Solubility. In the case of the mixture with MC, the concentration of amobarbital in the filtrate of the suspension of the KH_2PO_4–Na_2HPO_4 buffer solution increased gradually with shaking, and then it stayed nearly constant after shaking for more than 2 h. However the concentration was at a maximum at the shaking time of 5 min for the other mixtures. In Figs. 12, 13, and 14, $c_{5\,min}$, $c_{2\,h}$, and c_e are the concentrations for the suspension shaken for 5 min, for 2 h, and set aside at 30 °C for a week after shaking for 2 h, respectively. The values of $c_{2\,h}$ or $c_{5\,min}$ for amobarbital in the ball-milled mixture were larger than the values for amobarbital ball-milled in the absence of the diluent. In Fig. 12, the $c_{5\,min}$ value for the mixture with dextran was at a maximum at a ball-milling time around 30—70 h; this was probably attributable to the fact that the surface energy of the amobarbital particles was at a maximum at this stage. In Figs. 10 and 11, D_{50} for the mixture with MC was larger than that for the mixture with dextran, but c_{2n} and c_e for the mixture with MC were larger than $c_{5\,min}$ for the mixture with dextran. To judge from this fact, it does not seem that the surface energy is the main reason for the increase in the solubility of amobarbital.

The amorphous part in the amobarbital particles in the ball-milled mixtures was larger than the part for amobarbital ball-milled in the absence of diluents. In Figs, 3, 4, 6, 12, 13, and 14, the increase in $c_{5\,min}$ upon ball-milling with dextran or MCC at the first stage and the increase in c_e for the mixture with MC were parallel to the increase in the amorphous part. These facts suggest that the increase in the solubility of amobarbital upon ball-milling is due to the increase in the amorphous part. The solubility of amobarbital in the ball-milled mixture is expected to be 6—8.5 times as high as that of the original amobarbital, from the thermodynamical consideration using the data of ΔH_{obsd} and T_2, if the solid state of amobarbital in the ball-milled mixture is equilibrated with amobarbital in the solution.[2)]

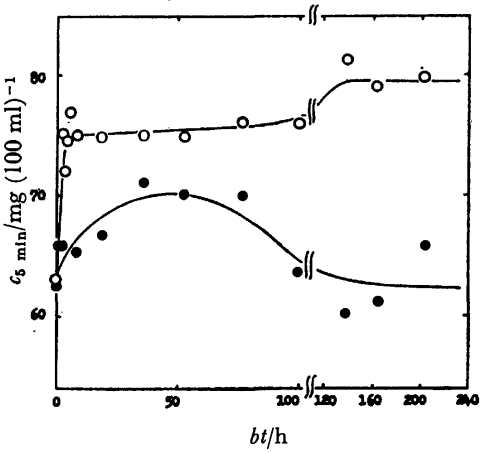

Fig. 12. Effect of ball-milling with the diluent on dissolution of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution.
The content of amobarbital: 30 w/w%, diluent: ●; dextran, ○; MCC.

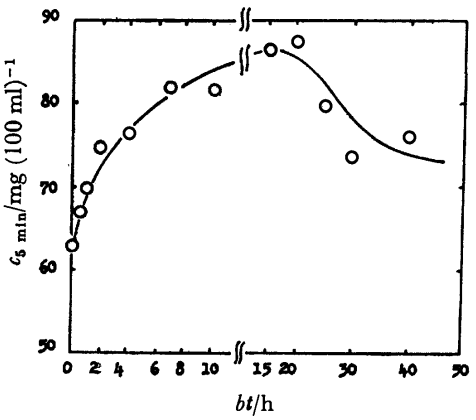

Fig. 13. Effect of ball-milling with MCC on dissolution of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution.
The content of amobarbital: 10 w/w%.

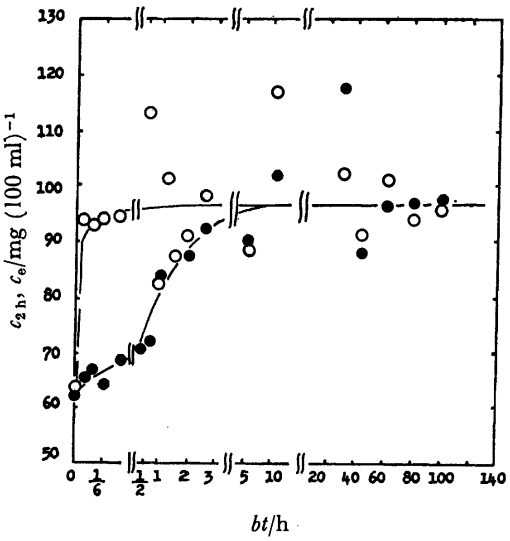

Fig. 14. Effect of ball-milling with MC on dissolution of amobarbital in the KH_2PO_4–Na_2HPO_4 buffer solution.
○: c_{2h}, ●: c_e.

In Figs, 3, 4, 5, and 6, the percentage of the amorphous part in amobarbital for the mixture with MC is nearly equal to the percentage for the mixture with MCC, though the percentage for the mixture with dextran is a little smaller than the percentage for the other mixtures. However, the c_{2h} for the mixture with MC was larger than the $c_{5\,min}$ for the other mixtures. For the mixture with MC, c_e was nearly identical with c_{2h}, but for the other mixtures c_e was smaller than $c_{5\,min}$ and nearly identical with the solubility of the original amobarbital. This fact suggests that the interaction of amobarbital with the diluent caused by ball-milling is one of the important reasons for the increase in the solubility. More details will be reported in another paper concerning this problem.

(Received August 3, 1981)

The first and second order dipole moment parameters along the CH bond in benzene, chloroform, and cyclohexane were obtained by deducing the local mode intensities on the basis of the one-dimensional Morse oscillator model. The validity of the one-dimensional model is discussed according to a newly introduced formula which helps us to understand the nature of local mode absorptions. The relative intensities of the first overtones to the other bands were found to be crucially important in determining M_2/M_1 together with its sign, because the contributions of the mechanical and electrical anharmonicities to M_1/M_2 are often cancelled out each other accidentally. The M_2/M_1 values for benzene, cyclohexane, and chloroform were 2.3, 1.45, and -0.93 Å^{-1} respectively. These values for benzene and cyclohexane were excellently reproduced by the *ab initio* calculations for benzene and methane respectively.

The local mode idea has been recognized as a convenient representation for highly excited vibrational states, where anharmonic characters can never be neglected, since it was introduced by Henry and Siebrand[1] and later developed by Albrecht *et al.*[2] Surprisingly simple features in high overtone spectra of many hydrocarbons were successfully explained by a virtually isolated diatomic model which represents each local CH bond. However, these facts do not immediately mean that highly excited vibrational states are always so simple. What an absorption spectrum tells us directly is change in dipole moments rather than motions of atoms. There could exist many other vibrational motions which are not responsible for an absorption spectrum line. A question is why intensities tend to concentrate into some particular transitions among many other candidates, or in other words, what restrictions on the Hamiltonian and the dipole moment operator are required for the formation of a so-called local mode spectrum. Understanding of this point is important to clarify the usefulness and the limitations of the one-dimensional oscillator model, which is used to determine dipole moment parameters from the intensities observed for both fundamental and very high overtones.

In this paper we will express the absorption spectrum in a general way using more physically meaningful basis states rather than eigenstates. Such a formulation would be convenient when the eigenstates of the Hamiltonian are severely mixed states of many physically meaningful basis states. Then we apply the formulation to deducing one-dimensional dipole moment functions of benzene, cyclohexane, and chloroform. The experimental parameters thus obtained will be compares with the theoretical values and with the results obtained by Burberry and Albrecht.[3] More rigorous treatment was necessary to analyze the 1st and 2nd overtones of 1,1-dichloroethylene because of the mixings between the combinations and pure overtones which have non-zero intrinsic intensities. The result will appear in a separate paper.

Theoretical Background for Intensity Analysis

An absorption intensity at a frequency ν is generally expressed by:

$$B(\nu) = C\nu|\langle 0|M|E\rangle|^2 \tag{1}$$

where $|E\rangle$ is an eigenstate of the Hamiltonian with an eigenvalue $E=h\nu$, $|0\rangle$ is the ground state, M is the dipole moment function, and C is a constant. Inserting an identity operator,

$$I = \sum_v |v_1,v_2,\cdots\rangle\langle v_1,v_2,\cdots|, \tag{2}$$

into Eq. 1, we obtain the relation

$$B(\nu) = C\nu|\sum_v \langle 0|M|v_1,v_2,\cdots\rangle\langle v_1,v_2,\cdots|E\rangle|^2, \tag{3}$$

where $|v_1,v_2,\cdots\rangle$'s are basis states which are not necessarily eigenstates as far as Eq. 2 is satisfied. Here we express the density of a basis state $|v_1,v_2,\cdots\rangle$as a function of E as

$$\rho(E) = \langle v_1,v_2,\cdots|E\rangle^2. \tag{4}$$

Equation 4 represents the probability function of finding a state $|v_1,v_2,\cdots\rangle$ at E or the contribution of $|v_1,v_2,\cdots\rangle$ to the eigenstate $|E\rangle$. If $|v_1,v_2,\cdots\rangle$ is an eigenstate, $\rho(E)$ is a delta function which has a non-zero value only when E is the eigenvalue of the Hamiltonian. In this case Eq. 3 becomes

$$B(\nu) = C\nu\sum\langle 0|M|v_1,v_2,\cdots\rangle^2\delta(\nu-E_v). \tag{5}$$

This is a conventional expression which uses a continuous function. If $|v_1,v_2,\cdots\rangle$ is not an eigenstate but a more physically meaningful state such as local mode state or a normal mode state, on the other hand, $\rho_v(E)$ can not be so simple anymore; there appears splitting or braodening because of the mixings. Even in such a case, Eq. 3 can be reduced approximately to

$$B(\nu) = C\nu\sum_v\langle 0|M|v_1,v_2,\cdots\rangle^2\rho_v(E), \tag{6}$$

unless both of the mixing partners have non-zero intrinsic intensities at the same time. Here, the intrinsic intensity associated with a basis state, $|v_1,v_2,\cdots\rangle$, is defined by

$$I'(v_1,v_2,\cdots) = C\nu\langle 0|M|v_1,v_2,\cdots\rangle^2. \tag{7}$$

Therefore, Eq. 6 becomes

$$B(\nu) = \sum_{v} I'(v_1,v_2,\cdots)\rho_v(E). \quad (8)$$

Equation 8 or 6 means that an absorption band which is associated with one of the basis states, $|v_1,v_2,\cdots>$, must have the same structure or lineshape as $\rho_v(E)$ and that the integrated intensity over the whole band is directly related to the square of the matrix element represented by the same states used for the assignment. Any complicated interactions with other states which do not have intrinsic intensities will not affect the integrated intensity at all and the center of gravity of the band will remain unchanged, to the first order approximation, at the position which would be expected for the unperturbed state.

The above description is the theoretical basis for the intensity analysis of the present work. Equation 8 can be conveniently applied to a band which is broadened by the interactions with almost continuous background states of highly excited vibrational modes as well as external lattice mode, because such background states do not usually have their own intrinsic intensities.

Experimental

The absorption spectra of liquid benzene, cyclohexane and chloroform were observed for the C–H stretching fundamental and its overtones. A Fourier transform spectrometer (NICOLET 7199) was used for the observation of 1,2,3←0 bands, while UV-visible spectrophotometers (CARY 17 and Shimadzu D-40R) were used for the observation of 4,5,6←0 bands. 6←0 bands were also measured by the use of a dual-beam thermal lensing spectrometer which was designed and constructed in our laboratory. The optical path lengths of the cells used were 25 μm, 58 μm, and 10 mm depending upon the intensity of each absorption band. The fundamental bands of benzene and cyclohexane were so strong that the 1 : 10 diluted solutions in carbon tetrachloride were used with a 25 μm cell instead of the pure liquid.

The observed spectra were integrated over the whole of the bands corresponding to the C–H stretching modes. The integrated intensity Γ is defined by the relation:

$$\Gamma = \frac{1}{cl}\int_{\text{band}} \ln\left(\frac{I_0}{I}\right) \mathrm{d}\ln\nu \quad (\text{cm}^2/\text{mol}), \quad (9)$$

where c is the concentration of the sample in mol/cm^3, l is the thickness of sample in cm, and I_0 and I are the intensities of the incident and transmitted light, respectively. The observed integrated intensity was corrected for the dielectric effect. The corrected integrated intensity, Γ^c, can be expressed in terms of a transition matrix element as,

$$\Gamma^c = \frac{8\pi^3 N}{3hc}|<0|M|v>|^2$$

$$= 2.508 \times 10^5 M_{0v}^2 \quad (\text{cm}^2/\text{mol}), \quad (10)$$

where $M_{0v} \equiv <0|M|v>$ is a transition moment and M is a dipole moment operator. If we experess M in Debye units, Γ^c can be expressed in the units of cm^2/mol.

Results and Discussion

Observed Spectra. The spectral patterns observed in the present work are essentially the same as those of the previous work.[3,4]

The fundamental band of benzene consists of three peaks. The v=2←0 bands are more complicated. Such complex structures were explained by Fermi resonances between the pure C–H stretching mode and overtones and/or combinations of other lower frequency modes which are probably skeletal stretching modes.[5] These overtones and combination tones do not seem to have their own intensities, because all three peaks in the C–H fundamental region of benzene disappear in deuterated benzene.[5] Then we assumed that the total integrated intensities over each v←0 band were responsible for the C–H stretching mode.

The structure of the fundamental and the overtones of cyclohexane was primarily doublet, although it contained other weak peaks or shoulders. The doublet of the fundamental vibrations can be assigned to the in-phase and out-of-phase stretching modes of the two nearly identical C–H bonds which share a common carbon atom. On the other hand, the doublet structure of the high overtones should be considered as a reflection of the difference between the axial and equatorial C–H bonds, since local mode characters are dominant in highly excited states. However, independent analyses for each bond are still very difficult. Thus, we integrated the intensity over the doublets for the determination of the effectively averaged dipole moment parameters.

In Table 1 the integrated intensities, corrected for the

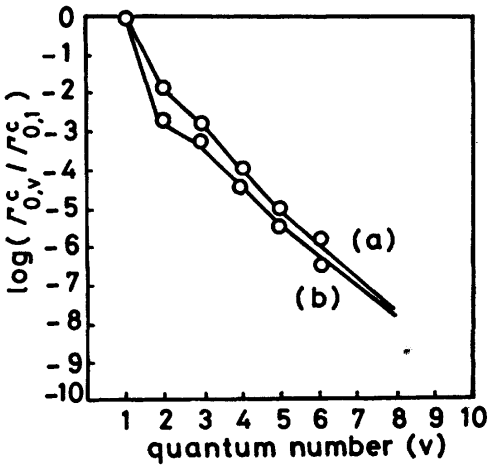

Fig. 1. The logarithmic relative intensities, $\Gamma^c_{0,v}/\Gamma^c_{0,1}$, for liquid benzene (a) and liquid cyclohexane (b) plotted against a vibrational quantum number, v. Open circles represent the observed values, while the solid line connect these values calculated from the best-fit parameter, M_2/M_1=2.30 Å^{-1} for benzene and M_2/M_1=1.45 Å^{-1} for cyclohexane.

local field effect, $\Gamma^c_{0,v}$, are summarized. In Fig. 1(a) the logarithmic relative intensities, $\Gamma^c_{0,v}/\Gamma^c_{0,1}$, observed for benzene are plotted against the vibrational quantum number, v. It can be seen from the figure that the intensity of the $v=2\leftarrow0$ band is about half of that expected from the interpolation of other $\Gamma^c_{0,v}$ values. A similar plotting for cyclohexane is shown in Fig. 1(b). The decrease in the intensity of the $v=2\leftarrow0$ band is more pronounced in cyclohexane than in benzene. In the experimental results reported by Albrecht[3] and Yamamoto,[4] the same tendencies are clearly observed. Unfortunately they did not pay any attention to this point, but rather emphasized the monotonous decrease in $\ln(\Gamma^c_{0,v}/\Gamma^c_{0,1})$ with the increase of v. We will focus our attention on this singular behaviour of the $v=2\leftarrow0$ band intensity because it is far beyond the experimental error.

Calculation of Intensity and Dipole Moment Function. We assume a one-dimensional Morse oscillator for the local mode oscillator. The Morse parameters, D_e and α, were determined from these spectral parameters: $\omega_e=3173\ \mathrm{cm}^{-1}$ and $\omega_e\chi_e=60.7\ \mathrm{cm}^{-1}$ for benzene, and $\omega_e=3020\ \mathrm{cm}^{-1}$ and $\omega_e\chi_e=65.94\ \mathrm{cm}^{-1}$ for cyclohexane, which were obtained from the observed frequencies of the local mode spectra. Using these Morse potentials, we have numerically calculated the wavefunctions and the dipole matrix elements.[6] The dipole moment function, $M(R)$, is expanded as a power series of a displacement coordinate, $R-R_e$, as

$$M(R) = M_0 + M_1(R-R_e) + M_2(R-R_e)^2, \qquad (11)$$

and the effects of M_1 and M_2 on the absorption intensities are to be studied. After determining the M_2/M_1 value so as to reproduce the relative intensities of the overtones, the absolute values of M_1 and M_2 were determined by scaling to the absolute intensity of the fundamental band. In order to clarify the origin of the anomalous intensity behaviour observed for the $v=2\leftarrow0$ band, the magnitude of M_2/M_1 and the signs of M_1 and M_2 were investigated in relation with the calculated intensity values. In Fig. 2 we demonstrate the dependency of the calculated $\Gamma^c_{0,v}/\Gamma^c_{0,1}$ value of benzene on the magnitude of M_2/M_1. The general qualitative feature which can be observed from Fig. 2 does not change much with the slight change in the Morse potential parameters. It can be seen from Fig. 2 that the relative intensity of the $v=2\leftarrow0$ band is quite sensitive to the M_2/M_1 value: the relative intensity of the $v=2\leftarrow0$ is diminished for a small positive M_2/M_1 value, while it is enhanced for a negative M_2/M_1 value. It is also clarified that the relative intensity of the $v=2\leftarrow0$ band is also enhanced if M_2/M_1 takes a large positive value; this situation is illustrated in Fig. 3. So far as we know, this is the first time for anyone to recognize the fact that the overtone intensity is so sensitive to a slight change in M_2/M_1. This anomalous behaviour of the $v=2\leftarrow0$ band intensity is considered to arise from the accidental cancellation of the mechanical and electrical anharmonicities. The magnitudes of the matrix elements are, for benzene,

$$\langle 0|(R-R_e)|2\rangle = -0.0077064\ \text{Å},$$
$$\langle 0|(R-R_e)^2|2\rangle = 0.0079453\ \text{Å}^2.$$

So the mechanical and electrical anharmonicities can completely cancel out each other if $M_2/M_1=0.970\ \text{Å}^{-1}$ (see Eq. 11). Of course, this accidental cancellation can occur even for the v values other than 2. The M_2/M_1 value which brings about the abnormality of the $v=2\leftarrow0$ band intensity, however, is not likely to bring about this accidental cancellation for other v values.

The observed intensities of benzene were reproduced best for $M_2/M_1=2.3\ \text{Å}^{-1}$ (see Fig. 1(a)), while those of cyclohexane were reproduced best for $M_2/M_1=1.45$

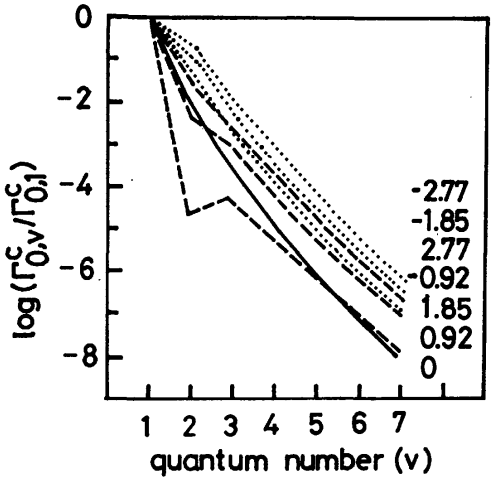

Fig. 2. The dependence of the logarithmic relative intensity, $\Gamma^c_{0,v}/\Gamma^c_{0,1}$ of liquid benzene on the parameter, M_2/M_1. The numbers at the ends of the curves indicate the M_2/M_1 value.

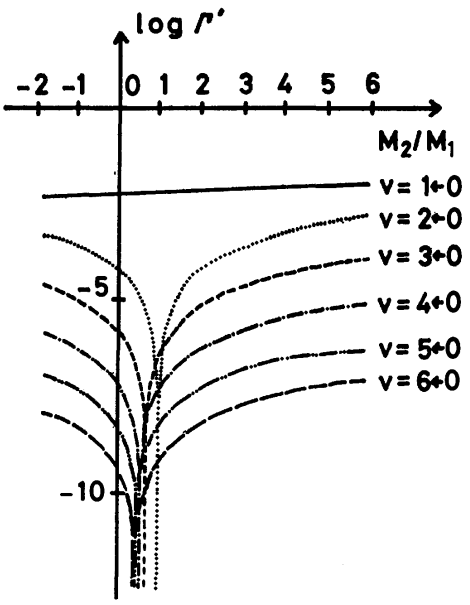

Fig. 3. The dependence of the absolute intensities of the overtones on the M_2/M_1 value in Å^{-1}. At $(M_2/M_1)\simeq1$, the effects of the mechanical and electrical anharmonicities cancell out with each other. The absolute intensity, Γ', is defined by this relation,
$\Gamma'=|\langle 0|(R-R_e)+(M_2/M_1)(R-R_e)^2|v\rangle|^2$
$=\frac{3hc}{8\pi^3N}\cdot\frac{\Gamma^c_{0,v}}{M_1^2}$.

Å^{-1} (see Fig. 1(b)). The disagreement between the observed and calculated intensities for the $v=5\leftarrow0$ and $v=6\leftarrow0$ bands may be due to the neglect of these terms higher than M_2 (see Eq. 11). We did not try to add the higher order terms to get better agreement, although it is not particularly difficult, because the one-dimensional oscillator model is not accurate enough. The final results are summarized in Table 3. In addition to the absolute value, the sign of M_2/M_1 was determined to be positive. However, the signs of M_1 and M_2 could be determined separately only after the *ab initio* calculations which will be described in the next section.

A chloroform molecule has only one C–H bond. Therefore, the one-dimensional oscillator model is considered to be most appropriately applied to this molecule. Actrually, the situation was not so simple, because the intensity of the ν_1 fundamental (the C–H stretching vibration) is abnormally weak and is extremely sensitive to the molecular environment. A detailed study on this problem will be described in a separate paper.[11] We only report here the final result, that M_1 is almost zero.

For 1,1-dichloroethylene, we adopted the two-dimensional oscillator model and obtained the M_{12} value, which is the coefficient of the cross-term, $(R_1-R_e)(R_2-R_e)$, in addition to M_1 and M_2. Although the details of this analysis will also appear in a separate paper,[12] we include the final results in Table 3. Here again $M_1M_2>0$.

Ab Initio *Calculation of Dipole Moment Function.* A dipole moment function has been determined only for a very few diatomic molecules like HCl and HF. Therefore, we cannot ascertain the validity of the dipole moment functions obtained here on the basis of the local mode representation. So we tried to compare the present results with the predictions of the *ab initio* calculation for benzene, chloroform, ethylene, and methane. Methane was chosen as a model system for cyclohexane, and ethylene was added for the convenience of understanding those molecules having double bonds. The program used for the present calculation was IMSPACK GAUSSIAN 70.[7] As a basis set, the 4-31G[8] was chosen for methan and ethylene, while the 6-31G*[9,10] was chosen for the calculations of benzene and chloroform. The calculated results are summarized in Table 3, in the brackets.

Dipole Moment Functions. From the comparison of the experimentally determined M_1 and M_2 values of Table 3, we can understand the following facts. First, M_1 and M_2 take the same sign for all the molecules except chloroform. This corresponds to the fact that the dipole moment function takes a extremum at a distance smaller than R_e. We designated this distance as R_m, and calculated the deviation from the equilibrium distance, R_e-R_m; these results are summarized in the last column of Table 3. It can be seen from the table that chloroform is quite different from other molecules in the sense that R_m is very close to R_e.

The M_1 values are different for different molecules, while the M_2 values are rather constant for all the molecules studied: that is, $-1.3<M_2<-0.9$. It is of same interest to emphasize that even the M_2 value for chloroform was obtained in this range of magnitude.

The *ab initio* calculation reproduces the observed M_1 and M_2 values very well. So far, very few experimental M_2 values have been compared with the M_2 values calculated by the *ab initio* calculation, because the corresponding experimental values have been so poor. The present study shows that the agreement between the calculated and observed M_2 values are excellent for various hydrocarbons. The characteristic features of the dipole moment function of chloroform are also well reproduced by the *ab initio* calculation: M_2 is not very different from those of the other molecules, although M_1 is exceptionally small in magnitude. It may be giving too many compliments to the *ab initio* calculation to say that the slight deviations of the calculated dipole moment functions from the observed ones may be

Table 4. The dipole moment function for liquid benzene obtained by Burberry and Albrecht.[a)]

	Semiempirical		Theoretical	
	Morse potential	Quartic potential	CNDO	*Ab initio*
M_1/D Å^{-1}	−0.81	−0.59	−1.0	−1.78
M_2/D Å^{-2}	0.20	−1.16	−0.99	−1.48

a) See Ref. 3.

ascribed to the over-simplification of the oscillator model, *i.e.* the one-dimensional local mode model.

Burberry and Albrecht[3)] determined the dipole moment function of benzene by the use of an oscillator model which is analogous to ours; their results are given in Table 4. It is puzzling to see from the table that the signs of M_1 and M_2 are different, although they use a Morse potential in their calculation. We do not see any clear reasons for this. We only emphasize the fact that Burberry and Albrecht do not seem to have paid special attention to the anomalous intensity decrease of the $v=2\leftarrow0$ bands, although the anomaly can clearly be seen in their intensity data. Strange to say, their calculation has led to a dipole moment function which is very close to our present result; they used the quartic potential function in the place of the Morse potential. We are not sure at present why the quartic potential is preferrable to the Morse potential for the treatment of an oscillator whose anharmonic character is very strong. Perhaps the dipole moment function is sensitive to the anomalous intensity behaviour of the $v=2\leftarrow0$ band.

Mechanical and Electrical Anharmonicities. Next, we consider the contributions of mechanical and electrical anharmonicities on overtone spectra.

If a potential is completely harmonic, the dipole term related with M_2 simply allows the $v=2\leftarrow0$ transition. If a potential is of a Morse type, on the other hand, all the highly excited vibrational bands can be expected to have considerable intensities even if $M_2=0$. For example, about 10% of the observed intensity for the $v=6\leftarrow0$ band in liquid benzene can be ascertained to be originating from the Morse potential only ($M_2=0$). In other words, M_2 contributes only to the appearence of a $v=2\leftarrow0$ band under a harmonic potential, while it can have large contributions to the appearence of the high overtones other than $v=2\leftarrow0$ under the influence of a harmonic potential. Thus, we can conclude that the mechanical and electrical anharmonicities cooperatively contribute to the appearance of the high overtones. In some cases, the contribution of mechanical and electrical anharmonicities cancel out each other, as we have seen in the $v=2\leftarrow0$ band. This phenomenon is most distinct in the $v=2\leftarrow0$ band, simply because M_2 contributes directly to the $v=2\leftarrow0$ transition. Thus, we can recognize that the present system was only a lucky case for the determination of M_2/M_1 in the sense that we could use the anomalous intensity decrease of the $v=2\leftarrow0$ band. If the intensity of the $v=2\leftarrow0$ band were normal, in comparison with the other high overtones, or if it were enhanced instead of diminished, we could not determine even the sign of M_2/M_1.

Incidentally, the present theoretical treatment is quite general, provided that the dipole matrix elements related with the other modes are negligible and that the cross terms in a dipole moment function which represent the couplings between each mode in question and the other modes can be neglected. The coupling originating from the nature of the Hamiltonian does not spoile the generality of the present theory. The effects of the cross term in a dipole moment function can properly be treated by introducing a coupled oscillator model; the results of this treatment will appear in a separate paper.

Conclusion

The absolute intensities of the high overtones were observed for liquid benzene, cyclohexane, and chloroform. From these intensity values, the dipole moment functions were obtained up to quadratic terms, based upon the one-dimensional oscillator model. The corresponding parameters for benzene, methane, chloroform, and ethylene were estimated by the *ab initio* calculations. The agreement between the experimental and theoretical dipole moment functions, in turn, confirmed the validity of the one-dimensional oscillator model and the reliability of the *ab initio* calculation simultaneously.

The anomalous intensity behaviour of the $v=2\leftarrow0$ band was ascertained to be arising from the accidental interaction between the mechanical and electrical anharmonicities. This effect was conveniently used for the determination of the M_2/M_1 value.

We are indebted to Dr. Shigeki Kato of Institute for Molecular Science for his invaluable assistance with the *ab initio* calculations.

(Received August 10, 1981)

The absorption spectra of liquid chloroform were observed for the C–H stretching fundamental vibration and its overtones up to $v=\leftarrow 50$. The spectral parameters were analyzed on the basis of the one-dimensional local mode representation, which led to the determination of the mechanical and electrical anharmonicities. The solvent effects on the absorption intensities are discussed from the viewpoint of the solvent effect on the dipole moment function. The finally obtained dipole moment function was compared with that obtained by the *ab initio* calculation.

The absolute intensity of the C–H stretching fundamental band of chloroform in the gas phase has been known to be anomalously weak in comparison with the absolute intensity of its pure overtone, *i.e.*, the $v=2\leftarrow 0$ band. The reason of this anomaly has been vaguely attributed to same electric anharmonicity related with this vibrational mode.[1] Since the intensities of overtones are influenced by both mechanical and electrical anharmonicities, however, we cannot obtain any definite conclusions about this problem without analyzing these two kinds of anharmonicities simultaneously.

Previously we have reported the intensity analysis of the C–H stretching overtones for a few molecules.[2] In the report, we emphasized the usefulness of the one-dimensional local mode model for the analysis of intensity data. At the same time, the choice of the Morse-type potential function was found to give a satisfactory approximation for the elucidation of the mechanical anharmonicity, if we are able to define the absorption bands in terms of the local mode representation. This result indicates, at the same time, that we are now able to obtain accurate knowledge about the electrical anharmonicity for a system in which a local mode can be well defined.

A chloroform molecule has only one C–H bond. Therefore, it is the most appropriate molecule to which to apply our one-dimensional oscillator model. The intensity of the $v=1\leftarrow 0$ band of chloroform is sensitive to the change of molecular environment. Such spectral changes of the $v=1\leftarrow 0$ band have been interpreted in terms of the hydrogen bonding in the liquid or solution phase.[3] Suzuki *et al.* have reported that the concentration dependence of the intensities and the line width of the C–H stretching vibration of chloroform in carbon tetrachloride solutions can be well explained by considering the coexistence of two different types of chloroform molecules; one is a molecule which interacts with other molecules and the other is a non-interacting molecule.[4] The role of the carbon tetrachloride molecule is to break the interaction between chloroform molecules.

The present work has examined the absorption spectra of the C–H stretching vibration of chloroform observed for the fundamental and overtone bands. The observed spectral parameters will be analyzed on the basis of the one-dimensional local mode model to obtain the dipole moment function. Based upon these results, the remarkable solvent effect observed for the intensity of the fundamental band will be discussed in relation to the solvent effect on the dipole moment function.

Experimental

All the chemicals used in this work were commercially available reagents. Chloroform was purified by column chromatography on alumina to remove ethanol.

The absorption spectra were measured for the C–H stretching vibrations of liquid chloroform with the use of a Fourier transform infrared spectrometer (NICOLET 7199) at room temperature. For the measurement of the $v=1\leftarrow 0$ band, a water-cooled Glober source and a mercury cadmium telluride detector were used. The used beam-splitter was a Ge on KBr substrate. An NaCl window cell having a thickness of 0.0025 cm was used for the $v=1\leftarrow 0$ band intensity measurement. For the measurements of the $v=2\leftarrow 0$, $v=3\leftarrow 0$, and $v=4\leftarrow 0$ bands, a water-cooled tungsten-halogen lamp, a quartz beam-splitter, and an InAs detector were used. An NaCl window cell having a thickness of 0.0107 cm was used for the $v=2\leftarrow 0$ band, while a quartz cell having a thickness of 1 cm was used for the $v=3\leftarrow 0$ and $v=4\leftarrow 0$ bands.

The concentration dependences of the absorption spectra were observed in the carbon tetrachloride solutions at the concentrations of 80, 60, 40, and 20 mol %.

For the measurement of the $v=5\leftarrow 0$ band, a UV-visible spectrometer (CARY 17) and a quartz cell having an optical path length of 10 cm were used.

All the absorption spectra were measured with a resolution of about 1 cm^{-1}.

Results and Discussion

Analysis of Intensity Data. The absolute intensity $\Gamma_{n',n''}$ related with the $v=n''\leftarrow n'$ transition can be expressed in terms of the experimentally observable quantities as

$$\Gamma_{n',n''} = \frac{f_d}{nl}\int_{band} \ln\left(\frac{I_0}{I}\right) d\ln \nu \qquad (1)$$

where n is the concentration of sample, l is the sample thickness, I_0 and I are the intensities of the incident and transmitted light, respectively, and ν is the frequency of light. f_d is the correction factor for the dielectric-field effect. Since the absolute intensities of the observed

a) After Rossi *et al.* (see Ref. 1).

bands are weak, the Polo-Wilson's scheme[5] can safely be applied to the dielectric-field correction.[6] Thus, the correction factor f_d can be expressed as

$$f_d = \frac{9n_D}{(n_D^2+2)^2}, \tag{2}$$

where n_D is the refractive index of the solution. The used n_D data were found in the International Critical Tables.[7]

Concentration Dependence of Absolute Intensity. The cencentration dependence of band parameters (the peak frequency and the intensity) observed for the carbon tetrachloride solutions are summarized in Table 1. The intensities of the $v=1\leftarrow0$ and $v=2\leftarrow0$ bands observed for the gas phase by Rossi *et al.*[1] are also included in the last column of Table 1.

The absolute intensity of the $v=1\leftarrow0$ band in 20 mol% of carbon tetrachloride solution is about half of that in the pure liquid chloroform. No remarkable solvent effects on the intensities were observed for the overtone bands; this result in sharp contrast with that for the fundamental band. It has been shown in our previous report that the intensities of overtone bands are determined by both the electrical and the mechanical anharmonicities.[2] Let us consider the mechanical anharmonicity first.

Mechanical Anharmonicity and Absorption Frequency. The mechanical anharmonicity is directly related with the potential term of the Hamiltonian. Therefore, it can be determined by the frequency measurement of the absorption maximum for the fundamental and overtone bands. It has been established that the frequencies of the absorption maxima of the overtone bands are well approximated by the Birge-Sponer equation, if we can assign the overtone spectra on the basis of the local mode representation,[8–10] that is

$$\frac{E_v-E_0}{v} = A + Bv, \tag{3}$$

where A and B are constants and E_v and E_0 are the eigenvalues of the vibrational states $|v>$ and $|0>$ respectively. Equation 4 shows that the anharmonic character of the vibrational eigenvalues can be well explained by considering the v and v^2 dependences. We assume a one-dimensional Morse oscillator for the local mode oscillator. The Morse parameters, D_e and α, were determined from these spectral parameters: $\omega_e=3130\,\text{cm}^{-1}$ and $\omega_e\chi_e=60.0\,\text{cm}^{-1}$, which were obtained from the observed frequencies of the local mode spectra. Thus we could quantify the mechanical anharmonicity and, therefore, the wavefunction $|v>$.

Electrical Anharmonicity and Intensity. Next we consider the electrical anharmonicity. Using the Morse potential, we have numerically calculated the wavefunctions and the dipole matrix elements.[11] The dipole moment function, $M(R)$, is expanded as a power series of a displacement coordinate, $R-R_e$, as

$$M(R) = M_0 + M_1(R-R_e) + M_2(R-R_e)^2 \tag{4}$$

and the effects of M_1 and M_2 on the absorption intensities are to be studied. We have already described, in our

previous report,[2] the way of determining the M_1 and M_2 values on the basis of the one-dimensional local mode model. Here again, we adopt this one-dimensional oscillator model and determine the M_1 and M_2 values for chloroform. As we did not see any remarkable solvent effects on the intensities for the $v=2\leftarrow0$, $v=3\leftarrow0$, and $v=4\leftarrow0$ bands, we may regard the absolute intensity value observed at the concentration of 20 mol% as the absolute intensity value in the gas phase. In facts the intensity values for the $v=2\leftarrow0$ band were observed to be almost identical in the gas and solution phases.

Figure 1 shows the logarithms of the observed absolute intensities plotted against the vibrational quantum number of the upper state, v. The open circles correspond to the absolute intensities in solutions, while the closed circles correspond to the absolute intensities in the gas phase reported by Rossi *et al.*[1] The open circles arranged on the vertical line at $v=1$ correspond to the $\Gamma_{0,1}$ values associated with the pure liquid and the solutions of 80, 60, 40, and 20 mol%. The concentration dependence of the $\Gamma_{0,2}$, $\Gamma_{0,3}$, or $\Gamma_{0,4}$ values were too small to be identified in this logarithmic scale.

Using the intensity data for pure liquid chloroform,

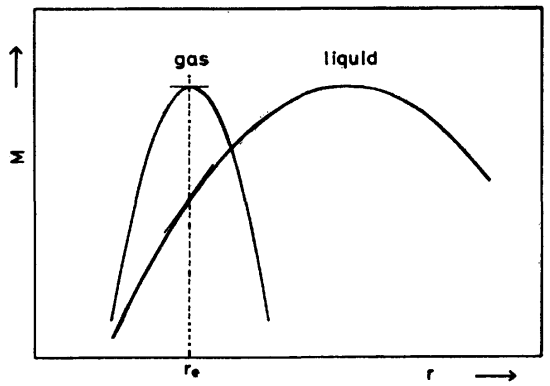

Fig. 2. The schematic drawing of the dipole moment functions for the gas and liquid phases.

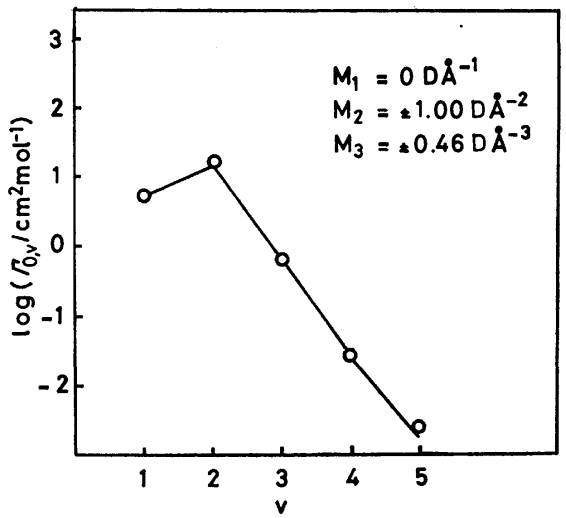

Fig. 3. The best fit curve for the gas phase intensity data. The Taylor expansion of the dipole moment function is truncated at the cubic term, $M=M_0+M_1(R-R_e)+M_2(R-R_e)^2+M_3(R-R_e)^3$.

the best fit parameters were obtained to be: $M_1=\pm0.43$ D Å^{-1} and $M_2=\mp0.40$ D Å^{-2}. In Fig. 3 the best fit values for this case are shown by the solid line. The dotted line, on the other hand, shows the intensity values calculated for the parameter values of $M_1=\pm0.33$ D Å^{-1} and $M_2=\mp0.61$ D Å^{-2}, which are the best fit parameter values for the intensity observed in the 20 mol% solution. The dot-and-dash line indicates the theoretical values calculated from the M_1 and M_2 values which were determined from the gas phase intensities of the $v=1\leftarrow0$ and $v=2\leftarrow0$ bands, namely, $M_1=0$ D Å^{-1} and $M_2=\mp1.25$ D Å^{-2}. Similarly, the best fit parameters, M_1 and M_2, were determined for various concentrations: these results are summerized in Table 2.

Table 2. The M_1 and M_2 values of chloroform in the liquid, carbon tetrachloride solution, and gas phases

a) The Taylor expansion of the dipole moment function was truncated at the quadratic term. The observed intensities for the $v=1\leftarrow0$ and $v=2\leftarrow0$ bands were used. b) The Taylor expansion of the dipole moment function was truncated at the cubic term. The observed intensities for the $v=1\leftarrow0$, $v=2\leftarrow0$, $v=3\leftarrow0$, $v=4\leftarrow0$, and $v=5\leftarrow0$ were used for the fitting.

Miyazaki and Yamamoto have calculated the M_1 and M_2 values for the C–H stretching vibration of methylchloride, methylenechloride, and chloroform by the CNDO method.[12] The $\Gamma_{1,0}/\Gamma_{2,0}$ ratio of chloroform obtained from their calculation agrees well with the observed one, although the absolute intensities are smaller than the observed ones by about an order of magnitude. Their results agrees with the present experimental results in the sense that the M_1 value of chloroform is smaller than those of the other molecules. However, the M_2 values were calculated to be four times as small as our present results, presumably because the absolute intensity values which were calculated by the CNDO method were too small. The potential energy calculated from the CNDO method for the C–H stretching vibration does not seem appropriate, because the energy increase with the displacement from the equilibrium distance is much larger than those generally found. Therefore, we will perform the *ab initio* closed shell SCF calculation and compare the results with the experimental ones.

Ab Initio *Calculation of Dipole Moment Function.*

A dipole moment function has been determined experi-

mentally only for a very few diatomic molecules like HCl and HF. Therefore, we cannot ascertain the reliability of the dipole moment function obtained on the basis of the local mode representation. So we tried to compare the present result with the prediction of the *ab initio* closed shell SCF calculation. The programme used for the present calculation was IMSPACK GAUSSIAN 70.[13] As a basis set, the 6-31G*[14] was chosen for this calculation. The number of the inner-shell orbitals for a chlorine atom was set to be four. The 3d orbital for a chlorine atom was taken into account to improve the accuracy in the calculation of force constants or dipole matrix elements. The geometry optimization was carried out by the energy gradient technique.[15] The dipole moment derivatives were obtained by numerizal differentiations of calculated dipole moments in the Cartesian Coordinate system. The final results for M_1 and M_2 are given at the bottom of Table 2. It can be understood that the calculated M_1 and M_2 values agree well with those observed in the gas phase. It is noticeable that the M_2 values was calculated to be almost zero, which is in good agreement with the experimental result. As for the sign of these parameters, we may safely conclude that M_2 should be negative from this *ab initio* calculation. The sign of M_1, on the other hand, cannot be determined from this calculation, because the magnitude was calculated to be almost zero.

Dipole Moment Function and Solvent Effect. Let us consider now the concentration dependence of the dipole moment function observed in the carbon tetrachloride solutions. It can be seen from Table 2 that M_2 increases its magnitude and M_1 decreases its magnitude with the increase in concentration. Of course we cannot give too much quantitative meaning to the M_1 and M_2 values obtained for the liquid or solution phases, because it has been established that there exist two types of chloroform molecules in the liquid and solution phases. One is a molecule which interacts with other molecules and the other is a non-interacting molecule.[4] Therefore, the true M_1 value of the interacting molecule, for example, in pure liquid chloroform may be much larger than ± 0.43 D Å^{-1}. Thus, the M_1 and M_2 values in the liquid phase should be regarded as effective values. However, the general tendency of the concentration dependence of M_1 and M_2 is important. We remember that M_1 and M_2 values approach those of the gas phase in the infinite dilution limit.

The parameter values of $M_1 \simeq 0$ means that the dipole moment function M takes an extremum at the equilibrium distance of the C–H bond or at the distance where the C–H internuclear potential function takes a minimum value. On the other hand, the increase of M_1 with the increasing concentration corresponds to the fact that the distance at which the dipole moment function takes an extremum deviates from that of the potential minimum. This deviation may be due to the intermolecular interaction of the hydrogen bonding type between chloroform molecules. We discussed the details of this interaction in our previous reports,[4,16] where the effect of the charge transfer complex formation has been emphasized. If this charge transfer model can be applied to the present case, the sign of M_1 should be positive in the liquid and solution phases.[16] This conclusion is consistent with the fact that M_1 and M_2 should have opposite signs (see Fig. 1); the latter conclusion is drawn from the present intensity analysis.

The decrease in the absolute value $|M_2|$ with the increasing chloroform concentration corresponds to the decrease in the curvature of the dipole moment function. Taking these situations into account together with the signs of M_1 and M_2, we can draw the dipole moment functions in the gas and liquid phases schematically in Fig. 2. We cannot give any further meanings to the behavior of M_2 with the concentration change at this stage. But we can conclude that the apparent anomalous intensity behavior of the fundamental band is not due to the electrical anharmonicity M_2, but to the harmonic term M_1. The fundamental band looks quite sensitive to the change of the molecular environment, simply because the dipole moment function takes a extremum at the equilibrium distance of the C–H bond, which brings about the anomalously weak intrinsic intensity for the fundamental band. The $\Gamma_{0,1}$-value change from 5.2 cm^2/mol to 245 cm^2/mol on passing from the gas to the pure liquid phases is only a small change from the viewpoint of the hydrogen bonding. As we have proposed in our report,[16] the strength of the hydrogen bonding should be evaluated by the $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ value instead of the Γ_b/Γ_f value, where Γ_b and Γ_f correspond to the absorption intensities of the hydrogen-bonded and free molecules, respectively. The $(\sqrt{\Gamma_b}-\sqrt{\Gamma_f})$ value of the present case is $\sqrt{245}-\sqrt{5.2} \simeq 10$, which is equivalent to an excess enthalpy of only 200 cal/mol.

The reflection of the dipole moment function on the intensities will be understood in more detail if we watch the numerically calculated matrix elements. The absolute intensity $\Gamma_{0,v}$ corresponding to the transition from the ground state $|0>$ to a vibrationally excited state $|v>$ is proportional to the square of the dipole matrix element $|<0|M|v>|$. Therefore,

$$\begin{aligned}\Gamma_{0,v} &\propto |<0|M|v>|^2 \\ &= M_1^2<0|R-R_e|v>^2 \\ &\quad + 2M_1M_2<0|R-R_e|v><0|(R-R_e)^2|v> \\ &\quad + M_2^2<0|(R-R_e)^2|v>. \end{aligned} \tag{5}$$

The numerical values for the three terms of Eq. 5 are summarized in Table 3. It can be seen from the table that the intensity of the $v=1\leftarrow 0$ band is governed by rather complicated factors. In the gas phase, the intensity is determined completely by the third term. As the concentration and, therefore, the intermolecular interaction increase, the intensity comes to be governed by the first term. The concentration dependence of the $v=1\leftarrow 0$ band is obviously governed by the magnitude of M_1. In the case of the $v=2\leftarrow 0$ band, on the other hand, the three terms can equally contribute to the intensity. It is noticeable that the second term is almost independent of the concentration. The third term decreases, while the first term increases, with the increase of the chloroform concentration. The increase and decrease of the first and third terms compensate each other, which keeps the $v=2\leftarrow 0$ band intensity almost independent of the chloroform

Table 3. The numerical values for the dipole matrix elements of chloroform

concentration.

Higher Order Terms in Dipole Moment Function. In Fig. 1, it is seen that the dash-and-dot line deviates from the observed values at the higher vibrational quantum numbers. If we choose the parameter values which can explain the intensities of the $v=3\leftarrow0$, $v=4\leftarrow0$, and $v=5\leftarrow0$, we cannot explain the intensity of the $v=1\leftarrow0$ band. This is probably arising from the fact that the effects of the higher order term of the dipole moment function on the intensities are relatively accentuated at the higher v values, because M_1 is extremely small in chloroform. Conversely speaking, it may be possible to determine the higher term in the dipole moment function for this particular case, although the one-dimensional oscillator model may be too over-simplified to do so in general.[2] We only add here the results of the intensity analysis by taking into account the cubic term M_3 in the dipole moment function. In Fig. 3, the best fit values are shown by the solid line, while the observed values are given by the open circles. The best fit parameter values were: $M_1=0$ D Å^{-1}, $M_2=1.00$ D Å^{-2}, and $M_3=0.46$ D Å^{-3}. The sign of M_2 is probably negative, while that of M_3 can be negative because M_2 and M_3 should have the same signs.

Conclusion

The dipole moment functions of chloroform were determined from the observed intensities. The solvent effects on the absorption intensity were discussed as related to the concentration dependence of the dipole moment function. The anomalous intensity behavior of the fundamental band was clarified to arise from the accidental coincidence of the positions at which the potential function and the dipole moment function take extrema, which brings about the anomalously weak intrinsic intensity of the fundamental band. The reliability of the finally determined electrical anharmonicity parameters was confirmed by the *ab initio* calculation.

Incidentally, the one-dimensional local mode representation was shown to be useful for an intensity data analysis in the sense that a mechanical anharmonicity can be fairly easily determined for a complicated polyatomic molecule like chloroform. This, in turn, makes it possible to elucidate an electrical anharmonicity or a higher order term of a dipole moment function.

We are indebted to Dr. Shigeki Kato of Institute for Molecular Science for his assistance with the *ab initio* calculation.

(Received September 10, 1981)

A symmetrized local mode (SLM) model based on the two dimensional Morse oscillator was developed and applied to the analysis of the spectrum of the CH stretching modes in 1,1-dichloroethylene in the range of 3000—17000 cm^{-1}. More than twelve absorption peaks were assigned in terms of the mixed SLM states. The calculated frequencies with finally determined parameters: $\omega_e=3191.6$ cm^{-1}, $\omega_e\chi_e=57.63$ cm^{-1}, and $f_{12}=2170$ cm^{-1} agreed well with the observed ones. The kinetic coupling was found to be more responsible for the mixings between SLM states than the potential coupling. The observed intensity data were analyzed by the use of the obtained mixing coefficients and the two dimensional dipole moment function parameters: M_1, M_2, M_{12}, and θ. The finally determined dipole moment function parameters were: $M_1=-0.290$ D $Å^{-1}$, $M_2=-0.875$ D $Å^{-2}$, $M_{12}=0.386$ D $Å^{-2}$, and $\theta=38.4°$. Careful examination of the influence of M_{12} upon the integrated intensities clarified the validity of the one dimensional intensity analysis of our preceding work. An SLM representation was confirmed to be useful for the systematic analysis of the CH stretching spectrum through the fundamental and the high v local mode bands which include highly structured low v summation bands. An SLM representation was also found to be convenient for making a simple correlation between local mode and normal mode pictures.

Many reports on local mode (LM) spectra[1] have been published in recent years since the idea was introduced by Henry and Siebrand[2] and later developed by Albrecht.[3] Our preceding articles[4,5] on the determinations of the dipole moment functions of CH bonds in benzene, cyclohexane, and chloroform were based upon the one-dimensional LM model. A simple LM picture is not adequate, however, for an explanation of the complicated spectral structures in the fundamental band and low v overtone bands. These structured bands are usually analyzed by the conventional method[6,7] developed in a normal mode (NM) picture, although the NM picture is not so convenient either, because of the large Darling-Dennison resonance[8] in the summation band regions. In relation to the above statment, there still exist some problems which have been not solved thoroughly. One is how to express the states which are assigned in the NM picture in terms of the LM picture, or how to clarify the correlation between LM and NM quantitatively. The other is to examine the magnitude of the interactions between equivalent LM states quantitatively. The latter would be necessary to test the validity of the one-dimensional LM approximation when it is applied to various particular subjects, such as the deduction of dipole moment parameters.

In this paper, we introduce symmetrized local mode states (SLM) for the analysis of the spectrum of the CH stretching modes in 1,1-dichloroethylene. An SLM representation would be one of the most convenient pictures because some of the large interactions between equivalent LM states are automatically included in the diagonal elements in zero-th order and because it could be easily correlated to the states in a NM picture which were intrincically symmetrized at the stage of the construction of the coordinates. Two dimensional analysis of the CH_2 stretching modes in an SLM picture would also enable us to determine two-dimensional dipole moment parameters.

The vibrational spectra of 1,1-dichloroethylene and its deuterated compounds were measured by Winter *et al.*[9] and by Enomoto *et al.*[10] Yamaoka and Machida[11] have analyzed these spectra, including the overtones and the combinations, and have determined some anharmonic potential parameters. It would be interesting to compare their parameters for the CH_2 group with ours, which are determined by a completely different method.

Experimental

The absorption spectra of 1,1-dichloroethylene in the liquid phase were measured with a Fourier transform spectrometer (NICOLET 7199) in the frequency region of 2800—10000 cm^{-1} and with a UV-visible spectrometer (CARY 17) in the visible region. The sample was purchased from Tokyo Chemical Industry Co., Ltd. and used without further purification.

The observed frequencies at the absorption maxima, ν_{obsd}, and the integrated intensities, Γ_{obsd}, are listed in the first and the second columns of Table 1, respectively. The definition of Γ and the correction for the dielectric field are the same as those described in our preceding paper.[4]

Results and Discussion

NM Approach and LM Approach. In Fig. 1, two different approaches to reach the eigenstates are schematically summarized. In the NM approch, the coordinates of the oscillators are first delocalized by symmetrization and diagonarization of a GF matrix[12] prior to the quantizations and the quantum mechanical mixings caused by the anharmonic characters of the potential. On the other hand, the quantizations precede the symmetrizations and mixings in the LM approach. The differences between these two approaches may be analogized with those of the MO and VB theories for electronic structures, since orbitals are symmetrized and delocalized in MO before adding electrons whereas electronic structures in VB are constructed by making

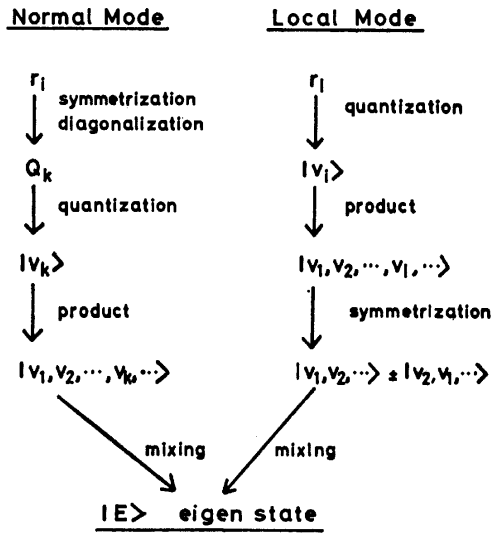

Fig. 1. Two different approaches to the eigen states.

proper pairs of the electrons which already belong to individual localized atomic orbitals.

The most different step in both approaches is the quantum mechanical mixings which may correspond to configuration interactions (CI) in the electronic theory. Therefore, the question of which method is more suitable must be answered from several points of view. One is to see which representation would cause smaller mixing or which can give closer states to the true eigenstates when the mixing process is discarded. The mixings in the NM representation are caused only by anharmonic terms in the potential, whereas any cross terms in kinetic and potential parts can cause mixings in the LM representation even in a completely harmonic system. So the NM approch would be better for fundamentals and also for low v overtones and combinations of skeletal vibrations where anharmonic characters are usually not so significant. However, hydrogen stretching motions in CH, OH, or NH are very anharmonic because of their large amplitude and high frequency. If there is a large anharmonic coupling term in the potential, and if there are more than two equivalent or nearly equivalent anharmonic oscillators, the anharmonic coupling term causes a mixing of the NM states, even if these two anharmonic oscillators are completely independent of each other in the internal coordinate system, that is,

$$v = \frac{1}{2}kq_1^2 + hq_1^3 + \frac{1}{2}kq_2^2 + hq_2^3$$
$$= \frac{1}{2}kQ_s^2 + \frac{1}{2}kQ_a^2 + \frac{h}{\sqrt{2}}Q_s^3 + \frac{3h}{\sqrt{2}}Q_sQ_a^2, \quad (1)$$

where

$$Q_s = \frac{1}{\sqrt{2}}(q_1+q_2) \text{ and } Q_a = \frac{1}{\sqrt{2}}(q_1-q_2). \quad (2)$$

Such induced anharmonic coupling causes very strong perturbations in the overtone region of CH_2 or CH_3 stretching modes, which are known by the name of Darling-Dennison resonances. The LM approach in such an anharmonic system, however, may not cause such strong mixing since all the effects of the anharmonic character can be considered at the stage of a one-dimensional oscillator problem. Although the harmonic coupling is large in this representation, the symmetrization procedure can greatly reduce the final mixings, as will be seen in the following section.

The second point of view on the choice of the LM or NM representation is to see which representation makes it easier to obtain the interaction terms related with the mixing. The third is to see which can give more physically meaningful descriptions for the finally obtained eigenstates. The answers from these points of view are obvious. Perturbation terms in the NM representation cannot be so simple because a normal coordinate itself is an already complicated linear combination of internal coordinates. By the same reason, an eigenstate expressed by a linear combination of NM states is difficult to visualize. On the other hand, an LM or SLM representation would make it much easier to obtain the perturbation terms as well as to understand the meaning of each eigenstate because of the simplicity of the basis modes. It must be emphasized that this advantage of LM or SLM is extremely important for wider application of the assigned spectra rather than for prediction of the absorption frequencies.

Hamiltonian of Coupled Morse Oscillator. The Hamiltonian of two equivalent interacting Morse oscillators may be written as

$$H = H_1 + H_2 + H_{12}, \quad (3)$$

where

$$H_i = \frac{1}{2m}p_i^2 + D_e(1-\exp(-\alpha q_i))^2, \quad (4)$$

$$H_{12} = g_{12}p_1p_2 + f_{12}q_1q_2. \quad (5)$$

H_i is the one-dimensional Hamiltonian for the i-th oscillator and H_{12} is the perturbation which couples the two oscillators. The first and second terms in Eq. 5 correspond to the kinetic and potential coupling, respectively. The higher order anharmonic coupling terms in the potential were neglected in Eq. 5. The eigenvalue of the H_i is expressed by

$$E_{v_i} = \omega_e\left(v_i+\frac{1}{2}\right) - \omega_e\chi_e\left(v_i+\frac{1}{2}\right)^2, \quad (6)$$

where

$$\omega_e = \left(\frac{\alpha}{\pi c}\right)\sqrt{\frac{D_e}{2m}}, \quad (7a)$$

$$\omega_e\chi_e = hc\omega_e^2/4D_e. \quad (7b)$$

Then the matrix elements of the two dimensional Hamiltonian, H, can be written as

$$\langle v_1,v_2|H|v_1,v_2\rangle = E_{v_1} + E_{v_2} + g_{12}\langle v_1|p|v_1\rangle\langle v_2|p|v_2\rangle + f_{12}\langle v_1|q|v_1\rangle\langle v_2|q|v_2\rangle, \quad (8)$$

$$\langle v_1,v_2|H|v_1',v_2'\rangle = g_{12}\langle v_1|p|v_1'\rangle\langle v_2|p|v_2'\rangle + f_{12}\langle v_1|q|v_1'\rangle\langle v_2|q|v_2'\rangle, \quad (9)$$

where $|v\rangle$ is an eigenstate of a one-dimensional Hamiltonian H_i, and

$$|v_1,v_2\rangle = |v_1\rangle|v_2\rangle. \quad (10)$$

Harmonic approximation for the matrix elements of H_{12} may be convenient for a preliminary analysis or for qualitative understanding of the mixing effects,

although the exact matrix elements based on the Morse oscillator wavefunctions are not so difficult to obtain. Some values used for 1,1-dichloroethylene are tabulated in the Appendix. The off-diagonal elements other than $v_1'=v_1\pm1$ and $v_2'=v_2\pm1$ are all zero in harmonic approximation or small even in exact solution.

Introducing the symmetrized local mode (SLM) states as

$$(u_1,v_2)^{\pm}=\begin{cases}\frac{1}{\sqrt{2}}(|v_1,v_2\rangle\pm|v_2,v_1\rangle) & \text{for } v_1>v_2\\ |v_1,v_2\rangle & \text{for } v_1=v_2 \text{ and } (+) \text{ state}\end{cases}, \quad (11)$$

the Hamiltonian matrix is reduced to

$$\langle v_1,v_2,\pm|H|v_1',v_2',\pm\rangle=\langle v_1,v_2|H|v_1',v_2'\rangle \pm\langle v_1,v_2|H|v_2',v_1'\rangle \quad \text{for } v_1>v_2 \text{ and } v_1'>v_2', \quad (12)$$

$$\langle v,v,+|H|v,v,+\rangle=\langle v,v|H|v,v\rangle, \quad (13)$$

$$\langle v,v,+|H|v_1,v_2,+\rangle=\sqrt{2}\langle v,v|H|v_1,v_2\rangle. \quad (14)$$

Since the states which have the same value of v_1+v_2 form a nearly degenerate group, and since the off-diagonal elements are very small compared to the energy difference between the different groups, the mixing of the states may essentially occur between these states belonging to the same group.

The degenerate pair states in LM, (v_1,v_2) and (v_2,v_1), split into doublets, $(v_1,v_2)^+$ and $(v_1,v_2)^-$, in SLM. The magnitude of the splitting, however, is large only when $v_2=v_1-1$, as easily seen in harmonic approximation. For other states, splitting is mainly caused by small differences of mixings between (+) and (−) states through higher order perturbations, although the anharmonic character of the off-diagonal matrix elements may be also responsible to some extent. The splitting of $(v,0)^{\pm}$ decreases rapidly with the increase of v and the states behave as a pure local mode state. Figure 2 shows a schematical energy diagram which correlates NM states to LM states from the above considerations.

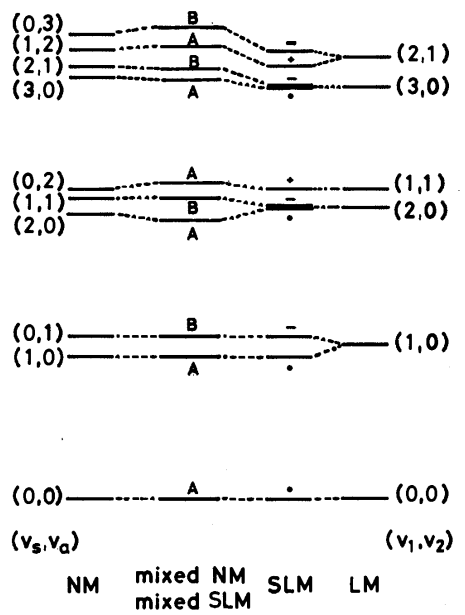

Fig. 2. Schematical energy diagram wich correlates NM states to LM states. The structure in NM was drawn using the tentative values for the parameters, $(\omega_e\chi_e)_s$ and $(\omega_e\chi_e)_a$, the effects of $\chi_{s,a}$ were taken in mixed NM. A and B denote the symmetric stretching and antisymmetric stretching states for the C_2 operation around the molecular axis. (+) and (−) states were defined by Eq. 11.

Frequency Analysis and Potential Parameters. Prior to the two dimensional analysis of the spectrum, ω_e and $\omega_e\chi_e$ were estimated to be 3194 cm^{-1} and 58 cm^{-1} respectively by the use of the Birge-Sponner relation[13] for the overtone series, assuming a one dimensional oscillator model. There were two more parameters, f_{12} and g_{12}, necessary for the two dimensional calculation. It was, however, very difficult to determine these two parameters independently because $\langle v_1,v_2|H|v_1+1,v_2-1\rangle$, which is most responsible for mixing, always contains f_{12} and g_{12} in the same combined form in harmonic approximation, although such constraint is to be destroyed in $\langle v_1,v_2|H|v_1+1,v_2+1\rangle$ which connects different groups and also in the anharmonic calculation. Therefore, we used the calculated value of $(1/m_C)\cos(\angle HCH)=-0.04167$ amu^{-1} for g_{12} using the assumed angle of $\angle HCH=120°$. g_{12} was fixed at this value throughout the present analysis.

A preliminary calculation was done neglecting f_{12} under a harmonic approximation for the off-diagonal

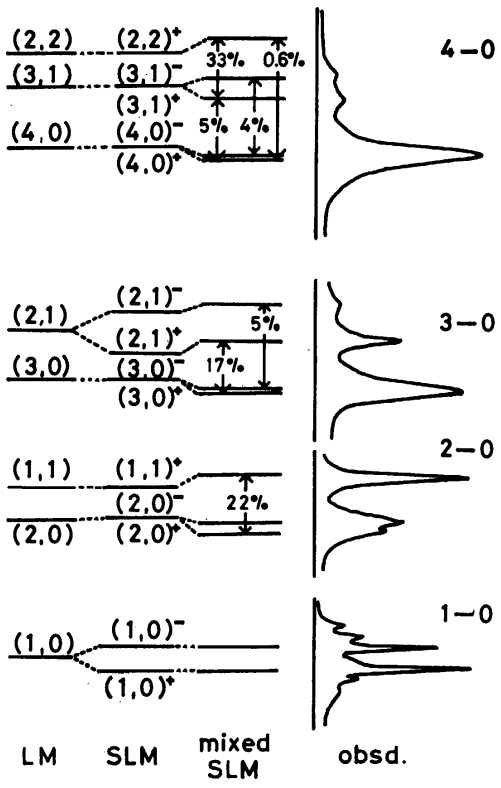

Fig. 3. Observed spectrum and their assignment. The energy diagram was shown by the diagonal elements in each representation in order to show how to approach to the eigen values. The numbers in % show the degree of the mixing between the two states which are connected by the arrows.

a) Most dominant SLM state.

matrix elements. The results were good enough to assign all the peaks in the observed spectra. The three peaks at 5990 cm^{-1}, 6025 cm^{-1}, and 6210 cm^{-1} in the first overtone region were assigned to the $(2,0)^+$, $(2,0)^-$, and $(1,1)^+$ dominant states. These bands were assigned to $2\nu_1$, $\nu_1+\nu_9$, and $2\nu_9$, respectively, in the NM representation by Yamaoka and Machida.[11] The 8860 cm^{-1} peak was assigned to the unresolved $(3,0)^+$ and $(3,0)^-$ pairs corresponding to $3\nu_1$ and $2\nu_1+\nu_9$ respectively, whereas $(2,1)^+$ and $(2,1)^-$ were assigned to the 9070 cm^{-1} peak ($\nu_1+2\nu_9$, in the NM representation) and 9230 cm^{-1} peak ($3\nu_9$, in the NM representation), respectively, which show larger splitting. Other peaks were also assigned as shown in the third column of Table 1 and in Fig. 3.

Next, f_{12} and more refined ω_e and $\omega_e\chi_e$ values were determined by the least squares methods still within the harmonic approximation. The final parameters in Table 2 were obtained using the exact matrix elements based on the Morse potential which are listed in the Appendix. The calculated frequencies were in good agreement with the observed ones, as shown in the fourth column of Table 1. The last column of Table 1 shows the calculated eigenstates as a linear combination of SLM.

D_e/cm^{-1}	44190
α/Å^{-1}	1.755

a) Calculated assuming $\angle$HCH=120°.

The changes of the spectral structures with the change of the basis representations are schematically shown in Fig. 3 together with the observed spectra. The degeneracy of the fundamental bands, (1,0) and (0,1) in LM, was easily resolved into $(1,0)^+$ and $(1,0)^-$ in the SLM representation as well as in the other $(v,v-1)$, $(v-1,v)$ pair states. However, (2,0) and (0,2) in LM were still practically degenerate in pure SLM. The splitting of these levels were caused by a second order perturbation which mixed $(2,0)^+$ and $(1,1)^+$ by 22%. The other pair states which did not show splitting in SLM were also split by mixing to a greater or lesser degree, although the splitting of $(v,0)$ states became smaller with the increase of v, as stated in the previous paragraph.

