of solution is below 4.0 or 3.0, no precipitate is formed by mixing PSLG with EA (system A) or chitosan with CMD solution (system B), respectively, and when the pH of chitosan solution is higher than 6.0, chitosan remains undissolved. Thus, reactions were carried out at pH 5.0, 6.0, and 8.0 (system A) and pH 3.5, and 5.5 (system B). General conditions, the apparatus and chemical analyses, and the blood clotting test used are the same as those described in previous papers.[1-4]

ACD bloods of types O and A (Red Cross Hospital Blood Center) were kept in a thermostat at 4—6 °C for 2—6 d.

Conditions, yields and results of elemental analyses for PECs prepared in such a way that a PSLG or CMD solution was added to EA or chitosan and *vise versa*, are given in the previous paper[4] and in Table 1.

In system B, all the PECs prepared at pH 5.5 have higher nitrogen contents, which represent the molar ratio CMD/chitosan, than the PEC prepared at pH 3.5 because of the higher dissociation of chitosan at pH 3.5 and similarly, in system A, all the PECs prepared at pH 5.0 have lower PSLG/EA molar ratios than the PECs prepared at pH 6.0 and 8.0 and those prepared by reagent addition in the reverse order have higher ratios as shown in the previous paper.[4]

IR spectra of PECs are similar to those of their corresponding mixtures of PSLG and EA or of CMD and chitosan.

Table 1. Experimental conditions[a], polymer yield, and elemental analyses of polyelectrolyte complexes[b] of chitosan[c] with CMD[d]

Sample code[e]	V_{CMD}[f] / cm^3	R[g]	Y[h] / g	N[i] / %
A-1	442	4.0	0.96	3.3
A-2[j]	298	2.7	0.96	3.3
A-3[k]	274	2.5	0.93	3.6
A-4	221	2.0	0.74	3.8
B-1	442	4.0	0.71	4.5
B-2[j]	88	0.8	0.69	4.8
B-3[k]	76	0.7	0.67	4.8
B-4	55	0.5	0.44	4.9
C-1	442	4.0	0.98	3.5
C-2	298	2.7	0.97	3.8
C-3	274	2.5	0.93	3.6
C-4	221	2.0	0.76	3.4
D-1	442	4.0	0.75	4.6
D-2	88	0.8	0.67	4.4
D-3	76	0.7	0.60	4.2
D-4	55	0.5	0.42	4.9

a) Concentrations of chitosan and sodium carboxymethyldextran (CMD), 2 and 4 g/L. b) Nitrogen analyses carried out according to the Kjeldahl method. c) Chitosan: Nitrogen content, 7.89%; intrinsic viscosity, 1.50 dl/g in 1 M NaCl of pH 3.0 at 30 °C. d) CMD: Degree of substitution, 1.38 mol/A.G.U.; molecular weight, about 5000. e) A, B series: CMD solution was added dropwise to chitosan solution; C, D series: Chitosan solution was added dropwise to CMD solution; A, C series: Both chitosan and CMD solutions were adjusted to pH 3.5; B, D series: Both chitosan and CMD solutions were adjusted to pH 5.5 (see text). f) V_{CMD} is one amount of CMD solution in ml/200 ml chitosan. g) R is the molar ratio of Na(CMD)/N(chitosan) for solution. h) Y is the yield of polymer. i) N is the nitrogen content. j) End of coagulation range. k) Beginning of coagulation range.

However, the PEC prepared at pH 5.0 (system A) or pH 3.5 (system B) has an absorption band around 1740 cm^{-1} which appears neither in the PEC prepared at pH 8.0 (system A) or pH 5.5 (system B) nor in the mixture of PSLG and EA or of chitosan and CMD; the PEC prepared at pH 6.0 (system A) has weaker absorption bands than the one prepared at pH 5.0. These absorption bands have been assigned to carboxyl groups.[5] Furthermore, the absorption band around 3500 cm^{-1} (assigned to the hydroxyl group) of the PEC prepared at pH 5.0 (system A) or pH 3.5 (system B) is caused to shift to lower wave numbers in both systems. In view of the formation of hydrogen bond between the hydroxyl and other functional groups, it is reasonable to expect such a shift in frequency.

The PECs differ appreciably from one another in such

properties as the degree of swelling, color reaction with Toluidine Blue, and solubility depending on experimental conditions of hydrogen ion concentration and molar mixing ratio of constituents, although they have common constituents. It appears that the degree of dissociation and the conformation of PSLG, EA, chitosan, and CMD change with hydrogen ion concentration.

The PECs of the same nitrogen content, representing the CMD content in PEC, is similar to one another, in such properties as IR spectra, solubility, swelling, and color reaction with Toluidine Blue, under the same conditions. Consequently, blood clotting tests were performed on PEC tables 1-B, 2-B, 3-B, 1-b, 2-b, and 3-b as reported in the previous paper,[4] and on PEC tablets A-1 A-2, B-1, B-2, C-1, D-3, and D-4 as given in Table 1, which were selected arbitrarily from within the nitrogen content range 3.3—4.9 according to the gravimetric procedure of Imai and Nose.[6] No change in IR absorption intensity for one carboxyl group was detected for the PECs which had long been kept dipped at pH 7.3. No firm clot was formed even after 10 min dipping with PEC tablets. Percentage formation of thrombus for the PECs (system A: 1-B, 2-B, and 3-B; system B: A-2, C-1, and D-3) is given in Figs. 1 and 2. For the PECs (system A: 1-b, 2-b, and 3-b; system B: A-1, B-1, B-2, and D-4) were obtained similar reactions between the percentage of thrombus formed and the molecular structure as well as results of observation similar to the above-mentioned. All the PEC tablets suppress the coagulation of blood. Moreover, quantities of clots for the PEC tablets prepared at pH 5.0, 6.0 (system A) and 3.5 (system B) are more than those for the PEC tablets prepared at pH 6.0 and 8.0, 8.0, and 5.5, respectively, although the content of PSLG or CMD (suppression of coagulation) in the PEC tablets prepared at pH 5.0 and 6.0 and 3.5 are higher than that in those prepared at pH 8.0 and 5.5, respectively. We have reported an experimental work on clot formation of PEC consisting of EA, CMD, and sodium dextran sulfate, pointing out a definite correlation between the character of blood coagulation and the molecular structure and the significance of formation of carboxyl or sulfo groups in PECs. Thus, the present experimental results have confirmed that the difference in the characters of blood coagulation is attributable to the difference in molecular structures of the PECs prepared; especially, the formation of carboxyl group in PECs has a great contribution to the increase in the quantity of clots as well as the above-mentioned experimental results.[3]

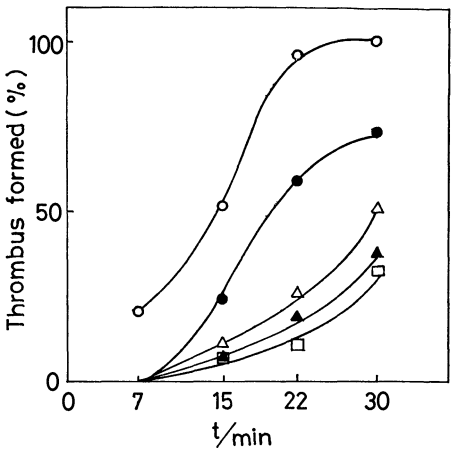

Fig. 1. Percentage of thrombus formed on polyelectrolyte complexes (PSLG→EA) compared with that on glass.
Storage time of A type blood: 6 d, ○: glass, ●: poly(vinyl chloride), △: 1-B, ▲: 2-B, □: 3-B. Sample codes 1-B, 2-B, and 3-B correspond to those in Table 1 in the previous paper.

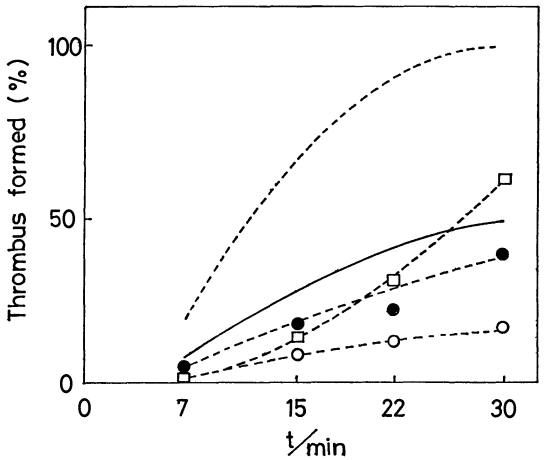

Fig. 2. Percentage of thrombus formed on polyelectrolyte complexes (EA–CMD) compared with that on glass.
Storage time of A type blood: 3 d, ----: glass, ——: poly(vinyl chloride), □: A-2, ●: C-1, ○: D-3. Sample codes A-2, C-1, and D-3 correspond to those in Table 1.

The mechanism of increasing the quantity of clots makes it likely that facters effective for blood coagulation are activated delicately by interaction of carboxyl groups in PEC with blood. On the other hand, the mechanism for the suppression of coagulation suggests the possibility that negative charges such as the carboxylate group may exist active on the surface of PEC.[7]

(Reçu Novembre 10, 1981)

Synopsis. Les auteurs ont synthétisé deux benzile-monoximes et deux dichloro-4,4′ benzile-monoximes. L' introduction de deux atomes de chlore en para sur les cycles permet, par comparaison des moments dipolaires expérimentaux et calculés, de confirmer les configurations et de préciser les conformations de chaque isomère.

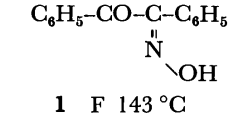
Les configurations attribuées par Meisenheimer[1] aux benzile-monoximes *E* (composé **1**) et *Z* (composé **2**) ont été confirmées dans la suite par voie chimique[2,3] et par des études de radiocristallographie,[4] de spectroscopie IR[5,6] et RMN.[7,8]

Les conformations peuvent être influencées par l'état physique:

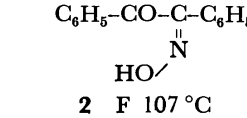
a) A l'état cristallin les dérivés *O-p* bromobenzoylés des benzile-monoximes *E* ou *Z* ont des conformations *s-trans* d'après l'étude de leurs spectres de rayons X.[4]

b) A l'état dissous: Sadler[9] par l'étude des spectres infrarouge en solution chloroformique et Armand[10] par l'étude du pK_a du groupe oxime attribuent à **2** la conformation *s-cis*. Cherry[6] en se basant sur les données de la RMN dans le chloroforme deutérié et de la spectrographie infrarouge dans le tetrachlorure de carbone suppose pour **1** et **2** la conformation *s-trans*. Lumbroso[11] à la suite d'une étude dipolemétrique en solution dans le dioxanne a émis la même hypothèse.

Nous avons déterminé en solution dioxannique les moments dipolaires de **1** et **2** ainsi que ceux de leurs dérivés dichlorés en para sur les cycles (**3** et **4**). Par comparaison avec les moments dipolaires calculés, l'introduction des substituants chlorés permet, si l'on admet la conjugaison du groupe O=C–C=N–OH, de confirmer les configurations *E* et *Z* de ces composés et surtout de lever l'indétermination sur leur conformation *s-cis* ou *s-trans* dans ce solvant. La polarité du chloroforme et le trop faible pouvoir dissolvant du tetrachlorure de carbone[12] ne permettent pas une étude dipolemétrique analogue.



1 F 143 °C
(isomère *E*)



2 F 107 °C

Partie expérimentale

Synthèse. Les composés **1** et **2** ont été préparés selon la méthode de Taylor[13] reprise par Cherry[6] à partir du benzile par réaction avec l'hydroxylamine.

Les composés **3** et **4** ont été préparés selon la même méthode à partir du dichloro-4,4′ benzile; celui-ci est obtenu par condensation du chloro-4 benzaldéhyde en dichloro-4,4′ benzoine[14] puis oxydation.[15]

L'identification a été effectuée par IR et RMN, la pureté vérifiée par chromatographie; les configurations ont été confirmées par l'essai à l'acétate de cuivre[16] (**1** et **3** donnent un complexe vert, **2** et **4** ne donnent pas de complexes) et par RMN en solution dans le DMSO hexadeutéré en concentration inférieure à 5%: δ_{OH} en ppm=**1** 12,50, **2** 11,80 (8), **3** 12,82, **4** 12,05 (ce travail).

Moments Dipolaires. Moments Calculés (μ_{calc}): Par analogie avec la diméthylglyoxime[17] nous supposerons plan le motif conjugué O=C–C=N–OH. Nous avons obtenu les moments par additivité d'incréments de liaison suivant deux modes de calcul:

1°—avec les angles CCO, ONC, NCC, HON égaux à 120°,

2°—avec CCO=120°, ONC=111°, NCC=126°, HON=103°,

valeurs déduites des molécules de formaldoxime[18] et de diméthylglyoxime.[17]

Les incréments utilisés sont: μ(C=N)=1,8 D; μ(C=O)=3,0 D; μ(H–O)=1,5 D; μ(C_{Ar}–Cl)=1,5 D; μ(N–O)=0,3 D (19,20).

Moments Expérimentaux (μ_{exp}): Les moments μ_{exp} ont été mesurés dans le dioxanne à 25 °C, avec des fractions massiques comprises entre 0,0005 et 0,010; la formule de Debye a été utilisée ainsi que la méthode d'extrapolation mathématique d'Halverstadt et Kumler[21] pour le calcul de la polarisation totale. Les résultats figurent dans les tableaux:

	∞	β	RM_D	$P_{2\infty}$	μ_D
1	6, 05	−0, 27	66, 00	269, 96	3, 16
2	5, 85	−0, 20	66, 00	266, 95	3, 13
3	4, 90	−0, 26	75, 67	297, 80	3, 29
4	3, 33	−0, 28	75, 67	219, 99	2, 67

Discussion

La valeur expérimentale obtenue pour **1** n'est compatible qu'avec les structures **a** et **e**; pour **3**, le moment mesuré ne peut correspondre qu'aux structures **b** ou **e**. L'introduction d'un atome de chlore en para sur les cycles benzéniques ne peut avoir d'influence sur la conformation, l'halogène étant très éloigné du motif O=C–C=N–OH.[22,23] On doit alors attribuer à ces composés **1** et **3** la structure **e**.

De même, les valeurs expérimentales obtenues pour **2** et **4** sont compatibles respectivement avec les for-

COMMENTS

Hydrogenolysis and Hydrogenation of Ethylene on $LaCoO_3$

Maria Alicia ULLA and Eduardo Agustin LOMBARDO*

Instituto de Investigaciones en Catálisis y Petroquímica (INCAPE), Facultad de Ingeniería Química, Santiago del Estero 2829, 3000 Santa Fe, Argentina

(Received May 25, 1981)

Synopsis. The hydrogenation and hydrogenolitic activity of $LaCoO_3$ reported by Ichimura *et al.*[1] can be rationalized in terms of the current literature by a model in which Co°, produced under reaction conditions, is the locus of catalytic activity. This interpretation disagrees with the model supported by the authors.

Recently, Ichimura *et al.*[1] reported the results of a study of the hydrogenolysis of ethylene and ethane on $LaCoO_3$. Regarding the nature of the possible active sites they advanced a model that, we understand, does not take into account and to a certain extent contradicts the existing body of knowledge in the field. They concluded that the pairs of lanthanum and oxygen ions are mainly responsible for the hydrogenation activity while the Co^{3+} ions play a role in the rupture of the carbon-carbon bond. Opossing this view we have reasons to believe that the loci of both hydrogenation and hydrogenolytic activities are Co° atoms that appear on the surface as a consequence of the reduction of Co^{3+} by hydrogen at the reaction temperature. We will now review the pertinent literature that support our point of view.

Sis *et al.*[2] have carefully studied the reduction of $LaCoO_3$ using various techniques. They were able to reduce the mixed oxide up to a mixture of La_2O_3 + Co° when the temperature reached 650 °C. However, they detected the appearance of Co° at temperatures as low as 300 °C. Similar results were reported by Petunchi *et al.*[3] and Crespin *et al.*[4] Furthermore, we have observed that at 80 °C $LaCoO_3$ could be rapidly reduced, under 170 Torr† of hydrogen pressure in a recirculating system, to $LaCoO_{2.9}$. Therefore, under the conditions Ichimura *et al.*[1] did the experiments, $H_2/C_2H_4 = 10$ and temperatures between 80 °C and 300 °C, it is very likely they had a partially reduced perovskite.

Another important clue to ascribe a metallic behavior to their system was found within the data reported by Ichimura *et al.*[1] The reaction between C_2H_4 and D_2 is a diagnostic tool to distinguish between metallic and metal oxide behavior. In the case of group VIII metals multiple exchanged ethylene and ethane are produced during the reaction.[5–8] Oxides on the other hand, produce $C_2H_4D_2$ almost exclusively while the unreacted ethylene shows none or very little deuterium exchanged.[9–12] This general trend also holds true for higher reaction temperatures (250—450 °C) in the case of a relatively inactive catalyst such as TiO_2.[12] In the table it is shown for comparisson the data obtained by Ichimura *et al.*[1] at 80 °C, our own data and a sample experiment reported by Tanaka *et al.*[9] on Co_3O_4. In both cases in which $LaCoO_3$ was the catalyst either pre-reduced or not, the product hydrocarbons show similar exchange patterns, *e.g.* the calculated binomial distributions closely duplicate the experimental values. The typical Co_3O_4 data shows the selective addition of deuterium to the double bond while the ethylene remains virtually free of deuterium.

Ichimura *et al.*[1] also reported tracer data obtained at 300 °C at which temperature there is no doubt Co° is already present in the solid.[2,13] Both ethane and ethylene were multiple exchanged but the data show some deviation from binomial distribution. The deuterium distribution in methane formed by hydrogenolisis does not seem to fit in line with those reported for both ethylene and ethane. Additional data would

be needed to interpret the methane tracer results.

Ichimura *et al.*[1] argued that catalyst deactivation was due to the reduction of Co^{3+} to lower oxidation states. This is at variance with our finding[13] that the oxidized catalyst is inactive and its activity increases sharply going through a maximum with the extent of reduction of the oxide. Our experiments were conducted on two different aliquots of the catalyst that before each run received a standard re-oxidation and reduction pretreatment. The reaction temperature was 253 K. However, extrapolation of their results at this temperature fall within the activity range of our slightly reduced catalyst, *e.g.* $LaCoO_{3-x}$ ($x<0.2$). An alternative explanation for the deactivation process comes from the fact that most hydrocarbon reactions leave "residues" or "coke" on the surface which poison the catalyst. This system is no exception in this regard for we have measured the amount of strongly adsorbed molecules that remains on the surface after evacuation at reaction temperature, $2.2\pm1.0\times10^{14}$ atoms of C/cm^2.[14] This value is of the same order of magnitude as the maximum number of active sites estimated to exist on our catalyst by CO poisoning technique.[14]

In summary, the very likely reduction of even small amounts of Co^{3+} to Co° under reaction conditions and the tracer data that resemble those obtained over group VIII metals support a model in which finelly dispersed Co° on the matrix oxide is the responsible for both the hydrogenation and hydrogenolitic activity of $LaCoO_3$.

Active State of the $LaCoO_3$ Catalyst. A Reply to the Comment, "Hydrogenolysis and Hydrogenation of Ethylene on $LaCoO_3$"

Kenji Ichimura, Yasunobu Inoue, and Iwao Yasumori*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 23, 1981)

The catalytic activities of mixed oxide perovskite, $LaCoO_3$, for oxidation as well as hydrogenation have been subjects of many researches because of this substance's peculiar valence-band structure, similar to those of transition metals. We have investigated this unique activity for ethylene hydrogenation and ethane hydrogenolysis,[1] and the hydrogenolysis of C_3–C_5 alkanes,[2] and have performed a comparative study of $LaCoO_3$, $LaAlO_3$, and $LaFeO_3$, in which the latter two perovskites showed only hydrogenation activity.[3] In our study, the activity of $LaCoO_3$ was stabilized by evacuation at 300 °C for 1 h prior to each kinetic run, and the catalyst exhibited a good reproducible activity for runs repeated several tens of times. After more than one hundred times, the catalyst was deactivated and an XPS analysis of the surface indicated that the Co^{3+} ions in the surface layer were reduced to Co^{2+} ions, which were characterized by the shake-up satellite peaks in the spectrum.[1]

Recently, Crespin and Hall have studied in detail the surface states of perovskite compounds, $BaTiO_3$, $SrTiO_3$, and $LaCoO_3$, and their changes during reduction.[4] They found that the Co^{3+} ions in their $LaCoO_3$ sample were easily reduced to the Co^{2+} by heating in hydrogen at 400 °C and that the compound was then decomposed to Co^0 and La_2O_3 by reduction at 500 °C. This reduced mixture was found to recover its original perovskite structure by reoxidation at as low a temperature 400 °C. By the use of $LaCoO_3$ prepared by the same procedure, Petunch *et al.* examined the change in activity for ethylene hydrogenation with an increase in the degree of reduction and proposed that the active state of $LaCoO_3$ was finely dispersed zerovalent Co particles on the La_2O_3 surface; a maximum activity for ethylene hydrogenation at −20 °C was observed on the $LaCoO_{3-x}$ catalyst at the $x=0.7$ composition for the first oxidation-reduction cycle and at $x=1.2$ for the second cycle.[5]

These results are quite different from ours, especially with regard to the stability of the catalyst in a reducing atmosphere; this difference may be attributed to the variation in the catalyst preparation and to the structure of the perovskite particles thus formed. The calcination of mixed hydroxides precipitates in the preparation of our catalyst was carried out by heating them at 900 °C for 3 h and then at 1100 °C for 12 h; a well-developed crystal of $LaCoO_3$ with a surface area of 0.33 m^2/g was thus obtained. The calcination temperature in their preparation was, however, lower than 800 °C, and the obtained compound had a large surface area of 16 m^2/g, about 50 times as large as that of ours, predicting that the difference in the average particle size between the two catalysts will be of the same order of magnitude.

This high reducibility of their compound and the recovery of the original structure by reoxidation at an extremely low temperature are surprising, as Crespin and Hall stated in their report; they ascribed those phenomena to the structure containing vacancies in the perovskite lattice and to the resultant high mobility of ions.[6] The fact that the surface area decreased from 16 to 13 m^2/g after the reoxidation, whereas the crystallite size decreased to some extent, supports this view. Such lattice imperfections may be exposed on the surface with a high concentration, so that some fraction of Co occupies "coordinatively unsaturated sites." The reported instability of hydrogenation activity which is seen from the drastic decrease in activity with an increased degree of reduction and the shift of activity maximum may reflect the labile nature of their catalyst. Moreover, it is amazing that the catalyst prepared by them is more reducible than that studied by Crespin and Hall, since their catalyst was reduced to some extent at 80 °C.[7]

It is not possible to compare the behavior of their catalyst for ethane hydrogenolysis with ours, since they examined the hydrogenation of ethylene only at temperatures up to 50 °C. As for the hydrogenolysis of ethane over our catalyst, the reaction orders with respect to ethane and hydrogen are 1.0 and −0.5 respectively, and the activation energy was estimated at 35 kJ/mol in the temperature range of 200—300 °C. These values of kinetic parameters are quite different from those for the reaction on metallic Co dispersed on carriers; the ethane and hydrogen orders are 1.0 and −0.8 respectively, the value of activation energy is 125 kJ/mol for Co/SiO_2.[8] The hydrogen order of −1.3 and the activation energy of 134 kJ/mol for Co/MgO were reported.[9] These results evidently show that the active state of our catalyst is far from that of metallic Co. By comparing the observed deuterium distributions of the reactant and the product molecules in the reaction of ethylene with D_2, Ulla and Lombardo insisted that our results were close to theirs and those obtained from the catalysis by "metal," and deviated from those observed in the reaction on "oxide," by illustrating the results of a reaction over Co_3O_4 at 23 °C.[10] It is, however, not reasonable to compare directly the properties of reactions which proceed in different temperature ranges and to classify the active state as simply "metal" or "oxide" without considering the variation in the character of oxides; in the cases of typical oxides, such as CaO[11] and MgO,[12] the most abundant species in the deuterium distribution of ethane, ethane-d_2, decreased its fraction with an increase in the reaction temperature and the distribution became broader. Even a comparison of our results (80 °C) with theirs (50 °C) shows that our distribution has a distinct maximum at ethane-d_2 and so is different from theirs.

It should also be noted that there is a limit to the amount of surface atoms detectable by means of XPS, a small percentage of the fraction of surface coverage, and that it is difficult to determine the oxidation state of a surface species when its amount is below this limit. Accordingly, a more sensitive method of surface analysis is needed to obtain a definite solution of this problem.

In conclusion, this reply does not detract from the results obtained by the use of their own catalyst, but we wish to point out that it is premature to generalize their view immediately on the basis of the conclusion deduced from a study using only a catalyst in a highly reducible state.

The Structure of the Cyclodextrin Complex. XIII. Crystal Structure of β-Cyclodextrin-1,4-Diazabicyclo[2.2.2]octane Complex Tridecahydrate

Kazuaki HARATA

Research Institute for Polymers and Textiles, 1-1-4, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received September 26, 1981)

The crystal structure of β-cyclodextrin–1,4-diazabicyclo[2.2.2]octane complex tridecahydrate was determined by the X-ray method. The crystal is monoclinic with the space group $P2_1$, $Z=2$, $a=15.395(2)$, $b=16.598(1)$, $c=15.441(2)$ Å, and $\beta=117.35(1)°$. The structure was solved by inspection of a Patterson map and a trial-and-error method combined with the rigid-body least-squares technique and refined by the block-diagonal least-squares method to the final R-value of 0.048 for 5649 reflections ($\sin\theta/\lambda<0.61$). The β-cyclodextrin molecule is in the shape of a distorted and truncated heptagonal pyramid. Two of seven primary hydroxyl groups are in a *gauche-trans* conformation, the others being in a *gauche-gauche* conformation. Secondary hydroxyl groups form intramolecular hydrogen bonds between adjacent glucose residues. The guest 1,4-diazabicyclo[2.2.2]octane is almost fully included in the cavity of β-cyclodextrin. Its methylene groups are in van der Waals contact with the methine groups and the glycosidic oxygen atoms at the interior surface of β-cyclodextrin, while two nitrogen atoms form hydrogen bonds with a water molecule and a secondary hydroxyl group of the neighboring β-cyclodextrin. β-Cyclodextrin molecules are arranged nearly parallel to the crystallographic ac plane to form a corrugated sheet of molecular layer. All of the thirteen water molecules fill vacant spaces between the molecular layers, forming a hydrogen-bond network in the crystal.

β-Cyclodextrin forms many crystalline inclusion complexes with a variety of guest molecules. Crystals of uncomplexed β-cyclodextrin[1] and its ethanol complex[2] have a cage-type structure in which β-cyclodextrin molecules are arranged in a zigzag mode. Crystal structures of the complexes with 1-propanol[3] and some benzene derivatives[4] consist of a dimer unit formed by two β-cyclodextrin molecules with their secondary hydroxyl sides facing each other. In this paper, we present a crystal structure of the β-cyclodextrin-1,4-diazabicyclo[2.2.2]octane (1,4-DO) complex; its molecular packing is different from those found previously. The host-guest geometry of the complex is interesting in relation to the 1,4-DO catalyzed hydrolysis of acyl-β-cyclodextrin.

Experimental

β-Cyclodextrin and 1,4-DO in a 1 : 1 molar ratio were dissolved in a hot aqueous solution, and the solution was allowed to stand at room temperature. Colorless and prismatic crystals were obtained. Lattice parameters and reflection intensities were measured on a Nicolet P3/F diffractometer with graphite-monochromated Cu $K\alpha$ radiation. The crystal was sealed in a quartz capillary with a drop of mother liquor since it breaks up in air. 5649 independent reflections with $|F_o|\geqq 3\sigma(F)$ were collected up to 140° in 2θ by using θ-2θ scan mode. No corrections were made for absorption or extinction effect.

Crystal Data: $C_{42}H_{70}O_{35}\cdot C_6H_{12}N_2\cdot 13H_2O$, $F.W.=1481.4$ monoclinic, space group $P2_1$, $Z=2$, $a=15.395(2)$, $b=16.598(1)$, $c=15.441(2)$ Å, $\beta=117.35(1)°$, $V=3504.7(7)$ Å^3, $D_x=1.404$, $D_m=1.40$ g cm^{-3}.

Determination and Refinement of the Structure

A Patterson map showed that the *pseudo* heptagonal axis of β-cyclodextrin makes an angle of *ca.* 10° against the crystallographic b axis. The rotation around the molecular axis and the translational parameters along the a and c axes were determined by a trial-and-error method. After the correction of the position and orientation of each glucose residue by the rigid-body least-squares technique, atomic parameters were refined by the block-diagonal least-squares method. Successive Fourier and difference-Fourier syntheses revealed the positions of 1,4-DO and hydrated water molecules. An occupancy factor of disordered water molecules (W10A and W10B) was estimated from an electron-density map, but it was not refined. Hydrogen atoms were found on a difference-Fourier map. Further refinement of the structure by the block-diagonal least-squares method converged the R-value to 0.048. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections. Atomic scattering factors were taken from the "International Tables for X-Ray Crystallography."[6] Final atomic coordinates and B_{eq} of non-hydrogen atoms are given in Table 1. Tables of the observed and calculated structure factors, anisotropic temperature factors, atomic parameters of hydrogen atoms, bond distances, angles, and conformation angles of β-cyclodextrin are kept at The Chemical Society of Japan (Document No. 8232). The computation was carried out on a FACOM M-200 computer at the RIPS Center, Tsukuba.

Description and Discussion of the Structure

Outline of the Structure. A numbering scheme of the β-cyclodextrin–1,4-DO complex is shown in Fig. 1. β-Cyclodextrin is in the shape of a distorted and truncated heptagonal pyramid with the wide aperture at the secondary hydroxyl side and the smaller aperture at the primary hydroxyl side. The guest 1,4-DO molecule is situated in the β-cyclodextrin cavity at the secondary hydroxyl side (Fig. 2). β-Cyclodextrin molecules are arranged nearly parallel to the ac plane and form a corrugated sheet of molecular layers (Fig. 3). All the water molecules are located outside the β-cyclodextrin

a) Occupancy factors of O(W10A) and O(W10B) are 0.7 and 0.3, respectively. b) $B_{eq} = 8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid.

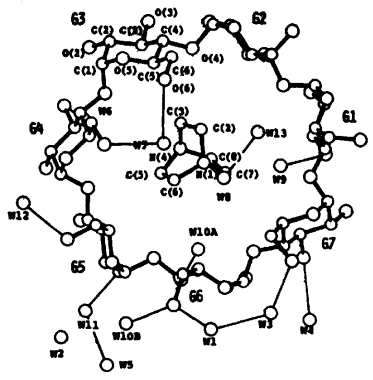

Fig. 1. A numbering scheme of β-cyclodextrin-1,4-DO complex tridecahydrate.

cavity. They fill the intermolecular space and form the hydrogen-bond network in the crystal.

Conformation of β-Cyclodextrin. β-Cyclodextrin consists of seven α-1,4-linked D-glucose residues of the $^4C_1$ chair conformation. Except for the orientation of the C(6)–O(6) bonds, the conformations of seven glucose residues are nearly identical with each other. The primary hydroxyl groups show two different types of conformations (Fig. 1). In G3 and G4 residues, they are inclined toward the β-cyclodextrin axis, having a *gauche-trans* conformation. This conformation is held by the hydrogen-bonds linking these hydroxyl groups through the W7 water molecule. The other primary hydroxyl groups in a *gauche-gauche* conformation turn away from the center of the β-cyclodextrin ring.

Average bond distances and angles for seven glucose residues are shown in Fig. 4. Characteristics similar to those found in α-cyclodextrin complexes[7] are also observed in them; the C(2)–C(3) and C(3)–C(4) bonds are slightly shorter than the C(1)–C(2) and C(4)–C(5) bonds, and the C(3)–C(4)–O(4) angle is smaller than the ideal tetrahedral angle. This indicates that the glucose conformation is only slightly affected by the size of the macrocyclic ring. A significant difference is observed in the glycosidic oxygen angle between α- and β-cyclodextrin. The average value of 117.4° is smaller than the corresponding angle of α-cyclodextrin (118—119°), but it is in good agreement with the angle of

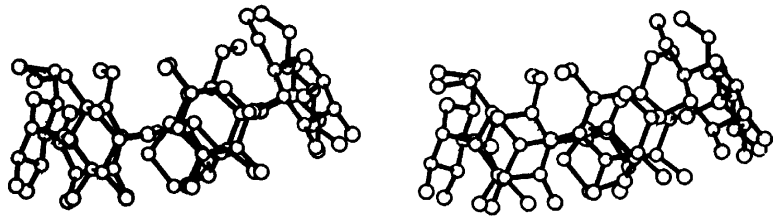

Fig. 2. A stereo-drawing of a side-view of the complex.

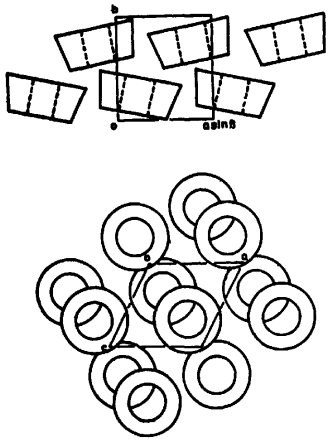

Fig. 3. An illustration of the packing feature of β-cyclodextrin in the crystal.

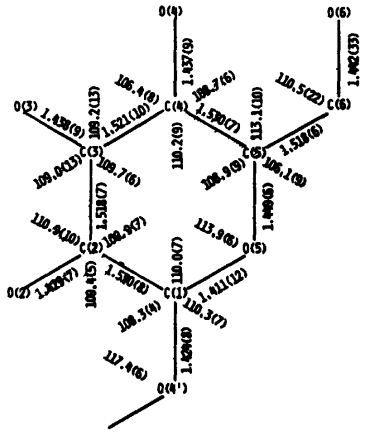

Fig. 4. Average bond distances and angles over seven glucose residues.
Standard deviations in parentheses were estimated according to the equation: $\sigma=[\sum_{i=1}^{7}(x_i-\bar{x})^2/6]^{1/2}$, where x_i referes to the bond distance or angle in the i-th glucose residue, and $\bar{x}$ is the average value.

disaccharides.[8–10] Distances between glycosidic oxygen atoms of adjacent glucose residues are in the range 4.25—4.46 Å. The average value of 4.36 Å is larger than that of the α-cyclodextrin complexes (4.23—4.25 Å). The torsion-angle indices[11] (Table 2) vary from 111.0° to 126.6°. A linear correlation between these values and O(4)···O(4) distances is shown in Fig. 5. Although the torsion-angle index and O(4)···O(4) distances are limited to a rather small region, the correlation is stronger than that found in the α-cyclodextrin complexes.

Seven glycosidic oxygen atoms form a distorted heptagon. The distances between the center of gravity of the seven O(4) atoms and each individual O(4) atom are in the range 4.91—5.10 Å with an average value of 5.02 Å. These O(4) atoms are roughly coplanar with a maximum deviation of 0.26 Å from their least-squares plane (Table 3). This deviation is larger than that observed in the β-cyclodextrin complexes which have a head-to-head dimer-type arrangement. The tilt-angles[12] of glucose residues were measured as the angle made by the O(4) plane and the plane through C(1), C(4), O(4), and O(4′) of each residue. Since the β-cyclodextrin ring is distored from the regular heptagon, the tilt-angles are not the same but vary within the

Table 2. Geometrical data for β-cyclodextrin

I. Radius of the O(4) heptagon.
The radius is measured from the center of gravity of seven O(4) atoms to each O(4) atom.

Residue	Radius l/Å	Residue	Radius l/Å
G1	5.10	G5	5.10
G2	5.00	G6	4.97
G3	4.91	G7	4.94
G4	5.09	Average	5.02

II. O(4)···O(4) distance between adjacent glucose residues.

	Distance l/Å		Distance l/Å
O(4,G1)···O(4,G2)	4.32	O(4,G5)···O(4,G6)	4.36
O(4,G2)···O(4,G3)	4.41	O(4,G6)···O(4,G7)	4.46
O(4,G3)···O(4,G4)	4.38	O(4,G7)···O(4,G1)	4.25
O(4,G4)···O(4,G5)	4.35	Average	4.36

III. Tilt-angle and torsion-angle index.[a,b]

Residue	Tilt-angle ϕ/°	Torsion-angle index ϕ/°
G1	7.5	125.0
G2	2.8	119.3
G3	21.1	122.0
G4	15.8	124.3
G5	5.7	120.8
G6	3.9	111.0
G7	23.1	126.6
Average	11.4	121.3

a) The tilt-angle is defined as an angle between the O(4) plane and the plane through C(1), C(4), O(4), and O(4′) of each glucose residue (see Ref. 12). b) The torsion-angle index is defined as: $|\phi(C(1)-C(2))|+|\phi(C(2)-C(3))|-|\phi(C(3)-C(4))|-|\phi(C(4)-C(5))|+|\phi(C(5)-O(5))|+|\phi(O(5)-C(1))|$, where $\phi(C(1)-C(2))$ is the conformation angle of O(5)-C(1)-C(2)-C (3) (see Ref. 11).

TABLE 3. LEAST-SQUARES PLANE THROUGH SEVEN O(4) ATOMS

The plane equation is of the $AX+BY+CZ=D$ form, where X, Y, and Z are the coordinates in Å units along the a, b, and c* axes, respectively.

$0.107X+0.984Y+0.144Z=4.966$

Atomic deviations

C(8,DO)–C(7,DO)–N(1,DO)	108(2)
C(7,DO)–C(8,DO)–N(4,DO)	112(2)

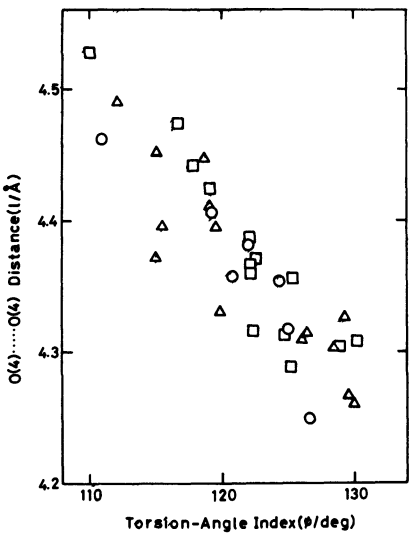

Fig. 5. Plot of the O(4)···O(4) distance against the torsion-angle index in β-cyclodextrin complexes with 1,4-DO (○) and 1-propanol (stable form △, unstable form □, see Ref. 13).

range 2.8—23.1°. The G2 and G6 residues are roughly perpendicular to the O(4) plane, while the G3 and G7 residues are inclined by angles of 21.2° and 23.1°, respectively, with the primary hydroxyl side nearer to the molecular axis.

β-Cyclodextrin-Guest Interaction. The guest 1,4-DO is situated near the secondary hydroxyl side in the β-cyclodextrin cavity, as shown in Figs. 1 and 2. The N(1) atom is located near the center of the cavity, while the N(4) atom located at the open end of the cavity is in contact with the neighboring β-cyclodextrin. The molecular axis through N(1) and N(4) does not coincide with the β-cyclodextrin axis, but inclines with the N(4) atom toward the G3 residue. The open space at the primary hydroxyl side is filled with three water molecules (W7, W8, and W13).

Bond distances and angles in 1,4-DO are shown in Table 4. The lengths of the chemically equivalent six C–N bonds vary from 1.40 Å to 1.48 Å with an average value of 1.45 Å, and the three C–C bonds are 1.57 Å. The C–N–C and C–C–N angles are in the range of 107—109° and 108—112°, respectively, and the corresponding average values are 108° and 110°. Figures 1 and 2 show that the hydrophobic methylene groups of 1,4-DO are in contact mainly with the hydrophobic surface in the host cavity. Most of these methylene

groups are in van der Waals contact with the C(3) and C(5) methine groups and the O(4) atoms of β-cyclodextrin, although the C(8) methylene group located near the open end of the cavity is in contact with the neighboring β-cyclodextrin. The hydrophilic nitrogen atoms are not in contact with the host molecule, but instead are hydrogen-bonded to water or to a hydroxyl group lying outside the cavity.

Molecular Packing and Hydrogen Bonds. β-Cyclodextrin is located with its molecular axis making an angle of 10.3° with the b axis. The molecules arranged parallel to the ac plane form the corrugated molecular layers, of which the crystal is constructed. The intermolecular spaces between these layers are filled by water molecules which link these layers by hydrogen-bond bridges. A similar molecular packing has been observed in the α-cyclodextrin complexes with *para*-disubstituted benzenes,[7] but this is the first one found in the β-cyclodextrin complex. Other β-cyclodextrin complexes whose structures have been determined have a channel-type structure with head-to-head dimer-type packing or a cage-type structure in which the molecules are arranged in a zigzag mode. The crystal structure of the present β-cyclodextrin complex may belong to a modified cage-type structure. But unlike the typical cage-type structure, both ends of the β-cyclodextrin cavity are not completely blocked by neighboring β-cyclodextrin molecules, as shown in Fig. 3. Although the guest 1,4-DO is almost fully inserted into the host cavity, the C(8)–H bonds protrude outside the cavity. This may prevent the close contact between β-cyclodextrin molecules, and causes β-cyclodextrin to be packed more loosely, as indicated by the comparison of cell volumes between uncomplexed β-cyclodextrin (3070.3 Å^3) and the present complex (3504.7 Å^3).

Figure 8 shows the hydrogen-bond network in the crystal. Hydrogen-bond distances and angles are given in Table 5. Adjacent glucose residues in β-cyclodextrin are linked by O(2)–H···O(3) or O(3)–H···O(2) hydrogen bonds. Both the O(2) and the O(3) hydroxyl groups of the G3 and G7 residues donate hydrogen atoms to the hydroxyl groups of the adjacent residues, while those of the G2 and G5 residues only act as hydrogen acceptors.

Neighboring β-cyclodextrin molecules are linked by hydrogen bonds directly or through water molecules. N(1) and N(4) atoms of 1,4-DO act as hydrogen acceptors; thus, they are the terminal points of the hydrogen-bond chains. Of thirteen water molecules, the W10 water molecule is disordered, having a major position W10A of occupancy 0.7 and a minor position W10B of occupancy 0.3. There are two pairs and three trios of water molecules, in which individual water molecules are linked to each other by hydrogen bonds: O(W1)···H–O(W3), O(W9)–H···O(W2)···H–O(W10A), O(W4)···H–O(W12), O(W7)–H···O(W5)–H···O(W11), and O(W6)–H···O(W13)–H···O(W8). An infinite hydrogen-bond chain consists of a repetition unit comprising five hydroxyl groups and five water molecules: [···H–O(6,G7)···H–O(W3)–H···O(W1)–H···O(6,G6)–H···O(W10A)–H···O(3,G6)–H···O(2,G5)–H···O(W11)–H···O(3,G1)–H···O(W9)···]. W2 links this chain and that related by the translation along the z direction (x, y, 1+z) by the O(W10A)–H···O(W2)···H–O(W9) bridge.

(Received December 26, 1981)

The crystal and molecular structure of the title compound has been determined by the X-ray diffraction method. The crystal is monoclinic, space group $P2_1/c$, $a=11.694(1)$ Å, $b=12.117(1)$ Å, $c=14.482(1)$ Å, $\beta=100.01(1)°$, and $Z=4$. The structure was solved by the direct method and refined by a block-diagonal least-squares procedure to a final R value of 0.082. An intramolecular hydrogen bond between the amide nitrogen and the methoxyl oxygen atoms forms a new six-membered ring fused with the benzene ring. Structural features are discussed in relation to neuroleptic activity.

Typical neuroleptic drugs are classified into five major types by their parent molecules, benzamide, butyrophenone, phenothiazine, benzo[6,7]cyclohepta[1,2,3-*de*]pyrido[2,1-*a*]isoquinoline and pyrido[4,3-*b*]indole. These are antagonists to dopamine receptors located on synaptic membranes.[1] The molecular mechanisms for dopamine antagonists have not been completely established yet, though many studies on the structure-activity relationships and conformational requirements for neuroleptic drugs have been reported.[2–11]

The title compound, *N*-[(2*RS*,3*RS*)-1-benzyl-2-methyl-3-pyrrolidinyl]-5-chloro-2-methoxy-4-methylaminobenzamide (YM-09151-2), is a potent dopamine antagonist** (Fig. 1), and in the present paper we described its three-dimensional crystal structure and discuss on its structural features in relation to neuroleptic activity.

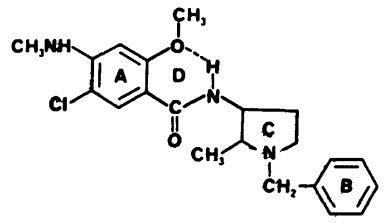

Fig. 1. Schematic structure of *N*-[(2*RS*, 3*RS*)-1-benzyl-2-methyl-3-pyrrolidinyl]-5-chloro-2-methoxy-4-methylaminobenzamide and the notation of each ring.

Experimental and Structure Determination

The title compound was prepared by the reaction of 5-chloro-2-methoxy-4-methylaminobenzoic acid with (2*RS*,3*RS*)-3-amino-1-benzyl-2-methylpyrrolidine as described in the previous paper.[13] It was recrystallized from acetone solution to give colorless plate crystals.

Preliminary Weissenberg photographs indicated a monoclinic space group $P2_1/c$. A crystal, $0.6\times0.3\times0.4$ mm in size, was used for data collection on a Rigaku automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). Accurate unit-cell constants were determined using 40 high angle reflections of the angular range of $20°<2\theta<30°$. Density was measured by flotation in a mixture of benzene and carbon tetrachloride. The crystal data were summarized in Table 1.

A complete set of independent reflections was collected within the angular range of $2°\leqq2\theta\leqq50°$ in the θ-2θ scan mode at scanning rate of 4° (2θ) min^{-1}. Stationary background counts were accumulated for 10 s before and after each scan. Five reference reflections showed no significant intensity deterioration throughout the data collection. A total of 3548 independent reflections were measured, of which 796 weak reflections below background were considered zero-reflections; the observational threshold value, F_{1lm}, was 2.12. The intensities were corrected for Lorentz and polarization factors, but not for absorption and secondary extinction. The standard deviations were estimated by the equation of $\sigma^2(F_o)=\sigma_P^2\times(F_o)+qF_o^2$, where $\sigma_P(F_o)$ was evaluated by counting statisitcs and $q(3.64\times10^{-5})$ was derived from the variations of monitored reflections.[14]

The structure was solved by the direct method. The refinement of the structure was carried out by block-diagonal least-squares calculations. All the hydrogen atoms found on a difference map were included. The quantity minimized was

** The affinity for the present molecule, as determined by [^3H]spiperone binding to the synaptic membrane obtained from canine caudate nucleus, exceeds apparently that for haloperidol by a factor of about 3 and that for chloropromazine by a factor of about 30.[12]

TABLE 2. FRACTIONAL COORDINATES AND ISOTROPIC TEMPERATURE FACTORS

The B values accompanied with 〈 〉 are the equivalent isotropic temperature factors calculated from anisotropic thermal parameters using the equation $B=8\pi^2(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are principal components of the mean square displacement matrix $\boldsymbol{U}$. Values in 〈 〉 are anisotropicity defined by $(\sum(B-8\pi^2U_i)^2/3)^{1/2}$. The e.s.d.'s in ( ) refer to last decimal places.

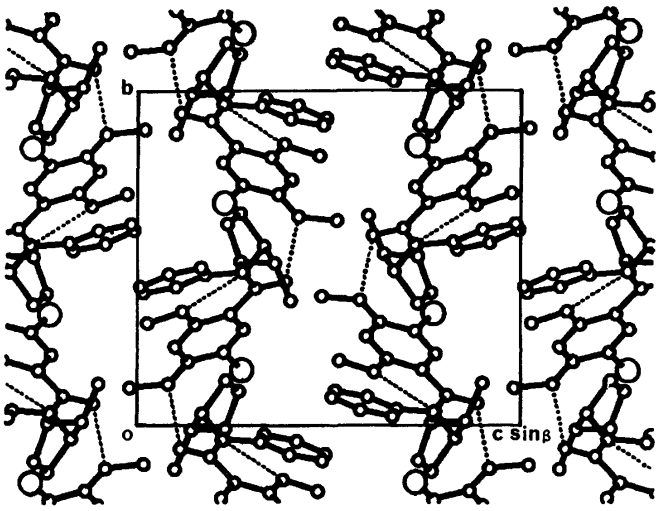

Fig. 2. Crystal structure of *N*-[(2*RS*, 3*RS*)-1-Benzyl-2-methyl-3-pyrrolidinyl]-5-chloro-2-methoxy-4-methylaminobenzamide projected along the a axis, and drawn by TSD:XTAL.[24]

$\sum w(|F_o|-|F_c|)^2$, with $w=1/\sigma^2(F_o)$. In the refinemetn procedure, the zero-reflections were assumed to be $F_o=F_{lim}$, but those for which $|F_c|<F_{lim}$ were omitted. The final R was 0.082; the maximum shifts of parameters in the last cycle were 0.3 σ for C, 0.2 σ for N, 0.07 σ for O, 0.01 σ for Cl and 0.9 σ for H atoms. Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[15] Atomic parameters are listed in Table 2.[16]

Results and Discussion

Crystal Structure. The crystal structure is shown in Fig. 2. An intermolecular hydrogen bond is observed between the amino nitrogen N(1) and the carbonyl oxygen O(2) in the molecule related by screw, the N(1)–O(2) distance being 3.059 Å. The other intermolecular contacts are all larger than the sum of the van der Waals radii. The molecules are arranged to form columns along the screw axis by mediating the intermolecular hydrogen bond system. Benzamide moieties are inner part of the column, whereas pyrrolidine rings and benzyl groups are protruded from it and dove-tailed with those of adjacent one. Thus the molecules have some mobility in the latter two parts, as indicated by rather large temperature factors.

Molecular Structure. The stereoscopic view of the molecule is shown in Fig. 3. The bond lengths and bond angles are shown in Fig. 4 together with numbering system. The lengths C(2)–C(3) and C(5)–C(6) are short in comparison with the other lengths in the ring, whereas angles C(2)–C(1)–C(6) and C(3)–C(4)–C(5) are somewhat small. Moreover, the lengths C(1)–N(1) and C(4)–C(9) are short. These results indicate that the molecule has the contribution of the quinonoidal form shown in Fig. 5. This should be related to the hydrogen bond between N(1) and O(2) as mentioned above. The benzene ring A is almost planar with maximum atomic deviation of 0.013 Å.[16] The *N*-methylamino, methoxyl, and carbamoyl groups attached to this ring also lie on the plane. Torsion angles in

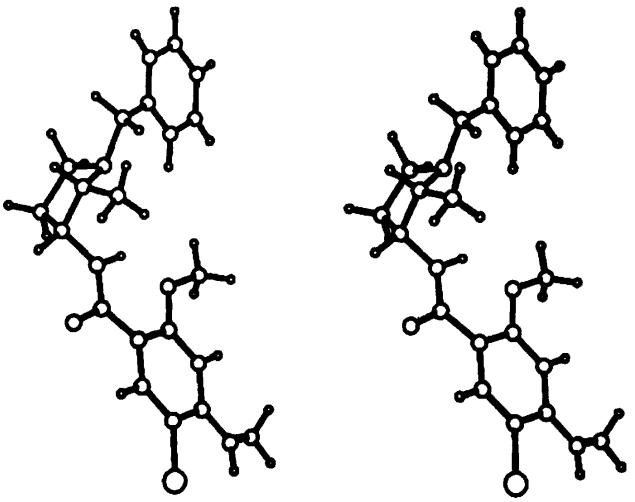

Fig. 3. Stereoscopic view of *N*-[(2*RS*, 3*RS*)-1-benzyl-2-methyl-3-pyrrolidinyl]-5-chloro-2-methoxy-4-methylaminobenzamide, drawn by TSD: XTAL.[24]

benzamide moiety are listed in Table 3.

An intramolecular hydrogen bond between the amide N(2) and the methoxyl O(1) (Fig. 6) forms a new six-membered ring (hereafter called as ring D) fused with the benzene ring A. This type of hydrogen bond is also observed in the benzamide neuroleptics such as metoclopramide[17] and sulpiride.[18] The N(2)–O(1) distance, 2.680 Å, is almost the same as that of metoclopramide, 2.683 Å.[17] The rings A and D are almost coplanar (the dihedral angle between them being 3.8°), and constitute a rigid part of this molecule.

The bond lengths and angles of the pyrrolidine ring do not differ significantly from those reported for the other related compound.[19] This ring has an intermediate conformation between the envelope and half-chair forms (deviations from the mean plane are −0.224, 0.326, −0.159, 0.177, and 0.039 Å for C(10), C(11), N(3), C(13), and C(14) atoms, respectively); the value of pseudorotation phase angle P is −9.85° (for the

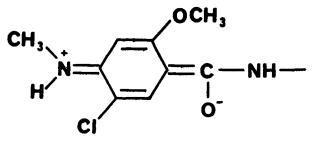

Fig. 5. Quinonoidal form of the benzamide moiety.

envelope conformation P is 18° or −18°, while for a half-chair P=0°).[20] Torsion angles of this ring are also given in Table 3. The methyl group and the acylamino group attached to this ring are in the same side about the least-squares plane of the ring, the internal rotation angle of these two groups around the C(10)–C(11) bond being 47.4° as shown in Fig. 7. On the other hand, the relative orientation of the methyl group and benzyl group is *trans*, to relax their steric repulsions. As a result, the molecule takes a rather folded conformation; the nitrogen lone pair lobe is buried by the methyl, methoxyl, and benzyl groups.

The torsion angle A–X–Y–B is the dihedral angle between planes AXY and XYB, measured clockwise when viewed down the bond X–Y.

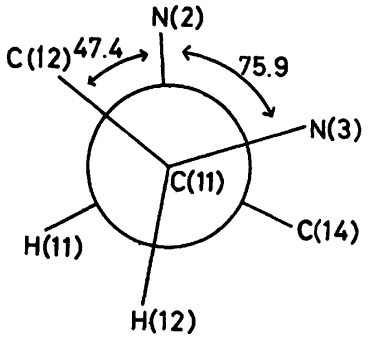

Fig. 7. Internal rotation angle along the C(10)–C(11) bond.

Bond angles in the benzene ring B are all close to 120°, but bond lengths are relatively shorter than 1.395 Å, probably due to the large thermal motions. This ring is almost planar with maximum atomic deviation of 0.014 Å.[16] The dihedral angle between this ring and the benzene ring A is 19.5°, so that these are nearly parallel. Relevant torsion angles are listed in Table 3.

Structure-activity Relationships. Every active neuroleptics ever known has at least a tertiary amino nitrogen atom and benzene or isosteric aromatic ring, and belong to one of the nine general structures classified by Janssen.[21] The present compound belongs to the class of the benzamide neuroleptic molecules with a common partial structure of the type A–C–N–C–C–N– (A= benzene or isosteric aromatic ring). Moreover, the present study reveals that this compound can also belong to another class with the type AA′–C–C–N– (AA′= indole or an isosteric aromatic fused ring structure), if the rings A and D are assumed to form an isosteric aromatic fused ring structure.

Geometrical parameters to express the relative arrangement of the benzene ring and the tertiary amino nitrogen atom have been used in the study of structure of neuroleptic drugs; the first is the distance, *l*, between the nitrogen atom and the center of the benzene ring, and the second is the deviation, *d*, of the nitrogen atom from the mean plane of the benzene ring.[8] Table 4 lists these parameters for the present molecule together with other typical neuroleptics. The distance, *l*, of the present molecule is almost the same as that of metoclopramide[17] and also compatible of those of the other classes of the neuroleptics. Moreover, the deviation, *d*, of the present molecule agrees with the values of the other neuroleptics except for chlorpromazine hydrochloride (for the active conformer of (+)-butaclamol,[8] see a foot-note of Table 4).

In addition to these two parameters, however, one more structural aspect should be taken into account. The tertiary amino nitrogen atom, common to all neuroleptic molecules should play an important role to be recognized by and interact with receptors. Since the nitrogen atom of the present molecule seemed to be buried, we calculated the accessible surface area of it.[23] The calculated area is zero. It suggests that the nitrogen lone pair lobe is unfavorable to interact with them and the present conformation may be different from that under the binding condition. A probable active conformer could be obtained by changing the pyrrolidine ring conformation so as to expose the nitrogen atom with retaining the two geometrical parameters.

Table 4. Geometrical parameters for typical dopamine antagonists

(Received December 28, 1981)

The crystal structure of 1′,1‴-dipropylbiferrocenium $(PrFcFcPr)^+I_3^-$, which shows averaged-valence irons at 298 K and trapped-valence irons at 110 K, was determined by X-ray diffraction. The crystal at 298 K is triclinic, space group $P\bar{1}$, $a=8.5148(8)$, $b=8.5482(5)$, and $c=10.9032(13)$ Å, $\alpha=89.546(9)$, $\beta=115.582(9)$, and $\gamma=108.488(7)°$, $U=671.10(9)$ Å^3, and $Z=1$. The crystal at 110 K is triclinic, space group P1, $a=8.431(2)$, $b=8.478(2)$, and $c=10.816(3)$ Å, $\alpha=88.58(3)$, $\beta=117.39(2)$, and $\gamma=108.65(2)°$, $U=643.4(3)$ Å^3, and $Z=1$. Structures were refined to $R=0.042$ at 298 K and $R=0.050$ at 110 K. At 298 K cation $(PrFcFcPr)^+$ sits on the symmetry center and the two Fc units are crystallographically equivalent, whereas at 110 K the symmetry center is lost and ferrocene-like and ferrocenium-like Fc units are distinguished. A three-dimensional hydrogen-bond network is clearly found between the cation and iodine atoms at 110 K, in contrast to the result at 298 K. Infrared spectra of 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium$^+I_3^-$a nd μ-(as-indacenyl)-bis(cyclopentadienyliron)$^+I_3^-0.5I_2$ salts measured at 294 and 78 K indicate that a remarkable change in peak intensity is observed at 680 and 1525 cm^{-1} in the dialkyl salts, whereas no change is found in the remainder.

A number of mono-oxidized salts of binuclear ferrocene derivatives have been investigated to clarify the electronic interaction between two metal sites and the electron transfer process,[1] especially in connection with Mössbauer spectroscopic behavior, electronic configuration, and magnetic and optical properties of these compounds. The compounds are classified roughly into two types: one is the mixed-valence or trapped-valence type which contains ferrocene-like bivalent and ferrocenium-like tervalent iron atoms, including biferrocenium$^+$,[2,3] diferrocenylacetylenium$^+$,[4] and diferrocenylselenium$^+$ [5] cations; the other is the averaged-valence type which contains equivalent iron atoms, including 1′,1‴-diiodobiferrocenium$^+$,[6] [2.2]ferrocenophane-1,13-diyne$^+$,[4] and biferrocenylenium$^+$ [7,8] cations.

Recently, it was reported that 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium$(PrFcFcPr)^+I_3^-$ salts and μ-[1-3a(8b)-η : 6-8a(5a)-η-as-indacenyl]-bis(η-cyclopentadienyliron)$^+I_3^-0.5I_2$ salt give rise to a transition from the averaged-valence state of iron atoms to the trapped-valence state as temperature is lowered.[9–11] In addition, in the latter salt the line-broadening of Mössbauer spectrum was observed at higher temperatures.

We determined the crystallographic change in $(PrFcFcPr)^+I_3^-$ at 298 and 110 K, in order to clarify whether or not the transition in cation $(PrFcFcPr)^+$ from the averaged-valence to the trapped-valence state is accompanied with structural changes and how anion I_3^- affects this transition. It has been known that unsubstituted cation biferrocenium$^+$ shows a temperature-independent trapped-valence state, whereas cation 1‴,1′-diiodobiferrocenium$^+$ shows a temperature-independent averaged-valence state. The present paper also provides information concerning the effect of the propyl group on the electronic state of the cation.

Although Mössbauer spectroscopy can distinguish whether or not the rate of the thermal electron transfer between two iron atoms in these salts is higher than *ca.* 10^7 s^{-1}, infrared spectroscopy involves a different time scale of *ca.* 10^{13} s^{-1}. By comparing infrared spectra of 1′,1‴-diethyl and 1′,1‴-dipropylbiferrocenium$^+I_3^-$ salts and μ-(as-indacenyl)-bis(cyclopentadienyliron)$^+I_3^-0.5I_2$ salt at 294 and 78 K with Mössbauer spectra, the difference in electronic state between these salts is discussed.

Experimental

X-Ray Measurements. Crystals in dark-red thin plate were sealed into Lindemann-glass capillaries filled with Ar gas, since they will break down when exposed to air. Preliminary oscillation and Weissenberg photographs were taken at room temperature by using Cu *Kα* radiation. The crystal was determined to be triclinic. The space group was later confirmed to be $P\bar{1}$ at 298 K and P1 at 110 K by structure refinements. The final unit cell dimensions are refined by the least-squares method based on θ values of 27 reflections at 298 K and of 18 reflections at 110 K.

The cooling equipment was constructed of stainless steel according to the description by Bolhuis.[12] Crystal specimens were cooled by a stream of cold N_2 gas which was surrounded by warmer N_2 gas. Temperature was maintained at 110 ± 1 K electrically by monitoring with a chromel-almel thermocouple throughout the experiment.

Intensities were collected on an automated four-circle diffractometer with Ag *Kα* radiation monochromated by graphite. The absorption coefficient of elements for Ag *Kα* radiation is about half as large as that for Mo *Kα* radiation. Three standard reflections were observed every fifty reflections. Correction was made for Lorentz and polarization effects and for absorption. Crystal data and experimental conditions are summarized in Table 1.

Infrared Measurements. Infrared spectra were recorded

on a Fourier-transform spectrometer (NICOLET 7199). All samples were prepared as KBr pellets 13 mm in diameter. For low temperature measurements, the sample mounted in a holder was cooled by a copper plate linked to liquid nitrogen in a Dewar with KRS-5 windows.

Structure Determination

High-temperature Phase (298 K). The structure was solved by the conventional heavy-atom method. The positions of Fe and I atoms were deduced from sharpened Patterson maps. Successive three-dimensional Fourier syntheses phased by these atoms yielded the positions of all C atoms. Difference Fourier maps clarified not only the positions of H atoms but also the existence of rotational disorder of propylcyclopentadienyl ring. Several cycles of full-matrix least-squares refinements were carried out by using the RADIEL program.[13] The population of disordered propylcyclopentadienyl was also refined so as to converge to the ratio 75 : 25. Anisotropic thermal parameters were used for non-hydrogen atoms and isotropic thermal parameters for hydrogen and carbon atoms of disordered propylcyclopentadienyl with low population. Atomic scattering factors for non-hydrogen atoms were taken from International Tables for X-Ray Crystallography,[14] and those for H atoms from Stewart *et al.*[15] Unit weights were adopted for all reflections. Refinements led to a convergence of $R=0.042$. Final atomic parameters are given in Table 2.†††

Low-temperature Phase (110 K). The starting coordinates of the low-temperature phase could readily be deduced from the atomic coordinates of the high-temperature phase. Several cycles of full-matrix least-squares refinements reduced the R value to 0.064 for the structure with space group $P\bar{1}$ without disorder. At this stage, difference Fourier syntheses showed not only rotational disorder of propylcyclopentadienyl but also positional disorder of triiodide. Refinements with these disorders considered gave $R=0.055$. The space group was assumed to be P1 with no symmetry center. The structure was assumed to consist of a ferrocene-like divalent unit and ferrocenium-like tervalent unit for cation $(PrFcFcPr)^+$. Anisotropic thermal parameters were used for the I, Fe, and C atoms of fulvalene moiety and isotropic thermal parameters for the C atoms of disordered propylcyclopentadienyls and H atoms. The populations of two types of disorders were also refined and R was converged to 0.050. The final difference Fourier maps showed peaks of about 1.0 eÅ^{-3} near anion I_3^-. The final atomic parameters are tabulated in Table 3.†††

Results and Discussion

Description of Crystal Structure. High-temperature Phase: Packing: Projections of the structure in the high-temperature phase along the a and c axes are shown in Figs. 1 and 2. $(PrFcFcPr)^+$ cations are stacked along the c axis in a plane-to-plane manner to form a column. The structure is dominated by segregated columns of cation $(PrFcFcPr)^+$ and anion I_3^-. The column of anion I_3^- is surrounded by four columns of the cations. The cation and anion are interacted by van der Waals' force between hydrogen atoms of the cation and iodine atoms as shown in Table 4. Figures 3(a) and (b) show packing views in the high- and low-temperature phases, respectively. Five-membered rings of propylcyclopentadienyls between neighboring $(PrFcFcPr)^+$ cations overlap as shown in Fig. 4(b). Their interplanar distance is 3.47(2) Å and an intermolecular interaction is expected

††† Lists of structure factors and anisotropic thermal parameters in the high- and low-temperature phases and atomic parameters of hydrogen atoms in the low-temperature phase are kept in the Chemical Society of Japan as Document No. 8238.

to exist between the neighboring cations.

Structure of Cation (PrFcFcPr)$^+$: Each iron atom in a cation (PrFcFcPr)$^+$ is sandwiched by five-membered rings in *trans*-configuration. The cation sits on a symmetry center and the two Fc units are crystallographically equivalent. Therefore, electronic states of the two iron atoms are expected to be in an averaged-valence (+2.5) state. The interplanar distance between the two five-membered rings in a Fc unit is 3.33(2) Å and their dihedral angle is 6.6°. This ring-ring distance in the ferrocene-like unit was found to be 3.32 Å in the unoxidized compound biferrocene[16] and 3.277(19) Å in the trapped-valence salt diferrocenylselenium$^+$ iodine triiodide$^-$ hemi(dichloromethane),[5] whereas that for ferrocenium-like unit 3.40 Å in ferrocenium$^+$ tetrachlorobismuthate$^-$ [17] and 3.397(22) Å in cation diferrocenylselenium$^+$. Distances of the iron atom from the least-squares planes of two five-membered rings are found to be 1.656(5) Å for the fulvalene moiety and 1.678(13) Å for the propylcyclopentadienyl ring. Bond distances and bond angles are given in Table 5. Mean bond distances between the iron atom and five carbon atoms are 2.047(9) and 2.072(16) Å for the inner and outer rings, respectively. The mean distance between them is 2.059 Å, which lies midway between 2.045 Å for molecule ferrocene[18] and 2.075 Å for cation ferrocenium$^+$.[17]

The propylcyclopentadienyl ring is found to be

rotationally disordered, with two sites in population ratio 75 : 25, as shown in Fig. 4(a). The two sites are related to each other by a pseudo-mirror plane normal to the fulvalene moiety and passing through the C(5)–C(5′) bond. The outer ring with the high population and the five-membered ring of the fulvalene moiety are mutually displaced by about 0.5 Å in their gravity centers, are mutually rotated away from the eclipsed

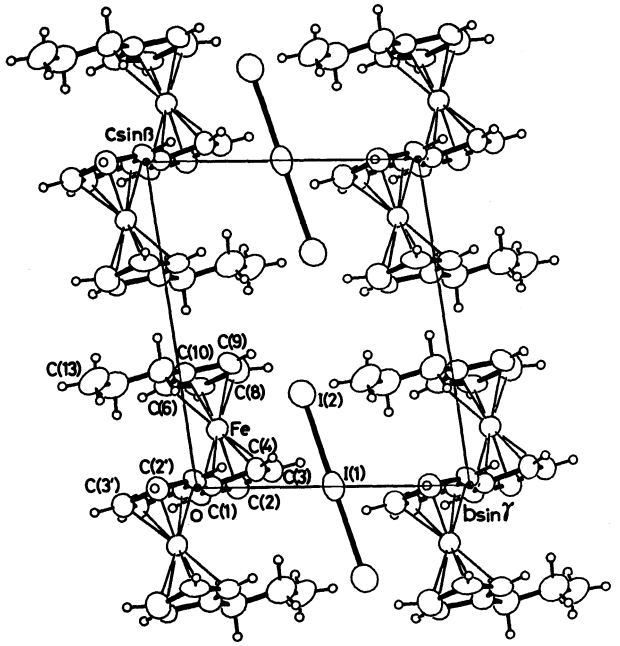

Fig. 1. The projection of the structure for the high-temperature phase (298 K) along the a axis.

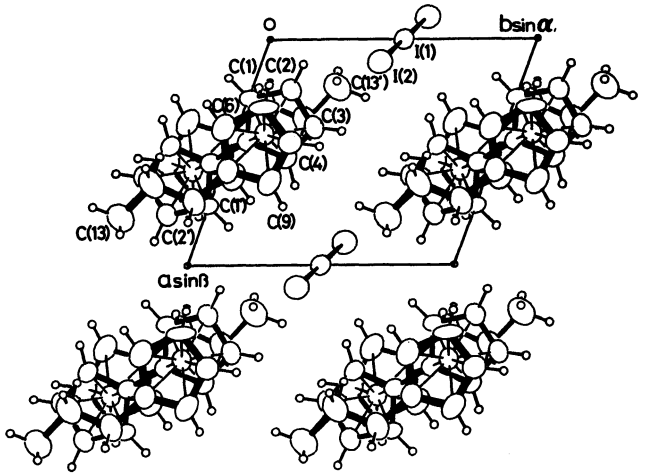

Fig. 2. The projection of the structure for the high-temperature phase (298 K) along the c axis.

conformation by 10° in the mean value, and remain in a nearly eclipsed conformation. On the other hand, for the site with the low population the Fc unit is rotated in the opposite direction by about 15° and is about midway between eclipsed (0°) and staggered (36°) positions. Molecule ferrocene is known to take a nearly eclipsed conformation with a rotational angle of 9° in the disordered high-temperature phase and in the ordered low-temperature phase.[18,19] Rotational angles were observed to be 17, 3.6, 5.2, and 4.1° for biferrocene, 1′,1‴-diethylbiferrocene, 1′,1‴-dichlorobiferrocene, and 1′,1‴-diacetylbiferrocene,[16,20-22] respectively.

Data of some least-squares planes and deviations of atoms from their planes are given in Table 6. The dihedral angle between the planes of five-membered ring and propyl group within propylcyclopentadienyl is 3.5° and they sit essentially coplanar. The propyl group is also parallel to the fulvalene plane and sits at the position above the ring of the other sandwich of the fulvalene moiety deviating from the ideal position overlapped between their C–C bonds. This is in contrast to the unoxidized compound 1′,1‴-diethylbiferrocene, in which the ethyl group is not parallel to the fulvalene moiety and stands away from it.[20] Hydrogen atoms H(11a) and H(12a) in the propyl group are situated at 2.77(12) and 2.86(12) Å from the least-squares plane of the fulvalene moiety. There seems to exist a strong interaction within the cation between the propyl group

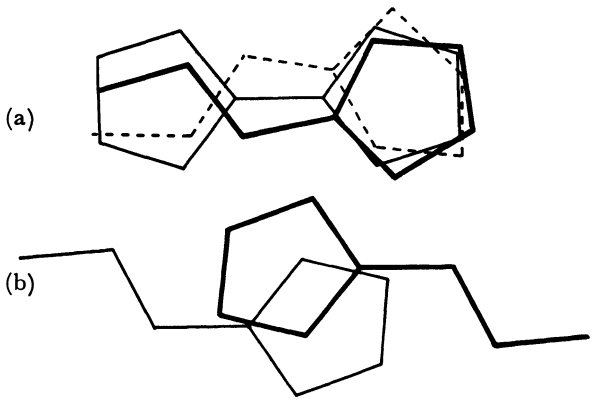

Fig. 4. Overlap between rings for the high-temperature phase.
(a) The projection of a disordered propylcyclopentadienyl along the normal to the plane of a fulvalene moiety (—— for the site with the high population and ------ for the site with the low population). (b) The projection of a propylcyclopentadienyl of a neighbouring $(PrFcFcPr)^+$ cation along the normal to the plane of a propylcyclopentadienyl.

and the fulvalene moiety in the high-temperature phase.

The mean C–C bond distances in the inner and outer five-membered rings are 1.413(4) and 1.428(18) Å, respectively, and the outer ring shows larger thermal vibrations. This distance agrees with 1.425 Å observed in compound ferrocene at 169 K.[18] The C(5)–C(5′) bond distance in the fulvalene moiety is 1.46(2) Å.

Anion I_3^-: The triiodide anion is at the symmetry center, showing a symmetric structure. The I(1)–I(2) bond distance is 2.926(1) Å corresponding to 2.920 Å in free I_3^- ion.[23]

Low-temperature Phase (110 K): *Packing*: Figure 3(b) shows a packing view at 110 K. The structure is constructed by segregated columns of cation $(PrFcFcPr)^+$ and anion I_3^- similarly to that in the high-temperature phase. A three-dimensional hydrogen bond network is clearly found between the hydrogen atoms of a cation and the iodine atoms, in contrast to that at 298 K. Short contacts are found in the data given in Table 4. The interplanar distance of five-membered rings between neighboring cations is 3.40(4) Å, which is shorter by 0.07 Å than that at 298 K.

Structure of Cation $(PrFcFcPr)^+$: The symmetry center is lost and ferrocene- and ferrocenium-like units are crystallographically discernible in the cation. Their ring-ring distances are 3.28(4) and 3.41(5) Å for ferrocene- and ferrocenium-like units, respectively. These values are in agreement with 3.277(19) Å for the ferrocene-like unit and 3.397(22) Å for the ferrocenium-like unit in the trapped-valence cation diferrocenylselenium$^+$ [5] and 3.291—3.320 Å for three ferrocene-like units and 3.428 Å for a ferrocenium-like unit reported for ferricenyl(III) tris(ferrocenyl(II))borate.[24] The mean bond distances of Fe(2)–C and Fe(1)–C are 2.04(3) and 2.11(2) Å for the ferrocene- and ferrocenium-like units, respectively.

The rotational disorder of the propylcyclopentadienyl rings remains at 110 K but the population increases from 0.75(2) to 0.90(4) and 0.82(4) in the sites having the high population in the ferrocene- and ferrocenium-like units, respectively.

Anion I_3^-: The triiodide anion sits at the regular position at 298 K, whereas it exhibits a positional disorder with population ratio 0.90 : 0.10 at 110 K. When the propylcyclopentadienyl ring changes its position from the site with the low population to that with the high population, the propyl group ought to rotate around the C(10)–C(11) bond. As this rotation gives rise to a short contact between the propyl group and iodine atoms, the I_3^- anion seems to move away from the propyl group, and the I_3^- anion causes a positional disorder with population ratio 0.90 : 0.10. Bond distances of I(1)–I(2) and I(1)–I(3) are found to be 2.948(8) and 2.902(7) Å, respectively.

Infrared Spectroscopy. Infrared spectral data obtained at 294 and 78 K are shown in Table 7. No

difference is found in the infrared spectral shapes for the two unoxidized compounds between 294 and 78 K, except for the narrowing of band width found at 78 K.

μ-(as-Indacenediyl)-bis(cyclopentadienyliron) System: Infrared spectra of the unoxidized molecule and mono-oxidized salt are illustrated in Fig. 5. The spectra of the mono-oxidized salt as well as the unoxidized molecule show no change at 294 and 78 K. A discernible difference between the infrared spectra of the unoxidized and mono-oxidized species is found in the band region from 400 to 500 cm^{-1} and in the bands in the vicinity of 800 cm^{-1}. By analogy with ferrocene,[25] the 470 cm^{-1} band of the unoxidized molecule may be assigned to the asymmetric ring-metal-ring strech and the 485 cm^{-1} band to the asymmetric ring-metal-ring tilt. These bands are reduced in intensity in the mono-oxidized salt as compared with the unoxidized molecule. A similar tendency was also observed in the ferrocene system.[26] The bands in the vicinity of 800 cm^{-1} can be assigned to the perpendicular CH bend. Although it was observed by means of Mössbauer spectroscopy that the mono-oxidized salt gradually undergoes a transition from an averaged-valence state of iron atoms to a trapped-valence state as temperature was lowered, infrared spectra of this salt is found to be temperature-independent. Supposing that the rate of electron transfer between two iron atoms is higher than the time scale of Mössbauer spectroscopy (*ca.* 10^7 s^{-1}), is lower than that of infrared spectroscopy (*ca.* 10^{13} s^{-1}) at room temperature, and becomes lower than 10^7 s^{-1} at 78 K, the results may be considered not to be in contradiction to the observation of line broadening at higher temperatures found in Mössbauer spectroscopy.[9,10]

1′1‴-Diethyl- and 1′,1‴-Dipropylbiferrocene System: Infrared spectra of the mono-oxidized salts of diethyl- and dipropylbiferrocene are similar except for the band at 736 cm^{-1}, which appears in cation dipropylbiferroce-

Table 7. Comparison between infrared spectral data and Mössbauer spectral data

Compound	Tmperature/K	Infrared spectra	Mössbauer spectra[9-11]
μ-(as-Indacenediyl)-bis-(cyclopentadienyliron)	294 78	No change	
1′,1‴-Diethylbiferrocene	294 78	No change	
μ-(as-Indacenyl)-bis(cyclopentadienyliron)$^+I_3^-$ 0.5 I_2	294 78	No change	Averaged-valence Trapped-valence
1′,1‴-Diethylbiferrocenium$^+I_3^-$	294 78	Remarkable change in intensity of bands at 680 and 1525 cm^{-1}	Averaged-valence Trapped-valence
1′,1‴-Dipropylbiferocenium$^+I_3^-$ (PrFcFcPr)$^+I_3^-$	294 78	Remarkable change in intensity of bands at 680 and 1525 cm^{-1}	Averaged-valence Trapped-valence

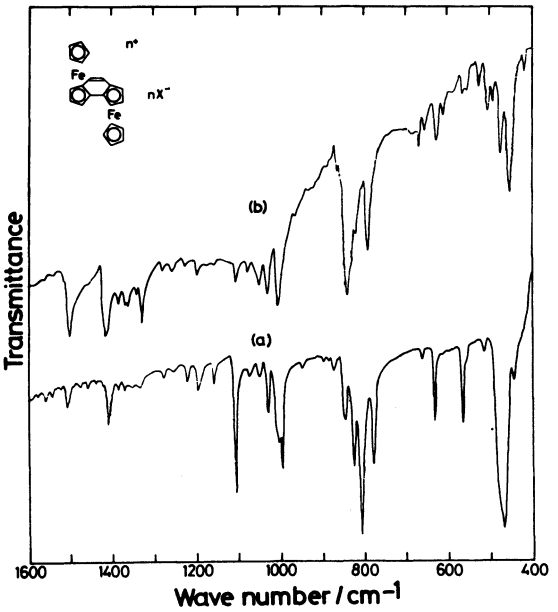

Fig. 5. Infrared spectra of KBr pellets of (a) μ-(as-indacenediyl)-bis(cyclopentadienyliron) at 294 K (n=0, X= none) and (b) μ-(as-indacenyl)-bis(cyclopentadienyliron)$^+I_3^-$ 0.5I_2 at 78 K (n=1, X=I_3-0.5I_2).

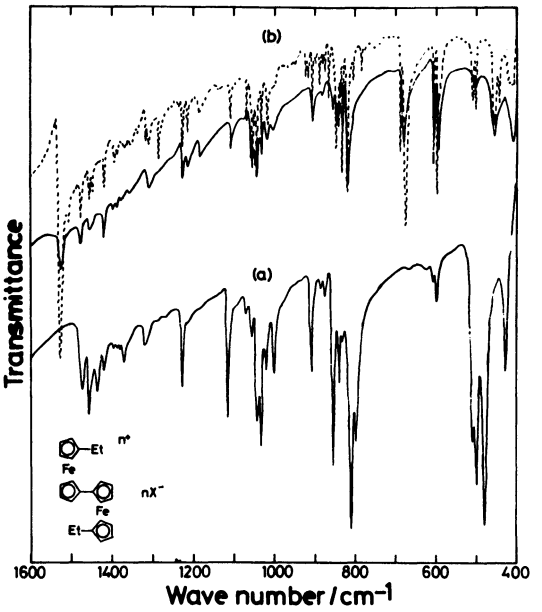

Fig. 6. Infrared spectra of KBr pellets of (a) 1′,1‴-diethylbiferrocene at 294 K (n=0, X=none) and (b) 1′,1‴-diethylbiferrocenium$^+I_3^-$ at 294 K (——) and 78 K (------) (n=1, X=I_3^-).

nium$^+$, attributable to the propyl group. Figure 6 shows spectra of diethylbiferrocene and its mono-oxidized salt. A discernible difference between these two species is observed in the band region from 400 to 500 cm^{-1} and in the bands around 800 cm^{-1}, similarly to the case of μ-(as-indacenediyl)-bis(cyclopentadienyliron) and its mono-oxidized cation. However, these bands change in the mono-oxidized salt, depending on temperature. It should be noted that new intense bands appear at 680 and 1525 cm^{-1} on going from the unoxidized molecule to the mono-oxidized salt. These bands are remarkably larger at 78 K than at 294 K. The band at 680 cm^{-1} seems to be assigned to the fulvalene moiety, because it is observed that a new band appears at 674 cm^{-1} in the biferricenylenium$^+PF^-_6$ salt with two fulvalene moieties.[6]

Conclusion

According to the results of infrared spectra and Mössbauer spectra,[11] the electrons in the (PrFcFcPr)$^+I_3^-$ salt are fully delocalized above the transition point (240 K), whereas below the transition temperature the salt has its electrons localized more in one Fc moiety than in the other. At 78 K, the electrons are almost localized and the ferrocene- and ferrocenium-like conformations become observable. The result of crystal structure suggests that a strong interaction within the cation is found between the propyl group and fulvalene moiety and the electrons get delocalized easily through the fulvalene moiety in consonance with this interaction, whereas at 110 K a three-dimensional hydrogen bond network is formed between the cation and iodine stoms, causing the interaction between the propyl group and fulvalene moiety to get weaker and the electrons to get localized. It was reported that the transition temperatures of 1′,1‴-diethylbiferrocenium$^+$-I_3^- and (PrFcFcPr)$^+I_3^-$ are 270 and 240 K, respectively. If the interaction between the substituent and fulvalene moiety brings about easier delocalization of electrons between the two iron atoms, the propyl group is expected to cause a stronger interaction than the ethyl group, and accordingly, to make the transition point from the averaged-valence state to the trapped-valence state lower in dipropyl- than in diethylbiferrocenium$^+$ cation.

The reason why the unsubstituted biferrocenium$^+$ cation is in a temperature-independent trapped-valence state, is also interpreted similarly by assuming an absence of this kind of interaction with the fulvalene ring. It should be mentioned that the interaction between the cation and the anion also has much to do with the electronic state of the cation.

In cation μ-(as-indacenyl)-bis(cyclopentadienyliron)$^+$, the electrons hop faster between the two iron atoms as temperature is raised. This indicates that the resonance energy is not large enough to delocalize the electrons between the two iron atoms.

We thank Professor Hirotoshi Sano of Tokyo Metropolitan University for his helpful suggestions and discussions. We also thank the late Professor Tsunetake Fujiyama of the Institute for Molecular Science for his valuable advice, discussions, and kind permission to use the infrared instruments. This work was partially supported by the Joint Studies Program (1981) of the Institute for Molecular Science.

Phase Transition in Concentrated Latices and the Electrical Double Layer on Their Surfaces

Kunio FURUSAWA* and Satoshi YAMASHITA
Department of Chemistry, The University of Tsukuba, Sakura-Mura, Ibaraki 305
(Received January 21, 1982)

The phase diagrams of monodisperse latices were constructed under the various conditions. The variable of the phase diagrams, the particle size, the surface charge densities of the latices, the counter-ion valences, and the medium temperature were taken up. The results, especially, the coexistent/ordered boundary curves were analysed in terms of the closed packing of the effective particle volumes which consisted of the latex particles which were surrounded by the electrical double layer. The value of 1.5 kT ergs† of electrical repulsion, when used as a criterion in the DLVO potential to back-calculate the weight fraction of solid contents as a function of KCl concentration, yields a curve that is very similar to the experimental boundary curve. The same agreement was found in the curves mapped out for the other latices with a different particle size and a different surface charge density using KCl as an electrolyte. In the boundary curve constructed using $MgCl_2$, however, the agreement with the analyses was not enough where the divalent cation would be adsorbed preferentially on their surfaces as a Stern layer charge. The temperature effect could be reasonably explained by the same procedure.

Monodisperse polymer latices which usually appear milky white, exhibit beautiful irridescent colours under a certain condition. This irridescence is due to the Bragg reflection of visible light by the orderly arrays of the uniform spherical particles of latices.[1]

To date, several attempts have been made to give a reasonable explanation as to their order-disorder phase transitions. One explanation is based on the double layer interactions between the particles:[2,3] The latex particle in an aqueous system may be regarded as an effective particle volume whose size is determined by the thickness of an electrical double layer on its surface and the boundary curve between the ordered and coexistent states corresponds to the closed packing of the effective particle volumes with a critical thickness of an electrical double layer.

Another approach is based on the concept of the Kirkwood-Alder transition[4] which is expected only from the pure computer calculations. Their approach accounts for the presence of reasonable coexistent states of ordered and disordered structures.[5]

The problem is that these analytical works have been performed using very limited experimental data and only a few authors have mapped out the phase diagrams by themselves. In this work, the conditions for the occurrence of ordered and disordered structures were studied systematically under the various conditions. As the parameters of the phase diagram, the particle size and the surface charge densities of latices, the valency of added counter ions, and the medium temperature were taken up. Thereafter, the resulted phase diagrams, especially, the coexistent/ordered boundary curves were analysed according to the concept of closed packing of the effective particle volumes using the DLVO theory.[6]

Experimental

Latex Samples. In this work, three kinds of polystyrene latices were employed. Sample-A was prepared by an emulsion polymerization using sodium dodecyl sulfate as an emulsifier and $K_2S_2O_8$ as a polymerization initiator. Sample-B and -C were polymerized in the absolute absence of conventional emulsifiers.[7] Table 1 shows their preparation conditions and the characteristic results. The particle diameters were determined by measuring the diameters on an electron micrograph which was equipped with a projection scope. The diameters for Sample-A and -C are almost the same, and the diameter for Sample-B is about threefold more than either of the other two. Size distribution of these samples is kept very narrow, with $D_w/D_n < 1.01$.

The surface charge densities of these latices were determined by potentiometric and conductometric titrations according to the method described by Van den Hul and Vanderhoff.[8] The charge densities for Sample-A and -B are not so different, but the density is extremely high for Sample-C which is prepared by incorporating a small amount of ionic comonomer (sodium *p*-vinylphenylsulfonate) into the polystyrene chains.[9]

All samples were dialysed fully against pure water, and deionized by the ion-exchange resins to remove the ionic impurities, and then they were condensed by ultrafiltration using a Visking tube up to 30% of solid contents by the volume

TABLE 1. PREPARATION AND CHARACTERIZATION OF POLYSTYRENE LATICES

Sample	Polymerization conditions			Characterization		
	Styrene (g dm^{-3})	Svps[a] (g dm^{-3})	$K_2S_2O_8$ (g dm^{-3})	Diameter $2a$ / Å	Surface charge σ_0 / μC cm^{-2}	ζ-Potential / mV (25 °C, 10^{-3} mol KCl)
A	1.5×10^2	—	0.5	1960	0.9	−42

† 1 erg = 10^{-7} J.

fraction.

Electrophoresis. The electrophoretic measurements of the latex samples were performed in a Rank Brothers micro-electrophoresis apparatus, using a rectangular cell. A complete parabolic curve for the velocity as a function of cell depths was measured on each sample and electrophoretic mobility(particle velocity at the level of zero liquid flow) was given at the reproducibility in samll percentages. The mobility of the particle was measured in various concentrations of KCl and $MgCl_2$. Also, the measurements were conducted under the different medium temperatures. Zeta-potential for the particle in each condition was calculated from the electrophoretic mobility with an allowance of Henry correction (if possible, Wiersema correction[10] was applied). The typical results obtained at 40 °C are shown in Fig. 1, in the form of a curve of zeta-potential against the molar concentration of each electrolyte.

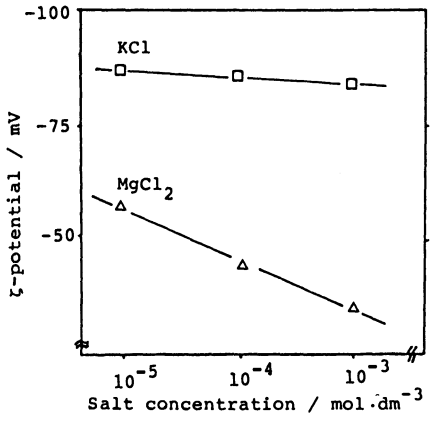

Fig. 1. Curves of zeta-potential of polystyrene latex (Sample-C) against molar concentration of salts at 40 °C.

Phase Diagrams. The conditions for the occurrence of ordered and disordered structures were measured using a slight modification of the method described by Hachisu *et al.*[5] The modification is related to the equilibration time of sample and the short equilibration took in this work brought about a reasonable removal from gravitational effect of the latex samples. The concentrated latices were diluted in Pyrex-stoppered vials of 10 cm^3 to desired solid content levels with some salt solutions of several concentrations, and left in the thermostat which was kept at various temperatures. After 3 d (Hachisu's work took the equilibration of 2 weeks), the conditions for the occurrence of ordered and disordered structures were studied making use of the irridescence exhibited by the ordered structures as an indicator.

In relation to the electrical double layer effects, phase diagrams were constructed with the volume fractions of solid content as the ordinate and log molar concentrations of electrolyte in the medium as the abscissa.

Results and Discussion

The phase changes in the monodisperse latices are depicted schematically in Fig. 2. Under a constant volume of solid, at high electrolyte concentrations, the electrical double layer around each particle is thin, the particles do not interact with each other and are distributed randomly (Fig. 2a). Decrease in electrolyte concentration leads to an increasing effective radius of the particle, and at a definite point, the interaction between the paticles becomes more favourable energetically to accommodate some of these particles in an ordered state which corresponds to the disordered/coexistent boundary state as shown in Fig. 2b. The existence of this state would be based on thermodynamic reasons where the entropy of the system is minimized by creating coexistent regions rather than going directly to an ordered state.[3] As the electrolyte concentration is further reduced, the system steadily increases the fraction of the ordered state (Fig. 2c), and finally the effective particle volumes are all in the closed-packed ordered arrangement as shown in Fig. 2d which is called a coexistent/ordered boundary state. In the present experiment, this coexistent/ordered boundary is thought as an important criterion and analysed in the terms of closed packing of effective particle volumes of the latex particles using the DLVO theory. Also, a further decrease in the electrolyte concentration leads to an overlap of the effective particle volumes (Fig. 2e), and then strong repulsive potentials will build up.

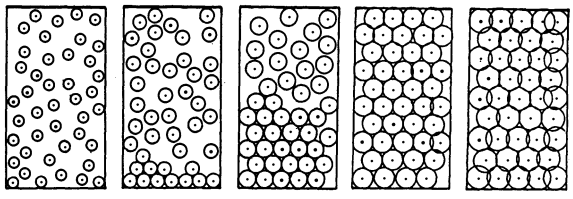

Fig. 2. Schematic representation of the phase changes in a monodisperse latex.
b: Disordered/coexistent boundary, d: coexistent/ordered boundary.

The size of the effective volumes at the coexistent/ordered phase boundary will be related to the particle separation at which some critical electrostatic repulsions are operating; the separation distances, (H), are calculated using the following relation in assuming that the particles in ordered phase are arranged in a hexagonal array.[3]

$$H = 2a[V_f(1 + \rho_p/\rho_s(1/\phi - 1))^{1/3} - 1], \quad (1)$$

where a is the radius of the particles, ρ_p and ρ_s the densities of the particles (1.05 g/ml for polystyrene) and the suspending fluid (1.00 g/ml for water), and ϕ the critical volume fraction at the coexistent/ordered phase boundary, and V_f is the packing density for a closed-packed arrangement, thus the value of 0.74 was chosen for regularly closed-packed spheres.

Furthermore, the interparticle distances at the critical boundary state can be estimated using the DLVO theory by assuming that at such a condition some definite repulsive energies which may be comparable to the thermal energies, are operating to maintain the ordered structures. As the formula to estimate the double layer potential, a following relation derived by Overbeek was employed.[6]

$$V_R = 3.469 \times 10^{19}\varepsilon(kT)^2(a\gamma^2/z^2)\exp(-\kappa aH)$$
$$\kappa = (8\pi nz^2e^2/\varepsilon kT)^{1/2} \quad (2)$$
$$\gamma = [\exp(ze\psi_o/2kT) - 1]/[\exp(ze\psi_o/2kT) + 1]$$

in the above equation, ε is the dielectric constant of the

medium, k the Boltzmann constant, T the absolute temperature, z the valency of the counter ion, n the counter ion density, e the elementary charge and ψ_0 the surface potential of the particles. If we assume the values of critical potential to maintain the ordered structure, the interparticle distances(H) can be calculated from Eq. 2, and, by introducing the H-values into Eq. 1, we can back-calculated the weight fraction of the solid(ϕ) as a function of electrolyte concentration-(n) through Eq. 2. Hereafter, the boundary curve calculated following the above process would be called an analytical boundary curve. In Fig. 3 the analytical

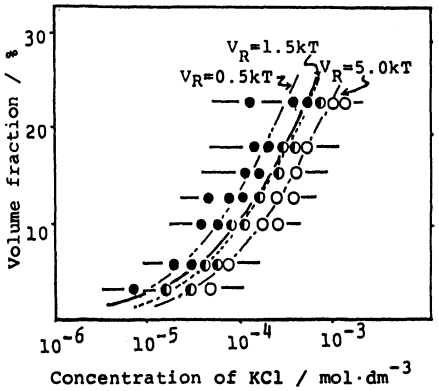

Fig. 3. Phase diagram of Sample-A ($2a$=1960 Å, σ_0= 0.9 μC cm^{-2}) constructed using KCl at 25 °C.
●: Ordered state, ○: disordered state, ◐: coexistent state. Each curve shows the experimental (——) and the analytical coexistent/ordered boundary curve assuming the various critical potentials; (-·-·-): V_R= 0.5 kT, (------): V_R=1.5 kT, (-···-···-): V_R=5.0 kT.

boundary curves with the experimental phase diagram of Sample-A, using KCl as the electrolyte, are compared. Each analytical line shows the calculated phase boundary for respective critical V_R which is illustrated on the figure. In this calculation, ζ-potential measured at the respective salt concentration was employed in place of ψ_0 in Eq. 2. As can be seen from Fig. 3, 1.5 kT ergs as a criterion of V_R yields a curve that closely fits the experimental coexistent/ordered boundary curve and the accordance attains the whole electrolyte levels examined. According to the computer analyses for the nature of the potential well in ordered state, revealed that with only 0.5 kT of interaction between the individual particles, it would require more than 8 kT to escape from the twelve nearest neighbours.[3] Under such an analysis, the value of 1.5 kT ergs estimated by the present calculation is a significant barrier as a criterion for the phase transition.

This critical value of 1.5 kT ergs is also confirmed by the direct observation study on the interparticle distances in the ordered state near the phase boundary.[11]

This analytical procedure may be used to predict the effect of the particle size, the surface potential, the valency of counter ion and the temperature of the medium on the phase boundary curves, since the interparticle potential between the particles varies also by these variables. To see the effects of the particle size, Fig. 4 shows a comparison of the experimental and

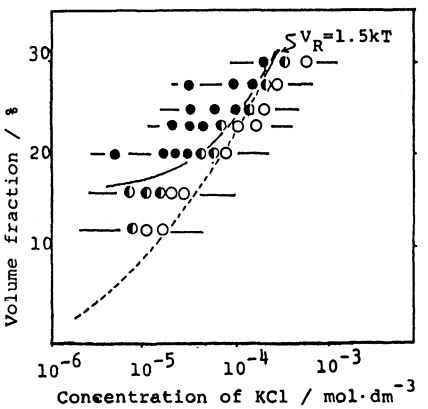

Fig. 4. Phase diagram of Sample-B($2a$=5720 Å, σ_0=0.7 μC cm^{-2}) constructed using KCl at 25 °C.

an analytical boundary curve for the Sample-B ($2a$= 5720 Å) using KCl. In these analyses, 1.5 kT ergs was used as a criterion of phase transition potential. Increasing the particle size, favours the disordered state as expected from the double layer theory. But the agreement between the experimental and the analytical boundary curves is very limited at the high electrolyte region and there are definite discrepancies in the low electrolyte level. These would be based on the gravitational settling of the large particles, where the particles form a sediment rather quickly to their own gravity of the large mass and the soft repulsive potential at the low electrolyte level.

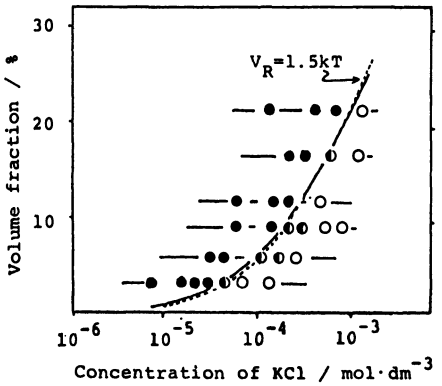

Fig. 5. Phase diagram of Sample-C ($2a$=1650 Å, σ_0= 7.0 μC cm^{-2}) constructed using KCl at 25 °C.
●: Ordered state, ○: disordered state, ◐: coexistent state. Each curve shows the experimental (——) and the analytical coexistent/ordered boundary curve assuming the critical potential of V_R=1.5 kT (------).

Figure 5 represents the effect of the surface potential on the phase transition curve. The Sample-C used here has the surface charge density of 7 μC cm^{-2}. As can be seen in Fig. 5, the ordered state becomes much more favourable and the analytical boundary curve which can calculated using the value of ζ-potential for the ψ_0 in Eq. 2 and the critical V_R of 1.5 kT ergs, agreed

exactly with the whole range of electrolyte concentration in the experimental. From such an accordance with the analytical curve, it is apparent that ζ-potential is a good measure for the electrostatic repulsion of colloid particle and is allowed analytically to use ζ-potential instead of the Stern layer potential.

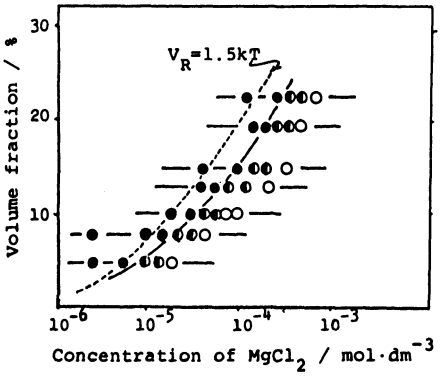

Fig. 6. Phase diagram of Sample-A ($2a$=1960 Å, σ_0= 0.9 μC cm^{-2}) constructed using $MgCl_2$ at 25 °C.
●: Ordered state, ○: disordered state, ◐: coexistent state. Each curve shows the experimental (——) and the analytical coexistent/ordered boundary curve assuming the critical potential of V_R=1.5 kT (------).

Figure 6 shows the phase diagram that was constructed using the electrolyte containing the divalent cation. In this coexistent/ordered boundary curve, there is some discrepancy on the whole electrolyte levels. It is probable that the divalent cation will be adsorbed preferentially on the latex surface as a Stern layer charge and the effective diffuse layer charge for the double layer repulsion would become much lower than the added electrolyte concentrations. According to Vanderhoff *et al.*,[12] Ba^{2+} ions adsorb extensively on the surface sulfonate groups of the latex particles and show an inflection point on the conductometric titration curve based on the strong fixation of Ba^{2+} ions. So, we can assume that the degree of deviation from the analytical curve reflects the extent of adsorbability of each counter ion in the Stern layer.

As a final parameter, the influence of temperature was studied. As can be seen in Fig. 7, over the whole electrolyte levels the ordered state becomes unfavorable at the high temperatures. It is because of this reason that the high temperature makes the double layer more diffusive. The precise analyses of temperature effects were carried out by taking into account the effects of medium dielectricity, ζ-potential and temperature itself. The results are compared to the experimental values on the two special salt concentrations. As can be seen in Fig. 8, the trends are the expected ones and qualitatively agree with the experimentals except for the results at the high temperatures of more than 40 °C, where the structural effects on desorption of the Stern layer ions exist, the desorbed ions would make unfavourable the ordered state and increase the volume fraction of the boundary.

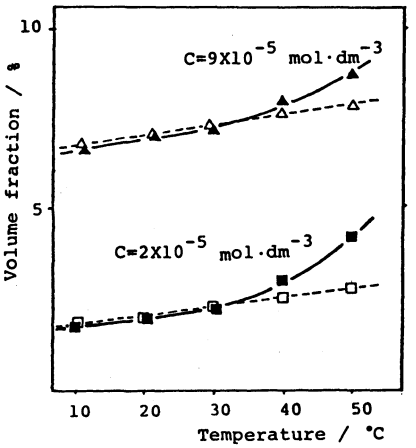

Fig. 8. Comparison of the temperature effect of phase boundary with the analytical one on the two KCl concentrations.
——: Experimental, ------: analytical.

At any rate, it can be concluded from the present work that the disordered/ordered phase transition in the concentrated latices is controlled largely by the electrostatic repulsion between the particles and the critical boundary condition of the coexistent/ordered state is reasonably explained by the DLVO electrostatic potential. Also, it is realized that the phase boundary analyses provides useful information on the nature of the electrical double layer and contributes as a new technique in the study of the electrical double layer.

Transient Species in Picosecond Pulse Radiolysis of Liquid Carbon Tetrachloride

Takashi SUMIYOSHI, Sadashi SAWAMURA, Yoshio KOSHIKAWA, and Meiseki KATAYAMA*

Department of Atomic Science and Nuclear Engineering, Hokkaido University, Sapporo 060

(Received January 5, 1982)

Formation and decay of transient species produced in pure liquid carbon tetrachloride by ionizing radiation were studied by using a stroboscopic pulse radiolysis technique in the time region 35—350 ps. Optical absorption spectra show two principal bands. One narrow band centered at 325 nm, which is formed during each fine structure electron pulse and decayed after pulse with $t_{1/2}=6.5$ ns, is attributed to CCl_4^+ cation. The other broad band centered at 470 nm built up after electron pulse is assigned to ($CCl_4^+ \cdot Cl^-$). A consideration on effects of cation scavengers on these bands furnishes a support for the above assignment.

Radiolysis of carbon tetrachloride in the condensed phase has been studied extensively over the past fifteen years. This is mainly because the comparatively high ionization potential of carbon tetrachloride ($I_p(CCl_4)=11.47$ eV) makes the carbon tetrachloride cation (CCl_4^+) quite suitable for transfer of a positive charge to a solute molecule. Optical spectra of a wide variety of solute cations have been obtained by the matrix isolation[1,2] and pulse radiolysis methods.[3,4] In pure CCl_4 and solutions of CCl_4 in alkane and argon matrices, many attempts have been made to establish the nature of primary species involved by means of low-temperature matrix isolation[1,5,6] and pulse radiolysis.[7-9] Both experiments revealed characteristic absorption bands with maxima located in two wavelength regions around 320—370 and 400—500 nm. However, the assignment of these absorption bands is not satisfactory as described below. Both the 367 nm band[5] observed in γ-radiolysis studies of CCl_4 in alkane hydrocarbons at 77 K and the 340 nm band[8] observed by pulse radiolysis on pure CCl_4 at 20 °C were assumed to be due to CCl_4^+. On the other hand, the band centered at 330 nm was assigned to dichlorocarbene radical (CCl_2) on the basis of an *ab initio* SCF CI study.[10] An earlier γ-radiolysis work with polycrystalline CCl_4 at 77 K revealed an absorption at 400 nm, which was assigned to positive hole.[1] Also, a spectrum of CCl_4, observed in an argon matrix at 25 K after argon discharge photoionization, exhibited a broad absorption at 425 nm,[6] which was assigned to CCl_4^+ cation since cation infrared absorptions in similar experiments exhibited the same photolysis behavior. On the contrary, both the broad absorption band centered around 470 nm,[5] observed in a γ-irradiated sample of CCl_4 in alkane hydrocarbons at 77 K, and the short-lived absorption band, observed at 480 nm[8] in an ns pulse radiolysis of CCl_4 at 20 °C, were assigned to a complex ($CCl_4^+ \cdot Cl^-$). A 500 nm band observed in a pulse irradiated liquid CCl_4 at −22 °C was assigned to another type of complex ($CCl_3^+ \cdot Cl^-$) on the basis of cation scavenger studies;[7,11] however, an *ab initio* configuration calculation[12] predicted no stability for any isolated contact ion-pairs between CCl_3^+ and Cl^-. We have constructed a stroboscopic pulse radiolysis instrument with time resolution of picoseconds and applied it to studying transient absorptions obtained in the pulse radiolysis of liquid CCl_4. By means of this instrument, it is possible to observe the formation and decay kinetics in the time region of 35—350 ps from the beginning of pulse.

The stroboscopic pulse radiolysis system was first designed and built by Bronskill *et al.*[13] Using 35 ns pulses from an S-band linear accelerator (LINAC) and a conventional photomultiplier optical detection system, they were able to study reactions of solvated electrons,[14] dry electrons,[15] and solvation of electrons in alcohols[16] in the time region of 20—350 ps. Jonah[17] applied this technique to a single picosecond pulse from an L-band LINAC[18] and was able to study similar aqueous systems in the time range 100 ps to as long as 3.5 ns after irradiation.[19,20] A distinct contribution of his method is that it has removed the upper limit on observation time (350 ps for an S-band LINAC and 770 ps for an L-band LINAC), which has inevitably accompanied experimental works using a train of fine structure pulses.

The present experiments were carried out with a 45 MeV S-band LINAC with no subharmonic prebuncher. Although the stroboscopic method using a train of electron pulses is essentially accompanied by a long time limit as mentioned above, it is capable of providing a good time resolution (≈20 ps) even with a conventional photomultiplier detection system.[13]

Experimental

Stroboscopic Pulse Radiolysis System. The stroboscopic pulse radiolysis system is shown in Fig. 1. The radiation source is 11 ns, 45 MeV electron pulse from the S-band LINAC installed in Hokkaido University. This 11 ns electron pulse consists actually of a train of fine structure pulses with time intervals of 350 ps. Simultaneous flashes of Čerenkov light are produced by these fine structure electron pulses in a 10 cm air path between the LINAC and a thin mirror. These light flashes are delayed 0.87 to 1.80 ns by a system of mirrors and are used as analyzing light flashes to observe absorption signals in irradiated samples. Čerenkov light has a continuous spectrum and is radiated outward from the path of 45 MeV electrons with an angle of 1.2°. A conical-shaped (axicon) lens was used to refract this conical beam of Čerenkov light into a pseudo-parallel beam.

In the stroboscopic pulse radiolysis system, three types of signals are required to obtain the absorption signal (S).[13] The electron beam and analyzing light are mechanically chopped to produce the three types of signals A, B, and C as illustrated in Fig. 2. Signal A is the sum of the analyzing light decreased in intensity by the absorption in the cell and the background Čerenkov light. Signal B consists of only the Čerenkov

analyzing light, and signal C consists of the background Čerenkov lights produced in and near the sample cell. The absorption signal can be obtained by addition and subtraction of these signals, *i.e.*,

$$S = B + C - A,$$

and the percent absorption is calculated as

$$(S/B) \times 100\ \%.$$

These three signals are produced sequentially at the rate of 50 Hz with line-locking to minimize 50 Hz ripple effects in the LINAC and detection system.

Detection System. The three types of light pulses are detected by a system which consists of a monochromator (Bausch & Lomb), a photomultiplier (Hamamatsu TV Co., R446UR), a preamplifier, an amplifier (ORTEC 451), and an A/D converter (NAIG D-161). The photomultiplier was used in a five-stage configuration that had a linear response of up to 4 mA with a rise time of less than 3 ns. The linearity of the detection system was carefully checked by using pulses from a pulse generator and actual, well-known absorption signals, as will be described in the following section. The output signal from the A/D converter is fed into an on-line minicomputer (TACC 1200M) and stored before arrival of the next signal. Both the averaging of signals and the operation of the movable mirrors in the optical delay system are performed by a minicomputer. The timing sequence for synchronization of pulses and choppers is shown in Fig. 3.

Linearity and Time Resolution. Observation on the formation and decay of e^-_{aq} and Br_2^- was carried out as a critical check on the performance of the stroboscopic pulse radiolysis system. Linearity was tested by use of the baseline and the first-order decay of e^-_{aq} in concentrated $HClO_4$ solutions. Results obtained at 633 nm in solutions of 0.5—2 M $HClO_4$ are shown in Fig. 4. The baseline approaches a near-zero level with increasing concentration of H^+_{aq} as expected. The dashed lines in Fig. 4 are results from a computer simulation for the first order decay of e^-_{aq}. In these calculations it is assumed that a value of ε_{633nm} is 1.44×10^4 M^{-1} cm^{-1} for e^-_{aq},[21] and the decay of e^-_{aq} during the electron pulse is taken into account. Agreement on the decay traces is quite satisfactory. The rate constant was calculated to be $(1.2\pm0.06)\times10^{10}$ M^{-1} s^{-1}, which is in good agreement with the reported value of $(1.2\pm0.2)\times10^{10}$ M^{-1} s^{-1} over the range of 0.5—5 M H^+_{aq} by Bronskill *et al.*[22] A further test on the linearity of the detection system was carried out in the ultraviolet region. Figure 5 shows kinetic traces for the formation of Br_2^- at 360 nm in 0.5—2 M NaBr aqueous solutions. Both a fast and a slow component are shown, along with the contribution of the fast component, to increase with increasing NaBr concentration. These results are quite similar to those reported by Hunt *et al.*,[23] who suggested that the fast component is due to reactions of dry hole (H_2O^+) and Br^-:

$$H_2O^+ + Br^- \longrightarrow Br + H_2O,$$

followed by reaction

$$Br + Br^- \longrightarrow Br_2^-.$$

The observed rise time (10—90%) for the formation of hydrated electron in Fig. 4 is about 35 ps. Since the formation time of e^-_{aq} has been estimated to be less than 10 ps,[22] this rise time is attributed mainly to the following two factors: One is the width of fine structure electron pulses. The width of the fine structure pulse observed with a streak camera system (Hamamatsu TV Co., HTV-C979X) having a rise time of 10 ps is approximately 39 ps (FWHM), which is longer than the observed rise time of e^-_{aq}. It is thus thought that the real pulse width is less than 30 ps. The other factor is the desynchronization of pulses, which is due to different velocities of the high energy electrons and analyzing light in water. The 45 MeV electron pulse moves with a velocity close to that of light *in vacuo*, while the analyzing light moves more slowly with a velocity of c/n, where n is the index of refraction of light in solution and c is the velocity of light *in vacuo*. The desynchronization of pulses is given by

$$\Delta t = (n-1)l/c,$$

where l is the length of cell. The time difference of a 2 cm path in water is 21 ps. A shorter optical path is desirable for faster detection, though it will possibly decrease the absorption signal.

Chemicals and Flow System. The chemicals used were NaBr, 60% $HClO_4$, cyclohexane, and CCl_4 (Wako Junyaku), and all were used without further purification since on the experimental time scale, any small amounts of impurities would have a negligible effect. Aqueous solutions were prepared with triply distilled water.

Experiments were carried out in a 2 cm sample cell which connects to a 1 dm^3 sample reservoir and a pump. To prevent buildup of heat and radiolytic products, the sample was circulated at 160 ml/min. No attempt was made to degas the sample solution since on the experimental time scale, O_2 is known to have no effect on experiment results in aqueous solutions[22] or in pure CCl_4.[8] All experiments were carried out at room temperature 15—20 °C.

Results

Kinetic Traces. Figure 6 shows typical kinetic absorption traces in pure CCl_4 at 320, 350, and 480 nm. These traces were obtained by averaging more than 30 runs including those conducted on different days and by applying correction for variation in irradiation doses. There appear to be at least two different main formation processes of transient species. The absorption at 320 nm grows only during the irradiation of fine structure electron pulses and decays after the pulse, while the absorption at 480 nm grows after the pulse. The trace at 350 nm shows a rather fast buildup and a slow one, and sould consist of a set of contributions from the two

components described above. The dashed line is a result from computer simulations of kinetic traces at 320 nm. The simulations were done assuming a first-order decay and a contribution from only one transient species. The best fitted curve was obtained when the half-life time and $G\times\varepsilon$ were assumed to be 6.5 ns and 25500 M^{-1} cm^{-1}, respectively.

Spectra. Figure 7 shows absorption spectra obtained immediately after pulse (17 ps from the middle of pulse) and 100 ps after the pulse. Only the narrow band centered around 320 nm was observed immediately after pulse. In addition, at 100 ps a broad band was observed around 480 nm. Since none of the transient species observed decays considerably within 350 ps, the absorption signal produced by the fine structure electron pulse is superimposed by the background absorption

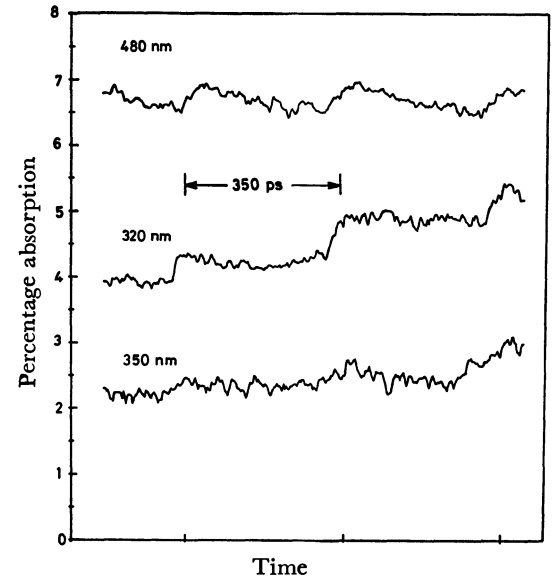

Fig. 9. Kinetic traces of the formation of the transient species observed at 320, 350, and 480 nm in 0.5 M cyclohexane in CCl_4.

shown in Fig. 6. The background absorption spectrum obtained by fixing the movable mirrors at the position nearest to the beam is shown in Fig. 8. In this spectrum two absorption bands are clearly shown and the broad band centered at 470 nm is more intense than that at 325 nm, in contrast to the spectrum at 100 ps after pulse in Fig. 7. Since in the stroboscopic method it is essential that the analyzing light is absorbed by transient species of different ages, the slower decaying species will contribute more to the background absorption. The difference between the spectra in Figs. 7 and 8 is that the former shows absorption by a fine structure pulse and that the latter shows contributions of both absorption intensity and decay rate.

Effect of Cation Scavenger. Since cyclohexane has a lower ionization potential (9.88 eV) than CCl_4, it was used as a cation scavenger.[7,8] Figure 9 shows kinetic absorption traces observed at 320, 350, and 480 nm in 0.5 M cyclohexane. Both the step height of absorption signals (the maximum absorption signal by a fine structure pulse) and the buildup absorption signal decrease to less than half of those in pure CCl_4 in Fig. 6. The buildup absorption spectrum is compared with that of pure CCl_4 in Fig. 7. The band centered at 320 nm observed in pure CCl_4 could not be observed any more, and instead the band peaked at $<$290 nm began to be observed. The latter species does not show fast decay as clearly seen in Fig. 9. From these results it is apparent that the species, having given the band at 325 nm, was scavenged more effectively than the one for 470 nm.

Discussion

Identification of the 325 nm Band. In th epresent study, observations showed that radiolysis of liquid CCl_4 initially produces a sharp band centered at 325 nm as seen in Fig. 7. This band is reduced to almost zero by addition of 0.5 M cyclohexane, which is known as a

scavenger for cationic species. The residual species which peaks below 290 nm does not show any decay. It was not clear whether this species originated from CCl_4 or from cyclohexane in this experiment. The 325 nm band can be assigned to a primary cation formed in the initial act of ionization for CCl_4. This assignment is consistent with previous works in which ns pulse radiolysis and low temperature matrix were used. Mehnert *et al.*[8] observed a transient absorption which peaked at 340 nm in pure liquid CCl_4 by ns pulse radiolysis and assigned it to CCl_4^+ cation. They determined rate constants of charge transfer reaction for 17 solutes from observations on the decay of cation. Ha *et al.*[10] carried out *ab initio* configuration calculations on electronic states of the CCl_2 radical and assigned a 330 nm band obtained by a pulse radiolysis experiment to it. Their assignment is based on a kinetic behavior which indicates that the band can be due to neither a transient ion nor any of the simple radicals of Cl and CCl_3; their experimental data have not yet been published. Also, in low temperature matrix studies, the CCl_4^+ cation was observed at 400 nm in a γ-irradiated polycrystalline CCl_4 at 77 K,[1] at 367 nm in a γ-irradiated CCl_4 in alkane hydrocarbons at 77 K,[5] and at 425 nm in an argon discharge photoionization during condensation at 25 K.[6] This variation in band peaks of CCl_4^+ cation seems to depend on the nature of matrix. For example, glassy solutions of CCl_4 in alkane hydrocarbons give a band maximum similar to that obtained in pulse radiolysis experiments. It should be pointed out that in an argon matrix, CCl_4^+ has been attributed to assymmetric $Cl_2CCl_2^+$ species by Prochaska and Andrews[24] through infrared studies. They suggested that one set of two carbon-chlorine bonds involves normal electron pair bonding, whereas the other set involves electron-deficient bonding with presumably delocalized electrons around the cation center.

Identification of the 470 nm Band. The present experiments revealed that the broad absorption band at 470 nm builds up after the electron pulse and is less sensitive to the cation scavenger than the species which peaked at 325 nm. These results suggest that the corresponding species should be an electrically neutral intermediate produced by reaction of primary radiation products, though more detailed investigations are needed before a precise conclusion is reached.

Mehnert *et al.*[8] observed a similar broad band centered at 480 nm by ns pulse radiolysis at 22 °C and assigned it to a complex ($CCl_4^+ \cdot Cl^-$). Also Bühler and Hurni[7] observed by ns pulse radiolysis a transient spectrum which peaked at 500 nm in CCl_4 at -22 °C and decayed with a half-life time of 33 ns. They studied effects of cation scavengers on this band and found that, though reducing the pulse end absorbance of the 500 nm band, they have no effect on the life time. They concluded that the CCl_4^+ cation must be a precursor to the 500 nm species and that the 500 nm species behaves like both cation and neutral species. They assigned the 500 nm band to another type of complex ($CCl_3^+ \cdot Cl^-$) on the assumption of a very short life time of CCl_4^+ cation. Since no mass spectrum of CCl_4^+ has been observed,[25] CCl_4^+ is considered to eliminate Cl atom readily in the gas phase. In liquid phases, however, stabilization of CCl_4^+ by surrounding molecules can be expected.[5,6] Considering the life time of 6.5 ns for CCl_4^+ observed in this work, it is strongly suggested that the 470 nm band is due to rather a neutral complex ($CCl_4^+ \cdot Cl^-$).

Louwrier and Hamill[5] observed an isothermal decay of 367 nm absorption and a growth of 470 nm absorption in γ-irradiation studies on solutions of CCl_4 in alkane hydrocarbons at 77 K and attributed these bands to CCl_4^+ and $CCl_4^+ \cdot Cl^-$), respectively. Their observations are in good agreement with the present work.

In conclusion, the present picosecond pulse radiolysis studies have provided direct observations on the initial process in irradiated CCl_4 as follows, provided that the absorption at 325 nm can be assigned to CCl_4^+:

$$CCl_4 \rightsquigarrow CCl_4^+(325\text{ nm}) + e^-, \quad (1)$$

and subsequent fomation of ion pairs

$$CCl_4 + e^- \longrightarrow CCl_3 + Cl^-, \quad (2)$$

$$CCl_4^+ + Cl^- \longrightarrow [CCl_4^+ \cdot Cl^-]\ (470\text{ nm}). \quad (3)$$

The authors wish to acknowledge Dr. John W. Hunt for his helpful discussions on the construction of the stroboscopic pulse radiolysis system. The authors also wish to acknowledge Dr. Takeaki Enoto and Messrs. Hiroaki Tanida and Koichi Sato for their help in stabilizing and operating the LINAC. Thanks are due to Messrs. Kaichi Takahashi and Keiji Kuriyama and Dr. Yoshikazu Kondo for their experimental assistance and to Dr. Masako Tanaka for her helpful advices in the early stage of the present investigation. The cooperation through designing and manufacturing the instrument by Shimadzu Seisakusho, Ltd., especially by Engineer Mr. Tadashi Kōtani, and the financial support by the Mitsubishi Foundation are gratefully acknowledged by one of the present authors (M. K.).

Pulse Radiolysis Studies on Methyl Methylthiomethyl Sulfoxide in Aqueous Solutions

Takashi SUMIYOSHI, Nobuyuki MIURA, Masayuki AIKAWA,† and Meiseki KATAYAMA*

Department of Atomic Science and Nuclear Engineering, Hokkaido University, Sapporo 060

†*College of General Education, Hokkai Gakuen University, Asahimachi Toyohiraku, Sapporo 062*

(Received January 25, 1982)

Reaction mechanisms between methyl methylthiomethyl sulfoxide (MTMSO) and hydrated electron (e^-_{aq}) or hydroxyl radical (OH· radical) have been studied in aqueous solutions with various pH values by means of pulse radiolysis technique. The acid and basic components of equilibrium

$$CH_3SCH_2\overset{\overset{OH}{|}}{S}CH_3 \rightleftharpoons CH_3SCH_2\overset{\overset{O}{|}}{S}CH_3 + H^+$$
$$(-)$$
$$(I)$$

and

$$CH_3\overset{\overset{OH}{|}}{S}CH_2\overset{\overset{O}{\downarrow}}{S}CH_3 \rightleftharpoons CH_3\overset{\overset{O}{|}}{S}CH_2\overset{\overset{O}{\downarrow}}{S}CH_3 + H^+$$
$$(-) \quad (II)$$

are formed for the reaction of $e^-_{aq} + CH_3SCH_2SOCH_3$ and OH· + $CH_3SCH_2SOCH_3$, respectively. The pK_a values of the respective equilibrium are 10 and 9. The anion (I) and (II) have absorption maxima at 375 nm and 360 nm, respectively. The sulfinic acid $CH_3SCH_2SO_2^-$ is also formed in the reaction of $CH_3SCH_2SOCH_3$+OH·. The rate constants have been determined to be $k(e^-_{aq} + \text{MTMSO}) = 1.3 \times 10^8$ M^{-1} s^{-1} and k (OH· + MTMSO) = 3.1×10^9 M^{-1} s^{-1} (1 M = 1 mol dm^{-3}). Relative reactivities of OH· radical with thio-methyl bond and sulfinyl group are also discussed.

Two organic bonds involving sulfur atoms, thiomethyl bond (sulfide S–C bond) and sulfinyl-methyl bond (sulfoxide S–C bond), are known to change reactivities with pH of the solutions. Pulse radiolysis method has provided one of the most successful approaches to investigate dynamics of the compounds. Meissner, Henglein and Beck have reported the study on the primary processes for the irradiated aqueous solutions of dimethyl sulfide and dimethyl sulfoxide.[1] They suggested that the formation of the radical anion $CH_3SOCH_3^-$· and the radical cation complex $(CH_3SCH_3)_2^+$· for the reaction of the OH· radical with CH_3SCH_3, and that the formation of the radical anion $CH_3SOCH_3^-$· in the reaction of the hydrated electron with CH_3SOCH_3. The formation of sulfinic acid RSO_2^- for the reaction of the OH· radical with sulfoxide (R_2SO) have been found by Veltwisch, Janata and Asmus from a pulse radiolysis study with the conductivity detection method.[2] Although primary processes of the individual compounds have been fairly well studied, relative reactivities of the sulfide S–C bond and sulfinyl group with OH· radical are not known.

Methyl methylthiomethyl sulfoxide ($CH_3SOCH_2SCH_3$; MTMSO) possessing the sulfide S–C bond and the sulfinyl group within one molecule is expected to show interesting reactivities. In the present study we propose the primary processes for the reaction of e^-_{aq}+MTMSO and OH·+MTMSO in aqueous solution in comparison with the dimethyl sulfide and the dimethyl sulfoxide. Spectral analysis of the transient absorption in the UV-Vis regions and an electrical conductivity analysis after pulse irradiation were two techniques to identify the transient species produced. Experimental results of reaction yields and reaction rate constants give information on the relative reactivities between the sulfide S–C bond and the sulfinyl group with OH· radical.

Experimental

MTMSO was purchased from Nisso LTD. and used without further purification. Solutions were prepared by dissolving *t*-BuOH, $HClO_4$, NaOH, and $NaClO_4$ in triply distilled water, and the pH values of the solutions were adjusted by adding perchloric acid or sodium hydroxide. For studies on the reaction of MTMSO with e^-_{aq}, solutions were bubbled with argon to remove oxygen. On the other hand, solutions for studies on the reaction with OH· radical were bubbled with dinitrogen monoxide in order to convert the e^-_{aq} into OH· radicals *via* the following reaction:

$$N_2O + e^-_{aq} \longrightarrow OH\cdot + OH^- + N_2. \quad (1)$$

Pulse radiolysis measurements were performed with electron pulses (45 MeV) from a S-band linear accelerator (Mitsubishi) installed at Hokkaido University.[3] The half-width of the electron pulse used was 20 ns and dose per pulse was up to 14 krad. The optical detection system was basically the same as that designed by Hunt and Thomas.[4] Analyzing light from Xe arc lamp (1 kW, Wako Denki) was chopped by a rotating disk at 25 Hz and sent to a sample cell. The absorption signal, after passing through the monochromator (Shimadzu-Bausch and Lomb, 200 mm, f/3.5), was detected by a photomultiplier (Hamamatsu T. V. R446UR) system. The output signal was displayed on to an oscilloscope (National VP5405A).

The sample cell for the D–C conductivity analysis has two rectangular electrodes (3×5 mm^2), which were set 5 mm apart. By the conductivity method, charged species being produced after pulse irradiation are monitored *via* a variation of the signal voltage. The relation between the change in the concentration of i-th charged species ΔC_i and a signal voltage on the oscilloscope ΔV_s as a result of the formation or

disappearance of the species in a solution is given by the following equation:[5]

$$\Delta V_s = \frac{VR}{k\,10^3} \sum \Delta C_i |Z_i| \Lambda_i, \qquad (2)$$

where V, R, and k indicate a voltage between two electrodes in the irradiation cell, a resistance and a cell constant (in cm^{-1}), respectively. $|Z_i|$ and Λ_i represent the number of charges (1 for one electron oxidation) and the corresponding conductivities (in $\Omega^{-1}\,cm^2$) for i-th charged species, respectively.

If only one acid species (XH) is produced by irradiation and G value of the species is given by G_{XH} which is directly proportional to ΔC_{XH}, then Eq. 2 is rewritten as

$$\Delta V_s \times K = G_{XH} \times (\Lambda_{X^-} + \Lambda_{H^+}), \qquad (3)$$

here K denotes certain constant determined experimentally.

Results and Discussion

Reaction of e^-_{aq} with MTMSO; Formation of Radical Anion. MTMSO aqueous solutions containing 1 M *t*-BuOH as a hydroxyl radical scavenger were irradiated to investigate the reaction mechanism of e^-_{aq} with MTMSO.

Figure 1 shows a representative decay curve for the transient absorption of e^-_{aq} which are produced after the pulse irradiation of the MTMSO aqueous solution. The decay curve fit a simple first-order kinetics as is shown in the figure. The pseudo-first-order rate for the absorption of the hydrated electron was plotted as a function of MTMSO concentration and the rate constant for the reaction e^-_{aq}+MTMSO was determined from

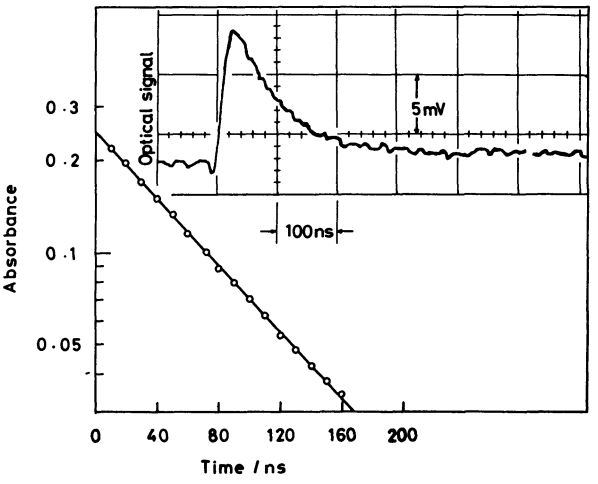

Fig. 1. First-order kinetic plot of log Abs. (e^-_{aq}) against time after the pulse irradiation of MTMSO aqueous solution ([MTMSO]=0.1 M, pH 7.1, monitoring wavelength; 600 nm). The solution was saturated with argon gas prior to the irradiation. Inset: an oscillogram trace of the decay curve for the absorption of e^-_{aq}. A change of 5 mV in the vertical axis corresponds to 22% transmittance.

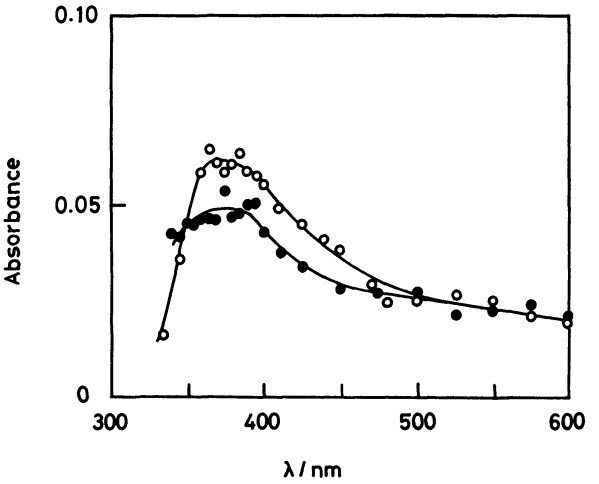

Fig. 2. Transient absorption spectra 2 μs after the pulse irradiation of MTMSO aqueous solutions ([MTMSO] =0.05 M, [*t*-BuOH]=1 M). Solutions were saturated with argon gas prior to the irradiation. ●: pH 6, ○: pH 10.

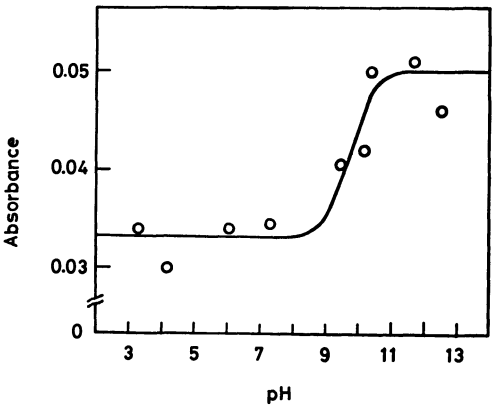

Fig. 3. Optical densities at 375 nm as a function of pH, 2 μs after the pulse. MTMSO aqueous solutions ([MTMSO]=0.05 M, [*t*-BuOH]=1 M) were saturated with argon gas prior to the irradiation.

the slope of the linear plot to be $(1.30\pm0.08)\times10^8\ M^{-1}\ s^{-1}$. The rate constant values thus obtained are summarized in Table 1 as a function of pH values. The values were constant with respect to the pH (from pH 6 to 11) of the solutions.

Figure 2 shows the transient absorption spectra observed for aqueous solutions containing MTMSO (0.05 M, pH 6 and 10) at 2 μs after the pulse where the absorption of e^-_{aq} is sufficiently diminished. The transient absorption spectrum thus obtained has a broad band with a λ_{max}=375 nm.

Figure 3 shows the change in the absorbance of the transients at λ=375 nm with changing pH values of MTMSO solutions. The intensity of the transient absorption increases sharply at pH 10. It has been

Table 1. Reaction rate constants of hydrated electron with MTMSO in aqueous solutions as a function of pH

pH	6.1	7.1	9.0	10.4	11.0
$k(e^-_{aq}+MTMSO)/M^{-1}\,s^{-1}$	1.30×10^8	1.38×10^8	1.28×10^8	1.30×10^8	1.23×10^8

reported for the reaction of $e^-_{aq}+CH_3SOCH_3$ that the following equilibrium between both species of acid and its conjugated basic form should be taken into consideration:[1]

$$CH_3SCH_3 + e^-_{aq} \longrightarrow CH_3\overset{\cdot}{S}CH_3 \underset{pK_a = 10.2}{\overset{+H^+}{\rightleftharpoons}} CH_3\overset{\cdot}{S}CH_3. \quad (4)$$
(O; O (−); OH)

The pK_a value of the equilibrium (4) is 10.2. From our observation of the pH dependence for the transients and by analogy with the reaction scheme (4), we may reasonably assign the transients formed in the reaction $e^-_{aq}+MTMSO$ to the radical anion which is in the following equilibrium:

$$CH_3SCH_2SCH_3 + e^-_{aq} \longrightarrow CH_3\overset{\cdot}{S}CH_2SCH_3$$
(O; O (−))

$$\underset{pK_a = 10}{\overset{+H^+}{\rightleftharpoons}} CH_3\overset{\cdot}{S}CH_2SCH_3. \quad (5)$$
(OH)

Thus, from Fig. 3 the pK_a value of the equilibrium (5) is determined to be 10.

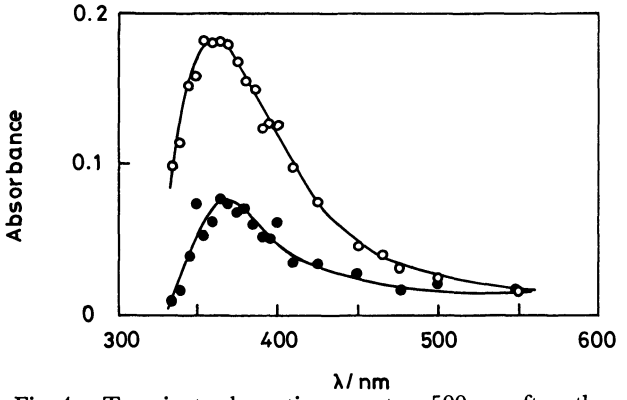

Fig. 4. Transient absorption spectra 500 ns after the pulse irradiation of MTMSO aqueous solutions ([MTMSO]=0.05 M). Solutions were saturated with N_2O gas prior to the irradiation. ●: pH 6, ○: pH 10.