Intensity Analysis and Dipole Moment Function. The change of the dipole moment with the displacement of q_1 and q_2 could be expressed by

$$\boldsymbol{D}(q_1,q_2) = \boldsymbol{D}_1(q_1) + \boldsymbol{D}_2(q_2) + \boldsymbol{D}_{12}(q_1,q_2), \tag{15}$$

where $\boldsymbol{D}_1$ or $\boldsymbol{D}_2$ is the change induced by the change of q_1 or q_2, respectively, while the other coordinate q_2 or q_1 remains unchanged. $\boldsymbol{D}_{12}$ expresses the interacting effect which appears when q_1 and q_2 change simultaneously. Instead of Eq. 15, $\boldsymbol{D}(q_1,q_2)$ may be written in another form as

$$\boldsymbol{D}(q_1,q_2) = D_{//}(q_1,q_2)\,\boldsymbol{i} + D_{\perp}(q_1,q_2)\,\boldsymbol{j}, \tag{16}$$

where $\boldsymbol{i}$ and $\boldsymbol{j}$ are the unit vectors parallel and perpendicular to the molecular axis respectively, as shown in Fig. 4. Here, we assume that directions of $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$ do not change because of the magnitude of q_1 and q_2. Let θ be the angle of $\boldsymbol{D}_1$ measured from the direction of $\boldsymbol{i}$ and let M be the scalar part of $\boldsymbol{D}_1$. Then we obtain this relations:

$$D_{//} = (M(q_1) + M(q_2))\cos\theta + M_{12}q_1q_2, \tag{17}$$

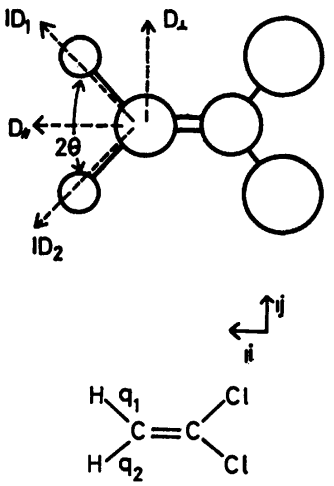

Fig. 4. The change of the dipole moment of CH_2CCl_2 and its relation to the molecular framework.

$$D_\perp = (M(q_1) - M(q_2))\sin\theta. \quad (18)$$

Here, we make a further approximation by neglecting the higher order terms in $\boldsymbol{D}_{12}(q_1,q_2)$ such as $M_{122+}(q_1q_2^2+q_1^2q_2)\,\boldsymbol{i}$ and $M_{122-}(q_1q_2^2-q_1^2q_2)\boldsymbol{j}$. $M(q)$ is a dipole moment function in one dimensional approximation as treated in our preceding paper[4] and we can expand it in a power series of q:

$$M(q)=M_1q+M_2q^2+\cdots. \quad (19)$$

The higher order terms in Eq. 19 were again neglected. θ is an unknown parameter because $\boldsymbol{D}_1$ will not necessarily be parallel to the direction of the displacement of q_1. So we have four parameters to be determined from the intensity analyses of the observed spectra.

The symmetry considerations show that a transition from the ground state to any (+)-state or to any (−)-state must be induced by $D_{//}$ or $D_\perp$, respectively. The transition moments in the SLM representation are given by

$$\langle v,0,+|\boldsymbol{D}|0\rangle = \sqrt{2}\cos\theta\langle v|M|0\rangle\,\boldsymbol{i} + \sqrt{2}\,M_{12}\langle v|q|0\rangle\langle 0|q|0\rangle\,\boldsymbol{i}, \quad (20)$$

$$\langle v,0,-|\boldsymbol{D}|0\rangle = \sqrt{2}\sin\theta\langle v|M|0\rangle\,\boldsymbol{j}, \quad (21)$$

$$\langle v_1,v_2,+|\boldsymbol{D}|0\rangle = \begin{cases} \sqrt{2}\,M_{12}\langle v_1|q|0\rangle\langle v_2|q|0\rangle\,\boldsymbol{i} & \\ \qquad\qquad \text{for } v_1\neq v_2>0 & \\ M_{12}\langle v|q|0\rangle^2\,\boldsymbol{i} \quad \text{for } v_1=v_2>0. & \end{cases}$$

The second term of Eq. 20 is smaller than the first term because an anharmonic character is necessary for $\langle 0|q|0\rangle\neq 0$. Thus, we may say that M is responsible for the appearence of the fundamental and pure overtone bands whereas M_{12} is responsible for the appearence of pure combinations with (+)-symmetry. Pure combination bands with (−)-symmetry are inactive in this approximation, although they may appear in higher order approximation through the terms such as M_{122-}.

The transition moment corresponding to a mixed state, $|n\rangle=\sum C_{nv}|v\rangle$, is written as

$$\langle n|D|0\rangle = \sum C_{nv}\langle v|D|0\rangle \quad (24)$$

where $|v\rangle$ is a representative of a pure SLM state $|v_1,v_2\rangle$ and C_{nv} is a linear combination coefficient as listed in Table 1.

Deduction of the Dipole Moment Parameters. The appearence of the combination bands would be totally attributed to the degree of mixing with allowed pure overtones in the absence of M_{12}. The 6210 cm^{-1} peak assigned to the $(1,1)^+$ dominant state, however, was stronger than the 5990 cm^{-1} assigned to the $(2,0)^+$ dominant state, although the calculation showed only 22% of mixing between the two SLM's. This fact indicated considerable contribution of M_{12} to the spectrum.

Analyzing the observed intensities of the five peaks in the fundamental and the first overtones using Eqs. 20—24 and the matrix elements of the Appendix, we obtain:

$$|\langle 1|M|0\rangle| = 2.56\times10^{-2}\ \text{D},$$
$$|\langle 2|M|0\rangle| = 4.76\times10^{-2}\ \text{D},$$
$$|M_{12}| = 0.386\ \text{D Å}^{-1},$$
$$\theta = 38.4°\pm0.2°.$$

Here, the sign of M_{12} depends on M. It must be chosen so that it can be constructive with M in the $(1,1)^+$ dominant band but destructive in the $(2,0)^+$ dominant band.[14] From these values, the contribution of M_{12} to the total integrated intensity over the second overtone region was estimated to be less than a few per cent, and much less for the higher overtones. Thus we could use the one-dimensional approximation for the other $|\langle v|\boldsymbol{D}|0\rangle|$'s with $v>2$. In the determination of M_1 and M_2 in M, the procedure described in our preceding papers[4,5] was employed. The intensity values were converted to those of the one-dimensional model by subtracting small contributions from M_{12}. These corrected values showed a slight dip in the 2←0 transition (see Fig. 5) as seen in benzene and cyclohexane.[4] Therefore, the relation, $M_1M_2>0$, could be obtained.[4] It would be reasonable to choose $M_1<0$ and $M_2<0$, according to the *ab initio* calculation for ethylene and also

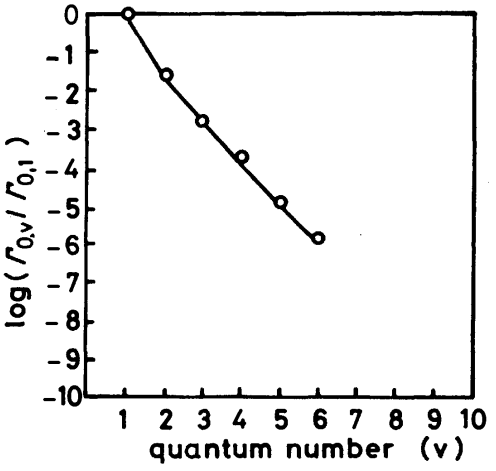

Fig. 5. The logarithmic relative intensity, $\Gamma_{0,v}/\Gamma_{0,1}$, for liquid 1,1-dichloroethylene plotted against a vibrational quantum number, v. Open circles represent the observed values, while the solid line connects these values calculated from the best-fit parameter, $M_2/M_1=3.03$ Å^{-1}.

TABLE 3. DIPOLE MOMENT PARAMETERS

	This work	Ethylene (*Ab initio*)
M_1/D Å^{-1}	−0.29	−0.64
M_2/D Å^{-2}	−0.88	−1.23
M_{12}/D Å^{-2}	0.39	0.57
θ/°	38.4	52.3

considering the results of benzene and cyclohexane. This choice of the sign for M enforced $M_{12}>0$. The finally obtained parameters are listed in Table 3.

Comments on the Final Results. There are two causes which mix the states in the SLM representation, namely, kinetic coupling and potential coupling. We ignored the anharmonic coupling in the potentials. The excellent agreement between the calculated and observed frequencies seems to confirm this approximation. The contributions from these two types of coupling were evaluated numerically to see which is more effective in the 1,1-dichloroethylene system. One off-diagonal elements, shown as

$$\begin{aligned}\langle 2,0,+|0|1,1,+\rangle &= \sqrt{2}(q_{12}\langle 2|p|1\rangle\langle 0|p|1\rangle \\ &\quad + f_{12}\langle 2|x|1\rangle\langle 0|x|1\rangle) \\ &= -111.5\ \mathrm{cm^{-1}} + 26\ \mathrm{cm^{-1}}\end{aligned}$$

indicated that f_{12} was less effective in the mixing. This might be one of the reasons why the preliminary calculation with $f_{12}=0$ led to the frequencies which are satisfactory enough to allow assignment of the observed spectrum.

The f_{12} value determined in this work was positive, unlike that of Yamaoka and Machida.[11] Our value is close to f_{12} of ethylene, 0.0185 mdyne/Å, including its sign, which was obtained by the same authors.[15] D_e and the Morse parameter, α, were deduced from ω_e and $\omega_e\chi_e$ and are listed in Table 2. The α-value of 1.75 Å^{-1} was 10% larger than Machida's value.

Our approach has the advantage of giving more physically meaningful assignments for the spectrum as well as some simplicity of the analysis. The assignments in the NM representation, such as $2\nu_1$ or $\nu_1+2\nu_9$, may not have much physical meaning except for the symmetry because of the strong mixing due to the Darling-Dennison reasonance in the CH overtone regions. Although the mixing can never be neglected in SLM, the meaning of the mixing is still clear. We found the $(v,0)^{\pm}$ dominant states tended to be more isolated and tended to degenerate rapidly for $v>3$. This corresponds to the formation of pure local modes in spectra. The other states, however, did not show these tendencies even in the highest states examined. So we may say that the LM representation is surely preferable in the cases of the optically allowed high v states. But we should remember that there are many other excited states which neither LM nor NM can describe in a simple form, although they are almost forbidden in absorption spectra.

The intensities calculated from the parameters in Table 3 are listed in the fourth column of Table 4. The numbers in the parentheses are the intrinsic intensities of the pure SLM bands in the absence of mixing. The contributions of M and M_{12} to each transition moment are separately listed in the sixth and seventh columns respectively. The last column shows the percent contribution of M_{12} to the total integrated band intensities, f_{M12}. It can be seen that f_{M12} is not very large. It is only 13.6% even in the largest case, for the 2←0 band. The second largest is 3.4% for the 3←0 band. If the effects of M_{12} in other molecules are the same order in magnitude, the one-dimensional analysis in the preceding paper[4] would be

Intensities and matrix elements are connected by the following relation:

$$\Gamma = \frac{8\pi^3 N}{3hc}|\langle 0|M|v\rangle|^2 = 2.508\times 10^5|\langle 0|M|v\rangle|^2 \quad \text{(see Ref. 4).}$$

practically assured.

M_{12}, however, shows a great deal of perturbations on the intensity distributions in the overtones. This is due to interferring interactions with M which happened to contribute to the same transition moment through mixing of the states. From columns 6 and 7, we see that M alone and M_{12} alone explained only 31% and 20% of the total intensity of the $(1,1)^+$ dominant transition. The remaining 49% must be attributed to the constructive property[14] of M and M_{12} in the transition moment. In contrast to this transition, $(2,0)^+$ dominant states were 40% smaller in intensity than what M alone could induce. This was attributed to the destructive[14] contribution of M_{12}.

The obtained dipole moment parameters were compared with the *ab initio* values of ethylene, since we failed to find the corresponding experimental parameters in the literature. The *ab initio* calculation was the one described in the preceding paper.[4] The sign of M_{12} was found to be positive, as shown in Table 3. However, θ was smaller than expected. The direction of the change of the dipole moment induced by a displacement of one CH bond deviates more than 20° from the direction of the displacement, whereas the *ab initio* value of θ in ethylene was very close to what we expected from the direction of the displacement. We believe the experimental error in θ is not so large, since it is strongly correlated to the ratio of the intensities of $(1,0)^-$ and $(1,0)^+$ bands. Polarization of the electrons in chlorine atoms induced by the stretching of CH bonds might be responsible for such small values of θ.

Salting-out Phenomenon and Clathrate Hydrate Formation in Aqueous Solution of Polar Nonelectrolyte

Tadashi KATO,* Masako YUDASAKA, and (the late) Tsunetake FUJIYAMA

Institute for Molecular Science, Myodaiji, Okazaki 444

(Received August 14, 1981)

The Salting-out Phenomenon has been carefully observed by adding ammonium chloride into aqueous solutions of *t*-butyl alcohol, acetone, dioxane, and 2-butoxyethanol. The experimental results have been well explained by considering the formation of a clathrate hydrate-like local structure in the aqueous solution of each nonelectrolyte. In addition, the role of the chloride ion has been found to be the promotion of the aggregation of the clathrate hydrate-like local structures. The line-width measurement of ^{35}Cl-NMR spectra has been shown to be an extremely powerful method for studying the state of mixing of ions in solutions.

The mutual solubility of a nonelectrolyte and water is decreased by the addition of inorganic salts. The interpretation of this salting-out phenomenon from a molecular viewpoint originated in the work of Debye *et al.*[1] They presented an equation which relates the solubility of a nonelectrolyte with the salt concentration in terms of the dielectric constant of the solution. Later on, some modifications of Debye's theory have been reported.[2-4] These theories are based on the idea that the solubilities of nonelectrolytes diminish by adding salts into aqueous solutions because the ions draw water molecules around themselves and, therefore, rob the water molecules from the nonelectrolytes. The scaled particle theory has been proposed from a completely different point of view.[5] This theory does not imply any model for the structure of the solvent and calculates thermodynamic quantities through the estimation of a free energy which is necessary first to make cavities in solvents and, then, to introduce nonelectrolyte molecules into the cavities. There are currently many attempts to explain salting-out phenomena by the use of this theory.[6,7]

In general, the solubilities of polar nonelectrolytes in water are much larger than those of nonpolar molecules; sometimes the two components are miscible in all proportions. Therefore, the salt concentration required to cause a phase-separation is higher than that in the case of nonpolar molecules. However, the application of the foregoing theories has been limited to the very low concentration range of salt or nonelectrolyte. Solubility curves such as those shown in Fig. 1 cannot be explained by these theories even qualitatively.

In our previous reports, the existence of clathrate hydrate-like local structures has been suggested in aqueous solutions of polar nonelectrolytes such as *t*-butyl alcohol (TBA) and acetone.[8-10] Although these nonelectrolytes are miscible with water in all proportions, the addition of salt causes phase-separation.

In the present work, we consider the salting-out phenomena based on the results of the above studies and emphasize the role of a clathrate hydrate-like local structure formed in the aqueous solutions of a nonelectrolyte. It will be shown that the line-width measurement of the ^{35}Cl-NMR spectrum is a useful method for the clarification of these problems. Ammonium chloride was chosen as a salt because it has been known that ammonium chloride changes the structure of water very little.[11]

Experimental

Materials. Dioxane, *t*-butyl alcohol, 2-butoxyethanol, and ammonium chloride were commercially available in a guaranteed grade; they were used without further purification. Water was distilled and passed through an exchange resin.

Determination of Solubility Curve. Weighed ammounts of water, nonelectrolyte, and ammonium chloride were sealed in glass tubes. The phase-separation temperature, T_p, of each ternary solution was determined in a water bath by the observation of the temperature at which the solution became turbid. The accuracy of T_p was ± 0.5 °C. The solubility curves at various temperatures were determined by the observation of T_p at various concentrations.

NMR Measurement. The ^{35}Cl-NMR spectra were recorded on a Varian FT80A spectrometer at 7.794 MHz. For a spectral width of 4000 Hz and an aquisition time of 0.4 s. 8000 data points are available in the time domain spectra. The alpha delay was kept at 1000 s, while the Fourier number was kept at 16384. No weighting function was applied; this avoided artificial broadening of the line-widths. The accuracy of the half-line-width was ± 1.5 Hz.

Results and Discussion

Solubility Curve. The solubility curves of ternary solutions of water, ammonium chloride, and various nonelectrolytes (TBA, acetone, dioxane, and 2-butoxyethanol) at 40 °C are shown in Fig. 1. We define two kinds of concentrations, X_2' and X_3,

$$X_2' = \frac{n_2}{n_1+n_2}$$

and

$$X_3 = \frac{n_3}{n_1+n_2+n_3},$$

where n_1, n_2, and n_3 are the number of moles of a water, nonelectrolyte, and ammonium chloride, respectively. In Fig. 1, X_2' is plotted as abscissa, while X_3 as ordinate. We define here a new quantity, $X_3^{\min}$ as the minimum value of the mole fraction of ammonium chloride which is necessary to make the ternary solution separate into two liquid phases. The figure shows that $X_3^{\min}$ decreases rapidly as X_2' increases in the low concentration range. For each system, there exists a concentration range where ammonium chloride is precipitated before phase-separation occurs. This concentration range is defined as $0 \leq X_2' \leq X_2^{\mathrm{p}}$.[12] For example, X_2^{p} is about 0.03 for the TBA system. Figure 2 shows the

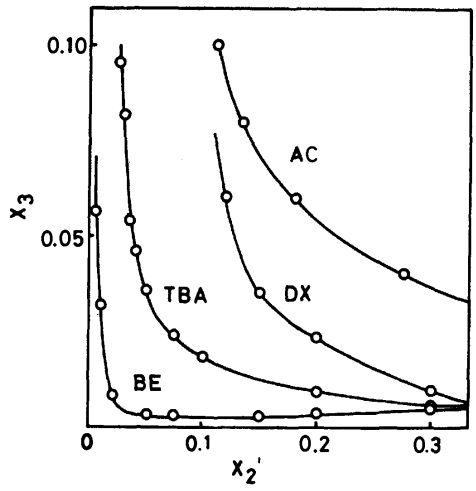

Fig. 1. Solubility curve for ternary solutions of water, ammonium chloride, and various nonelectrolytes (acetone(AC), dioxane(DX), *t*-butyl alcohol(TBA), and 2-butoxyethanol(BE)) at 40 °C.

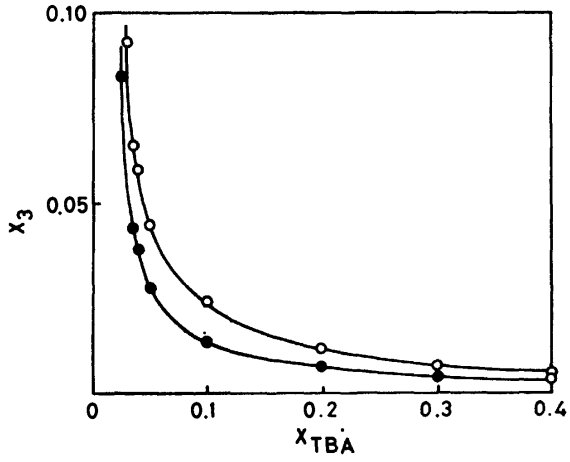

Fig. 2. Solubility curve for TBA–water–ammonium chloride solution at 30 °C (○) and 50 °C (●).

solubility curves for the TBA system at 30 °C and 50 °C. The figure shows that X_3^{min} decreases as the temperature increases, but that X_2^s is only slightly dependent on temperature. These results may depend on the mixing state of the binary solution of water and the nonelectrolyte. We will thus compare the solubility curves with the mean-square concentration fluctuations for the binary solution, which sensitively reflect the mixing state.

Concentration Fluctuations for Binary Solution and Solubility Curve. Figure 3 shows the mean-square concentration fluctuation, $N<(\Delta X)^2>$, for the aqueous solutions of TBA,[8] dioxane,[8] and 2-butoxyethanol[13] at 40 °C where N is the mean number of total molecules included in the field within which the concentration fluctuations are considered. It is seen from the figure that the $N<(\Delta X)^2>$ value is nearly equal to that for an ideal solution in the low concentration range and begins to increases abruptly at a certain mole fraction, X_2^s. For example, X_2^s is about 0.04 for the TBA system. Figures 1

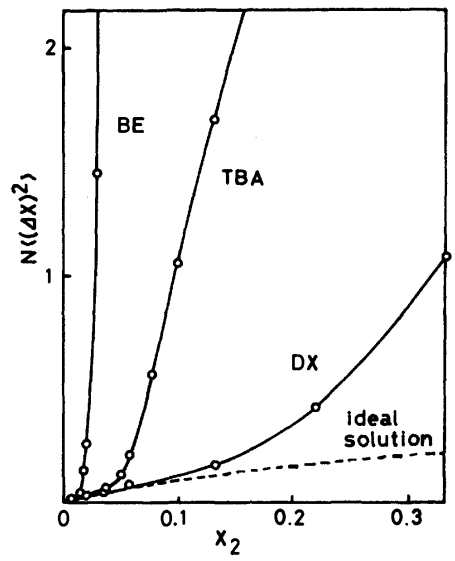

Fig. 3. Concentration dependence of mean-square concentration fluctuation for aqueous solutions of dioxane (DX), *t*-butyl alcohol(TBA), and 2-butoxyethanol(BE) at 40 °C.

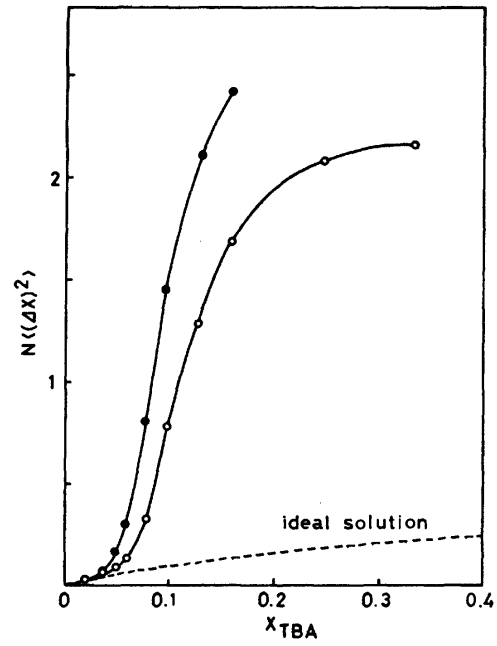

Fig. 4. Concentration dependence of mean-square concentration fluctuation for TBA–water solution at 24 °C (○) and 50 °C (●).

and 3 show that X_2^s is nearly eaual to X_2^p. Figure 4 shows the temperature dependence of the $N<(\Delta X)^2>$ values for the TBA–water system. $N<(\Delta X)^2>$ increases in magnitude with the elevation of temperature in the concentration range of $X_{TBA}>X_{TBA}^s$. Similar results have been obtained for other systems. These results suggest that the solution is rapidly approaching the phase-separation with the increase of the temperature. In fact, 2-butoxyethanol(BE)–water system has a lower critical temperature. The phase diagram (T-X_2 curve) for this system is shown in Fig. 5.[14] Figures 3 and 5 show

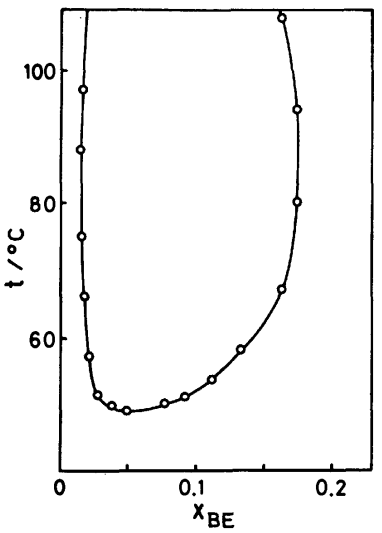

Fig. 5. Phase diagram for 2-butoxyethanol–water solution.

that the phase diagram is strongly correlated with the concentration dependence of the $N\langle(\Delta X\rangle)^2$ value. The phase-separation temperature decreases with the increase of $N\langle(\Delta X)^2\rangle$ in the concentration range of $X_{BE}<X_{BE}^s$ and the phase-separation does not occur in the concentration range of $X_{BE}<X_{BE}^s$. Similar results have been obtained for other systems, such as, the 2,6-lutidine–water system.[13] The relation between the X_3-X_2' curve (Fig. 1) and the concentration dependence of the $N\langle(\Delta X)^2\rangle$ value is similar to that between the T-X_2 curve and the concentration dependence of the $N\langle(\Delta X)^2\rangle$ value. X_2^{min} rapidly decreases with the rapid increase of the $N\langle(\Delta X)^2\rangle$ value and salting-out does not occur in the concentration range of $X_2<X_2^s$. It can be concluded that an addition of salt causes phenomenologically the same change of the mixing state of the binary aqueous solutions as that caused by an elevation of temperature.

The temperature dependence of the mixing state for the TBA–water system has been discussed based on the quantitative analysis of the concentration fluctuations.[8,10] The conclusion is as follows. In the concentration range of $0<X_{TBA}<X_{TBA}^s$, water molecules form a polyhedron which encages a TBA molecule in water. In the concentration range of $X_{TBA}>X_{TBA}^s$, the polyhedra gather together in TBA. As the temperature increases, the polyhedra continue gather in this concentration range. This suggest that microscopic phase-separation occurs in the solution. One is a TBA-rich phase and the other is a water-rich phase. In the water-rich phase, almost all the molecules take part in the formation of polyhedra.

The salting-out phenomenon is considered to be governed by a mechanism similar to that described above. Namely, on adding ammonium chloride into an aqueous solution of TBA, the polyhedra formed in the TBA–water solution gather together; this results in the separation of the water-rich layer.

Surroundings of Ion in Aqueous Solution of Nonelectrolyte. We now consider the state of mixing of ammonium chloride in the aqueous solution of a nonelectrolyte based on the results of the measurement of the ^{35}Cl-NMR spectra. The half-line-width of ^{35}Cl-NMR spectra, $\Delta\nu$, is proportional to the product of the square of the electric field gradient at the nucleus, q^2, and the correlation time of the fluctuation of the electric field gradient at the nucleus, τ_c.[15] The magnitude of q^2 depends on the local asymmetry of the local structure around the chloride ion. If τ_c is assumed to be proportional to viscosity η, we can discuss the concentration or temperature dependence of the asymmetry of the local structure around the chloride ion from the concentration or temperature dependence of the quantity, $\Delta\nu^\circ\equiv\Delta\nu/(\eta/\eta_0)$, where η_0 is the viscosity of the solution whose $\Delta\nu$ value is chosen as reference.[16] As an absolute value of $\Delta\nu^\circ$ will not be discussed in the present report, the η_0 value will be fixed to 10^{-3} Pa s.

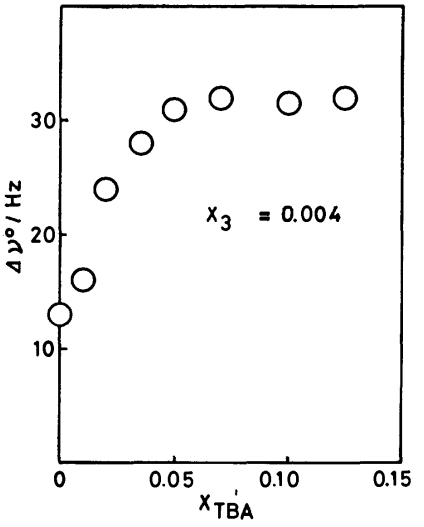

Fig. 6. Dependence of the $\Delta\nu^\circ$ value (see tle text) for TBA–water–ammonium chloride solution on the mole fraction of TBA at 32 °C (mole fraction of ammonium chloride is 0.004).

Figure 6 shows the relation between $\Delta\nu^\circ$ and X'_{TBA} for $X_3=0.004$ at 32 °C. It is seen from the figure that $\Delta\nu^\circ$ increases in magnitude as X'_{TBA} increases in the concentration range of $0<X'_{TBA}<0.05$. In the aqueous solution of ammonium chloride ($X'_{TBA}=0$), the $\Delta\nu^\circ$ value was observed to be only about 13 Hz for the wide salt concentration range from dilute to $X_3=0.11$. As the molar ratio of (ammonium ion) : (chloride ion) : (water) at $X_3=0.11$ is about 1 : 1 : 9, there are only two layers of water molecules between ammonium and chloride ions. This result indicates that $\Delta\nu^\circ$ increases only when the symmetry of the local structure around a chloride ion is broken down. The increase of $\Delta\nu^\circ$ observed in the TBA–water–ammonium chloride solution may reflect the break-down of the local symmetry around the chloride ion. Some chloride ions probably take part in the formation of the polyhedra in the solution. The concentration dependence of $\Delta\nu^\circ$ confirms the validity of the above picture. As ammonium chloride is only slightly soluble in TBA by itself, the number of chloride ions which take part in the formation

of the polyhedra is expected to be proportional to the number ratio, R, of water molecules which form polyhedra to all the water molecules. According to the results obtained from the analysis of concentration fluctuations, R can be calculated from the relations:[8]

$$R = lX_{TBA}/(1-X_{TBA}) \text{ for } 0<X_{TBA}<X^{s}_{TBA},$$

$$R = 1 \quad \text{for } X_{TBA}>X^{s}_{TBA},$$

where $l(\simeq 20)$ is the number of water molecules which encage a TBA molecule. Figure 7 shows the concentration dependence of R calculated for $l=20$. It can be seen from Figs. 6 and 7 that $\Delta\nu^{\circ}$ is nearly proportional to R.

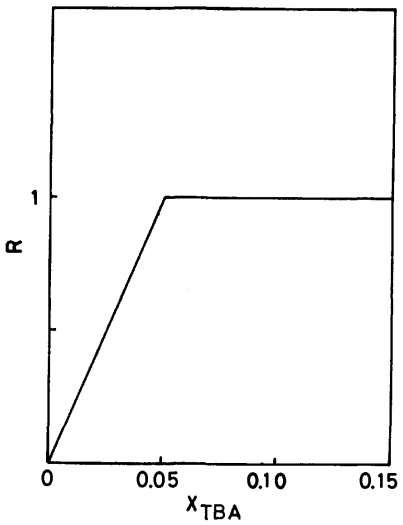

Fig. 7. Dependence of the number ratio of water molecules which form polyhedra to all the water molecules for TBA–water solution on the mole fraction of TBA.

For an ammonium ion, we have no experimental information about its state of mixing in this solution. However, it is only natural to consider that an ammonium ion is also taking part in the formation of a polyhedra, because an ammonium ion has similar size and property to those of a water molecule. Therefore, the water molecule which forms a polyhedra can be replaced by an ammonium ion much more easily than by a chloride ion.

Role of Ammonium Chloride in Phase-separation. Next, we focus our attention on the dependence of the $\Delta\nu^{\circ}$ value on salt-concentration. The acetone (AC) system was chosen for this experiment because the salt-concentration can be widely changed in a one-phase region. In Fig. 8, the $\Delta\nu^{\circ}$ values observed for $X'_{AC}=0.3$ at 32 °C are plotted against the salt-concentration, X_3. It can be seen from the figure that $\Delta\nu^{\circ}$ decreases its magnitude with the increase of the ammonium chloride concentration. Note that the phase-separation occurs at $X_3>0.004$. These results cannot be explained if we consider that all the chloride ions are engaged in the formation of polyhedra, because the local symmetry around a chloride ion should attain higher symmetry with the increase of salt-concentration. Therefore, it may be reasonable to consider that, at high salt-concentration, some chloride ions can exist in this solution,

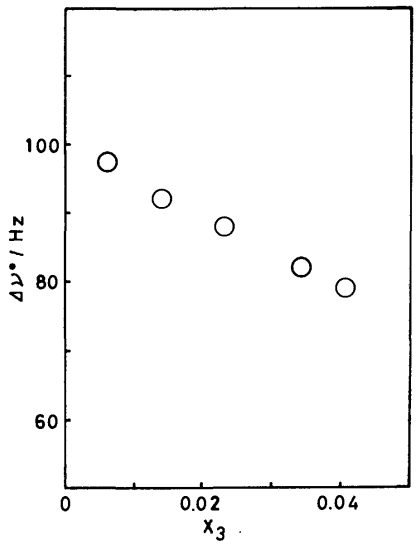

Fig. 8. Dependence of the $\Delta\nu^{\circ}$ value for acetone–water ammonium chloride solution on the mole fraction of ammonium chloride at 32 °C (mole fraction of acetone is 0.3).

surrounded by polyhedra. In other words, some chloride ions can attract polyhedra around themselves, which results in the formation of a high local symmetry around the chloride ion. As the aggregation of polyhedra is one of the necessary conditions for phase-separation, it can be said that chloride ions promote the phase-separation by attracting polyhedra around themselves.[17]

From the above discussion, the picture for the salting-out phenomenon can be drawn as follows. When ammonium chloride is added to the aqueous solution of nonelectrolyte in the concentration range of $X_2>X^{s}_{2}$, not only water molecules but also ammonium and chloride ions form polyhedra and each of them encages a nonelectrolyte molecule. As the concentration of ammonium chloride increases, the polyhedra begin to gather around a chloride ion. When the concentration of ammonium chloride is raised to X_3^{min}, the aggregate of the polyhedra grows into a macroscopic phase and the phase-separation occurs. This situation is schematically visualized in Fig. 9.

Lastly, we consider the temperature dependence of the mixing state at a constant salt-concentration. The temperature dependence of the $\Delta\nu^{\circ}$ value observed for $X'_{AC}=0.3$ and $X_3=0.04$ is shown in Fig. 10. Note that phase-separation occurs at 33 °C at this concentration. It can be seen from the figure that the $\Delta\nu^{\circ}$ value decreases with the elevation of temperature. This experimental result corresponds to the fact that, as the temperature approaches the phase-separation temperature, polyhedra begin to gather together around a chloride ion, which in turn results in the formation of a symmetric local field around a chloride ion.

Concluding Discussion. We have shown the existence of the clathrate hydrate-like local structure plays an important role in the salting-out phenomena in the aqueous solutions of polar nonelectrolytes such as TBA and acetone. Even if the solution does not contain

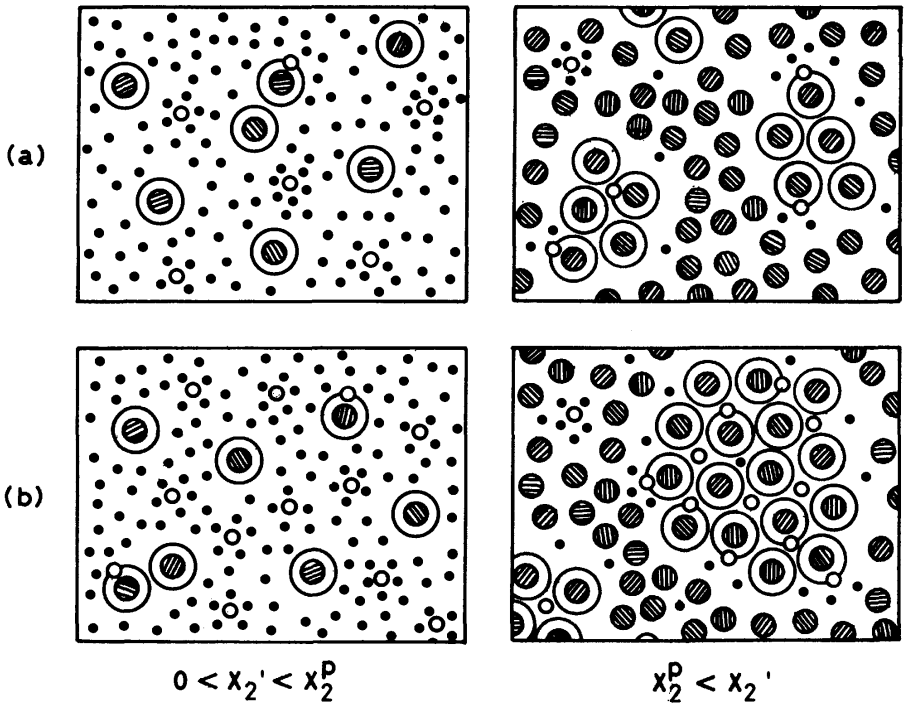

Fig. 9. Mixing state of ternary solution of water–ammonium chloride–nonelectrolyte (schematic) in the low (a) and high (b) concentration range of ammonium chloride. salts, the chlathrate hydrate-like local structure grows with the increase of the temperature. That is, the number of polyhedra which gather increases as the temperature increases. This property of the solution is considered to originate in the difference between the affinity of the polyhedron (strictly speaking, the water molecules which form a polyhedron) for nonelectrolyte and the affinity of the polyhedron for the polyhedron. The salt performs the task of promoting the gathering of the polyhedra. The present result shows that the ions take part in the formation of polyhedra; this may arise from the fact that the affinity of the ion for nonelectrolyte is weaker than that of the ion for water. The facts that the salting-out does not occur in the concentration range of $X_2 < X_2^s$ can be explained from this point of view. Roughly speaking, the polyhedra rarely contact with nonelectrolyte molecules in this concentration range because most of the nonelectrolyte molecules are encaged by water molecules. So, the phase-separation does not occur.

The above picture is rather different from the classical picture that ions rob the water molecules from the nonelectrolyte. Of course, we are not going to deny this classical picture wholly. In fact, the result that X_2^p is slightly smaller than X_2^s may arise from the fact that the number of water molecules which can form polyhedra is decreased by some ions which rob water molecules from the polyhedra. However, the rapid decrease of X_3^{min} with the increase of X_2', and the existence of the concentration range where salting-out does not occur cannot be explained by the classical picture.

The strong correlation between the solubility curve for the ternary solution and the concentration dependence of the concentration fluctuation for the binary solution indicates that the phase behavior is determined principally by the mixing state of the binary solution at least in the concentration range near X_2^s. So, the validity of our picture is considered to be dependent

on the validity of the picture for the mixing state of the binary solution.

The authors wish to express their sincere thanks to Dr. Tadashi Sugawara for his helpful advice on the measurement of NMR spectra.

An Ion-impact Study of Singlet-Triplet Transitions in Ethylene and Alkyl-substituted Ethylenes

Yukinori SATO,* Kazuki SATAKE, and Hokotomo INOUYE
Research Institute for Scientific Measurements, Tohoku University, Sanjyo-machi, Sendai 980
(Received August 21, 1981)

The $T \leftarrow N$ ($\pi \rightarrow \pi^*$) transitions in ethylene, all of its methyl derivatives, and 1-butene were observed by means of He^+-impact energy-loss spectroscopy. With a resolution of better than 0.1 eV, a vibrational structure was just resolved in the $T \leftarrow N$ excitation spectrum of ethylene. The $T \leftarrow N$ transition energy was measured for the alkylethylenes with a lower resolution. The results are in good agreement with the electron-impact data, indicating that the vibro-rotational excitation due to the impulsive momentum transfer is negligible in the present method. The $T \leftarrow N$ excitation cross-sections were found to decrease by half upon the unit substitution of alkyls. The relative invariance of the $T \leftarrow N$ transition energy and the decrease in the $T \leftarrow N$ cross-sections upon alkyl substitution may be attributable to the decrease in the intra- and intermolecular Coulomb and exchange interactions between π- and π^*- orbitals.

The alkylation red shift has been of some interest in studies of the electronic spectra of ethylene and alkyl-substituted ethylenes.[1-3] After earlier studies using optical spectroscopy,[4,5] electron-impact methods have been applied to observe the bathochromic shift in the spin-forbidden $T \leftarrow N$ ($\pi \rightarrow \pi^*$) transition for a series of fundamental mono-olefinic hydrocarbons.[6-8] It has been revealed that the shift is much smaller in the $T \leftarrow N$ transition than in the optically allowed $V,R \leftarrow N$ transitions.

Measurements of energy loss by ion impact have also proved to be useful for observing spin-exchange transitions.[9-11] In the ion-impact method, a singlet-triplet transition of a target molecule is induced by electron exchange between the projectile ion and the target molecule. Therefore, the proton impact on a singlet spin-state molecule results in excitations only to singlet states, whereas the He^+ impact, for example, can induce both singlet-singlet and singlet-triplet transitions in the molecule. Under a suitable collision energy, the lowest energy singlet-triplet transition of a molecule may be observed as the most intense peak in the ion-impact spectrum. Moore and his co-workers have performed several ion-impact experiments in order to investigate the effect of substitution on the $T,V,R \leftarrow N$ transition energies in substituted ethylenes[9] and in methyl-substituted butadienes[10] and the effect of ring size on the $T,V,R \leftarrow N$ transition energies in cycloalkenes.[11]

In the present study, the He^+-impact method was used for observing the $T \leftarrow N$ transition in ethylene and alkylethylenes. Semiempirical calculations of the transition energies were also performed in order to analyze the experimental results. The purposes of the present study were; (1) to achieve a better energy resolution in the ion-impact spectroscopy; (2) to accumulate systematic data by means of ion impact to see if the ion-impact and electron-impact methods are consistent in determining the $T \leftarrow N$ transition energy; (3) to obtain some insight into the cause of the alkylation red shift, and (4) to investigate the effect of alkylation on the cross-section of $T \leftarrow N$ excitation induced by the ion-molecule interaction.

Experimental

The apparatus consists of an ion source, a mass analyzer, an energy monochromator for the incident-ion beam, a collision cell, an energy analyzer for the scattered ions, and a detector. The projectile He^+ ions are produced in a low-voltage plasma source.[12] The ions extracted from the source are focused into a beam, mass-analyzed by means of a Wien filter (COLUTRON Model 300), and directed into the ion spectrometer which is schematically shown in Fig. 1.

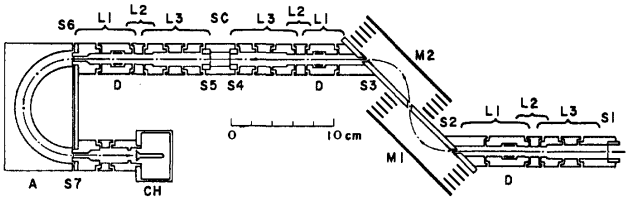

Fig. 1. Schematic of the ion spectrometer.
S1—S7: Apertures, L1: fixed ratio lens, L2: field lens, L3: variable ratio lens, D: beam steering deflectors, M1 and M2: parallel plate deflectors for an energy monochromator, SC: scattering cell, A: hemispherical energy analyzer, CH: channel electron multiplier.

The mass-analyzed beam is decelerated to an energy of 15—30 eV and focused into the electrostatic energy monochromator. The monochromator consists of two parallel-plate deflectors with an incident angle of $\pi/4$. The two deflectors are symmetrical in geometry and are directly connected so that they have a common inner plate. A coupling hole ($5 \times 10\ mm^2$) is bored at the center of the inner plate for the ion beam to pass from the first deflecting stage to the second deflecting stage. The entrance and the exit apertures (0.5 mm in diam.) are 116 mm apart and are held on the inner plate equidistantly from the coupling hole.

The ion beam transmitted through the monochromator is accelerated to an energy in the range of 2—3 keV through an acceleration-lens system and then enters into the collision cell. The target gas is introduced into the collision cell at a sufficiently low pressure to assure the single collision condition. The entrance and the exit apertures of the cell are 0.6 mm in diameter. The scattered ions are decelerated and focused onto the entrance aperture of the energy analyzer. The acceleration and deceleration of the ions are performed by means of a series of electrostatic cylinder lenses. The lenses

consist of a variable ratio lens (L1) and a fixed ratio lens (L3). An einzel lens (L2) is inserted as a field lens between the L1 and L3 lenses. The lenses are designed by using the optical properties of the two-element cylinder lens calculated by Read *et al.*[13]

A hemispherical electrostatic deflector is used for the energy analyzer. The hemispheres are made of aluminum alloy. The mean radius of the outer and the inner hemispheres is 47.5 mm. The entrance and the exit apertures are 0.3 mm in diameter. The entrance aperture of the analyzer is 132 mm from the exit of the collision cell. The geometrical acceptance angle of the analyzer for scattered ions is 6.8×10^{-3} rad in a scattering plane, which is a measure of the present angular resolution. The voltage difference between the outer and inner hemispheres is held constant so as to pass ions at a constant transmission energy in the range of 15—30 eV.

After passing the analyzer, the ions are again accelerated and detected by a channel electron multiplier (MULLARD B318-AL).

The whole system is housed in connected metal vessels and pumped by means of oil-diffusion pumps. The ultimate pressure is 3×10^{-5} Pa, and the working background pressure is 5×10^{-4} Pa when the target gas and the ion-source gas are introduced.

An energy-loss spectrum is obtained by tracing the intensity of ions transmitted through the analyzer as a function of the deceleration potential between the collision cell and the analyzer. A voltage ramp applied to the deceleration lens is generated by a D/A converter, which is controlled by a personal-computer (SHARP MZ80-K). Output pulses from the detector are amplified, discriminated, and accumulated in the computer.

For a small-angle scattering at a high collision energy, the laboratory energy lost by the projectile is approximately given by:

$$\Delta E = (M_p/M_t)E\theta^2 + Q,$$

where M_p and M_t are the masses of the projectile and the target respectively; E is the laboratory collision energy; θ, the laboratory scattering angle, and Q, the change in the internal (vibrational, rotational, and electronic) energy. The term proportional to the collision energy, E, is the elastic loss due to the momentum transfer from the projectile to the target. The elastic loss can be minimized by observing the glancing collision at the forward scattering angle ($\theta=0$). The internal energy defect, Q, is also dependent on the scattering angle, because the vibro-rotational excitation, in addition to the vertical electronic excitation, is induced by the impulsive momentum transfer from the projectile to the target.[14,15] The degree of the impulsive vibro-rotational excitation is dependent on the impact parameter and can also be minimized in the forward scattering. In the present study, observations are made only for the forward scattering. Under the present angular resolution, the energy loss is expected to correspond to the vertical electronic transition energy, and the vibrational excitation is expected to follow the Franck-Condon principle. This is verified by the results to be presented in the following section. An overall energy resolution of better than 0.1 eV FWHM is achieved. This enables us to observe the vibrational structures in the electronic excitation spectrum of ethylene.

Results and Discussion

T←N *Spectrum of Ethylene.* The spectrum of ethylene in the energy-loss region from 3 to 6 eV is shown in Fig. 2. The spectrum was obtained with a resolution of 95 meV FWHM by the impact of 2.3 keV He^+. A broad feature modulated by small structures appears with its maximum intensity at around 4.25 eV. The shape and position of the gross feature are in good agreement with those obtained by Moore.[9] The whole band has been assigned to the transition of ethylene from the ground state, N, to the lowest lying triplet state, T ($\pi \rightarrow \pi^*$). The small structures superimposed on the envelope are reproducible under the present resolution and show a spacing of 0.13 eV. The structures have an essential similarity, both in spacing and intensity distributions, with the high-resolution electron-impact spectrum obtained by Wilden and Comer,[16] though the present resolution is lower than theirs. The structures have been assigned to the vibrational progressions in the C–C stretching mode (ν_2). The spacing of 0.13 eV (1050 cm^{-1}) is the vibrational energy spacing of the ν_2 mode in the triplet state.

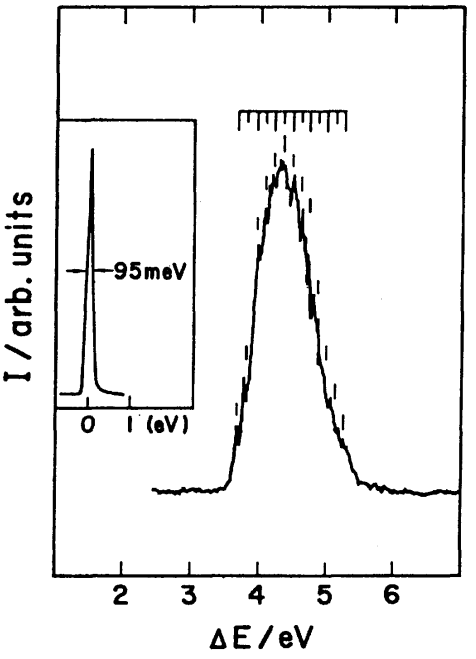

Fig. 2. Energy loss spectrum of ethylene by 2.3 keV He^+ impact. The inset shows the elastic peak.

The similarity of the vibrational structures obtained from the ion-impact and electron-impact methods is evidence that the momentum transfer from the projectile to the target is not significant in the present observation; it can be thought, then, that the electronic excitation occurs in the Franck-Condon manner. The $T \leftarrow N$ excitation requires exchange interaction between the collision pair. It should be noticed that the exchange interaction, whose range is much shorter than the range of direct Coulomb interaction, is still effective in these glancing collisions.

Alkylation Shift in T←N *Transition.* The energy-loss spectra obtained by means of 2.5 keV He^+ impact are shown in Fig. 3 for ethylene, its six methyl derivatives, and an ethyl derivative. Because of a considerable decrease in the $T \leftarrow N$ excitation intensity in alkylethylenes, a lower resolution of about 0.35 eV FWHM was employed to accumulate these spectra. Common

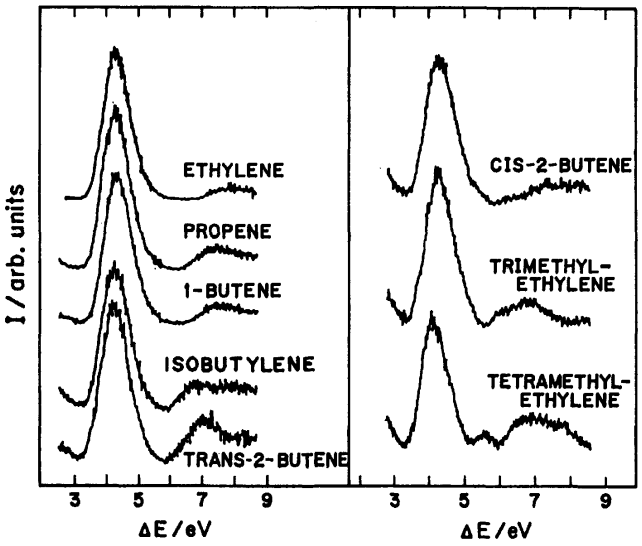

Fig. 3. Energy loss spectra of ethylene and alkyl-substituted ethylenes by 2.5 keV He^+ impact.

spectral features are seen for all of the alkylethylenes studied. The most intense $T \leftarrow N$ band at about 4.2 eV is followed by weaker $V,R \leftarrow N$ bands at higher-energy losses. The relative intensities of the $T \leftarrow N$ band and the $V,R \leftarrow N$ bands are dependent on the impact energy. The shape and position of the $T \leftarrow N$ band are relatively invariant with respect to the alkyl substitution, while the $V,R \leftarrow N$ bands rise at lower energies as the number of substitution increases from zero to four. The separation of the $R \leftarrow N$ bands from the $V \leftarrow N$ band is not possible at this level of resolution, but the growth of the low-energy tail of the 7 eV peak with an increase in substitution may be attributable to the rapid red shift of the $2R \leftarrow N$ band.[7,8] A small peak at 5.5 eV is distinguishable in the tetramethylethylene; it has been assigned to the $2R \leftarrow N$ ($\pi \rightarrow 3s$) transition.[7,8] The position of the maximum intensity of the $T \leftarrow N$ band is listed in Table 1. Data obtained by the use of a variety of methods are included for comparison. The consistency of the present data with the electron-impact data indicates again that glancing collision without any significant momentum transfer is observed on these target molecules under the present scattering angular resolution. The present measurement gives an overall red shift of 0.20 eV for the $T \leftarrow N$ transition in going from ethylene to tetramethylethylene. The degree of shift in the $T \leftarrow N$ transition is much smaller than the corresponding 1.75 eV shift[8] in the $2R \leftarrow N$ transition.

Mulliken has indicated that the alkylation decrease in the ionization potential and the red shift in the $R \leftarrow N$ transition are largely attributable to a change in the effective nuclear charge of carbons due to charge transfer within the sigma system, while the red shift in the $V \leftarrow N$ transition may be entirely explained by the hyperconjugation in the pi system. The relative invariance of the $T \leftarrow N$ transition energy upon the alkylation has been predicted from VESCF-CI calculations by

Table 1. $T \leftarrow N$ transition energy in alkyl-substituted ethylenes

a) The transition energies are the CI results within single-excitation configurations.

Allinger *et al.*[17] and by Watson *et al.*[18] In order to see more specifically how this invariance arises, semiempirical calculations of the vertical $T\leftarrow N$ and $V\leftarrow N$ transition energies were performed by using a CNDO/S program made by Tajiri *et al.*[19] In the SCF level of the calculation, the $\pi\rightarrow\pi^*$ transition energy is given by;

$$E(T\leftarrow N) = (\varepsilon_{\pi^*}-\varepsilon_{\pi}) - J_{\pi\pi^*} \quad (1)$$

for the $T\leftarrow N$ transition and by;

$$E(V\leftarrow N) = (\varepsilon_{\pi^*}-\varepsilon_{\pi}) - J_{\pi\pi^*} + 2K_{\pi\pi^*} \quad (2)$$

for the $V\leftarrow N$ transition, where ε_{π} and ε_{π^*} are the SCF orbital energies and where $J_{\pi\pi^*}$ and $K_{\pi\pi^*}$ are, respectively, the Coulomb and the exchange energies between π- and π^*-orbitals. The calculated values for the quantities appearing in Eqs. (1) and (2) are listed in Table 2. The transition energies, $E(V\leftarrow N)$ and $E(T\leftarrow N)$, in the table are the results of partial configuration mixing within single-excitation configurations. The calculated results of $E(T\leftarrow N)$ are lower than the corresponding experimental data by more than 0.5 eV. This would be improved by taking the configuration mixing including double excitations at the expense of the worse agreement for the $V\leftarrow N$ transition energy.[20,21] Our attention will be confined to the gross results appearing in the SCF level. The differences $(\varepsilon_{\pi^*}-\varepsilon_{\pi})$ in the orbital energy, the Coulomb energy, and the exchange energy decrease altogether upon the methyl substitution. A remarkable point is that the degrees of change in $(\varepsilon_{\pi^*}-\varepsilon_{\pi})$, $J_{\pi\pi^*}$ and $2K_{\pi\pi^*}$ are all comparable in their magnitudes. Thus, the changes in $(\varepsilon_{\pi^*}-\varepsilon_{\pi})$ and $J_{\pi\pi^*}$ cancel each other to result in a small net change in the $T\leftarrow N$ transition energy upon the substitution. The changes in $J_{\pi\pi^*}$ and $K_{\pi\pi^*}$ may be taken to reflect, to some extent, the degree of hyperconjugation. The decrease in $(\varepsilon_{\pi^*}-\varepsilon_{\pi})$ arises mostly from the change in ε_{π}, which is largely attributable to the charge-transfer effect in the sigma system according to Mulliken. Thus, the relative invariance of the $T\leftarrow N$ transition energy arises from the cancellation of the hyperconjugation effect in $J_{\pi\pi^*}$ with the charge-transfer effect in $(\varepsilon_{\pi^*}-\varepsilon_{\pi})$, while the hyperconjugation effect in $K_{\pi\pi^*}$ remains, resulting in the red shift in the $V\leftarrow N$ transition to an extent similar to the decrease in $2K_{\pi\pi^*}$.

Alkylation Effect in T←N *Excitation Cross-section.* It was found that the scattering intensity of the $T\leftarrow N$ excitation was considerably influenced by the alkyl substitution. The relative $T\leftarrow N$ cross-section decreases by almost half when the number of substitution increases by one. The $T\leftarrow N$ cross-section of 1-butene is nearly equal to that of propene. Three dimethylethylenes (*trans*- and *cis*-2-butene, and 2-methylpropene) have nearly identical $T\leftarrow N$ cross-sections. These facts indicate that the number of substitution is more important for the hypochromic effect than is either the size of a substituent or the site of substitution. It was also observed that the $V,R\leftarrow N$ cross-sections were less sensitive to the degree of substitution than were the $T\leftarrow N$ cross-sections. Quite the same hypochromic effect has been observed in the ion-impact study of methyl-substituted butadienes.[10]

Mechanisms of excitation in heavy-particle collisions may be divided into two types.[22,23] In low-energy collisions, an electronic excitation requires a close encounter of a collision pair. A quasi-molecular description and the potential crossing mechanism will be adequate for these collisions. In this mechanism, the threshold law of impact parameter holds and an excitation occurs for scattering angles larger than a threshold value. For high-energy collisions, on the other hand, excitations are possible in a distant encounter by means of the direct Coulomb or the exchange mechanism. Because of the delocalized character of the mechanism, one expects an excitation with no definite impact-parameter threshold. This is the case in the present experiment. The effective range of the ion-molecule interaction leading to the $T\leftarrow N$ excitation may be longer than the spatial extent of the surrounding alkyl groups. Otherwise, the momentum transfer between projectile and target would be considerable and would violate the vertical excitation. The spatial shielding effect does not seem to be important for the present hypochromic effect. We suggest that the hypochromic effect occurs through a change in the π- and π^*-wavefunctions upon the alkyl substitution, and that this in turn causes a decrease in the ion-molecule interaction. The exchange interaction for singlet-triplet transition[24] includes an integral such as;

$$\langle\pi^*(1)\chi(2)|r_{12}^{-1}|\pi(2)\chi(1)\rangle, \quad (3)$$

where χ is the electronic wavefunction of the projectile He^+ ion and where r_{12} is the distance between the electrons to be exchanged. Since we have seen the decrease upon the substitution in the intramolecular Coulomb and exchange integrals between π- and π^*-orbitals, a decrease can also be expected in the ion-molecule exchange integral given by Eq. 3. The same reasoning leads to a decrease upon the substitution in the ion-molecule Coulomb interaction responsible for the $V,R\leftarrow N$ excitation. However, the alkylation decrease in the energy defect of the $V,R\leftarrow N$ excitation favors for an increase in the cross-section and makes the hypochromic effect less obvious than in the $T\leftarrow N$ excitation.

The authors wish to express their thanks to Dr. Noriyuki Shimakura for his help in the CNDO/S calculations. The present work was partially suported by a Grant-in-Aid for Scientific Research No. 454117 from the Ministry of Education, Science and Culture. The present work was also partially suported by the Nishina Memorial Foundation.

The Aggregation of a Merocyanine Dye in Solution and Film

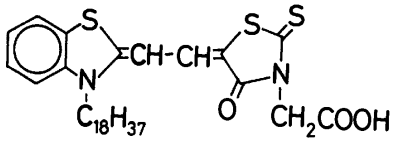
Fumio Mizutani,* Sei-ichiro Iijima, and Keishiro Tsuda
Research Institute for Polymers and Textiles, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received August 27, 1981)

Two low-energy bands, one near 595 nm and the other near 630 nm, were observed in the visible absorption spectra of a merocyanine dye (3-carboxymethyl-5-[2-(3-octadecyl-2-benzothiazolinylidene)ethylidene]-2-thioxo-4-thiazolidinone) dissolved in methanol–water mixtures containing KOH and Triton X-100. From the dye-concentration dependence on the spectra, the band near 595 nm was assigned to the tetramer, and the one near 630 nm, (probably) to the hexamer of the carboxylate form of the dye. The same bands were observed in the dye films when they were soaked in aqueous solutions of pH$\geq$5.5. The relative intensities of the two bands were strongly affected by the ionic strength of the aqueous solution.

Merocyanine dyes have come to attract particular interest as materials for photoelectric[1–8] or photoelectrochemical[8–12] devices because of their high quantum efficiencies. We have reported previously[11] that a thin film of 3-carboxymethyl-5-[2-(3-octadecyl-2-benzothiazolinylidene)ethylidene]-2-thioxo-4-thiazolidinone (MD) showed two low-energy absorption bands near 595 and 625 nm. This spectral change seems of interest because it is induced by a simple treatment, *i.e.*, by soaking the MD film in an aqueous solution of an adequate pH and ionic strength, and also because it is accompanied by a drastic enhancement of the cathodic photocurrent at the MD-coated electrode.[11] Sugi *et al.* have also reported[6,7] that Langmuir multilayers containing MD or its analogue exhibited an enhanced photoconductivity in the lateral direction, associated with the appearance of a low-energy band near 595 nm. Although these low-energy bands have been taken as aggregates of MD,[6,7,11] only a limited number of experiments have so far been carried out, and little is known about the nature of the bands.

We have found that methanolic aqueous solutions of MD containing KOH show low-energy bands depending on the concentration of methanol as well as on that of MD. In this paper, the visible absorption spectra of MD in the solution system are investigated in order to characterize the low-energy bands. The spectral change in the MD film is also discussed with the aid of the results obtained for the solution system.



Experimental

The MD was obtained from the Japanese Research Institute for Photosensitizing Dyes and used without further purification, since preliminary tests showed that the purification of MD by means of column chromatography on silica gel (eluent; chloroform containing 10% v/v methanol) brought about no discernible change in the results. The other reagents used were of an analytical GR grade and were also used without further purification.

Methanolic aqueous solutions, each containing 0.01 M† KOH, were employed as solvents of MD, and 0.005% v/v of Triton X-100 was added to each solution in order to prevent the precipitation of MD. The visible absorption spectra of the MD solutions were recorded 2 h after the preparation of each solution using a Cary 17 DX spectrophotometer. An absorption cell with the optical path of 10 cm was mostly employed because the measurements had to be carried out on very dilute MD solutions.

MD films were prepared by means of the vacuum evaporation of the dye onto Pyrex-glass plates (size; 0.9 × 4.5 cm^2) below 5×10^{-4} Pa using a tungsten boat heated up to *ca.* 220 °C. Film with an absorption of 0.25±0.01 at 516 nm was used for the experiments. For IR spectral measurements, CaF_2 single crystal plates were employed as bases of the MD films in place of the glass plates. The permeability of the MD film to an aqueous solution was checked by soaking the film on a water-soluble substrate in the solution. In the present study, a KBr tablet coated with epoxy resin on only one side was used as the substrate; MD was evaporated onto the uncoated side. A phosphate buffer solution (KH_2PO_4 plus K_2HPO_4, pH 7.0; ionic strength, 0.01) was prepared, and the ionic strength of the solution used for the experiments was adjusted by diluting the buffer solution with water or by adding KCl to it. The MD film on glass was placed in an absorption cell (size; $1.0\times1.0\times4.5$ cm^3), and the visible absarption spectra were recorded using a Shimadzu UV-220 spectrophotometer before and after adding an aqueous solution to the cell. The IR spectrum of the MD film soaked in an aqueous solution and then dried was measured using a JEOL JIR 40 IR spectrophotometer.

The chemical stability of MD during the course of the experiment was always checked by means of silica-gel thin layer chromatography.[3] No degradation products were observed on the silica-gel plate after soaking the film.

All the spectral measurements were carried out at 25±1 °C.

Results and Discussion

Aggregation of MD in Solutions. Methanolic solutions of MD gave a single peak at 524 nm, along with a discernible shoulder at 495 nm, on their visible absorption spectra, and they followed Beer's law, at least in the concentration range from 0.1 μM to 14.0 μM (which corresponds to the saturated solution of MD). Since conformity to Beer's law was found at such a low concentration, the absorption of the methanolic solution can be assigned to the monomer of MD. The shape of the monomer-absorption spectrum of MD is typical of the monomers of polymethine dyes.[13,14] The peak absorption is induced by the 0←0 transition, and the shoulder on the high-energy side is a result of the

† Throughout this paper, 1 M = 1 mol dm^{-3}.

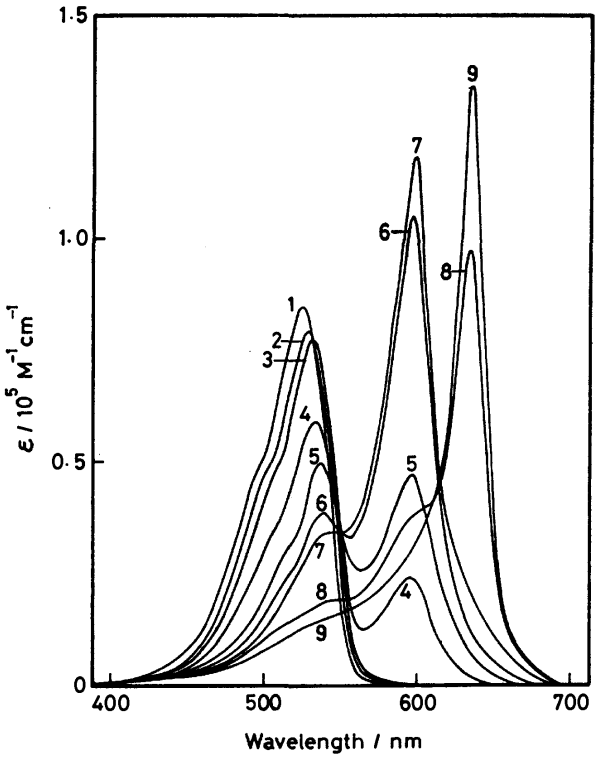


Fig. 1. Absorption spectra of 0.75 μM MD in methanolic aqueous solutions containing 0.01 M KOH and 0.005% v/v Triton X-100. The methanol concentrations in the solvents are given in M: (1) 22.5; (2) 20.0; (3) 17.5; (4) 15.0; (5) 13.5; (6) 12.5; (7) 11.0; (8) 9.0; (9) 7.5.

"forbidden" transition of high energy due to molecular vibration.[13,14] The addition of an alkaline aqueous solution to the methanolic solution of MD strongly affected the shape of the absorption spectrum. Figure 1 shows the visible absorption spectra of 0.75 μM MD in mixed solution of methanol and water, each containing 0.01 M KOH and 0.005% v/v Triton X-100. The features of the spectra can be roughly classified into three groups, depending on the methanol concentration of the solution. The MD solutions containing 17.5 M or above methanol give an absorption similar in shape to that obtained in the methanolic solution (Lines 1—3). On the other hand, a new band starts to appear near 595 nm in addition to the above absorption, and the intensity of the new band increases with a decrease in the concentration of methanol, in the concentration range of methanol from 15.0 M to 11.0 M (Lines 4—7). Further decreasing methanol concentration below 11.0 M brings about the appearance of another low-energy band near 630 nm associated with a significant intensity lowering of the band near 595 nm (Lines 8 and 9).