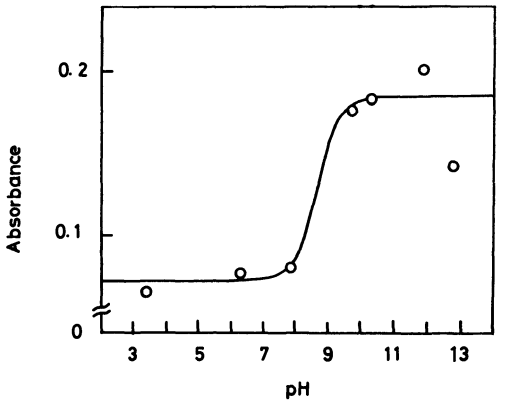

Fig. 5. Optical densities at 360 nm as a function of pH, 500 ns after the pulse. MTMSO aqueous solutions ([MTMSO]=0.05 M) were saturated with N_2O gas prior to the irradiation.

Reaction of OH· Radical with MTMSO. *a) Sulfide and OH· Radical*: Pulse radiolysis experiments of N_2O saturated MTMSO solutions (0.05 M, pH 6 to 10) were carried out in order to test the reaction mechanism of MTMSO with OH· radical. For N_2O saturated MTMSO solutions, no transient absorption being assignable to hydrated electron was observed. Figure 4 shows the transient absorption spectra observed at 500 ns after the pulse. Figure 5 shows the pH dependence of MTMSO aqueous solutions on the intensity of the transient absorption at 360 nm. The absorption intensity increases sharply at pH 9. The pH dependence indicates that the transients is in an acid-base equilibrium whose pK_a value is equal to 9. It has been reported that a radical anion $CH_3SOCH_3^-\cdot$ is formed in the reaction of the OH· radical with dimethyl sulfide, and that the radical anion is in an acid-base equilibrium:[1]

$$CH_3SCH_3 + OH\cdot \longrightarrow CH_3\overset{\cdot}{S}CH_3 \underset{pK_a = 10.2}{\overset{-H^+}{\rightleftharpoons}} CH_3\overset{\cdot}{S}CH_3. \quad (6)$$
(OH; O (−) 350 nm)

It is also known that the radical anion ($CH_3SOCH_3^-\cdot$) has the absorption with $\lambda_{max}=350$ nm.[1]

These facts suggest that the transient absorption spectrum observed here originates from the radical anion ($CH_3SOCH_2SOCH_3^-\cdot$) which is formed in the reaction between the OH· radical and sulfur atom of the thiomethyl bond of MTMSO. The radical anion is in an acid-base equilibrium with the $pK_a=9$:

$$CH_3SCH_2SCH_3 + OH\cdot \longrightarrow CH_3SCH_2\overset{\cdot}{S}CH_3$$
(O; O OH)

$$\underset{pK_a = 9}{\overset{-H^+}{\rightleftharpoons}} CH_3SCH_2\overset{\cdot}{S}CH_3. \quad (7)$$
(O O (−) 360 nm)

b) Sulfoxide and OH· Radical: It is probable that the OH· radical attacks not only the sulfide S–C bond but also the sulfoxide S–C bond of MTMSO. The following route has been also suggested for the reaction between OH· radical and R_2SO:[2]

$$RSR + OH\cdot \longrightarrow R\cdot + RSO_2^-/H^+. \quad (8)$$
(O)

By the analogy with Reaction 8, the sulfinic acid ($CH_3SCH_2SO_2^-$) is expected to be formed for the case of MTMSO, when the OH· radical attacks the sulfoxide S–C bond of MTMSO:

$$CH_3SCH_2SCH_3 + OH\cdot$$
(O)

$$\longrightarrow CH_3\cdot + CH_3SCH_2SO_2^-/H^+. \quad (9)$$

Detection of ionic species for the acidic solution of MTMSO will give a proof for the formation of the sulfinic acid. The conductivity detection method combined with the pulse radiolysis experiment was adopted for the acidic MTMSO (10^{-3} M) solution saturated by N_2O gas.

For the acid solution (pH 5.6), an increment in

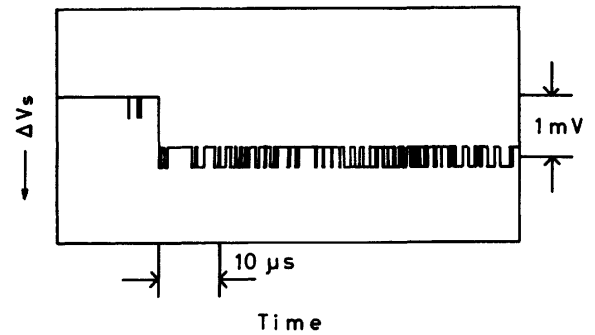

Fig. 6. Conductivity-time curve of pulse-irradiated aqueous N_2O saturated solutions of 10^{-3} M MTMSO at pH 5.6.

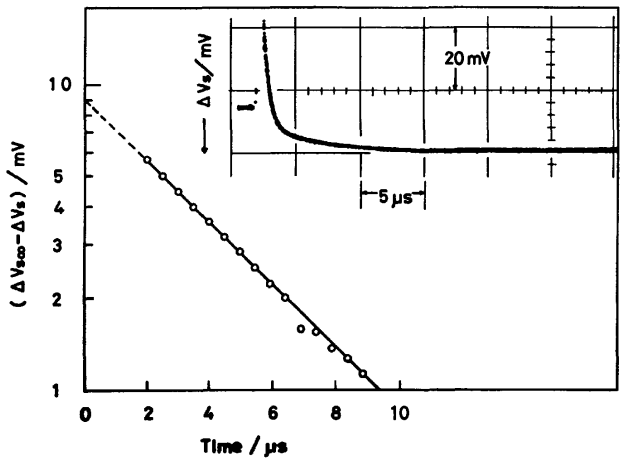

Fig. 7. First-order kinetic plot of $\log(\Delta V_{s\infty}-\Delta V)$ against time after the pulse irradiation of MTMSO aqueous solution ([MTMSO]$=5\times10^{-5}$ M, pH 4.9, $V=-30$ V, $R=50\ \Omega$). The solution were saturated with N_2O gas prior to the irradiation. Inset: An oscillogram trace of the conductivity change as a result of the formation of sulfinic acid $CH_3SCH_2SO_2^-$.

conductivity was observed. The signal of the conductivity after the pulse was a step function since the $CH_3SCH_2SO_2^-/H^+$ ion pair is stable over the detection period (Fig. 6). From the signal in Fig. 6, the yield of sulfinic acid can be determined as:

$$0.99\times K = G_{CH_3SCH_2SO_2^-/H^+}\times[\Lambda_{CH_3SCH_2SO_2^-}+\Lambda_{H^+}]. \quad (10)$$

Here the value of Λ_{H^+} is known to be 315 Ω^{-1} cm^2 and $K=9.74\times10^2$ which is determined experimentally. Using these values and assuming that $\Lambda_{CH_3SCH_2SO_2^-}$ is equal to $\Lambda_{CH_3SO_2^-}=42\ \Omega^{-1}$ cm^2 which is determined by Veltwisch *et al.*,[2] the yield of $CH_3SCH_2SO_2^-$ anion is calculated to be $G_{CH_3SCH_2SO_2^-}=2.7$. The value of the yield is 45% of the total yield of the OH· radicals ($G_{OH\cdot}=6.0$).[6] This fact indicates that 45% of the OH· radicals produced after the pulse irradiation attack the sulfinyl group of MTMSO, and that the residual 55% attack the sulfide S–C bond. Thus, in this case if we can ignore other reaction routes of OH· radical, it has the same reactivity for both the sulfoxide S–C bond and the sulfide S–C bond of MTMSO.

c) Kinetics for the Reaction between OH· Radical and MTMSO: Two methods were adopted for the determination of the rate constant for the reaction of OH·+ MTMSO. One is the conductivity method and the other is the KSCN method.

By the conductivity method, the rate constant was evaluated from a rise portion of build-up curve of the conductivity change after the pulse irradiation. Figure 7 shows a representative build-up curve in which the conductivity signal ΔV_S grows at short time and reaches a constant value $\Delta V_{S\infty}$. A plot of log $(\Delta V_{S\infty}-\Delta S_S)$ against time t gives a straight line, and the rate constant for the OH· radical with MTMSO was determined from the slope of the line to be 4.8×10^9 M^{-1} s^{-1}. The rate constant obtained from the conductivity method may correspond to the rate constant for the reaction of OH· radical with MTMSO.

By the KSCN method, the rate constant was determined utilizing the following competitive reaction of OH· radical with MTMSO.

$$\text{MTMSO} + \text{OH}\cdot \longrightarrow \text{Products} \quad (11)$$

$$CNS^- + OH\cdot \longrightarrow CNS\cdot + OH^- \quad (12)$$

$$CNS^- + CNS\cdot \longrightarrow (CNS)_2^{-}\cdot. \quad (13)$$

From the above reaction scheme, the concentration of $(CNS)_2^{-}\cdot$ after the pulse is obtained as follows:

$$[(CNS)_2^{-}\cdot] = \frac{k_C[CNS^-][OH\cdot]_0}{k_C[CNS^-]+k_F[MTMSO]}$$
$$[1-\exp\{-(k_F[MTMSO]+k_C[CNS^-])t\}], \quad (14)$$

where k_C and k_F denote the rate constants for Reactions 12 and 11, respectively, and $[OH\cdot]_0$ represents initial concentration of OH· radical after the pulse. From Eq. 14, one can evaluate the rate constant values k_C and k_F by monitoring the growth for the absorption intensity of $(CNS)_2^{-}\cdot$ which has an absorption maximum at 475 nm. Figure 8 shows some representative rise-curve of $(CNS)_2^{-}\cdot$ absorption in the absence and the presence of MTMSO. Absorption intensities of $(CNS)_2^{-}\cdot$ increase

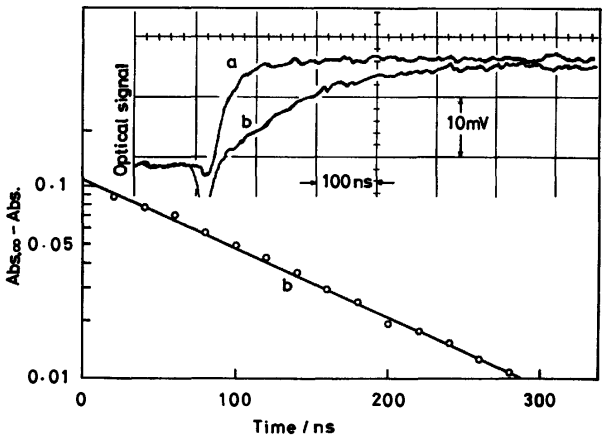

Fig. 8. First-order kinetic plot of $\log(Abs._\infty-Abs.)$ against time after the pulse irradiation of MTMSO aqueous solution. Solutions were saturated with N_2O gas prior to the irradiation. Inset: a) an oscillogram trace for the absorption of $(CNS)_2^-$. after the pulse irradiation of KSCN (10^{-2} M) solution in the absence of MTMSO solution. b) An oscillogram trace for the absorption of KSCN (10^{-3} M) solution in the presence of MTMSO (10^{-3} M). A change of 10 mV in the vertical axis corresponds to 16% transmittance. The monitoring wavelength for all the solution is 475 nm.

Table 2. Reaction rate cosntants of OH· radical with MTMSO obtained from KSCN method

[MTMSO]/M	τ/ns[a]	k_F/M^{-1} s^{-1}
0	199	5.02×10^{6} [b]
0.5×10^{-3}	157	2.68×10^{9}
1×10^{-3}	118	3.43×10^{9}
3×10^{-3}	85	2.25×10^{9}
6×10^{-3}	33[c]	4.19×10^{9}

a) The lifetime τ is the reciprocal value of (k_c[CNS^-]+k_F[MTMSO]). b) The value represent that for k_c[CNS^-]. c) The value may not be very accurate since the pulse width used is $\approx$20 ns.

within a short period of time, reach maxima and decay slowly. As is shown in the figure, a plot of log (Abs.$_\infty$ − Abs.) against t gives a straight line, where Abs.$_\infty$ and Abs. represent a maximum value and a value at t of the absorbances of $(CNS)_2^-\cdot$, respectively. The rate constants k_C[CNS^-] and (k_C[CNS^-]+k_F[MTMSO]) are determined from a slope of the linear plots for KSCN aqueous solutions in the absence and the presence of MTMSO. k_F is then evaluated by the use of k_C[CNS^-] and [MTMSO]. Table 2 summarizes k_F values obtained as a function of MTMSO concentration. Thus, the observation of the rise-curve of $(CNS)_2^-\cdot$ absorption after the pulse irradiation of the KSCN (1×10^{-3} M) with the different concentration of MTMSO (0 to 6×10^{-3} M), gives the k_F value to be 3.1×10^{9} M^{-1} s^{-1}. The rate constant value represents the rate constant for all kinds of reaction between OH· radical and MTMSO.

As well as the results of the yield values for the transients which is discussed in the previous section, information on the rate constants which are obtained independently from two methods leads to the conclusion that the OH· radical has almost the same reactivities with both the sulfoxide S–C bond and the sulfide S–C bond of MTMSO.

The authors wish to acknowledge Dr. Takeaki Enoto and Messrs. Hiroaki Tanida and Koichi Sato for their help in stabilizing and operating the LINAC.

Dynamic Studies on Electron Transport Across Micellar Phase. Intermicellar Migration of Hydrated Electrons

Masayuki AIKAWA,* Takashi SUMIYOSHI,† Nobuyuki MIURA,† and Meiseki KATAYAMA†

College of General Education, Hokkai Gakuen University, Asahimachi Toyohiraku, Sapporo 062

†*Department of Atomic Science and Nuclear Engineering, Hokkaido University, Sapporo 060*

(Received February 20, 1982)

The dynamics of hydrated electrons generated by pulsed electron beams was studied for micellar systems with a series of halogenated naphthalenes as substrates exclusively dissolved in micellar phase. Time behavior of absorption for hydrated electrons, displayed as a curve consisting of two exponential decays, affords evidence that two different routes exist in advance of dissociative electron attachement: 1) direct penetration of electrons through micellar phase with substrates, and 2) migration of hydrated electrons between micells in the absence and presence of substrates, prior to the penetration of electrons into the reactive center in the micelle. Electrostatic interaction of hydrated electrons with positively charged surface of micelles is also discussed.

Knowledge of electron transfer mechanisms with donor–acceptor systems, separated from each other by hydrophobic compartments in aqueous micellar solution, is essential for constructing artificial photosynthetic devices.[1-3] Ionic micelles, like charged colloids and ion-exchange resins, have the property of being able to bind with oppositely charged ions.[4] This aspect of micelles has been used to study a variety of reactions in conjunction with their ability to solubilize hydrophobic molecules in aqueous solutions. In previous works, it has been reported that adsorbed metal ions on anionic micelles can act as efficient electron acceptors from excited micelle solubilized species,[5] and that they can promote the rate of phosphorescence in some aromatic hydrocarbons.[6] Recently, kinetic studies on the movement of metal ions in aqueous micellar solutions have also been reported.[4,7,8] The use of hydrated electrons, generated in bulk aqueous phase, as a source of electrons for redox reactions seems to provide information on the reactivity of electrons with micelle-bound substrate. Few kinetic studies, however, have been directed at studying the movement of hydrated electrons in aqueous micellar solutions.[6,9] Hydrated electrons in aqueous cationic micellar solutions are expected to act in the same manner as metal ions which accelerate or inhibit reactions with oppositely or commonly charged surface of micelles.[4,10] We report here results of dynamic studies on the movement of hydrated electrons in an aqueous cationic micellar solution. The reaction of dissociative electron attachment was utilized to determine the rate of electron transfer from the surface to core of micelles.

Experimental

1-Chloronaphthalene (CN) and 1-bromonaphthalene (BN), purchased from Nakarai Chemicals, were purified by repeated vacuum distillation. 1,4-Dibromonaphthalene (DBN, Wako) was purified by vacuum sublimation. Hexadecyltrimethylammonium bromide (HDTBr, Sigma Chemicals) was used as supplied. For solubilization of halonaphthalenes as substrates, HDTBr detergent in triply distilled water was shaken with the substrate overnight. Concentrations of the substrates in micellar solutions were determined by their absorbances.

Halogenated naphthalenes (XN) are frequently used as effective electron scavengers in radiolyses of various chemical substances. This is based on the fact that XNs are highly reactive toward electrons, and that when an electron attaches to XN, it will dissociate into a neutral radical and a halide ion:[11]

$$XN + e^- \longrightarrow X^-N \longrightarrow X^- + N\cdot. \quad (1)$$

Reaction 1 is a so-called dissociative attachement. Since, however, kinetics between hydrated electrons (e^-_{aq}) and halogenated naphthalenes are not well known because of their low solubilities in water, the reactivity of reaction $e^-_{aq}+XN$ should be tested by monitoring the decay of hydrated electrons prior to running experiments on micellar systems. The decay curve for hydrated electron in an aqueous solution with EtOH (1.0 M) (1 M=1 mol dm^{-3}) consisted of a single exponential component over the range of halonaphthalene concentrations examined (5×10^{-5}—5×10^{-6} M). From observed decay rates of hydrated electrons as a function of XN concentration, rate constants of the reactions of e^-_{aq} with DBN, BN, and CN were determined to be 3.0×10^{10}, 1.8×10^{10}, and 1.4×10^{10} M^{-1} s^{-1}, respectively. These values should represent the rate constant for the following reaction:

$$XN + e^-_{aq} \longrightarrow N\cdot + X^- + H_2O. \quad (2)$$

By monitoring the decay rate for the absorption of hydrated electron after pulse irradiation, reaction kinetics of the electron transport from bulk aqueous phase to micellar phase could be examined if the rate changes with change in the concentration of substrates and/or micelles. Two series of micellar solutions were prepared by 1) changing the concentration of substrates (from 0 to 3×10^{-4} M) at a fixed HDTBr detergent concentration (0.05 M), and 2) changing both the concentrations of substrates [XN] and detergent [Det] at a fixed mean occupancy number ⟨XN⟩, which is the number of substrates bound per micelle. The substrates used are known to be exclusively micellized under the experimental conditions studied, since the binding constants between HDTBr micelle and halogenated naphthalenes are known to be 1.7×10^6 and 3.7×10^6 M^{-1} for BN and CN, respectively.[12,13]

Micellar solutions were deaerated by bubbling purified argon for 10 min through them.

Pulse radiolysis measurements were performed with electron pulses (45 MeV) from a linear accelerator (Mitsubishi) installed in Hokkaido University. The half-width of the electron pulse used was 20 ns. The dose per pulse was in a range of 9—12 krad. The design and performance of the optical detection system combined with the LINAC have been described in a previous paper.[14] The output signal from the detection system was displayed on a transient digitizer (IWATSU) with the shortest resolvable time of 10 ns.

Results and Discussion

Transient adsorption after pulse irradiation on micellar solution without substrate shows a broad spectrum around 400—750 nm, which is exclusively assigned to hydrated electron. With increase in detergent concentration, a little change in absorption decay of e^-_{aq} was observed. From the change in the decay rate of e^-_{aq}, rate constant for the reaction of e^-_{aq} with HDTBr micelle is approximately estimated to be less than 3×10^8 M^{-1} s^{-1}. Since the reaction of hydrated electrons with positively charged micelle does not occur,[6] though the attractive force of micelle for e^-_{aq} sometimes catalyzes reactions, the rate constant obtained in our experiment might be related partly to reactions of e^-_{aq} with some impurities contained in the micelle.

Variation in Absorption Decays of e^-_{aq} as a Function of Micelle and Substrate Concentrations at Fixed Mean Occupancy Number. The mean occupancy number of substrate in a micelle ⟨XN⟩ is defined as

$$\langle XN\rangle = \frac{[XN]}{[M]} = \frac{n}{[Det]-cmc}[XN], \qquad (3)$$

where [XN], [M], and [Det] are bulk concentrations of XN, micelle, and detergent, respectively, and n is the aggregation number of the detergent. Thus, [XN] may be changed by varying ⟨XN⟩, [Det], or n. All experiments were performed in concentration ranges of detergent for which n is not subject to significant variation.

Above the critical micelle concentration (*cmc*), dilution of a micellar solution with water does not significantly alter the value of ⟨XN⟩, *i.e.*, since the ratio [XN]/[Det] and n remain constant with aqueous dilution, ⟨XN⟩ also remains constant. Figure 1 shows the effect of aqueous dilution on absorption decays of e^-_{aq}, where a stock micellar solution with CN ([CN] $=1.4\times10^{-4}$ M; [Det] = [HDTBr] $=5\times10^{-2}$ M) was diluted with water by half, one fourth, and so on. From the literature values of $n=72$ and $cmc=8.5\times10^{-4}$ M,[15] we obtained by calculation that ⟨XN⟩ will vary from 0.21 to 0.25 in our experimental conditions. The increase in total decay rate with increasing concentration of micelle-bound substrate implies that the hydrated electron will react effectively with halogenated naphthalenes *via* Reaction 2.

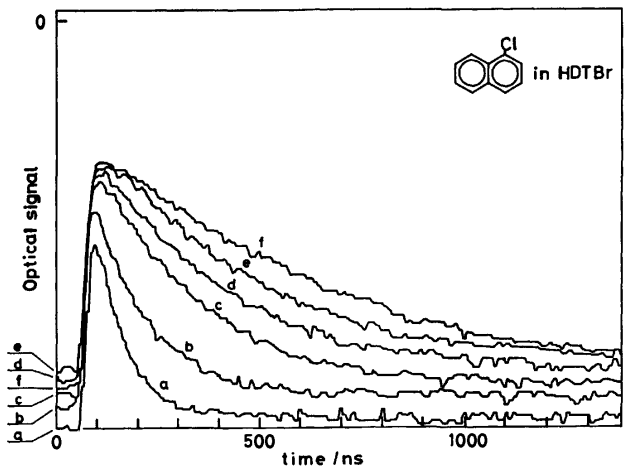

Fig. 1. The decay curves of e^-_{aq} after the pulse irradiation for the aqueous micellar solutions. The concentrations are a) [CN] $=1.4\times10^{-4}$ M, [HDTBr] $=5\times10^{-2}$ M, b) [CN] $=7\times10^{-5}$ M, [HDTBr] $=2.5\times10^{-2}$ M, c) [CN] $=3.5\times10^{-5}$ M, [HDTBr] $=1.25\times10^{-2}$ M, d) [CN] $=1.8\times10^{-5}$ M, [HDTBr] $=6.3\times10^{-3}$ M, and e) [CN] $=1.2\times10^{-5}$ M, [HDTBr] $=4.2\times10^{-3}$ M, respectively. The decay curve (f) is obtained for triply distilled water. The monitoring wavelength and the dose per pulse are 650 nm and 9 krad, respectively.

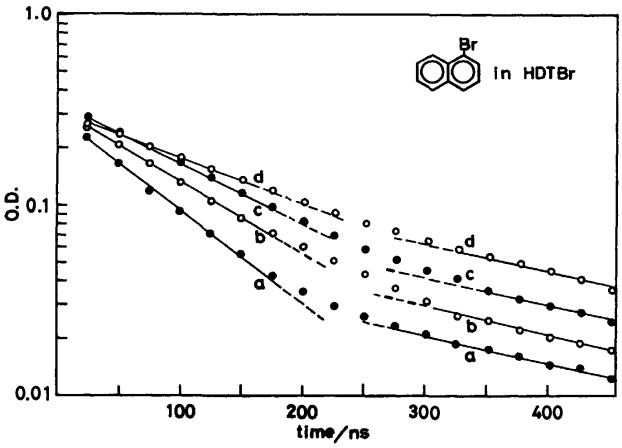

Fig. 2. First-order decay curves of the absorption of e^-_{aq} *vs.* time in aqueous solutions at different [BN] and [HDTBr]. The concentrations are a) [BN] $=2.9\times10^{-4}$ M, [HDTBr] $=5\times10^{-2}$ M, b) [BN] $=1.5\times10^{-4}$ M, [HDTBr] $=2.5\times10^{-2}$ M, c) [BN] $=7.3\times10^{-5}$ M, [HDTBr] $=1.3\times10^{-2}$ M, and d) [BN] $=3.7\times10^{-5}$ M, [HDTBr] $=6.3\times10^{-3}$ M, respectively. The monitoring wavelength and the dose per pulse are 650 nm and 9 krad, respectively.

The decay curves for the absorption of e^-_{aq}, however, do not fit a simple first-order decay, but consist of fast- and slow-decaying components. Figure 2 shows plots of log *O.D.* (e^-_{aq}) against time t as a function of [BN] and/or [M]. With increasing concentration of substrate, the fast-decaying component increases in decay rate, whereas the slow-decaying component remains constant, as shown in the figure. The plot of log *O.D.*(e^-_{aq}) *vs.* t for the time range far away from the time of pulse irradiation gives the first-order decay rate τ_s^{-1}, corresponding to the decay rate for the slow-decaying component. The decay rate for the fast-decaying component, τ_f^{-1}, can be obtained from the difference between the total decay curve and the first-order decay curve extrapolated toward shorter times by use of τ_s^{-1}. Apparent rate constants for the reaction of e^-_{aq} with XN in micelles were then obtained from the slope of the linear plots of τ_f^{-1} *vs.* [XN]. Rate constants thus obtained are summarized in Table 1.

The constancy of rate for the slow-decaying component with the change in micelle concentration at constant ⟨XN⟩ may arise from a constant ratio in number of the micelles possessing one substrate M_{XN} to those possessing zero substrate M_0. Since multiple occupancy of the substrate per micelle is neglected from

TABLE 1. RATE CONSTANTS/$M^{-1}s^{-1}$ OF REACTION OF HYDRATED ELECTRON WITH HALOGENATED NAPHTHALENES

	DBN	BN	CN
Aqueous solution (+1 M EtOH)	3.0×10^{10}	1.8×10^{10}	1.4×10^{10}
HDTBr micellar solution[a)]	2.9×10^{10}	2.0×10^{10}	2.2×10^{10}

a) Evaluated from fast-decaying components.

the Poisson statistics, hydrated electrons can encounter only those micelles with one or zero substrate.

It should be noted here that the initial intensity of absorption decay of e^-_{aq} after the pulse does not change with varying [XN] and/or [M], implying that only the reactions after the formation of hydrated electrons with micelles or substrates are observed.

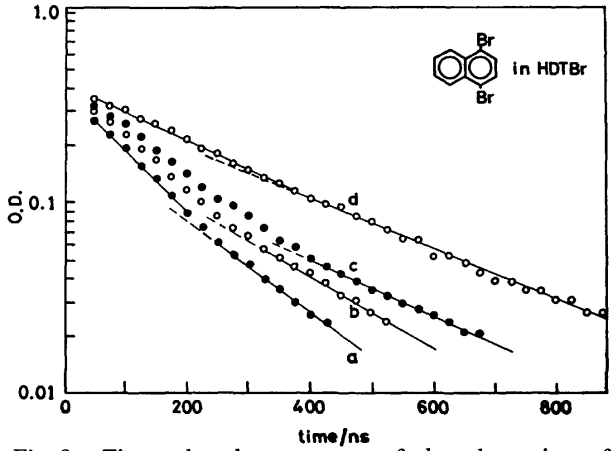

Fig. 3. First-order decay curves of the absorption of e^-_{aq} *vs.* time in 5×10^{-2} M HDTBr solutions at different [DBN]. The concentrations of DBN are a) 3.3×10^{-4} M, b) 9.8×10^{-5} M, c) 6.5×10^{-5} M, and d) 3.3×10^{-5} M, respectively. The monitoring wavelength and the dose per pulse are 650 nm and 9 krad, respectively.

Variation in Absorption Decays of e^-_{aq} as a Function of Substrate Concentration at Fixed Micelle Concentration.

In a series of experiments with [HDTBr] fixed at $=5\times10^{-2}$ M, the concentration of [XN] was varied from 3.3×10^{-5} to 3.3×10^{-4} M. Figure 3 shows semi-logarithmic plots of e^-_{aq} absorption against time as a function of [DBN] at fixed detergent concentration. The decay curves for the absorption of e^-_{aq} also consist of fast- and slow-decaying components. In this case, however, unlike the case of aqueous dilution experiments, both the fast- and slow-decaying components increase in decay rate with increasing concentration of substrate. Apparent rate constants for the reaction of e^-_{aq} with micelle-bound substrates were obtained from the slope of the plots of τ_f^{-1} *vs.* [XN] as in the case of aqueous dilution experiments. The rate constant values obtained are comparable with that obtained in the aqueous dilution experiment.

The rate of encounter between M_{XN} and M_0 is given by

$$k_e[M_{XN}][M_0] = k_e\cdot P_{XN}\cdot P_0[M]^2, \qquad (4)$$

where k_e is the rate constant for encounter between M_{XN} and M_0. P_{XN} and P_0 represent respective probability distributions of M_{XN} and M_0, which are based on the Poisson statistics. With increasing $\langle XN\rangle$ value from 0.05 to 0.5 at constant [M] (6.8×10^{-4} M), the value for $P_{XN}\times P_0$ increases from 0.048 to 0.23. The increase in the slow reaction rate τ_S^{-1} with increasing rate of encounter between M_{XN} and M_0 (in consequence of increasing $\langle XN\rangle$) suggests that, in the absence of substrates, micelles play a mechanistic role in electron transport from hydrated electrons to micelle-bound substrates.

Mechanisms for Electron Transport in Micellar Systems. The large positive charge on micelle surface forms a Gouy-Chapman double layer which is spread over several hundred Å from the surface of micelle.[16,17] Along the electrostatic field which is produced by the double layer, hydreted electrons move toward the surface. The electrostatic interaction between hydrated electrons and positive charges on the surface, then may lead to formation of a complex ($M_0\cdots e^-_{aq}$) or ($M_{XN}\cdots e^-_{aq}$). Electron transfer reaction (*viz.*, ($M_{XN}\cdots e^-_{aq}$)$\rightarrow$ $M_{X^-N}+H_2O$) will take place quickly for micelles in the presence of substrates. On the other hand, hydrated electrons may survive to form a complex ($M_0\cdots e^-_{aq}$), since the lifetime of hydrated electrons is practically unchanged by the addition of cationic detergent to aqueous solution. The following scheme represents the electron transport reaction relevant to our experimental data:

$$\begin{array}{ccc} & & M_{X^-N} \\ & & \uparrow \\ (M_0\cdots e^-_{aq}) + M_{XN} & \rightleftharpoons & M_0 + (M_{XN}\cdots e^-_{aq}). \\ \downarrow\uparrow & & \uparrow \\ M_0 + e^-_{aq} & & M_{XN} + e^-_{aq} \end{array} \qquad (5)$$

If a sizable percent of complex ($M_0\cdots e^-_{aq}$) is formed, migration of hydrated electrons from ($M_0\cdots e^-_{aq}$) to M_{XN} will occur on micelle surface before an electron penetrates the reactive center in micelle M_{XN}. This migration behavior of hydrated electron is similar to that of micelle-bound metal ion which moves through micelle-micelle collision, at which overlap of ionic charge clouds of micelles allows the ion to migrate from one micelle to another.[4,8] The migration of surface-bound hydrated electrons leads eventually to an electron transfer reaction from the surface to reactive halonaphthalenes. Qualitatively, this migration mechanism interprets the "slow" electron transport reaction which controls the slow-decaying component. Direct encounter between M_{XN} and e^-_{aq} leads to the "fast" electron transport reaction which controls the fast-decaying component. Collectively, the experimental results relating to the decay curves for e^-_{aq} absorption consisting of the slow- and fast-decaying components are consistent with Reaction Scheme 5 which would be expected from an electrostatic consideration.

A further kinetic and spectroscopic study was designed to investigate these systems and to evaluate exactly rate constants for the reaction scheme. Details of the kinetic analysis will appear in the successive paper.

Conclusion

This paper has described electron transport reactions between hydrated electrons and micelle-bound electron acceptors. Preliminary kinetic measurements indicate that, together with direct encounter between e^-_{aq} and M_{XN}, micelle plays a significant role in the reaction of electron transport from hydrated electron to micelle-bound substrate.

The authors wish to acknowledge Dr. Takeaki Enoto and Messrs. Hiroaki Tanida and Koichi Sato for their help in stabilizing and operating the LINAC.

(Received July 31, 1981)

A hydridoruthenium(II) complex [RuClH(CO)(PPh_3)$_3$] reacted easily with acrylonitrile and fumaronitrile to give chloro-bridged binuclear (1-cyanoethyl)ruthenium(II) complexes, [{Ru(MeCHCN)Cl(CO)(PPh_3)$_2$}$_2$] (**2**) and [{Ru(NCCH$_2$CHCN)Cl(CO)(PPh_3)$_2$}$_2$], respectively. Complex **2** reacted with 4-picoline (pic), Na[$BHPz_3$] (Pz=1-pyrazolyl), Na[BPz_4], and Na[Et_2NCS_2]·3H$_2$O to afford the corresponding (1-cyanoethyl)ruthenium(II) complexes, [{Ru(MeCHCN)Cl(CO)(pic)(PPh_3)}$_2$] (**3**), [Ru(MeCHCN)($BHPz_3$)(CO)(PPh_3)] (accompanied by a small amount of [Ru$_2$(MeCHCN)$_2$Cl($BHPz_3$)(CO)$_2$(PPh_3)$_4$]), [Ru$_2$(MeCHCN)$_2$Cl(BPz_4)(CO)$_2$(PPh_3)$_2$], and Na[Ru(MeCHCN)Cl(Et_2NCS_2)(CO)(PPh_3)], respectively. Complex **3** reacted with thallium(I) acetylacetonate [Tl(acac)], resulting in the formation of [{Ru(MeCHCN)(acac)(CO)(PPh_3)}$_2$] and [Ru(MeCHCN)(acac)(CO)-(pic)(PPh_3)]. These new complexes were characterized by means of elemental analysis and spectroscopic data. The diastereoisomerism was also discussed as regards these (1-cyanoethyl)ruthenium(II) complexes.

It is interesting to investigate the coordination behavior of (1- and 2-cyanoalkyl)ruthenium(II) complexes, in connection with catalytic hydrodimerization[1–3] and polymerization[4] of acrylonitrile with ruthenium complexes. However, little has been known about the (cyanoalkyl)ruthenium(II) complexes,[5] whereas only a few papers have been reported concerning the coordination behavior of octahedral alkylruthenium-(II) complexes.[6–9]

It has been recently reported from our laboratory that some substituted olefins insert into the hydridoruthenium (H–Ru) bond of (carbonyl)chlorohydridotris-(triphenylphosphine)ruthenium(II) (**1**) to give stable organoruthenium(II) complexes.[5] Since [{Ru-(MeCHCN)Cl(CO)(PPh_3)$_2$}$_2$] (**2**), prepared from the reaction of **1** with acrylonitrile, was insoluble in usual organic solvents, its 4-picoline (pic) derivative [{Ru-(MeCHCN)Cl(CO)(pic)(PPh_3)}$_2$] (**3**) was prepared. Complex **3** had also a binuclear structure and was assumed to consist of a few diastereoisomers.[5] In this paper, reactions of **2** and **3** with several anionic chelating ligands were carried out, in order to prepare mononuclear (1-cyanoethyl)ruthenium(II) complexes and to confirm whether the isomers in **3** were caused by asymmetric 1-carbon and ruthenium atoms or not. In addition, the resulting complexes were isolated and characterized on the basis of elemental analysis and spectroscopic data.

Experimental

General Procedures and Materials. Melting points, IR spectra, and ^{1}H and ^{31}P-NMR spectra were obtained according to the previous paper.[10] The molecular weight of a complex was determined in benzene using a Corona model 114 vapour pressure osmometer.

Solvents were dried and distilled by the usual methods, and all preparative operations were performed in an atmosphere of dry nitrogen. Complex **1**,[11] sodium poly(1-pyrazolyl)borates Na[BPz_3H] (Pz=1-pyrazolyl) and Na[BPz_4],[12] and thallium-(I) acetylacetonate[13] were prepared according to the literature methods. The other reagents were commercial samples, and were used without further purification.

Reaction of 1 with Acrylonitrile. A THF suspension (60 ml) containing **1** (1 mmol) and acrylonitrile (7.5 mmol) was stirred at room temperature for 23 h to give a pale yellowish green precipitate. The precipitate was collected and washed with hexane and diethyl ether to yield a greenish gray solid [{Ru(MeCHCN)Cl(CO)(PPh_3)$_2$}$_2$] (**2**).

Reaction of 2 with 4-Picoline. A THF suspension (35 ml) involving **2** (0.24 mmol) and 4-picoline (1.4 mmol) was stirred at room temperature for 20 h to yield a yellow solution. After concentration, the yellow solution was diluted with diethyl ether to give a pale green powder, [{Ru(MeCHCN)Cl(CO)-(pic)(PPh_3)}$_2$] (**3**).

Reaction of 1 with Fumaronitrile. A THF suspension (30 ml) containing **1** (1 mmol) and fumaronitrile (3.75 mmol) was stirred at room temperature for 20 h to result in an orange-brown solution. After concentration under a reduced pressure, the orange-brown solution was diluted with 80 ml of hexane to yield an orange-brown powder. The powder was collected and washed with diethyl ether to give a yellow-brown powder, [{Ru(NCCH$_2$CHCN)Cl(CO)(PPh_3)$_2$}$_2$] (**4**).

Reaction of 2 with Na[$BHPz_3$]. A THF suspension (20 ml) involving **2** (0.27 mmol) and Na[$BHPz_3$] (0.55 mmol) was stirred at 40 °C for 4 h. After filtration, the resulting filtrate was evacuated under a reduced pressure, and chromatographed over silica-gel column (Wako gel, 200 mesh, 150×12ϕ mm). A yellow fraction was eluted with benzene, and concentration of this afforded yellow solids, [Ru(MeCHCN)($BHPz_3$)(CO)-(PPh_3)] (**5**). Moreover, a pale yellow fraction was eluted with acetone, and evaporation of this gave a small amount of pale yellow solids, [Ru$_2$(MeCHCN)$_2$Cl($BHPz_3$)(CO)$_2$(PPh_3)$_4$] (**6**).

Reaction of 2 with Na[BPz_4]. A benzene suspension (40 ml) containing **2** (0.25 mmol) and Na[BPz_4] (0.55 mmol) was refluxed for 9 h. After filtration, the filtrate was concentrated and diluted with hexane to yield cream-yellow precipitates. The precipitates were recrystallized from dichloromethane-hexane to give a cream-yellow powder, [Ru$_2$(MeCHCN)$_2$Cl-(BPz_4)(CO)$_2$(PPh_3)$_2$] (**7**).

Reaction of 2 with Na[Et_2NCS_2]·3H$_2$O. A THF suspension (60 ml) of **2** (0.2 mmol) and Na[Et_2NCS_2]·3H$_2$O (0.48 mmol) was stirred at room temperature for 91 h to yield greenish white precipitates. The precipitates were washed with diethyl ether and hexane, successively, to afford greenish white solids, Na[Ru(MeCHCN)Cl(Et_2NCS_2)(CO)(PPh_3)] (**8**).

Reaction of 3 with Thallium(I) Acetylacetonate. A dichloromethane suspension (30 ml) containing **3** (0.52 mmol) and Tl(acac) (1.05 mmol) was stirred at room temperature for 72 h.

After filtration, the resulting solution was chromatographed upon the silica-gel column. A yellow fraction was eluted with benzene, concentrated under a reduced pressure, and diluted with hexane to give a light yellow powder, [{Ru(MeCHCN)(acac)(CO)(PPh_3)}$_2$] (**9**). The second yellow fraction was eluted with dichloromethane, and evacuated to dryness *in vacuo*. The resulting residue was washed with hexane to afford a pale yellow powder, [Ru(MeCHCN)(acac)(CO)(pic)(PPh_3)] (**10**).

Results and Discussion

Preparation. The hidridoruthenium(II) complex **1** reacted smoothly with acrylonitrile and fumaronitrile in THF at room temperature to give sparingly soluble binuclear complexes [{Ru(MeCHCN)Cl(CO)(PPh_3)$_2$}$_2$] (**2**)[5] and [{Ru(NCCH$_2$CHCN)Cl(CO)(PPh_3)$_2$}$_2$] (**4**), respectively. Complex **2** was treated with 4-picoline (in THF at room temperature), with Na[BPz_4] (in refluxing benzene), and with Na[Et_2NCS_2]·3H$_2$O (in THF at room temperature) to yield [{Ru(MeCHCN)Cl(CO)(pic)(PPh_3)}$_2$] (**3**), [Ru_2(MeCHCN)$_2$Cl(BPz_4)(CO)$_2$(PPh_3)$_2$] (**7**), and Na[Ru(MeCHCN)Cl(Et_2NCS_2)(CO)(PPh_3)] (**8**), respectively. Complexes **3** and **7** have also binuclear structures, whereas **8** has an ionic structure and is actually insoluble in usual organic solvents.

In order to obtain neutral mononuclear-type complexes, reactions between **2** and Na[$BHPz_3$] and between **3** and Tl(acac) were examined. The former reaction produced two complexes, which were separated by column chromatography and formulated as [Ru(MeCHCN)($BHPz_3$)(CO)(PPh_3)] (**5**) and [Ru_2(MeCHCN)$_2$Cl($BHPz_3$)(CO)$_2$(PPh_3)$_4$] (**6**). From the latter reaction, two complexes were formed, separated similarly, and formulated as [{Ru(MeCHCN)(acac)(CO)(PPh_3)}$_2$] (**9**) and [Ru(MeCHCN)(acac)(CO)(pic)(PPh_3)] (**10**). The yields and elemental analyses of **2**—**10** are summarized in Table 1.

General Properties. The IR spectra of **2**—**10** lacked a ν(Ru–H) band near 2000 cm^{-1}, which had been observed in the starting complex, **1**, and showed one strong band in the range of 1905—1945 cm^{-1}, assignable to a terminal carbonyl group, whereas **4**, **5**, and **7** exhibited one or two additional shoulders near 1910 and 1950 cm^{-1} (Table 2). Furthermore, **2**, **3**, **5**—**8**, and **10** exhibited a medium band near 2200 cm^{-1}, characteristic of an uncoordinated cyano group. The ^{1}H-NMR spectra of **3**, **5**—**7**, and **10** each exhibited two, three or four doublets in the region of δ 0.2—1.4, ascribable to methyl group adjacent to methine group. On the basis of these data and the elemental analyses, **2**, **3**, **5**—**8**, and **10** were attributed to carbonyl(1-cyanoethyl)ruthenium(II) complexes. Complex **4** showed two ν(C≡N) bands at 2205 and 2230 cm^{-1}, implying that **4** contained a 1,2-dicyanoethyl group.

Complexes **2**—**10** are stable in a solid state in the air and considerably stable in solution under a nitrogen stream. Their stability is possibly associated with electron-delocalization effect due both to the coordination of appropriately σ-donating and π-accepting carbonyl group and PPh_3 ligand and to the electron-accepting cyano group adjacent to the 1-carbon.

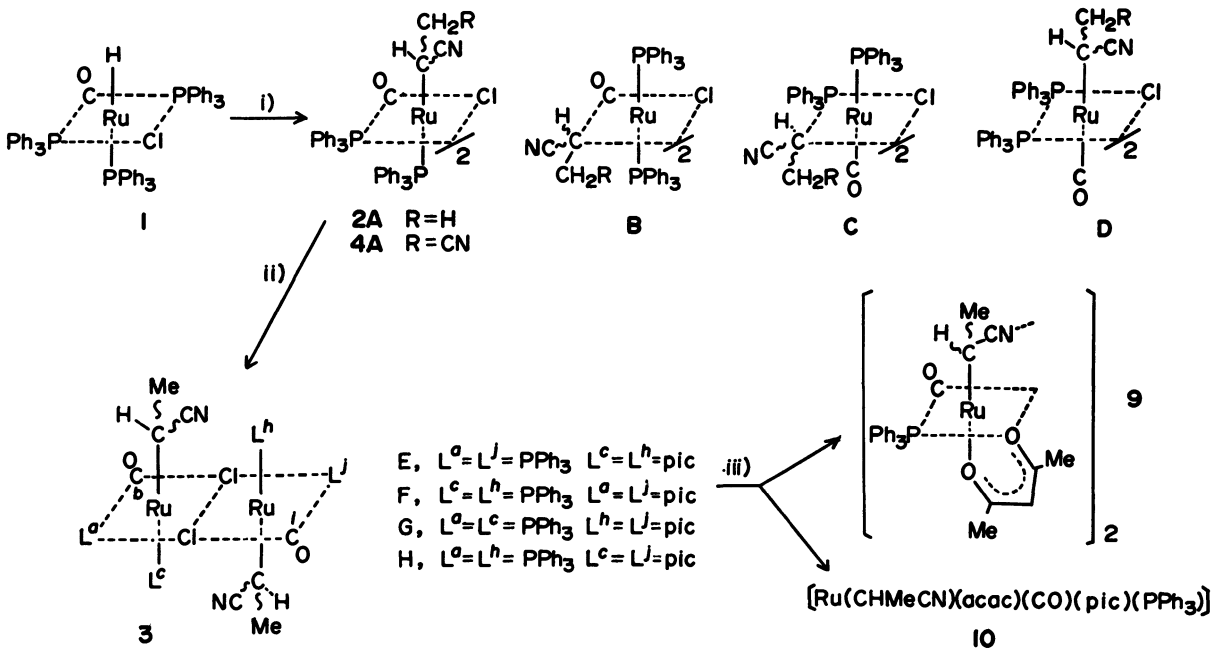

Scheme 1. i) Acrylonitrile (for **2**) or fumaronitrile (for **4**). ii) 4-Picoline (pic) with **2**. iii) Tl (acac). See Fig. 2 as regards the diasteroisomers of **3** and **4** and Fig. 4 as regards those of **9** and **10**.

Chloro-bridged Binuclear Complexes **2**—**4**. The elemental analyses of **2**—**4** imply that each of these three complexes has one chlorine atom and four other coordination sites per ruthenium atom, indicating a chloro-bridged binuclear structure (Scheme 1).[10] Indeed, chlorine atoms have been reported to serve as bridge-forming ligands in many chlororuthenium(II) complexes.[10,14,15] It is noteworthy that **2** and **3** showed the single intensive ν(C≡O) band, although they have the binuclear structures and consist of a few diastereoisomers (*vide infra*).[5] This indicates that the diastereoisomerism for **2** and **3** has actually little influence on the ν(C≡O) band and that the two carbonyl groups in the binuclear structure are coordinated in an inversion symmetry (a *b,i*-CO type in Scheme 1) rather than in a C_2 rotational one around the Cl-Cl axis (a *b,j*-CO type) and in a C_1 one (a *b,g*- or a *b,h*-CO type). A binuclear dicarbonyl complex in the C_2 or the C_1 symmetry would show two ν(C≡O) bands, according to group theory. As concerns mononuclear moiety in **2** or **4**, four types A-D are possible, as shown in Scheme 1. However, types C and D are ruled out, because relatively bulky ligands, two PPh_3 ones and one 1-cyanoethyl group are located at facial positions in these types, and because both carbonyl ligand and chloro one in **1** must remain unmoved at trans positions to each other in the mild reaction conditions from **1** to **2** and **4**, as elucidated in the cases of the reactions of **1** with carbon disulfide[16] and with 2-formylpyridine.[17]

The mononuclear moiety in **2** and **4** is diastereomeric, owing to both asymmetric 1-carbon and ruthenium atoms (Fig. 1). Accordingly, **4**, which consists of two $\{Ru(NCCH_2CHCN)Cl(CO)(PPh_3)_2\}$ moieties, has two, three, or four diastereoisomers. Indeed, the $^{31}P\{^1H\}$-NMR spectrum of **4** in CH_2Cl_2[18] showed six fairly sharp signals at 20.5, 28.1, 35.1, 45.9, 47.0, and 47.9 ppm to the lower field from 85% H_3PO_4 as an external

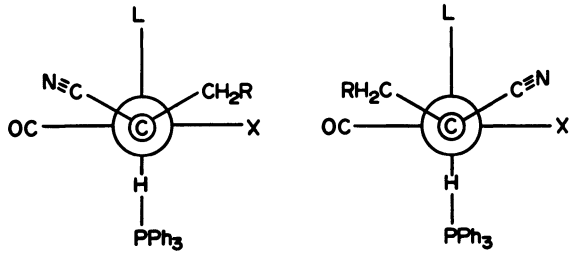

Fig. 1. Diastereoisomerism of $\{Ru(RCH_2CHCN)X(CO)L(PPh_3)\}$ moiety. The ruthenium atom is represented as an outer circle.

reference (virtually equal intensity, each *ca.* 0.45P; without clearly detectable coupling), two fairly broad ones at 23.0 and 30.1 ppm (each intensity, *ca.* 0.25P), and complicated ones in the range of 37.3—43.7 ppm (total intensity, *ca.* 0.8P).[19] Furthermore, it is clearly demonstrated by **10** that each of the $^{31}P\{^1H\}$-NMR signals corresponds to coordinated PPh_3 ligand in each diastereoisomer, unless the signals overlap with each other (*vide infra*). Therefore, the eight signals of **4**, *i.e.*, the six fairly sharp ones and the two fairly broad ones correspond to eight kinds of coordinated PPh_3 ligands due to three diastereoisomers of **4** (Fig. 2)[20] and are inconsistent with types B and D as regards the major components of **4**, since each of these two types would produce two diastereoisomers, and show only four ^{31}P-NMR signals. Accordingly, type A, where two PPh_3 ligands are situated at *cis* positions to each other, is most probable as the mononuclear moiety of the major components of **4** and possibly as that of **2**.[21] This conclusion is strongly supported both by the fact that $[\{Ru(MeCHCN)Cl(CO)(PPh_3)[P(OMe)_3]\}_2]$, derived from **2** and $P(OMe)_3$ at room temperature, exhibited relatively small ^2J(PP) values (26—32 Hz), which were

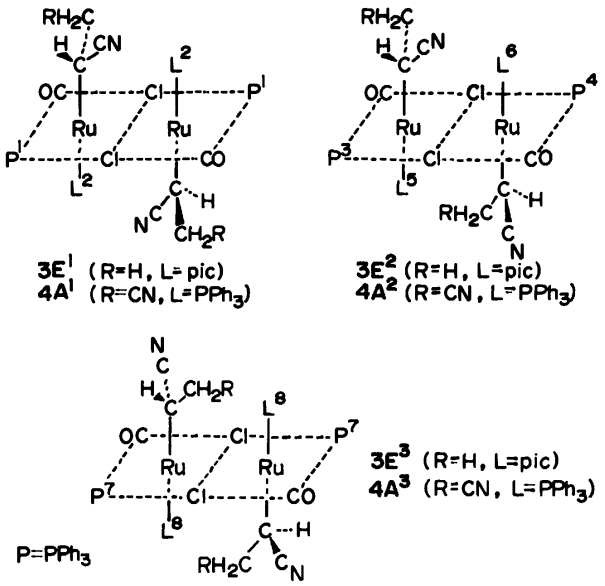

Fig. 2. Proposed structures for the diastereoisomers of **3** or **4**. See Ref. 19 as regards the minor components of **4**.

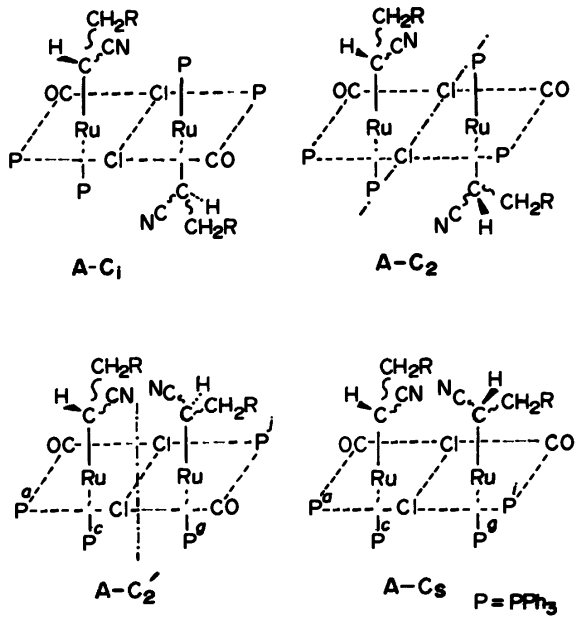

Fig. 3. Possible binuclear structures for **2A** and **4A**. See Ref. 23.

ascribable to *cis*-couplings between two nonequivalent phosphorus nuclei,[22] and by the *cis*-coordination of the two PPh_3 ligands confirmed for the analogous insertion products obtained from **1** and CS_2[16] or 2-formylpyridine[17] at mild conditions.

As for the binuclear structure of **2** or **4**, which consists of two A-typed $\{Ru(RCH_2CHCN)Cl(CO)(PPh_3)_2\}$ moieties, four structures A-C_1, -C_2, -C_2', and -C_s are possible in consideration of their symmetry groups,[23] as shown in Fig. 3. However, structures A-C_2' and -C_s

a) Value (ppm). In $CDCl_3$, except **3**. Proton number is given in parentheses. Phenyl protons and pyridine-ring protons are omitted. b) Doublet with $^3J(HH)$=*ca.* 8 Hz, unless noted elsewhere. c) Signal shape is also given in parentheses. d) Signal shape and assignment are also given in parentheses. 3-, 4-, and 5-H's belong to the 1-pyrazolyl groups. e) In CD_2Cl_2. f) Methine proton resonance was obscured by the other signals. g) Methyl group of 4-picoline. h) Resonances in two neighboring lines correspond to one isomer. i) $^3J(HH)$=2—2.3 Hz. j) The other signal was obscured by the phenyl protons. k) Doublet with $^3J(HH)$=*ca.* 7 Hz.

are unfavorable, because these two structures would give rise to considerable steric repulsion between four relatively bulky PPh_3 ligands coordinated together at near positions, *i.e.*, at *a*, *c*, *g*, and *i* or *j* sites. Both structures A-C_2 and -C_8 seem unlikely in consideration of the single ν(C≡O) band (*vide ante*).[24] On the basis of these discussions, both **2** and the major components of **4** are attributable to structure A-C_1.

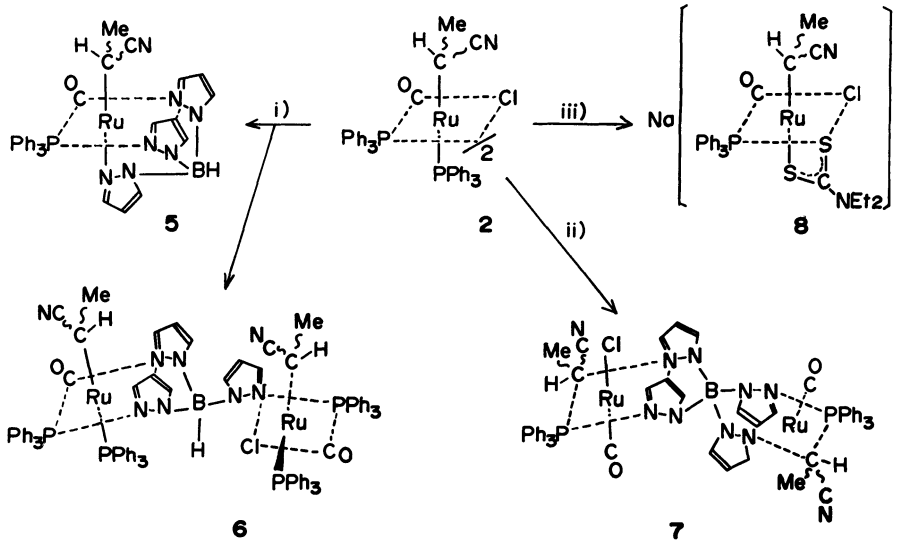
It is noteworthy that 4-picoline gave rise to the replacement of two PPh_3 ligands in **2** instead of the splitting of the chloro-bridge,[10] to afford **3** with **E**-, **F**-, **G**-, and/or **H**-type structures due to geometrical isomerism and coordination position one (Scheme 1).[25] This replacement was facilitated both by strong trans influence of the 1-cyanoethyl groups located at *trans* positions to the leaving PPh_3 ligands and somewhat by steric interaction between the two *cis*-located PPh_3 ligands in **2**.[16,17] In addition, types **G** and **H** are unfavorable, since each of them is composed of two nonequivalent {Ru(MeCHCN)Cl(CO)LL'} moieties (where L and L' are PPh_3 and/or pic) which would show two ν(C≡O) bands (*vide ante*). Moreover, type **G** is also inadequate, because the second PPh_3 ligand coordinated to the ruthenium atom is insusceptible to the replacement by 4-picoline, owing to the considerably strong *trans* influence of PPh_3. On the basis of these considerations, **3** was assignable to type **E**.

The ^{1}H-NMR spectrum of **3** exhibited both two picoline-methyl resonances at δ 2.26 (3H) and 2.37 (3H) and two doublets at δ 0.23 (3H) and 0.36 (3H), assignable to the methyl protons of the 1-cyanoethyl moieties (Table 3). These data indicate that **3**, which consists of two {Ru(MeCHCN)Cl(CO)(pic)(PPh_3)} moieties, has three diastereoisomers, **3E**^{1}, **3E**^{2}, and **3E**^{3} similar to the cases of **4** (Fig. 2). Indeed, the ^{31}P-{^{1}H}-NMR spectrum in CH_2Cl_2 showed four singlets of a virtually equal intensity at 89.13, 89.25, 95.82, and 95.91 ppm from trimethyl phosphite as an external reference,[5] corresponding to four kinds of PPh_3 ligand in **3E**^{1}, **3E**^{2}, and **3E**^{3}. The population ratio of **3E**^{1}, **3E**^{2}, and **3E**^{3} is virtually 1 : 2 : 1 on the basis of the ^{31}P nuclear resonances, indicating an actually statistical isomer ratio. This implies that acrylonitrile was inserted into the H-Ru bond in **1** in a non-stereoselective fashion.

$BHPz_3$ and BPz_4 Complexes ***5*****—*****7***. The ^{1}H-NMR spectrum of the mononuclear $BHPz_3$ complex **5** exhibited both two sets of doublets at δ 0.52 (1.8H, Me) and 1.36 (1.2H, Me) and two sets of quartets at δ 1.77 (0.6H, CH) and 2.05 (0.4H, CH) (Table 3). These data indicate that **5** consists of two diastereoisomers, with a population ratio of about 6 : 4. Furthermore, **5** showed four triplets in the range of δ 5.8—6.3 and a broad signal at δ 6.16, assignable to 4-H's of the 1-pyrazolyl groups, supporting the existence of the two diastereoisomers.

Thus, the two diastereoisomers were detected for the mononuclear complex, **5**, which contains the C_3-symmetric $BHPz_3$ ligand. This is quite consistent with the three diastereoisomers, proposed for **3**. The two diastereoisomers of **5** could not be separated by the silica gel column chromatography. Similar [hydrotris(1-pyrazolyl)borato]ruthenium(II) complexes, [Ru(C_6H_4–N=NPh-*o*)($BHPz_3$)(CO)$_2$] and [Ru(C_6H_4–N=NPh-*o*,1-*C*,*N*')($BHPz_3$)(CO)] have been reported by Bruce *et al.*[15]

The reaction of **2** with Na[$BHPz_3$] produced a small amount of the binuclear complex, **6**, in which one tridentate [$BHPz_3$] group possibly serves as a bridging ligand. Since **6** contains two PPh_3 ligands per ruthenium atom, similarly to **2**, the relative positions of the two PPh_3 ligands are assumed to remain unchanged during the reaction. Two 1-pyrazolyl groups in the $BHPz_3$ ligand form a six-membered boat-typed ring[26–28] with one of the two ruthenium atoms. The third 1-pyrazolyl group is coordinated to the other ruthenium atom at the *cis* or *trans* position to the 1-carbonyl group. Accordingly, two {Ru(MeCHCN)(CO)(PPh_3)$_2$} moieties in **6** are nonequivalent. It looks unlikely that the third 1-pyrazolyl group is located at the axial site of the six-membered boat-formed Ru-(N-N)$_2$-B ring, because this configuration would give rise to a serious steric interaction between the Pz-Ru(MeCHCN)Cl(CO)(PPh_3)$_2$ moiety and the PPh_3 ligand coordinated



Scheme 2. i) Na[$BHPz_3$] at 40 °C. ii) Na[BPz_4] in refluxing benzene. iii) Na[Et_2NCS_2]·$3H_2O$.

to the first ruthenium atom. Since **6** is associated both with two kinds of diastereoisomerism due to the two nonequivalent [Ru(MeCHCN)(CO)(PPh_3)$_2$] moieties and with one *cis-trans* geometrical isomerism, there are at least eight possible isomers for **6**. However, **6** showed only three doublets at δ 1.36, 1.24, and 0.94 attributable to the methyl protons of the 1-cyanoethyl groups with about 3 : 1 : 1 of intensity ratio. While it is difficult to assign the three doublets to the isomers of **6**, probable configurations for **6** are tentatively shown in Scheme 2.[29] Complex **6** might be an intermediate in the reaction from **2** to **5**.

The binuclear complex, **7** involves one PPh_3 ligand per ruthenium atom in sharp contrast with **6**, and has one quadridentate $[BPz_4]^-$ ligand, which acts as two sets of bidentate chelates, bridging both a {Ru(MeCHCN)-Cl(CO)(PPh_3)} moiety and a {Ru(MeCHCN)(CO)-(PPh_3)} one. Trofimenko[30] has reported on similar bridging $[BPz_4]$-typed complexes, $[(\eta^3\text{-}CH_2CRCH_2)$-$Pd(Pz_2BPz_2)Pd(\eta^3\text{-}CH_2CRCH_2)]^+$.
Then, the two ruthenium atoms in **7** are six- and five coordinate, and nonequivalent. The latter five coordination of the ruthenium(II) complexes is unusual and probably associated with a steric interaction between fairly bulky PPh_3 ligand and BPz_4 one. Analogous five-coordinate ruthenium(II) complex has been reported as regards [Ru(dtim)Cl(PPh_3)$_2$] (dtim=1,3-di-*p*-tolyl-2-imidazolidinylidenato-2-*C*,2'-*C*).[31] On the basis of these discussions, there are many possible isomers for **7**. However, **7** exhibited only two doublets at δ 0.84 and 0.93 for the methyl protons of the 1-cyanoethyl moieties with a vertually equal intensity. Probable configurations for **7** are tentatively shown in Scheme 2,[32] like the case of **6**.

Acac Complexes **9** *and* **10**. The binuclear acac-type complex **9** was obtained together with the mononuclear complex, **10**. These two complexes showed two bands near 1590 and 1510 cm^{-1}, characteristic of the *O,O'*-chelating acac ligand. Complex **9** exhibited a ν(C≡N) band at 2240 cm^{-1}, which is about 20—40 cm^{-1} higher than those of the other (1-cyanoethyl)ruthenium-(II) complexes. The molecular weight of **9** was 1091; Calcd for [{Ru(MeCHCN)(acac)(CO)(PPh_3)}$_2$], 1089. These data indicate that **9** has a binuclear structure, and that two 1-cyanoethyl groups bridge two ruthenium atoms. A bridge structure with the acac-oxygen atoms is unfavorable in **9**. In a non-bridging state, bond angles Ru–C–C(≡N) and C–Ru←N(≡C) in a *cis*-form are expected to be approximately 109°28' and 90°, respectively, and a bonding chain, C–C≡N→Ru is virtually straight. Then, the bridging {Ru–CHMe–C≡N→}$_2$ moiety forms a rhombus or an octagon, and presumably holds more or less strain.

The ^{1}H-NMR spectrum of **9** exhibited four acac-methine proton resonances in an intensity ratio of nearly 6 : 2 : 1 : 1, whereas only two doublets (MeCHCN–) and four acac-methyl proton resonances were distinguished (Table 3). The ^{31}P-{H}-NMR spectrum in CH_2Cl_2 also showed four singlets at 34.6, 54.6, 31.6, and 53.0 ppm to the lower field from 85% H_3PO_4 in the similar intensity ratio to the acac-methine protons. It is noteworthy that the four ^{31}P-NMR signals appeared in unequal intensities as well as the four methine-proton ones did. Furthermore, the Ru–Ru

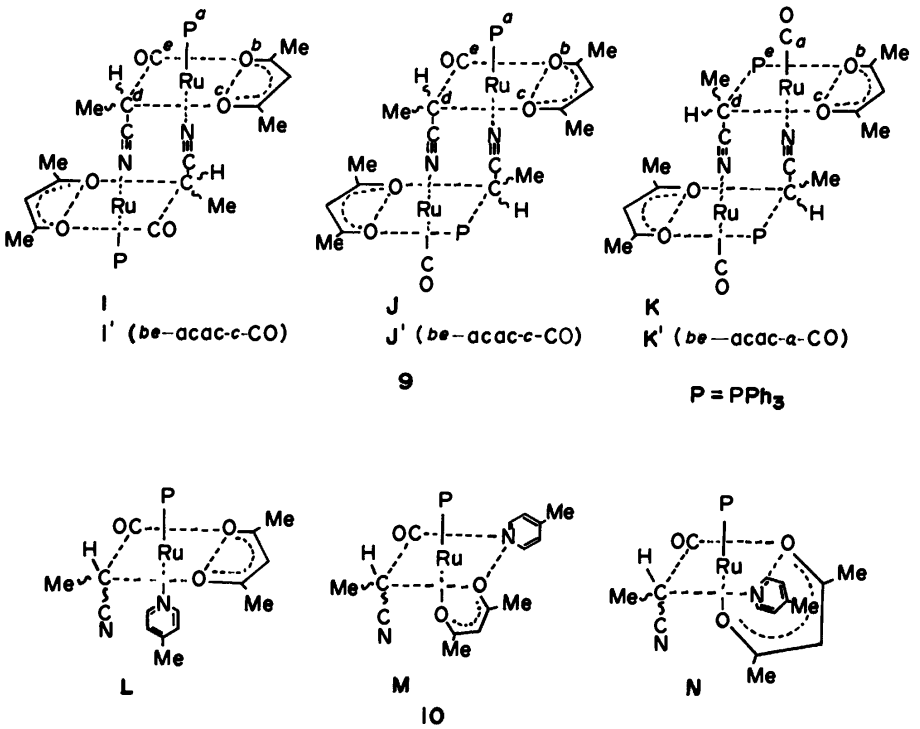


Fig. 4. Proposed structures for the isomers of **9** and **10**. The visual angles for **9** are changed from that in Scheme 1. See Ref. 33 as regards I', J', and K', the geometrical isomers of I, J, and K, respectively.

distance in **9** is so long that the two {Ru(MeCHCN)(acac)(CO)(PPh_3)} moieties have little influence on each other except the bridge formation through the two cyano groups. These facts indicate that the four ^{31}P-NMR signals are not caused by the diastereoisomerism of the binuclear structure of **9**, in contrast with the chloro-bridged binuclear complexes, **3** and **4**, but correspond to four kinds of PPh_3 ligand in the mononuclear {Ru(MeCHCN)(acac)(CO)(PPh_3)} moiety. It is certain that **9** retains PPh_3 and carbonyl and 1-cyanoethyl groups at facial positions together as well as **3** does, since these three ligands show the comparatively strong *trans* influence. Accordingly, the four kinds of PPh_3 ligand are assignable both to the diastereoisomerism due to the asymmetric 1-carbon and ruthenium atoms and to geometrical isomerism exemplified by PPh_3 ligand at *a*- or *e*-site, as shown in Fig. 4. Since the two {Ru(MeCHCN)(acac)(CO)(PPh_3)} moieties are combined in the binuclear structure with fairly free fashion, another geometrical isomerism in the binuclear structure probably takes place to produce new pairs, *e.g.*, I and I'.[33] Thus, **9** was associated with many isomers, as shown in Fig. 4.

Complex **10** contains 4-picoline ligand and is monomeric. Its ^{1}H-NMR spectrum showed six acac-methine proton resonances in an intensity ratio of approximately 4 : 2 : 2 : 1 : 0.5 : 0.5, together with four doublets (MeCHCN–), seven singlets for acac methyl protons and three singlets for picoline-methyl protons (Table 3). The ^{31}P-{^{1}H}-NMR spectrum in CH_2Cl_2 exhibited six singlets, overlapping with each other, at 52.6, 53.8, 54.6, 57.1, 58.2, and 58.9 ppm to the lower field from 85% H_3PO_4. These facts indicate that **10** consists of three geometrical isomers, L, M, and N, each of which contains two diastereoisomers with respect to {Ru(MeCHCN)(CO)(pic)(PPh_3)} moiety. The three ligands, PPh_3 and carbonyl and 1-cyanoethyl groups, which had been coordinated at facial positions in **3**, remain unmoved after the reaction with Tl(acac), by the same reason as the case of **9**. Then, it is certain that no other geometrical isomers than L, M, and N were formed. It is noted that the six isomers for **10** correspond to the ^{31}P-NMR signals very well as well as to the acac-methine proton ones (*vide ante*). Replacement of 4-picoline must take place during the reaction from **3** to two isomers, L and N.

Attempts to separate these isomers were unsuccessful, because chromatographic treatment of **10** yielded a mixture of **9** and **10**. The former complex was produced by liberating 4-picoline from **10** on the silica gel column with adsorbing ability.

Concluding Remarks. The binuclear 1-cyanoethyl complex **2** reacted fairly easily with 4-picoline and some uni-negative chelating ligands to give **3** and **5**—**8**. It is noteworthy that one of the two PPh_3 ligands per ruthenium atom in **2** is easily replaced, except for **6** produced in a low yield. The reaction of **3** with Tl(acac) gave rise both to the detachment of 4-picoline yielding **9** and to the rearrangement of 4-picoline yielding **10**-L and -N, in addition to the normal bridge-cleavage yielding **10**-M. The strong *trans* influence of the 1-cyanoethyl group is responsible for the substitution of the ligand located *trans* to the 1-cyanoethyl group.

The {Ru(RCH_2CHCN)(CO)(PPh_4)} moiety in **3**—**10** contains the asymmetric 1-carbon and ruthenium atoms, and gives rise to the diastereoisomerism. Accordingly, the mononuclear complex **5** involving the C_3-symmetric $BHPz_3$ ligand consists of two isomers, whereas the binuclear complex **3** is composed of three isomers. On the other hand, **6**, **7**, **9**, and **10** consist of several isomers, owing to the nonequivalent {Ru(MeCHCN)(CO)(PPh_3)$_n$} moieties and/or the geometrical isomerism, in addition to the diastereoisomerism.

The authors are grateful to Professor Yasukazu Saito, University of Tokyo, for the valuable discussions of the ^{31}P-NMR spectra and are thankful to Miss Yumi Kojima, Nagasaki University, for her technical assistance.

33) As for I′, J′, and K′, the geometrical isomers of I, J, and K, respectively, the coordination sites only for the acac ligand and carbonyl group are given in parentheses in Fig. 4 for simplification.

Structures of Cys-containing Peptide Complexes of Pd(II) in Organic Solvents

Norikazu UEYAMA, Kazuko SASAKI, Michio NAKATA, and Akira NAKAMURA*
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received September 16, 1981)

Cysteine-containing peptide (pep) complexes of Pd(II) have been synthesized and their structures in organic solvents such as dimethyl sulfoxide (Me_2SO) and *N,N*-dimethylformamide (DMF) were examined by use of ^1H-, ^{13}C-NMR, visible, and CD spectroscopies. In all cases of the Pd(II) complexes, only the thiolato group of the peptides coordinates to the metal. Upon mixing $[PdCl_4]^{2-}$ and the peptide, a *trans*(*S*) isomer $[PdCl_2(pep)_2]^{2-}$ immediately forms, which gradually isomerizes to the *cis*(*S*) isomer at 20 °C in DMF. The reactivity of Pd(II)–S bonds in these complexes was examined by addition of 2,2′-bipyridyl, 2-mercaptoethanol, or 3,4-toluenedithiol.

Transition metal complexes of amino acids, and oligo- and polypeptides have been investigated on the basis of their importan e for providing fundamental chemical information about the coordination environment of metal ions in metalloenzymes and metalloproteins. The thiolato group of cysteine has been found to coordinate to bioactive metal ions such as Fe, Cu, Mo, Zn *etc.*, for example, in ferredoxin,[1] molybdoenzymes,[2] and blue copper proteins.[3] Recently, Ni(II)–cysteine thiolato bonding has been verified in urease.[4]

We have focussed our research efforts upon establishing the coordination behavior of a variety of cysteine-containing oligopeptides to d-block transition metal ions. Cysteine-containing peptides are generally air sensitive and are not easily prepared or purified because of the reactive thiol groups. The heavy metal ions usually form polynuclear complexes with alkanethiols through thiolato bridges (μ-thiolato groups),[5] and these complexes defy attempts to elucidate their structures by conventional chemical techniques.

We have chosen Pd(II) as the metal ion for the present investigation because a) it forms complexes which are usually square planar and diamagnetic, b) it possesses a high affinity for thiolato ligands and suitable rates in ligand exchange reactions, c) fairly intense electronic absorptions in the visible region are expected, and d) it resists electron-transfer reduction by the thiolato ligand, which helps the characterization process.

The general importance of aqueous media in the study of peptide/metal ion systems has provided an impetus for investigation of structures in aqueous solutions.[6,7] However, the active sites of many metalloenzymes or metalloproteins are found to be in hydrophobic parts of the proteins. These findings prompted us to study aprotic solutions of metal/peptide systems. The behaviour and structures of metal peptide complexes in such solutions were found to be totally different in some cases.

In this paper, Pd(II) complexes of Cys-containing peptides such as *N*-acetyl-L-cysteine(Ac-Cys), *N*-benzyloxycarbonyl-L-alanyl-L-cysteine methyl ester (Z-Ala-Cys-OMe) and *N*-benzyloxycarbonyl-L-prolyl-L-cysteine methyl ester (Z-Pro-Cys-OMe) were investigated in aprotic solvents such as *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (Me_2SO). For comparison, $Na_2[PdCl_2(Z\text{-}Ala\text{-}cys\text{-}OMe)_2]$ and $Na_2[PdCl_2(Z\text{-}Pro\text{-}cys\text{-}OMe)_2]$ were synthesized by the direct reactions of Na_2PdCl_4 with the corresponding Cys(Acm)-peptides (Acm=acetamidomethyl). In order to help to identify the part of amino acid residues coordinating to a metal, we used lower case symbols, *e.g.* cys, in the chemical formulas.

Experimental

Starting Materials. All solvents were distilled by standard procedures and stored under nitrogen. 2,2′-Bipyridyl, 3,4-toluenedithiol, and 2-mercaptoethanol used were of reagent grade quality. Ac-Cys was gifted by Sun-Orient Chemical Co. The preparations of Z-Ala-Cys(Acm)-OMe and Z-Pro-Cys(Acm)-OMe and the deprotections of their Cys(Acm) residue will be metioned elsewhere.[8]

Preparations. *1)* $Na_2[PdCl_2(Ac\text{-}cys)_2]\cdot 1/2(DMF)$: To a solution of Ac-Cys (0.4 g, 2.5×10^{-3} mol) in DMF (5 cm^3), 7 cm^3 of a Na_2PdCl_4 (0.36 g, 1.25×10^{-3} mol) solution in DMF was added, followed by the addition of ethyl acetate (50 cm^3). An orange powder precipitated immediately, which was collected, washed with ethyl acetate, and dried over silica gel. Found: C, 23.86; H, 3.81; N, 5.62%. Calcd for $C_{11.5}H_{19.5}N_{2.5}O_{6.5}S_2Cl_2PdNa_2$: C, 23.64; H, 3.36; N, 5.99%. ^1H NMR signals were observed at 2.9, 3.0, and 8.0 ppm assignable to DMF.

2) $Na_2[PdCl_2(Z\text{-}Ala\text{-}cys\text{-}OMe)_2]$[8b]: To a solution of Z-Ala-Cys(Acm)-OMe (0.2 g, 5.9×10^{-4} mol) in DMF (3 cm^3), 7 cm^3 of a Na_2PdCl_4 (0.09 g, 3.0×10^{-4} mol) solution in DMF was added, and stirred overnight. Water (50 cm^3) saturated with NaCl was added, and the powder precipitated was collected, washed with water, and dried. Found: C, 38.92; H, 4.35; N, 6.34%. Calcd for $C_{30}H_{38}N_4O_{10}S_2Cl_2PdNa_2$: C, 39.94; H, 4.25; N, 6.21%. Molar conductivity of the complex in DMF was 19.7 S cm^2 $equiv.^{-1}$ (5 mmol/dm^3, 20 °C).

3) $Na_2[PdCl_2(Z\text{-}Pro\text{-}cys\text{-}OMe)_2]$: This complex was prepared by the same procedure used for the synthesis of *1*). Found: C, 43.95; H, 4.85; N, 6.61%.† Calcd for $C_{34}H_{42}N_4O_{10}S_2Cl_2PdNa_2$: C, 42.79; H, 4.44; N, 5.90%. The molar conductivity was 14 S cm^2 $equiv.^{-1}$ in DMF (7.8 mmol/dm^3, 20 °C).

Spectral Measurement. To a DMF solution of an oligopeptide (concentration: approximately 2×10^{-3} mol/dm^3), a solution of Na_2PdCl_4 in DMF was added in appropriate molar ratios at room temperature. A Varian XL-100 was used to obtain ^1H- and ^{13}C-NMR spectra. CD spectra were recorded on a JASCO J-40 spectropolarimeter. Visible spectra and IR spectra were obtained on JASCO UVIDEC 5A and Hitachi

† The Cl ligand of the Pd(II) complexes was found gradually substituted with water. Drying *in vacuo* results in slight change in the values of elemental analysis.

Table 1. Circular dichroism spectra of Pd(II)–oligopeptide complexes in DMF at room temperature

Complex	Molar ratio (metal : ligand)	λ/nm[a] (Δε)					
Pd/Ac-Cys	(1 : 1)	540 (+0.04)	442 (+0.13)		376 (+0.17)	340 (+0.07)	312 (−0.97)
Pd/Ac-Cys	(1 : 2)	510 (−0.02)	470 (−0.34)		404 (−0.70)	351 (−0.60)	319 (−0.78)
Pd/Z-Ala-Cys-OMe	(1 : 1)		430 (+0.09)	399 (−0.06)	375 (+0.15)		309 (−0.88)
Pd/Z-Ala-Cys-OMe	(1 : 2)		485 (−0.28)	436 (+0.16)	396 (−0.57)	350 (+1.05)	318 (−0.76)
Pd/Z-Pro-Cys-OMe	(1 : 1)		428 (+0.18)	390 (−0.08)	360 (+0.03)		314 (−0.06)
Pd/Z-Pro-Cys-OMe	(1 : 2)		493 (−0.23)	438 (+0.17)	382 (−0.50)	343 (+0.16)	

a) These spectra were obtained after 24 h, and the Δε values were calculated on the basis of the concentration of Pd(II) ion.

FIR-3. CD spectra of the complexes on ligand substitution were also recorded after addition of 2,2′-bipyridyl, 3,4-toluenedithiol, and 2-mercaptoethanol to the DMF solution of these complexes with the corresponding molar ratios.

Results and Discussion

Stoichiometry of Interaction of Pd(II) with Cys-containing Peptides. Reactions between Pd(II) and Cys-containing oligopeptides were investigated stoichiometrically. CD and visible spectra of the reaction products in DMF solutions were obtained with various molar ratios of Pd(II) to peptide. When a molar ratio of 1 : 2 was taken, a Pd(II)/peptide (1 : 2) complex was formed immediately. CD and visible spectra of the solution changed slowly on standing. After 24 h, a (1 : 1) and another isomeric (1 : 2) complex were found to be formed, as indicated by the CD spectra. The transitions and absorptions of the CD and visible spectra thus obtained are listed in Tables 1 and 2. The similarities among the CD spectra of the Pd(II) complexes of Ac-Cys, Z-Ala-Cys-OMe, and Z-Pro-Cys-OMe suggest coordination of the same portion of the peptide to the metal atom in each case.

Functional Groups Coordinating to Pd(II). Pd(II)/Ac-Cys Complexes: As the simplest member of Cys-containing peptides, complexes of Ac-Cys were examined. Ac-Cys has i) a thiolato group, ii) a nitrogen atom in the amide bond, iii) an oxygen atom in the amide bond, and iv) an oxygen atom in the carboxylic acid part as possible donor sites. The ^{1}H- and ^{13}C-NMR spectra of Pd(II)/Ac-Cys (1 : 1) and (1 : 2) complexes

Table 2. Visible spectra of Pd(II)–oligopeptide complexes in DMF at room temperature

Complex	Molar ratio (metal : ligand)	λ/nm[a] (ε×10^{-3})		
Pd/Ac-Cys	(1 : 1)	390 (1.6)		310 (5.5)
Pd/Ac-Cys	(1 : 2)	405 (2.8)	370 (3.6)	310 (6.8)
Pd/Z-Ala-Cys-OMe	(1 : 1)	386 (1.4)		305 (5.2)
Pd/Z-Ala-Cys-OMe	(1 : 2)	380 (2.2)		310 (6.6)
Pd/Z-Pro-Cys-OMe	(1 : 1)	386 (1.3)		307 (5.0)
Pd/Z-Pro-Cys-OMe	(1 : 2)	382 (1.8)		309 (5.7)

a) ε was calculated on the basis of the concentration of Pd(II) ion.

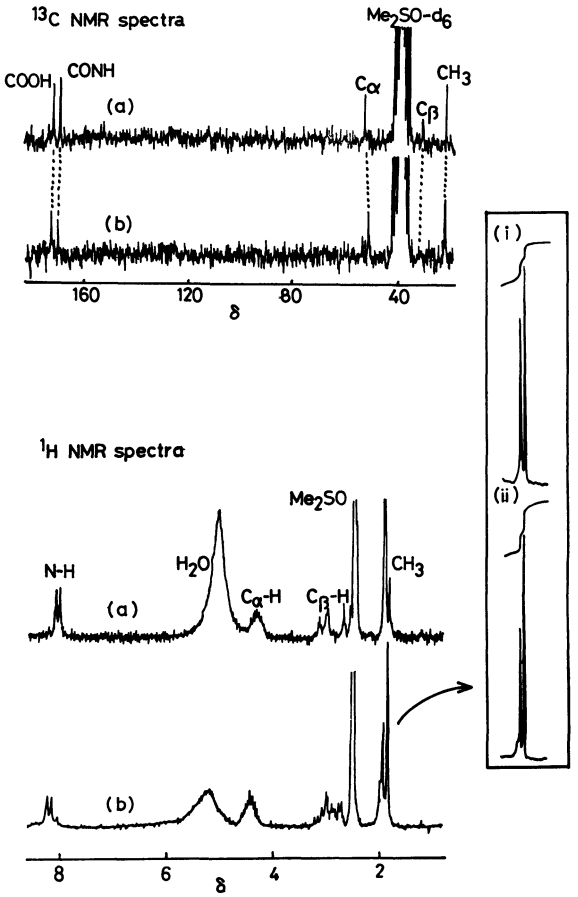

Fig. 1. ^{1}H- and ^{13}C-NMR spectra of Pd(II)/Ac-Cys in Me_2SO-d_6 at room temperature with a) the molar ratio of Pd(II)/Ac-Cys=1/1 and b)=1/2. The inset spectra show the time dependence of methyl signals in ^{1}H NMR spectra in Me_2SO-d_6 at 70 °C (Pd(II)/Ac-Cys=1/1). The spectra were taken i) after 1 h and ii) after 21.5 h.

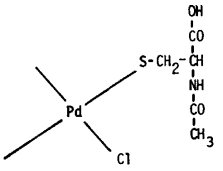
in Me_2SO-d_6 are shown in Fig. 1. There were negligible differences between the spectra obtained in Me_2SO-d_6 and DMF, and similar spectra were obtained in each solvent. In the ^{13}C-NMR spectra, the resonance due to C_β of the cysteine residue was shifted downfield on complexation. The C_β of the (1 : 2) complex was observed with broadening at 33.73 ppm. A larger shift of Cys C_β (8.31 ppm from the C_β of the SH-free cysteine residue) for the (1 : 2) complex compared with that of the (1 : 1) complex (5.84 ppm from the Cys C_β of the SH-free cysteine) indicates the formation of the (1 : 2) complex with a stronger Pd(II)–S bond.

Possibility of the coordination of the other donor groups occurring in organic solvents was examined by recording the ^1H- and ^{13}C-NMR spectra. Especially, a deprotonated nitrogen atom in the amide bond is a potential candidate as a ligand group. For example, most of the known metal-peptide complexes have a metal-nitrogen bond formed by the deprotonated amide group[6,7] and a metal-oxygen bond with the carboxyl group[9] in aqueous solution.

Two carbon peaks around 170 ppm are assignable to the carbons of the amide and carboxylic acid groups. The shift of the signal of either the (1 : 1) or (1 : 2) complex from that of free Ac-Cys was observed to be less than 0.3 ppm. This fact suggests that only the thiolato group of Ac-Cys coordinates to the metal in Me_2SO-d_6 as illustrated in the following scheme. The H^+ released on the thiol of Ac-Cys should protonate the solvent such as DMF since the CD spectrum of the Pd(II)/Ac-Cys (1 : 2) complex with addition of the equimolar triethylamine remained the same. Fuhr and

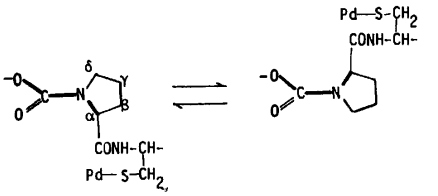


Rabenstein reported that Zn(II)/glutathione mixtures in aqueous solution provided a carbon signal due to Glu–CONH with a shift of 0.2 ppm from free glutathione.[10] Ionization of the peptide protons at pD 10.5 is followed by bonding of Zn(II) to the anionic N atom. Shifts of 0.8—1.0 ppm of the amide carbon and 1.0—3.0 ppm for the carboxyl carbon are observed, presumably due to their coordination to the Zn atom. The absence of deprotonation in the Pd(II)–peptide complex was also supported by the ^1H NMR spectra shown in Fig. 1. One NH proton was observed at 8.19 ppm for the (1 : 1) complex, and at 8.31 ppm for the (1 : 2) complex. The chemical shift values clearly show the absence of amide group coordination. Even if the amide NH is involved in coordination, a broad NH peak will be observed. As proton peak from contaminating water observed at 5.1—8.0 ppm (see Fig. 1) reveals that proton exchange between water and carboxylic acid occurs in Me_2SO-d_6. Usually, a peak assignable to water contaminated in the commercial Me_2SO-d_6 was observed at about 3 ppm, shifting to 5.1 ppm with an increase in the amount of water. The presence of the exchangeable proton assignable to the carboxyl group clearly indicates that the carboxylic acid part of the AcCys ligand does not coordinate to the metal.

TABLE 3. ^1H-NMR SPECTRA OF Cys-CONTAINING OLIGOPEPTIDES AND THE CORRESPONDING Pd(II) COMPLEXES IN Me_2SO-d_6 AT ROOM TEMPERATURE[11]

Compound	N–H region ppm	C_α–H region ppm
Ac-Cys	8.33	4.33
$Na_2[PdCl_2(Ac\text{-}cys)_2]$	8.31	4.43
Z-Ala-Cys-OMe	8.38(Cys)	4.50(Cys)
	7.3(Ala)	4.12(Ala)
$Na_2[PdCl_2(Z\text{-}Ala\text{-}cys\text{-}OMe)_2]$	8.32(cys)	4.70(cys)
	7.3(Ala)	4.14(Ala)
Z-Pro-Cys-OMe	8.38(Cys)	4.52(Cys)
		4.30(Pro)
$Na_2[PdCl_2(Z\text{-}Pro\text{-}cys\text{-}OMe)_2]$	8.24(cys)	4.70(cys)
		4.26(Pro)

Pd(II) Complexes of Dipeptides. The Pd(II) complexes of Z-Ala-Cys-OMe and Z-Pro-Cys-OMe, of which the amino- and carboxylic acid-ends are protected, were examined by CD and visible spectra. The

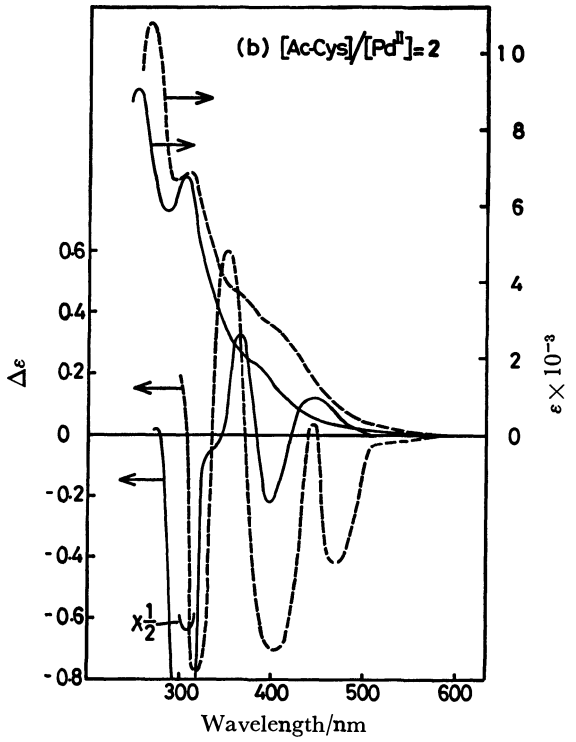


trans conformer *cis* conformer

same type of (1 : 2) complexes derived from the corresponding S-blocked peptides and Na_2PdCl_4 were isolated, which are air-stable and soluble in DMF, Me_2SO, methanol, or acetonitrile. The spectra of the isolated Pd(II) complexes were essentially the same as those of the reaction mixtures of $[PdCl_4]^{2-}$ and the SH peptides.

Table 3 shows the chemical shifts of the N–H and C_α–H protons for the isolated Pd(II) complexes. The urethane N–H signal of $[PdCl_2(Z\text{-}Ala\text{-}cys\text{-}OMe)_2]^{2-}$, which was overlapped with that of the benzyl protons, was made observable by the upfield shift of the peak resulting from the addition of chloroform. This observation indicates that even the more basic urethane group than the amide group was not involved in coordination.

The simple monodentate coordination through the thiolato group was supported by the ^{13}C-NMR spectra. The *cis* and *trans* conformers resulting from the planarity of the urethane bond in the above equilibrium were detectable by using the ^{13}C-NMR spectra of $[PdCl_2(Z\text{-}Pro\text{-}cys\text{-}OMe)_2]^{2-}$ in Me_2SO-d_6. The *cis* and *trans* signals of Pro C_β and C_γ which present in the equilibrium were clearly observed at 30.5 and 23.5 ppm, respectively. Assignments of the *cis* and *trans* signals of Pro C_β or C_γ were carried out according to the chemical shifts of a number of Pro-containing peptides in Me_2SO-d_6 assigned by Dorman and Bovey.[12] The same probabilities of the *cis* and *trans* conformers as those of the S-blocked peptide as shown in Fig. 3 imply that only the thiolato group is involved in the coordination. If



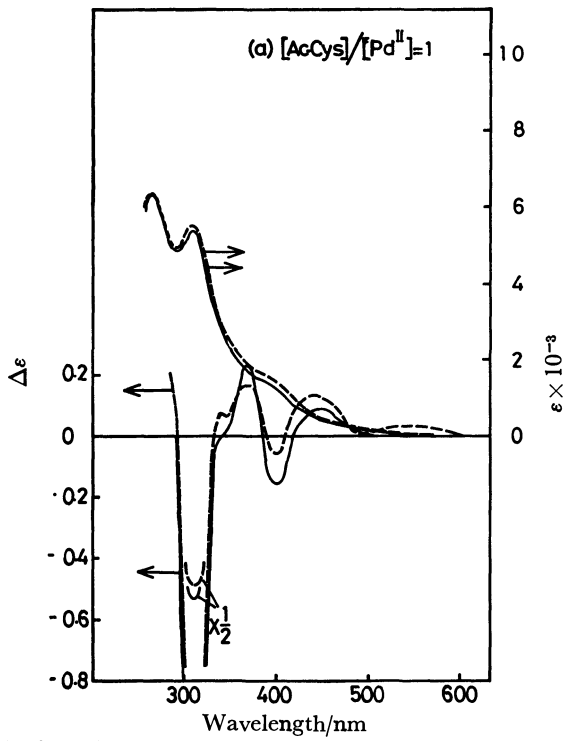


Fig. 2. Time dependence of the CD and visible spectra of Pd(II)/Ac-Cys= a) 1/1 and b) 1/2 in DMF at room temperature. The spectra after 10 min are represented by (——) and after 38 h by (------).

the N atom of the Pro residue coordinates to the metal, the probability of the *cis* or *trans* conformers will change with the coordination in the above equilibrium.

The presence of chloride ligands on the Pd(II) may not favor coordination of the amide nitrogen atoms of

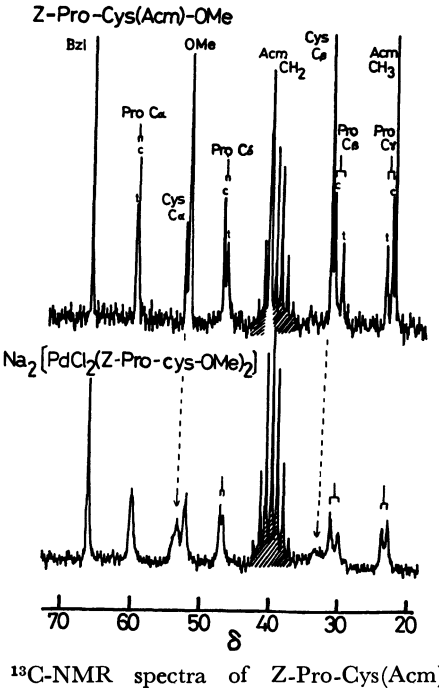

Fig. 3. ^{13}C-NMR spectra of Z-Pro-Cys(Acm)-OMe (Acm=acetamidomethyl) and $Na_2[PdCl_2(Z\text{-Pro-cys-OMe})_2]$ in Me_2SO-d_6 at room temperature.

the peptides used in this study. Therefore $Pd(NO_3)_2$ was used to further examine Pd(II)/peptide interactions in DMF. The CD spectrum of $Pd(NO_3)_2$/Z-Ala-Cys-OMe indicated the presence of the same type of the (1 : 2) complex as that of $PdCl_4^{2-}$/Z-Ala-Cys-OMe. The solvent seems to occupy the remaining coordination sites on Pd(II) in the case of $Pd(NO_3)_2$. Addition of NR_4Cl to the solution gave the same $[PdCl_2(Z\text{-Ala-cys-OMe})_2]^{2-}$ anion as prepared from $PdCl_4^{2-}$. Thus, absence of the amide coordination is one of the consequences of solvent effect coupled with the influence of thiolato coordination on the metal.

Infrared absorptions of these complexes are listed in Table 4 in comparison with those of the peptides themselves. The ν(S–H) band in all the peptides examined at 2500—2600 cm^{-1} disappeared in the Pd(II) complexes because of the coordination of the thiolato group to the metal. No shift of the ν(C=O) band of the Pd/Ac-Cys complex from the band of the free carboxylic acid was observed. The coordination of carboxylate usually results in thift to the lower wave number (1600—1650 cm^{-1}).[6] The bands of ν(N–H) and ν(C–O) of the amide group for all complexes remained unchanged. Observation of the bands due to Pd(II)–S and Pd(II)–Cl in the far infrared region indicates that the complexes possess a $PdCl_2S_2$ core.

Therefore the visible absorption and CD transitions mentioned above (Tables 1 and 2) should be due to the chromophore of the $PdCl_2S_2$ core. A visible absorption at 370—405 nm in Table 2 corresponds mainly to the overlapped bands of the d-d transitions of the Pd(II) ion.[13,14] On the other hand, an absorption around 310 nm is assignable to a charge transfer band (Pd(II)–S).[13,14] These bands are similar to the charge transfer band of $Pd(cys\text{-}OEt)_2$ at 312 nm,[15] and a d-d transition

TABLE 4. SELECTED IR FREQUENCIES OF Cys-CONTAINING OLIGOPEPTIDES AND THE CORRESPONDINGPd(II) COMPLEXES IN SOLID STATE

Compound	IR (ν/cm^{-1})				
	ν(N–H)	ν(S–H)	ν(C=O)	ν(Pd–S)	(Pd–Cl)
Ac-Cys	3360	2450	1710[a)] 1640[b)]		
$Na_2[PdCl_2(Ac\text{-}cys)_2]$	3250br	—	1730[a)] 1645[b)]	388	330

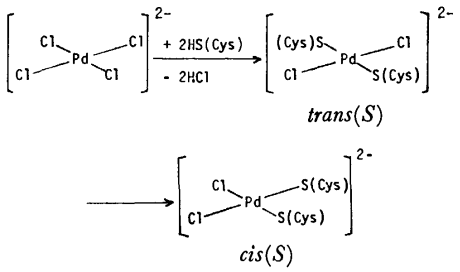
Z-Pro-Cys-OMe	3310	2590	1740[c)] 1690 1665[b)]		
$Na_2[PdCl_2(Z\text{-}Pro\text{-}cys\text{-}OMe)_2]$	3300	—	1740[c)] 1670br	362	310

a) Assignable to carbonyl group of free carboxylic acid. b) Carbonyl group of amide. c) Carbonyl group of ester. d) br refers to a broad band.

at 423 nm and a charge transfer band at 319 nm of $Pd(cys)_2$.[16] In the d-d transitions, the transitions of d_{xy}-$d_{x^2-y^2}$ and d_{xy},d_{yx}-$d_{x^2y^2}$ are magnetic dipole-allowed, while the transition of d_{xy}-$d_{x^2-y^2}$ is magnetic dipole-forbidden. The CD peak of the former transitions should be strongest and that of the latter transition should be weakest. In the CD spectra of the isolated (1 : 2) complexes in Table 1, the bands at about 480 nm are therefore assignable to d_{xy}-$d_{x^2-y^2}$ transition, and the positive peaks about 435 nm and the negative peaks about 390 nm to the d_{xy},d_{xy}-$d_{x^2-y^2}$ transitions. The strong peaks around 350 and 320 nm correspond to charge transfer bands (Pd(II)–S).

Coordination Geometry of Pd(II)/Peptide Complexes. Two acetyl peaks in the ^{1}H-NMR spectrum of the 1 : 2 complex, as shown in Fig. 1, were observed at 1.94 and 1.86 ppm. The latter peak grew up gradually at 70 °C, as shown in the inset of Fig. 1. In addition, the peaks due to NH and contaminating water were observed intact even after the solution was kept overnight. The water peak at 5.4 ppm indicates the existence of a proton exchange between water and –COOH because a peak of usual water in Me_2SO-d_6 should be observed between 2.5 and 5.1 ppm. The results indicate the interchange between *trans*(*S*) and *cis*(*S*) isomers of the $[PdCl_2(Ac\text{-}cys)_2]^{2-}$ complex. This interconversion was also observed in the CD and visible spectra. The *cis*(*S*) (1 : 2) complex could be isolated from a mixture of DMF and ethyl acetate, and the *cis*(*S*) isomer is thus thermodynamically more stable. Pneumatikakis and Hadjiliadis[6] concluded that a medium intensity band at 330 cm^{-1} for $PdCl_2(cys\text{-}OMe)_2$ which was immediately isolated after mixing $PdCl_4^{2-}$ and Cys-OMe is due to ν(Pd–Cl) stretching of a *trans*(*S*) isomer. Similarly the $Na_2[PdCl_2(Ac\text{-}cys)_2]$ isolated immediately showed a band at 330 cm^{-1} due to ν(Pd–Cl) of a *trans*(*S*) isomer. The same (1 : 2) complex obtained after aging overnight in DMF at 70 °C showed a few broad bands at 320—340 cm^{-1} due to ν(Pd–Cl) of a *cis*(*S*) isomer.

Figure 2 shows the CD and visible spectra of the DMF solution of Pd(II)/Ac-Cys (1 : 1) and (1 : 2) after 10 min or after one day from complex formation. The CD patterns of the both complexes are similar immediately after reaction, indicating formation of a (1 : 2) complex. The spectrum of the (1 : 1) solution does not change with time significantly, but that of the (1 : 2) solution clearly changes at 470 and 404 nm in DMF. The same trend was observed in the visible spectra. The absorption coefficient of the (1 : 2) solution after 1 d was 1.7 times larger than that after 10 min. This slow interchange between the *trans*(*S*) and *cis*(*S*) isomers with time is illustrated in the following scheme. A kinetically-controlled formation of the

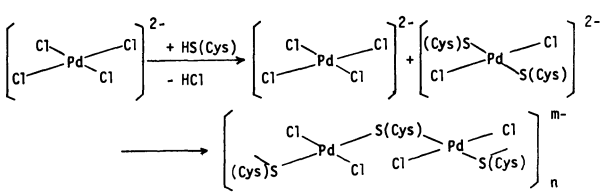


trans(*S*)

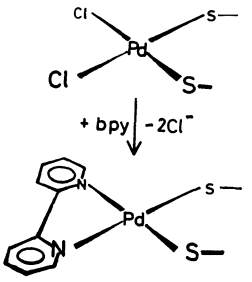
cis(*S*)

trans(*S*) isomer occurs immediately when $[PdCl_4]^{2-}$ and Ac-Cys are mixed. Then the complex isomerizes to a thermo-dynamically stabilized *cis*(*S*) form. A visible absorption of the *cis*(*S*) isomer (local C_{2v} symmetry) is known to be stronger than that for the *trans*(*S*) isomer (local D_{2h} symmetry).[9,17] Also, the stronger CD peak should be expected for the *cis*(*S*) isomer compared to that for the *trans*(*S*) isomer, in which the dipole moment is negligible. Figure 2(b) shows the peaks of d-d transitions at 472 nm in the CD spectra shifting to a longer wavelength. These results indicate that d electrons are delocalized over the PdS_2 core and the Pd(II)–S bond is stabilized in the *cis*(*S*) complexes.

In the case of the (1 : 1) solution, the *trans*(*S*) (1 : 2) isomer may form as an intermediate and is converted to polynuclear complexes. Similar complexes were formed by the corresponding dipeptides.



Reactivity of the Pd(II)–Dipeptide Complexes. The strength of the Pd(II)–thiolate bond was examined as follows. Addition of 3,4-toluenedithiol, 2-mercaptoethanol, or 2,2′-bipyridyl results in cleavage of the weaker bonds among the Pd(II)–S or Pd(II)–Cl bonds of the $PdCl_2S_2$ core. Figure 4 shows the spectral changes



that occurred on addition of the above ligands to $Na_2[PdCl_2(Z\text{-Ala-cys-OMe})_2]$. Addition of 3,4-toluenedithiol first diminished the $\Delta\varepsilon$ values of the CD peaks. Addition of two molar equivalents of 3,4-toluenedithiol then results in complete disappearance of the CD peaks, while in the visible spectra, a d-d band at 860 nm and a charge transfer band at 360 nm were observed due to the formation of $[Pd(dithiolato)_2]^{2-}$. The results indicate that the 3,4-toluenedithiol easily breaks Pd(II)–Cl and Pd(II)–S(Cys) bonds because of its *cis*(*S*) chelating effect and the formation of an electron-delocalized complex having strong Pd(II)–S(–Ph–) bonds.

On the other hand, addition of 2-mercaptoethanol, which is a primary thiol, as is the cysteine residue, induced the formation of a different complex with two moles of the thiol to one mol of the Pd(II). Addition

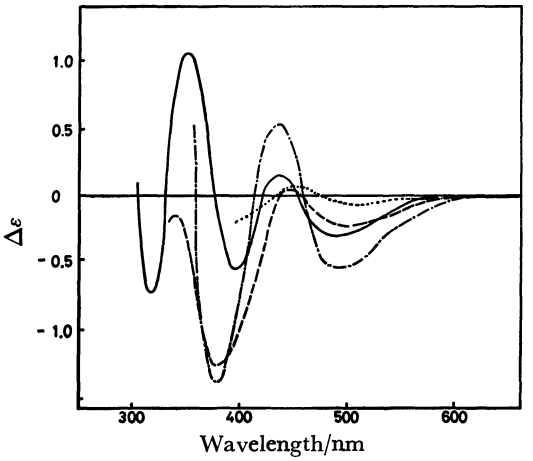


Fig. 4. CD-spectral change of $Na_2[PdCl_2(Z\text{-Ala-cys-OMe})_2]$ (——) in DMF upon addition of 2,2′-bipyridyl (– – –), 2-mercaptoethanol (–·–·–), and 3,4-toluenedithiol (------), the ratio, Pd(II)/additive, is 1/2.

of larger amounts of the thiol over the (1 : 2) molar ratio does not change the spectrum. These results clearly indicate the formation of $[Pd(SCH_2CH_2OH)_2(Z\text{-Ala-cys-OMe})_2]^{2-}$ which contains a PdS_4 core. 2-Mercaptoethanol cleaves the Pd(II)–Cl bonds, but does not affect the original Pd(II)–S bonds. Although simple thiols such as CH_3SH, PhSH, *etc.*, usually give polynuclear complexes $[Pd(SR)_2]_n$, the Pd(II)/peptide complex system containing a cysteine residue does not form a $[Pd(S(cys))_4]^{2-}$ or polynuclear species because of the steric hindrance around the cysteine thiolato group.

The CD spectrum obtained by addition of 2,2′-bipyridyl at a (1 : 1) molar ratio does not change with further addition of 2,2′-bipyridyl. Two chloride ligands of the complex are easily replaced by one 2,2′-bipyridyl. However, the Pd(II)–S bonds are resistant to such a substitution with 2,2′-bipyridyl.

It is plausible that the entering ligand such as 2,2′-bipyridyl or 3,4-toluenedithiol would give a transient five-coordinate intermediate with a trigonal bipyramidal configuration. Then each of the *cis*(*S*) or *trans*(*S*) complex provides the same *cis*(*S*) complex having the chelating ligand. However, further information is necessary for discussing the mechanism of such ligand substitution reaction.

Conclusion. Cys-containing peptides coordinate to Pd(II) ions through only the thiolato group in organic solvents, giving (1 : 1) and (1 : 2) Pd(II)–peptide complexes. A (1 : 2) molar ratio of reagents gives the kinetically controlled *trans*(*S*) isomers immediately, which are subsequently converted to the *cis*(*S*)-isomers. The Pd(II)–S bonds of the *cis*(*S*) complexes are not cleavable even with the strong donor ligand such as 2,2′-bipyridyl.

(Received November 5, 1981)

Several amine or phosphine adducts of bis (*O,O'*-dialkyl dithiophosphato)cobalt(II), which were hardly oxidized in air at room temperature, were obtained as crystalline solids. The crystal and molecular structure of one adduct, $Co(Me_2dtp)_2$(triphenylphosphine) (Me_2dtp=*O,O'*-dimethyl dithiophosphato group), was determined by means of the X-ray diffraction method. The crystal is monoclinic: space group $P2_1/n$, a=26.712(4), b=9.495(1), c=11.180(5) Å, β=95.43(3)°, Z=4, D_x=1.495, D_m=1.45 g cm^{-3}, μ(Mo $K\alpha$)=1.17 mm^{-1}, and the final R value obtained is 0.062 for 4466 observed reflections. The coordinated atoms around the cobalt atom are in a trigonal bipyramidal configuration. The approximate first formation constants of the adducts, K=[Co(II)$(R_2dtp)_2$·X]/{[Co(II)$(R_2dtp)_2$][X]} (R=alkyl group, and X=donor) in solution, were obtained by means of the spectrophotometric as well as the NMR technique.

Dithioacid ions, such as *N,N*-dialkyl dithiocarbamate, *O*-alkyl dithiocarbonate, and *O,O'*-dialkyl dithiophosphate ions, are able to make four-membered chelates with 3d transition metals. Among them, the *O,O'*-dialkyl dithiophosphato chelates have various properties different from those of common Werner-type complexes. For example, bis(*O,O'*-diethyl dithiophosphato)nickel(II) (abbreviated as Ni(II)$(Et_2dtp)_2$ hereafter; the related complexes are also shown by the same type of abbreviation) is typical, and many studies have already been published about the complex itself as well as its adducts.[2-5)] On the other hand, only a few publications are to be found about Co(II)$(Et_2dtp)_2$, although Cavell and others[6)] have reported the isolation of Co(II)-$(Et_2dtp)_2$, and Jørgensen[7,8)] claimed the formation of its ethanol adducts in solution. This is probably because of the low stability of the complex. By way of studying sulfur-coordinated metal complexes, we found that, contrary to Co(II)$(R_2dtp)_2$ (R=alkyl group), some amine or phosphine adducts of them were very stable when once obtained in their solid state; they could be kept in air at room temperature for many months without any decomposition or air-oxidation.

As Co(II)$(Et_2dtp)_2$ is in a tetrahedral configuration, the geometry of the originally bonded Et_2dtp must be seriously affected by the formation of its adducts, while in the case of Ni(II)$(Et_2dtp)_2$, which is originally in a square planar form, the positions of the ligands are not much moved by the coordination of additional ligands. The adduct of the Co(II)$(R_2dtp)_2$·X_n type (where X=donor) will exhibit either a trigonal bipyramidal or a square pyramidal coordination around the central metal atom. In order to elucidate the geometry of the adduct, we have determined the crystal and molecular structure by means of the X-ray diffraction method.

Although the Co(II)$(R_2dtp)_2$·X_n adducts (n=1 or 2) are very stable in their solid states, they are easily hydrolyzed with water and are turned into hexaaquacobalt(II) ions in a dilute aqueous solution. The R_2dtp ligands are bonded strongly to the cobalt(II) atom in the complexes in a non-polar organic solvent, although a rapid broadening of the R_2dtp alkyl proton peak due to the ligand-exchange reaction between the two chelates is observed in their NMR spectra when the cobalt(II) complexes or their adducts in solution are added to a solution of the R_2dtp complexes of other diamagnetic metal ions, such as zinc(II) or cadmium(II).

On the other hand, the donor, X, of the Co(II)-$(R_2dtp)_2$·X adduct is shown to be labile in an organic solvent, and the equilibrium,

$$Co(II)(R_2dtp)_2 + X = Co(II)(R_2dtp)_2\cdot X$$

is attained soon after they are dissolved. Therefore, when more of the donor is added to a solution of the adduct, it shows more resistivity to air-oxidation. A quantitative study of the equilibrium will be presented in the later part of this paper.

Experimental

Synthesis of Adducts. All the chemicals used were GR-grade from Wako Pure Chemicals Co., Ltd., and were used without any further purification. The Co(II)$(R_2dtp)_2$·X_n (n=1 or 2) were synthesized as follows.

Synthesis of Co(II)$(Et_2dtp)_2$(hexamethylenetetramine). The benzene solution of cobalt(II)$(Et_2dtp)_2$ was obtained by extracting it from a mixture of cobalt(II) chloride hexahydrate (0.7 g, 3 mmol) and Na(Et_2dtp) (1.2 g, 6 mmol) in a concentrated aqueous solution with benzene. After the addition of an excess of hexamethyleneteramine (0.9 g, 6.4 mmol), the obtained mixture was stirred for several min, after which the supernatant fluid was separated and evaporated by the use of a vacuum rotary evaporator. From the residue, the adduct was extracted with a hot mixture of benzene and ligroine (1/1=v/v); crystals came out when it was cooled. Found: Co, 10.27; C, 29.74; H, 5.69; N, 10.01%. Calcd for $CoC_{14}H_{32}O_4P_2S_4$: Co, 10.35; C, 29.52; H, 5.66; N, 9.84%. Yield, 1.3 g (77%).

Synthesis of Co(II)$(Et_2dtp)_2$(triphenylphosphine). Six tenth of a gram (2.5 mmol) of cobalt(II) chloride hexahydrate, 1.1 g

†† Present address: Department of Chemistry, Faculty of Science, Toho University, Miyama, Funabashi, Chiba 274.

††† Present address: Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi 3-14-1, Kohoku-ku, Yokohama, Kanagawa 223.

(5.4 mmol) of $Na(Et_2dtp)$, about 20 cm^3 of a benzene solution containing 1.5 g (5.7 mmol) of triphenylphosphine, and 1 cm^3 of water were mixed and stirred for several min, after which benzene layer was separated and dried with anhydrous sodium sulfate. The solution was evaporated, and the residue was recrystallized from ligroine. Found: Co, 8.52; C, 45.24; H, 5.10%. Calcd for $CoC_{26}H_{35}O_4P_3S_3$: Co, 8.52; C, 45.15; H, 5.10%. Yield, 1.1 g (64%).

Synthesis of Co(II)(Me_2dtp)$_2$(triphenylphosphine) (Where Me=CH_3). This complex was synthesized in almost the same way as the Co(II)(Et_2dtp)$_2$(triphenylphosphine) described above by using 0.6 g (2.5 mmol) of cobalt(II) chloride hexahydrate and 0.9 g (3.0 mmol) of $Na(Me_2dtp)$. As the complex is more sensitive to air oxidation than Et_2dtp derivative, it was recrystallized from benzene–hexane (1/1=v/v) mixed solvent under a nitrogen atmosphere. Found: Co, 9.20; C, 41.16; H, 4.27%. Calcd for $CoC_{22}H_{27}O_4P_3S_3$: Co, 9.27; C, 41.58; H, 4.29%. Yield 0.8 g (50%).

Synthesis of Cobalt(II)(Et_2dtp)$_2$(benzothiazole)$_2$. This adduct was synthesized in the same way as was used for the triphenylphosphine adduct of Co(II)(Et_2dtp)$_2$, starting from 0.47 g (2 mmol) of cobalt(II) chloride hexahydrate, 0.83 g (4 mmol) of $Na(Et_2dtp)$, and 0.81 g (6 mmol) of benzothiazole. Recrystallized from ligroine. Found: Co, 8.41; C, 37,82; H, 4.33; N, 3.96%. Calcd for $CoC_{22}H_{30}O_4N_2P_2S_6$: Co, 8.42; C, 37.76; H, 4.32; N, 4.00%. Yield, 0.75 g (54%).

Synthesis of Co(II)(Et_2dtp)$_2$(benzothiazole). This adduct was obtained by the same method as was the bis adduct described above, except that a lower molar ratio of benzothiazole to cobalt(II) chloride was employed. For example, from 0.7 g (3 mmol) of cobalt(II) chloride hexahydrate, 1.25 g (6 mmol) of $Na(Et_2dtp)$, and 0.81 g (6 mmol) of benzothiazole, the mono-adduct was obtained as a blue green solid in a low yield. From the mother liquor, the bis-adduct was obtained, too. Found: Co, 10.34; C, 32.03; H, 4.47; N, 2.48%. Calcd for $CoC_{15}H_{25}NP_4S_5$: Co, 10.44; C, 31.91; H, 4.46; N, 2.48%. Yield, 0.4 g (24%).

Synthesis of Co(II)(Et_2dtp)$_2$(benzimidazole). The crude product was obtained by mixing and stirring 0.95 g (4 mmol) of cobalt(II) chloride hexahydrate, 1.7 g (8 mmol) of $Na(Et_2dtp)$, about 10 cm^3 of an acetone solution containing 0.9 g (8 mmol) of benzimidazole, 20 cm^3 of benzene, and 1 cm^3 of water, and by then evaporating the fluid. The residue containing the crude adduct was recrystallized from benzene. Found: Co, 8.64; C, 39.86; H, 4.85; N, 8.44%. Calcd for $CoC_{22}O_4N_4P_2S_4$: Co, 8.85; C, 39.70; H, 4.85; N, 8.42%. Yield, 1.6 g (73%).

Synthesis of Co(II)(Et_2dtp)$_2$(piperazine). This adduct was synthesized, using 2-propanol in place of benzene as the solvent, by means of the method used for the benzimidazole adduct mentioned above. We started with 0.71 g (3 mmol) of cobalt(II)chloride hexahydrate, 1.25 g (6 mmol) of Na(Et_2dtp), and 0.5 g (6 mmol) of piperazine. Recrystallized from ligroine. Found: Co, 11.57; C, 27.85; H, 5.76; N, 5.43%. Calcd for $CoC_{12}H_{30}O_4N_2P_2S_4$: Co, 11.43; C, 27.96; H, 5.87; N, 5.43%. Yield, 0.95 g (62%).

Synthesis of Co(II)(Et_2dtp)$_2$(pyrazine). To about 20 cm^3 of a benzene solution containing 0.16 g (2 mmol) of pyrazine, 1 cm^3 of water, 0.4 g (2 mmol) of $Na(Et_2dtp)$, and 0.24 g (1 mmol) of cobalt(II) chloride hexahydrate were added, after which the mixture was stirred for several min. The adduct was then precipitated, filtered, and washed with water. Recrystallized from the benzene–ligroine mixture (1/1=v/v). Found: Co, 11.50; C, 28.30; H, 4.73; N, 5.49%. Calcd for $CoC_{12}H_{24}O_4N_2P_2S_4$: Co, 11.57; C, 28.29; H, 4.75; N, 5.50%. Yield, 0.7 g (69%).

Attempt to Synthesize the 4,4'-Bipyridine Adduct of Co(II)(Et_2dtp)$_2$. Although many kinds of synthetic techinques have been applied to obtain the adduct, they have not been successful. It was found that the addition of 4,4'-bipyridine to a solution of Co(II)(Et_2dtp)$_2$ rather accelerated the air oxidation of the complex.

X-Ray Measurement. The single crystal of bis(*O,O'*-dimethyl dithiophosphato)(triphenylphosphine)cobalt(II) used for the X-ray measurement was a parallelepiped 0.28×0.35×0.39 mm^3 in size. All the edges of the crystal were ground off beforehand. The crystallographic data are: $CoC_{22}H_{27}O_4P_3S_4$, F. W.=635.55, monoclinic, space group $P2_1/n$,** a=26.712(4), b=9.495(1), c=11.180(5) Å, β=95.43(3)°, Z=4, D_x=1.495, D_m=1.45 g cm^{-3}, μ(Mo $K\alpha$)=1.17 mm^{-1}. The reflections within the range of $2\theta<55°$ were collected on a Rigaku automated four-circle diffractometer, with Mo $K\alpha$ radiation (0.7107 Å), the ω scan technique being employed. In total, 4466 independent reflections with $|F_o|>3\sigma(|F_o|)$ among the 6819 measured ones were used for the structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction. No decrease in the intensities attributable to the decomposition of the sample was recognized during the intensity measurement.

The calculations were mainly carried out on the FACOM 230-48 computer at The Institute for Solid State Physics, The University of Tokyo, but a part of them were done on the HITAC 8800/8700 computer at The Computer Center of The University of Tokyo, using the local version of the UNICS program.[9] The atomic-scattering factors were taken from the tables.[10]

Structure Determination. The structure was solved by the heavy-atom method. The positions of the Co, P, and S atoms were deduced from three-dimensional Patterson maps, while all the other non-hydrogen atoms were located by successive Fourier syntheses. Their positional and thermal parameters were refined by the block-diagonal least-squares method. Then the positions of all the hydrogen atoms, except one, were obtained from a difference Fourier synthesis, they were also refined. The coordinates of the H atom, H(1-2), that could not be located by the difference synthesis, was supplied by calculation. The isotropic temperature factor of 10.0 $Å^2$ was assumed for it. Anisotropic temperature factors were assumed for all non-hydrogen atoms. In the last cycle of the refinement, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value was 0.062 for 4466 reflections.[11]

Other Measurements. The megnetic monents of the solid products were measured using a Gouy balance at room temtemperature (20—15 °C).

The infrared absorption spectra were obtained by a Nujol and hexachloro-1,3-butadiene mull procedure using a 403G-type infrared spectrophotometer of JASCO, Ltd.

The visible spectra were recorded on Hitachi EPS-3- and Hitachi 124-type spectrophotometers. The reflectance spectra of the solid adducts were measured by a Hitachi 124-type spectrophotometer using an attachment. The temperatures of the sample solution and of the cell chamber were kept constant by circulating thermostated water through using a Haake F 4391 thermostat.

The ^1H-NMR spectra were obtained using a JEOL JNM-MH-100 (100 MHz) NMR spectrometer (TMS as the internal standard).

** The systematic absence of the reflections were those of $0k0$ (where k=odd) and those of $h0l$ (where $h+l$=odd).

TABLE 1. FINAL ATOMIC COORDINATES ($\times 10^4$ FOR NON-HYDROGEN ATOMS, AND $\times 10^3$ FOR HYDROGEN ATOMS) AND ISOTROPIC TEMPERATURE FACTORS (B/Å^2), WITH ESTIMATED STANDARD DEVIATIONS IN PARENTHESES

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=(4/3)(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

Results and Discussion

The crystal structure of bis(*O*,*O*′-dimethyl dithiophosphato)(triphenylphosphine)cobalt(II) will now be summarized. The final atomic parameters are listed in Table 1,[12] while the interatomic distances as well as bond angles are given in Table 2. A perspective drawing of the complex and a partial numbering scheme of the atoms are shown in Fig. 1. The remaining

numberings are: the phenyl carbons of the triphenylphosphine ligand are C(5)–C(10), C(11)–C(16), and C(17)–C(22) for those of the I, II, and III phenyl groups respectively, where C(5), C(11), and C(17) are bonded to P(3). The numbering of each hydrogen atom is the same as that of the phenyl carbon atom to which it is bonded. The hydrogen atoms of the methyl groups of Me_2dtp ligands are numbered H(n-1—3), where n is the number of the bonded methyl carbon atom. The arrangement of the molecules in a unit cell is shown in Fig. 2 (projection along the b axis).

The crystal consists of discrete molecules of [Co(II)-

TABLE 3. SPECTRAL AND MAGNETIC PROPERTIES OF THE ADDUCTS, $[Co(II)(Et_2dtp)_2L_n]$ (Et_2dtp=DIETHYL DITHIOPHOSPHATO LIGAND), IN THEIR SOLID STATE

PPh_3=Triphenylphosphine, hex=hexamethylenetetramine, bzt=benzothiazole, pip=piperazine, pyr=pyrazine, bzi=benzimidazole. a) 1 BM=9.274078(36)$\times 10^{-24}$ J T^{-1}.

$\{S_2P(OCH_3)_2\}_2(PPh_3)]$, where PPh_3 means $P(C_6H_5)_3$, and no intermolecular interactions were observed except for van der Waals interaction. The central metal atom in this complex has a trigonal bipyramidal environment; two sulfur atoms of each Me_2dtp ligand are coordinated to the central metal from both the axial and equatorial directions. The phosphorus atom of the PPh_3 ligand is coordinated in the equatorial plane. As is shown in Fig. 1, Co, S(1), S(3), and P(3) atoms are almost on a plane, although the Co atom is deviated to the S(4) direction by about 0.097 Å from the S(1)–S(3)–P(3) plane. The bond angles around the Co atom on the equatorial plane (1 ∠S–Co–S and 2 ∠S–Co–P) are all about 120°. Although the ∠S(2)–Co–P(3) is almost rectangular, the ∠S(4)–Co–P(3) angle is 102.31(5)°. The Co–S(1) and Co–S(3) are about 2.33 Å, while Co–S(2) and Co–S(4) are about 2.6 Å; the latter are longer than the former. The two P–S bond distances in each Me_2dtp ligand also differ from each other; that for S(2) or S(4) atom, which coordinates to the Co atom from the axial direction, is shorter than the other. As the common P=S bond distance is about 1.92 Å, while that of P–S about 2.10 Å,[13] the double-bond character of the $-PS_2-$ moiety of the Me_2dtp ligand is localized rather to the P–S(axial) bond. The Co–P(3) bond distance is 2.551(2) Å; this is probably the longest Co–P distance of metal complexes ever reported. This may be due to the steric hindrance between the bulky ligands.

As will be described below, the magnetic as well as the spectral properties suggest that $Co(II)(Et_2dtp)_2(PPh_3)$, $Co(II)(Et_2dtp)_2$(hexamethylenetetramine), and $Co(II)(Et_2dtp)_2$(benzothiazole) have structures similar to that of $Co(II)(Me_2dtp)_2(PPh_3)$, whose crystal structure has been determined. Elemental analyses show that they are all 1 : 1 adducts with the general formula of $Co(II)(R_2dtp)_2\cdot X$. As may be seen from Table 3, their magnetic moments at room temperature range from 4.3 to 4.5 BM. The reflectance spectra of their solids give two peaks which can assigned to the $^4A'_2(P)\leftarrow{}^4A'_2(F)$ (higher wave number peak) and $^4E''(P)\leftarrow{}^4A'_2(F)$ of the pentacoordinated trigonal bipyramidal cobalt(II) complexes.[14,15]

Another group of adducts are the 1 : 1 adducts of piperazine and pyrazine, as well as the 2 : 1 adducts of benzothiazole and benzimidazole. As is shown in Table 3, their magnetic moments are 5.0—5.1 BM, and two peaks (one of them splits into three peaks) are observed in their reflectance spectra. They can be identified as $^4A_{2g}(F)\leftarrow{}^4T_{1g}(F)$ and $^4T_{1g}(P)\leftarrow{}^4T_{1g}(F)$ respectively of the octahedral cobalt(II) complexes.[16,17] In the 1 : 1 adducts of piperazine and pyrazine, these amines are likely to function as bidentate ligands with their two nitrogen atoms; consequently, the complexes may be polymeric. The splitting of the spectral peaks may be attributable to some deviation from an exact octahedral coordination.

The infrared spectra of all of these adducts show some characteristic bands; for example, ν(P–S) and a mixture of ν(P–S) and ν(P–O) appeared at about 800, 680, and 570 cm^{-1}, and ν(Co–S), at about 275 cm^{-1}.[18] The ν(Co–N) bands of amine adducts are rather ambiguous, although some peaks are found in the near-360 cm^{-1} region in their far-infrared spectra.

The visible absorption spectra of the benzene solution of $Co(II)(Et_2dtp)_2$(hexamethylenetetramine), which is the most stable in the series of adducts, gives five peaks in the region of 7100—28000 cm^{-1}. The absorption maxima given by the wave numbers with the log ε values in parentheses, are 9090(0.91), 12100(1.09), 15900(1.80), and 17200(1.76) for a 0.01 mol dm^{-3} solution, and 26100(3.17) for 0.0002 mol dm^{-3} one. The spectral pattern resembles that of pentacoordinated trigonal bipyramidal cobalt(II) complexes.[14] However, the absorption coefficients of the bands in the visible region do not obey Beer's law for they increase when the solution is diluted; moreover, the peak at 15900 cm^{-1} is broadened, and the maximum shifts to about 15000 cm^{-1}, which corresponds to the peak of the free $Co(II)(Et_2dtp)_2$.[6] This observation indicates that $Co(II)(Et_2dtp)_2$ and the pentacoordinated adduct are in equilibrium in the solution. The solutions of other adducts also show almost the same pattern as that of the hexamethylenetetramine adduct. Even the hexacoordinated adducts in their solid states also give a spectral pattern similar to that of pentacoordinated cobalt(II) in their solution; this is a result of partial dissociation. Therefore, the equilibrium studies described below take into account only the 1 : 1 adduct formation process; the second-step association is assumed to be negligible

Table 4. Formation constants of 1 : 1 adducts, $[Co(II)(R_2dtp)_2 \cdot X]$

compared to the first one.

Although the $Co(II)(Et_2dtp)_2$ or $Co(II)(Me_2dtp)_2$ in carbon tetrachloride or in a benzene solution is gradually air-oxidized, the solutions were spectrophotometrically stable for 2 h after dissolution when the concentration was of the order of 3×10^{-3} mol dm^{-3}. Thus, practically, the absorbance of the solution did not change during the period of the measurement. After mixing a solution of $Co(II)(R_2dtp)_2$, or $Co(II)(R_2dtp)_2(PPh_3)$ with PPh_3, the equilibrium was attained in several min. All the other adducts also behaved in the same way. Therefore, the absorbance measurement of the mixture could be started about 7 min after mixing and could be finished in about 1 h. A series of the spectra of the mixture of $Co(II)(Me_2dtp)_2(PPh_3)$ and PPh_3 are shown in Fig. 3. Two isosbestic points are found, and the wavelengths of the absorption maxima of these spectra are kept at about 662 nm in the mixing-ratio region.

The same type of spectra posessing two isosbestic points were observed in the $Co(II)(Et_2dtp)_2$–PPh_3, and $Co(II)(Et_2dtp)_2$–benzothiazole systems. In the case of the $Co(II)(Et_2dtp)_2$–hexamethylenetetramine system, the hexamethylenetetramine adduct itself could not be used as the starting material because the formation constant of the adduct is too high. In this case, the PPh_3 adduct rather than the free complex was used as the starting material. Since the formation constant of the hexamethylenetetramine adduct is about 200 times that of PPh_3, the co-existence of the phosphine due to the use of its adduct was expected to be outside the range of experimental error. The isosbestic points were found in this system when $[Co(II)(Et_2dtp)_2]=3.0\times10^{-3}$ mol dm^{-3}, and [hexamethylenetetramine]$=0$—6.0×10^{-3} mol dm^{-3}.

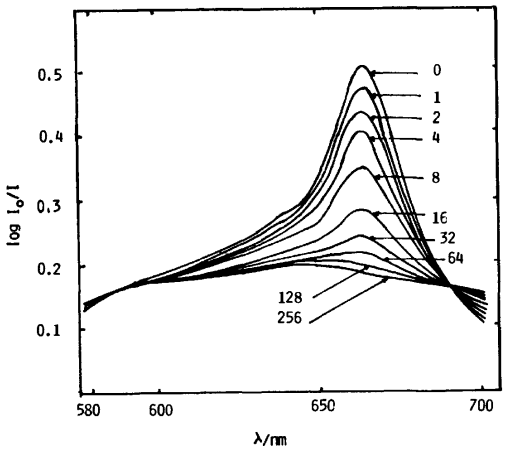

Fig. 3. Absorption spectra of the mixture of $[Co(II)(Me_2dtp)_2(PPh_3)]$ and PPh_3 (where Me_2dtp=*O,O'*-dimethyl dithiophosphato ligand, PPh_3=triphenylphosphine) in benzene, at 25 °C. $[Co(II)(Me_2dtp)_2(PPh_3)]$ added was always 2.00×10^{-3} mol dm^{-3}, and the concentration ratio of $[PPh_3]/[Co(II)(Me_2dtp)_2(PPh_3)]$ (originally added, mol/mol) are shown by numbers in the figure.

The apparent formation constants of the adducts, $K=[Co(II)(R_2dtp)_2\cdot X]/\{[Co(II)(R_2dtp)_2][X]\}$, where R=$CH_3$ or C_2H_5, X=PPh_3, benzothiazole, or hexamethylenetetramine are listed in Table 4. That of the pyrazine adduct was not obtained because of its low solubility.

The formation constant, K, was calculated as follows. Let the total concentration of Co(II) be m_o, and let that of the donor X be d, while x is the concentration of the $Co(II)(R_2dtp)_2\cdot X$ adduct.*** Then, $[Co(II)(R_2dtp)_2]$ and [X] in the solution are given by m_o-x and $d-x$ respectively. As the wavelength of the maximum absorption does not change in the concentration region, while the isosbestic points are retained, the absorbance can be written as $A=\varepsilon_1 x+\varepsilon_2(m_o-x)$, where ε_1 stands for the absorption coefficient of the $Co(II)(R_2dtp)_2\cdot X$ adduct, and ε_2, that of the free complex, $Co(II)(R_2dtp)_2$. From these relations, the following equation can be derived:

$$\frac{1}{m_oK[X](\varepsilon_1-\varepsilon_2)}+\frac{1}{m_o(\varepsilon_1-\varepsilon_2)}=\frac{1}{A-\varepsilon_2 m_o}.$$

Therefore, when $d\gg x$; *i.e.* $[X]\fallingdotseq d$, a linear relationship exists between $1/d$ and $1/(A-\varepsilon_2 m_o)$. From the gradient of the line and the intercept, the values of $1/\{m_oK(\varepsilon_1-\varepsilon_2)\}$ and $1/\{m_o(\varepsilon_1-\varepsilon_2)\}$ respectively can be known. Then, the ε_1 and K of each adduct can be calculated. The ε_2 of $Co(II)(Et_2dtp)_2$ was determined from the absorbance of the complex, extracted by the organic solvent from a mixture of cobalt(II) chloride and $Na(Et_2dtp)$ in aqueous solution; the concentration of Co(II) was estimated by titration after decomposing the ligand. The ε_2 of $Co(II)(Et_2dtp)_2$ and that of $Co(II)(Me_2dtp)_2$ were almost the same; *i.e.*, 315 mol^{-1} dm^3. This is slightly smaller than that reported by Jørgensen,[8b] although he stated that his result might be a little too high.

These apparent first-order adduct formation constants were also obtained from the ^{1}H-NMR paramagnetic

*** m_o, d, and x are in mol dm^{-3} units, accordingly, K is in mol^{-1} dm^3 units.

shifts of the donor protons caused by the addition of the $Co(II)(R_2dtp)_2 \cdot X$ adduct to the solution of a donor. The broadening of the peak by the addition of the adduct was not much, indicating that the exchange rate of the donors between the free state and that in the adduct is high. The paramagnetic shifts of the proton peak of the donor protons can thus be expected to be given by the weighed average of the chemical shifts of the proton of the donor in the free and bonded states. The most probable species existing in the solution is the 1 : 1 adduct, and the fraction of the 2 : 1 adduct or the higher ones can be expected to be low, even in such relatively concentrated solution of a donor.

Therefore, in this case, too, only the first step was considered, and the adduct formation constant was obtained by the use of the equation: $K=[Co(II)(R_2dtp)_2 \cdot X]/\{[Co(II)(R_2dtp)_2] \cdot [X]\}$. The calculations were as follows. The chemical shift of a proton of a donor, X, in a free state is denoted by δ_B; that in an adduct, by δ_A, and that of the observed, by δ_o. As in the case of the spectrophotometric method, m_o, d, and x are defined as the total concentration of Co(II), the total concentration of the donor, and the concentration of the existing adduct, respectively. Since d is enough larger than m_o and x in the NMR measurement, too, we use the approximation of $[X] \fallingdotseq d$. Therefore, we have $K=x/\{(m_o-x)d\}$. On the other hand, $\delta_o=\delta_B+x(\delta_A-\delta_B)/d$. From these relations, we obtain:

$$d = (\delta_A-\delta_B)\{m_o/(\delta_o-\delta_B)\} - (1/K).$$

From this linear relation between d and $m_o/(\delta_o-\delta_B)$, δ_A was obtained from its gradient. Next, the δ_o's of a series of samples with different d values, but with the same $m_o/d(\equiv a)$, were measured. The equation can be rewritten as: $1/\Delta=[1/\{a(\delta_A-\delta_B)\}][1+(1/K)(1/d)]$, where $\Delta=\delta_o-\delta_B$. When a is kept constant, there is a linear relationship between $1/\Delta$ and the formation constant, K, which was obtained from the gradient. The proton peaks used for the calculations were those of the phenyl ortho protons for the PPh_3 adduct, and the methine proton at the 2-position for the benzothiazole adduct. In the case of hexamethylenetetramine or the pyrazine adduct, a single peak in the ^1H-NMR was used. The obtained results, the δ_A, δ_B, and log K values, are listed in Table 4, also; they agreed well with those obtained from spectrophotometry.

The authors wish to express their appreciation to Mr. Yukio Yamada for his assistance about the experimental operations. We are also indebted to Professor Toschitake Iwamoto for his helpful discussions concerning the thesis. The cooperation in the calculations for the structure analysis by Dr. Fujio Ebina is also greatly appreciated.

The Extractability of Potassium as Picrates (KPic and K(L)Pic, L: 18-Crown-6) and Its Relationship to the Properties of the Solvents

Tadashi IWACHIDO,* Masayoshi MINAMI,† Hirohiko NAITO,† and Kyoji TÔEI†

College of Liberal Arts, Okayama University, 2-1-1, Tsushima-naka, Okayama 700

†*Department of Chemistry, Faculty of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700*

(Received November 19, 1981)

The distribution ratios, D, of potassium between an aqueous KCl solution and 57 organic solvents (8 alcohols, 12 ketones, 6 esters, 3 ethers, and 28 hydrocarbons (24 halo- and 2 nitro-substituted and 2 unsubstituted)) were determined in the presence or in the absence of L. The presence of L markedly enhances the extractability of potassium when the halogenated hydrocarbon solvents are used, but only a slight enhancement can be observed for the oxygen-containing solvents. Among the properties showing good correlations with D, Hansen's three-dimensional solubility parameters and Dimroth's E_T values are most satisfactory for their applicability to a wide variety of solvents.

Potassium picrate in an aqueous solution can be extracted only when a highly polar substance is used as a solvent. Most such solvents are miscible with water; hence, only a limited number of water-immiscible solvents can be used.

L is a well-known ligand of the endopolarophilic type, with the polar binding sites turned inside towards the cation and the lipophilic methylene groups turned outside. A wider variety of solvents, therefore, are made subjects of the extraction study of K(L)Pic because of its increased lipophilicity.

Although the knowledge of the polarity of a solvent is important in solvent-extraction chemistry, there are only a few reports which describe a quantitative relation between the extractability of the ion-pair and the polarity of the solvent.[1,2] In chelate-extraction systems, however, the solubility parameter of the solvent is known to have a close relationship with the extractability of the chelate.

This paper will describe how, besides the solubility parameter, the transition energy for a solvatochromic indicator can serve as a numerical polarity scale for the present extractions.

Experimental

Materials. Reagent-grade solvents (Tokyo Kasei Co., Ltd.) were washed with an aqueous sodium carbonate solution and then with water several times. The K(L)Pic was prepared by adding an equimolar amount of commercially available L (Nisso Co., Ltd.) to an aqueous KPic solution and was then recrystallized repeatedly from methanol.

Distribution Ratios. Aqueous picrate solutions (10^{-4} mol dm^{-3}) were prepared by dissolving each picrate in a solvent-saturated potassium hydrogencarbonate solution, the total potassium concentration being 10^{-2} mol dm^{-3}. Twenty milliliters of the aqueous solution and an equal volume of a water-saturated solvent were transferred to a 50-cm^3 centrifuge tube. After being shielded tightly, the vessel was immersed in a water bath thermostated at (25±0.01) °C and gently shaken for 1 h. The value of D was calculated from the aqueous picrate concentration, as determined by the use of a Hitachi 124 spectrophotometer.

Water Miscibilities. The water content of the organic phase was determined in each distribution run by the use of a Mitsubishi Kasei CA-01 Karl-Fischer titrator.

Solubilities. The solubilities of the picrates in the water-saturated solvents at 25 °C were determined by means of HPLC (Shimadzu liquid chromatograph; column: 250 mm × 4 mm Zorbax PCH, mobile phase: methanol, detector: SPD-1 spectrophotometer).

Results and Discussion

D Values and Structures. The D values for oxygen-containing solvents are listed in Table 1, together with some other data.

Table 1 shows that the D value for benzyl alcohol is greater than that for 1-heptanol, though both have the same number of carbon atoms. Such a phenyl-substitution effect can also be seen with acetophenone, benzyl acetate, and probably anisole. The presence of double bonds also enhances the extractabilities of the picrates, as can be seen for mesityl oxide. Such is the case with allyl chloride, as will be seen later. The presentation of the D values on a logarithmic scale produces relatively simple relations with the number of carbon atoms, N, of the solvent molecule, as is shown in Fig. 1. It must

be noted that, in Fig. 1, modified N values are used for the phenyl-substituted ($N-3$) and double-bond-containing solvents ($N-1$), so that the best fit can be obtained. Among the solvents with the same number of carbon atoms, the extractabilities of K(L)Pic decrease in the following sequence: ketones>alcohols>esters>ethers. A quite similar plot is obtained for the extraction of KPic.

The D values for hydrocarbon solvents are listed in Table 2. No hydrocarbon solvents can extract KPic. Nitro-substituted ones show exceptionally high extractabilities both for KPic and K(L)Pic. It is obvious that the D values decrease with an increase in the number of the CH_2 units of the solvent: C_3H_7Cl, C_4H_9Cl>$C_5H_{11}Cl$ >$C_6H_{13}Cl$. The double-bond containing solvents likewise show higher extractabilities than the corresponding saturated ones: allyl chloride>propyl chloride.

The extractability of K(L)Pic tends to decrease with an increase in the number of halogen atoms (CH_2Cl_2> $CHCl_3$>CCl_4, *o*-dichlorobenzene>chlorobenzene), and completely halogenated solvents, such as CCl_4 and $CBrCl_3$, do not show any appreciable extractabilities. The position of halogen atoms also has a significant influence, as can be seen for 1,1- and 1,2-dichloroethane, for example. It is noticeable that the extractability is greatly affected by the *cis-trans* isomerism (*cf.* 1,2-dichloroethylene).

The chlorinated solvents always show the highest extractability among the halogenated solvents, as is best shown in monohalogen derivatives of benzene.

Dielectric Constant, ε, and Dipole Moment, μ. The log D values tend to increase with ε, in accordance with Irving and Lewis' observation of the partition of indium chloride,[1] though the correlation is far from satisfactory. Freiser also pointed out, for the distribution of tridodecylammonium perrhenate, that there isverylittle correlation between the logarithmic distribution constants and the ε values.[2] The log D values also increase with μ, though the degree of correlation is much lower than that observed between log D and ε. It should, however, be noted that, among the solvent parameters investigated, only ε and μ show the expected low extractabilities of K(L)Pic into CCl_4 and *trans*-1,2-dichloroethylene.

Solubilities of the Picrates, s. The solubilities of the picrates in water-saturated solutions are shown in Tables 1 and 2. A log D *vs.* log s plot for K(L)Pic in the oxygen-containing solvents yields a straight line for

each solvent group, as is shown in Fig. 2. Such a linear relation holds for the extraction of KPic as well. The data points for the double-bond-containing and phenyl-substituted solvents show remarkable deviations; hence, these points are omitted from Fig. 2 so that the linear relationships for each solvent group can easily be seen.

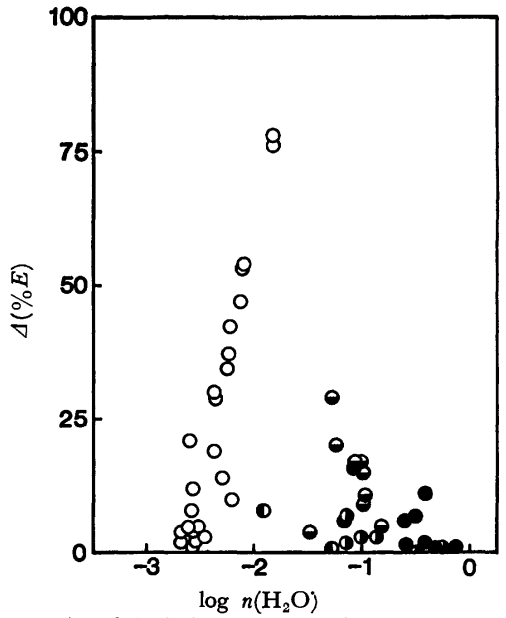

Fig. 4. Plot of $\Delta(\%E)$ *vs.* log $n(H_2O)$.
$\%E$=(picrate extracted/total picrate)×100. Symbols: see Fig. 1.

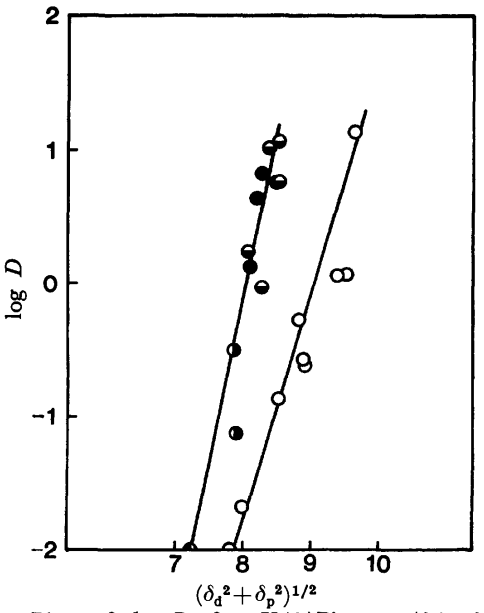

Fig. 6. Plot of log D for K(L)Pic *vs.* $(\delta_d^2+\delta_p^2)^{1/2}$.
Symbols: see Fig. 1.

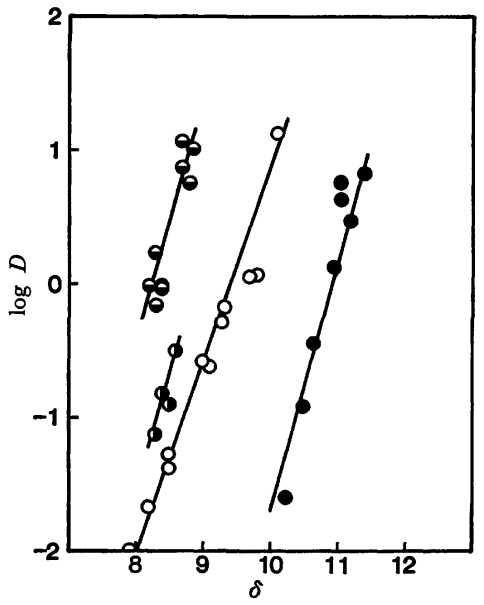

Fig. 5. Relation between log D for K(L)Pic and the solubility parameter of the solvent.
Symbols: see Fig. 1.

For the hydrocarbon solvents, the log D values for K(L)Pic also increase linearly with log s, though the fit is not so good as that which can be seen for the oxygen-containing solvents.

Water Miscibilities. Figure 3 shows that the log D values bear a linear relation to the logarithm of $n(H_2O)$, the mole fraction of water in the organic phase.

In order to investigate the effect of the complexation, percentage extraction increments, $\Delta(\%E)=\%E_{K(L)Pic}-\%E_{KPic}$, are plotted against log $n(H_2O)$ (Fig. 4). The extractability enhancement is maximal at $n(H_2O)=0.015$, indicating that the solvents which can dissolve water to a moderate extent are the best. The oxygen-containing solvents, contrary to the halogenated ones, exhibit a very slight enhancement. Taking into account the fact that crown-ether complexes are less stable in aqueous solutions than in alcohol solutions,[3] the reason for this is that the picrate complex is destabilized by the hydration of the potassium cations.

Solubility Parameters, δ. The regular solution theory has become increasingly important in chelate-extraction studies. However, little is known of its application to ion-pair extraction studies.

The dependence of the log D value for K(L)Pic on δ is illustrated in Fig. 5. The log D values increase linearly with δ. The slopes are identical for each solvent group except the halogenated one. It must be noted that modified δ values (*i.e.*, $\delta-1$ and $\delta-0.33$ for the phenyl-substituted and double-bond-containing solvents respectively) are used for the plot.

A solubility parameter can be divided into three components; thus, $\delta_o^2=\delta_d^2+\delta_p^2+\delta_h^2$, where δ_d, δ_p, and δ_h refer to the dispersion (London), polar (dipole-dipole), and hydrogen-bonding components of the solubility parameter respectively. A log D *vs.* $(\delta_d^2+\delta_p^2)^{1/2}$ plot yields a straight line for the oxygen-containing solvents, including strongly hydrogen-bonded solvents, such as alcohols, as is shown in Fig. 6; this finding indicates that the hydrogen-bonding components contribute much to the increase in δ_o values, but little to the enhancement of the extractabilities. It must noted that data points for the hydrocarbon solvents fall of another regression line, though the reason for this is not clear.

Molar Volume, V. A linear relation is also found between log D and V, as is shown in Fig. 7. The molar volume looks promising as a measure of the extractability in the following respects: V bears a closer relation with log D, especially for the hydrocarbon solvents, and there is no need to use modified V values, not even for the

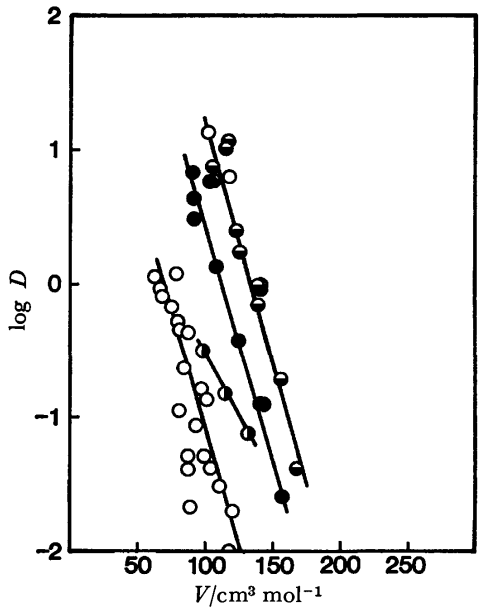

Fig. 7. Relation between log D for K(L)Pic and the molar volume of the solvent.
Symbols: see Fig. 1.

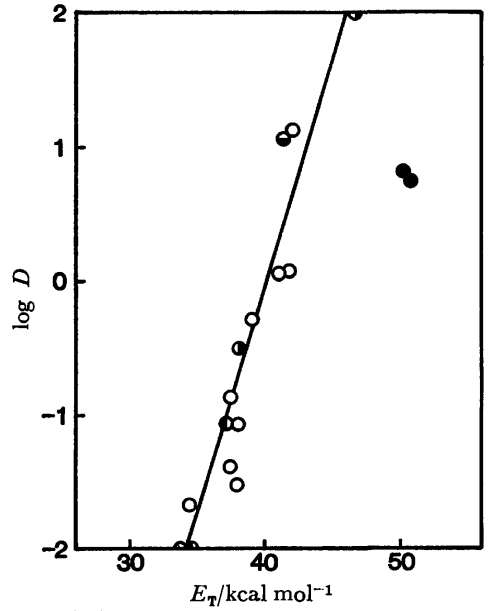

Fig. 8. Relation between log D for K(L) Pic and the E_T value of the solvent.
Symbols: see Fig. 1.

phenyl-substituted and double-bond-containing solvents. The data points for the chloro-substituted solvents (*i.e.*, CCl_4, $CBrCl_3$, *trans*-1,2-dichloroethylene, and 1,2-dichloroethane) and the nitro-substituted solvents show remarkable deviations from the regression line.

E_T Values. Several numerical scales for solvent polarity have been proposed based on the solvatochromism of indicators. The E_T values for 4-(2,4,6-triphenyl-1-pyridinio)-2,6-diphenylphenolate are known for as many as 70 solvents.[6] The dependence of log D on E_T is shown in Fig. 8. It is worth noting that the data points for all solvents except the alcohols fall on a linear line. A similar correlation is found to hold between log D and the spectral shift of 1-ethyl-4-(methoxycarbonyl)pyridinium iodide, which is known as Kosower's Z value,[7,8] though only 8 values are available. The data point for 1-butanol is significantly displaced from the regression line. The E_T values for Phenol Blue (N-[4-(dimethylamino)phenyl]-p-benzoquinone monoimine)[9] are found to correlate with log D, though the fit is not wholly satisfactory.

Miscellaneous. Kovats and Weisz have reported gas-chromatographic retention index values for 38 substances.[10] Although only 7 of them are available for the present purpose, they all fall on a line when plotted against log D.

On the other hand, no satisfactory correlation was observed between log D and Brownstein's S values.[11]

It can be concluded that, among the properties described here, the solubility parameters and Dimroth's E_T values are the most promising numerical scales for the extraction of the picrate.

Theoretical Prediction of Cotton Signs in CD Spectra of Λ-$[Co(N)_2(O)_4]^-$- and Λ-$[Co(N)_4(O)_2]^+$-type Complexes

Shuhei Fujinami,* Kenshi Tsuji, and Muraji Shibata
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Recieved December 11, 1981)

The crystal field model of d-d optical activity has been applied to complexes with *cis*(*N*)-$[Co(N)_2(O)_4]^-$ and *cis*(*O*)-$[Co(N)_4(O)_2]^+$ chromophores, and the Cotton signs of these complexes have been predicted. The model has shown that the Cotton signs in CD spectra of the complexes depend upon: 1) the energy difference between E_g^a and A_{2g} states, 2) the coordination angle in a bidentate chelate, and 3) the effective charge of the ligating atoms. The CD spectral difference between an optically active carbonato complex and the corresponding diaqua complex derived from the carbonato complex has been understood in terms of the effective charge of the ligating O atoms.

In our laboratory, we have been investigating CD spectra in the ligand-field transition region of complexes with *cis*(*N*)-$[Co(N)_2(O)_4]$ and *cis*(*O*)-$[Co(N)_4(O)_2]$ chromophores.[1-3] A method of assigning a transition component of a given Cotton peak was proposed on the basis of a regular CD spectral change due to a change of chelate ring size of bidentate OO ligand.[1] The CD spectrum of a diaqua complex, which had been derived from an optically active carbonato complex by an acid-hydrolysis, was found to be remarkably different from that of the parent carbonato complex.[1,3] For examples, $(-)_{589}[Co(CO_3)(ox)(en)]^-$ exhibits a single positive Cotton peak in the first absorption band region, which is assignable to the $A_{1g}\rightarrow E_g^a(D_{4h})$ transition component. On the other hand, $(+)_{589}[Co(ox)(en)(H_2O)_2]^+$ complex derived from the $(-)_{589}$ carbonato complex exhibits negative and positive Cotton peaks from the lower-frequency side in the region, the negative peak being assigned to the same transition component. That is to say, the Cotton sign in the diaqua complex is opposite to that in the parent carbonato complex.

The optical activity associated with the d-d transition of *cis*-$[Co(a)_2(en)_2]^{n+}$ (a represents unidentate ligands such as H_2O, Cl^-, *etc.*) has been discussed by McCaffery *et al.*[4] They attempted to relate the Cotton signs in the bis(ethylenediamine) complexes with those in the tris(ethylenediamine)cobalt(III) complex with D_3 symmetry, and found a rule that the Cotton peak of the $A_{1g}\rightarrow E_g$ transition component in the Λ-$[Co(a)_2(en)_2]^{n+}$ complexes has a positive sign, as does that in the Λ-$[Co(en)_3]^{3+}$ complex. However, an exception to the rule was reported, that is, the Cotton peak assignable to $A_{1g}\rightarrow E_g$ transition in Λ-$[Co(N_3)_2(en)_2]^+$ has a negative sign.[5] The rule is not useful for an understanding of the CD spectrum of $(+)_{589}[Co(ox)(en)(H_2O)_2]^+$.

There are two types of theoretical treatments of optical activity; one is called a crystal field model (or static coupling model), developed by Piper *et al.*,[6] and the other is called a dynamic coupling model, developed by Mason *et al.*[7] The former is based upon the crystal field theory, and optical activity of a metal complex is explained by anadmixture of d-orbitals with p- or f-orbitals in a central metal ion. In the latter, the optical activity is explained by an interaction of the hexadecapole moment at a central metal ion with transient electric dipole moments at ligands. However, the application of these models is mostly limited to the tris(diamine) complex with D_3 symmetry.

In this paper, a crystal field model for mixed complexes with lower symmetry than D_3 is proposed, in which the signs of rotatory strength of $A_{1g}\rightarrow A_{2g}(D_{4h})$ transition component are predicted in Λ-$[Co(NN)(OO)_2]^{n-}$ and Λ-$[Co(NN)_2(OO)]^{n+}$ complexes (OO=CO_3^{2-}, ox^{2-}, mal^{2-}, or $2H_2O$; NN=en or tn). The proposed model is useful for the understanding of the CD spectrum of the appropriate diaqua complex.

General Theory

The Hamiltonian for the octahedral coordination system may be written as

$$\boldsymbol{H} = \boldsymbol{H}_o + \boldsymbol{V}_g + \boldsymbol{V}_u \quad (1)$$

where $\boldsymbol{H}_o$ represents the unperturbed Hamiltonian in the regular octahedron, and $\boldsymbol{V}_g$ and $\boldsymbol{V}_u$ represent the potentials with even and odd parity, respectively. The eigenstates of $\boldsymbol{H}_o$ in cobalt(III) complexes are classified as

$|A_{1g}\rangle$ =nondegenerate ground state with even parity,
$|T_{1g}i\rangle$ =octahedral components (i=a, β, γ) of the first excited state with even parity,
$|T_{2g}j\rangle$ =octahedral components (j=ξ, η, ζ) of the second excited state with even parity,
$|M_uk\rangle$=octahedral components of higher excited states with odd parity.

The first-order perturbed wavefunctions for the ligand field excited states can be written in terms of the perturbation theory as follows:

$$\begin{aligned}|A_{1g}) = |A_{1g}\rangle &+ \sum_k |M_uk\rangle\langle M_uk|\boldsymbol{V}_u|A_{1g}\rangle\{E(M_uk) - E(A_{1g})\}^{-1} \\ &+ \sum_i |T_{1g}i\rangle\langle T_{1g}i|\boldsymbol{V}_g|A_{1g}\rangle\{E(T_{1g}i) - E(A_{1g})\}^{-1} \\ &+ \sum_j |T_{2g}j\rangle\langle T_{2g}j|\boldsymbol{V}_g|A_{1g}\rangle\{E(T_{2g}j) - E(A_{1g})\}^{-1} \quad (2)\end{aligned}$$

$$\begin{aligned}|T_{1g}i) = |T_{1g}i\rangle &+ \sum_k |M_uk\rangle\langle M_uk|\boldsymbol{V}_u|T_{1g}i\rangle\{E(M_uk) - E(T_{1g}i)\}^{-1} \\ &+ \sum_{i'\neq i} |T_{1g}i'\rangle\langle T_{1g}i'|\boldsymbol{V}_g|T_{1g}i\rangle\{E(T_{1g}i') - E(T_{1g}i)\}^{-1} \quad (3) \\ &+ \sum_j |T_{2g}j\rangle\langle T_{2g}j|\boldsymbol{V}_g|T_{2g}j\rangle\{E(T_{2g}j) - E(T_{1g}i)\}^{-1},\end{aligned}$$

where $E(M_uk)$, *etc.* denote the energy of the unperturbed states.

The rotatory strength associated with a $A_{1g}\rightarrow T_{1g}i$ transition, $R(T_{1g}i)$, is expressed by

$$R(T_{1g}i) = \mathrm{Im}\{(A_{1g}|\boldsymbol{P}|T_{1g}i)\cdot(T_{1g}i|\boldsymbol{M}|A_{1g})\}, \quad (4)$$

where $\boldsymbol{P}$ and $\boldsymbol{M}$ are the electric and magnetic dipole operators, respectively. If we neglect higher terms of the energy differences, the rotatory strength $R(T_{1g}i)$ can be expressed by using the first-order wavefunctions given in Eqs. 2 and 3.

A Crystal Field Model for Mixed Complexes

We deal with cobalt(III) complexes with *cis*(*N*)-$[Co(N)_2(O)_4]$ or *cis*(*O*)-$[Co(N)_4(O)_2]$ chromophore. Since the holohedrized symmetry[8] of those complexes is D_{4h}, the electronic states can be approximated by a treatment in D_{4h} symmetry. Therefore, we use tetragonal basis sets of 3d and 4p orbitals as zero-order wavefunctions. The wavefunction of the ground state is written in determinant form as follows:

$$|A_{1g}) = |\overset{+}{(yz)}\overset{-}{(yz)}\overset{+}{(zx)}\overset{-}{(zx)}\overset{+}{(xy)}\overset{-}{(xy)}|.$$

As for the excited states, T_{1g} state in octahedral symmetry splits into A_{2g} and E_g^a states in tetragonal symmetry, while T_{2g} state splits into B_{2g} and E_g^b states. The wavefunctions of the excited states are listed in Table 1, in which the wavefunctions are represented by a d- or p-orbital component of the occupied orbital and a d-orbital component of the hole orbital. Thus, the wavefunction for $|A_{2g})$ is:

$$|(xy)(x^2-y^2)| = \{|\cdots\overset{+}{(yz)}\overset{-}{(yz)}\overset{+}{(zx)}\overset{-}{(zx)}\overset{+}{(xy)}(x^2-\overset{-}{y^2})| + |\cdots(\overset{+}{x^2-y^2})\overset{-}{(xy)}|\}/\sqrt{2}.$$

Non-vanishing matrix elements of $\boldsymbol{P}$ and $\boldsymbol{M}$ are gathered in Tables 2 and 3. Using the wavefunctions in Table 1, the rotatory strength of $R(A_{2g})$, which arises from d-p and d-d mixings, can be expressed as follows:

$$\begin{aligned}
R(A_{2g}) = {} & (\sqrt{3}/4)[\langle x|\boldsymbol{V}_u|x^2-y^2\rangle\Delta E_{u2}^{-1} \\
& - \langle y|\boldsymbol{V}_u|xy\rangle\Delta E_{u1}^{-1}] \\
& \times [\{\langle x^2-y^2|\boldsymbol{V}_g|zx\rangle - \sqrt{3}\langle z^2|\boldsymbol{V}_g|zx\rangle\}\Delta E_1^{-1} \\
& - 2\langle xy|\boldsymbol{V}_g|yz\rangle\Delta E_2^{-1} \\
& - (3\sqrt{2}/2)\{\langle x^2-y^2|\boldsymbol{V}_g|zx\rangle \\
& + \sqrt{3}\langle z^2|\boldsymbol{V}_g|zx\rangle\}\Delta E_3^{-1} \\
& + 3\sqrt{2}\langle xy|\boldsymbol{V}_g|yz\rangle\Delta E_4^{-1}] \quad (5) \\
& - (\sqrt{3}/4)[\langle y|\boldsymbol{V}_u|x^2-y^2\rangle\Delta E_{u2}^{-1} \\
& + \langle x|\boldsymbol{V}_u|xy\rangle\Delta E_{u1}^{-1}] \\
& \times [\{\langle x^2-y^2|\boldsymbol{V}_g|yz\rangle \\
& + \sqrt{3}\langle z^2|\boldsymbol{V}_g|yz\rangle\}\Delta E_1^{-1} \\
& + 2\langle xy|\boldsymbol{V}_g|zx\rangle\Delta E_2^{-1} \\
& - (3\sqrt{2}/2)\{\langle x^2-y^2|\boldsymbol{V}_g|yz\rangle \\
& - \sqrt{3}\langle z^2|\boldsymbol{V}_g|yz\rangle\Delta E_3^{-1} \\
& - 3\sqrt{2}\langle xy|\boldsymbol{V}_g|zx\rangle\Delta E_4^{-1}].
\end{aligned}$$

Here,

$$\begin{aligned}
& \Delta E_{u1} = E(M_u) - E(A_{1g}),\ \Delta E_2 = E(E_g^a) - E(A_{2g}) \\
& \Delta E_{u2} = E(M_u) - E(A_{2g}),\ \Delta E_3 = E(E_g^b) - E(A_{1g}) \\
& \Delta E_1 = E(E_g^a) - E(A_{1g}),\ \Delta E_4 = E(E_g^b) - E(A_{2g}). \quad (6)
\end{aligned}$$

We use an average energy $E(M_u)$ instead of the individual energy levels of odd parity states.

We are interested in the Cotton sign of $A_{1g}\rightarrow A_{2g}(D_{4h})$ transition for the CD spectra of Λ-$[Co(NN)_2(OO)]^{n+}$ and Λ-$[Co(NN)(OO)_2]^{n-}$ complexes ($OO=CO_3^{2-}$, ox^{2-}, mal^{2-}, or $2H_2O$; NN=en or tn). To predict the Cotton sign, it is necessary to define the spherical coordinate (R_i, θ_i, ϕ_i) of the ligating atom L_i (i=1,2,⋯6). The adopted spherical and Cartesian coordinate systems are drawn in Fig. 1. In this model, we

consider a simplified arrangement of the ligating atoms, and ignore the existence of non-ligating atoms. The coordinate (R_i, θ_i, ϕ_i) of the ligating atom L_i (i=1,3,5) is converted into (R_{i+1}, θ_{i+1}, ϕ_{i+1}) by a C_2 axis intersecting the bidentate ligand L_iL_{i+1}. These three C_2 axes are supposed to deviate from the x, y, or z axis by 45°. The R_{i+1} coordinate is assumed to be equal to the R_i (i=1,3,5). On these assumptions, the V_u and V_g potentials at the non-vanishing matrix elements in Eq. 5 can be expressed as

$$\begin{aligned} V_u &= er^3\{A_{33}Y_3^3 + A_{3-3}Y_3^{-3}\} \\ V_g &= er^2(A_{21}Y_2^1 + A_{2-1}Y_2^{-1}) \\ &\quad + er^4(A_{41}Y_4^1 + A_{4-1}Y_4^{-1}) \\ &\quad + er^4(A_{43}Y_4^3 + A_{4-3}Y_4^{-3}), \end{aligned} \tag{7}$$

where r denotes the electron radical coordinate and e is the charge of an electron. The functions Y_l^m are spherical harmonics normalized to unity. The factors A_{lm} are defined as

$$\begin{aligned} A_{3\pm3} &= \mp(3\sqrt{5}/4)\sum_{k=1}^{6} q_k R_k^{-4}\sin^3\theta_k \exp(\mp 3\phi_k i) \\ A_{2\pm1} &= \pm\sqrt{6}\sum_{k=1}^{6} q_k R_k^{-3}\sin 2\theta_k \exp(\mp\phi_k i) \\ A_{4\pm1} &= \pm(\sqrt{5}/2)\sum_{k=1}^{6} q_k R_k^{-5}\sin 2\theta_k(7\cos^2\phi_k - 1)\exp(\mp\phi_k i) \\ A_{4\pm3} &= \pm(3\sqrt{5}/2)\sum_{k=1}^{6} q_k R_k^{-5}\sin 2\theta_k \sin^2\theta_k \exp(\mp 3\phi_k i), \end{aligned} \tag{8}$$

where q_k expresses the effective charge associated with the ligating atom L_k.

Idealized Model. We first consider the Cotton sign of $R(A_{2g})$ in Λ-$[Co(NN)_2(OO)]^{n+}$ and Λ-$[Co(NN)_2(OO)_2]^{n-}$ by an idealized model in which all ligating atoms are located on the xy, yz, and zx planes. The complexes can be classified into three groups.

Group 1) L_1CoL_2, L_3CoL_4, and L_5CoL_6<90°

Group 2) L_1CoL_2<90°, L_3CoL_4 and L_5CoL_6>90°

Group 3) L_1CoL_2>90°, L_3CoL_4 and L_5CoL_6<90°

The coordination angles of concerned complexes are cited in Table 4. The complexes Λ-$[Co(CO_3)(en)_2]^+$, Λ-$[Co(ox)(en)_2]^+$, Λ-$[Co(CO_3)(ox)(en)]^-$, and Λ-$[Co(ox)_2(en)]^-$ belong to Group 1), Λ-$[Co(ox)(tn)_2]^+$ and Λ-$[Co(mal)_2(en)]^-$ complexes to Group 2), and Λ-$[Co(mal)(en)_2]^+$, Λ-$[Co(CO_3)(mal)(en)]^-$, and Λ-$[Co(ox)(mal)(en)]^-$ complexes to Group 3).

The expressions for the rotatory strength of $R(A_{2g})$ in these groups are given in Table 5. Since the values of $\langle r^3\rangle$ and ΔE_{u2} are positive, the constant, K, becomes positive. In order to predict the sign of $R(A_{2g})$, the

following variables have to be estimated:

1) radial integrals $\langle r^2\rangle$ and $\langle r^4\rangle$,
2) coordinates of the ligating atom L_i, (R_i, θ_i, ϕ_i),
3) energy differences, ΔE_1, ΔE_2, and ΔE_4,
4) effective charges of ligating atoms, q_i.

The radial integrals can be evaluated by Watoson's Hartree-Fock wavefunction,[9] that is, $\langle r^2\rangle$=0.293 Å and $\langle r^4\rangle$=0.184 Å. The coordinates of the ligating atoms can be estimated from the X-ray analytical data listed in Table 4. As for the energy differences, the ΔE_1 and ΔE_2 values can be evaluated in terms of an angular overlap model,[10] and the ΔE_4 value is approximated by the energy difference between the absorption maximum of the first absorption band and that of the second absorption band, the values being listed in Table 6. It is difficult to estimate accurately the effective charges of the ligating atoms. Since this model ignores the existence of the non-ligating atoms, it is better to treat the effective charge of a ligating atom as an empirical parameter. The effect of the non-ligating atom upon the rotatory strength may be included into the parameter. We adopt a crude assumption that the effective charge on an anionic ligand of OO type is minus and that on a neutral ligand is plus.

The Cotton sign of $R(A_{2g})$ of the Λ-$[Co(en)(ox)(ox)]^-$ ($=\Lambda$-$[Co(L_1L_2)(L_3L_4)(L_5L_6)]^-$) complex is predicted as follows. From the data of the bond distances and the coordination angles, the coordinates of the ligating atoms in the complex are written as

$$\begin{aligned}(R_1, \theta_1, \phi_1) &= (1.98, 90°, 2°)\\ (R_3, \theta_3, \phi_3) &= (1.94, 2.5°, 180°)\\ (R_5, \theta_5, \phi_5) &= (1.94, 177.5°, 270°).\end{aligned} \quad (9)$$

Using these coordinates and the values of the radial integrals, $R(A_{2g})$ of Λ-$[Co(ox)_2(en)]^-$ is expressed as the product of an effective charge term and an energy difference term:

$$R(A_{2g}) = -C \times q_{ox}(5.8q_{en} - 7.0\gamma q_{ox}) \times (8\ 5\,\Delta E_1^{-1} + 6.1\,\Delta E_2^{-1} - 13\,\Delta E_4^{-1}), \quad (10)$$

where q_{en} and q_{ox} denote the effective charge of the ligating atoms of en and ox, respectively, and C is a positive constant. Since the ΔE_1, ΔE_2, and ΔE_4 values are evaluated as 17800, −1180, and 7500 cm^{-1} respectively (Table 6), the sign of the energy difference term in Eq. 10 becomes minus, on account of a small minus value of ΔE_2. It may be noted that the energy difference term becomes minus in all $cis(N)$-$[Co(N)_2(O)_4]$ complexes. The q_{en} value is evaluated to be plus and the q_{ox} value to be minus. Since the value of $\gamma=\Delta E_{u2}/\Delta E_{u1}$ becomes plus, $R(A_{2g})$ is considered to be negative in the Λ-$[Co(ox)_2(en)]^-$ complex. Similar procedures in calculation lead to the same result in the Λ-$[Co(CO_3)(ox)(en)]^-$ and Λ-$[Co(CO_3)_2(en)]^-$ complexes.

As to the Λ-$[Co(ox)(en)_2]^+$ complex, which also belongs to Group 1), the following equation of $R(A_{2g})$ is obtained by a similar calculation:

$$R(A_{2g}) = -C \times q_{en}(6.1\,q_{ox} - 6.5\,\gamma q_{en}) \times (4.6\,\Delta E_2^{-1} - 0.8\,\Delta E_4^{-1} + 6.4\,\Delta E_1^{-1}). \quad (11)$$

In this complex, the energy difference term in Eq. 11 becomes plus, on account of the small plus value of ΔE_2. It is worth noting that the energy difference term is always plus in $cis(O)$-$[Co(N)_4(O)_2]$ complexes. If $q_{en}>0$ and $q_{ox}<0$, the resultant sign of $R(A_{2g})$ in Λ-$[Co(ox)(en)_2]^+$ becomes positive. Similarly, $R(A_{2g})$ in Λ-$[Co(CO_3)(en)_2]^+$ is predicted to have a positive sign.

Since the coordination angle of mal^{2-} in Λ-$[Co(mal)_2(en)]^-$ is reported to be 96°,[11] this complex belongs to Group 2). Using the equation in Table 5, $R(A_{2g})$ of the complex can be written as

$$R(A_{2g}) = Cq_{mal}(5.8\,q_{en} - 7.6\,\gamma q_{mal}) \times (7.7\,\Delta E_2^{-1} - 16\,\Delta E_4^{-1} + 11\,\Delta E_1^{-1}), \quad (12)$$

where q_{mal} denotes the effective charge on the malonato ligand. Since the chromophore is $cis(N)$-$[Co(N)_2(O)_4]^-$, the energy difference term becomes minus on account of the minus value of ΔE_2. The malonato ligand is anionic, and q_{mal} is also regarded to be minus. Therefore, $R(A_{2g})$ in Λ-$[Co(mal)_2(en)]^-$ is predicted to have a positive sign.

The Λ-$[Co(ox)(tn)_2]^+$ complex is also of Group 2), and its $R(A_{2g})$ is written as

$$R(A_{2g}) = Cq_{tn}(6.1\,q_{ox} - 6.3\,\gamma q_{tn}) \times (6.9\,\Delta E_2^{-1} - 15\,\Delta E_4^{-1} + 9.4\,\Delta E_1^{-1}). \quad (13)$$

The energy difference term is estimated to be plus, and if $q_{tn}>o$, the effective charge term becomes minus. Consequently, the sign of $R(A_{2g})$ in the complex is regarded as negative.

For complexes of Group 3), when the angle ϕ_1 is measured to have a minus value, the equation for group 1) can be utilized. For example, the coordinates of Λ-$[Co(mal)(en)_2]^+$ are,

$$\begin{aligned}(R_1, \theta_1, \phi_1) &= (1.90, 90°, -3°)\\ (R_3, \theta_3, \phi_3) &= (1.98, 2°, 180°)\\ (R_5, \theta_5, \phi_5) &= (1.98, 178°, 270°).\end{aligned} \quad (14)$$

The sign of $R(A_{2g})$ is plus, which is the same as in the case of Λ-$[Co(ox)(en)_2]^+$.

If it is postulated that H_2O molecules are linked on the coordinate axes, the Λ-$[Co(en)_2(H_2O)_2]^{3+}$ and Λ-$[Co(ox)(en)(H_2O)_2]^+$ complexes may be classified into Group 1). The rotatory strength for the former complex is given by

$$R(A_{2g}) = -C \times q_{en}(7.1\,q_{H_2O} - 6.5\,\gamma q_{en}) \times (6.4\,\Delta E_1^{-1} + 4.6\,\Delta E_2^{-1} - 9.8\,\Delta E_4^{-1}) \quad (15)$$

and, for the latter complex, by

$$R(A_{2g}) = -C \times q_{ox}(5.8\, q_{en} - 7.1\, \gamma q_{H_2O}) \times (8.5\, \Delta E_1^{-1} + 6.1\, \Delta E_2^{-1} - 13\, \Delta E_4^{-1}), \quad (16)$$

where q_{H_2O} denotes the effective charge of the ligating atom in H_2O. The energy difference term in the former complex is estimated to be plus, and that in the latter complex to be minus. According to the estimation of the q_{H_2O} value, the $R(A_{2g})$ in Eqs. 15 and 16 change their signs; if q_{H_2O} has a minus or slightly plus value, the $R(A_{2g})$ of the former complex exhibits positive sign and that of the latter complex a negative one. On the other hand, if q_{H_2O} has a considerable plus value compared with q_{en}, the $R(A_{2g})$ of the former shows a negative sign and that of the latter a positive one.

Deviated Ligand Model. In this model, the influence of the deviation of ligating atoms from xy, yz, and zx planes is studied. For example, the coordinates of a complex in Group 1) are given by

$$\begin{aligned}
(R_1, \theta_1, \phi_1) &= (R_1, 90° + \Delta\theta, \phi_1)\\
(R_2, \theta_2, \phi_2) &= (R_1, 90° - \Delta\theta, 90° - \phi_1)\\
(R_3, \theta_3, \phi_3) &= (R_3, \theta_3, 180° + \Delta\phi)\\
(R_4, \theta_4, \phi_4) &= (R_3, 90° - \theta_3, 180° - \Delta\phi)\\
(R_5, \theta_5, \phi_5) &= (R_5, \theta_5, 270° - \Delta\phi)\\
(R_6, \theta_6, \phi_6) &= (R_5, 270° - \theta_5, 270° + \Delta\phi)
\end{aligned} \quad (17)$$

When the angles $\Delta\theta$ and $\Delta\phi$ were varied from 1° to 3° in the calculation, the predicted sign of $R(A_{2g})$ was essentially coincident with that obtained by the idealized model.

Results and Discussion

1) CD Sign. For the *A*-$[Co(CO_3)_2(en)]^-$, *A*-$[Co(CO_3)(ox)(en)]^-$, and *A*-$[Co(ox)_2(en)]^-$ complexes with *cis*(*N*)-$[Co(N)_2(O)_4]$ chromophore, which are classified into Group 1),the signs of $R(A_{2g})$ are predicted to be negative. On the other hand, for the *A*-$[Co(CO_3)(en)_2]^+$ and *A*-$[Co(ox)(en)_2]^+$ complexes with *cis*(*O*)-$[Co(N)_4(O)_2]$ chromophore, which are also classified into Group 1), the predicted sign of $R(A_{2g})$ is positive. For the *A*-$[Co(mal)_2(en)]^-$ and *A*-$[Co(ox)(tn)_2]^+$ complexes of Group 2), the sign of $R(A_{2g})$ in the former is predicted to be positive, and that in the latter to be negative. Therefore, we can say that the sign of $R(A_{2g})$ in a *A*-$[Co(N)_2(O)_4]^-$ complex is reverse to that in a *A*-$[Co(N)_4(O)_2]^+$ complex, provided that the two complexes belong to the same group. This is because the equation of $R(A_{2g})$ is expressed as a product of two terms, one of which is an effective charge term and the other is an energy difference term, which is a function of inverted ΔE_1, ΔE_2, and ΔE_4. In both the *A*-$[Co(N)_2(O)_4]^-$ and the *A*-$[Co(N)_4(O)_2]^+$ complexes, the effective charge terms become minus. Since $|E_2|$ is much smaller than ΔE_1 and ΔE_4, the sign of the energy difference term depends upon the sign of ΔE_2, which is a energy difference between E_g^a and A_{2g} states. The ΔE_2 value becomes minus and plus in the *A*-$[Co(N)_2(O)_4]^-$ complexes and in the *A*-$[Co(N)_4(O)_2]^+$ complexes, respectively. Accordingly, the energy difference term becomes minus in the former complexes, and plus in the latter complexes.

With complexes with the same chromophore, the $R(A_{2g})$ in a complex of Group 1) is predicted to have the reverse sign to that in a complex of Group 2). This is because, for both the complexes, the products of the effective charge term and the energy difference term have the same sign, provided that the complexes have the same chromophore. However, the product has a minus coefficient in a complex of Group 1) and a plus one in a complex of Group 2), so these coefficients depend upon the coordinates of the ligating atoms. When the coordination angle of a bidentate ligand is smaller than 90°, the coefficient has a minus sign, whereas when the angle is larger than 90°, the coefficient has a plus sign.

Piper and Karipides[6] have predicted that the Cotton sign for $E^a(D_3)$ component in *A*-$[Co(tn)_3]^{3+}$ would be opposite to that in *A*-$[Co(en)_3]^{3+}$. The coordination angle in the trimethylenediamine complex is larger than 90° and that in the ethylenediamine complex is smaller than 90°. By the measurement of a single crystal CD spectrum in *A*-$(+)_{589}[Co(tn)_3]^{3+}$, Judkins and Royer[12] have concluded that a Cotton sign of a given transition should change when the coordination angle of the bidentate chelate ring changes from less than 90° to more than 90°. Our predictions in the mixed-complexes with lower symmetry corresponds well to these conclusions.

2) Absolute Configuration. It has been reported[1] that the $(-)_{589}[Co(CO_3)_2(en)]^-$, $(-)_{589}[Co(CO_3)(ox)(en)]^-$ and $(-)_{589}[Co(ox)_2(en)]^-$ complexes have *A* configurations, and the CD spectra of these complexes exhibit a single positive Cotton peak in the first absorption band region. In our previous paper,[2] these positive Cotton peaks were assigned to a component of $A_{1g} \rightarrow E_g(D_{4h})$. On the other hand, a component of $A_{1g} \rightarrow A_{2g}(D_{4h})$ was regarded as having a negative Cotton sign. Since these complexes have a *cis*(*N*)-$[Co(N)_2(O)_4]$ chromophore and belong to Group 1), the assignments agree well with our calculation results.

The CD spectra of $(+)_{589}[Co(CO_3)(en)_2]^+$, $(+)_{589}$-$[Co(ox)(en)_2]^+$, and $(+)_{589}[Co(mal)(en)_2]^+$ show a single positive Cotton peak in the first absorption band region. The first two complexes belong to Group 1), and the third to Group 3). Previously, the positive Cotton peaks in these complexes were assigned to the $A_{1g} \rightarrow A_{2g}(D_{4h})$ transition component.[2] The absolute configuration of $(+)_{589}[Co(ox)(en)_2]^+$ was determined to be *A* by an X-ray analysis.[13] Since the $(+)_{589}$-isomers of $[Co(ox)(en)_2]^+$ and $[Co(mal)(en)_2]^+$ can be derived from the $(+)_{589}$-isomer of $[Co(CO_3)(en)_2]^+$ by the reaction with oxalic and malonic acids, respectively, the absolute configurations of the carbonato and malonato complexes are also regarded to be *A*. Our calculation for $R(A_{2g})$of these three complexes predicts positive signs, which agrees with the previous experimental results.

The $(-)_{589}[Co(mal)_2(en)]^-$ complex that belongs to Group 2) exhibits three Cotton peaks with (+), (−), and (+) signs from the lower-frequency side in the first absorption band region.[14] The absolute configuration of the complex has been determined to *A*,[11] and the

component with the (−) sign has been assigned to the $A_{1g}\rightarrow A_{2g}(D_{4h})$ component.[1] However, our calculation for $R(A_{2g})$ of this complex predicts a positive sign. This discrepancy seems to arise from the neglect of non-ligating atoms in our model. It is known that non-ligating atoms have an important role in the optical activities of tris(diamine) cobalt(III) complexes.[7] The degenerate $E_g^a(D_{4h})$ state may split into two non-degenerate states by an action of the non-ligating atoms.

The $(+)_{589}[Co(ox)(tn)_2]^+$ complex that also belongs to Group 2) exhibits a single (+) Cotton peak in the first absorption band region. Although the absolute configuration of the complex has not yet been determined, if the positive peak is assignable to the $A_{1g}\rightarrow A_{2g}(D_{4h})$ component, as in the case of the $(+)_{589}[Co(ox)(en)_2]^+$ complex, our calculation predicts a *Δ* configuration.

3) The CD Spectra of Diaqua Complexes. As mentioned in the Introduction, when an optically active diaqua complex is derived from an optically active carbonato complex by an acid-hydrolysis, the CD spectrum of the diaqua complex is quite different from that of the parent carbonato complex. For example, Λ-$(-)_{589}[Co(CO_3)(ox)(en)]^-$ exhibits a Cotton peak with a positive sign in the first absorption band region. The Λ-$[Co(ox)(en)(H_2O)_2]^+$ complex which is derived from the Λ-$(-)_{589}[Co(CO_3)(ox)(en)]^-$ complex exhibits (−) and (+) Cotton peaks from the lower-frequency side in the region.

This phenomenon can be understood in terms of the effective charge of the ligating O atom of the water molecule; the rotatory strength $R(A_{2g})$ is expressed as a product of the effective charge term and the energy difference term, and the energy difference terms have a negative sign in the above two complexes. If q_{CO_3} is evaluated to be minus, the effective charge term in the $[Co(CO_3)(ox)(en)]^-$ complex becomes minus, the resultant sign of $R(A_{2g})$ being negative. In the previous section, it is pointed out that, if q_{H_2O} has a large, plus value, the effective charge term attains a plus value, resulting in a positive sign of $R(A_{2g})$. In order to understand the CD spectrum of the diaqua complex, it is better to regard the empirical q_{H_2O} parameter as plus. Since the aqua ligand is a neutral molecule and the diaqua complex is a cation, it is probable that the donor atom of the aqua ligand has a plus effective charge.

The CD spectrum of Λ-$[Co(CO_3)(en)_2]^+$ exhibits a positive Cotton peak which is assignable to $A_{1g}\rightarrow A_{2g}$ component.[2] Two Cotton peaks with opposite signs are observed in the CD spectrum of Λ-$[Co(en)_2(H_2O)_2]^{3+}$, and the negative peak is assigned to the $A_{1g}\rightarrow A_{2g}$ component. The significant difference of CD spectral shapes between the carbonato and the diaqua complex can also be understood by the difference between the effective charge of the donor atoms in the aqua molecules and that in the carbonato ligand. Our model is useful to explain the CD spectral behavior of the diaqua complexes.

4) CT States in the Crystal Field Model. Since a d-d transition is electronically forbidden, d-orbitals need to admix with an odd parity state. Piper and Karipides[6] have considered the admixture of p-orbitals of a central metal ion in their crystal field model of the optical activities. Our model is also constructed by considering the admixture of p-orbitals of a central metal ion. However, it is possible to consider the admixture of p-orbitals of a ligand, (*i.e.* CT states). Since the wavefunctions of the metal to ligand CT states have the same forms as those listed in Table 1,[15] the formula of rotatory strength expressed in Table 5 is obtained for the d-CT mixing model. The differen point between the d-p mixing model and the d-CT mixing model appears at the evaluation of the $\gamma=E_{u2}/E_{u1}$ value. However, the evaluation of the γ value has no influence upon predicting the sign of $R(A_{2g})$, since the γ value is always plus. Therefore, it is concluded that the d-CT mixing model gives the same results as the d-p mixing model, for the prediction of Cotton signs of a given transition.

Experimental

Derivation of the Malonato Complex. To an aqueous solution of $(+)_{546}[Co(CO_3)(en)_2]Cl$[16] (10 mg, 0.04 mmol in 10 cm^3 H_2O), potassium malonate (1 g, 5 mmol) and malonic acid (0.5 g, 5 mmol) were added, and the mixed solution was stirred at 40 °C for 3 h. The resulting solution was kept in a refrigerator for 2 d, and then filtered. The filtrate was diluted by water (250 cm^3), and charged onto a column of Dowex 50W-X8 resin in Na^+ form (100—200 mesh, 1 cm×5 cm). By elution with a 0.1 mol/dm^3 NaCl solution, one red band was discharged. The absorption and CD spectral data of the effluent were identical with those of $(+)_{546}[Co(mal)(en)_2]^+$.[17]

Cobalt(III) Complexes with Tripodlike Quadridentate Ligands. III.[1,2] Absorption and Circular Dichroism Spectra of Cobalt(III) Complexes Containing *N*-(2-Aminoethyl)iminodiacetate and Amino Carboxylate or 1,2-Diamine

Keiji Akamatsu,* Takashi Komorita, and Yoichi Shimura
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received January 5, 1982)

Glycinato, L-alaninato, ethylenediamine, *N,N*-dimethylethylenediamine, (*R*)-propylenediamine, (*R,R*)-1,2-cyclohexanediamine and meso-2,3-butanediamine cobalt(III) complexes of a tripodlike ligand, *N*-(2-aminoethyl)-iminodiacetate have been prepared. The geometrical configurations are assigned on the basis of their absorption, circular dichroism, and ^{1}H-NMR spectra. The *trans*(*O*) isomer of *meso*-2,3-butanediamine complex is optically resolved and the relationship between the absolute configurations of the chiral 1,2-diamine complexes and their circular dichroism is discussed.

The aeida[3] ligand is a tripodlike quadridentate ligand with two nitrogen and two oxygen atoms as donors and, as well as *i*-dtma, can take two different configurations in the six-coordinate metal complex (s-type and u-type in Fig. 1). The s-type configuration with a plane of symmetry is achiral, while the u-type, for lack of it, chiral. The isomerism of the u-type [Co(tripod)-(bidentate)] complexes was mainly argued in the previous paper[2] concerning the *i*-dtma complexes.

Two different kinds of isomerism occur in the s-type [Co(tripod)(bidentate)] complexes: the geometrical isomerism in the glycinato complexes and the optical isomerism in the *meso*-2,3-butanediamine complexes, where both bidentate ligands, gly and *meso*-2,3-bn, are achiral (Fig. 2). When bidentate ligands are chiral (such as L-ala and (*R*)-pn), the two kinds of isomerism

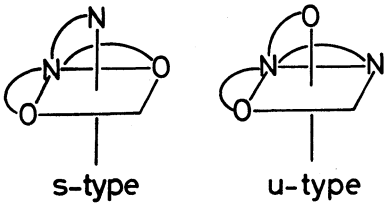

Fig. 1. Two different coordination modes of aeida ligand.

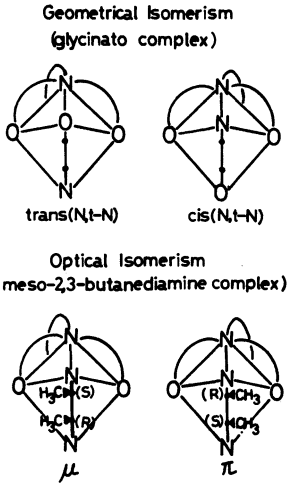

Fig. 2. Two different kinds of the s-type isomerism.

(geometrical and optical) arise at the same time.[1]

In the present paper the u- and s-types of isomersim in the aeida cobalt(III) complexes with an amino carboxylate or 1,2-diamine are reported.

Experimental

Preparations. *1)* [*Co(gly)(aeida)*]: One gram of Na-[Co(NO_2)$_2$(aeida)]·2H_2O[4] was treated with 10 cm^3 of acetic acid and 2 cm^3 of water on a steam bath for 1 h. The resulting red-violet solution was concentrated almost to dryness and to the residue was added 30 cm^3 of acetone to precipitate a pale violet powder, which contained the complex anion, [Co(CH_3CO_2)$_2$(aeida)]$^-$. The powder was filtered with suction and washed with a small amount of acetone several times and then with ether and dried in a desiccator. The dry powder was dissolved in 10 cm^3 of water and to this red-violet solution was added a solution of glycine (0.5 g) neutralized with an equimolar amount of NaOH. The solution was mechanically stirred for 2 h at 60 °C. The resulting deep red solution was poured into a cation-exchanger column (Dowex 50w-x2, H^+ form, 200—400 mesh) and the product was eluted with water. The adsorbed band separated into seven bands. The first and second bands were found to contain complex anions and the seventh band seemed to contain [Co(aeida)(H_2O)$_2$]$^+$ because it was not eluted with water. Fractions from the third to the sixth band contained neutral complexes. The fourth and the sixth turned out to contain *mer*- and *fac*-[Co-(gly)$_3$], respectively, from their absorption spectra and elemental analyses. The third (red; G-3) and the fifth (purple; G-5) contained the desired complexes. Each of them was evaporated almost to dryness and a small amount of methanol was added to the residue to precipitate the complex as a powder, which was recrystallized from warm water, washed with methanol and ether and dried in air. Found for G-3: C, 28.00; H, 5.27; N, 12.26%. Calcd for [Co(gly)(aeida)]·2H_2O: C, 27.99; H, 5.30; N, 12.25%. Found for G-5: C, 31.06; H, 4.65; N, 13.57%. Calcd for [Co(gly)(aeida)]: C, 31.28; H, 4.60; N, 13.68%.

2) [*Co(L-ala)(aeida)*]: This complex was prepared in the same way as that for the glycinato complex in *1)* using L-alanine instead of glycine. Sparingly soluble isomers of [Co-(L-ala)$_3$] deposited during the substitution reaction were filtered off and the filtrate was loaded on a cation-exchanger column. On elution with water, seven bands appeared, the desired bands being A-3 (red) and A-5 (purple). The other fractions turned out to be complex anions (A-1 and -2) and *mer*- and *fac*-[Co(L-ala)$_3$] (A-4 and -6) from their absorption

and circular dichroism spectra. Found for A-3: C, 29.86; H, 5.66; N, 11.65%. Calcd for [Co(L-ala)(aeida)]·$2H_2O$: C, 30.26; H, 5.65; N, 11.76%. Found for A-5: C, 30.85; H, 5.37; N, 11.76%. Calcd for [Co(L-ala)(aeida)]·$1.5H_2O$: C, 31.04; H, 5.51; N, 12.07%.

3) [Co(aeida)(en)]ClO_4: A reaction mixture containing this complex was prepared by the same method as described in the literature.[4] Two isomers, called E-1 and E-2 in the elution order, were obtained by a column chromatographic method, using a Sephadex C-25 column and 0.05 M $NaClO_4$ as an eluting solvent (1 M=1 mol dm^{-3}). Found for E-1: C, 24.50; H, 4.66; N, 14.39%. E-2: C, 24.33; H, 4.62; N, 14.15%. Calcd for [Co(aeida)(en)]ClO_4: C, 24.47; H, 4.63; N, 14.27%.

4) Other 1,2-Diamine Complexes with Aeida: (*R*)-Propylenediamine, (*R,R*)-1,2-cyclohexanediamine and *N,N*-dimethylethylenediamine complexes were prepared in the same way as that for the ethylenediamine complex using the relevant 1,2-diamine instead of en. Two isomers (M-1, blue-violet, and M-2, red-violet, in the elution order) were isolated for *N,N*-Me_2-en and only one isomer (*trans(O)*) for (*R*)-pn and (*R,R*)-chxn. Found for the (*R*)-pn complex: C, 26.46; H, 5.07; N, 13.88%. Calcd for [Co(aeida){(*R*)-pn}]ClO_4: C, 26.58; H, 4.97; N, 13.78%. Found for the (*R,R*)-chxn complex: C, 30.15; H, 5.90; N, 11.74%. Calcd for [Co(aeida){(*R,R*)-chxn}]ClO_4·$2H_2O$: C, 29.85; H, 5.89; N, 11.61%. Found for M-1: C, 27.96; H, 5.22; N, 13.07%. Calcd for [Co(aeida)(*N,N*-Me_2-en)]ClO_4·$0.5H_2O$: C, 27.95; H, 5.41; N, 13.04%. Found for M-2: C, 28.40; H, 5.32; N, 13.13%. Calcd for [Co(aeida)(*N,N*-Me_2-en)]ClO_4: C, 28.54; H, 5.28; N, 13.32%.

*5) Preparation and Optical Resolution of [Co(aeida)(*meso*-2,3-bn)]Cl·H_2O*: A red-violet solution prepared from Na[Co$(NO_2)_2$(aeida)]·$2H_2O$ (1 g), acetic acid (10 cm^3) and water (2 cm^3) was evaporated to about one tenth of the initial volume. To the syrupy material was added a small amount of water and the solution was evaporated again on a steam bath. To the residue were added 5 cm^3 of water and a solution (3 cm^3) of *meso*-2,3-butanediamine dihydrochloride[5] (0.8 g) neutralized with an equimolar amount of NaOH. The mixture was heated on a steam bath for 30 min. The resulting deep red solution was poured into a Sephadex C-25 column (Na^+ form) as is described in *1)* and the adsorbed band was eluted with a 0.05 M NaCl aqueous solution. Two bands appeared; the first band was overwhelmingly larger than the second. The first eluted band (B-1) was evaporated on a rotary evaporator almost to dryness below 40 °C and to the residue was added 50 cm^3 of methanol to extract the complex. The extract containing the desired chloride was evaporated and the red-violet powder deposited was collected on a glass filter and recrystallized from a small amount of warm water by adding methanol. The second band (B-2) was also treated with the same method as that for B-1 and pale pink powder was isolated. Found for B-1: C, 32.21; H, 6.34; N, 15.00%. For B-2: C, 32.00; H, 6.27; N, 14.84%. Calcd for [Co(aeida)(*meso*-2,3-bn)]Cl·H_2O: C, 32.05; H, 6.47; N, 14.95%.

The racemate, B-1, [Co(aeida)(*meso*-2,3-bn)]Cl·H_2O, (0.68 g; 1.8×10^{-3} mol) was dissolved in 10 cm^3 of water and to the solution was added a solution of $(+)_{546}$-Ag[Co(edta)][6] (0.87 g; 1.9×10^{-3} mol) in 10 cm^3 of water and the mixture was mechanically stirred for 10 min at 40 °C. Silver chroide deposited was filtered off, 20 cm^3 of methanol was added to the filtrate, and the solution was kept standing overnight in a refrigerator. Pale red-violet crystals deposited were collected with suction and recrystallized from a small amount of water by adding methanol. Found: C, 32.29; H, 5.45; N, 11.28%. Calcd for [Co(aeida)(*meso*-2,3-bn)][Co(edta)]·$4H_2O$: C, 32.44; H, 5.73; N, 11.35%.

The less-soluble diastereomer was dissolved in a small amount of water and converted into $(+)_{589}$-chloride by passing through an anion-exchanger column (Cl^- form) and evaporating the eluate on a rotary evaporator. Found: C, 32.70; H, 6.36; N, 15.13%. Calcd for $(+)_{589}$-[Co(aeida)(*meso*-2,3-bn)]Cl·$0.5H_2O$: C, 32.84; H, 6.35; N, 15.32%.

Measurements. The visible and ultraviolet absorption spectra were measured by a Shimadzu UV-200 spectrophotometer in aqueous solutions. The CD spectra were recorded on a Jasco MOE-1 spectropolarimeter in aqueous solutions and the ^{1}H-NMR spectra were obtained in deuterium oxide (D_2O) on a Varian XL-100-15 spectrometer using DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as an internal standard.

Results and Discussion

a) Aeida Complexes with Amino Carboxylates. As an aeida ligand can take both s- and u-type configurations, four geometrical isomers are possible for the (amino carboxylato) complex (Fig. 3). In Fig. 3 the upper two are s-type and the lower two u-type with respect to the tripodlike ligand, and only one isomer, u-β, of the four is a *fac(O)*-isomer and the others (s-α and -β, and u-α) are *mer(O)*-isomers. Two isomers were isolated for each of the glycinato and the L-alaninato complexes: G-3 and -5 for gly; A-3 and -5 for L-ala. The fact that G-3 and A-3 show splitting of the first d-d absorption band (see Fig. 5) implies that A-3 and G-3 are *mer*-isomers, of structure s-α, s-β, or u-α. The absorption spectrum of A-5 corresponds well to that of G-5 showing a *fac* pattern, while the splitting of the first d-d band for A-3 is quite different from that for G-3. Thus G-3 and A-3 should have different geometrical structures in spite of their resemblance both in the column chromatographic behavior and in their formation ratio to the corresponding *fac*-isomer (G-5 or A-5).

^{1}H-NMR spectra lead one to more explicit distinction between the isomers. Figure 4 shows the ^{1}H-NMR spectra of four isomers obtained for the glycinato and L-alaninato complexes. For the gly complex, G-3 and -5 show an AB quartet pattern (4.42, 4.27, 4.08, and 3.94 ppm for G-3; 4.22, 4.06, 3.88, and 3.72 ppm for G-5) and a singlet peak due to the acetate methylene protons of aeida (G-3, 4.08; G-5, 3.92 ppm). Thus they are suggested to have the u-type structure (u-α or -β). Because G-5 is assigned to have the structure *mer*(u-β)

[Co(aeida){(*R*,*R*)-chxn}]$^+$	18.94 (2.18) ≈22 (sh 1.8)	28.05 (2.33)	44.44 (4.33)

1.51 ppm) due to L-alaninate was assigned to have the s-type structure (s-*α* or s-*β*), while A-5 isomer which was assigned to the *fac*-isomer exhibits two methyl doublets (1.45 and 1.38; 1.43 and 1.36 ppm) with about the same intensity, and thus was assigned to a mixture of two diastereomers of the structure u-*β*.

Figure 5 shows the absorption and CD spectra of the gly and the L-ala complexes. The first absorption band of G-3 shows a large splitting: $\tilde{\nu}_{max}/10^3$ cm^{-1} (log (ε_{max}/cm^{-1} mol^{-1} dm^3)), ≈18.5 (sh 1.5), 20.55 (2.04); while G-5 a narrow and simple peak 18.87 (2.30). For the L-ala complex, A-3 shows a broad peak 19.47 (2.14) with an ambiguous shoulder at higher energy $\approx 22 \times 10^3$ cm^{-1}, while A-5 a simple peak. The CD pattern of A-3 resembles that of *trans*(*N*)-[Co(ata)(L-ala)]$^-$ complex;[1] three (−, + and −) for the first and one (+) component for the second d-d band. This suggests that A-3 has the structure s-*α*. The CD of A-5 (about 1 : 1 mixture of the diastereomers of the structure u-*β*) shows a pattern similar to those of the [Co(ata)(L-ala)]$^-$ and [Co(tren)(L-ala)]$^{2+}$ complexes of *cis*(*N*,*t*-*N*)-structure;[1] two (− and +) for the first and two (− and −) components for the second d-d band. These observations suggest that the relationship between the CD patterns in the d-d absorption band region and the coordination geometry of L-amino carboxylato complexes found for the ata and tren complexes also holds for the aeida complex, because structures s-*α* and s-*β* correspond to the structure *trans*(*N*,*t*-*N*) and *cis*(*N*,*t*-*N*), respectively. An equimolar mixing of the diastereomers of the structure u-*β* will cancel the chiralities of u-type aeida and leave only those of L-amino carboxylates to give a CD pattern corresponding to the structure *cis*(*N*,*t*-*N*).

Though four isomers are possible (Fig. 3) for each of the glycinato and the L-alaninato complexes, only two were isolated. It is difficult to explain why the main products isolated have different structures (s-*α* for the L-ala complex; u-*α* for the gly complex).

b) Aeida Complexes with 1,2-Diamines. Two isomers are possible for the en complex; *trans*(*O*) s-type and *cis*(*O*) u-type, and they can be distinguished by means of their absorption and ^{1}H-NMR spectra.[7] Though the *N*,*N*-Me_2-en complex has four possible isomers (two s-type and two u-type isomers similar to those in Fig. 3), only two were isolated. They can also be assigned to *trans*(*O*) and *cis*(*O*) by the same method as used for the en complex. Both E-1 and M-1 show a large splitting of the first d-d band: 19.05 (2.16), ≈22 (sh) for E-1; 18.47 (2.20), ≈21.5 (sh) for M-1), while E-2 and M-2 only a simple broad peak (Fig. 6 and Table 1). E-1 and M-1 show an AB quartet pattern (4.49, 4.32, 4.09, and 3.93 ppm for E-1; 4.41, 4.24, 3.99, and 3.82 ppm for M-1) due to the acetate methylene protons of aeida (Fig. 7). Though E-2 and M-2 show complicated acetate signals, two AB quartets are observed for E-2 (4.26, 4.10, 4.06, and 3.90; 4.23, 4.04, 4.02; and 3.84 ppm). The *N*-methyl signals (two singlets at 2.66 and 2.59 ppm) are more useful in the structural assignment than AB quartets for M-2. These results imply that E-1 and M-1 have s-type and E-2 and M-2 u-type structures, respectively, though the optical resolution of the u-type isomers was not successful. It is found that the two more-stable isomers the for the *N*,*N*-Me_2-en complex should have such structures that the two tertiary amine groups occupy *trans* positions each other by examining molecular models. The absorption spectra of the *N*,*N*-Me_2-en complex showed an absorp-

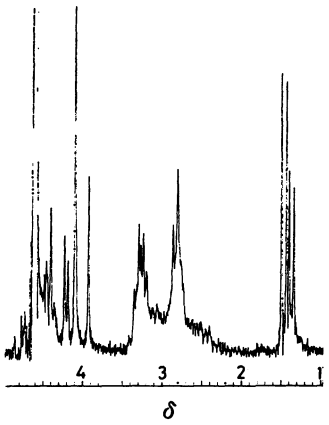

Fig. 8. ^{1}H-NMR spectrum of [Co(aeida){(*R*)-pn}]$^+$.

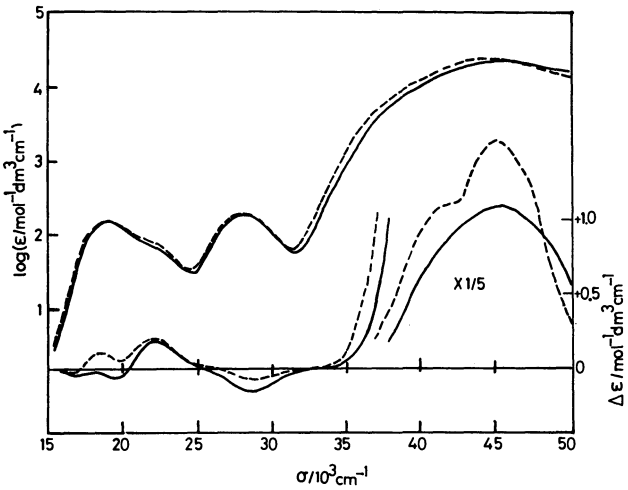

Fig. 9. Absorption and CD spectra of [Co(aeida){(*R*)-pn}]$^+$ (——) and [Co(aeida){(*R*,*R*)-chxn}]$^+$ (------).

tion shoulder at *ca.* 37×10^3 cm^{-1} characteristic of the complexes containing *N*,*N*-Me$_2$-en ligand.[8]

Six diastereomeric isomers (two s-type and four u-type), three diastereomeric isomers (one s-type and two u-type) and three pairs of the enantiomeric isomers (one s-type pair and two u-type pairs) are possible for the (*R*)-pn, (*R*,*R*)-chxn, and *meso*-2,3-bn complexes, respectively. Only one complex isolated for the (*R*)-pn or (*R*,*R*)-chxn was assigned to *trans*(*O*) s-type structure and two complexes B-1 and -2 of *meso*-2,3-bn to *trans*(*O*) and *cis*(*O*), respectively, from their absorption spectra (Table 1). The ^{1}H-NMR spectrum of the (*R*)-pn complex (Fig. 8) showed two methyl doublets (1.40 and 1.34; 1.30 and 1.24 ppm), indicating that the complex is composed of about 3 : 2 mixture of the two s-type isomers.

All possible two isomers of the s-type complexes with a chiral amino carboxylate have been isolated for the ata, tren and *i*-dtma, except for the aeida. The CD intensities in the d-d transition band region have been explained by assuming two contributions from the "intrinsic vicinal effect" of the asymmetric carbons and from the "quasi-enantiomeric effect" of the substituents. Meanwhile, the separation of the s-type isomers of the (*R*)-pn complexes for ata,[1] *i*-dtma[2] and aeida was unsuccessful and the only one isomer of the two for the tren complex was isolated.[1]

The (*R*)-pn complex has two sources of the optical activity, similar to those of the L-ala complex, one is the "intrinsic vicinal effect," and the other is the "quasi-enantiomeric effect," while the (*R*,*R*)-chxn complex has only one source of the optical activity from the "intrinsic vicinal effect" because the coordination of (*R*,*R*)-chxn produces no quasi-enantiomeric isomerism. The CD spectrum of the (*R*)-pn complex (a mixture of two diastereomers) exhibited three (−, −, and +), one (−) and one (+) component, while that of the (*R*,*R*)-chxn three (−, + and +), one (−) and one (+) component in the first, second d-d, and charge-transfer band region, respectively (Fig. 9 and Table 2). Their CD intensities and patterns in the d-d transition band region are similar to those of the complexes which have no "quasi-enantiomeric effect."

In the previous paper[1] it was pointed out that the (*R*)-pn complex with tren, which contains only one isomer, showed larger CD than the other (*R*)-pn complexes with ata and *i*-dtma, which contain two isomers. The large CD intensity of the (*R*)-pn tren complex is due to the "quasi-enantiomeric effect."

Table 2. CD Data of [Co(A-B)(aeida)]-type complexes (A-B=L-ala,(*R*)-pn, (*R*,*R*)-chxn, and *meso*-2,3-bn)
Wave numbers and Δε values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively.

Complex	d-d transition band		UV band
	1st	2nd	
(A-3)-[Co(L-ala)(aeida)]	17.24(−0.116) 19.14(+0.057) 21.53(−0.685)	27.55(+0.375)	42.02(−1.59) 47.85(−1.24)
(A-5)-[Co(L-ala)(aeida)]	18.25(−0.632) 20.35(+0.389)	≈25(−0.08) 27.40(−0.094)	38.76(−2.23) 43.86(+3.06) 47.85(−2.35)
[Co(aeida){(*R*)-pn}]$^+$	16.95(−0.045) 19.35(−0.064) 22.12(+0.190)	28.53(−0.150)	45.46(+5.48)
[Co(aeida)(*R*,*R*)-chxn]$^+$	16.53(−0.020) 18.52(+0.111) 21.98(+0.208)	28.99(−0.071)	≈41.5(sh+5.6) 44.84(+7.75)
(+)$_{589}$-[Co(aeida)(*meso*-2,3-bn)]$^+$ (B-1)	18.66(+0.232) 22.32(−0.208)	26.11(+0.009) 28.09(−0.035)	35.71(−0.17) 40.65(+2.53)

The *trans*(*O*) isomer of the *meso*-2,3-bn complex has the optical isomers which is "enantiomeric," and the CD pattern will be a measure of the "quasi-enantiomeric effect" for the (*R*)-pn complexes. The CD pattern of the $(+)_{589}$-[Co(aeida)(*meso*-2,3-bn)]$^+$ (**B-1**) showed two (+ and −), two (+ and −) and two (− and +) components in the first, second d-d transition and charge-transfer band region, respectively (Fig. 6 and Table 2) and the intensity in the d-d transition band region was similar to those of the "intrinsic vicinal effect" for the (*R*)-pn complexes with ata, *i*-dtma and aeida. The absolute configuration of the $(+)_{589}$-[Co(aeida)(*meso*-2,3-bn)]$^+$ complex can be assigned to π structure in Fig. 2 from the CD pattern in the d-d transition band region, if the relationship between the CD patterns of the "quasi-enantiomeric effect" and the absolute configurations for the [Co(tripod)(L-ala)] complexes is supposed to be applied to the *meso*-2,3-bn complex; The s-type *trans*(*N*,*t*-*N*) isomers of the L-ala complexes with ata, tren[1] and *i*-dtma,[2] which have π structure with regard to the methyl substituents, show two (+ and −) and one (+) component in the first and second d-d band region, respectively.

(Received January 8, 1982)

A rapid method has been established for determination of mixtures of hydrazine and hydroxylamine by potentiometric titration using an iodide ion-selective electrode. Accurate values are obtainable when nitric acid is added to the sample solution. A recommended procedure is proposed in which the sum of hydrazine and hydroxylamine is titrated with an aliquot of sample solution and another aliquot is titrated to the end point for hydrazine after hydroxylamine has been decomposed with nitric acid. Hydrazine and hydroxylamine in mixture can be determined in the concentration range of 0.01—0.5 mmol/dm³. The best result, with relative error and relative standard deviation both of less than 0.7%, may be obtained on 0.5 mmol/dm³ hydrazine and hydroxylamine.

Hydrazine and hydroxylamine are widely used in chemical analysis as reducing agents. These two toxic substances have very similar chemical properties and therefore, it is very difficult to determine their respective concentrations in their mixtures.

Rapid methods for determination of each of hydrazine and hydroxylamine were previously reported.[1] The present paper describes a continuation of that work, in which concentrations of hydrazine and hydroxylamine in mixtures were measured.

Experimental

Apparatus. An automatic potentiometric titrator equipped with an iodide ion-selective indicator electrode and a pH meter were used; they were the same apparatus as described in the previous paper.[1]

Reagents. All reagents were of analytical-reagent grade (Wako Pure Chemical Industries, Ltd.). Redistilled water was used. For experimental runs, the following stock solutions were diluted as needed: 10 mmol/dm³ hydrazine sulfate (standardized by the JIS method[2]); 10 mmol/dm³ hydroxylamine sulfate (standardized by the JIS method[3]); 50 mmol/dm³ iodine–methanol solution (prepared by dissolving *ca.* 12.7 g of pure iodine in 1000 cm³ of pure methanol, stored in an amber bottle, and standardized by the indicator titration method); 100 mmol/dm³ silver nitrate solution (standardized by the amperometric titration[4]).

Recommended Procedure. Into one of two titration cells is measured exactly 5 cm³ of each of 0.2—10 mmol/dm³ hydrazine sulfate and hydroxylamine sulfate, and added 15 cm³ of 50 mmol/dm³ iodine–methanol solution. The volume is adjusted to 100 cm³ with redistilled water. The resulting solution is titrated potentiometrically with 10—100 mmol/dm³ standard silver nitrate solution.

Into the other cell is measured exactly 5 cm³ of each of 0.2—10 mmol/dm³ hydrazine sulfate and hydroxylamine sulfate, added 20 cm³ of 16 mol/dm³ nitric acid which will decompose hydroxylamine and 10 cm³ of 50 mmol/dm³ iodine–methanol solution, and finally added redistilled water to 100 cm³. The resulting solution is titrated in the same way as above.

Results and Discussion

Potentiometric Titration Curves. Potentiometric titration curves are shown in Fig. 1. The end point of curve (A) corresponds to the equivalence point for hydrazine, and that of curve (B) corresponds to the cquivalence point for the sum of hydrazine and hydroxylamine. The amount of hydroxylamine in the mixture is determined from the difference between these two end points. The procedure requires about 5 min for curve (A) and 15 min for curve (B).

Effect of the Amount of Nitric Acid. When the nitric acid is added, hydroxylamine tends to decompose immediately. Therefore, stabilities of hydrazine and hydroxylamine in nitric acid were examined. As shown in Fig. 2, measurement of hydrazine is not affected by the addition of 16 mol/dm³ nitric acid (0—30 cm³), but analytical values for hydroxylamine decrease with increase in the volume of nitric acid added, reaching zero at 15 cm³ of 16 mol/dm³ nitric acid. Similar results were obtained with a mixture of hydrazine and

v=Volume of 16 mol dm^{-3} HNO_3 solution added. —○—: Solution: 100 cm^3, containing hydrazine sulfate (10 mmol dm^{-3}, 5 cm^3), hydroxylamine sulfate (10 mmol dm^{-3}, 5 cm^3), nitric acid and iodine–methanol (50 mmol dm^{-3}, 10 cm^3), —●—: solution: 100 cm^3, contining hydrazine sulfate (10 mmol dm^{-3}, 5 cm^3), hydroxylamine sulfate (10 mmol dm^{-3}, 5 cm^3), nitric acid and iodine–methanol (50 mmol dm^{-3}, 10 cm^3).

hydroxylamine (Fig. 3). All subsequent titrations of hydrazine were carried out in the presence of 20 cm^3 of 16 mol/dm^3 nitric acid.

Effect of the Amount of Iodine–Methanol. A mixture of hydrazine and hydroxylamine was titrated in the presence of various amounts of iodine–methanol (Fig. 4). Analytical values for hydrazine are in good agreement with those obtained by the JIS method provided that iodine is added in excess. Values for hydroxylamine are also in good agreement with those obtained by the JIS method provided that iodine is added in more than 1.7 times the equivalent amount.

In this experiment, in the presence of nitric acid iodine (50 mmol/dm^3, 10 cm^3) was added in 2.5 times the equivalent amount.

Effect of Temperature. Titration of hydrazine and

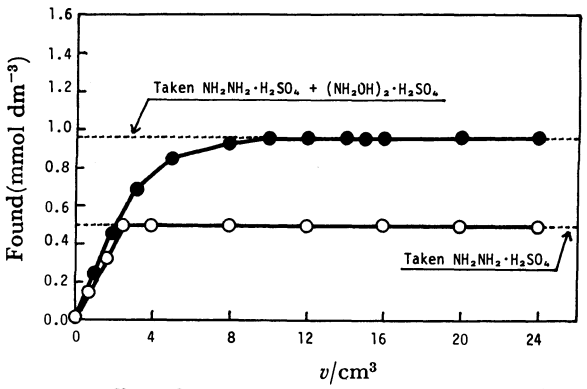

Fig. 4. Effect of the amount of iodine–methanol solution on the determination of hydrazine and hydroxylamine in mixtures.
v=Volume of 0.05 mol dm^{-3} I_2-CH_3OH solution added. —○—: Solution: 100 cm^3, of hydrazine sulfate (10 mmol dm^{-3}, 5 cm^3), hydroxylamine sulfate (10 mmol dm^{-3}, 5 cm^3), nitric acid (16 mol dm^{-3}, 20 cm^3) and iodine–methanol, —●—: solution: 100 cm^3, of hydrazine sulfate (10 mmol dm^{-3}, 5 cm^3), hydroxylamine sulfate (10 mmol dm^{-3}, 5 cm^3) and iodine–methanol.

—○—: Solution: 100 cm^3, of hydrazine sulfate (10 mmol dm^{-3}, 5 cm^3), hydroxylamine sulfate (10 mmol dm^{-3}, 5 cm^3), nitric acid (16 mol dm^{-3}, 20 cm^3), and iodine–methanol (0.05 mol dm^{-3}, 10 cm^3), —●—: solution: 100 cm^3, of hydrazine sulfate (10 mmol dm^{-3}, 5 cm^3), hydroxylamine sulfate (10 mmol dm^{-3}, 5 cm^3), and iodine–methanol (50 mmol dm^{-3}, 15 cm^3).

hydroxylamine mixtures is affected by temperature neither in the range of 5—30 °C when no nitric acid is added, in nor the range of 5—40 °C when nitric acid was added (Fig. 5). Hydroxylamine decomposes above 30 °C and hydrazine decomposes above 40 °C.

For convenience all subsequent measurements were conducted at room temperature (20 °C).

Effect of Concomitant Compounds. Mixtures of hydrazine and hydroxylamine were titrated in the presence of each of 15 compounds, the results being shown in Table 1.

The following compounds have little or no effect: sodium or magnesium nitrate in a molar ratio to hydrazine sulfate or hydroxylamine sulfate of 100 : 1,

TABLE 1. EFFECTS OF CONCOMITANT COMPOUNDS ON DETERMINATION OF HYDRAZINE AND HYDROXYLAMINE IN MIXTURE[a)]

a) Solution: 100 cm^3, containing 5 cm^3 of 10 mmol dm^{-3} hydrazine sulfate, 5 cm^3 of 10 mmol dm^{-3} hydroxylamine sulfate, a concomitant compound, and 10 cm^3 of 50 mmol dm^{-3} iodine–methanol with or without 20 cm^3 of 16 mol dm^{-3} nitric acid. b) With 10 cm^3 of 10 mmol dm^{-3} aluminium nitrate.[5)]

ammonium sulfate in a molar ratio of 50 : 1, nickel nitrate in a molar ratio of 20 : 1, and cadmium nitrate in a molar ratio of 1 : 1. Hydrazine and hydroxylamine can be determined with an error of about ±1% in the presence of any one of these compounds. However, lead nitrate, ammonium carbonate, and nitrous acid cause an interference. Ammonium chloride, sodium fluoride, potassium carbonate, ammonium iron(II) sulfate, and ammonium iron(III) sulfate do not affect the titration of hydrazine, and potassium chloride and potassium bromide do not affect the titration of hydroxylamine when aluminium nitrate is added.[5)]

Effect of the Ratio of Hydrazine to Hydroxylamine. Mixtures of hydrazine and hydroxylamine in various ratios were titrated (Table 2). Mixtures of hydrazine sulfate and hydroxylamine sulfate in ratios of 1 : 1, 5 : 2, and 5 : 1 can be determined with an error of less than ±1% and a relative standard deviation of less than 0.4%. However, with a mixture of hydrazine sulfate and hydroxylamine sulfate in a ratio of 1 : 5, the error is of the order of several percent.

Therefore, the amount of hydroxylamine should not be more than that of hydrazine.

Accuracy and Precision of the Method. Table 3 shows results obtained by the recommended procedure from four repeated titrations on mixtures of hydrazine and hydroxylamine of various concentrations.

Hydrazine and hydroxylamine in mixture can be determined in the concentration range of 0.01—0.5 mmol/dm^3. The best result, with relative error of less than ±0.7% and relative standard deviation of less than 0.4%, is obtained with the concentration of 0.5 mmol/cm.

Conclusion. Rapid and accurate differential determination is possible of hydrazine and hydroxylamine in mixture by potentiometric titration with silver nitrate solution and an iodide ion-selective electrode, if nitric acid is added to the sample solution. When 15 cm^3 or more of 16 mol/dm^3 nitric acid is added to a sample solution, analytical results for 0.05—0.5 mmol/dm^3 hydrazine sulfate in the presence of hydroxylamine sulfate are in good agreement with those obtained by the JIS method. The best result, with relative error and relative standard deviation both of less than 0.7%, is obtained with 0.5 mmol/dm^3 hydrazine sulfate and hydroxylamine sulfate.

By this method both hydrazine and hydroxylamine can be determined accurately at 5—30 °C.

Non-covalent Interactions in Metal Complexes. V.[1] Stereoselectivity in Cobalt(III) Mixed-chelates with a Salen-like Schiff Base and 1-*l*-Menthyloxy-3-benzoylacetone

Michio NAKAMURA, Hisashi ŌKAWA,* Takahiko INAZU, and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received February 1, 1982)

Cobalt(III) mixed-chelates, Co(SB)(*l*-moba), containing a salen-type Schiff base (SB) and 1-*l*-menthyloxy-3-benzoylacetone (H(*l*-moba)) have been synthesized, where H_2salen stands for *N,N'*-disalicylideneethylenediamine. These complexes were shown to have a *cis*-β-octahedral structure, based on electronic and infrared spectra. They showed circular dichroism in the visible region, demonstrating an induction of an asymmetry around the metal ion. On the basis of NMR and CD spectra and in comparison with the CD spectrum of Λ-Co(sal-(*S, S*)-ch)(bazc), it was shown that the Co(SB)(*l*-moba) complexes prefer the Λ-*cis*-β_1-configuration. The reaction of racemic *N,N'*-disalicylidene-*trans*-1,2-cyclohexanediaminatocobalt(II) (Co(salch)) and racemic *N,N'*-disalicylidene-1,2-propanediaminatocobalt(II) (Co(salpn)) with H(*l*-moba) in a 2 : 1 mole ratio yielded Λ-*cis*-β_1-Co(sal-(*S, S*)-ch)(*l*-moba) and Λ-*cis*-β_1-Co(sal-(*R*)-pn)(*l*-moba), respectively, as a main species. The stereoselectivity in the present complexes has been discussed in terms of the inter-ligand, hydrophobic CH/π-interaction which may occur between the *l*-menthyl group and an aromatic ring of the Schiff bases.

Recently, there has been an increasing interest in inter-ligand, hydrophobic interactions which bring about stereoselectivity and stereospecificity in metal complexes.[1-3] In the preceding paper of this series,[2] we have shown that tris(1-*l*-menthyloxy-3-benzoylacetonato)M(III), [M(*l*-moba)$_3$] (M=Co, Cr, Mn), prefers the *cis*-Δ-configuration. This stereoselectivity was attributed to the inter-ligand, hydrophobic CH/π-interaction[4] operating between an *l*-mentyl group of one ligand and the phenyl group of the adjacent ligand in the complex. In this study, we have prepared the cobalt(III) mixed-chelates, Co(SB)(*l*-moba), containing a salen-like Schiff base (SB) and *l*-moba$^-$, where H_2salen denotes *N,N'*-disalicylideneethylenediamine, and examined their configuration on the basis of ^{1}H-NMR and circular dichroism (CD) spectra. The purpose of this study is to investigate the stereoselectivity in Co(SB)(*l*-moba) in terms of the hydrophobic CH/π-interaction, which may occur between an aromatic ring of the Schiff base and the *l*-methyl group of *l*-moba$^-$. Schiff bases used in this study are *N,N'*-disalicylideneethylenediamine (H_2salen), its ring-substituted homologs (H_2(R-salen); R=3-MeO, 4-OH, 5-Me, 5-Br), (1*S*,2*S*)-*N,N'*-disalicylidene-1,2-cyclohexanediamine (H_2sal-(*S,S*)-ch), and (*R*)-*N,N'*-disalicylidene-1,2-propanediamine (H_2sal-(*R*)-pn). Further, in order to examine if *l*-moba$^-$ selectively reacts with one of the optical isomers of the racemic cobalt(II) complexes, cobalt(III) mixed-chelates, Co(salch)(*l*-moba), and Co(salpn)(*l*-moba), were prepared by reacting racemic *N,N'*-disalicylidene-*trans*-1,2-cyclohexanediaminatocobalt(II) (Co(salch)) and racemic *N,N'*-disalicylidene-1,2-propylenediaminatocobalt(II) (Co(salpn)) with H(*l*-moba) in a 2 : 1 mole ratio, respectively, and their configurations were studied.

Experimental

Syntheses. Synthetic method of H(*l*-moba) is described in the previous paper.[2] Syntheses of Co(salen) and its homologs were carried out by the usual method in the literatures.[5,6] (*R*)-1,2-Propanediamine[7] and (1*S*,2*S*)-1,2-cyclohexanediamine[8] were obtained by resolving racemic diamines.

Co(SB)(l-moba). Cobalt(III) mixed-chelates were obtained in nearly the same way. Synthesis of Co(salen)-(*l*-moba) is exemplified. A mixture of Co(salen) (0.2 g) and H(*l*-moba) (0.2 g) in methanol (30 cm^3) were refluxed for 3 h in an open atmosphere. Color of the solution turned from red to green. The reaction mixture was concentrated to 5 cm^3 and to this was added peroleum ether to give a green precipitate. It was dissolved in a benzene–ethanol mixture (5 : 3 in volume) and the solution was passed through an alumina column (1.5 cm × 20 cm). The eluent was concentrated to *ca.* 10 cm^3 and allowed to stand overnight in a refrigerator to give Co(salen)(*l*-moba) as green crystals.

Co(sal-(*S,S*)-ch)(bzac) was also prepared by the reaction of Co(sal-(*S,S*)-ch) and benzoylacetone (Hbzac).

Table 1. Elemental analyses of cobalt(III) mixed-chelates

Complex	Found(%)			Calcd(%)		
	C	H	N	C	H	N
Co(salen)(*l*-moba)	67.39	6.30	4.40	67.49	6.45	4.37
Co(5-Me-salen)(*l*-moba)	68.02	6.89	4.19	68.25	6.78	4.19
Co(5-Br-salen)(*l*-moba)	53.92	5.08	3.48	54.15	4.92	3.51
Co(4-OH-salen)(*l*-moba)	64.19	6.52	4.18	64.28	6.14	4.16
Co(3-MeO-salen)(*l*-moba)	63.98	6.40	4.31	64.13	6.47	4.00
Co(sal-(*S,S*)-ch)(*l*-moba)	68.80	6.81	4.02	69.15	6.82	4.03
Co(sal-(*S,S*)-ch(bzac)	66.49	5.54	5.25	66.66	5.41	5.18
Co(sal-(*R*)-pn)(*l*-moba)	68.40	6.66	4.32	68.09	6.33	4.29

Elemental analyses of the cobalt(III) mixed-chelates are given in Table 1.

Measurements. Electronic spectra were recorded on a Shimadzu MPS-5000 spectrophotometer in methanol. NMR spectra were recorded on JEOL Fourier Transform NMR Spectrometer Model FX90Q in $CDCl_3$, tetramethylsilane being used as an internal standard. CD spectra were recorded on a JASCO ORD/SP spectrometer in methanol.

Results and Discussion

It is known that cobalt(III) mixed-chelates of the Co(salen)(ab) type are obtainable by the reaction of Co(salen) and a bidentate ligand (ab) in the presence of molecular oxygen.[9-11] X-Ray analyses of Co(salen)-(acac) (acac$^-$=2,4-pentanedionate anion)[12] and Co-(salen)(bzac)[13] have revealed that salen^{2-} coordinates to the metal to form a *cis*-β-octahedral structure and the diketonate ion (acac$^-$ and bzac$^-$) coordinates to the metal with the oxygen atoms. The present complexes Co(SB)(*l*-moba) bear a marked similarity in infrared spectrum to Co(salen)(acac) and show the bands at 1590—1550 and 1540—1520 cm^{-1} characteristic of chelated 1,3-diketonate ion.[14,15] Electronic spectra of the complexes also resemble the spectra of Co(salen)-(acac)[10] and Co(salen)(bzac),[9] showing the bands around 16×10^3 (log $\varepsilon\approx2.5$) and 26×10^3 cm^{-1} (log $\varepsilon\approx3.9$) (Table 2). This spectral feature is quite comparable with those of pseudo-octahedral cobalt(III) complexes with a N_2O_4-donor set.[16,17] Based on these facts, we may conclude that the Co(SB)(*l*-moba) complexes possess a *cis*-β-octahedral structure.

There are two possible geometrical isomers for Co-(SB)(*l*-moba) due to the coordination attitude of *l*-moba$^-$. With respect to the imino nitrogens of the Schiff base and the carbonyl oxygen at the 2-position of *l*-moba$^-$, the geometrical isomers are described as *mer*(N,N,O) and *fac*(N,N,O). Hereafter, these isomers will be represented by *cis*-β_1 and *cis*-β_2, respectively. Each of these isomers is asymmetric about the central metal ion. Hence, four isomers are considered for Co(SB)(*l*-moba). They are exemplified by the isomers of Co(salen)(*l*-moba) in Fig. 1.

In order to determine the geometrical structure for Co(SB)(*l*-moba), ^{1}H-NMR spectra were measured in $CDCl_3$. The spectrum of Co(salen)(*l*-moba) is shown in Fig. 2 as an example. The signal of relatively high intensity in the region 0.65—0.94 ppm can be assigned to the menthyl protons. The signal at 3.77 ppm is ascribed to the methylene proton adjacent to the *l*-menthyloxyl group. This is obscured by the signals attributable to the ethylene signals of the Schiff base. However, assignment of the methylene signal of *l*-moba$^-$ can be unambiguously performed by comparing the spectrum with those of Co(salen)(acac) and Co(salen)-(bzac). The signal due to the methine proton of *l*-moba$^-$ should exist around 6.6 ppm, but this is concealed or superposed by the complicated signals of the aromatic protons. The most characteristic feature in the NMR spectrum is the singlets at 7.57 and 7.82 ppm, which can be attributed to the azomethine protons. Unequivalence of the azomethine signals is consistent with the *cis*-β-configuration of the salen^{2-} moiety. More careful examination of the NMR spectrum revealed that there are another pair of singlets at 7.47 and 7.84 ppm of weaker intensity. They are also assigned to the azomethine protons. Appearance of two pairs of azomethine signals implies that the two geometrical isomers, *cis*-β_1

Co(salch)(*l*-moba)[a]	16.6(0.20)	19.4(0.08)	
Co(salpn)(*l*-moba)[b]	16.0(0.58)	19.4(0.16)	22.7(−0.84)

a) Complex obtained by the reaction of racemic Co(salch) and *l*-moba. b) Obtained by the reaction of racemic Co(salpn) and *l*-moba.

and *cis*-β_2, are present in solution.

The intensities of two pairs of the azomethine signals were shown to be time-dependent. The major pair decreased their intensity slightly with time, while the minor pair increased their intensity. This suggests that the *cis*-β_1- and *cis*-β_2-isomers are in equilibrium in solution. The equilibrium was attained within 2 d. A part of the NMR spectrum of Co(salen)(*l*-moba) at equilibrium is shown in Fig. 2. Judging from the intensities of the azomethine singlets at equilibrium, two geometrical isomers are assumed to exist in a *ca.* 1 : 5 mole ratio in the case of Co(salen)(*l*-moba). The ratio of two geometrical isomers for the other Co(SB)(*l*-moba) complexes is also estimated at 1 : 3—1 : 6. Some selected ^{1}H-NMR spectral data for Co(SB)(*l*-moba) at equilibrium are given in Table 3. Table 3 also includes the NMR spectral data for free H(*l*-moba).

When the NMR spectrum of Co(SB)(*l*-moba) is compared with that of H(*l*-moba), it is noted that the signal due to the methylene protons of *l*-moba$^-$ shifts upfield by complex formation. In the case of [Co(*l*-moba)$_3$], the methylene signal shifts downfield (4.31 ppm).[2] The downfield shift of the methylene signal relative to that of H(*l*-moba) is also observed for Pd(*l*-moba)$_2$ (4.20 ppm) and for [Pd(bipy)(*l*-moba)]ClO_4 (4.20 ppm).[18] These facts suggest that the methylene group adjacent to the *l*-methyloxyl group is shielded by a ring current in a predominant species of Co(SB)(*l*-moba). NMR spectrum of Co(salen)(acac) shows two methyl signals at 1.94 and 1.76 ppm. The latter has been assigned to the methyl group which is in a close proximity above the benzene ring (B benzene ring) (see Fig. 1).[12,19] Thus, upfield shift of the methylene signal in Co(SB) (*l*-moba) relative to that of H(*l*-moba) leads us to a conclusion that the *cis*-β_1-isomer is predominantly formed at the equilibrium.

Each Co(SB)(*l*-moba) complex showed CD bands around 16×10^3 (positive), 19×10^3 (positive shoulder), and 23×10^3 cm^{-1} (negative). This is a good indication for the occurence of an inter-ligand, hydrophobic CH/π-interaction between the B benzene ring of the Schiff base and the *l*-menthyl group of *l*-moba$^-$. Typical CD spectra are shown in Fig. 3, and the numerical data are given in Table 4.

In order to determine the absolute configuration of the present complexes, Co(sal-(*S*,*S*)-ch)(*l*-moba) and Co(sal-(*S*,*S*)-ch)(bzac) were prepared and their CD spectra were recorded (Fig. 3 and Table 4). CD spectra of these complexes bear a marked resemblance both in sign and in intensity. It is likely that the stereoselectivity in these complexes is mostly due to the steric requirement of the sal-(*S*,*S*)-ch^{2-} moiety and the weak hydrophobic CH/π-interaction is practically supressed in Co(sal-(*S*,*S*-ch)(*l*-moba). Fujii *et al.* have demonstrated that Co(sal-(*S*,*S*)-ch)(ab) preferentially takes the *A*-configuration because of the steric control of the (1*S*,2*S*)-1,2-cyclohexanediamine moiety.[20,21] Despite the low intensity of the CD bands, the similarity of the CD spectra of Co(SB)(*l*-moba) to those of Co(sal-(*S*,*S*)-ch)(*l*-moba) and Co(sal-(*S*,*S*)-ch)(bzac) leads us to the conclusion that the *A*-*cis*-β_1-isomer is predominantly formed in the present complexes. CD spectral pattern of Co(sal-(*R*)-pn)(*l*-moba) is also the same as those of Co(SB)(*l*-moba). This implies that the stereo-

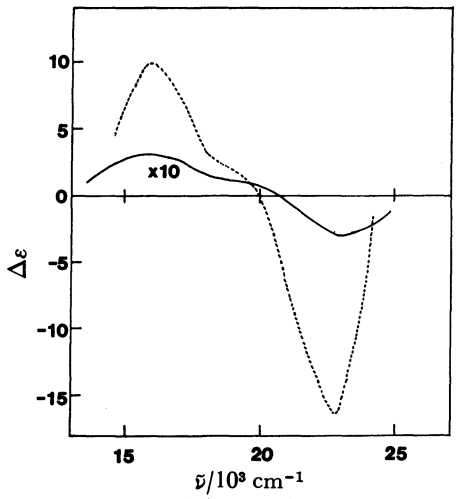

Fig. 3. CD spectra of (——) Co(salen)(*l*-moba) and (------) Co(sal-(*S,S*)-ch)(bzac).

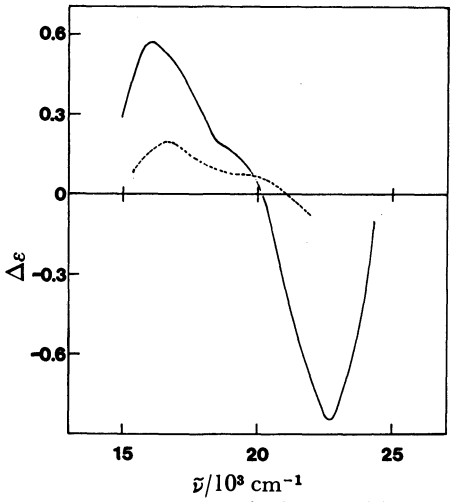

Fig. 4. CD spectra of (——) Co(salpn)(*l*-moba) and (------)Co(salch)(*l*-moba).

selectivity of sal-(*R*)-pn^{2-} is identical with that of sal-(*S,S*)-ch^{2-}.

In order to further demonstrate the potential contribution of the inter-ligand, hydrophobic CH/π-interaction to geometrical and optical selectivities in Co(SB)(*l*-moba), we have prepared Co(salch)(*l*-moba) and Co(salpn)(*l*-moba) by the reaction of racemic Co(salch-and racemic Co(salpn) with H(*l*-moba) in a 2 : 1 mole ratio, respectively. These complexes showed circular dichroism in the visible region (Fig. 4). For Co(salch)-(*l*-moba) eight isomers are considered: *Δ-cis-*β_1-Co(sal-(*S,S*)-ch)(*l*-moba), *Λ-cis-*β_1-Co(sal-(*S,S*)-ch)(*l*-moba), *Δ-cis-*β_1-Co(sal-(*R,R*)-ch)(*l*-moba), *Λ-cis-*β_1-Co(sal-(*R,R*)-ch)(*l*-moba), *Δ-cis-*β_2-Co(sal-(*S,S*)-ch)(*l*-moba), *Λ-cis-*β_2-Co(sal-(*S,S*)-ch)(*l*-moba), *Δ-cis-*β_2-Co(sal-(*R,R*)-ch)(*l*-moba), and *Λ-cis-*β_2-Co(sal-(*R,R*)-ch)(*l*-moba). Similarly eight isomers are considered for Co(salpn)-(*l*-moba). Although no informations are available at present on proportions of the isomers and on the sign and the intensity of circular dichroism of each isomer, a marked resemblance of the CD spectra of Co(salch)(*l*-moba) and Co(salpn)(*l*-moba) to those of Co(SB)(*l*-moba) suggests that *l*-moba$^-$ reacts selectively with one of the optical isomers, Co(sal-(*S,S*)-ch) and Co(sal-(*R*)-pn), respectively. This stereoselectivity may be interpreted in terms of the inter-ligand, hydrophobic CH/π-interaction between the *l*-menthyl group and the B benzene ring. Notably the CD intensity of Co(salch)(*l*-moba) is lower than that of Co(salpn)(*l*-moba) and the lowest among the complexes obtained in this study, although the CD intensity for Co(sal-(*S,S*)-ch)(*l*-moba) much exceeds that of Co(sal-(*R*)-pn)(*l*-moba). A strong stereoselectivity originated from the (1*S*,2*S*)-1,2-cyclohexanediamine moiety must diminish the contribution from the hydrophobic CH/π-interaction. It is likely that the stereoselectivity and the discrimination in metal complexes owing to the hydrophobic interactions are induced when a hydrophobic side chain attached to the ligand is flexible.

(Received March 12, 1982)

Dihydrochloride of a binucleating ligand, 1,5-diamino-3-pentanol (Hdpl·2HCl) has been synthesized by a new method in a high yield (>70%). This ligand forms 1 : 1 complexes with copper(II), Cu(dpl)X(X=BF_4, ClO_4, NO_3, and Cl(H_2O)). The cryomagnetic study of the copper complexes has shown that they are binuclear, and a strong antiferromagnetic interaction is operating between two copper ions. The binuclear structure seems to be quite stable even in aqueous solution. The 1 : 1 complex with nickel(II) was also isolated as tetraphenylborate, which was essentially diamagnetic. A planar binuclear structure similar to the copper complexes was assumed for this complex. Its absorption band at 29.8×10^3 cm^{-1} ($\varepsilon=160$) was attributed to the charge transfer transition from the bridging oxygen to the nickel similarly to the bands in the 25—29×10^3 cm^{-1} region usually observed for alkoxo-oxygen bridged binuclear copper(II) complexes. Some 2 : 1 copper(II)–dpl complexes have also been synthesized and characterized as binuclear complexes. 1,5-Bis(dimethylamino)-3-pentanol has been synthesized, and its 2 : 1 copper(II) complexes have been isolated.

It is well known that linear aliphatic amino alcohols such as $R_2N(CH_2)_nOH$ and $R_2N(CH_2)_mNH(CH_2)_nOH$ (R=alkyl; m and n=2 or 3) form bi-, tri-, and tetranuclear complexes with copper(II).[1-7] The complexes have been extensively studied for their magnetisms, spectra,[3-7] and structures.[8-16] Since they are limited to those bridged with terminal alkoxo-oxygen atoms, they are readily hydrolyzed in water forming mononuclear species. In connection with the increasing attention to binuclear copper complexes in view of the elucidation of the function of copper protein, it has been desired to prepare binuclear copper complexes which are soluble and stable in water. The purpose of this study is to prepare such complexes with a saturated aliphatic amino alcohol. One of the reasons to adopt the saturated amino alcohol as a ligand is that it is transparent throughout the region of conventional electronic spectral measurements; this would facilitate the spectroscopic study of the complex with this ligand.

The molecular model investigation has revealed that the most suitable ligand for our purpose is 1,5-diamino-3-pentanol (abbreviated as Hdpl), which is capable of forming 6·6-membered fused chelate rings involving two metal ions bridged by an alkoxo-oxygen atom (*cf.*, Fig. 1-a). In this study we have succeeded in preparing the 1 : 1 binuclear copper(II) complexes with dpl which are stable even in aqueous solution. This ligand also enabled us to prepare the 1 : 1 binuclear nickel(II) complex similar to the copper complexes.

Alkoxo-oxygen bridged binuclear copper(II) complexes generally show an absorption band in the 23—28×10^3 cm^{-1} region which is attributed to a charge transfer transition from bridging oxygen to copper.[2] Such a band is naturally expected for the binuclear copper(II) complexes with dpl. It is interesting to see if a similar band is observed for the nickel complex, since planar binuclear nickel(II) complexes bridged by alkoxy-oxygen atoms have not been reported so far.

The ligand Hdpl was already prepared as a picrate by Taniyama *et al.*,[17] but the yield was so poor that it was difficult to prepare enough sample for the synthesis of metal complexes. Hence, in this study we have exploited a new synthetic route to this ligand with a high yield (>70%). This enabled us to prepare the new complexes as reported in this paper.

Experimental

Syntheses. *1,5-Diamino-3-pentanone Dihydrochloride*: To a suspension of potassium phthalimide (370 g, 2 mol) in 1.3 dm^3 of dry *N,N*-dimethylformamide (DMF), crude 1,5-dichloro-3-pentanone[18] (240 g, 1.3 mol) was added dropwise in 1 h with vigorous stirring. The temperature spontaneously rose from 15 °C to 65 °C during the addition, and the mixture was further heated at 80—85 °C for 6 h and allowed to stand overnight at room temperature. The resulting 1,5-diphthalimido-3-pentanone was collected by filtration and washed succesively with chloroform, water, and acetone. Curde yield 280 g (76%).

While the phthalide (280 g) was boiled with a mixture of 700 cm^3 of acetic acid and 450 cm^3 concd hydrochloric acid for 3 d, each 50 cm^3 of concd hydrochloric acid was added to this solution at 10 h intervals (total 250 cm^3). Phthalic acid deposited on cooling was filtered off and washed with water. The combined filtrate and washings were evaporated to near dryness under reduced pressure and the residue was treated with water to remove undissolved materials. The aqueous solution was again concentrated and a large amount of ethanol was added. The resulting precipitates were collected by filtration. Crude yield 135 g (96%).

The pure sample was obtained by repeated crystallization from dilute ethanol; mp 190—192 °C. IR: ν_{CO} 1720 cm^{-1}. Found: C, 31.52; H, 7.32; N, 14.79%. Calcd for $C_5H_{12}N_2O$·2HCl: C, 31.75; H, 7.46; N, 14.82%.

1,5-Diamino-3-pentanol dihydrochloride(Hdpl·2HCl): Crude 1,5-diamino-3-pentanone dihydrochloride (40 g, 0.21 mol) was added portionwise keeping the temperature below 20 °C to a solution containing sodium hydroxide (17 g, 0.4 mol) and sodium borohydride (8 g, 0.2 mol) in 300 cm^3 water. The mixture was stirred at room temperature for 48 h. Dilute hydrochloric acid was carefully added to the cold solution and a pH was brought to ≈1. The solution was evaporated to dryness under reduced pressure, and methanol was added

to the residue and evaporated. Addition of methanol and evaporation under reduced pressure was repeated several times to remove resulting boric acid as a methyl ester. The final residue was boiled with 100 cm³ of methanol, undissolved sodium chloride was filtered off, and the filtrate was concentrated to a small volume. A large amount of ether was added to the residual solution and the mixture was kept in a refrigerator overnight. The resulting crystals were collected and washed with ether. Crude yield 32 g (80%). They were recrystallized from methanol–ether mixture; mp 158—160 °C. Found: C, 31.35; H, 8.65; N, 14.57%. Calcd for $C_5H_{14}N_2O\cdot 2HCl$: C, 31.43; H, 8.45; N, 14.66%.

1,5-Bis(dimethylamino)-3-pentanol (Hmdpl):[19] A mixture of 1,5-bis(dimethylamino)-3-pentanone (30 g, 0.17 mol)[20] and sodium borohydride (5 g, 0.13 mol) in 130 cm³ of methanol was heated at 60 °C for 1 h. It was poured on ice, acidified to pH 2—3 with concd hydrochloric acid, and the solution was evaporated to near dryness under reduced pressure. The residue was dissolved in a small amount of water, saturated with potassium hydroxide, and extracted with 300 cm³ of ether. The ether extracts were dried over potassium carbonate and the ether was evaporated. The oily residue was distilled and the fraction bp 115—116 °C (1800 Pa) was collected. Yield 20 g (70%). Found: C, 61.58; H, 12.71; N, 15.97%. Calcd for $C_9H_{22}N_2O$: C, 62.02; H, 12.72; N, 16.07%.

$Cu_2(dpl)_2Cl_2\cdot H_2O$: To a solution of Hdpl·2HCl (1.9 g, 10 mmol) in 40 cm³ of methanol was added triethylamine until the solution became alkaline, and to this solution was added an equimolar amount of anhydrous copper(II) chloride in methanol. The resulting deep blue solution was heated on a water bath for a few minutes. On cooling to room temperature bluish violet crystals were separated and were recrystallized from a dilute methanol–water (1 : 1) mixture. Found: C, 26.58; H, 6.27; N, 12.23; Cu, 28.00%. Calcd for $C_{10}H_{28}N_4O_3Cl_2Cu$: C, 26.67; H, 6.27; N, 12.44; Cu, 28.22%.

The bromide, perchlorate, tetrafluoroborate, and nitrate were also prepared in similar manners using corresponding copper(II) salts and recrystallized from water containing soudim salt of the corresponding anion.

$Cu_2(dpl)_2Br_2\cdot H_2O$: Found: C, 22.14; H, 5.28; N, 10.31 %. Calcd for $C_{10}H_{28}N_4O_3Br_2Cu_2$: C, 22.27; H, 5.23; N, 10.39%.

$Cu_2(dpl)_2(ClO_4)_2$: Found: C, 21.48; H, 4.68; N, 9.80; Cu, 22.49%. Calcd for $C_5H_{13}N_2O_5CuCl$: C, 21.44; H, 4.68; N, 10.00; Cu, 22.68%.

$Cu_2(dpl)_2(BF_4)_2$: Found: C, 22.58; H, 4.95; N, 10.23; Cu, 23.52%. Calcd for $C_5H_{13}N_2OCuBF_4$: C, 22.45; H, 4.90; N, 10.45; Cu, 23.75%.

$Cu_2(dpl)_2(NO_3)_2$: Found: C, 24.75; H, 5.44: N, 17.23%. Calcd for $C_5H_{13}N_3O_4Cu$: C, 24.74; H, 5.40; N, 17.31%.

$Cu_2Cl_2(OCH_3)(dpl)\cdot CH_3OH$: To a warm methanol solution (20 cm³) of Hdpl·2HCl (0.4 g, 2 mmol) was added trimethylamine to make the solution alakline. Anhydrous copper(II) chloride (0.5 g, 4 mmol) dissolved in methanol was added to this solution and the mixture was heated on a water bath. Deep green crystals were soon separated out. They were collected by filtration, washed with methanol, and dried at room temperature under vacuum. The yield was almost quantitative. The complex is sparingly soluble in ordinary organic solvents and no further purification was carried out. Found; C, 22.44; H, 4.99: N, 7.51; Cu, 33.60; Cl, 18.48%. Calcd for $C_7H_{20}N_2O_3Cl_2Cu_2$: C, 22.23; H, 5.33; N, 7.41; Cu, 33.60; Cl, 18.75%.

$Cu_2Br_3(dpl)\cdot 2CH_3OH$: The procedure was the same as the above except for the use of anhydrous copper(II) bromide in place of the chloride. Olive green crystals, only slightly soluble in ordinary organic solvents. Found: C, 15.92: H, 3.68; N, 5.28%. Calcd for $C_7H_{21}N_2O_3Br_3Cu_2$: C, 15.34; H, 3.86; N, 5.11%.

$Cu_2Cl_2(mdpl)OH$: A solution of Hmdpl (0.4 g, 2.5 mmol) in 20 cm³ of methanol was mixed with anhydrous copper(II) chloride (0.7 g, 5 mmol) in methanol and the solution was made alkaline by the addition of excess trimethylamine. Green crystals were soon deposited on warming. They were collected by filtration and recrystallized from 1-butanol. Yield 0.8 g (90%). Found: C, 28.33; H, 5.55; N, 7.19; Cu, 33.23; Cl, 18.20%. Calcd for $C_9H_{22}N_2O_2Cu_2Cl_2$: C, 27.84; N, 5.71; N, 7.22; Cu, 33.73; Cl, 18.26%.

$Cu_2Br_2(mdpl)OH$: The synthetic procedure was the same as the above. Dark green fine needles were obtained by recrystallization from 1-butanol. Found: C, 22.27; H, 4.38; N, 5.67; Cu, 26.78; Br, 33.79%. Calcd for: $C_9H_{22}N_2O_2Cu_2Br_2$: C, 22.65; H, 4.65; N, 5.87; Cu, 26.63; Br, 33.49%.

$Ni_2(dpl)_2(Bph_4)_2(CH_3OH)_2$: Nickel perchlorate hexahydrate (0.76 g, 2 mmol) and Hdpl·2HCl (0.4 g, 2 mmol) were dissolved in 15 cm³ of methanol. To this solution was added solid sodium hydroxide (0.25 g, 6 mmol). The green solution gradually changed into dark red yielding a white preicpitate as the sodium hydroxide dissolved in the solution. The precipitate was filtered off, and to the filtrate was added an excess of sodium tetraphenylborate (about 1 g). Fine pink-red crystals were formed in the solution. These were filtered and washed with methanol. The crystals thus obtained were recrystallized from a methanol–DMF (10 : 1) solution by adding a methanol solution saturated with sodium tetraphenylborate (1 g). This compound is readily soluble in DMF, slightly soluble in methanol, and practically insoluble in water. Found: C, 68.21; H, 7.10; N, 5.45%. Calcd for $C_{30}H_{37}N_2O_2BNi$: C, 68.36; H, 7.07; N, 5.31%.

Measurements. The electric conductivities of solutions were measured with a Yanagimoto Conductivity Outfit Model MY 7. Infrared and electronic spectra were recorded on a Hitachi 295 Infrared spectrophotometer and a Shimadzu MPS-5000 Spectrophotometer, respectively. Magnetic susceptibilities were measured by the Faraday method. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$.[21] The susceptibilities were corrected for the diamagnetism of the constituting atoms by the use of Pascal's constants.[22] The effective magnetic moments μ_{eff} was calculated based on the equation $\mu_{eff}=2.828\sqrt{(\chi_A-60\times10^{-6})T}$.

Results and Discussion

1 : 1 Copper(II)–dpl Complexes. $Cu_2(dpl)_2X_2H_2O$ (X= Cl, Br), $Cu_2(dpl)_2Y_2$ ($Y=ClO_4$, BF_4, NO_3): These complexes show subnormal magnetic moments at room temperature (Table 1). The temperature dependence of magnetic susceptibility was measured for the chloride, tetrafluoroborate and perchlorate, and the results were well simulated by the Bleaney-Bowers equation[23] based on the assumption of binuclear structure with parameters, $2J=-640$ cm^{-1}, $Na=40\times10^{-6}$ cgs emu, $g=2.1$ for the chloride and $2J=-965$ cm^{-1}, $Na=46\times10^{-6}$ cgs emu, $g=2.1$ for the tetrafluoroborate, where J, Na, and g denote the general meanings. The perchlorate was practically diamagnetic in this temperature range. The binuclear structure was verified by the single-crystal X-ray structural analysis for $Cu_2(dpl)_2Cl_2(H_2O)_3$ which was obtained by recrystallization of $Cu_2(dpl)_2Cl_2H_2O$ from an aqueous solution. This compound consists of discrete binuclear units, where two dpl molecules and two copper atoms are roughly on a plane and a chloride ion and a water molecule weakly coor-

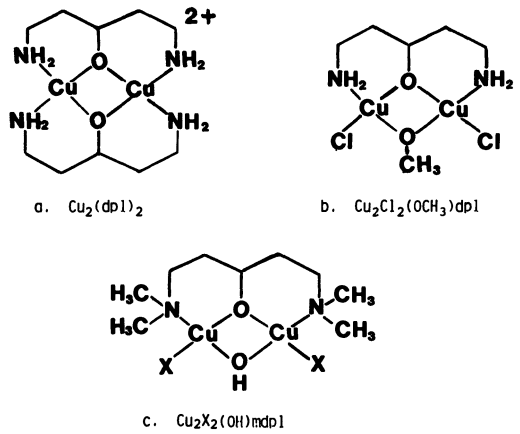

Fig. 1. Chemical structures of complexes.

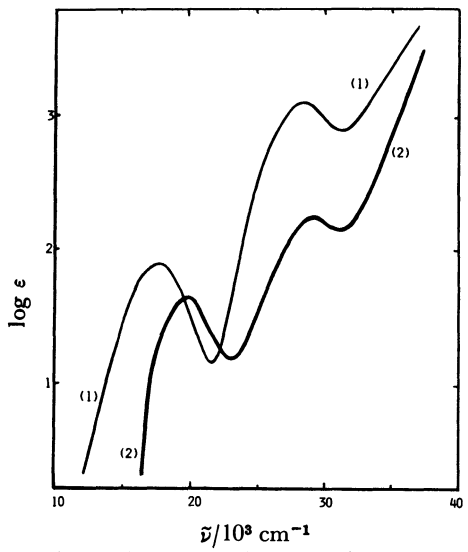

Fig. 2. Electronic spectra of (1) $Cu_2(dpl)_2(BF_4)_2$ in water (2) $Ni_2(dpl)_2(Bph_4)_2 \cdot 2CH_3OH$ in methanol.

dinate to the copper ions from the same side of the coordination plane. The details of the structural data were reported in a separate paper.[24]

The measurements of molar conductivities (Table 1) revealed that the perchlorate and tetrafluoroborate are 1 : 2 electrolytes in methanol solution (10^{-3} mol dm^{-3}), whereas in the case of the chloride partial coordination of Cl^- is occuring in the methanol solution, since its conductivity is considerably lower than those of the former ones.

Aqueous solutions of these complexes gave the same spectra (Fig. 2) irrespective of the counter anion, showing a d-d band at 17.7×10^3 cm^{-1} ($\varepsilon=76.6$) and a CT band at 28.4×10^3 cm^{-1} ($\varepsilon=1300$) which is characteristic of alkoxo-bridged copper(II) complexes. Since Beer's law is held for the aqueous solution, the complex ion, probably $[Cu_2(dpl)_2(H_2O)_4]^{2+}$, should be quite stable in aqueous solution. This is an important result, since no binuclear copper(II) complexes with alkoxide bridges which are stable in aqueous solution have been known so far.

2 : 1 Copper(II)–dpl Complexes. $Cu_2Cl_2(dpl)(OCH_3)CH_3OH$: This compound shows subnormal magnetic moments at room temperature (0.89 BM) and the temperature dependence of magnetic susceptibility can be simulated by the Bleaney-Bowers equation[23] with the parameters $-2J=595$ cm^{-1}, $g=215$, $N\alpha=60\times10^{-6}$ cgs emu in the range 130—300 K. The deviation from the theoretical curve in the low-temperature range (80—130 K) may be attributed to paramagnetic impurity, since recrystallization was not carried out due to the low solubility in any available solvents. From the above results we assume the binuclear structure as depicted in Fig. 1.

The Nujol mull spectrum shows two bands at 16.5 and 27.0×10^3 cm^{-1}. The former is assigned to the d-d transition and the latter to the CT (O→Cu) transition similarly to the case of the 1 : 1 complexes. The d-d band shifts to the lower energy side by 2.5×10^3 cm^{-1} relative to that of the $[Cu_2(dpl)_2]X_2$ (X=ClO_4 and BF_4) as shown in Table 1. This is compatible with the proposed structure in Fig. 1, where chloride ions are substituted for amino groups as compared with the structure in Fig. 1-a.

This compound decomposes in water forming a blue solution with pale blue amorphous precipitates. When

the solution was filtered and evaporated, well formed blue crystals of $Cu_2(dpl)_2Cl_2 \cdot 3H_2O$ separated out. Thus, the reaction that had taken place can be described as

$$2Cu_2(dpl)Cl_2(OCH_3)CH_3OH + 2H_2O \longrightarrow [Cu_2(dpl)_2]^{2+} + Cu(OH)_2 + Cu_{aq}^{2+} + 4Cl^- + 4CH_3OH.$$

Copper(II) Complexes with mdpl. $Cu_2X_2(mdpl)OH$ (X=Cl, Br): All attempts to prepare the 1 : 1 complexes with mdpl similar to the dpl complexes were unsuccessful. This is most probably due to the steric repulsion between the methyl groups on the amine nitrogens. In contrast, the 2 : 1 complexes Cu_2X_2-(mdpl)OH (X=Cl, Br) were readily obtained. The electric conductivities showed that both compounds are nonelectrolytes in DMF (*cf.* Table 1). This is consistent with the structure in Fig. 1.

Magnetic moments of these complexes at room temperature are both subnormal, *i.e.*, 1.19 BM (X=Cl) and 1.55 BM (X=Br) for one copper atom, but their magnetic behaviors over the temperature range 80—300 K are quite different from each other. As seen in Fig. 3 the χ_A-T curve of the chloro complex can be well simulated by the Bleanery-Bowers equation[23] with $-2J=375$ cm^{-1}, $g=2.1$, and $Na=60\times10^{-6}$ cgs emu. Thus, the binuclear structure as illustrated in Fig. 1 is assigned to the chloro complex. On the other hand, the χ_A-T curve of the bromo complex cannot be interpreted by the Bleaney-Bowers equation,[23] but the χ_A^{-1}-T plots make a straight line in the range 110—300 K, giving a large Weiss constant -100 K (*cf.* Fig. 3). Such a magnetic behavior just corresponds to that of the group C-a according to the classification of Nishida and Kida.[7]

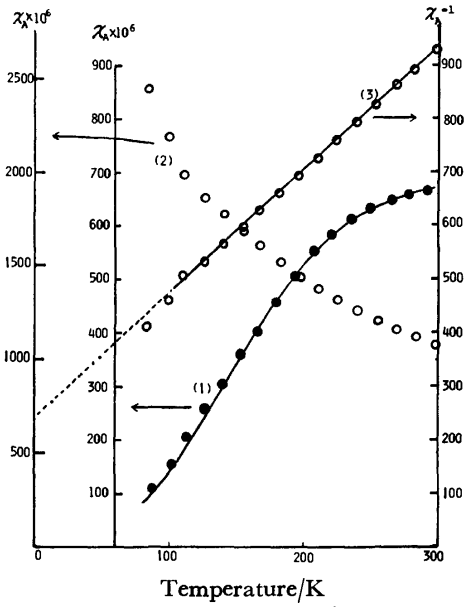

Fig. 3. Temperature dependence of magnetic susceptibilities, χ_A(cgs emu). (1) $CuCl_2$(mdpl)OH; The second left side scale. The solid line is the theoretical curve based on the Bleaney-Bowers equation[23] with the parameters, $2J=-375$ cm^{-1}, $g=2.1$, and $Na=60\times10^{-6}$ cgs emu. (2) $CuBr_2$(mdpl)OH: The first left side scale. (3) $CuBr_2$(mdpl)OH: The right side scale (χ^{-1}—T plots).

1 : 1 Nickel(II) Complex with dpl. $Ni_2(dpl)_2(Bph_4)_2 \cdot 2CH_3OH$: The magnetic susceptibility of this compound is very low ($\chi_A=223\times10^{-6}$ cgs emu at 294 K) and nearly constant in the range 80—300 K (234×10^{-6} cgs emu at 80 K). This indicates that the compound is a spin-paired planar complex similar to the structure of Fig. 1-a, and the observed paramagnetism is due to the second-order Zeeman term.

The absorption spectrum in methanol is shown in Fig. 2. In the ultraviolet and visible region a single absorption band is observed at 19.8×10^3 cm^{-1} ($\varepsilon=46$), which is undoubtedly attributed to the d-d transitions. Such a spectral feature is consistent with the planar coordination of nickel(II) with an N_2O_2 donor set. The band at 28.9×10^3 cm^{-1} ($\varepsilon=160$), however, is not likely to be of a d-d origin, though the intensity is a reasonable one for a d-d band. Because, the red nickel(II) complex with a planar N_2O_2 donor set, such as bis(*N*,*N*-dimethylethylenediamine *N*-oxide)nickel(II) perchlorate, has only a single broad absorption band at 19.34×10^3 cm^{-1} in the region of wavenumber lower than 30×10^3 cm^{-1};[25] furthermore, no d-d band has ever been reported for planar nickel(II) complexes in the region of wavenumber higher than 23×10^3 cm^{-1}.[26] Therefore, this band is attributable to the charge transfer transition from the bridging oxygen to nickel, similarly to the bands at 28.6×10^3 cm^{-1} observed for $[Cu_2(dpl)_2]^{2+}$.

It is to be noted that a stable alkoxo-oxygen bridged planar nickel(II) complex has been first reported and characterized in this study, and it shows a band in the near-ultraviolet region whose origin seems to be similar to that of the bands characteristic of alkoxo-oxygen bridged copper(II) complexes.

No trials have been so far succesful to isolate pure crystals of the complexes other than tetraphenylborate.

The Enhancement of Formose Formation with 2-Hydroxyacetophenone. A Mechanism Involving Aldol and Retro-aldol Reactions

Tomoya SAKAI,* Masahiko ISHIZAKI, and Masafumi GOTO

Department of Chemical Reaction Engineering, Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received March 12, 1981)

The rapid aldol addition of formaldehyde to 2-hydroxyacetophenone (HAP), an efficient accelerator for formose formation, took place to yield addition products of HAP with one and two molecules of formaldehyde at 35 °C in an aqueous 40% methanol mixture of formaldehyde, HAP, and $Ca(OH)_2$. No further addition product with more than two molecules of formaldehyde attached to HAP was detected throughout the reaction. On the contrary, benzaldehyde and benzoic acid were formed, accompanied by formose sugars. The initial molar amount of HAP corresponded to the sum of the compounds substituted with the phenyl group including benzaldehyde and benzoic acid. The retro-aldol reaction of the HAP derivatives is likely to be involved in the overall reaction to yield glycolaldehyde or trioses, which are good accelerators for formose formation.

Formose formation in an aqueous mixture of formaldehyde(C_{1A}) and $Ca(OH)_2$ at 50—60 °C reveals an autocatalytic feature: an S-shaped profile of the C_{1A} conversion *vs.* the reaction time. This characteristic feature arises from the slow dimerization of C_{1A} to form glycolaldehyde(C_{2A}) and a successive rapid aldol addition of C_{1A} to C_{2A}.

It is well known[1] that the introduction of compounds which have the structure of R–CO–CH_2OH or R–CH(OH)–CHO to the above reaction mixture enhances the formose formation by shortening the induction period and accelerating the successive consumption of C_{1A}. The initial step has been reported to be the addition of C_{1A} to the accelerator.[2] The order of efficiencies of accelerators has been evaluated by Langenbeck as follows : 2-hydroxyacetophenone (HAP)>2-hydroxy-2′-acetonaphthone> 1-hydroxy-2-propanone> 1,3-dihydroxyacetone (C_{3K}) > C_{2A} > 5-hydroxyacetylacenaphthene>D-fructose>D-glucose.[3] HAP is a unique accelerator because of its high efficiency and its structure containing a phenyl group. HAP seems to be a good candidate for analyzing the action of the accelerators because it is easy, with the accelerator, to distinguish the addition products of C_{1A} from the usual formose sugars by tracing the phenyl group among the products.

In this paper we describe the identification of addition products of C_{1A} with HAP and the change in the amounts of the products originated from HAP with the reaction time. No product with more than two molecules of C_{1A} attached to HAP was detected. On the contrary, degraded products, such as benzaldehyde and benzoic acid, were formed, accompanied by low-molecular-weight formose sugars. These observations suggest that the C–C bond dissociation of HAP derivatives through retro-aldol reaction is essential for the acceleration.

Experimental

Materials. The reagents, formaldehyde (C_{1A}), 1,3-dihydroxyacetone (C_{3K}), HAP, and $Ca(OH)_2$, were the same as those described previously.[4] Guaranteed-grade NaOH, $CaCl_2$, $NaBH_4$, $Si(CH_3)_3Cl$, D-fructose, and hexamethyldisilazane were used as received from Wako. The pyridine (Wako) was dried with molecular sieve 4A.

The 2,3-dihydroxypropiophenone (DHPP) was prepared according to the method of Cahnmann;[5] mp 78 °C (lit, 81.5 °C; softening point 78 °C).[5]

Formose-formation Procedure. The reaction was conducted following the "normal procedure" described previously.[4] An aliquot of the reaction mixture was periodically withdrawn from the flask and was neutralized with a dilute hydrochloric acid to quench the reaction.

Product Analyses. The C_{1A} and formic acid were determined by the use of a high-performance liquid (HPL) chromatograph, as has been described previously.[4] The benzoic acid and benzaldehyde were analyzed with an Ohkura 701 gas liquid chromatograph (GLC) equipped with a FID detector and a Silicone Grease (SE-30) column at 130 °C. Biphenyl was used as the internal standard. The other products were determined as trimethylsilyl derivatives after the reduction of the reaction mixture with $NaBH_4$[6] using the same GLC by increasing the temperature from 100 to 250 °C at the rate of 2 °C min^{-1}. Phenethyl alcohol was added as an internal standard prior to the trimethylsilylation. Several peaks detected in the GL chromatogram were identified by means of GLC-mass spectrometry employing a Hitachi M-52 mass spectrometer. The area of the GL chromatogram of each equimolar amount of C_{3K}, DL-glyceraldehyde (C_{3A}), glucose, HAP, and DHPP after the trimethylsilylation was confirmed to be proportional to the molecular weight; accordingly, the amounts of the product appearing in the GL chromatogram were determined on the basis of this proportionality. The amount of C_{2A} might be estimated too low, however, because of a partial loss during the evaporation of the reaction mixture.

The conversion of C_{1A} to formose (%) is defined by means of Eq. 1;

$$C_{1A}\text{ conversion to formose (\%)} = \left(1 - \frac{[C_{1A}]_{remained} - [HCOOH]}{[C_{1A}]_{initial}}\right) \times 100. \quad (1)$$

The recovery of C_{1A} (%) is defined by Eq. 2:

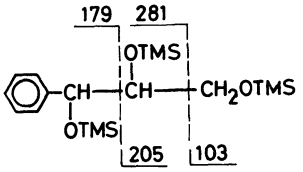
$$\text{Recovery of } C_{1A}(\%) = \{([C_{1A}]_{remained} + [HAPC_1] + 2[HAPC_2] + \sum_{n=2}^{7} n[C_n] - 6[Fru]_{initial} + [HCOOH])/[C_1]_{initial}\} \times 100, \quad (2)$$

where $HAPC_1$ and $HAPC_2$ represent the addition products of one and two molecules of C_{1A} respectively with HAP, where C_n represents the carbohydrates of n carbon atoms, and where Fru represents D-fructose.