The similarity of Lines 1—3 to the absorption of the methanolic solution of MD indicates that MD is in the monomeric form in the mixed solvents containing 17.5 M or more methanol. The MD in these solvents followed Beer's law over a relatively wide concentration range; *i.e.*, the solution containining 20.0 M methanol follows the low from 0.1 μM to 2.0 μM of MD. As can be seen from Lines 1—3, the monomer band of MD exhibits a small shift to the low-energy side and a

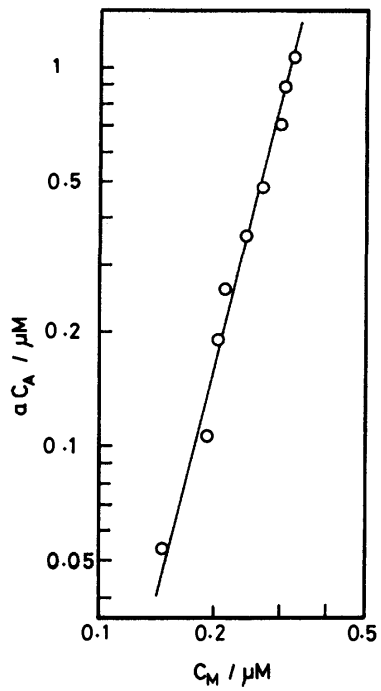

Fig. 2b. Determination of the aggregation number a, for the equilibrium $aC_M \rightleftharpoons C_A$. C_M and C_A are the concentrations of monomer and aggregate, respectively, and they derived from Fig. 2a.

lowering of the molar absorptivity, ε_M, with a decrease in the concentration of methanol in the mixed solvent; this could be explained by the increase in the dielectric

constant of the solvent, since the monomer band obtained in methanol and in other organic solvents (such as benzene, tetrahydrofuran, acetone, *N*,*N*-dimethylformamide, and diethyl sulfoxide) showed a slight shift to the low-energy side with the increase in the dielectric constant of the solvent, and since the ε_M of the band decreased when the dielectric constant of the solvent was above *ca.* 30.

Deviations from Beer's law become noticeable when low-energy bands appear in addition to the monomer band. Figure 2a shows the dependence of the absorption spectra on the MD concentration in the solvent containing 12.5 M methanol. An isosbestic point is observed near 550 nm; this indicates that the monomer band and the band near 595 nm are expressed by a single equilibrium. Since the decreased intensity of the monomer absorption near 535 nm and the accompanied enhancement of the low-energy band near 595 nm are observed with a growing MD concentration, the curves in Fig. 2a can be analyzed in termes of an equilibrium between the monomeric and aggregate forms of MD:

$$aC_M \rightleftharpoons C_A, \quad K = C_A/(C_M)^a, \qquad (1)$$

where C_M and C_A are the concentrations of the monomer and the aggregate respectively, a is the number of monomer units in the aggregate, and K is the association constant. Hence, the a-value is determined by plotting log aC_A and log C_M. The peak intensity of the monomer band and that of the aggregate band were evaluated according to the procedure of West and Pearce.[14] The molar absorptivity of the monomer at the peak, ε_M, was taken as 7.40×10^4 M^{-1} cm^{-1} in the solvent by extrapolating the ε_M *vs.* methanol concentration curve measured in the methanol-concentration region where only the monomer band is given. By subtracting the C_M thus determined from the total dye concentration, C_T, aC_M $(=C_T-C_M)$ was evaluated. As is shown in Fig. 2b, the plots follows a straight line, and the a-value is determined as *ca.* 4. Accordingly, the spectral change is explained by a monomer⇌tetramer equilibrium, and the low-energy band near 595 nm can be assigned to the tetrameric form of MD. The molar absorptivity of the tetramer at the peak, ε_4, was obtained as 6.27×10^5 M^{-1} cm^{-1}.

Similarly, the dependence of the band near 630 nm on the MD concentration was examined in the solvent containing 7.5 M methanol (Fig. 3a). In this case, however, the absorption change cannot be described by a simple equilibrium, because two bands, the monomer and the tetramer bands, appear in addition to the band near 630 nm. Since the relative intensities of the monomer and tetramer absorptions decreased and the absorption of the band near 630 nm increased with a growing MD concentration, the band near 630 nm may well be assigned to a higher-order aggregate. The following equilibrium is, therefore, proposed in addition to the monomer⇌tetramer equilibrium:

$$C_4 + bC_M \rightleftharpoons C_{(4+b)}, \quad K' = C_{(4+b)}/C_4\cdot(C_M)^b, \qquad (2)$$

where $C_{(4+b)}$ is the concentration of the aggregate which shows the band near 630 nm; $(4+b)$, the number of monomer units of the aggregate; C_4, the concentration of the tetramer; and K', the association constant. If the total dye concentration is given by C_T, the following relations are obtained:

$$\log[(4+b)C_{(4+b)}/C_4] = b\log C_M + \log[(4+b)K'], \qquad (3)$$

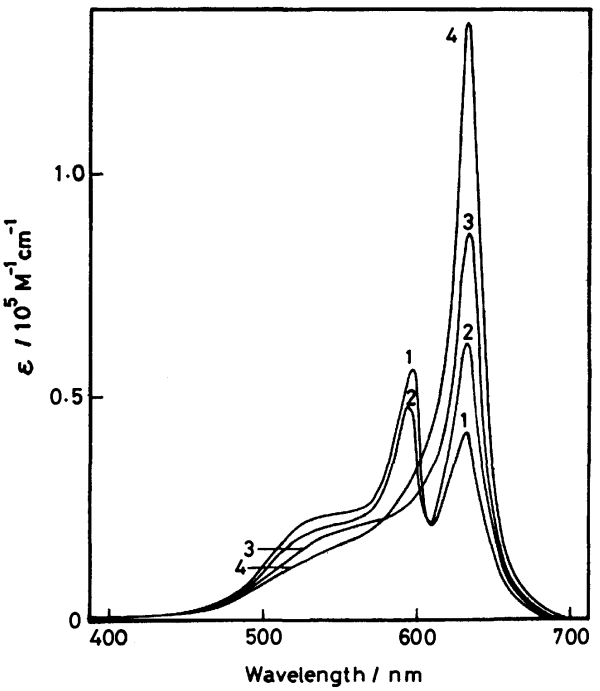

Fig. 3a. Absorption spectra of MD of various concentrations in 7.5 M methanol–water containing 0.01 M KOH and 0.005% v/v Triton X-100. MD concentrations are given in μM: (1) 0.1; (2) 0.2; (3) 0.5; (4) 0.75.

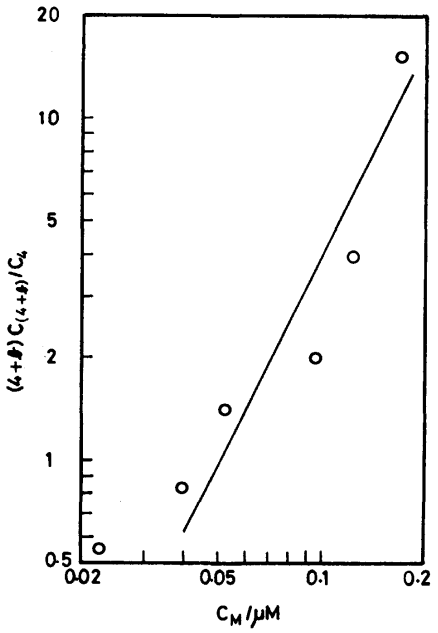

Fig. 3b. Determination of the b-value, for the equilibrium $C_4 + bC_M \rightleftharpoons C_{(4+b)}$. C_M, C_4, and $C_{(4+b)}$ are the concentrations of monomer, tetramer, and aggregate which shows the band near 630 nm, respectively, and they are derived from Fig. 3a. See Eqs. 2—4 and text for details.

$$(4+b)C_{(4+b)} = C_T - C_M - 4C_4. \quad (4)$$

By evaluating the peak intensities of the monomer and tetramer bands according to the procedure of West and Pearce[14] and by applying the value of ε_M and ε_4 obtained for the mixed solvent containing 12.5 M methanol, C_M and C_4 were determined, and the values according to Eq. 3 were plotted. The results are shown in Fig. 3b. Although the data scatter somewhat, the b-value can be roughly estimated as 2. The low-energy band near 630 nm is, therefore, (probably) assigned to the hexamer of MD.

In the methanol-water mixtures containing KOH, MD is considered to be in the anionic form because of the dissociation of the carboxymethyl group of MD. For the formation of the above-mentioned tetramer and hexamer, the anionic form is concluded to be essential, since such aggregates were not formed when MD was dissolved in any methanol-water mixtures containing HCl, in which MD is considered to be in the neutral molecule form. As MD anions are polymerized by overcoming the electrostatic repulsive force between the anions, the addition of cations may play an important role in the screening effect.[13-16] Our preliminary results indicate that the addition of KCl to the alkaline solution used in the present study enhanced the formation of both kinds of aggregates, especially of the hexamer. On the contrary, the increase in the concentration of Triton X-100 enhanced the intensity of the monomer band because of the dissociation of the aggregates, as has previously been reported in the case of a cyanine dye solution.[13]

Aggregation of MD in Films. The vacuum-deposited MD film exhibits, similarly to the cast film of MD,[11] two visible absorption peaks at 516 nm and at 546 nm. The peak at 516 nm has been assigned to the dimeric (or oligomeric) form, and the one at 546 nm, to the monomeric form, of MD molecules since a dicrease in the absorbance at 516 nm was observed in the cast film of MD which contained arachidic acid as a diluent.[11] MD is insoluble in water as well as in aqueous solutions which are free from surfactants in the pH range from 0 to 13. Therefore, no coloration of aqueous solutions was observed when MD film was soaked in them. A slight alteration has been observed in the spectrum of the film soaked in a 0.5 M HNO_3 aqueous solution,[11] while the monomer and the dimer (or oligomer) bands remain practically unchanged. Similar results were obtained for the film soaked in any aqueous solution with a pH below 5.5. When the film was soaked in aqueous solutions of pH 5.5 or above, on the other hand, the spectrum was changed to form two low-energy bands, at 595 nm and at 625 nm. Figure 4 shows the spectral change in the MD film in the aqueous solution of pH 7.0 and an ionic strength of 0.10. The observed absorption bands for the MD film at 595 nm and at 625 nm are very similar, with regard to the peak position and the band shape, to those near 595 nm and near 630 nm for the methanolic aqueous solutions of MD described in the preceding section. Therefore, it can be concluded that the observed low-energy band at 595 nm and at 625 nm for the film are also to be assigned to the tetramer and (probably) the hexamer of the MD anion respectively.

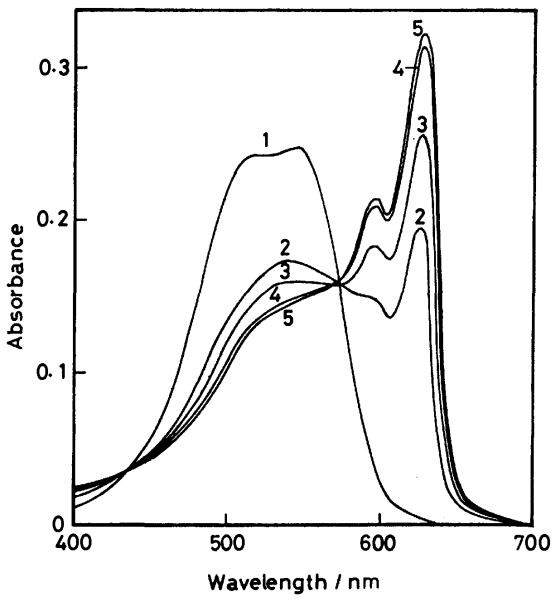

Fig. 4. Absorption spectra of the MD film (1) before and after sorking in an aqueous solution of pH 7.0 and ionic strength 0.10 for (2) 5 min, (3) 30 min, (4) 2 h, and (5) 24 h.

When the MD film on a KBr tablet was soaked in an aqueous solution of pH 7.0 with an ionic strength of 0.10, the tablet immediately began to dissolve (within a few seconds). The finding indicates that the solution can permeate rapidly into the film. Accordingly, the dissociation of the carboxymethyl group of MD in the bulk of the film is expected to proceed immediately after soaking the film in the aqueous solution. The formation of the MD anion in the bulk of the film was ascertained by IR measurements. The deposited film shows a C=O stretching absorption band for -COOH at 1740 cm^{-1}. The intensity of the absorption band becomes almost negligible after the film is dipped in the solution, probably because of the formation of the carboxylate form. The spectral change in the MD film is, on the contrary, very slow, as is shown in Fig. 4; the film needs *ca.* 2 h to give an almost stationary spectrum after being soaked in the aqueous solution. Therefore, slow processes for the aggregation, such as the re-arrangement, of MD anions proceed after the fast permeation of the aqueous solution into the film.

As has been described in the preceding section, the addition of KCl to the solution (which corresponds to the increment in the ionic strength of the solution) significantly affects the relative intensities of the two low-energy bands. In the case of the MD film/solution system, the change in the ionic strangth of the aqueous solutions also showed a marked effect on the relative intensities of the two bands. The results are given in Fig. 5, where the values of absorbance at 595 nm and at 625 nm are recorded after the MD film has been soaked for 2 h in each solution. As is shown in Fig. 5, the lowering of the ionic strength below 0.08 brings about a decrease in the absorbance at 625 nm and a simultaneous increase in that at 595 nm; further, only

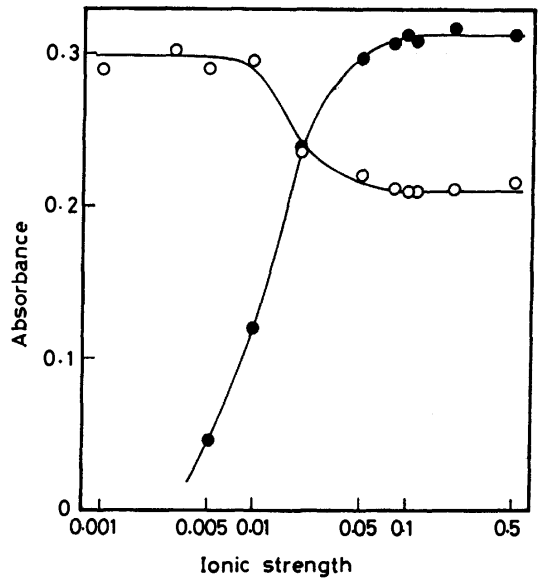

Fig. 5. Role of ionic strength of aqueous solutions on the absorptions of (○) the peak at 595 nm and (●) that at 625 nm.

the band at 595 nm is observed below the ionic strength of 0.003. Similar results were given by Sugi *et al.*[7] and also by Nakahara *et al.*;[17] they found[7,17] that the MD containing monolayer which was spread on an aqueous subphase of 0.4 mM $CdCl_2$ (pH *ca.* 6.5 and ionic strength *ca.* 0.001) exhibited only a low-energy absorption near 595 nm. The results given in Fig. 5 clearly indicate that very concentrated cations surrounding MD anions lead to a highly-ordered aggregation.

The dye film with aggregate(s) which shows a low-energy band is of practical importance as a photosensitizer[7,11,18–22] because of its high quantum efficiency, broad spectral response, and high stability. The change in the electrochemical behavior of the MD-coated electrode due to the formation of the aggregates will be described in detail in the following paper.

The authors are grateful to Drs. Masahiko Yoshiura, Keiji Iriyama, Michio Sugi, and Yukio Shimura for their informative suggestions. The authors are also grateful to Dr. Shigeo Yasui for synthesizing the MD.

Interaction between Ethidium Bromide and Various Polyelectrolytes and DNA with Emphasis on Spectral Characteristics and Binding Curves of the Bound Dye[1)]

Kiwamu YAMAOKA,* Takumi MATSUDA, Daisuke SHIBA, and Mineo TAKATSUKI
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received September 19, 1981)

Visible and ultraviolet absorption spectra of ethidium bromide (EB) were measured by the optical titration method in the presence of each of three synthetic polyelectrolytes—sodium salts of poly(*p*-styrenesulfonate) (NaPSS), polyphosphate (NaPP), and polyacrylate (NaPA)—and native and heat-denatured DNA at 25 °C. By use of the principal component analysis (PCA) method, the number of EB species present in each EB–polymer system was determined to be two, *i.e.*, free and bound EB, in the range of the polymer residue-to-EB ratio between zero and about one. The spectrum and the fraction of EB species bound to each polymer were determined by the extended PCA method. The bound-EB spectra are bathochromic and hypochromic relative to the spectrum of free EB, but they show no metachromasy band. The apparent binding constants K_a for EB bound to polymers are in the order of NaPSS>denatured DNA>NaPP>NaPA≒native DNA.

In order to understand the general mechanism of metachromasy which results from the binding between dyes of particular classes and polyelectrolytes with highly charged sites, the pure spectrum of a given dye species bound to a particular polymer site, *i.e.*, the bound-dye spectrum, should be studied. This spectrum reflects the mode of interaction between the dye and the polymer site. Its extraction with a high resolution from observed absorption spectra of a dye–polymer system is, however, not an easy task because of the overlapping of the spectra of an unknown number of free and bound dye species and also because of the complicated reaction schemes with which the binding proceeds. It has been shown that the principal component analysis (PCA) method can be utilized to unravel the bound-dye spectrum.[2–8)] The bound-dye spectra of Crystal Violet (CV) and Trypaflavine (TF) show the characteristics of metachromasy, *i.e.*, the appearance of more than one absorption band, hypsochromism, and hypochromism.[3–6)] In the absence of polymers, CV and TF show a broad absorption band in the visible wavelength region, which consists of more than one electronic transition.[9,10)] A recent work on simpler acridine dyes, *N*-methylacridinium, and 9-aminoacridinium chlorides, has revealed that these bound-dye spectra exhibit only bathochromism and hypochromism.[5,7,8,11)]

Ethidium bromide (EB) has two amino groups at 3-, and 8-positions, but it belongs to a class of dyes different from 3,6-diaminoacridines such as Proflavine and TF. The interaction of EB with various biomolecules and biopolymers, particularly nucleic acids, has been studied by a number of physicochemical methods,[12–32)] but, precise information on the optical property of EB is still needed. In the present work, therefore, attempts were made to extract the bound-EB spectra by the PCA method. For this purpose, the spectroscopic interaction of EB with three polyelectrolytes with different functional groups and native and heat-denatured DNA was investigated in the low region of polymer residue-to-EB mixing ratio (P/D), where the binding scheme is rather simple. The empirical formula previously utilized for binding reactions was also improved upon to fit the thermodynamic concepts.

Experimental

Materials. Ethidium bromide (EB), 3,8-diamino-5-ethyl-6-phenylphenanthridinium bromide, was purchased from Sigma Chemical Co. (St. Louis, Mo., USA). It was purified by the method of column chromatography. The three synthetic polyanions used in this work are sodium salts of poly(*p*-styrenesulfonate) (NaPSS, the degree of polymerization $DP=1360$),[3)] polyphosphate (NaPP, $DP=154$),[3,4)] and polyacrylate (NaPA, $DP=7700$).[3)] Calf thymus DNA was obtained from Worthington Biochemical Corp. (Freehold, N. J., USA).

Preparation and Measurement of Sample Solutions. Throughout optical titration measurements, the concentrations of EB were kept constant at about 7×10^{-5} and 1.5×10^{-5} mol dm^{-3} in the visible and ultraviolet regions, respectively. The concentrations were determined by using the molar absorption coefficient, ε, of 5850 mol^{-1} dm^3 cm^{-1} at 480 nm.[18,19,27)] No ionic additives, such as neutral salt and buffer reagent, were added to EB–polyanion solutions to avoid undesired side effects, while EB–DNA solutions contained 1×10^{-3} mol dm^{-3} NaCl to prevent denaturation. The hyperchromicity of DNA was about 34%.[33)] The concentration of native DNA (nDNA) solution was 9.35×10^{-4} mol dm^{-3}; this was determined by using the ε value of 6400 at 260 nm. Heat-denatured DNA (dDNA) was prepared by the heating-shock cooling method.[33)] Optical titrations were carried out by adding a stock polymer solution, prepared as before,[3,4)] to an EB solution in an absorption cell successively in about 20—60 μl portions with a graduated or a Gilson microburet. The mixture was stirred for a few minutes and its absorption spectrum was recorded at 25 °C.[3)] Volume corrections were made whenever necessary.[3,4)] The P/D ratio was defined as the concentration of polymer in monomer unit per concentration of EB present in a mixture.[33)] Path lengths of quartz cells were 2 cm in the visible and 1 cm in the ultraviolet region.

Data Analysis by the Principal Component Analysis. The principal component analysis (PCA) method has been described in detail[2–5)] and also in outline.[6)] By this method, the number of light-absorbing species, *i.e.*, *components*, can be determined. These components are responsible for serial changes in the absorption spectra of a given dye successively titrated with a given polymer in solution. When the number was two, the apparent equibrium constant, K, and the pure absorption spectrum, ε^b_λ, of the dye bound to the polymer

could be evaluated by the extended PCA method with the following equilibrium scheme:[3-8]

$$K = \frac{[DP^*]}{[D][P]^{\alpha}}, \quad (1)$$

where DP* is the dye–polymer complex or the bound dye in the low P/D region, D is the unbound or free dye, P is the polymer residue which is not occupied by the dye, the brackets indicate the equilibrium concentration of each species, and α is a single adjustable parameter. The fraction of the bound dye in a dye–polymer solution, f_b ($=[DP^*]/[D]_0$), may be calculated at any given P/D, $[D]_0$ being the initial concentration of the dye.[1-3,5]

Equation 1 is an empirical one which was introduced to explain observed optical titration curves for various dye–polymer combinations.[3-9] The problem associated with this formula is that the dimension of K is given by $[dm^3/mol]^{\alpha}$ rather than $[dm^3/mol]$. This irregularity is now resolved by dividing both side of Eq. 1 by $[D]_0^{1-\alpha}$, which is a constant, because optical titrations are carried out at the constant initial dye concentration. Equation 1 is rewritten as

$$K_a \equiv \frac{K}{[D]_0^{1-\alpha}} = \frac{[DP^*]}{[D][P]}\left(\frac{[P]}{[D]_0}\right)^{1-\alpha}. \quad (2)$$

According to Tanford,[34] the apparent association constant, k, for the ligand–polymer site may be expressed as

$$k = \frac{(DP^*)}{(D)(P)} = \frac{[DP^*]}{[D][P]}\left(\frac{\gamma_{DP}}{\gamma_D\gamma_P}\right)e^{-\phi(\tilde{\nu})} \quad (3)$$

where the parentheses stand for the activity, γ's for the activity coefficients, and $\phi(\tilde{\nu})$ is a general function for electrostatic interaction. It is interesting to note that Eq. 2 may be transformed into Eq. 3 by formally equating the appropriate factors:

$$\left(\frac{D}{P}\right)^{\alpha-1}\exp[(1-\alpha)\ln(1-\tilde{\nu})] = \left(\frac{\gamma_{DP}}{\gamma_D\gamma_P}\right)\exp[-\phi(\tilde{\nu})], \quad (4)$$

since $f_b = \tilde{\nu} \times (P/D)$ and since $[D]_0/P \equiv D/P$. Not entering into theoretical implications of this relationship in the present work, we shall discuss the experimental results by using values of K_a in Eq. 2.

Results and Discussion

Three EB–Polyanion Systems. A series of observed visible spectra of EB–NaPSS solutions are shown in Fig. 1 as an example. These spectra reveal two isosbestic points, at 513 and 395 nm, in the low P/D range. By dropwise addition of NaPSS, the peak of EB at 480 nm decreases and concurrently shifts toward the long wavelength. This spectral behavior is also observed for EB–NaPP (isosbestic points 527 and 395 nm) and EB–NaPA (516 and 392 nm) solutions. A similar result has been reported for the EB–NaPP system.[18] Optical titrations of EB are shown in Fig. 2, where values of ε_{480} of EB–polyanion solutions are plotted against P/D. Values of ε_{480} decrease less for NaPA and NaPP than for NaPSS. In any case, they do not decrease linearly but are curved, the curvature being convex at the initial P/D (<0.5). This sigmoidal trend in titration curves has already been pointed out.[3-5]

The presence of isosbestic points in each EB–polyanion system indicates that this may be a binary system, but the possibility that it contains three or more independent components cannot be excluded. (If the molar absorption coefficients of these components have an identical value at some wavelength, this would be an isosbestic point.) By applying the PCA method to each EB–polyanion system, the exact number of components was determined. The results are shown in Fig. 3, where ratios of the eigenvalue of the ith component to the largest eigenvalue of the *first component*, Λ_i/Λ_1, are plotted on a logarithmic scale. A large gap is seen between the second and third components in each case; the ratio of $\Lambda_1 : \Lambda_3$ is larger than $10^5 : 1$. These results confirm that each EB–polyanion system contains two absorbing species. Thus, it is reasonable to conclude that observed spectral changes are an interplay of two EB species, *i.e.*, free EB and EB–polyanion complex (bound EB),

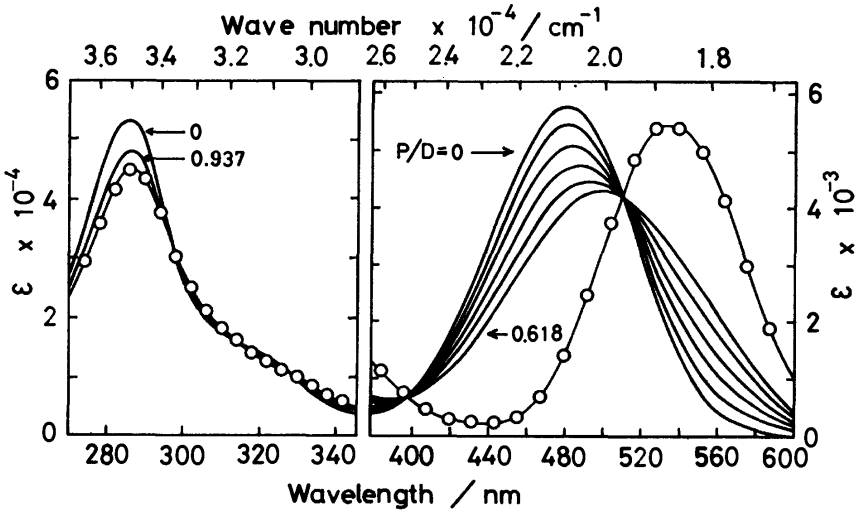

Fig. 1. Visible and ultraviolet spectra of EB titrated with salt-free NaPSS solution. The ordinates are the apparent molar absorption coefficients, ε, expressed in $mol^{-1}\,dm^3\,cm^{-1}$. Values of P/D are 0 (EB alone), 0.125, 0.243, 0.368, 0.493, and 0.618 in this order for the right, while they are 0 and 0.937 for the left. The concentration of EB $= 7.47 \times 10^{-5}$ mol dm^{-3}. Open circles represent the molar absorption coefficients, ε_λ^b, or the bound-EB spectra.

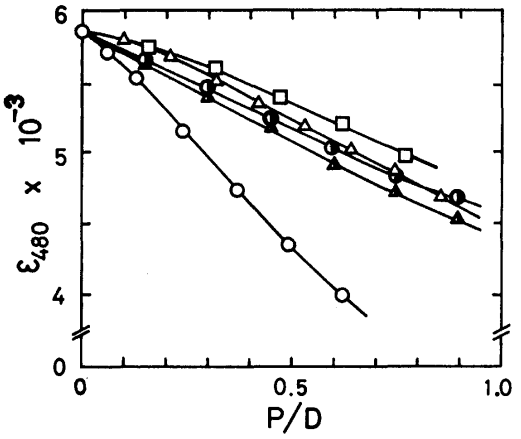

Fig. 2. Optical titration of EB with five different polymer solutions. The ordinate is the value of ε at 480 nm where the free EB shows the absorption peak. The abscissa is the mixing ratio. (○) NaPSS, (△) NaPP, (□) NaPA, (◑) native DNA, and (◭) heat-denatured DNA.

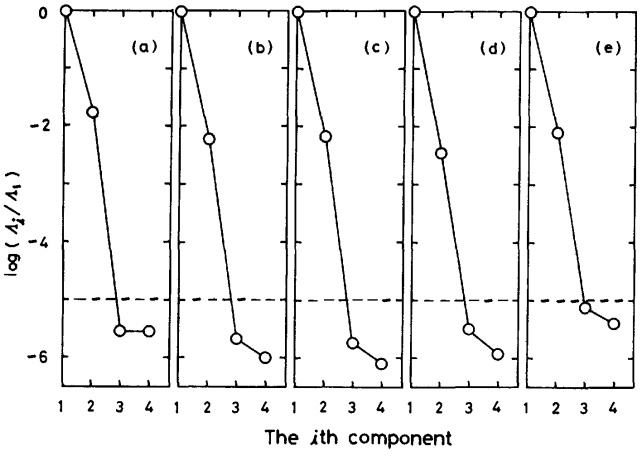

Fig. 3. Variations in the eigenvalue A_i with the ith light-absorbing component for five different EB–polymer systems. (a) NaPSS, (b) NaPP, (c) NaPA, (d) native DNA, and (e) heat-denatured DNA. The ordinate is the ratio of the eigenvalue of the ith component to that of the first. Dashed lines represent the upper limit to any significant components and are set under due considerations of experimental conditions.[2]

TABLE 1. THE APPARENT EQUILIBRIUM CONSTANTS, K_a AND K', AND THE EMPIRICAL PARAMETER α FOR EB–POLYMER SYSTEMS IN THE LOW P/D RANGE

Systems	α	$K_a \times 10^{-4}$ / dm^3 mol^{-1}	$K' \times 10^{-4}$ a) / dm^3 mol^{-1}
EB–NaPSS	1.4	9.9	6.6
EB–NaPP	1.7	1.4	1.0
EB–NaPA	1.4	1.2	1.0
EB–nDNA	1.1	1.2	1.1
EB–dDNA	1.1	1.6	1.5

a) $K' = K_a\left(\frac{[P]}{[D]_0}\right)^{\alpha-1}$. Values of K' were calculated at $P/D=1$.

in the low P/D range.

The Extended PCA Procedure and Bound-EB Spectra. On the basis of the above conclusion, Eq. 2 was used for evaluating the apparent equilibrium constant K_a and the empirical parameter α. The results are summarized in Table 1. Values of α are larger than unity for three EB–polyanion systems, corresponding to the convex curvature observed for titration curves in Fig. 2.[3-7] Values of the commonly-postulated apparent equilibrium constant, $K'=[DP^*]/[D]\cdot[P]=K_a([P]/[D]_0)^{\alpha-1}$, were computed at a convenient P/D value, *i.e.*, $P/D=1$.[3,4,6-8] They are given in Table 1, so that they may be compared with values reported for other dye–polymer systems.

With the optimized elements of the **t** matrix [Eq. 5 in Ref. 3], the spectrum of bound EB in the EB–NaPSS complex was calculated in the visible region (circles in Fig. 1). The spectral change of EB in the ultraviolet region is small, when a polyanion solution is added, and the strong absorption of free EB dominates the 340—235 nm region; hence, application of the extended PCA procedure is restricted. The ultraviolet spectrum of bound-EB, ε_λ^b, was therefore calculated with the fraction of bound EB, f_b, as

$$\varepsilon_\lambda^b = \varepsilon_\lambda^f + \frac{\varepsilon_\lambda - \varepsilon_\lambda^f}{f_b}, \qquad (5)$$

where ε_λ^f and ε_λ are the molar absorption coefficients at λ of EB and EB–polymer solutions, respectively. The ultraviolet spectrum of EB bound to NaPSS is shown in Fig. 1. It is hypochromic relative to the spectrum of free EB.

The bound-EB spectra of three EB–polyanion complexes are summarily shown in Fig. 4, and their spectral characteristics are given in Table 2. These visible spectra are bathochromic and hypochromic to different degrees. The bathochromic shift is about 37 nm (NaPA)—55 nm (NaPSS). The hypochromism of bound-EB spectra was expressed with the absorption maxima, $1-(\varepsilon_{max}^b/\varepsilon_{max}^f)$, and also with the oscillator strengths, $1-(F^b/F^f)$. When EB is bound to a charged polymer site, neither band-broadening, new peak, nor shoulder seems to appear in the bound-EB spectrum above 400 nm; the number of transition moments probably remains unchanged, as judged both from values of the half-intensity band width ($\Delta\tilde{\nu}_{1/2}$) and from values of the oscillator strength F. Since the 480 nm band of free EB is due to a single electronic transition,[17,35,36] the same probably holds for the visible band of bound EB. It may be concluded from the data in Table 2 that EB bound to various polyanions exhibits neither the metachromatic blue shift nor the metachromasy band. This conclusion is based on the fact that the bound-EB spectra were obtained in the low P/D range, where possible dye-stacking would be maximum, and lead to the most pronounced metachromatic behavior, if any. Hence, possessing two amino groups, EB differs markedly from many 3,6-diaminoacridine dyes[3,4,18,37,38] but resembles the unsubstituted acridinium or 9-aminoacridinium chloride.[7]

Spectral Characteristics of EB–DNA Complexes. In order to obtain the spectrum of EB bound to DNA,

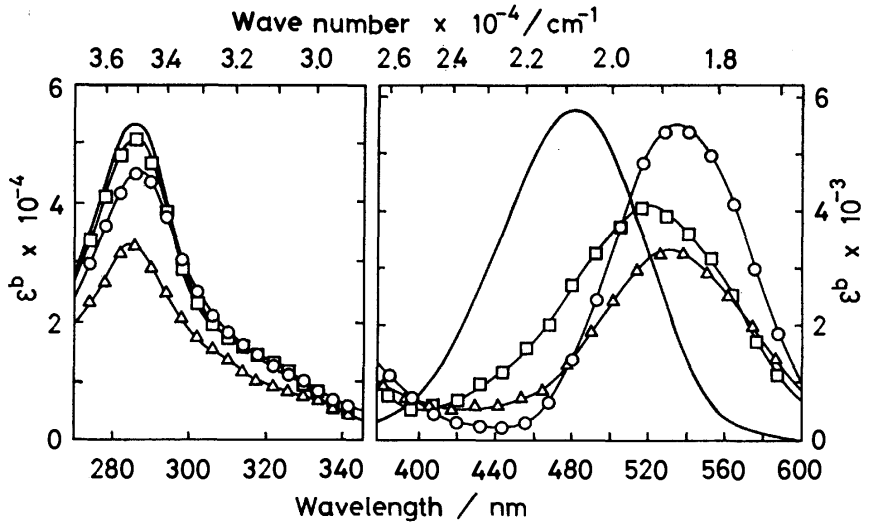

Fig. 4. Visible and ultraviolet spectra of EB bound to three different polyanions. (○) NaPSS, (△) NaPP, and (□) NaPA. The ultraviolet spectra were calculated at $P/D=0.937$ for NaPSS, 0.727 for NaPP, and 1.045 for NaPA. The concentration of EB is 7.47×10^{-5} mol dm^{-3}. Spectra of free EB are shown with solid lines for comparison.

Table 2. Characteristics of bound-EB spectra in the visible wavelength region

Systems	λ^b_{max} [a] / nm	ε^b_{max} [b] / mol^{-1} dm^3 cm^{-1}	H[c]	$\Delta\tilde{\nu}_{1/2}$ [d]	F[e]	H'[f]
EB[g]	480	5850	0	3920	0.107	0
EB–NaPSS	536	5550	5.1	2820	0.0751	29.5
EB–NaPP	532	3350	42.7	3410	0.0552	48.3
EB–NaPA	518	4160	28.9	3930	0.0785	26.4
EB–nDNA	524	4190	28.4	2950	0.0613	42.5
EB–dDNA	524	4090	30.1	3030	0.0595	44.2

a) Absorption peak of bound-EB spectrum. b) Molar absorption coefficient of bound EB at λ^b_{max} c) Hypochromicity in % defined as $[1-(\varepsilon^b_{max}/5850)]\times100$. d) Half-intensity band width, where $\varepsilon=\varepsilon^b_{max}/2$. e) Oscillator strength defined as $(4.315\times10^{-9})\int_{1/\lambda_1}^{1/\lambda_2}\varepsilon^b(\tilde{\nu})\cdot d\tilde{\nu}$, where λ_1 is set at 660 nm and λ_2 is the wavelength at which ε^b_λ is minimum. f) Hypochromicity in % defined as $[1-(F_{\text{bound EB}}/F_{\text{free EB}})]\times100$. g) Free EB as the reference.

the series of optical titration spectra were measured for EB–nDNA (isosbestic points 518 and 392 nm) and EB–dDNA (517 and 391 nm) systems. The results of optical titrations are similar to those in Fig. 1 and to those previously reported;[12,18,27] therefore, no detail will be reproduced here. Values of ε_{480} of EB decrease almost monotonously by addition of either native or denatured DNA solution, *i.e.*, the least convex curvature was observed (Fig. 2). The PCA result reveals that the number of EB components responsible for the visible spectra (the DNA moiety does not absorb in this wavelength region) is most probably two in the EB–nDNA and –dDNA systems, as indicated by the relative magnitudes of the eigenvalues in Fig. 3 (d and e). Hence, one free and one bound EB species are present in the low P/D range, regardless of the conformations of DNA.

By the extended PCA procedure, both K_a and α were evaluated (Table 1). Values of α are close to unity, indicating that the frequently-postulated binding scheme K' is nearly applicable to the EB–DNA system. Indeed, the value of K' calculated at $P/D=1$ (and that of K_a) is in good agreement with equilibrium constants previously reported for various EB–nDNA systems.[19,27] Figure 5 shows that the bound-EB spectrum in the native DNA complex (circles) is practically identical with that in the denatured DNA complex (triangles). These spectra are similar to a bound-EB spectrum which was obtained by equilibrium dialysis under different conditions.[19] The bound-EB spectra for DNA are very similar to those for three synthetic polyanions as regards their spectral characteristics, such as the red-shift and the absence of any new metachromasy band (Table 2). This close similarity suggests that the binding site of DNA may be related neither to the overall DNA conformation nor to the presence or absence of base-pairs. The polymer conformations or the functional groups thereof seem to be only of secondary importance for the bound-EB spectra. Thus, the most likely binding site is the charged moiety of the polymer, which is the common factor in the low P/D range.

Because of the reasons stated in the preceding section, the PCA procedure could not be applied to the ultraviolet spectra of EB–nDNA and –dDNA systems. By subtracting the contribution of the moiety of native and denatured DNA, the bound-EB spectra in the ultraviolet region were calculated with values of K_a and α according to Eq. 5 and are shown in Fig. 5. They are again very close to each other and to a reported spectrum.[16]

Fraction of Bound EB and Binding Curves. Values of the fraction of bound EB, f_b, or free EB, $1-f_b$, were calculated with K_a and α in Table 1 or with the elements of the **t** matrix. They are plotted against P/D on a

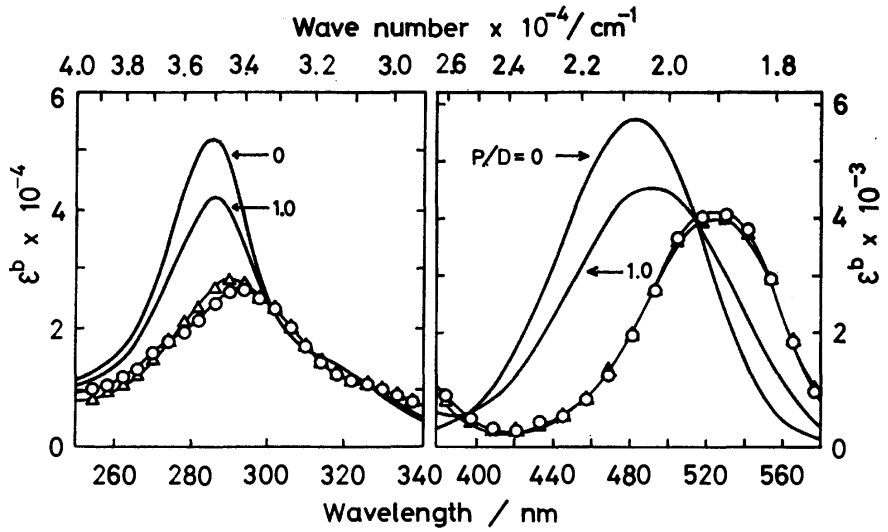

Fig. 5. Visible and ultraviolet absorption spectra of EB titrated with the 1×10^{-3} mol dm^{-3} NaCl-containing DNA solutions and the bound-EB spectra. Observed spectra are at $P/D=0$ and 1.0 for EB–nDNA solutions only. (○) EB bound to native DNA and (△) bound to heat-denatured DNA. The concentration of EB is 7.12×10^{-5} mol dm^{-3} in 1×10^{-3} mol dm^{-3} NaCl.

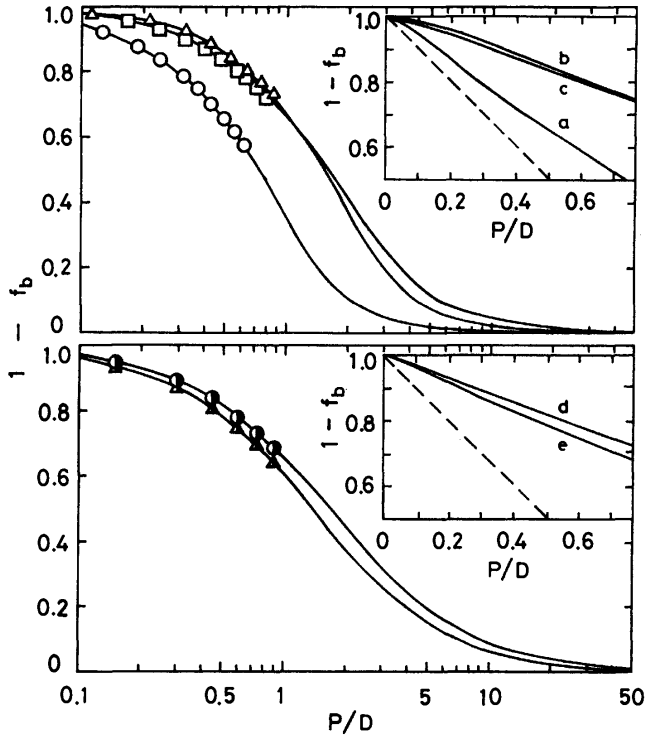

Fig. 6. Fractions of bound-EB in EB–polymer solutions and binding curves as a function of P/D. The ordinates are the fraction of free EB in EB–polymer solution, $1-f_b$. (○) NaPSS, (△) NaPP, (□) NaPA, (◑) nDNA, and (▲) dDNA. Binding curves, calculated with values of K_a and α, are shown by solid lines. In inserts, values of $(1-f_b)$ are plotted against P/D on a decadic scale. Dashed lines should be referred to the text. Each point was calculated with the aid of Eq. 4 in Ref. 4.

semi-logarithmic scale in Fig. 6. The fraction of free EB decreases gradually with the increase in P/D. Almost all EB molecules are estimated to be bound to NaPSS at $P/D>20$ but to NaPA, nDNA, and dDNA only at $P/D>50$, provided that the binding proceeds according to Eq. 1 or 2. The binding affinity of various polymers toward EB expressed by f_b at $P/D=1$ is in the order of NaPSS>dDNA (1 mM NaCl)>nDNA (1 mM NaCl)> NaPP≒NaPA. NaPSS has been noted for its high binding affinity toward various acridine dyes,[3,7] for which the strong ability for counterion condensation may be responsible.[39] Sigmoidal changes of binding curves are well reproduced for EB–polyanion systems ($\alpha>1$), as are indicated in the inserts of Fig. 6, where P/D values are plotted on a decadic scale. The binding curves decrease almost linearly for EB–DNA system ($\alpha=1.1$). In any case, it is worth mentioning that, except for NaPSS, no more than 50% of EB are bound to polymer sites when EB and the polymer residue are present in solution at equimolar amounts ($P/D=1$). Dashed lines in the inserts represent the relation $(1-f_b)=1-(D^b/P)(P/D)$, where $D^b/P=1$, *i.e.*, the number of bound EB per polymer residue in solution is unity. Hence, even in the P/D region where the amount of EB is in large excess ($P/D<1$), polymer sites are only partially occupied by EB (Fig. 6).

Closing Remarks. The common spectral features of five EB–polymer complexes are in that the absorption maximum of each bound-EB spectrum in the visible region shows both bathochromism and hypochromism but none of new "metachromasy" band, band-broadening, or hypsochromism. These features are in accord with those observed for *N*-methylacridinium and 9-aminoacridinium chlorides, but in contrast with the more complex acridine dyes. A possible explanation rests on the fact that the visible absorption band of metachromatic 3,6-disubstituted acridine dyes consists of two mutually perpendicular but overlapping transition moments,[10] while the visible band of EB[35,36] or

simple acridine cations[7,40] consists of a single electronic transition moment. Theoretical interpretations of these spectral characteristics would undoubtedly promote the understanding of metachromasy. For this purpose, accumulations of bound-dye spectra are highly desired for diverse combinations between metachromatic dyes of various chemical structures and polyelectrolytes with different conformations and functional groups.

Mechanism of Copper Transport through a Diaphragm-type Liquid Membrane

Takeshi KATAOKA, Tadaaki NISHIKI,* and Koretsune UEYAMA

Department of Chemical Engineering, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received March 13, 1981)

The permeation mechanism of copper with a liquid membrane process was studied by measuring the permeation rate of copper, which was allowed to permeate through a diaphragm-type liquid membrane with LIX64N as a mobile carrier at various concentrations of carrier and acid. The permeation rate is explained approximately by the diffusional process in the membrane for a chelating complex between copper and carrier and by the succeeding stripping reaction at the interface between the membrane and stripping phase.

A novel technique which can separate and concentrate dissolved solutes and ions in aqueous solution with liquid membranes has attracted special interest recently.[1,2] Especially, the liquid membrane process containing a mobile carrier can be expected to give high selectivity and concentrating effect, so researches have been actively advanced to apply the process to hydrometallurgy and waste water treatment.

The liquid-liquid extraction of copper with LIX reagents has been one of important commercial solvent extractions for practical applications in hydrometallurgical processes. Therefore, a number of studies on equilibria and kinetics of extraction reactions have been reported. However, concentration and separation of copper with liquid membrane containing LIX reagents as a mobile carrier has not sufficiently been studied,[3-6] and the mechanism of permeation through such a membrane has not been elucidated.

The purpose of the present investigation is to clarify the permeation mechanism of copper ion with a liquid membrane. The permeation rate of copper ion through a diaphragm-type liquid membrane was measured by adopting LIX64N as a mobile carrier. The effect of the concentration of carrier and acid on the permeation rate was examined, and the permeation mechanism was discussed.

Theoretical

Model for Permeation of Copper. The permeation mechanism of copper ion through a liquid membrane containing LIX64N as a mobile carrier is shown schematically in Fig. 1. Copper ion M^{2+} in the left cell diffuses to the interface $x=0$, where it undergoes chelating complex formation with the carrier RH. The complex R_2M formed diffuses across the membrane toward the interface $x=L$, reacts with hydrogen ion H^+ and liberates copper ion in the right cell. The regenerated carrier RH diffuses back to the left side of membrane and reacts again with M^{2+} in the left cell. As a result of repetition of such a mechanism, copper ions are permeated and concentrated from the left into the right cell.

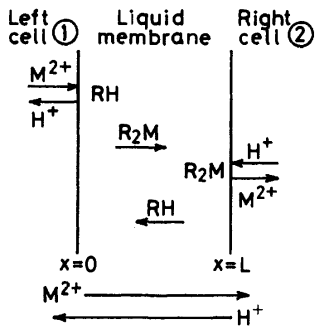

Fig. 1. Permeation mechanism.

Permeation Rate. If the permeation rate is controlled both by the diffusion process in the membrane and by the stripping process at the interface between the membrane and the right cell, the quasi-steady state may be assumed, and the fluxes J in the membrane and J in the right cell are respectively given by

$$J_M = \bar{k}_M\{(\bar{C}_T/2)-\bar{C}_{ML}\}, \quad (1)$$

$$J_{RH} = -\bar{k}_{RH}\bar{C}_{RHL}, \quad (2)$$

$$J_{M2} = k_{M2}(C_{ML}-C_{M2}), \quad (3)$$

where k is the mass-transfer coefficient and $\bar{C}_T$ the total concentration of mobile carrier. The bar superscript and the subscripts L and 2 denote the membrane phase, the interface $x=L$, and the right cell, respectively.

The following interfacial reaction model[7] may be applied to the stripping reaction at $x=L$:

$$(\overline{R_2M})_i + (H^+)_i \underset{k_{-r1}}{\overset{k_{r1}}{\rightleftharpoons}} (RM^+)_{ad} + (\overline{RH})_i \quad K_1, \quad (4)$$

$$(RM^+)_{ad} + (H^+)_i \rightleftharpoons (M^{2+})_i + (RH)_{ad} \quad K_2, \quad (5)$$

$$(RH)_{ad} \rightleftharpoons (\overline{RH})_i \quad K_3, \quad (6)$$

where K is the equilibrium constant, the subscript "ad" denotes the interfacially adsorbed species, and "i" denotes the species adjacent to the interface, either on the membrane side or on the right cell side. If the reaction shown in Eq. 4 is a rate-controlling step, the stripping reaction rate is expressed as

$$r = k_{r1}[\overline{R_2M}]_i[H^+]_i - \frac{k_{-r1}[M^{2+}]_i[RH]_{ad}[\overline{RH}]_i}{K_2[H^+]_i}$$

$$= k_{r1}\bar{C}_{ML}C_{HL} - \frac{\alpha C_{ML}\bar{C}_{RHL}}{C_{HL}}, \quad (7)$$

where $\alpha=\bar{k}_{-r1}[RH]_{ad}/K_2$.

From Eqs. 1, 2, 3, and 7, the concentration $\bar{C}_{ML}$ of the complex at the interface $x=L$ is given by

$$\bar{C}_{ML} = (1/4\alpha\beta\gamma)[2\alpha\beta\gamma\bar{C}_T + k_{r1}C_{HL}^2 + \bar{k}_M C_{HL} + 2\alpha\beta C_{M2} - \{k_{r1}C_{HL}^2(4\alpha\beta\gamma\bar{C}_T + k_{r1}C_{HL}^2 + 2(\bar{k}_M C_{HL} + 2\alpha\beta C_{M2})) + (\bar{k}_M C_{HL} + 2\alpha\beta C_{M2})^2\}^{1/2}], \quad (8)$$

where $\beta=\bar{k}_M/\bar{k}_{RH}$ and $\gamma=\bar{k}_M/k_{M2}$.

Consequently, with $\bar{C}_{ML}$ obtained from Eq. 8, the concentration C_{M1} of copper in the left cell can be calculated successively as a function of time by using Eq. 1 and the following equation:

$$-V(dC_{M1}/dt) = SJ_M, \quad (9)$$

where V and S represent the volume of cell and the area of diaphragm, respectively.

In the initial contact time, the second term on the right-hand side of Eq. 7 may be neglected and the copper concentration with time is expressed as

$$\frac{C_{M1}}{C_{M1,0}} = 1 - \frac{1}{2}\left(\frac{S}{V}\right)\left\{\frac{k_{r1}C_{HL}}{1+(k_{r1}/\bar{k}_M)C_{HL}}\right\}\left(\frac{\bar{C}_T}{C_{M1,0}}\right)t, \quad (10)$$

where $C_{M1,0}$ is the initial concentration of copper in the left cell.

The mass-transfer coefficient k_{M2} was evaluated from the following equation:

$$\frac{kd}{D} = 0.158\left(\frac{\mu}{\rho D}\right)^{1/3}\left(\frac{\omega d^2\rho}{\mu}\right)^{0.63}, \quad (11)$$

where D is the diffusivity, d the diameter of impeller, ρ the density, μ the viscosity, and ω the rotational speed of impeller. This equation is correlated with the mass-transfer coefficients obtained from the following experiment. Namely, benzoic acid was cast in a circular depression corresponding to the membrane in the same apparatus as used in this study. Rates of dissolution of benzoic acid from the flat surface into several liquids were measured for various speeds.

Experimental

Apparatus. The permeation apparatus used is illustrated in Fig. 2. The membrane was clampled between two glass half-cells with inner diameter of 8 cm. A Teflon millipore membrane filter, which has a thickness of 125 μm, a porosity of about 68%, and a pore size of 10 μm, was used as a diaphragm throughout this study. The volume of each cell is 370 cm^3 and the contact area between the membrane and aqueous solution is 33.2 cm^2. The turbine impellers of 4 cm diameter with six flat-blades filtted at the center of cell length were driven in the same direction at a constant speed of 82 min^{-1} with variable-speed motors in both cells. The apparatus was placed in an air bath which was maintained at 25 °C. In addition, all metal surfaces were coated with Teflon.

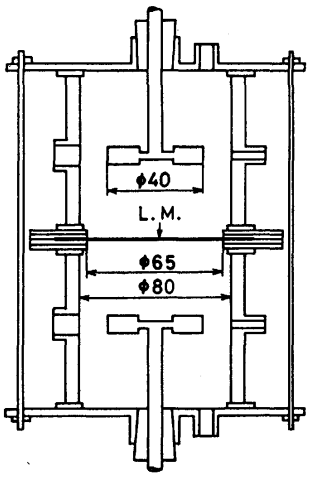

Fig. 2. Permeability cell.

Method. The pores in the membrane were filled up by immersing the membrane filter in the membrane solution. The membrane solution was prepared by dissolving LIX64N as a mobile carrier in kerosene. The concentration of active ingredient of LIX64N in kerosene was determined by measurement of the ultimate copper loading of LIX64N. The aqueous solutions were prepared by saturating degassed deionized water with kerosene.

The aqueous copper sulfate solution containing acetic acid–sodium acetate buffer was carefully poured into the left cell and the aqueous hydrochloric acid or sulfuric acid solution into the right cell so that the liquid levels in both cells might become equal. The time when the aqueous solution had come into contact with whole surface of membrane was taken as the beginning of experiment. After each cell was filled with the solution, both cells were stirred immediately.

Samples were taken from the left cell at regular time intervals by replacing them with fresh solution. The amount of sample was about 5 cm^3 and the number of samples was 5 or 6 in each run. The copper concentration was determined by titration with a standardized EDTA solution.

Results and Discussion

Effects of pH and Initial Concentration of Copper. The effect of pH on the partition equilibrium of copper between LIX64N in kerosene and aqueous solution was investigated by the batchwise method. The result obtained shows that the percent extraction of copper becomes constant around 100% above pH=3.

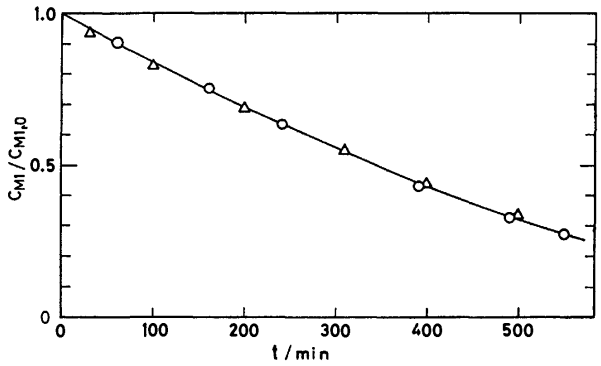

Fig. 3. Effect of pH on permeation rate of copper.
System: 0.01 mol dm^{-3} $CuSO_4$–L.M. ($\bar{C}_T$=0.490 mol dm^{-3})–2 mol dm^{-3} HCl. △: pH=3.5, ○: pH=4.5.

To examine the effect of pH on the permeation rate of copper, the copper concentration in the left cell with time was followed with time by keeping the pH in the left cell at 3.5 and 4.5. These results are shown in Fig. 3. No appreciable difference in permeation rate is detected for the above two pH values. Therefore, all the runs described below were performed for pH=4.5.

Figure 4 shows a result where differences in concentration, *i.e.*, the decreased amounts of copper in the left cell, were plotted against time for the initial copper concentrations of 0.01, 0.02, and 0.05 mol dm^{-3}. There

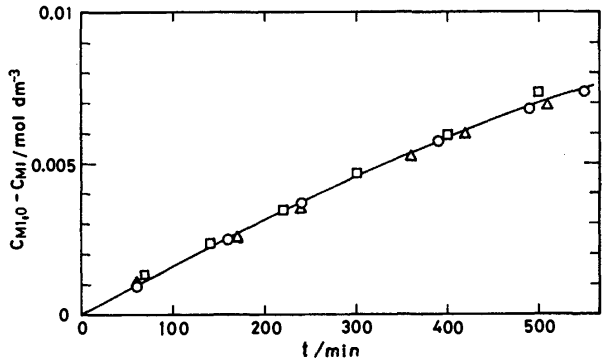

Fig. 4. Effect of initial coper concentration on permeation rate of copper.
System: $CuSO_4$(pH=4.5)-L.M. ($\bar{C}_T$=0.490 mol dm^{-3}) -2 mol dm^{-3} HCl. ○: $C_{M1,0}$=0.01, △: $C_{M1,0}$=0.02, □: $C_{M1,0}$=0.05 mol dm^{-3}.

is no change in concentration difference with the variation of initial concentration and the effect of the initial copper concentration on the permeation rate may be neglected.

From the above results, the foregoing assumption that the permeation rate is controlled both by the diffusion process in the membrane and by the stripping process seems to be reasonable.

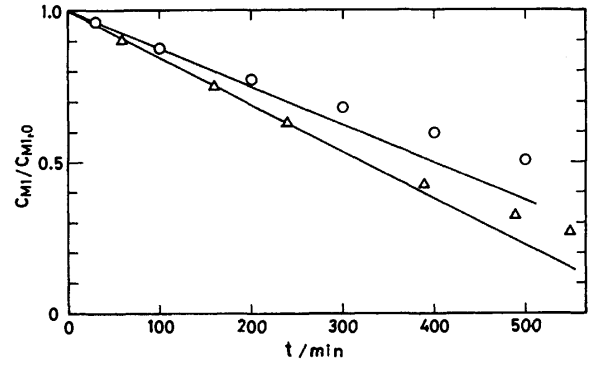

Fig. 5. Copper concentration in left cell *vs.* time (determination of k_{r1}).
System: 0.01 mol dm^{-3} $CuSO_4$(pH=4.5)-L.M.($\bar{C}_T$= 0.490 mol dm^{-3})-2 mol dm^{-3} acid. ○: H_2SO_4, △: HCl.

Determination of Reaction Rate Constant k_{r1}. Figure 5 shows results of runs in which time-dependent concentrations of copper in the left cell were measured by using 2 mol dm^{-3} hydrochloric acid or sulfuric acid as an acid in the right cell at the carrier concentration of 0.49 mol dm^{-3}. The solid lines are the slopes for each straight region near contact time zero. The values of k_{r1} obtained from each slope and Eq. 10 are 2.5 for HCl and 0.95 cm^4 mol^{-1} min^{-1} for H_2SO_4. The value of $\bar{k}_M$ in the membrane adopted in this calculation was evaluated by the same method as in the case of the concentration of chloride ion[8] and by using the diffusivity estimated from the Wilke-Chang equation. The estimated value of $\bar{k}_M$ is shown in Table 1. In the figure, the experimental values tend to deviate upward

TABLE 1. ESTIMATED VALUES OF MASS-TRANSFER COEFFICIENTS

$\bar{C}_T$ / mol dm^{-3}	$\bar{k}_M$ / cm min^{-1}	$\bar{k}_{RH}$ / cm min^{-1}
0.490	8.3×10^{-4}	1.3×10^{-3}
0.193	2.1×10^{-3}	3.2×10^{-3}
0.100	2.7×10^{-3}	4.2×10^{-3}

Acid	C_{HL} / mol dm^{-3}	k_{M2} / cm min^{-1}
HCl	2.0	4.6×10^{-2}
	1.0	4.8×10^{-2}
H_2SO_4	4.0	2.9×10^{-2}
	2.0	3.8×10^{-2}

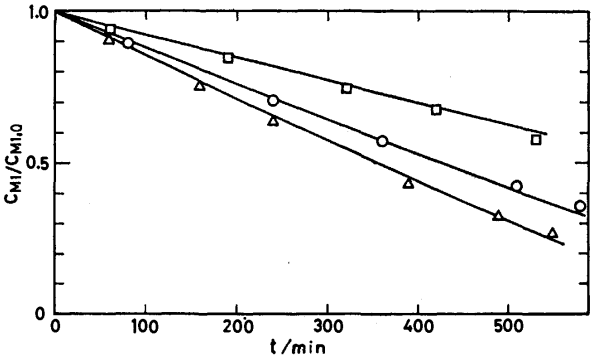

Fig. 6. Copper concentration in left cell *vs.* time (effect of carrier concentration).
System: 0.01 mol dm^{-3} $CuSO_4$ (pH=4.5)-L. M.-2 mol dm^{-3} HCl. α=0.16 cm min^{-1}. □: $\bar{C}_T$=0.100, ○: $\bar{C}_T$=0.193, △: $\bar{C}_T$=0.490 mol dm^{-3}.

from each straight line. This is caused by neglecting the second term on the right hand side of Eq. 7.

Effect of Carrier Concentration. Figure 6 shows the effect of the carrier concentration on the permeation rate at 2 mol dm^{-3} of hydrochloric acid. The solid lines are the concentrations as a function of time for each carrier concentration which were calculated from Eqs. 1, 8, and 9 by using the above value of k_{r1} and those of $\bar{k}_M$ and $\bar{k}_{RH}$ in Table 1. In this case, the mass-transfer coefficient k_{M2} in the right cell was obtained from Eq. 11 by using the diffusivity of copper ion estimated from the Nernst-Einstein equation, and is shown in Table 1. In addition, the value of α, which is constant because the value of $[RH]_{ad}$ becomes the saturated value at the high concentrations of LIX64N used, was determined by the trial and error method. The calculated values agree with the experimental results over the wide range of contact time for each carrier concentration.

The effect of carrier concentration on the permeation rate at 2 mol dm^{-3} of sulfuric acid is shown in Fig. 7. The solid line represents the calculated values for α= 0.20 cm min^{-1} obtained in the same way as in the case of hydrochloric acid by using the k_{r1} obtained above and the mass-transfer coefficients presented in Table 1. The calculated values agree with the observed over the whole range of contact time for all the carrier concentrations. The value of α for H_2SO_4 is a little different

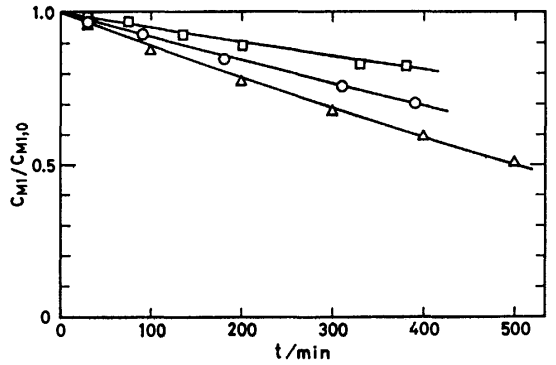

Fig. 7. Copper concentration in left cell *vs.* time (effect of carrier concentration).
System: 0.01 mol dm^{-3} $CuSO_4$ (pH=4.5)–L.M.–2 mol dm^{-3} H_2SO_4. α=0.20 cm min^{-1}. □: $\bar{C}_T$=0.100, ○: $\bar{C}_T$=0.193, △: $\bar{C}_T$=0.490 mol dm^{-3}.

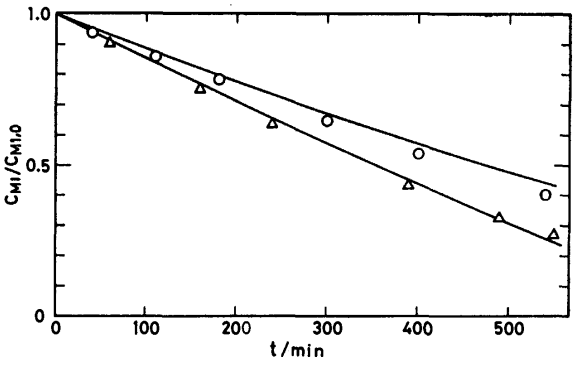

Fig. 8. Copper concentration in left cell *vs.* time (effect of hydrochloric acid concentration).
System: 0.01 mol dm^{-3} $CuSO_4$ (pH=4.5)–L. M. ($\bar{C}_T$= 0.490 mol dm^{-3})–HCl. α=0.16 cm min^{-1}. ○: HCl concn=1.0, △: HCl concn=2.0 mol dm^{-3}.

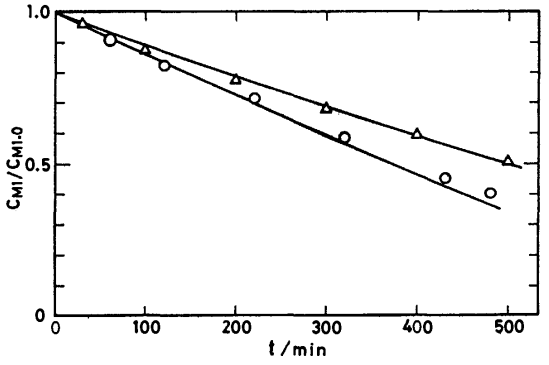

Fig. 9. Copper concentration in left cell *vs.* time (effect of sulfuric acid concentration).
System: 0.01 mol dm^{-3} $CuSO_4$ (pH=4.5)–L. M. ($\bar{C}_T$= 0.490 mol dm^{-3})–H_2SO_4. α=0.20 cm min^{-1}. △: H_2SO_4 concn=2.0, ○: H_2SO_4 concn=4.0 mol dm^{-3}.

from α=0.16 cm min^{-1} for HCl. This may be caused by a difference in k_{-r1} value between the two acids.

Effect of Acid Concentration. To clarify the effect of acid concentration in the right cell on the permeation rate, the copper concentration with time was measured by varying the concentration of hydrochloric acid at a constant carrier concentration of 0.49 mol dm^{-3}. These results are shown in Fig. 8. The solid lines are the calculated values obtained by using the same values of k_{r1} and α as in the case of the variation of carrier concentration. The calculated values agree approximately with the experimental ones, althought there are slight deviations between the calculated and experimental values in the region of long contact time.

Figure 9 shows results of the time-dependent concentration for sulfuric acid of 2 and 4 mol dm^{-3}. The agreement between the calculation and experiment is approximately good to the same extent as in the case of hydrochloric acid.

Conclusion

To clarify the permeation mechanism of copper ion with a liquid membrane, the time-dependent concentration of copper was measured for a diaphragm-type liquid membrane impregnated with LIX64N as a mobile carrier.

The permeation rate of copper ion is affected by the concentration of carrier and of the acid in the stripping phase. It has become apparent that the mechanism for the present permeation can be expressed by the diffusional process in the membrane for a chelating complex between copper and carrier and by the succeeding reaction at the interface between the membrane and stripping phase.

Photodimerization of Indeno[2,1-*a*]indene

Sang Chul SHIM* and Jeong Seok CHAE

Department of Chemistry, The Korea Advanced Institute of Science and Technology, P. O. Box 150 Chongyangni, Seoul, Korea

(Received October 16, 1980)

Indeno[2,1-*a*]indene, a *trans*-stilbene analogue with fixed planar configuration, yielded a head-to-head and a head-to-tail C_4-cyclodimer on direct irradiation with 300 nm UV light. The fluorescence quenching and sensitization studies indicated the reaction to proceed through excited singlet state, very likely through the singlet excimer intermediate.

Twisting around the C=C bond is normally an important decay mode of electronically excited singlet as well as triplet states of olefins as shown in stilbenes. However, fluorescence is the major decay route for stilbenes where the C=C bond is incorporated into a small ring such as cyclopropene, cyclobutene, or cyclopentene so that the twisting around the C=C bond is forbidden because of the ring strain.[1-3]

The photochemistry of stilbene has been extensively studied but relatively little is known about the photochemistry of the stilbene chromophore in small ring systems. Irradiation of 1,2-diphenylcyclobutene with 335 nm light in the crystal or in hexane solution yields $2\pi+2\pi$ C_4-cyclodimer, 1,2,5,6-tetraphenyltricyclo[4,2,-0,$0^{2,5}$]octane, through a finite-lived metastable singlet excimer along with the ring splitted photoproducts, diphenylacetylene and ethylene[1] while 1,2,3-triphenylcyclopropene yields no photoproduct with quantum yield greater than 10^{-2} on direct irradiation with 313 nm light but gives $2\pi+2\pi$ C_4-cyclodimer and a noncyclic hydrogen transfer dimer on triplet sensitization with benzophenone.[3] Thus, the photochemistry of stilbene chromophore in small ring systems is dependent on the size of the ring. The structure of indeno[2,1-*a*]indene, a *trans*-stilbene analogue, is restricted to a planar configuration and the compound cannot undergo *cis*⇌*trans* photoisomerization. Saltiel and coworkers utilized the fluorescence quantum yield of unity of the compound for backing up the singlet mechanism for the direct *cis*⇌*trans* photoisomerization of stilbene.[2,4] However, nothing is known about the photochemistry of indeno-[2,1-*a*]indene and photodimerization of the compound is studied in this report.