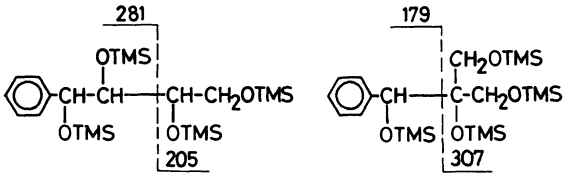
Results and Discussion

A typical GL chromatogram of the reaction mixture after reduction and trimethylsilylation is shown in Fig. 1. The four peaks indicated by arrows appeared exclusively in the presence of HAP. The other peaks are those found in the usual $Ca(OH)_2$-catalyzed formose formation. The peaks are resolved for trimethylsilylated sugar alcohols according to the differences in carbon numbers and in either a straight (s) or branched (b) carbon skeleton of sugar alcohols. Therefore, the peaks are denoted as C_{4s} and so on, where C_{4s} represents tetroses with a straight carbon chain.

The four peaks originating from HAP were identified by means of GLC-mass spectrometry. Characteristic mass fragments measured for the peaks indicated as $HAPC_1$, $HAPC_2$(s), and $HAPC_2$(b) in the GLC are tabulated in Table 1. The presence of strong fragments of m/e=103, 205, and 307 has been reported to indicate -CH_2OTMS, -CH(OTMS)-CH_2OTMS, and -C(OTMS)(-$CH_2OTMS)_2$ respectively, where OTMS stands for $OSi(CH_3)_3$.[7] The peak denoted as $HAPC_1$ was identical to the sample derived from DHPP. The characteristic main fragments of m/e=281, 205, 179, and 103 are in accordance with the bond scissions shown below, as well as the fragment of m/e=295 (M−OTMS).



The peaks denoted as $HAPC_2$(s) and $HAPC_2$(b) showed a mass fragment of m/e=383(M−CH_2OTMS). The former has mass fragments of 281 and 205, similar to those of the $HAPC_1$ peak. On the contrary, the latter is characterized by the main fragments of 307 and 179, together with a strong fragment of 218(307−OTMS). These fragmentations are in accordance with the respective bond scissions of the straight and branched structures, as is shown below:



$HAPC_2$(s) Peak $HAPC_2$(b) Peak

These characteristic fragmentations lead to the identifications of the $HAPC_2$(b) peak and $HAPC_2$(s) peak with tetrakis-*O*-trimethylsilyl-1-phenylerythritol and tetrakis-*O*-trimethylsilyl-1-phenyl-2-(hydroxymethyl)glycerol respectively. These results show that the addition products of C_{1A} with HAP belong to three classes of compounds which give 1-phenylglycerol, 2-(1-hydroxybenzyl)glycerol, and 1-phenyl-erythritol by reduction with $NaBH_4$. $HAPC_1$, $HAPC_2$(s), and $HAPC_2$(b) are, therefore, mixtures of phenyl-substituted sugars with the straight or branched carbon skeleton mentioned above.

The absence of compounds having a branched carbon skeleton for $HAPC_1$ in the product is worth notice.

The change in the amounts of HAP and its derivatives during the reaction is shown in Fig. 2. The rapid formation of $HAPC_1$ is the initial step of the reaction, followed by the formation of $HAPC_2$(b), presumably through a successive addition of C_{1A} to $HAPC_1$. Both $HAPC_1$ and $HAPC_2$(b) reach their maxima within

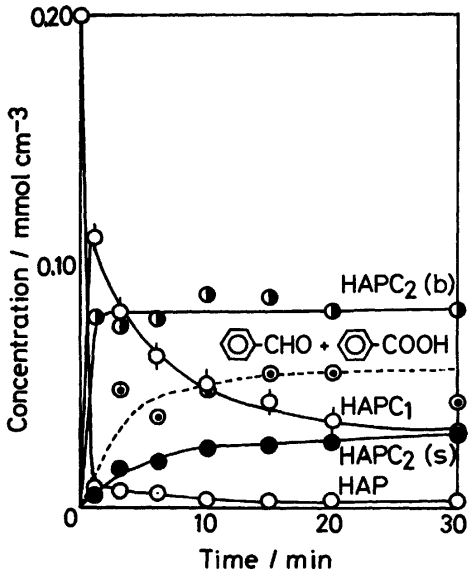

Fig. 2. Consumption of HAP and formations of $HAPC_1$, $HAPC_2$ (b), and $HAPC_2$ (s), and benzaldehyde+ benzoic acid. 35 °C, 40 vol % CH_3OH–H_2O, $Ca(OH)_2$; 0.10 mmol cm^{-3}, C_{1A}; 2.45 mmol cm^{-3}, HAP; 0.20 mmol cm^{-3}.

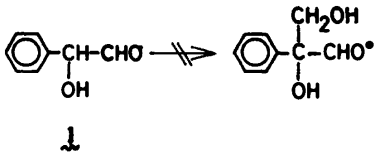
1 min after the addition of HAP to the mixture of $Ca(OH)_2$ and C_{1A}. The amount of $HAPC_1$ gradually decreases thereafter, but that of $HAPC_2$(b) is kept at *ca.* 0.8 mmol cm^{-3}. The formation of $HAPC_2$(s) appears to be slow, but its amount continues to increase as the reaction proceeds. As $HAPC_1$ decreases and $HAPC_2$(s) increases, benzaldehyde, benzoic acid, and low-molecular-weight formose sugars are formed in the reaction mixture. The summation over the molar amounts of HAP, $HAPC_1$, $HAPC_2$(s), $HAPC_2$(b), benzaldehyde, and benzoic acid was in agreement with the molar amount of HAP initially introduced.

The above observations suggest successive C_{1A} additions to HAP to form phenyl-substituted carbohydrates. However, no HAP derivative with more than two molecules of C_{1A} added to HAP was detected throughout the reaction. The occurrence of benzaldehyde and benzoic acid, accompanied by the simultaneous production of low-molecular-weight formose sugars, suggests the important role of the retro-aldol reaction of the phenyl-substituted carbohydrates. Benzaldehyde is expected to change to benzoic acid under the present reaction conditions, as will be discussed later.

A reaction scheme is drawn in Fig. 3 based on the aldol addition, retro-aldol reaction, and Lobry de Bruyn-Alberda van Ekenstein (LA) transformation, to which HAP and its derivatives are susceptible under basic conditions. In this scheme, $HAPC_1$ corresponds to either DHPP, **2**, and/or **3** : $HAPC_2$(s) corresponds to either **5**, **6**, **7**, and/or **8**, and $HAPC_2$(b) corresponds to either **4** and/or **9**.

HAP can undergo LA transformation, yielding 2-phenylglycolaldehyde (**1**) as has been reported previously,[4] and can undergo aldol addition, yielding DHPP. The results of GLC-mass spectrometry exclude the aldol addition of C_{1A} to **1** to form products possessing a

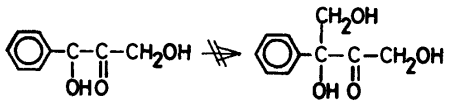


(3)

1

branched carbon skeleton, as is shown above. $HAPC_1$ and DHPP coincided exactly in the results of GLC and mass fragmentation data on reduction and trimethylsilylation. DHPP will isomerize to two isomers, 1-phenyl-1,3-dihydroxyacetone (**2**) and 3-phenylglyceraldehyde (**3**), through LA transformation and will undergo aldol addition with C_{1A} to yield 2-benzoylglycerol (**4**). The last compound can not add further C_{1A} because no hydrogen is available at the α-carbon atom to the carbonyl group. The retro-aldol reaction of DHPP can not be disregarded because a small amount of HAP remained throughout the reaction, as is shown in Fig. 2.

One of the tautomers of DHPP, **2**, which does not undergo retro-aldol reaction, adds C_{1A}, leading to 1-phenyl-2-ketotetrose (**6**). The product, **6**, can isomerize to three isomers; 1-benzoylglycerol (**5**), 4-phenyl-2-ketotetrose (**7**), and 4-phenylaldotetrose (**8**) and can undergo the retro-aldol reaction to yield C_{1A} and **2**. Compounds **5**, **7**, and **8** can degrade to C_{2A} and HAP, C_{3K} and benzaldehyde, C_{2A} and **1**, respectively, through retro-aldol reactions. The aldol addition of C_{1A} at the carbon atom adjacent to a phenyl group can be excluded in line with the fact that Eq. 3 scarcely proceeds.



(4)

2

The last tautomer of DHPP, **3**, decomposes to yield C_{2A} and benzaldehyde through retro-aldol reaction and undergoes aldol addition with C_{1A}, yielding a product, **9**, which can not be distinguished from **4** on reduction and trimethylsilylation. Compounds **9** decomposes to C_{3A} and benzaldehyde through the retro-aldol reaction.

The rapid formation of $HAPC_1$ and $HAPC_2$(b) suggests that the entities of $HAPC_1$ and $HAPC_2$(b) in the early stage of the reaction (less than 1 min) are DHPP and 2-benzoylglycerol (**4**) respectively. The aldol addition of C_{1A} to the carbon atom next to the carbonyl group seems to proceed quickly. The compound, **4**, is a terminal product in respect to the aldol addition, and its amount can be equilibrated by means of a retro-aldol reaction. The slow decrease in [$HAPC_1$] is accounted for by the loss of the tautomers of DHPP, **2** and **3**, due to the aldol additions and the retro-aldol reaction.

It is uncertain at present which is the main path for the production of benzaldehyde among retro-aldol reactions of **3**, **7**, and **9**. Benzaldehyde will be oxidized to benzoic acid under the present reaction conditions. The ratio of [benzaldehyde] to [benzoic acid] decreased from 1 : 9 in the early stage to 0.5 : 9.5 in the later stage. The absence of benzyl alcohol indicates that

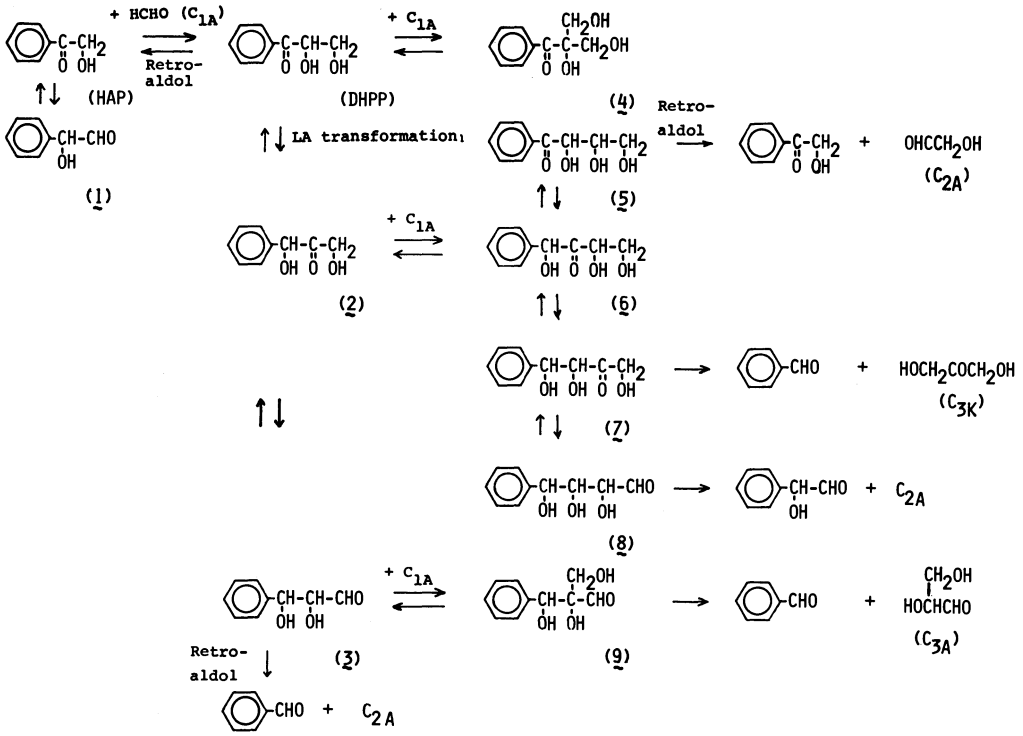


Fig. 3. A reaction scheme based on aldol addition, retro-aldol reaction and LA transformation.

benzoic acid is produced from benzaldehyde through cross-Cannizzaro reaction with aldoses and ketoses, as well as with C_{1A}.

The C_{1A} conversion to formose is plotted in Fig. 4 against the time in order to compare the reaction accelerated by HAP with that by C_{3K}, both in equimolar amounts. The initial rate in the presence of HAP exceeds that of C_{3K}, but the rate after *ca.* 1.5 min for the former is comparable to the initial rate for the latter. The amounts of C_{1A} consumed are 0.64 and 1.23 mmol cm^{-3} at 1 and 3 min respectively for an HAP-accelerated reaction, while the amounts of C_{1A} added to HAP are estimated to be 0.28 and 0.26 mmol cm^{-3} at 1 and 3 min respectively (Fig. 2). The remaining amounts of C_{1A}, 0.36 and 0.97 mmol cm^{-3} at 1 and 3 min respectively should have been converted to formose sugars which do not contain the phenyl group.

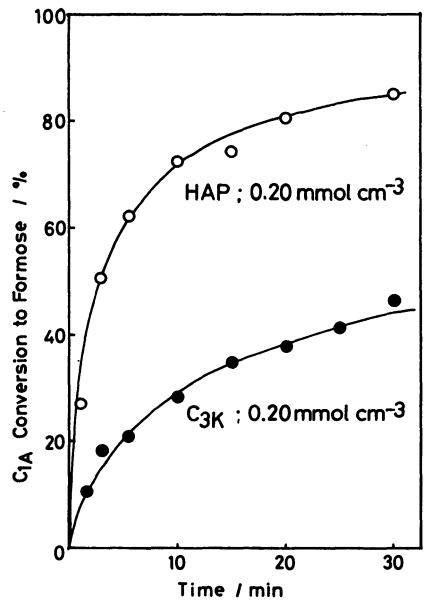

Fig. 4. Profiles of C_{1A} conversion to formose with HAP and C_{3K} as accelerators. 35 °C, 40 vol% CH_3OH–H_2O, $Ca(OH)_2$; 0.10 mmol cm^{-3}, C_{1A}; 2.45 mmol cm^{-3}, HAP or C_{3K}; 0.20 mmol cm^{-3}.

The sum of the amounts of benzaldehyde and benzoic acid in Fig. 4 is smaller than the amounts of glyceraldehyde and trioses estimated from the amount of C_{1A} converted to formose at 1 and 3 min. On the other hand, the dimerization of these low-molecular-weight sugars is expected to proceed more slowly than the C_{1A} addition to these sugars due to a high concentration of C_{1A} in the reaction mixture. Therefore, the efficient catalytic cycle of HAP *via* an intermediate, **5** or **8** (Fig. 3), can not be discarded at present.

The large initial consumption rate of C_{1A} in the presence of HAP is caused by the rapid aldol addition of C_{1A} to HAP; *i.e.*, HAP acts as a substrate. However the C_{1A} addition products of HAP are susceptible to a retro-aldol reaction to yield C_2 and C_3 compounds, which are accelerators in themselves for formose formation. The results shown above indicate that the high efficiency of HAP is a consequence of the pronounced production of glycolaldehyde, C_{3A}, and C_{3K}.

The efficiency of D-fructose in formose formation is lower than that of HAP.[3] The product distributions for the reaction accelerated by HAP and D-fructose are expected to be different in the production of lower carbohydrates. The product distributions for the HAP-accelerated reaction are illustrated in Fig. 5, while

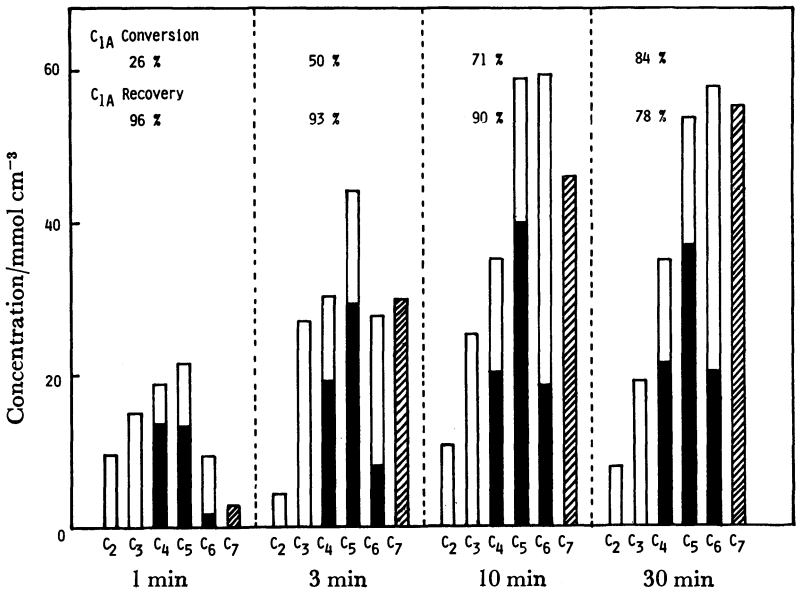

Fig. 5. C-number distributions in amounts of formose sugars and sugar alcohols obtained in the reaction accelerated by HAP. Reaction conditions; same as indicated in Fig. 2. C_n represents formose sugars and sugar alcohols having n carbon atoms. ■ or □ denotes branched chain or straight chain carbon skeleton, respectively.

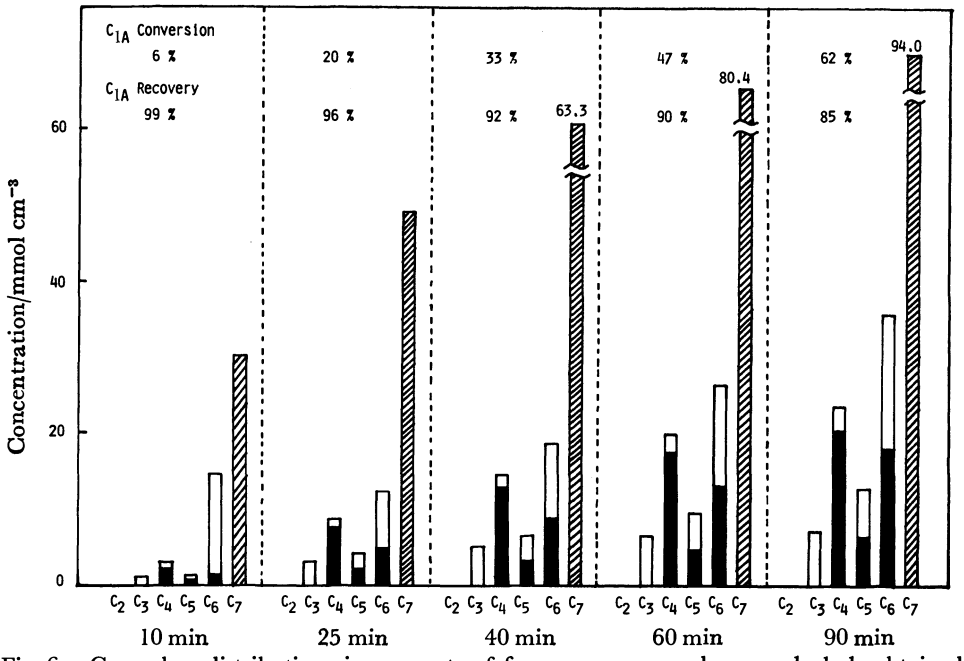

Fig. 6. C-number distributions in amounts of formose sugars and sugar alcohols obtained in the reaction accelerated by D-fructose. 45 °C, water, NaOH; 0.20 mol cm^{-3}, $CaCl_2$; 0.10 mmol cm^{-3}, C_{1A}; 2.0 mmol cm^{-3}, D-fructose; 0.05 mmol cm^{-3}.

analogous distributions for the fructose-accelerated reaction are illustrated in Fig. 6. These are determined from the GL chromatograms; therefore, the amount of C_{2A} is likely to have been evaluated too low as a result of evaporation loss during pretreatment. The amounts of C_2 and C_3 carbohydrates for the HAP-accelerated reaction are larger than those for the fructose-accelerated reaction. Moreover, the predominant carbohydrates for the fructose-accelerated reaction are aldo- and keto-heptuloses, which were presumably produced by the aldol addition of C_{1A} to D-fructose. The low efficiency of D-fructose is attributable to the low reactivity of D-fructose and/or heptuloses toward retro-aldol reactions.

Synthesis of Dihydrobenzofuran Derivatives from Substituted *p*-Benzoquinones

Tadashi KOZUKA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 30, 1981)

A series of *p*-benzoquinones having an ester functional group in the α position of alkyl side chains was prepared. Irradiation of these quinones, except for methyl 3-methyl-2-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-butyrate (**3e**), rapidly gave methyl 3-substituted 2,3-dihydro-5-hydroxybenzofuran-2-carboxylate in fairly good yields, and it was found that rearrangement of the side chain occurred concomitantly. Photolysis of quinone **3e** afforded methyl 2-(2,5-dihydroxy-4-methylphenyl)-3-methyl-3-butenoate as the major product. An intermediate was postulated to account for the isolated photoproduct.

2,3-Dihydrobenzofurans are of interest as a potential synthetic intermediate of a variety of medicinally important natural products[1] in addition to their own pharmacological activity.

In this report, syntheses of a variety of methyl 2,3-dihydro-5-hydroxybenzofuran-2-carboxylate derivatives by way of photochemical reactions are described. One of the possible approaches to the synthesis of this system is photocyclization of substituted *p*-quinones.[2,3] The present author has developed a simple general route to the dihydrobenzofuran derivatives starting from alkyl substituted *p*-benzoquinones. The alkyl group has a methoxycarbonyl grouping in its α position.[4] It is anticipated that the β-hydrogen atom of the alkyl side chain will occupy a favorable position for the γ-hydrogen abstraction by a photoexcited quinonoid carbonyl group, because of the dipole-dipole repulsion between quinonoid carbonyl and methoxycarbonyl groups. The most interesting aspect of the present results is that the photochemical reaction of these quinones occurs with rearrangement to give methyl 3-substituted, 2,3-dihydro-5-hydroxybenzofuran-2-carboxylates.

Results and Discussion

Preparation of Quinones. All quinones **3a**—**n** were prepared in excellent yields by the synthetic route shown in Scheme 1. That is, oxythallation of the ketone **1** with thallium(III) nitrate (TTN)[5] and trimethyl orthoformate (TMOF) in methanol followed by oxidation of the ester **2** with ceric ammonium nitrate (CAN)[6a] in 70% aqueous acetonitrile to give the quinone **3**.

Scheme 1.

Irradiation of Quinones. On irradiation of a solution of the quinone **3** (2 mmol) in dry benzene with a high pressure Hg lamp (300 W) after bubbling nitrogen, the quinone solution rapidly turned from yellow to colorless. The photochemical reaction was complete within several hours (0.5—5 h) at 0—10 °C and gave methyl 3-substituted 2,3-dihydro-5-hydroxybenzofuran-2-carboxylate **4** in relatively good yields after purification by column chromatography. The results of photolyses of the quinones **3a**—**n** are summarized in Table 1.

The structures of the irradiation products **4a**—**n** were established by their IR, ^1H NMR data, and chemical reactions. In particular, the structure of **4a** was confirmed as follows. The ^1H NMR spectrum of **4a** consisted of a characteristic AB pattern due to geminal protons at C-3 (J_{AB}=15 Hz),[7] indicating the presence of a C-2 methoxycarbonyl-substituted 2,3-dihydrobenzofuran ring (C-2 methoxycarbonyl, IR: 1740 cm^{-1}, CO). Such an ABX pattern of C-2 substituted 2,3-dihydrobenzofuran was similar to that of ethyl 2,3-

dihydro-5-hydroxybenzofuran-2-carboxylate.[8]

For the photoproduct **4c**, the ^{1}H NMR spectrum showed a coupling (J_{AB}=15 Hz),[7] which suggested that the substitution pattern was similar to that of **4a**. Furthermore, the structures of **4a** and **4c** were also supported by oxidation with ceric ammonium nitrate[6b] to the corresponding quinones **5a** and **5c**. ^{1}H NMR spectra of **5a** and **5c** showed the presence of methylene protons directly attaching to the quinone ring. The methylene protons were long-range coupled with the quinone ring proton (J=1.2 Hz).[9]

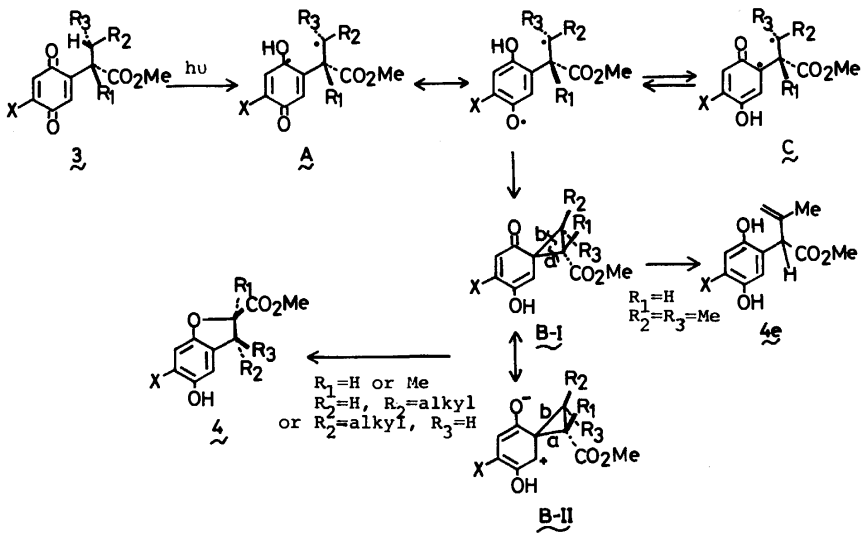
The photoproduct **4g** was compatible with the structure of dimethyl 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2,3-dicarboxylate on the basis of the spectral data outlined below. Its IR spectrum showed three characteristic bands at 3340 (phenolic OH), 1735 (ester CO), and 1695 cm^{-1} (ester CO). Its ^{1}H NMR spectrum showed two doublets at δ 4.41 (J=6 Hz) and δ 5.56 (J=6 Hz) due to the protons C_3–H and C_2–H, respectively, and a broad singlet at δ 5.32 due to the phenolic hydroxyl proton.

Irradiation of the quinones **3b**, **3d**, **3f**, **3l**, **3m**, and **3n** afforded predominantly the corresponding dihydrobenzofurans **4b**, **4d**, **4f**, **4l**, **4m**, and **4n**, respectively, and a small amount of isomers. The major photoproducts in the reactions wer eisolated by chromatoggraphy and/or fractional crystallization. The minor products were detected by ^{1}H NMR and GC, but not isolated. The ^{1}H NMR spectra of the above six major products showed similar chemical shifts and coupling constants for the proton signals at C-3 and C-2 on the dihydrobenzofuran ring as shown in Table 2. The regiochemistry for the substituents around C-2 and C-3 of these photoproducts cannot be determined directly by comparison with the chemical shifts of C-2 and C-3 protons of other products, *i.e.*, **4a**, **4c**, and **4g** as was already described. In general, chemical shifts of C-2 and C-3 protons on 2,3-disubstituted 2,3-dihydrobenzofurans are variable according to the substituent groups and stereospecific environment.[10] Therefore, **4b**, **4d**, and **4f** were converted by oxidation with CAN to quinones **5b**, **5d**, and **5f**, respectively. The structures of these three quinones were assigned on the basis of the spectroscopic data. For example, quinone **5f** showed three characteristic bands at 3470 (OH), 1720 (ester CO), and 1650 cm^{-1} (quinone CO) in its IR spectrum. Its ^{1}H NMR spectrum consisted of the signals at δ 1.64 (m, 4H), at δ 2.87 (d, J=7 Hz, 1H), at δ 3.31 (m, 1H), and at δ 4.31 (dd, J=3.5 Hz, and 7 Hz, 1H). On adding D_2O the signal at δ 2.87 disappeared and the double doublets signal at δ 4.31 was simplified to a doublet (J=3.5 Hz). Irradiation of the methylene proton at δ 1.64 changed the signal at δ 3.31 to a sharp doublet (J=3.5 Hz), and the signal at δ 4.31 coupled with the methine proton (δ 3.31) to a triplet (J=7 Hz) and the hydroxyl proton signal at δ 2.87 to a singlet. These results suggested that the quinone **5f** included the partial structure $-CH_2\overset{1}{C}HCH(OH)CO-$ in the side chains. Further support for the structure **5f** was provided by the reduction of the quinone **5f** with sodium dithionite followed by acetylation of the obtained hydroquinone with acetic anhydride–pyridine to the corresponding triacetate **7**. However, the methine proton signal adjacent to the acetoxyl group showed a downfield shift at δ 5.18 (d, J=5 Hz) due to a deshielding effect of the acetoxyl carbonyl. The above results indicated that these original photoproducts **4b**, **4d**, **4f**, **4l**, **4m**, and **4n** contain an ester group at C-2 position and other substituent group (R_2 and R_3) at C-3 position, respectively.

Irradiation of other substituted quinones **3h**, **3i**, **3j**, and **3k** also gave corresponding photocyclization products **4h**, **4i**, **4j**, and **4k**.

The ^{1}H NMR spectrum of photoproduct **4k** showed the presence of a methine proton signal at δ 5.02 (d, J=5.1 Hz), probably at C-2 position. This lower field shift can be explained in terms of the deshielding effect of the carbonate carbonyl group.

The structures of the major and the minor components were correlated with each other by their chemical reactions and by comparing their ^{1}H NMR spectra. Acetylation of crude photoproducts **4b**, **4d**, **4f**, and



Scheme 2.

TABLE 2. ^{1}H NMR SPECTRA OF DIHYDROBENZOFURANS **4** AND QUINONES **5**

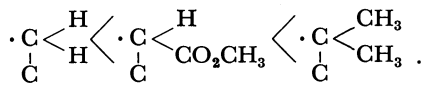
a) The *cis*-isomer, which was a minor component of the mixture of products, was detectable only by the ^{1}H NMR spectrum. (A) AB type: J=15 Hz, (B) Chemical shifts were not determined because of overlapping of the signal with those of other protons. (C) Not detected. (D) δ 2.69(dd), J=8.5 and 15 Hz, 1H), δ 2.98 (dd, J=5 and 15 Hz, 1H).

4i containing minor components with acetic anhydride in pyridine solution gave only the single monoacetate **6b**, **6d**, **6f**, and **6i**, respectively. The minor components are therefore presumed to be the stereoisomers of the thermodynamically stable major products. In the ^{1}H NMR spectra, the coupling constants due to C-2 and C-3 protons of 2,3-disubstituted 2,3-dihydrobenzofuran are $J_{cis}>J_{trans}$[11] as predicted by the Karplus equation.[12] The most striking differences between the ^{1}H NMR spectra of the *cis* and *trans* isomers of 2,3-disubstituted 2,3-dihydrobenzofuran, other than the values of $J_{2,3}$ are the different values for the chemical shift of the C-2 proton. The ^{1}H NMR signal of the C-2 proton of the *trans* isomers is located upfield at about δ 0.3 compared to the corresponding proton of the *cis* isomers. The major product **4** (δ 4.63—4.77, J=5—7 Hz) is concluded to be *trans*, and the minor to be *cis* (δ 5.14—5.17, J=8.5—9 Hz) as shown in Table 2.

On the other hand, the photolysis of quinone **3e** did not afford a dihydrobenzofuran derivative, but methyl 2-(2,5-dihydroxy-4-methylphenyl)-3-methyl-3-butenoate **4e** as the major product.

The proposed mechanism of these photochemical reactions is given in Scheme 2. γ-Hydrogen abstraction by photoexcited carbonyl of the quinone **3** forms the biradical intermediate **A**[13] and subsequently yields the spirocyclopropyl ketone **B-1**[3] and/or spirocyclopropyl zwitter-ion intermediate **B-2**;[3] then the cyclopropane

ring opens to afford the observed product **4**. However it is difficult to anticipate a ring-opened zwitter-ion intermediate,[14] because the three-membered ring may cleave to give a positive charge at the α position to the methoxycarbonyl group. From the present results preferential cleavage of bond **a** can be recognized **B-1** to give phenyl migrated products **4** with exception of only one case **3e** (R_2=R_3=Me). In the latter case cleavage of bond **b** may be the preferential course to give **4e**, in which no phenyl migration occurs. Thus, among the alkyl substituted *p*-benzoquinones examined, the trend of phenyl migration initiated by photochemical γ-hydrogen abstraction reaction may be explained in terms of the stability of the radical intermediates involved. The present results indicate the stability of the radical to be



Of course, this trend should be applied under the very limited conditions, for a contribution of a dipolar intermediate, such as **B-2**, could not be excluded in the present reactions.

Experimental

Melting points and boiling points were uncorrected. Bulb to bulb distillations were carried out on a Kugelrohr-type apparatus. IR spectra were measured on a JASCO IRA-1 spectrophotometer. ^{1}H NMR spectra were measured on a JEOL PS-100 instrument with tetramethylsilane as an internal standard and the chemical shifts are reported in δ values. Mass spectra were obtained with a Hitachi M-52 mass spectrometers (20 eV). Elemental analyses were performed by the Kyoto University Microanalytical Laboratories. Column chromatography was performed using Wako reagent grade silica gel (200 mesh). The irradiation was carried out in a Pyrex vessel at 0—10 °C, using an Eikosha 300-W high pressure Hg lamp.

Materials. 3-(Methoxycarbonyl)propionyl chloride[15] and 5-(methoxycarbonyl)pentanoyl chloride[16] were prepared from the corresponding methyl hydrogen succinate and methyl hydrogen adipate, respectively. 6-Phthalimidohexanoyl chloride[17] and 6-(trifluoroacetamido)hexanoyl chloride[18] were prepared from 6-aminohexanoic acid. Other acid chlorides were commercially available.

Preparation of Starting Materials. All of the compounds **1a**—**n**, except for **1k**, were prepared by the Friedel-Crafts acylation according to the previous reported methods.[5a]

Physical Properties of the Starting Materials. 2',5'-Dimethoxy-4'-methylpropiophenone ***1a***: 96%; mp 78 °C,[5a] (lit,[19] mp76—77 °C).

2',5'-Dimethoxy-4'-methylbutyrophenone ***1b***: 96%; bp 129—130 °C at 3 Torr (1 Torr=133.322 Pa); mp 46—46.5 °C (hexane–ether); IR (KBr): 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.93 (t, 3H), 1.67 (m, 2H), 2.23 (s, 3H), 2.92 (t, 2H), 3.80 (s, 3H), 3.84 (s, 3H), 6.74 (s, 1H), and 7.20 (s, 1H); Found: C, 69.99; H, 8.21%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

2',5'-Dimethoxy-2,4'-dimethylpropiophenone ***1c***: 99%; bp 125—127 °C at 3 Torr; mp 38—39 °C (petroleum ether); IR (neat): 1675 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.14 (d, 6H), 2.25 (s, 3H), 3.57 (m, 1H), 3.82 (s, 3H), 3.86 (s, 3H), 6.78 (s, 1H), and 7.14 (s, 1H); Found: C, 69.96; H, 8.20%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

2',5'-Dimethoxy-4'-methylvalerophenone ***1d***: 95%; bp 140—143 °C at 3 Torr; mp 33.5—34 °C (petroleum ether); IR (KBr): 1670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.92 (t, 3H,) 1.20—1.90 (m, 4H), 2.25 (s, 3H), 2.97 (t, 2H), 3.80 (s, 3H), 3.85 (s, 3H), 6.77 (s, 1H), and 7.21 (s, (1H); Found: C, 71.21; H, 8.75%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

2',5'-Dimethoxy-3,4'-dimethylbutyrophenone ***1e***: 88%; bp 140—143 °C at 3 Torr; mp 48—48.5 °C (petroleum ether); IR (KBr): 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.97 (d, 6H), 2.08—2.41 (m, 1H), 2.26 (s, 3H), 2.84 (d, 2H), 3.81 (s, 3H), 3.85 (s, 3H), 6.76 (s, 1H), and 7.19 (s, 1H); Found: C, 71.42; H, 8.69%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

2',5'-Dimethoxy-4'-methylhexanophenone ***1f***: 85%; bp 183 °C at 3 Torr; IR (neat): 1665 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.90 (t, 3H), 1.22—1.82 (m, 6H), 2.26 (s, 3H), 2.98 (t, 2H), 3.84 (s, 3H), 3.88 (s, 3H), 6.81 (s, 1H), and 7.27 (s, 1H); Found: C, 72.25; H, 8.87%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

Methyl 3-(2,5-Dimethoxy-4-methylbenzoyl)propionate ***1g***: 90%; mp 89—90 °C (petroleum ether–dichloromethane); IR (KBr): 1735 and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.26 (s, 3H), 2.69 (t, 2H), 3.32 (t, 2H), 3.70 (s, 3H), 3.81 (s, 3H), 3.88 (s, 3H), 6.77 (s, 1H), and 7.30 (s, 1H); Found: C, 63.33; H, 6.86%. Calcd for $C_{14}H_{18}O_3$: C, 63.14; H, 6.81%.

Methyl 5-(2,5-Dimethoxy-4-methylbenzoyl)pentanoate ***1h***: 73%; mp 80—81 °C (petroleum ether–dichloromethane); IR (KBr): 1730 and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.64—1.86 (m, 4H), 2.26 (s, 3H), 2.36 (m, 2H), 3.00 (m, 2H), 3.67 (s, 3H), 3.82 (s, 3H), 3.87 (s, 3H), 6.78 (s, 1H), and 7.23 (s, 1H); Found: C, 65.33; H, 7.58%. Calcd for $C_{16}H_{22}O_5$: C, 65.29; H, 7.53%.

2',5'-Dimethoxy-4'-methyl-6-(phthalimido)hexanophenone ***1i***: 71%; mp 156—157 °C (methanol–dichloromethane); IR (KBr): 1775, 1715, and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.31—1.87 (m, 6H), 2.25 (s, 3H), 2.97 (t, 2H), 3.69 (t, 2H), 3.81 (s, 3H), 3.86 (s, 3H), 6.75 (s, 1H), 7.21 (s, 1H), and 7.63—7.77 (m, 4H); Found: C, 69.92; H, 6.39, N, 3.54%. Calcd for $C_{23}H_{25}O_5N$: C, 69.85; H, 6.37; N, 3.54%.

2',5'-Dimethoxy-4'-methyl-6-(trifluoroacetamido)hexanophenone ***1j***: 56%; mp 87.5—89 °C (petroleum ether–dichloromethane); IR (KBr): 3300, 1730, and 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 1.20—1.84 (m, 6H), 2.25 (s, 3H), 3.00 (t, 2H), 3.39(q, 2H), 3.82 (s, 3H), 3.86 (s, 3H), 6.80 (s, 1H), 6.90 (bs, 1H), and 7.24 (s, 1H); Found: C, 56.43; H, 6.12; N, 4.00%. Calcd for $C_{17}H_{22}O_4NF_3$: C, 56.50; H, 6.14; N, 3.88%.

2',5'-Dimethoxy-4'-methyl-4-(phenoxycarbonyloxy)butyrophenone ***1k***: was prepared from **1g** in the following three steps. Reduction of the **1g** with excess lithium aluminum hydride in THF followed by reaction of the obtained 1-(2,5-dimethoxy-4-methylphenyl)-1,4-butanediol (1 mol equiv.) in dichloromethane with phenyl chloroformate (1.2 mol equiv.) in the presence of pyridine at 0 °C afforded 1-(2,5-dimethoxy-4-methylphenyl)-4-(phenoxycarbonyloxy)-1-butanol, which on oxidation with excess Cr–Pyr complex in dichloromethane yield **1k**, total yield: 30%; IR (neat): 1760 and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.00—2.36 (m, 2H), 2.21 (s, 3H), 3.12 (t, J=7 Hz, 2H), 3.81 (s, 3H), 3.87 (s, 3H), 4.31 (d, J=6.5 Hz, 2H), 6.78 (s, 1H), and 7.12—7.46 (m, 6H); Found: C, 66.81; H, 6.30%. Calcd for $C_{20}H_{22}O_6$: C, 67.02; H, 6.19%.

2',5'-Dimethoxybutyrophenone ***1l***: 90%; bp 121—123 °C at 3 Torr, (lit,[20] bp 172—175 °C at 25 Torr).

2',4',5'-Trimethoxybutyrophenone ***1n***: 88%; mp 79 °C (petroleum ether–dichloromethane), (lit,[21,22] mp 77 °C, 78.5—80 °C).

The following esters **2a**—**n**, except for **2m**, were prepared according to the reported methods.[5]

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)propionate ***2a***: was

prepared from **1a** with $Tl(NO_3)_3$–TMOF–MeOH as described previously[5a] (90%): bp 162—165 °C at 4 Torr (bulb to bulb).

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)butyrate **2b**: was prepared from **1b** with $Tl(NO_3)_3$–TMOF–MeOH following by the general procedure (96%): bp 150—152 °C at 3 Torr (bulb to bulb); IR (neat): 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.87 (t, 3H), 1.56—2.20 (m, 2H), 2.20 (s, 3H), 3.64 (s, 3H), 3.77 (s, 6H), 3.90 (t, 1H), 6.68 (s, 1H), and 6.74 (s, 1H); Found: C, 66.49; H, 8.17%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%.

Methyl 2-Methyl-2-(2,5-dimethoxy-4-methylphenyl)propionate **2c**: was prepared from **1c** with $Tl(NO_3)_3$–TMOF–MeOH following by the same general procedure (95%): bp 154—156 °C at 4 Torr (bulb to bulb); IR (neat): 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.49 (s, 6H), 2.18 (s, 3H), 3.60 (s, 3H), 3.68 (s, 3H), 3.78 (s, 3H), 6.63 (s, 1H), and 6.74 (s, 1H); Found: C, 66.50; H, 8.27%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%.

Methyl 2-(2,5-Dimethoxy-4-methoxy-4-methylphenyl)pentanoate **2d**: was prepared from **1d** with $Tl(NO_3)_3$–TMOF–MeOH following by the general reaction procedure (98%): bp 158—159 °C at 3 Torr (bulb to bulb); IR (neat): 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.90 (t, 3H), 1.09—2.10 (m,4H), 2.19 (s, 3H), 3.63 (s, 3H), 3.77 (s, 3H), 4.00 (t, 1H), 6.67 (s, 1H), and 6.76 (s, 1H); Found: C, 67.79; H, 8.49%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)-3-methylbutyrate **2e**: was prepared from **1e** with $Tl(NO_3)_3$–TMOF–MeOH following by the usual manner (81%): bp 133—135 °C at 3 Torr (bulb to bulb); mp 78—79 °C (petroleum ether); IR (KBr): 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.71 (d, 3H), 1.03 (d, 3H), 2.00—2.26 (m, 1H), 2.20 (s, 3H), 3.65 (s, 3H), 3.79 (s, 6H), 3.84 (d, 1H), 6.71 (s, 1H), and 6.91 (s, 1H); Found: C, 67.69; H, 8.41%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)hexanoate **2f**: was prepared from **1f** with $Tl(NO_3)_3$–TMOF–MeOH following by the general method (90%): bp 135—140 °C at 0.1 Torr (bulb to bulb); IR (neat): 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.86 (t, 3H), 1.00—2.19 (m, 6H), 2.19 (s, 3H), 3.64 (s, 3H), 3.78 (s, 6H), 3.98 (t, 1H), 6.68 (s, 1H), and 6.75 (s, 1H); Found: C, 68.30; H, 8.77%. Calcd for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63%.

Dimethyl 2-(2,5-Dimethoxy-4-methylphenyl)succinate **2g**: was prepared from **1g** with $Tl(NO_3)_3$–TMOF–MeOH following by the general procedure (95%): mp 93—94 °C (petroleum ether–dichloromethane); IR (KBr): 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.18 (s, 3H), 2.54 (dd, 1H), 3.14 (dd, 1H), 3.65 (s, 6H), 3.75 (s, 6H), 4.35 (dd, 1H), 6.62 (s, 1H), and 6.67 (s, 1H); Found: C, 60.57; H, 6.86%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%.

Dimethyl 2-(2,5-Dimethoxy-4-methylphenyl)hexanedioate **2h**: was prepared from **1h** with $Tl(NO_3)_3$–TMOF–MeOH by the same method (99%): bp 129—131 °C at 0.06 Torr (bulb to bulb); IR (neat): 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.40—2.20 (m, 4H), 2.22 (s, 3H), 2.34 (t, 2H), 3.66 (s, 6H), 3.80 (s, 6H), 4.02 (t, 1H), 6.72 (s, 1H), and 6.75 (s, 1H); Found: C, 62.68; H, 7.40%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46%.

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)-6-(phthalimido)hexanoate **2i**: was prepared from **1i** with $Tl(NO_3)_3$–TMOF–MeOH by the usual method (84%): mp 96—97.5 °C (methanol); IR (KBr): 1775, 1720, and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.16—1.84 (m, 6H), 2.14 (s, 3H), 3.60 (s, 3H), 3.60 (m, 2H), 3.73 (s, 6H), 3.95 (t, 1H), 6.62 (s, 1H), 6.68 (s, 1H), and 7.58—7.84 (m, 4H); Found: C, 67.70; H, 6.39; N, 3.28%. Calcd for $C_{24}H_{27}O_6N$: C, 67.75; H, 6.40; N, 3.29%.

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)-6-(trifluoroacetamido)hexanoate **2j**: was prepared from **1j** with $Tl(NO_3)_3$–TMOF–MeOH following by the general procedure (93%): mp 86.5—88 °C (petroleum ether–ether); IR (KBr): 3340, 1725, and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.20—2.20 (m, 6H), 2.20 (s, 3H), 3.34 (q, 2H), 3.66 (s, 3H), 3.79 (s, 6H), 6.56 (bs, 1H), and 6.71 (s, 2H); Found: C, 55.27; H, 6.30; N, 3.52%. Calcd for $C_{18}H_{24}O_5NF_3$: C, 55.24; H, 6.18; N, 3.58%.

Methyl 2-(2,5-Dimethoxy-4-methylphenyl)-4-(phenoxycarbonyloxy)butyrate **2k**: was prepared from **1k** with $Tl(NO_3)_3$–TMOF–MeOH following by the same procedure (70%): IR (neat): 1760 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.92—2.71 (m, 2H), 2.21 (s, 3H), 3.67 (s, 3H), 3.77 (s, 6H), 4.07—4.33 (m, 3H), 6.73 (s, 2H), and 7.13—7.42 (m, 5H); Found: C, 65.13; H, 6.25%. Calcd for $C_{21}H_{24}O_7$: C, 64.93; H, 6.23%.

Methyl 2-(2,5-Dimethoxyphenyl)butyrate **2l**: was prepared from **1l** with $Tl(NO_3)_3$–TMOF–MeOH following by the general procedure (91%): bp 120—121 °C at 3 Torr (bulb to bulb); IR (neat): 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.88 (t, 3H), 1.57—2.19 (m, 2H), 3.64 (s, 3H), 3.75 (s, 3H), 3.77 (s, 3H), 3.89 (t, 1H), and 6.77—6.83 (m, 3H); Found: C, 65.81; H, 7.80%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

Methyl 2-(4-Bromo-2,5-dimethoxyphenyl)butyrate **2m**: was prepared from **2l** with bromine in chloroform (96%): bp 136—140 °C at 0.05 Torr (bulb to bulb); IR (neat): 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.88 (t, 3H), 1.56—2.18 (m, 2H), 3.66 (s, 3H), 3.84 (s, 3H), 3.89 (s, 3H), 3.89 (m, 1H), 6.86 (s, 1H), and 7.04 (s, 1H); Found: C, 49.24; H, 5.52; Br, 25.18%. Calcd for $C_{13}H_{17}O_4Br$: C, 49.22; H, 5.40; Br, 25.20%.

Methyl 2-(2,4,5-Trimethoxyphenyl)butyrate **2n**: was prepared from **1n** with $Tl(NO_3)_3$–TMOF–MeOH following by the general method (60%): mp 60—62 °C (petroleum ether); IR (KBr): 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.87 (t, 3H), 1.60—2.12 (m, 2H), 3.64 (s, 3H), 3.80 (s, 3H), 3.82 (s, 3H), 3.88 (s, 3H and m, 1H), 6.49 (s, 1H), and 6.80 (s, 1H); Found: C, 62.91; H, 7.60%. Calcd for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

Preparation of Quinones **3**. Quinones **3a**—**n** were prepared from the corresponding **2a**—**n** with ceric ammonium nitrate (CAN) in aq acetonitrile by the method of Jacob *et al.*[6a]

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)propionate **3a**: (CAN oxidation of **2a**): 88%; mp 59—60 °C.[5a]

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)butyrate **3b**: (CAN oxidation of **2b**): 98%; bp 130—131 °C at 3 Torr (bulb to bulb); IR (neat): 1735 and 1655 cm^{-1}: ^1H NMR ($CDCl_3$) δ: 0.92 (t, J=7 Hz, 3H), 1.60—2.00 (m, 2H), 2.04 (d, J=1.6 Hz, 3H), 3.70 (s, 3H), 3.70—3.98 (m, 1H), 6.64 (q, J=1.6 Hz, 1H), and 6.70 (s, 1H); Found: C, 64.98; H, 6.60%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

Methyl 2-Methyl-2-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)propinate **3c**: (CAN oxidation of **2c**): 95%; mp 111—112 °C (petroleum ether); IR (KBr): 1740 and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.42 (s, 6H), 2.03 (d, J=1.6 Hz, 3H), 3.62 (s, 3H), 6.56 (q, J=1.6 Hz, 1H), and 6.59 (s, 1H); Found: C, 64.56; H, 6.35%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)pentanoate **3d**: (CAN oxidation of **2d**): 96%; bp 143—145 °C at 3 Torr (bulb to bulb); IR (neat): 1735 and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.92 (t, J=7 Hz, 3H), 1.15—2.04 (m, 4H), 2.04 (d, J=1.6 Hz, 3H), 3.68 (s, 3H), 3.90 (t, J=7 Hz, 1H), 6.62 (q, J=1.6 Hz, 1H), and 6.69 (s, 1H); Found: C, 66.05; H, 6.89%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Methyl 3-Methyl-2-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)butyrate **3e**: (CAN oxidation of **2e**): 96%; bp 140—143 °C at 3 Torr (bulb to bulb); IR (neat): 1735 and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.83 (d, J=7 Hz, 3H), 0.99 (d, J=7 Hz, 3H), 2.03 (d, J=1.6 Hz, 3H), 1.91—2.38 (m, 1H), 3.65 (s, 1H), 3.74 (t, J=7 Hz, 1H), 6.60 (q, J=1.6 Hz, 1H), and 6.84 (s, 1H); Found: C, 66.04; H, 6.96%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)hexanoate **3f**: (CAN oxidation of **2f**): 90%; IR (neat): 1735 and 1655 cm^{-1};

^{1}H NMR ($CDCl_3$) δ: 0.88 (t, J=7 Hz, 3H), 1.00—2.04 (m, 6H), 3.68 (s, 3H), 3.82 (t, J=7 Hz, 1H), 6.60 (q, J=1.6 Hz, 1H), and 6.68 (s, 1H); Found: C, 66.95; H, 7.38%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Dimethyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)succinate ***3g***: (CAN oxidation of **2g**): 80%; mp 85—86 °C (methanol–petroleum ether); IR (KBr): 1735 and 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.06 (d, J=1.6 Hz, 3H), 2.61 (dd, J=6 and 17 Hz, 1H), 3.06 (dd, J=6 and 17 Hz, 1H), 3.66 (s, 3H), 3.68 (s, 3H), 4.12 (t, J=7 Hz, 1H), and 6.63 (m, 2H); Found: C, 58.57; H, 5.36%. Calcd for $C_{13}H_{14}O_6$: C, 58.64; H, 5.30%.

Dimethyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadioenyl)hexanediate ***3h***: (CAN oxidation of **2h**): 88%; bp 169—172 °C at 0.03 Torr (bulb to bulb); IR (neat): 1735 and 1655 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.36—2.05 (m, 4H), 2.05 (d, J=1.6 Hz, 3H), 2.33 (t, J=7.5 Hz, 2H), 3.64 (s, 3H), 3.67 (s, 3H and m, 1H), 6.60 (q, J=1.6 Hz, 1H), and 6.64 (s, 1H); Found: C, 61.18; H, 6.30%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%.

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)-6-(phthalimido)hexanoate ***3i***: (CAN oxidation of **2i**): 88%; IR (neat): 1775, 1735, 1710, and 1655 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.18—1.88 (m, 6H), 2.03 (d, J=1.6 Hz, 3H), 3.61 (s, 3H), 3.56—3.7 (m, 2H), 3.87 (m, 1H), 6.58 (q, J=1.6 Hz, 1H), 6.64 (d, J=1.2 Hz, 1H), and 7.60—7.82 (m, 4H); Found: C, 66.77; H, 5.42; N, 3.58%. Calcd for $C_{22}H_{21}O_6N$: C, 66.82; H, 5.35; N, 3.54%.

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)-6-(trifluoroacetamido)hexanoate ***3j***: (CAN oxidation of **2j**): 80%; IR (neat): 3320, 1710, and 1650 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.00—2.00 (m, 6H), 2.04 (d, J=1.6 Hz, 3H), 3.35 (q, J=7 Hz, 2H), 3.68 (s, 3H), 3.76 (m, 1H), 6.63 (q, J=1.6 Hz, 1H), 6.67 (s, 1H), and 6.68 (bs, 1H); Found: C, 52.87; H, 5.13; N, 3.84%. Calcd for $C_{16}H_{18}O_5NF_3$: C, 53.18; H, 5.02; N, 3.88%.

Methyl 2-(4-Methyl-3,6-dioxo-1,4-cyclohexadienyl)-4-(phenoxycarbonyloxy)butyrate ***3k***: (CAN oxidation of **2k**): 71%; IR (neat): 1750 and 1655 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.05 (d, J=1.6 Hz, 3H), 2.05—2.59 (m, 2H), 3.72 (s, 3H), 3.88 (t, J=7.5 Hz, 1H), 4.28 (t, J=6.5 Hz, 2H), 6.63 (q, J=1.6 Hz, 1H), 6.71 (s, 1H), and 7.11—7.46 (m, 5H); Found: C, 63.29; H, 5.19%. Calcd for $C_{19}H_{18}O_7$: C, 63.68; H, 5.06%.

Methyl 2-(3,6-Dioxo-1,4-cyclohexadienyl)butyrate ***3l***: (CAN oxidation of **2l**): 54%; bp 131—134 °C at 3 Torr (bulb to bulb); IR (neat): 1730 and 1655 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.95 (t, J=7 Hz, 3H), 1.56—2.13 (m, 2H), 3.68 (s, 3H and m, 1H), 6.69 (m, 1H), and 6.75 (s, 2H); Found: C, 63.17; H, 6.06%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

Methyl 2-(4-Bromo-3,6-dioxo-1,4-cyclohexadienyl)butyrate ***3m***: (CAN oxidation of **2m**): 68%; bp 140—145 °C at 0.05 Torr (bulb to bulb); IR (neat): 1735 and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.95 (t, J=7 Hz, 3H), 1.56—2.15 (m, 2H), 3.62 (t, J=7.5 Hz, 1H), 3.68 (s, 3H), 6.88 (s, 1H), and 7.27 (s, 1H); Found: C, 45.81; H, 3.87; Br, 28.07%. Calcd for $C_{11}H_{11}O_4$-Br: C, 46.06; H, 3.86; Br, 27.83%.

Methyl 2-(4-Methoxy-3,6-dioxo-1,4-cyclohexadienyl)butyrate ***3n***: (CAN oxidation of **2n**): 60%; mp 70—72 °C (petroleum ether); IR (KBr): 1740 and 1665 cm^{-1} ^{1}H NMR ($CDCl_3$) δ: 0.94 (t, J=7 Hz, 3H), 1.55—2.13 (m, 2H), 3.69 (s, 3H and m, 1H), 3.83 (s, 3H), 5.95 (s, 1H), and 6.64 (s, 1H); Found: C, 60.29; H, 5.99%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

Irradiation of Quinones ***3***. *Irradiation of* ***3a***: A solution of **3a** (416 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 20 min and irradiated for 1 h. Evaporation of the solvent and column chromatography of the residue on silica gel with 10% ether–benzene as eluant gave methyl 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate **4a** (171 mg, 41%); mp 153—154 °C (dichloromethane–petroleum ether); IR (KBr): 3420 and 1740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 2.20 (s, 3H), 3.26 (dd, J=7 and 15 Hz, 1H), 3.51 (dd, J=10 and 15 Hz, 1H), 3.80 (s, 3H), 4.50 (s, 1H), 5.12 (dd, J=7 and 10 Hz, 1H), 6.60 (s, 1H), and 6.74 (s, 1H); MS, *m/e* (rel intensity), 208 (M^+, 65), 176 (42), 149 (100); Found: C, 63.18; H, 5.89%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

Irradiation of ***3b***: A solution of **3b** (444 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 20 min and irradiated for 1 h. After evaporation of the solvent, the residue was purified by chromatography on silica gel with 10% ether–benzene to give methyl 2,3-dihydro-5-hydroxy-3,6-dimethylbenzofuran-2-carboxylate **4b** (289 mg, 65%): mp 99—101 °C (dichloromethane–petroleum ether); IR (KBr): 3440 and 1745 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1,40 (d, J=7 Hz, 3H), 2.18 (s, 3H), 3.40—3.68 (m, 1H), 3.79 (s, 3H), 4.63 (d, J=7 Hz, 1H), 4.71 (bs, 1H), 6.56 (s, 1H), and 6.63 (s, 1H); MS, *m/e* (rel intensity), 222 (M^+, 100). 191 (17), 190 (17), 163 (68), 162 (91); Found: C, 64.85; H, 6.34%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

Irradiation of ***3c***: A solution of **3c** (222 mg, 1 mmol) in dry benzene (100 ml) was purged with nitrogen for 20 min and irradiated for 1 h. The solvent was evaporated, and the residue was chromatographed on silica gel with 10% ether–benzene to give methyl 2,3-dihydro-5-hydroxy-2,6-dimethylbenzofuran-2-carboxylate **4c** (100 mg, 45%): bp 170—180 °C at 0.01 Torr (bulb to bulb); IR (neat): 3420 and 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.64 (s, 3H), 2.16 (s, 3H), 3.00 (d, J=15 Hz, 1H), 3.50 (d, J=15 Hz, 1H), 3.75 (s, 3H), and 6.56 (s, 2H); MS, *m/e*, 222 (M^+); Found: C, 68.69; H, 6.21%. Calcd for $C_{12}H_{14}O_4$: C, 68.85; H, 6.35%.

Irradiation of ***3d***: A solution of **3d** (473 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 15 min and irradiated for 1 h. After evaporation of the solvent, the residue was chromatographed on silica gel with 10% ether–benzene to give methyl 3-ethyl-2,3-dihydro-5-hydroxy-6-methylbenzofuran-2-carboxylate **4d** (322 mg, 68%): mp 101—102 °C (dichloromethane–petroleum ether); IR (KBr): 3440 and 1740 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.00 (t, J=7 Hz, 3H), 1.40—2.00 (m, 2H), 2.19 (s, 3H), 3.42 (m, 1H), 3.76 (s, 3H), 4.51 (s, 1H), 4.74 (d, J=5 Hz, 1H), 6.58 (s, 1H), and 6.63 (s, 1H); MS, *m/e* (rel intensity), 236 (M^+, 100), 205 (31), 204 (55); Found: C, 66.36; H, 7.07%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Irradiation of ***3e***: A solution of **3e** (473 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 20 min and irradiated for 1 h. The solvent was removed, and the crude oil was chromatographed on silica gel with 20% ether–benzene to give methyl 4-methyl-2-(2,5-dihydroxy-4-methylphenyl)-3-butenoate **4e** (189 mg, 40%): mp 130—131 °C (dichloromethane–petroleum ether); IR (KBr): 3400, 3340, 1715, and 900 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.78 (s, 3H), 2.15 (s, 3H), 3.77 (s, 1H), 4.38 (bs, 1H), 4.84 (s, 1H), 5.02 (bs, 1H), 6.60 (s, 1H), and 6.64 (s, 1H); MS, *m/e* (rel intensity), 236 (M^+, 3), 204 (57), 175 (100).

Irradiation of ***3f***: A solution of **3f** (500 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 10 min and irradiated for 1 h. Removal of the solvent left a dark oil which was subjected to column chromatography on silica gel with 10% ether–benzene. The only component isolated was methyl 2,3-dihydro-5-hydroxy-6-methyl-3-propylbenzofuran-2-carboxylate **4f** (300 mg, 60%): IR (neat): 3440 and 1745 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.94 (t, J=7 Hz, 3H), 1.20—1.82 (m, 4H), 2.18 (s,1H), 3.46 (m, 1H), 3.77 (s, 3H), 4.54 (bs, 1H), 4.76 (d, J=5 Hz, 1H), 6.57 (s, 1H), and 6.63 (s, 1H); Found: C, 67.14; H, 7.50%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Irradiation of ***3g***: A solution of **3f** (532 mg, 2 mmol) in dry

benzene (200 ml) was purged with nitrogen for 20 min and irradiated for 2 h. The solvent was removed, and the residue was subjected to column chromatography on silica gel with 10% ether–chloroform. The product isolated was dimethyl 2,3-dihydro-5-hydroxy-6-methylbenzofuran-2,3-dicarboxylate **4g** (299 mg, 56%): 180—181 °C (dichloromethane–petroleum ether); IR (KBr): 3340, 1735, and 1695 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.17 (s, 3H), 3.77 (s, 3H), 3.80 (s, 3H), 4.41 (d, J=6 Hz, 1H), 5.32 (bs, 1H), 5.56 (d, J=6 Hz, 1H), 6.65 (s, 1H), and 6.78 (s, 1H); MS, *m/e* (rel intensity), 266 (M^+, 8), 264 (100); Found: C, 58.35; H, 5.24%. Calcd for $C_{13}H_{14}O_6$: C, 58.64; H, 5.30%.

Irradiation of ***3h***: A solution of **3h** (589 mg, 2 mmol) in dry benzene (300 ml) was purged with nitrogen for 10 min and irradiated for 1 h. The solution was concentrated, and the crude residue was purified by column chromatography on silica gel with 10% ether-chloroform to give methyl 2,3-dihydro-5-hydroxy-3-[2-(methoxycarbonyl)ethyl]-6-methylbenzofuran-2-carboxylate **4h** (300 mg, 51%): mp 136—137 °C (dichloromethane–petroleum ether); IR (KBr): 3480, 1750, and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.02 (m, 2H), 2.20 (s, 3H), 2.46 (t, J=7 Hz, 2H), 3.44—3.69 (m, 1H), 3.69 (s, 3H), 3.78 (s, 3H), 4.77 (d, J=6 Hz, 1H), 4.88 (s, 1H), 6.60 (s, 1H), and 6.67 (s, 1H); MS, *m/e* (rel intensity), 294 (M^+, 26), 174 (100); Found: C, 60.93; H, 6.13%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%.

Irradiation of ***3i***: A solution of **3i** (791 mg, 2 mmol) in dry benzene (300 ml) was purged with nitrogen for 15 min and irradiated for 1 h. The solvent was removed, and the residue was chromatographed on silica gel with 10% ether–chloroform to give methyl 2,3-dihydro-5-hydroxy-6-methyl-3-[3-(phthalimido)propyl]benzofuran-2-carboxylate **4i** (593 mg, 75%): mp 180—181 °C (dichloromethane–petroleum ether); IR (KBr): 3480, 1775, 1745, and 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.40—2.00 (m, 4H), 2.17 (s, 3H), 3.30—4.00 (m, 3H), 3.76 (s, 3H), 4.76 (d, J=5 Hz, 1H), 5.56 (bs, 1H), 6.63 (s, 2H), and 7.60—7.90 (m, 4H); MS, *m/e* (rel intensity), 395 (M^+, 61), 203 (100); Found: C, 66.50; H, 5.40; N, 3.56%. Calcd for $C_{22}H_{21}O_6N$: C, 66.82; H, 5.35; N, 3.54%.

Irradiation of ***3j***: A solution of **3j** (723 mg, 2 mmol) in dry benzene (300 ml) was purged with nitrogen for 10 min and irradiated for 1 h. Removal of the solvent left a crude oil which was purified by column chromatography on silica gel using 10% ether–chloroform. The only component isolated was identified as methyl 2,3-dihydro-5-hydroxy-6-methyl-3-[3-(trifluoroacetamido)propyl]benzofuran-2-carboxylate **4j** (499 mg, 69%): IR (neat): 3300 and 1740—1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.69 (m, 4H), 2.17 (s, 3H), 3.38 (m, 3H), 3.77 (s, 3H), 4.71 (d, J=5 Hz, 1H), 6.57 (s, 1H), 6.63 (s, 1H), and 6.95 (bs, 1H); MS, *m/e*, 361 (M^+); Found: C, 52.80; H, 5.16; N, 3.82%. Calcd for $C_{16}H_{18}O_5NF_3$: C, 53.18; H, 5.02; N, 3.88%.

Irradiation of ***3k***: A solution of **3k** (300 mg, 0.83 mmol) in dry benzene (150 ml) was purged with nitrogen for 5 min and irradiated for 1 h. The solution was concentrated. The residue was chromatographed on silica gel with 10% ether–chloroform to give methyl 2,3-dihydro-5-hydroxy-6-methyl-3-(phenoxycarbonyloxymethyl) benzofuran-2-carboxylate **4k** (117 mg, 39%): IR (neat): 3440 and 1750 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.17 (s, 3H), 3.79 (s, 3H), 3.90 (m, 1H), 4.35 (m, 2H), 5.02 (d, J=5.1 Hz, 1H), 5.55 (bs, 1H), 6.61 (s, 1H), 6.67 (s, 1H), and 7.08—7.43 (m, 5H); Found: C, 63.50; H, 5.20%. Calcd for $C_{19}H_{18}O_7$: C, 63.68; H, 5.06%.

Irradation of ***3l***: A solution of **3l** (416 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 20 min and irradiated for 1 h. Removal of the solvent left an oil which was subjected to chromatography on silica gel with 10% ether–benzene. The product obtained was methyl 2,3-dihydro-5-hydroxy-3-methylbenzofuran-2-carboxylate **4l** (250 mg, 60%): IR (neat): 3400 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.38 (d, J=7 Hz, 3H), 3.53 (m, 1H), 3.79 (s, 3H), 4.64 (d, J=7 Hz, 1H), and 6.60 (s, 3H and bs, 1H); Found: C, 63.19; H, 5.81%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

Irradiation of ***3m***: A solution of **3m** (574 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 20 min and irradiated for 1 h. Evaporation of the solvent gave a dark oil. The oil was chromatographed on silica gel to give methyl 6-bromo-2,3-dihydro-5-hydroxy-3-methylbenzofuran-2-carboxylate **4m** (178 mg, 31%): IR (neat): 3420 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.41 (d, J=7 Hz, 3H), 3.53 (m, 1H), 3.78 (s, 3H), 4.65 (d, J=7 Hz, 1H), 6.74 (s, 1H), and 6.90 (s, 1H); MS, *m/e* (rel intensity), 287 (M^+, 67); Found: C, 45.79; H, 3.95%. Calcd for $C_{11}H_{11}O_4Br$: C, 46.01; H, 3.86%.

Irradiation of ***3n***: A solution of **3n** (476 mg, 2 mmol) in dry benzene (200 ml) was purged with nitrogen for 10 min and irradiated for 1 h. Evaporation of the solvent and chromatographic separation of the crude oil by column chromatography on silica gel with 20% ether–benzene gave two compounds: The first fractions gave methyl 5-hydroxy-6-methoxy-3-methylbenzofuran-2-carboxylate (76 mg, 16%): mp 179—180 °C (dichloromethane–petroleum ether); IR (KBr): 3510 and 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.51 (s, 3H), 3.94 (s, 6H), 5.58 (s, 1H), 6.98 (s, 1H), and 7.04 (s, 1H), Found: C, 60.72; H, 5.24%. Calcd for $C_{12}H_{12}O_5$: C, 61.01; H, 5.12%. The second fractions gave methyl 2,3-dihydro-5-hydroxy-6-methoxy-3-methylbenzofuran-2-carboxylate **4n** (200 mg,42%): IR (neat): 3500 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.41 (d, J=7 Hz, 3H), 3.56 (m, 1H), 3.80 (s, 3H), 3.83 (s, 3H), 4.66 (d, J=7 Hz, 1H), 5.32 (s, 1H), 6.49 (s, 1H), and 6.68 (s, 1H); Found: C, 60.25; H, 5.87%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

Preparation of Quinones ***5*** *by Oxidative Cleavage*[6b] *of Photoproducts* ***4***. *Methyl 2-Hydroxy-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)propionate* ***5a***: A solution of **4a** (208 mg, 1 mmol) in 70% aq cetonitrile (5 ml) was treated with ceric ammonium nitrate 1.21 g, 2.2 mmol) in water (3 ml). The mixture was stirred at 0 °C for 30 min, poured into water (100 ml), and extracted with chloroform (2 × 20 ml). The extract was washed with water, dried, and evaporated to give **5a** (174 mg, 78%): IR (neat): 3500, 1735, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.03 (d, J=1.6 Hz, 3H), 2.69 (dd, J=8.5 and 15 Hz, 1H), 2.98 (dd, J=5 and 15 Hz, 1H), 3.81 (s, 3H), 4.18 (dd, J=5 and 8.5 Hz, 1H), 6.61 (q, J=1.6 Hz, 1H), and 6.71 (s, 1H); MS, *m/e* (rel intensity), 224 (M^+, 6), 206 (12), 164 (86), 136 (100); Found: C, 58.79; H, 5.50%. Calcd for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40%.

Methyl 2-Hydroxy-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-butyrate ***5b***: A solution of **4b** in aq acetonitrile was treated with CAN by the general procedure to give **5b** (80%): mp 104.5—105.5 °C (dichloromethane–petroleum ether); IR (KBr): 3480, 1725, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.28 (d, J=7 Hz, 3H), 2.04 (d, J=1.6 Hz, 3H), 3.00 (bs, 1H), 3.46 (dq, J=7 and 4 Hz, 1H), 3.76 (s, 3H), 4.30 (bs, 1H), 6.60 (q, J=1.6 Hz, 1H), and 6.71 (s, 1H); Found: C, 60.54; H, 6.12%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

Methyl 2-Hydroxy-2-methyl-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)propionate ***5c***: A solution of **4c** in aq acetonitrile was treated with CAN by the same method to give **5c** (67%): mp 78 °C (petroleum ether); IR (KBr): 3480, 1720, and 1655 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.47 (s, 3H), 2.04 (d, J=1.6 Hz, 3H), 2.70 (d, J=13.5 Hz, 1H), 2.97 (d, J=13.5 Hz, 1H), 3.34 (s, 1H), 3.78 (s, 3H), 6.59 (q, J=1.6 Hz, 1H), and 6.70 (s, 1H); Found: C, 60.74; H. 5.98%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

Methyl 2-Hydroxy-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-

pentanoate ***5d***: A solution of **4d** in aq acetonitrile was treated with CAN by the usual method to give **5d** (97%): mp 97—98 °C (petroleum ether); IR (KBr): 3420, 1720, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.94 (t, J=7.5 Hz, 3H), 1.57—1.94 (m, 2H), 2.04 (d, J=1.6 Hz, 3H), 2.98 (d, J=7.6 Hz, 1H), 3.27 (dt, J=3.5 and 7 Hz, 1H), 3.74 (s, 3H), 4.36 (dd, J=3.5 and 7.6 Hz, 1H), 6.58 (q, J=1.6 Hz, 1H), and 6.71 (s, 1H); Found: C, 61.64; H, 6.38%. Calcd for $C_{13}H_{16}O_5$: C, 61.89; H, 6.39%.

Methyl 2-Hydroxy-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-hexanoates ***5f***: A solution of **4f** in aq acetonitrile was treated with CAN by the usual manner to give **5f** (80%): mp 75—76 °C; IR (KBr): 3470, 1720, 1650, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.90 (t, J=7 Hz, 3H), 1.31 (m, 2H), 1.64 (m, 2H), 2.02 (d, J=1.6 Hz, 3H), 2.87 (d, J=7 Hz, 1H), 3.31 (m, 1H), 3.92 (s, 3H), 4.31 (dd, J=3.5 and 7 Hz, 1H), 6.55 (q, J=1.6 Hz, 1H), and 6.68 (s, 1H); Found: C, 62.87; H, 6.73%. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%.

Dimethyl 2-Hydroxy-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-succinate ***5g***: A solution of **4g** in aq acetonitrile was treated with CAN by the general procedure to give **5g** (50%): IR (neat): 3470, 1735, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.03 (d, J=1.6 Hz, 3H), 3.75 (s, 6H and 1H), 4.32 (d, J=4.2 Hz, 1H), 4.86 (d, J=4.2 Hz, 1H), 6.62 (q, J=1.6 Hz, 1H), and 6.87 (s, 1H); Found: C, 55.03; H, 5.23%. Calcd for $C_{13}H_{14}O_7$: C, 55.32; H, 5.00%.

Dimethyl 2-Hydroxy-3-(4-methyl-3,6-dioxo-1,4-cyclohexadienyl)-hexanedioate ***5h***: A solution of **4h** in aq acetonitrile was treated with CAN according to the general method to give **5h** (98%): IR (neat): 3460, 1730, and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.04 (d, J=1.6 Hz, 3H), 2.00—2.42 (m, 4H), 3.07 (bd, J=8 Hz, 1H), 3.38 (m, 1H), 3.68 (s, 3H), 3.37 (s, 3H), 4.35 (bs, 1H), 6.59 (q, J=1.6 Hz, 1H), and 6.74 (s, 1H); Found: C, 58.30; H, 6.01%. Calcd for $C_{15}H_{18}O_7$: C, 58.06; H, 5.85%.

Acetylation of Photoproducts ***4b***, ***4d***, ***4f***, *and* ***4i***. *Methyl 5-Acetoxy-2,3-dihydro-3,6-dimethylbenzofuran-2-carboxylate* ***6b***: The compound **4b** (111 mg, 0.5 mmol) was acetylated with acetic anhydride (5 ml) in the presence of pyridine (1 ml) to give **6b** (80%): mp 86—87 °C (petroleum ether); IR (KBr): 1750 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.45 (d, J=7 Hz, 3H), 2.13 (s, 3H), 2.30 (s, 3H), 3.64 (m, 1H), 3.83 (s, 3H), 4.73 (d, J=7.2 Hz, 1H), 6.75 (s, 1H), and 6.78 (s, 1H). Found: C, 63.50; H, 6.04%. Calcd for $C_{14}H_{16}O_5$: C, 63.62; H, 6.10%.

Methyl 5-Acetoxy-3-ethyl-2,3-dihydro-6-methylbenzofuran-2-carboxylate ***6d***: Acetylation of **4d** as described above gave **6d** (85%): mp 98—98.5 °C (dichloromethane–petroleum ether); IR (KBr): 1760 and 1745 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.01 (t, J=7.5 Hz, 3H), 1.78 (m, 2H), 2.13 (s, 3H), 2.31 (s, 3H), 3.50 (dt, J=5.5 and 7 Hz, 1H), 3.80 (s, 3H), 4.84 (d, J=5.5 Hz, 1H), 6.77 (s, 1H), and 6.82 (s, 1H); Found: C, 64.79; H, 6.49%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Methyl 5-Acetoxy-2,3-dihydro-6-methyl-3-propylbenzofuran-2-carboxylate ***6f***: The compound **4f** was treated with acetic anhydride–pyridine to give **6f** (82%): IR (neat): 1760 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.96 (t, J=7 Hz, 3H), 1.06—1.84 (m, 4H), 2.08 (s, 3H), 2.21 (s, 3H), 3.46 (m, 1H), 3.72 (s, 3H), 4.67 (d, J=5 Hz, 1H), 6.59 (s, 1H), and 6.65 (s, 1H); MS, *m/e* (rel intensity), 292 (M^+, 4), 250 (100). Found: C, 65.59; H, 6.97%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

Methyl 5-Acetoxy-2,3-dihydro-6-methyl-3-[3-(phthalimido)-propyl]benzofuran-2-carboxylate ***6i***: The title compound was prepared from **4i** by acetylation with acetic anhydride in pyridine (77%): mp 128—129 °C (methanol); IR (KBr): 1760 and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.40—2.00 (m, 4H), 2.10 (s, 3H), 2.28 (s, 3H), 3.47—4.00 (m, 3H), 3.76 (s, 3H), 4.81 (d, J=5 Hz, 1H), 6.72 (s, 1H), 6.80 (s, 1H), and 6.80 (s, 1H), and 7.60—7.90 (m, 4H); Found: C, 65.62; H, 5.24; N, 3.11%. Calcd for $C_{24}H_{23}O_7N$: C, 65.89; H, 5.30; N, 3.20%.

Methyl 2-Acetoxy-3-(2,5-diacetoxy-4-methylphenyl)hexanoate ***7***: A solution of **5f** (133 mg, 0.5 mmol) in ether (50 ml) was reduced with excess aq sodium dithionite to give methyl 2-hydroxy-3-(2,5-dihydroxy-4-methylphenyl)hexanoate, which was acetylated with acetic anhydride (2 ml) in the presence of pyridine (0.1 ml) to afford **7** (118 mg, 60%): IR (neat): 1760 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.86 (t, J=7 Hz, 3H), 1.27 (m, 2H), 1.64 (m, 2H), 2.10 (s, 3H), 2.16 (s, 3H), 2.33 (s, 6H), 3.46 (m, 1H), 3.65 (s, 3H), 5.18 (d, J=5 Hz, 1H), 6.96 (s, 1H), and 7.09 (s, 1H); MS, *m/e* (rel intensity), 394 (M^+, 1), 352 (38), and 310 (100); Found: C, 60.66; H, 6.87%. Calcd for $C_{20}H_{26}O_8$: C, 60.90; H, 6.64%.

The author is grateful to Professor Kazuhiro Maruyama for his invaluable suggestions to this work and his continuous encouragement.

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received December 3, 1981)

The isolation and structure elucidation of the title spirovetivane sesquiterpenes, stress metabolites produced in diseased potato tubers, are described.

In recent preliminary communications,[2,3] we reported the isolation and structure of three spirovetivane sesquiterpenes named epilubimin (**1**), epioxylubimin (**2**), and isolubimin (**3**), stress metabolites produced in diseased potato tubers. In the present paper we describe details of the modified isolation procedure and structure elucidation of these metabolites.

Isolation. The metabolites were isolated from tuber tissues of potatoes (Rishiri, *Solanum tuberosum*×*S. demissum*) infected with an incompatible race of *Phytophthora infestans* as follows. Neutral chloroform extracts[4] (83 g), obtained from the diseased potato tubers (300 kg), were roughly separated into five fractions (I—V) by chromatography. The fraction II (8.5 g) was again separated by chromatography to yield a "lubimin-rich" fraction (690 mg), containing epilubimin (**1**), isolubimin (**3**), and oxyglutinosone[5] (**4**) beside lubimin[6] (**5**) as its major component. This fraction was further separated by chromatography into "epilubimin-rich" and "oxyglutinosone and isolubimin-rich" fractions. Preparative TLC of the former gave **1** (59 mg), oil, $[\alpha]_D$ 0°, in pure state, and acetylation of the latter followed by preparative TLC afforded **4** and **3** as the respective acetates (**4a**)[5] (43 mg) and (**3a**) (37 mg), mp 49—50 °C, $[\alpha]_D$ +26.3°. The latter acetate (**3a**) was hydrolyzed smoothly to give **3**, oil, $[\alpha]_D$ +34.4°, in pure state. On the other hand, the fraction IV (5.0 g), including oxylubimin[6] (**6**) as its major constituent, contained two other metabolites, lubiminol[6] (**7**) (=dihydrolubimin) and epioxylubimin (**2**). This was separated and purified by repeated chromatography and recrystallization to give **2** (294 mg), mp 123—124 °C, $[\alpha]_D$ −12.1°, in pure state.

8b 10αH, $R^1=H$, $R^2=Ac$

Epilubimin. Epilubimin (**1**) had the same molecular formula $C_{15}H_{24}O_2$ [*m/e* 236 (M^+)] as **5** and gave its monoacetate (**1a**), oil, $[\alpha]_D$ 0°. Hydride reduction of **1** afforded its dihydro derivative, epilubiminol[7,8] (**8**), mp 135—136 °C, which also formed its diacetate (**8a**), oil. The mass, IR, and ^1H and ^{13}C NMR spectra of these compounds indicated the presence of the following structural units: $CH_3\dot{C}H$– [**1**, δ 0.94 (3H, d, J=6.5 Hz); **8**, 0.85 (3H, d, J=7 Hz)]: CH_2=C(CH_3)– [**1**, IR, 1640 and 891 cm^{-1}; δ 1.72 (3H, s) and 4.64(2H, s); **8**, IR, 1640 and 891 cm^{-1}; δ 1.68 (3H, s) and 4.64 (2H, s)]: –CHO [**1**, IR, 1715 cm^{-1}; δ 9.81 (1H, s),; **1a**, IR, no absorption near 3400 cm^{-1}; δ near 9.8]: –CH(OH)– [**1**, IR, 3300 cm^{-1}; δ 3.69 (1H, br, W_H=25 Hz); **1a**, IR, 1740 cm^{-1}; δ 4.64 (1H, br, W_H=25 Hz)]: a quaternary carbon atom (■)† of spiro type (**8**, δ 46.2, in Table 1). Addition of 0.25 mol equiv of the shift reagent Eu(dpm)$_3$ to the chloroform-*d* solution of **1** effected down-field shift of the ^1H NMR signals, leading to separation of most of the protons (Fig. 1), and spin-decoupling studies on the spectrum elucidated the following structural moiety: (■ ?)–CH(CH_3)–CH_2–CH(OH)–CH_2–CH(CHO ?)–(■). All the results strongly suggested that **1** would be an epimer (with an axial formyl group) of **5** (with an equatorial one). Compound **1** was treated with base under mild conditions to give a mixture of **1** and **5**, from which **5**, oil, $[\alpha]_D$ +31°, identical with natural lubimin, oil, $[\alpha]_D$ +36°, in the mass, IR, and ^1H NMR spectra, was isolated in 60% yield. Hence epilubimin is represented by formula **1**.

Epioxylubimin. Epioxylubimin (**2**) had the same molecular formula $C_{15}H_{24}O_3$ as **6**[6] and displayed the mass spectrum similar closely to that of **6**. The IR, and ^1H and ^{13}C spectra (see Experimental and Table 1) indicated the presence of the following structural units: $CH_3\dot{C}H$–, CH_2=C(CH_3)–, two –CH(OH)–, –CH(CHO)–, and (■). While the ^1H NMR spectrum differed in multiplicity of the formyl methine protons from that of **6** [**2**, δ 9.87 (1H, s) and 2.41 (1H, t, J=4 Hz); **6**,[6] δ 9.80 (1H, d, J=2.5 Hz) and 2.58 (1H, ddd, J=10, 4, and 2.5 Hz)], it also resembled as a whole closely to that of **6**. These facts, combined with the coocurrence of **1** and **5**, suggested that **2** would probably be a 10-epimer of **6**. Indeed, **2**, when treated with base, gave a mixture of **2** and **6** in 92% yield, from which

† The abbreviation denotes a carbon atom bearing no hydrogen atom.

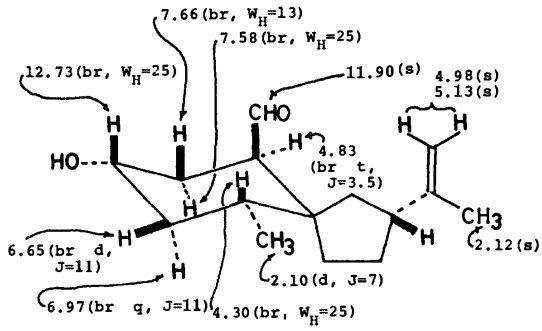

Fig. 1.

Table 1. The ^{13}C NMR spectra of epilubiminol (**8**), epioxylubimin (**2**), and isolubimin (**3**)[a]

Carbon No.	Chemical shift δ		
	8[b]	**2**	**3**[b]
1	42.1(42.1)	42.8	42.4(42.4)

14	17.1(17.2)	11.7	16.7(16.7)
15	61.2(62.1)	204.7	64.2(64.3)

a) Measured in chloroform-*d* at 25.2 MHz. b) The figures in the parentheses denote the chemical shifts reported by Stoessl *et al.*, *cf.*, Ref. 8.

6, mp 83—85 °C, $[\alpha]_D$ +52.6°, identical with natural oxylubimin, mp 85—86 °C, $[\alpha]_D$ +55.6°, was isolated in 60% yield.

Isolubimin and Epiisolubimin. Isolubimin (**3**), with the same molecular formula $C_{15}H_{24}O_2$ as that of **1**, exhibited the IR, ^1H and ^{13}C NMR spectra (Experimental and Tables 1 and 2), indicating the presence of the following structural units: CH_3CH–, CH_2=C(CH_3)–, $HOCH_2$–, O=C–, and (■). The structure of **3** was elucidated by correlation with **5** as follows. Lubiminol[6] (**7**), derived from **5**, was converted by treatment with acetic anhydride and pyridine in benzene into its 15-*O*-monoacetate (**7a**), oil, in 70% yield, which on Collins oxidation gave keto acetate in 60% yield, which was identified as acetylisolubimin (**3a**), in all respects. The same structure (**3**) had been proposed for "isolubimin" isolated from infected potato tubers independently by Kalan,[9] Stoessl,[8] and coworkers. In fact, the ^{13}C NMR spectrum of **3** was indistinguishable from that of Stoessl's isolubimin (Table 1).[10] However, the ^1H NMR spectrum appeared to be different from that reported by Kalan and Osman[9] (Table 2). Thus we prepared epiisolubimin (**9**), a 10-epimer of **3**, from epilbiuminol (**8**); namely, **8** underwent partial acetylation under the aforementioned conditions to give its 15-*O*-monoacetate (**8b**), $[\alpha]_D$ −9.0°, which on Collins oxidation afforded keto acetate (**9a**), oil, $[\alpha]_D$ −2.7°, isomeric from **3a**, in 60% yield. Interestingly, epiisolubimin (**9**), oil, obtained by hydrolysis of **9a**, exhibited the ^1H NMR spectrum, which resembled closely to that of "isolubimin" reported by Kalan and Osman (Table 2)[11].

Experimental

All the melting points were uncorrected. The purity of each compound was always checked by TLC over silica gel (Wakogel B-5 or Merck GF-254) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid, iodine, and/or concd sulfuric acid. The optical rotations, UV, IR, and NMR (100 MHz) were measured in ethanol, in ethanol, in liquid state (oil) or in Nujol (crystals), and in chloroform-*d*, respectively, unless otherwise stated. The preparative TLC was carried out over silica gel (Merck GF-254), and the column chromatography over silca gel (Mallinckrodt AR-100) or silicic acid (Kiesel gel 60), respectively.

Isolation of Epilubimin (1), Epioxylubimin (2), and Isolubimin (3). The neutral chloroform extracts (83 g), corresponding to "neutral syrup" described in the section of "Isolation of rishitin,"[4] obtained from the diseased potato tubers (300 kg), were separated roughly into five fractions I—V by column chromatography over silica gel (1.8 kg), benzene, benzene–ethyl acetate (1 : 1), ether, ethyl acetate, and methanol being used as eluents, successively.

Fraction II (8.5 g), yellow oil, corresponding to "fraction E,"[4] was separated by chromatography over silica gel (100 g). Fractions (5.9 g) eluted with hexane–ethyl acetate (100 : 1) contained sterols as main components, which were not further examined. Successive elution with hexane–ethyl acetate (3 : 1) gave a "lubimin-rich" fraction (688 mg), which contained epilubimin (**1**), isolubimin (**3**), and oxyglutinosone (**4**) besides lubimin (**5**). This fraction was further separated into five fractions with hexane–ethyl acetate (5 : 1) as an eluent. Preparative TLC of the second fraction afforded epilubimin

Table 2. Comparison of the ^1H NMR spectra of isolubimin (**3**) and epiisolubimin (**9**) with that of Kalan's isolubimin (K–I)[a]

Proton	Chemical shift (δ) and splitting pattern (Hz)		
	3	**9**	K–I[b]
14-H	0.99(3H, d, J=7)	0.93(3H, d, J=6)	0.90(3H, d)
13-H	1.73(3H, s)	1.75(3H, s)	1.69(3H, s)
15-H	3.41(1H, dd, J=11, 8)	3.52(1H, dd, J=10, 8)	3.70(2H, m)
	3.85(1H, dd, J=11, 3)	3.79(1H, dd, J=10, 3)

(**1**) (59 mg), oil, $[\alpha]_D$ 0°, in pure state, showing a single spot on TLC; MS, *m/e* 236 (M^+), 218, 193, 175, 161, 149, 147, 145, 119, 107 (base), and 93; IR, 3300, 2730, 1715, 1640, and 891 cm^{-1}; ^1H NMR, δ 0.94 (3H, d, J=6.5 Hz), 1.72 (3H, s), 3.69 (1H, br, W_H=25 Hz), 4.64 (2H, br s), and 9.81 (1H, s). The third fraction, showing a single spot on TLC, was identified as slightly crude lubimin (**5**) (450 mg). The fifth, most polar fraction (160 mg) was an inseparable mixture of isolubimin and oxyglutinosone and treated with acetic anhydride and pyridine at room temperature overnight. The resulting acetate mixture (167 mg) was separated into two components by column chromatography over silica gel (4.0 g) with hexane–ethyl acetate (10 : 1) to give isolubimin acetate (**3a**) (37 mg), mp 49—50 °C, $[\alpha]_D$ +26.3°; MS, *m/e* 278 (M^+), 218, 203, 175, 146, 133, 107, 93, and 43 (base); IR, 1745, 1725, 1645, 1240, 1040, and 885 cm^{-1}; ^1H NMR, δ 1.00 (3H, d, J=6 Hz), 1.75 (3H, s), 2.04 (3H, s), 3.87 (1H, dd, J=11 and 9), 4.41 (1H, dd, J=11 and 3 Hz), and 4.73 (2H, s), and oxyglutinosone acetate[5] (**4a**) (43 mg) in pure state. The former (**3a**) was hydrolyzed to give isolubimin (**3**) as follows. A solution of **3a** (11 mg) in 50% aqueous methanol (2 ml) containing potassium carbonate (20 mg) was stirred at room temperature for 1 h under nitrogen. After removal of the solvent, the mixture was extracted with ether (25 ml), and the ether solution was washed with saturated brine (10 ml), dried and evaporated to leave an oily residue, which was purified by chromatography over silica gel with hexane–ethyl acetate (1 : 1) to give isolubimin (**3**) (8 mg) in pure state, oil, $[\alpha]_D$ +34.4°; MS, *m/e* 236 (M^+), 218, 205, 193, 175, 165, 149, 147, 135, 108 (base), and 93; IR, 3300, 3080, 1725, 1645, and 889 cm^{-1}; ^1H and ^{13}C NMR, in Tables 2 and 1.

Fraction IV (5.0 g), corresponding to "fraction H,"[4] was separated by column chromatography over silica gel (200 g), benzene and benzene–ethyl acetate mixtures being used as eluents. Fractions eluted with benzene–ethyl acetate (5 : 1) yielded a crystalline substance, which was recrystallized from diisopropyl ether to give epioxylubimin (**2**) (294 mg) in pure state, mp 123—124 °C, $[\alpha]_D$ −12.1°; MS, *m/e* 252 (M^+), 234, 219, 209, 191, 177, 165, 136, 135, 121, 107, and 93 (base); IR, 3390, 1720, 1640, and 893 cm^{-1}; ^1H NMR, δ 1.06 (3H, d, J=7Hz), 1.75 (3H, s), 2.411 H, d, J=4 Hz, 10-H), 3.08 (1H, t, J=9 Hz, 3-H), 3.49 (1H, dt, J=4 and 9 Hz, 2-H), 4.77 (2H, s) and 9.87 (1H, s): ^{13}C NMR, in Table 1. The follwing fractions eluted with benzene–ethyl acetate(3 : 1)gave oxylubimin[6] (**6**) (415 mg), mp 85—86 °C, $[\alpha]_D$ +55.6°. The more polar fractions eluted with benzene–ethyl acetate (2 : 1) afforded crystalline material (112 mg), showing a single spot, which on recrystallization from ether afforded lubiminol[6] (**7**) (dihydrolubimin), mp 129—130 °C, $[\alpha]_D$ +33°.

*Acetylepilubimin (**1a**).* Epilubimin (**1**) (25 mg) was treated with acetic anhydride (0.5 ml) and pyridine (0.5 ml) at room temperature for 14 h. The mixture was diluted with water and extracted with ether. The ether solution was washed with 1 M (1 M=1 mol dm^{-3}) hydrochloric acid, 5% aqueous sodium hydrogencarbonate, and saturated brine, dried, and evaporated to yield **1a** (26 mg), showing a single spot on TLC, oil, $[\alpha]_D$ 0°; MS, *m/e* 278 (M^+), 234, 218, 149 (base), 147, 107, 105, 93, and 91; IR, 1740, 1720, 1642, 1240, 1030, and 888 cm^{-1}; ^1H NMR, δ 0.96 (3H, d, J=7 Hz, 14-H), 1.71 and 1.95 (each 3H, s, 13-H and $OCOCH_3$), 4.64 (2H, s, 12-H), 4.64 (1H, br m, W_H=25 Hz, 2-H), and 9.78 (1H, s, 15-H).

*Epilubiminol (**8**) and Its Diacetate (**8a**).* A solution of **1** (20 mg) in methanol (2 ml) was stirred with sodium borohydride (50 mg) at room temperature for 6 h under nitrogen. After being diluted with water (10 ml), the mixture was extracted with ether. The ether solution was worked up as usual to give **8** (16 mg), mp 135—136 °C (from ether), $[\alpha]_D$ +3.4°; MS, *m/e* 238 (M^+), 220, 202, 177, 107, and 93; IR, 3400, 1640, 1030, 1010, and 891 cm^{-1}; ^1H NMR, δ 0.85 (3H, d, J=7 Hz, 14-H), 1.68 (3H, s, 13-H), 6.75 (3H, br m, 2- and 15-H), and 4.64 (2H, s, 12-H); ^{13}C NMR, in Table 1.

Compound **8** (25 mg) was treated with acetic anhydride (0.5 ml) and pyridine (0.5 ml) at room temperature for 16 h. The reaction mixture was worked up as usual to leave an oily residue (28 mg), which was purified by preparative TLC to give **8a** (22 mg), oil; MS, *m/e* 322 (M^+), 279, 262, 202 (base), 159, 107, and 93; IR, 1742, 1639, 1244, and 888 cm^{-1}; ^1H NMR, δ 0.89 (3H, d, J=7 Hz, 14-H), 1.69 (3H, s, 13-H), 1.90 and 1.97 (each 3H, s, $OCOCH_3$), 4.04 (2H, br m, W_H= 26 Hz, 15-H), 4.62 (2H, s, 12-H), and 4.64 (1H, br m, W_H= 25 Hz, 2-H); ^{13}C NMR, δ 16.8 and 20.9 (each q), 30.4, 31.1, and 31.5 (each t), 35.2 and 35.2 (each d), 36.0 and 41.3 (each t), 46.2 (s), 47.5 and 69.1(each d), 63.9 and 108.0(each t), and 147.3 (s).

*Epimerization of Epilubimin (**1**) into Lubimin (**5**) and That of Epioxylubimin (**2**) into Oxylubimin (**6**).* A solution of **1** (10 mg) in 5% methanolic potassium hydroxide (5 ml) was stirred at room temperature for 30 min under nitrogen. The reaction mixture was diluted with water (10 ml) and extracted repeatedly with ether (total 50 ml). The combined ether extracts were worked up as usual to leave an oily residue (11 mg), which was separated by column chromatography over silica gel. Elution with benzene–ether (5 : 1) gave the unchanged starting material (**1**) (3 mg) and its 10-epimer (**5**) (6 mg), oil, $[\alpha]_D$ +31°, which was identical with natural lubimin,[6] oil, $[\alpha]_D$ +36°, in the mass, IR, and ^1H NMR spectra.

Compound **2** (26 mg) was treated in the same manner as described above. The mixture, after being worked up as usual, left to oily substance (23 mg), which was separated by column chromatography over silica gal. Elution with benzene–ethyl acetate (1 : 1) gave the starting material (**2**) (6 mg) and its 10-epimer (**6**) (14 mg), mp 85—86 °C (from diisopropyl ether), $[\alpha]_D$ +52.6°, which was identical with natural oxylubimin,[6] mp 85—86 °C, $[\alpha]_D$ +55.6°, in the mass, IR, and ^1H NMR spectra.

*Conversion of Lubimin (**5**) into Isolubimin (**3**).* A solution of lubiminol[6] (**7**) (50 mg), obtained from **5**, in benzene (1 ml) was stirred with acetic anhydride (42 μl) and pyridine (0.2 ml) at room temperature for 5 h. The reaction mixture was mixed with methanol (1 ml) under cooling, stirred at room temperature for 10 min, and evaporated to leave an oily residue, which was extracted with ether (30 ml). The ether solution was worked up as usual to give an oily mixture (53 mg), which was separated into three fractions by chromatography over silica gel with benzene–ethyl acetate (1 : 1). Middle fractions gave crude 15-*O*-monoacetate (**7a**) (37 mg), showing a single spot on TLC, oil; ^1H NMR, δ 0.92 (3H, d, J=7 Hz, 14-H), 1.73 and 2.06 (each 3H, 13-H and $OCOCH_3$), 3.70 (1H, br, W_H=25 Hz, 2-H), 3.79 (1H, dd, J=11 and 9 Hz, 15-H), 4.35 (1H, dd, J=11 and 4 Hz), and 4.65(2H, s, 12-H). This was used for the next reaction without further characterization.

A solution of **7a** (37 mg) in dichloromethane (1 ml) was stirred with chromiun(VI) oxide (92 mg) and pyridine (68 μl) at room temperature for 30 min. The reaction mixture was mixed with ether (50 ml) and filtered. The filtrate was washed with 5% aqueous sodium hydrogencarbonate (15 ml) and saturated brine (15 ml), dried, and evaporated to yield oily substance (35 mg), which was purified by preparative TLC to give **3a** (28 mg), mp 45—48 °C, $[\alpha]_D$ +20.0°, identical with natural isolubimin acetate, mp 49—50 °C, $[\alpha]_D$ +26.3°, in the mass, IR, and ^1H NMR spectra.

Conversion of Epilubimin (1) into Epiisolubimin (9). A solution of epilubiminol (**8**) (19 mg), obtained from **1**, in benzene (20 μl) was treated with acetic anhydride (21 μl) and pyridine (60 μl) for 3 h at room temperature under stirring. The reaction mixture was mixed with methanol, stirred for 10 min, and evaporated to leave an oily residue, which was extracted with ether (30 ml). The ether solution was worked up as usual to give a colorless oil (22 mg), showing three spots on TLC, which was separated by column chromatography over silica gel. Elution with hexane–ethyl acetate (1 : 1) afforded diacetylepilubiminol (**8a**) (5 mg), the starting material (**8**) (2 mg), and 15-*O*-acetylepilubiminol (**8b**) (12 mg), oil, $[\alpha]_D$ −9.0°; MS, *m/e* 280 (M^+), 262, 220, 202, 187, 107 (base); IR, 3600, 3440, 3080, 1730, 1645, 1254, 1032, 1020, and 890 cm^{-1}; ^1H NMR, δ 0.89 (3H, d, J=6 Hz, 14-H), 1.71 (3H, s, 13-H), 2.05 (3H, s, $OCOCH_3$), 3.86 (1H, m, W_H= 20 Hz, 2-H), 4.12 (2H, d, J=7 Hz, 15-H), and 4.68 (2H, s, 12-H).

To a solution of pyridine (43 μl) and dichloromethane (1 ml) was added chromium(VI) oxide (30 mg), and the mixture was stirred for 15 min at room temperature under nitrogen. A solution of **8b** (12 mg) in dichloromethane (0.5 ml) was added into the above deep-red colored reaction mixture. After being stirred for 15 min, the mixture was diluted with ether (30 ml) and filtered. The ethereal filtrate was worked up as usual to leave an oily residue (12 mg), showing two spots on TLC, which was purified by preparative TLC over silica gel with hexane–ethyl acetate (10 : 1) to give the unreacted alcohol (**8b**) (3 mg) and acetylepiisolubimin (**9a**) (7 mg), oil, $[\alpha]_D$ −2.7°; MS, *m/e* 278 (M^+), 236, 218, 203 ,107, 105, 93, and 91; IR, 3090, 1735, 1712, 1646, 1238, 1034, and 895 cm^{-1}; ^1H NMR, δ 0.95 (3H, d, J=6 Hz, 14-H), 1.75 (3H, s, 13-H), 2.03 (3H, s, $OCOCH_3$), 3.86 (1H, dd, J=9 and 11 Hz, 15-H), 4.27 (1H, dd, J=3 and 11 Hz, 15-H), and 4.37 (2H, s, 12-H).

A solution of **9a** (5 mg) in methanol (1 ml) was stirred with potassium carbonate (5 mg) at room temperature for 1.5 h under nitrogen. The reaction mixture was diluted with ether (30 ml) and washed with water (10 ml) and saturated brine (10 ml), dried, and evaporated to give **9** (3 mg), oil; MS, *m/e* 236 (M^+), 218, 205, 149, 135, 107, 105 (base), 93, and 91; ^1H NMR, in Table 2.

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received December 3, 1981)

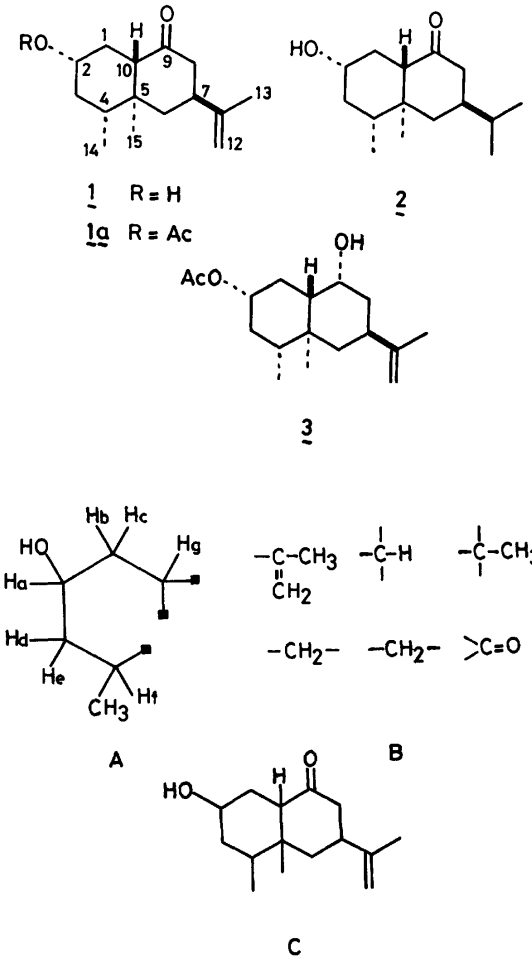
The isolation and structure elucidation of the title valencane sesquiterpene, a stress metabolite produced in diseased potato tubers, are described.

In a recent communication,[2)] we reported the isolation and structure of a valencane sesquiterpene named rishitinone (**1**), a stress metabolite produced in diseased potato tubers. In view of the fact that all stress metabolites so far isolated from the Family Solanaceae differ in planar structure and/or stereochemistry from usual naturally occurring sesquiterpenes, the sesquiterpene (**1**) with the valencane skeleton stands unique on biogenetic grounds as stress compounds.[3)] In the present paper we describe details of the isolation and structure elucidation of the compound.

Isolation. The metabolite was isolated from tuber tissues of potatoes (Rishiri, *Solanum tuberosum*×*S. demissum*) infected with an incompatible race of *Phytophthora infestans* as follows. Neutral chloroform extracts[4)] (83 g), obtained from the diseased potato tubers (300 kg), were separated as described previously[1)] to give "rishitin-rich" fractions (Fraction III,[1)] 5.5 g), which on acetylation followed by chromatography over silica gel afforded a semi-crystalline mixture of acetates. Fractional recrystallization of the mixture gave pure rishitin diacetate[4)] (3.3 g), mp 65—67 °C, and crude oily rishitinone acetate (**1a**) (0.11 g), which was purified by chromatography to yield **1a** (68 mg), oil, $[\alpha]_D$ −2.4°, in pure state. The acetate (**1a**) was then hydrolyzed smoothly to give rishitinone (**1**), mp 72—75 °C, $[\alpha]_D$ +10.1°.

Planar Structure. Rishitinone (**1**) was analyzed for $C_{15}H_{24}O_2$ (*m/e* 236, M^+) and converted by hydrogenation over palladium into dihydrorishitinone (**2**), mp 80—82 °C, $[\alpha]_D$ +7.2°, and by acetylation into the acetate (**1a**). The latter (**1a**) was reduced with sodium borohydride to give hydroxy acetate (**3**), $C_{17}H_{28}O_3$ (*m/e* 280, M^+), mp 96—98 °C, $[\alpha]_D$ −6.9°, as a sole product (90%). The IR and ^{1}H NMR spectra of these compounds indicated the presence of the following structural units: CH_3-(■)-[5)] [**1**, δ 0.76 (3H, s)]: $CH_3\overset{|}{C}H$- [**1**, δ 0.84 (3H, d, J=7 Hz)]: CH_2-C(CH_3)- [**1**, IR, 1651 and 900 cm^{-1}; δ 1.76 (3H, s) and 4.77 (2H, br s); **2**, IR, 1388 and 1372 cm^{-1}, δ 0.91 (6H, d, J=6 Hz)]: -C(=O)- [**1**, IR, 1710 cm^{-1}]: -CH(OH)- [**1**, IR, 3500 cm^{-1}; δ 3.65 (1H, br m, W_H=25 Hz); **1a**, IR, 1739 and 1248 cm^{-1}; δ 2.02 (3H, s) and 4.77 (1H, br m, W_H=25 Hz)]. The ^{13}C NMR spectra of **1**, obtained under proton-noise decoupled and single-frequency off-resonance decoupled conditions, provided additional information of the other carbon atoms, four $-CH_2$- [δ 30.2, 39.3, 42.8, and 46.0 (each t)] and two -CH- [δ 41.3 or 41.5 and 56.1 (each d)], indicating that the ketone (**1**) possesses a bicyclic skeleton.

The ^{1}H NMR spectra of **1** in the presence of the shift reagent Eu(dpm)$_3$ (0.2 and 0.4 mol equiv.) led to downfield shift of all the signals and revealed one-proton signals (W_H=25 Hz) at δ 6.80 and 10.50 in the respective spectra, which were reasonably assigned to the proton on the carbon atom bearing the hydroxyl group. The spectra, coupled with spin-decoupling studies (Table 1), strongly suggested that the ketone (**1**) would probably involve partial formula A. In view of the remaining nine carbon units (formula B) deduced from the afore-mentioned spectra, specially from the ^{13}C NMR spectra [only two (■) at δ 40.7 and 211.1, and one -CH- and one $-CH_2$- at low field, δ 69.5 and 46.0], formula C was presented as one of the most plausible planar structures for **1**. The following comments on the stereochemistry are based on the formula (C).



1 R = H
1a R = Ac

6 **7**

methyl group and 10β-hydrogen atom was deduced from the following facts: (i) dihydrorishitinone (**2**) showed a typical positive Cotton effect with a=+25.7, and the value was in good accord with that reported[6] (a=+26) for ketone **4**, which had been derived from natural (−)-aristolochene[6] (**5**), a valencane sesquiterpene with the established configurations. (ii) Angular methyl protons of *trans*-10-methyl-1-decalones (**6**) are usually observed at higher fields than the corresponding protons of the *cis*-analogues (**7**): *trans*, δ 0.7—0.9; *cis*, δ 1.0—1.2.[7] The observed chemical shifts (δ 0.76, 0.73, and 0.67) of **1**, **1a**, and **2** were in good agreement with those of the *trans*-fused model compounds (**6**).

The hydroxyl at C-2 and methyl groups at C-4 were assigned equatorial conformation and hence α-configuration on the basis of the spectral data. The signal multiplicities in Table 1 (*cf.*, formula A) revealed the following coupling constants: $J_{g\text{-}b}$, $J_{g\text{-}c}$, $J_{a\text{-}b}$, $J_{b\text{-}c}$, and $J_{f\text{-}e}$ (or $J_{f\text{-}d}$)=4, 12, 4, 12, and 11 Hz, respectively. Since the ring A must take a chair conformation, these values, combined with the large half-width value (25 Hz) of the signal due to the C-2 proton (Ha), not only support the axially oriented β-configuration of the C-10 hydrogen atom but also confirm the afore-mentioned stereochemical assignment to the relevant groups at C-2 and C-4.

The presumption that the isopropenyl group would be located at C-7 and possess β-configuration was deduced from interpretation of the ^{1}H NMR spectrum of the hydroxy acetate (**3**), in which two new well-resolved signals were observed at δ 3.95 (1H, q, J=4 Hz) and 2.52 (1H, tt, J=12 and 4 Hz). The former was ascribed readily to the hydroxy-methine proton at C-9, and its coupling constants indicated that the hydrogen is oriented equatorial (β-configuration). On the other hand, the latter would be attributed reasonably to the proton on the carbon adjacent to the isopropenyl group. The observed multiplicity accounting for two axial-axial (J=12 Hz) and two equatorial-axial (J=4 Hz) coupling constants indicated that the carbon atom in question must be flanked by two unsubstituted methylene groups, and hence the isopropenyl group must be disposed at C-7 (neither C-6 nor C-8). Moreover, the splitting pattern revealed that the relevant C-7 proton is oriented axial, and hence the isopropenyl group must take β-configuration. It follows that the angular methyl group at C-5, the hydrogen atom at C-7, and the hydroxyl group at C-9 all have 1,3-diaxial relationship each other on the ring B with a chair conformation. In accordance with this conformational assignment, the hydroxy acetate (**3**) exhibited the signal due to the C-5 angular methyl protons at lower field (δ 1.02) than the corresponding oxo acetate (**1a**) (δ 0.73).[8] Furthermore, in the ^{1}H NMR spectrum in pyridine-d_5, remarkable down-field shifts were observed for the C-7 proton ($\Delta\delta$ 0.35) and the C-5 angular methyl protons ($\Delta\delta$ 0.25) (Table 2) (the solvent-induced NMR shift correlation).[9] In summary, all the chemical evidence and spectral data strongly suggested that rishitinone would probably be represented by formula **1**. This presumption was confirmed by correlation of **1** with (+)-nootkatone[10] (**8**), a well-known sesquiterpene with the established configurations, as described below.

Transformation of Nootkatone into Dihydrorishitinone. (+)-Nootkatone[10] (**8**), mp 28—30 °C, $[\alpha]_D$ +172°, was submitted to partial hydrogenation in benzene, containing tris(triphenylphosphine)chlororhodium[11] at room temperature for 14 h to give dihydronootkatone (**9**), oil, $[\alpha]_D$ +167°, in 81% yield. The compound (**9**) was converted by a modification of the Edwards procedure[12] into the corresponding dienol acetate (**10**), oil, $[\alpha]_D$ +45.3°, in 69% yield, showing the following

TABLE 2. THE SOLVENT EFFECT IN THE CHEMICAL SHIFTS OF HYDROXY ACETATE (3) IN CHLOROFORM-*d* AND PYRIDINE-d_5

Proton	Chemical shift δ		
	$CDCl_3$	C_5D_5N	$\Delta\delta$

spectra: IR, 1759 and 1664 cm^{-1}; NMR, δ 2.12 (3H, s, $OCOCH_3$), 5.42 (1H, W_H=10 Hz, 9-H), and 5.71 (1H, s, 1-H). Reduction of **10** with sodium borohydride produced a 1 : 5 mixture of stereoisomeric homoallyl alcohols (**11**) and (**12**), which were separated by preparative TLC. The minor (**11**) (9%), oil, $[\alpha]_D$ −30.7°, and the major alcohols (**12**) (45%), oil, $[\alpha]_D$ −34.2°, were assigned 2-axial and 2-equatorial alcohols respectively, on the basis of the NMR spectra: **11**, δ 3.99 (1H, m, W_H=8 Hz, 2-H) and 5.43 (1H, m, W_H= 12 Hz, 9-H); **12**, δ 3.56 (1H, m, W_H=25 Hz, 2-H) and 5.38 (1H, m, W_H=12 Hz, 9-H). The hydroxyl group of the latter (**12**) was then protected by treatment with *t*-butyldimethylsilyl (TBS) chloride and imidazole in *N*,*N*-dimethylformamide. The resulting silyl ether (**12a**), oil, $[\alpha]_D$ −16.3°, obtained in 76% yield, underwent hydroboration followed by oxidation with alkaline hydrogen peroxide, producing a mixture of the starting alkene (**12a**) and two stereoisomeric alcohols (**13**) and (**14**), which were separated by column chromatography in 23, 8 (crude), and 42% (pure) yields, respectively. The major product (**14**), oil, $[\alpha]_D$ +38.0°, was assigned 9β-hydroxy-*trans*-valencane structure on the basis of the spectral data: MS, *m*/*e* 354(M^+); IR, 3360 cm^{-1}; NMR, δ 0.72 (3H, s, 15-H), 3.49 (1H, dt, J=4.5 and 10 Hz, 9-H), and 3.58 (1H, m, W_H=25 Hz, 2-H). Supporting this assignment, the acetate (**14a**), oil, $[\alpha]_D$ +35.5°, of **14** displayed the following NMR spectrum: δ 0.76 (3H, s, 15-H), 3.76 (1H, m, W_H=25 Hz, 2-H), and 4.74 (1H, dt, J=4 and 11 Hz, 9-H). The assigned stereostructure to the major alcohol (**14**) was also consistent with the currently accepted steric manner of hydroboration; namely, the reaction of the alkene (**12a**) took place mainly in a *cis*-addition manner at the less-hindered β-side opposite to the angular methyl group,[6,13] in contrast with formation of *cis*-eremophilane from dihydroeremophilene.[14] On the other hand, the minor crude alcohol (**13**) was submitted to acetylation followed by purification by chromatography. The resultant pure acetate (**13a**), oil, $[\alpha]_D$ −2.8°, exhibited two signals due to the C-2 and C-9 protons at δ 3.60 (1H, m, W_H=25 Hz) and 5.00 (1H, q, J=4 Hz), respectively, in the NMR spectrum, indicative of the axial conformation of the relevant hydroxyl group at C-9.

The *trans*-decalol (**14**) was oxidized with Collins reagent at room temperature for 15 h to yield the corresponding ketone (**15**), mp 51—53 °C, $[\alpha]_D$ +2.1°, in a quantitative yield, showing the IR absorption at 1717 cm^{-1}. Hydrolysis of the silyloxy ketone (**15**)

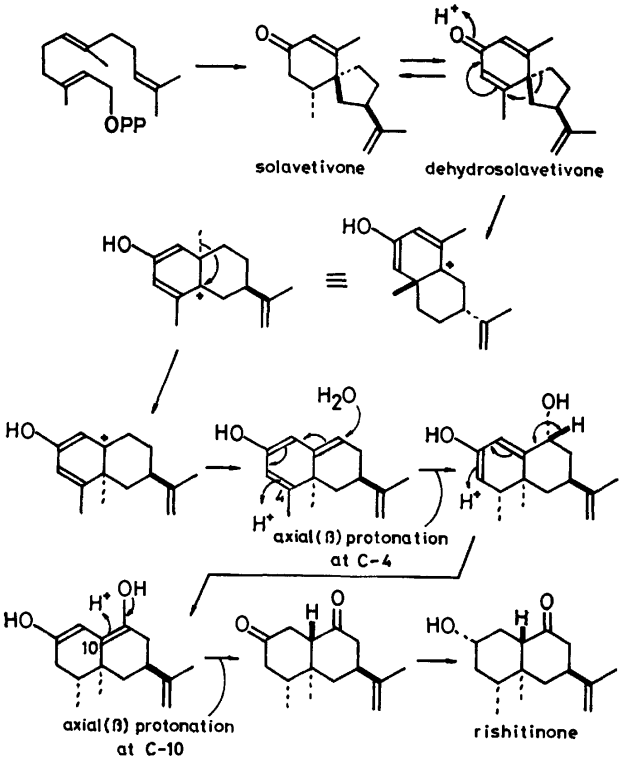

Scheme 1.

without epimerization at C-10 was effected by treatment with a 3 : 1 : 1 mixture of acetic acid, water, and tetrahydrofuran to give hydroxy ketone, mp 82—83 °C, $[\alpha]_D$ +7.8°, in 95% yield, which was identical with an authentic specimen of natural dihydrorishitinone (**2**) in all respects. All these results establish that the structure and configuration of (+)-rishitinone are represented by formula **1**.

Rishitinone (**1**), a stress metabolite with the valencane skeletone from diseased potato tubers, has a comparable fungitoxicity as rishitin, and would be qualified as a phytoalexin. In view of the facts that the phytoalexins (stress metabolites) produced in the Solanaceae plants possess structures which differ from usual sesquiterpenes in planar structure and/or configuration,[3] the following scheme 1 is proposed as one of plausible biogeneses for formation of the compound (**1**), considering the biosynthetic pathway of rishitin.[15]

Experimental

All the melting points were uncorrected. The purity of each compound was always checked by TLC over silica gel (Wakogel B-5 or Merck GF-254) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid, iodine, and/or concd sulfuric acid. The optical rotations, UV, IR, and NMR (100 MHz) were measured in ethanol, in ethanol, in liquid state (oil) or in Nujol (crystals), and in chloroform-*d*, respectively, unless otherwise stated. The preparative TLC was carried out over silica gel (Merck GF-254), and the column chromatography over silica gel (Mallinckrodt AR-100) or silicic acid (Kiesel gel 60), respectively.

Isolation of Rishitinone (1). The neutral chloroform extracts[4] (83 g), obtained from the diseased potato tubers[4] (300 kg) were separated roughly into five fractions I—V by column chromatography over silica gel (1.8 kg), benzene, benzene–ethyl acetate (1 : 1), ether, ethyl acetate, and methanol being used as eluents, successively. Fraction III (5.5 g), yellow oil, corresponding to "fraction F,"[4] was treated with acetic anhydride and pyridine, and the acetate mixture was separated by column chromatography over silica gel to give a semi-crystalline mixture (3.4 g), composing of rishitin diacetate[4] and rishitinone acetate (**1a**). Fractional recrystallization of the mixture from hexane afforded pure rishitin diacetate (3.3 g), mp 65—67 °C, and crude **1a** (112 mg). The latter was again purified by chromatography over silica gel (5.0 g) with a 10 : 1 mixture of hexane–ethyl acetate as an eluent to yield a crude semi-crystalline acetate mixture (82 mg), which was subjected to repeated crystallization from hexane, the resulting crystals being removed by filtration. Pure rishitinone acetate (**1a**) (68 mg) was obtained from the filtrate as an oil, $[\alpha]_D$ −2.4°, which on hydrolysis with potassium carbonate in methanol at room temperature for 1 h under nitrogen gave rishitinone (**1**), mp 72—75 °C (from diisopropyl ether), $[\alpha]_D$ +10.1°; MS, *m/e* 236 (M^+), 221, 218, 203, 193, and 153 (base); IR, 3500, 3400, 1710, 1651, and 900 cm^{-1}; ^1H NMR, δ 0.76 (3H, s, 15-H), 0.84 (3H, d, J=7 Hz, 14-H), 1.76 (3H, s, 13-H), 3.65 (1H, m, W_H=25 Hz, 2-H), and 4.77 (2H, br s, 12-H); ^{13}C NMR, δ 12.9, 15.5, and 20.4 (each q), 30.2, 39.3, 42.8, 46.0, and 109.9 (each t), 41.3, 41.5, 56.1, and 69.5 (each d), 40.7, 147.4, and 211.1 (each s). Found: C, 76.38; H, 10.01%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

Acetylation and Hydrogenation of 1. Compound **1** (14 mg) was treated with acetic anhydride (0.2 ml) and pyridine (1 ml) at room tem erature for 6 h. The reaction mixture was worked up as usual to give rishitinone acetate (**1a**) (16 mg), oil, $[\alpha]_D$ −2.4°; MS, *m/e* 278 (M^+), 236, 218, 203 ,195, and 135 (base); IR, 1739, 1717, 1644, 1248, 1030, and 893 cm^{-1}; ^1H NMR, δ 0.73 (3H, s, 15-H), 0.89 (3H, d, J=6 Hz, 14-H), 1.75 (3H, s, 13-H), 2.02 (3H, s, $OCOCH_3$), 4.77 (1H, m, W_H= 25 Hz, 2-H), and 4.80 (2H, s, 12-H).

A solution of **1** (13 mg) in ethanol (1.0 ml) was hydrogenated over 5% palladized charcoal (1.5 mg) at room temperature for 20 h under stirring. After removal of the catalyst the reaction mixture was evaporated *in vacuo* to leave a colorless crystalline substance, which was recrystallized from diisopropyl ether to afford dihydrorishitinone (**2**) (12 mg), mp 80—82 °C, $[\alpha]_D$ +7.2°; ORD, $[\Phi]_{310}^{peak}$ +1140°, $[\Phi]_{268}^{trough}$ −1430°, a= 25.7; MS, *m/e* 238 (M^+), 223, 205, 195, 177, 166, 153, 140, and 97; IR, 3580, 3440, 1702, 1388, 1372, 1063, and 1027 cm^{-1}; ^1H NMR, δ 0.67 (3H, s, 15-H), 0.90 (3H, d, J=6 Hz, 14-H), 0.91 (6H, d, J=6 Hz, 12- and 13-H), and 3.61 (1H, m, W_H= 25 Hz, 2-H).

Reduction of 1a with Sodium Borohydride ($NaBH_4$). A solution of **1a** (12 mg) in ethanol (1.5 ml) was stirred with $NaBH_4$ (20 mg) at room temperature for 30 min under nitrogen. The reaction mixture was diluted with ether (30 ml), and the whole mixture was washed with water (10 ml) and saturated brine (10 ml), dried, and evaporated to leave a colorless oil (12 mg), showing a single spot on TLC, which crystallized on trituration with hexane. Recrystallization from hexane–diisopropyl ether afforded hydroxy acetate (**3**) (10 mg), mp 96—98 °C, $[\alpha]_D$ −6.9°; MS, *m/e* 280 (M^+), 262, and 220; IR, 3620, 3480, 1728, 1645, 1259, 1028, and 895 cm^{-1}; ^1H NMR in $CDCl_3$ and C_5D_5N, in Table 2.

Hydrogenation of Nootkatone (8). A solution of **8** (653 mg), mp 28—30 °C, $[\alpha]_D$ +172° (lit,[10] mp 28—30 °C, $[\alpha]_D$ +170°), and tris(triphenylphosphine)chlororhodium (450 mg) in benzene (90 ml) was stirred with hydrogen at room temperature for 14 h, and the mixture was passed through an activated alumina column (Merck, activity II—III, 30 g). The column

was eluted with benzene–ethyl acetate (1 : 1) (0.5 l), and the eluate was evaporated to give dihydronootkatone (**9**) (523 mg), showing a single spot on TLC, colorless oil, $[\alpha]_D$ +167°; MS, *m/e* 220 (M^+), 178, 177, and 135 (base); IR, 1670, 1621, 1435, 1414, 1383, 1372, 1355, and 1290 cm^{-1}; ^1H NMR, δ 0.69, 0.72, and 0.78 (each 3H, d, J=7 Hz, 12-, 13-, and 14-H, or *vice versa*), 1.08 (3H, s, 15-H), and 5.78 (1H, s, 1-H). Found: C, 81.45; H, 11.23%. Calcd for $C_{15}H_{24}O$: C, 81.76; H, 10.16%.

Treatment of ***9*** *with Acetic Anhydride and Perchloric Acid.* The Edwards reagent A,[12] an absolute ethyl acetate solution (50 ml) containing acetic anhydride (4.8 ml) and 60% perchloric acid (0.06 ml), was prepared according to the reported procedure. Compound **9** (350 mg) was dissolved in the soltion and stirred at room temperature for 10 min. The reaction mixture was mixed with 5% aqueous sodiumhydrogencarbonate (20 ml), shaken, and separated. The aqueous solution was extracted with ethyl acetate (2 × 10 ml). The combined acetate solution was washed with 2 M hydrochloric acid (10 ml), 5% aqueous sodium hydrogencarbonate (10 ml), and saturated brine (10 ml), dried, and evaporated to yield an oily substance (362 mg), which was purified by column chromatography over silica gel (15 g). Elution with hexane–ethyl acetate (20 : 1) afforded dienol acetate (**10**) (353 mg), showing a single spot on TLC, oil, $[\alpha]_D$ +45.3°; MS, *m/e* 262 (M^+), 236, 220, and 177; IR, 1759, 1664, and 1212 cm^{-1}; ^1H NMR, δ 0.90 (12H, br s, 12-, 13-, 14-, and 15-H), 2.12 (3H, s, $OCOCH_3$), 5.42 (1H, m, W_H=10 Hz, 9-H), and 5.71 (1H, s, 1-H).

Reduction of ***10*** *with* $NaBH_4$. A solution of **10** (300 mg) in ethanol (20 ml) was stirred with $NaBH_4$ (300 mg) at room temperature for 3 h. The reaction mixture was evaporated *in vacuo*, mixed with water (30 ml), and extracted with ether (50 ml). The ether solution was worked up as usual to leave an oily substance, consisting of two components on TLC, which were successively separated by column chromatography over silica gel (20 g) with hexane–ethyl acetate (5 : 1) as an eluent to give two epimeric homoallyl alcohols (**11**) (22 mg) and (**12**) (118 mg): **11**, oil, $[\alpha]_D$ −30.7°; MS, *m/e* 222 (M^+), 204, 189, 175, and 161; IR, 3300, 1382, 1365, 1060, 1024, and 1002 cm^{-1}; ^1H NMR, δ 0.90 (12H, br s, 12-, 13-, 14-, and 15-H), 2.58 (1H, dt, J=14 and 2 Hz, 1-H), 3.99 (1H, m, W_H=8 Hz, 2-H), and 5.43 (1H, m, W_H=12 Hz, 9-H): **12**, oil, $[\alpha]_D$ −34.2°; MS, *m/e* 222 (M^+), 204, 189, 179, and 161; IR, 3320, 1381, 1368, and 1021 cm^{-1}; ^1H NMR, δ 0.90 (12H, br s, 12-, 13-, 14-, and 15-H), 3.56 (1H, m, W_H=25 Hz, 2-H), and 5.38 (1H, m, W_H=12 Hz).

t-*Butyldimethylsilylation of* ***12***. A solution of **12** (104 mg) in *N*,*N*-dimethylformamide (4 ml) was stirred with *t*-butyldimethylsilyl (TBS) chloride (200 mg) and imidazole (180 mg) at room temperature for 8 h. The reaction mixture was cooled, diluted with water (30 ml), and extracted with ether (4 × 20 ml). The combined ether solutions were washed with water (2 × 30 ml), dried, and evaporated to give practically pure silyl ether (**12a**) (120 mg), showing a single spot on TLC, oil, $[\alpha]_D$ −16.3°; MS, *m/e* 337 (M^+ +1), 279, 203, and 147 (base); IR, 1460, 1370, 1258, 1100, 1060, 910, 883, 850, and 839; ^1H NMR, δ 0.90 (12H, br s, 12-, 13-, 14- and 15-H), 3.49 (1H, m, W_H=25 Hz, 2-H), and 5.35 (1H, m, W_H=12 Hz, 9-H).

Hydroboration of ***12a*** *Followed by Oxidation.* To a cooled solution of **12a** (110 mg) in tetrahydrofuran (THF) (0.5 ml) at 0 °C was added a 1.87 M solution of diborane in THF (0.5 ml). The mixture was stirred at room temperature for 1 h and cooled at 0 °C, and water (2 ml) was then added to decompose the excess reagent. The aqueous mixture was stirred with 3 M aqueous sodium hydroxide (0.1 ml) and 30% hydrogen peroxide (0.2 ml) at 0 °C for 1 h. The reaction mixture was diluted with water (20 ml) and extracted with ether (5 × 10 ml). The combined ether solution was worked up as usual to leave an oily residue (113 mg), which was separated into three fractions by column chromatography over silica gel with hexane–ethyl acetate (1 : 1) as an eluent. The most mobile fraction (25 mg) gave the practically pure starting alkene (**12a**). The middle fraction (8 mg) showed three spots on TLC and was then treated with acetic anhydride (0.1 ml) and pyridine (1 ml) at room temperature overnight for purification. The reaction mixture was purified by preparative TLC over silica gel with hexane–ethyl acetate (10 : 1) as a solvent. A fraction with R_f value of 0.36 afforded 9*α*-acetate (**13a**) (4 mg) in pure state, oil, $[\alpha]_D$ −2.8°; MS, *m/e* 395 (M^+ −1), 339, 335, 279, and 205; IR, 1721, 1252, 1100, 1051, 1020, 855, and 836 cm^{-1}; ^1H NMR, δ 0.05 (6H, s), 0.88 (9H, s), and 0.90 (br s, 12-, 13-, 14-, and 15-H), 2.04 (3H, s, $OCOCH_3$), 3.60 (1H, m, W_H=25 Hz), and 5.00 (1H, q, J=4 Hz, 9-H). The least mobile fraction (49 mg), showing a single spot on TLC, was purified by preparative TLC to give 9*β*-alcohol (**14**), oil, $[\alpha]_D$ +38.0°; MS, *m/e* 354 (M^+), 229, 205, and 75 (base); IR, 3360, 1258, 1100, 1077, 1050, 1038, 859, 837, and 773 cm^{-1}; ^1H NMR, δ 0.05 (6H, s), 0.72 (3H, s, 15-H), 0.88 (9H, s), 0.90 (9H, br s, 12-, 13-, and 14-H), 3.49 (1H, dt, J=4.5 and 10 Hz, 9-H), and 3.58 (1H, m, W_H= 25 Hz, 2-H). Compound **14** (49 mg) was converted by treatment with acetic anhydride (0.5 ml) and pyridine (2 ml) at room temperature for 14 h into the corresponding 9*β*-acetate (**14a**) (52 mg), oil, $[\alpha]_D$ +35.5°; MS, *m/e* 395 (M^+ −1), 335, 279, and 205 (base); IR, 1740, 1240, 1238, 1100, 1077, 1053, 1030, 856, 833, and 770 cm^{-1}; ^1H NMR, δ 0.05 (6H, s), 0.76 (3H, s, 15-H), 0.88 (9H, s), 0.90 (9H, br s, 12-, 13-, and 14-H), 2.02 (3H, s, $OCOCH_3$), 3.76 (1H, m, W_H= 25 Hz, 2-H), and 4.74 (1H, dt, J=4 and 11 Hz).

Collins Oxidation of ***14***. A mixture of chromium(VI) oxide (54 mg) and pyridine (54 μl) in dichloromethane (0.8 ml) was stirred at room temperature for 15 min under nitrogen. To the mixture was added a solution of **14** (16 mg) in dichloromethane (0.2 ml) under stirring. The mixture was further stirred at room temperature for 15 h, and diluted with ether (40 ml) and filtered. The filtrate was washed with 5% aqueous sodium hydrogencarbonate (2 × 30 ml), dried, and evaporated to yield a crystalline substance, which on recrystallization from diisopropyl ether gave ketone (**15**) (15 mg), mp 51—53 °C, $[\alpha]_D$ +2.1°; MS, *m/e* 352 (M^+), 337, 309, and 295 (base); IR, 1717, 1468, 1390, 1380, 1372, 1362, 1258, 1101, 1080, 1057, 860, 839, and 778 cm^{-1}; ^1H NMR, δ 0.05 (6H, s), 0.66 (3H, s, 15-H), 0.88 (9H, s), 0.90 (9H, br s, 12-, 13-, and 14-H), 3.78 (1H, m, W_H=25 Hz, 2-H).

Hydrolysis of ***15***. A solution of **15** (14 mg) in a 3 : 1 : 1 mixture (2 ml) of acetic acid, water, and THF was stirred at room temperature for 17 h. The reaction mixture was diluted with ether (40 ml) and washed with 5% aqueous sodium hydrogencarbonate (15 ml), dried, and evaporated to leave a crystalline substance, which on recrystallization from diisopropyl ether afforded hydroxy ketone (7 mg), mp 82—83 °C, $[\alpha]_D$ +7.8°; MS, *m/e* 238 (M^+), 223, 220, 205, 195, 177, 168, 167, 166, 153, 140, and 97; IR, 3580, 3440, 1702 1063, and 1027 cm^{-1}; ^1H NMR, δ 0.66 (3H, s, 15-H), 0.89 (6H, d, J=6 Hz, 12- and 13-H), 0.91 (3H, d, J=6 Hz, 14-H), and 3.62 (1H, m, W_H=25 Hz, 2-H). The compound was identical with an authentic sampel of dihydrorishitinone (**2**) derived from natural rishitinone (**1**) in all respects (TLC, $[\alpha]_D$, MS, IR, ^1H NMR, and mixed mp).

Synthesis of Paracyclo(1,8)napthalenophane and Paracyclo(5,6)acenaphthenophane[1]

Akira KASAHARA,* Taeko IZUMI, Iwao SHIMIZU, Masahiro SATOU, and Takao KATOU
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received December 5, 1981)

[2]Paracyclo[2]paracyclo[2](1,8)naphthalenophan-9-ene-1,17-diyne, [0]paracyclo[2]paracyclo[0](5,6)acenaphthenophan-7-ene, and [2]paracyclo[2]paracyclo[2](5,6)acenaphthenophan-9-ene-1,17-diyne, were synthesized by intramolecular reductive coupling reaction of the corresponding carbonyl compounds with low-valent titanium reagent. The structures of the compounds were elucidated by NMR analyses, and the transannular π-electronic interactions between two benzene rings were examined on the basis of electronic spectra.

Recently, a wide variety of [2.2]phanes containing benzene or heteroaromatic rings has been synthesized in order to study the effect of transannular π-electronic interactions on their physical and chemical properties.[2] However, there are only a few investigations of paracyclonaphthalenophane having a bridged system in a peri-position of the naphthalene ring: the only compounds of this class which have been described are [0]paracyclo[2]paracyclo[0](1,8)naphthalenophane[3](**1**) and [0]paracyclo[2]paracyclo[0](1,8)naphthalenophan-7-ene[3] (**2**). The distance between atoms 1 and 8 in naphthalene is 2.44 Å, while the van der Waals separation in the parallel π-system is 3.4 Å.[4] Thus, in compounds **1** and **2**, substantial repulsive interactions must exist between the two peri-aryl rings, which are bound closely by ethano bridges at both ends. These results have prompted us to study the synthesis of [2]paracyclo[2]paracyclo[2](1,8)naphthalenophan-9-ene-1,17-diyne (**3**), [0]paracyclo[2]paracyclo[0](5,6)-acenaphthenophane (**4**), [0]paracyclo[2]paracyclo[0]-(5,6)acenaphthenophan-7-ene (**5**), and [2]paracyclo-[2]paracyclo[2](5,6)acenaphthenophan-9-ene-1,17-diyne (**6**).

Experimental

Materials and Measurement. All the melting points are uncorrected. 1,8-Diiodonaphthalene (**7**),[5] 5,6-dibromoacenaphthene (**8**),[6] 5,6-diiodoacenaphthene (**9**),[7] 5-iodoacenaphthene (**10**),[7] (*p*-bromophenylethynyl)trimethylsilane (**11**),[8] and *p*-bromobenzaldehyde ethylene acetal (**12**)[9] were prepared as described in the literature. The IR, NMR, mass, and electronic spectra were recorded with a Hitachi 260-10, a Hitachi R-22, a Hitachi RMU-6M, and a Hitachi 200-10 spectrometer, respectively.

*p-Ethynylbenzaldehyde Diethyl Acetal (**15**).* The Grignard reagent prepared from **11** (10.2 g, 0.04 mol) and 1.0 g (0.042 mol) of magnesium turning in 80 ml of dry THF was cooled to 20 °C; a solution of 2.8 g (0.038 mol) of anhydrous *N,N*-dimethylformamide in 20 ml of dry THF was then added dropwise over a 0.5 h period. After the addition was complete, the reaction was stirred for 4 h and then was allowed to remain overnight under a nitrogen atmosphere. The mixture was hydrolyzed with a saturated aqueous solution of ammonium chloride, the organic layers were separated, and the aqueous layers were extracted twice with a 50 ml portion of ether. The organic layers and ether extracts were combined and dried over anhydrous $MgSO_4$. After removal of the solvent under reduced pressure, the residue was chromatographed in benzene on silica gel. Colorless crystals of (*p*-formylphenylethynyl)-trimethylsilane (**13**), mp 56—58 °C, were obtained in 80% yield (6.5 g). IR (KBr): 2150 (–C≡C–), 1700 cm^{-1} (–CHO). NMR ($CDCl_3$): δ=0.18 (s, 9H, –C<u>H</u>$_3$), 7.47 (d, 2H, Ar–<u>H</u>), 7.68 (d, 2H, Ar–<u>H</u>), 9.87 ppm (s, 1H, –C<u>H</u>O). Found: C, 71.08; H, 6.86%. Calcd for $C_{12}H_{14}OSi$: C, 71.23; H, 6.97%.

A solution of **13** (5.6 g, 0.028 mol), triethyl orthoformate (5.5 g, 0.037 mol), and *p*-toluenesulfonic acid (0.16 g) in ethanol (20 ml) was refluxed for 5 h under stirring. After pouring into an aqueous solution of ammonia (50 ml), the mixture was extracted with ether. The extracts were then washed successively with aqueous ammonia and a saturated sodium chloride solution, dried over potassium carbonate, and evaporated to give a dark red liquid: [*p*-(diethoxymethyl)phenylethynyl]trimethylsilane (**14**). The liquid shows no IR absorption due to a formyl group, but it does show that due to an acetal. IR (neat): 1100, 1070, 1050 cm^{-1}.

The crude product (**14**) in methanol (200 ml) was stirred with a solution of potassium hydroxide (3.6 g) in water (36 ml). The mixture was then heated under reflux for an additional 3 h, poured into water (1000 ml), and extracted with ether. The extracts were washed with a saturated sodium chloride solution and dried over potassium carbonate. The dark red liquid which remained after the evaporation of the solvents was distilled under reduced pressure to give **15**, a colorless liquid, bp 98—103 °C/2 mmHg,† 4.1 g (72% yield based on **13**). IR (neat): 3350 (–C≡C–H), 2150 (–C≡C–), 1100, 1040 cm^{-1} (–C–O–C–). NMR ($CDCl_3$): δ=1.16 (t, 6H, –C<u>H</u>$_3$), 3.02 (s, 1H, –C≡C–<u>H</u>), 3.54 (q, 4H, –C<u>H</u>$_2$–), 5.47 (s, 1H, –C–<u>H</u>), 7.06 (d, 2H, Ar–<u>H</u>), and 7.68 ppm (d, 2H, Ar–<u>H</u>). Found: C, 76.35; H, 7.81%; M^+, 204. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.89%; M, 204.

*1,8-Bis(p-formylphenylethynyl)naphthalene (**17**).* A mixture of **7** (9.6 g, 25 mmol), **15** (10.2 g, 50 mmol), copper(I) iodide (0.048 g, 0.25 mmol), dichlorobis(triphenylphosphine)palladium(II) (0.70 g, 1 mmol), and diethylamine (180 ml) was heated under nitrogen in an autoclave at 80 °C for 10 h. After the removal of diethylamine under reduced pressure, ether and water were added to the residue. The ether phase was separated, washed thoroughly with 10% hydrochloric acid, a saturated sodium hydrogencarbonate solution, and a saturated sodium chloride solution, dried over anhydrous magnesium sulfate, filtered, and concentrated. The residue was purified by column chromatography (silica gel–benzene). First elution with benzene gave 1-(*p*-formylphenylethynyl)-8-iodonaphthalene (**16**), colorless needles, mp 113—115 °C in 42% yield (4.05 g): IR (KBr): 2200 (–C≡C–), 1700 cm^{-1} (–CHO). NMR ($CDCl_3$): δ=7.36—7.93 (m, 10H, Ar–<u>H</u>), 9.95 ppm (s, 1H, –C<u>H</u>O). Found: C, 59.55; H, 2.78%; M^+ 382. Calcd for $C_{19}H_{11}IO$: C, 59.70; H, 2.90%; M, 382.

A second elution with benzene afforded 3.39 g (35% yield) of **17**, colorless needles, mp 168—169 °C. IR (KBr): 2200

† 1 mmHg ≈ 133.322 Pa.

(-C≡C-), 1700 cm^{-1} (-CHO). NMR ($CDCl_3$): δ=7.42—7.95 (m, 14H, Ar-H), 9.98 ppm (s, 2H, -CHO). Found: C 87.40; H, 4.68%; M^+, 384. Calcd for $C_{28}H_{20}O_2$: C, 87.48; H, 4.79%; M, 384.

5,6-Bis(p-formylphenyl)acenaphthene (19). Under a nitrogen atmosphere, the Grignard reagent prepared from **12** (9.1 g, 40 mmol) and magnesium turnings (1.2 g, 49 mmol) in dry THF (60 ml) was dropwise added to a mixture of **8** (2.5 g, 8 mmol) and dichloro[1,3-bis(diphenylphosphino)propane]-nickel(II) (0.9 g, 1.6 mmol) in dry THF (60 ml) at 0 °C with stirring over 2.5 h. The reaction mixture was stirred for 4 h at 0 °C and then was allowed to remain overnight at room temperature. The mixture was hydrolyzed with 10% hydrochloric acid under cooling with an ice bath. The organic layers and ether extracts from the aqueous layer were combined, washed with 10% hydrochloric acid, water, a saturated sodium hydrogencarbonate solution, and water again, and then dried over anhydrous $MgSO_4$. After removal of the solvents, the residue was purified by column chromatography (silica gel–benzene). The first elution with benzene gave 5-(*p*-formylphenyl)-6-bromoacenaphthene (**18**), colorless needles, mp 115—116 °C, in 37% yield (1.00 g). IR (KBr): 1690 (-CHO), 1600, 810 cm^{-1}. NMR ($CDCl_3$): δ=3.36 (s, 4H, -CH$_2$-), 7.09 (d, J=7 Hz, 2H, Ar-H), 7.47 (d, J=8 Hz, 2H, Ar-H), 7.62 (d, J=7 Hz, 2H, Ar-H), 7.83 (d, J=8 Hz, 2H, Ar-H), 10.02 ppm (s, 1H, -CHO). Found: C, 67.58; H, 3.80%; M^+, 337. Calcd for $C_{19}H_{13}BrO$: C, 67.67; H, 3.88%; M, 337.

The second elution with benzene afforded 0.37 g (13% yield) of **19**, colorless needles, mp 244—245 °C. IR (KBr): 1695 (-CHO), 1600, 810 cm^{-1}. NMR ($CDCl_3$): δ =3.49(s, 4H, -CH$_2$-), 7.07 (d, J=7 Hz, 4H, Ar-H), 7.33 (d, J=8 Hz, 2H, Ar-H), 7.39 (d, J=7 Hz, 4H, Ar-H), 7.45 (d, J=8 Hz, 2H, Ar-H), 9.97 ppm (s, 2H, -CHO). Found: C, 86.02; H, 4.88%; M^+, 362. Calcd for $C_{26}H_{18}O_2$: C, 86.16; H, 5.01%; M, 362.

5,6-Bis(p-formylphenylethynyl)acenaphthene (21). In the presence of $(Ph_3P)_2PdCl_2$ and CuI, the palladium-catalyzed substitution of **9** with **15** was carried out in the same way as described for **17**, and 5-(*p*-formylphenylethynyl)-6-iodoacenaphthene (**20**) (colorless needles, mp 154—155 °C) and **21** (pale yellow needles, mp 175—176 °C) were obtained in 24 and 50% yields, respectively.

20: IR (KBr): 2190 (-C≡C-), 1690 cm^{-1} (-CHO). NMR ($CDCl_3$): δ=3.33 (s, 4H, -CH$_2$-), 7.05—7.77 (m, 8H, Ar-H), 9.96 ppm (s, 1H, -CHO). Found: C, 61.63; H, 3.13%; M^+, 408. Calcd for $C_{21}H_{13}IO$: C, 61.78; H, 3.21%; M, 408.

21: IR (KBr): 2200 (-C≡C-), 1690 cm^{-1} (-CHO). NMR ($CDCl_3$): δ=3.41 (s, 4H, -CH$_2$-), 7.29 (d, J=7 Hz, 2H, Ar-H), 7.41 (d, J=8 Hz, 4H, Ar-H), 7.55 (d, J=7 Hz, 2H, Ar-H), 7.78 (d, J=8 Hz, 4H, Ar-H), 9.90 ppm (s, 2H, -CHO). Found: C, 87.70; H, 4.33%; M^+, 410. Calcd for $C_{30}H_{18}O_2$: C, 87.78; H, 4.42%; M, 410.

The Intramolecular Reductive Coupling of 17 with $TiCl_4$–$LiAlH_4$. To a solution of $TiCl_4$ (9.5 g, 0.05 mol) in dry THF (200 ml) was added $LiAlH_4$ (0.90 g, 0.024 mol) with cooling under a nitrogen atmosphere. The mixture was refluxed for 2 h; to the metal complex solution thus obtained, was added dropwise a solution of **17** (3.84 g, 0.01 mol) and tributylamine (1.86 g, 0.01 mol) in dry THF (250 ml) over 8 h under refluxing, followed by an additional 10 h period of reflux. The reaction mixture was then cooled to room temperature and quenched with 20% aqueous K_2CO_3 solution. After filtration, the filtrate was extracted with chloroform. The chloroform extracts were washed with water and dried over anhydrous $MgSO_4$. After removal of the solvents, the residue was dissolved in hexane and chromatographed on silica gel.

The first fraction, eluted with hexane, gave colorless needles, mp 115—117 °C, in 35% yield, which were identified as 1,8-bis(*p*-tolylethynyl)naphthalene (**22**) by a comparison of the IR, NMR, and mass spectra and by a mixed-melting-point determination with an authentic sample (lit,[10] mp 116—117 °C).

The second fraction, eluted with hexane, gave 1,8-bis[[(*p*-hydroxymethyl)phenyl]ethynyl]naphthalene (**23**) (from CH_3-OH), colorless needles, mp 166—167 °C, in 11% yield. IR (KBr): 3300 (-OH), 2150 (-C≡C-), 1600, 1500, 860 cm^{-1} *p*-disubstituted benzene ring). NMR ($CDCl_3$): δ=2.32 (br-s, 2H, -OH), 4.58 (s, 4H, -CH$_2$-), 7.14—7.54 ppm (m, 10H, Ar-H). Found: C, 86.46; H, 5.07%; M^+, 388. Calcd for $C_{28}H_{20}O_2$: C, 86.57; H, 5.19%; M, 388.

The third fraction, eluted with hexane, gave **3** (from benzene–hexane), pale yellow needles, mp 239—241 °C (decomp), in 7.5% yield. IR (KBr): 1660, 1600, 1500, 830, 770, 750, 720, 690 cm^{-1}. Found: C, 95.28; H, 4.51%; M^+, 352. Calcd for $C_{28}H_{16}$: C, 95.42; H, 4.58%; M, 352.

The Intramolecular Reductive Coupling of 19 with $TiCl_4$–Zn. To a solution of $TiCl_4$ (2.6 g, 14 mmol) in dry THF (70 ml) was added Zn dust (1.8 g, 28 mmol) with cooling. The mixture was refluxed 1.5 h under a nitrogen atmosphere to give a deep black solution. To the metal complex solution thus obtained was added a solution of **19** (1.0 g, 2.8 mmol) and dry pyridine (0.20 g) in dry THF (150 ml) over 9.5 h under refluxing, followed by an additional 10 h period of refluxing. The reaction mixture was then cooled to room temperature and quenched with 20% K_2CO_3 solution. After filtration, the filtrate was extracted with $CHCl_3$. The $CHCl_3$ extracts were washed with water and dried over $MgSO_4$. After removal of the solvents, the residue was dissolved in hexane and chromatographed on silica gel.

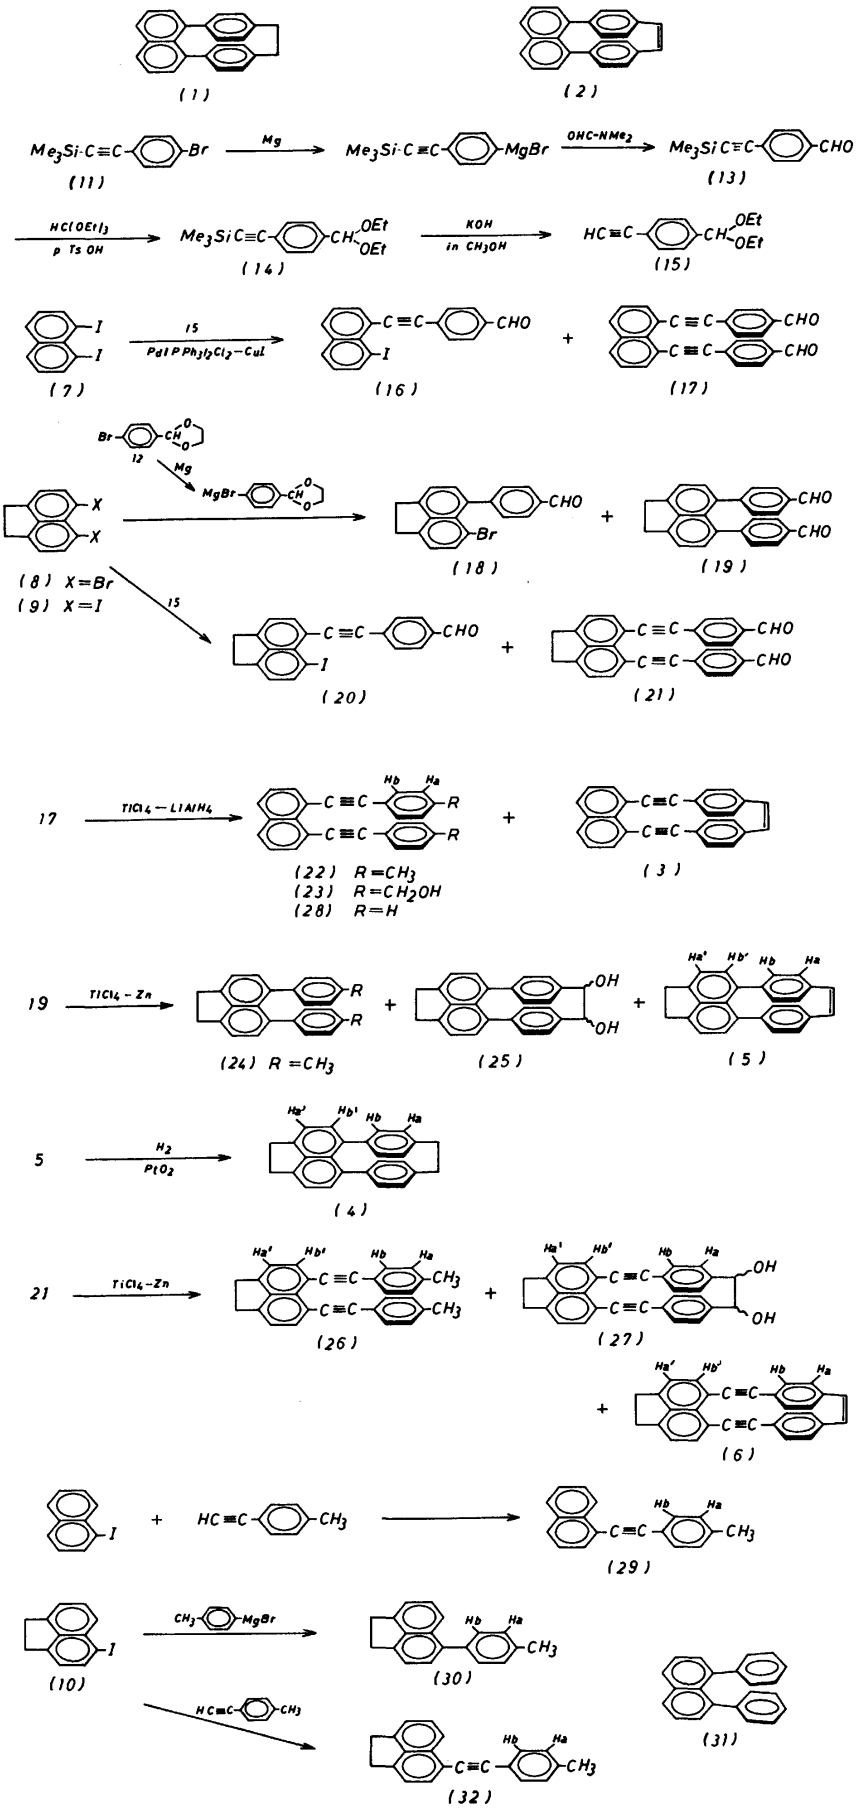
The first fraction, eluted with hexane, gave 5,6-di-*p*-tolylacenaphthene (**24**), colorless needles, mp 142—144 °C, in 12.5% yield. IR (KBr): 1600, 1510, 820, 800 cm^{-1}. Found: C, 93.32; H, 6.57%; M^+, 334. Calcd for $C_{26}H_{22}$: C, 93.37; H, 6.63%; M, 334. The compound **24** is identical in all respects with 5,6-di-*p*-tolylacenaphthene, which was prepared by the nickel-phosphine catalyzed Grignard cross coupling reaction of **8** with *p*-tolylmagnesium bromide.

The second fraction, eluted with hexane, gave **5**, pale yellow needles, mp 186—188 °C, in 24% yield. IR (KBr): 1600, 1490, 825, 805, 720, 690 cm^{-1}. Found: C, 94.44; H, 5.40%; M^+, 330. Calcd for $C_{26}H_{18}$: C, 94.51; H, 5.49%; M, 330.

The third fraction, eluted with benzene, gave [0]paracyclo-[2]paracyclo[0](5,6)acenaphthenophane-7,8-diol (**25**), colorless needles, mp 210—211 °C (decomp), in 2.5% yield. IR (KBr): 3420 (-OH), 1610, 1600, 1500, 835, 810, 715, 690 cm^{-1}. Found: C, 85.60; H, 5.45%; M^+, 364. Calcd for $C_{26}H_{20}O_2$: C, 85.69; H, 5.53%; M, 364.

The Catalytic Hydrogenation of 5 to 4. In the mixture of THF (10 ml) and ethanol (70 ml), **5** (0.4 g) was hydrogenated with PtO_2 (0.1 g) at room temperature under ordinary pressure. The reaction mixture was filtered to remove the catalyst and the filtrate was evaporated. The residue was chromatographed on silica gel with hexane to give 0.35 g (87.5% yield) of **4**, colorless needles, mp 263—265 °C. IR (KBr): 1600, 1500, 820, 800, 725, 695 cm^{-1}. Found: C, 93.87; H, 6.58%; M^+, 332. Calcd for $C_{26}H_{20}$: C, 93.94; H, 6.06%; M, 332.

The Intramolecular Reductive Coupling of 21 with $TiCl_4$–Zn. The reductive coupling of **21** was carried out in the same way as described for the reaction of **19** with $TiCl_4$–Zn, and the products were separated by chromatography on silica gel. The first fraction, eluted with hexane, gave 5,6-bis(*p*-tolylethynyl)acenaphthene (**26**), pale yellow needles, mp 179—180 °C, in 8.5% yield. IR (KBr): 1590, 1490, 830, 800 cm^{-1}.



Scheme 1.

Found: C, 94.07; H, 5.71%; M+, 382. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%; M, 382. The compound **26** is identical in all respects with 5,6-bis(*p*-tolylethynyl)acenaphthene, which was prepared by the palladium-catalyzed substitution of **9** with *p*-tolylacetylene.

The second fraction, eluted with hexane, gave **6**, yellow needles, mp 219—220 °C, in 32% yield. IR (KBr): 1630, 1600, 1500, 900, 840, 810, 765, 720, 690 cm^{-1}. Found: C, 95.08; H, 4.68%; M+, 378. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%; M, 378.

The third fraction, eluted with benzene–$CHCl_3$ (4 : 1), gave [2]paracyclo[2]paracyclo[2](5,6)acenaphthenophane-9,10-diol (**27**), yellow needles, mp 219—221 °C, in 15% yield. IR (KBr): 3350 (-OH), 1590, 1490, 1020, 820, 715, 690 cm^{-1}. Found: C, 87.24; H, 4.80%; M+, 412. Calcd for $C_{30}H_{20}O_2$: C, 87.35; H, 4.89%; M, 412.

1-p-Tolylethynylnaphthalene (29). In the presence of $(Ph_3P)_2PdCl_2$ and CuI, the palladium-catalyzed substitution of 1-iodonaphthalene with *p*-tolylacetylene was carried out in the same way as described for **17**, and the compound **29**, colorless needles, mp 61—63 °C (from CH_3OH), was obtained in 78% yield. IR (KBr): 1600, 1500, 810, 790, 765 cm^{-1}. Found: C, 94.04; H, 5.77%; M+, 242. Calcd for $C_{19}H_{14}$: C, 94.18; H, 5.82%; M, 242.

5-p-Tolylacenaphthene (30). In the presence of dichloro-[1,3-bis(diphenylphosphino)propane]nickel(II), the cross coupling reaction of **10** with *p*-tolylmagnesium bromide in dry THF was carried out in the same way as described for **19**, and the compound **30**, colorless needles, mp 55—57 °C (from CH_3OH) was obtained in 63% yield. IR (KBr): 1600, 1500, 840, 790, 760, 720 cm^{-1}. Found: C, 93.28; H, 6.51%; M+, 244. Calcd for $C_{19}H_{16}$: C, 93.40; H, 6.60%; M, 244.

5,6-Di-p-tolylacenaphthene (24). In the presence of nickel phosphine complex, the cross coupling reaction of **8** with *p*-tolylmagnesium bromide in dry THF was carried out in the same way as described for **19**, and the compound **24**, mp 142—144 °C, was obtained in 65% yield.

5-p-Tolylethynylacenaphthene (32). In the presence of $(Ph_3P)_2PdCl_2$ and CuI, the palladium-catalyzed substitution of **10** with *p*-tolylacetylene was carried out in the same way as described for **17**, and the compound **32**, colorless needles, mp 116—118 °C (from ethanol) was obtained in 67% yield. IR (KBr): 1600, 1500, 830, 800 cm^{-1}. Found: C, 93.92; H, 5.89%; M+, 268. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.01%; M, 268.

5,6-Bis(p-tolyethynyl)acenaphthene (26). In the presence of $(Ph_3P)_2PdCl_2$ and CuI, the palladium-catalyzed substitution of **9** with *p*-tolylacetylene was carried out in the same way as described for **17**, and the compound **26**, mp 179—180 °C, was obtained in 58% yield.

Results and Discussion

A number of synthetic methods have been recently developed for [2.2]cyclophane.[11] The naphthalenophane **1** has been prepared by pyrolytic method of sulfone derivative **31**.[3] But a reductive coupling of carbonyl compounds with low valent titanium reagents[12] is still very convenient and advantageous for the synthesis of cyclophane because of the facile availability of the intermediary compounds.[13]

In the present work, we applied the same method for

TABLE 2. NMR SPECTRA OF THE CYCLOPHANE AND REFERENCE COMPOUNDS (δ, IN $CDCl_3$)

Compound	Aromatic protons	Naphthalene or acenaphthene ring	Other protons

a) The spectra of **25** and **27** were observed in acetone-d_6.

the synthesis of cyclophanes **3**, **5**, and **6**. The synthesis of intermediates, dialdehydes **17** and **21**, were carried out by the palladium-catalyzed substitution[14] of diiodo compounds **7** and **9** with acetylene derivative **15**; in the presence of phosphino nickel complex, dialdehyde **19** was obtained by the cross coupling reaction[15] of **8** with a Grignard reagent prepared from **12**.

The intramolecular reductive coupling of **17** with a low valent titanium reagent ($TiCl_4$-$LiAlH_4$[12d]) afforded a mixture of the reduction products (**22** and **23**) of carbonyl group and cyclophane **3**. On the other hand, the intramolecular reductive coupling of **19** or **21** with a low valent titanium reagent ($TiCl_4$-Zn[12a]) gave a mixture of the reduction products (**24** or **26**), cyclophanes (**5** or **6**), and dihydroxycyclophane derivatives (**25** or **27**), respectively. It has already been reported that aldehydes and ketones were reduced by low valent titanium compounds, produced from $TiCl_4$ and Zn, to give the corresponding pinacols and olefins in high yields.[12a] The cyclophane **4** was also obtained by the catalytic hydrogenation of **5**.

The structures of the compounds were assigned on the basis of the IR, NMR, and mass spectra and the elementary analyses.

The IR spectra of [2.2]paracyclophane system show these two obvious features. One is the increase of the intensity of the band in 1600—1580 cm^{-1}, which is related to the increased double bond character due to the distortion of the benzene rings.[16] The other is the appearance of a strong new maximum near 710 cm^{-1} region. Longone and Warren[17] reported that the strong maximum at 725 cm^{-1} in [2.2]paracyclophane and at 710 cm^{-1} in 4,7,12,15-tetramethyl[2.2]paracyclophane might be a characteristic band associated with the distorted benzene rings in the [2.2]paracyclophane system. Otsubo *et al.*[18] reported the same phenomena in the multilayered [2.2]paracyclophane system. In practice, besides the strong peak around 1600 cm^{-1}, the cyclophanes (**3**—**6**, **25**, and **27**) also exhibit two strong peaks near 720 and 690 cm^{-1} (Table 1). This result indicates that the compounds all bear strained benzene rings.

The NMR spectral data of all the cyclophanes and the reference compounds are summarized in Table 2. The most remarkable feature is that the chemical shifts of all the benzene ring protons appear at high field, as in the case of [2.2]paracyclophane.[19] For example, in the NMR spectrum of **3**, the signal of benzene protons (δ, 6.38 ppm) is shifted upfield by 0.53 and 0.84 ppm compared with that of the reference compound **22**

(δ, 6.93 and 7.23 ppm). Since the benzene ring protons of **3** are probably deshielded by the bridging vinylene group, this phenomenon indicates that the two benzene rings in **3** are held face to face in more close proximity by the vinylene bridge than in **22**. Staab and Ipaktschi[10] have previously reported from the X-ray analysis of 1,8-bis(phenylethynyl)naphthalene (**28**) that the nonbonding interaction between the two phenylethynyl groups of **28** results in a splaying out of the two phenylethynyl groups and, as a result, that the distance between the centers of two triple bonds is near the sum of van der Waals radii of π-systems. Similar to the case of **28**, the tolyl groups in **22** are relatively more distant from one another, compared with those of **3** in which the tolyl groups are bound together by vinylene bridges at both ends. Moreover, as in the electronic spectra of other cyclophanes, the electronic spectrum of **3** shows a general broadening of all bands in the spectrum and hyperchromic and bathochromic shifts of the long wavelength bands, compared with that of **22** (see Fig. 1). This result may be due to a more strong transannular π-electronic interaction in **3** than in **22**. On the other hand, the NMR signals of benzene ring protons in **22** are shifted somewhat upfield, compared with those of monosubstituted analog, 1-(*p*-tolylethynyl)naphthalene (**29**). In addition, in the electronic spectrum of **22**, the longest wavelength bands appear at a wavelength longer by 32 nm than those of **29**. This bathochromic shift and an increase of intensity in the spectrum of **22** may be caused by the transannular π-electronic interaction between the two chromophores in **22**.

The structures of **4** and **5** can be also assigned to cyclophane structure by a comparison of their NMR data with those of the reference compounds: **24** and 5-*p*-tolylacenaphthene (**30**). Similar to the case of **3**, the upfield shifts of benzene ring protons in **4** (Δ, 0.24 and 0.20 ppm) and in **5** (Δ, 0.09 and 0.12 ppm), compared with those in **24**, are explained by cyclophane structure, in which the benzene ring protons in **4** and **5** lie in more close proximity to the π-cloud of the opposed moiety than in **24**. House *et al.*[5] have previously reported that the molecule of 1,8-diphenylnaphthalene (**31**) should be deformed to alleviate the nonbonding interaction between the two phenyl rings and that the approximately parallel planes of the two phenyls are at an angle of approximately 70° to the plane of the naphthalene ring. Similar to the case of **31**, in **24** the nonbonding interaction between the two aryl rings results in a splaying out of the two aryl rings and as a result, the aryl rings in **24** are relatively more distant from one another, compared with those of **4**. Furthermore, the NMR spectrum of saturated cyclophane **4** showed H_a at 6.41 ppm and H_b at 6.54 ppm, indicating a marginal upfield shift (0.06 and 0.15 ppm) with respect to the unsaturated cyclophane **5**; this is characteristic of such pairs of cyclophanes (with saturated and unsaturated bridges).[20] On the other hand, similar to the case of **22**, the NMR signals of aryl ring protons in **24** are shifted upfield, compared with those of **30**. Additionally, in the electronic spectrum of **24**, compared with that of **30**, all the absorption curves exhibit broadening, and bathochromic and hyperchromic shifts, caused by the transannular π-electronic interaction between the two aryl moieties in **24** (see Fig. 2).

The NMR and electronic spectra of **6** are also consistent with a cyclophane structure. The chemical shifts for H_a and H_b protons of benzene rings of **6** are found respectively at 0.30 and 0.13 ppm upfield relative to those (H_a and H_b) of the reference compound **26**. These upfield shifts are due to the fact that, as in the case of **3**, the two benzene rings in **6** are held face to face in more close proximity by the vinylene bridge at both ends than in **26**. Furthermore, the electronic spectrum of **6** shows a general broadening of all bands in spectrum and hyperchromic and bathochromic shifts of the long wavelength bands, compared with that of **26** (see Fig. 3). It is probably due to more strong transannular π-electronic interaction between the two aryl moieties in **6** than in **26**. On the other hand, in the NMR spectrum of **26**, the upfield shifts of H_a (Δ, 0.29 ppm) and H_b (Δ, 0.32 ppm) are also observed, compared with the corresponding ones in the reference compound: 5-*p*-tolylacenaphthene (**32**). Moreover, in the electronic spectrum of **26**, the electronic absorption curve becomes even more structureless with bathochromic shift and increased intensity of the band, compared with those of **32**. It indicates that the two aryl moieties in **26** interact strongly with each other, similar to the case of **22**.

Ruthenium-catalyzed Reduction of Carbonyl Compounds Using Formic Acid

Yoshihisa WATANABE,* Tetsuo OHTA, and Yasushi TSUJI
Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
(Received November 19, 1981)

Carbonyl compounds were hydrogenated to the corresponding alcohols in excellent yields using formic acid with a ruthenium complex at 125 °C for 3 h. 2-Propanone was reduced to 2-propanol by $RuCl_2(PPh_3)_3$–HCOOH system in 94% yield with 98% selectivity. 3-Pentanone, cyclohexanone, acetophenone, and propiophenone were hydrogenated to the corresponding alcohols in 86, 78, 84, and 86% yields respectively. The ketone having the bulkier alkyl groups showed lower reactivity. The catalytic activity was found to decrease in the order $RuCl_2(PPh_3)_3$, $RuHCl(PPh_3)_3$, $RuHCl(CO)(PPh_3)_3$, and $RuH_2(PPh_3)_4$.

Catalytic transformation of carbonyl compounds to alcohols is an important unit processes in organic synthesis. Since the first report of Schrock and Osborn using a cationic rhodium complex as a catalyst, several methods have been reported for the homogeneous catalytic hydrogenation of carbonyl compounds.[1] On the other hand, catalytic transfer hydrogenation using organic compounds as hydrogen sources is of current interest and there have been several reports using iridium,[2] cobalt,[3] iron,[4] rhodium,[5] and ruthenium[6] complexes. In these reactions alcohols have most often been used as hydrogen sources.

Formic acid is easily derived from synthesis gas and its application to organic synthesis is worth pursuing; we found that the $RuCl_2(PPh_3)_3$–HCOOH system is effective for the homogeneous hydrogenation of carbonyl compounds to alcohols without solvent. The preliminary results have been reported[7] briefly. In this paper we will describe the detailed investigation of the optimum conditions and the scope of this catalyst system.

Results and Discussion

Ketones and aldehydes were reduced to the corresponding alcohols in excellent yields by formic acid with a ruthenium catalyst such as $RuCl_2(PPh_3)_3$ without solvent. In a representative example, an equimolar mixture of acetophenone (80 mmol) and formic acid was heated without solvent at 125 °C for 3 h in an autoclave in the presence of a catalytic amount of $RuCl_2(PPh_3)_3$ (0.10 mmol). As a reaction product, 1-phenylethanol was formed in 84% yield with 98% selectivity.

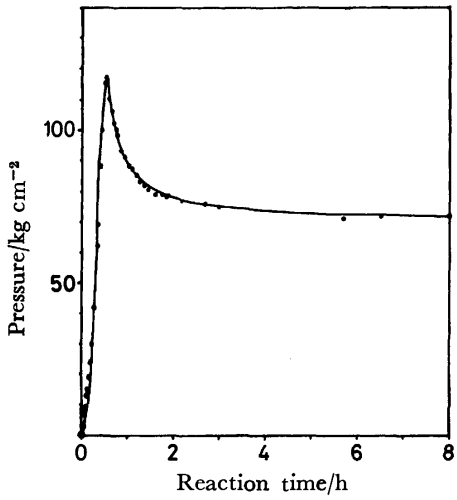

Fig. 1. Time dependence of the pressure in the hydrogenation of acetophenone by $RuCl_2(PPh_3)_3$–HCOOH.
The mixture of acetophenone (80 mmol), formic acid (97 mmol), and $RuCl_2(PPh_3)_3$ (0.10 mmol) was stirred at 125 °C for 3 h in 50 ml stainless steel autoclave.

$$R\text{–}\overset{O}{\overset{\|}{C}}\text{–}R' + HCOOH \xrightarrow{RuCl_2(PPh_3)_3} R\text{–}\overset{OH}{\overset{|}{C}}H\text{–}R' + CO_2 \quad (1)$$

Results of the hydrogenation of various ketones are listed in Table 1. Methyl alkyl ketones and methyl aryl ketones such as acetone, 2-butanone, 4-methyl-2-pentanone, and acetophenone were hydrogenated to the corresponding alcohols in excellent yields. Similarly, 3-pentanone, cyclohexanone, and propiophenone gave the corresponding alcohols in good yields. But 3-methyl-2-butanone and 3,3-dimethyl-2-propanone showed poor reactivity and 2,4-dimethyl-3-pentanone was not reduced under the conditions used. These results show that the ketones having the bulkier alkyl groups would have the lower reactivity.

α- and β-Keto esters were also reduced by this method. Ethyl pyruvate was reduced in *ca.* 100% conversion to give ethyl lactate in 78% isolated yield. Ethyl acetoacetate gave the mixture of ethyl 3-hydroxybutyrate and 1-methyl-2-(ethoxycarbonyl)ethyl 3-hydroxybutyrate. The latter seems to be formed by two steps, hydrogenation of ethyl acetoacetate followed by the ester exchange reaction between two molecules of ethyl 3-hydroxybutyrate.

$$2\ CH_3\overset{OH}{\overset{|}{C}}HCH_2COOEt \longrightarrow CH_3\overset{OH}{\overset{|}{C}}HCH_2COO\overset{CH_3}{\overset{|}{C}}HCOOEt + EtOH \quad (2)$$

2-Acetylpyridine was also reduced by this system to give 2-(1-hydroxyethyl)pyridine in 17% isolated yield, but 3-acetylpyridine was reduced very little.

When an equimolar mixture of 2,3-butanedione and formic acid was heated in the presence of $RuCl_2(PPh_3)_3$, 2-hydroxy-3-butanone and 2,3-butanediol were given in 35 and 28% yields respectively. When the ratio of formic acid/2,3-butanedione was two, 2-hydroxy-3-butanone was given in 6% yield and 2,3-butanediol was given in 54% yield. 2-Hydroxy-3-butanone was also reduced by this system to give a 57% yield of 2,3-

TABLE 1. THE HYDROGENATION OF KETONES BY $RuCl_2(PPh_3)_3$–HCOOH[a]

a) The mixture of a ketone (160 mmol), formic acid (160), and $RuCl_2(PPh_3)_3$(0.20 mmol) was stirred at 125 °C for 3 h. b) Determined by GLC and based on the amount of ketone used. The figures in parentheses show isolated yields. c) $RuCl_2(PPh_3)_3$ (0.10 mmol). d) $RuCl_2(PPh_3)_3$ (0.05 mmol).

butanediol.

A few examples of the transfer hydrogenation of ketones in the presence of ruthenium complexes are known; benzyl alcohol,[6c] 1-phenylethanol,[6b,f] and 2-propanol[6f] are used as hydrogen donors. These reactions, however, give products in lower yields and severer reaction conditions are required. These transfer hydrogenations of carbonyl compounds by alcohols are reversible and the maximum yield of the hydrogenated product is determined by the equilibrium unless the product is removed from the reaction mixture. Since carbon dioxide derived by the decomposition of the formic acid is not reduced to formic acid in the reverse direction in the present system, the yield of the product would be expected to be determined kinetically.

The present system, $RuCl_2(PPh_3)_3$–HCOOH, can be used for the hydrogenation of aldehydes such as benzaldehyde, 2-ethylhexanal and octanal (Table 2). The aldehydes were reduced to the corresponding alcohols in 80—63% yields accompanied by the formation of the corresponding formate in 5—20% yields.

Catalyst. Catalytic activities of several ruthenium complexes for the hydrogenation of acetophenone are shown in Table 3. Among the ruthenium complexes examined, $RuCl_2(PPh_3)_3$ exhibited the highest activity, followed by $RuHCl(PPh_3)_3$, $RuHCl(CO)(PPh_3)_3$, $RuH_2(CO)(PPh_3)_3$, $Ru(CO)_3(PPh_3)_2$, and $RuH_2(PPh_3)_4$. One cluster, $Ru_3(CO)_{12}$, showed no catalytic activity. Although $RuCl_3$ showed only low catalytic activity, an addition of PPh_3 markedly improved the activity (Fig. 2). When the ratio of $PPh_3/RuCl_3$ was 6, the reactivity was almost equal to that of $RuCl_2(PPh_3)_3$. The large excess of the PPh_3 resulted in the decrease of the yield of the alcohol. Tributylphosphine and triphenyl phosphite had much poorer effects as additives (3 mol/mol of $RuCl_3$) and gave the alcohols in 6 and 3% yields respectively.

Effects of Reaction Conditions. Effects of reaction temperature, reaction time, amounts of $RuCl_2(PPh_3)_3$, and the molar ratio of substrate/formic acid were examined. The effects of reaction temperature in the hydrogenation of acetophenone by the $RuCl_2(PPh_3)_3$–

26	$Ru_3(CO)_{12}+9PPh_3$	91	9

a) The mixture of acetophenone (160 mmol), formic acid (160 mmol), and a Ru complex (0.20 mmol) was stirred at 125 °C for 3 h. b) Determined by GLC and based on the amount of acetophenone used.

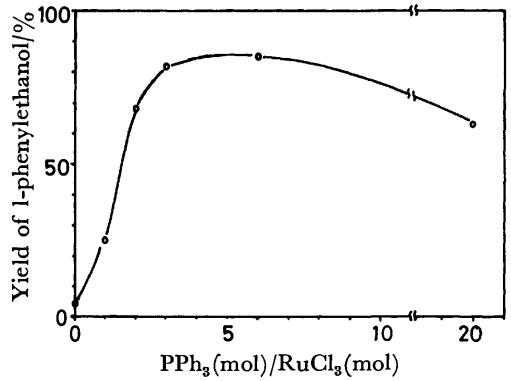

Fig. 2. Effect of the ratio of $PPh_3/RuCl_3$ on the hydrogenation of acetophenone with formic acid.
The mixture of acetophenone (80 mmol), formic acid 80 mmol), $RuCl_3 \cdot nH_2O$ (0.10 mmol), and PPh_3 (0—2.0 mmol) was stirred at 125 °C for 3 h. Yield was determined by GLC and based on the amount of acetophenone used.

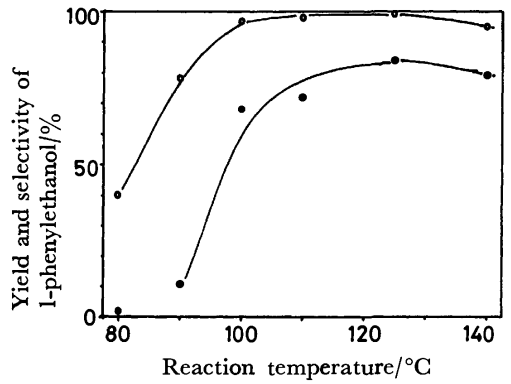

Fig. 3. The temperature dependence on the yield and selectivity of 1-phenylethanol in the hydrogenation of acetophenone by $RuCl_2(PPh_3)_3$ with formic acid.
●: Yield, ○: selectivity.
The mixture of acetophenone (80 mmol), formic acid (80 mmol), and $RuCl_2(PPh_3)_3$ (0.10 mmol) was stirred for 3 h. Yield was determined by GLC and based on the amount of acetophenone used.

HCOOH system are shown in Fig. 3. The yield of 1-phenylethanol and its selectivity had a peak at about 125 °C, because the formate and a small amount of condensation products were obtained at lower (95 and 110 °C) and higher (140 °C) temperatures respectively.

In this procedure, 0.10 mmol (0.063 mol%) of $RuCl_2(PPh_3)_3$ appears to be sufficient for the hydrogenation of cyclohexanone (Table 1: Runs 9, 10, and 11).

The effect of the amount of formic acid is shown in Table 4. Excellent yields and selectivities of the products can be achieved by using an equimolar amount of formic acid. The presence of an excess amount of the formic acid improves the yield of the alcohol but it decreases the selectivity of the alcohol by formation of the corresponding formate (See Runs 10, 28, and 29).

For the reduction of unsaturated compounds with formic acid, the Leukert-Wallach reaction is well known, but reducible substrates are limited. Formic acid is also used for conversion of benzaldehyde, acetophenone, and acetylpyridine to toluene, ethylbenzene, and ethylpyridine respectively[8] in the presence of heterogeneous catalysts. There have been only a few reports on hydrogenation by ruthenium complexes using formic acid.[9,10] They have been applied only for the hydrogenation of olefinic bonds.

The results obtained here clearly demonstrate that a $RuCl_2(PPh_3)_3$–HCOOH system is applicable for the transformation of carbonyl compounds to alcohols efficiently without solvent. This procedure has the following advantages. 1) As formic acid is liquid handling is easier than that of molecular hydrogen. 2) As the reaction is carried out without solvent and the formic acid used is completely decomposed through the reaction, products are easily separated. 3) The reaction proceeds with excellent yields and selectivities of the products.

The pressure *vs.* the reaction time through the reduction are shown in Fig. 1. At the maximum pressure, acetophenone was reduced to 1-phenylethanol in 39% yield and molecular hydrogen was produced in 36% yield, based on the formic acid used. It has been reported that the catalytic hydrogenation of carbonyl compounds by $RuHCl(CO)(PPh_3)_3$ using molecular hydrogen is accelated by the addition of water.[1a] In the present hydrogenation using formic acid, a considerable amount of molecular hydrogen was first evolved and then it was absorbed in the cource of the reaction. In this case the formic acid used contained some water. The fact that the reaction of acetophenone with molecular hydrogen in the presence of water without formic acid gave a 65% yield of 1-phenylethanol (Run 31) also supports the mechanism described above. Thus the main part of the present reaction can be explained as follows. First, formic acid is decomposed to hydrogen gas and carbon dioxide. Then the carbonyl compounds

Table 4. The hydrogenation of acetophenone by $RuCl_2(PPh_3)_3$[a]

Run	Hydrogen source	Reaction time/h	Acetophenone recovered/%	Yield/% of 1-phenylethanol[b]
10	HCOOH (160 mmol)	3	15	84

30	H_2 (73 kg/cm² at 15 °C)	3	84	16
31[c]	H_2 (88 kg/cm² at 15 °C)	3	34	65

a) The mixture of acetophenone (160 mmol), hydrogen source, and $RuCl_2(PPh_3)_3$ was heated at 125 °C. b) Determined by GLC and based on the amount of acetophenone used. The figures in parentheses show the yields of 1-phenylethyl formate. c) Water (16 mmol) was added.

are catalytically hydrogenated in the presence of water by a ruthenium complex. However, since Sasson has reported, the transfer hydrogenation of α,β-unsaturated ketones by formic acid,[10] the transfer hydrogenation of the carbonyl compounds by formic acid may not be ruled out completely.

Experimental

GLC analysis was performed on a Shimadzu-GC 3BT. ^{1}H NMR spectra were obtained at 60MHz with a JEOL PM-60 and ^{13}C NMR spectra were obtained at 60 MHz with a JEOL PM-60 and ^{13}C NMR spectra were recorded at 25.05 MHz with a JEOL pulsed Fourier Transform spectrometer, model FX-100, using tetramethylsilane as an internal standard. IR spectra were measured on a Hitachi model 215 grating spectrophotometer.

Materials. All substrates used were commercial products. The aldehydes and ketones were distilled before use. Moist formic acid (*ca.* 90% aq solution) was used without further purification. $RuCl_3 \cdot nH_2O$, PPh_3, $P(n\text{-}Bu)_3$, $P(OPh)_3$, and $Ru_3(CO)_{12}$ were commercial products. $RuCl_2(PPh_3)_3$,[11] $RuHCl(PPh_3)_3$,[12] $RuHCl(CO)(PPh_3)_3$,[13] $RuH_2(PPh_3)_4$,[14] $RuH_2(CO)(PPh_3)_3$,[13] and $Ru(CO)_3(PPh_3)_2$[13] were prepared by published methods.

Procedures of Hydrogenation. A substrate (160 mmol), formic acid (160 mmol), and a ruthenium complex (0.20 mmol) were placed in a 100 ml stainless steel autocleave with a magnetic stirring bar. The air was replaced with argon. The autoclave was then heated at the appropriate temperature in an oil bath for 3 h. Reaction products were isolated by the usual method and identified by comparing the ^{1}H and/or ^{13}C NMR and IR spectra with those of the authentic samples. Amounts of the substrate recovered and of the products were determined by GLC (3 mm$\phi \times$3 m column packed with 10% Versamide 900 on Neopack 1A 60—80 mesh or with 20% DEGA on Uniport B 80—100 mesh) using internal standards.

In the reaction of benzophenone, amounts of benzophenone recovered and of diphenylmethanol formed were determined by ^{1}H NMR spectra.

Reduction of Acetophenone with Molecular Hydrogen. Acetophenone (160 mmol) and $RuCl_2(PPh_3)_3$ (0.20 mmol) were placed into a 100 ml stainless steel autoclave. The air was replaced with argon and then hydrogen was charged at room temperature. Then the autoclave was heated at 125 °C for 3 h.

The Transition Metal-catalyzed *N*-Heterocyclization. A Reductive Transformation of Aminonitroarenes and Dinitroarenes into Phenanthroline Derivatives Using Aliphatic Aldehydes under Carbon Monoxide Pressure

Yoshihisa WATANABE,* Naoki SUZUKI, and Yasushi TSUJI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 21, 1981)

The Catalytic *N*-heterocyclization of aminoarenes and dinitroarenes using aliphatic *n*-C_3—C_5 aldehydes was carried out at 180 °C under the pressure of carbon monoxide (70 atm at room temperature) in the presence of $RhCl(PPh_3)_3$ and $PdCl_2$ as a binary catalyst system. The reaction of *p*-nitroaniline with propanal, butanal, and pentanal gave 3,8-diethyl-2,9-dimethyl-4,7-phenanthroline, 2,9-diethyl-3,8-dipropyl-4,7-phenanthroline, and 3,8-dibutyl-2,9-dipropyl-4,7-phenantroline in 43, 57, and 54% yields respectively. On the other hand, *m*-nitroaniline and *o*-nitroaniline gave 1,7-phenanthroline and imidazole derivatives in rather low yields (21 and 24%) under the reaction conditions employed.

Recently, novel methods have been developed for building up a quinoline nucleus using transition-metal complexes as catalysts under nonacidic conditions.[1,2] In previous papers, we have demonstrated that rhodium, ruthenium, and palladium complexes are effective catalysts for the *N*-heterocyclization of aminoarenes and nitroarenes.[3-6] μ,μ'-Dichlorobis(norbornadiene)dirhodium(I)($[RhCl(NBD)]_2$) was active for the *N*-heterocyclization of aminoarenes using aliphatic aldehydes.[3] Nitroarenes were reductively converted into quinolines and (dialkylamino)arenes using an aldehyde in the presence of a binary catalyst system, $RhCl(PPh_3)_3$–$PdCl_2$, under the pressure of carbon monoxide.[4] $RuCl_2(PPh_3)_3$ is also active for the *N*-heterocyclization of aminoarenes using $\Delta^{2,3}$-unsaturated alcohols[5] and for that of nitroarenes using saturated alcohols.[6] These methods provided a variety of methods for synthesizing quinoline derivatives.

In this paper, phenanthroline derivatives were prepared by the double *N*-heterocyclization of nitroanilines and dinitrobenzenes using *n*-C_3—C_5 aliphatic aldehydes in the presence of a binary catalyst system ($RhCl(PPh_3)_3$–$PdCl_2$) under the pressure of carbon monoxide.

1,7-Phenanthroline and imidazole derivatives were also obtained by the reaction of *m*-nitroaniline and *o*-nitroaniline respectively with propanal.

Results and Discussion

At the outset, *p*-nitroaniline was allowed to react with propanal at 180 °C in the presence of a rhodium and/or palladium complex under carbon-monoxide pressure. In this reaction, 3,8-diethyl-2,9-dimethyl-4,7-phenanthroline (**1**), 2-ethyl-3-methyl-6-(propylamino)quinoline (**2**), and 2-ethyl-3-methyl-6-nitroquinoline (**3**) were obtained as the products (Eq. 1). This reaction was examined in detail in order to determine the optimum conditions for the preparation of **1**.

A variety of rhodium and/or palladium complexes

a) A mixture of *p*-nitroaniline (20 mmol), propanal (90 mmol), water (2 ml), a rhodium and/or palladium complex, and ethanol (20 ml) was heated at 180 °C under the pressure of carbon monoxide (70 atm) for 4 h. b) Based on the amount of *p*-nitroaniline used. Determined by GLC. c) **1**: 3,8-Diethyl-2,9-dimethyl-4,7-phenanthroline, **2**: 2-ethyl-3-methyl-6-(propylamino) quinoline, **3**: 2-ethyl-3-methyl-6-nitroquinoline.

was examined as catalysts, the results are shown in Table 1. In these runs, the conversion of nitroaniline was high. In some cases, a tarry material was also formed.

The yields of the products depended greatly on the catalysts used. A binary catalyst system was effective for the double *N*-heterocyclization to give **1** in 43—46% yields (Runs 1, 2, and 3). The catalyst systems, such as $RhCl(PPh_3)_3$–$PdCl_2$ (Run 1), $RhCl_3$–$Pd(PPh_3)_4$ (Run 2), and $RhCl_3$–$PdCl_2$–PPh_3 (Run 3), gave almost the same yield of **1**. The presence of triphenylphosphines enhanced the yield of **1** (Runs 3 and 4), although the addition of triphenylphosphine to the combination of $RhCl(PPh_3)_3$–$PdCl_2$ retarded the formation of **1** (Run 5). On the other hand, when a rhodium catalyst was used alone, the yield of **1** decreased considerably. In those cases, $RhCl_3$–$3H_2O$ was effective for the formation of **1** (Run 6), followed by μ,μ'-dichlorobis(cyclooctadiene)dirhodium ($[RhCl(COD)]_2$) (Run 9), $Rh_4(CO)_{12}$ (Run 10), and $RhCl(PPh_3)_3$ (Run 8). An increase in the amount of the $RhCl_3 \cdot 3H_2O$, however, resulted in only a small increase in the yield of **1** (Runs 6 and 7). Palladium complexes alone, such as $PdCl_2$ and $Pd(PPh_3)_4$, also showed catalytic activities, but with low yields of **1** (Runs 11 and 12).

Next, the effects of other reaction variables were examined. The results are listed in Table 2. A binary system, $RhCl(PPh_3)_3$ (0.17 mmol) and $PdCl_2$ (0.26 mmol), was used as the catalyst. A four-fold molar quantity of propanal (80 mmol) is required for the double *N*-heterocyclization of nitroanilines (20 mmol) stoichiometrically. A moderate yield of **1** (43%) was obtained when 90 mmol of the aldehyde was used. An increase in the amount of the aldehyde to 120 or 160 mmol, however, resulted in a decrease in the yields of **1**, **2**, and **3** and an increase in the amouns of tarry materials. An aldol condensation may interfere with the reaction in these cases (Runs 13 and 14). Concerning the reaction temperature, an elevated temperature (180 °C) was needed for the reaction. Lower and higher temperatures gave poorer yields of **1** (Runs 15 and 16). Prolonging the reaction time from 4 h to 8 h slightly improved the yield of **1** and **2** (Run 18). Even a 2 h reaction time almost completed the reaction (Run 17). Among the solvents examined, ethanol was the best, followed by methanol, benzene, and tetrahydrofuran

TABLE 2. EFFECTS OF REACTION VARIABLES ON PRODUCTS DISTRIBUTION[a]

Run No.	Propanal (mmol)	Reaction temp/°C	Reaction time/h	Solvent	Conversion[b] %	Product yield/%[b,c] 1	2	3

a) A mixture of *p*-nitroaniline (20 mmol), propanal (90—160 mmol), water (2 ml), $RhCl(PPh_3)_3$ (0.17 mmol), $PdCl_2$ (0.26 mmol), and a solvent (20 ml) was treated at 150—200 °C under the pressure of carbon monoxide (70 atm) for 2—8 h. b) Based on the amount of *p*-nitroaniline used. Determined by GLC. c) **1**: 3,8-Diethyl-2,9-dimethyl-4,7-phenanthroline, **2**: 2-ethyl-3-methyl-6-(propylamino)-quinoline, **3**: 2-ethyl-3-methyl-6-nitroquinoline. d) Without water. e) Under the pressure of hydrogen (70 atm) instead of carbon monoxide.

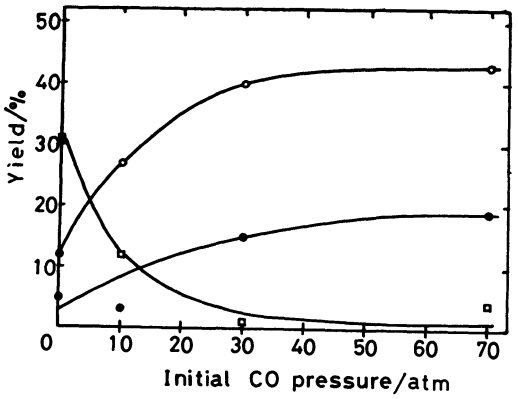

Fig. 1. Effects of pressure of carbon monoxide on products distribution.
A mixture of *p*-nitroaniline (20 mmol), propanal (90 mmol), water (2 ml), $RhCl(PPh_3)_3$ (0.17 mmol), $PdCl_2$ (0.26 mmol), and ethanol (20 ml) was treated at 180 °C for 4 h. Yields were based on an amount of *p*-nitroaniline used and determined by GLC. ○: 3,8-Diethyl-2,9-dimethyl-4,7-phenanthroline, ●: 2-ethyl-3-methyl-6-(propylamino)quinoline, □: 2-ethyl-3-methyl-6-nitroquinoline.

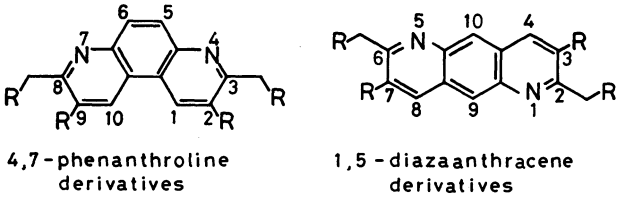
(Runs 1, 20, 21, and 22). The yields of **1** and **2** decreased considerably when the reaction was carried out without water (Run 19). Thus, water is indispensable for the reductive *N*-heterocyclization of nitroarene under carbon-monoxide pressure. Furthermore, under hydrogen pressure (70 atm) instead of carbon monoxide, **1** was also produced, but in only low yield (Run 23). These results indicated that the water-gas-shift reaction was operative for the reaction.

The relation between the initial pressure of carbon monoxide and the yield of the products is shown in Fig. 1. Under an argon atmosphere ($P_{CO}=0$), **3** was a dominant product in a yield of more than 30%, while **1** and **2** were given as minor products, indicating that carbon-monoxide pressure is not necessary for the *N*-heterocyclization of the aminoarene moiety, as was shown in previous paper.[3] However, with increases in the pressures of carbon monoxide to 10—70 atm, the yields of **3** decreased and then **1** and **2** became the major products, with a reduction of the nitroarene moiety. A pressure of carbon monoxide higher than 30 atm is required for the major production of **1**.

By inference from the result of the *N*-heterocyclization of aminoarene,[3] we first expected *p*-phenylenediamine to be a suitable substrate for the double *N*-heterocyclization. However, that is not the case. A mixture of *p*-phenylenediamine (20 mmol), $[RhCl(NBD)]_2$ (0.17 mmol), which was an excellent catalyst for the formation of quinoline derivatives from aminoarene and aldehyde,[3] propanal (90 mmol), ethanol (20 ml), and *p*-nitroaniline (30 mmol) or nitrobenzene (60 mmol) as oxidizing agents was heated at 180 °C under an argon atmosphere for 4 h. The yields of **1** were only 1—2%, based on the *p*-phenylenediamine used. In this case, one amino group may interfere with the *N*-heterocyclization of the other amino group in the same molecule.

This procedure can be applied to a variety of other aliphatic aldehydes and nitroarenes for the preparation of phenanthroline derivatives. The results are summarized in Table 3. *p*-Nitroaniline reacted with propanal, butanal, and pentanal to give the corresponding phenanthroline derivatives in fairly good yields of 43, 57, and 54% respectively (Runs 1, 24, and 25). The conbination of *p*-nitroaniline and ethanal, however failed to give the product, and a tarry material was formed. As the substrate, *p*-dinitrobenzene can be employed in this reaction, although the yield was rather low (Run 26).

As for the structure of the product mentioned above, two isomers were possible because of the two directions in the cyclization. In the reaction of *p*-nitroaniline or *p*-dinitrobenzene with the aldehyde, two isomers, 4,7-phenanthroline and 1,5-diazaanthracene derivatives, were possible (Scheme 2). The absence of J_{C-C-H} in the non-decoupling ^{13}C-NMR spectra clearly indicated that the products are not 1,5-diazaanthracene, but 4,7-phenanthroline derivatives, as is shown in Eq. 1. In the non-decoupling ^{13}C-NMR spectrum of the product, one of the aromatic carbon resonances, with a shoter T_1, appeared as a doublet ($J_{C-H}=163$ Hz) without any further long-range coupling. The resonance is assigned



Scheme 2.

Table 3. Synthesis of phenanthroline derivatives from nitroarenes and aldehydes[a]

Run No.	Nitroarene	Aldehyde	Product	Yield/%[b]
1	*p*-Nitroaniline	Propanal	3,8-Diethyl-2,9-dimethyl-4,7-phenanthroline	43 (26)
24	*p*-Nitroaniline	Butanal	2,9-Diethyl-3,8-dipropyl-4,7-phenanthroline	57 (13)
25	*p*-Nitroaniline	Pentanal	3,8-Dibutyl-2,9-dipropyl-4,7-phenanthroline	54 (33)
26	*p*-Dinitrobenzene	Propanal	3,8-Diethyl-2,9-dimethyl-4,7-phenanthroline	14
27	*m*-Nitroaniline	Propanal	2,8-Diethyl-3,9-dimethyl-1,7-phenanthroline	21
28	*m*-Dinitrobenzene	Propanal	2,8-Diethyl-3,9-dimethyl-1,7-phenanthroline	15
29	*o*-Nitroaniline	Propanal	2-Ethylbenzimidazole	24
30	*o*-Dinitrobenzene	Propanal	2-Ethylbenzimidazole	10

a) A mixture of nitroarene (20 mmol), aldehyde (90 mmol), water (2 ml), $RhCl(PPh_3)_3$ (0.17 mmol), $PdCl_2$ (0.26 mmol), and ethanol (20 ml) was treated at 180 °C under the pressure of carbon monoxide (70 atm) for 4 h. b) GLC yield based on the amount of nitroarene used. Parentheses indicate isolated yields.

to C_5 (or C_6) of 4,7-phenanthroline derivatives, since $J_{C_5\text{-}C\text{-}C\text{-}H_1}$ is too small and since the C_5 (or C_6) carbon resonance does not show any long-range coupling in the spectra. If the product is the 1,5-diazaanthracene derivative, all the resonances of the aromatic carbon resonances having shorter T_1 values will appear as peaks with a long-range coupling of 4—5 Hz ($J_{C_9\text{-}C\text{-}H_8}$, $J_{C_8\text{-}C\text{-}H_9}$). The absence of such a long-range coupling clearly indicated the product was 4,7-phenanthroline derivative.

Subsequently this reaction is applied to other nitroaniline and dinitrobenzene isomers. In the reaction with propanal, *m*-nitroaniline and *m*-dinitrobenzene gave 1,7-phenanthroline derivative in yields of 21 and 15% respectively (Runs 27 and 28) (Eq. 2). In this case, there are also two possible structures of the product based on a direction of the cyclization. However, in this case two nonequivalent peaks of methyl and ethyl groups appeared in the ^1H and ^{13}C-NMR spectra. This fact clearly indicated that the product was a 1,7-phenanthroline derivative, not a synmetric 1,8-diazaanthracene derivative.

o-Nitroaniline and *o*-dinitrobenzene failed to give a 1,10-phenanthroline derivative, but 2-ethylbenzimidazole was produced in poor yields (Runs 29 and 30) (Eq. 3).

The mechanism of the binary catalyst system is not yet clear, but several palladium complexes have been reported to form a ortho-metalated complex easily.[7] We previously suggested that the ortho-metalated species was a key intermediate in the rhodium complex-catalyzed *N*-heterocyclization of aminoarenes with aldehydes.[3] In the present reaction, palladium complex might be operative in the ortho-metalated step in the catalytic cycle. However, another factor, the so-called synergism, might also work in the reaction.

Experimental

The melting points and boiling points are uncorrected. The melting points were taken on a Yanagimoto capillary melting-point apparatus. The IR spectra were measured on a Hitachi model 215 grating spectrophotometer. The ^1H-NMR-spectra were obtained at 60 MHz with a JEOL JNM-PMX 60 spectrometer or at 220 MHz with a Varian Model HR-220 spectrometer. ^{13}C NMR spectra were measured at 25.05 MHz with a JEOL JNM FX 100. Samples were dissolved in $CDCl_3$, and the chemical-shift values were expressed in δ relative to Me_4Si as the internal standerd. Elemental analyses were performed at the Microanalytical Center of Kyoto University. The mass spectra were recorded on a JMS OISG mass spectrometer.

The aldehydes, the nitroarenes, and the other materials employed in this study were commercial products. The aldehydes were distilled before use. Carbon monoxide was used without further purification. Anhydrous ethanol was dried by the usual method with Mg.

A 100 ml stainless steel autoclave equipped with a magnetic stirrer was used. The general experimental procedure is exemplified by the reaction of *p*-nitroaniline with propanal. A mixture of *p*-nitroaniline (2.76 g, 20 mmol), propanal (5.23 g, 90 mmol), water (2.0 ml), $RhCl(PPh_3)_3$ (0.17 mmol), $PdCl_2$ (0.26 mmol), and anhydrous ethanol (20 ml) was stirred at 180 °C under carbon monoxide (initial pressure, 70 atm at room temperature).

The autoclave was heated to 180 °C (20 min required) and then held at this temperature for 4 h. After cooling, the autoclave was discharged and the ethanol was evaporated from the reaction mixture under a vacuum. The GLC analysis of the reaction product was made using an internal standard (*N,N*-dibenzylaniline): A column (0.3 cmϕ × 3 m) packed with 5% Silicone GE SE-30 on Shimalite W 60—80 mesh. The reaction products were then subjected to fractional distillation or column chromatography (silica gel, $CHCl_3$). Recrystallization was done by means of ether. The identity of the compound was comfirmed by IR, ^1H-NMR, ^{13}C-NMR, mass spectra, and elemental analysis.

The analytical data of the phenanthroline derivatives and other products obtained here may be described as follows:

3,8-Diethyl-2,9-dimethyl-4,7-phenanthroline. Yellow crystals, mp 133—136 °C. ^1H-NMR (220 MHz) ($CDCl_3$): δ 1.39 (t, 6H, $2CH_3$), 2.55 (s, 6H, $2CH_3$), 3.01 (q, 4H, $2CH_2$), 8.08 (s, 2H), 8.46 (s, 2H). ^{13}C-NMR (25.05 MHz) ($CDCl_3$): δ 12.8 (q, $2CH_3$), 19.3 (q, $2CH_3$), 29.2 (t, $2CH_2$), 122.7 (s), 129.3 (s), 130.3 (d), 130.7 (d), 145.5 (s), 162.3 (s). MS: *m/e* 264 (M^+). Found: C, 80.79; H, 7.60; N, 10.49%. Calcd for $C_{18}H_{20}N_2$: C, 81.78; H, 7.63; N, 10.60%.

2,9-Diethyl-3,8-dipropyl-4,7-phenanthroline. Yellow crystals, mp 77—79 °C. ^1H-NMR (220 MHz) ($CDCl_3$): δ 1.09 (t, 6H, $2CH_3$), 1.41 (t, 6H, $2CH_3$), 1.87 (sex, 4H, $2CH_2$), 2.95 (q, 4H, $2CH_2$), 2.96 (t, 4H, $2CH_2$), 8.09 (s, 2H), 8.58 (s, 2H). ^{13}C-NMR (25.05 MHz) ($CDCl_3$): δ 14.4 (q, $2CH_3$), 15.1 (q, $2CH_3$), 23.0 (t, $2CH_2$), 25.7 (t, $2CH_2$), 37.5 (t, $2CH_2$), 122.9 (s), 129.1 (d), 130.5 (d), 135.5 (s), 145.4 (s), 161.1 (s). Found C, 82.52; H, 9.00; N, 8.66%. Calcd for $C_{22}H_{28}N_2$: C, 82.45; H, 8.81; N, 8.74%.

3,8-Dibutyl-2,9-dipropyl-4,7-phenanthroline. Yellow crystals, mp 79—81 °C. ^1H-NMR (220 MHz) ($CDCl_3$): δ 0.99 (t, 6H, $2CH_3$), 1.09 (t, 6H, $2CH_3$), 1.51 (sex, 4H, $2CH_2$), 1.46—1.56 (m, 8H, $4CH_2$), 2.87 (t, 4H, $2CH_2$), 3.02 (t, 4H, $2CH_2$), 8.08 (s, 2H), 8.54 (s, 2H). ^{13}C-NMR (25.05 MHz) ($CDCl_3$): δ 14.1 (q, $2CH_3$), 14.2 (q, $2CH_3$), 23.0 (t, $2CH_2$), 24.2 (t, $2CH_2$), 32.0 (t, $2CH_2$), 34.9 (t, $2CH_2$), 35.3 (t, $2CH_2$), 122.8 (s), 130.0 (d), 130.4 (d), 134.0 (s), 145.4 (s), 161.4 (s). Found: C, 83.01; H, 9.91; N, 7.32%. Calcd for $C_{26}H_{36}N_2$: C, 82.93; H, 9.64; N, 7.44%.

2,8-Diethyl-3,9-dimethyl-1,7-phenanthroline. Yellow crystals, mp 101—104 °C. ^1H-NMR (220 MHz) ($CDCl_3$): δ 1.40 (t, 3H, CH_3), 1.48 (t, 3H, CH_3), 2.48 (s, 3H, CH_3), 2.60 (s, 3H, CH_3), 3.02 (q, 2H, CH_2), 3.05 (q, 2H, CH_2), 7.74 (d, 1H), 7.83 (s, 1H), 7.93 (d, 1H), 9.24 (s, 1H). ^{13}C-NMR (25.05 MHz) ($CDCl_3$): δ 12.3 (q, CH_3), 13.0 (q, CH_3), 18.9 (q, CH_3), 19.2 (q, CH_3), 29.1 (t, CH_2), 29.3 (t, CH_2), 124.2 (s), 125.3 (s), 127.1 (d), 127.3 (d), 129.6 (s), 129.8 (s), 132.8 (d), 135.7 (d), 143.2 (s), 147.0 (s), 161.5 (s), 163.0 (s). Found: C, 80.49; H, 7.74; N, 10.53%. Calcd for $C_{18}H_{20}N_2$: C, 81.78; H, 7.63; N, 10.60%.

2-Ethylbenzimidazole. White crystals, mp 175—177 °C. ^1H-NMR (220 MHz) ($CDCl_3$): δ 1.42 (t, 3H, CH_3), 3.00 (q, 2H, CH_2), 7.17—7.21 (m, 2H), 7.53—7.57 (m, 2H), 9.29 (s, 1H, N-H). ^{13}C-NMR (25.05 MHz) ($CDCl_3$): δ 12.6 (q, CH_3), 22.6 (t, CH_2), 114.5 (d), 122.0 (d), 138.6 (s), 156.8 (s). Found: C, 74.08; H, 6.77; N, 19.38%. Calcd for $C_9H_{10}N_2$: C, 73.94; H, 6.89; N, 19.16%.

2-Ethyl-3-methyl-6-nitroquinoline. Yellow crystals, mp 118—120 °C. IR (KBr): 1340, 1520 cm^{-1}. ^1H-NMR (220 MHz) ($CDCl_3$): δ 1.41 (t, 3H, CH_3), 2.53 (s, 3H, CH_3), 3.03 (q, 2H, CH_2), 7.97 (s, 1H), 8.09 (d, 1H), 8.34 (d, 1H), 8.63 (s, 1H). ^{13}C-NMR (25.05 MHz) ($CDCl_3$): δ 12.2 (q, CH_3), 19.1 (q, CH_3), 29.6 (t, CH_2). MS (*m/e*): 216 (M^+). Found: C, 67.61; H, 5.48; N, 11.78%. Calcd for $C_{12}H_{12}N_2O_2$: C,

66.65; H, 5.59; N, 12.96%.

2-Ethyl-3-methyl-6-(propylamino) quinoline: Yellow crystals. IR (KBr): 3300 cm^{-1}. ^{1}H-NMR (220 MHz) ($CDCl_3$): δ 0.89 (t, 3H, CH_3), 1.19 (t, 3H, CH_3), 1.55 (sex, 2H, CH_2), 2.30 (s, 3H, CH_3), 2.84 (q, 2H, CH_2), 3.05 (t, 2H, CH_2), 3.73 (s, 1H, N–H), 6.50—7.73 (m, 4H).

Intramolecular 1,3-Dipolar Cycloadditions and Intramolecular Ene Reactions of 2-(Alkenyloxy)benzaldehyde Arylhydrazones[1]

Tomio SHIMIZU,* Yoshiyuki HAYASHI, Yoshitaka KITORA, and Kazuhiro TERAMURA
Department of Dyeing, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received December 4, 1981)

2-(3-Aryl-2-propenyloxy)benzaldehyde (or 1-naphthaldehyde) arylhydrazones undergo an intramolecular cycloaddition reaction *via* their 1,3-dipolar tautomers, azomethine imines, to the alkenyl group. Initial cycloadducts were converted to dehydrogenated compounds under the reaction conditions. On the other hand, introduction of cyano or ethoxycarbonyl groups instead of the aryl group into 3-position of the ortho propenyloxy group gave 3-cyanomethyl-4-chromanone arylhydrazones or the corresponding ethoxycarbonyl derivatives, respectively. The formation of these hydrazones was interpreted in terms of intramolecular ene reaction. The course of the reactions depends on the nature of the alkenyl substituents.

1,3-Dipolar cycloaddition reactions provide the most versatile synthesis of 5-membered heterocycles.[2] The syntheses of a number of fused ring compounds using intramolecular cycloadditions have been reported.[3]

Hydrazones are ambident nucleophiles and can react with electrophiles at either carbon or nitrogen. Recent investigations show that monosubstituted hydrazones undergo ene reactions (and subsequent cyclization),[4] 1,3-dipolar cycloadditions *via* azomethine imine tautomer,[5] acid-catalyzed [3+2] cycloadditions,[6] and/or Michael additions (and subsequent cyclization)[4] with alkenes (the four reactions may provide a simple route to a variety of unusual pyrazoles). It is interesting to examine substituent effects on the competing processes of arylhydrazones in the presence of intramolecular olefins. As one of a series of benzopyranopyrazoles preparations,[7] we report here thermal transformations of 2-(alkenyloxy)benzaldehyde (or 1-naphthaldehyde) arylhydrazones to [1]benzo (or naphtho[1',2':5,6]) pyrano[4,3-*c*]pyrazoles or 3-substituted 4-chromanone arylhydrazones.

Results and Discussion

2-(Alkenyloxy)benzaldehyde (or 1-naphthaldehyde) arylhydrazones (**2**) were prepared from salicylaldehyde (or 2-hydroxy-1-naphthaldehyde) *via* 2-(alkenyloxy)-benzaldehydes (or 1-naphthaldehydes) (**1**) in two steps. Although the preparation of **1** was worked up in the usual manner[8a,b] by etherification with alkenyl bromides in the presence of potassium carbonate, some (**1d—e**, **1k—m**) of **1** underwent further base-promoted cyclization, giving furans (**3**) (see Eq. 1). On the other hand, the etherification in the presence of potassium fluoride (fluoride-assisted etherification[8c]) gave **1** in satisfactory yields (Table 1). The reaction of **1** with arylhydrazines gave hydrazones (**2**) in good yields (Table 2). Satisfactory spectral and analytical data for **1** and **2** were obtained. Though some of the hydrazones bearing an ethoxycarbonyl group were not isolated in a crystalline form, it was found from NMR spectra that these hydrazones were formed almost

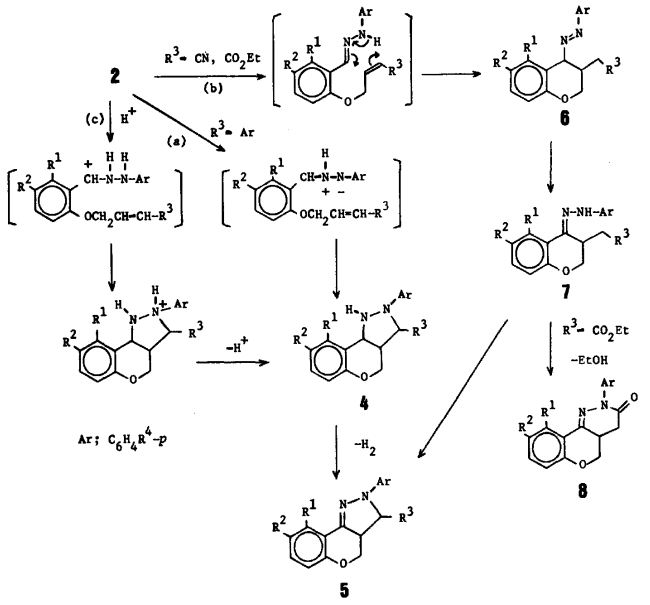
a) Recrystallized from ethanol. b) Satisfactory analytical data were obtained for these compounds. c) A: Refluxing the solution of **2** in xylene for 24 h; B: Refluxing the ethanol solution of **1** and aryl hydrazine for 24 h; C: Refluxing the pyridine solution of **1** and *p*-tolylhydrazine hydrochloride for 24 h. d) **7dr**, **ds**, **kq**, and **7kr** were dissolved in DMSO-d_6, the others were dissolved in $CDCl_3$.

quantitatively. The oily hydrazones were used for the thermal reaction without further purification.

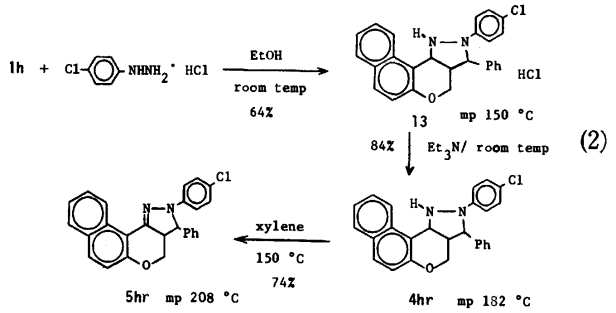
The treatment of the arylhydrazones (**2**) in xylene at 150 °C for 20 h gave 2-aryl-2,3,3a,4-tetrahydro[1]-benzo (or naphtho[1′,2′:5,6])pyrano[4,3-*c*]pyrazoles (**5**). The structure of **5** was assigned on the basis of a comparison of its physical properties (Table 3) with those of specimens prepared by authentic methods[9] (see Scheme 1). On the other hand, 3-cyanomethyl-4-chromanone arylhydrazones (**7**) were the only isolable products from the reaction mixtures of hydrazones (**2**) bearing a 3-cyano-2-propenyloxy group at *o*-position and none of the corresponding cycloadducts (**5**) could be detected. The structure of **7** was determined on the basis of its spectral and analytical data (see Table 4). Reaction of the hydrazones (**2**) bearing an ethoxycarbonyl group as R^3 might occur by different mechanisms: for example, a) The reaction of **1e** with phenylhydrazine



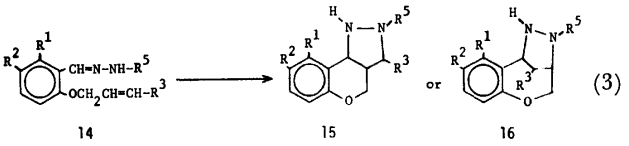
Scheme 2.

in neutral solvents such as ethanol or xylene at refluxing temperatures over 20 h resulted in the formation of ene type product **7eq** in 45% yield. The same reaction in a basic solvent such as pyridine gave **8eq** along with **7eq**. b) The reaction in ethanol containing a small amount of an acid such as acetic acid or sulfuric acid gave the cycloadduct **5mq** in 55% yield without contamination of the ene product.

One of the most plausible mechanisms of the formation of **5** is as follows: arylhydrazones (**2**) undergo intramolecular 1,3-dipolar cycloaddition reaction *via* their azomethine imine tautomer[5] to give pyrazolidines (**4**). which were dehydrogenated to pyrazolines (**5**) under the reaction conditions [route (a) in Scheme 2]. Several possible pathways for the reaction of aldehyde or ketone hydrazones with alkenes are shown in Scheme 2. The route (c) in Scheme 2 is an alternative mechanism, an acid-catalyzed concerted [3+2] cycloaddition reaction,[6] for the formation of **4**. Presence or absence of a base ($NaHCO_3$, Et_3N, or DABCO) has no effect on the reaction of **2jq** in refluxing xylene giving only **5jq**, but an addition of an acid in the reaction of some hydrazones even at room temperature induced a marked increase in yields of the cycloadducts (**5**). The temperatures (150 °C) used in our reactions are apparently high enough to permit substantial presence of the azomethine imine tautomer. If the cyclization reaction of **2** was carried out in solvents containing trace amounts of acid,



(2)



(3)

the [3+2] cycloaddition proceeds much faster than the azomethine imine cycloaddition. Therefore the treatment of **2** in the presence of acid is more convenient for the preparation of **5** (see Eq. 2) and we confirmed that the reaction was facilitated in order of $CO_2Et \approx CN > Ph > alkyl$ group at R^3. Another alternative pathway for the formation of **5** suggested by Snider *et al.*,[4a] intramolecular *N*-alkylation (**7**→**5**) of initial ene type product (**6**→**7**), would be excluded because **7** was stable under the reaction conditions. The intramolecular ene reaction [route (b) in Scheme 1] of the substrate bearing cyano or ethoxycarbonyl group as R^3 may proceed faster than the intramolecular 1,3-dipolar cycloaddition reaction, although we could not find a reasonable explanation of the competitive reactivity in the ene and 1,3-dipolar reaction studied here in terms of FMO theory.[10] Azo compound (**6**), apparent ene reaction products, would easily isomerize to hydrazone structure (**7**), which is a thermodynamically more stable structure under the reaction conditions.

In the case of the reaction with the substrate bearing electron-rich alkenyl group (**2fq** and **2gq**), neither cycloadducts nor ene reaction products was obtained from the reaction mixture, and starting materials were recovered unchanged. It is known[10] that these electron-rich olefins are more reluctant than electron-poor or conjugated olefines to either nucleophilic addition or 1,3-dipolar cycloaddition. Electron-withdrawing substituents on the hydrazone would lower its reactivity, because of the lowered HOMO energy. Thus, we examined the reactivity of phenyl-, *p*-tolyl-, and *p*-chlorophenylhydrazones in the reaction. The more electron-deficient mono- and dinitrophenylhydrazones should be less reactive toward electrophilic species[11] and we, in fact, could not obtain any **5**, **7**, or **8** from the thermal treatment of **2at**—**qt**. Intramolecular Michael type cyclization (Eq. 3) bearing electron deficient olefins would give a product (**16**) containing a seven-membered ring and we could isolate no such products. On the other hand, alkylhydrazones (R^5= alkyl at **14**) have higher reactivity at nitrogen than at carbon atom[12] and only a small amount of Michael adducts (the structure is not yet confirmed) were isolated from the reaction.

Our results show that the thermal intramolecular 1,3-dipolar and ene reactions of **2** proceed in a manner similar to the intermolecular 1,3-dipolar[5] and ene reactions,[4] giving good yields of complex heterocycles. We could obtain **5** in two or three steps from salicylaldehyde (or 2-hydroxy-1-naphthaldehyde) and our procedure is simpler than a reported one.[9b] Our procedure is also suitable for the preparation of 3-substituted 4-chromanone derivatives (**7** or **8**), which are generally difficult to prepare by other methods.

Experimental

Measurements. All the melting and boiling points are

uncorrected. The IR spectra were determined on a Hitachi 215 Infrared Spectrophotometer. The ^1H NMR spectra were measured on a Varian T-60A instrument with TMS as an internal standard.

Materials. 3-Bromo-1-*p*-tolyl-1-propene[13a] and 3-bromo-1-(*p*-chlorophenyl)-1-propene[13b] were prepared according to the method described in the literature.

Preparation of the 2-(Alkenyloxy)benzaldehydes (or 1-naphthaldehydes) (1). *General Procedure*: A mixture of salicylaldehyde (or 2-hydroxy-1-naphthaldehyde) (0.2 mol), 1-substituted 3-bromo-1-propenes (0.25 mol), and potassium fluoride (0.8 mol) in acetone (300 ml) was refluxed for 72 h. After filtration of inorganic salts, evaporation of the filtrate gave a viscous oil which solidified upon scratching with a glass rod. Recrystallization from ethanol gave colorless needles (**1a—m**) in the yields shown in Table 1. In the cases of **1d—e** and **1k—m**, 0.4 mol of KF was used.

Preparation of Hydrazones (2). *General Procedure*: Into a stirred ethanol solution (300 ml) of **1** (0.1 mol) was added first an ethanol solution (50 ml) of phenylhydrazine (or *p*-chlorophenylhydrazine) (0.1 mol) and then 3 ml of acetic acid at room temperature. After stirring the mixture for 6 h at room temperature, evaporation of the ethanol and acetic acid *in vacuo* gave hydrazones (**2**), which was recrystallized from ethanol. Yields and spectral data are shown in Table 2. *p*-Tolylhydrazones are apt to undergo subsequent cycloaddition under the conditions described above, and several attempts to isolate the *p*-tolylhydrazones failed because of subsequent thermal transformation of the hydrazones.

Thermal Reactions of Hydrazones (2) *General Procedure*: Hydrazones (5 mmol) shown in Table 2 and hydrazones bearing an ethoxycarbonyl group as R^3 were refluxed in xylene (50 ml) with a small amount of hydroquinone for 24 h. After distillation of the solvent, the residue was mixed with a small amount of ethanol and was allowed to stand for several days. The crystals which separated were recrystallized from ethanol to give colorless needles (**7**) or yellow crystals (**5**). A chloroform solution of **5** has a brilliant greenish fluorescence.

Specific Procedure. *A)*: A mixture of **1** (10 mmol) and *p*-tolylhydrazine hydrochloride (10 mmol) in pyridine (50 ml) was heated to reflux for 24 h. Then the reaction mixture was poured into water and extracted with ether several times. The ethereal layer was washed with a dilute hydrochloric acid solution, dried over anhydrous sodium sulfate, and evaporated to give **5** from **1a—c**, **1h**, and **1j** or **8** along with **7** from **1d** or **1e**, respectively. The results are shown in Tables 3 and 4.

B): A mixture of **1e** (or **1m**) (10 mmol) and arylhydrazines (10 mmol) was refluxed in ethanol (150 ml) for 24 h. The evaporation of the solvent gave a viscous oil without contamination of **5**. Crystallization from ethanol gave **7**.

C): An ethanol solution (150 ml) of **1m** (10 mmol), arylhydrazine (or arylhydrazine hydrochloride) (10 mmol), and acetic acid (3 ml) was allowed to stand for 10 h at 20—80 °C. Concentration of the reaction gave yellowish crystals, which were recrystallized from ethanol to give **5mq—ms** in 40—70% yields.

Intramolecular Condensation Reaction of 7 to 8. A solution of **7eq** (1 mmol) in acetic acid (10 ml) was heated to reflux for 6 h, then poured into water (50 ml), and extracted with ether several times. The combined ether layer was washed with a dilute sodium carbonate aqueous solution and dried over anhydrous sodium sulfate. Evaporation of the solvent gave **8eq** in 85% yield. Treatment of **7eq** in pyridine also gave **8eq** in 82% yield.

Independent Synthesis of 5aq and 5as. *A)*: 2-Phenyl-5-[2-(3-phenyl-2-propenyloxy)phenyl]-2*H*-tetrazole (**10a**) was prepared from 2-(3-phenyl-2-propenyloxy)benzaldehyde phenylsulfonylhydrazone (**9**)[7a] and benzenediazonium chloride according to a method analogous to that of Ito *et al.*[9a] in 34% yield; mp 104—105 °C (from ethanol). NMR ($CDCl_3$): δ 4.82 (d, 2H, J=4 Hz), 6.15—7.6 (m, 13H), and 8.0—8.3 (m, 3H). Found: C, 74.68; H, 5.13; N, 15.77%. Calcd for $C_{21}H_{18}N_4O$: C, 74.55; H, 5.12; N, 15.81%. 2-(*p*-Tolyl)-5-[2-(3-phenyl-2-propenyloxy)phenyl]-2*H*-tetrazole (**10b**) was prepared in the same manner as described above in 53% yield; mp 106—108 °C (from ethanol). NMR ($CDCl_3$): δ 2.37 (s, 3H), 4.80 (d, 2H, J=4 Hz), 6.12—7.8 (m, 10H), and 7.9—8.2 (m, 3H). Found: C, 74.97; H, 5.31; N, 15.38%. Calcd for $C_{22}H_{20}N_4O$: C, 74.98; H, 5.47; N, 15.21%. Pyrolysis of **10a** (or **10b**) at 140—160 °C for 5 h gave **5aq** (or **5as**) in 100 (or 83) % yields.

B): A mixture of methyl salicylate (0.1 mol), 3-bromo-1-propenyl-2-propene (0.11 mol) and potassium carbonate (0.1 mol) in acetone (400 ml) was set to reflux for 25 h. Filtration of inorganic salts and evaporation of the solvent gave a solid, which was recrystallized from ethanol to give methyl 2-(3-phenyl-2-propenyloxy)benzoate (**11**) in 71% yield; mp 67—68 °C. IR (Nujol): 1725 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$): δ 3.9 (s, 3H), 4.95 (d, 2H, J=6 Hz), and 6.2—7.7 (m, 11H). A mixture of **11** (10 mmol) and phenylhydrazine (17 mmol) was heated at 80 °C for 10 h and subsequently allowed to stand at room tempetature for several days, giving crystals of 1-phenyl-2-[2-(3-phenyl-2-propenyloxy)benzoyl]hydrazine(**12**) as precipitate in 30% yield; mp 161—163 °C (from ethanol). IR (Nujol): 3360 and 3230 cm^{-1} (NH), 1635 cm^{-1} (CONH); NMR ($CDCl_3$): δ 4.95 (d, 2H, J=6 Hz), 6.23—7.70 (m, 16H), 8.17—8.40 (m, 1H) and 9.6 (s, 1H). Found: C, 76.69; H, 5.75; N, 8.00%. Calcd for $C_{22}H_{20}N_2O_2$: C, 76.72; H, 5.85; N, 8.13%. Chlorination of **12** with PCl_5 was carried out in ether at 35 °C for 6 h. The reaction mixture was poured into ice–water and extracted with ether several times. The combined ether layer was washed with water several times and dried over anhydrous sodium sulfate. Subsequent evaporation of the ether yielded a viscous oil (chlorohydrazone). To a stirred benzene solution of the oil was added dropwise an excess mole of triethylamine at 5 °C. The mixture was stirred at the same temperature for 1 h and then at room temperature for 5 h. The reaction mixture was washed with water and dried over sodium sulfate. Evaporation of the solvent gave a viscous oil, which was chromatographed (silica gel) with chloroform to give **5aq** in 5% yield.

The Reaction of 1h with p-*Chlorophenylhydrazine Hydrochloride at Room Temperature.* 0.7 g (3.91 mmol) of *p*-chlorophenylhydrazine hydrochloride was dissolved in hot ethanol (200 ml). The solution was allowed to cool to room temperature. We added an ethanol solution (20 ml) of **1h** (1 g, 3.48 mmol) into the ethanol solution of the hydrazine at room temperature and stirred for 2 h. Precipitated crystals (**13**) was filtered, 64% yield (1.0 g); mp 149—150 °C. After treatment of a chloroform solution (50 ml) of **13** (1.0 g, 2.23 mmol) with triethylamine (3 ml) at room temperature for 2 h, the mixture was washed with water several times. Subsequent evaporation of the solvent gave pyrazolidine (**4hr**) in 84% yield (0.77 g); mp 180—182 °C (from ethanol). Thermal treatment of **14** (0.5 g, 1.22 mmol) in xylene (50 ml) at 150 °C for 4 h yielded pyrazoline (**5hr**) in 74% yield (0.37 g).

Intramolecular 1,3-Dipolar Cycloaddition of Nitrilimines Bearing Alkenyl Groups[1]

Tomio SHIMIZU,* Yoshiyuki HAYASHI, Susumu ISHIKAWA, and Kazuhiro TERAMURA
Department of Dyeing, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606
(Received December 4, 1981)

The reaction of the arylhydrazones of some 2-(alkenyloxy)benzaldehydes(or 1-naphthaldehydes) with $Pb(OAc)_4$ leads, *via* the nitrilimine intermediates, to intramolecular 1,3-dipolar cycloadducts, 3-substituted 2-aryl-2,3,3a,4-tetrahydro[1]benzopyrano(or naphtho[1′,2′:5,6]pyrano)[4,3-*c*]pyrazoles, in 10—80% yields. In the presence of an excess of $Pb(OAc)_4$, these cycloadducts were dehydrogenated to 3-substituted 2-aryl-2,4-dihydro[1]benzopyrano-(or naphtho[1′,2′:5,6]pyrano)[4,3-*c*]pyrazoles. In the presence of a large excess of $Pb(OAc)_4$, some of the pyrazoles were acetoxylated to give the corresponding 4-acetoxypyrazoles. The effect of substituents of the alkenyl group on reactivity of the reaction was interpreted in terms of the frontier molecular orbital (FMO) theory.

1,3-Dipolar cycloaddition reactions are one of the most useful methods for the preparation of five-membered heterocycles.[2] Intermolecular 1,3-dipolar cycloaddition reactions can be rationalized in terms of FMO theory.[3] In this decade, a number of applications for preparation of heterocycles *via* intramolecular cycloadditions have been reported.[4] But the explanation of electronic effects of substituents on the intramolecular cycloaddition in terms of FMO theory is not completely satisfactory, mainly owing to the large entropy term. It is therefore interesting to investigate in detail the substituent effects on the reaction. Besides these mechanistic points of interests, intramolecular 1,3-dipolar cycloaddition reactions are very convenient and useful ones for the preparation of complex polycyclic, annelated, and fused molecules, which are difficult to prepare by other methods. The intramolecular nitrilimine cycloaddition shown below[5] was reported for preparation of benzopyranopyrazoles (**3**), but the method is cumbersome because multi-step reactions are required for the preparation of chlorohydrazone (**1**), a precursor of nitrilimine (**2**). One of the aims of our work was to find a simpler preparative method for **3**.[6] We found that application of the method[7] reported by Gladstone for preparation of the nitrilimine to this system gave the corresponding cycloadducts (**3**) in satisfactory yields.

Results and Discussion

Arylhydrazones of 2-(alkenyloxy)benzaldehyde(or 1-naphthaldehydes) (**5**) are prepared in two steps from salicylaldehyde (or 2-hydroxy-1-naphthaldehyde) as shown in the preceding paper.[6c] The reaction of **5** with an equimolar or excess amount of $Pb(OAc)_4$ was carried out in chloroform for 3—6 h at room temperature or below. 2,4-Dihydro[1]benzopyrano[4,3-*c*]pyrazoles (**8**) were isolated from the reaction of **5** in the presence of three equivalents of $Pb(OAc)_4$, while an equimolar mixture of **5** and $Pb(OAc)_4$ gave pyrazolines (**7**). The results of the reaction are shown in Tables 1 and 2, respectively. The structures of **7** and **8** were established on the basis of elemental analyses and spectral data. The assignment of the structures was further supported

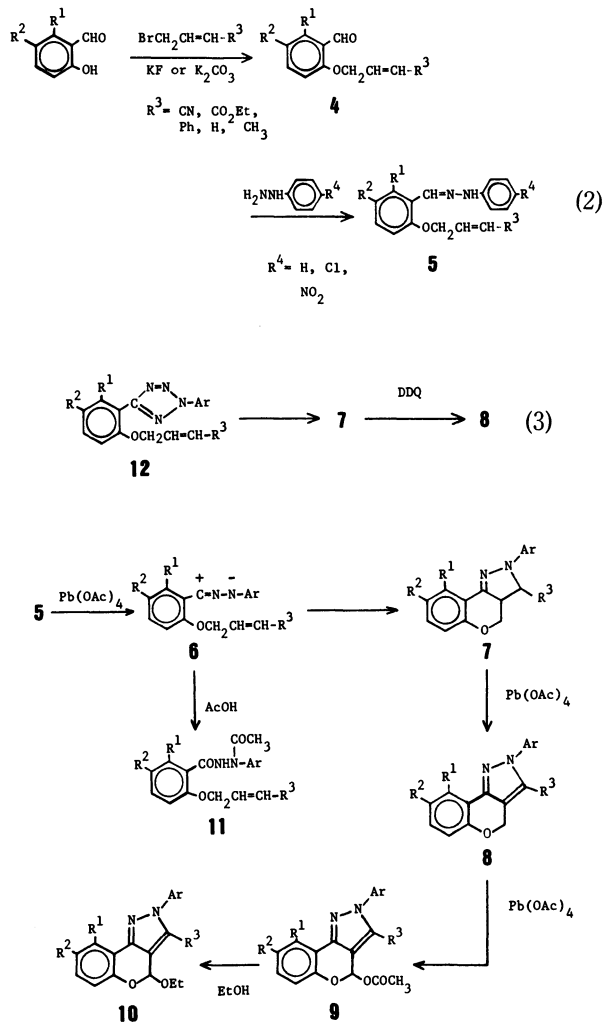
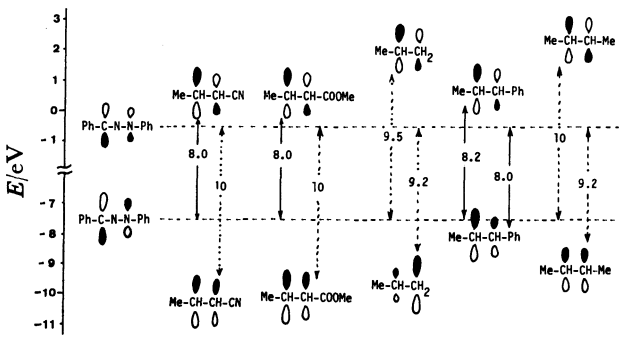
a) **8a**—**f** and **8h** were obtained from the reaction of **5** with three equivalents of $Pb(OAc)_4$. **8g** was obtained from the oxidation of **7g** with DDQ. b) Recrystallized from ethanol. c) **8f** was dissolved in DMSO-d_6; the others were dissolved in $CDCl_3$.



Scheme 1.

by comparison of the physical properties of **7d** and **8d** with those of the authentic samples prepared according to the published procedures:[8,9] **12**→**7d**→**8d**. The most plausible reaction mechanism for the reaction is shown in Scheme 1; formation of nitrilimines (**6**) was followed by intramolecular cycloaddition to give pyrazolines (**7**), which were further oxidised to **8**. The rates of the oxidation of hydrazones (**5**) to nitrilimines (**6**), the following intramolecular cycloaddition, and the oxidation of **7** to **8** were quite fast. It was found that **5** disappeared within ten minutes in the presence of three equivalents of $Pb(OAc)_4$ and the product was shown to be **8f** along with a trace amount of **7f**. Thus, it was rather difficult to isolate some of **7** in high yields from the equimolar reaction of **5** with $Pb(OAc)_4$. Phenylhydrazones bearing an alkenyl group may exhibit other intramolecular reactions besides the reaction mentioned here: a) thermal 1,3-dipolar cycloaddition *via* azomethine imine,[6c,10] b) ene reaction,[6c,11] and c) acid-catalyzed [3$^+$+2] cycloaddition.[6c,12] It was confirmed that none of the three intramolecular reactions occurred under our reaction conditions. Thus the starting materials (**5**) in chloroform were definitely stable at room temperature, even in the presence of acetic acid. The most remarkable substituent effects on the reaction products were observed in the case of the substituents of R^3 on **5**, as expected from the results of intermolecular nitrilimine cycloaddition, while relatively small substituent effects were observed in spite of the wide variation in R^1, R^2, and R^4. The reactivity in the cycloaddition has been rationalized in terms of FMO theory,[3] although some of the intramolecular cycloaddi-



Scheme 2. Interaction scheme of diphenylnitrilinime with several 1-substituted 1-propenes (see Refs. 3a, 13, and 14).

a) **10a** was obtained from the reaction of **8f** with a large excess of $Pb(OAc)_4$. The others were obtained from the reaction of **5** with three equivalents of $Pb(OAc)_4$. b) Recrystallized from ethanol. c) **10b** and **10g** were dissolved in DMSO-d_6; the others were dissolved in $CDCl_3$.

tions take place easier than the intermolecular one because of an activation in entropy terms.[4] The interaction scheme of frontier orbitals of diphenylnitrilimine[3a,13] and several 1-substituted 1-propenes[3a,14] are shown in Scheme 2. Examination of the scheme led us to expect following general tendencies:

i) Dipole-HOMO controlled cycloaddition is the most probable route for the substrates bearing cyano or methoxycarbonyl group as R^3.

ii) Both dipole-HOMO and dipole-LUMO controlled cycloaddition may be allowed for the substrates bearing a phenyl group as R^3 but the rate of the reaction would be slower than that described in i).

iii) The substrates bearing H or CH_3 as R^3 would be less reactive, due to the relatively lowered HOMO energy of the dipolarophile by the substituents.

The qualitative reactivity of **5** was in accordance with the tendencies mentioned above. When R^3=Ph on **5**, the reaction gave pyrazoline (**7f**), pyrazole (**8h**), and *N*-acetyl hydrazide (**11a**), roughly in the ratio of 1 : 2 : 2. On the other hand, none of cycloadducts could be isolated when R^3=H or CH_3, and *N*-acetyl hydrazide (**11b**) was only isolable product. The reaction of aldehyde hydrazones with $Pb(OAc)_4$ generally gave *N*-acetyl hydrazides in the absence of suitable dipolarophiles.[15]

2-(Alkenyloxy)-1-naphthaldehyde arylhydrazones (**5**) gave better yields of cycloadducts (**8**), partly because of the ease of isolation from the reaction mixture. Whereas the cycloadducts, **8a**—**f** and **8h**, from 2-(alkenyloxy)benzaldehyde arylhydrazones are stable in the presence of an excess amount of $Pb(OAc)_4$, **8** from 2-(alkenyloxy)-1-naphthaldehyde aryhydrazones gave acetoxylated products (**9**) at position 4 under the same reaction conditions. Radical acetoxylation has been achieved wiht $Pb(OAc)_4$.[15b] Thus, when **8f** was treated with an excess of $Pb(OAc)_4$ in refluxing chloroform for 3 h, the susceptible position in **8**, the α-position of the ethers, was acetoxylated to give product (**9**). The acetoxyl group was easily displaced by the ethoxyl group, giving **10**, when **9** was recrystallized from ethanol.

Experimental

Measurements. All the melting and boiling points are uncorrected. The IR spectra were recorded on a Hitachi 215 Infrared Spectrophotometer. The NMR spectra were measured on a Varian T-60A instrument using suitable solvents and TMS as an internal standard.

Materials. Lead tetraacetate (90.6%) was commericallly available (Nakarai Chem. Co.,) and was used without further purification. The arylhydrazones of 2-(alkenyloxy)benzaldehydes (or 1-naphthaldehydes) (**5**) were prepared according to the method described in the preceding paper.[6c]

Reaction of Arylhydrazones (5) with Three Equivalents of Pb(OAc)$_4$. General Procedure: A mixture of **5** (5.4 mmol) and $Pb(OAc)_4$ (7.97 g, 16.2 mmol) was stirred in chloroform (300 ml) for 6 h at room temperature. The insoluble material thus precipitated was filtered off using a Celite bed. The filtrate was mixed with water, and the mixture was filtered using the Celite bed. The organic layer was washed with water several times and dried over magnesium sulfate. Evaporation of the organic layer yielded a viscous oil, which solidified upon being scratched with a glass rod. Recrystallization from ethanol gave colorless needles of the cycloadducts (**8**). Concentration of the filtrate and subsequent chromatography on silica gel with chloroform gave an additional amount of needles (**8**). The yields and some physical data are given in Table 2.

Reaction of 2-(3-Phenyl-2-propenyloxy)benzaldehyde p-*Nitrophenylhydrazone with Pb(OAc)$_4$.* The reaction was carried out by the General Procedure. The reaction mixture was chromatographed (silica gel) with chloroform to give cycloadducts (**7h** and **8h**) and *N*-acetylated compound (**11a**) in 10, 21, and 17% yield, respectively. The spectral data for **7h** and **8h** are shown in Tables 1 and 2, respectively. The

spectral data for **11a** (mp 114 °C from ethanol) was as follows: IR (Nujol): 3250 (NH), 1710 (CONH), and 1670 cm^{-1} (CON). NMR ($CDCl_3$): δ 2.25 (s, 3H), 4.9 (d, 2H, J=6 Hz), 6.5—8.3 (m, 13H), and 10.2 (s, 1H).

Reaction of 2-(3-Butenyloxy)benzaldehyde p-*Nitrophenylhydrazone with* $Pb(OAc)_4$. The reaction was carried out by the General Procedure. An *N*-acetylated compound (**11b**) was obtained from the reaction mixture in 41% yield; mp 159 °C (from ethanol). IR (Nujol): 3200 (NH), 1700 (CONH), and 1670 cm^{-1} (CON). NMR ($CDCl_3$): δ 2.7 (d, 3H, J=5 Hz), 3.3 (s, 3H), 5.5—5.8 (m, 2H), 6.7—7.0 (m, 2H), 8.0—9.3 (m, 8H), and 11.2 (s, 1H).

An Equimolar Reaction of Arylhydrazones with $Pb(OAc)_4$. A mixture of **5** (5.4 mmol) and $Pb(OAc)_4$ (2.66 g, 5.4 mmol) was stirred in chloroform for 6 h at room temperature. The reaction mixture was washed with water several times. The organic layer was dried over magnesium sulfate. Evaporation of the solvent yielded cycloadducts (**7**) in the yields shown in Table 1.

Oxidation of 7f to 8f with $Pb(OAc)_4$. A mixture of **7f** (1.0 g, 3.1 mmol) and $Pb(OAc)_4$ (1.37 g, 3.1 mmol) was stirred in chloroform for 6 h at room temperature. The reaction mixture was treated in a manner similar to the procedure described above to give **8f** in 76% yield.

Oxidation of 7g to 8g with DDQ (2,3-Dichloro-5,6-dicyano-p-benzoquinone). A mixture of **7g** (0.5 g, 1.3 mmol) and DDQ (0.29 g, 1.3 mmol) was heated to reflux in benzene (50 ml) for 12 h. The reaction mixture was washed with water and evaporation of the organic layer gave **8g**, 0.39 g (78%) (recrystallized from ethanol).

Reaction of 8f with $Pb(OAc)_4$. A mixture of **8f** (0.2 g, 0.65 mmol) and $Pb(OAc)_4$ (2.0 g, 4.1 mmol) was heated to reflux in chloroform (50 ml) for 3 h. The reaction mixture was treated in a manner similar to the General Procedure. Crystals obtained were shown to be 4-acetoxylated product (**9**) in 92% yield; IR (Nujol): 2230 (CN) and 1760 cm^{-1} (COO). NMR (DMSO-d_6): δ 2.1 (s, 3H) and 7.0—8.6 (m, 9H). Found: C, 60.03; H, 3.25; N, 14.62%. Calcd for $C_{19}H_{12}N_4O_5$: C, 60.64; H, 3.21; N, 14.89%. Recrystallization of this compound from ethanol gave the corresponding 4-ethoxy derivative quantitatively; Found: C, 62.88; H, 3.94; N, 15.26%. Calcd for $C_{19}H_{14}N_4O_4$: C, 62.98; H, 3.89; N, 15.46%.

Preparation of an Authentic Sample of 7d. 2-(*p*-Chlorophenyl)-5-[2-(3-cyano-2-propenyloxy)phenyl]-2*H*-tetrazole (**12**) was prepared from the reaction of 2-(3-cyano-2-propenyloxy)benzaldehyde *p*-tolylsulfonylhydrazone[6a] with *p*-chlorobenzenediazonium chloride according to a method analogous to that of Ito *et al.*,[8] in 73% yield; mp 192—193 °C (decomp). IR (Nujol): 2230 cm^{-1} (CN). Found: C, 60.43; H, 3.45; N, 20.69%. Calcd for $C_{17}H_{12}N_5OCl$: C, 60.45; H, 3.58; N, 20.73%. Pyrolysis of **12** at 200 °C for 3 h gave **7d** in 30% yield.

Oxidation of 7d to 8d with DDQ. A mixture of **7d** (1.0 g, 3.3 mmol) and DDQ (0.67 g, 3.3 mmol) was heated to reflux in benzene (50 ml) for 12 h. The reaction mixture was washed with water and evaporation of the organic layer gave **8d**, 0.58 g (58%) (recrystallized from ethanol).

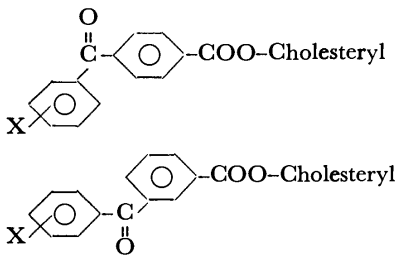
Substituent Effects on the Mesophase Stability for Cholesteryl Benzoylbenzoates

Mitsuhiro KODEN, Shunsuke TAKENAKA, and Shigekazu KUSABAYASHI*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received December 7, 1981)

The thermal properties of cholesteryl esters of substituted benzoylbenzoic acids were examined. The substituent effects on the thermal stability of the chloesteric phase of these esters are quite striking. For cholesteryl 4-(4′-substituted benzoyl)benzoates, the Ch-I transition temperatures are slightly influenced by an electronic effect of the substituents, because the bond direction of the substituents is tilted with respect to the long molecular axis. For cholesteryl 4-(3′-substituted benzoyl)benzoates and cholesteryl 3-(4′-substituted benzoyl)benzoates, the Ch-I transition temperatures are influenced by the polarizability anisotropy of the terminal phenyl ring, which probably gives rise to a change in the ratio of the number of more-linear isomers to the number of less-linear isomers. For cholesteryl 4-(2′-substituted benzoyl)benzoates, the substituents increase the angle between the two phenyl rings, *i.e.*, the thickness of the benzophenone moiety, due to the repulsive interaction between the substituent(s) and ortho-hydrogens of the other phenyl ring, and therefore decrease the Ch-I transition temperature largely.

Recently we examined the mesomorphic properties of some cholesteryl esters of arylbenzoic acids incorporating the angular linkages, such as –CO–, –O–, –S–, and $-CH_2-$.[1,2] In spite of the angular geometry, these esters exhibit a cholesteric phase and their thermal stabilities are in the order of $-CO->-O->-CH_2->-S-$. These results indicate that the mesophase stability is strongly dependent on the electronic effect of the carboxylic acid moieties. But a replacement of the aryl ring by the cyclohexyl ring at the terminal position of cholesteryl 4-benzoylbenzoate gives rise to a depression of the Ch-I transition temperature by only 6 °C, and the replacement at the inner position enhances it by 7 °C,[2] though the replacement would decrease the electronic effect of the carboxylic acid moiety because of the reduced conjugative interactions among carbonyl and ester groups and rings. These results appear to be inconsistent. So we are interested in the role of the electronic effect of the carboxylic acid moiety on the mesophase stability. For this purpose, we have prepared two types of cholesteryl esters of substituted benzoylbenzoic acids with the following formula:



In this paper, the substituent effect on the mesophase stability will be discussed in terms of the structural features of the benzophenone moiety and the electronic effect of the substituents.

Experimental

Preparation of Materials. Substituted 4-methylbenzophenones were prepared by the Friedel-Crafts reaction[3] of toluene with the substituted benzoyl chloride, which was prepared from the substituted benzoic acid and thionyl chloride[4] or phosphorus pentachloride.[5]

3- And 4-(substituted benzoyl)benzoic acids, except for 3- and 4-(4′-alkylbenzoyl)benzoic acids, were prepared by sodium dichromate oxidation[6] of the substituted 4-methylbenzophenone.

4-(4′-Alkylbenzoyl)benzoic acids were prepared by the Friedel-Crafts reaction[3] of the alkylbenzene with terephthaloyl chloride, followed by hydrolysis.

3-(4′-Alkylbenzoyl)benzoic acids were prepared by the Friedel-Crafts reaction[3] of the alkylbenzene with isophthaloyl chloride, followed by hydrolysis.

3-(3′-Methylbenzoyl)benzoic acid was prepared by Grignard reaction[7] of dimethyl isophthalate with 3-methylphenylmagnesium bromide.

3- And 4-(substituted benzoyl)benzoyl chlorides were prepared from the 3- and 4-(substituted benzoyl)benzoic acid and phosphorus pentachloride.[5]

Cholesteryl esters were prepared from the 4- and 3-(substituted benzoyl)benzoyl chloride and chloesterol.[8] All esters were purified by column chromatography on silica gel, followed by recrystallization from a suitable solvent. The elemental analyses are listed in Table 3.

Physical Measurement. Identification of the mesophase and determination of the transition temperatures were made using a Nikon polarizing microscope in conjunction with a Mettler FP 52 heated stage and control unit. Transition enthalpies were determined using a Daini Seikosha differential scanning calorimeter, model SSC-560. Entropy values were calculated using the equation, $\Delta S=\Delta H/T$.

Results and Discussion

The thermal properties of cholesteryl 4-(substituted benzoyl)benzoates and cholesteryl 3-(substituted benzoyl)benzoates are summarized in Tables 1 and 2, respectively.

Cholesteryl 4-(4′-Substituted benzoyl)benzoates. Generally, terminal groups with a small, compact structure such as cyano, halogen, methoxy, nitro, methyl, raise the N-I or Ch-I transition temperature relative to hydrogen because of increased polarizability anisotropy.[9,10] As is evident from Table 1, although the melting points appreciably change by introduction of the substituent at the 4′-position of **1**, the effect on the Ch-I transition temperature is remarkably small. Generally, introduction of methyl or methoxyl groups at the terminal position of a molecule gives rise to an increase in the N-I or Ch-I transition temperature

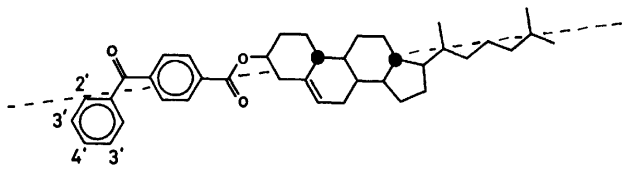

Fig. 1. Structural model of cholesteryl 4-benzoylbenzoates. The dotted line represents the long molecular axis.

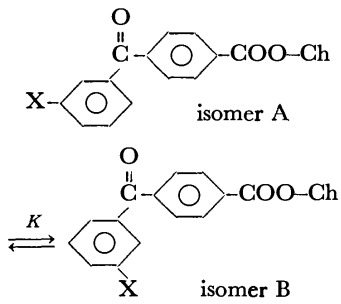
by more than 50 °C.[11] For **1**, this trend is absent. Furthermore, when the number of the carbon atoms in the alkyl chain at the 4′-position is increased (**1**—**4**), the Ch-I transition temperatures decrease steeply without any distinct alternation between odd and even members.[12] These characteristics are quite striking and should be related to the angular geometry of the benzophenone moiety.

The molecular structure of cholesteryl 4-benzoylbenzoates is illustrated in Fig. 1. The valence angle between the C–C bonds linking two phenyl rings is *ca.* 120°.[13] Then, the substituent, X, located at the 4′-position contributes in two ways to the mesophase stability. One is that it increases the molecular breadth as well as the molecular length. These structural characteristics should depress the Ch-I transition temperature due to an action similar to that of the lateral substituents for ordinary mesogenic compounds. According to Gray's studies, the depression of the clearing points has a good correlation with the molecular diameter.[14] The efficiency order is reported to be H>F>CH_3>Cl>Br>NO_2. The other effect is to produce changes in conjugative interactions within the molecule, thus affecting factors such as polarizability and dipolarity. For example, the longitudinal substituent effect on the mesophase stability for cholesteryl benzoates is reported to be CN($T_{Ch\text{-}I}$=287.0 °C)>CH_3O(267.0 °C)>Cl(252.8 °C)>Br(251.6 °C)>CH_3(241.1 °C)>F(193.1 °C)>H(179.9 °C).[15] The dominant effect for the substituents is attributable to the increase in polarizability and dipolarity due to conjugation between aryl group and substituent. For cholesteryl 4-benzoylbenzoates, the substituent at the 4′-position also increases the molecular polarizability and dipolarity due to conjugative interactions between aryl and carbonyl groups. However, the anisotropy of these terms along the long molecular axis indicated by the dotted line in Fig. 1 should be smaller than that for cholesteryl benzoates, because the C–X bond is tilted by *ca.* 60° from the long molecular axis.

As is evident from Table 1, the Ch-I transition temperature in this series isn't very susceptible to changes in the effect of substituent, and the efficiency order is quite different from that for cholesteryl benzoates. Supposing that a methyl group at the 4′-position lowers the Ch-I transition temperature by 50 °C due to a steric repulsion similar to that from the methyl group at 3-position of cholesteryl benzoate,[16] and enhances it by 63 °C due to the electronic effect similar to that from the methyl group at the 4-position of cholesteryl benzoate,[15] we can expect the Ch-I transition temperature for **2** to be 223 °C. The observed Ch-I transition temperature for **2** appears to be considerably lower than the calculated one. The trend is also recognized in **6**—**9**. These facts indicate that the electronic effect of the substituent at the 4′-position isn't so large, compared with that for ordinary mesogens, because the directions of the polarizability and dipolarity arising from the terminal benzoyl portion including substituent intersect the long molecular axis.

Cholesteryl 4-(3′-Substituted benzoyl)benzoates. The effect of a substituent at the 3′-position on the

mesophase stability exhibits some interesting trends. Generally, a meta-substituent (lateral substituent) increases the molecular breadth, giving rise to a decrease in the lateral interaction. However, the substituent at 3′-position slightly enhances the Ch-I transition temperatures and the di-substitution gives rise to a depression of the Ch-I transition temperature (**13**). This unusual behavior should be related to the angular geometry of the benzophenone moiety. Let's consider the conformational equilibrium, as shown below:



The energy of both isomers will be quite similar under usual conditions, such as in an isotropic medium ($K=1$). The substituent X in isomer A will elongate the molecular length and enhance a local polarizability arising from the C–X bond along the long molecular axis. The substituent X in isomer B, on the other hand, will increase the molecular breadth, causing the Ch-I transition temperature to decrease. Certainly, **11** and **12** exhibit higher Ch-I transition temperature than **6** and **9**, whereas the substituents are located at the meta-position with respect to the carbonyl group. Temperature differences for the transition between **5** and **10**, **6** and **11**, and **9** and **12** are −7.5 °C, 7.4 °C, and 17.4 °C, respectively. These tend to increase with increasing the bond polarizabilities, 0.5, 2.5, and 4.0 Å^3.[17] This fact indicates that polarizability and/or dipolarity of the C–X bond tends to move the equilibrium point toward isomer A in the mesophase. However, this contribution should be small, since we can't recognize it in the entropy change for the Ch-I transition. On the other hand, the disubstituted compound, **13**, exhibits a lower Ch-I transition temperature than that for **10**—**12**. This is caused by one of chlorine atoms inevitably occupying the unfavorable site in isomer B.

Cholesteryl 4-(2′-Substituted benzoyl)benzoates. As is evident from Table 1, the substituent effect at the 2′-position on the Ch-I transition temperature is striking. The 2′-substituted compounds, **15**—**17**, show no mesophase. So-called "virtual" Ch-I transition temperatures were determined from binary phase diagrams, as shown in Fig. 2. By mixing **15** with known amounts of **1**, and determining the Ch-I transition temperatures of the mixtures, a phase diagram for the binary system was constructed. The "virtual" Ch-I transition temperature for **15** was found, by extrapolation, to be 90 °C. Similar phase diagrams were constructed for **16** and **17**, the "virtual" ones being 90 and −10 °C, respectively. As one can assume from the structural model (Fig. 1), introduction of the substituent at 2′-position will increase not the molecular breadth but the thickness of the carboxylic acid moiety due to

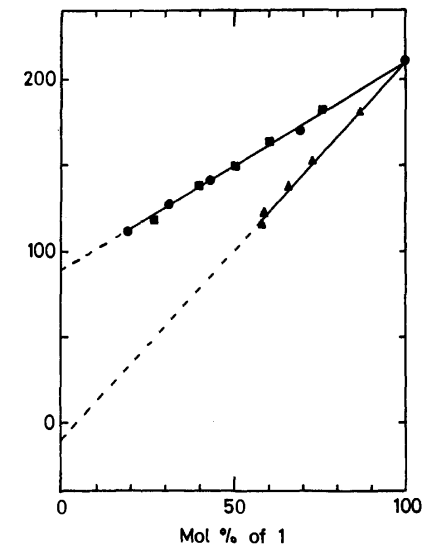


Fig. 2. Ch-I transition lines in the binary phase diagrams for (a) **1** and **15** (●), (b) **1** and **16** (■), and (c) **1** and **17** (▲).

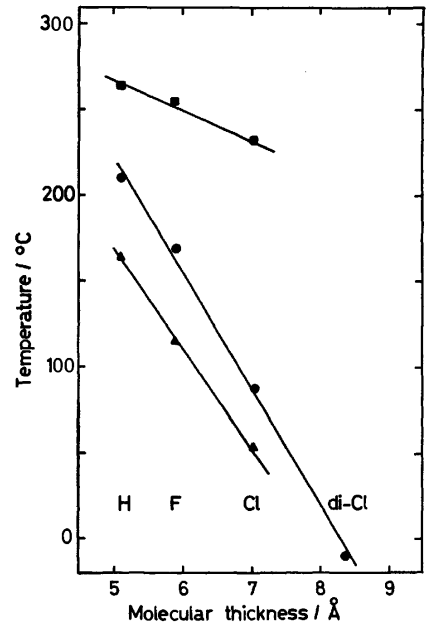

Fig. 3. A plot of molecular thickness of the benzophenone moiety[18] against the $T_{Ch\text{-}I}$ of cholesteryl 4-(2′-substituted benzoyl)benzoates (●), the $T_{N\text{-}I}$ of 2-substituted 4-*p*-(octyloxy)benzylideneaminobiphenyls (▲),[19,20] and the $T_{N\text{-}I}$ of 3′-substituted 4′-(octyloxy)biphenyl-4-carboxylic acids (■).[21]

increased interaction between the substituent(s) and ortho-hydrogens at the other ring, and also will decrease the molecular polarizability arising from the resonance between both aryl and carbonyl groups. Then, the Ch-I transition temperatures for **1** and **15**—**17** are plotted against the molecular thickness of the carboxylic acid moieties[18] (Fig. 3). Similar to the other cases, these exhibit linear correlation. The slope is close to that for 2-substituted 4-*p*-(octyloxy)benzylideneaminobiphenyls[19,20] rather than 3′-substituted 4′-(octyloxy)biphenyl-

Table 3. Elemental analyses of cholesteryl esters

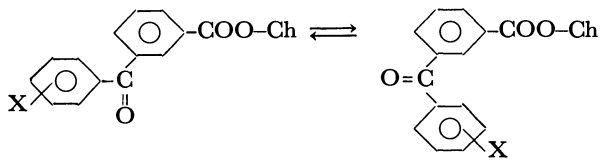
4-carboxylic acids,[21] indicating that an increased molecular thickness due to repulsion between the substituent(s) and the ortho-hydrogens is the major cause of rapid depression of the Ch-I transition temperatures.

Cholesteryl 3-(Substituted benzoyl)benzoates. Although **18** has a low Ch-I transition temperature relative to **1**, its derivatives exhibit an apparent substituent effect on the mesophase stability, *i.e.*, the substituent at the 4′-position enhances the Ch-I transition temperature, and that at the 3′-position depresses it. These trends are in contrast with the substituent effect for **1**. These results can be accounted for by considering the conformational models shown below:



isomer C isomer D

The energy of these two isomers will be also equivalent in the isotropic state. For preservation of the parallel arrangement in the mesophase, isomer C will be preferable to isomer D, because the former is less wide than the latter. Furthermore, the substituent at the 4′-position in isomer C will increase the molecular length and anisotropy of polarizability along the long molecular axis. Then, the role of the substituent seems to be analogous to that of the substituent at the 3′-position in isomer A for **1**. The substituents at both 3′- and 4′-position in isomer D, on the other hand, give rise to an increase in molecular breadth. Then, the enhanced Ch-I transition temperatures for **19** and **20** must indicate that the position of the conformational equilibrium for **18** slightly inclines toward the left side, as the substituent is introduced at the 4′-position. We could recognize it in the entropy data (**18** and **19**). On the contrary, methyl group at the 3′-position is assumed to be inevitably unfavorable for the mesophase stability. **21** shows that case.

Studies on Heteropentalenes. V.[1] Cycloadditions of 5-Aryl-3-methylimidazo-[5,1-*b*]thiazoles with Acetylenic Esters Leading to 5-Aryl-3-methylthiazolo[2,3-*c*]benzimidazoles and Related Heterocycles

Noritaka Abe,* Tarozaemon Nishiwaki, and Kotaro Ikeda

(Received December 10, 1981)

Cycloaddition of 5-aryl-3-methylimidazo[5,1-*b*]thiazoles with dialkyl acetylenedicarboxylate in an aprotic nonpolar solvent gives a number of products including epimeric thiazolo[2,3-*c*]benzimidazoles (**3** and **4**) [1:2-cycloadducts], epimeric 5,10b-ethenothiazolo[3′,2′:3,4]imidazo[1,5-*a*]pyridines (**5** and **6**) [1:3-cycloadducts], and thiazolo[3′,2′:3,4]imidazo[1,2-*a*]pyridines [1:3-adducts]. At higher temperature, formation of the 1:2-cycloadducts is favored over the 1:3-adducts, whereas the latter predominates at room temperature. In an aprotic polar medium, the 1:3-cycloadducts (**5** and **6**) and tetraalkyl 6-arylpyridine-2,3,4,5-tetracarboxylates are substantially produced. Epimerization of **3** and **4** has been found to compete well with fragmentation to 4*H*-1,4-benzothiazine.

Although the chemistry of aromatic azapentalenes has been dealt with from various angles,[2] studies on cycloadditions to them had been undeservedly neglected before we first reported the 1,4-cycloadditions[3] of imidazo-[2,1-*b*]thiazoles and of imidazo[2,1-*b*]benzothiazoles with acetylenic esters (*e.g.*, dimethyl acetylenedicarboxylate (DMAD)[4] and methyl propiolate[5]). The present paper is concerned with the 1,4-cycloadditions[3] of imidazo[5,1-*b*]thiazoles (**1**). The result will prove of some interest for the synthesis of thiazolo[2,3-*c*]benzimidazoles (**3** and **4**) and 4*H*-1,4-benzothiazine rings (**10**).

The reactions of imidazo[5,1-*b*]thiazoles with acetylenic esters are highly solvent dependent, like those of imidazo[2,1-*b*]thiazoles[4] and of imidazo[2,1-*b*]benzothiazoles.[4] With DMAD in acetonitrile, 3-methyl-5-phenylimidazo[5,1-*b*]thiazole (**1a**) produced tetramethyl 6-phenylpyridine-2,3,4,5-tetracarboxylate (**2**),[6] two diastereoisomers **3a** and **4a** of tetramethyl 3-methyl-5-phenylthiazolo[2,3-*c*]benzimidazole-7,8,9,10-tetracarboxylate [1:2-cycloadducts], and two diastereoisomers **5a** and **6a** of hexamethyl 3-methyl-5-phenyl-5,10b-ethenothiazolo[3′,2′:3,4]imidazo[1,5-*a*]pyridine-7,8,9,10,11,12-hexacarboxylate [1:3-cycloadducts]. However, use of benzene, xylene, or tetrahydrofuran (THF) as a solvent resulted in the formation of a new 1:3-adduct [dimethyl 2-(5,6,7,8-tetramethoxycarbonyl-3-methyl-4a-phenylthiazolo[3′,2′:3,4]imidazo]1,2-*a*]pyridin-10-yl)fumarate (**8a**)] in addition to **3a**, **4a**, **5a**, and **6a**, but did not yield the pyridine (**2**).

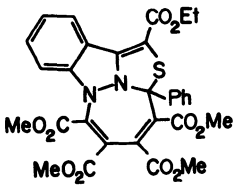
acetonitrile, and a series of the products **3b**, **4b**, **5b**, **6b**, and **8b** in benzene or xylene. With diethyl acetylenedicarboxylate (DEAD), **1a** yielded the diastereoisomers **3c** and **4c** alone in either of acetonitrile or benzene, however. Irrespective of the polarity of the solvent, formation of the 1:2-cycloadducts seems to become favorable at higher temperature than that of the 1:3-adducts. These results are provided in Table 1.

Structures of these new compounds were deduced from their elemental analyses and spectroscopic behaviors. Elemental analyses of **3a** and **4a** gave the same elemental composition of $C_{24}H_{22}N_2O_8S$. The compound **3a** exhibits three ν(C=O) absorptions at 1705, 1725, and 1750 cm^{-1} in the IR spectrum, and the ^{13}C NMR signals for two sp^3-carbons of the ring at δ 47.1 (d) (C-6a) and 118.9 (s) (C-10a) and one easily identified sp^2-carbon flanked by two nitrogens at δ 166.6 (s). Specific ^1H NMR resonances observed for **3a** include four ester Me singlets at δ 3.47, 3.51, 3.77, and 3.79, and two 1H-singlets at δ 7.12 (H-2) and 6.68 (H-6a).

The ^{13}C NMR signals of the compound **4a** are very similar to those of the compound **3a**, and the ^1H NMR spectra of **3a** and **4a** resemble each other except for the resonance of one ester Me and H-6a protons. As to the differences, **3a** has an ester Me signal at δ 3.51 and a methine singlet at δ 6.68 (H-6a), whereas **4a** at δ 3.73 and 6.27 respectively. These significant changes strongly suggest that stereochemical disposition of the hydrogen at C-6a of differs from that of **4a**. As the hydrogen disposed *syn* must be susceptible to anisotropic deshielding effect of the ring sulfur atom, the compound whose H-6a proton is seen at lower field should be *syn*-isomer **3a** and the one displaying its H-6a proton at higher field *anti*-isomer **4a**.

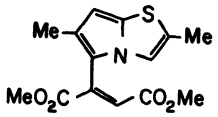
Interconversion of **3a** and **4a**, though not attained thermally (*e.g.*, heating in xylene), takes place readily in the presence of base. Heating of either **3a** or **4a** with sodium methoxide in methanol or 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) in benzene produced a mixture of **3a**, **4a**, and tetramethyl 3-methyl-4*H*-1,4-benzothiazine-5,6,7,8-tetracarboxylate (**10a**)[7] whose structure is delineated later. These observations firmly show the compounds **3a** and **4a** to be epimers. Similarly, the epimerization of **3c** to **4c** was found to compete significantly with the fragmentation to **10c**.

The structures **5a** and **6a**, both being analyzed as $C_{30}H_{28}N_2O_{12}S$, were assigned as follows. Their UV spectra resemble each other, possessing a maximum absorption even at the wavelength greater than 400 nm. As the ^{13}C NMR spectra of **5a** and **6a** also resemble each other, they must be stereoisomers. Besides signals for carbons associated with Me, Ph, and CO_2Me groups, eleven carbons are seen, among which six singlets at δ 120—150 are assigned to =C–CO_2Me groups by reference to the spectra of **3a** and **4a**. Signals at δ 117—118 and at δ 153—154 are assigned to a CH=CH–Me group. Two sp^3-carbons which appear at δ 56—58 and δ 71—72 are assigned to >CH and >C–Ph groups with the aid of proton-decoupled off resonance spectra. The remaining singlet observed at lower field (δ 113—114) must be due to a quarternary carbon flanked by sulfur and nitrogen atoms. This is supported by the ^{13}C NMR spectrum of **7** whose C-4a has been reported to resonate at δ 114.[8]



7

It is therefore deduced that a new six membered ring incorporating 2 mol of DMAD is annelated to **1** at the N(6)–C(7) bond and the remaining DMAD forms an etheno bridge whose termini are at C-5 and C-8 of **1**. The isomers **5a** and **6a** reveal their H-10a proton at δ 5.12 and 5.15 respectively. With the same reasonings for the stereochemical assignments of **3a** and **4a**, the *syn*-hydrogen at C-10a of a 5,10b-ethenothiazolo-[3′,2′:3,4]imidazo[1,5-*a*]pyridine ring must resonate at lower field than its counterpart, and hence the compound whose methine hydrogen is seen at δ 5.12 is assigned the *anti*-structure (**5a**) and the one displaying the methine hydrogen at δ 5.15 the *syn*-structure (**6a**).