Experimental

Materials. *Indeno[2,1-a]indene*: Indeno[2,1-*a*]indene was synthesized by the method reported from benzyl chloride[5-7] and recrystallized from ethyl acetate and acetone. Mp 203—205 °C; NMR: δ 3.63 (s, 4H), 7.35 (m, 8H); IR: 3035, 2905, 1608, 1461, 1397, 1203, 775, 714 cm^{-1}; UV: 314 (ε_{max} 32500), 236 nm (ε_{max} 16500).

Spectra: UV spectra were recorded on a Cary 17 spectrophotometer. Infrared spectra were measured on a Perkin-Elmer Model 267 spectrophotometer in KBr pellet. Nuclear magnetic resonance spectra were measured on a Varian T-60A spectrometer against tetramethylsilane standard in chloroform-*d*. Mass spectra were determined with Hewlett Packard 5985 A GC/MS system. Fluorescence spectra were recorded on a Aminco Bowman spectrofluorometer with Aminco XY-recorder. Elemental analysis were carried out on a Coleman C, H, N analyzer.

Determination of Fluorescence Quantum Yields. Fluorescence quantum yield (Φ_F^s) of dilute solutions were calculated by Eq. 1.

$$\Phi_F^s = \Phi_F^r \times \frac{\int I_F^s(\tilde{\nu})d\tilde{\nu}}{\int I_F^r(\tilde{\nu})d\tilde{\nu}} \times \frac{O \cdot D_\lambda^r}{O \cdot D_\lambda^s} \times \frac{n_r^2}{n_s^2}, \quad (1)$$

where Φ_F^r is the fluorescence quantum yield of the reference compound. $I_F(\nu)$ and n are the corrected fluorescence intensity and refractive index respectively ($\tilde{\nu}$ in cm^{-1}). The reference compound, 2,5-diphenyloxazole (DPO) from Aldrich Chemical Co. was dissolved in benzene. Absolute quantum yield of the reference DPO in benzene is known to be 0.58. All sample compounds were dissolved in ether. The corrected fluorescence spectra were recorded on a Perkin-Elmer spectrofluorometer Model MPF-3.

Fluorescence-lifetime Measurements. The fluorescence lifetimes were measured at room temperature with an SLM-Model 480 phase-modulation spectrofluorometer utilizing continuous light that had been sinusoidally modulated.

Irradiation of the Sample and Separation of Dimers. Purified benzene solution of indeno[2,1-*a*]indene (100 mg/100 ml) was degassed by bubbling nitrogen through the solution for 30 min and irradiated in a Rayonet reactor (The Southern New England Ultraviolet Company) equipped with 300 nm fluorescence lamps for 10 h. The solvent was evaporated off and compound A was isolated by extraction of the residue with ethanol and recrystallized from methanol–water mixture. Compound B was isolated from the remaining residue by recrystallization from ethanol.

Found: Compound A; C, 94.00; H, 5.59%, compound B; C, 94.13; H, 5.98%. Calcd for $C_{32}H_{24}$: C, 94.09; H, 5.91%.

Quantum Yield Measurements. A solution of 3 ml of indeno[2,1-*a*]indene (2.3×10^{-3} M†) in several purified solvents[6] was put into a Pyrex ampoule and degassed by three freeze-pump-thaw cycles with cooling in liquid nitrogen and then sealed. Thus prepared samples were irradiated in a "merry-go-round" unit with 450 W Hanovia mercury arc lamp (Type 679 A 36). A Corning glass filter #7-54 and a solution filter of 2.5×10^{-3} M potassium chromate in 1% sodium carbonate aqueous solution were used to get a monochromatic light of 313 nm. The light intensity was measured by tris(oxalato)ferrate(III) actinometry and the amounts of photoproducts were analyzed by UV spectrophotometer at 314 nm.

Results and Discussion

Product Analysis. A benzene solution of indeno-

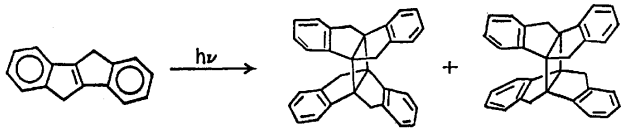
† 1 M=1 mol dm^{-3}.

[2,1-*a*]indene (4.9 mM) was irradiated for 10 h in a Rayonet reactor equipped with 300 nm fluorescent lamps. Separation of products by extraction and recrystallization gave products A and B in 2: 1 ratio. The photochemical conversion was almost complete. Both compounds were pure as shown by their Mp; compound A 183—184 °C, compound B decomposes at 290 °C before melting. The structures of compounds A and B were determined by their IR, ^{1}H NMR, mass, UV spectral data and elemental analyses.

Mass spectra of both compounds A and B show molecular ion peak at *m/e* 408 which is twice the molecular weight of indeno[2,1-*a*]indene. The base peak appears at *m/e* 204 which is exactly the molecular weight of starting material in both compounds. This indicates that compounds A and B easily undergo splitting into starting materials on electron impact suggesting compounds A and B to be C_4-cyclodimers. The elemental analyses of compounds A and B gave exactly the same data which are consistent with the dimeric structure.

The central double bond stretching of starting material at 1608 cm^{-1} are not apparent in the infrared spectra of compounds A and B and λ_{max} at 314 nm disappeared. These observations further substantiate the structure of compounds A and B to be $2\pi+2\pi$ type C_4-cyclodimers.

The ^{1}H NMR spectrum of compounds A in chloroform-*d* shows two doublets at 2.8 (d, 4H, J=17 Hz) and 3.2 (d, 4H, J=17 Hz) and two mutiplets at 6.9 (m, 8H) and 7.2 (m, 8H) ppm (δ). That of compound B also shows two doublets at 3.1 (d, 4H, J=17 Hz) and 3.7 (d, 4H, J=17 Hz) and a multiplet at 6.9 (m, 16H). The data are in agreement with the C_4-cyclodimers of indeno[2,1-*a*]indene, compound A being a head-to-tail (HT) cyclodimer and compound B being a head-to-head (HH) cyclodimer.



Indeno[2,1-*a*]indene Head-to-Head Head-to-Tail

Fig. 1

In HT dimer, H_b, the outer proton of methylene bridge is deshielded by the ring current of upper benzene ring, but H_a, the inner proton of methylene group, is shielded by the same ring current. Thus H_b resonance corresponds to 3.2 ppm peaks and that of H_a corresponds to 2.7 ppm peaks. The same ring currents cause the ring protons H_c and H_d to be shielded and the protons H_e and H_f to be deshielded as two multiplets appear in the NMR spectrum of compound A.

In HH dimer, H_a is deshielded in contrast to that of HT dimer and 3.7 ppm peaks correspond to H_a resonance. All ring protons, H_c, H_d, H_e, and H_f of HH dimer are shielded by the ring current of upper benzene ring and only one multiplet appears in the NMR spectrum of compound B.

Fluorescence Studies. Indeno[2,1-*a*]indene is strongly fluorescent and the fluorescence quantum yield is reported to be unity. However, the fluorescence quantum yield of the compound in ether was determined to be 0.85 when 2,5-diphenyloxazole which has same UV absorption characteristics as indeno[2,1-*a*]indene was used as a reference compound. This implicates that there is some radiationless decay routes other than fluorescence from the excited singlet state of indeno-[2,1-*a*]indene in contrast to the results reported earlier.[2)]

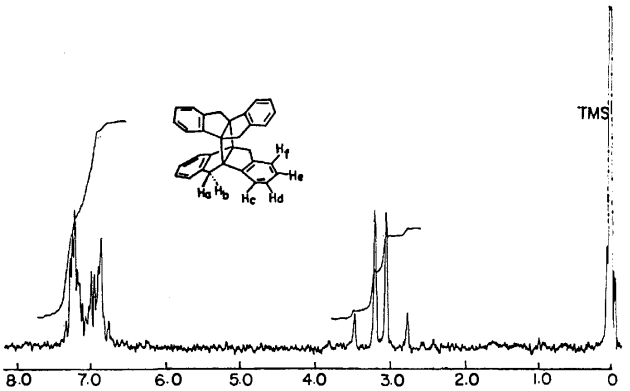


Fig. 2. ^{1}H NMR spectrum of H-T dimer of indeno[2,1-*a*]indene.

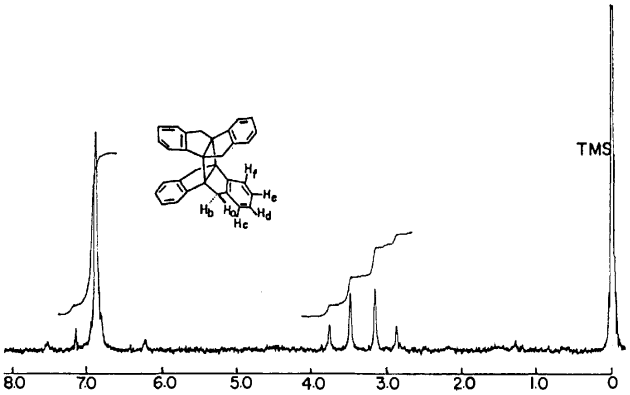

Fig. 3. ^{1}H NMR spectrum of H-H dimer of indeno[2,1-*a*]indene.

The fluorescence quenching of indeno[2,1-*a*]indene by electron deficient olefins, fumaronitrile and dimethyl fumarate, is very efficient while electron rich olefin, 2,3-dimethyl-2-butene (TME) does not quench fluorescence of indeno[2,1-*a*]indene.

The lifetime calculated from the slope of Stern-Volmer plot for fluorescence quenching by fumaronitrile and dimethyl fumarate is about 3.3 ns if $k_q = k_{diff} = 2.25 \times 10^{10}$ M^{-1} s^{-1} is assumed. This value is in agreement with the value of 1.99 ns measured directly from the fluorescence.

Reaction Mechanism. If the cyclodimerization occurs *via* a singlet excimer, the following mechanistic scheme can be proposed for the reaction

$$I \longrightarrow I^*, \quad (2)$$

$$I^* \xrightarrow{k_f} I + h\nu_f', \quad (3)$$

$$I^* \xrightarrow{k_d} I, \quad (4)$$

Table 1. Solvent effects and external heavy atom effects on the photocyclodimerization of indeno[2,1-*a*]indene

Solvent	Hexane	Acetonitrile	Benzene	Methyl iodide	Ethyl bromide
Viscosity	0.294 cP†	0.345 cP	0.564 cP	0.500 cP	0.402 cP
Quantum yield	1.80×10^{-2}	1.35×10^{-2}	0.75×10^{-2}	Undetectable	0.62×10^{-2}

† 1 P=0.1 Pa s.

$$I^* + I \underset{k_{-e}}{\overset{k_e}{\rightleftharpoons}} \text{Excimer}, \quad (5)$$

$$\text{Excimer} \xrightarrow{k_{dim}} \text{Dimers}, \quad (6)$$

$$\text{Excimer} \xrightarrow{k_{ed}} 2\,I, \quad (7)$$

where I is indeno[2,1-*a*]indene.

By steady state approximation,

$$\Phi_{dim}^{-1} = \frac{(k_f+k_d)(k_{-e}+k_{dim}+k_{ed})}{k_{dim}\,k_e}[I]^{-1} + \frac{k_{dim}+k_{ed}}{k_{dim}}. \quad (8)$$

The linear relationship between Φ_{dim}^{-1} and $[I]^{-1}$ is expected if the mechanism is valid.

When Φ^{-1} is plotted against $[I]^{-1}$ for the [I] of 5×10^{-3}—2×10^{-2} M in benzene solution at 21 °C, a good linear relationship (correlation coefficient: 0.999) is obtained as shown in Fig. 4.

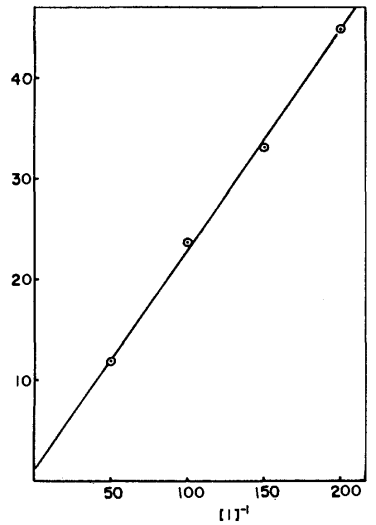

Fig. 4. Plot of the reciprocal of the quantum yield for photodimerization *vs.* the reciprocal of the indeno[2,1-*a*]indene concentration in benzene solution at 21 °C.

The intercept, $(k_{dim}+k_{ed})/k_{dim}$, is 1.20 and the slope which is given by $(k_f+k_d)(k_{-e}+k_{dim}+k_{ed})/k_{dim}k_e$ is 0.22. From these results and $\tau=1/(k_f+k_d)=1.99$ ns in dilute solution,

$$k_e\times\frac{k_{dim}}{k_{-e}+k_{dim}+k_{ed}} = k_e\,\frac{1}{\dfrac{k_{-e}}{k_{dim}}+\dfrac{(k_{dim}+k_{ed})}{k_{dim}}}$$

$$= 2.3\times10^9\ M^{-1}\,s^{-1}.$$

Thus the minimum value for k_e which is the rate constant for singlet excimer formation is $2.76\times10^9\ M^{-1}\,s^{-1}$ and the maximum value for that will be diffusion controlled rate constant of $2.25\times10^{10}\ M^{-1}\,s^{-1}$, the value obtained by the simplified Debye expression, $k_{diff}=8RT/3000\eta$, taking the viscosity of hexane as 0.294 cP at 25 °C.[8]

The ratio of A/B monitored by NMR is about two and is independent on indeno[2,1-*a*]indene concentration indicating that the two dimers are formed through a common intermediate.

From these results, it is suggested that two dimers, HH and HT, are formed through a singlet excimer. The direct evidence for this mechanism will be obtained through the investigation of the temperature effect[9,10] on the

$$k_e\times\frac{k_{dim}}{k_{-e}+k_{dim}+k_{ed}},$$

and this work is in progress.

The quantum yield of cyclodimerization in various solvents are shown in Table 1. The higher quantum yields are obtained in less viscous solvents indicating that the photocyclodimerization is dependent on the diffusion and association of solute molecules. External heavy atom effect as shown in methyl iodide decreases cyclodimerization quantum yield drastically indicating unequivocally that the excited singlet state is the reactive state for cyclodimerization. This mechanism was strongly substantiated by the triplet sensitization studies. No dimerization was observed when the benzene solution of indeno[2,1-*a*]indene was irradiated for 20 h with 366 nm UV light in the presence of benzophenone as a triplet sensitizer (E_T=68.3 kcal/mol). In acetonitrile solvent, the intersystem crossing from singlet to triplet state is perhaps enhanced as in the case of pyrimidine bases[11] and this enhanced intersystem crossing along with the slower diffusion of singlet excited molecules decreases the photocyclodimerization yield.

We thank Mr. Minjoong Yoon of Texas Tech University for fluorescence quantum yield and lifetime measurements. This work is supported by the Korea Science and Engineering Foundation.

Spectral Changes in X-Ray *K* Emission Lines of Potassium in Various Compounds

Seiji YASUDA* and Hitoo KAKIYAMA

The Government Industrial Research Institute, Kyushu, Shuku-machi, Tosu, Saga 841

(Received May 16, 1981)

Synopsis. The chemical shifts and profile changes in the $K\alpha_{1,2}$, $K\beta_{1,3}$ and their satellite lines of potassium from 21 chemical compounds were measured with a two-crystal X-ray spectrometer. The data obtained are discussed qualitatively and related to the nature of the surrounding groups.

The valences or coordination numbers of elements in unknown samples or the ionic character of chemical bonds can be readily distinguished by the spectral changes in X-ray emission lines.[1] Such studies have received considerable attention from analytical chemists. However, so far as the elements such as potassium and calcium are concerned, only a few measurements have been directed to the theoretical interpretation of the $K\beta_{1,3}$ and its satellite lines.[2-4]

In the previous paper,[5] we have shown that the surrounding atoms or anions give appreciable line shifts and profile changes in the $K\alpha$ and $K\beta$ emission lines of calcium. The present note deals with potassium in an analogous way by measuring the chemical shifts and profile changes in the potassium $K\alpha_{1,2}$, $K\alpha_{3,4}$, $K\beta_{1,3}$, $K\beta''$, and $K\beta_5$ lines from 21 chemical compounds. The purpose for our previous and present studies is to examine whether a change of the nature of the surrounding groups leads to line shifts or profile changes in X-ray K emission lines of elements with constant formal charges in most compounds.

Experimental

The potassium X-ray emission spectrum was measured automatically by a step-scanning method at regular intervals of 0.005° 2θ using a Rigaku two-crystal X-ray spectrometer with Ge(111) crystals ($2d$=6.5327 Å). The primary radiation used for exciting the spectrum was provided by a chromium X-ray tube operated at 50 kV, 30 mA. The detector was a flow proportional counter. The 2θ position of the potassium $K\alpha_1$ was determined by averaging the goniometer settings at which the same intensity was measured on either side of the peak at the half-maximum intensity. The $K\alpha_2$, $K\alpha_4$, and $K\beta_{1,3}$ positions were also determined in the same way at approximately 70% intensity, whereas the $K\beta''$ and $K\beta_5$ positions were estimated from their apparent maxima. The chemical shift was calculated as an energy difference between the respective lines from the compound under study and KF. The experimental errors in such procedures were estimated to be±0.02 eV in the $K\alpha_1$, $K\alpha_2$, and $K\beta_{1,3}$ shifts and ±0.06 eV in the other lines. No corrections were made on the spectrum measured.

All potassium compounds used were of the highest commercial grade available and were confirmed by X-ray diffraction.

Results and Discussion

Potassium Kα *Spectrum.* The potassium $K\alpha$ emission spectrum consists of the $K\alpha_{1,2}$ doublet and its high energy satellites, namely the $K\alpha_{3,4}$ group. For all compounds, the $K\alpha_1$ full width at half-maximum intensity and the peak separation in the doublet seemed nearly constant at about 1.90 and 2.68 eV, respectively. In addition, the observed chemical shifts of both the $K\alpha_1$ and $K\alpha_2$ lines did not exceed the limits of the experimental errors at ±0.02 eV. The potassium $K\alpha_{3,4}$ group of satellites was observed on the high energy tails of the parent $K\alpha_{1,2}$ doublet. In every case, three components $K\alpha'$, $K\alpha_3$, and $K\alpha_4$ could be resolved, about 11, 18, and 22 eV apart from the $K\alpha_1$, respectively. However, there were no significant changes in the energy positions, profiles and relative intensities of the resolved satellite components in all compounds. These results indicate that the $K\alpha_{1,2}$ and its high energy satellite lines of potassium in different compounds are little affected by the changes of surrounding groups or of the crystal structures of compounds.

Potassium Kβ *Spectrum.* The potassium $K\beta$ spectrum from KF is shown in Fig. 1. According to the relative positions in similar spectra which have appeared in the literature,[2,6] the main peak was assigned to $K\beta_{1,3}$ and its high energy satellites were assigned to $K\beta''''$, $K\beta'''$, $K\beta_5$, and $K\beta''$ beginning from the high energy side in every case. The weak emission structures on the

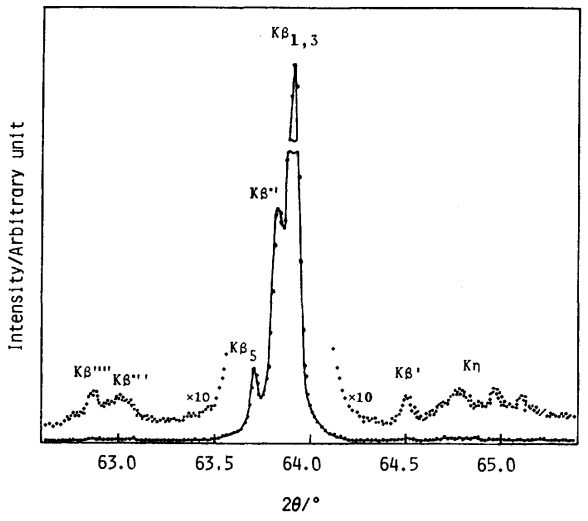

Fig. 1. Potassium $K\beta$ spectrum from KF.

low energy side of the $K\beta_{1,3}$ were assigned to $K\beta'$ and $K\eta$. The observed spectrum of each compound was characterized by the chemical shifts of the $K\beta_{1,3}$, $K\beta''$, and $K\beta_5$ relative to the respective lines in KF and the energy difference (ΔE) between $K\beta_5$ and $K\beta_{1,3}$. The measured data of these four parameters are listed in Table 1, according to the increase of the last parameter.

The potassium $K\beta_{1,3}$ line had an almost constant full width at half-maximum intensity of 1.67 eV for all compounds, but a slight difference in the energy positions was detectable. The experimentally observed shifts of the $K\beta_{1,3}$ lay in the range +0.03 to +0.13 eV, although they rarely exceeded +0.05 eV. However, a simple correlation in relating the observed $K\beta_{1,3}$ shifts to the nature of surrounding atoms or anions could not be found. The potassium $K\beta''$ bands was found to occur at about 4 eV higher energies than those of the $K\beta_{1,3}$. This band of most compounds was shifted slightly to lower energies by 0.1—0.4 eV relative to that of KF. The $K\beta''$ is generally regarded as a satellite, but the origins of this band and the observed shifts are at present unclear.

At 10—14 eV above $K\beta_{1,3}$, the potassium $K\beta_5$ band appeared as a well-defined peak in the spectra from potassium halides, carbonate and nitrate, while the other compounds gave the broad asymmetric $K\beta_5$ band with some structure and an ambiguous maximum. The chemical shifts of this band were as much as several electron Volts in the range −0.4 to +3.5 eV; these shifts are remarkably larger than those of the $K\beta_{1,3}$ and result in an increase in the energy difference ΔE with increasing the $K\beta_5$ shifts toward higher energies; these are shown in the last two columns of Table 1. A similar trend has been found by the photographic determinations of the potassium $K\beta_{1,3}$ and $K\beta_5$ energies from potassium carbonate, sulfate, and halides.[6] Since the $K\beta_5$ bands of potassium sulfates and phosphates shifted slightly to lower energies by 0.2—0.4 eV and to higher energies by 0.1 eV, respectively, the energy difference ΔE in these compounds was rather close to the value 10.1 eV for the reference material, KF. The remaining compounds showed the $K\beta_5$ shifts in the range +0.7 to +3.5 eV, which are almost comparable to those of calcium compounds.[5] On the other hand, the energy differences ΔE by 11—12 eV in most compounds were about 0.5 times as large as those in calcium compounds. In a series of potassium halides, the $K\beta_5$ maximum was found to shift toward higher energies with a decrease in the electronegativity of surrounding atoms with a consequent decrease in the charge of the potassium atom. This finding was the only possible regularity obtained in the present study on the spectral changes in the potassium X-ray K emission lines.

Every measured spectrum revealed very broad high energy structures $K\beta''''$ and $K\beta'''$ at about 53 and 44 eV above $K\beta_{1,3}$ and the low energy structures $K\beta'$ at about 31 eV below $K\beta_{1,3}$ and $K\eta$ with several maxima mostly occurring at about 42, 52, and 60 eV below $K\beta_{1,3}$. However, their profile changes and line shifts could not be investigated in detail because of the extremely faint intensities.

The Raman Spectra of Cobalt(III) Complexes. IV. Differentiation between *cis* and *trans* Isomers of Bis(trimethylenediamine)cobalt(III) Complexes

Kan KANAMORI,* Hiroko ICHINOSE, and Kiyoyasu KAWAI

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received June 19, 1981)

Synopsis. The Raman and the infrared spectra of bis(trimethylenediamine)cobalt(III) complexes have been studied to establish a definite distinction between the *cis* and *trans* isomers. A differentiation between the isomers can be made on the bases of the number of the Raman bands in the region of 480—550 cm^{-1} and of the mutual exclusion in the region of 400—500 cm^{-1}.

In the previous paper,[1] the Raman criterion has been established for differentiating *cis* and *trans* isomers of bis(ethylenediamine)cobalt(III) complexes. Many infrared studies[2-6] have been done on the stereochemistry of bis(ethylenediamine)cobalt(III) complexes, but few vibrational studies of bis(trimethylenediamine)cobalt(III) complexes have been reported. Kawaguchi and Kawaguchi[7-9] have applied Baldwin's criteria[5] and Hughes and McWhinnie's criteria[6] for bis(ethylenediamine)cobalt(III) complexes to isomeric pairs of bis(trimethylenediamine)cobalt(III) complexes. They have noted that the former criteria have not been useful for $[Co(NCS)_2(tn)_2]Cl$ and $[Co(N_3)_2(tn)_2]NO_3$, and the latter were not useful for $[Co(CN)(SO_3)(tn)_2]$.

In the present work, we tried to establish vibrational criteria for differentiating *cis* and *trans* isomers of bis(trimethylenediamine)cobalt(III) complexes on the basis of the Raman and the infrared spectra. The established criteria were then applied to the isomeric pair of $[Co(NH_3)_2(tn)_2]Cl_3$ obtained in the present work.

Experimental

Preparation. *Isomeric Pair of* $[Co(NH_3)_2(tn)_2]Cl_3$: This complex has been obtained by Ogino[10] through the reaction of $[Co(NH_3)_5(H_2O)]^{3+}$ with trimethylenediamine, but he did not refer to its geometrical configuration. We have prepared the isomeric pair by two methods.

Method I. Powdered *trans*-$[CoCl_2(tn)_2]Cl$ (5 g) was dissolved in 100 cm^3 of liquid ammonia. The ammonia was then allowed to evaporated spontaneously, leaving behind an orange powder. This powder was washed with a large amount of ethanol and dissolved in a minimum amount of warm water, then the solution was cooled in a refrigerator. The reddish orange precipitate (isomer I) was filtered and dried. The other isomer was obtained by adding a large amount of ethanol to the filtrate as an orange powder (isomer II). Yields: isomer I: 1.5 g; isomer II: 0.3 g.

Method II. Powdered *trans*-$[CoCl_2(tn_2)]Cl$ (5 g) was dissolved in 200 cm^3 of methanol which was saturated with ammonia. The solution was warmed on a water bath for 5 min. The orange powder which deposited was filtered and washed with ethanol. The same compounds as those obtained by method I were isolated by a fractional crystallization, but the ratio of the yields was reversed. Yields: isomer I: 0.7 g; isomer II: 2.5 g. Found: C, 19.16; H, 8.15; N, 22.45% for isomer I. C, 19.18; H, 8.07; N, 22.46% for isomer II. Calcd for $[CoC_6H_{26}N_6]Cl_3 \cdot 1.5H_2O$: C, 19.24; H, 7.81; N, 22.45%.

Isomeric Pair of $[Co(NO_2)_2(tn)_2]Cl$: This isomeric pair was first obtained by Kawaguchi and Kawaguchi.[7,8] Later, Celap *et al.*[11] have prepared it by different methods; they have shown that the property of the *cis* isomer is different from that obtained by Kawaguchi and Kawaguchi.[8] We have prepared the isomeric pair from the reaction mixture obtained by Kawaguchi's method[7] for the *trans* isomer by using an ion-exchange column chromatography (SP-Sephadex, C-25; ϕ 30 mm × 500 mm; eluent-0.04 mol/dm^3 KCl solution). The electronic spectrum of each isomer obtained by this method is identical with that of respective isomer observed by Celap *et al.*[11]

Other Complexes. All the other complexes were obtained by the method of Kawaguchi and Kawaguchi.[7-9]

Measurements. The Raman spectra were recorded on a JASCO R-800 Laser Raman spectrometer, using a He–Ne (632.8 nm) or an Ar^+ ion (514.5 nm) laser as an excitation source. The infrared spectra were recorded on a JASCO A-3 spectrometer. The observed frequencies were calibrated by the 533.8 cm^{-1} band of indene for the Raman spectra and the 618.0 cm^{-1} band of polystylene film for the infrared spectra. The observed frequencies are accurate within ± 2 cm^{-1}.

Results and Discussion

The most consistent variation between the vibrational spectra of *cis* and *trans* isomers has been found in the region of 400—550 cm^{-1}. The Raman and the infrared spectra in this region for the *cis* and *trans* isomeric pair of bis(trimethylenediamine)cobalt(III) complexes are shown in Fig. 1 and those of other *trans* isomers are in Fig. 2. The very strong Raman bands at *ca.* 450 cm^{-1} can be confidently assigned to the Co–N(tn) stretching mode, ν(Co–N(tn)), by comparison with the Raman

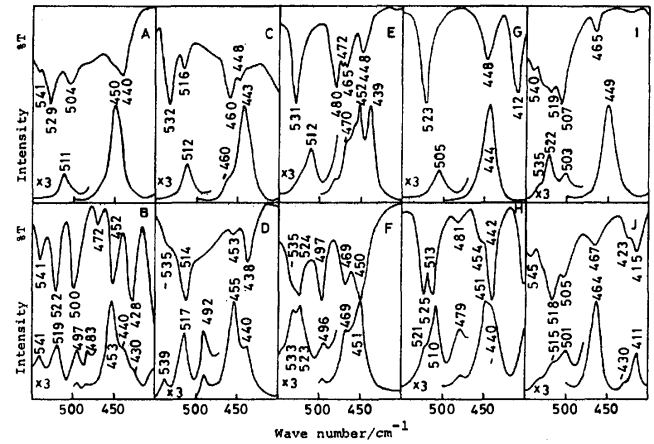

Fig. 1. The Raman and the infrared spectra of the isomeric pair of $[Coab(tn)_2]X$-type complexes. A(*trans*) and B(*cis*); a=b=CN^-, X=Cl^-. C(*trans*) and D(*cis*); a=b=NO_2^-, X=Cl^-. spectra of bis(ethylenediamine)cobalt(III) complexes.[1] Therefore, the infrared bands in the vicinity of 450 cm^{-1} may be assigned to the ν(Co–N(tn)), though Kawaguchi and Kawaguchi[8,9] have regarded the infrared bands in the region of 500—550 cm^{-1} as the ν(Co–N(tn)). The bands in the region of 480—550 cm^{-1} are assignable to the deformation vibration of the chelate ring, δ(CCN), by considering the assignment for ethylenediamine complexes based on the normal coordinate analysis.[12]

It can be seen from Figs. 1 and 2 that the *trans* isomers generally show one band due to δ(CCN) in the 480—550 cm^{-1} region of the Raman spectra and also in the infrared region. Further, the mutual exclusion between the Raman and the infrared spectra occurs, as expected from the approximate symmetry (D_{2h}) of the *trans* isomers. All the *cis* isomers have at least two bands in the 480—550 cm^{-1} region of the Raman spectra and most bands have their counterparts in the infrared spectra. Thus a complex which has one band in the Raman spectra and/or in the infrared spectra of 480—550 cm^{-1} region can be unambiguously assigned to the *trans* isomer. In the sulfito-containing complexes, the band due to the degenerate bending of the sulfito group, δ_d(SO$_3$), obscured the band due to the δ(CCN), so this region is not helpful for structural diagnosis. Forbidden vibrations under the assumption of a D_{2h} symmetry appear as a very weak band in the infrared spectrum of the *trans*-dinitro complex and in the Raman spectrum of the *trans*-dichloro complex, but the mutual exclusion approximately holds between the strongest band of the Raman spectrum in the 480—550 cm^{-1} region and that of the infrared one in the same region, in contrast to the *cis* isomers. The bands in the region of 460—480 cm^{-1} for the bis(isothiocyanato)complexes can be assigned to the δ(NCS).

The mutual exclusion generally holds also in the region of the ν(Co–N(tn)) of the *trans* isomers (see Figs. 1 and 2). This criterion can be used even for the sulfito-containing complexes. But in the *trans*-dinitro and the *trans*-diazido complexes, the mutual exclusion does not hold. This may be interpreted as a symmetry lowering in the solid state or as an accidental degeneracy.

In conclusion, three criteria for differentiating the geometrical isomers of bis(trimethylenediamine)cobalt-(III) complexes are established: the first is based on the

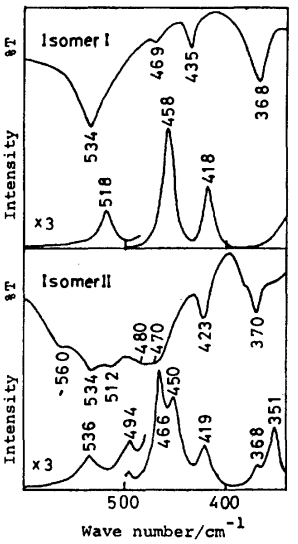

Fig. 3. The Raman and the infrared spectra of the isomeric pair of [Co(NH$_3$)$_2$(tn)$_2$]Cl$_3$.

number of bands in the region of 480—550 cm^{-1}, the second on the mutual exclusion in the same region, and the last on the mutual exclusion in the ν(Co–N(tn)) region. But each criterion has some exceptions, so only a combination of the three criteria would provide reliable diagnosis.

These criteria were applied to the isomeric pair of [Co(NH$_3$)$_2$(tn)$_2$]Cl$_3$. The Raman and the infrared spectra of the isomers are shown in Fig. 3. It is clear that isomer I has a *trans* configuration and isomer II has a *cis* configuration.

We wish to express our sincere thanks to Professor Yoichi Shimura of Osaka University, and to Dr. Isao Kanesaka for valuable discussions. We also thank Miss Naomi Shimizu for carrying out a part of the experiment

The Viscosities of Aqueous Solutions Containing Metal Complexes. IV. Nitrilotriacetato Complexes

Kiyoshi MIZUTANI and Motoo YASUDA*

College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received July 17, 1981)

Synopsis. Viscosity *B*-coefficients of bivalent metal complexes formed with nitrilotriacetic acid (H_3nta) were determined with Cannon-Fenske capillary viscometers at 25±0.01 °C. The *B*-coefficients obtained are smaller for metal chelates having larger stability constants, and larger for metal chelates having smaller stability constants.

The viscosities of aqueous electrolyte solutions have been measured by many authors, but few data are available for the metal complexes. In the previous papers of this series, the viscosity *B*-coefficients were reported for metal complexes formed with several amino polycarboxylic acid.[1-3] The results showed valuable information concerning the metal complexes. For example, it was shown that for a particular ligand a bivalent metal ion with a greater affinity for the ligand generally formed a chelate with a smaller *B*-value. In order to extend these conclusions further, a viscosity study was made of aqueous solutions of bivalent metal chelates formed with nitrilotriacetic acid.

Experimental

Viscosity measurements were made using Cannon-Fenske capillary viscometers with efflux times of *ca.*240—320 s for distilled water. The time of flow was measured with a stopwatch graduated to 0.1 s. All measurements were made at 25±0.01 °C. Solutions of metal chelates were made up using metal nitrate (or chloride) and K_3nta stock solutions.

For each of the 1 : 1 chelates studied, the variation in the relative viscosity η_{rel} with the solute concentration c was expressed by the Jones-Dole equation:[4]

$$\eta_{rel} = \frac{\eta}{\eta_0} = 1 + A\sqrt{c} + Bc, \qquad (1)$$

where η and η_0 are viscosities of solution and water. respectively. A is a constant depending on the ion-ion interaction between the solute ions, and B is a constant depending on the size of the ion and on the interaction between the ion and the surrounding solvent molecules. A and B are called the Jones-Dole viscosity A- and B-coefficients. These constants were fully discussed by Gurney,[5] who showed the *B*-coefficient of the electrolyte was composed additively of contributions from each of the solute species present in the solution. So *B*-values of the complex ions were obtained by subtracting a relatively smaller correction for the coexisting species.

Results and Discussion

In each case the *A*-coefficient was found to be zero within experimental error. The same was also found, for example, in ethylenediaminetetraacetato chelates[6] $[M(edta)]^{2-}$ and *trans*-1,2-cyclohexanediaminetetraacetato chelates[2] $[M(cydta)]^{2-}$. The *B*-coefficients of the nitrilotriacetato chelates obtained here at 25 °C are listed in Table 1, together with stability constants reported by Schwarzenbach *et al.*[7] For metal ions studied, the stability constants of nitrilotriacetato chelates are sufficiently large, and so even for magnesium chelate, which is the least stable, the estimated error due to dissociation of the complex is less than 0.01 in *B*-value.

TABLE 1. *B*-VALUES, STABILITY CONSTANTS k, AND AVERAGE RADII r OF NITRILOTRIACETATO COMPLEXES

Metal	B / dm³ mol⁻¹	log k[7]	r / Å
Cu^{2+}	0.52	12.96	4.4
Ni^{2+}	0.63	11.54	4.6
Co^{2+}	0.61	10.4	4.6
Zn^{2+}	0.62	10.66	4.6
Pb^{2+}	0.50	11.39	4.3
Mg^{2+}	0.71	7.0	4.8
Ca^{2+}	0.74	8.2	4.9

Larger *B*-values seem to indicate more free carboxylato groups of the ligand, which will make the chelates less stable. As seen from Table 1, the more stable the chelate is, in general, the smaller is its *B*-value. This was already seen in the case of amino polycarboxylato chelates studied previously.[2,3,6] It is interesting to compare the *B*-values of amino polycarboxylato chelates for a particular metal ion. The order of the *B*-value for each bivalent metal is as follows:

$$[M(nta)]^- < [M(ida)_2]^{2-} < [M(mida)_2]^{2-} \approx [M(edta)]^{2-} < [M(cydta)]^{2-},$$

where H_2ida is iminodiacetic acid and H_2mida is *N*-methyliminodiacetic acid. This order meets our expectations. However, there seems to be no special relation between the *B*-values of nta-chelate and those of $(ida)_2$-chelate, although a linear relationship[2] was found between *B*-values of edta- and cydta-chelates. This might be due to the fact that $[M(nta)]^-$ and $[M(ida)_2]^{2-}$ chelates do not have such similar structures, whereas $[M(edta)]^{2-}$ and $[M(cydta)]^{2-}$ do. The difference between *B*-values of $[M(nta)]^-$ and $[M(ida)_2]^{2-}$ chelates decreases as follows:

$$Pb > Cu > Zu > Ni \approx Co.$$

In this connection it is interesting to note that the ratio of the 1st and 2nd stability constants of iminodiacetato chelates, that is k_1/k_2, decreases in the order:[8]

$$Cu > Pb \gg Zn > Ni > Co.$$

This means that lead and copper form relatively unstable 1 : 2 chelates compared with the corresponding 1 : 1 chelate and so that $[Pb(ida)_2]^{2-}$ and $[Cu(ida)_2]^{2-}$ chelates may have relatively large *B*-values.

Since the *A*-value of each chelate was within experimental error of zero, we may calculate the volume of the hydrated chelate v_h from Eq. 2, because its radius is large compared with that of the solvent molecules:[2]

$$v_h = \frac{4000\,B}{6.02}\ (\text{Å}). \qquad (2)$$

Thus the average radius of the chelate r can be obtained from its B-coefficient, and is also listed in Table 1. This varies from 4.3 Å for the lead chelate to 4.9 Å for the calcium chelate. The variation may be in part due to the difference in effective ionic radii of metal ions, but cannot be wholly explained by this difference. For example, though the effective ionic radii of octahedral Mg^{2+} and Ca^{2+} are 0.86 and 1.14 Å, respectively,[9] both average radii of the chelates calculated are about the same. As we discussed previously,[2] the larger average radius may be ascribed to the larger extent of free carboxylato groups of nitrilotriacetic acid ligand which do not attach to the metal ion.

Synthesis and Circular Dichroism Spectra of *mer*(*N*)-*cis*(NH_3)-[Co(OO)(NH_3)$_2$-(py)(H_2O)]$^+$ and *mer*(*N*)-[Co(OO)(en)(py)(H_2O)]$^+$ Complexes

Shuhei FUJINAMI,* Kenshi TSUJI, Kumiko MINEGISHI, and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received August 13, 1981)

Synopsis. The *mer*(*N*)-*cis*(NH_3)-[Co(OO)(NH_3)$_2$-(py)(H_2O)]$^+$ and *mer*(*N*)-[Co(OO)(en)(py)(H_2O)]$^+$ complexes (OO=ox^{2-} or mal^{2-}) have been prepared and optically resolved. The CD spectra are different. The difference seems to be due to the additional optical activity derived from the helical arrangement of two bidentate ligands in the latter ethylenediamin complexes.

Recently, the complexes of *cis,cis,cis*-[Co(a)$_2$(b)$_2$-(c)$_2$],[1,2] *cis,cis*-[Co(a)$_2$(b)$_2$(CC)],[2] *fac*(*D*)-[Co(a)(b)-(c)(DDD)],[3] and *fac*(*a*)-[Co(a)$_3$(b)(CD)] types,[4] which derive their dissymmetry mainly from the distribution of donor atoms, have been prepared in our laboratory. In this note, novel complexes, *mer*(*N*)-*cis*(NH_3)-[Co-(OO)(NH_3)$_2$(py)(H_2O)]$^+$, and related complexes, *mer*(*N*)-[Co(OO)(en)(py)(H_2O)]$^+$ (OO=ox^{2-} ormal^{2-}), are reported. The CD spectra of these complexes are of interest in investigating the optical activity of *mer*-[Co(N)$_3$(O)$_3$] chromophore.

Experimental

Preparation and Optical Resolution. *a)* mer(N)-cis(NH_3)-*Diammineaquaoxalatopyridinecobalt(III) Perchlorate*, mer(N)-cis-(NH_3)-[*Co(ox)*(NH_3)$_2$(*py*)(H_2O)]ClO_4: To a solution of *cis*-K[Co(CO_3)(ox)(NH_3)$_2$]·H_2O[5] (20 g, 0.067 mol, in 200 cm^3 H_2O) was added pyridine (17 cm^3, 0.21 mol), and the solution was adjusted to pH 5.5 with 60% $HClO_4$ in an ice-bath. After filtration, the filtrate was stirred at room temperature for 0.5 h. The crude product which deposited was recrystallized from warm water. The yield was *ca.* 5 g. Found: C, 22.26; H, 3.47; N, 10.84%. Calcd for [Co(C_2O_4)(NH_3)$_2$(C_5H_5N)-(H_2O)]ClO_4: C, 22.26; H, 3.48; N, 11.13%.

The perchlorate was converted into chloride by using a column of Dowex 50W-X8 in Na^+ form. To a solution of the chloride (6 g, 0.02 mol, in 90 cm^3 H_2O) was added $(+)_{546}$-K[Co(edta)]·2H_2O (4 g, 0.01 mol) with mechanical stirring, and the whole was kept in an ice-bath. The less-soluble diastereoisomeric salt containing the $(-)_{589}$-oxalato complex was recrystallized five times from water. The final yield was *ca.* 1.5 g. Found: C, 31.17; H, 4.31; N, 10.16%. Calcd for [Co(C_2O_4)(NH_3)$_2$(C_5H_5N)(H_2O)][Co($C_{10}H_{12}N_2O_8$)]·2H_2O: C, 30.87; H, 4.43; N, 10.59%.

b) mer(N)-*Aquaethylenediamineoxalatopyridinecobalt(III) Chloride*, mer(N)-[*Co(ox)(en)(py)*(H_2O)]*Cl*: Pyridine (24 cm^3, 0.3 mol) was added to a solution of K[Co(CO_3)(ox)(en)]·H_2O[5] (32.5 g, 0.1 mol, in 100 cm^3 H_2O), and pH of the solution was adjusted to 5.5 with 60% $HClO_4$. After filtration, the filtrate was stirred at room temperature for a day. The solution, once filtered, was chromatographed on a column of Dowex 50W-X8 in Na^+ form (5 cm×30 cm) using a 0.15 mol/dm^3 NaCl solution. The red-violet band which descended was collected. After concentrating the effluent to *ca.* 30 cm^3, followed by filtering, the filtrate was kept in a refrigerator. The crude product thus obtained was recrystallized from warm water. The yield was 5.5 g. Found: C, 31.83; H, 4.45; N, 12.36%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)-(C_5H_5N)(H_2O)]Cl: C, 31.97; H, 4.39; 12.46%.

Optical resolution was performed by using $(+)_{546}$Na[Co-(edta)]·2H_2O in a way similar to that in *a)*. The less-soluble diastereoisomeric salt of the $(-)_{589}$-oxalato complex was recrystallized from water. Found: C, 33.95; H, 4.42; N, 10.48%. Calcd for [Co(C_2O_4)($C_2H_8N_2$)(C_5H_5N)(H_2O)][Co-($C_{10}H_{12}N_2O_8$)]·H_2O: C, 34.09; H, 4.33; N, 10.46%.

c) mer(N)-cis(NH_3)-*Diammineaquamalonatopyridinecobalt-(III) Chloride Monohydrate*, mer(N)-cis(NH_3)-[*Co(mal)*(NH_3)$_2$-*(py)*(H_2O)]*Cl*·H_2O: A solution containing a *cis*-[Co(CO_3)-(mal)(NH_3)$_2$]$^-$ complex, which had been prepared according to the literature method[5] (*cis*-K[Co(CO_3)$_2$(NH_3)$_2$]·H_2O, 27 g, 0.1 mol scale), was treated in the same manner as *b)*. By elution with 0.15 mol/dm^3 NaCl, red-violet and pink bands successively descended. The aimed red-violet band was collected, and the effluent was concentrated to *ca.* 20 cm^3. After filtration, the filtrate was kept in a refrigerator. The product thus obtained was recrystallized from warm water. The yield was *ca.* 0.2 g, Found: C, 27.62; H, 5.01; N, 12.35%. Calcd for [Co($C_3H_2O_4$)(NH_3)$_2$(C_5H_5N)(H_2O)]Cl·H_2O: C, 27.79; H, 4.92; N, 12.15%.

This complex was partially resolved by means of chromatography on a column of Dowex 50W-X8 in Na^+ form (100—200 mesh, 2 cm×30 cm), using 0.1 mol/dm^3 K_2[Sb_2(*d*-tart)$_2$] as the eluent. The earlier eluted species was the $(+)^{CD}_{500}$-isomer.

d) mer(N)-*Aquaethylenediaminemalonatopyridinecobalt(III) Chloride Trihydrate*, mer(N)-[*Co(mal)(en)(py)*(H_2O)]*Cl*·3H_2O: This complex was prepared by the same way as described in *c)* except for the use of a [Co(CO_3)(mal)(en)]$^-$ complex,[5] which had been prepared from K[Co(CO_3)$_2$(en)]·H_2O (30 g, 0.1 mol scale). The yield was *ca.* 0.3 g. Found: C, 29.47; H, 5.75; N, 10.77%. Calcd for [Co($C_3H_2O_4$)($C_2H_8N_2$)(C_5H_5N)-(H_2O)]Cl·3H_2O: C, 29.45; H, 5.64; N, 10.31%.

This complex was partially resolved in a way similar to that in *c)*, except for the use of a long column (2 cm×60 cm). The earlier eluted species was the $(+)_{589}$-isomer.

Measurement. The absorption spectra were measured with a Hitachi 323 spectrophotometer. The CD spectra were recorded on a JASCO J-40CS automatic recording spectropolarimeter. Samples were converted into the chloride by an ion-exchange technique, and the $\Delta\varepsilon$ values were evaluated from the absorption spectral data. For the measurements of the optical rotation, a JASCO DIP-SL automatic polarimeter was used.

Results and Discussion

For the [Co(OO)(NH_3)$_2$(py)(H_2O)]$^+$ complexes four geometrical isomers are possible: (a) *mer*(*N*)-*cis*-(*NH_3*), (b) *mer*(*N*)-*trans*(*NH_3*), (c) *fac*(*N*)-*cis*(*py*, *H_2O*), and (d) *fac*(*N*)-*trans*(*py*, *H_2O*). On the other hand, for the [Co(OO)(en)(py)(H_2O)]$^+$ complexes, three geometrical isomers are possible: (e) *mer*(*N*), (f) *fac*(*N*)-*cis*(*py*, *H_2O*), and (g) *fac*(*N*)-*trans*(*py*, *H_2O*). Among these isomers, (a), (c), (e), and (f) are resolvable into enantiomeric pairs. All complexes prepared in the present work could be resolved as described in the Experimental section.

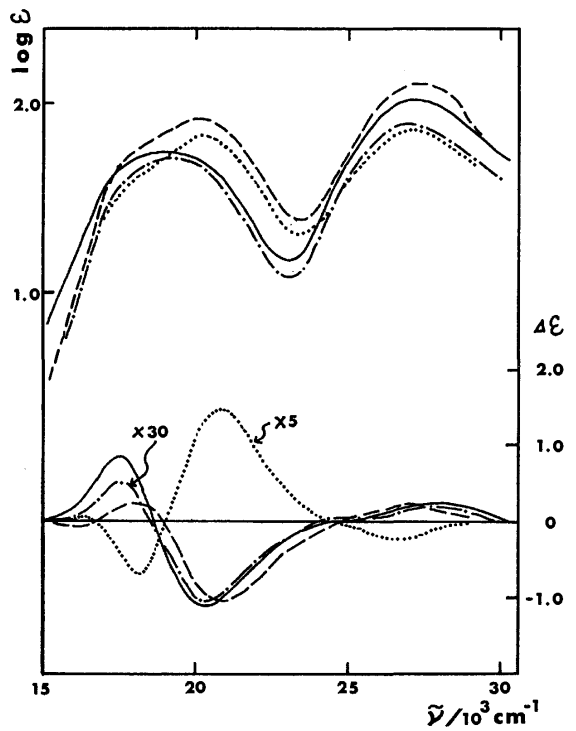

Fig. 1. Absorption and CD Spectra.
——: *mer*(*N*)-*cis*(*NH*$_3$)-(−)$_{589}$[Co(ox)(NH$_3$)$_2$(py)(H$_2$O)]$^+$, ——: *mer*(*N*)-(−)$_{589}$[Co(ox)(en)(py)(H$_2$O)]$^+$, —·—·: *mer*(*N*)-*cis*(*NH*$_3$)-(−)$^{CD}_{500}$[Co(mal)(NH$_3$)$_2$(py)(H$_2$O)]$^+$, ·····: *mer*(*N*)-(+)$_{589}$[Co(mal)(en)(py)(H$_2$O)]$^+$

As shown in Fig. 1, the first absorption bands of the [Co(OO)(NH$_3$)$_2$(py)(H$_2$O)]$^+$ complexes are broad, and those of the [Co(OO)(en)(py)(H$_2$O)]$^+$ complexes exhibit obvious shoulders, suggesting that these complexes have *mer*-[Co(N)$_3$(O)$_3$] chromophores. On this basis, the present [Co(ox)(NH$_3$)$_2$(py)(H$_2$O)]$^+$ and [Co(mal)(NH$_3$)$_2$(py)(H$_2$O)]$^+$ complexes can be assignable to *mer(N)-cis(NH$_3$)* isomers, and the [Co(ox)(en)(py)(H$_2$O)]$^+$ and [Co(mal)(en)(py)(H$_2$O)]$^+$ complexes to *mer(N)* isomers.

The CD spectra of the diammine complexes exhibit two Cotton peaks with opposite signs in the first absorption band region. The peaks at the higher-frequency side are dominant: 17300 cm^{-1} ($\Delta\varepsilon$=0.90) and 20300 cm^{-1} ($\Delta\varepsilon$=−1.07) for the (−)$_{589}$[Co(ox)(NH$_3$)$_2$(py)(H$_2$O)]$^+$ complex, and 17600 cm^{-1} ($\Delta\varepsilon$=0.017) and 20400 cm^{-1} ($\Delta\varepsilon$=−0.035) for the (−)$^{CD}_{500}$[Co(mal)(NH$_3$)$_2$(py)(H$_2$O)]$^+$ complex. On the other hand, the CD spectra of the ethylenediamine complexes exhibit three peaks with alternating signs, the peaks at the lowest frequency being extremely weak compared with the dominant peaks at the highest frequency: 16100 cm^{-1} ($\Delta\varepsilon$=−0.03), 18000 cm^{-1} ($\Delta\varepsilon$=0.26), and 20800 cm^{-1} ($\Delta\varepsilon$=−1.05) for the (−)$_{589}$[Co(ox)(en)(py)(H$_2$O)]$^+$ complex, and 16200 cm^{-1} ($\Delta\varepsilon$=0.016), 18200 cm^{-1} ($\Delta\varepsilon$=−0.09), and 20800 cm^{-1} ($\Delta\varepsilon$=0.28) for the (+)$_{589}$[Co(mal)(en)(py)(H$_2$O)]$^+$ complex.

The CD spectral shapes are little affected by the change of a five-membered oxalato chelate to a six-membered malonato chelate, while a large difference in CD spectral shapes is observed between the diammine and the corresponding ethylenediamine complexes. It is considered that the optical activity of [Co(OO)(NH$_3$)$_2$(py)(H$_2$O)]$^+$ is mainly derived from an arrangement of four kinds of ligating atoms, two O donors in OO and aqua, and two N donors in ammine and pyridine. On the other hand, that of [Co(OO)(en)(py)(H$_2$O)]$^+$ is mainly derived from two sources, one of which is an arrangement of four kinds of donor atoms, and the other is a helical distribution of two chelate rings. Therefore, the CD spectral difference between the diammine and ethylenediamine complexes, which is clearly observable at the lower frequency side, may be attributed to the additional optical activity derived from the helical distribution of the chelates.

Dividing the optical activity between the two sources is justified by the CD spectral comparison between the *all-cis*-[Co(C)$_2$(N)$_2$(O)$_2$] complexes, which have a rhombic crystal field like the present complexes.[1] A CD spectrum of *all-cis*-[Co(CN)$_2$(H$_2$O)$_2$(NH$_3$)$_2$]$^+$ resembles that of *cis,cis*-[Co(CN)$_2$(H$_2$O)$_2$(en)]$^+$. On the other hand, a spectrum of *cis,cis*-[Co(CN)$_2$(ox)(NH$_3$)$_2$]$^-$ is different from that of *cis*-[Co(CN)$_2$(ox)(en)]$^-$; the former exhibits two extrema in the first absorption band region, and the latter, three extrema. From these comparisons, the chiral environments are considered not to be derived by the ethylenediamine chelate itsel but to be derived by forming a ring pair with the oxalate chelate.

Studies of 8-Quinolinethiol as Chelating Agents. III.[1] Distribution Behavior of 8-Quinolinethiol between Chloroform and Aqueous Solutions

Eiichi SEKIDO,* Tadashi KOBAYASHI, and Yoshitaka MASUDA
Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada-ku, Kobe 657
(Received September 4, 1981)

Synopsis. The distribution behavior of 8-quinolinethiol between chloroform and aqueous solutions was examined and compared with that of 8-quinolinol. The distribution coefficient was $K_{D_R}=2140$ and macroscopic acid dissociation constants were $pK_{a_1}=2.05$ and $pK_{a_1}=8.39$.

8-Quinolinethiol is a useful organic reagent for the chloroform extraction and photometric determination of heavy metals.[2,3] Equilibrium constants for the extraction of the reagent itself are necessary to study the stoichiometric extraction of metals with 8-quinolinethiol. It is also interesting to compare the extraction behavior of 8-quinolinethiol with that of 8-quinolinol because it is assumed that 8-quinolinethiol exists predominantly as the zwitter ionic form in aqueous solutions,[4] but that almost all 8-quinolinol exists as the neutral form.

Experimental

Reagents. 8-Quinolinethiol was prepared by the method of Kealey and Freiser[5] and its sodium salt by the method of Nakamura and Sekido.[6] The sodium salt was purified by recrystallization three times from ethanol and dried *in vacuo*. 8-Quinolinol was also recrystallized three times from ethanol. The chloroform solution of 8-quinolinethiol was prepared as following. Into a 200 ml separatory funnel containing 10 ml of pH 4—5 buffer solution was added the required amount of sodium salt of 8-quinolinethiol under nitrogen gas, and then the resulting solution was shaken for 3 min with the aliquot of chloroform taken so as to obtain the required concentration of the reagent, 2×10^{-5} M (1 M=1 mol dm^{-3}).

Apparatus. Extraction was made with a Taiyo M-100N type incubator. UV and visible absorption spectra were taken with a Hitachi 124 type double beam spectrophotometer. A Hitachi-Horiba pH meter M-5 with a glass-calomel electrode pair was used.

Procedures. Into a 50 ml cylindrical tube containing 10 ml of 2×10^{-5} M 8-quinolinethiol chloroform solution was added 10 ml of the aqueous solution, which was adjusted to the desired pH by a buffer solution and to 0.1 ionic strength by the addition of sodium perchlorate. After shaking at 25 °C until the equilibrium was attained, two phases were separated with a centrifuge for 2 min, then 5 ml of the aqueous phase was pipetted out and its pH was measured. Concentrations of the reagent in the chloroform phase and/or the aqueous phase were spectrophotometrically obtained and distribution ratios were calculated.

Results and Discussion

8-Quinolinethiol exists as both the neutral form, HR, and the zwitter ionic form, H^+R^-, in a solution. Therefore, acid dissociation phenomena of 8-quinolinethiol are represented by the following explanatory Scheme 1. The relationships between the various equilibrium constants in Scheme 1 and macroscopic acid dissociation constants, called K_{a_1} and K_{a_2}, are as follows:

$$K_{a_1} = K_{a_A} + K_{a_B}, \tag{1}$$

$$\frac{1}{K_{a_2}} = \frac{1}{K_{a_C}} + \frac{1}{K_{a_D}}, \tag{2}$$

$$K_t = \frac{[\text{Zwitter ion}]}{[\text{Neutral}]} = \frac{[H^+R^-]}{[HR]} = \frac{K_{a_A}}{K_{a_B}} = \frac{K_{a_D}}{K_{a_C}}. \tag{3}$$

As it is expected that the species existing in the organic phase is only HR, the distribution ratio of the reagent, D_R, is represented by Eq. 4:

$$D_R = \frac{[HR]_o}{[H_2R^+]+[HR]+[H^+R^-]+[R^-]}, \tag{4}$$

where the subscript o represents the concentration in the organic phase. The simplifications of Eq. 4 on the lower pH (<2) and the higher pH (>8) media and the appropriate substitutions give Eqs. 5 and 6 respectively:

$$D_R = \frac{[HR]_o}{[H_2R^+]+[HR]+[H^+R^-]} = \frac{K_{a_1}K_{D_R}}{(1+K_t)\{[H^+]+K_{a_1}\}}, \tag{5}$$

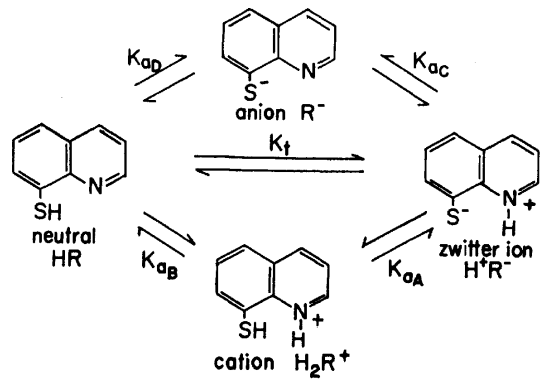
$$D_R = \frac{[HR]_o}{[HR]+[H^+R^-]+[R^-]} = \frac{[H^+]K_{D_R}}{(1+K_t)\{[H^+]+K_{a_2}\}}, \tag{6}$$

where K_{D_R} is the distribution coefficient of the reagent, defined as $K_{D_R}=[HR]_o/[HR]$. Moreover, on the condition of $[H^+]\gg K_{a_1}$, and $[H^+]\ll K_{a_2}$ Eqs. 5 and 6 are simplified and expressed in logarithmic forms as Eqs. 7 and 8, respectively.

$$\log D_R = \log\frac{K_{D_R}}{1+K_t} - pK_{a_1} + pH \tag{7}$$

$$\log D_R = \log\frac{K_{D_R}}{1+K_t} + pK_{a_2} - pH \tag{8}$$

The plots of $\log D_R$ for 8-quinolinethiol as a function of pH are shown in Fig. 1 with those for 8-quinolinol. A horizontal portion of maximum $\log D_R$ for 8-quinolinethiol, $\log D_{R_{max}}=2.65$, appears in the range of pH 4 to 7, which indicates that the reagent exists completely as HR and H^+R^-. As K_{D_R} is related with $D_{R_{max}}$ by Eq. 9, $K_{D_R}=2140$ is obtained by substituting the values $D_{R_{max}}=10^{2.65}=447$ and $K_t=3.8$[3] in Eq. 9. A linear



Scheme 1.

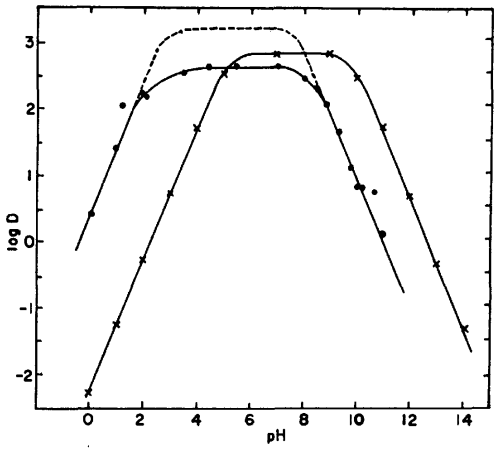


Fig. 1. Effects of pH on distribution of 8-quinolinethiol and 8-quinolinol between chloroform and aqueous solutio.

$$K_{DR} = D_{Rmax}(1+K_t) \quad (9)$$

portion with the slope of +1 in the range of pH −0.5 to 1.5 and that with the slope of −1 in the range of pH 8.5 to 11 are found as expected from Eqs. 7 and 8, respectively, and $pK_{a_1}=2.05$ and $pK_{a_2}=8.39$ were obtained from the pH values at log $D_R=0$. As was expected from the values of $pK_{a_1}=5.13$ and $pK_{a_2}=9.89$ for 8-quinolinol,[6] 8-quinolinethiol is extracted into chloroform in the lower pH range than that which 8-quinolinol is extracted. Although $K_{D_R}(2140)$ for 8-quinolinethiol is much larger than $K_{D_R}(772)$ for 8-quinolinol, the horizontal portion of the maximum distribution ratio for 8-quinolinethiol is lower than that for 8-quinolinol, because about 78% of 8-quinolinethiol

Table 1. Equilibrium consstants for 8-quinolinethiol

	Present work	Previous work
K_t		3.8[a]
pK_{a_1}	2.05	2.0[b]
pK_{a_B}	2.15	2.10
pK_{a_A}	2.73	2.68
pK_{a_2}	8.39	8.36[c]
pK_{a_C}	8.29	8.26[c]
pK_{a_D}	7.72	7.68[c]

a) Ref. 3. b)Ref. 7. c) Ref. 8.

in aqueous solution exists as the zwitter ionic form, while almost all 8-quinolinol exists as the neutral form.[4] If all of 8-quinolinethiol exists as the neutral form, the horizontal portion of the log D-pH curves will be higher than that for 8-quinolinol, as shown on the broken line in Fig. 1. Equations 10 and 11 are derived from Eqs. 5 and 6, respectively.

$$\log\left(\frac{1}{D_R}-\frac{1+K_t}{K_{DR}}\right) = -\mathrm{pH} - \log K_{D_R} + pK_{a_B} \quad (10)$$

$$\log\left(\frac{1}{D_R}-\frac{1+K_t}{K_{DR}}\right) = \mathrm{pH} - \log K_{D_R} - pK_{a_D} \quad (11)$$

The plots of log $\{(1/D_R)-(1+K_t)/K_{D_R}\}$ *vs.* pH are shown in Figs. 2a and 2b. Two straight lines with slopes of −1 and 1 are given and $pK_{a_B}=2.73$ and $pK_{a_D}=7.72$ are obtained from the values of log K_{D_R} and of the pH on log $\{(1/D_R)-(1+K_t)/K_{D_R}\}=0$. Thus, the values of pK_{a_A}, pK_{a_C}, pK_{a_1}, and pK_{a_2} are calculated by using Eqs. 1, 2, and 3, and these values are tabulated in Table 1 with values obtained by potentiometric and photometric methods. As shown in Table 1, these values are in fair accord with those reported previously.[7,8] Such agreement confirms that 8-quinolinethiol exists predominantly as the zwitter ionic form in aqueous solutions.

Cycloadditions of Constrained Dicyclopropylethylenes and Divinylcyclopropanes with Tetracyanoethylene

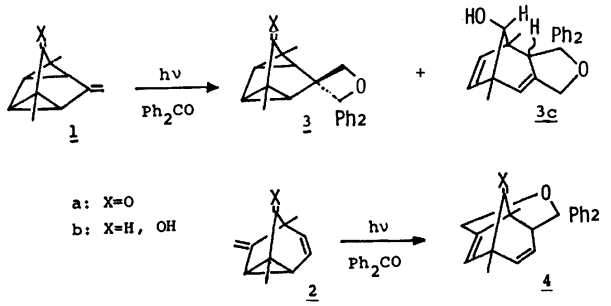
Makoto NITTA* and Toshio KUROKI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received May 14, 1981)

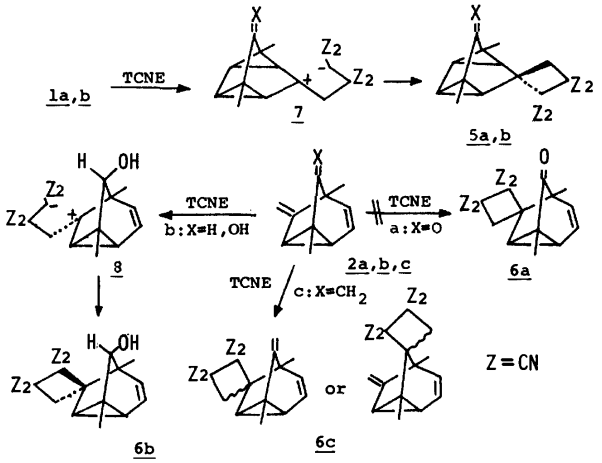
Synopsis. 2,4-Dimethyl-7-methylenetetracyclo[3.3.0.0^{2,8}0^{4,6}]octan-3-one and its corresponding alcohol were reacted with TCNE to give $\pi 2+\pi 2$ cycloadducts at the exomethylene group. On the other hand, 1,5-dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one did not react with TCNE, whereas its corresponding alcohol and 1,5-dimethyl-6,8-dimethylenetricyclo[3.2.1.0^{2,7}]oct-3-ene afforded $\pi 2+\pi 2$ cycloadducts. The reactivities were correlated with the ^{13}C-NMR data of the exomethylene groups, the electron densities of which are affected by the carbonyl group.