9

The ^1H NMR spectrum of **8a**, $C_{30}H_{28}N_2O_{12}S$, confirmed the presence of six ester Me groups and two olefinic protons, one Me group and a phenyl group. Of the two olefinic protons, the one has its chemical shift (δ 6.72) close to the olefinic proton of dimethyl fumarate (δ 6.83) and of the compound **9** (δ 6.79).[9] As both of the other olefinic singlet (δ 6.96) and a Me singlet at δ 2.38 broaden, as seen for the ^1H NMR spectra of **1a**, **3a**, **4a**, **5a**, and **6a**, the thiazole ring of **1a** would have remained intact. These observations, together with the disappearance of the H-7 proton of **1a** and complete difference of the UV spectrum of **8a** from those of the other 1 : 3-adducts **5a** and **6a**, allowed the structure to be proposed.

UV, IR, and ^1H NMR spectroscopic properties of the compounds **2a**—**2b**, **3a**—**3c**, **4a**—**4c**, **5a**—**5b**, **6a**—**6b**, and **8a**—**8b** are collected in Table 2 and full ^{13}C NMR spectral assignments of **3a**, **4a**, **4b**, **5a**, and **6a** in Table 3.

The structure **10a**, $C_{17}H_{17}NO_8S$, was determined as follows. The ^1H NMR spectrum shows a Me doublet at δ 2.41 which couples (J=0.5 Hz) with an olefinic proton at δ 6.74. Of the two singlets at δ 3.83 and 3.90 associated with four ester Me groups, the latter was found to be overlapped with an additional proton, which could be exchangeable. Furthermore, the spectrum indicated the absence of a benzene ring. The IR spectrum had ν(C=O) bands at 1695, 1715, and 1730 cm^{-1} and a broad ν(NH) band at 2300—2850 cm^{-1}

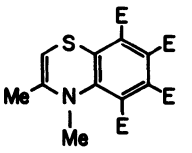
10a, c



11a

indicative of hydrogen-bonding with the CO_2Me absorbing at 1695 cm^{-1}. This compound, though resistant toward acetylation, was found to react with methyl fluorosulfate giving the corresponding *N*-methyl derivative (**11a**). These data are accounted for in terms of the structure **10a**.

Plausible mechanisms for the reactions of imidazo-[5,1-*b*]thiazoles (**1**) with acetylenic esters are given in Scheme 1. Electrophilic attack of the acetylenic ester would occur at either C-5 or C-7 of **1**. The attack at C-7 gives an intermediate **A**, from which the 1:2-cycloadducts **3** and **4** are formed (Path a). When the attack takes place at C-5, the position presumed to be more electron-rich than C-7 due to electron release from the sulfur and the nitrogen at the 4-position, an intermediate **B** is generated. Cyclization of **B** to **C**

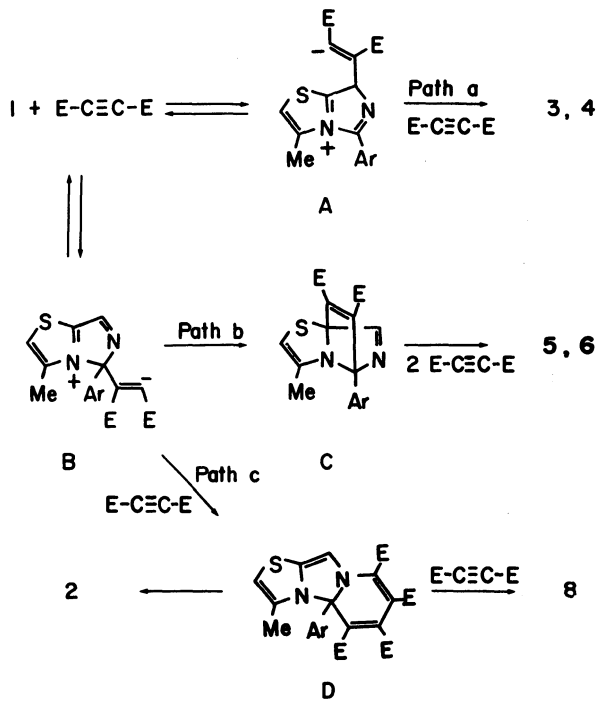
a) Three peaks degenerate. b) Two peaks degenerate.

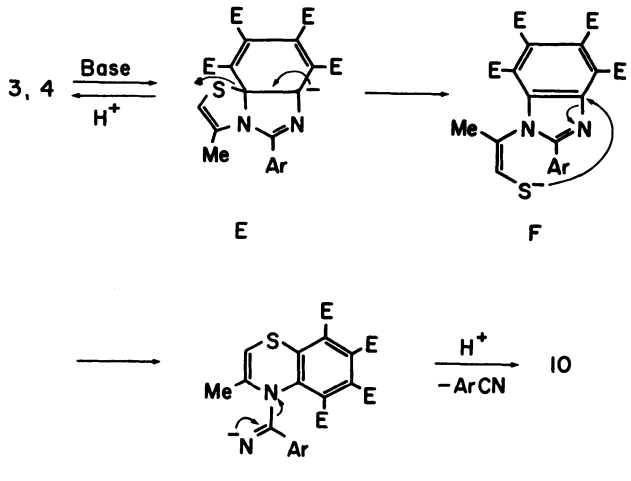


Scheme 1.

followed by a 1,4-dipolar cycloaddition[3] affords the 1:3-cycloadducts **5** and **6** (Path b). Alternatively, cycloaddition of **B** with an additional acetylenic ester would lead to an intermediate **D**, which undergoes either the Michael-type addition in a nonpolar solvent to produce **8** or fragmentation in polar medium to the pyridine **2** (Path c).

Conceivably, an equilibrium will be established between **1** and the dipolar species **A** and **B**. As cyclization of **A** leading to **3** or **4** (Path a) would be unfavorable because the acetylenic ester has to approach from a sterically crowded site, formation of **3** or **4** will require higher temperature. By comparison with the Path a, the pathways b and c would be easier to proceed because neither cyclizations of **B** to **C** nor **D** is sterically disturbed by the C-3-Me or C-5-Ar groups.

A likely mechanism for the base-promoted fragmentation of **3** or **4** to the benzothiazine (**10**) is depicted in Scheme 2. Abstraction of the hydrogen at C-6a by base gives rise to a carbanion **E** and a sulfide anion **F**, successively. Cyclization of the sulfide anion **F** leads to a new anion **G**, which subsequently undergoes loss of a nitrile followed by protonation to give **10**.



Scheme 2.

Experimental

Melting points were uncorrected. IR spectra were determined as Nujol mulls unless otherwise stated. ^1H NMR spectra were recorded in $CDCl_3$ with Me_4Si as internal standard with a Hitachi R-24B (60 MHz) or JEOL FX-100 (100 MHz) spectrometers, and ^{13}C NMR spectra with a Varian FT-80A instrument (20 MHz; solutions in $CDCl_3$ with Me_4Si as internal standard). Mass spectra were determined with a Hitachi M-80 spectrometer by means of either electron impact or field desorption ionization methods. Kieselgel 60 was used for chromatography.

3-Methyl-5-phenylimidazo[5,1-*b*]thiazole (**1a**) was prepared as reported.[10] **1a**: mp 105—106 °C (lit,[10] 106 °C), UV_{max} (chloroform) 303 nm (log ε 4.08), IR 775 and 700 cm^{-1} (phenyl), ^1H NMR δ=2.02 (3H, d, J=1 Hz), 6.27 (1H, q, J=1 Hz), 7.04 (1H, s), 7.15—7.6 (5H, m). Found: C, 67.20; H, 4.75; N, 13.12; S, 14.88%.

a) Recrystallized from petroleum ether. b) Recrystallized from ligroine. c) Recrystallized from ethanol. d) Recrystallized from ligroine–dichloromethane. e) Lit,[6] mp 128—129 °C.

tuer of 4-methyl-2-(*p*-toluoylaminomethyl)thiazole (7.4 g) and $POCl_3$ (25 ml) in dry benzene (50 ml) was heated under reflux for 6 h and evaporated under reduced pressure. Water was added to the residue and the solution was neutralized with NH_3 to deposit **1b** (4.0 g, 58%), which crystallized as colorless prisms from ligroine [mp 123—124 °C, UV_{max} (chloroform) 300 nm (log ε 4.14), IR 825 cm^{-1} (phenyl), ^1H NMR δ=2.07 (3H, d, J=1 Hz), 2.42 (3H, s), 6.36 (1H, q, J=1 Hz), 7.10 (1H, s), 7.20 (2H, d, J=8 Hz), 7.42 (2H, d, J=8 Hz). Found: C, 68.50; H, 5.14; N, 12.13; S, 14.14%. Calcd for $C_{13}H_{12}N_2S$: C, 68.39; H, 5.30; N, 12.27; S, 14.04%].

General Procedure for the Reactions of ***1*** *with DMAD.* A mixture of **1** (2.0 mmol), DMAD, and the solvent (30 ml) was allowed to react under the conditions specified in Table 1 and evaporated to dryness under reduced pressure. Chromatography of the residue with benzene, benzene–chloroform (1 : 1), and chloroform, successively, gave the compounds, **1**, **2**, **3**, **4**, **5**, and **6**, in the order. Analytical data are collected in Table 4 and spectroscopic data in Tables 2 and 3.

Reaction of ***1a*** *with DEAD.* A mixture of **1a** (2.0 mmol), DEAD, and the solvent (30 ml) was allowed to react under the conditions specified in Table 1 and evaporated to dryness under reduced pressure. Chromatography of the residue with benzene–chloroform (1 : 1) gave **3c** and **4c**, successively. Analytical data are given in Table 4 and spectroscopic data in Table 2.

Epimerization of ***3*** *and* ***4****.* *a)*: **3a** (0.150 g) was added to a sodium methoxide solution prepared from sodium (0.069 g) and abs methanol (30 ml). The mixture was heated under reflux, cooled, acidified with dil hydrochloric acid, and extracted with chloroform. The extracts were washed with water, dried (Na_2SO_4), and evaporated. Chromatography of the residue with benzene–chloroform (2:1) gave **3a** followed by **4a**. Elution with chloroform gave **10a**, which crystallized as yellow needles from benzene and had mp 223—225 °C, UV_{max} (ethanol) 238 nm (log ε 4.28), 275 (4.42), 394 (4.37), IR (chloroform) 2300—2850 (NH), 1730, 1715, and 1695 cm^{-1} (C=O), ^1H NMR δ=2.41 (3H, d, J=0.5 Hz), 3.83 (6H, s), 3.90 (7H, s) (one proton is exchangeable), 6.74 (1H, q, J=0.5 Hz), δ (CF_3CO_2H)=2.72 (3H, bs), 3.93 (6H, s), 4.18 (6H, s), 7.70 (1H, bs), 10.47 (1H, bs) (exchangeable). Found: C, 51.94; H, 4.23; N, 3.55; S, 8.16%. Calcd for $C_{17}H_{17}NO_8S$: C, 51.64; H, 4.33; N, 3.54; S, 8.11%. MS *m/e* (rel intensity) 395 (9%, M^+), 363 (61), 332 (100). Treatment of **8a** with methyl fluorosulfate in $CDCl_3$ in an NMR tube produced **11a**; ^1H NMR δ=2.50 (3H, bs), 3.87 (12H, s), 3.96 (3H, s), 6.87 (1H, bs). Yields of **3a**, **4a**, and **8a** are given in Table 5.

b): A mixture of **3a** (0.100 g) and DBU (1 drop) in dry benzene (5 ml) was heated under reflux for 1 h and evaporated under reduced pressure. The residue was chromatographed with benzene–chloroform (1 : 1) to give **3a**, **4a**, and **8a**, successively, whose yields are given in Table 5.

c): A mixture of **3c** (0.300 g) and a sodium ethoxide solution prepared from sodium (0.124 g) and abs ethanol (30 ml) was heated under reflux for 5 h and worked up as dercribed above. Elution with benzene–chloroform (2 : 1) gave **3c**

Table 5. Conditions and yields for the reactions of **3** and **4** with base

Substrate	Conditions	Time/h	(Yield/%)

Syntheses and Properties of the Polymethylenebis-(diphenylcyclopropenium) Dications[1)]

Koichi Komatsu, Katsuhisa Masumoto, Yoshinori Waki, and Kunio Okamoto*
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 26, 1981)

A series of polymethylenebis(diphenylcyclopropenium) dications with the polymethylene chain of one to six carbons ($\mathbf{4}_{n=1-6}$) were synthesized and characterized by spectral and analytical means. Among the dications $\mathbf{4}_{n=3-6}$ which were isolated as perchlorates, $\mathbf{4}_{n=3}$ was shown by the pK_{R^+} measurements to be destabilized by 1.3 pK units as compared with $\mathbf{4}_{n=4-6}$. The values of reduction potential exhibited the same tendency. The chromium(II) ion reduction of $\mathbf{4}_{n=6}$, a representative dication, afforded a polymeric material containing a hexylbenzene unit. The dication $\mathbf{4}_{n=2}$ was isolable only as a complex salt with $SbCl_6^-$ and Cl^-: the conventional hydride abstraction from 1,2-dicyclopropenylethane using trityl perchlorate resulted in rearrangements affording 4,9,10-triphenylphenanthrene and the unknown monocation $C_{32}H_{25}^+$ containing the tropylium ring. A possible mechanism for these rearrangements is presented. On the other hand, the dication $\mathbf{4}_{n=1}$ was observable only in a highly acidic solution due to the ready deprotonation yielding a new fully conjugated monocation **17**. This cation, characterized by remarkable stability (pK_{R^+} 8.9 in 50% aq acetonitrile), is formally represented as a triafulvene with a cyclopropenium ring substituted at the 4-position, but is shown to have a partially polarized electronic structure by ^{13}C NMR spectroscopy.

The divalent carbocations are typically classified into two groups, namely, the dipositive ions, in which the dipositive charge resides on one fully conjugated π-system, as exemplified by the cyclobutadienyl[2)] and cyclooctatetraenyl[3)] dipositive ions, and the carbodications, which contain two separate monocationic units in the same molecule.

In the latter class of dications, those having tertiary-alkyl cationic units are observable only in solution under stable-ion conditions,[4)] but those carrying nonbenzenoid aromatic cations are generally stable enough for isolation and for further investigation on their structure and reactivity. Thus, there have already been reported as stable species a variety of polyvalent cations containing two[5)] or more[6)] tropylium rings. Dications composed of two diaminocyclopropenium rings connected by a cyclopentadiene ring[7a)] and by various hetero-atom linkages[7b-d)] have also been synthesized, together with the directly bonded bis(diaminocyclopropenium) dications;[7e)] even the tetracation consisting of three diaminocyclopropenium rings bonded to the central cyclopropenium ring has been reported.[8)] However, studies on the dicyclopropenylio-dications carrying no stabilizing hetero atom seem to be quite limited; the reported examples are *p*-phenylenebis(diphenylcyclopropenium) dication (**1**) synthesized by Eicher and Berneth,[9)] and 1,8- (**2**) and 1,5-naphthylenebis(diphenylcyclopropenium) dication (**3**), synthesized by us.[10)]

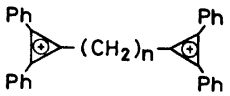
In connection with our previous work on the syntheses and both inter- and intramolecular reductive cyclization of the polymethylenebistropylium dications,[5h)] we have synthesized a series of new dicyclopropenylio-dications, *i.e.* the polymethylenebis(diphenylcyclopropenium) dications ($\mathbf{4}_{n=1-6}$), and examined their stability and reducibility with reference to the polymethylene chain length. In this paper, these results will be described, together with unusual molecular rearrangements observed during the course of syntheses.[1b)]



$\mathbf{4}_{n=1-6}$

Syntheses of Polymethylenebis(diphenylcyclopropenium) Dications ($\mathbf{4}_{n=1-6}$). It has been reported that chlorophenylcarbene thermally generated from chlorophenyldiazirine readily adds to mono- and diphenylacetylenes to give the chlorocyclopropene derivatives, which can be converted to the cyclopropenium ions.[11)] This method has been successfully applied to the synthesis of the dication **3** in our previous work.[10)] Thus, we first attempted the thermal reaction of two molar equivalents of chlorophenyldiazirine with 1,8-diphenyl-1,7-octadiyne as a representative alkadiyne. The product, however, was an intractable mixture of unwanted materials, and there was observed no indication of the formation of the cyclopropenyl or cyclopropenium ring. Apparently the first formed 1-alkyl-3-chloro-2,3-diphenylcyclopropene was unstable and was subjected to further reactions; several modifications of the reaction conditions did not improve the results.

Subsequently, we examined direct coupling of the di-Grignard reagent, α,ω-(bromomagnesio)alkanes, with the diphenylcyclopropenium ion as shown in Scheme 1, and obtained the corresponding α,ω-bis(2,3-diphenyl-2-

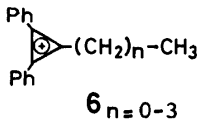
cyclopropenyl)alkanes ($\mathbf{5}_{n=4-6}$) in 37—60% yield. This method, however, is applicable only to the compounds with $n \geq 4$ due to the synthetic limitation for the di-Grignard reagent. For the syntheses of the dicyclopropenylalkanes $\mathbf{5}_{n=1-3}$, we adopted a stepwise method involving the addition of chlorophenylcarbene to the α,ω-alkadienes and the subsequent elimination of HCl, as shown in Scheme 2. The crude overall yield for $\mathbf{5}_{n=1-3}$ was 43—57%, based on the alkadienes. The dicyclopropenylalkanes $\mathbf{5}_{n=1-6}$ thus obtained were characterized by the spectral data listed in Table 1.

For the purpose of conversion to the polymethylenebiscyclopropenium dication **4**, the dicyclopropenylalkanes $\mathbf{5}_{n=1-6}$ were treated with two equivalents of trityl perchlorate. In the case with the polymethylene chain length of three to six carbons, the corresponding perchlorate salts of the dications $\mathbf{4}_{n=3-6}\cdot 2ClO_4^-$, were obtained as white powder in 70—94% yield. When the 1,2-dicyclopropenylethane $\mathbf{5}_{n=2}$ was treated with the trityl cation, an unexpected rearrangement occurred as a main reaction, as will be described later in detail. Among various other hydride-abstraction reagents examined, only antimony pentachloride[12] was effective to give a dicationic salt, which was analyzed as $\mathbf{4}_{n=2}\cdot 0.5SbCl_6^-\cdot 1.5Cl^-$, with no attendant rearrangement. On the other hand, the methylenebiscyclopropenium dication $\mathbf{4}_{n=1}$,[1b] obtained by the reaction of $\mathbf{5}_{n=1}$ with two equivalents of the trityl cation, was observable only in the highly acidic solution (*e.g.* in CF_3CO_2H–CF_3SO_3H (9 : 1)) owing to its ease in deprotonation which afforded the fully conjugated monocations, as will also be shown later.

Properties of the Polymethylenebis(diphenylcyclopropenium) Dications ($\mathbf{4}_{n=1-6}$). The dicyclopropenylio-dications $\mathbf{4}_{n=1-6}$ are characterized by the spectral properties shown in Table 2, which also includes the data for the related monocations $\mathbf{6}_{n=0-3}$ and **17** (*vide infra*) for



$\mathbf{6}_{n=0-3}$

comparison. All the di- and monocations (except **17**) exhibit strong IR absorption due to the cyclopropenium ring stretching near 1420 cm^{-1} and characteristic UV absorptions near 247, 293, and 307 nm. In the ^{1}H NMR spectra the methylene protons of the dications **4** are generally deshielded compared with the corresponding protons of the monocations **6**. Among the dications, the signals for each methylene proton are gradually shifted downfield as the chain length decreases. This tendency in methylene chemical shifts suggests the presence of some repulsive interaction between the two cationic rings through the polymethylene chain.

In order to examine the effect of such repulsive interaction, the pK_{R^+} and reduction potential of the purely isolated perchlorates of the dications $\mathbf{4}_{n=3-6}$ were determined by the use of the spectrophotometric method and cyclic voltammetry (CV), respectively. The results are shown in Table 3, together with the data for $\mathbf{6}_{n=2}$ as the representative monocation for comparison. For the dications, two pK_{R^+} values were determined, corresponding to the stepwise neutralization sequences for the two cationic units present at both ends of the polymethylene chain. The comparison of pK_{R^+} values for the first neutralization clearly shows that the dication $\mathbf{4}_{n=3}$, with the chain length of only three carbons, is destabilized by 1.3 pK units, *i.e.* *ca.* 1.8 kcal/mol at 25 °C, as compared with the dications with longer chain length.

The values of reduction potential also exhibit the same tendency; the dication $\mathbf{4}_{n=3}$ is most susceptible towards the electrochemical one-electron reduction. Notice here that the reduction wave observed at the potential listed in Table 3 is irreversible, and only corresponds to the first one-electron transfer to the dicationic species; this was determined from the comparison of the peak current with that of ferrocene determined under the identical conditions. The second reduction wave was not clearly observed in the sweep range of 0 to −2.0 V *vs.* Ag/Ag$^+$. This is presumably

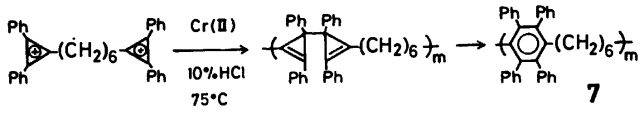
due to the rapid coupling of the first formed cation-radical to give the dimeric dication, which upon further reduction and repeated coupling gives some polymeric material which accumulates at the electrode surface. Actually, this polymerization, which supposedly results in the coating of the working electrode, caused marked depression of the reduction wave (to less than one third of the peak height of each previous scan) at the second and subsequent scans.

Chromium(II) Ion Reduction of the Hexamethylenebis-(diphenylcyclopropenium) Dication ($\mathbf{4}_{n=6}$). The above-mentioned result of the electrochemical reduction led us to investigate the chemical reduction of the dicyclopropenylio-dication. In our previous kinetic

and product study, the 1,2-diphenyl-3-propylcyclopropenium ion was found to be reduced by the chromium(II) ion in 10% HCl at 75 °C smoothly to give the dimer of the corresponding cyclopropenyl radical in good yield (82.1%).[13] Thus, the chromium(II) ion reduction was carried out under similar reaction conditions on $\mathbf{4}_{n=6}$ as the representative dication. The product, obtained as a yellowish solid in 81% yield, exhibited the IR absorptions only for the polymethylene chain and the benzene nuclei, but no absorption for the cyclopropene structure near 1800 cm^{-1}; the ^1H NMR spectrum showed only two broad signals, one centered at δ 7.2 and the other ranging from δ 2.5 to 0.9, with an integrated ratio of 5 : 3. This product was developed on a TLC plate (SiO_2) as a streak with benzene–hexane (1 : 1) as a solvent but not as spots, as are commonly observed for polymeric hydrocarbons. Based on these findings, the product is supposed to be an oligomer or a polymer of the structure such as **7**, formed by repeated coupling of the cyclopropenyl radicals generated at both ends of the polymethylene chain, followed by the subsequent "bicyclopropenyl→benzene" rearrangement,[14] as shown



Scheme 3.

in Scheme 3. The same type of polymerization has already been observed upon the chromium(II) ion reduction of polymethylenebistropylium dications under similar reaction conditions.[5h]

Reaction of 1,2-Bis(2,3-diphenyl-2-cyclopropenyl)ethane ($\mathbf{5}_{n=2}$) with the Trityl Cation Accompanied by Molecular Rearrangements. As has been mentioned, unexpected rearrangements were observed upon hydride abstraction from the dicyclopropenylethane $\mathbf{5}_{n=2}$. When two equivalents of trityl perchlorate were allowed to react with $\mathbf{5}_{n=2}$ in dichloromethane at room temperature, a mild exothermic reaction took place, as shown by the immediate darkening of the reaction mixture. However, no dicationic salt was obtained but rather some unknown monocationic salt with the molecular formula $C_{32}H_{25}ClO_4$† (40.7% yield based on $\mathbf{5}_{n=2}$) upon

† This cation salt is yellow and exhibits no IR absorption for the cyclopropenium ring. From the ^1H and ^{13}C NMR data (see Experimental), the long-wave UV-Vis absorption (λ_{max} (MeCN) 433 nm), high stability (pK_{R^+} 6.89 in 23% EtOH),and the facile $NaBH_4$ reduction to the cycloheptatriene derivative, this cation is supposed to have a structure composed of the tropylium ring with a conjugative substituent. Assuming that this cation is derived as shown below from the same reaction intermediate (**13** in Scheme 6) as the one leading to the phenanthrene **15**, the structure **16** may be tentatively assigned to this cation.

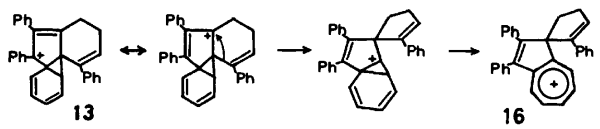


Table 3. The pK_{R^+} and reduction potential of the dications $\mathbf{4}_{n=3-6}$ and the monocation $\mathbf{6}_{n=2}$

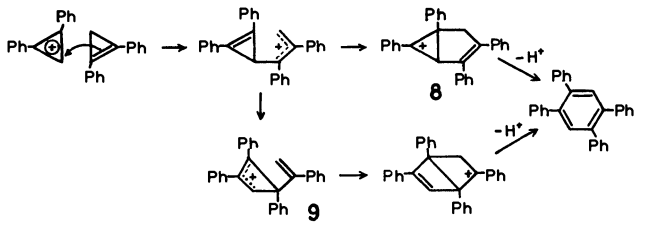
Cation	pK_{R^+} [a]	Red'n potential[b] V *vs.* Ag/Ag^+
$\mathbf{4}_{n=3}$	2.06 (4.50)	−0.95
$\mathbf{4}_{n=4}$	3.38 (4.75)	−1.16
$\mathbf{4}_{n=5}$	3.35 (4.80)	−1.26
$\mathbf{4}_{n=6}$	3.35 (4.67)	−1.28
$\mathbf{6}_{n=2}$	3.52	−1.31

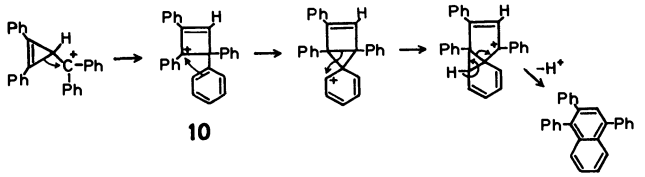
a) Measured in 50% aq MeCN at 25°C. The values for the second neutralization are given in the parentheses. b) The peak potential observed by CV in MeCN with $Bu_4N^+ClO_4^-$ as a supporting electrolyte.

precipitation with ether. After hydrolysis of the filtrate and the usual work-up, the rest of the products were separated and identified as a hydrocarbon with the molecular formula $C_{32}H_{22}$ (46.3% yield based on $\mathbf{5}_{n=2}$), triphenylmethane (50.9% yield based on Ph_3C^+), and triphenylmethanol (32.9% yield based on Ph_3C^+). The product distribution was not affected greatly, the variation in the yield being less than 15% of the above values, upon changes in reaction temperature (0 to 60 °C), in mode of addition (*i.e.* inverse addition), and in the solvent to more polar acetonitrile and even to trifluoroacetic acid. Triphenylmethanol is apparently derived from the unchanged trityl cation, since the product distribution was not changed when the reaction was carried out with only one equivalent of the trityl salt. These results suggest that some rearrangement of the dicyclopropenylethane structure took place immediately after abstraction of one equivalent of the hydride ion from $\mathbf{5}_{n=2}$.

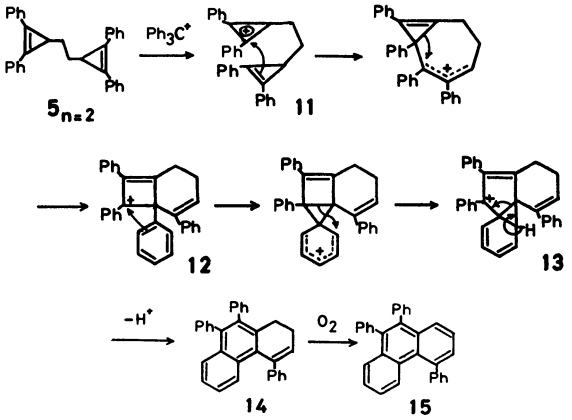
The hydrocarbon $C_{32}H_{22}$, which exhibits the parent peak at *m/e* 406 in the mass spectrum, does not react with bromine, and no longer retains any cyclopropene ring, as is also shown by the absence of specific IR absorption near 1800 cm^{-1}; rather, the absorptions at 820 and 727 cm^{-1} suggest the presence of a phenanthrene framework. In the ^1H NMR spectrum taken in CCl_4, which exhibits signals for only the aromatic protons mainly at δ 7.47—7.10, two rather broad singlets are prominent at δ 7.42 (5H) and 7.15 (10H), together with a small doublet at δ 7.78 (1H, J=8.5 Hz). The two broad singlets seem to represent two types of phenyl groups, both of which are in a conformation that prevents effective conjugation with the other aromatic nucleus, and are thus reasonably correlated with the phenyl signals in 4-phenylphenanthrene (δ 7.36)[15] and in 9,10-diphenylphenanthrene (δ 7.20),[16] respectively. The doublet at δ 7.78, on the other hand, seems to correspond to 4-phenylphenanthrene's H-5 (δ 7.60),[15] which is markedly shielded by the oposing phenyl group as compared with H-4,5 (δ 8.55)[15] in phenanthrene itself. Based on these facts, together with other similarities in the UV spectrum (λ_{max} (cyclohexane) 264 nm (log ε, 4.59), 271 sh (4.57), 304 sh (4.18)) with that for 9,10-diphenylphenanthrene (λ_{max} (cyclohexane) 260 nm (log ε, 4.52), 271 (4.20), 302 (4.00)),[16,17] the hydrocarbon $C_{32}H_{22}$ is assigned to 4,9,10-triphenylphenanthrene (**15**) as the most probable structure.



Scheme 4.



Scheme 5.

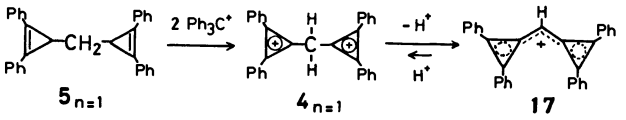


Scheme 6.

1,2-Diphenylcyclopropene is known to react with the diphenylcyclopropenium ion to give 1,2,4,5-tetraphenylbenzene according to Scheme 4.[18] The mechanism proceeding through the cation **9** seems more likely than the originally reported one involving the cation **8**, as judged from the results of later work by Moerck and Battiste[19] and by Weiss and Andrae.[14b] On the other hand, a unique rearrangement of the cyclobutenyl cation **10** giving the naphthalene derivative (Scheme 5) has also been reported by Breslow and Battiste.[20] Considering the mutual accessibility of the two three-membered rings connected by an ethylene linkage in $\mathbf{5}_{n=2}$, it seems reasonable to interpret the observed transformation of $\mathbf{5}_{n=2}$ to **15** in analogy with these two reported rearrangements, as shown in Scheme 6: the intramolecular cyclization of the first formed monocation **11**, followed by the subsequent rearrangement to the cyclobutenyl cation **12**, and the ring expansion of **12** to **14** through **13** are formally analogous to the rearrangements shown in Schemes 4 and 5, respectively. Since in the ^{1}H NMR spectrum of the crude product the presence of the ethylenic linkage was indicated by two rather broad multiplets at δ 2.45 and 2.15, the aromatization of **14** to the phenanthrene **15** is supposed to have occurred by air oxidation during the course of isolation procedures involving the repeated preparative TLC, in which exposure to air was inevitable.

The reaction of $\mathbf{5}_{n=2}$ with various other hydride abstraction reagents was surveyed to see if the rearrangement of **11** can be suppressed to allow the formation of the dication $\mathbf{4}_{n=2}$. However, the course of the reaction was not changed by the use of such reagents as: diphenylmethyl cation,[12] which is less stable and supposed to have stronger hydride abstracting ability than the trityl cation; 2,3-dichloro-5,6-dicyano-*p*-benzoquinone[21] with high complexing ability with the produced cation; and the Lewis acids, *e.g.* phosphorus pentachloride and boron trifluoride etherate.

*Reaction of Bis(2,3-diphenyl-2-cyclopropenyl)methane ($\mathbf{5}_{n=1}$) with the Trityl Cation——The Formation of the 1,2-Diphenyl-3-(1,2-diphenyltriafulven-4-yl)cyclopropenium Ion (**17**).*[1b] As has already been described briefly, when the dicyclopropenylmethane $\mathbf{5}_{n=1}$ was treated with two equivalents of trityl perchlorate, the perchlorate of the expected dication was not obtained but rather that of the monocation, which was yellow and analyzed as $C_{31}H_{21}ClO_4$. The spectral data are included in Table 2. While the presence of the cyclopropenium ring is clearly exhibited by the broad and strong IR absorption at 1435 cm^{-1}, in the ^{1}H NMR spectrum taken in CD_3CN (Fig. 1a) the signal for the proton of the central carbon appears as a singlet at the olefinic range (δ 6.52), and the signals for the phenyl protons are somewhat shifted upfield compared with those for the dications $\mathbf{4}_{n=3-6}$ implying an appreciable decrease of positive charge in the three-membered rings. The multiplicity of the phenyl signals also indicates the restricted rotation of the three-membered ring with respect to the bond



Scheme 7.

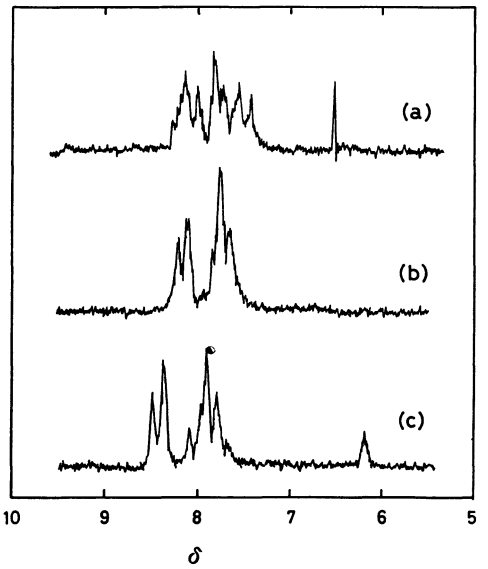


Fig. 1. The ^{1}H NMR spectra of the triafulvenylcyclopropenium ion **17** (a) in CD_3CN, (b) in CF_3CO_2H, and (c) in CF_3CO_2H–CF_3SO_3H (9 : 1).

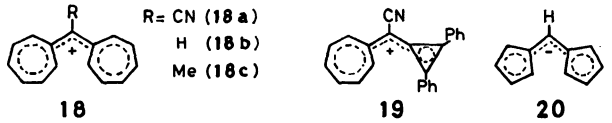
connecting the central carbon and the three-membered ring. These data are most compatible with the assignment of the fully conjugated structure **17**, formed by deprotonation of the first formed dication $\mathbf{4}_{n=1}$ (Scheme 7), to this new monocation. In the ^1H NMR spectrum taken in trifluoroacetic acid (Fig. 1b), the olefinic proton signal disappears, presumably owing to the rapid proton exchange process occurring in the equilibrium between **17** and $\mathbf{4}_{n=1}$. When the stronger acid, CF_3SO_3H, is added (*ca.* 10%), the equilibrium is shifted towards the dication $\mathbf{4}_{n=1}$, as shown by the appearance of a methylene singlet at δ 6.19 (2H) and the downfield shift of the phenyl protons (Fig. 1c). Similarly, the long-wavelength absorption of **17** at 353 nm in acetonitrile, reflecting the fully conjugated structure, is shifted upon addition of CF_3SO_3H to 313 nm (log ε, 4.78) and 298 nm (4.77), which is a characteristic absorption pattern for the cyclopropenium ion, as shown in Fig. 2.

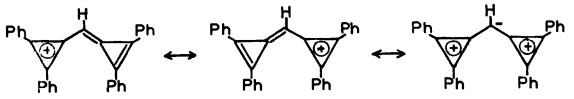
The stable monocations having a similar type of cross-conjugated structure, such as **18**[22] and **19**,[23] have been synthesized by Kitahara *et al*, and the analogous anion **20** by Jutz and Amschler.[24] The



18 **19** **20**

monocation **17** is thus regarded as the smallest-ring member in the family of these cross-conjugated ionic systems, and its stability is of much interest. The preliminary measurement of its pK_{R^+} value was carried out spectrophotometrically in 23% ethanol. In this solvent a considerable decomposition of the cation was observed after partial hydrolysis commenced at pH 7.1. Based on the plot of absorbance of the cation at 350 nm recorded at 15 min after preparation of the sample solution against the pH value, the pK_{R^+} was determined to be 7.23; however, this value should be considered as somewhat smaller than the true value, when the partial decomposition is taken into account. In 50% aq acetonitrile, the cation was found to be more stable, not being neutralized appreciably until the pH of the solution reached 8.0. In the solution with the pH near 10, almost all of the cation was neutralized, but about 90% of the cation was regenerated upon acidification. From the absorbance-pH plot, the most probable value for pK_{R^+} was determined to be surprisingly high, *i.e.* 8.9±0.2, for such a strained molecule. This remarkable increase in stability, as compared with the cation **18b** (pK_{R^+} 7.49 in 10% ethanol),[22b] may have arisen from the increased aromatic character in **17** with four stabilizing phenyl substituents. This result is in good agreement with the ^{13}C NMR data shown below.

The ^{13}C NMR spectrum of **17** measured in CD_3CN exhibited the following signals (in the parentheses are given the peak multiplicity in the off-resonance spectrum, assignments,†† and the charge density calculated by simple HMO method using the following parameters; $\beta_{1,3}=\beta_{2,3}=0.9$, $\beta_{C-Ph}=0.8$): δ (ppm from Me_4Si) 144.0 (s), 145.0 (s) (C-1, C-2; charge density +0.1833); 148.4 (s) (C-3; +0.1955); 68.6 (d) (C-4; −0.2632); 122.6 (s), 123.0 (s) (C-*i*, C-*i'*; −0.0106); 133.4 (d), 134.4 (d) (C-*o*, C-*o'*; +0.0166); 130.5 (d), 131.0 (d) (C-*m*, C-*m'*; −0.0007); and 135.7 (d), 136.4 (d) (C-*p*, C-*p'*; +0.0134). The planarity of the whole π-system in **17** is clearly demonstrated by the appearance of C-1, C-2, and phenyl carbons in sets of pairs of signals. It should be noted here that the central carbon, C-4, is resonating at an unusually high field at δ 68.6. This marked upfield shift is attributable to the considerable amount of negative charge residing on this carbon, which is in agreement with the calculated result. This spectral feature thus demonstrates the significant contribution of the dipolar structure, **17c**, with both of the three-membered rings positively charged, to the

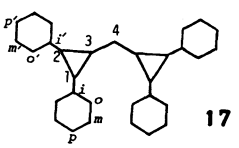


17a **17b** **17c**

Scheme 8.

resonance hybrid of **17** (Scheme 8). A similar type of polarization seems to be present also in cation **18**, as shown by the charge density (−0.1972) calculated by the same method for the central carbon of **18b** and the ^{13}C chemical shift (δ 100.1) observed for **18a**.[25] However, comparison of these values with those for the cation **17** indicates that the contribution of such a polar structure is greater in **17** than in **18**. Thus, it is supposed that this greater polarization in **17**, which forms the two Hückeloid aromatic rings, has caused a considerable

†† The numbering system is as follows:



17

increase in the aromatic stabilization of the cation **17**, as has already been noted from its pK_{R^+} value.

Experimental

Melting and boiling points are uncorrected. Elemental analyses were performed by the Microanalytical Center, Kyoto University, Kyoto. IR and UV-Vis spectra were recorded with a Hitachi 215 and a Hitachi 200-10 spectrometers, respectively. ^{1}H NMR spectra were taken on a Hitachi R-24 (60 MHz) and on a Varian HA-100 (100 MHz) spectrometers, with Me_4Si as an internal standard. ^{13}C NMR spectra were obtained on a JEOL FX-100 spectrometer (25 MHz) operated in the pulse Fourier transform mode. Mass spectra were recorded with a JEOL JMS-01SG spectrometer.

All reagents were of reagent-grade quality unless otherwise noted. MeCN and CH_2Cl_2 were refluxed and distilled over P_2O_5, and THF was distilled over $LiAlH_4$. Merck SiO_2 type GF_{254} and type PF_{254} were used for analytical and preparative TLC, respectively.

Diphenylcyclopropenium Perchlorate. To a stirred solution of bis(2,3-diphenyl-2-cyclopropenyl) ether[11] (3.32 g; 8.33 mmol) in THF (10 ml) and ether (90 ml) was added dropwise 70% $HClO_4$ (3.62 g) at 0 °C. The resulting white precipitates were filtered, washed with ether, and dried under reduced pressure to give diphenylcyclopropenium perchlorate (4.01 g; 82.8%) as white powder: mp 148.5—150.0 °C (decomp) (lit, mp 149.5—150.5 °C (decomp)).[26]

Bis(2,3-diphenyl-2-cyclopropenyl)methane ($\mathbf{5}_{n=1}$). 1,5-Diphenyl-1,4-pentadiene was prepared by dehydration of 1,5-diphenyl-1,5-pentanediol, which had been obtained by Grignard reaction of phenylmagnesium bromide with pentanedial, by the use of $KHSO_4$[27] in 63.3% yield: bp 132—138 °C/0.2 Torr (1 Torr=133.322 Pa) (lit, bp 205—211 °C/12 Torr);[28] ^{1}H NMR (CCl_4) δ 7.17 (s, 10H, Ph), 6.41 (d, J=15.5 Hz, 2H, =CHPh), 6.07 (dt, 2H, =CH–), 3.03 (t, 2H, $-CH_2-$). A solution of 1,5-diphenyl-1,4-pentadiene (3.03 g; 13.7 mmol) and chlorophenyldiazirine[11] (6.75 g; 44.2 mmol) in dry C_6H_6 (180 ml) was heated to reflux with magnetic stirring for 4 h. After removal of the solvent *in vacuo*, the crude product was separated by the use of preparative TLC (R_f 0.34; C_6H_6–n-C_6H_{14}(1 : 4)/SiO_2) to give bis(2-chloro-2,3-diphenylcyclopropyl)methane (3.79 g; 58.9%) as a pale yellow solid: ^{1}H NMR (CCl_4) δ 7.30, 7.07 (br s×2, 20H, Ph), 2.9—1.5 (br m, 6H, >CH– +$-CH_2-$).

To a stirred solution of the bis(chlorocyclopropyl)methane (3.60 g; 7.68 mmol) in THF (250 ml) was added *t*-BuOK (17.2 g; 0.153 mol) in portions during 5 min under nitrogen. After stirring for 18 h at room temp, the mixture was poured into 1 dm^3 of cold water and extracted with ether. The ethereal extract was washed with 10% NaCl, dried ($MgSO_4$), and evaporated to give the crude dicyclopropenylmethane $\mathbf{5}_{n=1}$ (2.93 g; 96.2%) as a yellow solid. Recrystallization from C_6H_6–n-C_6H_{14} afforded white needles: mp 118.0—118.6 °C. Found: C, 94.17; H, 6.06%. Calcd for $C_{31}H_{24}$: C, 93.90; H, 6.10%.

1,2-Bis(2,3-diphenyl-2-cyclopropenyl)ethane ($\mathbf{5}_{n=2}$). 1,6-Diphenyl-1,5-hexadiene was prepared by dehydration of 1,6-diphenyl-1,6-hexanediol, derived from hexanedial, in 83.9% yield: bp 154—157 °C/0.5 Torr, mp 77.4—77.8 °C (lit, bp 115 °C/0.005 Torr, mp 80.5—81 °C);[29] ^{1}H NMR (CCl_4) δ 7.18 (s, 10H, Ph), 6.41 (d, J=15.5 Hz, 2H, =CHPh), 6.08 (dt, 2H, =CH–), 2.31 (d, 4H, $-CH_2-$). The reaction of 1,6-diphenyl-1,5-hexadiene (3.27 g; 14.0 mmol) with chlorophenyldiazirine (4.94 g; 32.4 mmol) in dry C_6H_6 (100 ml) afforded 1,2-bis-(2-chloro-2,3-diphenylcyclopropyl)ethane (2.87 g; 42.5%) as a pale yellow viscous oil: ^{1}H NMR ($CDCl_3$) δ 7.3—6.9 (m, 20H, Ph), 2.7—1.6 (br m, 8H, >CH–+$-CH_2-$). The reaction of the 1,2-bis(chlorocyclopropyl)ethane (4.61 g; 9.53 mmol) with *t*-BuOK (17.93 g; 0.160 mol) in THF (300 ml) gave the crude 1,2-dicyclopropenylethane $\mathbf{5}_{n=2}$ (3.95 g; 100.9%) as a yellow solid. Recrystallization from MeCN afforded white needles: mp 120.1—120.9 °C. Found: C, 93.32; H, 6.46%. Calcd for $C_{32}H_{26}$: C, 93.62; H, 6.38%.

1,3-Bis(2,3-diphenyl-2-cyclopropenyl)propane ($\mathbf{5}_{n=3}$). 1,7-Diphenyl-1,6-heptadiene was prepared by dehydration of 1,7-diphenyl-1,7-heptanediol, obtained from heptanedial, in 51.7% yield: bp 177—180 °C/0.6 Torr; ^{1}H NMR (CCl_4) δ 7.15 (s, 10H, Ph), 6.36 (d, J=15.5 Hz, 2H, =CHPh), 6.03 (dt, 2H, =CH–), 2.20 (dt, 4H, $-CH_2-$), 1.26 (quint, 2H, $>CH_2-$). The reaction of 1,7-diphenyl-1,6-heptadiene (1.16 g; 4.67 mmol) with chlorophenyldiazirine (2.14 g; 14.0 mmol) in dry C_6H_6 (65 ml) yielded 1,3-bis(2-chloro-2,3-diphenylcyclopropyl)propane (1.21 g; 52.0%) as a pale yellow viscous oil: ^{1}H NMR ($CDCl_3$) δ 7.3—6.9 (m, 20H, Ph), 2.6—1.4 (br m, 10H, >CH–+$-CH_2-$). The dehydrochlorination of the 1,3-bis(chlorocyclopropyl)propane (0.989 g; 1.99 mmol) with *t*-BuOK (4.63 g; 41.3 mmol) in THF (80 ml) gave the crude 1,3-dicyclopropenylpropane $\mathbf{5}_{n=3}$ (0.774 g; 91.6%) as a yellow-brown solid. Recrystallization from MeCN afforded white needles: mp 94.8—95.6 °C. Found: C, 93.65; H, 6.56%. Calcd for $C_{33}H_{28}$: C, 93.35; H, 6.65%.

1,4-Bis(2,3-diphenyl-2-cyclopropenyl)butane ($\mathbf{5}_{n=4}$). A solution of the di-Grignard reagent, 1,4-bis(bromomagnesio)-butane, was prepared from 1,4-dibromobutane (1.74 g; 8.06 mmol) and Mg (0.371 g; 15.3 mmol) in THF (40 ml). To the stirred solution of the di-Grignard reagent cooled at 0 °C was added diphenylcyclopropenium perchlorate (3.97 g; 13.7 mmol) slowly, at a rate such that the temperature did not exceed 5 °C, in portions under nitrogen during 15 min. After stirring for 15 h at 0 °C, the mixture was hydrolyzed with 10% HCl and extracted with C_6H_6. The extract was washed with 10% NaCl, dried ($MgSO_4$), and evaporated to give 3.19 g of the crude product, which afforded the 1,4-dicyclopropenylbutane $\mathbf{5}_{n=4}$ (1.52 g; 51.0%) as white needles after recrystallization from C_6H_6–n-C_6H_{14}: mp 122.1—123.1 °C. Found: C, 93.40; H, 7.00%. Calcd for $C_{34}H_{30}$: C, 93.11; H, 6.89%.

1,5-Bis(2,3-diphenyl-2-cyclopropenyl)pentane ($\mathbf{5}_{n=5}$). Similarly, the reaction of diphenylcyclopropenium perchlorate (2.01 g; 6.88 mmol) with 1,5-bis(bromomagnesio)pentane, prepared from 1,5-dibromopentane (0.960 g; 4.17 mmol) and Mg (0.188 g; 7.75 mmol) in THF (20 ml), gave 1.81 g of the crude product, which afforded, by the use of preparative TLC (R_f 0.47, C_6H_6–n-C_6H_{14} (1 : 9)/SiO_2), the 1,5-dicyclopropenylpentane $\mathbf{5}_{n=5}$ (0.574 g; 36.9%) as a colorless viscous oil. Found: C, 92.12; H, 7.12%. Calcd for $C_{35}H_{32}$: C, 92.88; H, 7.12%.

1,6-Bis(2,3-diphenyl-2-cyclopropenyl)hexane ($\mathbf{5}_{n=6}$). The reaction of diphenylcyclopropenium perchlorate (3.97 g; 13.8 mmol) with 1,6-bis(bromomagnesio)hexane, prepared from 1,6-dibromohexane (1.96 g; 8.03 mmol) and Mg (0.368 g; 15.2 mmol) in THF (40 ml), gave 5.00 g of the crude product, which afforded the 1,6-dicyclopropenylhexane $\mathbf{5}_{n=6}$ (1.89 g; 59.8%) as white needles after recrystallization from C_6H_6–n-C_6H_{14}: mp 126.0—126.9 °C. Found: C, 92.42; H, 7.61%. Calcd for $C_{36}H_{34}$: C, 92.66; H, 7.34%.

*The Hydride Abstraction from $\mathbf{5}_{n=1}$——Formation of 1,2-diphenyl-3-(1,2-diphenyltriafulven-4-yl)cyclopropenium Perchlorate (**17**·ClO_4^-).* A solution of trityl perchlorate ($Ph_3C^+ClO_4^-$)[30] (0.417 g; 1.22 mmol) in MeCN (7 ml) was slowly added to a stirred solution of the dicyclopropenylmethane $\mathbf{5}_{n=1}$ (0.234 g; 0.589 mmol) in dry C_6H_6 (2 ml) at room temp during 1 h under nitrogen, and the resulting dark red solution was heated at 65 °C for 10 min. To this solution was added, with stirring

and ice-bath cooling, dry AcOEt (2 ml) and dry ether (100 ml) to cause the formation of orange-colored precipitates. These were filtered, washed with dry ether, and dried *in vacuo* to give the triafulvenylcyclopropenium perchlorate **17**·ClO_4^- (0.220 g; 75.8%) as yellow powder: mp 227.0—228.0 °C (decomp) after recrystallization from MeCN. Found: C, 75.52; H, 4.14%. Calcd for $C_{31}H_{21}ClO_4$: C, 75.53; H, 4.29%.

The Methylenebis(diphenylcyclopropenium) Dication ($4_{n=1}$). The dication $4_{n=1}$ was observed by the use of ^1H NMR and UV spectra on the CF_3CO_2H solution of the triafulvenylcyclopropenium ion **17** with CF_3SO_3H added (*ca.* 10%) (see Figs. 1 and 2).

The Hydride Abstraction from $5_{n=2}$ *with the Trityl Cation—— Rearrangements to* **15** *and the Cation* $C_{32}H_{25}^+$. A solution of the dicyclopropenylethane $5_{n=2}$ (0.201 g; 0.489 mmol) in CH_2Cl_2 (3 ml) was slowly added during 10 min to a stirred solution of $Ph_3C^+ClO_4^-$ (0.339 g; 0.988 mmol) in CH_2Cl_2 (7 ml) at room temp. During the addition the color of the solution changed from orange to dark red with an increase of the temperature from 23.0 to 26.5 °C. After stirring the mixture for 30 min at room temp and for 10 min at 40 °C, dry ether (100 ml) was added to the stirred and ice-cooled mixture to cause the formation of yellow precipitates, which were then filtered, washed with dry ether, and dried *in vacuo* to give the yellow powder (0.101 g; 40.7% based on $5_{n=2}$) tentatively assigned as **16**·ClO_4^-: mp 215.5—218.0 °C (decomp) after recrystallization from MeCN; IR (KBr) 3070, 2930, 2860, 1600, 1500, 1483, 1450, 1440, 1358, 1250, 1148, 1090, 840, 763, 740, 700 cm^{-1}; UV-Vis (MeCN) λ_{max} 256 nm (log ε, 4.46), 280 sh (4.19), 433 (4.15); ^1H NMR (100 MHz) (CF_3CO_2H) δ 8.90—8.52 (br m centered at 8.66, 5H, ···CH···+), 7.58—7.06 (m, 15H, Ph), 7.02 (t, 1H, =CH–), 3.13—2.85 (m, 2H, $-CH_2-$), 2.73—2.54 (m, 2H, $-CH_2-$); ^{13}C NMR (CD_3CN) δ 177.4 (s), 170.0 (s), 168.9 (s), 152.2 (d), 149.7 (d), 149.2 (d), 144.6 (d), 144.3 (s), 144.1 (d), 140.7 (s), 140.0 (d), 135.3 (s), 133.7 (s), 133.0 (s), 131.4 (d), 130.6×2 (d), 130.5 (d), 130.3 (d), 129.8 (d), 129.5 (d), 129.3 (d), 126.4 (d), 75.4 (s), 36.6 (t), 33.1 (t). Found: C, 75.23; H, 4.91%. Calcd for $C_{32}H_{25}ClO_4$: C, 75.51; H, 4.95%.

The filtrate from the above procedure was washed with 10% NaCl, dried ($MgSO_4$), and evaporated to give 0.368 g of the crude product, which was then separated by preparative TLC (C_6H_6-*n*-C_6H_{14}(1 : 4)/SiO_2) repeated twice. From the fraction with R_f 0.55 was obtained triphenylmethane (0.123 g; 50.9% based on Ph_3C^+), identified by comparison of the IR and ^1H NMR spectra with those of the authentic sample. From the fraction with R_f 0.30 was isolated the hydrocarbon $C_{32}H_{22}$ (0.923 g; 46.3% based on $5_{n=2}$), determined to be the triphenylphenanthrene **15**, as white crystals: mp 219.1—219.6 °C; IR (KBr) 3060, 3030, 1600, 1592, 1575, 1495, 1480, 1440, 1160, 1070, 1025, 1000, 920, 820, 782, 763, 750, 727, 700 cm^{-1}; for UV, see text; ^1H NMR (CCl_4) δ 7.78 (d, J=8 Hz, 1H), 7.50—7.05 (m+br s×2, 21H); MS *m/e* 406. Found: C, 94.18; H, 5.77%. Calcd for $C_{32}H_{22}$: C, 94.54; H, 5.46%. From the fraction with R_f 0.1 was obtained triphenylmethanol (0.0846 g; 32.9% based on Ph_3C^+), identified by comparison of the IR and ^1H NMR spectra with those of the authentic sample.

The cation $C_{32}H_{25}ClO_4$ was reduced with $NaBH_4$ as follows. A solution of $C_{32}H_{25}ClO_4$ (0.116 g; 0.228 mmol) in MeCN (3 ml) was added dropwise to a stirred suspension of $NaBH_4$ (0.0182 g; 0.481 mmol) in MeCN (2 ml) with ice-bath cooling under nitrogen. After stirring for 30 min, the mixture was hydrolyzed with H_2O and worked up in the usual way to give 0.0985 g of the crude product, which showed mainly one spot at R_f 0.41 on an analytical TLC plate (C_6H_6-*n*-C_6H_{14} (1 : 4)/SiO_2). Purification with preparative TLC afforded a pale yellow solid (0.0741 g; 79.3%), supposed to be an isomeric mixture of substituted cycloheptatrienes ($C_{32}H_{26}$) corresponding to the cation $C_{32}H_{25}^+$ (supposedly **16**): IR (KBr) 3040, 2970, 2860, 1600, 1575, 1495, 1485, 1452, 1442, 1380, 1070, 1030, 755, 735, 705 cm^{-1}; ^1H NMR (CCl_4) δ 7.17 (br s, 10H, Ph), 6.95 (br s, 5H, Ph), 6.55—5.80 (br m, 4H, =CH–), 5.50—5.00 (br m, 1H, =CH–), 2.85—1.85 (br m, 6H, $-CH_2-$); MS *m/e* 410.

The Complex Salt of Ethylenebis(diphenylcyclopropenium) Dication ($4_{n=2}$). A solution of the 1,2-dicyclopropenylethane $5_{n=2}$ (0.411 g; 1.00 mmol) in CH_2Cl_2 (5 ml) was added dropwise to a stirred solution of $SbCl_5$ (1.44 g; 4.80 mmol) in CH_2Cl_2 (10 ml) with ice-bath cooling under nitrogen during 10 min. After stirring the resulting dark-gray suspension for 1 h, dry ether (180 ml) was added to the mixture to cause the formation of additional dark green precipitates. The precipitates were filtered, washed with dry ether, and dried *in vacuo* to give grayish powder (0.601 g; 93.2%) analyzed as $C_{32}H_{24}$·0.55$SbCl_6$·1.45Cl: mp>300 °C. Found: C, 59.62; H, 3.43%. Calcd for $C_{32}H_{24}Cl_{4.75}Sb_{0.55}$: C, 59.62; H, 3.75%.

Trimethylenebis(diphenylcyclopropenium) Perchlorate ($4_{n=3}$·$2ClO_4^-$). To a stirred suspension of the 1,3-dicyclopropenylpropane $5_{n=3}$ (0.145 g; 0.342 mmol) in MeCN (2 ml) was added $Ph_3C^+ClO_4^-$ (0.238 g; 0.695 mmol) in one portion at room temp. After stirring at room temp for 15 min and at 60 °C for 15 min, dry AcOEt (10 ml) and dry ether (30 ml) were added to the cooled mixture to cause the formation of yellowish white precipitates, which were then filtered, washed with dry ether, and dried *in vacuo* to give $4_{n=3}$·2ClO_4^- (0.200 g; 94.2%) as white powder: mp 214.0—215.0 °C (decomp) after recrystallization from MeCN; ^{13}C NMR (CD_3CN) δ 166.9 (s), 162.3 (s), 139.8 (d), 137.2 (d), 131.4 (d), 120.5 (s), 27.9 (t), 23.9 (t). Found: C, 63.60: H, 4.17%. Calcd for $C_{33}H_{26}Cl_2O_8$: C, 63.78; H, 4.23%.

Tetramethylenebis(diphenylcyclopropenium) Perchlorate ($4_{n=4}$·$2ClO_4^-$). In the same way, the reaction of the 1,4-dicyclopropenylbutane $5_{n=4}$ (0.0975 g; 0.222 mmol) with $Ph_3C^+ClO_4^-$ (0.155 g; 0.452 mmol) was carried out in MeCN (2 ml) to give $4_{n=4}$·2ClO_4^- (0.132 g; 93.7%) as white powder: mp 229.8—231.3 °C (decomp) after recrystallization from MeCN; ^{13}C NMR (CD_3CN) δ 167.9 (s), 162.2 (s), 139.6 (d), 137.0 (d), 131.4 (d), 120.5 (s), 27.7 (t), 26.6 (t). Found: C, 64.16; H, 4.35%. Calcd for $C_{34}H_{28}Cl_2O_8$: C, 64.26; H, 4.44%.

Pentamethylenebis(diphenylcyclopropenium) Perchlorate ($4_{n=5}$·$2ClO_4^-$). To a stirred solution of the 1,5-dicyclopropenylpentane $5_{n=5}$ (0.233 g; 0.515 mmol) in CCl_4 (1 ml) and MeCN (2 ml) was added $Ph_3C^+ClO_4^-$ (0.356 g; 1.04 mmol). After stirring at room temp for 20 min and at 60 °C for 30 min, dry AcOEt (15 ml) was added to the cooled mixture. The formed precipitates were filtered, washed with dry AcOEt and dry ether, and dried *in vacuo* to give $4_{n=5}$·2ClO_4^- (0.232 g; 69.2%) as white powder: mp 223.4—224.2 °C (decomp) after recrystallization from MeCN; ^{13}C NMR (CD_3CN) δ 168.3 (s), 162.2 (s), 139.5 (d), 137.0 (d), 131.4 (d), 120.6 (s), 29.7 (t), 28.0 (t), 26.3 (t). Found: C, 64.72; H, 4.90%. Calcd for $C_{35}H_{30}Cl_2O_8$: C, 64.84; H, 4.66%.

Hexamethylenebis(diphenylcyclopropenium) Perchlorate ($4_{n=6}$·$2ClO_4^-$). Similarly, the reaction of the 1,6-dicyclopropenylhexane $5_{n=6}$ (0.444 g; 0.950 mmol) with $Ph_3C^+ClO_4^-$ (0.652 g; 1.90 mmol) in MeCN (5 ml) afforded $4_{n=6}$·2ClO_4^- (0.545 g; 86.5%) as white powder: mp 229.6—230.3 °C (decomp) after recrystallization from MeCN; ^{13}C NMR (CD_3CN) δ 168.5 (s), 162.2 (s), 139.5 (d), 137.0 (d), 131.4 (d), 120.6 (s), 29.4 (t), 28.1 (t), 26.7 (t). Found: C, 64.88; H, 4.78%. Calcd for $C_{36}H_{32}Cl_2O_8$: C, 65.16; H, 4.86%.

The Chromium(II) Ion Reduction of Hexamethylenebis(diphenylcyclopropenium) Perchlorate ($4_{n=6}$·2ClO_4^-). A solution (28.6

ml; 28.6 mmol) of the chromium(II) ion (1.00 M, 1 M=1 mol dm^{-3}) in 10% HCl, which had been prepared as previously reported,[31] was added to a stirred solution of $\mathbf{4}_{n=6}\cdot 2ClO_4^-$ (0.122 g; 0.183 mmol) in 10% HCl (100 ml), which had been deaired by bubbling with nitrogen for 2 h. The mixture was stirred with heating at 75 °C for 3 h. The color of the mixture gradually changed from blue to greenish blue with the concomitant formation of white paste-like precipitates. The mixture was extracted with C_6H_6 and worked up in the usual manner to give the polymeric material (supposedly **7**) (0.0691 g; 81.0%) as a yellowish solid: mp 73.5—99.2 °C; IR (KBr) 3065, 3030, 2930, 2855, 1600, 1577, 1495, 1480, 1460, 1440, 1073, 1030, 917, 760, 700, 680 cm^{-1}; for ^1H NMR see text.

Determination of pK_{R^+} *Values.* Buffer solutions of slightly different acidities (pH 2—8) were prepared by mixing a citric acid solution (0.1 M) in 50% aq MeCN (1 : 1 by volume) and a saturated solution of Na_2HPO_4 in 50% aq MeCN, in various proportions. For the preparation of a sample solution, each 1-ml portion of the stock solution, prepared by dissolving 1—2 mg of the cation salt in MeCN (20 ml), was pipetted out and made up to 10 ml by adding H_2O (1 ml) and the buffer solution. The sample solution with higher or lower acidity was made by further addition of 1—3 drops of H_2SO_4 or 10% NaOH. The UV-Vis spectrum was recorded, using a 1-cm cell thermostated at 25 °C, on each cation in 15—20 solutions of buffers spaced through a pH range of about two units on each side of the pK_{R^+}. Immediately after recording the spectrum, the pH of each sample solution was determined on a Horiba Model H pH meter calibrated with standard buffers before use. After complete neutralization of each cation, the reversibility was confirmed by quantitative regeneration of the cation spectrum upon acidification of the solution with H_2SO_4. The observed absorbance at the specific absorption wavelength of each cation was plotted against the pH to give a classical titration curve, whose midpoint was taken as the pK_{R^+}.

Cyclic Voltammetry. The measurements were carried out with a Hokuto-Denko Model HA 104 potentiostat equipped with a Hokuto-Denko Model HB 107A function generator. A three-electrode cell was used, consisting of Pt wire working and auxiliary electrodes and a reference electrode, $Ag/AgNO_3$ (0.01 M) with $Bu_4N^+ClO_4^-$ (0.1 M) in MeCN. The reference electrode was connected to the bulk of the sample solution by a salt bridge made up with a $Bu_4N^+ClO_4^-$ solution (0.1 M) in MeCN. Ferrocene, used as a reference compound (*vide infra*), was found to exhibit $E_{1/2}$+0.083 V against this reference electrode.[32] All the sample solutions were 1 mM in the cation and 0.1 M in $Bu_4N^+ClO_4^-$ as a supporting electrolyte in MeCN, and were deaired by bubbling with nitrogen for 10 min. The measurements were made at the scan rate of 0.1 V/s, and the voltammograms recorded on a Hitachi Model 057 X-Y recorder. Immediately after the measurements. ferrocene (0.2 mM) was added as an internal standard,[33] and the observed cathodic peak potential was corrected with reference to this standard.

The Reaction of Isocyanides with Halogens or *N*-Halosuccinimides and Alcohols

Hideyo YAMADA,† Yasuo WADA,† Shigeo TANIMOTO, and Masaya OKANO*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received December 28, 1981)

The reaction of aliphatic isocyanides with bromine or chlorine in primary alcohols, followed by hydrolysis, afforded the corresponding carbamates in moderate yields, together with various amounts of amines. Bromine was superior to chlorine as a halogen source for the formation of carbamates. unexpectedly, the addition of $HgCl_2$ resulted in a decrease in the carbamate yield. When *N*-halosuccinimides were used in the place of halogens, an additional formation of the succinimide-incorporated product was observed to some extent.

Previously we reported that the reactions of isocyanides with *t*-butyl hypochlorite and with wet *N*-bromo amides in chlorinated methanes in either the presence or absence of the $ZnCl_2$ catalyst, followed by treatment with water, gave *t*-butyl carbamates and acylureas respectively, although the yields were low.[1] In order to know whether or not the combined use of halogens and alcohols in the place of the alkyl hypohalite is feasible for the former reaction, and also to determine to what extent the formation of carbamates may compete in the latter reaction using alcohols as solvents, we have examined the reaction of isocyanides with halogens or *N*-halosuccinimides and alcohols. Taking into account the nucleophilic nature of isocyanides, the reaction was carried out with or without an acid catalyst. The present paper deals with these results.

$$R\text{–}N{\equiv}C + X_2(\text{or } X\text{–}Y) + R'OH \longrightarrow \left[R\text{–}N{=}C(X)(OR')\right] \xrightarrow{H_2O} RNHCOOR' \quad (1)$$

X=Br or Cl, Y=N(CO–CH$_2$)$_2$(CO–CH$_2$)$_2$

In this connection, the facile addition of chlorine or bromine to both aliphatic and aromatic isocyanides to afford the corresponding carbonimidoyl dihalides (isocyanide dihalides) is well-known, except for the case of unstable alkylcarbonimidoyl dibromides, but studies of the alcoholysis and hydrolysis of carbonimidoyl dihalides has been confined to the *N*-aryl compounds, which afford *N*-arylcarbamates and/or arylamines as final products under neutral or acidic conditions.[2,3]

Results and Discussion

The treatment of isocyanides with bromine or chlorine in various alcohols without a catalyst for several hours at room or a higher temperature, followed by a work-up procedure with water, gave the expected carbamates (**1**) in moderate yields, along with various amounts of amines, as is shown in Table 1. A controlled experiment indicated that the amines were formed by the hydrolysis of the unreacted imidoyl dihalides (**2**) during the work-up procedure and that iminocarobates [R–N=C(OR')$_2$], if they are formed, did not give amines at least under the given work-up conditions.

When an equimolar reaction of cyclohexyl isocyanide with bromine was carried out in a small quantity of methanol, a yellowish-orange solid separated out in a considerable amount at an early stage of the reaction, leaving nearly a half equivalent amount of the isocyanide in the solution. Further, when a methanol solution of this solid was allowed to stand for several hours at room temperature, the expected **1** (R=cyclo-C_6H_{11}, R'=Me) was produced in a good yield (see Experimental). Based on these facts the solid was tentatively presumed to be a 1 : 1 molecular complex of **2** (R=cyclo-C_6H_{11}, X=Br) and bromine. The use of chlorine in place of bromine did not cause any formation of such a complex, but the conversion of **2** (R=cyclo-C_6H_{11}, X=Cl) into **1** (R=cyclo-C_6H_{11}, R'=Me) with methanol was also confirmed by another experiment. We may thus conclude that **2** is the initial intermediate of this reaction.

$$R\text{–}N{\equiv}C + X_2 \rightleftharpoons \underset{\mathbf{2}}{\left[R\text{–}N{=}C(X)_2\right]}$$

X=Br or Cl **3**

$$\xrightarrow{\text{slow}} [R\text{–}N{=}\overset{+}{C}\text{–}X + X^-]$$

$$\xrightarrow[\text{fast}]{R'OH} \underset{\mathbf{4}}{\left[R\text{–}N{=}C(X)(OR')\right]} \xrightarrow{H_2O} \underset{\mathbf{1}}{RNHCOOR'} \quad (2)$$

Relating to the transformation of **2** to **4**, it has been reported that both neutral and acidic hydrolyses of **2**, where R=aryl and X=Cl, in aqueous dioxane proceeds by means of the S_N1 mechanism, based on an aryl-substituent effect on the rate (the rate decreases in this order: *p*-Me>H>*p*-Cl>*m*-Cl).[3] This mechanism involving the rate-determining heterolysis to afford the cation, **3**, can be safely adapted for the case of R=alkyl; thus, the yields of **4**, and hence those of **1**, may be expected to decrease in this order: R=tertiary> secondary>primary and R=alkyl>aryl. The obtained data agree with this expectation. Further, the fact is known that the relative reactivity of acyl halides, the structure of which is similar to **2**, decreases in this order: X=Br>Cl in alcoholysis with ethylene glycol[4] and in the a cylation of active aromatics.[5] A similar feature may be expected for the ionization of one C–X bond, since the effect of another X (being not ionized) may not be so important on the ground that only a slight difference in polar (both inductive and resonance) effect between Br and Cl is known. Thus, in the reaction with bromine, the better the yields of **1** compared with

the case of chlorine can be ascribed to the higher reactivity of **2** where X=Br, while the poorer yields of amine can be explained by the same reason.

The effect of the alcohol component on the yields of **1** was not so significant, except for one case. In the reaction with isopropyl alcohol, the considerable decrease in the yield of **1** may be due mostly to the decreased stability of the corresponding **4** (R=cyclo-C_6H_{11}, R'=*i*-Pr, X=Br). In connection with this, we previously observed a considerable formation of cyclohexyl isocyanate, which probably arose from the initially formed **4** (R=cyclo-C_6H_{11}, R'=*t*-Bu, X=Cl), in the reaction of cyclohexyl isocyanide with *t*-butyl hypochlorite.[1] Besides, in the hydrolysis of alkyl chloroformates (ClCOOR") where R"=secondary alkyls, such as *i*-Pr and cycloalkyls, their relatively sacile ionization by means of the S_N1 mechanism and the succeeding rapid decomposition leading to olefins and/or secondary alcohols have been cited, in contrast to the cases of R=primary alkyls.[6,7] Thus, a partial loss of **4** (R=cyclo-C_6H_{11}, R'=*i*-Pr, X=Br) by a limilar process is highly probable.

We also have to note the effect of a Lewis-acid catalyst on the reaction. When 10 mol% of $HgCl_2$ was added as a catalyst in the cyclohexyl isocyanide–bromine–methanol reaction, a 12% decrease in the yield of **1** (R=cyclo-C_6H_{11}, R'=Me) was observed. This result is somewhat surprising in view of our previous information that $HgCl_2$ is the most efficient catalyst for the formation of **1** from isocyanides and halogens in cyclic ethers.[9] Further, the addition of a larger amount of $HgCl_2$ resulted in the formation of another product, besides considerable decreases in the yields of both **1** and amine. That is, when 50 mol% of $HgCl_2$ was added, 18 and 23% drops in the yields of **1** and cyclohexylamine respectively were observed, while a white, solid product was formed in a considerable quantity. In this case, it was observed that the reaction mixture became homogeneous by the dissolution of $HgCl_2$ at an earlier stage, and that then a white solid separated out gradually. Here, the existence of an equilibrium (Eq. 3) may be presumed for the homogeneous system, because a marked solubility of $HgCl_2$ in alcohols and the existence of a similar equilibrium between $HgCl_2$ and HgCl(OH) in an aqueous $HgCl_2$ solution has been

$$HgCl_2 + MeOH \rightleftharpoons HgCl(OMe)\,HCl + HCl \quad (3)$$

known.[10] The same solid was also obtained by the reaction of **2** (R=cyclo-C_6H_{11}, X=Cl) with equimolar $HgCl_2$ in methanol. On the contrary, we previously observed that a similar treatment in tetrahydrofuran did not afford any product and that most of the **2** was recovered.[7] The above solid was soluble in dil. hydrochloric acid and was reprecipitated by adding aqueous potassium carbonate. This suggests the presence of a basic nitrogen other than the C=N group. The absence of this group was also confirmed by the IR spectrum. The result of the elemental analysis of the solid corresponded to that for $C_8H_{14}NCl_3Hg$. Based on these facts, it was supposed that the product was a 1 : 1 adduct of either **2** (R=cyclo-C_6H_{11}, X=Cl) and HgCl(OMe) or **4** (R=cyclo-C_6H_{11}, R'=Me, X=Cl) and $HgCl_2$ (see Experimental). Considering both the substantial decrease in the amine yield and the probably high reactivity of HgCl(OMe) compared with $HgCl_2$, the former structure, *i.e.*, $C_6H_{11}N(HgCl)CHCl_2(OMe)$, is highly probable. An analogous example which involves an electrophilic attack of $HgOAc^+$ on the methine N of aromatic aldehyde arylhydrazone has been reported in a recent article.[11]

Next, when *N*-bromo- and *N*-chlorosuccinimide (NBS and NCS respectively) were used as halogen sources, the yields of **1** were generally not so good as in the case of halogens, even when a large excess of alcohol was used. Besides, the formation of *N*-carbamoylsuccinamates (**7**), a succinimide-incorporated product,

TABLE 2. REACTION OF CYCLOHEXYL ISOCYANIDE WITH *N*-HALOSUCCINIMIDES AND ALCOHOLS

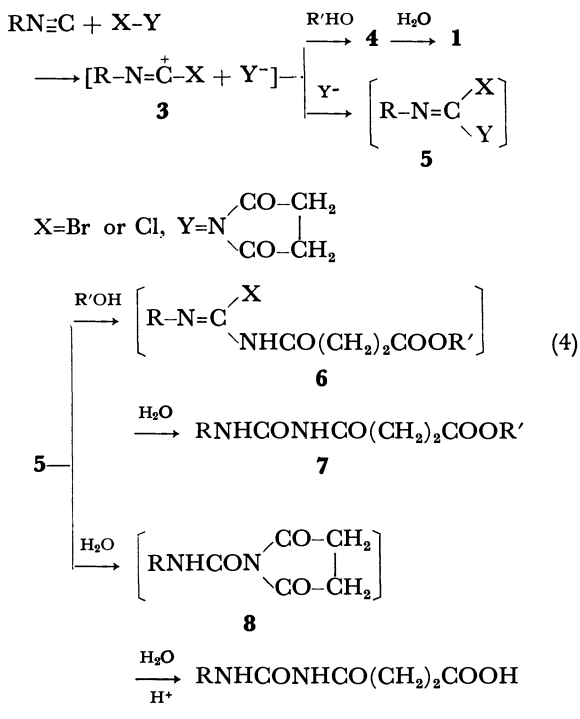
a) Isolated yield (based on isocyanide). b) Thirty ml of MeOH was used. c) Reaction conditions: near 5 °C, 1 h and 20—25 °C, 6 h. d) Other product, *N*-(cyclohexylcarbamoyl)succinimide (**8**), 18%.

in lower yields was observed. In the cyclohexylamine–NBS–methanol reaction, a change in the amount of methanol from 10 ml (*ca.* 10 equiv.) to 30 ml (*ca.* 30 equiv.) resulted in a slight increase (only 2%) in the yield of **1** and a considerable decrease in that of **7**. Some results are shown in Table 2. The reaction proceeded readily even in the dark. Further, it is generally accepted that *N*-halo imides act as electrophiles in polar media. Thus, a pathway *via* the haloimidoyl cation, **3**, formed by the electrophilic attack of X^+ (or the highly polarized halo imide), may be suggested (Eq. 4). Here, both **8** and **9** are products formed from **5** during the work-up procedure.



In the cyclohexyl isocyanide–NBS–isopropyl alcohol reaction, the marked decrease in the yield of the corresponding **1** is due to the lower stability of the corresponding **4** described above, and a steric hindrance in the ring-opening alcoholysis of the isocyanide–NBS adduct, **5**, resulted in a poor yield of the corresponding **7**. The reaction in benzyl alcohol appears to be somewhat complex, and none of products derived from **5** are found. The reason for this is not clear, but the competitive consumption of NBS for the oxidation of benzyl alcohol may be postulated, at least in part, since its facile oxidation with *N*-bromoacetamide is known.[12]

It is obvious from Table 2 that NBS is more effective than NCS as a halogen source for the formation of **1** from isocyanides, but no sufficient explanation of the observed different selectivities of the cation **3** (X=Br and Cl) can be offered at the present time, since the mechanistic details of the **3**-forming stage(s) and the relative stabilities of **3** are not yet available.

Experimental

The GLC analyses were carried out on a Shimadzu 5APTF apparatus, using EGSS-X(30%)-Chromosorb W(1 m) (with N_2 as the carrier gas). The ^1H NMR, IR, and mass spectra recorded on Varian A-60, Hitachi EPI-S2, and JEOL-01SG spectrometers respectively. The isocyanides (RNC) were prepared by the method of Ugi *et al.*[13] R=*n*-Bu, bp 119—120 °C (lit,[13] bp 116—117 °C/730 Torr); R=cyclo-C_6H_{11}, bp 69—71 °C/22 Torr (lit,[13] bp 56—58 °C/11 Torr); R=*t*-Bu, bp 91—92 °C (lit,[13] bp 91—92 °C/730 Torr); R=Ph, bp 60 °C/19 Torr (lit,[13] bp 50—51 °C/11 Torr). Commercial organic materials were used after distillation or recrystallization. Commercial inorganic materials were used without further purification.

Reaction of Isocyanides with Halogens and Alcohols. Some typical examples are shown below.

a): Into a stirred solution of bromine (3.20 g, 20 mmol) in methanol (16 ml), a solution of cyclohexyl isocyanide (2.18 g, 20 mmol) in methanol (4 ml) was added over a 0.5-h period, the temperature being maintained at near 5 °C by cooling with ice water. The mixture was stirred for an additional 0.5 h at that temperature and for 5 h at room temperature, and then added to a stirred suspension of $CaCO_3$ (4 g) in water. After the mixture had been stirred for 2 h at room temperature, the precipitated inorganic substance was filtered off and the filtrate was extracted with ether. Then the organic layer separated from the aqueous one washed with aqueous K_2CO_3 and water, and dried over anhydrous $MgSO_4$, and most of the solvent was evaporated. Distillation afforded crude methyl cyclohexylcarbamate (**1**, R=cyclo-C_6H_{11}, R'=Me) (2.40 g, 76% yield). The pure compound was obtained by redistillation; bp 82 °C/3 Torr, mp 72—74 °C (lit,[14] mp 75 °C); IR (KBr), 3380, 1530 (NH), 1690 (CO), and 1220, 1052 cm^{-1} (C–O–C); ^1H NMR ($CDCl_3$), δ=4.50 (1H, b), 3.50 (3H, s), 3.30 (1H, b), 2.1—0.9 (10H, m). The filtrate was made basic (pH *ca.* 10) with aqueous K_2CO_3 and steam-distilled. The aqueous distillate was made acidic with concd. HCl and dried up to afford cyclohexylamine hydrochloride (0.11 g, 4% yield) (mp 208—209 °C), which was identified by the mixed-melting-point method.

When the amount of methanol was reduced to a half volume (total 10 ml) in the above reaction, a yellowish-orange solid separated out from the reaction mixture during an early stage of the reaction, and finally the stirring became difficult. After

all the isocyanide had been added, the solid was filtered off, washed with a small amount of methanol, and dried. . The solid weighed 1.93 g. From the filtrate, the unreacted isocyanide (9 mmol) was recovered. Assuming that the above solid is a 1 : 1 complex of **3** (R=cyclo-C_6H_{11}, X=Br) and Br_2, the yield of the solid is estimated to be 82% (based on the isocyanide consumed). In addition, when the solid (0.43 g, 1 mmol) was dissolved in methanol (2 ml) and this solution was allowed to stand for 5 h at room temperature, the above carbamate (0.11 g, 70% yield) was obtained after the usual work-up procedure.

b): Chlorine gas (4.26 g, 60 mmol) was bubbled into a stirred solution of cyclohexyl isocyanide (2.18 g, 20 mmol) in methanol (20 ml) over a period of 1.5 h at near 5 °C. After being maintained for 0.5 h at the same temperature and for 7 h at room temperature with stirring, the mixture was poured into water. The resulting mixture was stirred for 2 h at room temperature and then worked-up as has been described in *a*). A GLC analysis of the evaporation residue, using bibenzyl as the internal standard, showed the formation of the expected carbamate (1.35 g, 43% yield). From the acidic aqueous layer, cyclohexylamine hydrochloride (0.92 g, 34%) was isolated.

When this reaction was carried out in the presence of $HgCl_2$ (2.72 g, 10 mmol), a light brown solid was separated out by pouring the reaction mixture into ice water. This solid was dissolved in dil. HCl, and the subsequent neutralization of this acidic solution afforded a white precipitate (3.41 g), which was soluble in acetic acid, but insoluble in ether, chloroform, and methanol. This solid gave analytical figures corresponging to a 1 : 1 adduct of either **2** (R=cyclo-C_6H_{11}, X=Cl) and HgCl(OMe) or **4** (R=cyclo-C_6H_{11}, R'=Me, X=Cl) and $HgCl_2$. Found: C, 20.77; H, 3.72; N, 3.88%. Calcd for $C_8H_{14}NC_{13}Hg$. C, 21.49; H, 3.16; N, 3.13%. The IR spectrum revealed the absence of any C=N bond.

The physical properties and analytical data of other pure **1** substances are as follows. cyclo-C_6H_{11}NHCOOR': R'=Et, bp 87 °C/3 Torr, mp 54—55 °C (lit,[15] bp 123 °C/11 Torr, mp 56 °C). R'=*n*-Pr, bp 96—98 °C/3 Torr, mp 39—40 °C (lit,[16] mp 40—41 °C). R'=*i*-Pr, bp 84—85 °C/3 Torr, mp 65—66 °C (lit,[17] mp 66.5—67 °C). R'=*n*-Bu, bp 110—112 °C/3 Torr, mp 50—52 °C (Found: C, 66.19; H, 10.59; N, 6.62%. Calcd for $C_{11}H_{21}NO_2$: C, 66.29; H, 10.62; N, 7.03%). ^{1}H NMR ($CDCl_3$) δ=4.40 (1H, b), 3.90 (2H, t, J=6.0 Hz), 3.35 (1H, b), 1.8—1.05 (4H, m), 0.9 (3H, t, J=6.0 Hz), 2.05—0.9 (10H, m). R'=CH_2Ph, mp 85—87 °C (from 50% aq. EtOH) (Found: C, 71.73; H, 8.32; N, 5.96%; M$^+$, 233 Calcd for $C_{14}H_{19}NO_2$: C, 72.07; H, 8.21; N, 6.00%; M, 233). ^{1}H NMR ($CDCl_3$) δ=7.05 (5H, s), 4.90 (2H, s), 4.40 (1H, b), 3.40 (1H, b), 2.1—0.8 (10H, m). RNHCOOMe: R=*n*-Bu, bp 96 °C/20 Torr (lit,[18] bp 92 °C/15 Torr). R=*t*-Bu, bp 64 °C/20 Torr (lit,[18] bp 63.3 °C/17 Torr). R=Ph, bp 125—126 °C/10 Torr, mp 44—46 °C (lit,[19] mp 47 °C).

Reaction of Isocyanides with N-*Halosuccinimides and Alcohols.* A typical example is given below. A solution of cyclohexyl isocyanide (2.18 g, 20 mmol) in methanol (4 ml) was stirred into a solution of NBS (3.56 g, 20 mmol) in methanol (6 ml) over a 0.5-h period at near 5 °C. After the mixture had been stirred for an additional 0.5 h at the same temperature and for 1 h at room temperature, the reaction mixture was poured into water and allowed to stand for 2 h at room temperature with stirring. The work-up procedure was the same as above. Distillation gave the expected carbamate (1.54 g, 49% yield), leaving a solid residue of crude methyl *N*-(cyclohexylcarbamoyl)succinamate (**7**, R=cyclo-C_6H_{11}, R'=Me) (1.13 g, 22% yield). The recrystallization of this residue from 50% aq EtOH afforded the pure compound; mp 95—96 °C (Found: C, 56.37; H, 8.09; N, 10.89%; M$^+$, 256. Calcd for $C_{12}H_{20}N_2O_4$: C, 56.24; H, 7.87; N, 10.93%; M, 256. IR (KBr) 3300, 3150, 1550 (NH), 1740 (ester CO), 1710 (urethane CO), 1685 (amide CO), 1220, 1175 cm^{-1} (C–O–C). ^{1}H NMR ($CDCl_3$) δ=9.70 (1H, s), 8.05 (1H, d, J=7.0 Hz), 3.60 (3H, s), 3.45 (1H, b), 2.70 (4H, s), 2.1—0.9 (10H, m). When the aqueous layer was allowed to stand for a few days, needles of crude *N*-(cyclohexylcarbamoyl)succinamic acid (**9**, R=cyclo-C_6H_{11}) (0.09 g, 2% yield) separated out. A pure compound was obtained by recrystallization; mp 170—173 °C (lit,[1] mp 162—164 °C).

The ^{1}H NMR ($CDCl_3$) data of other **7** and **8** substances are as follows. cyclo-C_6H_{11}NHCONHCO$(CH_2)_2$COOR': R'=Et, δ=9.70 (1H, s), 8.10 (1H, d, J=8.0 Hz), 4.05 (2H, q, J=7.0 Hz), 3.55 (1H, b), 2.60 (4H, s), 1.25 (3H, t, J=7.0 Hz), 2.1—0.9 (10H, m). R'=*n*-Pr, δ=9.80 (1H, s), 8.10 (1H, d, J=8.0 Hz), 3.90 (2H, t, J=6.0 Hz), 3.55 (1H, b), 2.60 (4H, s), 1.60 (2H, m, J=6.0 Hz), 0.90 (3H, t, J=6.0 Hz), 2.1—0.9 (10H, m). R'=*i*-Pr, δ=9.20 (1H, s), 8.05 (1H, d, J=7.8 Hz), 4.80 (1H, m, J=6.0 Hz), 3.55 (1H, b), 2.60 (4H, m), 1.20 (6H, d, J=6.0 Hz), 2.0—0.9 (10H, m). **8** (R=cyclo-C_6H_{11}); δ=7.0 (1H, s), 3.65 (1H, b), 2.70 (4H, s), 2.1—1.0 (10H, m).

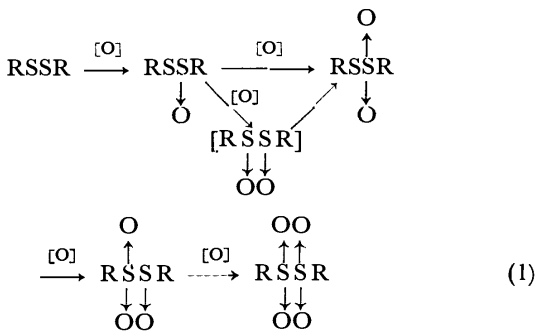
Oxidation of Unsymmetrical Disulfide and Thiosulfinic S-Esters with Peroxy Acids. Search for Formation of α-Disulfoxide as An Intermediate in the Electrophilic Oxidation of Thiosulfinic S-Ester[1]

Shigeru OAE,* Toshikazu TAKATA, and Yong Hae KIM[2]
Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305
(Received January 7, 1982)

Oxidation of an unsymmetrical disulfide, methyl phenyl disulfide, with peroxy acids takes place mainly at more electron-rich sulfur atom to form thiosulfinic *S*-ester at the first stage, while oxidation of unsymmetrical thiosulfinic *S*-ester with peroxy acids gives usually four thiosulfonic *S*-esters, together with sulfinic and sulfonic acids, further oxidation products. Oxidation of *S*-methyl benzenethiosulfinate **6** affords, as one of the products, *S*-phenyl methanethiosulfonate **11**, in which the original sulfinyl oxygen is brought into methanesulfonyl group. A small amount of *S*-phenyl benzenethiosulfonate **9** (or benzenesulfonic acid **15**) is obtained in the oxidation of *S*-phenyl methanethiosulfinate **7**. ^{18}O-Label of the starting thiosulfinic *S*-ester **6** was found to be incorporated to some extents into all four products, *i.e.* **8**—**11**, while a part of ^{18}O-label of *S*-phenyl methanethiosulfinate **7** was also observed in *S*-phenyl benzenethiosulfonate **9** and benzenesulfonic acid **15**, although most of ^{18}O-label of **7** was incorporated into *S*-phenyl methanethiosulfonate **11**. Thiosulfinic *S*-esters are stable and do not undergo disproportionation and ^{18}O-exchange under the conditions. These observations suggest the formation of α-disulfoxide as an intermediate in the oxidation of thiosulfinic *S*-ester to thiosulfonic *S*-ester, especially in the oxidation of **6**, although no peak corresponding to α-disulfoxide was observed directly in the NMR spectra taken during the oxidations of a few thiosulfinic *S*-esters with peroxy acids. Mechanism of the oxidation is discussed.

Oxidation of disulfide is considered to proceed *via* various stable intermediates as shown in Eq. 1. When the disulfide is unsymmetrical, oxidation with peroxy acids usually affords two regioisomeric thiosulfinic *S*-esters (thiolsulfinates) as the initial oxidation products, of which the ratio depends on the electron density of the sulfur atom, *i.e.* the more electron-rich sulfur atom is known to be oxidized predominantly.[3a,b] However, when the electron-rich sulfur atom is substituted by a bulky group, the ratio is known to be controlled by the steric effect instead of the electronic effect.[3]



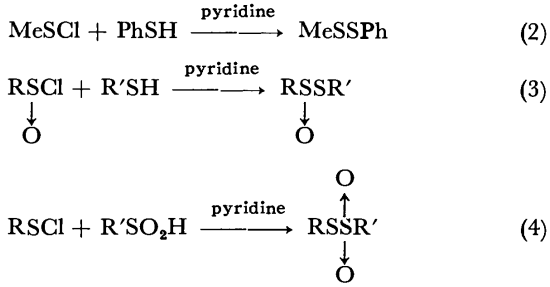
(1)

Mechanism of further oxidation of the thiolsulfinate has long been a matter of controversy, especially as to the question whether or not the oxidation of thiolsulfinate proceeds *via* forming "α-disulfoxide" as an intermediate. α-Disulfoxides have been long proposed as either stable products or intermediates in the oxidations of both disulfides[4,5] and thiolsulfinates.[5] Since the sulfenyl sulfur of thiolsulfinate is considered to be more prone to be oxidized than the sulfinyl sulfur, intermediary formation of α-disulfoxide has been believed in the oxidation of cystine.[5f-j] The fact that no one has succeeded in obtaining α-disulfoxide despite numerous attempts,[5k] by Barnard,[5b] Modena *et al.*,[5d,e] Kice and Chau,[5a] and others, is now explained in terms of the unusually small bond energy of "α-disulfoxide."[5a]

In order to understand the mechanism of oxidation of disulfide and thiolsulfinate with peroxy acids, the oxidations of unsymmetrical disulfide and thiolsulfinates have been investigated and evidence for formation of α-disulfoxide as an intermediate has now been obtained in the oxidation of thiolsulfinate. This paper describes our experimental observations and subsequent discussions.

Results

Methyl phenyl disulfide **3**, an unsymmetrical disulfide, was prepared by the reaction of methanesulfenyl chloride with thiophenol in the presence of pyridine (Eq. 2).[6] Unsymmetrical thiolsulfinates **6** and **7** were prepared by treating sulfinyl chloride with thiol (Eq. 3) according to the usual method.[7] In the same manner, authentic samples of thiosulfonic *S*-esters (thiolsulfonates) **9**, **10**, and **11** were synthesized by treating sulfenyl chloride with sulfinic acid in the presence of pyridine (Eq. 4).[7]



(2)

(3)

(4)

The disulfide and the thiolsulfinate thus prepared were oxidized with either H_2O_2 in AcOH or *m*-chloroperbenzoic acid (MCPBA) in CH_2Cl_2.

Product analysis was performed by using NMR, GLC, and HPLC. As shown in Fig. 1, fortunately all these compounds were able to be separated by HPLC. ^1H-

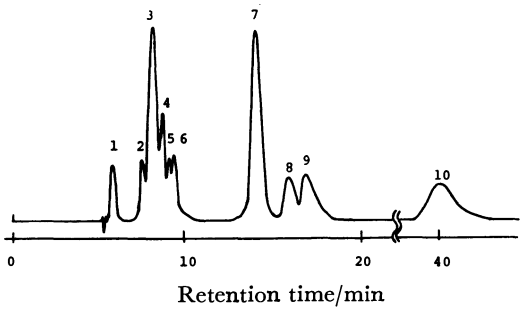

Fig. 1. High pressure liquid chromatography by Yanaco Model L-1030 at room temperature.
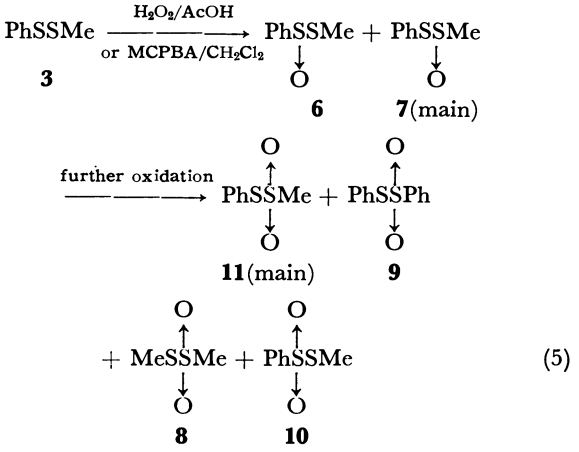
Column: Yanaco Gel 5510, carrier: MeOH, pressure: 125 kg/cm², flow rate: 16.1 ml/h.
Peak 1: $MeSS(O)_2Me$(**8**), 2: MeSSMe(**1**), 3: $PhSS(O)_2$-Me(**11**), 4: $PhS(O)_2SMe$(**10**), 5: PhSS(O)Me(**7**), 6: PhS(O)SMe(**6**), 7: $PhSS(O)_2Ph$(**9**), 8: PhSS(O)Ph-(**5**), 9: PhSSMe(**3**), 10: PhSSPh(**2**).
Peaks of $MeSO_2H$(**12**), $MeSO_3H$(**14**), $PhSO_2$(**13**), and $PhSO_3H$(**15**) appear earlier than that of peak of **8**, while peak of MeSS(O)Me(**4**) appears between peaks 1 and 2.

NMR chemical shifts of methyl groups of these compounds are listed in Table 1 together with the NMR data of the related compounds.

Oxidation of Disulfide **3**. When methyl phenyl disulfide **3** was treated with H_2O_2 in AcOH, *S*-phenyl methanethiosulfinate **7** was formed predominantly over *S*-methyl benzenethiosulfinate **6**, as shown in Figs. 2 and 3, which are drawn following the changes of NMR signals of methyl groups of **3** and the other products during the oxidation of **3** with 30% H_2O_2 in deuterated acetic acid (Eq. 5). When the oxidation of **3** was followed



by HPLC, the products, which could not be detected in GLC, were detected in NMR. Comparison of Figs. 2 and 3 reveals that the rate of disappearance of **3** is very sensitive to the change of reaction temperature. Since the oxidant used was substantially in excess over the disulfide **3**, the oxidation proceeded further. In the oxidation of the following step, the major product isolated was *S*-phenyl methanethiosulfonate **11**, accompanied with quite a small amount of *S*-methyl benzenethiosulfonate **10**, as shown in Figs. 2 and 3. Besides the products having original S–S linkage (*i.e.* **10** and **11**), formations of symmetrical thiolsulfinates, both *S*-methyl

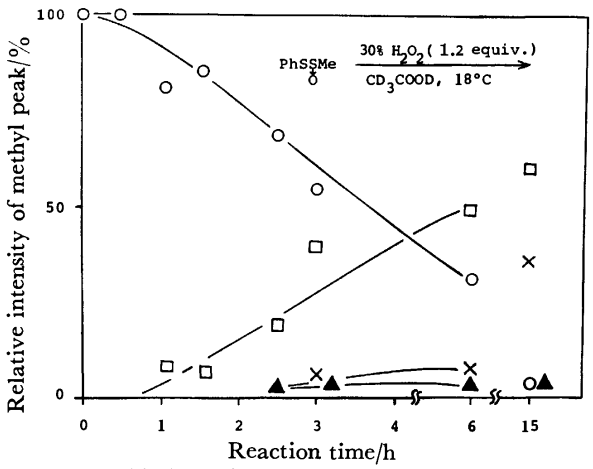

Fig. 4. Oxidation of PhSS(O)Me(**7**) with 30% H_2O_2 (1.2 equiv.) in acetic acid at 18 °C.
○: PhSS(O)Me (**7**), □: $PhSS(O)_2Me$ (**11**), ▲: $MeSS(O)_2Me$ (**8**), ×: $MeSO_3H$ (**14**).

methanethiosulfonate **8** and *S*-phenyl benzenethiosulfonate **9**, were also confirmed by GLC. Both methanesulfonic acid **14** and benzenesulfonic acid **15** were also detected by NMR and HPLC respectively, and found to be the end products upon oxidation with additional H_2O_2.

Oxidation products of **3** are listed in Table 2, which shows that nearly the same result is obtained in MCPBA oxidation of **3** (entry 4). In direct NMR study as shown in Figs. 2 and 3, the rate of the oxidation of **3** was comparable to those of **6** and **7**.[5d]

The methyl signal, corresponds to α-disulfoxide (PhS(O)S(O)Me, [A]) which may be formed by the oxidation of more electron-rich sulfenyl sulfur atom of thiolsulfinate (*e.g.* **6** or **7**), was not observed in the NMR spectra obtained during the oxidation of **3**.

On the other hand, in NMR study on the oxidation of symmetrical disulfide (dimethyl disulfide, **1**) with H_2O_2 in deuterated acetic acid, the products observed through NMR spectra were at first only *S*-methyl methanethiosulfinate **2**, then **8** and eventually **14**, in the final stage with no other methyl peak. The same transformation was observed in the oxidation of **1** to **8** with MCPBA in $CDCl_3$.

Oxidation of Thiosulfinic S-Esters **6** *and* **7**: In the oxidation of **7** with H_2O_2 in AcOH or *m*-chloroperbenzoic acid (MCPBA) in CH_2Cl_2, **11** was obtained as the major product, along with other thiolsulfonates such as **8** and **9**, and acids (**12**—**15**) (Table 3, Fig. 4) (Eq. 6). The

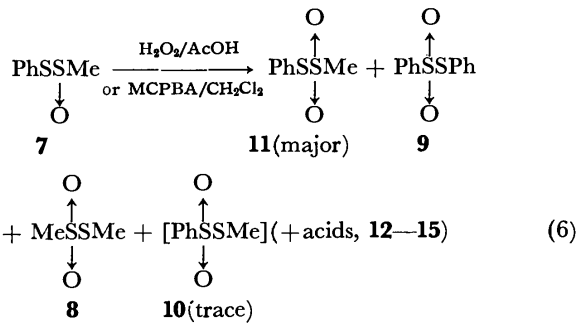
2	30% H_2O_2(1.4 equiv.) CD_3COOD	35	<1	0	8	21	12	21	28	7
3	30% H_2O_2(1.4 equiv.) CD_3COOD	18	<15	0	10	21	12	23	29	5
4	MCPBA(1.1 equiv.) CH_2Cl_2	20	20	≈0	14	14	25	34	0	—[c]
5	MCPBA(1.2 equiv.) CH_2Cl_2	0	4.5	6	7	7	27	32	10	—
6	MCPBA(1.2 equiv.) CH_2Cl_2	0	9	≈0	Trace	15	13	30	30[d]	—[c]

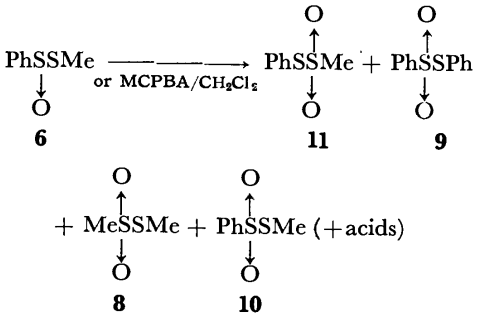
a) Yield was determined by NMR, GLC, and LLC. b) Isolated and purified yield. c) Unidentified methyl peak (14%) was observed. d) Containing $MeSO_2H$ (12%).

yield of **10** was only a trace or none in both oxidations. Although methyl signal of "α-disulfoxide" is expected to appear at 2.6—2.9 ppm (in CD_3COOD), no signal was observed in such a region during the oxidation of **7**. While the oxidation of **7** with 1.2 equiv. of 30% H_2O_2 was completed within 1 h at temperatures higher than 35 °C, the products obtained in the oxidation with ten equivalents of H_2O_2 in AcOH at 70 °C for 5 h, were only the sulfonic acids **14** and **15** as shown in Table 3 (entry 6).



(6)

Figures 5 and 6 show the changes of the NMR signals of the methyl groups of the starting thiolsulfinate and the products during the oxidation of **6** with H_2O_2 in CD_3COOD. One of the final products was also found to be **14**, though thiolsulfonates still remained. The oxidation of **6**, during which considerably complex methyl peaks were observed in NMR spectra, gave eventually two symmetrical and two unsymmetrical thiolsulfonates (**8**—**11**), along with further oxidation products (*i.e.* acids: **12**—**15**) (Eq. 7). This result is in contrast to that in the oxidation of **7**, and the oxidation of **6** gave nearly the same amounts of the four thiol-



(7)

sulfonates.† Yields of products in the oxidation of **6** are listed in Table 4. Inspection of the data in Table 4

† *S*-Methyl benzenethiosulfonate (**10**) was not confirmed at first[1] but then identified, since we found later that the ^{1}H-NMR chemical shift of **10** was unusually *higher* than that of **6**. (T. Takata, Y. H. Kim, S. Oae, and K. T. Suzuki, *Tetrahedron Lett.*, **1978**, 4303).

					9	0.181	80

a) ^{18}O Content of CO_2. b) 20.1% for $PhSO_3H$ (Eq. 11).

reveals that the oxidation of **6** with MCPBA in CH_2Cl_2 gives nearly the same result as that with H_2O_2 in AcO H No methyl peak corresponding to *α*-disulfoxide (at 2.6—2.9 ppm) was also observed in NMR spectra during the oxidation.

Since thiolsulfinate has been known to disproportionate readily to afford mainly a mixture of disulfides and thiolsulfonates,[8] **7** was heated in NMR tube in CD_3COOD–D_2O system at 35 °C for *ca.* 76 h and the disproportionation of **7** was found to proceed so slowly (Eq. 8, Fig. 7) that its contribution in product distribution can be neglected during the oxidation. Main products in the disproportionation of **7** were **11** and **3**, together with **8** and **2** as minor products. It is interesting to note that in the disproportionation of *S*-phenyl methanethiosulfinate **7** neither *S*-methyl not *S*-phenyl benzenethiosulfonates **9** and **10** was obtained.

$$\underset{\mathbf{7}}{\text{PhSSMe}(\text{O})} \xrightarrow[\text{CD}_3\text{COOD-D}_2\text{O, 35 °C, 76 h}]{\text{disproportionation}} \underset{\mathbf{11}(42\%)}{\text{PhSSMe}(\text{O})} + \underset{\mathbf{8}(14\%)}{\text{MeSSMe}(\text{O})} + \underset{\mathbf{3}(31\%)}{\text{PhSSMe}} + \underset{\mathbf{2}(13\%)}{\text{PhSSPh}} + \underset{\mathbf{1}(\approx 0\%)}{\text{MeSSMe}} \quad (8)$$

In the disproportionation of **6** in CD_3COOD–D_2O system at 35 °C, the same trend was observed as in the case of **7** (Eq, 9, Fig. 8). Namely, there was no product having methanesulfonyl group but only benzenesulfonyl derivatives **9** and **10** are the oxidation products. As shown in Fig. 6, Fig. 8 and Table 4, the disproportionation of **6** at 35 °C was much slower than the oxidation of **6** at the same temperature (≈1 h, Table 4, entry 2). Meanwhile, disproportionation was confirmed not to occur at 18—20 °C for 10—20 h.

^{18}O-Tracer Experiments. In order to examine the oxygen transfer of **6** or **7** to the products, **11** or **10**, ^{18}O-tracer experiments were carried out.

^{18}O-Labelled thiolsulfinate (**6** and **7**) were prepared (Eq. 3) by treating thiols with ^{18}O-labelled sulfinyl chlorides which were prepared according to the following reactions (Eq. 10), as described in detail in experimental section.

^{18}O-Labelled **6** and **7** were treated with an equimolar

Table 6. ^{18}O-Tracer experiments in the oxidation of PhS(O) SMe (**6**)

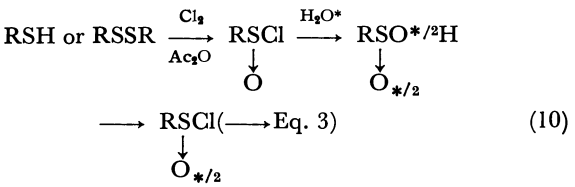
					9	0.311	110

amount of 30% H_2O_2 in AcOH or with an equivalent of MCPBA in CH_2Cl_2. After the disappearance of most



(10)

of **6** and **7** (monitored by TLC or HPLC), the reaction mixture was treated according to the usual work-up. The mixture of organic products was subjected directly to column chromatography (on silica gel, eluent : $CHCl_3$: EtOAc : hexane = 1 : 1 : 4) to separate into each product component. The products thus obtained and the starting materials were then subjected to the routine ^{18}O-analyses. The results are summarized in Tables 5 and 6.

While ^{18}O-labelled oxygen of **7** was found to be retained nearly completely in the major product **11**, the minor product **9** was also incorporated with a small amount of ^{18}O-label during the oxidation of **7** with 30% H_2O_2 in AcOH (Table 5, entry 1a). A similar trend was also seen in the ^{18}O distributions among the products formed in the oxidation of **7** with MCPBA (Table 5, entry 2). However, the ^{18}O incorporation of the minor product **9** was considerably larger in the oxidation with MCPBA than that with H_2O_2.

In another way to examine the possible oxygen transfer from methanesulfinyl group of **7** to the phenylthio moiety in the oxidation of **7** with H_2O_2, both acids **14** and **15** obtained under vigorous oxidation conditions (10 equiv. H_2O_2, 70 °C, 5 h: Table 5, entry 1b), were converted to the corresponding sulfonyl chlorides with $SOCl_2$ (eq. 11). Benzenesulfonyl chloride was purified by distillation and then treated with gaseous ammonia in dry ether to afford the sulfonamide. ^{18}O-Analysis of the sulfonamide showed that benzenesulfonic acid contained 20% of the original ^{18}O-label of **7**.

TABLE 7. ^{18}O INCORPORATION % OF RECOVERED THIOLSULFINATE **6** IN THE OXIDATION OF **6** WITH H_2O_2 IN AcOH

Entry	Excess ^{18}O content of **6** / %	Oxidation system	Reaction Temp/°C	Reaction Time/h	Excess ^{18}O content of **6** recovered/% (Incorporated %)
1	0.53	No H_2O_2/AcOH–H_2O	19	3	0.56 (106)
2	0.53	1.2 equiv. 30% H_2O_2/AcOH	20	0.5	0.52 (98)
3	0.53	1.2 equiv. 30% H_2O_2/AcOH	20	2.5	0.50 (94)

of **7** are summarized in Eq. 12. Meanwhile, as summarized in Table 6 and Eq. 13, all four thiolsulfonates obtained in the oxidation of **6** were incorporated with considerable amounts of the original ^{18}O-label of the ^{8}O-labelled **6**. A significant product **11**, obviously oxygen-transfered oxidation product formed from **6**, contained 58—70% of the original ^{18}O-label in the oxidation of **6** with H_2O_2/AcOH, while, 100% of the original ^{18}O-label was incoroporated into **11** in the oxidation with MCPBA/CH_2Cl_2. More than 100% of the original ^{18}O-label of **6** was incorporated into **9** and the incorporation was a little greater in the oxidation with MCPBA/CH_2Cl_2 than in that with H_2O_2/AcOH.

In both oxidations of ^{18}O-labelled **6** and **7**, the following observations may be noteworthy. i) The thiolsulfonate which was formed by apparent simple oxidation of sulfinyl sulfur, keeping the original S–S bond of the thiolsulfinate, *i.e.* **10**, in the case of **6** or **11** in the case of **7**, retained completely the original ^{18}O-label in the starting materials, regardless of the oxidation conditions. ii) In the thiolsulfonates in which their sulfonyl groups are originally the sulfenyl groups of the starting thiolsulfinates, *i.e.* **9** (or **15**) from **7** and **8** and **11** from **6**, ^{18}O-incorporations of **9** from **7** and **11** from **6** in the oxidation with H_2O_2/AcOH dramatically increased in the oxidation with MCPBA/CH_2Cl_2.

Control experiments show that **6** is sufficiently stable in AcOH–H_2O system in the absence of oxidant for 20 h at 20 °C and no ^{18}O-label was lost under the conditions (Table 7). The thiolsulfinate **6** recovered after partial oxidation of ^{18}O-labelled **6** with H_2O_2 in AcOH retained almost completely the original ^{18}O-label of **6** (Table 7).

Discussion

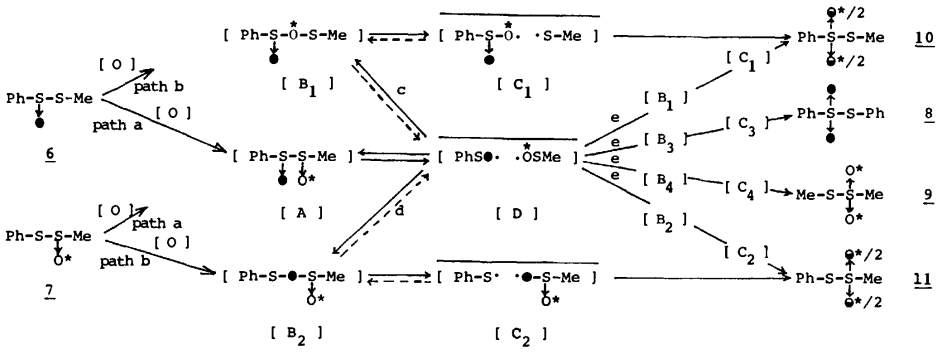
The orientation in the oxidation of unsymmetrical disulfide **3** with peroxy acid or hydrogen peroxide was in complete accordance with the reported results in which the more electron-rich sulfur atom of disulfide is mainly oxidized,[3] since the oxidation of **3** with such an electrophilic oxidant as MCPBA or H_2O_2/AcOH is expected to take place on the sulfur atom attached to methyl group of **3**. In direct NMR study no detectable intermediate was observed and therefore the oxidation must proceed *via* usual electrophilic attack of the oxidant at sulfur atom attached to methyl group. Further continuous oxidation gave a mixture of thiolsulfonates which are well-known products in the oxidation of unsymmetrical thiolsulfinate.[5c] The formation of sulfinic and sulfonic acids was confirmed to be derived by further oxidation of thiolsulfonate (RSO_2SR) in the control experiments.[9] The fact that there was no observable peak corresponding either to α-disulfoxide ([A]) or other possible intermediates in the NMR spectra during the oxidation, may not rule out the formation of [A] as an intermediate because of the expected instability of [A].[5a]

Since the total amount of **11** is comparable to that of **7** in the oxidation of **3**, **11** seems to be formed *via* direct oxidation of sulfinyl sulfur of **7** without breaking the S–S bond. However, only a trace amount of **10** was detected (*e.g.* Fig. 3) in further oxidation of **3**, during which a substantial amount of **6** was formed. This observation suggests that the oxidation of **6** does not always give **10**. Then a question remains if there is any direct oxidation of the electron-*poor* sulfinyl sulfur of thiolsulfinate to corresponding thiolsulfonate. This question may now be answered by scrutinizing the various data accumulated on the product analyses, NMR studies, and ^{18}O-tracer experiments in the oxidations of thiolsulfinates, **6** and **7**.

The control experiments on the disproportionation of both **6** and **7** reveal that the oxidations of **6** and **7** are not complicated by the disproportionation. Neither the oxygen migration nor S–O bond fission, was found to occur, although cleavage of S–S bond usually takes place. Even when the cleavage of S–S bond takes place in the disproportionations of both **6** and **7**, there is no thiolsulfonate in which the sulfenyl sulfur of original thiolsulfinate is oxidized among the products (Eqs. 8 and 9). No ^{18}O-exchange was observed with ^{18}O-labelled thiolsulfinate under the conditions (Table 7). Thus, no side reaction was observed in the oxidations.

Formation of a trace or none of **10** in the oxidation of **7** is in keeping with the result of the oxidation of **3** with excess H_2O_2. Formation of **11** as the main product and little or no formation of **10** in the oxidation of **7** indicate that the oxidation appears to take place mainly at sulfinyl sulfur atom of **7**, although the electron-rich sulfenyl sulfur atom is usually oxidized more readily than the electron-poor sulfinyl sulfur. However, the formation of small amounts of **9** (Eq. 6) from **7** may indicate the possible formation of α-disulfoxide as an intermediate. Especially, formation of a considerable amount of **11** from **6** strongly suggests the intermediary formation of α-disulfoxide. The ^{18}O-tracer results also support the formation of α-disulfoxide (Tables 5—7).

However, the difference in the product distributions between the two oxidations of **6** and **7** with both H_2O_2/AcOH and MCPBA/CH_2Cl_2, clearly indicates that the mechanism of the oxidation of **6** is somewhat different from that of **7**. Namely, the *S*-substituent, *i.e.* phenyl *vs.* methyl, may affects substantially the distribution of products. Therefore, the oxidations of **6** and **7** cannot be explained simply by assuming the formation of a common intermediate (*i.e.* α-disulfoxide, [A]). In



1. ●, O* ------ ^{18}O or ^{16}O(one of which is ^{18}O)

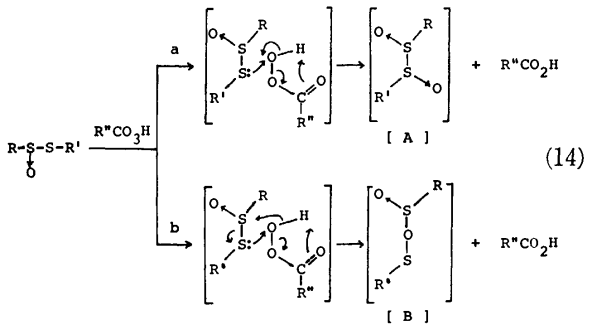
Chart



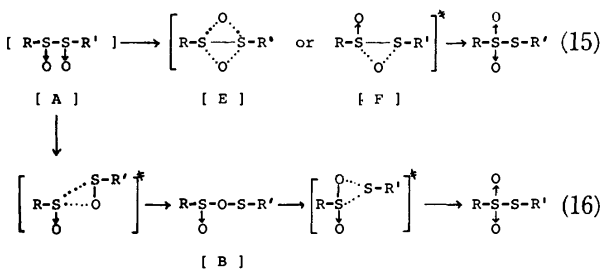
(14)

fact, the yields of the products formed by the cleavage of S–S bond (*i.e.* **8** and **9**) are greater in the oxidation of **6** than that of **7**. This may suggest that the oxidation of **6** proceeds *via* forming an intermediate of which S–S bond cleavage takes place more readily than that which would be formed in the oxidation of **7**.

Based on all these data on the product analyses and ^{18}O-tracer experiments, a few conceivable mechanistic pathways for the oxidation of unsymmetrical thiolsulfinates are illustrated in Chart. According to this chart, the initial oxidation step may involve the following two paths (Eq. 14). Path a involves the formation of α-disulfoxide *via* direct electrophilic attack of oxygen of oxidant, while path b involves the nucleophilic attack of oxygen on the sulfinyl sulfur to result in the oxygen insertion into S–S linkage to form *S*-sulfenyl sulfinate [B] which is considered to be more stable than α-disulfoxide. The oxidation of **6** may takes place mainly *via* path *a* to form α-disulfoxide, since sulfenyl sulfur of **6** is expected to be rather reactive to the electrophilic oxygen of peroxy acid. Actually, the rate of the oxidation of **6** seems to be slightly faster than that of **7**. This process is in good accordance with Kice's process on the product balance[5a] and explain the substituent effect in this oxidation.

In the mechanistic pathways, the ^{18}O-exchange process is neglected, since the homolytic cleavage of S–S bond of [A] thus formed would proceed very readily even at a low temperature to give a caged sulfinyl radical pair,[5a] which then recombines immediately to give *O*-sulfenyl sulfinate, [B_1] and [B_2]. The intermediate [B] must be also unstable and collapse to a caged radical pair [C] which recombines between both sulfur atoms to give thiolsulfonates. Since there is no energy barrier in the recombination of [C] to form stable S–S bond, the recombination of radical pair must be even faster than the diffusion of two radicals out of cage. In fact, no symmetrical disulfide was observed in our direct NMR studies, as reported earlier.[5a,e] On the other hand, since the recombination of two sulfinyl radicals [D] makes energy-rich S–O bond to form [B] (path c and d), some activation energy may be required for this process. Therefore, the diffusion of the radical pair may be faster than the recombination process. Sulfinyl radicals thus diffused may give finally two unsymmetrical thiolsulfonates (**10** and **11**) and two symmetrical thiolsulfonates (**8** and **9**), *via* [B] and [C].

The following concerted isomerization pathway cannot be completely excluded (Eqs. 15 and 16),



(15)

(16)

however, it is quite unlikely in view of a somewhat similar oxygen migration in the oxygen scrambling of aroyl alkyl carbonate.[10]

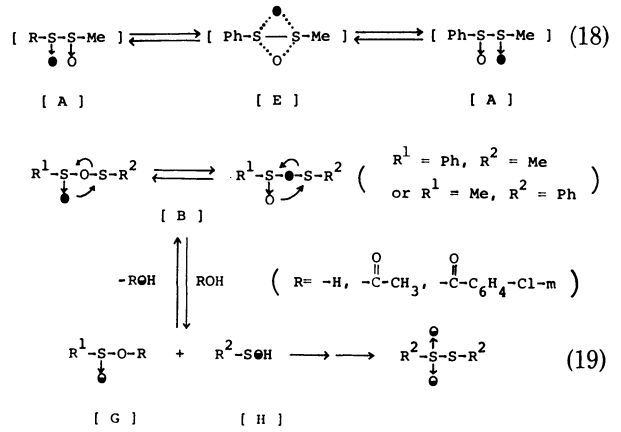
On the other hand, phenylthio group in **7** is a good leaving group and, the oxidation of **7** may proceed mainly *via* path b to form directly [B_2] which changes eventually to the thiolsulfonate **11** *via* [C_2]. This hypothesis may be supported by the following two observations: i) the formation of **11** predominates over those of other thiolsulfonates, *i.e.* **8**, **9**, and **10**, in the oxidation of **7**, ii) the ^{18}O-label of **11** retained nearly completely the original ^{18}O-label of **7** (Table 5).

There are following mechanistic pathways conceivable for the formation of ^{18}O-labelled **8** in the oxidation of ^{18}O-labelled **6** and that of ^{18}O-labelled **9** from ^{18}O-labelled **7**. i) If the homolytic fission-recombination

processes are all reversible as shown in Eq. 17, ^{18}O-scrambling should take place within the sulfinyl radical pair [D] and hence both **8** and **9** should be incorporated

$$[C_1] \rightleftharpoons [B_1] \rightleftharpoons [D] \rightleftharpoons [B_2] \rightleftharpoons [C_2] \quad (17)$$

with ^{18}O-label. ii) The following concerted oxygen scrambling in [A] as shown in Eq. 18 may be also



(18) (19)

conceivable. iii) The ionic path shown above is also conceivable in [B] (Eq. 19). According to this mechanistic path (iii), [B] may lose ^{18}O-label by the following reversible process, *i.e.* [B]⇄[G]+[H]. This ^{18}O-loss in [B] by this process must be greater in the oxidation system with H_2O_2/AcOH than in that with MCPBA/CH_2Cl_2. This hypothetical ^{18}O-exchange reaction between [B] and the medium can explain the fact that ^{18}O-incorporations in **11** obtained from **7** and both **9** and **11** from **6** (Eqs. 12 and 13) are greater in the oxidation with MCPBA/CH_2Cl_2 than those in the oxidation with H_2O_2/AcOH (Tables 5 and 6). Another explanation may be that the ionic ^{18}O-exchange process (Eqs. 18 and 19) is facilitated in less polar aprotic solvents while solvation of [B] and [C] does not promote the ^{18}O-exchange in a polar protic solvent.

Thus, all these hypotheses seem to be in accordance with all above experimental results in this study.

Our new selective oxidation of unsymmetrical thiolsulfinate with $NaIO_4$ gives quantitatively the corresponding unsymmetrical thiolsulfonate[11,12] by the selective oxidation of sulfinyl sulfur with IO_4^- ion without any cleavage of S–S linkage, in contrast to the oxidation with H_2O_2/AcOH or MCPBA/CH_2Cl_2 as mentioned in this paper.

Experimental

General. Melting points were taken on a Yanaco instrument and were uncorrected. NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 spectrometer. Infrared spectra were obtained on a Hitachi 215 spectrometer and are uncorrected. Mass spectra were recorded on a Hitachi RMU-6MG mass spectrometer. Gas and liquid chromatographs were obtained by Shimadzu GC-6A and Yanaco L-1030 instruments, respectively.

Both oxidizing agents, 30% H_2O_2 and MCPBA were obtained from Kanto Chemicals and Wako Pure Chemicals, respectively. Deuterated acetic acid and water were of Merck.

Disulfide. Both diphenyl and dimethyl disulfides are commercially available (Tokyo Kasei Kogyo Co.). Methyl phenyl disulfide was prepared by the following procedure, according to the reported method.[7]

Methanesulfenyl chloride (0.03 mol) which was prepared by the reaction of dimethyl disulfide with gaseous chlorine in CCl_4,[13] according to the known method and purified by distillation, was dissolved in dry CCl_4 (100 ml) which was cooled to *ca.* −10 °C. To the CCl_4 solution of MeSCl, dry pyridine (0.033 mol) was added and then thiophenol (0.03 mol) in dry CCl_4 (*ca.* 50 ml) was added dropwise under cooling below 0 °C. After the addition of thiophenol, cooling bath was removed and the heterogeneous reaction mixture was stirred until the solution reached room temperature. The resulting reaction mixture was transfered into a separatory funnel, and washed with water, 5% $NaHCO_3$ aq solution, and again water. Organic layer was dried over $CaCl_2$ and CCl_4 was evaporated. The residual crude oil was purified by distillation under reduced pressure (71—72 °C/2.5—3.0 Torr, lit,[6] 79—81 °C/1.0 Torr, 1 Torr=133.322 Pa). Complete purification of unsymmetrical disulfide is very difficult. Methyl phenyl disulfide purified by the distillation also contained a small amount of diphenyl disulfide (≈5%) which was detected by GLC. Yield was *ca.* 85%. NMR ($CDCl_3$, δ, TMS) 2.40 (s, 3H, CH_3).

Thiolsulfinate. S-*Methyl methanethiosulfinate (4)*[14] used as an authentic sample, was prepared by direct oxidation of dimethyl disulfide **1** with H_2O_2 in AcOH and purified by distillation (46—47 °C/1.5 Torr). *S*-Phenyl benzenethiosulfinate (**5**), *S*-methyl benzenethiosulfinate (**6**), and *S*-phenyl methanethiosulfinate (**7**) were also prepared by the condensation of the corresponding sulfniyl chlorides and thiols in the presence of pyridine at low temperature (<0 °C), according to the usual method.[7] Yields were 80—95%. Purification of **5** was carried out by recrystallization from hexane–chloroform while **6** and **7** were purified carefully by column chromatography (silica gel, eluent: hexane: $CHCl_3$: EtOAc= 4 : 1 : 1).

S-*Phenyl Benzenethiosulfinate* **5**: Mp 69—70 °C (lit,[15] 69—70 °C).

S-*Methyl Benzenethiosulfinate* **6**: Mp 26—28 °C; NMR ($CDCl_3$, δ, TMS) 2.53 (s, 3H, CH_3), 7.30 (m, 5H, Ar); IR (neat, cm^{-1}) 3050, 2975, 2900, 1570, 1470, 1095, and 1060 (S=O), (lit,[16] 1088 ($CHCl_3$)).

S-*Phenyl Methanethiosulfinate* **7**: Mp 15—20 °C; IR (neat, cm^{-1}) 3050, 2980, 2900, 1570, 1470, 1090 (S=O), (lit,[16] 1079 ($CHCl_3$)).

Thiolsulfonate. S-*Methyl Methanethiosulfonate* **8** was prepared by the oxidation of dimethyl disulfide with H_2O_2 in AcOH and purified by distillation (59—61 °C/2.5 Torr, (lit,[17] 56.5 °C/1.0 Torr)); NMR (Table 1); IR (neat, cm^{-1}) 2925, 1430, 1410, 1335, and 1305 (SO_2), 1140 (S=O), 960, 755.

Other thiolsulfonates, **9**, **10**, and **11**, were synthesized by condensation of sulfenyl chlorides with free sulfinic acids in the presence of pyridine, as reported.[7] Products were purified by column chromatography, in a yield of 80—95%. Purification of **11** was performed also by recrystallization from hexane.

S-*Phenyl Benzenethiosulfonate* **9**: Colorless crystals from EtOH; mp 44—45 °C (lit,[18] 44—45 °C).

S-*Methyl Benzenethiosulfonate* **10**: Colorless oil, IR (neat, cm^{-1}) 3050, 3000, 2920, 1580, 1475, 1445, 1330, and 1302 (SO_2), 1042 (S=O); NMR (Table 1). Found: C, 44.92; H, 4.18%. Calcd for $C_7H_8O_2S_2$: C, 44.66; H, 4.28%.

S-*Phenyl Methanethiosulfonate* **11**: Colorless crystals from hexane having mp 85—86.5 °C; IR (KBr, cm^{-1}) 3050, 3000, 2905, 1565, 1465, 1310 (SO_2), 1130 (S=O); NMR (Table 1). Found: C, 44.78; H, 4.25%. Calcd for $C_7H_8O_2S_2$: C, 44.66; H, 4.28%.

Sulfinic and Sulfonic Acids. Methanesulfinic acid **12** was prepared by hydrolysis of methanesulfinyl chloride.[19] Free benzenesulfinic acid **13** was obtained by acidification of commercial sodium benzenesulfinate (Tokyo Kasei Kogyo Co.) with concd HCl and purified by recrystallization from water. Both methanesulfonic (**14**) and benzenesulfonic acids (**15**) were obtained commercially.

^{18}O-Labelled Thiolsulfinates, 6 and 7. ^{18}O-Labelled **6** and **7** were prepared using both ^{18}O-labelled benzenesulfinyl and methanesulfinyl chlorides, respectively, as starting materials. ^{18}O-Labelled sulfinyl chlorides were derived from non-labelled sulfinyl chlorides and ^{18}O-enriched water (*ca.* 1.5%) (eqs. 10 and 3).

To a dry ether solution (30 ml) of benzenesulfinyl chloride (0.03 mol) which was purified by distillation (72 °C/2.0 Torr), was added dropwise ^{18}O-enriched water (0.05 mol) under ccoling with ice-water bath. The reaction was considerably exothermic, with evolution of HCl gas. Benzenesulfinic acid obtained after evaporation of ether and excess water under reduced pressure, was dissolved again in ether (*ca.* 20 ml). To the stirring ether solution of the free sulfinic acid, excess distilled thionyl chloride (0.067 mol) was added then a vigorous endothermic reaction took place evolving gaseous SO_2 and HCl. The residual oil after evaporation of ether and excess thionyl chloride was purified by distillation.

^{18}O-Labelled thiolsulfinate (**6**) was prepared by treating ^{18}O-labelled benzenesulfinyl chloride with methanethiol in the presence of pyridine,[7] as mentioned above. ^{18}O-Labelled methanesulfinyl chloride was also prepared by the same method. Since the crude thiolsulfinate decomposes readily, the crude thiolsulfinate thus obtained were immediately subjected to purification by careful column chromatography (on silica gel, eluent: hexane: $CHCl_3$: EtOAc=4 : 1 : 1), in order to avoid the fast catalytic decomposition by impurities. Purified ^{18}O-labelled thiolsulfinates (**6** and **7**) were fairly stable for several days under cooling below 0 °C and contained *ca.* 0.7—0.8 atom% of ^{18}O.

Oxidation of Disulfide and Thiolsulfinate. Oxidation with H_2O_2 in AcOH: Acetic acid (*ca.* 15 ml) dissolving *ca.* 1.0 g of the substrate (disulfide or thiolsulfinate) was cooled down to nearly freezing, by an ice-water bath. Thirty percent H_2O_2 (amount shown in Tables 2—7) was added slowly dropwise to the cooled and stirred solution of the substrate and the temperature of the solution rose up by the addition. After the whole addition of H_2O_2 the mixture was warmed up to a set temperature and stirred further at the same temperature until the starting material disappeared upon monitoring by TLC or HPLC. After the reaction, the reaction mixture was diluted with 50 ml of water, transfered into a separatory funnel and extracted three times with $CHCl_3$ (≈100 ml). The combined organic layer was washed with water, sat. $NaHCO_3$ aq solution, and then water again to remove AcOH and other acid species. $CHCl_3$ was evaporated and NMR spectrum of the residue was taken. The residue was, then, subjected to separation by column chromatography (silica gel, eluent: hexane: $CHCl_3$: EtOAc=4 : 1 : 1). First fraction gave *S*-phenyl benzenethiosulfonate, **9**, second one gave *S*-methyl benzenethiosulfonate **10**, then *S*-phenyl methanethiosulfonate **11** was eluted and the last fraction contained *S*-methyl methanethiosulfonate **8**. Thiolsulfinates, **5**, **6**, and **7** were eluted between **11** and **8**, while **4** appeared after **8**. **10** and **11** were separated completely by repeated column chromatography in which first fraction gave colorless solid **11** and the following fraction afforded colorless oil **10**. They were identified by comparing their NMR, IR, GLC, HPLC, and melting points with those of authentic samples prepared independently.

Meanwhile, the combined aqueous layer which was neutralized by sat. $NaHCO_3$ solution was concentrated by complete evaporation of water. Sulfinic and sulfonic acids (salts) were determined by NMR spectra in D_2O in which methyl signals of both sodium salts of **12** and **14** appeared in the range of 2.15—2.30 and 2.75—2.82 ppm, respectively, depending on the pH of the solution.

Oxidation with MCPBA in CH_2Cl_2: To a cooled (*ca.* 0 °C) solution of *ca.* 1.0 g of the substrate in CH_2Cl_2 (*ca.* 20 ml) was added powdered MCPBA (1.0—2.0 equiv., amount are shown in Tables 2—7) slowly. The reaction mixture was warmed and stirred at a set temperature until the starting material disappeared upon monitoring by TLC or HPLC. The reaction mixture was washed with 5% $NaHCO_3$ aq. solution and water after the reaction. Both the organic and aqueous layers were treated with the same procedures as described above.

Yields of the products which were determined in connection with the data of NMR, GLC, and HPLC, are shown in Tables 2—7.

Oxidation in NMR Sample Tube: An NMR spectrum of the substrate (0.4—0.5 mmol) was measured in CD_3COOD or $CDCl_3$ (430 μl). To the solution in NMR sample tube 30% H_2O_2 or powdered MCPBA (amount listed in Tables 2—7) was added at a set temperature and immediately MNR spectra of the resulting mixture were taken at a few time intervals. After the reaction completed, GC and HPLC of the reaction mixture were measured to determine the yields of the products.

^{18}O-Tracer Experiments: Products thus obtained and purified were well dried *in vacuo* with slightly heating. ^{18}O-Labelled *S*-methyl benzenethiosulfinate **6** recovered during the oxidation was purified by column chromatography (silica gel, eluent: hexane: $CHCl_3$: EtOAc=4 : 1 : 1). It was eluted as a colorless oil after **9**, **10**, and **11**.

^{18}O-Tracer analysis was carried out by the method developed by Rittenberg and Ponticorvo,[20] with a slight modification, using $Pb(OAc)_2$ to remove H_2S gas formed by the thermolysis of the sample.

Twenty mg of sample was pyrolyzed with 300 mg of purified $HgCl_2$ and $Hg(CN)_2$, respectively, in an evacuated, sealed Pyrex tube at *ca.* 500 °C for 12 h. Then the tube was broken in a vacuum line and CO_2 gas formed was purified by distillation and the mass peaks of *m/e* 44 and 46 which correspond to $C^{16}O_2$ and $C^{16}O^{18}O$, respectively, were recorded on a mass spectrometer.

Derivation of Benzenesulfonamide from Benzenesulfonic Acid in the Oxidation of ^{18}O-Labelled Thiolsulfinate 7 with H_2O_2/AcOH: The reaction mixture resulted by the complete oxidation of ^{18}O-labelled *S*-phenyl methanethiosulfinate **7** (437 mg) with ten equivalents of 30% H_2O_2 (2.65 g) in AcOH (9 ml) at 70 °C for 5 h, contained only both methane- and benzenesulfonic acids. To the reaction mixture a small amount of MnO_2 was added to decompose excess H_2O_2. After filtration, acetic acid and water were evaporated by heating. Into the residue containing two sulfonic acids, was added excess thionyl chloride (10 mmol). The resulting mixture, after evaporation under reduced pressure to remove excess thionyl chloride, was distilled to separate two fractions (bp 62 °C/21 Torr and 70 °C/1 Torr) which were methane- and benzenesulfonyl chlorides, respectively. Distilled benzenesulfonyl chloride was dissolved in dry ether and gaseous ammonia was introduced into the solution. The white solid of NH_4Cl was filtered. The solid residure after evaporation of ether was benzenesulfonamide (43 mg) which was purified by recrystallization from ether–ethyl acetate mixed solvent (30 : 1) and then subjected to the routine ^{18}O-analysis.