The electronic state and chemical reactivity of cyclopropane have attracted the continuous attention of organic chemists. Previously it has been reported that the photocycloaddition of benzophenone to 2,4-dimethyl-7,-methylenetetracyclo[3.3.0.0.^{2,8}0^{4,6}]octan-3-one (**1a**)[1] or its corresponding alcohol **1b**[1] afforded an oxetane, **3a** or **3b** and an adduct, **3c**.[2] The product composition of these reactions was understood by means of the electron-withdrawing property of the carbonyl group. A similar reaction of 1,5-dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (**2a**)[3] or its corresponding alcohol **2b**[4] was also investigated to afford **4a** or **4b**, as is summarized in Scheme 1.[5] A $\pi 2+\pi 2$ cycloaddtion of cyclopropylethylenes with tetracyanoethylene (TCNE) is generally accepted to proceed *via* a zwitterionic intermediate.[6] In this article, the cycloaddition of **1a** and **1b** and of **2a** and **2b**, to TCNE was investigated, and it was clarified that the reactivity of the exomethylene group toward TCNE was affected by the presence of the carbonyl group.



Scheme 1.

The reaction of **1a** and TCNE in acetonitrile at a refluxing temperature for 6 h provided, after recrystallization, an adduct **5a** in a 24% yield. The similar reaction of **1b** in refluxing dichloromethane for 1 h afforded an adduct **5b** in a 37% yield. The reaction of **1b** was faster than that of **1a** and proceeded at a lower temperature. The assignment of these structures, **5a** and **5b** was deduced from the spectral data (see Experimental). The hydroxyl proton in an NMR spectrum of **5b** could not be assigned distinctly. The stereochemistry of oxetane rings of **3a** and **3b** has been confirmed, as is depicted in Scheme 1.[2] This orientation of the benzophenone moiety must be favored by a steric hindrance. On the basis of a comparison with this observation, the stereochemistry of the cyclobutane rings of **5a** and **5b** depicted in Scheme 2 was proposed.



Scheme 2.

On the other hand, the reaction of the tricyclic ketone **2a** and TCNE in refluxing dichloromethane or acetonitrile did not afford any cycloadduct. The similar reaction of **2b** and TCNE in refluxing acetonitrile for 5 h, however, afforded an adduct **6b** in a 31% yield. The NMR spectrum of **6b** exhibited the proton signals of a vinylcyclopropane moiety and a resonable geminal coupling constant (J=14.0 Hz) for the hydrogens of the cyclobutane ring.[7] Therefore, the structure **6b** was deduced to be as is depicted in Scheme 2. Although the evidence for the stereochemistry of the cyclobutane ring of **6b** is not presented, the exo orientation of the TCNE moiety must be favorable because of the steric hindrance.[8]

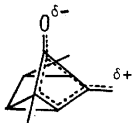
The zwitterionic species, such as **7** and **8**, would be the intermediate in the present cycloaddition reactions.[6] The following intramolecular combination in **7** and **8** from the less sterically hindered site afford the cycloadducts, **5a**, **5b**, and **6b**. The rearrangement of the intermediate **7** or **8** could not be observed. This feature is not like the case of radical reactions.[2,3,9] The corresponding radical species in the photocycloaddition of **1b** or **2a** and **2b** with benzophenone has been observed to rearrange (Scheme 1). The inertness of **2a** toward TCNE is noticeable. The inclusion of an electron-withdrawing substituent, such as CN or CO_2Me, in a

Table 1. ^{13}C-NMR chemical shifts of exomethylene group in $CDCl_3$

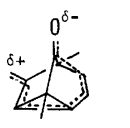
$\overset{A}{>}C=\overset{B}{C}H_2$	**1a**	**1b**	**2a**	**2b**
A	149.6	152.9	148.3	154.2
B	110.9	107.7	112.4	104.5
$\Delta\delta_{AB}$	38.7	45.2	35.9	49.7
$\Delta\Delta\delta_{AB}$	6.5		1.38	

cyclopropane ring has been demonstrated to preclude its reaction with TCNE.[10] The rate of the reaction of **1b** with TCNE was faster than that of **1a**. Therefore, the inertness of **2a** toward TCNE under the present conditions may be attributed to the presence of an electron-withdrawing carbonyl group.

The ^{13}C-NMR spectra of **1a**, **1b**, **2a**, and **2b** were recorded, the data for the carbons of the exomethylene groups are summarized in Table 1. Regarding the $\Delta\delta_{AB}$ value in the **1a**—**1b** and **2a**—**2b** pairs, **1b** and **2b** exhibit larger values than the corresponding ketones, **1a** and **2a** respectively. This fact seems to indicate that the polarization of the exomethylene group of **1b** or **2b** is greater than that of **1a** or **2a** respectively.[11] The $\Delta\Delta\delta_{AB}$ value between **1a** and **1b** is 6.5, while the



9



10

value between **2a** and **2b** indicates the larger value of 13.8. This fact may suggest that the difference in the polarization of the exomethylene group between **2a** and **2b** is very large as compared to that between **1a** and **1b**. The reduction of the polarization may be ascribed to the carbonyl group, which withdraws the electron of the exomethylene group of **1a** or **2a** through the cyclopropane ring, as is depicted in the structural formulae, **9** and **10**. This effect also seems to be reflected by the values of δ_A and δ_B of **1a**, **1b**, **2a**, and **2b**. Therefore, the exomethylene group of **2a** is probably electron-deficient as compared to that of **2b**, so **2a** would be inert to the present reaction. Support for the deactivation by the carbonyl group in **2a** may be given by the following observation. The reaction of TCNE with 1,5-dimethyl-6,8-dimethylenetricyclo[3.2.1.0^{2,7}]oct-3-ene (**2c**), which has a π-electron system similar to that of **2a**, was achieved to afford an adduct **6c** in a 30% yield. The structure of **6c** was deduced from the spectral data to have a cyclobutane ring. There are still two possible structures concerning the reaction site for the **6c** adduct.

Experimental

*Reaction of **1a** with TCNE.* A solution of **1a** (160 mg, 1 mmol) and TCNE (192 mg, 1.5 mmol) in 2 cm^3 of acetonitrile was refluxed for 6 h. The reaction mixture was then treated with 100 mg of Norit, and the filtrate was concentrated to give 56 mg (24%) of **5a**: mp 199—200 °C (from benzene): IR (KBr) 2955, 2250, 1710 cm^{-1}; NMR (DMSO-d_6) δ 1.12 (6H, s), 2.24 (2H, d, J=5.0 Hz), 2.72 (2H, d, J=5.0 Hz), 3.37 (2H, s); MS *m/e* 288 (M$^+$). Found: C, 70.56; H, 3.91; N, 19.80%. Calcd for $C_{17}H_{12}ON_4$: C, 70.82; H, 4.20; N, 19.44%.

*Reaction of **1b** with TCNE.* A solution of **1b** (324 mg, 2 mmol) and TCNE (379 mg, 2.4 mmol) in 2 cm^3 of dichloromethane was refluxed for 1 h. The subsequent evaporation of the solvent afforded a brown solid. This solid was dissolved in 5 cm^3 of acetone, followed by the addition of Norit. The Norit was removed by filtration, and then the acetone was evaporated. The residue was recrystallized from benzene to afford 199 mg (37%) of **5b**: mp 150—151 °C; IR (KBr) 3550, 2250 cm^{-1}; NMR (DMSO-d_6) δ 1.15 (6H, s), 1.70 (2H, d, J=5.0 Hz), 1.98 (2H, d, J=5.0 Hz), 3.30 (2H, s), 3.50 (1H, s); MS *m/e* 290 (M$^+$). Found: C, 70.16; H, 4.56; N, 19.35%. Calcd for $C_{17}H_{14}ON_4$: C, 70.33; H, 4.86; N, 19.30%.

*Reaction of **2a** with TCNE.* A solution of **2a** (160 mg, 1 mmol) and TCNE (128 mg, 1 mmol) in dichloromethane (3 cm^3) was refluxed for 31 h. After the removal of the solvent *in vacuo*, the residue was chromatographed on florisil, using benzene as the eluent, to give 144 mg (90%) of the starting material **2a**. A similar reaction in refluxing acetonitrile for 10 h afforded no adduct except **2a** in a 77% yield.

*Reaction of **2b** with TCNE.* A solution of **2b** (162 mg, 1 mmol) and TCNE (154 mg, 1.2 mmol) in 5 cm^3 of acetonitrile was refluxed for 5 h. After the removal of the solvent, the residue was chromatographed on florisil. The elution with benzene–dichloromethene (1/1) afforded 94 mg (31%) of **6b**, which was recrystallized from ethanol: mp 186—187 °C; IR (KBr) 3550, 2250 cm^{-1}; NMR (DMSO-d_6) δ 1.26 (3H, s), 1.41 (3H, s), 1.88 (2H, m), 3.13 (1H, d, J=14.0 Hz), 3.29 (1H, d, J=7.0 Hz), 3.31 (1H, d, J=14.0 Hz), 4.56 (1H, d, J=7.0 Hz), 5.17 (1H, d, J=8.0 Hz), 6.38 (1H, m); MS *m/e* 290 (M$^+$). Found: C, 70.47; H, 4.68; N, 19.00%. Calcd for $C_{17}H_{14}ON_4$: C, 70.33; H, 4.86; N, 19.30%.

*Reaction of **2c** with TCNE.* A solution of **2c**[12] (158 mg, 1 mmol) and TCNE (128 mg, 1 mmol) in acetonitrile (5 cm^3) was refluxed for 7 h. After the removal of the solvent *in vacuo*, the residue was chromatographed on florisil, using benzene as the eluent to give a crystalline solid. This solid was recrystallized from ethanol to give 110 mg (38%) of **6c**: mp 178—179 °C; IR (KBr) 2275, 1650 cm^{-1}; NMR (acetone-d_6) δ 1.16 (3H, s), 1.42 (3H, s), 2.32 (2H, m), 2.66 (1H, d, J=11.0 Hz), 2.75 (1H, d, J=11.0 Hz), 4.78 (1H, s), 4.85 (1H, s), 5.75 (1H, dxd, J=7.0, 2.0 Hz), 6.30 (1H, m); MS *m/e* 286 (M$^+$). Found: C, 75.15; H, 4.71; N, 19.29%. Calcd for $C_{18}H_{14}N_4$: C, 75.50; H, 4.93; N, 19.57%.

*^{13}C-NMR Spectra of **1a,b**, and **2a,b** in $CDCl_3$.* **1a**: 212.3, 149.6, 110.9, 44.8, 44.0, 38.9, 17.2 ppm. **1b**: 152.9, 107.7, 80.6, 42.7, 41.6, 37.8, 20.3 ppm. **2a**: 212.6, 148.3, 132.8, 125.5, 112.4, 52.0, 37.8, 36.9, 30.4, 12.2, 11.7 ppm. **2b**: 154.2, 131.6, 131.1, 104.5, 81.7, 51.4, 37.1, 36.6, 33.1, 20.9, 19.4 ppm.

A New Efficient and Stereoselective Synthesis of Ubiquinone-10

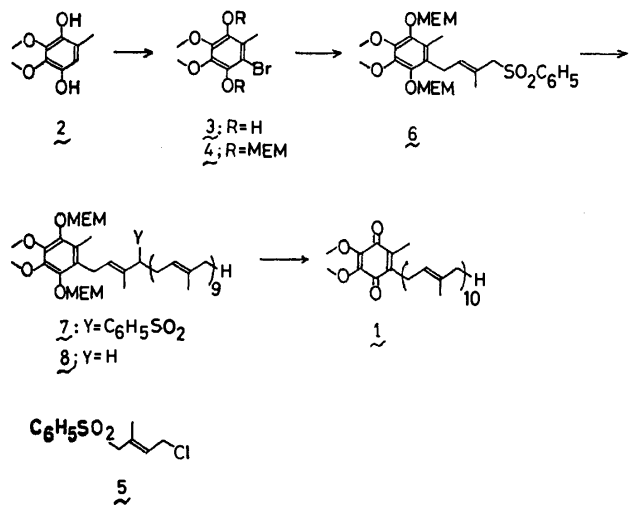
Yoshiji FUJITA,* Michihiro ISHIGURO, Takashi ONISHI, and Takashi NISHIDA
Central Research Laboratories, Kuraray Co. Ltd., Sakazu, Kurashiki, Okayama 710
(Received May 25, 1981)

Synopsis. Coupling reaction of 6-cupro-2,3-dimethoxy-5-methylhydroquinone bis(2-methoxyethoxymethyl) ether with (2*E*)-1-(phenylsulfonyl)-2-methyl-4-chloro-2-butene afforded the sulfone-functionalized prenylhydro quinone (**6**) in 82% yield. Stereoselective synthesis of ubiquinone-10 was achieved by the condensation of **6** and solanesyl bromide (yield 92%), reductive elimination of the sulfone group by sodium–ethyl alcohol in THF (yield 80%), and followed by air oxidation of the hydroquinone.

Recently much attention has been paid to ubiquinone-10 (**1**) owing to its remarkable physiological and clinical activity.[1] Various synthetic routes to **1** have been developed and these involve alkylation of the appropriate quinone or hydroquinone precursor.[2,3] However, the alkylating agent, decaprenyl bromide is obtained as a *Z*/*E* (=3/7) mixture *via* multi-step procedures from solanesol.[4] Thus, its use presents an intrinsic disadvantage for obtaining all-*E* ubiquinone-10. Terao and coworkers have demonstrated an efficient route to **1** using a sulfone-functionalized prenylhydroquinone **6**.[5] However, a simpler procedure for the synthesis of **6** starting with 2,3-dimethoxy-5-methylhydroquinone (**2**) still remains. Previously we have developed a new effective and simple method[6] for the introduction of the sulfone-functionalized isoprene skeleton into aromatic moieties using (2*E*)-1-(phenylsulfonyl)-2-methyl-4-chloro-2-butene (**5**) as a building block which is easily obtainable by the reaction of isoprene and benzenesulfonyl chloride in the presence of copper(I) chloride-triethylamine hydrochloride catalyst.[7] Here we extend the investigation to a stereoselective synthesis of **1** applicable to large scale production.

Alkylation of **3**[8] with 2-methoxyethoxymethyl [MEM] chloride[9] according to the previously reported procedure[8] afforded **4** in 91% yield, and the coupling reaction of **4** with **5** in the presence of copper(I) bromide afforded **6** in 82% yield.[6]

Condensation of **6** and solanesyl bromide in the presence of potassium *t*-butoxide, gave **7** in 92% yield. The next problem is to find the method of selective and economical reduction of the sulfone group. The well established method for this purpose is use of lithium-ethylamine system,[10] but it requires low reaction temperature (*ca.* −70 °C) and the product usually contains *ca.* 10—15% of $\Delta^{3,4}$-isomer. Then the modified Bouveault-Blanc reduction recently reported by Tsuchihashi *et al.*[11] was very attractive as an alternative. *The reaction could be carried out at room temperature by treating* **7** *with sodium (8 equiv.)–ethyl alcohol (12 equiv.) in THF.* The product **8** obtained in 80% yield was found to contain a trace of $\Delta^{3,4}$-isomer, although its amount could not be quantitatively determined because the retention time in high pressure chromatography (HPLC) is same as that of **8**. The mixture was treated with 48% hydrobromic acid catalyst in isopropyl alcohol at 50 °C to remove the protecting group. Neutralization of the reaction mixture with potassium hydroxide in methyl alcohol, followed by air oxidation at room temperature yielded a mixture consisting of 93% of **1** and 7% of $\Delta^{3,4}$-isomer (HPLC). Pure (all *E*)-ubiquinone-10 (mp 50 °C) was obtained by recrystallization of the mixture from ethyl alcohol.



Experimental

Boiling points and melting points are uncorrected. IR spectra were determined on a Digilab FTS-20 C/D spectorometer. NMR spectra were taken with a Varian EM 390 (with hexamethyldisiloxane as an internal standard) and mass spectra with Finnigan 9500 or JEOL JMS-D 300 instruments. HPLC analyses were made with a Waters Associate.

6-(4-Phenylsulfonyl-3-methyl-2-butenyl)-2,3-dimethoxy-5-methylhydroquinone Bis(2-methoxyethoxymethyl) Ether (6). This compound was synthesized in 82% yield according to the procedure reported previously[6] by the reaction of **5** (0.5 mol) and copper derivertive of **4** prepared by treating the Grignard reagent of **4** with copper (I) bromide (0.5 mol). NMR δ (in $CDCl_3$) 1.87 (s, 3H, CH_3), 1.97 (s, 3H, CH_3), *ca.* 3.03—4.00 (m, 24H, $6\times CH_2+4\times CH_3O$), 5.00, 5.07 (s, 4H, $2\times CH_2$), *ca.* 4.90—5.20 (m, 1H, -CH) and *ca.* 7.23—7.80 (m, 5H, arom).

6-(4-Phenylsulfonyl-3,7,11,15,19,23,27,31,35,39-decamethyltetraconta-2,6,10,14,18,22,26,30,34-decaenyl)-2,3-dimethoxy-5-methylhydroquinone Bis(2-methoxyethoxymethyl) Ether (7). Into a solution of **6** (20.5 g; 36 mmol) and solanesyl bromide (purity 95%; 17.5 g; 24 mmol) in THF–DMF (9 : 1; 150 ml) was added potassium *t*-butoxide (22.5 g; 29 mmol) at −20 °C under nitrogen atmosphere. Stirring was continued for 1 h at −20 °C, and further for 1 h at 20 °C. The reaction mixture was poured into saturated ammonium chloride solution and extracted with diisopropyl ether. Evaporation of the solvent and purification of the residue with silica-gel column chromatography (dioxane–hexane=3 : 7) afforded **7** (26.0 g) in 92% yield. IR (neat) 1660, 1450, 1300, 1250, 975, and 875 cm^{-1}. NMR δ (in $CDCl_3$) 1.53, 1.63 (s, 30H, $10\times CH_3$), 1.75 (s, 3H,

CH_3), *ca.* 1.95 (s, 35H, $16\times CH_2+CH_3$), *ca.* 2.68 (m, 2H, CH_2), *ca.* 3.00—4.00 (m, 23H, $4\times CH_3O+5\times CH_2+CH$), 4.97, 5.05 (s, 4H, $2\times CH_2$), 5.07 (broad s, 10H, $10\times CH$) and 7.20—7.80 (m, 5H, arom). Found: C, 73.95; H, 9.34%. Calcd for $C_{73}H_{112}O_{10}S$: C, 74.19; H, 9.55%.

Ubiquinone-10 (1). Into a solution of **7** (118 g; 0.1 mol) in ethyl alcohol (70 ml) and dry THF (350 ml) was added a small pieces of sodium (18.4 g; 0.8 atom) at 10—15 °C under nitrogen stream. After stirring was continued for 12 h, additional 100 ml of ethyl alcohol was dropped to consume the excess sodium, the reaction mixture was poured into saturated ammonium chloride solution and extracted with diisopropyl ether, washed with water, and dried over magnesium sulfate. Evaporation of the solvent, and purification with silica gel column chromatography (dioxane: hexane= 15 : 85) afforded **8** (83.6 g) in 80.4% yield. IR (neat) 2950, 1670, 1390, 1110 and 980 cm^{-1}. NMR δ (in $CDCl_3$) 1.57, 1.61, 1.69 (s, 33H, $11\times CH_3$), 1.97, 2.10 (s, 39H, $18\times CH_2+CH_3$), 3.32 (s, 6H, $2\times CH_3O$), 3.98 (s, 6H, $2\times CH_3O$), *ca.* 3.30—3.95 (m, 10H, $5\times CH_2$), *ca.* 5.05 (broad s, 10H, $10\times CH$) and 5.17 (s, 4H, $2\times CH_2$). Found: C, 77.02; H, 10.18%. Calcd for $C_{67}H_{108}O_8$: C, 77.26; H, 10.45%.

The NMR spectra agreed very closely with that of authentic sample obtained by reacting the Grignard reagent of **4** and (all *E*)decaprenyl bromide except for the signal of δ *ca.* 2.50 (m) which was supposed to originate from $\Delta^{3,4}$-isomer. Quantitative analyses by HPLC resulted in failure because the retention time was same as that of **8**. Deprotection of **8** was carried out with 48% hydrobromic acid (5 ml) in isopropyl alcohol (1500 ml) at 50 °C for 3 h under nitrogen atmosphere. After neutralization with 10% KOH–MeOH, air was bubbled into the reaction system at 25 °C for 3 h. After evaporation of the solvent, the mixture was poured into water, extracted with hexane, and dried over magnesium sulfate. Reaction product was purified with silica gel column chromatography (diisopropyl ether: hexane= 2 : 8) to obtain **1** (67.9 g) quantitaively. HPLC analyses [Lichrosorb SI 60-5; butyl acetate: hexane=6 : 94] showed that the product consisted of 93% of **1** (5.8 min) and 7% of $\Delta^{3,4}$-isomer (5.5 min). Pure all *E*-**1** (58.4 g; yield 77%) was obtained by recrystallization of the mixture from ethyl alcohol (2.5 l) at 5 °C. Mp 50 °C [lit,[5a] mp 48—49 °C].

Upon DNP-aromatic Rule. Effect of Chromophore Exchange on the CD Spectra of *N*-DNP-arylalkylamines

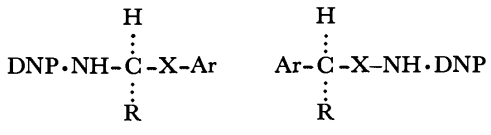
Masao KAWAI* and Ukon NAGAI

Mitsubishi-Kasei Institute of Life Sciences, Minamiooya 11, Machida, Tokyo 194

(Received September 30, 1981)

Synopsis. CD spectra of the analogs of aromatic DNP-α-amino acids and the related *N*-DNP-arylalkylamines, in which the positions of the two chromophoric groups were exchanged with each other, were studied. The analogs, in which the DNP-amino group is separated from the asymmetric carbon, did not show any marked Cotton effect near 400 nm, indicating the importance of direct attachment of the DNP-NH group to the chiral carbon atom for showing the characteristic CD spectra of *N*-DNP-aromatic α-amino acids.

Chiroptical properties of 2,4-dinitrophenyl (DNP) derivatives of aromatic α-amino acids and related compounds were studied extensively[1-6] and DNP-aromatic rule was proposed.[3] According to the rule the sign of $[\theta]_{\approx 400}$ is negative for the compounds of the formula **1**, where Ar and R are an aromatic and a nonaromatic groups, respectively. The symbol X represents a methylene chain, in which a hetero atom or such a group as ester, amide, *etc.* can be included.



1 **2**

(for Ar, R, and X see Table 1)

As an attempt to investigate the basis of the rule, DNP-amino compounds **2**, which are the chromophore exchanged analogs of **1**, were prepared and their CD spectra were compared. Assuming that the Cotton effects are due to the exciton coupling between the two chromophores,[7] essentially same spectra are expected for the compounds having the same relative orientation of the electric transition moments. Thus, if the transition moments of both chromophores have similar orientation relative to the attaching bond and exchange of the chromophoric groups doesn't cause significant change of molecular conformation, similar CD spectra can be expected for each pairs of **1** and **2**.

CD spectra of **1a—g** and **2a—g** measured in methanol are summarized in Table 1. All of the type **1** compounds exhibited distinctly negative Cotton effect around 400 nm reflecting the absolute configuration of the chiral center as stated by DNP-aromatic rule. In all the pairs examined, however, the molecular ellipticities of **2** at 400 nm were much weaker than those of **1**, and apparently no simple relation was found between the sign of the Cotton effect and the absolute configuration. Since the assumption of similar molecular conformation of **1** and **2** seems reasonable, the unexpected low $[\theta]_{\approx 400}$ values of **2** are attributed to the increased freedom of rotation around the DNPNH–C bond in **2** compared to that in **1**, which results in different average relative orientation of the transition moment. Direct attachment of DNP–NH to the asymmetric carbon restricts rotation around that bond as confirmed by the conformational energy calculation of DNP-L-alanine using ECEPP program;[8] *i.e.*, only the values −60°——85° and

2g	p-$NO_2C_6H_4NHCO$	$NHCO_2$-$C(CH_3)_3$	$(CH_2)_3$	−4(420sh),−40(345),0(313),+2(295)

a) sh: Shoulder. The underlined values are those of $[\theta]^{max}$ near 400 nm.

$-145°$——$-165°$ are allowed for ϕ.[9] Thus, much smaller ellipticities of **2** compared to those of **1** were deduced to be due to the loss of restricted rotation of DNP–NH group caused by the presence of intervening achiral chain X between the DNP–NH group and the chiral center.

It is noteworthy that introduction of just one methylene between the DNP–NH and asymmetric carbon of (*S*)-DNP-NHCH(CH_3)Ph ($[\theta]_{406}+16200$) affords **2a** possessing very low $[\theta]_{400}$ value. Insertion of a methylene chain [$(CH_2)_n$, $n=1$—5] between the asymmetric carbon and the phenyl group of L-DNP-NHCH(CO_2H)-Ph doesn't cause marked change of the CD spectra.[1,3]

Experimental

Melting points were uncorrected. Compounds **1a**—**e** and **1g** were described in Ref. 3. The DNP derivatives **1a**, **1f**, **2a**, and **2g** were prepared in enantiomeric form. 2,4-Dinitrophenylations were performed with the procedure of Sanger[10] unless otherwise stated. All the PMR spectra (Hitachi R-24 spectrometer; $CDCl_3$, acetone-d_6, or DMSO-d_6) of the compounds synthesized were consistent with the assigned structures.

(2R)-N-DNP-2-phenylpropylamine (Enantiomer of 2a). Dinitrophenylation of 404 mg (1 mmol) of (2*R*)-2-phenylpropylamine L-malate ($[\alpha]_D^{22}$ +21.1°, *c* 4.1, H_2O)[11] afforded enantiomer of **1a** (195 mg): orange crystals from benzene; mp 89—90 °C. Found: C, 59.30; H, 4.94; N, 13.83%. Calcd for $C_{15}H_{15}N_3O_4$: C, 59.79; H, 5.02; N, 13.95%.

(2R)-N-DNP-O-benzoyl-1-amino-2-propanol (2b). Dinitrophenylation of 112 mg (1 mmol) of (2*R*)-1-amino-2-propanol ($[\alpha]_D^{22}$ −32.8°, *c* 2, CH_3OH)[12] afforded *N*-DNP derivative (80 mg, mp 94—96 °C) as yellow needles from benzene–hexane. This compound was benzoylated with benzoyl chloride–pyridine to give **2b** (73 mg) as yellow powder from benzene: mp 131—132 °C. Found: C, 55.10; H, 4.35; N, 12.10%. Calcd for $C_{16}H_{15}N_3O_6\cdot(1/4)H_2O$: C, 54.94; H, 4.47; N, 12.01%.

(2R)-N¹-DNP-N²-benzoyl-1,2-propanediamine (2c). To a stirred mixture of 0.75 g (2 mmol) of (2*R*)-1,2-propanediamine L-tartrate ($[\alpha]_D^{23}$ +21.2°, *c* 1.63, H_2O) and $NaHCO_3$ (0.6 g, 7 mmol) in H_2O were added 1-fluoro-2,4-dinitrobenzene (0.37 g, 2 mmol) in acetone and then benzoyl chloride (0.47 ml, 4 mmol) and $NaHCO_3$ (1 g, 12 mmol). The main product **2c** was isolated using preparative TLC (SiO_2, developed 7 times with $CHCl_3$) as yellow powder (47 mg), which had slightly higher R_f value than that of the isomer **1c**.[3]

N^δ-DNP-N^α-benzoyl-L-ornithine (2d). N^δ-DNP-N^α-*t*-butoxycarbonyl-L-ornithine (mp 65—72 °C; 100 mg, 0.25 mmol), prepared from N^α-*t*-butoxycarbonyl-L-ornithine, was treated with trifluoroacetic acid and was benzoylated with benzoyl chloride (0.06 cm^3, 0.5 mmol) and NaOH to afford **2d** (78 mg) as yellow powder from methanol–H_2O: mp 181—183 °C. Found: C, 53.36; H, 4.67; N, 13.41%. Calcd for $C_{18}H_{18}N_4O_7\cdot(1/4)H_2O$: C, 53.14; H, 4.58; N, 13.77%.

N^ϵ-DNP-N^α-benzoyl-L-lysine (2e). N^α-Benzoyl-L-lysine (125 mg, 0.5 mmol) was dinitrophenylated to give **2e** (210 mg) as yellow crystals from ethyl acetate–hexane: mp 110—113 °C. Found: C, 54.23; H, 4.89; N, 13.35%. Calcd for $C_{19}H_{20}N_4O_7\cdot(1/4)H_2O$: C, 54.22; H, 4.91; N, 13.31%.

DNP-L-alanylglycine p-Nitroanilide (Enantiomer of 1f). DNP-L-alanine *N*-hydroxysuccinimide ester (mp 148—152 °C; 260 mg, 0.73 mmol) and trifluoroacetate of glycine *p*-nitroanilide, prepared from *t*-butoxycarbonylglycine *p*-nitroanilide (mp 180—181 °C; 200 mg, 0.67 mmol), were allowed to react in DMF to give enantiomer of **1f** (180 mg) as yellow fine needles from acetone: mp 292—295 °C. Found: C, 47.47; H, 3.96; N, 19.27%. Calcd for $C_{17}H_{16}N_6O_8$: C, 47.22; H, 3.73, N, 19.44%.

DNP-glycyl-L-alanine p-Nitroanilide (2f). Coupling reaction of *t*-butoxycarbonylglycine (117 mg, 0.67 mmol) and L-alanine *p*-nitroanilide trifluoroacetate, prepared from *t*-butoxycarbonyl-L-alanine *p*-nitroanilide (mp 130—135 °C; 103 mg, 0.33 mmol), using dicyclohexylcarbodiimide (83 mg, 0.4 mmol) in DMF afforded *t*-butoxycarbonylglycyl-L-alanine *p*-nitroanilide (90 mg) as an oil. This compound was treated with trifluoroacetic acid and dinitrophenylated to give **2f** (90 mg) as yellow crystals from ethyl acetate: mp 224—227 °C (decomp). Found: C, 47.03; H, 3.69; N, 19.23%. Calcd for $C_{17}H_{16}N_6O_8$: C, 47.22; H, 3.73; N, 19.44%.

N^δ-DNP-N^α-t-butoxycarbonyl-L-ornithin p-Nitroanilide (Enantiomer of 2g). N^δ-DNP-N^α-*t*-butoxycarbonyl-L-ornithine (120 mg, 0.3 mmol), *p*-nitroaniline (137 mg, 1 mmol), and dicyclohexylcarbodiimide (103 mg, 0.5 mmol) in THF afforded enantiomer of **2g**, which was purified by preparative TLC (SiO_2, developed 3 times with $CHCl_3$): yellow powder (7 mg); mp 190—200 °C (decomp).

We are grateful to the members of System Engineering Laboratory, Mitsubishi-Kasei Industries Ltd., for elemental analyses and computing facilities.

Reduction of α,β-Unsaturated Carbonyl Compounds to the Saturated Alcohols Using Hydridocarbonyliron Complexes

Masakazu YAMASHITA,* Kanako MIYOSHI, Yasuhiro OKADA, and Rikisaku SUEMITSU
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602
(Received October 2, 1981)

Synopsis. Tetracarbonylhydridoferrate was found to be effective for the selective reduction of α,β-unsaturated carbonyl compounds to the corresponding saturated alcohols. The reactions proceeded stereospecifically and (−)- and (+)-neodihydrocarveol were obtained exclusively from (+)- and (−)-carvone respectively. The reaction mechanism is briefly discussed.

Hydridocarbonyliron complex $[HFe_m(CO)_n^-]$ have been reported to be useful hydrogenating reagents for α,β-unsaturated carbonyl compounds,[1,2] conjugated dienes,[3] and the C=N double bond of *N*-benzylideneaniline,[4] giving saturated carbonyl compounds, monoenes, and *N*-benzylaniline, respectively. But the reduction of a carbonyl group to an alcohol has never been reported.

In the course of our research on the selective reduction of several essential oils with α-enone moiety using tetracarbonylhydridoferrate $[HFe(CO)_4^-]$ (**1**), we found unexpectedly that **1** in tetrahydrofuran was effective for the selective reduction of carbonyl groups to the corresponding alcohols. In this paper, we wish to report about these reactions.

Experimental

Infrared spectra were recorded on a Hitachi 260-10 Infrared Spectrophotometer, NMR spectra were measured on a Hitachi R-600 FT-NMR Spectrophotometer, and mass spectra were measured on a RM-50 Hitachi GC-MS. Gas chromatography was carried out on a Yanagimoto G-180 Model equipped with a glass column packed with polyethyleneglycol 20 M† (10%) on Chromosorb (0.3 cmϕ × 1.5 m) and a Yanagimoto G-8 Model equipped with a stainless column packed with Silicone Gum SE-30 (10%) on Chromosorb (0.3 cmϕ × 2 m). Optical rotations were measured on a Union High Sensibility Specific Rotary Meter PM-71.

Materials. Tetrahydrofuran (THF) was distilled over lithium aluminum hydride under argon just before use. Pentacarbonyliron and deuterium oxide (Merck) were used without further purification. The following organic compounds, (+)- and (−)- carvone, α- and β-ionone, diethyl ketone, benzylideneacetone and triethylenediamine, were commercial products of the highest available purity. Piperitenone was supplied from Ogawa and Co., Ltd. All reduction experiments were carried out under argon atmosphere.

Preparation of 1 in THF. To the THF solution (40 ml) of triethylenediamine (3.7 g, 33 mmol), deionized water (0.59 ml, 33 mmol) or D_2O (0.66 ml, 33 mmol) was injected by syringe and the mixture was stirred for 30 min at 60 °C under argon atmosphere. Then, pentacarbonyliron (1.5 ml, 11 mmol) was injected and the reaction mixture was stirred for further 1 h at the same reaction conditions. The solution was used for the next reaction *in situ*.[5]

Representative Reduction of α-Ionone Using 1. To the solution of **1** (22 mmol) in THF, α-ionone (1.13 ml, 5.5 mmol) was injected, and the mixture was stirred at 60 °C under argon atmosphere till the reaction was completed perfectly. After the air oxidation of the solution at room temperature for 1 d, iron oxide was centrifuged. And THF was removed with a rotary evaporator. The residue was purified by column or thin layer chromatography (silica gel, hexane: ethyl acetate= 4 : 1). The product was identified as 4-(2,6,6-trimethyl-2-cyclohexenyl)-2-butanol by means of IR, NMR, MS, and GLC. Yield >98% (GLC).

4-(2,6,6,-Trimethyl-2-cyclohexenyl)-2-butanol. IR (cm^{-1}): 3300, 2900, 1440, 1110; MS (*m/e*); 196 (M^+); NMR ($CDCl_3$) (δ): 0.88 (6H, d, $C(CH_3)_2$), 1.24 (3H, s, $=C-CH_3$). 1.44 (3H, s, $O-C-CH_3$), 0.98—2.2 (8H, m), 3.6—4.0 (1H, m), 5.25—5.6 (1H, m).

4-(2,6,6,-Trimethyl-1-cyclohexenyl)-2-butanol. IR (cm^{-1}): 3350, 2900, 1460, 1120; MS (*m/e*): 196 (M^+); NMR ($CDCl_3$) (δ): 0.97 (6H, s, $C(CH_3)_2$), 1.13 (2H, s, $=CH_2-$), 1.23 (2H, s, $-CH_2-$), 1.59 (3H, s, $O-C-CH_3$), 1.1—2.0 (6H, m), 3.4—3.92 (1H, m).

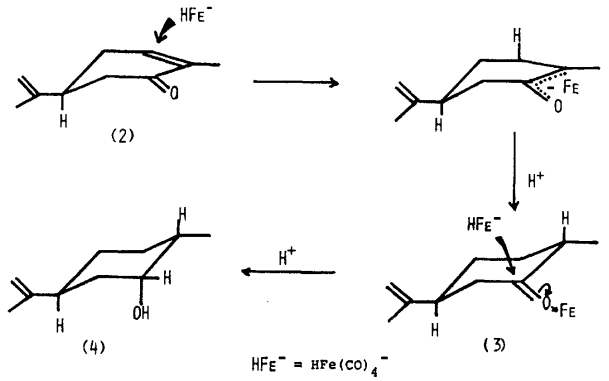
(−)-Neodihydrocarveol. IR (cm^{-1}): 3400, 880; MS (*m/e*): 154 (M^+); NMR ($CDCl_3$) (δ): 0.95 (3H, d, $-CH_3$), 1.05—1.65 (8H, m), 1.72 (3H, s, $=C-CH_3$), 3.2—3.7 (1H, m), 3.58 (1H, s), 4.76 (2H, s).

Results and Discussion

For example, **1** in THF generated *in situ* reacted with (+)-carvone at 60 °C for 9 d under argon atmosphere to give (−)-neodihydrocarveol in almost quantitative yield. This shows that **1** in THF is an efficient reductant of α,β-unsaturated carbonyl compounds to the corresponding saturated alcohols (Eq. 1), although **1** in

$$R^1-\underset{\underset{O}{\|}}{C}-CH=CH-R^2 \xrightarrow[THF]{HFe(CO)_4^- (1)} R^1-\underset{\underset{OH}{|}}{\overset{\overset{H}{|}}{C}}-CH_2-CH_2-R^2 \quad (1)$$

ethanol gives only (−)-dihydrocarvone from (+)-carvone. Other results are summarized in Table 1. As shown in Table 1, the compounds with α-enone moiety were reduced to the corresponding saturated alcohols in high yields. Piperitenone which has two carbon–carbon double bonds of α-enone moiety was also reduced to the corresponding menthol using 6 equiva-



Scheme 1.

† 1 M = 1 mol dm^{-3}.

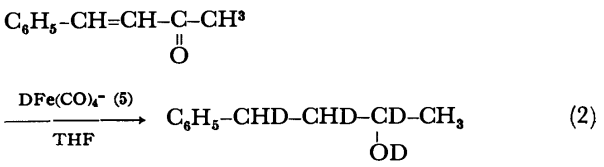
a) Yields were determined by GLC. b) $[\alpha]_D^{20}$ +49.8° (*c* 9.66, EtOH). c) $[\alpha]_D^{20}$ −13.5° (*c* 1.01, Et OH). d) $[\alpha]_D^{20}$ −60.1° (*c* 9.65, EtOH). e) $[\alpha]_D^{20}$ +21.4° (*c* 1.03, EtOH).

lents of **1**.

As to the stereochemistry, it was found that (+)- and (−)-carvone reacted with **1** to give exclusively (−)- and (+)-neodihydrocarveol respectively, but the corresponding diastereomers such as isodihydrocarveol, dihydrocarveol, and neoisodihydrocarveol were not produced, showing that these reactions proceeded stereospecifically.

The reaction mechanism was assumed as follows (Scheme 1). First, **1** attacked the carbon-carbon double bond of α,β-unsaturated carbonyl moiety of (+)-carvone (**2**) from the sterically less hindered side to form dihydrocarvone (**3**),[6] which was detected in the reaction mixture by means of GLC. Subsequently, **3** is reduced selectively to give (−)-neodihydrocarveol (**4**). However, although it is still uncertain, it seems that **3** exists as a complex with carbonyliron and that the carbonyl group is to some extent activated, because saturated ketones such as diethyl ketone did not react with **1** in THF.



(2)

Besides, the introduction of deuterium was tried using deuterium oxide (D_2O) instead of water (H_2O) for the preparation of tetracarbonyldeuterioferrate (**5**). The reaction of **5** with benzylideneacetone in THF at 60 °C for 3 d gave the corresponding deuterated alcohol, which was identified by means of IR, NMR, and MS. The similar introduction of deuterium was also noticed in the case of the reaction with (+)- and (−)-carvone.

The authors are grateful to Mr. Y. Enomoto of Ogawa and Co., Ltd. for providing of piperitenone.

Carbon-Carbon Bond Formation by the Use of Chloroiodomethane as a C_1 Unit. IV.[1] The Mannich Reaction of Ketones by Means of Dihalomethane and Secondary Amine[2]

Sotaro MIYANO,* Akira MORI, Hiroshi HOKARI, Katsuaki OHTA, and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

(Received October 2, 1981)

Synopsis. Treatment of ketones with dihalomethane (CH_2Br_2, CH_2ClI, and CH_2I_2) in the presence of secondary amine, preferably pyrrolidine, gave the corresponding Mannich base in varing yields depending on the substrate and/or combination of the reagents.

In previous papers[3] we have reported that chloroiodomethane reacts in the sense of I–CH_2Cl, in either homolytic or heterolytic fashion, enabling the introduction of chloromethyl moiety into various substrates. In a study to extend the scope and utility of the transformation by the use of CH_2ClI as a C_1 unit, we have for some time been trying to chloromethylate active methylene compounds with the aid of various base catalysts.

Although such attempts have not yet been realized,[4] it has been found that α-methylene protons of ketones (**1**) can be replaced with (dialkylamino)methyl moiety by a combination of dihalomethane (**2**) and secondary amine (**3**) (Eq. 1). The important features of the amino ketone products, the Mannich base, have been well documented for a long time,[5] and here we wish to report the results of the aminomethylation reaction.

$$\underset{\mathbf{1}}{R^1\text{–}\overset{\overset{O}{\|}}{C}\text{–}CHR^2R^3} + \underset{\mathbf{2}}{CH_2XY} \xrightarrow[(-HX,\ -HY)]{2R_2NH\ \mathbf{3}} \xrightarrow{NaOH/H_2O} \underset{\mathbf{4}}{R^1\text{–}\overset{\overset{O}{\|}}{C}\text{–}\underset{\underset{CH_2NR_2}{|}}{CR^2R^3}} \quad (1)$$

(X, Y = Cl, I; Br, Br; I, I)

The reaction was simply carried out by adding amine (**3**) to a stirred solution of the substrate ketone (**1**) and CH_2XY (**2**) in THF, followed by stirring the mixture under the conditions indicated in Table 1. Typical results obtained are as follows: 1) Among secondary amines examined, *i.e.* pyrrolidine, Et_2NH, and *i*-Pr_2NH, the first gave the best results while the last was almost ineffective. Attempted reactions of propiophenone with **2** in the presence of tertiary amine such as Et_3N or 1,4-diazabicyclo[2.2.2]octane resulted in the quaternization of the amine by the halide leaving the ketone almost intact. 2) The choice of the dihalide (**2**) should depend on the substrate **1**. For reactive ketones such as cyclohexanone and acetophenone, CH_2ClI gave better results than CH_2I_2; the latter yielded larger amounts of intractable tarry materials with the expense of **4**. On the other hand, CH_2I_2 was preferred for the less reactive ketones such as propiophenone and diethyl ketone. Dibromomethane showed intermediate character, and could be applicable to both types of ketones. 3) Heptanal was also aminomethylated in a low yield, while esters (ethyl butyrate, methyl phenylacetate, *etc.*) were recovered unchanged.

a) **1**, *ca.* 80 mmol; **1** : **2** : **3** ≈ 1 : 1.2 : 2.4 (molar ratio); THF 100 ml; under reflux. b) A, pyrrolidine (*c*-$(CH_2)_4$NH); B, Et_2NH; C, *i*-Pr_2NH. c) Isolated yields. Figures in parentheses refer to the crude products (see Experimental). d) Resulted tarry material with complete consumption of the substrate. e) Only *i*-Pr–CO-CH_2-  was detected. f) Room temp.

As is encountered in literatures,[6] attempts to isolate pure sample by distillation sometimes suffered from poor yields of **4**, probably due to thermal instability of the Mannich base. Although the conventional Mannich reaction with formaldehyde–R_2NH in the presence of acid catalyst,[5] or recent version by means of preformed methyleneiminium reagents,[7] has widely been utilized for the synthesis of amino ketones, the transformation described here may have some synthetic utility because of its operational simplicity and reasonable yields for certain ketone substrates.

The aminomethylation depicted in Eq. 1 seems to proceed *via* initial formation of methyleneiminium species **5** which is formed according to Eq. 2; upon

mixing pyrrolidine with CH_2ClI in DMSO-d_6, a new ^1H NMR absorption signal appeared at δ 8.8 (broad), which may be assigned to methylene protons of the iminium species,[8] and the strength of which was reduced gradually on addition of propiophenone. The Mannich reaction of ketones by means of preformed methyleneiminium species such as $Me_2\overset{+}{N}=CH_2,\bar{X}$ has well been precedented in the last decade.[10]

$$R_2NH + CH_2XY \xrightarrow[-HY]{R_2NH} R_2N\text{-}CH_2X \longleftrightarrow \underset{\mathbf{5}}{R_2\overset{+}{N}=CH_2,\bar{X}} \quad (2)$$

Experimental

Materials and measurements were the same as those described in a previous paper.[1]

The aminomethylation reactions were conducted in essentially the same manner under nitrogen, and the reaction of diethyl ketone is illustrative. To a water-chilled, stirred solution of diethyl ketone (7.13 g, 82.8 mmol) and CH_2Br_2 (16.5 g, 94.9 mmol) in 90 ml of THF was added dropwise 13.7 g (193 mmol) of pyrrolidine in 10 ml THF; the mixture was heated under reflux for 3 h. The cooled reaction mixture was diluted with 100 ml of 2 M HCl.† Non-basic components were extracted with portions of cyclohexane. The aqueous phase was made alkaline with 10% NaOH, and basic products were extracted with ether (100 ml×3), washed successively with 1 M Na_2CO_3, brine, and water, and then dried over $MgSO_4$. Evaporation *in vacuo* of the solvents, unchanged pyrrolidine, and di(1-pyrrolidinyl)methane, which was formed by the reaction of pyrrolidine and CH_2Br_2, left 8.60 g of the crude Mannich base (61% yield). Trap-to-trap distillation of the residue gave a middle cut boiling at 65—70 °C/6 mmHg†† (**4e**, 7.45 g, 53% yield); IR (neat) 2780 and 1710 cm^{-1}; ^1H NMR (CCl_4, hexamethyldisiloxane) δ 0.7—1.2 (6H, 2× $-CH_3$), 1.4—2.0 (4H, $-CH_2-(C\underline{H}_2)_2-CH_2-$, m), and 2.0—2.8 (9H, m). Weathering of H_3BO_3-ZnO Bond for Forming Glass Fiber Reinforced Composite

Yoshikazu UTSUMI,* Tadaki MURAKAMI, and Isao ISHII
Mitsubishi Electric Corporation, 80 Nakano, Minami-shimizu, Amagasaki, Hyogo 661
(Received August 14, 1981)

Synopsis. H_3BO_3–ZnO bond stored in humidity above 75% causes the bending strength of a fiber reinforced composite to decrease. The lowering behavior corresponds to formation of $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ and to a decrease of H_3BO_3. The weathering of the bond is attributed to the decreasing of H_3BO_3, which becomes liquid during hot pressing.

A powder mixture of H_3BO_3 and ZnO can be used as a bond for forming a glass fiber reinforced composite with hot pressing and subsequent heat treatment.[1] Hot pressing at 170 °C makes the powder mixture melt and makes it penetrate into the spaces of the reinforcing elements. Heat treatment advances the reaction in the bond and makes the composite durable. However, long term storage of the mixture sometimes decreases its bonding power. The decreasing behavior resembles the weathering of portland cement.

This study deals with the cause of weathering in this H_3BO_3–ZnO bond.

Experimental

The bond was prepared with a powder mixture in 3 : 1 mole ratio of H_3BO_3 and ZnO. It was stored in various humidity atmospheres at 30 °C for 7 d. Humidities were kept constant with water vapor of saturated aqueous solutions of salts, which were KNO_3, KCl, NaCl, and $Mg(NO_3)_2 \cdot 6H_2O$ for 92, 84, 75, and 52%, and with drying silica gel for 0%. A composite was prepared from the stored powder and glass fiber mats with the composition of 40 wt% and 60 wt%. To form a composite, the powder layer and the glass layer were laminated one after the other and were pressed under 100 kg cm^{-2} at 170 °C. The pressure was sometimes taken away to eliminate excess water produced by dehydration of H_3BO_3. The composites were used for testing the bending strength. On the other hand, the crystal phases and their behavior in the stored bond were examined by X-ray diffraction and differential thermal analysis.

Results and Discussion

In forming a composite, the bonds which were stored in low humidity penetrated fully into the spaces of glass fiber mats, whereas those which were stored in high humidity penetrated only partly into the spaces. The test pieces for the bending strength were taken from a part of a composite into which the bond had penetrated. Figure 1 shows the relationship between bending strength of composites and storing humidity of bond. As shown in Fig. 1, there was no significant difference between the bending strength of a composite which was formed by the bond stored in 0% humidity and the bending strength of one which was formed by the bond immediately after mixing. Moreover, the bending strength was independent of storing humidity up to 75%. However, the storage of the bond in humidity above

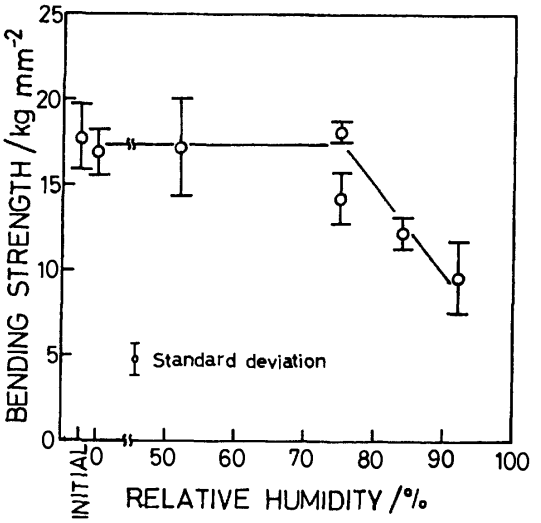

Fig. 1. Bending strength of composite formed with bond stored in various humidity.

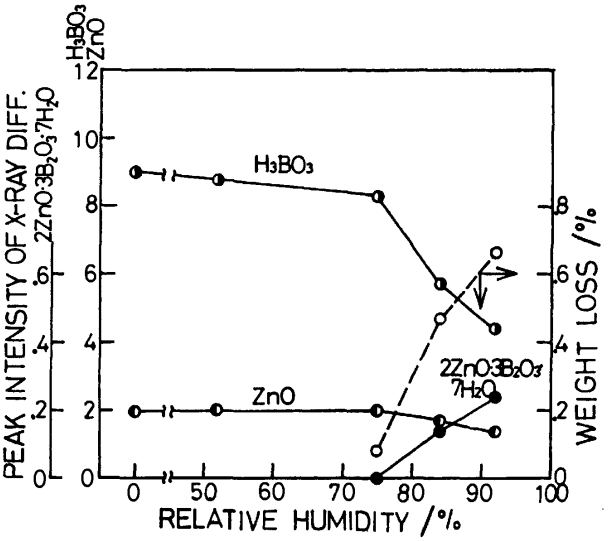

Fig. 2. Peak intensity of X-ray diffraction of crystal phases in bond stored in various humidity.

75% caused the bending strength to decrease.

The X-ray diffraction pattern of the bond immediately after mixing showed peaks of H_3BO_3 and ZnO crystals. However, the patterns showed that the bond stored in humid atmosphere contained not only H_3BO_3 and ZnO but also $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ crystal.[2,3]

The variation in each one of the diffraction peaks of H_3BO_3, ZnO, and $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ crystals is plotted as a function of storing humidity in Fig. 2. In humidity above 75%, H_3BO_3 was decreased in the bond and a new crystal of $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ was produced instead of H_3BO_3. The starting humidity of the decrease

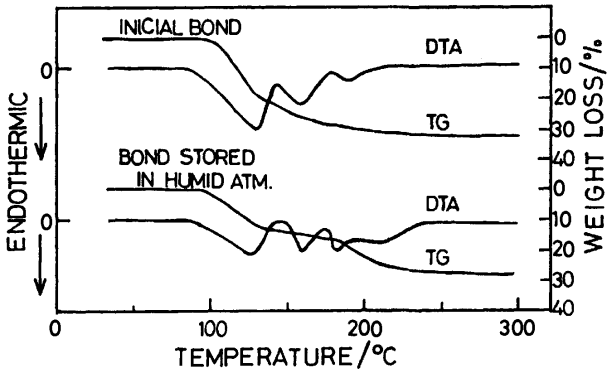

Fig. 3. DTA and TG of initial bond and of bond stored in 84% humidity.

or the production agrees with that of bending strength. Figure 2 also shows weight loss from the initial bond. The crystal $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ contains less water than the composition of initial bond, that is, $2ZnO \cdot 6H_3BO_3 = 2ZnO \cdot 3B_2O_3 \cdot 9H_2O$. The weight loss in Fig. 2 seems mainly to be water loss caused by production of the new crystal and partly to be H_3BO_3 loss due to its sublimation in humid atmosphere.[4]

Differential themal analysis of the bond is shown in Fig. 3. A broad peak appears from about 170 °C to 240 °C, omitting the three peaks of H_3BO_3 dehydration; this peak corresponds to dehydration of $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ crystal. The crystal became amorphous as a result of its dehydration. It seems to behave as a filler in a composite, because its dehydration temperature is rather higher than the hot pressing temperature. However, its production may somewhat obstruct the flow of the bonding liquid under hot pressing by bridging between ZnO particles. On the other hand, the decrease of H_3BO_3 causes the bonding liquid to decrease under hot pressing. H_3BO_3 considerably decreased as humidity increased above 75%, as shown in Fig. 2. Therefore the decreasing behavior of bending strength is attributed to H_3BO_3 decreasing in the bond due to the production of $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ crystals.

It is concluded that the decrease of H_3BO_3 in humid air gives rise to the weathering of the bond in the system $H_3BO_3 \cdot ZnO$.

Conformational Change of Delta-chymotrypsin Caused by Sodium Dodecyl Sulfate as Studied by Stopped-flow Circular Dichroic Method

Kunio TAKEDA

Department of Applied-Chemistry, Faculty of Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700

(Received April 8, 1981)

The conformational change of delta-chymotrypsin was studied in a sodium dodecyl sulfate (SDS) solution containing 3.33 mmol/dm^3 NaH_2PO_4 and 3.56 mmol/dm^3 Na_2HPO_4 (pH 7.0, μ=0.014) by means of the circular dichroism (CD) and absorbance stopped-flow methods. The protein adopts a conformation with a higher helix content than the native state upon the addition of SDS. The rate of the conformational change strongly depends on the SDS concentration. The corresponding rate constant sharply increases in the range of 5—12 mmol/dm^3 SDS, indicating that the higher the helix content, the faster the coil to α-helix transition. The nature of the conformational change was examined by parallel measurements of the CD, the difference spectra, and the binding isotherm. As a result, it was concluded that, at a certain SDS concentration above 5 mmol/dm^3, the native conformation of the protein is directly transformed to another conformation without passing through any intermediate one which may be caused when the SDS concentration is below the one mentioned above.

Sodium dodecyl sulfate (SDS) is now widely used in the purification and characterization of proteins.[1] The interactions of surfactants with proteins *per se* are interesting enough, and so have been extensively investigated.[2,3] However, the kinetic aspects of the interactions have been little studied, although many kinetic studies have been done on the conformational changes of proteins induced by other agents.[4] As is well known, several proteins clearly adopt conformations with high helix contents than their native states upon the addition of anionic surfactants such as SDS.[5,6] This is in marked contrast with the denaturation processes induced by the other denaturants. In this work, delta-chymotrypsin has been used as an example of a protein which can be converted in part to the α-helical conformation. As is also well known, the conformation of protein in an aqueous solution can be more clearly detected by the circular dichroism (CD) measurements. Although a few CD stopped-flow studies of conformational changes of proteins have recently been carried out, most of them have been done in the visible and near-ultraviolet regions.[7–11] Since the ellipticity in the far-ultraviolet region reflects the change of the protein backbone structure, such kinetic studies should be done in this region as well. The present author wishes to report on the SDS-induced conformational change of the protein followed by means of the far-ultraviolet CD and the near-ultraviolet absorbance stopped-flow methods. The main purpose of this paper is to discuss the characteristic process of the conformational change of the protein in the presence of the surfactant.

Experimental

Crystalline delta-chymotrypsin from beef pancreas (MW: 25400) was obtained from Miles Laboratories. The SDS and the phosphate buffer used have been described in a previous paper.[12]

The CD measurements were carried out with a JASCO J-500A spectropolarimeter equipped with a JASCO DP-501 data processor. The details of CD and CD stopped-flow measurements have been stated elsewhere.[13] The absorbance stopped-flow measurements were made with a rapid mixer of a stopped-flow apparatus, RA-401 of Union Giken Co., combined with a single-beam spectrophotometer, Unispec A of the same company, the time constant of which was modified to be less than 1.0×10^{-3} s. The static measurements of the ultraviolet absorbance were made with a Hitachi double-beam spectrophotometer, Model 200-10.

The binding isotherm of SDS to the protein was obtained by the use of gel chromatography, as has been reported before.[12]

Throughout the experiments, the protein concentration was constant, 1.0×10^{-5} M (as a concentration unit, 1 M= 1 mol/dm^3 was used), and its solution was used within 6 hours after preparation. The spectra of the CD and the absorbance of the protein were measured within 5 min after mixing the solutions of the protein with those of SDS.

Results and Discussion

The SDS-induced conformational change of delta-chymotrypsin was studied primarily by observing the changes in the CD spectra in the far-ultraviolet region in order to make clear the changes of the backbone structure of the protein polypeptide. Figure 1 shows the typical CD spectra of the protein in the absence (I) and in the presence (II) of 20 mM SDS and the difference CD spectrum(III) between them. The difference CD spectrum clearly indicates an increase in the α-helix content upon the addition of SDS, as in the case of alpha-chymotrypsin.[6] The SDS concentration dependence of the residue ellipticity at 206 nm, $[\theta]_{206}$, is shown in Fig. 2. The value of $[\theta]_{206}$ sharply increases at first and then attains a plateau at about 12 mM SDS, indicating that the helix content of the protein increases in such a concentration range of SDS.

Figure 3 shows the effect of added SDS on the absorbance spectra of delta-chymotrypsin. It is well known that the denaturation blue shift observed here is attributable to the exposure of chromophores, such as tryptophan and tyrosine, to an aqueous environment (the protein contains 9 tryptophan residues and 3 tyrosine ones). The difference spectrum of absorbance shows a blue shift and has a positive peak around 255 nm and a major negative peak at 295 nm. The SDS-induced difference absorption coefficient at 295 nm, $\Delta\varepsilon_{295}$, is plotted against SDS in Fig. 2. The

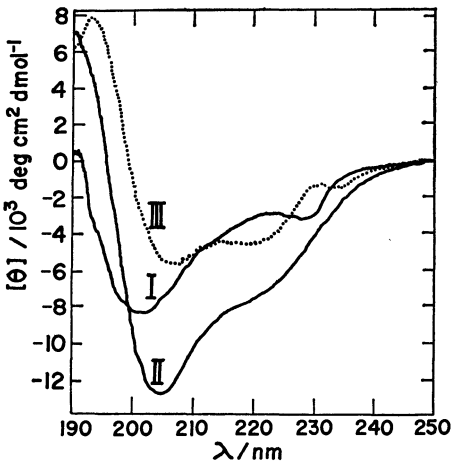

Fig. 1. Typical CD spectra of delta-chymotrypsin in the absence (curve I) and the presence (curve II) of 20 mM SDS and the difference CD spectrum between them (curve III) at 25 °C.
The difference spectrum was directly obtained by the use of the data processor. The concentration of the protein was 1.0×10^{-5} M. The thickness of cell used was 1.0 mm. These spectra are averaged over 8 repetitions.

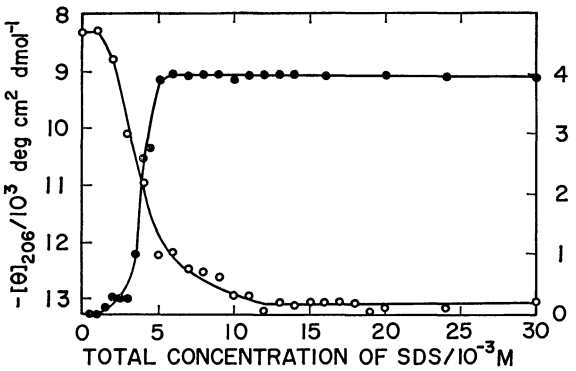

Fig. 2. The effects of total SDS concentration on the residue ellipticity at 206 nm, $[\theta]_{206}$ (○) and the difference absorption coefficient at 295 nm, $\Delta\varepsilon_{295}$ (●) at 25 °C.
The both values were obtained on the basis of the results at 1.0×10^{-5} M delta-chymotrypsin.

value of $\Delta\varepsilon_{295}$ increases just like that of $[\theta]_{206}$, but flattens out at a lower SDS concentration, 5 mM. Their importance will be referred to later in discussion of a reaction process and a transition state of the conformational change.

It is characteristic of the conformational change of a protein in a surfactant solution that large amounts of surfactant molecules bind to the protein. The binding isotherm of SDS to delta-chymotrypsin, as obtained by the gel chromatography, is shown in Fig. 4. The amounts of SDS bound to the protein (the protein concentration $=1.0\times10^{-5}$ M) are also plotted against the total SDS concentration (solid curve) in order to compare them with the total SDS concentration dependences of $[\theta]_{206}$ and $\Delta\varepsilon_{295}$. The amounts of SDS bound to the protein increase discontinuously at 1—2 and 4—5 mM of total SDS, and finally reach

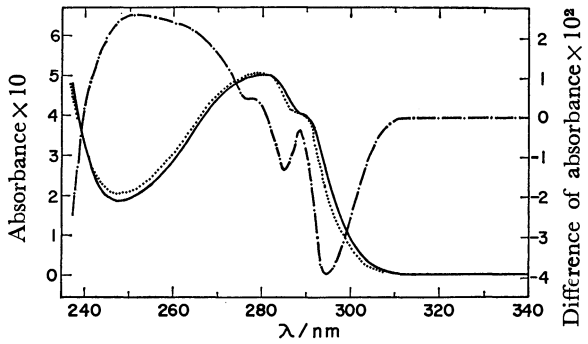

Fig. 3. Typical absorbance spectra of delta-chymotrypsin in the absence (solid curve) and the presence (dotted-curve) of 20 mM SDS and the difference spectrum of them (dot-dashed curve) at 25 °C.
The concentration of the protein was 1.0×10^{-5} M.

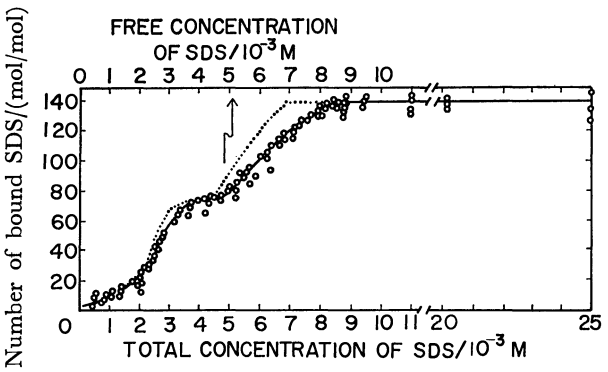

Fig. 4. Binding curve of SDS to delta-chymotrypsin *vs.* total concentration of SDS at 25 °C.
The dotted line indicates the binding isotherm plotted against free concentration of SDS. The total concentration of SDS was determined by the addition of the molar concentration of bound SDS per 1.0×10^{-5} M protein to its free concentration on the basis of the plot of number of bound SDS (mol/mol) *vs.* its free concentration.

a maximum, 140 mol of SDS per mole of the protein, in the vicinity of 8.5 mM SDS. This trend is the same as in the case of the system of SDS and bovine serum albumin.[12] We can approximately divide the binding curve into two stages, that is, the first binding stage of 70 mol of SDS per mole of the protein below 5 mM SDS and the second binding stage of a further 70 mol of SDS. In comparing the stepwise binding curve in Fig. 4 with the SDS concentration dependences of $[\theta]_{206}$ and $\Delta\varepsilon_{295}$, the exposure of chromophores to an aqueous environment completes in the first binding stage and the helix content also predominantly increases in this stage. The second binding of 70 mol of SDS can occur without a large-scale conformational change of the polypeptide chain.[14]

The CD stopped-flow measurements were carried out at 192 and 206 nm, where the positive and the negative maxima appeared in the difference spectrum of CD. The representative time courses of the conformational change are presented in Fig. 5. As is to be expected from the CD spectra in Fig. 1, the

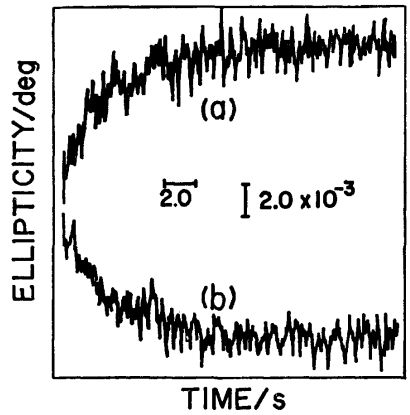

Fig. 5. Representative time courses of ellipticity changes at 192 (a) and 206 nm (b) at 25 °C.
The traces (a) and (b) are the averages of 32 and 2 repetitions, respectively. The final concentrations of SDS and delta-chymotrypsin were 20 mM and 1.0×10^{-5} M, respectively.

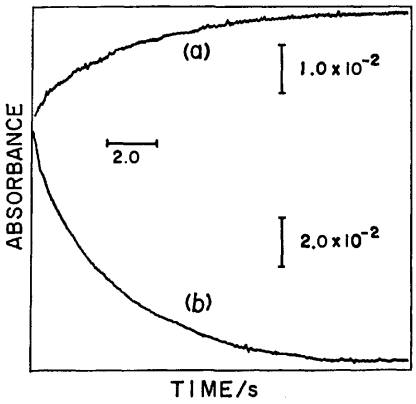

Fig. 6. Representative time courses of absorbance changes at 255 (a) and 295 nm (b) at 25 °C.
The experimental conditions were identical with those in Fig. 5.

ellipticity at 192 nm changed from the negative ellipticity to the positive one, while the negative ellipticity at 206 nm increased with time. The observed process, therefore, seems to correspond to an increase in the helix content. The absorbance stopped-flow measurements were made at 255 and 295 nm. The representative time courses are shown in Fig. 6. The directions of absorbance changes with time are in accordance with those expected from the difference spectrum of absorbance, as in the case of the CD stopped-flow measurements.

By the analysis of the curves shown in Figs. 5 and 6, the first-order rate constant, k, of the SDS-induced conformational change of the protein was obtained. The analysis was made by the ordinary treatment.[13] The magnitude of k is of the same order as those of the thermal denaturations of alpha-chymotrypsin[15] and lysozyme[16] and the denaturation of lysozyme by guanidine,[17] although the conformational changes caused by these agents are essentially different from that caused by SDS by which the helix content increases. The SDS concentration dependence of k is

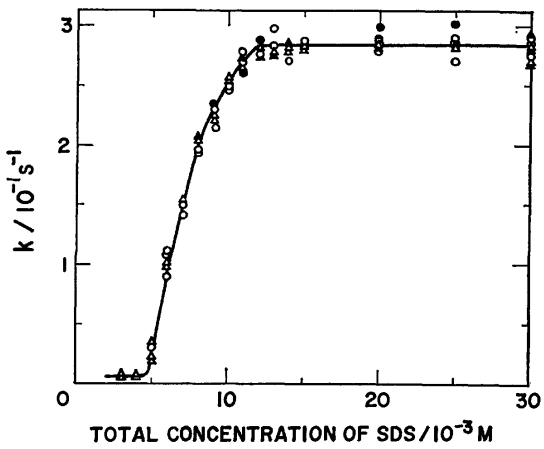

Fig. 7. Plot of rate constant, k *vs.* total concentration of SDS at 25 °C.
The values of k were obtained from time courses of ellipticity changes at 195 (●) and 206 nm (○), and those of absorbance changes at 255 (▲) and 295 nm (△).

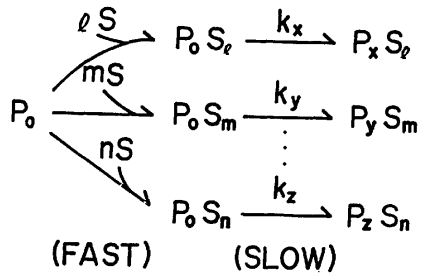
presented in Fig. 7. It is noticeable that the same values of k are obtained, irrespective of the method of detection, and that the behavior of chromophores is useful in following the conformational changes of the protein. The rate constant, k, begins to increase around 5 mM, reaching a constant value around 12 mM SDS. The sharp increase of the rate constant in the range of 5—12 mM SDS indicates that the higher the helix content, the faster the rate of coil to α-helix transition. The rate constant, k, is independent of the SDS concentration in the range below 5 mM,[18] where the values of $[\theta]_{206}$ and $\Delta\varepsilon_{295}$ change as is shown in Fig. 2. Thus, the discussion given below will be limited to the conformational change in the range of SDS concentrations above 5 mM.

It is expected that the binding ratio of surfactants to protein determines the conformation of the surfactant-protein complex. In reference to the results of the interactions of bovine serum albumin with some ionic surfactants,[3,19–24] there may be some limited particular binding ratios (surfactants/protein) in the present system. Therefore, the following process may be easily assumed for the complex formation and the accompanying conformational change:

$$P_0 \xrightarrow{a_1 S} \cdots \rightarrow P_x S_l \xrightarrow{a_2 S} P_y S_m \rightarrow \cdots \xrightarrow{a_i S} P_z S_n \qquad (1)$$

where P_0 is the native protein, S is the surfactant molecule, a_i is a particular number, and $\cdots P_xS_l$ and $P_yS_m \cdots P_zS_n$ denote the complexes (the helix content increases in the order $\cdots$ x, y, $\cdots$ z; the binding number of surfactants, $70 \leqq l < m < \cdots < n$). The reaction model (1) indicates that the longest time is required for the transition from P_0 to P_zS_n with the highest helix content. However, the transition rate becomes faster as the final helix content increases as seen in Fig. 7. On the other hand, with reference to many results of micellization kinetics,[25] the binding rate of

SDS to a protein seems to be rapid compared to the time range of the conformational change, since it should be of approximately the same order as the time of the association of surfactant molecules in a micelle formation. This suggests that the protein cannot adopt various different conformations as reaction intermediates in the presence of a certain quantity of SDS, because they would rapidly bind to the protein, causing the transition only to a particular conformation of the protein. The features of the conformational change may be drawn schematically as follows,



(2)

where k_x, k_y, and k_z denote rate constants of the corresponding processes ($\cdots k_x < k_y < \cdots < k_z$). This reaction model means that the binding of the surfactants completes before the conformational change of the native protein is completed. The conformation of the protein polypeptide must change together with many of the surfactant molecules bound to it. Through the particular conformational change of the protein polypeptide, the bound surfactants must be rearranged; that is, they may be forced to move from the initial binding sites to more favorable ones. Through this process, the bulky hydrophobic groups of the surfactant should come into maximum contact with the hydrophobic parts of the polypeptide, reconciling with the structure formation to reach a minimal free energy. Reaction 2 seems to be more suitable as an explanation of the present kinetic results, although Reaction 1 may be favorable for an understanding of the growth of the complex. Reaction 2 is also reminiscent of conformational changes of poly(L-lysine) in an octyl sulfate solution: the polypeptide, which adopts a disordered structure in the absence of the surfactant, takes an α-helix and a β-structure at low and high concentrations of the surfactant respectively, but the disordered structure of the polypeptide directly turns to the β-structure.[13] The author considers that, at a certain SDS concentration above 5 mM, the native conformation of the protein is directly transformed into another conformation without passing through any intermediate conformation such as may be caused when the SDS concentration is below the one mentioned above.

The temperature dependence of k was examined at 20 mM SDS in order to evaluate the activation parameters of the corresponding conformational change. Table 1 shows the temperature dependence of k and the activation parameters, ΔH^* and ΔS^*, of the process evaluated in a usual manner.[26] In the case of the conformational change induced by the surfactant, the entropic contributions must be due not only to the folding and unfolding of the polypeptide chain, but also to the rearrangement of the surfactant molecules bound to the polypeptide and the solvent-ordering process around the hydrophobic groups of the surfactant molecule exposed to an aqueous environment. The latter two contributions must be negative. If the new ordered structure is merely added to the original structure of the native protein, the value of ΔS must be negative, while that of ΔS^* may also be negative. However, the observed value of ΔS^* is positive and large. It is interesting to compare the present results with the activation parameters of the conformational change of lysozyme caused by other agents.[16,17] The values of ΔH^* and ΔS^* are similar to those of the unfolding process of the lysozyme. It may be noted here that the value of ΔS^* in the present study is similar to that of the conformational change in which the ordered structure decreases. As has been mentioned above, the helix content increases through the conformational change caused by SDS, while the degree of exposure of chromophores becomes greater in the denatured conformation than in the native one. Subsequently, the polypeptide chains must have been partially refolded in the transition process; that is, part of the polypeptide chains must have been unfolded, followed by a continuous refolding together with the bound surfactants in the transition process. As a result of the conformational change of the protein, more chromophores are exposed to the aqueous environment in the denatured state than in the native one. Therefore, the degree of unfolding becomes significant in the transition state relative to the native state, and the value of ΔS^* may reflect such a large-scale conformational change of the complex.

Table 1. KINETIC PARAMETERS OF CONFORMATIONAL CHANGE OF DELTA-CHYMOTRYPSIN BY SDS

Temperature/°C	15	20	25	30	35
$k/10^{-1}\,s^{-1}$ a)	0.40	0.85	2.9	7.0	15
ΔH^*/kJ mol^{-1}			140		
ΔS^*/J K^{-1} mol^{-1}			160		

a) These values were calculated from the results at 1.0×10^{-5} M protein and 20 mM SDS.

Further studies comparing the kinetic parameters of the same conformational change of proteins similar to the protein used here are in progress and will be reported in due course.

This work was partly supported by a Grant-in-Aid for Scientific Research No. 374149 from the Ministry of Education, Science and Culture of Japan.

A Temperature-dependent Desorption Process of Molecular Ions in Field Desorption Mass Spectrometry

Hiroaki SHIRAISHI,* Akira OTSUKI, and Keiichiro FUWA

Department of Chemistry and Physics, National Institute for Environmental Studies, Yatabe, Ibaraki 305

(Received April 17, 1981)

A temperature dependent desorption process of molecular ions operating in field desorption mass spectrometry (FDMS) was examined by means of measurements of desorption rates using cholesterol, stearic acid, and poly(oxyethylene) nonylphenyl ether. The desorption of ions formed under high electric field followed the first order kinetics. The desorption rate constants were measured at several emitter currents, and apparent activation energies for the desorption of molecular ions were calculated. A mass transfer process operating in FDMS is discussed.

Field desorption mass spectrometry (FDMS) has been successfully applied for various qualitative and quantitative analyses of organic compounds in many kinds of samples during the last several years.[1] In this technique, an activated emitter of 10 μm diameter tungsten wire covered with carbon microneedles is commonly employed in order to attain the high electric field essential to the ionization. The desorption of ions from the emitter is often assisted with heating by passing current through the emitter. Thus, the emitter temperature can strongly influence the FD mass spectra which are obtained.

Several types of emitter current programmers have been developed to control the emitter temperature.[2-4] Further detailed study for the temperature dependence of FD mass spectra is needed by use of these programmers in order to understand the picture of the FD process. A simple model for sample supply to activation sites of a tip emitter by field-enhanced surface diffusion from large reservoirs of adsorbed molecules on the shank of the tip has been proposed by Beckey *et al.*[5] in order to explain the results from angular distribution studies, and was supported by Cocke *et al.*[6] But, Holland *et al.* reported that the electric field has little effect on mass transfer from the activated emitter and proposed a model for the FD process which was later argued against by Beckey and Röllgen.[8] The uncertainty in the picture of the processes operaing in conventional FDMS may arise from the use of an activated emitter with many activated points under different field strengths and different temperatures.

This paper describes the temperature dependence of the field desorption process of molecular ions and the effect of high electric field on mass transfer operating in conventional FDMS.

Experimental

Mass spectrometry was performed on a JEOL JMS O1-SG double focusing mass spectrometer with a combined field desorption/field ionization/ electron impact ion source, connected to JMS-2000 mass data analysis system (Japan Electric and Optics Laboratory). The FD emitter used was 10 μm tungsten wire with carbon needles grown at high temperature.[9] An anode potential of 10 kV and cathode potential of −3 kV were applied. Emitter current was controlled by use of a modified emitter current programmer. The emitter was loaded with samples from a stock solution (1 μg/μl) using a dipping technique. Sample loading by dipping resulted in more reproducible determination of the desorption rate constants than that by microsyringe technique. Initial focusing was done on acetone introduced *via* the batch inlet, and finally using an FD ion of a sample at room temperature. A profile of FD ion current was measured by single ion monitoring. Ion current was integrated for every 0.2 s and stored in a computer. The mass chromatogram of poly(oxyethylene) nonylphenyl ether was measured by repetitive magnet scanning at an interval of 10 s. After measurement of each sample, the emitter current was increased to 60 mA in order to clean the emitter.

The emitter current-emitter temperature relationship was obtained in the following manner. An emitter was introduced into an electrically heated air bath, and its resistance was measured by means of an LCR meter (Yokokawa, Hewlett-Packard; model 4216A). Then the same emitter was introduced in an ion source and heated by passing direct current through it; the applied potential was measured by means of a voltmeter. Resistance was calculated according to the equation $R=V/I$.

All chemicals supplied by Wako Pure Chemical Industries, Ldt. were used without further purification.

Results and Discussion

Generation of many types of ions, such as molecular ion(M^+), protonated and cationated molecular ion ($(M+H)^+$, $(M+\text{cation})^+$), cluster ion ($(nM+H)^+$, multiple charged ion (M^{n+}, $(M+nH)^{n+}$), and fragment ion, make it difficult to investigate the mechanism of ion formation and desorption in FDMS. In order to simplify the mechanism of ion formation and desorption, typical samples, which give only molecular ions in their FD mass spectra, were used in the present study.

When the emitter current was kept constant during the measurement, the intensity of molecular ions was observed to decrease exponentially with time, as shown in Fig. 1. If the desorption process of ions formed under high electric field follows the following equation at a constant temperature:

$$C_t = C_0 e^{-kt},$$

C_t: Amount of neutral material to be ionized (or ions) remaining on the emitter at time t.

C_0: Initial amount of neutral material to be ionized (or ions) remaining on the emitter at time, 0.

k: First order rate constant (desorption rate constant).

a plot $\log[C_t]$ against time should give a linear relation.

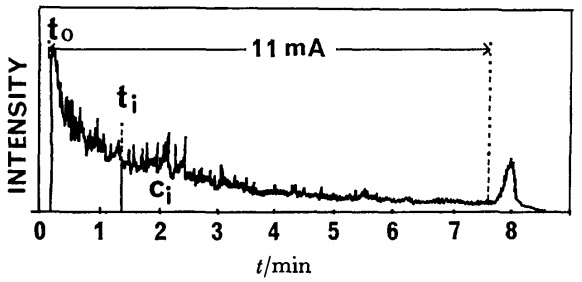

Fig. 1. Ion current profile for molecular ion of cholesterol (m/z 386) at 11 mA followed by linear increase in emitter current.

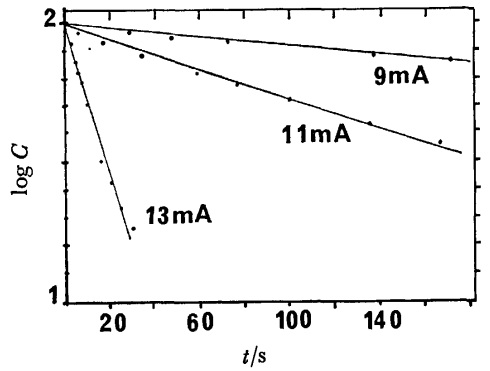

Fig. 2. log[C_t]-time plot for molecular ion of cholesterol (m/z 386) at 9, 11, and 13 mA.

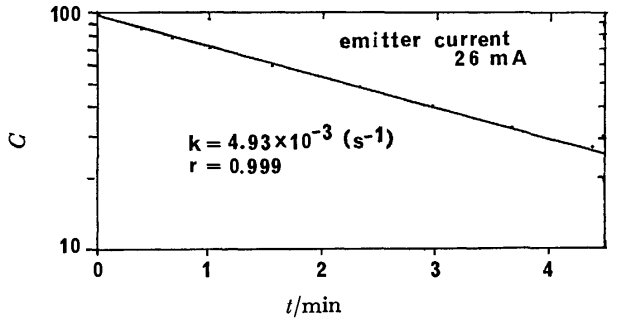

Fig. 3. log[C_t]-time plot for lithium ion attached molecular ion of lithium iodide (Li_2I^+, m/z 141) at 26 mA.

Figures 2 and 3 show log[C_t]-time plots for molecular ions of cholesterol at three different emitter currents and lithium-ion-attached molecular ion of lithium iodide (m/z 141) at 26 mA in emitter current, respectively. These results indicate that the desorption process of ions from the activated emitter at high electric field follows the first order kinetics. Table 1 shows first order rate constants for desorption of poly(oxyethylene) nonylphenyl ether containing different degrees of polymerization of ethylene oxide, calculated from each slope in the log[C_t]-time plots. Rate constants of lower molecular weight components have larger values than those of higher molecular weight components, and rate constants of each component are larger at higher emitter current than at lower emitter current. These results are consistent with the fact that fractional desorption occurs during increase in emitter current when a mixture is analyzed, permiting the analysis of a mixture under controlled conditions of emitter current.[4]

Table 1. First order rate constants k for desorption of molecular ions of poly(oxyethylene) nonylphenyl ether

m/z	8 mA	10 mA	11 mA
396	6.11×10^{-3}	1.73×10^{-2}	5.37×10^{-2}
440	3.69×10^{-3}	8.11×10^{-3}	1.88×16^{-2}
484	2.66×10^{-3}	5.79×10^{-3}	1.00×10^{-2}

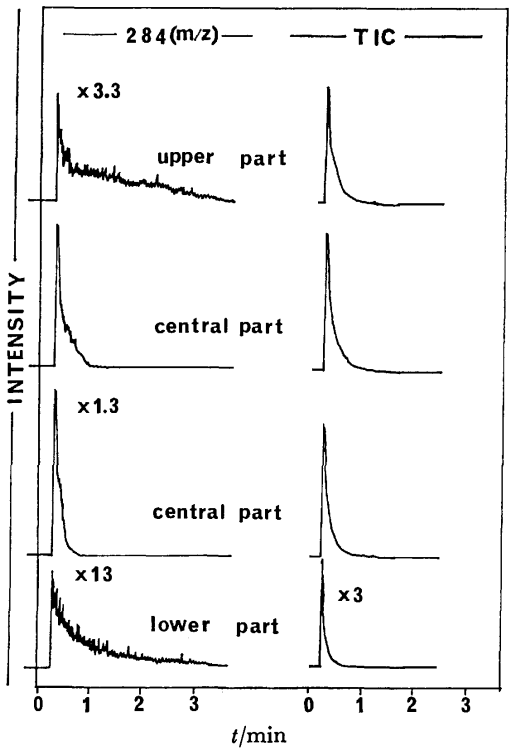

Fig. 4. Influnce of *axial* focus on ion current profile for molecular ion of stearic acid (m/z 284) at 10 mA. TIC (total ion current).

It was concluded from these results that desorption of ions formed under high electric field can be expressed as a first order reaction. Therefore, it is suggested that not only qualitative but also quantitative discussion about the fractional desorption should be done by use of desorption rate constants for each compound. However, it should be mentioned that these values given in Table 1 are relative because of uncertainty of the temperature gradient along the emitter wire and also along the carbon needles under the conditions used. Fugure 4 presents the evidence which suggests that a temperature gradient may be present in an activated emitter with 5 mm separation between the two supporting poles even if the emitter current is kept constant. In a Mattauch-Herzog type mass spectrometer, accelerated ions are focused by radial and axial foucs lens on the ion detector, but all widths of ion beam band desorbed from the 5 mm long emitter cannot be simultaneously focussed on the ion detector. Thus, one part of the ion beam band, usually the central part, is focussed on the ion detector by adjusting the axial foucs lens.

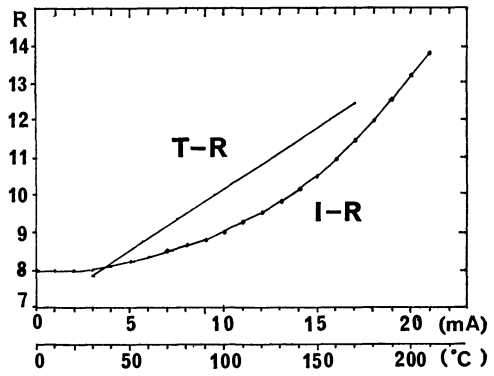

Fig. 5. Relations between emitter temperature and emitter resistance, and between emitter current and emitter resistance.

In Fig. 4, the molecular ion beam band of stearic acid was roughly divided into four parts: upper quarter, two central quarters, and lower quarter. Although similar profiles of the total ion current in each quarter were observed in every measurement, desorption profiles of the molecular ions from the two central parts of the emitter were different from the other two and the initial ion intensities were also much higher than those in the other two. These data would mean that there exists a temperature gradient on the activated emitter, and that the upper and lower parts near the two supporting poles were at a lower temperature than in the two central parts.

Since the average emitter temperature is one of the most important factors in the desorption process of ionization under high electric field, we tried to estimate the emitter temperature inside the ion source by a different way from that used in earlier papers on the estimation of emitter temperature.[10,11] Figure 5 shows a typical example of relations between emitter temperature and emitter resistance, and between emitter current and emitter resistance of 10 μm tungsten wire 5 mm long with carbon needles 20—30 μm in length. In this emitter, when the emitter current was adjusted to 9 mA, the emitter temperature was estimated to be about 65 °C with 9 Ω. The resistivity of tungsten varies as a function of temperature following the equation

$$R = R_0(1+\alpha\Delta T),$$

where $\alpha=0.0047\ K^{-1}$ is the temperature coefficient of resistivity. For the activated emitter, the tungsten wire is partially converted to tungsten carbide whose temperature coefficient of resistivity is $0.0049\ K^{-1}$.[12] The calculated coefficients of the activated emitters were in the range of about 0.0047 to 0.0050. The result indicated that each emitter has slightly different relations depending upon the length and number of carbon microneedles. Thus, the relations given in Fig. 5 may be used as a relative measure of the emitter temperature for the other emitters.

Using these relations, the apparent activation energy for desorption of ions formed under high electric field was obtained. Figure 6 shows an example of the Arrhenius plots (log k *vs.* $1/T$) for cholesterol and stearic acid. Apparent activation energies for the desorption of molecular ions of cholesterol and stearic acid at high electric field were calculated from the slopes to be 30 and 55 kcal/mol, respectively. The apparent activation energy obtained in the present study is not equivalent to that in field desorption, but may mean that required for an overall process of field desorption including migration of sample molecules to activation sites of carbon microneedles. Theoretically, the activation energy required for FD of ions under high electric field should be smaller than that for desorption of neutral molecules under no electric field.[13] These calculated values were apparently lower than the ionization potentials of both compounds, suggesting the importance of the electric field.

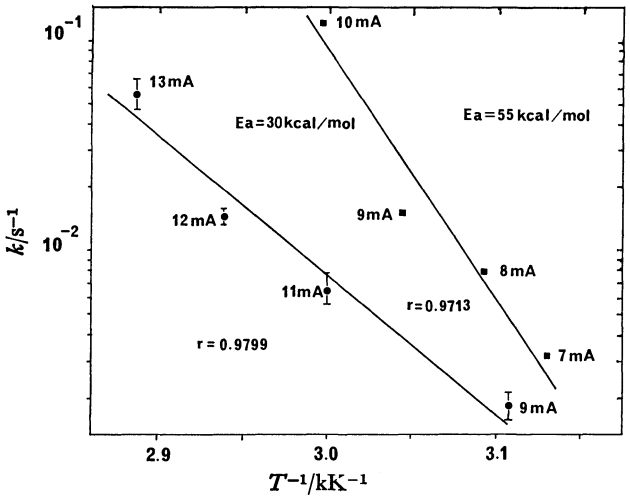

Fig. 6. $\log k - 1/T$ plot for desorption of molecular ions of cholesterol (●) and stearic acid (■).

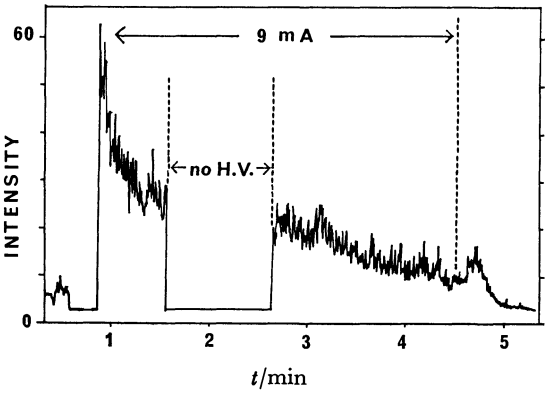

Fig. 7. Mass chromatogram of molecular ion of stearic acid measured at 9 mA followed by linear increase. High electric field was turned off for 1.5 to 2.7 min in the time course of measurement.

The fact that the desorption process follows the first order kinetics gives us the opportunity to investigate the role of high electric field for the desorption process. Figure 7 shows the mass chromatogram of molecular ions of stearic acid measured at 9 mA, followed by a linear increase. When the high electric field was turned off for 1.5 to 2.7 min in the time course of measurement, the molecular ion intensity was observed to become zero. Figure 8 shows the

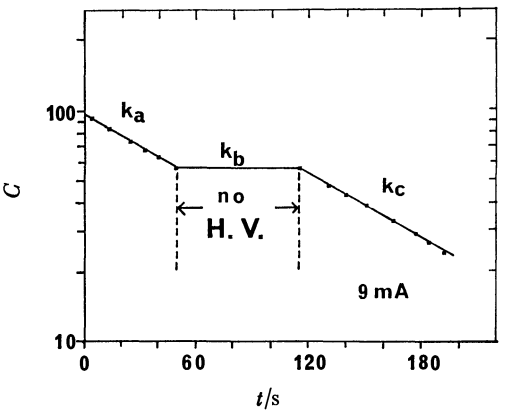

Fig. 8. log[C_t]-time plot for molecular ion of stearic acid, assuming that desorption of stearic acid did not occur under low electric field.

log [C_t]-time plot, assuming that desorption of stearic acid from the emitter under low electric field did not occur. As shown in Fig. 8, the desorption rate constant in the first stage was equal to that in the third stage when the high electric potentials were again applied. This result means that desorption of stearic acid under low electric field did not occur at 9 mA.

The same kind of experiment was carried out using cholesterol at 8 mA. It was found that the desorption rate of cholesterol under low electric field was nearly equal to that under high electric field. This result suggests that the desorption rate of cholesterol was little affected by the electric field. Similar field-independent desorption was reported by Holland *et al.*[7] and was explained on the basis of field ionization processes by Beckey and Röllgen, assuming the sample molecules to be evaporated before ionization takes place.[8] This means that the calculated apparent activation energy for desorption of cholesterol (30 kcal/mol) is mainly due to the heat of desorption of neutral molecules of cholesterol. Although there is no report on the heat of adsorption of stearic acid on the activated carbon surface, the fact that stearic acid was not desorbed at 9 mA under low field suggests that stearic acid having a carboxy group may be more strongly adsorbed on an emitter surface than cholesterol having a hydroxy group.

In conclusion, the present study indicated that desorption of ions formed under high electric field follows the first order kinetics, and that the desorption rate is temperature dependent.

Solvation Effect on the Complex Formation between *o*-Quinones and Metal Chlorides in Nonaqueous Media

Kazuaki KATAOKA, Tatsuya TAKAGI, and Yoshio SASAKI*

Faculty of Pharmaceutical Sciences, Osaka University, Yamadaoka 1-6, Suita, Osaka 565

(Received April 22, 1981)

The complex formation of *o*-quinones with metal chlorides was studied by means of spectrophotometry in CH_3NO_2 and CH_3CN, where the metal chloride behaved as a nonelectrolyte. The results obtained in both solutions showed that the complex formation was obviously affected by the solvation of CH_3CN to the metal chloride. The participation of CH_3CN in the *o*-quinone–$ZnCl_2$ complex was assumed as a result of comparing the $\Delta\nu_{max}$ values, and the results obtained by NMR and spectrophotometry proved the coordination of two molecules of CH_3CN to the complex. The values of K_c in CH_3NO_2 increased in the order of $BiCl_3 < ZnCl_2$, whereas those in CH_3CN were in the reverse order; this fact was ascribed to the number of the solvent molecules liberated in the complex formation. The conventional elimination of the solvation effect from the observed K_c was proposed in order to obtain a parameter of solvation-free K_c.

o-Quinones have been reported to form intensively colored complexes with various kinds of metal halides.[1,2] An extensive study of these complexes was first carried out by Crowley and Haendler.[2] However, there have been few reports on the equilibrium of the complex formation of *o*-quinones with metal halides in solution. The complex between *o*-quinones and some metal chlorides has already been examined in CH_3NO_2 by spectroscopy,[3] where the metal chloride behaved as a nonelectrolyte and a correlation was observed between the stability constants, K_c, and the complex shifts, $\Delta\nu_{max}$ ($=\nu_{max}$ of the free ligand $-$ ν_{max} of its complex) or $\Delta\delta_{ML}$ ($=\delta_{ML}-\delta_L$), of the 1:1 complex. On the other hand, when CH_3CN is used as a solvent, the order of the increment of K_c's is not consistent with that in CH_3NO_2, particularly in the case of the *o*-quinone–$ZnCl_2$ complex. The coordination of CH_3CN is reasonable, since the donor strength of CH_3CN is larger than that of CH_3NO_2 (the donor numbers of CH_3CN and CH_3NO_2 are 14.1 and 2.7 respectively[4]). The purpose of this paper is to investigate the solvation for the *o*-quinone–$ZnCl_2$ complex in detail. In this work, cryptotanshinone and related compounds are used as the ligands, since some *o*-quinones having ether-type oxygen atoms form more stable complexes with metal chloride than does 1,2-naphthoquinone or 9,10-phenanthraquinone.[5]

Experimental

Materials. The cryptotanshinone(1,2,6,7,8,9-hexahydro-1,6,6-trimethylphenanthro[1,2-*b*]furan-10,11-dione) was isolated from the Chinese drug "Tan-shen" by the method of Takiura.[6] The 4,5-dimethoxy-1,2-benzoquinone and 4,5-diethoxy-1,2-benzoquinone were synthesized by the methods of Wanzlich and Jahnke.[7] Commercially available metal chlorides were purified by sublimation or distillation under reduced pressure. The CH_3CN was fractionally distilled from P_2O_5. The CH_3NO_2 and CH_2ClCH_2Cl were purified by distillation after drying on $CaCl_2$. The remaining water in the rectified solvents was checked by the measurement of the degree of the dissociation of the cryptotanshinone–$FeCl_3$ complex, which is liable to be decomposed by water;[5] the data were reproducible.

Procedures. In order to determine K_c, sample solutions containing a fixed overall concentration of the ligand and varying amounts of the metal chloride were prepared; stoppered cells were placed in a dry box under an N_2 atmosphere. The visible absorption spectra were measured on a Shimadzu UV-200 spectrophotometer at 25 or 34 °C. Changes in the absorbance by the complex formation were significant between 460 and 500 nm, and measurements of the absorbance were made at several wavelengths in this range. The K_c values of 1:1 complex formation were obtained by the curve-fitting method;[3] the root mean-square deviations of the absorbance were always within 0.003. The proton NMR spectra were measured in a Hitachi R-22 spectrometer (90 MHz) at 34 °C. The chemical shifts were determined by a frequency counter within an error of ± 0.1 Hz, relative to the internal reference, TMS. The molar conductances ($\Lambda/\Omega^{-1}\,mol^{-1}\,cm^2$) of millimolar solutions of the metal chlorides, measured at room temperature on a Kyoto Denshi CM-07 conductivity meter, were as follows; $ZnCl_2=1.7$ and $BlCl_3=2.4$ in CH_3NO_2, and $ZnCl_2=2.2$ and $BiCl_3=1.2$ in CH_3CN. The values of the molar conductances of complexes prepared by adding an excess amount of cryptotanshinone to the above solutions were essentially invariable.

Results and Discussion

Stability Constant and Complex Shift. The K_c and $\Delta\nu_{max}$ values on the complex formation between cryptotanshinone and $BiCl_3$ or $ZnCl_2$ in CH_3NO_2 and CH_3CN are listed in Table 1. The values of K_c in CH_3CN are smaller than those in CH_3NO_2; this is reasonable considering the donor strength of the two solvents. However, the order of K_c in CH_3CN differs from that in CH_3NO_2. A detailed discussion of this disagreement will be given below.

On the other hand, the values of $\Delta\nu_{max}$ are almost invariable with the solvent, but those of K_c are much

Table 1. The $\log K_c$ and $\Delta\nu_{max}$ values of the complex formation between cryptotanshinone and metal chlorides in two solvents at 25 °C

Solvent	MX_n	$\log(K_c/mol^{-1}\,dm^3)$	$\Delta\nu_{max}/10^3\,cm^{-1}$
CH_3NO_2	$ZnCl_2$	3.27 ± 0.03	3.68
	$BiCl_3$	2.63 ± 0.03	2.73
CH_3CN	$ZnCl_2$	0.83 ± 0.06	3.35
	$BiCl_3$	1.39 ± 0.03	3.00

ν_{max} of cryptotanshinone/$10^4\,cm^{-1}=2.273$ in CH_3NO_2, 2.304 in CH_3CN.

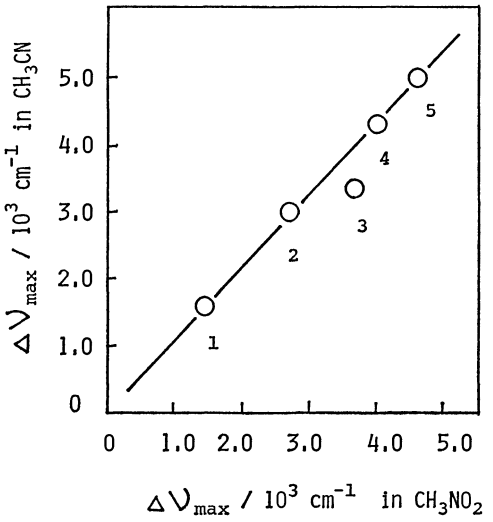

Fig. 1. Plot of $\Delta\nu_{max}$ of cryptotanshinone–MX_n complexes; CH_3CN *vs.* CH_3NO_2.
MX_n: 1; $HgCl_2$, 2; $BiCl_3$, 3; $ZnCl_2$, 4; $InCl_3$, 5; $SnCl_4$.

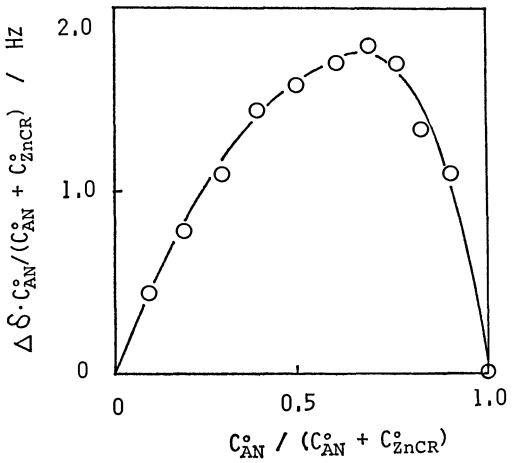

Fig. 2. Continuous variation method of cryptotanshinone–$ZnCl_2$+CH_3CN in 1,2-dichloroethane by NMR.
C°_{AN}: concn of CH_3CN, C°_{ZnCR}: concn of cryptotanshinone–$ZnCl_2$, $C^\circ_{AN}+C^\circ_{ZnCR}=0.13$ mol dm^{-3}, $\Delta\delta=\delta_{obsd}-\delta_{CH_3CN}$.

affected by the solvent. This fact suggests that $\Delta\nu_{max}$ does not depend on the donor strength of the solvent. A slope of *ca.* 1.0 was also given by plotting the values of $\Delta\nu_{max}$ in CH_3CN against those in CH_3NO_2, as shown in Fig. 1, where the plots of the $\Delta\nu_{max}$ values of other metal chlorides have been added. The value of the slope is consistent with the ratio of CH_3CN *vs.* CH_3NO_2 in the dielectric constant.

Participation of Solvent. The $\Delta\nu_{max}$ values of the cryptotanshinone–metal chloride complexes obtained in CH_3CN were of the same order as those obtained in CH_3NO_2. However, the plot of the $\Delta\nu_{max}$ values of the cryptotanshinone–$ZnCl_2$ complex deviated from the linear relation, as is shown in Fig. 1. This deviation should first be examined. Taking into account the complex formation of CH_3CN with $ZnCl_2$[8] or the reports[9,10] on the solvent participation in the complex, this deviation is probably to be ascribed to the coordination of the solvent molecules to the cryptotanshinone–$ZnCl_2$ complex in CH_3CN. The report on the Ni(II) complex[10] is cited as an example of the studies of the solvent participation, where the solvated species were estimated by the shift of the d-d transition band of the Ni(II) complex. In this work, however, the formation of the solvated species can not be confirmed by the method discribed above. Accordingly, the coordination of CH_3CN to the cryptotanshinone–$ZnCl_2$ complex was examined. In this work, CH_2ClCH_2Cl was used as a suitable solvent, since the cryptotanshinone–$ZnCl_2$ complex is sufficiently soluble in this solvent; in addition, the donor strength of CH_2ClCH_2Cl is very weak (*e.g.*, the donor number is 0[4]).

The chemical shifts of aromatic protons of the cryptotanshinone–$ZnCl_2$ complex, prepared by dissolving equimolar amounts of cryptotanshinone and $ZnCl_2$ in CH_2ClCH_2Cl, are concentration-independent in the range from 0.1 to 0.01 mol dm^{-3} of the complex. This suggests that cryptotanshinone and $ZnCl_2$ were almost transformed into the complex. It can therefore, be expected that the values of K_c of the cryptotanshinone–$ZnCl_2$ complex in CH_2ClCH_2Cl are very large. In order to obtain the number of CH_3CN coordinated, the continuous-variation method was performed by the NMR method. As is shown in Fig. 2, the results suggest that two molecules of CH_3CN take part in this equilibrium. In spite of the small displacement of the observed shift, the data were well reproduced. In addition, the molar conductance indicates that $ZnCl_2$ and the cryptotanshinone–$ZnCl_2$ complex in CH_3CN behave as nonelectrolytes. Accordingly, the above results lead to the following two equilibria, the addition type (Eq. 1) and the replacement type (Eq. 2):

$$CR\text{-}ZnCl_2 + 2CH_3CN \rightleftharpoons CR\text{-}ZnCl_2\text{-}2CH_3CN, \quad (1)$$

$$CR\text{-}ZnCl_2 + 2CH_3CN \rightleftharpoons CR + ZnCl_2\text{-}2CH_3CN, \quad (2)$$

where CR denotes cryptotanshinone. The possibility of Eq. 1 is a matter of concern in the present work, though the possibility of Eq. 2 will be estimated by considering the value of K_c of the cryptotanshinone–$ZnCl_2$ complex in CH_3CN.

The formation of solvated species was further examined by means of spectrophotometry. The change in the spectra of cryptotanshinone with $ZnCl_2$ in CH_2ClCH_2Cl having isosbestic points is shown in Fig. 3. When the concentration of CH_3CN increases gradually while the concentrations of cryptotanshinone and $ZnCl_2$ are held constant (*cf.* Fig. 3 IV), the absorption curves deviate from the isosbestic point, as is shown in Fig. 3 C. This fact suggests that the species containing cryptotanshinone, other than free cryptotanshinone and the cryptotanshinone–$ZnCl_2$ complex, are formed by the addition of CH_3CN. This result supports the priority of Eq. 1. In the case of the complex formation in CH_3CN, therefore, the cryptotanshinone–$ZnCl_2$ complex is almost completely transformed into the solvated species cryptotanshinone–$ZnCl_2$–$2CH_3CN$. On the other hand, the cryptotanshinone–$ZnCl_2$ complex is inert to CH_3NO_2.

It is well known that the partial charge on the metal

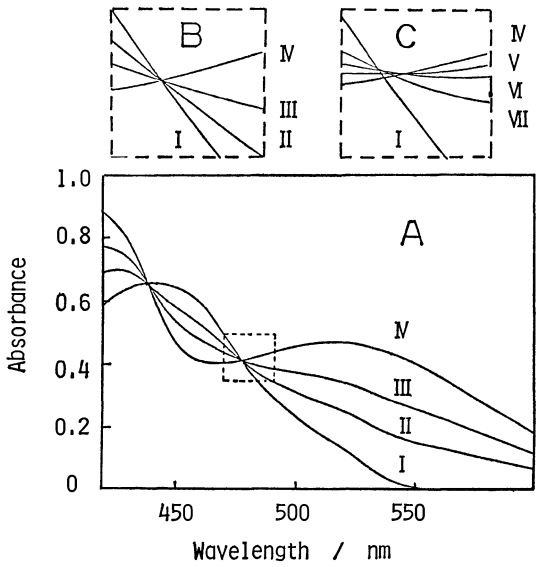

Fig. 3. Spectral change of cryptotanshinone with $ZnCl_2$ in 1,2-dichloroethane and the effect of CH_3CN. B and C are in the wavelength region surrounded by the dotted line in A.

atom of metal chloride is one of the factors controlling the complex formation.[3] The partial charges in the Zn of $ZnCl_2$ and $ZnCl_2$–$2CH_3CN$, as calculated by the method of Sanderson,[11] were 0.36 and 0.32 respectively. The decrease in the partial charge on the addition of CH_3CN (0.36→0.32) is consistent with the deviation of the plot of $\Delta\nu_{max}$ in the cryptotanshinone–$ZnCl_2$ complex (*cf.* Fig. 1). This fact also supports the presence of the solvated cryptotanshinone–$ZnCl_2$ complex in CH_3CN.

Number of Solvent Molecules Liberated in Complex Formation. In general, the complex formation in donor solvents is a replacement reaction, as is expressed by Eq. 3:

$$MS_m + L \overset{K_{obsd}}{\rightleftharpoons} MS_{m-n}L + nS, \quad (3)$$

where M, L, and S are the metal, the ligand, and the solvent, respectively. When $m=n$, K_{obsd} (the K_c of the complex formation is expressed by Eq. 3; *i.e.*, the K_c given in Table 1 corresponds to K_{obsd}) can be approximately expressed by Eq. 4, where K_{ML} and K_{MS} are the K_c's of the complex formation between M and L and between M and S in the inert solvents:

$$\log K_{obsd} = \log K_{ML} - \log K_{MS}. \quad (4)$$

In the complex formation of a given ligand with a series of metals, if $\log K_{MS} \ll \log K_{ML}$, or if the n's are constant in this series, K_{obsd} will be proportional to K_{ML}. That is, the increasing order of K_{obsd} agrees with that of K_{ML}. On the other hand, if the relative values of K_{MS} can not be ignored, and if the n's are variable between metals, the order of K_{obsd} probably disagrees with that of K_{ML}. In this work, the values of K_c in CH_3NO_2 increased in the order of $BiCl_3 < ZnCl_2$, whereas those in CH_3CN were in the reverse order. This disagreement in the order seems to be responsible for the difference of n. Accordingly, the values of n in the complex formation of cryptotanshinone with $ZnCl_2$ and $BiCl_3$ were examined.

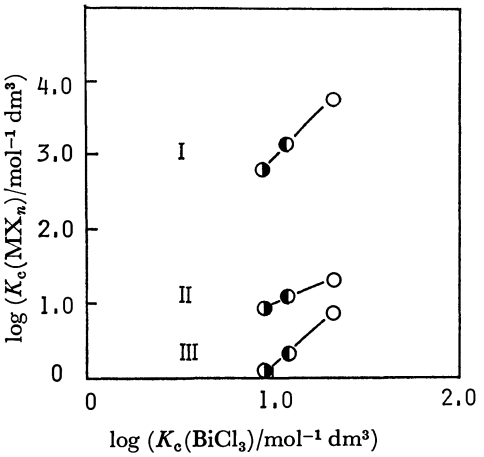

Fig. 4. Plots of $\log K_c$ of the complex formation of *o*-quinones with MX_n against that with $BiCl_3$ in CH_3CN.
MX_n: I; $InCl_3$, II; $BiCl_3$, III; $ZnCl_2$. *o*-Quinones: ○; cryptotanshinone, ◐; 4,5-diethoxy-1,2-benzoquinone, ◑; 4,5-dimethoxy-1,2-benzoquinone.

Formerly, a procedure for the determination of the number of solvent molecules liberated in the complex formation, utilizing the solubility equation and the solubility parameter,[13] was proposed by Tanaka.[12] In his work, $\log K_c$ is expressed in terms of the solubility parameter (δ) and the molar volume (V) as follows:

$$\log K_c = 0.43(V_M + V_L - V_{ML})\delta_S^2/RT + 0.86(V_M\delta_M + V_L\delta_L - V_{ML}\delta_{ML})\delta_S/RT + \text{constant}. \quad (5)$$

Equation 5 is modified to Eq. 6, providing $V_M+V_L-V_{ML}=nV_S$ and $\delta_{ML}=(V_M\delta_M+V_L\delta_L)/V_{ML}$:

$$\log K_c = 0.43\, nV_S\delta_S^2/RT + \text{constant}, \quad (6)$$

where n is the number of solvent molecules liberated in the complex formation. As two solvents were used in this work, n is given by solving two simultaneous equations for CH_3CN and CH_3NO_2; the values of δ_s are 11.9 and 12.6, while those of V_s are 52.9 and 54.0, respectively.[13] For $ZnCl_2$ and $BiCl_3$, the n values were 3.1 and 1.6 respectively. The calculated values of n are not integral: however, it is important that the value of n for $ZnCl_2$ is about twice that for $BiCl_3$.

In the case of the complex formation in CH_3NO_2, K_{MS} is negligible because of the weak donor strength of CH_3NO_2. It can be considered that there is no effect of the number of the liberated solvent molecule against the order of K_{obsd}. However, the donor strength of CH_3CN is strong, so K_{MS} could not be neglected. Therefore, it is estimated that the disagreement of the order of K_c among two solvents results from the difference in the number of the solvent molecule liberated in the complex formation.

Elimination of Solvation Effect. As was described in the previous section, it is evident that the order

Table 2. The $\log K_c$ and $\Delta\log K_c$ values of the complex formation between *o*-quinones and metal chlorides in CH_3CN at 34 °C

	$\log (K_c/\text{mol}^{-1}\,\text{dm}^3)$		$\Delta\log K_c$
	(a)	(b)	
$InCl_3$	3.15±0.04	2.81±0.04	0.34
$ZnCl_2$	0.34±0.04	0.08±0.04	0.26
$BiCl_3$	1.18±0.04	0.95±0.04	0.13

(a); 4,5-Diethoxy-1,2-benzoquinone, (b); 4,5-dimethoxy-1,2-benzoquinone, $\Delta\log K_c = \log K_c$ of (a) $-\log K_c$ of (b).

of K_c is very much affected by solvation, so information about solvation-free K_c is necessary in order to examine the acidity of metal chloride. However, the solubility of metal chloride inevitably requires donor solvents. As for the procedure for eliminating the term of solvation from an enthalpy of complex formation in donor solvents, ESP (Elimination of Solvation Procedure) has been proposed by Drago *et al.*[14] In ESP, the solvation term is cancelled by using a replacement reaction: A basic solvent is used to compare the donor strength of a series of bases, whereas an acidic solvent is used to compare the acceptor strength of a series of acids. In this work, a basic solvent is employed in order to compare the acceptor strength of a series of metal chlorides. ESP is not applicable as an intact whole, but the essentials of ESP are extended in this work. That is, the information of solvation-free K_c should be obtained from a comparison with $\Delta\log K_c$, given by subtracting the log K_c of ML′ from that of ML, where L and L′ are ligands with the same coordination geometry. On the other hand, to promote the quantitative accuracy, the slope a defined in Eq. 7 must be evaluated:

$$\log K_c \text{ of ML} = a \log K_c \text{ of M'L} + b. \quad (7)$$

The slope a indicates the relative value of the acidity of M to M′; it is given by the plots of log K_c of the complex formation of M and M′ with a series of ligands.

At first, the evaluation of a was attempted in CH_3CN. When M′ is $BiCl_3$, the a values of $InCl_3$, $ZnCl_2$, and $BiCl_3$ are 2.4, 2.0, and 1.0, respectively, as is shown in Fig. 4. This order of a was consistent with both the order of K_c in CH_3NO_2 and that of $\Delta\nu_{max}$ in the two solvents. For the sake of convenience, the values of $\Delta\log K_c$ can subsequently be compared with each other. The values of $\Delta\log K_c$ increased in the order of $BiCl_3 < ZnCl_2 < InCl_3$, as is shown in Table 2; this fact also supports the above results. Therefore, either $\Delta\log K_c$ or a is valid as a parameter of K_c without solvation.

Pressure Effect on Reaction Rate of Cycloaddition of Tetracyanoethylene with α-Methylstyrene in Some Aprotic Solvents

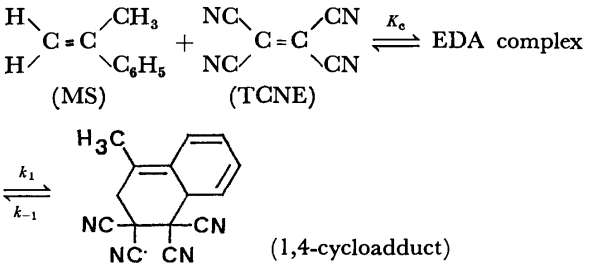
Hideaki Tsuzuki, Yasuhiro Uosaki, Masaru Nakahara,
Muneo Sasaki,* and Jiro Osugi

Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606

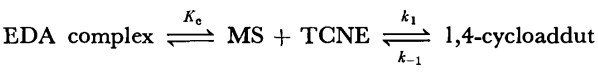
(Received May 22, 1981)

The high-pressure kinetic study of the title reaction was carried out at 25 °C up to 1500 bar in carbon tetrachloride, chloroform, 1,2-dichloroethane, and acetonitrile, taking into account the role of the EDA complex formation. The dipole moment at the transition state is as large as 8.5±0.5 debye by Kirkwood's electrostatic model. The solvent effect is also ascribable to the polarity change upon activation. The intrinsic volume of activation is −27±3 cm³/mol for the cycloadding process and −3.3±3 cm³/mol for the reverse reaction.

Styrene was believed to give only the electron-donor-acceptor(EDA) complex with tetracyanoethylene (TCNE) in nonaqueous solvents at the ambient pressure and temperature.[1] Thereafter it was found[2] that a species other than the EDA complex was accumulated sufficiently at pressure as high as several kilobars and that its reversible decomposition after pressure withdrawal could be retarded at temperature as low as 0 °C. This species was identified as the 1,4-cycloadduct from the ^{13}C NMR and other spectra.[2] Careful examination confirmed that not only styrene but some of its derivatives gave the 1,4-cycloadduct with TCNE even at 1 bar, coexisting with the EDA complexes.[2-5] α-Methylstyrene(MS) reacts with TCNE more rapidly than styrene in some alkyl halides as solvent at room temperature to give the 1,4-cycloadduct.[3,4]



Scheme 1.



Scheme 2.

Whether the EDA complex is an intermediate of the reaction (Scheme 1) or it is formed only in a dead-end equilibrium (Scheme 2) is of interest. However, it is impossible to distinguish the two schemes only by a simple kinetic study. We reported previously[5] that the second-order rate constant for the forward process being denoted by k_f, the reaction constant of its Hammett plot for the para-substituted styrenes was as negative as −5.5±0.2. Moreover, a linear correlation was induced between $\log k_f$ and $\log K_c$; k_f increased with increasing equilibrium constant K_c for the EDA complex formation. The latter fact will support Scheme 1; otherwise the overall free energy of activation would not be correlated necessarily with the free energy change of the EDA complex formation. A similar scheme is presented for the reaction of TCNE with 9,10-dimethylanthracene,[6] in which the overall enthalpy of activation is negative. We have pointed out already the importance of the role of the EDA complex in the reaction between TCNE and enol ethers.[7]

Moreover the present reaction attracts much attention in a sense that unlike most [4+2] reactions the reaction rate depends significantly on solvent polarity.[3,4] This paper deals with the pressure and solvent effects on the reaction rate for the purpose of elucidating the transition state character. While a volume of activation, as a result of pressure effect on a reaction rate, is known to provide an important knowledge to understand a reaction mechanism,[8,9] the kinetic study on the thermal reaction faster than *ca.* half an hour has been hardly done at high pressure by a usual convenient method because it takes long time to attain the thermal equilibrium at a desired pressure after initiating the reaction. We could overcome the problem by developing a high pressure stopped-flow method.[10]

Experimental

Materials. All reagents were commercially obtained (Nakarai Chemicals Co. Ltd.). Tetracyanoethylene (TCNE) was sublimed three times *in vacuo* at 50—55 °C in the presence of active carbon, mp 200—201 °C. α-Methylstyrene (MS) was washed twice with slightly alkaline water and stored for 24 h over KOH. After being refluxed with CaH_2, it was distilled twice under a reduced pressure. Chloroform was treated with molecular sieves 5A, and then distilled twice just before use, bp 61—62 °C. Acetonitrile was refluxed with $NaHCO_3$ and P_2O_5, then distilled, bp 81—82 °C. Spectrograde 1,2-dichloroethane and carbon tetrachloride were used without further purification.

Kinetic Measurement. The rate of the cycloaddition was spectrophotometrically determined by following the absorbance of the 1,4-cycloadduct. At 1 bar (1 bar=0.1 MPa) was used a Shimadzu UV-200S spectrophotometer equipped with a rapid mixing apparatus(Union Giken MX 703). At high pressure the kinetic measurement was done by using a high-pressure stopped-flow apparatus up to 1500 bar,[10] the absorbance change being traced in the whole course of the reaction. The weighed-in concentration of MS was less than 0.2 mol/dm³ and that of TCNE was less than 1 mmol/dm³. In all cases the former was *ca.* 100 fold over the latter. Temperature was maintained at 25±0.2 °C by circulating the thermostated fluid around the high-pressure vessels.

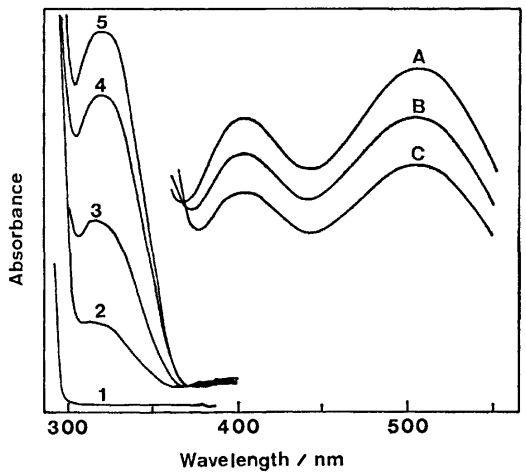


Fig. 1. Electronic spectra of the EDA complex (A—C, $[MS]_0=0.2$ mol/dm³, $[TCNE]_0=5$ mmol/dm³), and the 1,4-cycloadduct (2—5, $[MS]_0=0.1$ mol/dm³, $[TCNE]_0=1$ mmol/dm³) in chloroform at 1 bar at the following time/s after mixing.
A: 5, B: 90, C: 120, 1: TCNE, 2: 10, 3: 60, 4: 180, 5: 480.

Results and Discussion

The reaction mixture of TCNE and MS exhibited the increasing absorbance at 325 nm of the 1,4-cycloadduct with time, while the absorbances at 400 and 510 nm of the EDA complex decreased (Fig. 1); an isosbestic point appeared at 371 nm. When MS existed in large excess over TCNE, the rate of appearance of the adduct obeyed a first-order rate equation. Under the conditions that the EDA complex is always in equilibrium with TCNE and MS during the whole course of the reaction, we can represent the observed pseudo first-order rate constant k_{obsd} by Eq. 1 in terms of the rate and equilibrium constants as defined in Scheme 1:

$$k_{obsd} = \frac{k_1 K_c [D]_0}{1+K_c[D]_0} + k_{-1}, \quad (1)$$

where $[D]_0$ is the initial concentration of MS in molarity at a desired pressure. The correction of the weighed-in concentration for compression was made on the basis of the density data of Newitt *et al.*[11] for carbon tetrachloride, chloroform, and 1,2-dichloroethane, and of Srinivasan *et al.* for acetonitrile.[12] In chloroform and 1,2-dichloroethane where K_c was known even at high pressure,[13] the plot of k_{obsd} *vs.* $K_c[D]_0/(1+K_c[D]_0)$ was straight line to give k_1 and k_{-1} from the slope and the intercept, respectively (Fig. 2). In acetonitrile K_c being expected to be small enough, $1 \gg K_c[D]_0$, we obtain Eq. 2.

$$k_{obsd} = k_1 K_c [D]_0 + k_{-1}. \quad (2)$$

Hence, by the k_{obsd} *vs.* $[D]_0$ plot, $k_1 K_c$ and k_{-1} can be readily determined. In carbon tetrachloride in which K_c was unknown at high pressure, we first estimated k_{-1} at the region of $K_c[D]_0 \ll 1$, then obtained k_1 by

$$\frac{1}{k_{obsd}-k_{-1}} = \frac{1}{k_1 K_c [D]_0} + \frac{1}{k_1}. \quad (3)$$

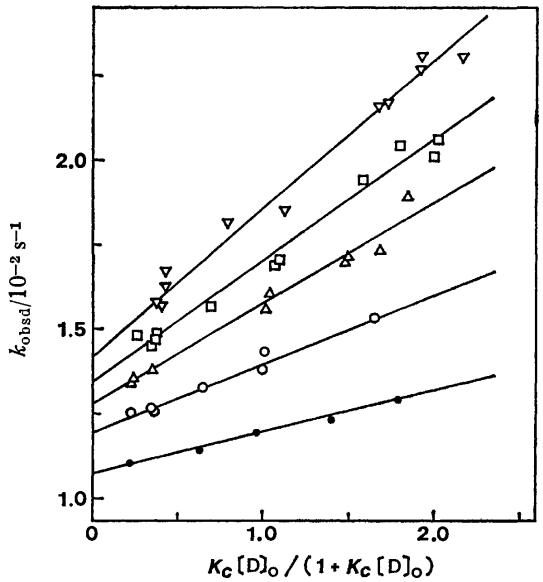

Fig. 2. Variation of k_{obsd} with $[D]_0$ according to Eq. 1 in chloroform at 25 °C.
●: 1 bar, ○: 250 bar, △: 500 bar, □: 750 bar, ▽: 1000 bar.

Table 1 shows the k_1 and k_{-1} values with K_c.

The volumes of activation ΔV_1^* for the step from the EDA complex to the 1,4-cycloadduct and ΔV_{-1}^* for the reverse one are calculated by the relation;

$$\Delta V^* = -RT\left(\frac{\partial \ln k}{\partial p}\right)_T, \quad (4)$$

where R, p, T, k, and ΔV^* are the gas constant, pressure, temperature, the rate constant(k_1 or k_{-1}) and the volume of activation(ΔV_1^* or ΔV_{-1}^*). The reaction volume ΔV_1 as calculated by $\Delta V_1^* - \Delta V_{-1}^*$ coincides with that by the equilibrium study.[13] In acetonitrile, K_c and k_1 are not reliable enough for the reaction volume associated with the EDA complex formation, ΔV_c, and ΔV_1^* to be recorded. If the volume of activation reflected only the structural change upon activation, the present value of ΔV_{-1}^* should be positive. It is worthy to note that ΔV_{-1}^* is negative in any solvent, since the volume decreases even for a bond-breaking process. As a consequence, in this case we are enforced to consider the electrostatic solvation in the transition state.

The solvent effect in which the electrostatic interaction plays an important role is sometimes successfully explained with Kirkwood's model,[14] which leads to Eq. 5 for the rate constants. Since the change of μ^2/r^3 terms with pressure is negligible up to a few kilobars compared to that of q, the volume of activation is represented by Eq. 6.

$$\ln k_1 = \ln k_{0(1)} + \frac{N}{RT}\left(\frac{\mu_*^2}{r_*^3} - \frac{\mu_{EDA}^2}{r_{EDA}^3}\right)q \quad (5a)$$

$$\ln k_{-1} = \ln k_{0(-1)} + \frac{N}{RT}\left(\frac{\mu_*^2}{r_*^3} - \frac{\mu_P^2}{r_P^3}\right)q \quad (5b)$$

$$\Delta V_1^* = \Delta V_{0(1)}^* - N\left(\frac{\mu^{*2}}{r^{*3}} - \frac{\mu_{EDA}^2}{r_{EDA}^3}\right)\left(\frac{\partial q}{\partial p}\right)_T \quad (6a)$$

$$\Delta V_{-1}^* = \Delta V_{0(-1)}^* - N\left(\frac{\mu_*^2}{r_*^3} - \frac{\mu_P^2}{r_P^3}\right)\left(\frac{\partial q}{\partial p}\right)_T \quad (6b)$$

$$q = \frac{D-1}{2D+1} \tag{7}$$

Here N is Avogadro's number, and r_*, r_{EDA}, and r_P are the radii of the transition state, the EDA complex and the 1,4-cycloadduct, respectively, and μ's denote the dipole moments. D is the dielectric constant of the solvent, and subscript 0 refers to the state free from the electrostatic interaction with the solvent. $\Delta V_{0(1)}^*$ and $\Delta V_{0(-1)}^*$ are the so-called intrinsic volumes of activation, and the second terms in Eq. 6 represent the volume contraction due to the solvation. The numerical values of q and $(\partial q/\partial p)_T$ are utilizable from the literatures.[12,15] The estimation of the radii was made on the assumption of the spherical model as follows:

$$r_{EDA}^3 = \frac{3}{4\pi N}\{\Delta V_c + V(\mathrm{TCNE}) + V(\mathrm{MS})\}, \tag{8a}$$

$$r_*^3 = \frac{3}{4\pi N}\{\Delta V_1^* + \Delta V_c + V(\mathrm{TCNE}) + V(\mathrm{MS})\}, \tag{8b}$$

$$r_P^3 = \frac{3}{4\pi N}\{\Delta V_1 + \Delta V_c + V(\mathrm{TCNE}) + V(\mathrm{MS})\}, \tag{8c}$$

and these approximated to be $r_{EDA}=4.6$, $r_* \approx r_P = 4.4$ Å.[4,16]

The plot of $\ln k$ *vs.* q exhibits a good straight line

a) Ref. 13.

for k_1 and k_{-1} as seen in Fig. 3; the slopes and r's provide the magnitudes of μ_* and μ_P to be 8.5 ± 0.5 and 6 ± 1 debye, respectively. Equation 6 is a severer test of this electrostatic model than Eq. 5. If not only the solvent effect on a reaction rate is expressed by Eq. 5 but also the volume of activation lies on a line of Eq. 6, the application of Kirkwood's theory is more justified, and the obtained value of μ_* becomes more reliable. That idea does not apply satisfactorily to the present results, as seen in Fig. 4. However, the relationship of Eq. 6 is useful to estimate the intrinsic volume terms. The slopes of the broken lines of Fig. 4 correspond to those of Fig. 3. The intercepts fall on -22 ± 3 and -3 ± 3 cm³/mol for the cycloaddition and the reverse reaction, respectively. The volume changes for most EDA complex formations, arising mainly from the intrinsic contribution are around -5 cm³/mol,[13,17] hence the intrinsic volume change from the reactants to the transition state results in about -27 cm³/mol; this is larger than the values for many reactions of Diels-Alder type,[8,9] -35—-40 cm³/mol. The fact that $\Delta V_{0(-1)}^*$, which should not be negative, is practically zero, suggests that the geometric structure at the transition state is not far from that of the cycloadduct. The apparent negative values for ΔV_{-1}^* must then be an indication of their difference in electronic character as reflected in the difference in their dipole moments.

The [2+2] cycloaddition of TCNE with a vinyl ether where the concerted mechanism is symmetrically forbidden by the Woodward-Hoffmann rule,[18] proceeds *via* a zwitterionic intermediate, and the dipole moment in the transition state is as large as 10—14 D.[19] Therefore, the volume contraction due to the electrostriction must be substantial in the transition state.[20,21] On the other hand, in many Diels-Alder reactions the dipole moment does not vary so much upon activation that the reaction rate cannot be affected by solvent and that the electrostriction hardly contributes to the volume of activation.

The present results that μ_* is large enough for the solvent polarity to affect the reaction rate remarkably and that ΔV_1^* is less negative than in usual Diels-Alder reactions strongly suggest that the 1,4-cycloaddition reaction undergoes a transition state of much higher polarity than do most [4+2] reactions.

The Penetration of Lysine into the Monolayers of Lecithin from the Underlying Aqueous Solutions

Masayuki NAKAGAKI and Emiko OKAMURA*
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-Shimoadachicho, Sakyo-ku, Kyoto 606
(Received May 27, 1981)

The surface pressure of the monolayers of dimyristoyl phosphatidylcholine (DMPC) on the lysine solutions was measured. The monolayer was more expanded on the solution than on pure water. The amount of lysine penetrating into the DMPC monolayer was calculated by means of a successive approximation. It was found that the amount of lysine penetrating increased with the increase in the concentration of the solution and with the decrease in the area per molecule of a DMPC monolayer, but it decreased with the further decrease in the area per molecule of DMPC. The average area per molecule of the monolayer consisting of lysine and DMPC was linearly related to the mole fraction of lysine. This linear relation indicates that partial molecular areas of both DMPC and lysine are independent of the amount of lysine in the monolayer. It is concluded that lysine and DMPC do not interact in the monolayer, although the monolayer of lysine and DMPC is formed as a result of the interaction between DMPC and lysine in a subsolution.

It has been widely believed, according to the fluid mosaic model of Singer and Nicolson,[1] that the biomembranes consist essentially of bimolecular lipid layers in which some proteins are dissolved. Much attention has been paid to the studies of the penetration of proteins into phospholipid monolayers, since lipid molecules in monolayers are oriented just as in the bimolecular layers. In these studies, the increase in either the area per molecule at a constant surface pressure or the surface pressure at a constant area per molecule has been measured for a phospholipid monolayer spread on an aqueous solution,[2,3] and the formation of mixed monolayers of phospholipid and protein has been discussed.[4] The monolayer method has thus been proved to be useful for investigating the lipid-protein interaction at the liquid-air interface.

In this work, the change in the surface pressure, caused by the penetration of L-lysine into the monolayer of lecithin, was measured. L-Lysine is an essential amino acid which is indispensable to growth and which plays various other important roles, for example, in the regulation of emzyme reactions[5] and in inactivating viruses,[6] and lecithin is the most typical component of biomembranes. As the lecithin, L-α-dimyristoyl phosphatidylcholine(DMPC) was used in this work; the amount of lysine penetrating into the monolayer of DMPC was calculated using the data obtained. The features of the interaction between lysine and DMPC were discussed.

Experimental

Materials. L-Lysine(free base) from Nakarai Chemicals, Ltd, was dissolved in redistilled water. DMPC from the Sigma Company was dissolved in distilled chloroform and the solution preserved in a refrigerator for several days before use.

Surface-tension Measurement. The surface tension of the lysine solution, γ_{lys}, was measured by the capillary-height method, while the surface pressure of lysine, F_{lys}, was obtained by means of Eq. 1:

$$F_{lys} = \gamma_0 - \gamma_{lys}, \quad (1)$$

where γ_0 is the surface tension of pure water. The temperature of the solution was kept at 25±0.5 °C.

Surface-pressure Measurement. The surface pressure of the DMPC monolayer was measured by Wilhelmy's plate method. Since the surface tension of a subsolution is not always equal to that of pure water, the surface pressure, F, was calculated by means of Eq. 2:[7]

$$F = \gamma_0 - \gamma = F' + F_{lys}, \quad (2)$$

where γ is the surface tension of a lysine solution covered with a lipid monolayer, while F' is the practical surface pressure defined by:

$$F' = \gamma_{lys} - \gamma, \quad (3)$$

and is measured directly by Wilhelmy's plate method as the decrease in the surface tension of a lysine solution upon the spreading of a lecithin monolayer. That is:

$$F' = (T_{lys} - T')/l, \quad (4)$$

where l is the length around the horizontal cross section of the plate. The values of T_{lys} and T' were measured as follows. A lysine solution of 57 cm³ was poured into a trough (5.0 cm×20.0 cm×0.4 cm) coated with Teflon: the temperature of the solution was kept at 25±0.5 °C by circulating thermostatted air. After the surface of lysine solution had been swept by a barrier covered with a Teflon sheet, a ground glass plate was suspended vertically on the liquid surface and the force acting on the plate, T_{lys}, was measured by means of a torsion balance, Shimadzu T-NR. The value of T_{lys} was measured several times until the equilibrium value was obtained. Then a lipid monolayer was spread from an AGLA micrometer syringe(accuracy ±0.0002 cm³) and left for 5 min. Then, the force acting on the plate, T', was measured by compressing the monolayer with a barrier. The equilibrium value of T' was obtained within 10 min.

The trough was used after any contaminants had been wiped off with ethanol and it had been rinsed well with redistilled water. The Teflon sheet and the ground glass plate were used after they had been immersed in heavy chromic acid and in fuming nitric acid respectively for more than one night and then rinsed well with redistilled water.

Results

Surface Tension of the Lysine Solution. Figure 1 shows the surface tension of a lysine solution. It is seen that the surface tension decreases slightly with the increase in the concentration of lysine, C_2. There-

fore, lysine is not adsorbed appreciably onto the liquid-air interface.

Surface Pressure-area Curves of the DMPC Monolayers. Figure 2 shows the relation between the surface pressure of the DMPC monolayer on an L-lysine solution, F, and the area per molecule of DMPC, A_3. When the concentration of lysine, C_2, is lower than 0.01 mol dm^{-3}, the F-A_3 curve of the DMPC monolayer on a lysine solution nearly coincides with that on pure water. This is because the amount of lysine penetrating into or adsorbed onto the monolayer is not so large as to change the surface pressure. When C_2 is higher than 0.01 mol dm^{-3}, the F-A_3 curve of the higher C_2 shifts to the right with an increase in C_2. This is attributable to the fact that the monolayer is expanded by the adsorption or penetration of lysine from the subsolution.

The Amount of Lysine Adsorbed. The relation between the surface pressure, F, and the concentration of lysine, C_2, at a constant area per molecule of lecithin, A_3, is shown in Fig. 3, from which the amount adsorbed may be calculated by use of Gibbs' adsorption equation:

$$\Gamma_2^\circ = \frac{1}{RT}\left(\frac{\partial F}{\partial \ln C_2}\right)_{A_3}, \tag{5}$$

where R is the gas constant, T is the absolute temperature, and Γ_2° is the amount of lysine adsorbed onto the portion of the interface where lecithin does not exist. The value of Γ_2° thus obtained is shown in Fig. 4 as a function of the concentration of lysine, C_2. It seems that lysine is not adsorbed appreciably onto the interface without a lecithin monolayer, but the amount of lysine adsorbed increases with the increase in C_2 when a lecithin monolayer exists at the interface.