(Received January 28, 1982)

Molecular mechanics calculations were successfully carried out to evaluate relative stabilities of each conformation of germacrenes in their ground states and transition states. In the calculation of such a transition state model as shown in Scheme 1, the parameters for partial bonds were taken as mean values of those for a reactant and a product. Thus, the calculation results on each transition state model indicate that the elemenes are formed from the corresponding germacrenes through the most stable transition state (CC), regardless of the most stable conformers in ground state. Calculations were also carried out on ground and transition states of acoragermacrone and isoacoragermacrone, both of which have an α,β-unsaturated carbonyl system. The calculation results on each transition state model indicate that shyobunone (**5**) and epishyobunone (**6**) both are formed from acoragermacrone through the corresponding transition states [**5** from CC; **6** from C'C' and C'T] in relative ratio (**5**/**6**=87/13) which is in good agreement with that of the experimental result (**5**/**6**=84/16). In the case of isoacoragermacrone, molecular mechanics calculations indicate that the preisocalamendiol-type transition state model is more favorable than the models corresponding to the Cope rearrangement products.

Conformation of ten-membered ring sesquiterpenes has been studied extensively, in connection with biosyntheses of many other types of sesquiterpene. Frequently, the ground state conformation of ten-membered ring sesquiterpenes was discussed in relation to the structure of their reaction products,[1] while it was also pointed out that the crown-like transition state is most favorable and determines the configuration of products.[2]

From the pioneering work by Hammond, a number of theoretical consideration to deduce the transition state structure have been made.[3] Moreover recently, semi-empirical[4] and non-empirical[5] molecular orbital methods have also been used to predict the transition states and reaction processes. At present, however, these theoretical methods can be applied to relatively small molecules and simple reactions.

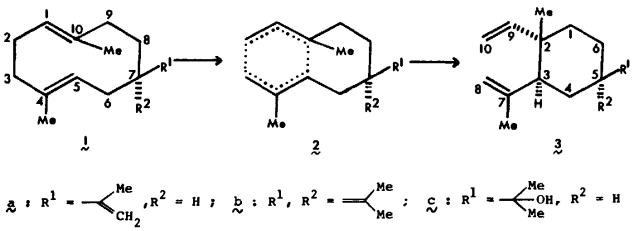
On the other hand, the frontier orbitals method[6] and the Woodward-Hoffmann rule,[7] both are extremely convenient and effective for deducing the structure of reaction product, but these methods are inefficient if the reaction conformer differs from the most stable conformer in the ground state.

The molecular mechanics calculations can be carried out easily and inexpensively, even on relatively large organic molecules, therefore, this calculation method has been widely used. Essentially, however, this method can only be used to such a molecule which consists of atomic groups with experimentally determined parameters. On this condition, there have been made some efforts to apply the molecular mechanics method on treatment of the transition states of oxidation reactions.[8] In the present paper, independently of these attempts, we wish to describe a successful application of the molecular mechanics calculations to a transition state model in thermal reactions of ten-membered ring sesquiterpenes. In this calculation method the transition state model was represented by a plausible structure with partial bonds, the parameters for which were taken as mean values of those for a reactant and a product.

Method of Calculation

Inspection of molecular models shows that each plane of the endocyclic double bond must be placed approximately perpendicular to the average plane of the ten-membered ring. Consequently, several stable conformers are possible for individual sesquiterpene. Steric energies of these conformers in ground state were calculated by means of the program COORD[9] with bond lengths, bond angles, and torsional angles obtainable from Dreiding molecular models, and then iterative calculations were made to minimize the steric energy of each conformer by means of the program MMI and MMPI.[10] Relative populations of these conformers at given temperature were calculated with energy values so far obtained, assuming they are in an equilibrium.

Transition State Model of Cope Rearrangement. In the reaction process of Cope rearrangement from germacrenes (**1**) to elemenes (**3**), we have proposed such a transition state model (**2**)[11] as shown in Scheme 1, and have applied molecular mechanics calculations to this model.[12]



Scheme 1. Thermal isomerizations of germacrenes.

Several modifications were required for application of program MMI to such a transition state model. Thus, in the energy minimize calculations of the transition state model (**2**), iterative calculations were made starting from the co-ordinate set corresponding to the each stable conformer in ground state, except for the co-ordinates of C_{10}. The position of C_{10} in **2** was located

TABLE 1. STERIC ENERGY AND RELATIVE POPULATION OF GERMACRENES IN EACH GROUND AND TRANSITION STATE

		Ground state		Transition state	
		Steric energy kcal mol^{-1}	Relative population % at 25 °C	Steric energy kcal mol^{-1}	Relative population[a] %
Germacrene-A	CC	22.91	62.3	33.47	at 25 °C 100.0
	TC	23.24	35.7	40.61	0.0
	T'C	25.09	1.6	39.36	0.0
	C'T	25.97	0.4	38.31	0.0
Germacrene-B	CC	23.13	34.7	35.85	at 120 °C 86.3
	CT	22.91	50.5	37.29	13.6
	TT'	23.94	8.8	41.57	0.1
	TC'	24.17	6.0	41.66	0.1
Hedycaryol	CC	25.57	28.8	37.56	at 400 °C 95.8
	C'T	26.45	6.5	42.38	2.6
	TC	25.11	62.0	44.44	0.6
	T'C	26.98	2.6	43.64	1.0

a) Experimentally, each thermal isomerization has been carried out at thecited temperature.

on a line between C_5 and C_{10} in **1**, assuming that the partially formed bond length ($C_5 \cdots C_{10}$) in **2** is equal to a mean value between the distance from C_5 to C_{10} in **1** and bond length $C_2—C_3$ in the product (**3**). The energy minimize calculations were executed fixing the positions of C_5 and C_{10} at the given positions and releasing all other part of molecule.

The parameters for the unusual bonds, which are characteristic of the transition state model (**2**) and not included originally in program MMI, were calculated by means of a simple arithmetical procedure. Accordingly, the parameters for the partial bonds were regarded as mean values of those of initial and final states: *e.g.* parameters for C···C in **2** were assumed to be mean values of C=C and C–C. Similarly, parameters for C···C were regarded as the half of C–C. The partially splitting bond length of $C_2 \cdots C_3$ was assumed to be 3.36 Å, which roughly corresponds to a mean value of the bond length C_2–C_3 in germacrenes and the average intramolecular distance between C_8 and C_{10} in elemenes.[13]

We supposed, furthermore, the steric energy calculated for the transition state model, corresponds or is at least proportional to the height of the energy barrier of the Cope rearrangement, and the probability of the reaction can be substituted by the relative population of the transition state models in each conformation, under assumption of the Boltzmann's distribution.

Transition State Model for Preisocalamendiol-type Rearrangement. On thermal rearrangement of preisocalamendiol, such a transition state model (**A**) as shown in Scheme 4 was proposed,[14] and application of molecular mechanics calculations to this type of transition state model revealed to be in good agreement with the experimental results.[15] The co-ordinates of C_1 in **A** was calculated according to the same manner as that of the Cope rearrangement-type transition state. Each position of the remaining atoms except for C_1 and C_6 varied in the course of energy minimization.

Of the plausible conformers which arise from calculations of the ground state, some of them can adopt such a transition state as **A**, in which the carbonyl group and the methyl group on vinylic carbon C_{10} both are located on the same side of a plane of the ten-membered ring.

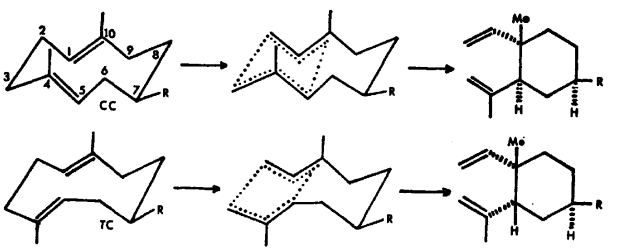
The partial bond lengths of O···H and C_{15}···H both are assumed approximately to be 1.7 Å, on the basis of the distance between O and C_{15} in the initial and final states of the reaction, as well as of an assumption in which this proton is nearly placed at the equidistant point from both O and C_{15} in the transition state model.

Parameters for the partial bonds were estimated according to the same procedure as described above.

Results and Discussion

Germacrene-A (1a). Germacrene-A (**1a**), a ten-membered ring sesquiterpene isolated from a sea fan, is an unstable compound and spontaneously converted into the corresponding elemene (**3a**),[16] as shown in Scheme 1. Molecular mechanics calculations on the four conformers of **1a** were carried out to deduce the main conformations with energy minima and their results were summarized in Table 1.

Further calculations were also made on the transition state models corresponding to the conformers in each ground state, as shown in Scheme 2. The resulting



Scheme 2. Two possible isomerization of germacrenes.

structures of CC and TC in their transition states are shown in Fig. 1 and their steric energies and relative populations are also summarized in Table 1.

From these data, it is evident that the most stable conformation of **1a** in a ground state is directly related to the corresponding elemene (**3a**) through the most stable transition state CC.

Germacrene-B (1b). Molecular mechanics calculations were carried out on germacrene-B (**1b**) which

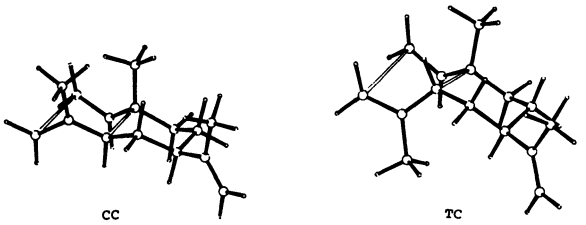


Fig. 1. Calculated minimum energy structures of two conformations of germacrene-A (**1a**) in transition states. The hollow bonds depict the partial bonds $C_5 \cdots C_{10}$ and $C_2 \cdots C_3$.[17]

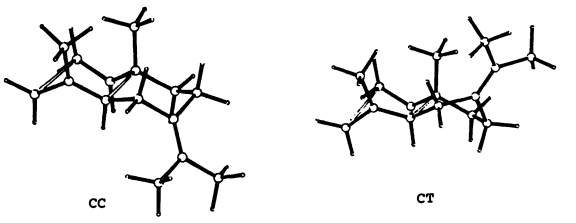

Fig. 2. Calculated minimum energy structures of two stable conformations of germacrene-B (**1b**) in transition states.

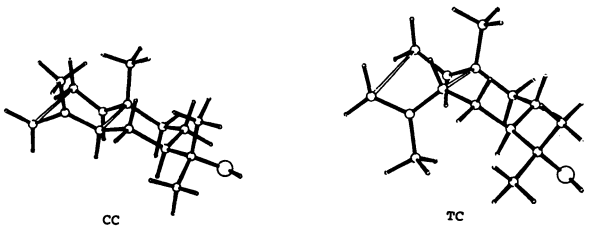

Fig. 3. Calculated minimum energy structures of two conformations of hedycaryol (**1c**) in transition states.

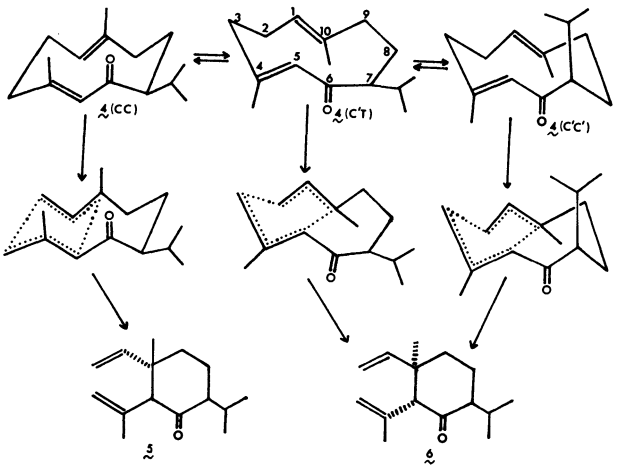
was also known to be thermally converted into the corresponding elemene (**3b**),[2b] indicating that the conformation CT is most stable,[18] although an X-ray crystallographic analysis revealed that a 1 : 1 silver nitrate adduct of **1b** adopts the conformation CC in a crystal state.[19] Of the two transition state models CC and CT (see Fig. 2), it is noteworthy that the former is more stable than CT,[20] as shown in Table 1. However, the same elemene must be derived from both CC and CT.

Hedycaryol (1c). In the case of hedycaryol (**1c**), its molecular mechanics calculations revealed that the favorable conformation in a ground state does not correspond to the structure of elemene (**3c**).[21] Therefore, we also applied the molecular mechanics calculations to such transition state models as shown in Scheme 2. The resulting structures of CC and TC in their transition states are shown in Fig. 3 and their steric energies and relative populations are also shown in Table 1. The conformation CC in the ground state is less stable than another conformation TC by 0.46 kcal/mol.[21] In their transition states, however, the conformation CC is more stable than the latter TC by 6.9 kcal/mol.

Acoragermacrone (4). Acoragermacrone (**4**) and isoacoragermacrone (**7**) both have an α,β-unsaturated carbonyl group. From a biogenetic point of view, acoragermacrone (**4**), an attractant of fruit-fly species,[22] is regarded as an important precursor of many sesquiterpenes which have been isolated from the plant *Acorus calamus* L.[11,23] In fact, Cope rearrangement of **4** affords shyobunone (**5**) and epishyobunone (**6**), both of which co-occur in the same plant, as shown in Scheme 3.[11,23]

Molecular mechanics calculations on the plausible conformers of **4** were carried out using program MMPI to deduce the main conformations with energy minima



Scheme 3. Thermal isomerization of acoragermacrone (**4**).

Table 2. Relative population of each conformation of **4** in both ground and transition states

Conformer	Ground state		Transition state		Product
	Steric energy[a] / kcal mol^{-1}	Relative population / % at 25 °C	Steric energy / kcal mol^{-1}	Relative population / % at 110 °C	
CC	25.17(−39.22)	80.8	36.40	87.0	Shyobunone (**5**)
C'C'	26.11(−38.29)	16.6	38.14	10.4

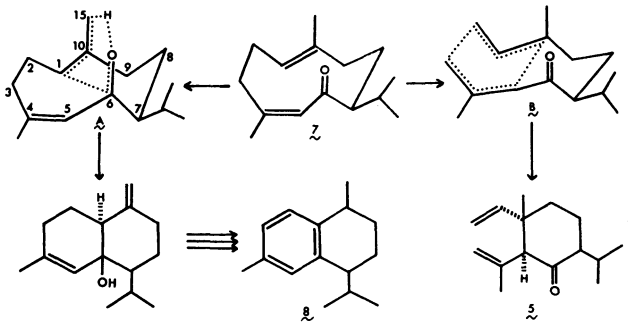

Scheme 4. Thermal isomerization of isoacoragermacrone (**7**).

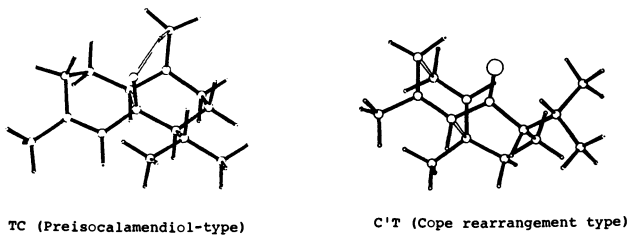

Fig. 5. Calculated minimum energy structures of most stable conformers in each different transition state model of **7**.

and their results were summarized in Table 2. Further calculations were also made on the transition state models corresponding to the conformers in each ground state (see Table 2). Thus, of seven transition state models, the most stable one is CC (see Fig. 4), from which shyobunone (**5**) must be produced. On the other hand, it is noted that epishyobunone (**6**) can be formed mainly from C'C' (see Fig. 4) and slightly from C'T, as seen in Table 2. Furthermore, the relative ratio (**5**/**6**=87/13) is in good agreement with that of the experimental result (**5**/**6**=84/16).

Isoacoragermacrone (7). We further applied molecular mechanics calculations to the possible conformers of isoacoragermacrone (**7**), in each ground state, and these results were summarized in Table 3. As expected from the base-catalyzed reactions of **7**,[11] clearly, isoacoragermacrone (**7**) is more stable than acoragermacrone (**4**) (see Tables 2 and 3). In the case of **7**, furthermore, two possible transition state models were considered as follows.

One of them is a presiocalamendiol-type transition state model (**A**)[15] leading to the formation of cadinene (**8**), as shown in Scheme 4. The remaining one is such a model as shown in Scheme 3, leading to the formation of Cope rearrangement products (see Scheme 4). Thus, molecular mechanics calculations were made on these two different models, and their results were summarized in Table 3. In addition, the most stable conformers in each different transition state model are shown in Fig. 5. As judged from these calculation data, clearly, the preisocalamendiol-type transition state model is more favorable than the models corresponding to each Cope rearrangement product.[24] This is compatible with the experimental results of thermal reaction of isoacoragermacrone (**7**).[25]

Conclusion

Although, germacrenes having an (*E*,*E*)-1,5-cyclodecadiene system are known to prefer the crossed conformation,[1a,2c,26] it has been proved that the stability of this system is affected by the substituent at C_7. Moreover, all sesquiterpenes calculated in this report exist in more than two conformers.[1a,21,27]

In the case of Cope rearrangement, however, the elemenes are formed from the corresponding germacrenes through the most stable transition state, regardless of the stable conformers in each ground state.[28] Moreover, the most favorable transition state of (*E*,*E*)-cyclodecadiene system is always CC, as pointed out before.[2] When the 1,5-cyclodecadiene system has carbonyl group at C_6 and one of the double bonds is *Z*-type or exocyclic,[15] the preisocalamendiol-type transition state is preferred rather than the Cope rearrangement type one. But, in the case of (*E*,*E*)-1,5-cyclodecadiene, large strain energy to form the $C_1 \cdots C_6$ partial bond prevents the preisocalamendiol-type transition state, resulting mainly in the formation of Cope rearrangement products.

Finally, our procedure, to which the ordinarily used programs are applied taking modified parameters

calculated by means of simple arithmetic way for partial bonds, has been proved to be quite useful in order to estimate the stereochemistry and the reaction product's ratio in thermal reactions of germacrenes and germacrones.

The authors wish to thank Professor N. L. Allinger (University of Georgia) and Professor E. Osawa (Hokkaido University) for their kind permission to use their MMI/MMPI programs. They are also indebted to Professor K. Sasaki (Nagoya University) for his helpful discussion. The molecular mechanics calculations were carried out using a FACOM 230-75 computer at Nagoya University Computation Center.

13) For a few conformers of acoragermacrone (**4**), a series of calculations were made changing the $C_2 \cdots C_3$ partial bond length, namely 2.2, 2.5, 2.7, and 3.36 Å in order. Although the length of 2.5 Å afforded the smallest strain energy value for each conformer, 3.36 Å was chosen, because this length gave best fit to experimental product's ratio. Therefore, it can be thought that the bond length of $C_2 \cdots C_3$ has some ambiguity.

24) Calculations for preisocalamendiol-type transition state model of acoragermacrone (**4**), revealed that the heat of formation of the lowest energy transition state is about 15 kcal/mol higher than corresponding one of Cope rearrangement. In fact, thermal reaction of accoragermarone (**4**) afforded exclusively the Cope rearrangement product, as shown in Table 2.

28) The energy barrier of the interchange between the conformational isomers in the ground state is much lower than the activation energy of the rearrangement. Therefore, it can be thought that the relative stabilities of conformers in the ground state are not so important for the consideration of the subsequent reaction process.

The Synthesis of Racemic Fomannoxin, Anodendroic Acid, and 5-Acetyl-2-[1-(hydroxymethyl)vinyl]-2,3-dihydrobenzofuran

Seiji YAMAGUCHI, Seizo KONDO, Keiko SHIMOKAWA, Osamu INOUE, Michiko SANNOMIYA, and Yoshiyuki KAWASE*

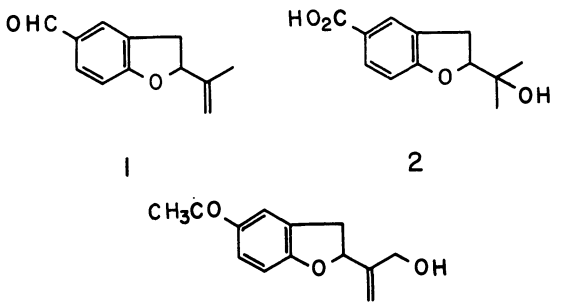
(Received February 4, 1982)

2-Isopropenyl-2,3-dihydrobenzofuran was effectively prepared by two new methods. Fomannoxin and 5-acetyl-2-[1-(hydroxymethyl)vinyl]-2,3-dihydrobenzofuran were synthesized from 2-isopropenyl-2,3-dihydrobenzofuran, while anodendroic acid was synthesized from 2-(1-hydroxy-1-methylethyl)-2,3-dihydrobenzofuran.

Three optically active 2,3-dihydrobenzofuran derivatives, fomannoxin (**1**),[1] anodendroic acid (**2**),[2] and (−)-5-acetyl-2-[1-(hydroxymethyl)vinyl]-2,3-dihydrobenzofuran (**3**),[3] have been isolated from natural sources. We have already reported the synthesis of these three compounds in two short communications.[4,5] Now, we wish to report the details and some added data.



1 2 3

Chart 1.

For the synthesis of **1** and **3**, an effective method of preparing 2-isopropenyl-2,3-dihydrobenzofuran (**7**) is required. In 1963, DeGraw *et al.* reported the preparation of **7**.[6] They prepared **7** by two methods, the Wittig reaction of 2-acetyl-2,3-dihydrobenzofuran (**4**) and the dehydration of 2-(1-hydroxy-1-methylethyl)-2,3-dihydrobenzofuran (**5**). However, the dehydration of **5** with phosphoryl chloride–pyridine gave a mixture of **7** and 2-isopropylbenzofuran, the components of which were difficult to separate. Also, the Wittig reaction of **4** gave only a 6% yield. We studied other dehydration methods. **7** was obtained in a 49% yield by refluxing in phenyl isocyanate for 16 h. In this dehydration reaction, longer refluxing caused a isomerization to 2-isopropylbenzofuran; 2-isopropylbenzofuran was only obtained after refluxing for 60 h, while a mixture of **7** and 2-isopropylbenzofuran was obtained after 22 h. In 1958, Nickl reported that a 2-isopropenyl-2,3-dihydrobenzofuran derivative was obtained from 2,4,6-trihydroxyacetophenone and 1,4-dibromo-2-methyl-2-butene.[7] Now, we have applied this reaction to phenol, thus obtaining **7** in one step in a 43% yield.

Hirotani *et al.* isolated (+)-2-isopropenyl-2,3-dihydrobenzofuran-5-carbaldehyde from *Fomes annosus*; they named it fomannoxin.[1] Fomannoxin had a structure very similar to that of tremetone (**16**), but it showed the opposite optical rotation and the opposite absolute

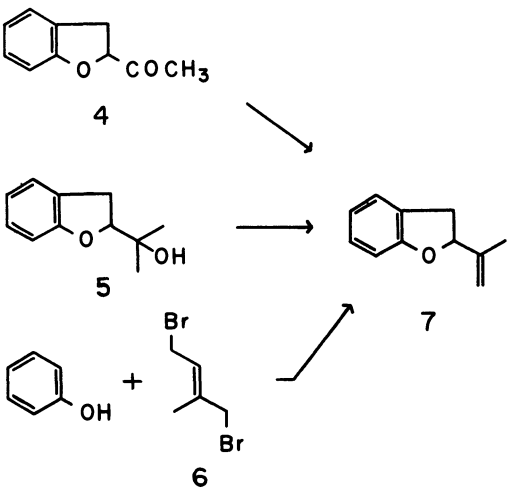


Chart 2.

configuration. This shows the existence of different biosynthetic cyclizations in different families of plants.[8] First, when Nickl's method was applied to *p*-hydroxybenzaldehyde, fomannoxin was not obtained. Next, it was used in an attempt to convert 5-bromo- and 5-iodo-2-isopropenyl-2,3-dihydrobenzofuran (**8a**, **b**), obtained from *p*-bromo- and *p*-iodophenol by Nickl's method, to **1** or 2-isopropenyl-2,3-dihydrobenzofuran-5-carboxylic acid (**13**) through the corresponding Grignard reagents. However, these attempts were all unsuccessful because of the inactivity of **8a** and **8b** to magnesium metal. Then, we tried to formylate **7** to **1**; the formylation of **7** with *N*-methylformanilide–phosphoryl chloride gave the desired aldehyde (**1**) in a 41% yield. The IR and ^{1}H-NMR spectra were identical with those of natural fomannoxin.[1]

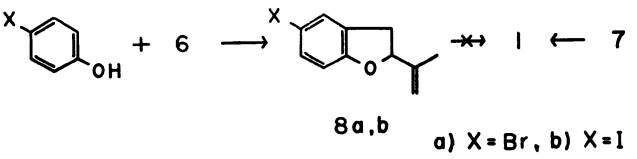

Chart 3.

Shima *et al.* isolated (−)-2-(1-hydroxy-1-methylethyl)-2,3-dihydrobenzofuran-5-carboxylic acid (**2**) from *Anodendron affine* and named it anodendroic acid.[2] The Vilsmeyer formylation of the acetate (**9**) with *N*-methylformanilide–phosphoryl chloride gave a mixture

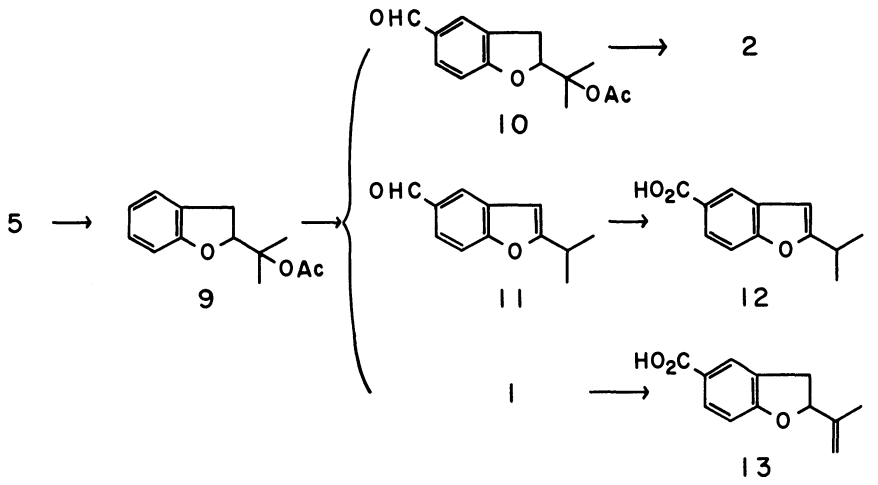

Chart 4.

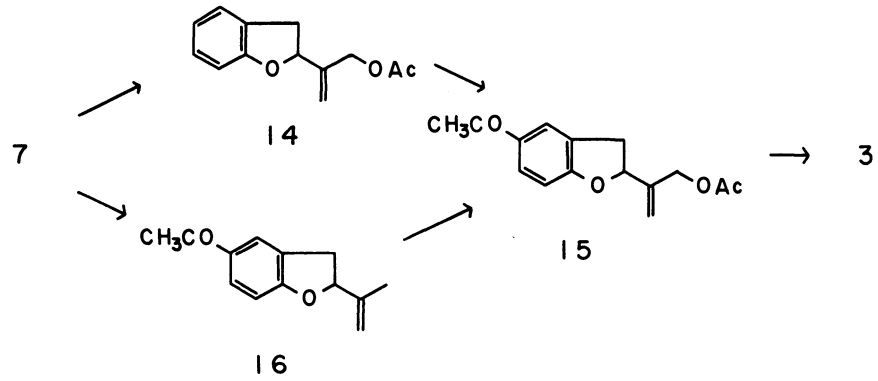

Chart 5.

of three aldehydes (**10**, **11**, and **1**; 4 : 3 : 3), which was separated to components by silica-gel chromatography. Then, these three aldehydes were oxidized to the corresponding carboxylic acids (**2**, **12**, and **13**) with silver oxide. The IR and ^{1}H-NMR spectra were identical with those of natural anodendroic acid.[2]

López and González isolated (−)-5-acetyl-2-[1-(hydroxymethyl)vinyl]-2,3-dihydrobenzofuran (**3**).[3] The acetylation of **7** with acetic acid–trifluoroacetic anhydride at room temp gave 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran (tremetone) (**16**). The spectral data of **16** were identical with those previously reported.[6] Then, **16** was converted to **15** by treatment with selenium dioxide in acetic anhydride at 130 °C. The ^{1}H-NMR spectrum was identical with that of natural **3**.[3] The keto acetate (**15**) was also prepared in a better yield from **7** by treatment with selenium dioxide in acetic anhydride to **14**, followed by acetylation with acetic acid–trifluoroacetic anhydride. The alkaline hydrolysis of **15** gave **3**, whose spectral data were identical with those previously reported.[3]

Experimental

The boiling points and melting points were uncorrected (in boiling points: 1 mmHg=133.322 Pa); the IR spectra were measured on a Hitachi EPI-S2 spectrophotomether, and the ^{1}H-NMR spectra, on a JEOL JNM-MH-60 spectrometer.

Preparation of **7**. *Method A). The Dehydration of* **5**: A mixture of **5** (1.42 g, 7.98 mmol) and phenyl isocyanate (9.50 g, 79.8 mmol) was refluxed for 16 h. The subsequent fractional distillation of the reaction mixture gave **7** (0.55 g, 44%); bp 105—106 °C/18 mmHg; IR (neat): 1650 cm^{-1}; ^{1}H-NMR (neat): δ=1.7 (3H, s), 3.0 (1H, dd, J=16+10 Hz), 3.1 (1H, dd, J=16+10 Hz), 5.1 (1H, broad s), 5.2 (1H, t, J=10 Hz), 5.3 (1H, broad s), 6.9—8.1 ppm (4H, m). Found: C, 82.67; H, 7.60%. Calcd: C, 82.46; H, 7.55%.

Method B). From Phenol and 1,4-Dibromo-2-methyl-2-butene: Sodium metal (10 g) was added by small portion, into a solution of phenol (9.4 g, 0.10 mol) in dry ether (100 ml). After the addition, stirring was continued for 30 min. Then, 1,4-dibromo-2-methyl-2-butene[7] (23.4 g, 0.10 mol) was added with vigorous stirring, drop by drop, into this suspended mixture. The mixture was then refluxed for 4.5 h with stirring. After the reaction, the ether layer was decanted, and the residual sodium metal was carefully treated with ethanol. The

ethanol was removed from the ethanolic solution, and the residue was acidified with 10% hydrochloric acid and then extracted with ether. The two ethereal layer obtained by the decantation and the extraction were combined and washed with a 5% aqueous sodium hydroxide solution. After drying over anhydrous sodium sulfate, the ether was removed. The resulting oil was distilled to give **7** (6.9 g, 43%) (bp 68—76 °C/2 mmHg), whose IR spectrum was identical with that of the product of the dehydration described above.

5-Bromo-2-isopropenyl-2,3-dihydrobenzofuran (8a). Upon treatment similar to that in the preparation of **7** described above, *p*-bromophenol (8.58 g, 49.6 mmol), sodium metal (5.0 g), and 1,4-dibromo-2-methyl-2-butene (11.3 g, 49.6 mmol) gave **8a** (1.9 g, 16%); bp 122—124 °C/4.5 mmHg; IR (neat): 1650 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.7 (3H, s), 2.9 (1H, dd, J=16+9 Hz), 3.1 (1H, dd, J=16+9 Hz), 4.8 (1H, broad s), 5.0 (1H, broad s), 5.0 (1H, t, J=9 Hz), 6.6 (1H, d, J=9 Hz), 6.9—7.4 ppm (2H, m). Found: C, 55.14; H, 4.90%. Calcd: C, 55.25; H, 4.64%.

5-Iodo-2-isopropenyl-2,3-dihydrobenzofuran (8b). Upon treatment similar to that in the preparation of **7** described above, *p*-iodophenol (3.0 g, 13.6 mmol), sodium metal (1.4 g), and 1,4-dibromo-2-methyl-2-butene (3.1 g, 13.6 mmol) gave **8b** (1.3 g, 33%); bp 118—119 °C/3 mmHg; IR (neat): 1655 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.8 (3H, s), (1H, dd, J=16+9 Hz), 3.3 (1H, dd, J=16+9 Hz), 5.0 (1H, broad s), 5.2 (1H, broad s), 5.2 (1H, t, J=9 Hz), 6.6 (1H, d, J=9 Hz), 7.5—7.7 ppm (2H, m). Found: C, 46.43; H, 3.60%. Calcd: C, 46.17; H, 3.88%.

2-Isopropenyl-2,3-dihydrobenzofuran-5-carbaldehyde (1). To a mixture of *N*-methylformanilide (4.46 g; 33.0 mmol) and phosphoryl chloride (5.05 g, 33.0 mmol), **7** (2.63 g, 16.4 mmol) was added. The mixture was then heated at 85—90 °C for 1 h with stirring. After cooling, the mixture was boiled with an aqueous sodium hydroxide solution (4 g in 20 ml) for 1 min and then extracted with ether. The ethereal layer was washed with 10% hydrochloric acid and a 5% sodium hydroxide solution, and then dried over anhydrous sodium sulfate. After the removal of the ether, the resulting oil was distilled to give **1** (1.26 g, 41%); bp 114—117 °C/2.5 mmHg; IR (neat): 1685 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.8 (3H, s), 3.2 (1H, dd, J=16+9 Hz), 3.4 (1H, dd, J=16+9 Hz), 5.1 (1H, broad s), 5.2 (1H, broad s), 5.4 (1H, t, J=9 Hz), 7.0 (1H, d, J=9 Hz), 7.7—8.0 (2H, m), 10.2 ppm (1H, s). Found: C, 76.38; H, 6.42%. Calcd: C, 76.57; H, 6.43%.

The Formylation of 9. Upon treatment similar to that in the preparation of **1** described above, **9**[9] (3.26 g, 14.8 mmol), *N*-methylformanilide (5.0 g, 37.0 mmol), and phosphoryl chloride (4.5 g, 29.3 mmol) gave a mixture of three aldehydes, which were subsequently separated into components by silica-gel chromatography. The fractions eluted with benzene gave **11** (0.40 g, 14%); bp 215—225 °C/18 mmHg; IR (neat): 1690 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.4 (6H, d, J=7 Hz), 3.2 (1H, m, J=7 Hz), 6.6 (1H, s), 7.7 (1H, d, J=9 Hz), 8.0 (1H, dd, J=9+2 Hz), 8.2 (1H, d, J=2 Hz), 12.1 ppm (1H, s). Found: C, 76.29; H, 6.43% (Calcd: C, 76.57; H, 6.43%); and **1** (0.42 g, 15%). The fractions eluted by chloroform gave **10** (0.75 g, 20%); bp *ca.* 130 °C/2 mmHg (bath temperature); IR (neat): 1740, 1695 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.4 (3H, s), 1.5 (3H, s), 2.0 (3H, s), 3.3 (2H, d, J=9 Hz), 5.2 (1H, t, J=9 Hz), 7.2 (1H, d, J=9 Hz), 7.9 (1H, d, J=2 Hz), 7.9 (1H, dd, J=9+2 Hz), 10.1 ppm (1H, s). Found: C, 67.73; H, 64.41%. Calcd: C, 67.73; H, 6.50%.

The Oxidation of 10 to 2. To a solution of silver nitrate (0.70 g, 41.2 mmol) in water (7 ml), sodium hydroxide (0.4 g) was added. To this silver oxide suspension, a solution of **10** (0.44 g, 17.7 mmol) in ethanol (4 ml) was added. The mixture was then refluxed for 2 h. After the reaction, the mixture was filtered, and the filtrate was washed with ether and then acidified with 10% hydrochloric acid. The crystals thus obtained were collected and recrystallized from ethanol to give **1** (0.11 g, 28%); mp 231—232 °C; IR (KBr disk): 3425, 1690 cm^{-1}; ^{1}H-NMR (in DMSO-d_6): δ=1.2 (6H, s), 3.3 (2H, d, J=9 Hz), 4.7 (1H, t, J=9 Hz), 6.9 (1H, d, J=9 Hz), 7.9 (1H, d, J=2 Hz), 7.9 ppm (1H, dd, J=9+2 Hz); ^{1}H-NMR (in pyridine-d_5): δ=1.4 (3H, s), 1.5 (3H, s), 3.3 (1H, dd, J=16+9 Hz), 3.5 (1H, dd, J=16+9 Hz), 4.9 (1H, t, J=9 Hz), 7.1 ppm (1H, d, J=9 Hz). Found: C, 70.78; H, 5.90%. Calcd: C, 70.57; H, 5.92%.

2-Isopropylbenzofuran-5-carboxylic Acid (12). Upon treatment similar to that in the oxidation of **2** described above, **11** (0.40 g, 21.3 mmol), silver nitrate (0.75 g, 44.2 mmol), and sodium hydroxide (0.4 g) gave **12** (0.14 g, 32%); mp 136.5—137.5 °C (recrystallized from ethanol–water); IR (KBr disk): 1675 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.4 (6H, d, J=7 Hz), 3.2 (1H, m, J=7 Hz), 6.6 (1H, s), 7.7 (1H, d, J=9 Hz), 8.4 (1H, dd, J=9+2 Hz), 8.6 (1H, d, J=2 Hz), 13.1 ppm (1H, s). Found: C, 70.78; H, 5.90%. Calcd: C, 70.57; H, 5.92%.

2-Isopropenyl-2,3-dihydrobenzofuran-5-carboxylic acid (13). Upon treatment similar to that in the oxidation of **2** described above, **1** (1.29 g, 6.85 mmol), silver nitrate (2.43 g, 14.3 mmol), and sodium hydroxide (1.1 g) gave **13** (0.68 g, 49%); mp 140.5—142.5 °C (recrystallized from benzene–cyclohexane); IR (KBr disk): 1675 cm^{-1}; ^{1}H-NMR (in $CDCl_3$): δ=1.8 (3H, s), 3.1 (1H, dd, J=15+9 Hz), 3.3 (1H, dd, J=15+9 Hz), 4.9 (1H, broad s), 5.1 (1H, broad s), 5.3 (1H, t, J=9 Hz), 6.8 (1H, d, J=9 Hz), 7.8 (1H, d, J=2 Hz), 8.0 (1H, dd, J=9+2 Hz), 10.6 ppm (1H, s). Found: C, 70.82; H, 5.79%. Calcd: C, 70.57; H, 5.92%.

2-[1-(Acetoxymethyl)vinyl]-2,3-dihydrobenzofuran (14). A mixture of **7** (6.7 g, 41.9 mmol), acetic anhydride (110 ml), and finely powdered selenium dioxide (4.3 g, 38.8 mmol) was refluxed for 45 min. Then, the mixture was diluted with ether and filtered. The filtrate was evaporated under reduced pressure to remove the ether and the acetic anhydride. The subsequent distillation of the residue gave **14** (1.42 g, 16%); bp 100—115 °C/4 mmHg; IR (neat): 1740 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=2.0 (3H, s), 3.1 (1H, dd, J=16+9 Hz), 3.4 (1H, dd, J=16+9 Hz), 4.7 (2H, broad s), 5.2 (1H, t, J=9 Hz), 5.2 (1H, broad s), 5.4 (1H, broad s), 6.7—7.4 ppm (4H, m). Found: C, 71.49; H, 6.53%. Calcd: C, 71.54; H, 6.47%.

5-Acetyl-2-isopropenyl-2,3-dihydrobenzofuran (Tremetone) (16). Under cooling in an ice-water bath, trifluoroacetic anhydride (7.7 g, 36.7 mmol) was added to a solution of **7** (2.9 g, 18.1 mmol) in acetic anhydride (2.2 g, 36.7 mmol). The mixture was then allowed to stand for 6 h at room temperature. After the reaction, the mixture was treated with ice water, and alkalified with a sodium hydrogencarbonate aqueous solution, and extracted with ether. The ether extracts were dried over anhydrous sodium sulfate. After the removal of the ether, the resulting oil was distilled to give **16** (1.67 g, 46%); bp 102—105 °C/2 mmHg; IR (neat): 1670 cm^{-1}; ^{1}H-NMR (in CCl_4): δ=1.9 (3H, s), 2.5 (3H, s), 3.2 (1H, dd, J=16+9 Hz), 3.4 (1H, dd, J=16+9 Hz), 5.1 (1H, broad s), 5.3 (1H, broad s), 5.4 (1H, t, J=9 Hz), 7.1 (1H, d, J=9 Hz), 8.0—8.3 ppm (2H, m). Found: C, 76.96; H, 6.74%. Calcd: C, 77.20; H, 6.98%.

2-[1-(Acetoxymethyl)vinyl]-5-acetyl-2,3-dihydrobenzofuran (15). *Acetylation of 14*: Upon treatment similar to that in the preparation of **16** described above, **14** (1.42 g, 6.51 mmol) was acetylated with acetic acid (0.78 g, 13.0 mmol) and trifluoroacetic anhydride (2.73 g, 13.0 mmol) to give **15** (0.79 g, 47%); bp 120—135 °C/4 mmHg; IR (neat): 1740, 1670 cm^{-1}; ^{1}H-

NMR (in CCl_4): δ=2.1 (3H, s), 2.6 (3H, s), 3.4 (1H, dd, J=15+8 Hz), 3.6 (1H, dd, J=15+8 Hz), 4.9 (2H, broad s), 5.5 (1H, broad s), 5.6 (1H, t, J=8 Hz), 7.2 (1H, d, J=10 Hz), 8.1—8.4 ppm (2H, m). Found: C, 69.31; H, 6.25%. Calcd: C, 69.21; H, 6.20%.

Selenium Dioxide Oxidation of **16**: Upon treatment similar to that in the preparation of **14** described above, **16** (1.41 g, 6.98 mmol) was oxidized with selenium dioxide (0.72 g, 6.49 mmol) in acetic anhydride (18 ml) to give **15** (0.099 g; 5.4%); bp 120—130 °C/4 mmHg; it was identical with the sample prepared from **14** in all its spectral data.

5-Acetyl-[1-(hydroxymethyl)vinyl]-2,3-dihydrobenzofuran (3). A mixture of **15** (0.27 g, 1.04 mmol), a 10% aqueous potassium hydroxide solution (5 ml), and ethanol (10 ml) was gently refluxed for 20 min. The mixture was then diluted with ice water and extracted with ether. The removal of the ether gave an oily residue, which was subsequently purified by silica-gel chromatography to give **3** as ethanol eluents; bp 103—105 °C/3 mmHg (bath temperature); IR (neat): 3400, 1655 cm^{-1}; ^{1}H-NMR (in $CDCl_3$): δ=2.6 (3H, s), 3.0 (1H, broad s), 3.3 (1H, dd, J=19+10 Hz), 3.5 (1H, dd, J=19+10 Hz), 4.3 (2H, broad s), 5.4 (2H, broad s), 5.5 (1H, t, J=10 Hz), 7.0 (1H, d, J=10 Hz), 7.9—8.2 ppm (2H, m). Found: C, 71.26; H, 6.62%. Calcd: C, 71.54; H, 6.47%.

We wish to thank Professor Hisashi Ishii (Chiba Univ.) for his valuable information about the dehydration with phenyl isocyanate. We also wish to thank Dr. Katsuhito Kondo (Tokushima University of Arts and Science) for providing a copy of the IR spectrum of natural anodendroic acid.

This paper is dedicated to Emeritus Professor Takeo Sakan on his 70th birthday.

Fluoride Salts on Alumina as Reagents for Alkylation of Phenols and Alcohols

Takashi Ando,* Junko Yamawaki, Takehiko Kawate, Shinjiro Sumi, and Terukiyo Hanafusa

The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka, Ibaraki, Osaka 567

(Received February 27, 1982)

The effectiveness of alkali metal fluorides impregnated on alumina as a reagent for promoting alkylation was optimized with respect to the metal cation, the amount of impregnation, and the reaction solvent. Potassium or caesium fluoride on alumina in acetonitrile or 1,2-dimethoxyethane was concluded to be the best reaction system for general use. *O*-Alkylation of substituted phenols, primary and secondary alcohols, and a glycol was carried out mostly in good yields under mild conditions with simple experimental procedures.

Increasing interest has been shown in the use of fluoride salts as potential bases to fascilitate a variety of synthetic reactions.[1,2] In recent studies by Clark, Miller, and their coworkers,[3,4] the effectiveness of alkali metal fluorides has been recognized in various types of alkylations with alkyl halides. According to them, nucleophilicity of protic organic compounds, *e.g.*, carboxylic acids or phenols, is greatly enhanced by the formation of strong hydrogen bonds with the fluoride anion; nucleophilic substitution proceeds with hydrogen bond assistance (Eq. 1). However, the low solubility

(1)

of alkali fluorides in ordinary solvents disturbs their wide application in organic synthesis. In order to overcome this difficulty, the reactions have been carried out at high temperatures with preformed hydrogen-bonded complexes or in a high-boiling solvent such as *N,N*-dimethylformamide,[4] but these methods are rather inconvenient.

On the other hand, there has been rapidly increasing use of organic and inorganic solids as supports of reagents or as reaction media in recent years.[5–8] In general, several advantages can be expected for their use: (1) work-up and purification of products are quite simple, (2) reactivity of functional groups can be modified, *i.e.*, enhanced or reduced, and (3) selectivity in the courses of reactions may be different from that in solution. These advantages may arise from the large effective surface area, the presence of pores, and the adsorption of reactants on the surface. In 1979, we communicated the preliminary results that potassium fluoride supported on diatomaceous earth (KF–Celite) is more efficient for promoting alkylations of various types of protic compounds than unsupported KF.[9] In this paper, we describe our detailed study on the scope and limitations of supported fluoride reagents for promoting *O*-alkylation of phenols and alcohols.

Results and Discussion

In order to optimize the efficiency of supported fluoride reagents, it is important to investigate the effects of the support, metal cation, amount of impregnation, and reaction solvent. We have previously discussed the efficiency of various inorganic solids as a support to enhance the reactivity of potassium fluoride,[10] and will not repeat that discussion here. In *O*-methylation of phenol with methyl iodide, the order of the effectiveness of supports has been found to be alumina>molecular sieves (MS) 13X and SK-40>montmorillonite>MS 4A and 5A>Celite.[10] Therefore, we used alumina as a support throughout this study.

The effect of varying the metal cation and the ratio of fluorides *vs.* alumina on the reactivity of alkali fluoride–alumina reagents was first studied. Various amounts of alkali metal fluorides (MF) and tetrabutylammonium fluoride (Bu_4NF) were impregnated on alumina; Classes I, II, III, and IV reagents were prepared with 0.1, 0.2, 0.5, and 1.0 mol of MF, respectively, impregnated on 100 g of alumina. Methylation of phenol with methyl iodide in acetonitrile was chosen as a reference

Table 1. Methylation of phenol with MF–alumina[a]

Reagent	Class[b]	Yield/%[c]		
		1 h	24 h	48 h
LiF–Alumina	I	0	1.3	2.5
	II	0.1	0.7	1.5
	IV	0	0.2	0.3
NaF–Alumina	I	1.5	6.1	9.6
	II	1.8	12.5	15.2
	IV	3.6	11.0	12.4
KF–Alumina	I	17.4	41.8	41.9
	II	57.7	97.0	
	IV	98.8		
CsF–Alumina	I	69.3	90.4[d]	
	II	99.6		
	III	100		
	IV	100[e]		
Bu_4NF–Alumina	I	100		
LiF[f]				0
NaF[f]				0
KF[f]				7.6
CsF[f]		19.5[e]		100
Bu_4NF[g]		98.3[e]		

a) Reaction of phenol (0.5 mmol) with methyl iodide (1 mmol) and MF–alumina (*ca.* 2.5 mmol MF) in 5 cm^3 of acetonitrile was carried out at room temperature. b) For Classes of reagents, see text. c) Yields were determined by GLPC using dodecane as an internal standard after a reaction time shown in Table. d) After 6 h. e) After 0.5 h. f) Without alumina. g) Trihydrate (Fluka) without alumina.

reaction, and the effectiveness of supported reagents was evaluated in terms of the yields of anisole after a definite time of reaction. The results are summarized in Table 1.

It is apparent from Table 1 that all the MF–alumina reagents are more effective than MF without a support and that the cation is a governing factor of the reactivity of the supported reagents. The order of effectiveness of MF–alumina is CsF>KF≫NaF>LiF. This is just the same as the reactivity order of MF without a support for the alkylation of phthalimide in *N,N*-dimethylformamide reported by Clark and Miller.[4] Although in general tetraalkylammonium fluorides are known as the most effective sources of the fluoride anion, they are expensive, hygroscopic, and thermally unstable. Clark reported that Bu_4NF supported on silica gel can be used as a non-hygroscopic source of the fluoride ion promoting various base-catalyzed reactions.[11] Bu_4NF–alumina prepared by us was somewhat easier to handle but not more effective than Bu_4NF alone. Although this Bu_4NF–alumina was most reactive among the supported reagents studied, CsF–alumina and KF–alumina can be regarded as more practical reagents than the Bu_4NF reagent when ease of handling and, especially for KF–alumina, economy of the reagents are taken into consideration. For these two reagents, the reactivity increased as the ratio of the fluoride *vs.* alumina was increased. However, as too much loading of the fluoride salts makes the reagents hygroscopic and thus cancels out their merit of easy handling, Class IV of KF–alumina and Class III of CsF–alumina are concluded to be the most practical reagents for general use.

The effect of varying the reaction solvent on the reaction rate was studied for these two reagents and for KF and CsF without a support (Table 2). Among the aprotic solvents used, the reaction became faster as the polarity of the solvent was increased. However, it was rather unexpected that the reaction was almost completed even in a nonpolar solvent such as hexane, although it took a longer reaction time. The adsorption of the reactants on the solid surface is obviously an important factor for the reaction. This is, to our knowledge, the first systematic study of the solvent effect on the reaction of supported reagents. KF and CsF both without alumina were effective only in very polar solvents; the effectivenesss might be due to the fact that they are slightly soluble in these solvents.[12] In conclusion, acetonitrile and 1,2-dimethoxyethane are adequate solvents for practical use with respect to their moderate boiling points and sufficient polarities.

Here we have reported that the effectiveness of the MF-support reagents is strongly affected by the metal cation, the amount of impregnation, and the reaction solvent. We have already reported that the kind and the form of solid supports and the drying conditions of the reagents are also important as factors which govern the efficiency of the supported fluoride reagents.[10] In this respect, the specific reactivities observed for "freeze-dried" and "spray-dried" potassium fluorides reported by Ishikawa and his coworkers is noteworthy;[13] the former is effective for alkylation and the latter is for fluorination. Although the role of the crystal structures of the supported fluorides and the role of a trace of the water remained in the reagents are not clear, the idea of the simple "hydrogen-bond-assistance" by the fluoride anion proposed by Clark and Miller[4] might be inapplicable in our case. Detailed study on the mechanism of the reaction promoted with MF–supports is now under way.

Applications of the most practical reagent, KF–alumina, were studied in some cases. As shown in

Table 2. Methylation of phenol in various solvents[a]

Solvent	Time/h	Yield/%[b] KF	CsF	KF–Alumina[c]	CsF–Alumina[d]

a) Reaction of an alcohol (1 equiv.) with an alkyl halide (1.2—1.5 equiv.) and KF–alumina (*ca.* 5 equiv. KF) was carried out in acetonitrile at room temperature. b) Yields determined with internal standards. c) Reagents were doubled for ethylene glycol.

Table 3, KF–alumina was effective for methylation of alkyl-substituted phenols with methyl iodide. Even methylation of sterically hindered 2,6-di-*t*-butylphenol proceeded quantitatively at room temperature in 2 h. When the substituent was electron attracting, the rate of methylation decreased. Methylation of *p*-Cl and *m*-NO_2 derivatives proceeded at room temperature, but *o*- and *p*-NO_2 derivatives were only slightly methylated under the same conditions. Alkylation of phenol with a variety of butyl halides was also examined (Table 3). The reaction with butyl bromide proceeded smoothly, although not as fast as with butyl iodide. The alkylation with *s*-butyl bromide proceeded with partial elimination to give a moderate yield of butyl phenyl ether. However, the reaction with *t*-butyl bromide gave only a trace of the product because of the elimination.

Alkylation of a less acidic hydroxyl group of an alcohol than that of a phenol by use of the fluoride anion has scarcely been reported.[1,14)] Nevertheless, KF–alumina was found to give satisfactory yields of alkyl ethers from alcohols (Table 4). It is noteworthy that methylation and benzylation of even secondary alcohols and a glycol proceeded smoothly at room temperature. Thus KF–alumina manifested the characteristic reactivity promoting alkylation of neutral alcohols under mild conditions.

In all cases studied, isolation procedures of reaction products were quite simple and nonaqueous: filtration, washing the solid with ether, evaporation of the solvent, and distillation or column chromatography when necessary. In conclusion, as reaction conditions are mild, yields are good in most cases, and work-up is simple, KF on alumina is a useful and practical supported reagent for promoting *O*-alkylation of phenols and alcohols.

Experimental

General. Unless otherwise mentioned, reagents were obtained commercially and used without further purification. Solvents were dried with molecular sieves 3A and 4A. Neutral alumina was purchased from Merck Japan Ltd. (Type 90 for column chromatography, activity I, 70—230 mesh) and used as obtained. Alkali metal fluorides were dried *in vacuo* at 120 °C for several hours. KF, CsF, and $Bu_4NF \cdot 3H_2O$ (Fluka, mp 60—61 °C) without a support were handled under nitrogen. GLPC analysis of product mixtures was carried out with a Varian Aerograph Model 2850-30 gas chromatograph with a flame ionization detector and a Hewlett-Packard 3370B digital integrator. A column packed with 20% Silicone DC 550 on Celite 545 was used. Yields were determined using internal standards.

Preparation of MF–Alumina Reagents. Alumina was mixed with metal fluoride in water, and the water was removed at 50—60 °C in a rotary evaporator. This impregnated alumina was further dried in a vacuum drying oven for several hours at 75 °C. Classes I, II, III, and IV of MF–alumina reagents were prepared from 100 g of alumina with 0.1, 0.2, 0.5, and 1.0 mol of MF, respectively. The typical KF–alumina reagent used for the alkylation of phenols and alcohols was prepared at the weight ratio of 2 : 3 which corresponds to 1.15 mol of KF on 100 g of alumina.

All these MF–alumina reagents except CsF–alumina (Class IV) and Bu_4NF–alumina can be handled in the atmosphere without special care. The effectiveness of the typical reagents remained unaltered after several months' storage in bottles kept in a desiccator.

Effectivity Determination of Supported Reagents. Methylation of phenol was carried out with methyl iodide and MF–alumina in a solvent, whose quantities are as shown below. Methylation of phenol with MF–alumina: phenol (47 mg, 0.5 mmol), methyl iodide (140 mg, 1.0 mmol), and MF–alumina (*ca.* 2.5 mmol MF) in 5 cm^3 of acetonitrile. Methylation of phenol in various solvent: phenol (0.24 g, 2.5 mmol), methyl iodide (0.71 g, 5.0 mmol), and MF–alumina (*ca.* 12.5 mmol MF) in 5 cm^3 of a solvent. The reaction mixture placed in a test tube with a Teflon-coated screw-cap was vigorously agitated at room temperature by a Vapor Mix S-10 vibrating apparatus (Tokyo Rikakikai Co., Ltd.). Yields of anisole formed after a definite reaction time were determined by GLPC with dodecane as an internal standard.

Alkylation with Supported Reagents. Experimental procedures for alkylation of phenols and alcohols in a preparative scale are given in the following typical examples. All the products are known compounds and gave ^1H NMR and IR spectra consistent with their structures and, when reported data are available, with those shown in the literature.

Methyl 2,6-Di-t-butylphenyl Ether: A mixture of 2,6-di-*t*-butylphenol (0.83 g, 4 mmol), methyl iodide (0.79 g, 5.6 mmol), and KF–alumina (3.00 g, *ca.* 20 mmol KF) in 6 cm^3 of acetonitrile was magnetically stirred at room temperature for 2 h. The solid material was filtered and washed with ether, and the solvent was evaporated. Purification by column chromatography (silica gel, hexane) gave 0.68 g of the product (78%): purity by GLPC 95%.

Butyl Phenyl Ether: Reaction of phenol (0.41 g, 4.4 mmol)

with butyl bromide (0.75 g, 5.5 mmol) and KF–alumina (3.3 g, *ca.* 22 mmol KF) in 6.5 cm^3 of acetonitrile was carried out at room temperature for 24 h. Work-up as above and purification by column chromatography (silica gel, chloroform) gave 0.52 g of the product (80%): purity by GLPC 99.7%.

Benzyl Butyl Ether: Reaction of 1-butanol (1.55 g, 20.9 mmol) with benzyl bromide (4.28 g, 25.0 mmol) and KF–alumina (15.8 g, *ca.* 104 mmol KF) in 30 cm^3 of acetonitrile was carried out at room temperature for 30 h. Work-up as above and purification by distillation gave 2.25 g of the product (66%): bp 92—94 °C/1.20—1.33 kPa (lit,[15] bp 88 °C/0.80—0.93 kPa); purity by GLPC 98.6%.

2-Methoxy-3-phenylpropane: A mixture of 3-phenyl-2-propanol (0.54 g, 4.0 mmol), methyl iodide (0.96 g, 6.8 mmol), and KF–alumina (3.0 g, *ca.* 20 mmol KF) in 6 cm^3 of acetonitrile was vigorously agitated at room temperature for 42 h. Work-up as above and purification by column chromatography (silica gel, chloroform) gave 0.43 g of the product (72%): purity by GLPC 97.9%.

The present work was supported in part by a Grant-in-Aid for Scientific Research No. 56740211 from the Ministry of Education, Science and Culture.

Restricted Rotation Involving the Tetrahedral Carbon. XLII. Barriers to Rotation and Populations of Rotamers in 9-[2-(Substituted methyl)-1-napthyl]fluorenes[1)]

Ryo SAITO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

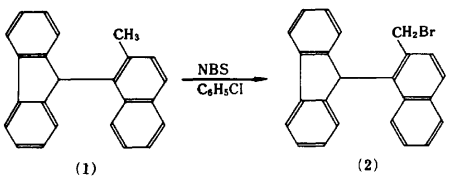
(Received March 30, 1982)

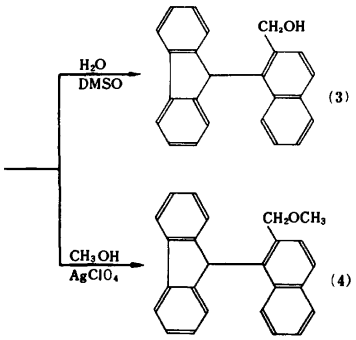
Rotational barriers in 9-[2-(substituted methyl)-1-naphthyl]fluorenes are found not significantly affected by the substituent on the methyl group, $\Delta G^{\ddagger}$'s being *ca.* 29 kcal/mol at 373 K. Populations of *sp*- and *ap*-rotamers at equilibriums show that the *sp* form is favored to some extent and the results are attributed to entropy factor. OH···π interaction is detected in the *ap* form of 9-(2-hydroxymethyl-1-naphthyl)fluorene.

In the classical work of Adams and his collaborators on restricted rotation of biphenyls,[2)] it was established that barriers to rotation are determined by the first atom with which substituents in the 2,2′,6,6′-positions are connected to the biphenyl skeleton. The results are understood by assuming that, in the transition state for rotation, atoms which are in a substituent but are not directly connected to the skeleton will avoid further interactions with those in other substituents to minimize the transition state energy.

While biphenyls give stable, enantiomeric atropisomers, 9-arylfluorenes give diastereomeric atropisomers.[3)] The interactions in the transition state for rotation in diastereomers are expected to be the same with the cases in biphenyls but the populations of diastereomeric atropisomers may be affected by a substituent which is not directly attached to the parent skeleton. Thus this work was undertaken 1) to confirm that the barrier to rotation in 9-arylfluorenes is not affected significantly by a remote substituent and 2) to examine whether the populations of rotamers can be affected by a substituent which is not directly attached to the skeleton.

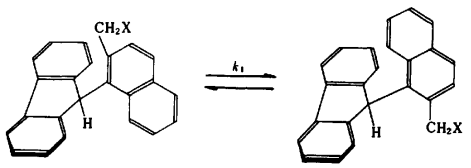
Syntheses of the compounds examined are straightforward. 9-(2-Methyl-1-naphthyl)fluorene (**1**)[4)] was brominated with *N*-bromosuccinimide to give 9-(2-bromomethyl-1-naphthyl)fluorene (**2**) which was hydrolyzed with water in dimethyl sulfoxide to afford 9-(2-hydroxymethyl-1-naphthyl)fluorene (**3**). 9-(2-Methoxymethyl-1-naphthyl)fluorene (**4**) was prepared by substitution reactions of **2** in methanol with the aid of silver perchlorate. *sp*-**4** could be prepared by methanolysis of *sp*-**2** as well.[5)]





The rate constants for rotation about the C_{naph}–C_9 bond obtained at various temperatures are given in Tables 1—3 together with equilibrium constants. Activation parameters calculated from these rate constants are listed in Table 4 together with those of the rotation in **1** for comparison.

The results indicate that the barriers to rotation in compounds **1**—**4** are about the same, thus confirming that a substituent on the methyl group has little effect on the height of the barrier to rotation: the CH_2 group determines the barrier to the first approximation in these compounds. Although the hydroxy compound (**3**)



(Designation of stereochemistry is reversed if X=H.)

a) Numericals in parentheses are molecular extinction coefficients. Those in parentheses for the solid state are as follows. s: Strong, m: medium.

gives a little low barrier, if we compare the rate constant at a given temperature with that of **4**, the reason for this lowering is not well understood at the moment.

In contrast, we see that the equilibrium constants are appreciably larger than 1.0 which is the value reported for compound **1** in tetrachloroethene.[4] In hexachlorobutadiene the *sp*/*ap* ratio of **1** becomes 1.14,[6] which is still close to unity. Therefore the increase in the equilibrium constants on substitution of a substituent for hydrogen of the methyl group is significant. One of the possibilities which favor the *sp* form is the dipolar interaction between the C-substituent bond and the C–Cl in the solvent molecule. We therefore determined the barrier to rotation and the equilibrium constants in compound **2** in toluene-d_8. The results shown in Table 5 yield $\Delta H^{\ddagger}$ 27.6±0.2 kcal/mol (1 cal=4.18 J) and $\Delta S^{\ddagger}$ −5.9±0.5 e.u. (1 e.u.=4.18 J mol^{-1} K^{-1}) for the *ap*→*sp* process. Thus $\Delta G^{\ddagger}$ at 373 K is 29.8 kcal/mol. Interestingly the equilibrium constants are 3.0 which are not different from those in hexachlorobutadiene. Independence of the population ratios from the solvent nature may mean that the solvation is not an important factor in determining the *sp*/*ap* ratio.

We wish to attribute the large equilibrium constants for compounds **2**—**4**, from the above results, to the entropy effect. If one considers conformations which change by rotation about the XCH_2–naphthyl bond, there is a restriction in some of the conformations in the *ap* form. Since X is larger than hydrogen, a conformation in which X is close to the fluorene ring is strongly disfavored due to the steric effect. That kind of steric effect is less severe in the *sp* form. This factor should contribute to decrease in entropy in the *ap* form relative to the *sp* form.

Close examination of the *sp*/*ap* ratios reveals that the *ap* form of the hydroxy compound (**3**) is slightly favored relative to other *ap* forms. One of the possibilities that favor the *ap* conformation in **3** is the presence of OH···π interactions. If the aryl group in 9-arylfluorenes is either 2-hydroxy-1-naphthyl or 2-hydroxy-4,6-dimethylphenyl, strong stabilization of the *ap* form is reported.[7] Thus infrared ν_{OH} spectra of these compounds were recorded. The results are shown in Table 6.

Since the frequencies are not calibrated, the absorption at *ca.* 3620 cm^{-1} may be considered to correspond to the benzylic OH···π type band.[8] We may call this band "free," since its shift is small from the really free band and there is another bonded band in *ap*-**3**. Then the *sp* form shows only a free band in 9.8 mM solution and, in more concentrated solution and in the solid state, it shows a polymeric band. In contrast, the *ap* form shows two ν_{OH} bands in 9.8 mM solution: the band due to a free form at 3630 cm^{-1} and that due to an OH···π bonded form at 3580 cm^{-1}. In 0.2 M solution, the *ap* form is present as free, OH···π bonded, and polymeric forms, whereas in the solid state it is still possible to see a band due to monomeric species. In the sterically hindered alcohols, the monomeric form is often observed even in the condensed phase,[9] and *ap*-**3** is another example of such a case.

The above results clearly indicate that there is an OH···π interaction in the *ap* form at the concentration (0.2 M) of the NMR measurement. We may attribute the favoredness of *ap*-**3** relative to other *ap*-forms to the OH···π interaction. It is interesting to note that the OH···π interaction is detected even though the OH group and the π-system are separated by 4 carbon atoms. Among 4-phenyl-1-butanol derivatives, even *p*-aminophenylbutanol, which should facilitate the interaction because of the high electron density of the phenyl group, failed to show an OH···π bond.[10] *o*-(2-Phenylethyl)phenol shows a weak intramolecular OH···π interaction, whereas such an interaction is not detected

in *o*-(3-butenyl)phenol:[11] the results are partly attributed to the entropy effect because the π-system in the former distributes widely relative to the latter. The skeleton of *ap*-**3** is fixed except the $HOCH_2$ part. Therefore the presence of the fairly strong intramolecular OH···π interaction in *ap*-**3** can be attributed to the favorable entropy factor. If the conformation of a molecule is fixed favorably, the intramolecular interaction may be found even though the two groups are separated by more than 4 carbons.

We may now compare the effect of a 1-naphthyl group with that of *o*-tolyl on the barrier to rotation, because a pair of compounds both of which carry a bromomethyl group next to the carbon connected to fluorene is available. Activation parameters for rotation in 9-(2-bromomethyl-6-methylphenyl)fluorene in hexachlorobutadiene are as follows for the *ap*→*sp* process: $\Delta H^{\ddagger}$ 26.3 kcal/mol, $\Delta S^{\ddagger}$ −9.3 e.u., and $\Delta G^{\ddagger}_{373}$ 29.8 kcal/mol.[6] Comparing these data with those for **2**, we see that the enthalpy of activation is definitely larger for **2** than for 9-(2-bromomethyl-6-methylphenyl)fluorene, although the free energy for activation at 373 K is the same. This enthalpy difference must be the reflection of the rigidity of the 1-naphthyl group relative to the *o*-tolyl, as suggested before.[6]

Experimental

9-(2-Bromomethyl-1-naphthyl)fluorene (2). A solution of 13.0 g (43 mmol) of a mixture of rotamers of 9-(2-methyl-1-naphthyl)fluorene (**1**)[4] and 18 g (100 mmol) of *N*-bromosuccinimide in 400 mL of chlorobenzene was refluxed for 1 h with stirring. After cooling, succinimide was removed by filtration and chlorobenzene was distilled off *in vacuo*. The residue was chromatographed on silica gel with hexane. *sp*-**1**, *ap*-**1**, *ap*-**2**, and *sp*-**2** were eluted successively. A typical run gave 0.8 g of *ap*-**2** and 3.6 g of *sp*-**2** with 2.7 g of a mixture containing *sp*-**2**, *ap*-**2**, and starting materials.

ap-**2**, mp 132—133.5 °C. Found: C, 74.99; H, 4.32; Br, 21.13%. Calcd for $C_{24}H_{17}Br$: C, 74.81; H, 4.45; Br, 20.74%. ^{1}H NMR ($CDCl_3$, δ): 3.56 (2H, s), 6.12 (1H, s), 7.0—8.0 (13H, m), 8.37—8.57 (1H, m).

sp-**2**, mp 123—124 °C. Found: C, 75.07; H, 4.29; Br, 21.05%. Calcd for $C_{24}H_{17}Br$: C, 74.81; H, 4.45; Br, 20.74%. ^{1}H NMR ($CDCl_3$, δ): 4.96 (2H, s), 5.81 (1H, s), 6.47 (1H, d, J=8.7 Hz), 6.7—8.0 (13H, m).

9-(2-Hydroxymethyl-1-naphthyl)fluorene (3). To a solution of 4.0 g of the bromo compound (**2**) in 50 mL of dimethyl sulfoxide, was added 20 mL of water with heating and stirring. The heating and the stirring were continued for 2 h. The mixture was poured into water and the organic material was extracted with ether. The ethereal layer was thoroughly washed with water and dried over magnesium sulfate. After evaporation of the solvent, the residue was chromatographed on silica gel with benzene. *ap*-**3** and *sp*-**3**, eluted in this order, were obtained in 0.4 g and 2.0 g yield with 2.0 g of a mixture of rotamers of **3**.

ap-**3**, mp 134—135.5 °C. Found: C, 89.18; H, 5.44%. Calcd for $C_{24}H_{18}O$: C, 89.41; H, 5.63%. ^{1}H NMR ($CDCl_3$, δ): 0.87 (1H, t, J=6.0 Hz), 3.55 (2H, d, J=6.0 Hz), 6.10 (1H, s), 7.0—8.0 (13H, m), 8.40—8.60 (1H, m).

sp-**3**, mp 103—105 °C. Found: C, 89.29; H, 5.52%. Calcd for $C_{24}H_{18}O$: C, 89.41; H, 5.63%. ^{1}H NMR ($CDCl_3$, δ): 2.07 (1H, t, J=6.0 Hz), 5.05 (2H, d, J=6.0 Hz), 5.76 (1H, s), 6.45 (1H, d, J=9.0 Hz), 6.6—8.0 (13H, m).

9-(2-Methoxymethyl-1-naphthyl)fluorene (4). To a solution of 0.30 g (0.78 mmol) of *ap*-**2** in 30 mL of methanol was slowly added 0.16 g (0.77 mmol) of silver perchlorate in 5 mL of methanol. A small amount of chloroform may be used to facilitate dissolution of *ap*-**2** in methanol. After excess of silver perchlorate was decomposed by adding aqueous lithium chloride, the precipitate was removed by filtration and the filtrate was poured into water. The organic material was extracted with ether. The ethereal extract was washed with water and dried over magnesium sulfate. Evaporation of the solvent afforded almost pure *ap*-**4**, oil, in 96% yield. High resolution mass spectrum showed a molecular ion peak at *m/e* 336.1544, whereas the calculated mass of the molecule for $C_{25}H_{20}O$ is 336.1514. ^{1}H NMR ($CDCl_3$, δ): 2.53 (3H, s), 3.33 (2H, s), 6.12 (1H, s), 7.1—8.0 (13H, m), 8.43—8.60 (1H, m).

sp-**4**, mp 114—115 °C, was prepared similarly in 94% yield. Found: C, 89.22; H, 5.89%. Calcd for $C_{25}H_{20}O$: C, 89.25; H, 5.99%. ^{1}H NMR ($CDCl_3$, δ): 3.45 (3H, s), 4.93 (2H, s), 5.82 (1H, s), 6.47 (1H, d, J=9.0 Hz), 6.7—8.0 (13H, m).

sp-**4** was also prepared by methanolysis of *sp*-**2**. A solution of 0.30 g of *sp*-**2** in 30 mL of methanol was refluxed for 15 h. After evaporation of the solvent, the residue was recrystallizaed from 1 : 5 benzene–hexane to give 0.21 g of *sp*-**4**. A small amount of *ap*-**4** was detected in the reaction mixture before recrystallization. Methanolysis of *ap*-**3** was too slow to be practical.

Determination of Barriers to Rotation. A solution was prepared by dissolving 30 mg of the *ap* form of arylfluorenes in 0.4 mL of hexachlorobutadiene or toluene-d_8 and was placed in an NMR sample tube. The tube was immersed in an appropriate boiling-solvent bath, the temperature of which was directly measured by a thermometer. The rate of isomerization was followed by ^{1}H NMR spectroscopy and was treated assuming a reversible first-order reaction. The rate constants thus obtained were put into the Eyring equation to obtain activation parameters. The following solvents were used for the bath (solvent and approximate boiling points given): benzene (77 °C), 1 : 1 benzene–toluene (87 °C), dioxane (95 °C), toluene (104 °C), 1 : 1 chlorobenzene–toluene (114 °C), chlorobenzene (124 °C).

Determination of Infrared Spectra. The spectra were recorded on a Hitachi EPI-G spectrometer. The wave numbers reported are not calibrated. The spectra of solid were obtained as KBr discs. The spectra of solution were obtained with a KBr cell of variable length. With solutions of *ca.* 0.2 M in carbon tetrachloride, the cell length was 0.25 mm and, with those of 9.8 mM, the cell length was 5.0 mm.

^{1}H NMR spectra were obtained with either a Hitachi R-20B or a Varian EM 390 spectrometer.

(Received March 30, 1982)

9-(2-Methoxy-4,6-dimethylphenyl)fluorenes carrying one or two bromo groups on the phenyl ring were prepared and the buttressing effect on the rotational barrier about the C_9–C_{ph} bond were investigated. The free energies of activation for rotation were 26.5, 25.9, and 27.2 kcal/mol at 56 °C for 3-bromo, 5-bromo, and 3,5-dibromo compounds, respectively. The buttressing effect was enhanced when the bromo group was next to the methoxyl group relative to that given to the methyl group. The results were attributed to the fact that a methoxyl group, which gives its steric effect by the oxygen atom in the normal cases, has to take conformations, not coplanar with the phenyl ring, caused by the presence of the bromo group.

Buttressing effect was found in biphenyls: barrier to rotation is raised if a substituent is introduced next to a substituent which gives direct interaction with others in the transition state for rotation. Thus in biphenyls, the barriers are enhanced by the buttressing effect.[2] However, buttressing effect does not always enhance the barrier to rotation. There is a case in which buttressing effect lowers the barrier in a triptycene system.[3] Since both triptycenes and 9-arylfluorenes are congested systems in the ground state, it is worthwhile to see whether the buttressing effect enhances the barrier to rotation in the 9-arylfluorene system. This paper reports the results of such an investigation.

Syntheses of required compounds were carried out in the following way. 2,4,6-Tribromo-3,5-dimethylanisole (**1d**) was prepared according to a known method. 2,4-Dibromo-3,5-dimethylanisole (**1b**) had been prepared by a cumbersome method but we found that bromination of 3,5-dimethylanisole with 2 mol of bromine gave a satisfactory result. Preparation of 2,6-dibromo-3,5-dimethylphenol was described in a patent which utilizes the isomerization of a 2,4-dibromo isomer.[4] However, tracing the method revealed that it was not satisfactory for the preparative purpose. Thus we utilized a method which had been used for preparation of 2,6-dibromophenol.[5] The method, when applied to 3,5-dimethylphenol, gave a satisfactory yield of 2,6-dibromo, -3,5-dimethylphenol which was methylated to afford 2,6-dibromo-3,5-dimethylanisole (**1c**). The bromoanisoles (**1**) were converted to Grignard reagents which were allowed to react with fluorenone. The products (**2**) were reduced to give the desired monobromo or dibromo derivatives (**3**) of 9-(2-methoxy-4,6-dimethylphenyl)-fluorene.

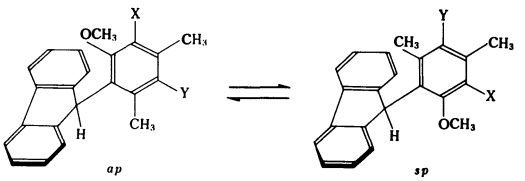
(3) a : X=Y=H
b : X=H, Y=Br
c : X=Br, Y=H
d : X=Y=Br

The assignment of the stereostructures of the products (**2** and **3**) was performed in the usual way. The *ap* forms exhibited a high field signal due to the methoxyl group in ^{1}H NMR spectroscopy relative to the *sp*, because the methoxyl group is located over the fluorene ring in the *ap*. The reverse is true for the 6-methyl protons: they give a low field signal in the *ap* conformation and a high field signal in the *sp*.



ap *sp*

Rates of isomerization of compounds **3b—d** at various temperatures are summarized in Tables 1—3. Kinetic parameters obtained by putting the rate data into the Eyring equation are shown in Table 4 together with those for the unsubstituted compound (**3a**),[6] for comparison. The data clearly show that there is the buttressing effect operating in compounds **3b—d**. We may call now the buttressing effect which raises the

barrier to rotation as positive. An interesting point is that the magnitude of the positive buttressing effect is different according to the position of the bromo group. When a bromo group is introduced to the ortho position of the 6-methyl group (**3a**→**3b** or **3c**→**3d**), the barrier is enhanced by less than 1 kcal/mol (1 cal=4.18 J). In contrast, if a bromo group is introduced ortho to the methoxyl group (**3a**→**3c** or **3b**→**3d**), the barrier is raised by *ca.* 1.5 kcal/mol.

The difference in the magnitude of buttressing effect caused by the same substituent may deserve further mention here. Electronic effect[7] may be neglected because a bromo group in the 3-position of the phenyl is ortho to the methoxyl and para to the 6-methyl, whereas that in the 6-position is para to the methoxyl and ortho to the 6-methyl. Probably the most important point is that a methoxyl group has an additional bond which can be involved in forming varieties of conformations: that is the CH_3–O bond. Anisole is known to be an almost planar molecule,[8] which can be interpreted that maximum stabilization is obtained in this conformation because of delocalization of electrons. However, if both ortho positions of the methoxyl group are occupied by substituents, the planar structure is no longer stable owing to the steric effect. There are some examples known in the literature.[9] If the methoxyl group in compound **3** is not coplanar with the phenyl group, the transition state for rotation rather than the ground state will be affected, as molecular models suggest. In conclusion, there are two facets of buttressing effect: prevention of angle deformation and the increase in relative bulkiness of a group by preventing certain conformations. In the methoxyl group, both factors are operative. By preventing the planar structure of the methoxyl group with the phenyl, the buttressing effect may even play a role of lengthening the C_{ar}–O bond, although the effect of this lengthening is not well understood. In contrast, the 6-methyl group suffers the buttressing effect of the neighboring group by being prevented from its angle deformation only.

The equilibrium constants suggest that the *sp* conformation is favored in every case. The reason for this is not well understood at the moment but it is possible that the solute-solvent interaction which is more favorable in the *sp* conformation than the *ap* is one of important reasons.

The kinetic and equilibrium data were obtained with chloroform-*d* solutions to see the effect of a weak hydrogen bonding.[10] The results are shown in Table 5. The free energies of activation were almost the same for the two kinds of solutions, *viz.* tetrachloroethene and chloroform-*d*. However, it is interesting to note that the *sp* form of **3c** and **3d** which carry the 3-bromo group shows larger K values (sp/ap) than **3a** and **3b** which lack the 3-bromo. It is possible that the hydrogen bond stabilization is more effective in the *sp* forms of **3c** and **3d** because their *ap* forms are really congested.

Experimental

*2,4,6-Tribromo-3,5-dimethylanisole (**1d**)* was prepared as described in the literature.[11]

*2,4-Dibromo-3,5-dimethylanisole (**1b**).* To a solution of 14 g (0.10 mol) of 3,5-dimethylanisole[12] in 50 mL of acetic acid, was added a solution of 32 g (0.20 mol) of bromine in 30 mL of acetic acid with stirring and cooling. The mixture was poured into water and crystals were collected by filtration. Although the product contained some monobrominated compounds, recrystallization of the mixture from benzene afforded 22.5 g (76.6%) of pure **1b**, mp 108—109 °C (lit,[13] mp 108—109 °C). ^{1}H NMR ($CDCl_3$, δ): 2.39 (3H, s), 2.61 (3H, s), 3.84 (3H, s), 6.63 (1H, s).

*2,6-Dibromo-3,5-dimethylanisole (**1c**).* To a cooled solu-

tion of 14.7 g (0.20 mol) of *t*-butylamine in 250 mL of toluene, 16.0 g (0.10 mol) of bromine was added at −20——−30 °C in about 10 min. To the mixture cooled at −70——−75 °C was added 6.1 g (0.05 mol) of 3,5-dimethylphenol in 30 mL of dichloromethane in 5 min with vigorous stirring. The stirring was continued for 9 h at that temperature and then the mixture was allowed to warm up to room temperature. The organic layer was extracted with 10% aqueous sodium hydroxide and the extract was acidified. Extraction of the mixture with dichloromethane and evaporation of the solvent left a solid residue. Treatment of the residue with hexane separated the desired product as an insoluble part. The crude yield was 58.6%. Recrystallization of the product from hexane afforded pure 2,6-dibromo-3,5-dimethylphenol, mp 93.5—94 °C. Found: C, 34.03; H, 2.95; Br, 57.05%. Calcd for $C_8H_8Br_2O$: C, 34.32; H, 2.88; Br, 57.08%. ^{1}H NMR ($CDCl_3$, δ): 2.34 (6H, s), 5.93 (1H, s), 6.74 (1H, s).

Treatment of the phenol (2.8 g) with 0.4 g of sodium hydroxide in 30 mL of water and 0.94 mL of dimethyl sulfate afforded 52.0% **1c** as a waxy solid. This compound was directly used for the next reaction. ^{1}H NMR ($CDCl_3$, δ): 2.34 (6H, s), 3.85 (3H, s), 6.93 (1H, s).

*9-(5-Bromo-2-methoxy-4,6-dimethylphenyl)fluoren-9-ol (**2b**).* To a vigorously stirred solution of 5-bromo-2-methoxy-4,6-dimethylphenylmagnesium bromide, prepared from 14.7 g (0.050 mol) of **1b** and 1.20 g (0.050 mol) of magnesium in tetrahydrofuran, was added 7.0 g (0.039 mol) of fluorenone in portions at 0 °C. The reaction mixture was stirred for 1 h at room temperature and was then heated under reflux for 2 h. The mixture was cooled and decomposed with aqueous ammonium chloride. The organic layer was separated and dried over magnesium sulfate. After evaporation of the solvent, the products were separated by chromatography on alumina, benzene–hexane mixtures being used as eluent. **2b**, mp 147—149 °C, was eluted first and then came a mixture of **2b** and 9-(3-bromo-4-methoxy-2,6-dimethylphenyl)fluoren-9-ol, as judged by its ^{1}H NMR spectrum ($CDCl_3$, δ): *sp*, 1.32 (3H, s), 1.75 (1H, s), 2.84 (3H, s), 3.75 (3H, s), 6.52 (1H, s), 7.0—7.6 (8H, m); *ap*, 1.13 (3H, s), 1.84 (1H, s), 3.01 (3H, s), 3.64 (3H, s), 6.13 (1H, s), 7.0—7.6 (8H, m). The *sp*/*ap* ratio of the latter was 0.5. The ratio of **2b** to 9-(3-bromo-4-methoxy-2,6-dimethylphenyl)fluoren-9-ol was 3 : 1 as ^{1}H NMR spectra indicated. The yield of **2b** was 57% based on fluorenone. Found: C, 67.03; H, 4.70; Br, 19.96%. Calcd for $C_{22}H_{19}BrO_2$: C, 66.84; H. 4.84; Br, 20.21%. ^{1}H NMR ($CDCl_3$ δ) indicated that **2b** was a mixture of *sp* and *ap* rotamers (8 : 1). *sp*: 1.45 (3H, s), 2.40 (3H, s), 4.03 (3H, s), 6.82 (1H, s), 6.90 (1H, s), 7.1—7.7 (8H, m). *ap*: 2.10 (1H, s), 2.40 (3H, s), 2.85 (3H, s), 3.12 (3H, s), 6.45 (1H, s), 7.1—7.7 (8H, m).

*9-(3,5-Dibromo-2-methoxy-4,6-dimethylphenyl)fluoren-9-ol (**2d**)*, mp 159—161 °C, was similarly prepared by treating 3,5-dibromo-2-methoxy-4,6-dimethylphenylmagnesium bromide, which was prepared from **1d**, with fluorenone. The yield was 43%. Found: C, 55.89; H, 3.68; Br, 33.67%. Calcd for $C_{22}H_{18}Br_2O_2$: C, 55.72; H, 3.83; Br, 33.67%. ^{1}H NMR ($CDCl_3$, δ) indicated that the compound was a 4 : 1 mixture of *sp* and *ap* forms: *sp*, 1.45 (3H, s), 2.70 (3H, s), 4.16 (3H, s), 6.57 (1H, s), 7.1—7.8 (8H, m); *ap*, 2.18 (1H, s), 2.65 (3H, s), 2.70 (3H, s), 3.10 (3H, s), 7.1—7.8 (8H, m).

*9-(3-Bromo-2-methoxy-4,6-dimethylphenyl)fluoren-9-ol (**2c**)* was similarly prepared from **1c** in 47% yield. ^{1}H NMR ($CDCl_3$, δ) indicated that the product was a 3.4 : 1 mixture of *sp* and *ap* forms: *sp*, 1.19 (3H, s), 2.36 (3H, s), 4.17 (3H, s), 6.85 (1H, s), 6.66 (1H, s), 7.1—7.8 (8H, m); *ap*, 2.06 (1H, s), 2.32 (3H, s), 2.65 (3H, s), 2.88 (3H, s), 6.93 (1H, s), 7.1—7.8 (8H, m). The product was directly used for reduction which is described below.

*9-(5-Bromo-2-methoxy-4,6-dimethylphenyl)fluorene (**3b**).* To a solution of 1.35 g (3.4 mmol) of **2b** in 50 mL of acetic acid was added 10 mL of 57% hydriodic acid. The solution was stirred for 3 h at 20 °C and poured into water. The organic materials were extracted with ether and the extract was washed with aqueous sodium hydrogencarbonate and then with aqueous sodium sulfite. The ethereal solution was dried over sodium sulfate. The solvent was evaporated and the residue was submitted to chromatography on alumina, hexane being used as an eluent. The chromatographed product was recrystallized from hexane to give pure *sp* form of **3b** in 92% yield. The melting point was 149—150 °C. Found: C, 69.83; H, 4.87; Br, 21.39%. Calcd for $C_{22}H_{19}BrO$: C, 69.67; H, 5.05; Br, 21.07%. ^{1}H NMR ($CDCl_3$, δ): 1.26 (3H, s), 2.43 (3H, s), 3.91 (3H, s), 6.02 (1H, s), 6.85 (1H, s), 7.1—7.9 (8H, m).

A rotameric mixture, which was obtained as the result of isomerization works, was submitted to TLC on alumina with hexane eluent. The *sp* form had a larger R_f value than the *ap*. Rechromatography afforded pure *ap*-**3b**, mp 132.2—133.0 °C. High resolution mass spectrum showed molecular ion peaks at 378.0675 and 380.0583, whereas $C_{22}H_{19}BrO$ requires 378.0620 and 380.0598. The relative intensities of the two peaks agreed well with those expected from the natural abundance of ^{79}Br and ^{81}Br. ^{1}H NMR ($CDCl_3$, δ): 2.38 (3H, s), 2.85 (3H, s), 2.88 (3H, s), 5.32 (1H, s), 6.45 (1H, s), 7.1—7.9 (8H, m).

*9-(3,5-Dibromo-2-methoxy-4,6-dimethylphenyl)fluorene (**3d**)*, mp 149—151 °C, was prepared similarly in 35% yield. Found: C, 57.57; H, 3.75; Br, 34.62%. Calcd for $C_{22}H_{18}Br_2O$: C, 57.67; H, 3.60; Br, 34.88%. ^{1}H NMR ($CDCl_3$, δ) data indicated that the product was pure *sp*-**3d**: 1.23 (3H, s), 2.66 (3H, s), 3.99 (3H, s), 5.87 (1H, s), 7.1—7.9 (8H, m). Since the population ratio at the equilibrium was very large, the isolation of the *ap*-form was not attempted. The following ^{1}H NMR ($CDCl_3$, δ) data for the *ap* form were recorded: 2.62 (3H, s), 2.65 (3H, s), 2.87 (3H, s), 5.39 (1H, s), 7.1—7.9 (8H, m).

*9-(3-Bromo-2-methoxy-4,6-dimethylphenyl)fluorene (**3c**)* was prepared similarly. Unlike other related compounds, reduction of 0.92 g of **2c** afforded 0.30 g of *sp*, mp 136.5—137.0 °C, and 0.28 g of *ap*, mp 115.5—116.5 °C, the total yield being 66.5%. The following ^{1}H NMR data ($CDCl_3$, δ) and analytical data were obtained.

sp. Found: C, 69.59; H, 5.00; Br, 21.39%. Calcd for $C_{22}H_{19}BrO$: C, 69.67; H, 5.05; Br, 21.07%. NMR: 1.04 (3H, s), 2.36 (3H, s), 4.03 (3H, s), 5.78 (1H, s), 6.64 (1H, s), 7.1—7.9 (8H, m).

ap. High resolution mass spectrum showed molecular ion peaks at 378.0604 and 380.0581, while $C_{22}H_{19}BrO$ requires 378.0620 and 380.0598. NMR: 2.35 (3H, s), 2.63 (3H, s), 2.63 (3H, s), 2.66 (3H, s), 5.22 (1H, s), 6.97 (1H, s), 7.1—7.9 (8H, m).

Determination of Barriers to Rotation. A pure sample (*ca.* 40 mg) of *sp*-**3** was dissolved in *ca.* 0.5 mL of tetrachloroethene or chloroform-*d* and placed in an NMR sample tube. The tube was immersed in an appropriate boiling-solvent bath, temperature being checked by a thermometer, and the appearance of *ap*-**3** was followed by ^{1}H NMR spectroscopy. The data were treated by assuming a reversible first-order reaction and the rate constants were put into the Eyring equation to obtain activation parameters. The following solvents were used for the bath (solvents and approximate temperatures given): methanol–hexane azeotrope (49.4 °C), acetone (56.5 °C), methanol (64 °C), hexane (69 °C), and ethanol (78 °C).

NMR Measurement. The spectra were obtained with

either a Varian EM 390 spectrometer or a Hitachi R-20B spectrometer. Integration was carried out 8—10 times and the average was used for the kinetic measurement.

The Influence of Molecular Conformation on the Electronic Relaxation Processes. Biphenyl in Solution

Tsuneo Fujii,* Shigeru Komatsu,† and Satoshi Suzuki
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received January 20, 1981)

The fluorescence spectra of biphenyl in an isopentane and methylcyclohexane mixture, in propylene glycol, and in glycerol have been observed as a function of temperature and excitation wavelength. The temperature dependence of the fluorescence spectra is interpreted in terms of the intramolecular geometric relaxation. The fluorescence spectra of biphenyl have been observed in various solvents at room temperature. The Ham effect was found in the biphenyl fluorescence.

The influence of molecular structure on photophysical processes has been investigated by several authors. Lim and Chakrabarti have studied the phosphorescence lifetimes and polarization of various aromatic amines and of phenoxide ion.[1] Kasha and Rawls have studied the phosphorescence lifetimes of twisted anilines.[2] They suggested that the enhanced spin-orbit coupling in heteroaromatic molecules should be attributed to the pseudo non-bonding character of the lone-pair electrons of the substituent. Huber *et al.* showed that the rate constant of $S_1 \rightarrow T_i$ intersystem-crossing, k_{TM}, and the radiative rate constant of $T_1 \rightarrow S_0$ decrease rapidly on going from diphenylamine to 9,10-dihydroxyacridine (acridan) and carbazole, while the radiative rate constant of $S_1 \rightarrow S_0$ is only slightly altered.[3]

The influence of molecular conformations on electronic relaxation processes is an interesting problem in photophysics. Two benzene rings of biphenyl are connected with a C-C single bond and vibrate torsionally around the C-C bond. It was reported that the planes of the two benzene rings of biphenyl are inclined at an angle of 20—40° in the ground state, while they are inclined at an angle of 0—20° in the excited states.[4-8] Electronic excitation and deexcitation processes of biphenyl inevitably include conformational changes.

Hughes *et al.* and Naqvi *et al.* studied the excitation-wavelength dependence of the fluorescence spectra of biphenyl[9] and polyphenyls,[10] but little attention has been directed to the effect of conformation on the electronic relaxation processes.

The preceding paper[11] presented the excitation-wavelength dependence of the fluorescence and phosphorescence quantum yields and of the phosphorescence lifetime of biphenyl in propylene glycol and discussed the influence of molecular conformations on the rate constants of the radiative and radiationless processes of biphenyl. It was shown that the intramolecular geometric relaxation[12] plays an important role in the temperature dependence of the photophysical processes of biphenyl.

This paper presents the experimental findings of the influence of solvent, temperature, excitation wavelength, and viscosity on the fluorescence spectra of biphenyl. The difference of the distribution of conformers in the ground and excited states of biphenyl satisfactorily explains the observed spectral changes.

Experimental

Biphenyl was purified by repeated recrystallizations from ethanol and passed 1000 times through a zone refiner. Methanol (Wako Pure Chemical Industries, Inc., Luminasol grade) and acetonitrile (Wako, Spectrosol grade) were used without further purification. Cyclohexane, isopentane, methylcyclohexane, glycerol, propylene glycol (Wako, JIS S grade), and ethanol (Wako, Super special grade) were dehydrated by the use of molecular sieves 3A and passed through a silica-gel column. Isopropyl alcohol, *N*-methylformamide, and tetrahydrofuran (Wako, JIS S grade) were used without further purification. The absorption and emission spectra were recorded on a Hitachi EPS-3 recording spectrophotometer and a Hitachi MPF-2A fluorescence spectrophotometer respectively. The concentrations of the sample solutions used in fluorescence measurements at room temperature are less than 10^{-3} mol dm^{-3} and the solutions were not degassed. The degree of polarization, P, was measured by the method of photoselection.[13,14] The temperature of solutions was varied from 77 to 300 K by the use of a metal cryostat (Torisha Laboratory, Ltd.).

Results

Figure 1 shows the fluorescence spectra of biphenyl in isopentane (dielectric constant $\varepsilon = 1.843$ at 20 °C), isopropyl alcohol ($\varepsilon = 19.92$ at 25 °C), methanol ($\varepsilon = 32.70$ at 25 °C), and *N*-methylformamide ($\varepsilon = 182.4$ at 25 °C). The spectrum of biphenyl in isopentane shows a sharp vibrational structure but has no 0-0 band. The spectra observed in cyclohexane, in methylcyclohexane, and in an isopentane–methylcyclohexane mixture (3 : 1) are almost the same as those in isopentane. Biphenyl shows less sharp fluorescence spectra in ethanol, methanol, and isopropyl alcohol than in isopentane. The shoulder which is assigned to the 0-0 band is observed. The spectrum in *N*-methylformamide exhibits a diffuse vibrational structure and has an obvious 0-0 band. Spectra similar to that in *N*-methylformamide are observed in propylene glycol, glycerol, acetonitrile, and tetrahydrofuran. These findings indicate that the appearance of the 0-0 band depends on the solvent polarity and the spectral sharpness decreases with an increase in the dielectric constant of the solvent.

The temperature and excitation-wavelength dependence of the fluorescence spectra in an isopentane–

methylcyclohexane mixture, propylene glycol, and glycerol are shown in Figs. 2, 3, and 4 respectively. Figure 2 shows that the fluorescence spectra in a hydrocarbon solvents are slightly dependent on the excitation wavelength at room temperature. The spectra at 128 K has the sharpest vibrational bands among the observed fluorescence spectra. At 83 K, the vibrational bands become wide again. The freezing point of isopentane is

113 K; the mixed solvent appears to be rigid at 83 K and fluid at 128 K. The broadening of the vibrational structure with lowering temperature from 128 K to 83 K can be related to the freezing of the solvent. The width of vibrational bands is broader at 173 K and 83 K than at 128 K. The width of vibrational bands increases with increasing the excitation energy. The individual vibrational bands observed at 83 K are displaced more to the blue than those observed at higher temperature. The increase in excitation energy also shifts the individual vibrational bands to the blue. Figure 3 shows that the 0-0 vibrational band is obvious in propylene glycol at room temperature. The excitation-wavelength dependence of the biphenyl fluorescence increases with lowering the temperature. Figure 4 shows that the excitation-wavelength dependence of biphenyl fluorescence is also obvious in viscous solvents such as glycerol even at room temperature.

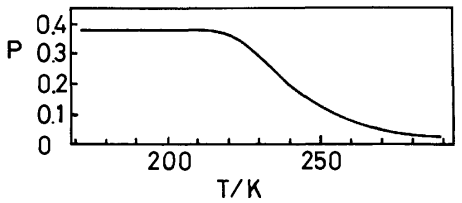

Fig. 5. The temperature dependence of the fluorescence polarization excited at 270 nm and monitored at the peak of 0-1 vibrational band.

The temperature dependence of P of the biphenyl fluorescence in propylene glycol is shown in Fig. 5. Figure 5 shows that the value of P of the biphenyl fluorescence reaches a maximum at 210 K in propylene glycol. The value of the fluorescence spectra for naphthalene derivatives also reaches a maximum at 210 K in the same solvent.[15]

Discussion

Effect of Molecular Conformations on the Fluorescence Spectra of Biphenyl. At high temperature, the fluorescence spectra of biphenyl in an isopentane–methylcyclohexane mixture are not dependent on the excitation wavelength and no 0-0 band is observed (Fig. 2). The spectrum observed at 128 K is more structured than that at 288 K and the 0-0 band becomes obvious. The spectrum at 83 K has more diffuse vibrational bands than those at 128 K.

The temperature and excitation-wavelength dependences in propylene glycol and glycerol are shown in Figs. 3 and 4. The spectral sharpness in the two solvents is different from that in hydrocarbon solvents but the energies of the individual vibrational bands are almost the same in these solvents. Figures 2—4 show that the temperature and viscosity of sample solutions, as well as the excitation wavelength, have an important effect upon the biphenyl fluorescence. This complex behavior may be interpreted in terms of the intramolecular geometric relaxation.[12]

We can classify the processes of the intramolecular

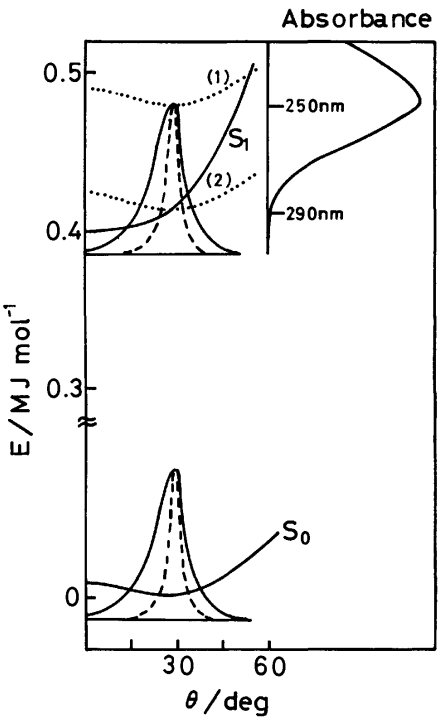

Fig. 6. A schematic potential energy curves of biphenyl for the angle of twist.
Curves (1) and (2) plot the potential curves which are higher in energy by an amount corresponding to 250 and 290 nm radiation respectively. Absorption and Boltzmann distribution at 300 K (——) and 77 K (·····) are also indicated.

geometric relaxation of biphenyl into five categories. (1) Vibrational relaxation, (2) emission without geometric relaxation, (3) geometric relaxation along the angle of twist between the planes of two benzene units of biphenyl(θ), (4) emission from incompletely relaxed conformers, (5) emission from the completely relaxed conformers in the excited state. Process (3) is considered to be rate-determing. When solvent viscosity increases with lowering the temperature, process (3) is gradually prevented and process (4) gradually increases. At sufficiently low temperature, process (3) is prevented completely due to high viscosity of solvent and emission occurs only *via* process (2). Under such conditions emission emerges only from the conformers having the same conformation as in the ground state. Figure 6 illustrates such a situation. The ground- and excited-state potential curves as a function of θ and the Boltzmann distribution of conformational population were estimated from the calculations by Imamura and Hoffmann[6] and Golebiewski and Parczewski.[7] Curves (1) and (2) indicate the energy levels obtained by exciting the ground-state biphenyl with 250-nm and 290-nm radiations respectively. The potential curve of the ground state has two minimums at about $\theta = \pm 30°$, while that of the S_1 has a minimum at $\theta = 0°$. The energy required to excite biphenyl to the S_1 excited state is larger at large θ than at small θ. The 290-nm radiation excites only biphenyl whose θ is smaller than about 30°, while the 250-nm radiation makes it possible to excite

all possible conformers of biphenyl in the ground state This leads to different distributions of conformers dependent on the excitation wavelength in the excited state and results in the fluorescence spectra being dependent on the excitation wavelength.

If process (3) is completed before emission, fluorescence emerges from the well-relaxed excited conformers. Under such conditions, a fluorescence spectrum independent of the excitation wavelength is expected to be observed. As the temperature decreases, the distribution about the equilibrium conformation becomes narrow due to the Boltzmann distribution law. This makes the fluorescence spectrum sharpen on lowering the temperature down to the freezing point of the solvent.

The fluorescence spectrum of biphenyl varies slightly with the excitation wavelength even at room temperature (Fig. 2). This implies that the fluorescence from the incompletely relaxed conformers can not be neglected at room temperature.

When process (3) is gradually hindered with decrease in temperature, biphenyl molecules tends to fluoresce from the imcompletely relaxed or unrelaxed conformers in the excited state. When process (3) in completely hindered, the distribution of excited conformers is the same as that of the ground-state conformers. The fluorescence under such conditions is the superposition of various fluorescences corresponding to different conformations and is broader than at higher temperature. Berlman also found that nonplanar conformers of polyphenyls show diffuse fluorescence spectra and planar conformers show structured ones.[16]

The above discussion is supported by the results in Fig. 2. The isopentane–methylcyclohexane mixture is fluid at 128 K and rigid at 83 K. Intramolecular geometric relaxation occurs effectively at 128 K and is prevented completely at 83 K. The features of the fluorescence spectra at 128 K are determined by the distribution of conformers which attain equilibrium fitting to the S_1 state, while those at 83 K are determined by a conformational distribution identical to that in the ground state. In addition to this, the potential curve for S_1 is steeper around $\theta=30°$ than that for S_0. As a consequence of these facts, biphenyl shows a more broad and blue-shifted fluorescence in an isopentane–methylcyclohexane mixture at 83 K than at 128 K. In the case of the fluorescence spectra in propylene glycol and glycerol, the solution is viscous to a certain extent even at room temperature. Since viscousness of the solvent prevents the complete intramolecular geometric relaxation of excited-state biphenyl even at higher temperature, the excitation-wavelength dependence of the biphenyl fluorescence in viscous solvents is larger than that in fluid solvents. The viscosity of the solvents such as propylene glycol and glycerol gradually increase with lowering the temperature; no drastic change with lowering the temperature is observed in these solvents, unlike the result for the isopentane–methylcyclohexane mixture (Figs. 3 and 4).

The above interpretation is also supported by considering the temperature dependence of the intersystem-crossing rate constants. The values of k_{TM} for biphenyl in propylene glycol by 250-nm and 290-nm excitations are almost the same in the temperature range from 303 to 200 K. There is a difference in the k_{TM} values based on the two excitations at 250 and 290 nm below 200 K.[11] These findings indicate that propylene glycol is completely rigid below 200 K against any molecular rotation including the relaxation along θ during the lifetime of the fluorescent state. The rigidity of propylene glycol is also confirmed by the result of Fig. 5. The P of the biphenyl fluorescence in the solvent reaches a maximum at 210 K. At the temperature below 200 K the distribution of conformers in the fluorescent state is the same as in the ground state. In conclusion, the effects of temperature, viscosity, and excitation-wavelength on biphenyl fluorescence can be interpreted by considering the intramolecular geometric relaxation.

The Ham Effect on the Fluorescence Spectra of Biphenyl. The symmetry-forbidden 0-0 band appears in the absorption spectra of benzene[17,18] and in the fluorescence spectra of pyrene.[19] The band is known as the Ham band. The MO calculations[5,6,20] and experimental findings[21] revealed that the lowest absorption band of biphenyl is symmetry-forbidden regardless of θ. It is seen from Fig. 1 that the appearance and the intensity of the 0-0 band of biphenyl fluorescence are related to the solvent polarity. The 0-0 band is also affected by the change of temperature. The lowering of temperature changes the solvent polarity, solvent viscosity, and the dispersion forces between biphenyl and solvent molecules. Figures 2—4 indicate that the 0-0 band becomes obvious with lowering the temperature. It is therefore concluded that the intensity change of the 0-0 band of biphenyl fluorescence in various solvents is attributable to the Ham effect.

The Electric-field Analyses of a System with an Axial Symmetry and Its Application to the Infrared Intensity

Isao KANESAKA,* Yoshihiro HIROYA, and Kiyoyasu KAWAI
Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received April 25, 1981)

The method of solving the Laplace equation for a system with axial symmetry is formulated in terms of the finite element method. The molecule having C_{3v} point symmetry is assumed to have axial symmetry, and the van der Waals radii of the component atoms are used to estimate the shape of the central molecule. The method is applied to the IR intensity of the C≡N stretching mode of acetonitrile in various states. The observed intensities are adequately explained by the use of the local and reaction fields, except for the intensity in a solution diluted infinitely in chloroform. The intensity in chloroform can, however, reasonably be explained by taking the hydrogen bond into consideration.

It should be possible to determine the electric properties relevant to the estimation of the IR intensity in a liquid phase with a polar molecule by means of the Laplace equation. Ordinarily, however, the Laplace equation under a boundary condition is not easy to solve analytically, except for a system with spherical symmetry, (spherical model). The finite element method, which has been developed for just such a problem,[1,2] is used for the present study.

In this paper we regard a system with a central molecule with C_{3v} point symmetry as having axial symmetry. Under this assumption, we can treat any system by the finite element method; the difficulty in placing the precise shape of the central molecule into the Laplace equation is thereby eliminated. The present study is, thus, more general than that previously reported for a uniformly polarized ellipsoid.[3]

Since the quantities obtained directly from the Laplace equation are the potential, Ψ, and the macroscopic field, E_m, we propose a method of obtaining the local radiation field, E_L, or the reaction field, E_R, derived by the permanent dipole moment; E_L depends partially on the polarization charge stored on the boundary between the central molecule and the media, while E_R depends completely on it.

The absolute infrared intensity, Γ_a, is given by:[4]

$$\Gamma_a = \frac{8\pi^3}{3hc} N_a m_1^2, \tag{1}$$

where h is the Planck constant, c is the velocity of light, N_a is the Avogadro constant, and m_1 is the transition dipole moment, defined as follows:

$$m_1 = \mu_1 + \alpha_1 E_R, \tag{2}$$

where μ_1 and α_1 originate from the dipole moment and the polarizability derivatives respectively. It is well known that Γ_a is related to the observed intensity, Γ, as follows:

$$\Gamma = \Gamma_a E_L^2/n, \tag{3}$$

where n is the refractive index.

The value of E_L has been estimated mainly from the spherical model, and a quantitative discussion of Eq. 2 has been undertaken by several authors.[5,6] Kakimoto and Fujiyama[5] have calculated E_R on the basis of the model of dipole-dipole interaction and referred to the values of μ_1 and α_1. Since their method is essentially different from ours, the values of E_R obtained from their method should also differ from ours.

The intensity of the IR band of the C≡N stretching mode of acetonitrile diluted infinitely in chloroform (≈0% chloroform solution) has been reported to be stronger[7] than that to be expected qualitatively. Since our method can easily be expanded to a hydrogen-bonded system, it is also applicable to a quantitative treatment of this abnormal behavior.

Method

The Laplace equation for a system with axial symmetry is given, in terms of the cylindrical coordinates as follows:

$$\varepsilon_r \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \Psi}{\partial r}\right) + \varepsilon_z\left(\frac{\partial^2 \Psi}{\partial z^2}\right) = 0, \tag{4}$$

where ε_r and ε_z are the dielectric constants of the r and z directions respectively; in the present system, we have the following conditions: $\varepsilon_r \neq \varepsilon_z$ in the central molecule and $\varepsilon_r = \varepsilon_z = \varepsilon_2$ in the media. The functional equivalent to Eq. 4 in one of the elements is given by:[1]

$$\chi_e = \frac{1}{2}\iiint\left[\varepsilon_r\left(\frac{\partial \Psi}{\partial r}\right)^2 + \varepsilon_z\left(\frac{\partial \Psi}{\partial z}\right)^2\right] r dr dz. \tag{5}$$

On the basis of the isoparametric elements,[1,2] the trial function, Ψ, and the variables, r and z, are assumed to be:

$$\Psi = (2L_1-1)L_1\Psi_1 + (2L_2-1)L_2\Psi_2 + (2L_3-1)L_3\Psi_3 + 4L_1L_2\Psi_4 + 4L_2L_3\Psi_5 + 4L_3L_1\Psi_6 = \mathbf{N}\Psi_e, \tag{6}$$

and:

$$r = \mathbf{N}|r_1r_2r_3r_4r_5r_6| = \mathbf{N}\mathbf{r}_e, \tag{7}$$

and:

$$z = \mathbf{N}|z_1z_2z_3z_4z_5z_6| = \mathbf{N}\mathbf{z}_e \tag{8}$$

where $\mathbf{N}$ is the displacement model, where L_i is defined as $\Delta L_i/\Delta ABC$, and where Ψ_j, r_j, and z_j are the nodal values of the potential, r and z respectively, as is shown in Fig. 1. According to the definition of L_i, we can introduce the transformation $\xi = L_1$, $\eta = L_2$, and $1-\xi-\eta = L_3$. By the use of $\mathbf{N}$, ξ, and η, we obtain the derivatives in Eq. 5 as follows:

$$\begin{vmatrix} \frac{\partial \Psi}{\partial r} \\ \frac{\partial \Psi}{\partial z} \end{vmatrix} = \mathbf{J}^{-1} \begin{vmatrix} \frac{\partial \mathbf{N}}{\partial \xi} \\ \frac{\partial \mathbf{N}}{\partial \eta} \end{vmatrix} \Psi_e, \tag{9}$$

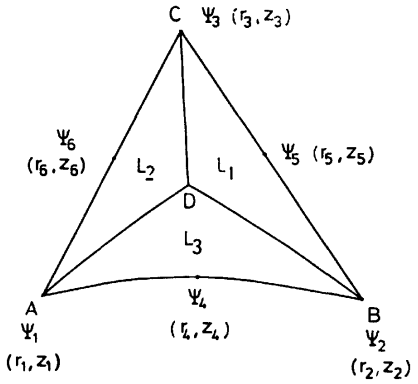

Fig. 1. The isoparametric element and the definition of Ψ_i, r_i, or z_i.

where:

$$\mathbf{J} = \begin{vmatrix} \frac{\Sigma \partial N_i}{\partial \xi} r_i & \frac{\Sigma \partial N_i}{\partial \xi} z_i \\ \frac{\Sigma \partial N_i}{\partial \eta} r_i & \frac{\Sigma \partial N_i}{\partial \eta} z_i \end{vmatrix}. \tag{10}$$

By substituting Eq. 9 into Eq. 5, we obtain the functional as a function of $\boldsymbol{\Psi}_e$:

$$\chi_e = \frac{1}{2} \tilde{\boldsymbol{\Psi}}_e \mathbf{Q}_e \boldsymbol{\Psi}_e, \tag{11}$$

where:

$$\mathbf{Q}_e = \iint \left(\varepsilon_r \frac{\partial \tilde{\mathbf{N}}}{\partial \xi} \tilde{\mathbf{J}}^{-1} \mathbf{J}^{-1} \frac{\partial \mathbf{N}}{\partial \xi} + \varepsilon_z \frac{\partial \tilde{\mathbf{N}}}{\partial \eta} \tilde{\mathbf{J}}^{-1} \mathbf{J}^{-1} \frac{\partial \mathbf{N}}{\partial \eta} \right) \mathbf{N} r_e \det[\mathbf{J}] d\xi d\eta. \tag{12}$$

According to the stationary condition of $\delta \chi_e = 0$, we obtain this equation:

$$\mathbf{Q}_e \boldsymbol{\Psi}_e = 0. \tag{13}$$

Since Eq. 13 holds for all elements, we obtain a final equation constructed from all the nodal values (see Appendix) as follows:

$$\mathbf{A} \boldsymbol{\Psi} = 0. \tag{14}$$

Equation 14 is solved under a given boundary condition, and we get the electric field from Eq. 9. E_m is obtained under the boundary condition of $\Psi_\infty = E_\infty z (= z)$ at r, $|z| \to \infty$.

Analyses of E_L and E_R

Although E_m is a field already compensated for by that of polarization, E_S, the extent of the compensation depends on the shape of the central molecule. Generally, the extent of a prolate top molecule is smaller than that of an oblate one.[3] This is reflected in E_L through the self-field of polarization, E_S^v, in a vacuum. For instance, the value of E_L in the present study is smaller than that to be expected from the spherical model, especially in liquid acetonitrile; E_L in the spherical model[8] is: $E_L = (\varepsilon_\infty + 2) E_\infty / 3$ ($\varepsilon_\infty = n^2$). Since this discrepancy is inevitable, we define E_L as follows:

$$E_L = E_m - E_S^v. \tag{15}$$

We calculate E_S^v by means of the general method, which corresponds to the field analysis of permanent polarization or of a magnet with axial symmetry.

The polarization charge, ρ_p, stored on a boundary results from induced polarization, so that ρ_p is given according to Gauss' expression as follows:

$$\rho_p = \mathbf{P} \cdot \mathbf{n} = \{(\varepsilon_r - 1) E_r + (\varepsilon_z - 1) E_z\} \cdot \mathbf{n}, \tag{16}$$

where $\mathbf{n}$ is the normal vector at the boundary. In the present problem, Eq. 16 is, thus, the boundary condition, and the functional is given by:

$$\chi_e = \frac{1}{2} \iint \left[\varepsilon_r \left(\frac{\partial \Psi}{\partial r} \right)^2 + \varepsilon_z \left(\frac{\partial \Psi}{\partial z} \right)^2 \right] r dr dz + \int_C \rho_p \Psi r dC, \tag{17}$$

where the linear integral is carried out along the boundary, C, between the central molecule and the media. The formulation of Eq. 17 is similar to that of Eq. 5; accordingly, we obtain the following equation (see Appendix):

$$\mathbf{A} \boldsymbol{\Psi} = \mathbf{B}, \tag{18}$$

where $\mathbf{A}$ is the matrix given in Eq. 14, except that $\varepsilon_r = \varepsilon_z = 1$ in all regions, and $\mathbf{B}$ is the column matrix determined from the linear integral in Eq. 17. Since $\mathbf{B}$ is known from the boundary condition of Eq. 16, E_S^v can be obtained from $\boldsymbol{\Psi}$ in Eq. 18.

The polarization charge, ρ_μ, stored on the boundary by the dipole-moment field is obtained from an equation similar to Eq. 16. Then we get E_R from Eq. 18. However, since E_R is zero if $\varepsilon_1 = \varepsilon_2$ and depends on $\varepsilon_1 - \varepsilon_2$, where ε_1 represents the dielectric constant of the central molecule, E_R can be obtained by the simple method to be described below.

We first calculate the potentials of $\Psi_{\varepsilon\infty}$ and $\Psi_{\varepsilon s}$, which are obtained, respectively, under the conditions of $\varepsilon_1 = \varepsilon_2 = \varepsilon_\infty$ and $\varepsilon_1 \neq \varepsilon_2 = \varepsilon_S$ (static dielectric constant). Second, we calculate this equation:

$$\Psi_R = \Psi_{\varepsilon s} - \Psi_{\varepsilon\infty}. \tag{19}$$

Ψ_R may be regarded as the potential, as for E_R. This method is simple because we have an analytical solution of $\Psi_{\varepsilon\infty}$; we assume the position of the point dipole to be the center of the C≡N bond of acetonitrile. $\Psi_{\varepsilon s}$ is obtained under the boundary condition of $\frac{\mu}{\varepsilon_1} \frac{z}{(r^2+z^2)}$ at r, $z \to 0$. It should be noted that the central molecule interacts with the media through the static dielectric constant;[9] the molecules around the central molecule are oriented so as to produce ε_s.

Since E_L and E_R in the central molecule are generally heterogeneous, it is necessary to average them. As long as we regard α_1 in Eq. 2 as the molecular constant, it is clear that the average of E_R over the z axis of the central molecule should be used as the reaction field. This process is given by:

$$\bar{E}_R = \frac{\int_b^a E_R dz}{D} = -\frac{\Psi(a) - \Psi(b)}{D}, \tag{20}$$

where a and b are the coordinates of the boundary on the z axis and where D is the distance between them. The average of the E_L values, $\bar{E}_L$, is also given by Eq. 20.

Equation 20 does not have a serious influence on E_L and E_R under the boundary conditions described above, but it does play an important role if E_R varies drastically.

Results and Discussion

The shape of acetonitrile, as estimated from the van der Waals radii[10] of the component atoms, is given in Fig. 2. The values of ε_∞ are obtained from the refractive indices,[11] and those of ε_s from the standard Table;[12] apart from the formulation, we use the condition of $\varepsilon_r=\varepsilon_z=\varepsilon_l$. The dipole moment of acetonitrile, 3.39 D,[13] is used.

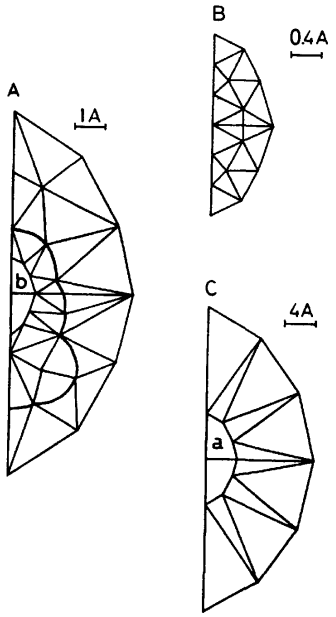

Fig. 2. The molecular shape (broad solid line) and the elements used for E_R. A and B are the expansion of a and b, respectively.

Table 1. Observed and calculated intensities (cm^2/mol) of the C≡N stretching of acetonitrile

State	$\Gamma^{a)}$	$\bar{E}_L/E_\infty$	Γ_a	$\bar{E}_R\times10^{-5}$	Γ_c
Liquid	444	1.20	415	0.906	396
≈0% In CCl_4	222	1.25	208	0.125	240
Gas	159	1.00	159	−0.493	144
≈0% In $CHCl_3$	500	1.24	470	0.535	317
H. B.[b)]	500	1.27	448	1.080	436

$\bar{E}_R$ in D/cm^3. a) From Ref. 7. b) From the hydrogen-bondmodel.

The intensities of the C≡N stretching mode in various states[5,7] are given in Table 1. As has been mentioned above, E_∞ is assumed to be 1.0, and the value of $\bar{E}_L$ in a liquid is smaller than that of 1.27 obtained from the spherical model. Accordingly, the values of $\bar{E}_L$ in Table 1 vary more gently with the dielectric constants than those to be expected from the spherical model. Since E_R is taken to be zero if $\varepsilon_1=\varepsilon_2$, the value of $\bar{E}_R$ in the gaseous state becomes negative. The value of $\bar{E}_R$ in a liquid is also smaller than that to be expected from the spherical model, 0.11×10^6 D/cm^3.

In order to estimate the values of the two parameters, μ_1 and α_1, we use the values of Γ_a defined by Eq. 3 and obtained using $\bar{E}_L$ in Table 1, except for the value of Γ_a for a ≈0% chloroform solution; the values thus obtained, $\mu_1=0.0295$ (D) and $\alpha_1=0.113$ (A^3), are used to calculate the intensity of $\Gamma_c=8\pi^3/(3hc)N_a\cdot(\mu_1+\alpha_1E_R)^2$ in Table 1. The agreement between Γ_a and Γ_c is satisfactory in each state, except for a ≈0% chloroform solution. The most important features are that the intensity in the gaseous state is explained simultaneously and that the value of α_1 agrees well with the observed value.[5,14]

The value of $\bar{E}_R$ for a ≈0% chloroform solution in Table 1 is reasonable if the interaction between the central molecule and the media takes place through the static electric force. However, Table 1 shows the imperfection in this static electric model. On the other hand, it is reasonable to expect that the hydrogen bond is formed between the nitrogen atom of actonitrile and the hydrogen atom of chloroform in a dilute solution and that, accordingly, the two molecules coordinate, as is shown in Fig. 3.

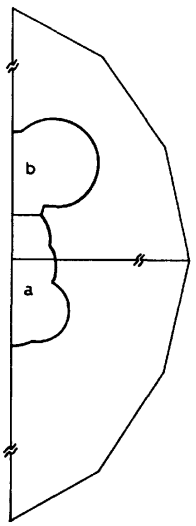

Fig. 3. The hydrogen-bond model of acetonitrile with chloroform. The shapes of acetonitrile and chloroform are given in a and b, respectively.

According to this hydrogen-bond model, the dipole-moment field, $\bar{E}_\mu$, which arises from the chloroform is added to $\bar{E}_R$; $\bar{E}_s$ should be recalculated under the condition of $\varepsilon_s=\varepsilon_\infty$ in the region of the chloroform. To calculate $\bar{E}_\mu$, the dipole moment of the chloroform, 1.55 debye,[13] is set at the center of the hydrogen and chlorine atoms on the z axis in the region of b in Fig. 3. The distance of the hydrogen bond of [C-H···N] is assumed to be 2.8 Å.

In the molecular shape of acetonitrile shown in Fig. 3, $\bar{E}_L$ and $\bar{E}_R$ are 1.27 and 0.331×10^5 D/cm^3 respectively, and $\bar{E}_\mu$ is 0.750×10^5 D/cm^3, resulting in $\Gamma_c=436$ (cm^2/mol) by the use of the same values of μ_1 and α_1 as have been presented above; they are also

given in Table 1. The refinement of Γ_c shows that E_μ is quite important in the intensity of the hydrogen-bonded system. The conclusion to be drawn from the fact that μ_1 is constant in various states is that the intensity in the present system depends only on the electric properties.

The numerical calculations were carried out by the use of the computer, FACOM 230-45S, of Toyama University.

Appendix

We will here outline in more detail the matrix **A** or **B** in Eq. 18 according to our computer program. **A** is constructed by the interconnection of each element. We define the nodal points for two elements (a and b), as is shown in Fig. A-1; the

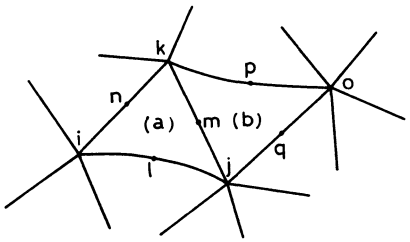

Fig. A-1. The two adjacent elements a and b. The numberings of the nodes (●) are given by i, j, ….

nodal points are numbered arbitrarily. The matrices, $\mathbf{Q}(6\times 6)$, of these elements, a and b, are denoted, respectively, by $\mathbf{Q}'$ and $\mathbf{Q}''$, which are defined as follows:

$$\mathbf{Q}' = \begin{vmatrix} i\ j\ k\ l\ m\ n \\ Q'_{rs} \end{vmatrix} \qquad \text{(A-1)}$$

and:

$$\mathbf{Q}'' = \begin{vmatrix} j\ o\ k\ q\ p\ m \\ Q''_{rs} \end{vmatrix} \qquad \text{(A-2)}$$

where $1\leq r,s\leq 6$. According to the condition of $\delta\chi=\sum\delta\chi_e$, we have a matrix element of **A** as follows:

$$\mathbf{A}\Psi =$$

i	j	k	m	
Q'_{11} ·····	Q'_{12} ·····	Q'_{13} ·····	Q'_{15} ·····	Ψ_i
	$Q'_{22}+Q''_{11}$ ···	$Q'_{23}+Q''_{13}$ ···	$Q'_{25}+Q''_{16}$ ···	Ψ_j
Sym.		$Q'_{33}+Q''_{33}$ ···	$Q'_{35}+Q''_{36}$ ···	Ψ_k
			$Q'_{55}+Q''_{66}$ ···	Ψ_m

(A-3)

All the matrix elements of **A** in Eq. A-3 are obtained in a similar manner.

We get the **B** column matrix by means of numerical integration. We define the following linear integral in an element:

$$\chi_B = \int_C \rho_p \Psi r dC \qquad \text{(A-4)}$$

It then follows that:

$$\delta\chi_B/\delta\Psi_e = \int_C \rho_p \mathbf{N} r dC$$

$$= \int_C \rho_p |(2L_1-1)L_1\ (2L_2-1)L_2\ 0\ 4L_1L_2\ 0\ 0\ |rdC \qquad \text{(A-5)}$$

where C is the boundary defined in Fig. A-2. This process is carried out for the elements with the C boundary in the central molecule.

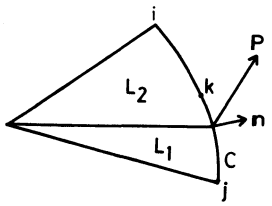

Fig. A-2. Linear integral along the boundary C. **P** is the induced polarization in the central molecule on C, and **n** is the normal vector. L_1 and L_2 are defined in Fig. 1.

The Interaction of a Neutral Polymer with Small Ions in Solution. I. A Method for the Analysis of Ion Binding to a Neutral Polymer

Hiroshi Awano, Katsumichi Ono,* and Kenkichi Murakami
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received October 28, 1981)

A method for the analysis of ion binding to a neutral polymer, such as poly(oxyethylene) (POE), based on the one-dimensional lattice model has been proposed. The grand partition function for the one-dimensional lattice has been given by the product of the statistical weight matrix. Interaction between the ions bound to the lattice points has been well approximated by the Debye-Hückel pair-by-pair potential, and the distance between the bound ions has been assumed to be the root mean square end-to-end distance of the partial chain. Based on the model, an equilibrium constant has been defined which is referred to the *binding constant.*

It has been well known that a neutral polymer, such as poly(oxyethylene) (POE), forms complexes with a variety of metal salts in organic solvents.[1-6] In our previous paper,[6] we have given a method for elucidating the quantitative aspects of the ion binding to POE by means of conductometry. This method, which is based on a discrete site-binding model, enables us to calculate the minimum separation between two adjacent bound charges as a function of the ionic strength. The stoichiometry of the potassium ion complex in a methanol solution was determined to be four monomer units per ion from the intrinsic value of the charge separation at a high concentration limit.

The next important step in the investigation is the interpretation of the binding behavior in terms of the electrostatic potential set up by bound cations. The investigation along this line has been developed extensively for the potentiometric titration of polyacid,[7] but, because of the high charge density on the polymer chain, the straightforward application of the screened Debye-Hückel potential fails to reproduce the experimental titration curves in most cases. For the POE–salt systems, however, the charge density on a polymer chain is far lower than in the cases of typical polyelectrolyte systems. Thus the electrostatic interaction can be expected to be represented by the sum of the Debye-Hückel pair-by-pair interactions between bound cations.

In this paper, we propose a method for analyzing ion binding to POE based on the one-dimensional lattice model. It is therein assumed that a lattice point is composed of four monomer units; that is to say, a bound cation is surrounded by four ether-oxygen atoms.[6] The grand partition function for the one-dimensional lattice is expressed by means of a matrix method. In calculating the Debye-Hückel pair-by-pair potential, the distance between bound cations is approximated by the root mean square end-to-end distance of the partial chain, which is given by the Porod-Kratky model. The concrete application of the method will be discussed in the following paper.[8]

Treatment of Binding Equilibria. It can be considered that there are three approaches to treat the binding equilibria of linear polymer and small ions in solutions.

The first approach is to treat the equilibrium as a usual chemical equilibrium, regarding each polymer and its complexes as a different chemical species. In general, however, a ligand containing n sites can be completely characterized by $2^{n-1}n$ equilibrium constants.[9] For a very large n, an infinite number of species must be considered, and the problems becomes quite complicated and no effective results are obtained. Therefore, we must abandon this approach.

The second approach is to assume that binding sites supposed to be arranged on a polymer chain are uniformly distributed in the solution and behaved like low-molecular ligand; this is the so called *low-molecular analogy*. Many workers in this field have used this approach, but it has several defects. The assumption of a uniform distribution of binding sites becomes less tenable as the solution is more dilute, since the binding sites are connected with one another on a polymer chain. Next, since all the thermodynamic quantities are usually defined as adopting an infinite dilution as the reference state, these quantities, including the equilibrium constant, have an ambiguous physical meaning in the case of these polymer systems. In dilute solutions, the interaction between bound ions are, in general, greater than those between unbound ones. As a result, a marked anti-cooperativity appears on ion binding. In this approach, therefore, the equilibrium constant does not only depend intensely on the concentrations of the polymer and of the ion, but also has itself an ambiguous physical meaning, whereas the treatment is very easy. An example will be discussed in the following paper.[8]

The third approach is to regard the polymer chain as a one-dimensional lattice and to consider the binding equilibrium as the equilibrium between the *bulk* solution and the lattice (*one-dimensional lattice model*). The equilibrium constant can be defined as a measure of the tendency of the occupation of the lattice points, as will be discussed below, and the equilibrium constant has no ambiguity in its physical meaning, unlike the equilibrium in low-molecular analogy. If the interaction between the ions occupying the lattice points can be estimated by any method, analysis can be performed without difficulty. This approach, which keeps of the connectivity of the polymer, seems to be the most appropriate. Liem *et al.*[7] analyzed the potentiometric titration curves of polyacid using this approach, but they confused the one-dimensional lattice model with the low-molecular analogy throughout their discussion. In this paper, we overcome this type of confusion and develop a systematic discussion based on the one-dimensional lattice model.

The One-dimensional Lattice Model. We consider a one-dimensional lattice having N lattice points, where the total energy of the system may be expressed by the following equation:

$$\Phi(N,M) = \sum_{i=1}^{N} E\sigma_i + \sum_{i=1}^{N} \sum_{j=i+1}^{N} J_{ij}\sigma_i\sigma_j, \quad (1)$$

$$M = \sum_{i=1}^{N} \sigma_i, \quad (2)$$

where E is the binding energy; J_{ij}, the interaction energy between the particles occupying the ith and jth lattice points, and σ_i, the index whose value is 1 or 0 when the ith lattice point is occupied or unoccupied respectively. Thus, the partition function of the system is given by:

$$Z(N,M) = \sum_{\text{all}} \exp[-\Phi(N,M)/RT], \quad (3)$$

where $\sum_{\text{all}}$ means the summation over all the states in which M out of N lattice points are occupied. Introducing the chemical potential, μ, of the particle, we have the grand partition function given by:

$$\Xi = \sum_{M=0}^{N} Z(N,M)\exp(M\mu/RT). \quad (4)$$

Now we alter the form of Eq. 3 to:

$$Z(N,M) = \exp(-ME/RT) \times \sum_{\text{all}} \exp\left(-\sum_{i=1}^{N} \sum_{j=i+1}^{N} J_{ij}\sigma_i\sigma_j/RT\right). \quad (5)$$

If we define the normalized activity of the particle as:

$$\xi = \exp[(\mu-E)/RT], \quad (6)$$

then Eq. 4 becomes:

$$\Xi = \sum_{M=0}^{N} \xi^M \sum_{\text{all}} \exp\left(-\sum_{i=1}^{N} \sum_{j=i+1}^{N} J_{ij}\sigma_i\sigma_j/RT\right). \quad (7)$$

If we calculate Ξ, then the degree of binding, that is, probability that a lattice point is occupied, will be given by:

$$\theta = \frac{RT}{N}\frac{\partial \ln \Xi}{\partial \mu} = \frac{1}{N}\frac{\partial \ln \Xi}{\partial \ln \xi}. \quad (8)$$

Calculation of the Grand Partition Function by the Matrix Method. It is actually impossible to calculate the grand partition function straightforwardly using Eq. 7, particularly in the case of a very large N, so we shall use the matrix method as follows.

Let us first truncate the range of the interaction, supposing that, for a positive integer, k:

$$J_{ij} = \begin{cases} -RT\ln A_m, & \text{for } m \equiv j-i \leqslant k. \\ 0, & \text{for } j-i > k. \end{cases} \quad (9)$$

Thus, Ξ is given by the product of a statistical weight matrix:[7]

$$\Xi = \boldsymbol{e}\boldsymbol{U}_k^N \boldsymbol{e}', \quad (10)$$

where $\boldsymbol{e}$ and $\boldsymbol{e}'$ are the end vectors, as follows:

$$\boldsymbol{e} = (1,1,\cdots,1), \quad \boldsymbol{e}' = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}.$$

$\boldsymbol{U}_k$ is a statistical weight matrix with dimensions of $2^k \times 2^k$, as follows:

For $k=1$,

$$\boldsymbol{U}_1 = \begin{bmatrix} 1 & 1 \\ \xi & \xi A_1 \end{bmatrix}.$$

For $k=2$,

$$\boldsymbol{U}_2 = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ \xi & \xi A_2 & 0 & 0 \\ 0 & 0 & \xi A_1 & \xi A_1 A_2 \end{pmatrix}.$$

For $k=3$,

$$\boldsymbol{U}_3 = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ \xi & \xi A_3 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \xi A_2 & \xi A_2 A_3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \xi A_1 & \xi A_1 A_3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \xi A_1 A_2 & \xi A_1 A_2 A_3 \end{pmatrix}.$$

Similarly, $\boldsymbol{U}_k$ can be expressed for $k>3$.