In Eq. 5, the existence of an insoluble component, DMPC, at the interface is disregarded. Actually, however, both adsorbed lysine and the DMPC monolayer coexist at the interface, and the part of the interface already occupied by DMPC is not available for the adsorption of lysine. Gibbs' adsorption equation 5 is, therefore, modified by taking the partial molecular area of DMPC, $\overline{A}_3$, into account. The designed modification of Gibbs' adsorption equation is given by:

$$\Gamma_2 = (1-\overline{A}_3/A_3)\Gamma_2^\circ, \tag{6}$$

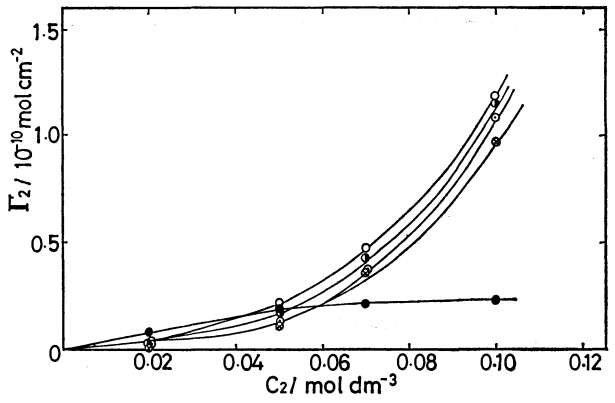

Fig. 5. The amount of lysine adsorbed onto DMPC monolayer, Γ_2, *vs.* C_2.

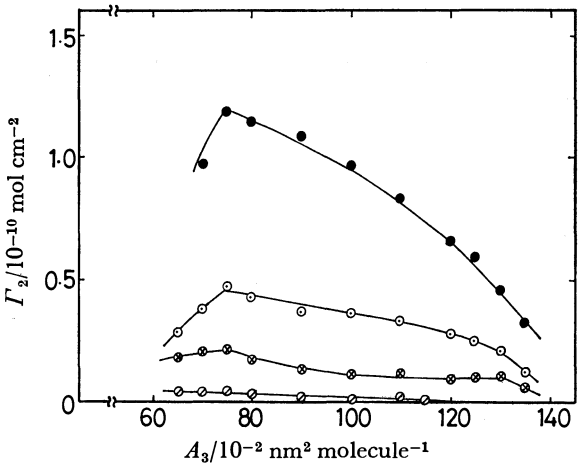

Fig. 6. The relation of the amount of lysine adsorbed, Γ_2, and the area per molecule of DMPC, A_3.
C_2/mol dm^{-3}: ∅ 0.02, ⊗ 0.05, ⊙ 0.07, ● 0.10.

where Γ_2 is the amount of lysine adsorbed onto the unit area of the interface in the presence of DMPC. According to Pethica,[8] $\overline{A}_3$ is approximated by the molecular area of DMPC on pure water, $A_3°$; Eq. 6 is, therefore, rewritten as follows:

$$\Gamma_2 = (1 - A_3°/A_3)\Gamma_2°. \tag{7}$$

Hereafter, this will be called the first approximation. This equation has been used to calculate the amount of solute molecules adsorbed onto the monolayer on subsolutions.[9,10]

The relation between the amount of lysine adsorbed, Γ_2, as calculated from Eq. 7, and the concentration of lysine, C_2, is shown in Fig. 5. The amount of lysine adsorbed decreased in the presence of an insoluble component at the interface, but it is still larger than the value in the case of no insoluble component, at least in the high-C_2 region. This would indicate that there exists a strong affinity between lysine and lecithin.

If the concentration of lysine, C_2, is kept constant, the amount of lysine adsorbed, Γ_2, changes with the area per molecule of DMPC, A_3, as is shown in Fig. 6. The amount adsorbed is higher at a higher concentration of lysine, and the curve has a maximum at high values of C_2. This would indicate the following points. As has already been shown in Fig. 1, lysine is not adsorbed appreciably onto a clean interface. The value of Γ_2 is, therefore, small when A_3 is large. Lysine is, however, adsorbed more onto a lecithin monolayer than onto a clean interface, and the amount adsorbed increases with the density of lecithin, that is, with the decrease in A_3. However, lysine is excluded from the monolayer, and the amount adsorbed decreases with the further decrease in the area per molecule of lecithin.

Discussion

The Mixed Monolayers Formed by the Penetration of Lysine. It may be stated that a mixed monolayer of lysine and DMPC is formed as a result of the penetration of lysine into a DMPC monolayer when a lysine solution is used as a subphase. The mole fraction of lysine in this mixed monolayer, X_2, is given by:

$$X_2 = \frac{\Gamma_2}{\Gamma_2 + \Gamma_3}. \tag{8}$$

Here, Γ_3 is the moles of DMPC per unit of area defined by:

$$\Gamma_3 = \frac{1}{A_3 \cdot N_A}, \tag{9}$$

where N_A is the Avogadro number. The average area per molecule of a lysine–DMPC mixed monolayer, A_{23}, is defined by:

$$A_{23} = \frac{1}{(\Gamma_2 + \Gamma_3)N_A}. \tag{10}$$

The relation between the average area per molecule and the mole fraction of lysine at a constant surface pressure is shown in Fig. 7. It may be seen from this figure that the partial molecular areas of both DMPC and lysine are dependent on X_2, but they

are practically independent of X_2 and are nearly constant in the region where X_2 is larger than 0.07. By extrapolating the linear portion of X_2, it is found that the partial molecular area of DMPC on a lysine solution, $\overline{A}_3$, is not equal to that on pure water, $A_3°$, at each surface pressure. This indicates that the approximation, $\overline{A}_3=A_3°$, used in Eq. 7 was not appropriate.

Since all the curves on Fig. 7 had the same shape, $(A_{23}-A_3°)$ was plotted against X_2 in Fig. 8. It was found that all the plots come on one curve and that $(A_{23}-A_3°)$ is linearly related to X_2 when X_2 is larger than 0.07. This linear portion is written by:

$$A_{23}-A_3° = 5.1—55.0X_2, \quad (11)$$

and when X_2 is equal to zero, Eq. 11 is rewritten as follows:

$$\overline{A}_3 = A_3° + 5.1. \quad (12)$$

The amount adsorbed, Γ_2, was, therefore, recalculated by Eqs. 6 and 12; this will be called the second approximation. The successive approximation was repeated until the value of Γ_2 converged to a defined value.

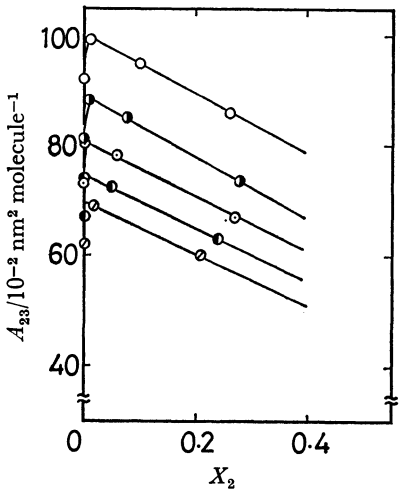

Fig.10. The relation of the average area per molecule, A_{23}, and the mole fraction of lysine, X_2, by the 4th approximation.
F/mN m^{-1}: ○ 5, ◑ 10, ⊙ 15, ◐ 20, ⊘ 25.

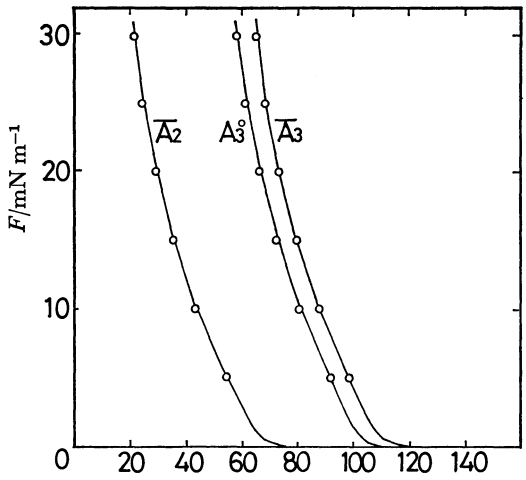

Fig.11. The relation of the surface pressure, F, and the partial molecular areas of lysine, $\overline{A}_2$, and DMPC, $\overline{A}_3$.
The F-A_3 curve of DMPC on pure water was designated as $A_3°$.

The approximation was repeated in this way, by using $\overline{A}_3-A_3°=6.5$ for the third and 7.0 for the fourth approximation. The values of Γ_2 thus obtained are plotted against A_3 in Fig. 9. Although the value of Γ_2 decreased with higher approximations, the general features did not change; *i.e.*, (1) Γ_2 increases with the increase in C_2 and (2) Γ_2 increases with the decrease in A_3 at a constant C_2, but decreases at a small value of A_3.

The Interaction between Lysine and DMPC. The relation between the average area per molecule, A_{23}, and the mole fraction of lysine, X_2, obtained by the fourth approximation is shown in Fig. 10. By com-

paring it with Fig. 7, we may conclude that A_{23} is linearly related to X_2, in the higher approximations at each surface pressure and that the relation may be expressed by the following empirical equation:

$$A_{23} = A_3^\circ + 7.0 - 44.0X_2. \quad (13)$$

This yields the following equations for the partial molecular areas of lysine and DMPC, $\overline{A}_2$ and $\overline{A}_3$, respectively:

$$\overline{A}_2 = A_3^\circ - 37.0, \qquad \overline{A}_3 = A_3^\circ + 7.0. \quad (13a)$$

The dependence of these quantities on the surface pressure is shown in Fig. 11.

The linear relation between A_{23} and X_2 shown in Fig. 10 thus shows that the partial molecular areas of both DMPC and lysine are independent of the extent of mixing as long as X_2 is smaller than about 0.3. This means that lysine and DMPC do not interact in the monolayer, although a mixed monolayer is formed by the interaction between lysine and DMPC. It can, therefore, be concluded, with regard to the intermolecular interaction between two components of a mixed monolayer formed by the penetration of one component, that the lateral interaction in the monolayer is quite different from the longitudinal interaction effective for the formation of a mixed monolayer, as is naturally to be expected from the high degree of orientation of molecules in the monolayer.

Relation between Exchange Interaction and Crystal Structure of Verdazyl Radicals. As Studied by Means of McConnell's Spin Density Hamiltonian*

Nagao AZUMA†

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received July 15, 1981)

The exchange interactions in four kinds of verdazyl crystals, 2,4,6-triphenylverdazyl (TPV), 2,4,6-triphenyl-3-methylverdazyl (MeTPV), 2,4,6-tri-*p*-tolylverdazyl (TTV), and 2,6-di-*p*-tolyl-4-phenylverdazyl (DTPV), have been studied by means of McConnell's spin density Hamiltonian. The calculated exchange parameters, J, have been compared with the experimental values derived from the magnetic susceptibilities. The observed order of J's, $J/k=-5.4$ (TPV), -9.1 (MeTPV), -11.1 (DTPV), and 0——0.3 K (TTV), can be qualitatively explained by the following equation:

$$J \propto \sum_{ij} (-1/r_{ij})\rho_i^l \rho_j^{l+1},$$

where ρ_i^l and ρ_j^{l+1} are π-spin densities on atoms i and j of the l-th and $(l+1)$-th molecules in the *crystallographic column* and r_{ij} is the interatomic distance between atoms i and j. The magnetic susceptibility data of MeTPV and TTV between 1.6 and 300 K are presented and interpreted with the Heisenberg linear chain model. The susceptibility of DTPV is re-interpreted in the same framework as above.

The magnetic susceptibilities of some organic free-radical solids show a characteristic temperature dependence[1] which can be well explained based on the Heisenberg-type magnetic linear chain model.[2] The spin Hamiltonian for the exchange interaction in the magnetic linear chain can be given by a familiar form:

$$H = -2J \sum_l \boldsymbol{S}_l \boldsymbol{S}_{l+1}, \quad (1)$$

where $\boldsymbol{S}_l$ and $\boldsymbol{S}_{l+1}$ are the spin operators for the l-th and $(l+1)$-th magnetic electrons, and J is the exchange interaction parameter which depends on the crystal structure. However, the relation between J and the crystal structure has not been understood well.

The verdazyls first synthesized by Kuhn and Trischmann[3] are a series of stable organic radicals containing four nitrogen atoms per molecule with unpaired electrons over the entire molecules. The magnetic susceptibility of 2,4,6-triphenylverdazyl (TPV) between 77 and 300 K[4] has indicated existence of the substantial exchange interaction between the unpaired electrons. We have studied the magnetic susceptibilities of TPV, 2,4,6-triphenyl-3-methylverdazyl (MeTPV), 2,4,6-tri-*p*-tolylverdazyl (TTV), and 2,6-di-*p*-tolyl-4-phenylverdazyl (DTPV) (*cf.* Fig. 1) in order to understand the relationship between J and the crystal structure. J's determined from the magnetic susceptibilities are very different depending on the radicals in spite of the similarity in their spin distributions. X-Ray studies have shown that the crystal structures of these radicals are different from one another. Therefore, these four verdazyls form a suitable set for such a study.

In order to understand the observed J from the crystal structure, we have calculated the exchange parameter using McConnell's spin density

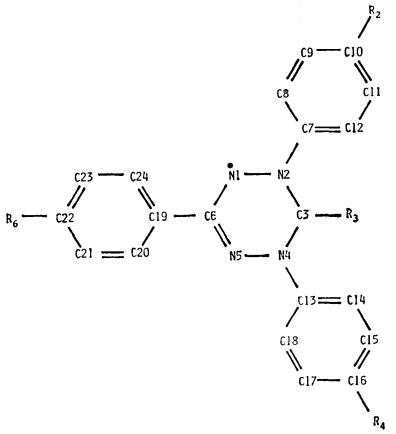

Fig. 1. Chemical structures and numbering system of verdazyls.

Hamiltonian:[5]

$$H^{AB} = -\boldsymbol{S}^A \boldsymbol{S}^B \sum_{ij} J_{ij}^{AB} \rho_i^A \rho_j^B, \quad (2)$$

where $\boldsymbol{S}^A$ and $\boldsymbol{S}^B$ are the spin operators for Molecules A and B, and where ρ_i^A and ρ_j^B are the π-spin densities on Atoms i of Molecule A and j of B, respectively. In evaluating the two-center exchange integral J_{ij}^{AB}, four trial functions of the distance, r_{ij}^{AB}, between Atoms i and j were used. The observed order of J's was qualitatively explained when J_{ij}^{AB} was assumed as a function of $1/r_{ij}^{AB}$.

Experimental

Following the process of Kuhn and Trischmann,[6] the samples were prepared by the ring formation of the corresponding formazans with formaldehyde or acetaldehyde, followed by reduction with alkaline solutions of these aldehydes. The radicals were purified a few times through

recrystallization from a mixture of acetone and methanol. The results of the elementary analyses were in agreement with the calculated values within experimental errors.

The magnetic susceptibilities from 1.6 to 300 K were measured on the powdered samples of MeTPV and TTV by means of a magnetic torsion balance with an accuracy of 3%.[7] The temperature was measured with a carbon resister and an AuCo–Cu thermocouple calibrated by measurements of the susceptibility of manganese Tutton salt and of the vapour pressure of liquid helium.

The experiments of ESR and ENDOR in solution have been described elsewhere.[8] The analyses of the crystal structures of MeTPV, TTV, and DTPV by X-ray diffraction have been reported previously.[9–11]

Summary of Previous Results

Spin Density Distribution. The present radicals in dilute solution have exhibited nine-line ESR spectra due to four nearly equivalent nitrogen nuclei.[8] The nitrogen hyperfine coupling constants have ranged from 0.56 to 0.58 mT. The proton hyperfine coupling

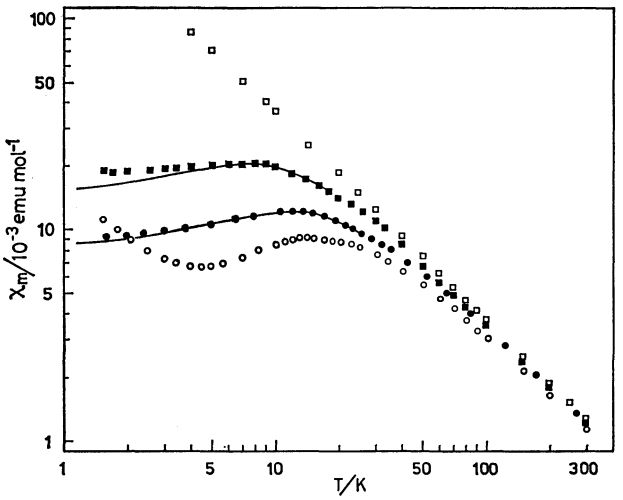

Fig. 3. Molar paramagnetic susceptibilities of crystalline verdazyls.
The solid square stands for the observed susceptibility of TPV, the solid circle of MeTPV, the open square of TTV, and the open circle of DTPV. The solid lines are theoretical susceptibilities calculated with the Heisenberg linear chain model.

constants of TPV, MeTPV, and TTV have been measured by means of the ENDOR technique.[8] The changes in the proton coupling constants caused by methyl substitutions are less than 5%. The spin densities in TPV calculated by Fischer[12] are given in Table 1. As these values explain the hyperfine coupling constants, we use these values for the calculation of the exchange parameters.

Crystal Structure. The molecular overlappings of four verdazyls are compared with one another in Fig. 2. TPV and DTPV molecules are arranged in zigzag chains along the respective c axes, and MeTPV and TTV ones form Venetian blinds along the respective c axes. No alternation is observed in the intermolecular distances in these chains and blinds (columns). The angular orientation of $p_z\pi$-orbitals in TTV crystal is much more unfavourable for overlapping than that in the MeTPV crystal. The order of the mean values of the interatomic distances between the π-frameworks of the neighbouring molecules in the columns is as follows: DTPV<MeTPV<TTV<TPV (see Table 3).

Magnetic Susceptibility

The susceptibility data were corrected for the diamagnetic contribution using Pascal's constants.[14] The molar paramagnetic susceptibility, χ_m, of MeTPV follows the Curie-Weiss law with the negative Weiss constant of $\theta = -10.3$ K in the high temperature region. In the low temperature region, however, it deviates from the Curie-Weiss law and exhibits a broad maximum, χ_{max}, at T_m (=11.7 K). When the temperature, T, is lowered below T_m, χ_m decreases towards a non-zero value at 0 K. This finite value, $\chi_{T=0}$, was estimated by extrapolation. The susceptibility of TTV complies with the Curie-Weiss law

Table 2. Results from susceptibility measurements

a) The value of the molar susceptibility in m^3 mol^{-1} (SI) can be obtained by multiplying the value in emu mol^{-1} (cgs) by $4\pi\times10^{-6}$.

with a small negative Weiss constant of −0.3 K over the whole temperature region examined. The spin concentrations of MeTPV and TTV, as determined from the susceptibilities in the Curie-Weiss region, were 100% within the experimental accuracy.

The susceptibilities of TPV[15] and DTPV[16] have been reported previously. However, the susceptibility of DTPV, which has been explained tentatively by the Ising model, is re-interpreted in the framework of the Heisenberg model in this paper. The susceptibility of DTPV displays a round maximum and a broad minimum at 4 K. An approximated $\chi_{T=0}$ is estimated by the extrapolation of the curve between the maximum and minimum. The susceptibilities of the verdazyls and the results obtained from the susceptibilities are shown in Fig. 3 and Table 2, respectively, together with the data of TPV. In Table 2, T_n for TPV shows the temperature at which χ_m-T curve exhibits a discontinuity in its slope.

Discussion

Susceptibility. The susceptibilities of the verdazyls are discussed here in order to obtain the experimental parameters for the exchange interactions. The columnar structure with a uniform intermolecular distance suggests a linear chain spin system, that is, the Heisenberg linear chain model with an isotropic exchange interaction or the Ising linear chain model with an extremely anisotropic one. In our case, therefore, the former is more adequate than the latter in view of the practically isotropic g-values of the verdazyls, $g=2.003$.[17] Edelstein[18] employed the Ising linear chain model to interpret the susceptibilities of organic radicals of BDPA and PAC at an earlier date. Recently, however, those susceptibilities were interpreted quantitatively in terms of the Heisenberg-type interaction.[1a,b]

According to the study of Bonner and Fisher,[2] the susceptibility of the Heisenberg linear chain with an antiferromagnetic exchange coupling exhibits a round maximum of height

$$\chi_{max}T_m = 0.142 \tag{3}$$

at

$$kT_m/|J| = 1.282, \tag{4}$$

where k is the Boltzmann constant. J parameters of TTV[15] and MeTPV have been estimated from Eq. 4 (see Table 2). The observed $\chi_{max}T_m$ values of TPV and MeTPV are 0.140 and 0.142, respectively. The ratios of $\chi_{max}/\chi_{T=0}$ estimated for TPV and MeTPV are, respectively, 1.19 and 1.42, while theory predicts 1.45.[2] These values indicate that the MeTPV crystal is a typical Heisenberg linear chain spin system. On the other hand, the TPV crystal is not an ideal one, which is indicated also by the discontinuity in the slope of the χ_m-T curve. However, the dominant exchange interaction is the Heisenberg-type one.

J value for TTV has been estimated by a familiar relation of $\theta=2\zeta JS(S+1)/3k$ given by the molecular field theory,[19] where the nearest-neighbour parameter, ζ, is 2 and $S=1/2$.

DTPV Spin System: The susceptibility of DTPV exhibited a maximum and a broad minimum, and $J/k=-17$ K was obtained by means of the Ising linear chain model.[16] However, application of the Ising model to such susceptibility may underestimate the contribution from magnetic chains with odd spins. Therefore, we re-interpreted the susceptibility of DTPV based on diamagnetic dilution.

When a magnetic linear chain with an infinite length is diluted by diamagnetic impurities, the resultant diluted system is composed of paramagnetic chains of various finite lengths; such finite chains will be called segments. When the interaction between the segments is disregarded, the susceptibility of the diluted system is given by

$$\chi_m = \sum_{n=1}^{\infty} P_{n,c}\chi_n, \tag{5}$$

where $P_{n,c}$ is a probability making the segment with n spins at c spin-concentration, and χ_n is the susceptibility of the n-spin segment. For random diamagnetic dilution of the linear chain, $P_{n,c}$ is approximately given by

$$P_{n,c} = nc^n(1-c)^2. \tag{6}$$

Because there is no analytical representation of χ_n, the susceptibility of DTPV is treated graphically in Fig. 4. The solid circles are the experimental values based on $J/k=-11.1$ K which is estimated from Eq. 4. The open circles were obtained by adjusting the experimental value at T_m to the theoretical value of the Heisenberg linear chain at the same temperature. The adjusting factor is 1.09; this corresponds to the spin concentration of 0.92, which is very close to 0.94 determined from the susceptibility measurement. The adjusted susceptibility is close to the mean of the theoretical values for 10- and 11-spin segments. This mean susceptibility is very similar to that of the Heisenberg linear chain except for the region below $kT/|J|=0.3$. On the other hand, $n=12$ is obtained from the equation derived by $\partial P_{n,c}/\partial n=0$ with $c=0.92$. These results suggest strongly that the DTPV spin system is characterized by the Heisenberg linear chain with $J/k=-11$ K.

Relationship between J and Crystal Structure. Comparing Eq. 2 with Eq. 1, the quantity in the summation in Eq. 2 is identified as $2J$ in Eq. 1, which is the exchange integral between the l-th and $(l+1)$-th radicals. In order to obtain a tractable form of J_{ij}^{AB}, we have calculated the summation for pairs of the

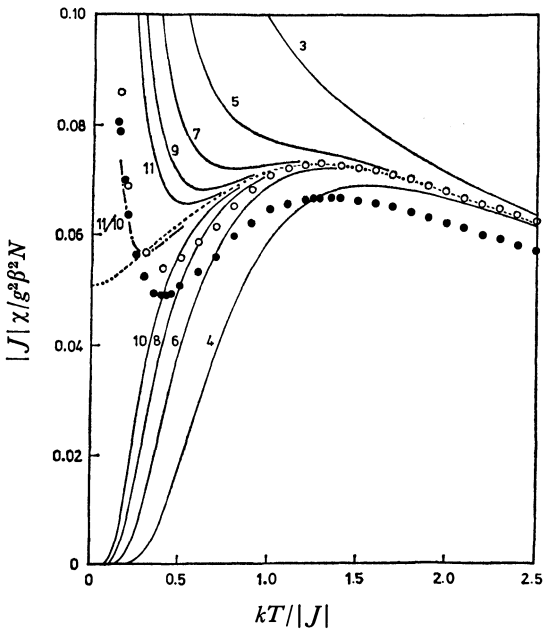

Fig. 4. Paramagnetic susceptibility of DTPV.
The solid circles are the experimental values. The open circles are the values corrected for the diamagnetic impurities. The broken line is the susceptibility of the Heisenberg linear chain.[2] The solid lines with n figures are the theoretical susceptibilities from rings of n Heisenberg-spins and dashed line is the mean of those of 10 and 11 spins.[2]

neighbouring molecules in the crystal. By analogy with the hydrogen molecule, the antiparallel spin-arrangement may be favourable with negative J_{ij}^{AB}. The negative J_{ij}^{AB} was assumed previously in this series[15] and also by Duffy *et al.*[20] in order to estimate J in DPPH-benzene crystal. Four trial functions with negative sign are adopted for J_{ij}^{AB}.

$$\text{Type A} \quad J_{ij}^{AB} = -C \exp[-Dr_{ij}^{AB}], \tag{6}$$

where C and D are positive constants. This equation can be derived from the result of the numerical calculation made by Dulčić and Herak[21] who have treated two carbon atoms in a radical pair by using the explicit form for the exchange integral given by Löwdin.[22]

On the other hand, it has been considered that the overlap between the orbitals occupied by the unpaired electrons serves as the path of the exchange interaction and the overlap has been used as a measure of the magnitude of the exchange interaction.[23] Then, this measure is adopted as the second trial function:

$$\text{Type B} \quad J_{ij}^{AB} \propto -S_{ij}^{AB}, \tag{7}$$

where S_{ij}^{AB} is the overlap integral between $p_z\pi$-orbitals of atoms i and j. The overlap integral can be easily computed with the recurrence formulae.[24]

In order to obtain the third trial function, the Hamiltonian for hydrogen molecule written by using the familiar symbols is referred:

$$H = -(h^2\nabla_1^2/8\pi^2m + e^2/r_{a1}) - (h^2\nabla_2^2/8\pi^2m + e^2/r_{b2}) + (-e^2/r_{a2} - e^2/r_{b1} + e^2/r_{12} + e^2/R).$$

The quantity in the last parentheses is known as the interaction operator, H'; $(H' - e^2/R)$ is the operator for the Heisenberg exchange interaction. The energy given by $(H' - e^2/R)$ approaches $-e^2/R$ when R becomes large. Then, the intermolecular exchange interaction may be approximated by

$$\text{Type C} \quad J_{ij}^{AB} \propto -1/r_{ij}^{AB}. \tag{8}$$

Several investigators have noted the linear correlation between the singlet-triplet energy separation and the zero-field splitting parameter for a number of aromatic hydrocarbons and biradicals.[25] This correlation suggests that the exchange energy follows r^{-3} where r is the mean distance between the unpaired electrons, so we adopted the following trial function.

$$\text{Type D} \quad J_{ij}^{AB} \propto -1/(r_{ij}^{AB})^3. \tag{9}$$

The exchange integral depends on both the distance and the angle between the $p_z\pi$-orbitals. However, the angular dependence is neglected in Types A, C, and D. A possible angular correction can be made by multiplying the trial functions by $\cos\theta_i^A \cos\theta_j^B$ where θ_i^A and θ_j^B are the angles between the respective axes of the $p_z\pi$-orbitals and the interatomic vector distance r_{ij}^{AB}.[20] However, we adopted the following correction factor, p,

$$p = \begin{cases} 1 & \text{when } r_{ij}^{AB} \leq 6\,\text{Å} \\ 0 & \text{when } r_{ij}^{AB} > 6\,\text{Å}. \end{cases} \tag{10}$$

Such a correction gives almost the same effect as that obtained by the cosine squared factors in our case.

The results of the calculation are shown in Table 3. Type A predicts J less than 1% of the observed one. This result arises from the short-range character of Eq. 6 which gives $J_{ij}^{AB}/k = -3.9$ and -0.01 K for $r_{ij}^{AB} = 3.4$ and 4.6 Å, respectively. Type B as well as Type A reverse the observed order of J's strikingly. Contrary to the case of Types A and B, Types C (and D) explain the order of the observed J's when the summation in Eq. 2 is performed over the pair of the neighbouring molecules in the column along the c axis of each crystal. This result shows that the magnetic chains in the present crystals are along the respective c axes and correspond to the *crystallographic columns*. The ratios of the interchain coupling to the intrachain one calculated by using Type C are 0.2, 0.04, 0.1, and 0.04 for TPV, MeTPV, TTV, and DTPV, respectively. This is consistent with the following fact based on the susceptibility: TPV crystal is not a typical Heisenberg linear chain spin system, while MeTPV and DTPV crystals are typical ones. Since the molecular packing along the column is generally different from those perpendicular to the column in the crystals of organic radicals, the ratios of the exchange coupling between the chains to the intrachain one may be hence more adequately estimated by using Type C than Types A and B.

Concluding Remarks

The susceptibilities of TPV, MeTPV, and DTPV can be explained in the framework of the Heisenberg linear chain model. The exchange parameters estimated from the susceptibilities are $J/k = -5.4$, -9.1, -11.1, and 0——0.3 K for TPV, MeTPV, DTPV,

Table 3. Results of summation in McConnell's spin density Hamiltonian

a) The constants in Eq. 6 (Type A) were obtained from the exchange integrals (in [K]) in Ref. 21. Those in Eqs. 7—9 were adjusted to give −11 K for the DTPV pair along the c axis. b) $\langle r \rangle$ is the mean value of the relevant interatomic distances [l/Å].

and TTV, respectively. These differences arise from the differences in the crystal structures. The McConnell's spin density Hamiltonian with $-1/r_{ij}^{AB}$ in place of J_{ij}^{AB} may be useful in finding the direction of the dominant exchange interaction and in estimating the order of the exchange coupling between the magnetic chains in crystals of aromatic radicals.

The author is much obliged to Professors Hiroaki Ohya-Nishiguchi and Yasuo Deguchi for continuous encouragement throughout this work and also indebted to Professors Noboru Hirota and Kazuo Mukai for illuminating discussions. Encouraging advices have been given by Professor Kazuhiko Ishizu, to which the author's thanks are due. Thanks are also due to the co-authors in this series for hearty cooperation. The calculations were performed at the Computer Centers of Kyoto and Ehime Universities.

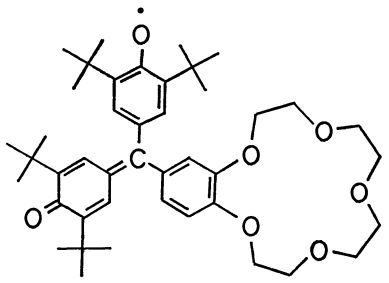
ESR Investigation of Alkali Metal Complexes of Galvinoxyl-labeled Benzo-15-crown-5 in Frozen Solution

Kazuo Mukai,* Nobuhito Ida, and Kazuhiko Ishizu
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received July 18, 1981)

A stable galvinoxyl derivative (**1**) of benzo-15-crown-5 was prepared and the complex formation between the spin labeled crown ether **1** and the alkali metal and ammonium salts was studied by the ESR technique. Existence of the (2:1) complex of **1** with potassium, rubidium, and ammonium salts was confirmed by the observation of the triplet ESR spectra in ethanol rigid matrix at 77 K. Essentially the same ***g***- and ***D***-tensor values are observed for all the (2:1) complexes, indicating similar conformation of the ligand molecule **1**. The zero-field splitting parameters (*D* and *E*) are calculated on the basis of the spin distribution of **1** and the assumed molecular structures for the (2:1) complex. By comparing the observed *D* and *E* parameters with the calculated ones, the structure of the (2:1) complex in ethanol rigid matrix is discussed. On the other hand, the sodium complexes of **1** show a slightly asymmetric single line, suggesting the (1:1) complex formation between **1** and the sodium salts. No anions (SCN^-, Br^-, and I^-) have any appreciable effect on the ESR spectra of both the (2:1) and (1:1) complexes.

It is well known that the cyclic polyethers synthesized by Pedersen form stable complexes with alkali and alkaline earth metal ions, both in solution and in the solid state.[1-3] The stoichiometry of the crystalline complexes depends on the relative size of the "hole" in the cyclic polyether and of the cation. For instance, benzo-15-crown-5 with a hole 1.7—2.2 Å in diameter usually forms a (1:1) complex with sodium (1.90 Å in diameter), and (2:1) complexes with the ions larger than the hole. Recently, we have prepared a galvinoxyl derivative (**1**) of benzo-15-crown-5 (*i.e.*, galvinoxyl-benzo-15-crown-5 (**1**)) (see Fig. 1) and studied the complex formation of the spin-labeled crown ether (**1**) with NaSCN or KSCN salt by using the ESR technique.[4] A triplet ESR spectrum has been observed for the KSCN complex of **1** in ethanol rigid matrix at 77 K, indicating the formation of a sandwiched dimer. On the other hand, the result of ESR measurement of the NaSCN complex suggested a (1:1) complex formation between **1** and NaSCN.

In the present paper, in order to obtain further information on such complex formations, we have measured ESR spectra of the complexes of **1** with eight kinds of salts in ethanol rigid matrix. Typical triplet ESR spectra have been observed for the K^+, Rb^+, and NH^+_4 complexes of **1**, clearly showing the (2:1) complex formation between **1** and the salts. The zero-field splitting (ZFS) parameters (*D* and *E*) were calculated for the assumed molecular structures by using McLachlan's spin densities of **1** which is a monoradical half of the sandwiched dimer. On the basis of these data, the structure of the (2:1) complex has been discussed. Solvent effect on the structure of the (2:1) complex has also been studied. On the other hand, the sodium complexes of **1** showed a slightly asymmetric single line, suggesting the (1:1) complex formation between **1** and the sodium salts. Three anions, SCN^-, Br^-, and I^-, used in this study have been found to have little effect on the spectral characteristics of either the (2:1) or the (1:1) complex.



1

Fig. 1. Molecular structure of galvinoxyl-benzo-15-crown-5 (**1**).

Experimental

The phenol precursor of **1** was synthesized by condensation of 2,6-di-*t*-butylphenol (2.06 g) with 4′-formylbenzo-15-crown-5 (2.96 g) in KOH (0.66 g)–ethanol (30 cm^3) solution under a nitrogen atmosphere at 30 °C, as described in a previous paper.[4] An orange crystal of the phenol precursor showed a melting point 209—211 °C (softens at 176 °C): Found: C, 74.13; 8.74%. Calcd for $C_{43}H_{60}O_7$: C, 74.97: H, 8.78%. UV and visible (C_2H_5OH) 276 (ε 18500) and 434 nm (ε 30200); NMR (CCl_4) δ=1.23 (18H, s, *t*Bu, ring A), 1.43 (18H, s, *t*Bu, ring B), 3.5—4.2 (16H, m, $-CH_2-$), 5.37 (1H, s, OH, ring A), 6.70—6.82 (3H, m, ring C), 7.00 (2H, s, aromatic H, ring A), and 7.08 (2H, s, aromatic H, ring B).

Compound **1** was prepared by oxidation of the above phenol precursor with alkaline potassium hexacyanoferrate-(III) in diethyl ether solvent under a nitrogen atmosphere, with the temperature kept between 0—5 °C. Compound **1** was isolated as a stable dark brown crystal from the etherial solution: UV and visible (C_2H_5OH) 280 (ε 17000), 388 (ε 18400), and 455 nm (ε 49500).

The magnetic susceptibility of **1** was measured in the temperature range 55—300 K. The data have been corrected for the diamagnetic contribution of $\chi_{dia}=-0.437\times10^{-3}$ emu/mol calculated by Pascal's method. The susceptibility follows the Curie-Weiss law, with a paramagnetic Curie constant of 0.369±0.010 K·emu/mol and a Weiss constant of −2±3 K. The radical concentration of **1** calculated from the above Curie constant is 98%. All the ESR spectra were measured in a sealed, degassed system.

Table 1. *D*- and *g*-tensor values of the complexes of **1** with several salts in ethanol at 77 K

Salt	Complex	$\frac{\lvert D\rvert}{G}$ [a]	$\frac{\lvert E\rvert}{G}$ [a]	g_{zz} [b]	g_{yy}	g_{xx}	g_{av} [c]

Results and Discussion

Ethanol Rigid Matrix ESR Spectra of the Alkali Metal Complexes of ***1***. An ethanol solution of **1** (3.0×10^{-3} mol dm^{-3}) containing equimolar KI salt clearly shows three pairs of absorption lines with the same order of intensity at 77 K, as shown in Fig. 2(a). A slightly asymmetric central line with a width of about 6.0 G (1 G $=10^{-4}$ T) at $g\simeq 2.005$ shows a shape essentially the same as that of the metal-free **1** ($\Delta H_{msl}=$ 6.5 G and $g\simeq 2.005$), and the relative intensity of this central line changes depending on the ratio of the potassium salt to **1**. Therefore, this line is attributable to the metal-free **1** and/or the (1:1) complex between **1** and KI. The three pairs of absorption lines apparently represent zero-field splittings arising from the intermolecular spin-spin dipolar interaction of two electrons in a triplet state. In fact, the forbidden transition ($\Delta m_s=\pm 2$) was observed at about 1638 G, as shown in Fig. 2(b). These results clearly indicate the (2:1) complex formation between **1** and KI.

The spin Hamiltonian for the triplet radical pair may be expressed by

$$H=\beta \boldsymbol{H}\cdot\hat{\boldsymbol{g}}\cdot\boldsymbol{S}+\boldsymbol{S}\cdot\hat{\boldsymbol{D}}\cdot\boldsymbol{S} \quad (1)$$

$$=\beta \boldsymbol{H}\cdot\hat{\boldsymbol{g}}\cdot\boldsymbol{S}-XS_x^2-YS_y^2-ZS_z^2, \quad (2)$$

where $\hat{\boldsymbol{g}}$ is $\boldsymbol{g}$ tensor, $\hat{\boldsymbol{D}}$ is the fine structure tensor with principal values of $-X$, $-Y$, and $-Z$, and the other symbols have the usual meanings. The separations (ZZ', YY', and XX') between the three pairs of absorption lines in the spectrum of the KI complex are 151.8 $\pm$0.6, 102.0$\pm$0.6, and 49.8$\pm$0.6 G, respectively, so the ZFS parameters, $|D|$ and $|E|$, were evaluated as 75.9$\pm$0.3 and 8.7$\pm$0.3 G, respectively, by the method of Wasserman *et al.*[5] Assuming that the principal axes of the *D*- and *g*-tensors are coaxial, *g*-tensor values have been estimated from the positions of three pairs of turning points (ZZ', YY', and XX').[5,6] They are $g_{zz}=2.0029\pm 0.0002$ (Z, Z'), $g_{yy}=2.0049\pm 0.0002$ (Y, Y'), and $g_{xx}=2.0073\pm 0.0002$ (X, X').

First, the effect of the negative ions on the structure of the KI complex of **1** was examined. The ESR spectra of both the KBr and KSCN complexes of **1** in ethanol at 77 K are similar to that of the KI complex of **1**, and the observed *D*- and *g*-tensor values of these (2:1) complexes are summarized in Table 1. Live and Chan[7] have measured the proton NMR spectra of some crown ethers and their alkali metal complexes in organic solvents, and studied the solution structure of the "crown" cyclic polyether rings in detail. They observed the variation in chemical shifts of ether protons with anions (I^-, SCN^-, and ClO^-_4), and concluded that the difference in the shifts is due to the ion-pair formation. However, as it is clear from the results shown in Table 1, the variation in ZFS parameters with anions is almost negligible in the present (2:1) complexes. The result

indicates that the ion pairing is unimportant in determining the structure of the (2:1) complex.

Second, the effects of the positive ions on the complex formation and on the molecular structure of the complex were studied. The ESR spectrum of the RbI complex of **1** in ethanol rigid-matrix at 77 K shows a shape essentially the same as that of the KI complex (see Fig. 3), except for the difference in the central signal intensity, indicating the (2:1) complex formation. The ZFS parameters (D and E) and g-tensor values have been estimated from the positions of the three pairs of turning points (ZZ', YY', and XX'), as performed for the KI complex of **1**. These values are $|D|=76.4\pm0.3$ G, $|E|=8.8\pm0.3$ G, $g_{zz}=2.0028\pm0.0002$, $g_{yy}=2.0048\pm0.0002$, and $g_{xx}=2.0067\pm0.0002$. The ethanol rigid-matrix ESR spectrum of the NH_4SCN complex of **1** is also quite similar to that of the KI complex of **1**, giving the ZFS parameters of $|D|=76.2\pm0.3$ G and $|E|=8.6\pm0.3$ G. The ZFS constants are the same for all the (2:1) complexes of **1** examined in the present work. We can then conclude that the same molecular conformation persists in all the (2:1) complexes studied. On the other hand, the solution of **1** (3.0×10^{-3} mol dm^{-3}) containing the equimolar NaSCN salt shows a slightly asymmetric single line with a width of 6.6 G located at $g\simeq2.005$ at 77 K, unequivocally suggesting (1:1) complex formation between **1** and NaSCN. Further, by changing the anion of Na salt from SCN^- to Br^- and SO_4^{2-} in the ethanol solution, no detectable changes were observed in the ESR spectra (see Table 1).

*The Structure of the (2:1) Complexes of **1** with K, Rb, and NH_4 Salts.* The crystal structure of a (2:1) complex of benzo-15-crown-5 with potassium iodide has been investigated by Mallinson and Truter.[8] The crystal system of the complex is tetragonal with a space group of P4/n and with lattice constants of $a=b=17.84$, $c=9.75$ Å, and $z=4$. The complex cation has crystallographic symmetry $\bar{1}$, the potassium being 'sandwiched' between the two centro-symmetrically related ligand molecules. In each of these, the five ether-oxygen atoms are approximately coplanar, the cation lying 1.67 Å away from this plane, so that the ten oxygen neighbors form a pentagonal antiprism. The benzo-group is nearly coplanar with the oxygens, the greatest deviation being 0.11 Å. If the KI complex of **1** takes a conformation (hereafter referred to as the "*trans*" conformation) similar to that of the benzo-15-crown-5 complex, the interatomic distance between the central triphenylmethyl carbon atoms in the pair of **1** will become about 13 Å. A zero-field splitting of $|D|=75.9$ G has been observed for the KI complex of **1**, as described above. Consequently, the calculated average interelectronic distance, using a model of two-point dipoles ($|D|=(3/2)g\beta r^{-3}$), is about 7.2 Å. From comparison of these distances, the "*trans*" conformation is not acceptable for the KI complex of **1**. Therefore, in order to clarify the structure of the (2:1) complex of **1** with KI in ethanol rigid matrix, the calculations of the D-tensor values were performed for the assumed structure of the complex, using McLachlan's spin densities of **1** which is considered to be a monoradical half of the (2:1) complex.[9,10]

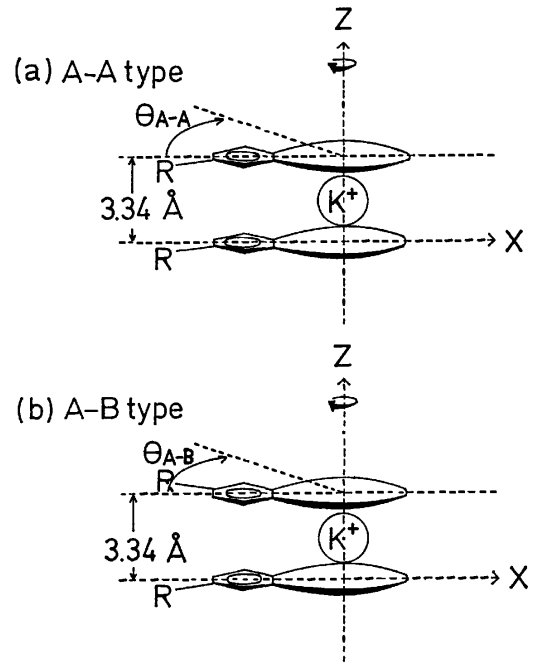

Fig. 4. Molecular structures and the coordinate systems chosen for "*cis*" conformation of the K complex of **1**.
(a) A–A type, (b) A–B type.

For the KI complex of **1**, we can expect two possible structures, (i) and (ii), in which each monoradical half is considered to have a planar structure, as a whole molecule. These two structures, (i) and (ii), are shown in Fig. 4 and named as "A–A type" and "A–B type" structures, respectively. Thus, as a most plausible case, the D-tensor values were calculated, assuming that the interplanar spacing between the two monoradical halves is 3.34 Å and varying the rotation angles θ_{A-A} and θ_{A-B}. The coordinate systems (x, y, and z) chosen for both the structures are shown in Fig. 4, where $\theta=0°$ corresponds to a planar "*cis*" conformation and $\theta=180°$ is a planar "*trans*" conformer in each structure.

The orbital containing the unpaired electron of phenylgalvinoxyl radical has, at least in the Hückel approximation, a node in the central phenyl ring; in fact, the results of McLachlan MO calculation of phenylgalvinoxyl[11] showed the exsistence of a very small unpaired electron density (1.0—1.5%) in the phenyl ring, and, further, an ENDOR study found a small hyperfine splitting ($a^H=0.207$ G) for the phenyl-ring protons.[11] In such a case, the unpaired electron distribution of **1** must be similar to that of phenylgalvinoxyl. In fact, the values of the hyperfine splittings ($a_m^H=1.31\pm0.02$ G) of the *meta* ring protons and the isotropic g_{iso} value ($=2.0044\pm0.0001$) of **1** show an excellent agreement with the corresponding values ($a_m^H=1.32\pm0.02$ G, $g_{iso}=2.0044\pm0.0001$) of phenylgalvinoxyl.

The D-tensor components of the dipolar splittings

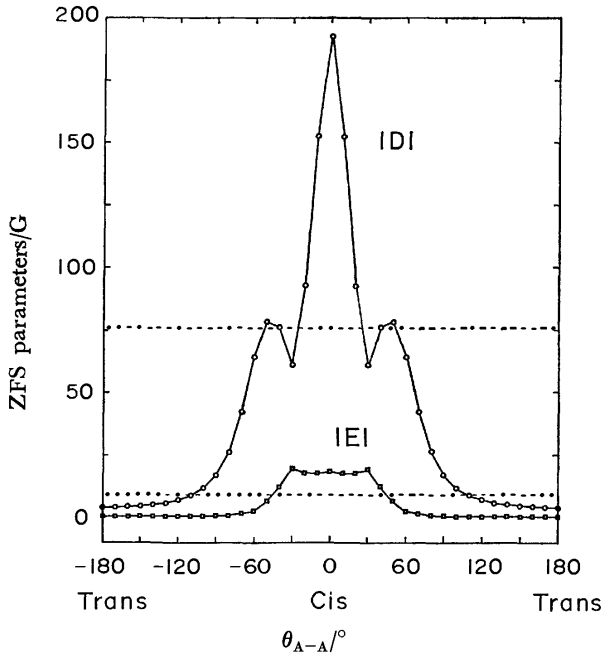

Fig. 5. The variation of the ZFS parameters $|D|$ and $|E|$ as a function of the rotation angle θ_{A-A}. Broken lines represent the observed $|D|$ (75.9 G) and $|E|$ (8.7 G) values for the KI complex of **1**.

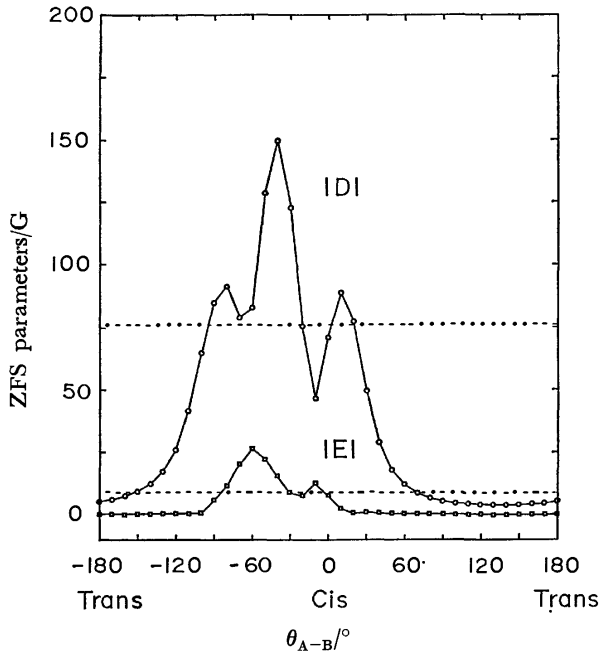

Fig. 6. The variation of the ZFS parameters $|D|$ and $|E|$ as a function of the rotation angle θ_{A-B}. Broken lines represent the observed $|D|$ (75.9 G) and $|E|$ (8.7 G) values for the KI complex of **1**.

can be calculated with the aid of the following equations:

$$D_{mm} = (1/2)g^2\beta^2 \sum_{i,j} \rho_i\rho_j(r_{ij}^2 - 3m_{ij}^2)/r_{ij}^5, \quad (3)$$

$(m = x, y, z)$

$$D_{mn} = (1/2)g^2\beta^2 \sum_{i,j} \rho_i\rho_j(-3m_{ij}n_{ij})/r_{ij}^5, \quad (4)$$

$(m, n = x, y, z;$ but $m \neq n)$

where r_{ij} is the distance between the i and j atoms, and ρ_i and ρ_j are the McLachlan π-spin densities[11] on the i-th atom in one phenylgalvinoxyl group and the j-th atom in the other phenylgalvinoxyl group, respectively, in a (2:1) complex. Here we have used the following bond lengths for the galvinoxyl group: the C–O bond length is 1.27 Å and the C–C bond length is 1.40 Å on the average, as obtained by an X-ray analysis of the galvinoxyl radical.[12] Atomic coordinates of benzo-15-crown-5 are taken from its KI complex reported by Mallinson and Truter.[8] Then, the resulting tensor was diagonalized, giving the principal values (X, Y, and Z) and thus, the zero-field splitting parameters, D and E.

Figures 5 and 6 show just how the ZFS parameters D and E vary as a function of θ_{A-A} and θ_{A-B}, respectively. In the case of A–A structure, the D parameter varies with θ_{A-A} from 192.3 G for $\theta_{A-A}=0°$ to 3.9 G for $\theta_{A-A}=180°$ and the E parameter from 19.3 G for $\theta_{A-A}=30°$ to 0.1 G for $\theta_{A-A}=180°$, but the dependence on the changes in θ_{A-A} is not simple. Similarly, in the case of A–B structure, the D and E parameters vary with θ_{A-B} from 149.3 G ($\theta_{A-B}=-40°$) to 3.9 G ($\theta_{A-B}=140°$) and from 26.2 G ($\theta_{A-B}=-60°$) to 0.1 G ($\theta_{A-B}=170°$), respectively. By comparing the observed D and E parameters ($|D|=75.9$ G, $|E|=8.7$ G) with the calculated ones, agreements were found for two cases of about $\theta_{A-A}=\pm45°$ ($|D|=77.5$ G, $|E|=9.1$ G) in A–A structure, and in A–B structure, for two cases of about $\theta_{A-B}=0°$ ($|D|=71.3$ G, $|E|=7.6$ G) and $\theta_{A-B}=-20°$ ($|D|=75.9$ G, $|E|=7.5$ G).

Unfortunately, it is not possible to decide whether the KI complex takes an "A–A" or "A–B" structure because both the D and E values experimentally obtained can be well explained by those calculated for the above structures. Although the calculation presented here is of a very approximate nature for the (2:1) complex of **1**, the result has shown that the "*trans*" conformation observed for the KI complex of benzo-15-crown-5 by the X-ray analysis is improbable for the present KI complex of **1** in ethanol rigid matrix. This is consistent with our previous expectation. The results of the calculation of the ZFS parameters suggest that the complex has a structure near to "*cis*" conformation rather than "*trans*" one, showing the overlap between two galvinoxyl groups in the complex. It is probable that the van der Waals interaction between two galvinoxyl groups induces such a conformation.

As described in a previous section, **1** makes the (2:1) complex with Rb and NH_4 salts as well. If the Rb and NH_4 complexes of **1** also have a "sandwiched" structure with an alkali metal ion between the two benzo-15-crown-5 rings, we can expect the increase in the interplanar spacing between the two crown ether rings, as the ion diameter increases from K^+ (2.66 Å) to Rb^+ (2.96 Å) or NH^+_4 (2.84 Å). This will induce the decrease in the ZFS parameter $|D|$. However, the $|D|$ and $|E|$ values observed for the K, Rb, and NH_4 complexes remain constant, within the limit of experimental error (see Table 1). As

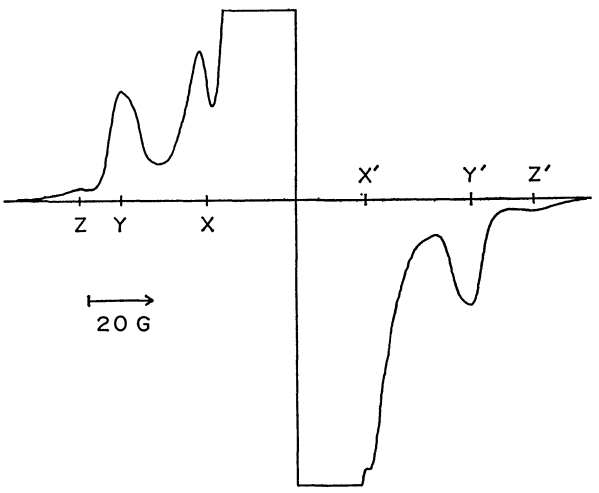

Fig. 7. ESR spectrum of the KSCN complex of **1** in 1,2-dichloroethane at 77 K.

Table 2. *D*- and *g*-tensor values of the KSCN complex of **1** in several solvents at 77 K

Solvent	$\frac{\lvert D\rvert}{G}$	$\frac{\lvert E\rvert}{G}$	g_{zz}	g_{yy}	g_{xx}	g_{av}
Ethanol	76.2	8.9	2.0032	2.0052	2.0072	2.0052
2-Propanol	76.1	8.8	2.0029	2.0048	2.0069	2.0049
1-Butanol	76.9	8.8	2.0032	2.0052	2.0073	2.0052
1,2-Dichloroethane	73.5	13.3	2.0029	2.0050	2.0072	2.0050

the results of the calculation of the ZFS parameters indicate, the KI complex of **1** is thought to have a structure close to "*cis*" conformation, in which the galvinoxyl skeletons stack over one another. In such a case, because of the overlapping of the bulky tertiary butyl group, the real interplanar spacing between the two crown ether rings will become larger than that (3.34 Å) reported for the KI complex of benzo-15-crown-5.[8] Therefore, the cavity which exists between the two polyether rings can accommodate the K^+, Rb^+, and NH^+_4 ions without varying the intermolecular distance between the two galvinoxyl group. Thus, we can understand the experimental fact that the ZFS constants are the same for all the (2:1) complexes of **1**.

Solvent Effect on the Structure of the Potassium Complex of 1. In addition to the above van der Waals interaction, the asymmetric environment due to frozen solvent molecules may contribute to the change in molecular structure found for the K complex of **1** in the low-temperature rigid matrix. Therefore, solvent effect on the structure of the (2:1) complex of **1** with KSCN has been studied. The solubilities of **1** and KSCN place some restriction on the choice of solvents. For this reason, ethanol, 2-propanol, 1-butanol, and 1,2-dichloroethane solvents could only be used in the present study. In the KSCN complex of **1**, identical triplet spectra were obtained in frozen ethanol, 2-propanol, and 1-butanol solutions, while a different triplet spectrum was obtained in frozen 1,2-dichloroethane solution, as shown in Fig. 7. The observed $|D|$ and $|E|$ values are summarized in Table 2. The result indicates that the change in conformation for the (2:1) complex is almost negligible for the above alcoholic solvents. On the other hand, the $|D|$ (73.5 G) and $|E|$ (13.3 G) values in 1,2-dichloroethane are 2.7 G smaller and 4.4 G larger than the corresponding ones in ethanol, respectively. These results may be explained by assuming that the rotation angle θ_{A-A} or θ_{A-B} varies several degrees in 1,2-dichloroethane solvent, as it can be seen from the results shown in Figs. 5 and 6. It has been reported that solvent molecules may play an important role in fixing the conformation of the triplet molecules in frozen solution.[13–15] However, the present experimental results suggest that such a role of solvent molecules is not notable in the (2:1) complex of **1**.

We wish to thank Miss Yoshiko Kumamoto for her kind help in the synthesis of **1**.

The Structure of the Cyclodextrin Complex. XII. Crystal Structure of α-Cyclodextrin-1-Phenylethanol (1 : 1) Tetrahydrate

Kazuaki HARATA

Research Institute for Polymers and Textiles, 1-1-4, Yatabe-Higashi, Tsukuba, Ibaraki 305

(Received August 1, 1981)

The crystal structure of the α-cyclodextrin–1-phenylethanol (1:1) tetrahydrate, $C_{36}H_{60}O_{30}\cdot C_8H_{10}O\cdot 4H_2O$, was determined by the X-ray method. The crystal is monoclinic, the space group being $P2_1$ with $Z=2$; the cell dimensions are $a=8.176(1)$, $b=23.930(2)$, $c=13.853(1)$ Å, and $\beta=106.69(1)°$. The structure was solved by means of the Patterson map and the trial-and-error method combined with the rigid-body least-squares technique. Refinement was carried out by the block-diagonal least-squares method to the final R-value of 0.040 for 3565 reflections. α-Cyclodextrin molecules are stacked along the a axis in the head-to-tail fashion to form a channel-type structure, and are tilted by 17.0° against the channel axis. Owing to the lateral shift of α-cyclodextrin ring parallel to the molecular plane, neighboring α-cyclodextrin molecules along the channel are linked by only one weak hydrogen bond. The 1-phenylethanol molecule is sandwiched between stacked α-cyclodextrin molecules. S-(−) and R-(+) isomers of 1-phenylethanol are each located at the same position with the statistical disorder of the hydroxyl group with the occupancy of 0.5. Columns formed by the stack of α-cyclodextrin are closely packed, being linked with one another by many hydrogen bonds. Water molecules are located in two kinds of intermolecular spaces between α-cyclodextrin columns.

Cyclodextrins form diastereoisomers with optically active guests since they consist of optically active glucose residues. On this basis, complexation of cyclodextrins has been applied as a method for resolution of racemic molecules.[1] We have investivated the host-guest stereospecificity in the complex formation of cyclodextrins with benzene derivatives by the X-ray method.[2] In this paper, we deal with the α-cyclodextrin complex with racemic 1-phenylethanol to investigate the interaction with optically active molecules.

Experimental

α-Cyclodextrin was dissolved in a hot aqueous solution saturated with 1-phenylethanol to prepare a 5% solution, and then the solution was allowed to stand at 40 °C. Colorless plate-like crystals were obtained. Measurements of lattice parameters and reflection intensities were carried out on a Nicolet P3/F diffractometer with graphite-monochromated Cu $K\alpha$ radiation. By the θ-2θ scan mode, 3565 independent reflections with $|F_o|\geqq 3\sigma(F)$ were obtained up to 115° in 2θ. No corrections were made for absorption and extinction effects.

Crystal Data: $C_{36}H_{60}O_{30}\cdot C_8H_{10}O\cdot 4H_2O$; F.W.=1239.1; monoclinic; space group $P2_1$; $Z=2$; $a=8.176(1)$, $b=23.930(2)$, $c=13.853(1)$ Å, $\beta=106.69(1)°$; $V=2596.2$ Å^3; $D_x=1.585$ and $D_m=1.577$ g cm^{-3}.

Determination and Refinement of the Structure

The orientation of α-cyclodextrin in a unit cell was deduced by inspection of a Patterson map. The position of the molecule was determined by the trial-and-error method. The positional and orientational parameters of each glucose residue were corrected by the rigid-body least-squares method. 1-Phenylethanol and water molecules were found on Fourier and difference-Fourier maps. Both S-(−) and R-(+) isomers of 1-phenylethanol are found with the statistical disorder of the hydroxyl group. The occupancy was estimated from an electron-density map but not refined. Hydrogen atoms were found on a difference-Fourier map. Refinement of the structure was carried out by the block-diagonal least-squares method. The quantity minimized was $\Sigma w(|F_o|-|F_o|)^2$ with $w=1.0$ for all the reflections. The final R-value was 0.040. The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography."[3] Final atomic coordinates are given in Table 1. Tables of anisotropic temperature factors of non-

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the i-th principal axis of the thermal ellipsoid. b) Occupancy of each of O(A,PE) and O(B,PE) is 0.5.

hydrogen atoms, atomic parameters of hydrogen atoms, observed and calculated structure factors, bond distances, angles, and conformation angles in α-cyclodextrin are kept at The Chemical Society of Japan (Document No. 8218). The calculations were performed on a FACOM M-200 computer at the RIPS Center, Tsukuba.

Description and Discussion of the Structure

Outline of the Structure. Structure and numbering scheme of the complex are shown in Fig. 1. A packing feature of α-cyclodextrin in the crystal is illustrated in Fig. 2. α-Cyclodextrin molecules are stacked with a head-to-tail mode along the a axis. The molecules are laterally shifted to each other parallel to the molecular plane. Both *S*-(−) and *R*-(+) isomers of the guest 1-phenylethanol molecule are sandwiched at the same position with a statistical disorder of the hydroxyl group by the two adjacent α-cyclodextrin molecules along the channel.

Conformation of α-Cyclodextrin. Average bond distances and angles over six glucose residues are shown in Fig. 3. Geometrical data of α-cyclodextrin ring are given in Tables 2 and 3. Average bond distances and angles are in good agreement with those of the α-cyclodextrin–benzaldehyde complex[2] having a similar crystal structure. All primary hydroxyl groups are in a *gauche-gauche* conformation; average conformation angles of O(5)–C(5)–C(6)–O(6) and C(4)–C(5)–C(6)–O(6) are −71.7° and 50.0°, respectively. Distances between adjacent glycosidic oxygen atoms (O(4)) are in the range from 4.17 to 4.31 Å with the average value of 4.23 Å. Torsion-angle indexes of glucose residues lie in rather a narrow region (124.5—137.5), indicating that the conformation of each pyranose ring is nearly identical.

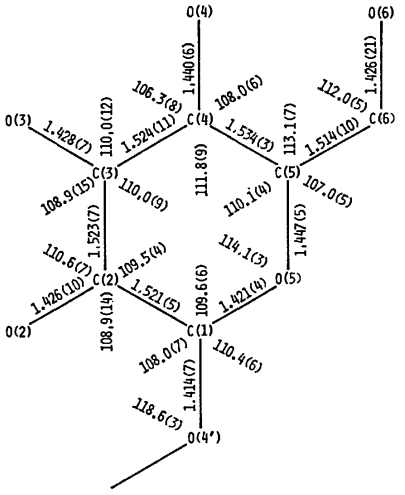

Fig. 3. Average bond distances and angles over six glucose residues in α-cyclodextrin.
Standard deviations in parentheses were estimated according to the equation: $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$ where x_i referes to bond distance or angle in i-th glucose residue and $\bar{x}$ is the average value.

Diagonal distances measured between glycosidic oxygen atoms and the good planarity of these atoms (Table 3) show that the α-cyclodextrin ring is a nearly regular hexagon although the G1···G4 distance is slightly larger than the G2···G5 distance. Distances between O(2) and O(3) of adjacent glucose residues

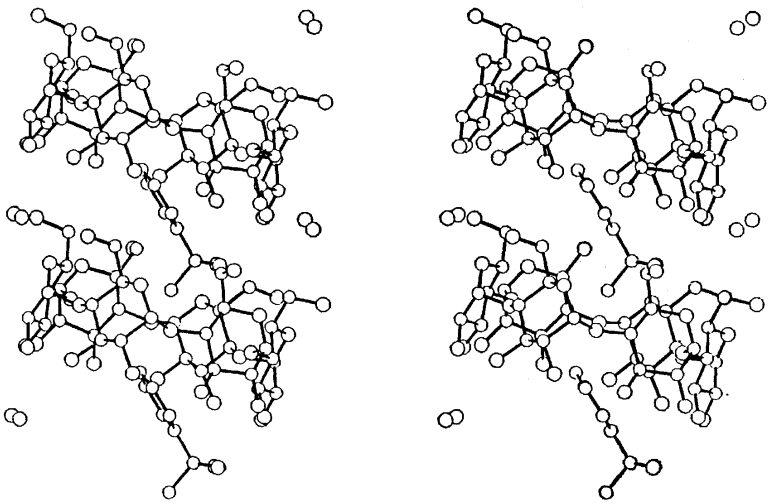

Fig. 4. A stereo-drawing of stacking feature of α-cyclodextrin.

Table 2. Selected geometrical data for α-cyclodextrin ring

I. O(4)···O(4) distances

Distance (l/Å)		Distance (l/Å)	
O(4,G1)···O(4,G2)	4.21	O(4,G5)···O(4,G6)	4.27
O(4,G1)···O(4,G6)	4.22	O(4,G1)···O(4,G4)	8.62
O(4,G2)···O(4,G3)	4.31	O(4,G2)···O(4,G5)	8.35
O(4,G3)···O(4,G4)	4.18	O(4,G3)···O(4,G6)	8.40
O(4,G4)···O(4,G5)	4.22		

II. Torsion-angle index[a] and tilt angle[b]

Residue	Torsion-angle index(ϕ/°)	Tilt-angle(ϕ/°)
G1	131.2	14.6
G2	124.5	8.1
G3	137.5	11.5
G4	132.5	8.7
G5	130.4	4.1
G6	132.9	10.1

a) The torsion-angle index is defined as: $|\phi(C(1)-C(2))|+|\phi(C(2)-C(3))|+|\phi(C(5)-O(5))|+|\phi(O(5)-C(1))|-|\phi(C(3)-C(4))|-|\phi(C(4)-C(5))|$. b) The tilt-angle is defined as the angle made by the plane through six O(4) atoms and the plane through C(1), C(4), O(4), and O(4′) of each glucose residue.

vary in the range from 2.81 to 3.04 Å. These hydroxyl groups form a round circle with six intramolecular O(2)···O(3) hydrogen bonds. Significant conformational differences in the macrocyclic ring, compared with the benzaldehyde complex,[2] are observed in the tilt-angles of glucose residues against the least-squares planes through six O(4) atoms, in spite of the similarity in the molecular packing. The tilt-angles of the 1-phenylethanol complex (4.1—14.6°) are smaller than those values of the benzaldehyde complex (10.9—19.9°). This may be interpreted in terms of differences in the molecular packing and intermolecular hydrogen bonds. As will be discussed later, the more tilted orientation of glucose residue in the benzaldehyde complex is held by intermolecular hydrogen bonds along the channel. In the 1-phenylethanol complex, however, the small tilt of glucose residue may be preferable to form hydrogen bonds with neighboring α-cyclodextrin molecules arranged in sheets parallel to the molecular plane.

Table 3. Least-squares planes and deviations of atoms from the plane

The plane equation is of the $AX+BY+CZ=D$ from, where X, Y, and Z are the coordinates in Å units along the a, b, and c* axes, respectively.