Equation 8 can be rewritten in the following form in obtaining θ:

$$\theta = \frac{\xi}{\Xi}\frac{\partial \Xi}{\partial \xi} = \frac{\xi \sum_{m=0}^{N-1} \boldsymbol{e}\boldsymbol{U}_k^m \boldsymbol{U}_k' \boldsymbol{U}_k^{N-m-1}\boldsymbol{e}'}{\boldsymbol{e}\boldsymbol{U}_k^N \boldsymbol{e}'}, \quad (11)$$

where

$$\boldsymbol{U}_k' = \frac{\partial \boldsymbol{U}_k}{\partial \xi}.$$

The values of θ can be calculated with a computer using the method of Jernigan.[10] The above method, which is based on the one-dimensional lattice model, follows the method discussed by Liem *et al.*[7] Since, However, a few mistakes regarding thermodynamics appear in their discussion, we have developed the discussion above.

Calculation of the Interaction Energy and Estimation of the Distance between Bound Ions. We shall confine ourselves to the POE–metal salt system as a model one. As has been stated before, it can be expected that, for the present system, the electrostatic interaction is represented by the sum of Debye-Hückel pair-by-pair interactions between bound cations. We therefore suppose that the statistical weight factor, A_m, in Eq. 9 can be expressed by:

$$RT\ln A_m = -\frac{e^2 \exp(-\kappa r_m)}{4\pi\varepsilon r_m}, \quad (12)$$

where e is the elementary charge; ε, the permittivity of the solvent; r_m, the distance between the ions bound to the ith and the $(i+m)$th sites (lattice points), and κ, the Debye's parameter, which is given by:

$$\kappa^2 = \frac{2N_A e^2 I}{\varepsilon k_B T}, \quad (13)$$

in which N_A is the Avogadro constant; I, the ionic strength, and k_B, the Boltzmann constant.

In order to obtain the Debye-Hückel pair-by-pair interaction from Eq. 12, it is necessary to estimate the distance between the bound ions, r_m. Let us now assume that r_m is given by the root mean square end-to-end distance, $\langle R^2_m\rangle^{1/2}$, for a partial chain of POE corresponding to m binding sites.

In the first place, let us estimate the mean square end-to-end distance in the unperturbed state, $\langle R^2_m\rangle_0$. According to Maeda *et al.*,[11] the real chain can be well approximated by a stiff chain, even in the case of a fairly short chain. Therefore, we will use the following equation for the stiff chain:

$$\langle R^2\rangle_0 = 2a_0L\left[1 - \frac{a_0}{L}(1-e^{-L/a_0})\right], \tag{14}$$

in which we take a contour length, L, in the following form:

$$L = nl\sin(\theta/2), \tag{15}$$

where a_0 is the persistence length; n, the number of bonds; l, the bond length, and θ, the bond angle. We thus obtain this relation:

$$\frac{2a_0}{l}\sin(\theta/2) = C_\infty, \tag{16}$$

in which C_∞ is the characteristic ratio. C_∞ is given by the following Flory-Fox relation:

$$C_\infty = \left(\frac{K}{\Phi}\right)^{2/3}\frac{M_b}{l^2}, \tag{17}$$

where $\Phi = 2.6\times10^{21}$ (universal constant), M_b is the molecular weight per bond, and K is the viscosity constant, which is given by $K = [\eta]_\theta/M^{1/2}$ if $[\eta]_\theta$ is the intrinsic viscosity in a theta solvent and M is the molecular weight of the polymer. Thus, Eq. 14 becomes:

$$\langle R^2_m\rangle_0 = C_\infty nl^2 \times\left[1 - \frac{C_\infty}{2n\sin^2(\theta/2)}\left\{1 - \exp\left(-\frac{2n\sin^2(\theta/2)}{C_\infty}\right)\right\}\right]. \tag{18}$$

If we suppose that a binding site is composed of four monomer units,[6] then we obtain:

$$\langle R^2_m\rangle_0 = 132.7\,m \times\left[1 - \frac{0.3150}{m}\{1 - \exp(-3.174\,m)\}\right]\text{Å}^2,** \tag{19}$$

by substituting the following values in Eq. 18:

$$n = 12\,m,$$
$$l = 1.46\text{ Å},**$$
$$\theta = 111.5°,$$
$$K = 1.7\times10^{-3}\text{ dl g}^{-1.12)}**$$

Next, let us estimate the expansion factor, α. Since α depends on m in general, we will express the expansion factor as $\alpha(m)$. If $\alpha(m)$ follows the fifth power law, then:

$$\alpha(m)^5 - \alpha(m)^3 = Cm^{1/2}, \tag{20}$$

where the constant, C, is determined from the value of m corresponding to the total number of binding sites on a polymer chain, m_0 (for example, $m_0 = 140.2$ for a chain of $M = 2.47\times10^4$), and from:

$$\alpha(m_0) = ([\eta]/[\eta]_\theta)^{1/3}, \tag{21}$$

that is,

$$C = \frac{\alpha(m_0)^5 - \alpha(m_0)^3}{m_0^{1/2}}. \tag{22}$$

By substituting Eq. 22 in Eq. 20, the value of $\alpha(m)$ corresponding to an arbitrary m is obtained. Finally, we obtain the distance between bound ions in the perturbed state from this relation:

$$\langle R^2_m\rangle = \alpha(m)^2\langle R^2_m\rangle_0. \tag{23}$$

Introduction of the Binding Constant. The chemical potential of the ion is written in the following form:

$$\mu = \mu^\ominus + ET\ln a, \tag{24}$$

where $\mu^\ominus$ is the standard chemical potential and a, the relative activity of the ion. Hence, experimentally the degree of binding θ, is obtained as a function of a. On the other hand, the degree of binding is calculated as a function of ξ. Let us now introduce the *binding constant* defined as follows:

$$K_0 = \exp[(\mu^\ominus - E)/RT]. \tag{25}$$

Thus, the normalized activity is expressed as:

$$\xi = K_0a. \tag{26}$$

Therefore, we can obtain a shift factor, $\log K_0$, which best fits the observed plots of θ *vs.* $\log a$ to the calculated curve of θ *vs.* $\log\xi$.

Discussion

Expansion Factors. We have calculated the mean square end-to-end distances for a partial chain of POE both in the unperturbed state and in the 2 mmol dm^{-3} KSCN-methanol system ($\alpha(m_0) = 1.386$). The dependence of these quantities on the number of bonds is shown in Fig. 1. In a perturbed state such as this system, the polymer chain is expanded to a great extent. However, for $m=6$, that is, $\log n = 1.86$ below the point at which

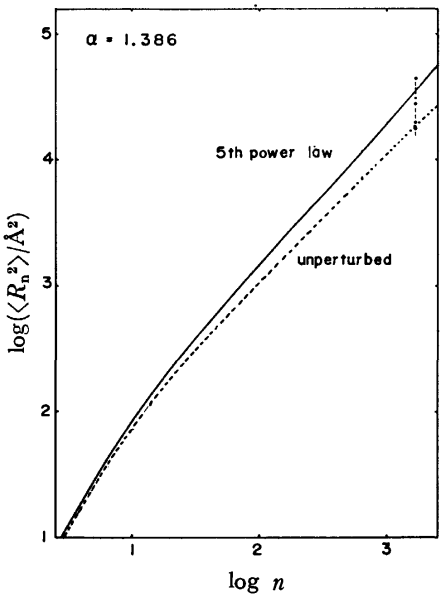

Fig. 1. Dependences of the mean square end-to-end distances for poly(oxyethylene) on the number of bonds, n, in the unperturbed state and in 2 mmol dm^{-3} KSCN–methanol system.

** 1 Å = 1×10^{-10} m; 1 dl = 1×10^{-4} m^3.

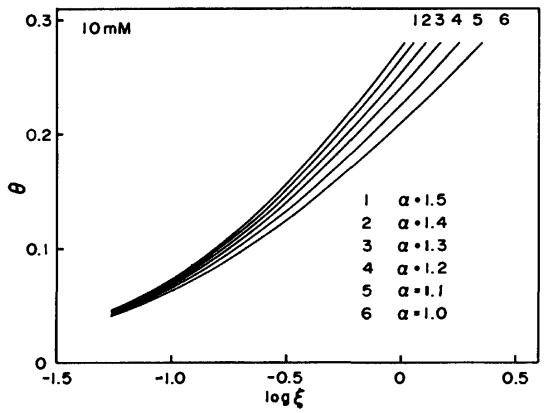

Fig. 2. Dependence of θ *vs.* log ξ curves on the expansion factor, α, for 10 mmol dm^{-3} KSCN–methanol system.

we are concerned, α is less than 1.15, and it is expected that the binding curve (θ *vs.* log ξ) is not very sensitive to the variation in α.

In Fig. 2, the dependence of the binding curve on $\alpha(m_0)$ is shown for the 10 mmol dm^{-3} KSCN–methanol system. As is suggested in Eq. 21, α is proportional to $[\eta]^{1/3}$, so the binding curve is quite insensitive to the variation in $[\eta]$.

Electrostatic Repulsion as a Long-range Interaction. In the foregoing discussion, the electrostatic interaction between bound ions has been assumed to range over only k sites. However, since the electrostatic interaction is a long-range one it is necessary to take a sufficiently large k. Figure 3 shows the binding curves for $k=0$—6, together with the extrapolated curve for $k\rightarrow\infty$ (see below). The degree of binding θ, decreases with an increase in k because of the long range electrostatic repulsion. Apparently, the convergence of the binding curve seems to be bad even for $k=6$. As k increases, however, the order of the statistical weight matrices exponentially increases. Hence it is actually impossible to obtain the degree of binding for a very large k in a

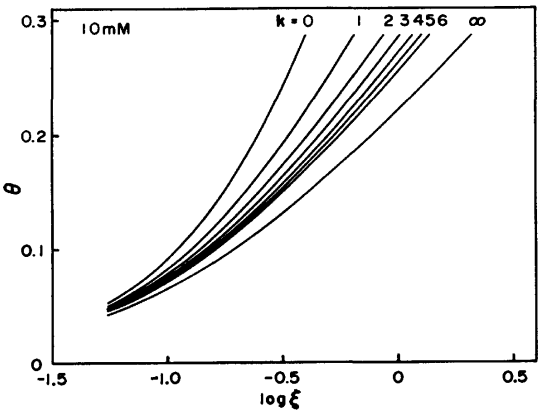

Fig. 3. Dependence of θ *vs.* log ξ curves on the number of sites over which the interaction ranges, k, for 10 mmol dm^{-3} KSCN–methanol system. The curve corresponding to $k\rightarrow\infty$ has been estimated from the extrapolation procedure shown in Fig. 4.

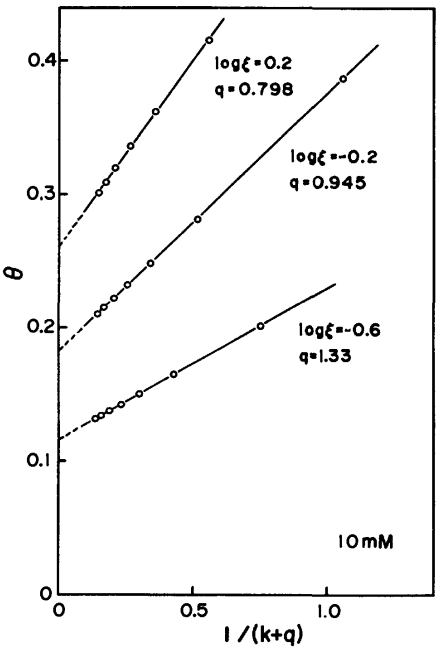

Fig. 4. Extrapolation procedure with the use of parameter, q, for 10 mmol dm^{-3} KSCN–methanol system.

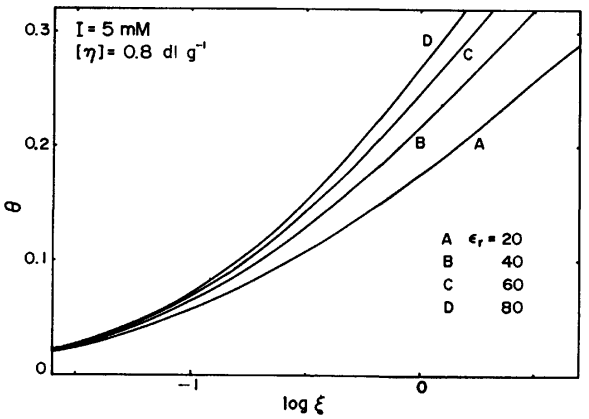

Fig. 5. Dependence of θ *vs.* log ξ curves of the relative permittivity of the solvent for an imaginary system.

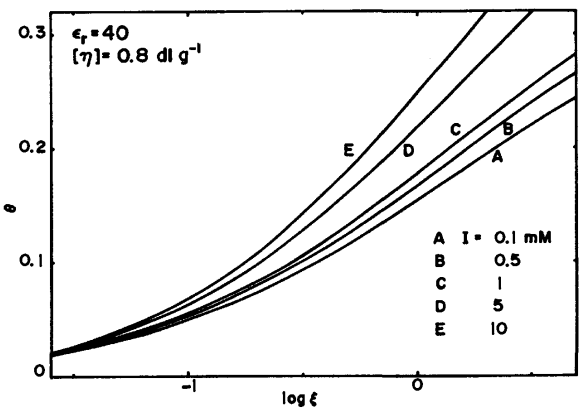

Fig. 6. Dependence of θ *vs.* log ξ curves on the ionic strength for an imaginary system.

straightforward manner.

For the extrapolation, we plotted θ against $1/(k+q)$, where q is a parameter which has been determined so that the correlation coefficient of the plot takes a maximum value. Figure 4 shows the plot thus obtained for several sets of log ξ and q for a fixed ion concentration. The degree of binding corresponding to $k\rightarrow\infty$ is determined as the intercept on the θ axis. This procedure seems to give a more precise extrapolated value than that of Liem *et al.*,[7] who have plotted the degree of the dissociation of polyacids against the reciprocal of the number of sites over which the interaction ranges.

The dependences of the binding curve on the relative permittivity, ε_r, of the solvent and on the ionic strength, I, are shown in Figs. 5 and 6 respectively for an imaginary model system. Both figures show that the degree of binding is less and the binding curve has a smaller slope when the interaction range is longer, that is, when the permittivity or the ionic strength is smaller, as has been expected.

The Interaction of a Neutral Polymer with Small Ions in Solution. II. The Binding of Alkali Metal Ions to Poly(oxyethylene) in Several Organic Solvents

Hiroshi Awano, Katsumichi Ono,* and Kenkichi Murakami
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980
(Received October 28, 1981)

The conductivities for several solutions of alkali metal salts, such as potassium thiocyanate, containing poly(oxyethylene) (POE) have been measured as functions of the POE concentration, C_p. A decrease in the conductivity with an increase in C_p has been observed, particularly in methanol, acetonitrile, propylene carbonate, and sulfolane. For these systems, the binding of the cation has been evaluated from the decrease in conductivity and analyzed by a method based on the one-dimensional lattice model. As well as the solvent effects, the effects of the salt concentration and the effect of the alteration of salt on the binding constant have been discussed.

In the preceding paper in this series,[1] we have established a method for the theoretical prediction of the ion binding to a neutral polymer, such as poly(oxyethylene) (POE), in solution.

In this paper, the binding of alkali metal ions to POE is observed by means of conductometry, and the results are analyzed by applying this method, which is based on the one-dimensional lattice model. Also discussed are the solvent effects on the binding of potassium ion, the effects of the salt concentration on the binding of the potassium ion in propylene carbonate (PC), and the effects of the alteration of salt on the binding of the cation in PC.

Experimental

Reagents. The poly(oxyethylene) sample, with an average molecular weight of 2.47×10^4, was obtained from Wako Pure Chemicals and was used without further purification. Methanol (Wako, >99.6%) was dried over calcium hydride, followed by distillation. The conductivity of the purified substance, κ, was 7×10^{-7} S cm^{-1}. Acetonitrile (Wako) was stirred with calcium hydride to dryness and then distilled in the presence of calcium hydride; $\kappa=3\times10^{-8}$ S cm^{-1}. Propylene carbonate (Wako) was stirred with a molecular sieve, 4A, to dryness, and then distilled under reduced pressure (87 °C at 2 mmHg†); $\kappa<10^{-8}$ S cm^{-1}. Sulfolane (Wako) was stirred with sodium hydroxide and distilled in the presence of sodium hydroxide under reduced pressure (105 °C at 4 mmHg) until a small amount of the sample did not show any development of visible color within 5 min after the addition of an equal volume of 100% sulfuric acid.[2] $\kappa<10^{-8}$ S cm^{-1}. *N,N*-Dimethylformamide (Kanto) was stirred with a molecular sieve, 4A, and distilled under reduced pressure; $\kappa=2\times10^{-8}$ S cm^{-1}. Dimethyl sulfoxide (Wako) was stirred with calcuim hydride and distilled under reduced pressure; $\kappa=2\times10^{-8}$ S cm^{-1}. Deionized water was used; $\kappa=3\times10^{-6}$ S cm^{-1}. All the salts used were reagent-grade and were dried under a vacuum.

Viscosity Measurements. The viscosity of a POE solution containing a salt was measured with a Ubbelohde viscometer. The effect of the shear rate was disregarded.

Conductivity Measurements. The conductiovity of the solution was measured in a fashion similar to the method of Ono *et al.*[3]

† 1 mmHg ≈ 133.322 Pa.

Results and Discussion

Evaluation of the Cation Binding. Procedure: In order to evaluate the degree of binding of the cation from the relationships between the equivalent conductivity of the salt, Λ, and the POE concentration (monomer base mole), C_p, we make the following assumptions: the decrease in the conductivity of the solution with the increase in C_p is solely due to the binding of the cation to POE, and the bound cations make no contribution to the conductivity. The reasonability of this assumption will be later checked in detail. According to Ono *et al.*,[4] the fraction of the unbound, free cation is given by:

$$\alpha = \frac{\Lambda - \Lambda_{ps}}{\Lambda_s - \Lambda_{ps}}, \tag{1}$$

where Λ_s is the equivalent conductivity at $C_p=0$ and Λ_{ps} is that supposing all the cations are bound. Λ_{ps} may be the ionic equivalent conductivity of the anion, based on the above assumption, and we assume, as a zeroth-order approximation, that:

$$\Lambda_{ps} = \Lambda_s[\lambda_-^\infty/(\lambda_+^\infty + \lambda_-^\infty)], \tag{2}$$

where λ_+^∞ and λ_-^∞ are the limiting ionic equivalent conductivities of the cation and the anion respectively. The values of λ_+^∞ and λ_-^∞ used here, together with those of $\lambda_-^\infty/(\lambda_+^\infty+\lambda_-^\infty)$ for the salts, are shown in Table 1. If we assume that a binding site is composed of four successive monomer units on a POE chain,[3] then the degree of binding θ, is:

$$\theta = \frac{(1-\alpha)C_s}{C_p/4}, \tag{3}$$

where C_s is the salt concentration. On the other hand, the relative activity of the cation in the bulk solution phase is given by:

$$a = \alpha y C_s, \tag{4}$$

where y is the activity coefficient on the molar concentration basis, which is regarded as equal to the activity coefficient on the molarity basis, γ, for a dilute solution. Hence, it is estimated using the Debye-Hückel extended equation for an activity coefficient. We thus obtain experimentally the relation of θ *vs.* log a.

Reasonability of Some Assumptions in the Evaluation of the Cation Binding. Although the assumptions presented above seem to be very daring, we shall verify

Table 1. Limiting ionic equivalent conductivity, λ_+^∞ and λ_-^∞, and $\lambda_-^\infty/(\lambda_+^\infty+\lambda_-^\infty)$ at 298.15 K

The values of λ_+^∞ and λ_-^∞ are cited in: a) Ref. 4; b) Ref. 5; Ref. 6.

in detail that these assumptions bring about no fatal results and that the derived conclusions are virtually correct.

In the first place, we have assumed that all the cations and anions behave freely and are independent of each other in the solution. If ionic association should occur, then, in addition to the equilibrium of binding of the cation to the POE lattice, another chemical equilibrium would have to be considered. According to the analysis of the equivalent conductivity data in the literature,[7] however, the ionic association constant is sufficiently small for the salt–solvent systems studied in this paper. Therefore, the influence of the ionic association is practically negligible. Moreover, since the degree of ion binding is not very large and the charge density on the polymer chain is small, the binding of the anion to the POE–cation complex can not be expected to occur.

Secondary, we have measured the equivalent conductivity by diluting a salt–POE solution with a salt solution which does not contain POE. If the volume changed on the dilution of POE, accurate values of the equivalent conductivity could not be obtained in this manner. Searching the literature for examples of the measurements of volume change on the dilution of ion–polymer solution systems, we find a few data for aqueous solutions of maleic acid–olefin copolymer[8,9] and of poly(acrylic acid).[9] The volume change accompanied by the protonation of the polyanion is, for both systems, in the order of $\Delta V \approx 10$ cm^{-3} mol^{-1} (monomer base mole). If, in our systems, the volume change is in this order, then $\Delta V\ C_p \approx 10^{-3}$ in the concentration of $C_p \approx 10^{-1}$ mol dm^{-3} and the error of the equivalent conductivity accompanied by the volume change is in the order of 0.1%. Although it will be necessary, in the future, to investigate this problem in detail, neglecting the influence of the volume change would not bring about any serious errors.

Thirdly, let us discuss the influence of the increase in the viscosity of the solution. It has been well known that, in a solution containing a polymer, the relationship between the equivalent conductivity and the viscosity of the solvent (a solution composed of a pure solvent and a polymer, in this case) deviates enormously from the Walden rule.[3,10] We have measured the equivalent conductivity as a function of C_p for the tetrapropylammonium iodide(TPrAI)–POE–PC system, in which the cation is expected not to be bound to POE. As may be seen in Fig. 1, the decrease in Λ with an increase in C_p is found to be very small. It is impossible, however, to conclude whether the decrease is caused by the binding of the cation or by the increase in the viscosity of the solvent. Even if the decrease in Λ were caused by an increase in the viscosity of the solvent in this case, neglecting the descent of Λ would bring about no serious errors in the systems in which the binding of the cation occurs to a large extent, because the contribution of the increase in the viscosity of the solvent to the decrease of Λ is expected to be very small. As long as no quantitative law has been established for the relationship between equivalent conductivity and viscosity in a system containing a polymer, we unavoidably neglect the influence of the increase in viscosity.

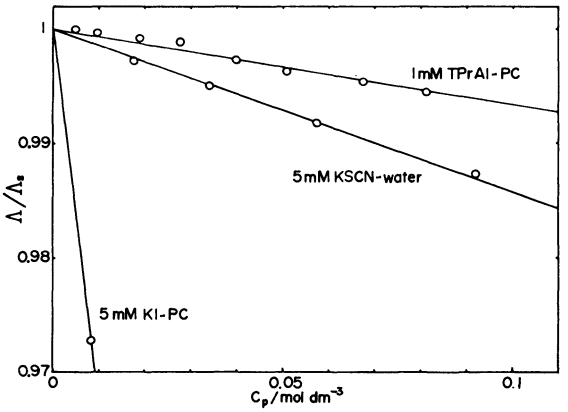

Fig. 1. The relation between Λ/Λ_s and C_p for 1 mmol dm^{-3} tetrapropylammonium iodide (TPrAI)–PC system, together with 5 mmol dm^{-3} KI–PC and 5 mmol dm^{-3} KSCN–water systems.

Fourthly, we shall examine the reasonability of Eq. 2. For ionic equivalent conductivity on the right-hand side of Eq. 2, it must be better to use the values of ionic equivalent conductivity in the salt concentration studied than to use those in the limit of $C_s \to 0$. For the KI–PC system, the limiting ionic equivalent conductivities of K^+ and I^- are, respectively, 11.17 and 18.35 S cm^2 mol^{-1},[5] so that $\lambda_-^\infty/(\lambda_+^\infty+\lambda_-^\infty)=0.6216$. On the other hand, if the Onsager limiting law holds, then the ionic equivalent conductivities of K^+ and I^- are, respectively, 10.09 and 17.12 S cm^2 mol^{-1} at 5 mmol dm^{-3}, so that $\lambda_-^\infty/(\lambda_+^\infty+\lambda_-^\infty)=0.6290$. Using these values, we analyzed the binding curve by a method to be described below; we found that the logarithmic binding constant is 1.99 in the

former case and 2.02 in the latter case. As this difference is very small, it is concluded that the approximation in Eq. 2 causes no essential errors.

Finally, we shall refer to the assumption that the bound cations make no contribution to the conductivity. As was observed by Ono *et al.*,[3] the conductivity of the solution at a given C_p decreases with an increase in the molecular weight of POE, M, but for $M>10^4$ the conductivity becomes independent of M. This finding implies that the assumption is reasonable.

In conclusion, the assumption in question does not reverse the quantitativity of the results which will be presented below.

The Solvent Effects on the Binding of the Potassium Ion. Binding Behavior in Various Solvents. Figure 2 shows η_{sp}/c *vs.* c relationships for POE in 5 mmol dm^{-3} KSCN solutions. The curves have a maximum in the methanol (MeOH), acetonictrile (AN), PC, and sulfolane (tetramethylene sulfone, TMS) systems, similar to the behavior of polyelectrolytes in added salt systems. These results imply that the polymer chain has some charges for these systems. The value of the intrinsic viscosity of the polymer, $[\eta]$, obtained by extrapolation to $c\rightarrow 0$, are shown in Table 2. As has been stated in the preceding paper,[1] these values can be used for the estimation of the intrinsic distance in a POE chain forming a one-dimensional lattice.

Table 2. Intrinsic viscosity of POE in the 5 mmol dm^{-3} KSCN system at 298.15 K

Solvent	$[\eta]$/dl g^{-1}
Methanol	0.57
Acetonitrile	0.72
Propylene carbonate	0.87
Sulfolane[a)]	0.54

Water	0.47

a) 303.15 K.

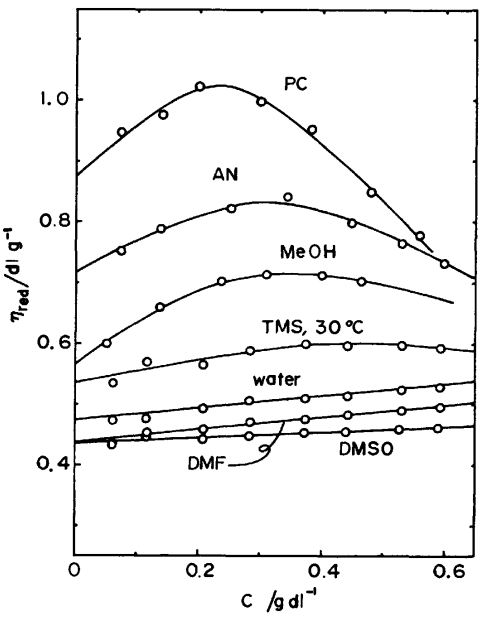

Fig. 2. Dependence of the reduced viscosity of POE, η_{red}, on POE concentration, c, in 5 mmol dm^{-3} KSCN solutions at 25 °C.

Figure 3 shows the relation between Λ/Λ_s and C_p for 5 mmol dm^{-3} of KSCN in seven solvent systems. In MeOH, AN, PC, and TMS systems, the degrees of the decrease in Λ/Λ_s with the increase in C_p are very large compared with other solvent systems. Thus, it can be qualitatively said that, in the MeOH, AN, PC, and TMS systems, ions are bound to the polymer. The preceding paper[1] states that log K_0 is a shift factor obtained by fitting the observed plots of θ *vs.* log a to the calculated curve of θ *vs.* log ξ, where ξ is the normalized activity.[1] Figure 4 shows the binding data obtained from the conductance values as well as the calculated binding curves. These binding data are in excellent agreement with the calculated curves over a wide range of activity of the potassium ion, using a single choice of the parameter, K_0. The binding constants obtained through this procedure are shown in Table 3. σ^2 is a measure of fitting (see Footnotes to Table 3). By the way, for the DMF, DMSO, and aqueous systems, the decrease in the conductivity with an increase in C_p is small, so the data are difficult to analyze with precision.

Comparison with the Method Based on the Low-molecular Analogy. As has been seen above, the analysis based on the one-dimensional lattice model seems to be most appropriate. We shall now compare this method with the method based on the low-molecular

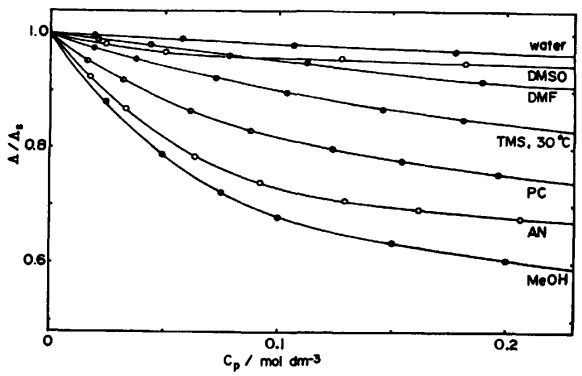

Fig. 3. The relation between the equivalent conductivity of KSCN, Λ, and POE concentration, C_p, at 25 °C.

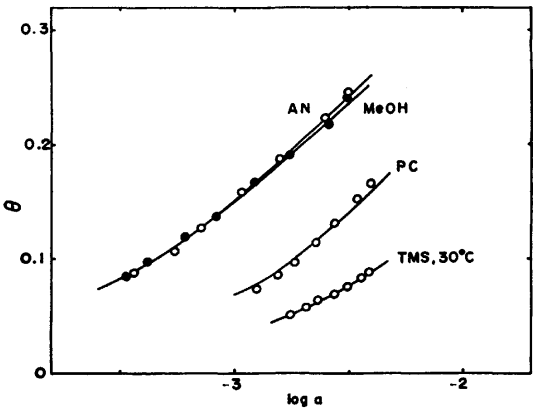

Fig. 4. Plots of the degree of binding, θ, against the logarithm of relative activity of potassium ion at 25 °C, together with the calculated curves.

Table 3. Binding constant of the potassium ion to POE determined for the 5 mmol dm^{-3} KSCN systems at 298.15 K

Solvent	log K_0	σ^{2} a)
Methanol	2.74	0.000173
Acetonitrile	2.68	0.000400
Propylene carbonate	1.97	0.00150
Sulfolane b)	1.63	0.000133

a) $\sigma^2=\frac{1}{n}\sum_{i=1}^{n}[(\theta_i^{\text{calcd}}-\theta_i^{\text{obsd}})/\theta_i^{\text{calcd}}]^2$. b) 303.15 K.

analogy. Based on the low-molecular analogy, we consider the following equilibrium:

$$\underset{(1-\theta)C_p/4}{\text{Site}} + \underset{C_s a}{\text{Ion}} \rightleftarrows \underset{\theta(C_p/4)}{\text{Site-ion complex.}} \quad (5)$$

We define the equilibrium constant, K, as in the following equation:

$$K=\frac{\theta}{(1-\theta)C_s a}. \quad (6)$$

Each simbol has the same meaning as that used in the preceding sections. In the system containing a polymer, however, the equilibrium constant defined in Eq. 6 intensively depends on θ, and K becomes greater as θ is smaller, in general. That is the problem that we brought forward in the introducion in the preceding paper.[1] The procedure often used in analyzing the proton dissociation of polyacids is to regard the intrinsic equilibrium constant as the value of K extrapolated to $\theta\rightarrow 0$, in which there is no interaction between the sites. Let us apply this procedure to our present systems. The relation of log K *vs.* θ is shown in Fig. 5. The degree of binding, θ, ranges widely, and the extrapolation to $\theta\rightarrow 0$ is then considerably easy in the MeOH and AN systems, whereas there is uncertainty in the extrapolation in PC and TMS systems. Even if the extrapolated value of log K can be accurately obtained, its physical meaning is ambiguous. As a result, it can be concluded that it is not effective to apply the method based on the low-molecular analogy to these systems.

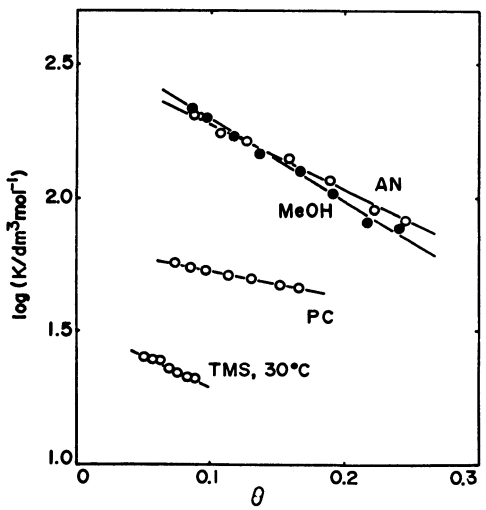

Fig. 5. Dependence of the equilibrium constant, K, which is defined in Eq. 6 based on the low-molecular analogy, on the degree of binding, θ, for 5 mmol dm^{-3} KSCN systems at 25 °C.

Interpretation of the Solvent Effects on the Binding Constant. We have obtained the binding constant, K_0, a quantity closely related to the intrinsic interaction between the site and the cation. Our next task is to discuss the solvent effects on K_0. In our treatment based on the one-dimensional lattice model, it is postulated that the solvent is to be regarded as a continuum. From the molecular-theoretical point of view, however, the cation binding to POE involves a process in which the solvent molecules coordinating to the cation are released. Thus, it can be said qualitatively that the cation binding to POE is less favorable as the solvent becomes a stronger solvator, *i.e.*, a stronger electron donor, to the cation. One of the parameters which represents the electron donicity of a solvent is the donor number (*DN*), proposed by Gutmann.[11] The *DN* values for several solvents are shown in Table 4. Roughly speaking, the binding of the potassium ion to POE occurs significantly in the solvents which have comparatively small *DN* values. By the way, the *DN* of diethyl ether, which is the low-molecular analog of POE, is 19.2. It might be noted that, in a solvent whose *DN* is larger than that of diethyl ether, the cation binding to POE is no longer observed. These quantitative considerations tell us that, in the interpretation of the solvent effects on K_0, we must pay attention to the problem of the solvation of the cation. However, the correlation between K_0 and *DN* is found to be bad.

Table 4. Correlation among the binding constant, K_0; the donor number of the solvent, *DN*, and the standard chemical potential of the potassium ion, $\mu^{\ominus}$

Solvent	*DN* a)	$\Delta\mu^{\ominus}$ b,c) / kJ mol^{-1}	$\Delta\log K_0$ b,c)
Nitromethane	2.7	9.64	
Ethanol		5.45	
Methanol	19.0	2.51	0.06
Acetonitrile	14.1	0	0
Propylene carbonate	15.1	−4.19	−0.71
Sulfolane e)	14.8	−6.70	−1.05
Diethyl ether	19.2		
Water	18.0 f)	−13.8	
DMF	26.6	−20.1	
DMSO	29.8	−25.1	

a) Ref. 11. b) Δ means that AN is chosen as the reference solvent. c) Ref. 13. d) This work (from Table 3). e) 303.15 K. For other solvent systems, 298.15 K. f) It is said that, although there is no theoretical ground for it, the value of 30 often explains experimental findings better for water as a solvent.[12]

Next let us try to correlate K_0 and the standard chemical potential of the potassium ion in each solvent, $\mu^{\ominus}$, which is a thermodynamic quantity reflecting the strength of the solvation of this ion as a whole. K_0 is composed of two factors, exp $(\mu^{\ominus}/RT)$ and exp$(-E/RT)$,

where E is the binding energy to the site (for details, see the preceding paper[1]). We introduce a rough assumption that E is constant, independent of the solvent. The binding energy, E can be expected to contain the complexation energy of the binding site and the desolvation energy of the polymer, the latter being dependent on the solvent. This assumption, however, seems to be sufficient as a zeroth-order approximation. According to this assumption, if we consider the ratio of the binding constant in an arbitrary solvent, S, $K_0(S)$, to that in a reference solvent, R, $K_0(R)$, then:

$$\begin{aligned}\Delta\log K_0 &\equiv \log[K_0(S)/K_0(R)] \\ &= [\mu^\ominus(S) - \mu^\ominus(R)]/2.303\,RT \\ &\equiv \Delta\mu^\ominus/2.303\,RT, \end{aligned} \quad (7)$$

where $\mu^\ominus(R)$ and $\mu^\ominus(S)$ are the standard chemical potential of the cation in the R and S solvents respectively. The $\Delta\mu^\ominus$'s of the potassium ion when AN is chosen as the reference solvent have been measured by Owensby *et al.***[13] They have measured the $\Delta\mu^\ominus$'s by several kinds of methods. We adopt the values obtained by assuming a negligible liquid-junction potential, which is believed to be the most reliable method. If we plot $\Delta\log K_0$ against $\Delta\mu^\ominus/2.303RT$, we find that Eq. 7 holds roughly, as is shown in Fig. 6. In the DMF, DMSO, and aqueous systems, we can say that, since $\Delta\mu^\ominus$ is very small, the cation is not bound in fact. As has been seen above, the solvent effects on the binding constant are mainly governed by the standard chemical potential of the cation in the solvent.

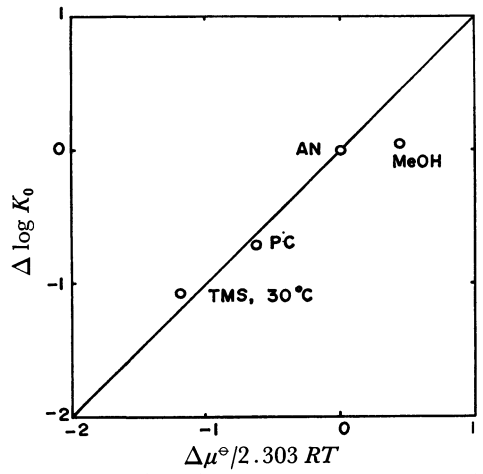

Fig. 6. The relationship between $\Delta\log K_0$ obtained in this study and $\Delta\mu^\ominus$ cited in Ref. 13. Acetonitrile (AN) is chosen as a reference solvent.

The Effects of the Salt Concentration on the Binding Constant. Figures 7 and 8 show the η_{sp}/c *vs.* c relationships for POE in various concentrations, C_s, of the KI-AN and -PC solutions. The curve is more raised in the region of small c values as C_s becomes smaller. This behavior closely resembles that of polyelectrolytes in salt-added systems.

** Owensby *et al.* have quantitatively discussed the relationship between $\Delta\mu^\ominus$ and the molecular structure of a solvent.

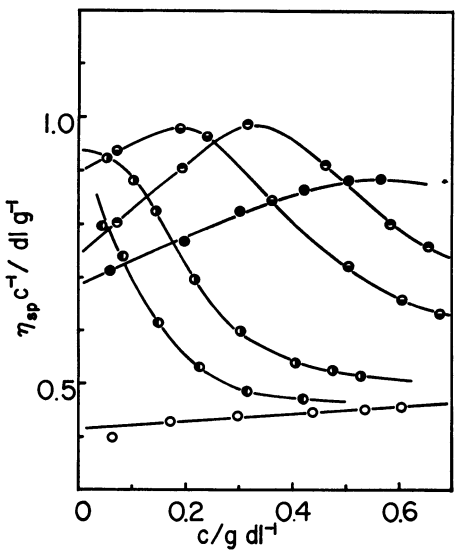

Fig. 7. η_{sp}/c *vs.* c relationships for POE in various concentration, C_s, of KI-AN solution at 25 °C.
●: C_s=10 mM, ◓: 5 mM, ◒: 3 mM, ◑: 1 mM, ◐: 0.5 mM, ○: salt-free.

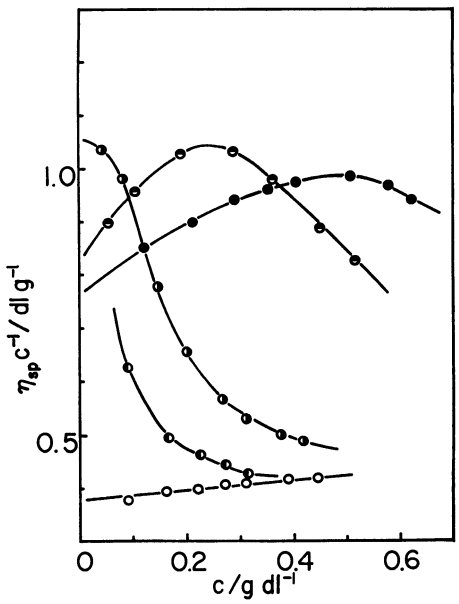

Fig. 8. η_{sp}/c *vs.* c relationships for POE in various concentration, C_s, of KI-PC solution at 25 °C.
●: C_s=10 mM, ◓: 5 mM, ◑: 1 mM, ◐: 0.4 mM, ○: salt-free.

We shall now investigate the dependence of the binding constant on the salt concentration. Plots of the degree of binding, θ, against log a and the calculated curves for the KI-POE-AN and KI-POE-PC systems are shown in Figs. 9 and 10 respectively. The binding constants for these systems are tabulated in Table 5. These results show that the binding constant, K_0, depends markedly on C_s in PC, whereas K_0 depends on it only a little in AN. As is illustrated in Fig. 11, K_0 increases with a decrease in C_s in both systems. The increase in K_0 can be explained by one of the following two ideas: (a) The cation is bound to a delocalized site

by nature, while our model has assumed a localized site, so that the entropy increment caused by the delocalized binding might result in an increase in K_0. (b) The factor of which K_0 is composed, $\exp(-E/RT)$, increases. The (a) idea will be discussed in the future. We will now verify phenomenologically that the (b) idea is valid.

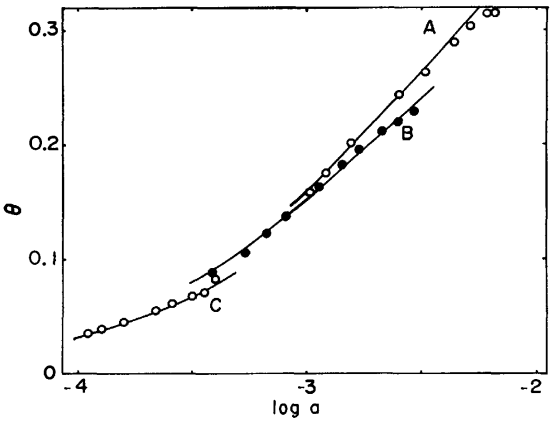

Fig. 9. Plots of θ *vs.* log a, together with the calculated curves, for KI–POE–acetonitrile systems at 25 °C.
A: C_s=10 mM, B: C_s=5 mM, C: C_s=1 mM.

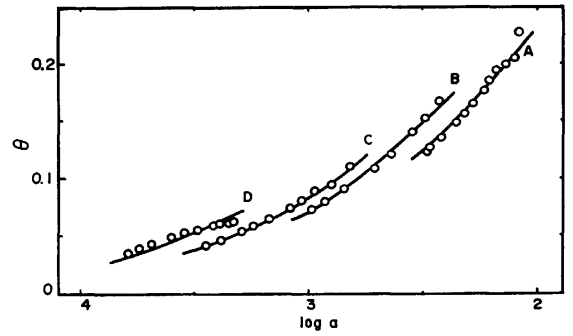

Fig. 10. Plots of θ *vs.* log a, together with the calculated curves, for KI–POE–propylene carbonate systems at 25 °C.
A: C_s=10 mM, B: C_s=5 mM, C: C_s=2 mM, D: C_s=0.5 mM.

Table 5. Dependence of the binding constant, K_0, on the salt concentration, C_s, at 298.15 K

KI–Acetonitrile		KI–Propylene carbonate	
C_s / mmol dm^{-3}	log K_0	C_s / mmol dm^{-3}	log K_0
0.1	2.86	0.5	2.38
0.5	2.70	1	2.28
1	2.63	2	2.15
5	2.56	5	1.99
10	2.42	10	1.83

In the preceding paper,[1] the binding constant, K_0, has been defined as follows:

$$K_0 = \exp[(\mu^\ominus - E)/RT]. \quad (8)$$

Let us differentiate the logarithm of Eq. 8 with respect to $1/T$. If we assume that:

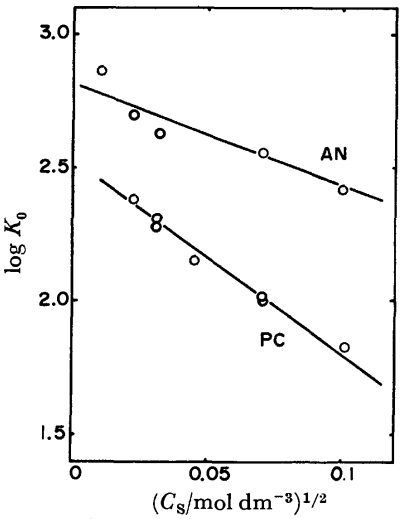

Fig. 11. Dependence of the binding constant, K_0, on the salt concentration, C_s, for KI–POE–AN and –PC systems at 25 °C.

$$\frac{\partial E}{\partial T} = 0, \quad (9)$$

then:

$$\frac{\partial \log K_0}{\partial (1/T)} = \frac{h^\ominus - E}{2.303RT}, \quad (10)$$

where $h^\ominus$ is the standard partial molar enthalpy of the cation. Figure 12 shows the plots of log K_0 against $1/T$ for 5 mmol dm^{-3} and 1 mmol dm^{-3} KI–POE–AN and –PC systems. The values of $h^\ominus - E$ obtained from the slope are tabulated in Table 6. Since $h^\ominus$ is common in both solvents, the differences between E in the 5 mmol dm^{-3} KI system and in the 1 mmol dm^{-3} KI system are 0.3 kJ mol^{-1} and 3.3 kJ mol^{-1} in AN and PC respectively. This finding phenomenologically supports

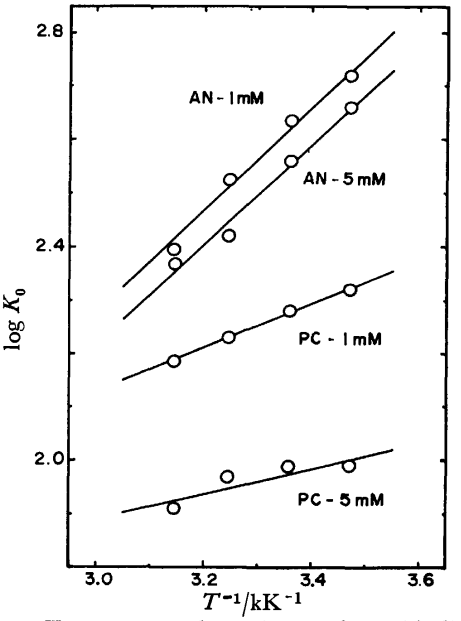

Fig. 12. Temperature dependence of the binding constant, K_0, for 1 mM and 5 mM KI–POE–AN and –PC systems.

the ideas that, as C_s grows smaller, E becomes smaller, that is, K_0 becomes greater, and that this tendency is notable in PC. The differences in the log K_0 calculated from the difference in E which has been just obtained are found to be 0.05 for the AN system and 0.58 for the PC system. These values do not agree with the observed values (AN, 0.07; PC, 0.26) very well. Taking account of the quality of the data, however, this result can be regarded as in rather better agreement and seems to support the idea (b).

Table 6. Values of $h^\ominus - E$ obtained from the slope of the plot of log K_0 against $1/T$.

Solvent	C_s/mmol dm^{-3}	$(h^\ominus - E)$/kJ mol^{-1}
Acetonitrile	1	18.2
	5	17.9
Propylene carbonate	1	7.9
	5	4.6

The Effects of the Variety of Salt. Table 7 shows the binding constants for various potassium salt–POE–PC systems. It is found that K_0 is little dependent on the variety of anion, as has been expected.

Table 7. Binding constants for potassium salt–POE–propylene carbonate systems at 298.15 K

Salt	log K_0
$KClO_4$	1.98
KSCN	1.97
KBr	1.91
KI	1.99

Table 8 shows the binding constants for various alkali metal iodide–POE–MeOH and –PC systems. It is clear that a large difference is found between the NaI and KI systems in MeOH, but not in PC. The differences between log K_0 values in the PC and MeOH systems are also shown in Table 8. $\Delta \log K_0$ is positive for NaI, but negative for other alkali metal iodides. The standard transfer Gibbs energies, $\Delta\mu^\ominus$, of the alkali metal ions from MeOH to PC[14] are added to Table 8 in the form of $\Delta\mu^\ominus/2.303\,RT$. The reason for the different behavior of NaI and KI is that $\Delta\mu^\ominus$ is negative for the potassium ion, but positive for the sodium ion.

Table 8. Binding constants for alkali metal iodide–POE–methanol and –propylene carbonate systems at 298.15 K

Salt	log K_0		$\Delta\log K_0$[a]	$\frac{\Delta\mu^\ominus}{2.303RT}$[b]
	Methanol	Propylene carbonate		
NaI	1.43	1.85	0.42	1.17
KI	2.72	1.99	−0.73	−0.74
RbI	2.77	1.93	−0.84	−2.28
CsI	2.58	1.80	−0.78	−3.82

a) $\Delta\log K_0 = \log K_0(\text{PC}) - \log K_0$ (MeOH). b) $\Delta\mu^\ominus$ is the standard transfer Gibbs energy from methanol to propylene carbonate (Ref. 11).

Conclusion

As has been seen above, the present method, which is based on the one-dimensional lattice model, is of great help in obtaining a unified understanding of the binding behavior on the solvent, the salt concentration, and the variety of salt.

This method, however, can be applied only to a system in which a strong interaction exists between POE and the ion and in which no specific interaction exists between the cation and the anion. If ionic association and/or binding of the anion to the polymer cation complex occurs, a modified method is required. The treatments for such systems will be discussed in the following paper.[15]

Theoretical Considerations of the Dimer-formation Energy and Electronic Structures of the Monomer and Dimer of the 2-Pyridone by the Molecular Orbital Method

Kozo Inuzuka* and Akira Fujimoto

Department of Applied Science, Faculty of Technology, Tokyo Denki University, Kanda, Chiyoda-ku, Tokyo 101

(Received October 30, 1981)

When the dimer-formation energy of 2-pyridone was measured by means of ^{1}H-NMR spectroscopy, the value of 65.3 kJ mol^{-1} was obtained. It is much larger than the hydrogen-bond energies which are generally observed for the C=O···H–N system. The dimer-formation energy of 2-pyridone was calculated by means of the CNDO/2 method; its formation energy ($-\Delta H$) was estimated to be 68.2 kJ mol^{-1}. The electronic structures of the monomer and dimer of 2-pyridone were calculated by means of the CNDO method with configuration interaction (CNDO/CI) in order to clarify the previous band assignment of the UV spectrum of 2-pyridone. According to the calculated results, the absorption bands at 305 and 228 nm in isooctane (2,2,4-trimethylpentane) were assigned to the monomer, while those at 297.5 and 230.5 nm were assigned to the dimer.

In the previous paper[1] the longest-wavelength UV absorption of 2-pyridone in isooctane (2,2,4-trimethylpentane) was ascribed to π-π^* electronic transitions of the monomer and dimer. The dimer-absorption band appears at a wavenumber higher than that of the monomer by *ca.* 830 cm^{-1}. The dimer band corresponds to the π-π^* transition from the ground ^1A_g state to the excited ^1B_u state. No π-π^* transition absorption from the ground ^1A_g state to the excited ^1A_g state could be observed.

In this paper, the previous experimental considerations of the UV spectrum of 2-pyridone[1] were examined and further clarified by means of the CNDO method with CI. In addition, the formation energy of 2-pyridone dimer was evaluated by the CNDO/2 method; also, the dimer-formation energy was measured by the method of ^{1}H-NMR spectroscopy. The calculated energy was compared with the observed value.

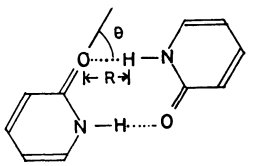
Experimental

2-Pyridone was purified in the way described previously.[1] Tetrahydrofuran (THF) was refluxed with solid potassium hydroxide for at least 24 h, distilled from it, and again distilled from lithium aluminum hydride immediately before use. Benzene-d_6, Canada Merck (99.5% purity), was used as the solvent without further purification. The measurement of the ^{1}H-NMR spectrum was carried out with a JEOL FX-90Q NMR spectrometer at each of four temperatures, 8, 19, 32, and 42 °C. The concentration of the 2-pyridone solution was changed twelve times in the range of 10^{-3} to 10^{-1} mol dm^{-3}. The UV absorption spectrum was obtained at room temperature with a Hitachi Model 323 spectrophotometer.

Methods of Calculation and Molecular Models

The formation energy of the dimer, the π-bond orders, and the charge densities of 2-pyridone in the ground state were calculated by the CNDO/2 method[2,3] using the same parameter as in the previous paper.[1] The values of the bond distance and bond angle of 2-pyridone as measured by Penfold[4] were used. The data of 1-methyl-2-pyridone were the same as in the previous paper.[1]

For the dimer, the following planar model was used:



The present dimer model without the C_{2h} symmetry has the two parameters of R and θ, which correspond to the distance between the O atom of the C=O group and the H atom of the N–H group, and to the angle between the C=O axis and the direction of hydrogen bond of the O···H–N, respectively. The dimer-formation energy was calculated under an assumption that the ring framework of the 2-pyridone monomer and its N–H distance are invariant on the dimer formation. The enthalpy change ($-\Delta H$) for the dimerization of 2-pyridone was obtained by changing the R and the θ until the value of $-\Delta H$ reaches its maximum.

The CNDO method with CI (CNDO/CI) using the parameter given by Jaffé *et al.*[5,6] was employed for the calculation of the transition energies, transition oscillator strengths, charge densities, and π-bond orders in the lower-excited states. The Mataga-Nishimoto approximation[7] was used for the calculation of two-center Coulomb integrals. All the π molecular orbitals were built into the singly excited configuration interactions, while the two bonding σ-MO's of the highest and next-highest energies and one anti-bonding σ-MO of the lowest energy were taken into account for the CI of the 2-pyridone monomer. For the CI of the 2-pyridone dimer, all the π-MO's, the four bonding σ-MO's in the order of energy from the highest occupied σ-MO, and the two anti-bonding σ-MO's in the order of energy from the lowest energy were taken into account. The oscillator strength of the n-π^* transition was calculated according to Jaffé *et al.*[6]

Results and Discussion

Dimer-formation Energy of 2-Pyridone. Experimental: It was assumed that the following equilibrium between the monomer and the dimer of 2-pyridone exists:

$$2A \rightleftharpoons A_2. \quad (1)$$

The equilibrium constant for the above reaction was

defined by the following equation:

$$K = [A_2]/[A]^2, \quad (2)$$

where $[A_2]$ is the equilibrium concentration of the dimer and [A] is that of the monomer. The chemical shift of the N–H group moves to a lower magnetic field side as the concentration of 2-pyridone increases. The chemical shift, δ^i, of 2-pyridone in benzene-d_6 was represented by the following equation:

$$\delta^i = (1 - x^i)\delta_M + x^i\delta_D \quad (3)$$

where x^i corresponds to the mole fraction of the dimer and where δ_M and δ_D stand for the chemical shift of the monomer and dimer of 2-pyridone. The superscript, i, represents the i-th concentration of 2-pyridone. To bring the value of δ^i close to the observed value, δ^i_{obsd}, the next equation was used:

$$S = \sum_i (\delta^i_{obsd} - \delta^i)^2 \qquad (i = 1,2,\cdots,n) \quad (4)$$

The K and δ_M values were determined by the trial-and-error method using Eqs. 2, 3, and 4 and the assumed value of 14.20 ppm for δ_D. In the present calculation, the value of 11.61 ppm was obtained for the chemical shift of the monomer of 2-pyridone. In Fig. 1 the values of the chemical shift, calculated by means of Eq. 3 with the assumed values of δ_M and δ_D, are plotted with the observed values for the various concentrations and temperatures. The agreement between the calculated and observed δ values seems relatively good except for the results at 42 °C. The enthalpy change, $-\Delta H$, that is, the hydrogen-bond dimer-formation energy, was obtained by plotting $\ln K$ *versus* $1/T$, as is shown in Fig. 2. The value of $-\Delta H_{obsd}$, 65.3 kJ mol^{-1}, was evaluated from Fig. 2 using the least-squares method.

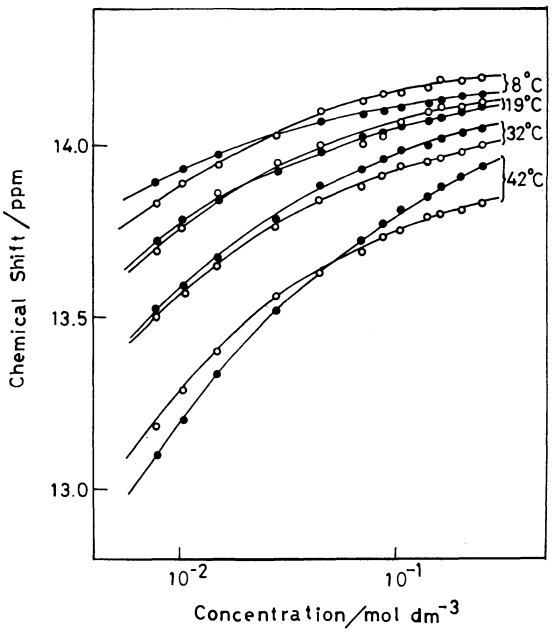


Fig. 1. The observed chemical shift (—○—) of NH proton of 2-pyridone *versus* total concentration of 2-pyridone and the calculated chemical shift (—●—) by Eq. 3. See Text.

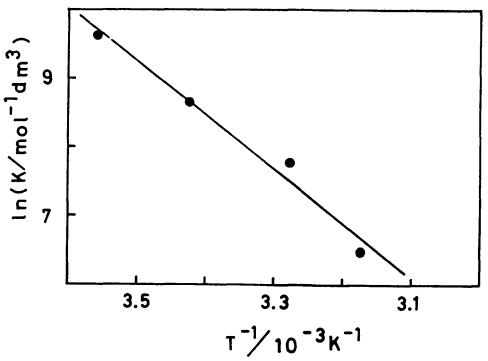

Fig. 2. Plots of $\ln K$ *vs.* $1/T$.

Theoretical: The dimer-formation energy, the π-bond order of the C=O group, the equilibrium distance, R_e, and angle, and the dipole moment of the dimer, which were obtained after the optimization of the parameters, R and θ, are given in Table 1. The optimized dimer model suggests that the 2-pyridone dimer belongs to the point group of the C_{2h} symmetry. The charge densities and π-bond orders of the 2-pyridone dimer are shown in Fig. 3. The dimer-formation energy $-\Delta H$, was 147.7 kJ mol^{-1}; the equilibrium distance, 1.35 Å, and the angle, 58.75°. The CNDO/2 method tends to overestimate the value of $-\Delta H$ and to underestimate Re.

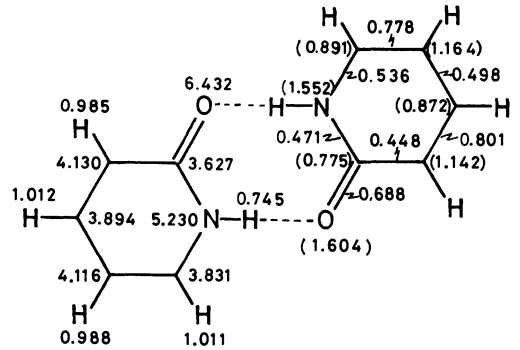

Fig. 3. Several molecular properties of 2-pyridone dimer calculated by the CNDO/2 method; the total charge densities of valence electron, π-charge densities, and π-bond orders. The values of π-charge densities are shown in parentheses.

Table 1. The calculated hydrogen-bond energy ($-\Delta H$), corrected hydrogen-bond energy ($-\Delta H_c$), equilibrium distance (R_e), and angle (θ), π-bond order of the carbonyl group ($p_{C=O}$), and dipole moment (μ) of the 2-pyridone dimer with observed hydrogen-bond energy

Dimer	Sym.	R_e/Å	θ/°	$p_{C=O}$	μ/D	$-\Delta H$ / kJ mol^{-1}	$-\Delta H_c$ / kJ mol^{-1}	$-\Delta H_{obsd}$ / kJ mol^{-1}
2-Pyridone	C_{2h}	1.35	58.75	0.688	0	147.7	68.2	65.3

The π-bond order of the C=O group of the dimer (0.688) is smaller than that of the monomer (0.782).[1] The IR band at 1654 cm^{-1} was assigned to the stretching vibration of the C=O group of the dimer, and the band at 1676 cm^{-1}, to that of the monomer in carbon tetrachloride.[1] This is in line with the calculated π-bond orders of the carbonyl groups of the dimer and monomer of 2-pyridone.

The charge density of the H atom of the N–H group of the dimer is smaller than that of the monomer (0.886).[1] This implies that the ^{1}H-NMR spectrum of the N–H group of the dimer may appear at a lower magnetic field than that of the monomer. The chemical shifts of the N–H group are 11.61 and 14.20 ppm for the monomer and dimer of 2-pyridone, respectively. This experimental result is in line with the theoretical result.

The present calculated value of the hydrogen-bond dimer-formation energy seems very large, although the hydrogen-bond energy calculated by the CNDO/2 method generally gives rise to values larger than the observed values.[9,10] In order to assess the reliability to be expected from the hydrogen-bond energy calculation by means of the CNDO/2 method and in order to obtain a correction factor by which to evaluate a desirable dimer-formation energy for 2-pyridone, the hydrogen-bond energies of several organic compounds were obtained theoretically by means of the CNDO/2 method and experimentally by means of the UV spectroscopic method. In the experiment, ethanol was used, but in the case of calculation, methanol was employed for the sake of simplicity.

The calculated and experimental results are listed in Table 2. When the calculated energy values are plotted against the experimental energy values, there is a good linear relationship between the calculated and experimental values. The line was determined by the least-squares method. The dimer-formation energy of 2-pyridone was obtained from the line using the calculated value of 147.7 kJ mol^{-1}. The present value of $-\Delta H_c$ was evaluated as 68.2 kJ mol^{-1}. The value of 68.2 kJ mol^{-1} is very close to the observed value. This value is larger than the dimer-formation energy of acetic acid (44.8 kJ mol^{-1}).[14] However, Hammes and Park,[15] by means of the ultrasonic absorption method, obtained 25 kJ mol^{-1} for the dimer-formation energy of 2-pyridone in chloroform. The values of 68.2 and 65.3 kJ mol^{-1} are much larger than Hammes and Park's value.[15] Chloroform is known to form a hydrogen bond. As 2-pyridone in chloroform is stabilized by a hydrogen-bond formation with the solvent, the dimer-formation energy of 2-pyridone may be smaller than it is in benzene. Another reason may be a difference in the experimental means for the measurement of the dimer-formation energy. The values of 68.2 and 65.3 kJ mol^{-1} are larger than the hydrogen-bond energy between the C=O and N–H groups which is generally observed.

The charge density of the O atom of the C=O group of the 2-pyridone monomer[1] is larger than that of the [1]benzopyrano[3,4-*c*]pyridine derivatives[9] and aldehydes.[10] The large charge density of the O atom of 2-pyridone may result in the large Coulombic interaction between the C=O and N–H groups of the 2-pyridone dimer.

Table 2. The hydrogen-bonding energies obtained theoretically by means of the CNDO/2 method and experimentally by means of the UV spectroscopic method for several hydrogen-bonding complexes

3	A″	5.475	226	0.000	
4	A′	5.553	223	0.377	228

Electronic Structures of 2-Pyridone. In order to clarify the n,π^* state of 2-pyridone, the calculation of the transition energies and oscillator strengths of the 2-pyridone monomer was carried out by means of the CNDO/CI method. The calculated results are given in Table 3, along with the experimental values.[1] It is noteworthy that the lowest excited singlet state is of an n,π^* character and that the n-π^* transition band is expected near 350 nm for 2-pyridone. However, we could not observe any band in this region. It may be difficult to observe the corresponding band near 350 nm for the following reasons: (1) a low intensity as suggested by the calculated f value, and (2) the band position near 350 nm is too close to the strong π-π^* band in the vicinity of 300 nm, and so the n-π^* band may overlap with the first π-π^* band.

As is shown in Fig. 4, the addition of THF to the 2-pyridone in isooctane separated the monomer bands from the dimer bands. As the addition of THF results in the red-shift of the absorption band of the 2-pyridone monomer, the peak at 228 nm in isooctane may be assigned to the band maximum of the second π-π^* system of the monomer, which corresponds to the peak at 230 nm in the THF-isooctane solvent.

In order to clarify the previous assertions that the band with the maximum at 297.5 nm belongs to the dimer and that the band maximum at 305 nm corre-

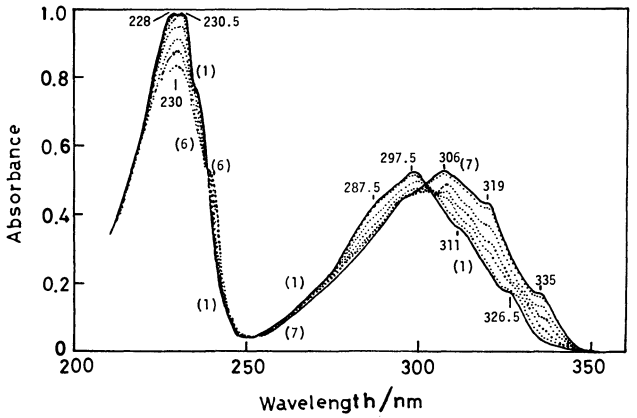

Fig. 4. The UV absorption spectrum of 2-pyridone in isooctane–THF mixed solvents at room temperature. Concentration of 2-pyridone: 1.22×10^{-4} mol dm^{-3}, concentrations of THF (mol dm^{-3}): (1) 0, (2) 4.89×10^{-2}, (3) 1.96×10^{-1}, (4) 4.98×10^{-1}, (5) 9.78×10^{-1}, (6) 4.89, (7) 7.33.

sponds to the monomer in isooctane,[1] and in order to clarify the assignment of the second band near 230 nm, the transition energy and oscillator strength of the dimer were calculated by the CNDO/CI method. The CI of 96th-orders was taken into account, including all π-MO's and six σ orbitals. The optimized equilibrium distance of 1.35 Å seems to be so short that it gives too large a hydrogen-bond energy. The equilibrium distance corresponding to the value of $-\Delta H_{obsd}$, 65.3 kJ mol^{-1}, should be longer than 1.35 Å. In the present calculation, the distances of 1.80 and 1.90 Å, which give rise to 76.27 and 61.34 kJ mol^{-1} for the values of $-\Delta H$ calculated by the CNDO/2 method, were used. The distance of the dimer with the formation energy of 65.3 kJ mol^{-1} lies between 1.80 and 1.90 Å.

The calculated transition energies and oscillator strengths for the dimer model (1.80 Å) are both listed in Table 4, because there is no essential difference between the two models with respect to the results of the CNDO/CI calculation. All the π,π^* excited states of the dimer are split into the two states of the A_g and B_u symmetries, while the n,π^* excited states are split into the two states of the B_g and A_u symmetries. A comparison of Table 3 with Table 4 shows that the 1st π-π^* transition energy of the dimer is higher than that of the monomer, but the 2nd π-π^* transition energy of the former is lower than that of the latter.

Table 4. Calculated transition energies (E), wavelengths(λ), and oscillator strengths (f) of the 2-pyridone dimer

State	Model (1.80 Å)				λ_{obsd}/nm
	Sym.	E/eV	λ/nm	f	
1	B_g	3.769	328	0	
2	A_u	3.771	328	0.000	
3	A_g	4.284	289	0	
4	B_u	4.412	281	0.469	297.5
5	B_g	5.252	236	0	
6	A_u	5.252	236	0.000	
7	B_u	5.515	224	0.893	230.5
8	A_g	5.567	222	0	
9	B_u	5.687	218	0.000	
10	A_g	5.688	218	0	

The present results, calculated by means of the CNDO/CI method and obtained by the use of the UV spectrum of 2-pyridone in the THF–isooctane system, agree with the previous band assignment of the 2-pyridone monomer and dimer.[1] Further, the calculation has clarified that the peak at 228 nm is to be assigned to the second π-π^* transition of the A′ symmetry of the monomer, and the peak at 230.5 nm, to that of the B_u symmetry of the dimer, although the assignments of those bands were unclear in the previous paper.[1]

Table 5. Energy difference between the ^{1}A′ state of the monomer and the ^1B_u state of the dimer in the first and second π-π^* regions

	Energy difference between ^{1}A′ and ^1B_u states in 1st- and 2nd-regions/cm^{-1}	
	(1st)	(2nd)
Dimer model (1.80 Å)	660	−310
Obsd	830	−480

In Table 5 the energy differences between the first ^{1}A′ state of the monomer and the first ^1B_u state of the dimer and between the second ^{1}A′ and ^1B_u states are given. The calculated energy differences between ^{1}A′ and ^1B_u states for the monomer and dimer are in good agreement with the observed values.

Multidentate Ligand Kinetics. IV. Computer Simulation of the Steady State of the Free Ligands in a Coordination Chain Reaction

Tetsuo KATSUYAMA* and Toshihiko KUMAI

Department of Basic Technology, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received November 2, 1981)

The ligand-substitution reactions between two multidentate ligand complexes in the presence of free ligands proceed by means of a coordination chain-reaction mechanism. The reaction was simulated on a computer under various conditions. The character of the steady state of the free ligands in the coordination chain reaction was discussed. The conditions under which the coordination chain reaction proceeds with the steady state of the free ligands were determined. The diagrams of the time development of the free ligands were found to be useful for studies using the coordination chain reaction.

In previous works,[1-3] the ligand-substitution reactions between two multidentate ligand complexes were studied in the presence of free ligands:

$$ML + ZX \longrightarrow MX + ZL, \quad (R1)$$

where ML, ZX, MX, and ZL are multidentate ligand complexes; the charges will be omitted hereafter for the sake of simplicity.

The reactions were shown to proceed by means of a coordination chain-reaction mechanism:

$$ML + X \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} MX + L, \quad (R2)$$

$$ZX + L \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} ZL + X, \quad (R3)$$

where X and L denote free ligands.

In the course of our studies, the rate law was derived from a steady-state treatment on the assumption that the concentrations of the free ligands (X and L) remain constant throughout the substitution. This assumption, however, was not examined.

Coordination chain reactions can be applied to the determination of trace metal ions.[4-6] In the analytical applications, the above assumption is taken to hold. However, in general, a coordination chain-reaction system can not necessarily be expected to satisfy the above assumption.

If the time development of the free-ligand concentration in the system can be known, it is useful for the studies using a coordination chain reaction. In this paper, coordination chain reactions were simulated on a computer under various conditions, and the concentration-time profiles for all the components were calculated. The purpose of this paper is to ascertain the conditions under which the reaction proceeds with the steady state of the free ligands.

Computational Method

The six-variable, four-rate constant isothermal model represented by Reactions R2 and R3 can be described by the following differential equations:

$$\frac{d[ML]}{dt} = -k_2[ML][X] + k_{-2}[MX][L], \quad (1)$$

$$\frac{d[ZX]}{dt} = -k_3[ZX][L] + k_{-3}[ZL][X], \quad (2)$$

$$\frac{d[MX]}{dt} = k_2[ML][X] - k_{-2}[MX][L], \quad (3)$$

$$\frac{d[ZL]}{dt} = k_3[ZX][L] - k_{-3}[ZL][X], \quad (4)$$

$$\frac{d[X]}{dt} = -k_2[ML][X] + k_{-2}[MX][L] + k_3[ZX][L] - k_{-3}[ZL][X], \quad (5)$$

$$\frac{d[L]}{dt} = k_2[ML][X] - k_{-2}[MX][L] - k_3[ZX][L] + k_{-3}[ZL][X]. \quad (6)$$

Using the known starting conditions and rate constants, the six above simultaneous differential equations were integrated by the numerical integration method of Runge-Kutta-Gill.[7] The starting conditions in the integration were as follows:

$$[ML]_0 = a\ \mathrm{M}(1\ \mathrm{M}=1\ \mathrm{mol\ dm^{-3}}), \quad (7)$$

$$[ZX]_0 = b\ \mathrm{M}, \quad (8)$$

$$[MX]_0 = [ZL]_0 = 0\ \mathrm{M}, \quad (9)$$

$$\begin{matrix}[X]_0 = c\ \mathrm{M} \\ [L]_0 = 0\ \mathrm{M}\end{matrix} \quad \text{or} \quad \begin{matrix}[X]_0 = 0\ \mathrm{M} \\ [L]_0 = c\ \mathrm{M}\end{matrix}, \quad (10)$$

where $[\ ]_0$ indicates the initial concentration of the species and where a, b, and c are not zero. In these calculations, it has been premised that $k_3 \geqq k_2$ and $[ZX]_0 \geqq [ML]_0$.[8]

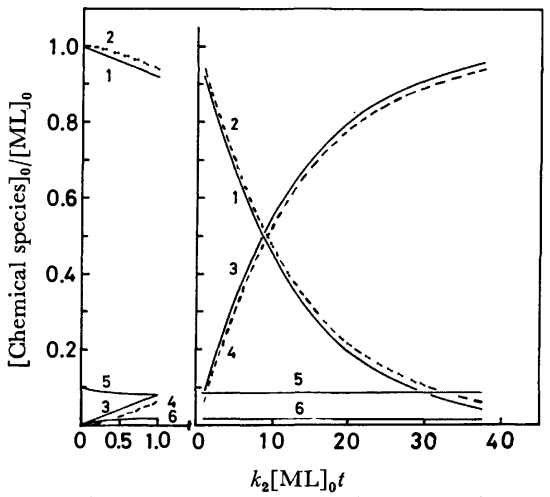

Fig. 1. An example of computer simulation of coordination chain reaction.[11]
Conditions: $[ML]_0=[ZX]_0=1$ M, $[MX]_0=[ZL]_0=0$ M, $[X]_0=0.1$ M, $[L]_0=0$ M; $k_2=1\ M^{-1}\ s^{-1}$, $k_3=4\ M^{-1}\ s^{-1}$, $k_{-2}=k_{-3}=0\ M^{-1}\ s^{-1}$. 1: ML, 2: ZX, 3: MX, 4: ZL, 5: X, 6: L.

The concentration-time profiles for all the components were obtained from the integration. The relative concentrations, expressed in terms of $[ML]_0$ as a unit, were then plotted against $k_2[ML]_0t$ (Fig. 1); this representation is convenient for the general treatment of the concentration-time profiles, since the ordinate and abscissa have no dimensions.[9]

In the studies using the coordination chain reaction, the reaction is usually run in the presence of the free ligand, and the relative concentration of the free ligand presented initially is ordinarily smaller than 0.1. Therefore, in this study, the simulations were carried out under the condition that $\frac{[\text{free ligand}]_0}{[ML]_0} \leqq 0.1$.

Calculations were carried out with an ACOS 900 computer of the Tohoku University Computation Center.

Results and Discussion

In order to clarify the nature of the coordination chain reaction, the reaction system was classified into the several cases shown in Table 1; *e.g.*, in the case of the I_1 system, the rate constants, k_{-2} and k_{-3}, can be regarded as zero, while the initial concentrations of ML and ZX are equal to one another.

The total free ligand concentration ([X]+[L]) is equal to the initial ligand concentration, c, throughout the substitution reaction. Therefore, if the X ligand reaches a steady state, the L ligand also reaches a steady state; the steady state of the free ligands can, then, be studied by examining the concentration-time profile for one of the two free ligands. In this study, the concentration-time profile for the X ligand was noted.

Reaction System I. *System* I_1 ($k_{-2}=k_{-3}=0$, $[ZX]_0=[ML]_0$): Figure 2 shows the time development of the concentration of X with the following specifications: $[X]_0/[ML]_0=0.1$ for Fig. 2.A and $[L]_0/[ML]_0=0.1$ for Fig. 2.B.

It may be seen that the greater the k_3/k_2 ratio, the closer the concentration of X comes to the steady state, and that the steady-state approximation in Fig. 2.A is superior to that in Fig. 2.B.

The concentration of the X ligand in the steady state can be estimated as follows. From $d[X]/dt=0$, the following relationship is obtained:

$$-k_2[ML][X] + k_3[ZX][L] = 0. \quad (11)$$

Since the $[X] \gg [L]$ inequality and the $[ML]_0=[ZX]_0$ equation hold, the following relation can be derived:

$$[ML] \approx [ZX]. \quad (12)$$

On the other hand, the following relationship also holds:

$$[X] + [L] = c. \quad (13)$$

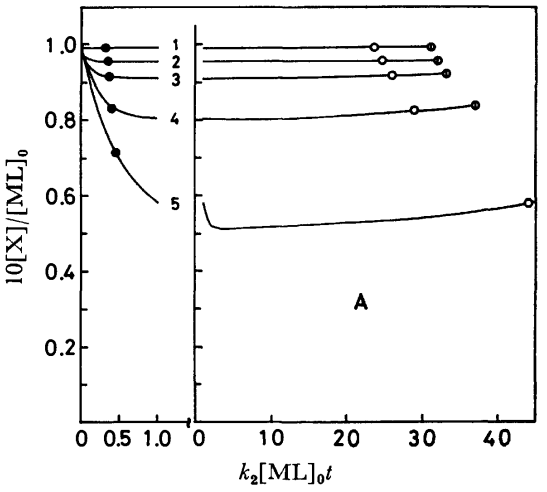
Thus, from Eqs. 11, 12, and 13, the concentration of the X ligand in the steady state is obtained as

$$[X] \approx \frac{k_3/k_2}{1+k_3/k_2}c. \quad (14)$$

The concentration of X as estimated by means of Eq. 14 agrees very well with the concentration of X in the leveling-off range of Fig. 2.

Figure 3 shows the effect of variations in the initial concentration of the free ligand on the time development of the concentration of X.

It appears that the smaller the initial concentration of the free ligand, the more precise the steady-state



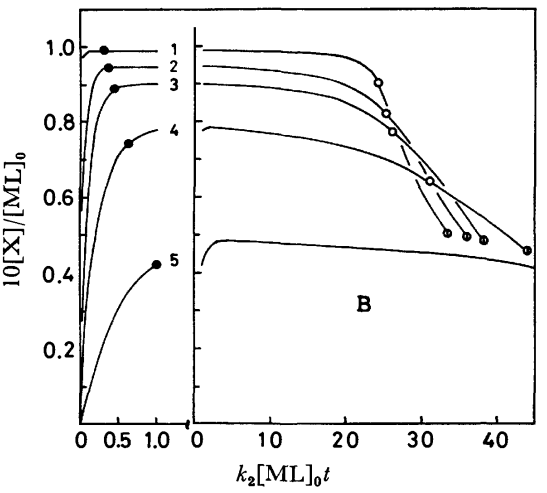


Fig. 2. The time development of the concentration of X for the system I_1 ($k_{-2}=k_{-3}=0$, $[ZX]_0=[ML]_0$). k_3/k_2; (1): 100, (2): 20, (3): 10, (4): 4, (5): 1. A shows the case in which $[X]_0/[ML]_0=0.1$, and B the case in which $[L]_0/[ML]_0=0.1$. Circles indicate the points of 3% (●), 90% (○), and 95% (◑) of the reaction proceeding, here and in the following figures.

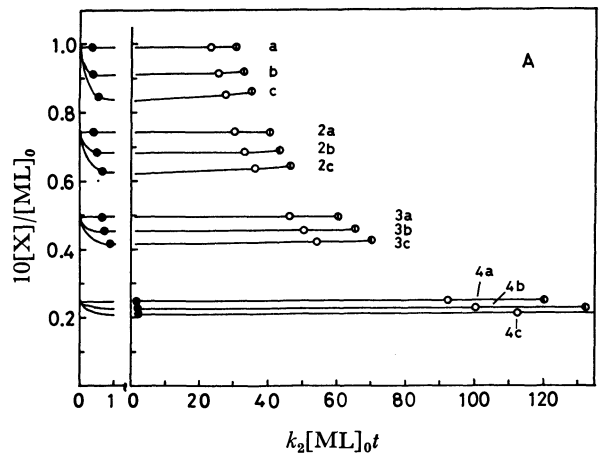
Table 1. Classification of coordination chain-reaction system

I		II		III	
I_1	I_2	II_1	II_2	III_1	III_2
$k_{-2}=k_{-3}=0$	$k_{-2}=k_{-3}=0$	$k_{-2}=0$	$k_{-2}=0$	$k_{-3}=0$	$k_{-3}=0$
$[ZX]_0=[ML]_0$	$[ZX]_0 \geqq 2[ML]_0$	$[ZX]_0=[ML]_0$	$[ZX]_0 \geqq 2[ML]_0$	$[ZX]_0=[ML]_0$	$[ZX]_0 \geqq 2[ML]_0$



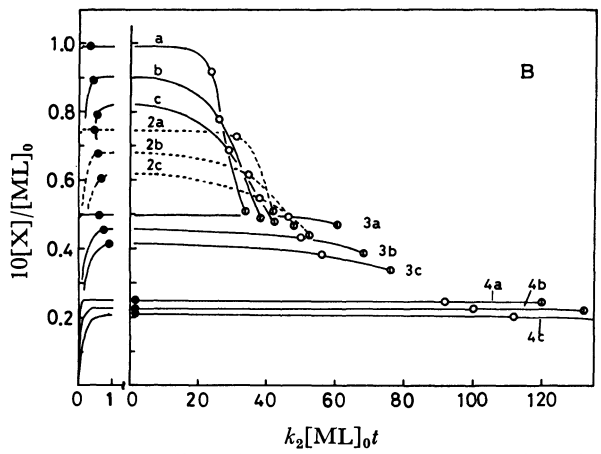


Fig. 3. The effect of the initial concentration of the free ligand on the development of the concentration of X for the system I_1 ($k_{-2}=k_{-3}=0$, $[ZX]_0=[ML]_0$). k_3/k_2, ([ligand]$_0$/[ML]$_0$); a: 100 (0.1), b: 10 (0.1), c: 5 (0.1),2a: 100 (0.075),2b: 10 (0.075),2c: 5 (0.075), 3a: 100 (0.050), 3b: 10 (0.050), 3c: 5 (0.050), 4a: 100 (0.025), 4b: 10 (0.025), 4c: 5 (0.025). A shows the case in which the ligand present initially is X, and B the case in which the ligand present initially is L.

approximation of X becomes, and that when the initial concentration of L is large, a good steady-state approximation of X can not be obtained (Fig. 3.B); moreover, the smaller the initial concentration of the free ligand, the longer the reaction time.

System I_2 ($k_{-2}=k_{-3}=0$, $[ZX]_0 \geqq 2[ML]_0$): Figure 4 shows the time dependence of the concentration of X for the I_2 system.

Where the X ligand is present initially (Case A), the concentration of X decreases at first, but very soon the concentration begins to increase. On the other hand, where L is present initially, the concentration of X increases rapidly at first, and later comes close to that in Case A. These modes differ from those of the I_1 system. Figure 5 shows the effect of the initial concentration of the free ligand on the time development of the concentration of X.

In system I, if the calculated curve of X is expressed as $([X]/[ML]_0)/c$ *vs.* $ck_2[ML]_0t$, the curve is little affected by the variations in the initial concentration

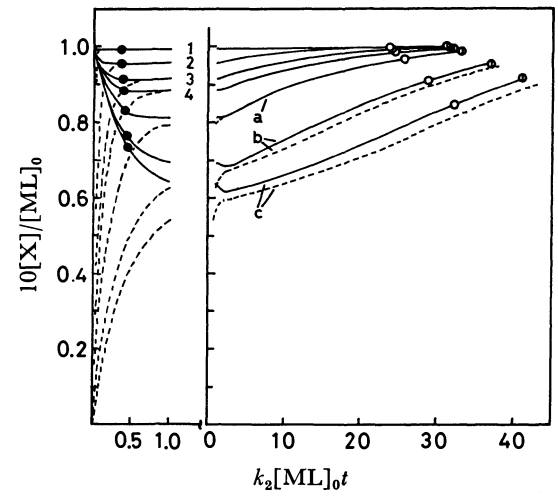

Fig. 4. The time development of the concentration of X for the system I_2 ($k_{-2}=k_{-3}=0$, $[ZX]_0 \geqq 2[ML]_0$).[12] $k_3/k_2 \cdot [ZX]_0/[ML]_0$; (1): 100, (2): 20, (3): 10, (4): 7. $[ZX]_0/[ML]_0$, (k_3/k_2); a: 4 (1.0), b: 2 (1.0), c: 1.5 (1.0). Full lines show the case in which $[X]_0/[ML]_0=0.1$, and dotted lines the case in which $[L]_0/[ML]_0=0.1$.

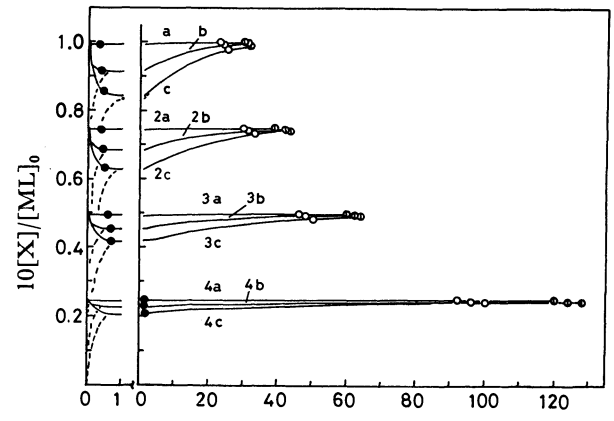

Fig. 5. The effect of the initial concentration of the free ligand on the time development of the concentration of X for the system I_2 ($k_{-2}=k_{-3}=0$, $[ZX]_0 \geqq 2[ML]_0$).[12] $k_3/k_2 \cdot [ZX]_0/[ML]_0$, ([ligand]$_0$/[ML]$_0$); a: 100 (0.1), b: 10 (0.1), c: 5 (0.1), 2a: 100 (0.075), 2b: 10 (0.075), 2c: 5 (0.075), 3a: 100 (0.050), 3b: 10 (0.050), 3c: 5 (0.050), 4a: 100 (0.025), 4b: 10 (0.025), 4c: 5(0.025). Full lines show the case in which the ligand presented initially is X, and dotted lines the case in which the ligand presented initially is L.

of the free ligand, except where $c=[L]_0$ and $[ZX]_0=[ML]_0$.

Therefore, X was henceforth used as the ligand present initially, and the concentration was set at $[X]_0/[ML]_0=0.1$; by these settings, the treatment of the system would be simplified.

Reaction System II. System II_1 ($k_{-2}=0$, $[ZY]_0=[ML]_0$): Figure 6 shows the time development of the concentration of X for the II_1 system. In this system, the time development of X is affected very much by the reverse reaction of R3; only when the k_3/k_{-3} ratio becomes more than 10^4, can the reverse reaction of R3

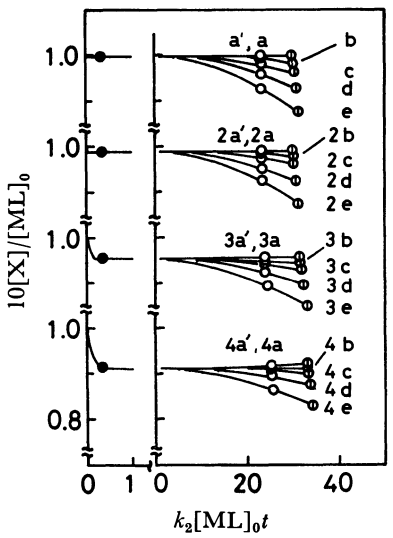

Fig. 6. The time development of the concentration of X for the system II_1 ($k_{-2}=0$, $[ZX]_0=[ML]_0$).
k_{-3}/k_{-2}, (k_3/k_2); a': 0 (1000), a: 0.1 (1000), b: 1 (1000), c: 2 (1000), d: 5 (1000), e: 10 (1000), 2a': 0 (100), 2a: 0.01 (100), 2b: 0.1 (100), 2c: 0.2 (100), 2d: 0.5 (100), 2e: 1.0 (100), 3a': 0 (20), 3a: 0.002 (20), 3b: 0.02 (20), 3c: 0.04 (20), 3d: 0.10 (20), 3e: 0.20 (20), 4a': 0 (10), 4a: 0.001 (10), 4b: 0.01 (10), 4c: 0.02 (10), 4d: 0.05 (10), 4e: 0.10 (10). The initial free ligand concentration ($[X]_0/[ML]_0$) is 0.1.

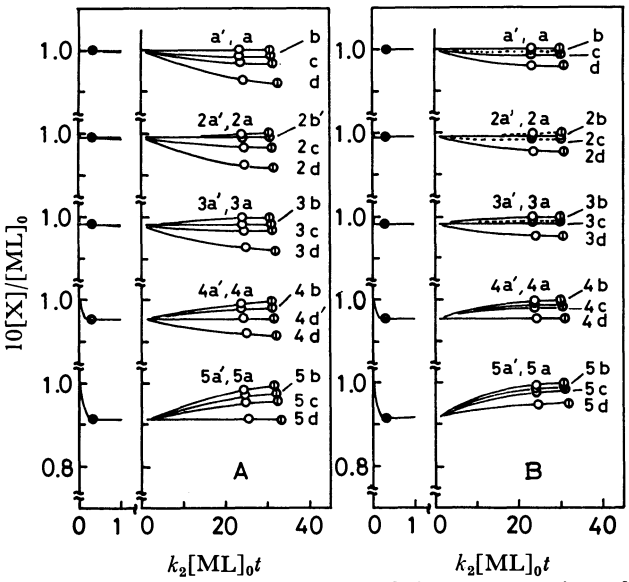

Fig. 7. The time development of the concentration of X for the system II_2 ($k_{-2}=0$, $[ZX]_0\geqq 2[ML]_0$).[12]
k_{-3}/k_2, ($k_3/k_2\cdot[ZX]_0/[ML]_0$); a': 0 (1000), a: 1 (1000), b: 10 (1000), c: 20 (1000), d: 50 (1000), 2a': (100), 2a: 0.1 (100), 2b': 0.5 (100), 2b: 1 (100), 2c: 2 (100), 2d: 5 (100), 3a': 0 (50), 3a: 0.05 (50), 3b: 0.5 (50), 3c: 1.0 (50), 3d: 2.5 (50), 4a': 0 (20), 4a: 0.02 (20), 4b: 0.2 (20), 4c: 0.4 (20), 4d': 0.5 (20), 4d: 1.0 (20), 5a': 0 (10), 5a: 0.01 (10), 5b: 0.1 (10), 5c: 0.2 (10), 5d: 0.5 (10). The initial free ligand concentration ($[X]_0/[ML]_0$) is 0.1. A shows the case in which $[ZX]_0/[ML]_0=2$, and B the case in which $[ZX]_0/[ML]_0\geqq 10$.

be neglected.

System II_2 ($k_{-2}=0$, $[ZY]_0\geqq 2[ML]_0$): Figure 7 shows the time development of the concentration of X for the II_2 system. In Fig. 7.A ($[ZX]_0=2[ML]_0$), it may be seen that, when the k_{-3}/k_2 ratio is equal to 0.5 (2b', 3b, 4d', 5d), the concentration of X is in a steady state.

The concentration of X in the steady state can be calculated as follows. From $d[X]/dt=0$, the following equation is obtained:

$$-k_2[ML][X] + k_3[ZX][L] - k_{-3}[ZL][X] = 0. \quad (15)$$

Combining Eqs. 13 and 15, the following equation is derived:

$$[X] = \frac{k_3[ZX]}{k_2[ML]+k_{-3}[ZL]+k_3[ZX]}c. \quad (16)$$

If the $k_{-3}/k_2=0.5$ and $[ZX]_0/[ML]_0=2$ equations hold, Eq. 16 can be rewritten as[10]

$$[X] = \frac{2k_3/k_2}{(2[ML]+[ZL])/[ZX]+2k_3/k_2}c \approx \frac{2k_3/k_2}{1+2k_3/k_2}c. \quad (17)$$

On the other hand, in Fig. 7.B ($[ZX]_0/[ML]\geqq 10$) it may be seen that, when the k_{-3}/k_2 ratio is equal to unity (a, 2b, 3c, 4d), the concentration of X is in a steady state.

The concentration of X in the steady state can also be calculated as follows. From Eq. 16, the following equation is obtained:

$$[X] = \frac{(k_3/k_2)([ZX]/[ML]_0)}{([ML]+(k_{-3}/k_2)[ZL])/[ML]_0+(k_3/k_2)([ZX]/[ML]_0)}c. \quad (18)$$

Since the $[X]\gg[L]$ inequality holds, the form of $[ML]_0=[ML]+[MX]\approx[ML]+[ZL]$ is obtained; moreover, the $k_{-3}/k_2=1$ equation holds under these conditions; thus, the following relationship is derived:

$$\frac{[ML]+(k_{-3}/k_2)[ZL]}{[ML]_0} \approx 1. \quad (19)$$

From Eqs. 18 and 19, and $[ZX]/[ML]_0\approx[ZX]_0/[ML]_0$, the following equation is derived:

$$[X] \approx \frac{(k_3/k_2)([ZX]_0/[ML]_0}{1+(k_3/k_2)([ZX]_0/[ML]_0)}c. \quad (20)$$

The concentrations of X, as estimated by Eqs. 17 and 20, agree very well with those of the steady state of X in Figs. 7.A and 7.B respectively.

Reaction System III ($k_{-3}=0$). Figure 8 shows the time development of the concentration of X for the III_1 system ($k_{-3}=0$, $[ZX]_0=[ML]_0$). As is shown in Fig. 8, the shape of the diagram for the time development of the concentration of X is not appreciably affected by the reverse reaction of R2. However, the reaction rate is greatly affected by it. These tendencies also appear in the III_2 system ($k_{-3}=0$, $[ZX]_0\geqq 2[ML]_0$), as is shown in Fig. 9.

From Figs. 8 and 9, it can be said that, in the III_1 system, when the k_3/k_{-2} ratio is greater than about 10^3, the III_1 system is approximately equal to the I_1 system, and that, in the III_2 system, when the $(k_3/k_{-2})([ZX]_0/[ML]_0)$ value is greater than about 10^2, the III_2 system is close to the I_2 system.

On the other hand, from Figs. 6 and 7, it can be said that, in the II_1 system, when the k_3/k_{-3} ratio is greater than about 10^4, the II_1 system is close to the I_1 system,

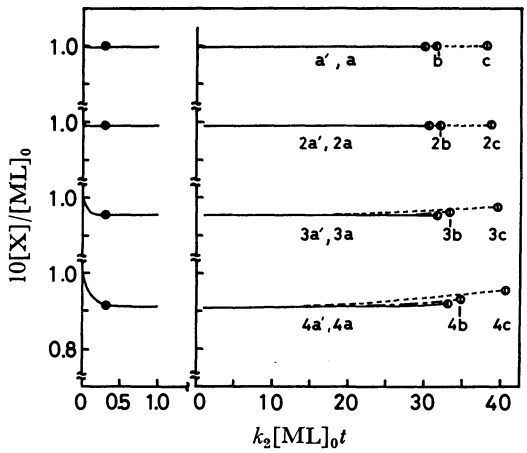

Fig. 8. The time development of the concentration of X for the system III_1 ($k_{-3}=0$, $[ZX]_0=[ML]_0$). k_{-2}/k_2, (k_3/k_2); a': 0 (1000), a: 1 (1000), b: 10: (1000), c: 50 (1000), 2a': 0 (100), 2a: 0.1 (100), 2b: 1 (100), 2c: 5 (100), 3a': 0 (20), 3a: 0.02 (20), 3b: 0.2 (20), 3c: 1.0 (20), 4a': (10), 4a: 0.01 (10), 4b: 0.1 (10), 4c: 0.5 (10). The initial free ligand concentration ($[X]_0/[ML]_0$) is 0.1.

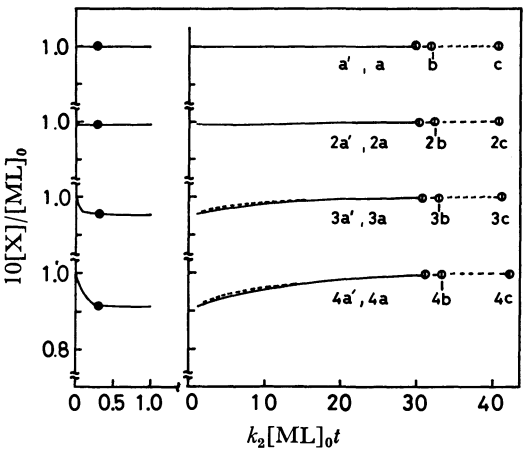

Fig. 9. The time development of the concentration of X for the system III_2 ($k_{-3}=0$, $[ZX]_0\geqq 2[ML]_0$).[12] k_{-2}/k_2, (k_3/k_2 $[ZX]_0/[ML]_0$); a': 0 (1000), a: 10(1000), b: 100 (1000), c: 500 (1000), 2a': 0 (100), 2a: 1 (100), 2b: 10 (100), 2c: 50 (100), 3a': 0 (20), 3a: 0.2 (20), 3b: 2 (20), 3c: 10 (20), 4a': 0 (10), 4a: 0.1 (10), 4b: 1 (10), 4c: 5 (10). The initial concentrations of X and ZX are as follows: $[X]_0/[ML]_0=0.1$ and $[ZX]_0/[ML]_0\geqq 10$.

and that, in the II_2 system, when the $(k_3/k_{-3})([ZX]_0/[ML]_0)$ value is greater than about 10^3, the II_2 system is close to the I_2 system.

In the II and III systems, one of the reverse reactions of R2 and R3 was considered to be negligible. From the above considerations, criteria for the omission of the reverse reaction may be presented as follows: $k_3/k_{-2}\approx 10^3$ for the II_1 system, $(k_3/k_{-2})([ZX]_0/[ML]_0)\approx 10^2$ for the II_2 system, $k_3/k_{-3}\approx 10^4$ for the III_1 system, and $(k_3/k_{-3})([ZX]_0/[ML]_0)\approx 10^3$ for the III_2 system; *i.e.*, for example, when $[ML]_0=[ZX]_0$, if the k_3/k_{-2} ratio is greater than 10^3, the system may be taken as the II_1 system, and when $[ZX]_0\geqq 2[ML]_0$, if the value $(k_3/k_{-2})([ZX]_0/[ML]_0)$ is greater than 10^2, the system may be taken as the II_2 system.

Reaction Rate. When the reaction rate of R1 is defined as the rate of the decrease in ML, the reaction rate of R1 can be written as

$$-\frac{d[ML]}{dt}=k_2[X]_s[ML]-k_{-2}[L][ZX]. \quad (21)$$

Therefore, if k_{-2} is negligibly small and if the concentration of X is constant throughout the reaction, the reaction can be regarded as a pseudo first-order reaction:

$$-\frac{d[ML]}{dt}=k_2[X]_s[ML]=k_o[ML], \quad (22)$$

where $[X]_s$ represents the concentration of X in the steady state.

It should be emphasized that the concentration of X in the steady state is not always equal to that of the ligand present initially. As is shown in Eqs. 14, 17, and 20, the ratio $[X]_s/c$ is little changed by the variations in the initial concentration of the free ligand. Thus, the following equation can be written:

$$\frac{[X]_s}{c}=a \quad (a\leqq 1), \quad (23)$$

where a is constant. Therefore, Eq. 22 can be rewritten as

$$-\frac{d[ML]}{dt}=k_2[X]_s[ML]=ack_2[ML]=k_o[ML]. \quad (24)$$

Consequently,

$$k_o=ack_2. \quad (25)$$

Therefore, if the pseudo first-order rate constant, k_o, is plotted against the free-ligand concentration present initially, the slope of the straight line represents, ak_2; only when $[X]_s=c$, is the value of the slope equal to k_2.

In the previous works,[1-3] it was a little laborious to derive Eq. 24. However, the conditions under which Eq. 24 is derived can be obtained from the diagrams presented above. Thus, the diagrams are useful for studies using a coordination chain reaction. One important fact is that a desired coordination chain reaction can be designed from the individual reactions (R2 and R3) on the basis of the diagrams presented above.

Simulation of the Practical Coordination Chain Reaction. As an example, the ligand-substitution reaction between the ethylenediaminetetraacetatocuprate(II) ion (Cu-(II)-edta) and the triethylenetetraminelead(II) ion (Pb(II)-trien) was undertaken. The reaction was considered to proceed by means of a coordination chain reaction mechanism:

$$\text{Cu(II)-edta} + \text{trlien} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{Cu(II)-trien} + \text{edta}, \quad (R4)$$

$$\text{Pb(II)-trien} + \text{edta} \xrightarrow{k_3} \text{Pb(II)-edta} + \text{trien}. \quad (R5)$$

The known information about these reactions at pH 9.0 is as follows. The conditional equilibrium constant (K) of R4 is 4.2×10, while the conditional rate constant, k_2, is $1.17\times 10^4\ M^{-1}\ s^{-1}$ (this was measured at pH 9.0, 25.0 °C and $I=0.2$); hence, if follows that $k_{-2}=k_2/K=$

2.8×10^{2} M^{-1} s^{-1}. The conditional equilibrium constant of R5 is so large ($K=4.8\times10^{7}$) that the reverse reaction of R5 can be neglected in the kinetic study. Furthermore, the reaction of R5 is very fast; this fact was taken into account by setting k_3 large (*e.g.*, $k_3=1\times10^{7}$ M^{-1} s^{-1}).

In accordance with the above classification, this system can be taken as the III system. Moreover, this system can also be treated as the I system, since the k_3/k_{-2} ratio is larger than 10^3.

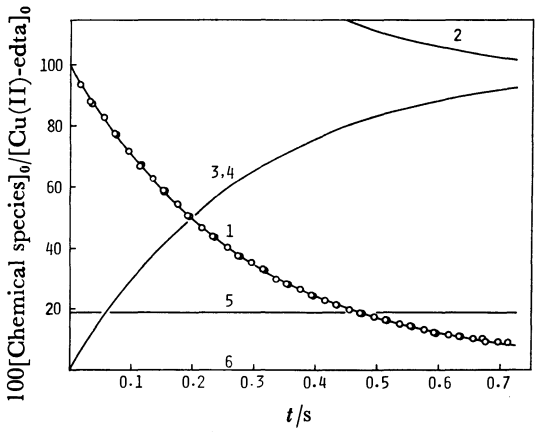

Fig. 10. Computer simulation of the Cu(II)-edta–Pb(II)trien system.[13]
Conditions: $[Cu(II)\text{-edta}]_0=1.86\times10^{-3}$ M, $[Pb(II)\text{-trien}]_0=3.62\times10^{-3}$ M, $[Cu(II)\text{-trien}]_0=[Pb(II)\text{-edta}]_0=0$ M, $[trien]_0=3.5\times10^{-4}$ M, $[edta]_0=0$ M; $I=0.2$ M, pH=9.0, 25.0 °C; $k_2=1.01\times10^{4}$ M^{-1} s^{-1}, $k_{-2}=k_2/K=2.8\times10^{2}$ M^{-1} s^{-1}, $k_3=1.0\times10^{7}$ M^{-1} s^{-1}, $k_{-3}=0$ M^{-1} s^{-1}.
1: Cu(II)-edta, 2: Pb(II)-trien, 3: Cu(II)-trien, 4: Pb(II)-edta, 5: trien, 6: edta. The circles indicate the experimental values.[14]

Figure 10 shows the results of the computer simulation of the Cu(II)-edta–Pb(II)-trien system (under the above conditions).[15] The experimental values (points of circle) agree with the calculated values. The calculated concentration of free trien is constant throughout the reaction and is nearly equal to the concentration of added free trien; these facts can also be predicted from Fig. 4, from which it follows that

$$\frac{k_3}{k_2}\frac{[ZX]_0}{[ML]_0}=\frac{k_3}{k_2}\frac{[Pb(II)\text{-trien}]_0}{[Cu(II)\text{-edta}]_0}=1.9\times10^{3}.$$

Using the diagrams stated above, the reaction of the practical system may be predicted.

8) The rate determining step in the reaction model represented by Reactions R2 and R3 is defined as R2.
9) If the values of $[ZX]_0/[ML]_0$, $[\text{free ligand}]_0/[ML]_0$, and k_n/k_2 ($n=-2, \pm3$) in one system are equal to the respective values in the other system, these systems give the same relative concentration-$k_2[ML]_0t$ curve.
10) $(2[ML]+[ZL])/[ZX]=N/D\approx1$ can be derived as follows. N is written as $N=2[ML]+[ZL]=2([ML]+[ZL])-[ZL]$. As the $[X]\gg[L]$ inequality holds, [ZL] is approximately equal to [MX]. Consequently, $N\approx2[ML]_0-[ZL]$. On the other hand, $D=[ZX]=[ZX]_0-[ZL]=2[ML]_0-[ZL]$. Thus, $N/D\approx1$.
11) In the diagram, the following relationships hold: $[X]+[L]=c$ and $[L]=c-[X]=[MX]-[ZL]=[ZX]-[ML]$. In general, the following relationships also hold: $[X]+[L]=c$ and $[L]=c-[X]=|[MX]-[ZL]|=|([ZX]-(n-1)[ML]_0)-[ML]|$, where n ($n\geqq1$) is equal to the $[ZX]_0/[ML]_0$ ratio; these relationships were confirmed to hold from the simulations.
12) If the $[ZX]_0/[ML]_0$ ratio is greater than about r(r: 5 for Figs. 4 and 5, and 10 for Figs. 7 and 9),the reactions which have the same value of the product of k_3/k_2 and $[ZX]_0/[ML]_0$ give almost the same time development of the concentration of X.
13) In the simulation, the time developments of all the species were little affected by the variation in k_3.
14) In the kinetic measurements, a stopped-flow technique was employed with a Hitachi Model RSP-2 Rapid-scan Spectrophotometer. The reactions were followed at 575 nm.
15) In this simulation, the value of $k_2=1.01\times10^{4}$ M^{-1} s^{-1} was used. This value agrees closely with that obtained from other experiments.

A Kinetic Study of the Interaction of Sodium Dodecyl Sulfate with Bovine Serum Albumin by Means of a Pressure-jump Method

Kunio TAKEDA

Department of Applied Chemistry, Faculty of Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700

(Received November 18, 1981)

A single relaxation was found in the system of sodium dodecyl sulfate and bovine serum albumin using a pressure-jump method with conductivity detection. The relaxation was observed in the concentration range of the surfactant below the critical micelle concentration. The relaxation time becomes fast with the stepwise formation of a complex between them and finally attains values compatible with those in the system of the pure surfactant micelle. This suggests a correlation of the relaxation phenomena with the partial breakdown and reformation of the complex. The similarity of the complex to the surfactant micelle was discussed on the basis of the kinetic aspects of the interaction of the surfactant with the protein.

The interactions between proteins and surfactants have been extensively investigated.[1] Quite recently, the present author and others have studied the interaction between sodium dodecyl sulfate (SDS) and bovine serum albumin (BSA).[2] They have found that an electric conductivity method is very useful in detecting the formation of complexes between them. This is because the measurement is highly sensitive to changes in the concentrations of surfactant ions. On the other hand, a pressure-jump method with conductivity detection has been used in many studies of micellization kinetics.[3] Therefore, it would be interesting to apply the pressure-jump method to the study of the surfactant-protein interactions. It is believed that further studies from a new aspect would be helpful in understanding the interactions.

It is worth noting that a similarity of the complex to the surfactant micelle is also found in the kinetic phenomena of the interaction. This paper will report the presence of a single relaxation process in the SDS–BSA system, which is strongly correlated with the stepwise growth of the complexes formed between them.

Experimental

The sources of SDS and BSA have been described previously.[2] The concentration of the protein was determined spectrophotometrically using $E^{1\%}_{1cm}=6.8$ at 280 nm.[4]

Kinetic measurements were made using a handmade pressure-jump apparatus similar to that described elsewhere.[5,6] However, it has been a little improved as follows. It is driven by water-pressure and a brass diaphragm bursts at a pressure of approximately 100 atm (1 atm=101.3 kPa). The triggering of the recording is done using a piezoelectricity of $PbTiO_3$ (see Acknowledgments). Circular dichroism measurements were carried out with a JASCO J-500A spectropolarimeter equipped with a DP-501 data processor.[2] A 1.0 mm light-pass-length cell was used in the measurements. The static conductivity was measured with a Universal Bridge 4265B of Yokogawa-Hewlett-Packard. Details of the conductivity measurements have been described elsewhere.[2]

All the measurements were made at 15 °C, because the accuracy of the relaxation time obtained by the pressure-jump method was greater at lower temperatures (see Fig .3 in Ref. 6). The only available solvent in high-precision conductometry has been limited to pure water in the pressure-jump measurements,[5] and so all the measurements were carried out in a non-buffered system, using water prepared by passing redistilled water through a mixed-bed ion-exchange column. The specific conductivity of the water used was above 1×10^{-6} Ω^{-1} cm^{-1}. The BSA concentration was held constant, 1.0×10^{-5} M (as the concentration unit, 1 M=1 mol/dm^3 is used).

Results

Prior to the application of the pressure-jump method to the study of the SDS–BSA interaction, the SDS-induced conformational change of the protein was examined by the circular dichroism measurements and the conductance changes with the complex formation were also measured. Figure 1 shows the SDS concentration dependence of the difference of residue ellipticity at 222 nm, $[\theta]_{222}$, which is one of the characteristic wavelengths for the helical structure of polypeptides. The addition of SDS caused a decrease of the helix-like structure, as may be seen in the insert of Fig. 1. The helix content decreased with an increase of the SDS concentration.

A conductivity method has so far been used in order to detect the micelle formation of ionic surfactants.[7] When the method was applied to the present SDS–BSA

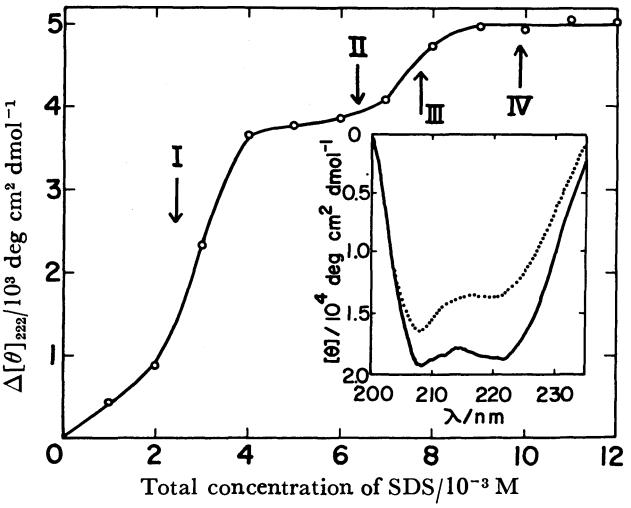

Fig. 1. The dependence of the residue ellipticity, $[\theta]_{222}$ on the SDS concentration. The typical circular dichroic spectra of BSA solutions in the absence (solid curve) and in the presence (dotted curve) of 12 mM SDS are shown in the insert. The arrows indicate the SDS concentrations where the inflection points appear in a plot such as Fig. 2.

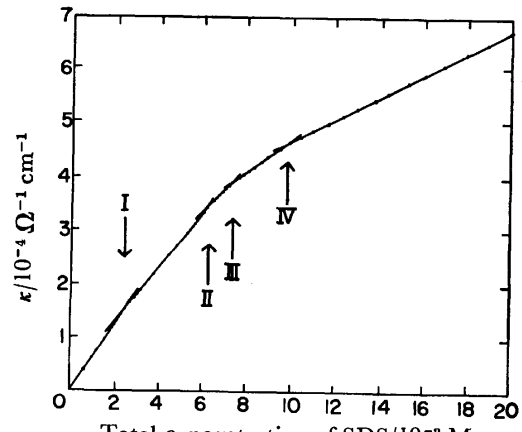

Fig. 2. The specific conductance, κ, of solutions of various SDS concentrations in the presence of 1.0×10^{-5} M BSA.

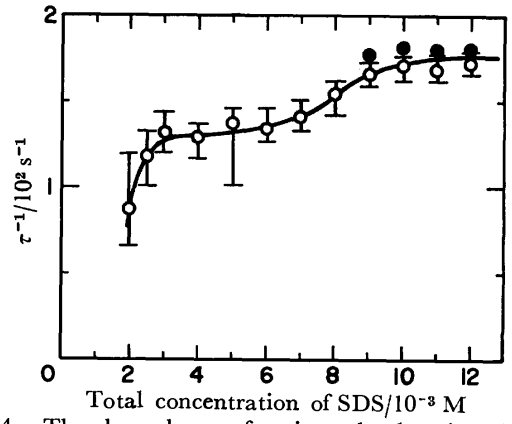

Fig. 4. The dependence of reciprocal relaxation time, τ^{-1}, on the SDS concentration (open circle). The vertical lines were drawn through the experimental points. Solid circles show the values of τ^{-1} in the pure SDS system.

system, four inflection points were observed in the plot of the specific conductance versus the concentration of SDS added to an aqueous BSA solution, as is shown in Fig. 2. These inflections can be demonstrated more clearly through an enlarged plot (not shown), as has been discussed before.[2] These inflection points appeared around 2.5, 6.5, 7.5, and 9.9 mM SDS. In comparing the SDS concentration dependence of the conformational change with the results of the conductivity measurements mentioned above, the first and the third inflections (corresponding to those at 2.5 and 7.5 mM SDS) appear in the courses of the first predominant conformational change and the subsequent one respectively, as is indicated by arrows in Fig. 1. The second and the fourth inflections (at 6.5 and 9.9 mM SDS) correspond to the beginning and the end of the second conformational change respectively (also shown by the arrows).

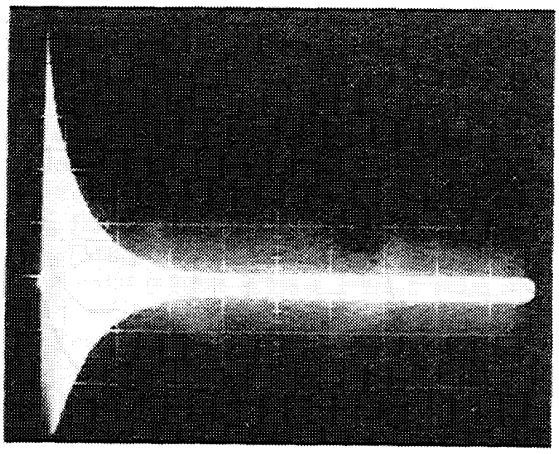

Fig. 3. The representative relaxation curve of 6.0 mM SDS solution containing 1.0×10^{-5} M BSA at 15 °C. The sweep rate is 10 m s/div.

The conductivity pressure-jump method was applied to the study of the SDS–BSA interaction. A representative relaxation curve is shown in Fig. 3. The relaxation phenomena in the presence of the protein were observed even in low SDS concentrations below the critical micelle concentration (CMC), although they had been observed only above the CMC in the pure SDS system.[3] The SDS concentration dependence of the relaxation time, τ, is presented in Fig. 4. The value of τ^{-1} gradually increased at first, attained a plateau between 3 and 7 mM SDS, and increased again up to about 9 mM SDS. The final values of τ^{-1} are compatible with those obtained in a solution containing only SDS micelles, indicating that the phenomena are not completely independent of those of micellization.

Discussion

The BSA has been proposed to have a few fairly independent domains.[8-11] The results obtained by the limited proteolysis of the protein strongly indicate that the protein consists of, at least, two independent domains.[8-10] It has been suggested by Jones *et al.*, in the light of the domain-structure theory, that the binding of surfactants initially occurs mainly to the C-terminal section of the protein molecule, bringing about its unfolding, and that the more stable N-terminal part then begins to unfold exposing new binding sites with an increase of the surfactant concentration.[11] At the same time, it is generally accepted that the surfactant molecules cooperatively bind to the protein by hydrophobic interaction following the first binding of approximately 8—10 molecules by electrostatic interaction.[1,12] In the interaction of the BSA with surfactants, the stepwise and all-or-none nature of the complex formation has been emphasized,[13] that is, there exist only complexes which consist of, at most, a few particular binding ratios (surfactants/protein), depending on the surfactant concentration ranges.[14-18] The binding isotherm has so far been explained in terms of the following expression;[12,18-20]

$$P \rightleftharpoons PS_{8-10} \rightleftharpoons PS_n \rightleftharpoons PS_{2n} \rightleftharpoons PS_{>2n} \quad (n = 40\text{—}50),$$

where P and S denote the protein and a surfactant, respectively, and n is the binding number of the surfactants (mol/mol). As has been discussed before,[2] and also as has been mentioned above, the profile of the conduc-

tance change is also reflected by the stepwise formation of complexes and the concomitant conformational changes of the protein with clearly separate domains. The binding of SDS to BSA and the accompanying conformational changes of the protein have previously been examined under experimental conditions[2] different from those of this work. In taking account of the SDS concentration dependence of the ellipticity at 222 nm[21] and the SDS concentration where the first inflection of the conductance change appears, it seems that there exist the complexes with bound surfactants above 40—50 molecules in the SDS concentration range where the relaxation has been observed. Thus, the discussion given below will be limited to the behavior of the complexes which have been considered to be formed cooperatively.

Three important facts should be taken into consideration in discussing the relaxation mechanism of the present system. The first is the fact that the contribution of the protein to the conductance is negligibly small compared with that of the surfactant, as has been stated previously.[2] This is also to be expected from the fact that the conductivity curve actually starts from the origin in Fig. 2 in spite of the existence of the protein. Naturally, the behavior of the surfactant molecules seems to be primarily related to the relaxation phenomena observed here. This may indeed be reasonable, when a similarity of the values of τ in the present system to those in the pure SDS system is taken into account. The second is that only complexes with particular binding ratios can exist at a certain SDS concentration, as has been stated above. Since the complexes are formed in the low SDS concentration range where the concentration of unbound surfactants is lower than the CMC,[1] the ordinary micelle does not exist in the total concentration range of SDS below about 10 mM (=about 8 mM (CMC) of unbound SDS+about 2 mM of SDS bound to 1.0×10^{-5} M BSA[2]). Therefore, the participating species of the surfactant may be limited to both free monomers and those bound to the protein with particular binding ratios. The nature of the latter participating species may critically change with the shift of the SDS concentration range.[11-16] Thirdly, it has been reported that the surfactant molecules bound to proteins are not easily removed from the proteins, so their removal needs specially designed techniques.[22] The difficulty of the removal of such surfactants is reminiscent of the long period necessary to attain the dialysis equilibrium which has frequently been utilized in studies of the binding of surfactants to proteins.[1,23-25] Therefore, it is improbable to assume a reversible process of a large-scale formation and complete dissociation of the complex such as $nS+P\rightleftharpoons PS_n$. This situation is also reminiscent of a previous experimental finding that only the relaxation process with relaxation times in the milli-second range exists in an emulsion system consisting of SDS and pentadecane.[26] In such an emulsion system, it would be impossible to assume a reversible process of a large-scale formation and complete dissociation of the emulsified particle. These facts might appear to contradict the previously proposed assumptions of micellization kinetics that the relaxation process with relaxation times in the milli-second range is related to the formation and complete dissociation of surfactant micelles.[3,27,28] Because of the reasons mentioned above, nevertheless, the formation and complete dissociation of the complex cannot be assumed, at least, in the present complexes system. Therefore, in the surfactant–protein system, a probable reversible process is the partial breakdown and reformation of the complex as follows;

$$mS + P_iS_{n-m} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} P_iS_n, \tag{1}$$

where $m \ll n$, P_i indicates the protein with the i-th conformation in the stepwise conformational change, and k_{12} and k_{21} are the corresponding apparent rate constants.

The rate of Reaction 1 is expressed as follows;

$$\frac{d[P_iS_n]}{dt} = k_{12}[S]^m[P_iS_{n-m}] - k_{21}[P_iS_n], \tag{2}$$

where [ ] designates instantaneous concentrations during the perturbation of the equilibrium. The following relationship can be defined between the instantaneous concentrations and the equilibrium ones designated by the subscript, e;

$$x=[S]-[S]_e,\ y=[P_iS_{n-m}]-[P_iS_{n-m}]_e, \text{ and}$$
$$z = [P_iS_n] - [P_iS_n]_e. \tag{3}$$

By substituting Eq. 3 into Eq. 2, and by then expanding it in a power series, we obtain;

$$\frac{d[P_iS_n]}{dt} = k_{12}([S]_e^m[P_iS_{n-m}]_e + m[S]_e^{m-1}[P_iS_{n-m}]_e x + [S]_e^m y) - k_{21}([P_iS_n]_e + z). \tag{4}$$

Here, by introducing both the definition of the equilibrium condition and these relations; $x=-mz$ and $y=-z$ obtained from the stoichiometry of Reaction 1, we obtain;

$$\frac{dz}{dt} = -\{k_{12}(m^2[S]_e^{m-1}[P_iS_{n-m}]_e + [S]_e^m) + k_{21}\}z. \tag{5}$$

Then, we obtain;

$$\tau^{-1} = k_{12}(m^2[S]_e^{m-1}[P_iS_{n-m}]_e + [S]_e^m) + k_{21}. \tag{6}$$

Since

$$K_{12} = \frac{k_{12}}{k_{21}} = \frac{[P_iS_n]_e}{[S]_e^m[P_iS_{n-m}]_e},$$

we obtain;

$$k_{12}[S]_e^m = k_{21}\frac{[P_iS_n]_e}{[P_iS_{n-m}]_e}. \tag{7}$$

By assuming

$$[P_iS_{n-m}]_e = [P_iS_n]_e, \tag{8}$$

and by neglecting the magnitude of the first term compared with the second one in parentheses of Eq. 6, we obtain;

$$k_{21} = \frac{\tau^{-1}}{2}. \tag{9}$$

Therefore, we can substantially evaluate 50—80 s^{-1} as the magnitudes of k_{21} depending on the SDS concentration. This treatment apparently indicates that the rate constant of the dissociation becomes faster with

the complex growth, as has been anticipated from Fig. 4. However, the apparent dependence of k_{21} on the SDS concentration range should be considered to be mainly due to changes in the $[P_iS_n]_e/[P_iS_{n-m}]_e$ ratio. Strictly considered, it is considered that the ratio becomes greater than 1 in higher SDS concentrations, because the average amounts of the surfactants bound to the protein increase with the total SDS concentration, as judged from the binding isotherms.[1,2] Such a change in the ratio with the complex growth leads to smaller values of k_{21} than those straightforwardly obtained by Eq. 9. Therefore, the present author considers that the magnitudes of k_{21} hardly change at all with the complex growth in the SDS concentration range discussed here.

The magnitudes of k_{21} can be connected with those of the elementary steps of Reaction 1 as follows. It should be assumed that Reaction 1 consists of these succesive bimolecular steps;

$$\begin{aligned} &P_iS_{n-m} + S \underset{k_-}{\overset{k_+}{\rightleftharpoons}} P_iS_{n-m+1} \\ &\qquad\vdots \\ &P_iS_{n-2} + S \rightleftharpoons P_iS_{n-1} \\ &P_iS_{n-1} + S \rightleftharpoons P_iS_n, \end{aligned} \tag{10}$$

where k_+ and k_- are forward and backward rate constants, respectively. If each bimolecular step has the same activation energy, we obtain;

$$\prod_{j=1}^{m} K_j = \frac{k_+^m}{k_-^m} = \frac{k_{12}}{k_{21}} = K_{12} (1 \leq j \leq m), \tag{11}$$

where K_j is the equilibrium constant of each elementary step. Then, we obtain;

$$k_+ = k_{12}^{1/m} \text{ and } k_- = k_{21}^{1/m}. \tag{12}$$

The m value has been assumed to be very small. Therefore, we can substantially evaluate the rate constant, k_-, of the elementary dissociation process to be in orders of 1 to 10.[29]

Kinetic studies have so far been neglected with regard to the surfactant-protein interactions. Needless to say, further studies are required in order to discuss the relaxation mechanism of the system in detail.

The micelle-like properties of the surfactant-protein complexes have previously been demonstrated.[30] It is worth noting that a similarity of the complexes to the surfactant micelle also appears in the kinetic aspects of the interactions.

The author wishes to express his thanks to Dr. T. Nagata of Wireless Research Laboratory of Matsushita Denki (Electric Co.) for his kind donation of the $PbTiO_3$ element. Thanks are also due to Mr. H. Takahashi for his cooperation in the construction of the pressure-jump apparatus. This work was partly supported by a Grant-in-Aid for Scientific Research No. 56540270 from the Ministry of Education, Science and Culture of Japan.

29) Through Eq. 12, we obtain k_-=50—80 s^{-1} (if m=1), 7.1—8.9 s^{-1} (m=2), 3.7—4.3 s^{-1} (m=3), and 2.2—2.4 s^{-1} (m=5). Equations 11 and 12 will not hold when the m value is large, because it may become impossible for each elementary step to have the same activation energy in such a case.[6]

The Molecular Structure of Trimethylphosphine-Boron Triiodide as Studied by Gas-phase Electron Diffraction

Kinya IIJIMA, Eiichi KOSHIMIZU, and Shuzo SHIBATA*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received December 9, 1981)

The molecular structure of trimethylphosphine-boron triiodide $(CH_3)_3P \cdot BI_3$ has been determined by means of gas-electron diffraction. The molecular parameters and their uncertainties were r_g(B–I)$=2.233\pm0.003$ Å, r_g(P–B)$=1.947\pm0.011$ Å, r_g(C–P)$=1.809\pm0.003$ Å, r_g(C–H)$=1.094\pm0.008$ Å, $\angle$IBI$=111.6\pm0.3°$, and $\angle$CPC$=106.0\pm0.5°$. The gaseous molecule was rigid with respect to the rotational vibration around the P–B bond.

Trimethylphosphine readily forms complexes with boron trihalides. The molecular structures of the boron trichloride, boron tribromide, and boron triiodide complexes have been determined in the solid phase,[1] and the first two complexes have also been determined in the gas phase.[2,3] In the solid phase, the P–B distances of the complexes decrease with the increase in the atomic numbers of halogen atoms in the boron trihalides, though in the gas phase, the P–B distances in the chloro and bromo complexes are nearly equal. On the other hand, the rotational barrier about the P–B bond of $(CH_3)_3P \cdot BBr_3$[3] is larger than that of $(CH_3)_3P \cdot BCl_3$[2] in the gas phase. Thus, it is of interest to study the molecular structure of trimethylphosphine-boron triiodide $(CH_3)_3P \cdot BI_3$ in the gas phase in order to determine the P–B bond distance and the rotational barrier about this bond, and to compare the molecular structures of trimethylphosphine complexes with one another.

Experimental

Trimethylphosphine-silver iodide was prepared by the procedure described elsewhere.[4] The complex was decomposed at 200 °C under a vacuum, and the trimethylphosphine was collected in a trap cooled by liquid nitrogen after the benzene solution of boron triiodide has previously been condensed. The mixture in the trap was warmed up to room temperature and then allowed to react. Activated charcoal was added to the acetone solution of the crude complex, and sublimations were repeated to remove any impurities. The purity of the complex was confirmed by a study of the IR spectra.[5]

In the electron-diffraction experiment, the sample was vaporized at 200 °C through a high-temperature nozzle. The photographs were taken using an r^3-sector on Kodak Electron-Image plates at camera distances of 293.5 and 143.6 mm. The accelerating voltage was 40 kV. The exposure times were 12 s for the long camera distance and 21 s for the short camera distance with an electron-beam current of 0.7 μA. The pressure in the diffraction chamber was below 1×10^{-5} Torr (1 Torr$=$133.322 Pa) during the experiment. The electron wavelength was determined from the diffraction patterns of thallium chloride.[6] The optical densities of four long camera-distance plates and four short-camera-distance plates were measured at 0.4 mm intervals by means of a digital microphotometer. The electron-diffraction unit and the digital microphotometer used in the present study have been described previously.[7]

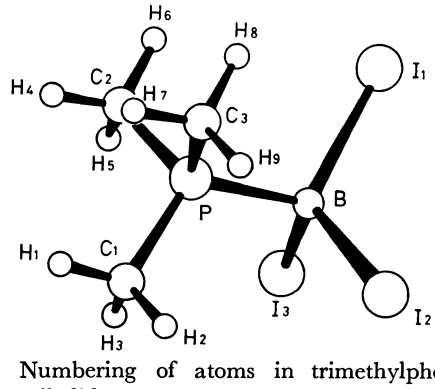

Fig. 1. Numbering of atoms in trimethylphosphine-boron triiodide.

Analysis and Results

The scattering intensities were obtained in the ranges of $s=2.5$—16.2 Å^{-1} and 7.5—34.2 Å^{-1} from the long- and short-camera-distance plates respectively. The intensities were leveled by means of theoretical backgrounds, and then the intensities for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer *et al.*[8] and by Cromer and Mann[9] respectively. The inelastic scattering factor for the hydrogen atom was taken from the table by Tavard *et al.*[10]

The background curves were drawn smoothly,[11] and the molecular intensities thus obtained are shown in Fig. 2.[12] The experimental radial distribution function,

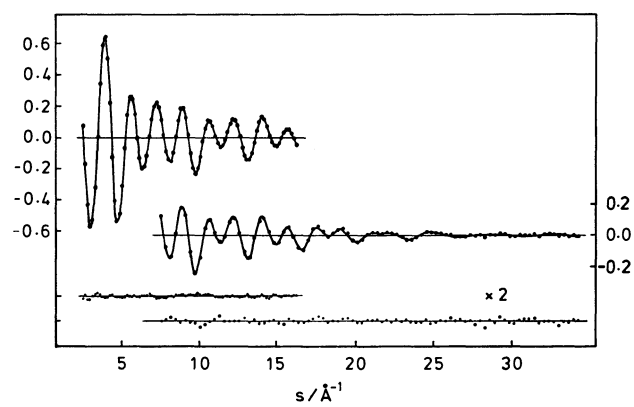

Fig. 2. Molecular intensities for trimethylphosphine-boron triiodide. The upper two curves are long and short camera-distance data. Dots represent observed ones, solid curves calculated ones, and two times the residuals are shown in below.

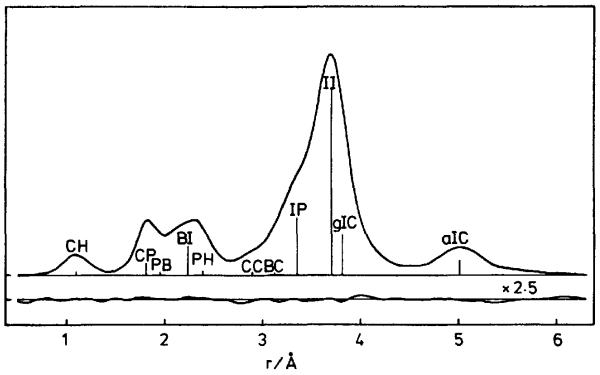

Fig. 3. Radial distribution curve for trimethylphosphine–boron triiodide. Solid curve represents the experimental curve, and lower curve 2.5 times the residuals.

shown in Fig. 3, was calculated from the observed molecular intensities of the range of $s=2.5$—34.2 Å^{-1}, where the long- and the short-camera-distance data were averaged in the overlapped region. A non-nuclear correction for the large difference between the atomic numbers of iodine and the other atom was made.[13,14]

The geometrical parameters listed in Table 3 and the mean amplitudes in Table 4 were determined by a least-squares analysis of the molecular intensities. It was assumed that the $(CH_3)_3P\cdot BI_3$ molecule has the C_{3v} symmetry in as taggered form, and that the methyl group has also C_{3v} symmetry in a staggered form with respect to the C–P bond. The asymmetry parameter, κ, for the C–H bond was assumed to be 1.2×10^{-5} Å^3, given by a diatomic approximation.[15] The asymmetry parameters for the other atomic pairs were neglected. The mean amplitudes and the shrinkage effects,[16] r_a-r_α, were calculated on the basis of the force field for $(CH_3)_3P\cdot BI_3$.[5]

The mean amplitudes for the B–I and I···I atomic pairs obtained in the least-squares analysis disagreed with those calculated from the force field given by Drake *et al.*[5] (see Table 4). On the basis of the fact that

Table 1. Force field for $(CH_3)_3P\cdot BI_3$

f(CH)	4.756	H(IBI)	0.20
f(HCH)	0.438	F(II)	0.27†

f(CPC)	0.82	f(CH/CH′)	0.045
f(CPB)	0.99	f(HCP/HCP′)	−0.107
f(CP)	3.32	f(CP/CP′)	0.36
K(PB)	2.22	f(CPB/CPB′)	−0.045
K(BI)	1.2†	f(PBI/PBI′)	−0.19
H(PBI)	0.22	Y(CP)	0.081†

In the present normal-coordinate calculations, the general-valence force constants, f, and the Urey-Bradley force constants, K, H, F, and Y, were used. The units are 10^2 N m^{-1} for the stretching and repulsion constants, 10^{-18} J rad^{-2} for the bending constants, and 10^{-18} N m for the torsional constants. The linear constant, F' was assumed to be $-0.1F$. The values of the force constants were taken from Ref. 5, but those indicated by daggers were estimated for the gaseous molecule in the present study.

I_1···H_6	3057	−73	H_2···H_9	3284	14

The numbering of atoms is shown in Fig. 1.

the force constants of K(BI) and F(II) are mainly related to l(B–I) and l(I···I) respectively, these constants were estimated to be $K(BI)=1.2\times10^2$ N m^{-1} and $F(II)=0.27\times10^2$ N m^{-1} respectively, so that the calculated values of l(B–I) and l(I···I) might be equal to the respective observed values.

In this calculation, the torsional vibration about the P–B bond was disregarded, for the mean amplitude for the *gauche* I···C atomic pair obtained from the least-squares analysis was nearly equal to that calculated from the force field neglecting this vibration. The force constant for the torsional vibration about the C–P bond was assumed to be 0.08×10^{-18} N m, which was estimated from the potential barrier of 2.6 kcal mol^{-1} for trimethylphosphine.[17] The force constants for gaseous $(CH_3)_3P\cdot BI_3$ modified in the present study are given in Table 1, while the calculated mean amplitudes and the shrinkage corrections for this molecule are given in Table 2.

The r_α parameters determined by the least-squares analysis are listed in Table 3, where the r_g parameters and the limits of error are also listed. The random errors are 2.6 times the standard errors in the least-squares calculations. The systematic errors were estimated from the errors in the measurement of the