I. The plane through six O(4) atoms			
$0.956X-0.016Y-0.292Z=-0.887$

II. The benzene plane			
$-0.517X-0.041Y+0.855Z=4.354$			
C(1,PE)	0.014	C(6,PE)	−0.011
C(2,PE)	−0.009	C(7,PE)	0.022
C(3,PE)	−0.001	C(8,PE)	1.462
C(4,PE)	0.004	O(A,PE)	−0.664
C(B,PE)	0.001	O(B,PE)	−0.716

α-Cyclodextrin–Guest Interaction. Bond distances and angles in 1-phenylethanol and intermolecular distances between 1-phenylethanol and α-cyclodextrin are shown in Fig. 5. The planarity of the phenyl group is quite good (Table 3). The hydroxyl group of 1-phenylethanol is statistically disordered with the same occupancy; O(A) and O(B) belong to *S*-(−) and *R*-(+) isomers, respectively. The C(7)-O(A) and C(7)-O(B) bonds are significantly short, and the C(1)-C(7)-O(A) and C(1)-C(7)-O(B) angles are somewhat large. This may be interpreted in terms of the thermal displacement and/or slight disorder of 1-phenylethyl moiety as discussed by Kim and Rosenstein.[4] The relatively large temperature factor indicates that the position of the 1-phenylethyl moiety of the two isomers is slightly shifted to each other in the asymmetric environment although such small disorder is not resolved on the electron-density map.

1-Phenylethanol is sandwiched between adjacent α-

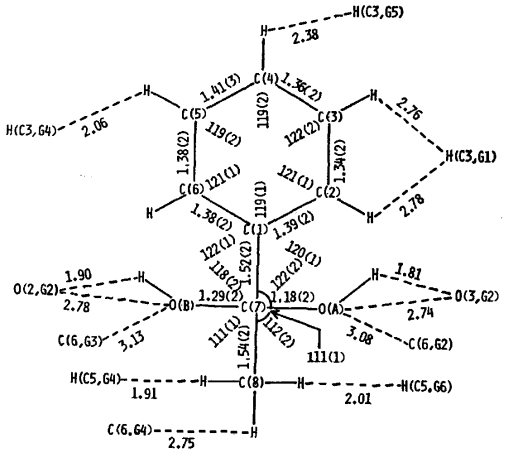

Fig. 5. Bond distances and angles in 1-phenylethanol and selected intermolecular distances between 1-phenylethanol and α-cyclodextrin.

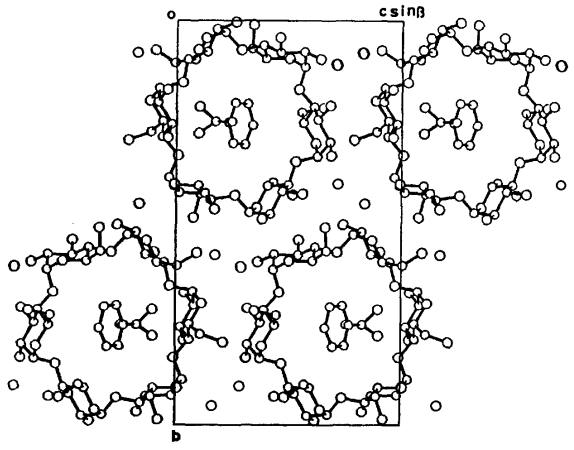

Fig. 6. Crystal structure viewed down along the a axis.

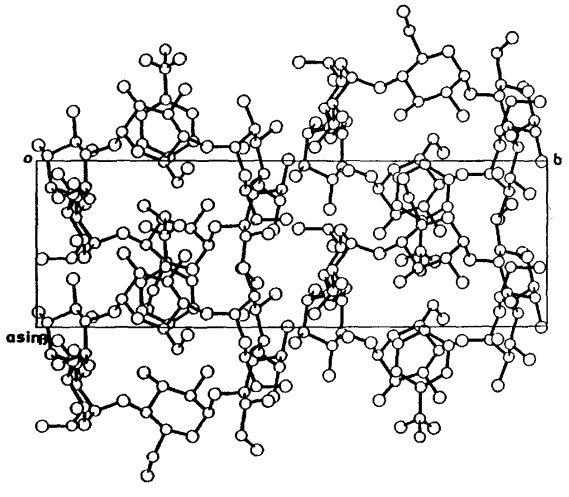

Fig. 7. Crystal structure viewed down along the c axis.

cyclodextrin molecules stacked along the channel (Fig. 4). The phenyl group is in contact with the secondary hydroxyl side of α-cyclodextrin, while the ethanol moiety is located at the O(6) side of the next α-cyclodextrin. The phenyl plane makes an angle of 42.0° with the plane through the six O(4) atoms. O(A) and O(B) hydroxyl groups form O(A)–H···O(3,G2) and O(B)–H···O(2, G2) hydrogen bonds, respectively. The C(7)–C(8) bond is inserted into the next α-cyclodextrin from the primary hydroxyl side. This type of the host-guest interaction has not yet been found. In the α-cyclodextrin complexes with other benzene derivatives,[2] the benzene ring is included at the O(2), O(3) side nearly parallel to the α-cyclodextrin axis. In the 1-phenylethanol complex, however, such inclusion geometry may be unfavorable since the hydrogen bonds involving O(A) and O(B) should be broken to include the phenyl group parallel to the α-cyclodextrin axis, and moreover, such parallel inclusion may cause steric hindrance between the C(8) methyl group of 1-phenylethanol and C(6) methylene groups of the next α-cyclodextrin. Somewhat short contacts involving hydrogen atoms are found between α-cyclodextrin and 1-phenylethanol; H(C3,G4)···H(C5,PE) (2.06 Å), H(C5,G4)···H(C8, PE) (1.91 Å), H(C5,G6)···H(C8,PE) (2.01 Å), and C(6,G4)···H(C8,PE) (2.75 Å). This suggests that the guest 1-phenylethanol molecule is bound in the channel by hydrogen bonds and the van der Waals force.

Molecular Packing and Hydrogen Bonds. Projections of crystal structure are shown in Figs. 6 and 7. α-Cyclodextrin molecules are stacked along the a axis forming an endless column. Since the α-cyclodextrin ring is tilted by 17.0° against the plane perpendicular to the channel axis, the rings are laterally shifted to each other parallel to the molecular plane. Except for a weak O(3,G5)–H···O(6,G5) hydrogen bond, no intermolecular hydrogen bonds along the column are formed. Most of the intermolecular hydrogen bonds are found between neighboring α-cyclodextrin molecules arranged parallel to the molecular plane. In other channel-type structures,[2] the stacked α-cyclodextrin molecules are linked by many hydrogen bonds along the column. In those complexes, the inclination and lateral shift of the α-cyclodextrin ring are so small that the hydrogen bonds cannot be broken; in the benzaldehyde complex, the glucose residues are remarkably tilted to compensate the effect of the molecular shift on the hydrogen bond formation. Moreover, α-cyclodextrin molecules belonging to different columns are linked with one another by hydrogen-bond bridges involving water molecules rather than by direct hydrogen bonds. In contrast to those complexes, α-cyclodextrin columns in the 1-phenylethanol complex are linked mainly by direct hydrogen bonds, and as the result, they are more closely packed in the crystal as indicated by the comparison of cell volumes; 2645.1 Å^3 in the benzaldehyde complex and 2596.3 Å^3 in the 1-phenylethanol complex. Between columns, adjacent glucose residues are faced to each other as shown in Fig. 6. The G1 and G3 residues are linked by the O(3,G3)–H···O(6,G1) and O(6, G3)–H···O(3,G1) hydrogen bonds. Two hydrogen bonds, the O(6,G2)–H···O(6,G5) and O(2,G5)–H··· O(6,G2), are also found between the G2 and G5 residues, but only the O(2,G6)–H···O(3,G4) hydrogen bond is formed between the G4 and G6 residues.

In the crystal, the hydrogen-bond network is built up of branched chains and circles of hydrogen bonds as shown in Fig. 8. Six intramolecular hydrogen bonds are observed between adjacent glucose residues. Except for the O(2,G4)–H···O(3,G5) hydrogen bond, the O(3) hydroxyl groups act as a hydrogen donor (Table 4). The G4 residue donates hydrogen atoms to the G3 and G5 resiues, while the G5 residue accepts two hydrogen atoms from the G4 and G6 residues. O(2,G4), O(3,G5), O(6,G5), and O(W2) from a four membered hydrogen-bond circle. O(2,G2), O(3,G3), O(6,G1), and O(W4) also form a cyclic hydrogen bond, although O(3,G3) donates a hydrogen atom to O(2,G2) and O(6,G1), forming weak bifurcated hydrogen bonds.[5] Water molecules are located in two kinds of intermolecular spaces as shown in Fig. 6; W1 and W3 are located in one space, while

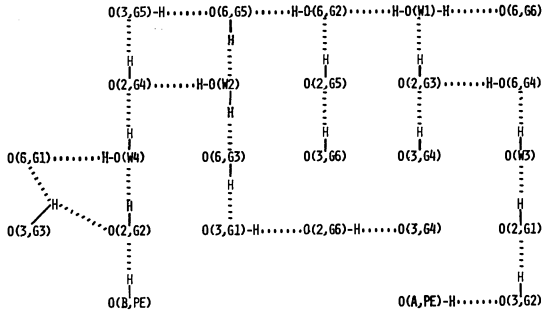

Fig. 8. A schematic representation of hydrogen-bond network.

W2 and W4 are in the other space. W2 and W4 are linked by the O(W2)–H···O(2,G4)···H–O(W4) hydrogen-bond bridge. W1 forms three hydrogen bonds with O(2,W3), O(6,G2), and O(6,G6), linking three columns surrounding it. W4 forms similar tripod-like hydrogen bonds with each of O(6,G1), O(2,G2), and O(2,G4) in different columns. W3 links two columns with the O(2,G1)–H···O(W3)–H···O(6,G4) hydrogen-bond bridge. Unlike these three water molecules, W2 links α-cyclodextrin rings along the column axis with the O(6,G5)–H···O(W2)–H···O(2,G4) hydrogen-bond bridge, and is also hydrogen-bonded to O(6,G3) of the neighboring column.

The Crystal and Molecular Structure of Strontium Bis(thiocyanate)-Hexaethylene Glycol (1/1)

Iwao YAMAGUCHI,† Kunio MIKI, Noritake YASUOKA,†† and Nobutami KASAI*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received August 8, 1981)

The molecular structure of strontium bis(thiocyanate)–hexaethylene glycol(1/1) has been determined from single crystal X-ray diffraction data(3121 observed reflections): triclinic, space group $P\bar{1}$, $a=12.086(4)$, $b=8.732(2)$, $c=10.628(2)$ Å, $\alpha=80.88(2)$, $\beta=101.99(3)$, $\gamma=100.55(2)°$, $D_m=1.48$, $D_c=1.48$ g cm^{-3} for $Z=2$. The central Sr ion is coordinated by seven O atoms from the hexaethylene glycol moiety and two N atoms from the SCN groups; the Sr–O distances range from 2.603(5) to 2.750(5), while the Sr–N distances are 2.628(8) and 2.634(8) Å. The hexaethylne glycol moiety assumes a $GT_2\bar{G}T_2GT_2\bar{G}T_2GTG_2$ conformation.

In connection with the studies of the metal-ion complexation of non-cyclic poly(oxyethylene) derivatives by Yanagida, Okahara, and their co-workers,[1] X-ray diffraction studies have been made of strontium bis(thiocyanate)–heptaethylene glycol(1/1) and –hexaethylene glycol(1/1) (EO7–$Sr(SCN)_2$ and EO6–$Sr(SCN)_2$) in order to examine the chelating behavior of heptaethylene glycol(EO7) and hexaethylene glycol (EO6) to the strontium. An account of the structure of the former, EO7–$Sr(SCN)_2$, has been reported.[2] This paper will deal with the structure of the latter, EO6–$Sr(SCN)_2$.

Experimental

Colorless, transparent, and prismatic crystals were recrystallized from acetone-hexane. A crystal with approximate dimensions of 0.5 mm × 0.2 mm × 0.1 mm was used for the X-ray experiments. The unit-cell parameters and diffraction intensities were measured on a Rigaku automated, four-circle diffractometer. Zr-filtered Mo $K\alpha$ radiation was used.

Crystal Data. $(C_{12}H_{26}O_7)\cdot Sr(SCN)_2$, *F.W.* 478.02, triclinic, space group $P\bar{1}$, $a=12.086(4)$, $b=8.732(2)$, $c=10.628(2)$ Å, $\alpha=80.88(2)$, $\beta=101.99(3)$, $\gamma=100.55(2)°$, $V=1070(1)$ Å^3, $D_m=1.48$, $D_c=1.48$ g cm^{-3} for $Z=2$, μ(Mo $K\alpha$)$=28.6$ cm^{-1}. The intensity data were measured by the θ-2θ scan technique at a 2θ rate of 2° min^{-1}. The scan width was $\Delta(2\theta)=(2.4+0.7\tan\theta)°$. Backgrounds were measured for 7.5 s at both ends of a scan. A total of 3957 reflections ($2\theta<50°$) were measured, of which 3121 ($|F_o|>3\sigma(F_o)$) were non-zero reflections. Usual Lorentz and polarization corrections were applied, but no absorption correction was made [max(μR)$=0.8$].

Structure Solution and Refinement

The structure was solved by the heavy-atom method. The positions of the Sr and S atoms were determined from the Patterson function. The subsequent Fourier map revealed the remaining non-hydrogen atoms.

The structure was refined anisotropically by the block-diagonal least-squares procedure (*HBLS*-V).[3] The difference Fourier map calculated at the stage with $R=0.085$ revealed the positions of 26 H atoms, those atoms were included in the subsequent cycles and refined isotropically. The final R was 0.061 for non-zero reflections ($R_w=0.069$). The weighting schemes used in the final cycle were $w=\{\sigma_{cs}(F_o)+a|F_o|+b|F_o|^2\}^{-1}$, where $a=0.0223$ and $b=0.0008$, for $|F_o|>0$ and $w=0.0508$ for $|F_o|=0$. The final atomic parameters are summarized in Table 1.†††

The atomic scattering factors used were taken from the International Tables for X-Ray Crystallography, Vol. IV.[4] Computations were done on an ACOS Series 77 NEAC System 900 computer at Osaka University.

Results and Discussion

The molecular structure as drawn by the *ORTEP* program[5] is shown in Fig. 1. The interatomic dis-

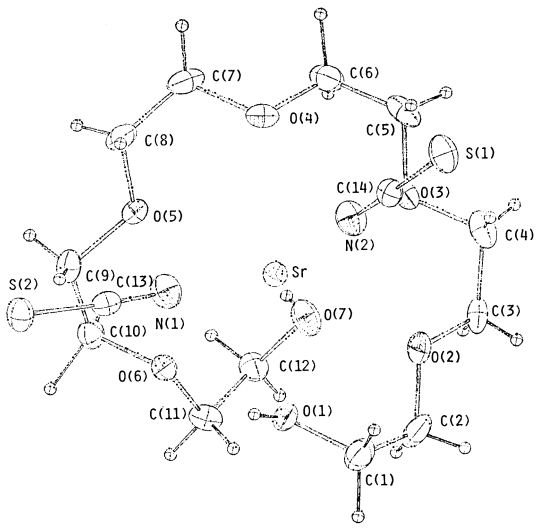

Fig. 1. A prespective view[5] of EO6–$Sr(SCN)_2$ molecule with the numbering scheme of non-hydrogen atoms.
Non-hydrogen atoms are expressed as thermal ellipsoids at 50% probability level and hydrogen atoms as spheres with the radius of 0.1 Å.

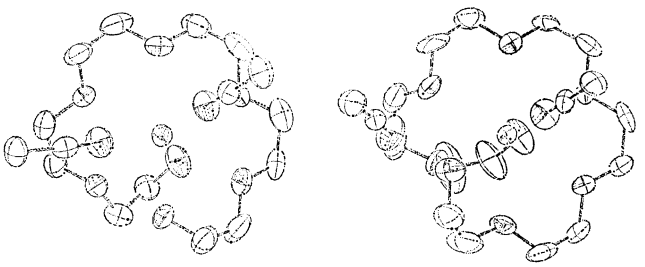

Fig. 2. Molecular structure of EO6-$Sr(SCN)_2$ (a) compared with that of EO7-$Sr(SCN)_2$[2] (b).
A similar conformation is observed at the central portions of the EO6 and EO7 chanis (See also Fig. 3).

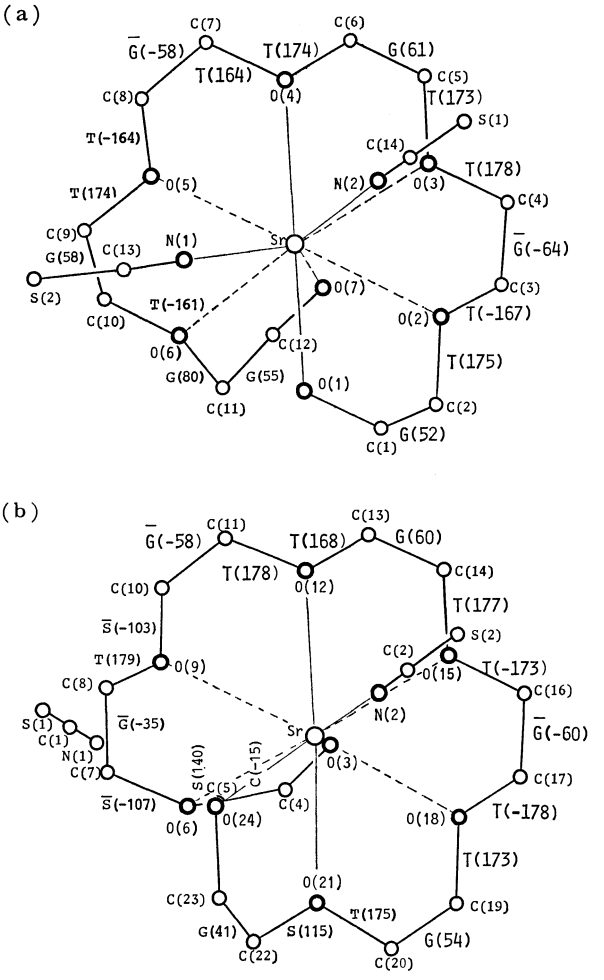

Fig. 3. Conformations and torsion angles(ϕ/°) in oligoethylene glycol part.
(a) EO6-$Sr(SCN)_2$, (b) EO7-$Sr(SCN)_2$.[2] Thick circles represent atoms coordinated to the Sr. Solid and broken lines respectively show the coordination bonds between the Sr and atoms above and below the planes defined by the (a) O(1), O(2), O(3), O(4), and O(5), (b) O(9), O(12), O(18), O(21), and O(24) atoms.

tances and angles are given in Table 2.

Coordination Geometry. Seven O atoms from the EO6 chain and two N atoms from two SCN anions are coordinated to the Sr ion. In EO7–$Sr(SCN)_2$, the eighth O atom takes part in the coordination instead of the N atom of the second SCN anion. The two Sr–N distances in the present complex are equal, within the limits of experimental error: 2.628(8) and 2.634(8) Å. The seven Sr–O distances are classed into three groups. Both of the terminal O atoms, O(1) and O(7), of the EO6 are rather close to the Sr atom; the Sr–O distances being 2.603(6) and 2.609(7) Å. The Sr–O(2), Sr–O(3), and Sr–O(4) distances are the second longest [2.709(6), 2.686(5) and 2.691(6) Å], while the Sr–O(5) and Sr–O(6) are the longest distances [2.750(5) and 2.762(5) Å].

Conformations of the EO6 Chain. The structure of and torsion angles in the EO6 chain are compared in Figs. 2 and 3 respectively with those found in the EO7 chain in EO7–$Sr(SCN)_2$.[2] The EO6 chain assumes a $\mathbf{GT_2\bar{G}T_2GT_2\bar{G}}T_2GTG_2$ conformation About 2/3 of the EO6 chain has a conformation similar to that of the central part of the EO7 chain in EO7–$Sr(SCN)_2$($\mathbf{GT_2\bar{G}T_2GT_2\bar{G}}$). This fact, and the similarity between the corresponding Sr–O distances in the EO6 [2.709(6), 2.686(5) and 2.691(6) Å] and EO7 chains [2.71(2), 2.69(2) and 2.72(2) Å], suggest that some part of the EO6 chain (from O(1) to O(5)) and the corresponding part of the EO7 chain (from O(21) to O(9)) have "rigid structure."

Crystal Structure. The crystal structure is drawn in Fig. 4. Close intermolecular distances (less than 3.5 Å) are listed in Table 3; the closest contact is S(2)(x, y, z)···O(1)($1-x$, $-y$, $-z$)=3.258(6) Å.

The authors wish to express their deep thanks to Dr. Shozo Yanagida and Professor Mitsuo Okahara of Osaka University for the supply of crystals and for their helpful discussions. The authors' thanks are also due to Miss Nobuko Kanehisa for the *ORTEP* drawings. A part of the cost of the present study was defrayed by a Grant-in-Aid (No. 535038) from the Ministry of Education, Science and Culture.

The Binding of Sodium Dodecyl Sulfate to Lysozyme in Aqueous Solutions. II. The Effect of Added NaCl

Kohsuke FUKUSHIMA,* Yoshio MURATA, Gohsuke SUGIHARA, and Mitsuru TANAKA

Department of Chemistry, Faculty of Science, Fukuoka University, Fukuoka 814-01

(Received August 12, 1981)

The isotherms for the binding of sodium dodecyl sulfate (SDS) to lysozyme have been investigated as a function of the concentration of added NaCl at pH 5.8 and 25 °C by a potentiometric method utilizing a surfactant-selective electrode. The equilibrium surfactant concentration at which the binding begins to occur increases with increasing NaCl concentration. The equilibrium surfactant concentration giving the same binding number above 10, on the contrary, decreases with increasing NaCl concentration. Thermodynamic analysis shows that there takes place not only the exchange between chloride ion (Cl^- ion) and dodecyl sulfate ion (DS^- ion) but also the binding of DS^- ion to the positively charged site unoccupied by Cl^- ion. The addition of NaCl does not change the equilibrium SDS concentration at which the binding number begins to exceed 10. This equilibrium concentration is regarded as a characteristic one at which the affinity between lysozyme and SDS can be evaluated. The value of standard free energy change upon DS^- ion binding and the number of Na^+ ions bound to a DS^- ion which forms a cluster on lysozyme were estimated from a thermodynamic equation based on the phase separation model.

In the previous paper, we discussed the binding mode of SDS to lysozyme and the accompanying structural change of lysozyme.[1] It was suggested from the previous experiments that the driving force of the initial binding (the binding number, $\bar{\nu}<10$) was mainly electrostatic, and that of the subsequent binding ($\bar{\nu}\geq 10$) was hydrophobic. If the binding force is different in the two regions, *i.e.*, regions of $\bar{\nu}<10$ and $\bar{\nu}\geq 10$, the addition of NaCl must give different effects on the binding in the respective regions. The effect of NaCl on the binding isotherm, therefore, is expected to give more detailed information about the binding mechanism of SDS to lysozyme.

A surfactant-selective electrode was used for potentiometry.[2-4] In this work, a poly(vinyl chloride) gel membrane was used as the ion exchange membrane instead of the nitrobenzene membrane, to prevent the solubilization of nitrobenzene.

Experimental

The solutions of hen egg-white lysozyme and other chemicals were prepared in the same way as in the previous paper.[1] The binding isotherms were made by means of potentiometry, as described previously,[1] except that the poly(vinyl chloride) gel membrane was used instead of the nitrobenzene liquid membrane. The carrier used in the surfactant-selective electrode was prepared by mixing equivalent amounts of SDS and dimethyldioctadecylammonium chloride (Kaō Soap Co. Ltd.,) in water. The details of the preparation of poly(vinyl chloride) gel membrane have been mentioned in the paper by Shirahama *et al.*[2] In the present case, a voltage follower amplifier was connected to the digital multimeter (Takeda Riken TR 6885) in order to raise the input impedance.

All measurements were carried out at pH 5.8 and 25 °C. NaCl concentrations were 10, 20, 30, 50, and 100×10^{-3} mol dm^{-3}. Every calibration curve of the electromotive force (emf) of SDS in NaCl solutions showed a good linearity over the concentration range from 3×10^{-5} mol dm^{-3} to the concentration near its critical micelle concentration(CMC) and gave a slope which was very close to a Nernstian response (55.2 ± 0.6 mV per decade of change in SDS at 25 °C).

In order to examine the accuracy of each emf value for the sample solution, emf's for several SDS solutions of known concentration were also measured after measurements of the three sample solutions.

Results and Discussion

As is shown in Fig. 1, the equilibrium concentration of SDS in the initial binding region ($\bar{\nu}<10$) increases with increasing concentration of NaCl. On the contrary, the equilibrium concentration of SDS in the region of subsequent binding ($\bar{\nu}\geq 10$) decreases with increasing concentration of NaCl. One should pay attention to the fact that all isotherms intersect each other at the equilibrium concentration of SDS at which $\bar{\nu}=10$.

The flat region in Fig. 1, where $\bar{\nu}$ could be kept at 10, becomes narrower with increasing NaCl concentration. The free energy difference of DS^- ion

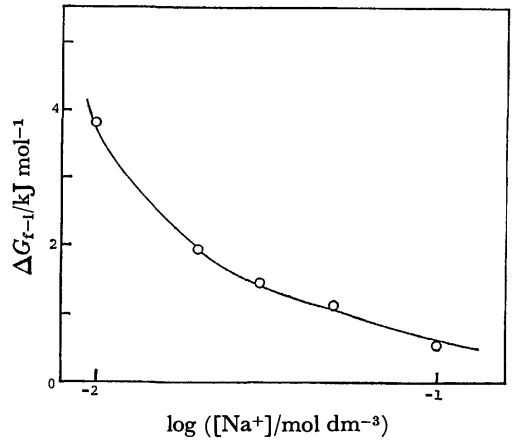

Fig. 2. ΔG_{f-1} *vs.* log [Na$^+$] plot evaluated from Eq. 1.

between the states of the initial and final points at this region can be obtained from the respective equilibrium SDS concentration as follows:

$$\Delta G_{f-1} = RT \ln \frac{a_f}{a_i} \simeq RT \ln \frac{C_f}{C_i}, \quad (1)$$

where a_i and a_f are the activities of DS$^-$ ions in solution at the initial and final points of the region, respectively, and C_i and C_f are the respective equilibrium SDS concentrations. The results obtained from Eq. 1 are shown in Fig. 2. ΔG_{f-1} is considered to be the free energy accumulation for the subsequent binding. ΔG_{f-1} decreases with increasing NaCl concentration and seems to approach zero. When ΔG_{f-1} becomes zero, the binding isotherm will show an inflection at the binding number of 10.

The plots of log $C_{\bar{\nu}}$ *vs.* log [Na$^+$] are given in Fig. 3. $C_{\bar{\nu}}$ and [Na$^+$], here, represent the equilibrium SDS concentration where $\bar{\nu}$ ions of DS$^-$ are bound to lysozyme and the total Na$^+$ ion concentration originating in NaCl and SDS, respectively. The plot of log $C_{0.5}$ *vs.* log [Na$^+$] gives a straight line with the positive slope of 0.5.

In the initiation of the binding of SDS to lysozyme, the Cl$^-$ ion must be taken into account along with the dodecyl sulfate ion (DS$^-$ ion), because both DS$^-$ and Cl$^-$ ions may be bound to the positively charged sites on lysozyme.[5] The initiation of SDS binding to the lysozyme–Cl$^-$ complex can be treated as the exchange reaction between Cl$^-$ and DS$^-$ ions, since lysozyme has been dissolved in respective NaCl solutions before the addition of SDS. The reaction scheme for the first step of initial binding of DS$^-$ ion to lysozyme is written as

$$\mathrm{P{\cdot}Cl}_m^- + \mathrm{DS}^- \overset{K}{\rightleftharpoons} \mathrm{P{\cdot}Cl}_{m-n}^-{\cdot}\mathrm{DS}^- + n\mathrm{Cl}^-, \quad (2)$$

$$K = \frac{[\mathrm{P{\cdot}Cl}_{m-n}^-{\cdot}\mathrm{DS}^-][\mathrm{Cl}^-]^n}{[\mathrm{P{\cdot}Cl}_m^-][\mathrm{DS}^-]}, \quad (3)$$

where P represents lysozyme and n is the number of Cl$^-$ ions excluded by the first binding of one DS$^-$ ion. Now, a special case, where $\bar{\nu}$ is 0.5 in average, is considered. The meaning is that 50% of the lysozyme molecule is bound by one DS$^-$ ion and the rest is not. This situation is realized if the concentration of SDS is reasonably low. Under this condition,

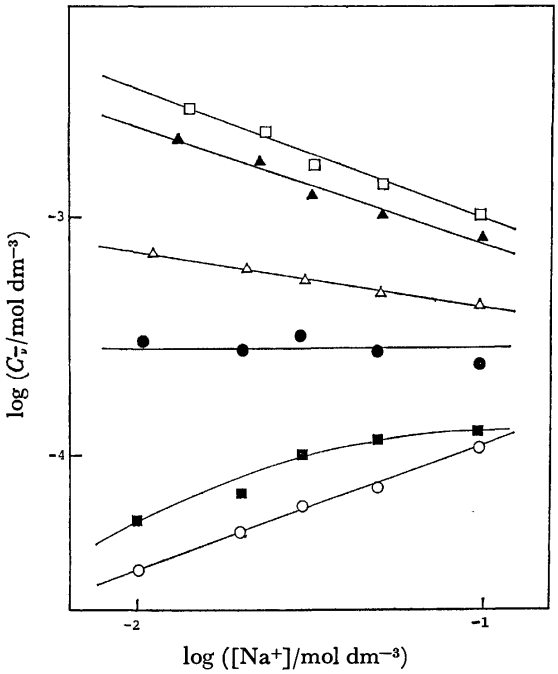

Fig. 3. Log $C_{\bar{\nu}}$ *vs.* log [Na$^+$] plots.
$C_{\bar{\nu}}$: Equilibrium SDS concentration at binding number $\bar{\nu}$, $\bar{\nu}$: ○ 0.5, ■ 5, ● 10, △ 17, ▲ 40, □ 60.

[P·Cl$_{m-n}^-$·DS$^-$] equals [P·Cl$_m^-$]. Then, Eq. 3 at the binding number of 0.5 can be rewritten as

$$\log [\mathrm{DS}^-] = n \log [\mathrm{Cl}^-] - \log K. \quad (4)$$

In Eq. 4, [Cl$^-$] can be replaced by [Na$^+$], because the concentration of NaCl is sufficiently large compared with those of SDS and lysozyme at a binding number of 0.5. Hence n is almost equal to the slope (0.5) of the plot of log $C_{0.5}$ *vs.* log [Na$^+$] in Fig. 3. As mentioned above, the slope n means the number of Cl$^-$ ions which are excluded by a DS$^-$ ion. The fact that n is not equal to unity but to 0.5, therefore, implies that the exchange between Cl$^-$ and DS$^-$ ions and the binding of DS$^-$ ions to the positively charged sites take place at the same time. This leads to the decrease in the number of positively charged sites and hence to the precipitation of lysozyme.[1]

For $\bar{\nu}$=5, the plot of log C_5 *vs.* log [Na$^+$] gives a convex curve, as is shown in Fig. 3. In this case, the assumption used in deriving Eq. 4 from Eq. 3 cannot be used, since lysozyme–Cl$^-$–DS$^-$ complexes with different numbers of Cl$^-$ and DS$^-$ ions distribute around the mean binding number ($\bar{\nu}$=5). It is difficult, therefore, to estimate the value of n from a log C_5 *vs.* log [Na$^+$] plot. The evaluation of n could not be made for other lysozyme–Cl$^-$–DS$^-$ complexes having different binding numbers either, without estimating the concentrations of the complexes from other experiments.

As is shown in the plot of log C_{10} *vs.* log [Na$^+$] in Fig. 3, C_{10}, the equilibrium SDS concentration at which $\bar{\nu}$ begins to exceed 10, is independent of the concentration of NaCl added. This equilibrium SDS concentration corresponds to the intersection point of the isotherms in Fig. 1. At this point, the Cl$^-$ ions on the positively charged sites are completely

replaced by DS^- ions. The lysozyme molecule has ionizable amino acid residues, *i.e.*, 6 Lys's, 11 Arg's, and 1 His, as basic residues and 7 Asp's and 2 Glu's as acidic residues. At the pH studied (pH 5.8), Lys and Arg are positively charged, since their pK values on lysozyme are within the ranges of 10.3—10.6 and 12.7—13.3[5] respectively. This means that a lysozyme molecule has 17 positive charges at this pH. On the other hand, the negatively charged residues are 7 Asp's and one Glu[7], since their pK values are within the ranges of 3.0—4.7 and 2.7—4.7[5] respectively. Therefore, the net charge of lysozyme is $+9(+17-8=+9)$ at pH 5.8. Accordingly, a lysozyme–DS^- complex is almost electrically neutral at C_{10}. The further binding of ions to the electrically neutral lysozyme–DS^- complex will be restricted to the ions having a hydrophobic part like DS^-. From these points of view, such an equilibrium concentration as C_{10} may be looked upon as a characteristic concentration of the lysozyme–DS^- system. The other system of charged protein-ionic surfactant also might have the same characteristic concentration as that of the lysozyme–SDS system.

Plots of log C_{17}, C_{40}, and C_{60} *vs.* log [Na^+] give straight lines with negative slopes, as is shown in Fig. 3. These trends seem to reflect the effect of added NaCl on micelle formation of an ionic surfactant on the surface of lysozyme. In the previous paper,[1] the site number of the first layer at pH 5.8 was estimated from the analysis by the use of BET equation to be about 17, which corresponds to the number of positively charged residues of lysozyme,[5] and it was suggested that the hydrophobic interaction between DS^-'s was expected for the subsequent binding over the first layer. Such behavior may be considered thermodynamically the same as that of the micelle formation. The standard free energy change of the micelle formation from the phase separation model is expressed as

$$\Delta G^\circ/RT = \ln X_{CMC} + \beta \ln X_{Na^+}, \quad (5)$$

where X_{CMC} and X_{Na^+} are the mole fractions of the surfactant and Na^+ ion in the intermicellar solution at CMC, respectively, and β is the binding number of Na^+ ions per surfactant molecule in micelle.[6] If the binding of SDS is assumed to proceed like a micelle formation above the first layer of SDS on the complex, the intercept and slope of the straight line in the plot of ln $X_{\bar{\nu}}$ *vs.* ln X_{Na^+} will give $\Delta G^\circ_{\bar{\nu}}$ and β, where $\Delta G^\circ_{\bar{\nu}}$ is the difference between the standard Gibbs free energy of a mole of monomeric hydrated DS^- ion with β counterion and that of a mole of DS^- ion with β counterion bound to the complex, and $X_{\bar{\nu}}$ is the mole fraction of DS^- ion in solution at the binding number $\bar{\nu}$. Equation 5 can be applied to the plots log $C_{\bar{\nu}}$ *vs.* log [Na^+] above $\bar{\nu}=17$ in Fig. 3, if the common logarithmic concentration in mol dm^{-3} is converted into the natural logarithmic mole fraction. The linearity of the plots is maintained even in the plots of the mole fraction unit. The results obtained by applying Eq. 5 to the plots in Fig. 3 are listed in Table 1.

TABLE 1. THERMODYNAMIC PARAMETERS

$\bar{\nu}$	β	ΔG°/kJ mol^{-1}
17	0.25	−33
40	0.50	−35
60	0.55	−36

The β increases with increasing binding number and seems to approach the value for the micelle of SDS. The negative charged density on the surface of the complex will increase with increasing DS^- ion binding above the binding number 10, which will cause the binding of Na^+ to the complex and hence the increment in β. The negative charge density on the surface of the complex is smaller than that of SDS micelle, because the surface area of the former is larger than that of the latter. Therefore, β of the complex must be smaller than β of the micelle.

$\Delta G^\circ_{\bar{\nu}}$'s are comparable to ΔG° (−37 kJ/mol at 25 °C estimated roughly by putting $\beta=0.7$) of SDS micelle formation. The difference between $\Delta G^\circ_{\bar{\nu}}$ and ΔG° can be attributed to the fact that the hydrocarbon part of the DS^- ion on the complex is in a less hydrophobic environment than in micelle. This suggests that lysozyme is somewhat loosely covered by DS^- ions. The results obtained here support the concept that the driving force of initial binding ($\bar{\nu}<10$) is electrostatic, and that of subsequent binding ($\bar{\nu}\geq 10$) is hydrophobic in nature.

The authors are grateful to Professor Keishiro Shirahama, Saga University, for his helpful discussion, and to Mr. Hiroshi Ninomiya, Fukuoka University, for his preparation of the voltage follower amplifier.

Internal Heavy Atom Effect on the T_1 States of Halogen-substituted Benzonitriles

Yoshinori Asahi and Noboru Hirota*,†

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received August 22, 1981)

The magnetic and decay properties of the ortho-, meta-, and para-substituted benzonitriles have been investigated and the nuclear charge and the position dependences of the internal heavy atom effects are examined in detail. From the single crystal EPR studies spin densities at the halogen atoms (ρ_H) are found to be in the order $\rho_H(\text{para}) > \rho_H(\text{ortho}) > \rho_H(\text{meta})$, but $\rho_H(\text{meta})$ is found to be much larger than that expected from the spin distribution in benzonitrile. The changes in the ZFS on going from the chloro-substituted molecules to the bromo-substituted molecules correlate with ρ_H and are explained in terms of the second order effect of the spin orbit mixing with $^3\sigma\pi^*$ ($^3\pi\sigma^*$) and $^3n\pi^*$ states. In the para-substituted molecules the relative increases of the T_y sublevel decay rates (k_y) are much greater than those of the T_z sublevel decay rates (k_z). The dependence of the average decay rate, $1/2(k_y+k_z)$ on the atomic spin orbit coupling constant (ζ), is considerably larger than expected from the ζ^2 dependence. These results were discussed in connection with the closeness of the $^3\sigma\pi^*$ ($^3\pi\sigma^*$) states in bromine containing molecules. A correlation between the decay rate and ρ_H is observed and the factors affecting the position dependence are examined.

When a halogen atom is substituted into an aromatic molecule, drastic changes in the properties of a triplet state molecule are observed.[1] The magnitude of this so-called internal heavy atom effect depends on the nuclear charge of the substituent, the type of molecule and the position of substitution. The nuclear charge dependence has been investigated rather intensively and in the systems so far studied the magnitude of the effect appears to be roughly proportional to the squares of the atomic spin orbit coupling constant ζ of the substituent.[1-5] Although this dependence has been rationalized qualitatively on the basis of the spin orbit matrix elements between the T_1 state and the perturbing singlet states, further examination of this dependence, especially in connection with the decay rates of the spin sublevels, may be useful in clarifying the relative importance of the different decay mechanisms.

The magnitude of the internal heavy atom effect is also dependent on the type of molecule. For example, the effects of the bromine substitution on the zero field splitting (ZFS) and the decay rates of the substituted benzenes[6,7] are far greater than those of naphthalene.[8,9] As for the position dependence Miller *et al.*[4] found in naphthalene and phenanthrene that there is a correlation between the magnitude of the heavy atom effect on the decay rate and the spin density on the carbon to which the heavy atom is attached. However, the data on the position dependence are scarce and further investigation seems to be worthwhile.

In the present work we have studied the T_1 states of the halogen-substituted benzonitriles by means of zero field optically detected magnetic resonance (ZFODMR) and EPR in order to examine the above mentioned dependences further. The main motives of the present study are the following.

(1) Benzonitrile may be considered as a typical example of the substituted benzenes having quinoid structures in the T_1 states. Our previous EPR investigation[10] has shown that the spin densities on the para, ortho, and meta positions are 0.33, 0.12, and 0.007, respectively. Because of the large differences in the spin densities it was thought that the halogen-substituted benzonitriles might be suited to investigate the position dependence of the internal heavy atom effect in detail.

(2) Previous ODMR studies on the bromine containing substituted benzenes have indicated that $^3\sigma\pi^*$ ($^3\pi\sigma^*$) and $^3n\pi^*$ states are likely to be rather close to the T_1 states.[6,7] This may lead to a nuclear charge dependence which is very different from those found for the other aromatics previously.

(3) The previous works on the nuclear charge dependence were made using the total decay rate constants. However, since different perturbing states are involved in the decay processes of the different sublevels nuclear charge dependence may depend on the sublevel significantly.

Here we first discuss the spin densities on the halogen atoms from the analysis of the hyperfine structures and the zero field splittings. We then examine the factors which affect the nuclear charge and position dependences of the decay rates in detail and discuss the observed dependences in connection with the spin distributions and the energy separations between the T_1 states and the main perturbing states.

Experimental

Guest molecules investigated here are 4-, 3-, and 2-fluorobenzonitrile (FBN), 4-, 3-, and 2-chlorobenzonitrile (ClBN), and 4-, 3-, and 2-bromobenzonitrile (BrBN). Hereafter we use the abbreviations given in parentheses. 3FBN and 2FBN were purified by distillation under reduced pressure and the others were purified by recrystallization from ethanol followed by sublimation under vaccum. The host crystals used here are *p*-xylene (PX), *o*-xylene (OX), *m*-xylene (MX) which were purified by distillation under reduced pressure and 1,4-dibromobenzene (DBB) and 1,4-dichlorobenzene (DCB) which were purified by recrystallization from ethanol and extensive zone refining. The molecular structure, the axis system and the numbering of the carbon atoms of para-substituted benzonitriles are

shown in Fig. 1.

The crystals were melt grown using the Bridgman method. When the host crystal was OX or MX, the solution containing a small amount of guest molecule was degassed by freeze-pump-thaw method and sealed in a 4 mm quartz tube. The sample mounted in the helical slow wave structure was cooled slowly to the liquid nitrogen temperature and was inserted rapidly into the helium cryostat. In other cases the crystals cut to the appropriate sizes were mounted in the helical slow wave structure in the ZFODMR experiments or on the acryl resin sample holder in the EPR experiments. The experimental setups and the procedure are essentially the same as those reported previously.[11,12]

Results and Disscussion

Hyperfine Splittings and Spin Distributions in the Halogen-substituted Benzonitriles. The spin densities in the T_1 state benzonitrile at the para, ortho, and meta positions were estimated to be 0.33, 0.12, and 0.007, respectively.[10] Halogen substitution, especially fluorine substitution, does not perturb the spin distribution of the parent molecule in the aromatic molecules such as naphthalene.[13] Fluorine or bromine substitution to benzonitrile at the para position also does not change the spin distribution much, although considerable spin delocalization of the unpaired electron into the halogen atom takes place.[12] The spin densities at the carbon 4 and the fluorine atom in 4FBN are 0.32 and 0.046, respectively.[12]

In Fig. 2 EPR spectra of 2FBN and 3FBN in DBB host taken with the applied field **B** perpendicular to the molecular plane are shown together with the simulated spectra. The fluorine splittings (A_x) estimated from the simulation are 2.6 mT for 2FBN and 2.0 mT for 3FBN. In the previous work on 4FBN[12] it was shown that a good agreement between the observed and calculated splittings was obtained using the molecular geometry of benzonitrile obtained from the bond orders calculated by the PPP UHF method for the T_1 state of benzonitrile. We have made similar calculations for 2FBN and 3FBN assuming the same geometries. The calculated A_x agrees reasonably well with the observed one in 2FBN, but the experimental value is far greater than the calculated one in 3FBN as shown in Table 1. This result seems to indicate that the structure of the T_1 state 3FBN is substantially different from that of benzonitrile. The normally used assumption[13] that the fluorine substitution does not perturb the spin distribution of

a) Taken from Ref. 6.

the parent molecule appears to be no longer correct in the case of 3FBN. Nevertheless, the spin densities on the fluorine $2P_x$ orbitals are in the order $\rho(4FBN)>\rho(2FBN)>\rho(3FBN)$ following the order of the spin densities on the carbon atoms of the corresponding positions of benzonitrile.

In view of the fact that the delocalization of the unpaired electron into the bromine $4P_x$ orbital is greater than that into the fluorine $2P_x$ orbital, deviation from the benzonitrile structure may even be more serious in 3BrBN than in 3FBN.

Zero Field Splittings and the Contribution of Spin Orbit Coupling. It is known that the ZFS of the para-bromo-substituted benzenes are greately affected by the second order effect of the spin orbit coupling.[6,7] We determined the magnitudes of the ZFS of the ortho-, meta-, and para-substituted benzonitriles from the microwave frequencies for the zero field ODMR transitions. From the previous EPR study[6] the relative ordering of the sublevels of 4BrBN are known to be $T_z>T_y>T_x$: Here, the z axis is parallel to the C–Br direction, the x axis is perpendicular to the molecular plane, and the y axis is perpendicular to the other two. For the ortho- and meta-substituted molecules the relative ordering of the zero field sublevels as well as the directions of the in-plane principal axes of the fine structure tensor are not known. In these cases we designate the sublevels $T_{z'}$, $T_{y'}$, and $T_{x'}$ from the top.

The ZFS of the halogen-substituted benzonitriles studied here are listed in Table 2. The ZFS of the bromo- and chloro-substituted molecules are substantially affected by the choice of the host crystal. However, if we compare the $|D|$ of the bromo-substituted molecules with those of the chloro-substituted molecules in the same host or in the X traps, the $|D|$ of the bromo-substituted molecules are always larger. This seems to indicate that the contribution of the second order effect of the spin orbit coupling is significant in both 2BrBN and 3BrBN.

The depression of the sublevel energy caused by the spin orbit mixing with the perturbing state p is given by[15,16]

$$\Delta E^1 = \sum_{p\neq T_1}\sum_{v}\frac{|\langle\Psi^0_{pv}|H_{so}|\Psi^0_{T_1o}\rangle|^2}{E^0_{T_1O}-E^0_{pv}}, \quad (1)$$

where $\Psi^0_{T_1^0}$ is the wave function of the sublevel i of the zeroth vibrational unperturbed T_1 state and Ψ^0_{pv} are of the zeroth order perturbing states. v stands for the vibrational states of the perturbing state. It was suggested that the spin orbit mixing with the $^3\sigma\pi^*$ ($^3\pi\sigma^*$) and $^3n\pi^*$ states primarily affects the sublevel energies of the bromine containing substituted benzenes. In 4BrBN the T_z and T_x sublevels are lowered by the spin orbit mixing with the $^3\sigma\pi^*$ ($^3\pi\sigma^*$) state, while the T_y and T_x sublevels are lowered by the mixing with the $^3n\pi^*$ state. The spin orbit interaction is given by[1]

$$H_{so} = \Sigma\xi(l_xs_x+l_ys_y+l_zs_z), \quad (2)$$

where the summation is taken over the electrons. Then the electronic matrix elements which govern the depressions of the sublevel energires due to these mixings are given by

$$\left.\begin{aligned} a &= \frac{|\langle\sigma|\xi l_y|\pi\rangle|^2}{4[E(^3\pi\pi^*)-E(^3\sigma\pi^*)]}\begin{pmatrix}\text{for the mixing with}\\ \text{the } ^3\sigma\pi^* \text{ state}\end{pmatrix}\\ b &= \frac{|\langle n|\xi l_z|\pi\rangle|^2}{4[E(^3\pi\pi^*)-E(^3n\pi^*)]}\begin{pmatrix}\text{for the mixing with}\\ \text{the } ^3n\pi^* \text{ state}\end{pmatrix}\end{aligned}\right\}. \quad (3)$$

If we only consider the one center integrals at the bromine atoms a and b are given by the following expressions.

$$\left.\begin{aligned} a &= \frac{(C^{\sigma}_{Br}C^{\pi}_{Br})^2|\langle p^{Br}_z|\xi l^{Br}_y|p^{Br}_x\rangle|^2}{4[E(^3\pi\pi^*)-E(^3\sigma\pi^*)]}\\ b &= \frac{(C^{n}_{Br}C^{\pi}_{Br})^2|\langle p^{Br}_y|\xi l^{Br}_z|p^{Br}_x\rangle|^2}{4[E(^3\pi\pi^*)-E(^3n\pi^*)]}\end{aligned}\right\} \quad (4)$$

Here, C^{σ}_{Br}, C^{n}_{Br}, and C^{π}_{Br} are the coefficients of the bromine atomic orbitals in the σ, n and π molecular orbitals, respectively. ξ is defined by the relation

$$\xi = \frac{1}{4\pi\varepsilon_0}\frac{e^2}{2m^2c^2}\frac{r^3}{Z}, \quad (5)$$

where Z and r are the atomic number of the bromine and the distance of electron from the bromine nucleus, respectively. In the cases of 2BrBN and 3BrBN the z' and y' directions are not parallel or perpendicular to the C–Br direction, and both the z' and y' sublevels are lowered by the mixings with the $^3\sigma\pi^*$ and $^3n\pi^*$ states. When we take θ as the angle between the y' axis and the C–Br direction, $T_{z'}$, $T_{y'}$ and $T_{x'}$ sublevels are depressed by $a\cos^2\theta+b\sin^2\theta$, $a\sin^2\theta+b\cos^2\theta$ and $a+b$, respectively. Thus it is convenient to take $\delta=\Delta E_{z'x'}+\Delta E_{y'x'}$ as a measure of the effect of the spin orbit coupling on ZFS. Here ΔE_{ij} are the changes of the energy difference between i and j sublevels on going from the chloro-substituted molecule to the bromo-substituted molecule. δ is equal to $|a+b|$, namely the sum of the contributions due to the mixings with both $^3\sigma\pi^*$ ($^3\pi\sigma^*$) and $^3n\pi^*$ states. These values amount to 0.066 cm^{-1} for the para-substituted benzonitrile in PX, 0.028 cm^{-1} for the ortho- and meta-substituted benzonitriles in the X trap. If we assume that the energy denominators are similar for the para-, ortho-, and meta-substituted molecules, δ are proportional to the spin densities

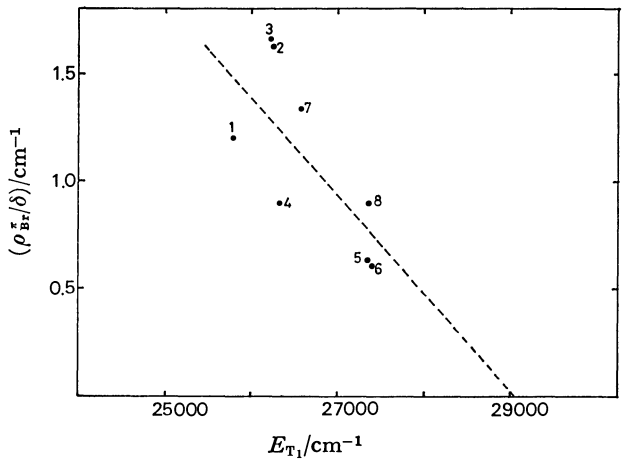

Fig. 3. Plot of ρ^{π}_{Br}/δ *vs.* E_{T_1}; (1) 4-bromobenzonitrile in PX, (2) 4-bromobenzonitrile in DCB, (3) 4-bromobenzonitrile in DBB, (4) 2-bromobenzonitrile X trap, (5) 1,4-dibromobenzene in PX,[7,21] (6) 1-bromo-4-chlorobenzene in PX,[7,21] (7) 4-bromoaniline in PX,[6,22], (8) 4-bromoanisole in PX.[6,22]

on the bromine atom ρ^{π}_{Br}. The observed values of δ are in the order of $\delta(\text{para}) > \delta(\text{ortho}) \simeq \delta(\text{meta})$ in qualitative agreement with that expected from the spin densities on the bromine $4P_x$ orbitals.

Possible Locations of the Perturbing States. From Eqs. 1—5 we obtain

$$\frac{(C^{\pi}_{Br})^2}{\delta} \propto \frac{1}{\zeta^2}\left\{\frac{(C^{\sigma}_{Br})^2}{E(^3\sigma\pi^*)-E(^3\pi\pi^*)}+\frac{(C^{n}_{Br})^2}{E(^3n\pi^*)-E(^3\pi\pi^*)}\right\}^{-1}. \quad (6)$$

If C^{σ}_{Br} and C^{n}_{Br} do not change much from one molecule to the other, $(C^{\pi}_{Br})^2/\delta$ approaches zero as the perturbing triplet states become close to the T_1 state. In Fig. 3 we plot ρ^{π}_{Br}/δ against the triplet state energy for these systems assuming that $(C^{\pi}_{Br})^2$ is proportional to ρ^{π}_{Br}. ρ^{π}_{Br} were estimated from the bromine hyperfine splittings when the bromine hyperfine splittings were observed. In others they were estimated from the fluorine hyperfine splittings by using the ratio of the fluorine splitting in 4FBN and the bromine splitting in 4BrBN. Though the points are scattered there seems to be a correlation between ρ^{π}_{Br}/δ and the triplet state energy (E_{T_1}) as indicated by the broken line in Fig. 3. The broken line intersects the horizontal axis at $\cong$29000 cm^{-1}. This seems to indicate that there are perturbing states around 29000 cm^{-1}. From the fact that both T_z and T_y sublevels are depressed by the bromine substitution for the para-substituted molecules both $^3\sigma\pi^*$ ($^3\pi\sigma^*$) and $^3n\pi^*$ states are likely to be in the vicinity of 29000 cm^{-1}.

Phosphorescence Spectra and the Main Radiative Mechanisms. The phosphorescence spectra of the representative systems are shown in Fig. 4. The phosphorescence spectra of 4- and 3BrBN, and 4- and 3ClBN in the corresponding xylenes and DCB are well resolved. On the other hand, the resolution of the phosphorescence spectra of 2BrBN and 2ClBN in OX are somewhat poorer, but they still give structures. In the X trap systems which contain small amount of the corresponding xylenes the phosphorescence spectra are broad with some structures. Nevertheless the frequencies of some of the main vibrations observed in the spectrum are similar to those of well resolved one in xylene. Therefore, it is considered that poorly resolved spectra are genuinely due to BrBN and ClBN.

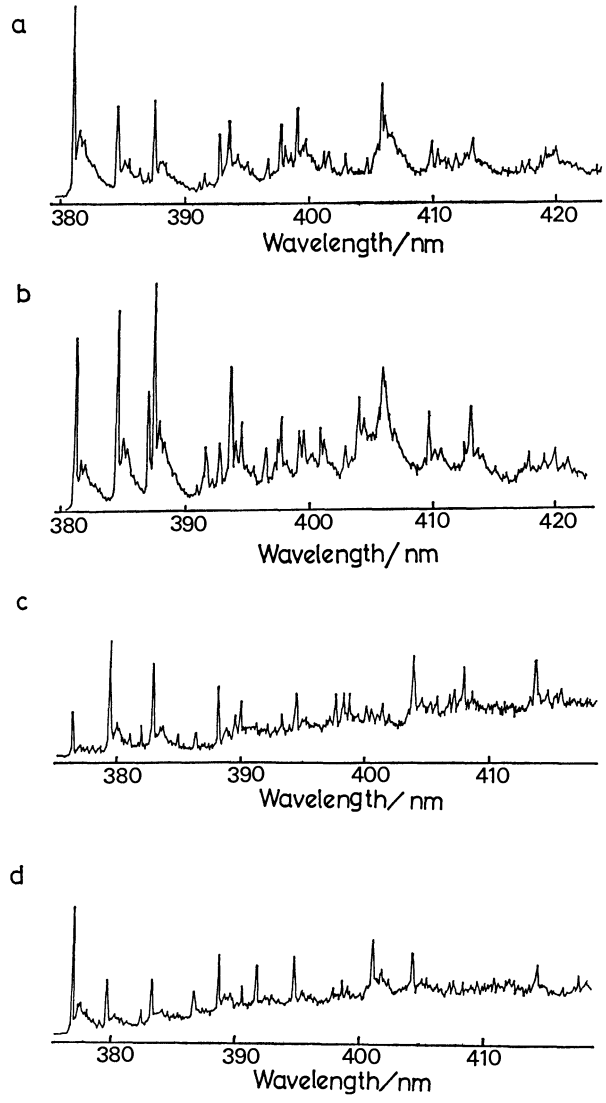

Fig. 4. Phosphorescence spectra of (a) 4-chlorobenzonitrile in DCB, (b) 4-bromobenzonitrile in DCB, (c) 3-chlorobenzonitrile in MX, (d) 3-bromobenzonitrile in MX.

The vibrational analyses of the phosphorescence spectra of 4BrBN and 4ClBN in DCB are given in Table 3. We have made assignments in reference to the infrared and Raman data.[17] In the 4ClBN spectrum the 0-0 band is the strongest. The vibrations of the a_1, b_1, and b_2 symmetries have moderate to weak intensities. On the other hand, in the spectrum of 4BrBN vibrations of the b_1 symmetry are the strongest. The possible mechanisms of the radiative transitions are summarized in Table 4. Since the perturbing states are close to the T_1 state vibronic coupling within the triplet manifold is considered to be dominant. The sublevel spectra of 4BrBN show that the enhanced intensity of the b_1 vibration of

State symbols give the total symmetries.

4BrBN is mainly due to the T_y sublevel emission. Then the importance of the spin orbit vibronic mechanism involving $^3\pi\pi^* \leftrightarrow {}^3\sigma\pi^*$ ($^3\pi\sigma^*$) vibronic coupling increases on going from 4ClBN to 4BrBN (Fig. 5).

In the case of the meta-substituted benzonitrile the 0-0 band is stronger in the bromo-substituted molecule than in the chloro-substituted molecule. This indicates that the relative importance of the mechanism involving the $^1\sigma\pi^*$ ($^1\pi\sigma^*$) state increases on going from the chloro-substituted molecule to the bromo-substituted molecule.

In spite of the poor molecular symmetry of 3BrBN the T_y' and T_x' sublevel spectra are very different (Fig. 6). If we assume that only one center integral at the bromine atom is important in determining the radiative decay, this observation implies that the directions of the z′ and y′ axes are either nearly parallel or perpendicular to the C–Br direction. This result is in agreement with the conclusion obtained from the analysis of hfs and ZFS that the halogen substitution at the meta position perturbs the spin distribution of the present molecule greately.

Nuclear Charge and Position Dependence of the Decay Rates. We measured the total and relative radiative decay rate constants of the sublevels by the technique of microwave induced delayed phosphorescence (MIDP). The decay properties of the halogen-substituted benzonitriles are summarized in Table 5. The decay rate constants obtained in methylcyclohexane glass at 77k are also shown in Table 5. In order to study the position dependence of the decay rates we use $k_{av}=1/2(k_{y'}+k_{z'})$, because many molecules

do not have C_{2v} symmetry and it is not possible to discuss the heavy atom effect on k_z' and k_y' seperately. Important results concerning the nuclear charge and position dependence may be summarized in the following.

(1) In the cases of the para-substituted benzonitrile the nuclear charge dependence is very dependent on the sublevel. $k_y(\mathrm{Br})/k_y(\mathrm{Cl})$ are 88 and 52 in PX and DCB host, respectively. These values are much larger than $\zeta^2_{Br}/\zeta^2_{Cl}$. On the other hand, $k_z(\mathrm{Br})/k_z(\mathrm{Cl})$ are only 22 and 11 in PX and DCB, respectively. $k_x(\mathrm{Br})/k_x(\mathrm{Cl})$ is also relatively small.

(2) $k_{av}(\mathrm{Br})/k_{av}(\mathrm{Cl})$ are 58, 35, and 35 for the para-substituted benzonitrile in PX, in DCB and in methylcyclohexane, 30 and 33 for the meta-substituted one in MX and in methylcyclohexane, and 38 and 34 for the ortho-substituted one in OX and in methylcyclohexane. These values are also substantially larger than those found for other systems (for 1- and 2-halonaphthalene in EPA glass these values are 20.9 and 21.4, respectively), though they depend on the host. The nuclear charge dependences are shown schematically in Fig. 7.

(3) k_{av} are in the following order, $k_{av}(\text{para}) > k_{av}(\text{ortho}) > k_{av}(\text{meta})$. Although the decay rate constants depend on the host considerably, k_{av}(para) are 2—3 times larger than k_{av}(ortho) and k_{av}(meta).

We discuss these results based on the factors which govern the radiative and nonradiative decay rates. The transition moment $\boldsymbol{M}(T_1 \rightarrow S_0)$ between the T_1 state and the ground state is given by[18]

$$\boldsymbol{M}(T_1 \rightarrow S_0) = \sum_k \frac{1}{E^0(T_1) - E^0(S_k)} \left\{ \langle S_k | H(1) | T_1 \rangle + \sum_n \frac{\langle S_k | H(2) | S_n \rangle \langle S_n | H(1) | T_1 \rangle}{E^0(T_1) - E^0(S_n)} + \sum_{n \neq 1} \frac{\langle S_k | H(1) | T_n \rangle \langle T_n | H(2) T_1 \rangle}{E^0(T_1) - E^0(T_n)} \right\} \langle S_k | \Sigma \boldsymbol{er}_l | S_0 \rangle, \quad (7)$$

where $H(1) = H_{so}^{(e)}$, $H(2) = \sum_k (\partial H_0 / \partial Q_k) Q_k$, and Q_k are the normal vibrational coordinates of the given electronic state. The first term inside the parentheses gives the transition at the electronic origin induced by the direct spin orbit coupling, while the second and the third terms embody the vibronic spin orbit mechanisms. In the present systems $^3\sigma\pi^*$ ($^3\pi\sigma^*$) and $^3n\pi^*$ states are close to the T_1 state and the vibronic interactions involving these states are considered to be dominant. The important singlet states which couple with the $T_1(\pi\pi^*)$ state are $^1\sigma\pi^*$ and $^1n\pi^*$ states. The matrix elements such as $\langle ^1\sigma\pi^* | H_{so} | ^3\pi\pi^* \rangle$ and $\langle ^1n\pi^* | H_{so} | ^3\pi\pi^* \rangle$ are reduced to $C_h^{\sigma} C_h^{\pi} \langle P_z^h | \xi | l_y^h | P_x^h \rangle$ and $C_h^{n} C_h^{\pi} \langle P_y^h | \xi | l_z^h | P_x^h \rangle$, when only one center integrals at the halogen atoms are taken into consideration. Here, C_h^{π}, C_h^{σ}, and C_h^{n} are the AO coefficients of the halogen atomic orbitals which constitute the π, σ and n orbitals. Similar expressions are obtained for the spin orbit couplings between the $^1\pi\pi^*$ state and $^3\sigma\pi^*$ and $^3n\pi^*$ states.

In the case of nonradiative decay we use the expression for nonradiative transition obtained by Metz *et al.*;[19] the pure spin Born-Oppenheimer functions are used as a zeroth order basis set,[20] the dominant perturbation is assumed to be the spin orbit coupling operator, and the electronic transition moment is expanded about the equilibrium nuclear configuration of the ground state, *viz.*,

$$\begin{aligned} \langle T_1 | H_{so} | S_0 \rangle &= \langle T_1^0 | H_{so} | S_0^0 \rangle \\ &+ \sum_{j,k} \{ (E_{S_0}^0 - E_{S_j}^0)^{-1} [\langle T_1^0 | H_{so} | S_j^0 \rangle \langle S_j^0 | H_{vlb} | S_0^0 \rangle]_0 Q_k \} \\ &+ \sum_{m,k} \{ (E_{T_1}^0 - E_{T_m}^0)^{-1} [\langle T_1^0 | H_{vlb} | T_m^0 \rangle \langle T_m^0 | H_{so} | S_0^0 \rangle]_0 Q_k \}. \end{aligned} \quad (8)$$

Here the superscript zeros denote the zeroth order wave functions and energies, the subscript zeros denote the reference configuration, H_{vlb} is the vibronic coupling operator and Q_k are the normal coordinates describing the displacements from the reference configuration. We neglect spin vibronic term.

The first term in Eq. 8 is vanishingly small for planar conformation because of $\pi\pi^*$ character of the T_1 state. The spin orbit matrix elements in the second and third terms in Eq. 8 depend on the coefficients of the halogen atomic orbitals as in the case of the radiative decay. The dependence of the spin orbit matrix elements on the coefficients of the halogen atomic orbitals and the relevant energy denominators for the radiative and nonradiative transitions are given in Table 6.

In the present approach the decay rate constants depend on the energy denominator, AO coefficient of the halogen atomic orbital, the matrix element for the vibronic interaction, the transition moments for $S_0 \rightarrow S_k$ transitions involved in the main decay mechanisms, and the spin orbit coupling constant ζ. If the factors other than ζ do not change on going from the chloro-substituted molecule to the bromo-substituted molecule, the decay rate constants would be approximately proportional to ζ^2. Since the extent of the spin delocalization into the halogen atom increases on going from fluorine to iodine, the increase in the decay rate may be somewhat larger than expected from ζ^2. When we take account of this increase, the ratio of the spin orbit coupling matrix elements for bromine and chlorine is 24.4. The values observed for naphthalene and phenanthrene are indeed close to this value.[14] In these systems the above condition may be satisfied.

Since different sublevels couple with different perturbing states, the heavy atom enhancement is in principle sublevel dependent. In 4BrBn the enhancement was found to be much larger for the T_y sublevel decay than for the T_z sublevel decay. The T_y sublevel decay is mostly due to the mechanisms involving the vibronic interaction between the T_1 state and the $^3\sigma\pi^*$ ($^3\pi\sigma^*$) state. The larger value of k_y(Br)/k_y(Cl) seems to imply that the energy denominator for the $^3\sigma\pi^*$ ($^3\pi\sigma^*$) state substantially decreases on going from 4ClBN to 4BrBN. On the other hand

Table 6. The radiative and nonradiative decay mechanisms, relevent spin orbit matrix elements and energy denominators

	Decay mechanism	Spin-orbit matrix element[b]	Energy denominator
Radiative decay			
spin-orbit	$^3\pi\pi^* \longleftrightarrow {}^1\sigma\pi^*$	$C_h^x C_h^z \langle P_x^h \vert \xi 1_{y'}^h \vert P_{z'}^h \rangle$	$\Delta E(^1\sigma\pi^* - {}^3\pi\pi^*)$

	$^3\pi\pi^* \longleftrightarrow {}^3n\pi^* \longleftrightarrow {}^1\pi\pi^*$	$C_h^n C_h^x \langle P_{z'}^h \vert \xi 1_{y'}^h \vert P_x^h \rangle$	$\Delta E(^1\pi\pi^* - {}^3\pi\pi^*) \times \Delta E(^3\sigma\pi^* - {}^3\pi\pi^*)$
	$^3\pi\pi^* \longleftrightarrow {}^3\pi\pi^* \longleftrightarrow {}^1\sigma\pi^*$	$C_h^z C_h^z \langle P_x^h \vert \xi 1_{y'}^h \vert P_{z'}^h \rangle$	$\Delta E(^1\sigma\pi^* - {}^3\pi\pi^*) \times \Delta E(^3\pi\pi^* - {}^3\pi\pi^*)$
	$^3\pi\pi^* \longleftrightarrow {}^3\pi\pi^* \longleftrightarrow {}^1n\pi^*$	$C_h^z C_h^n \langle P_x^h \vert \xi 1_{z'}^h \vert P_{y'}^h \rangle$	$\Delta E(^1n\pi^* - {}^3\pi\pi^*) \times \Delta E(^3\pi\pi^* - {}^3\pi\pi^*)$
Nonradiative decay			
	$^3\pi\pi^* \longleftrightarrow {}^3\sigma\pi^* \longleftrightarrow G$	$C_h^{z*} C_h^z \langle P_x^h \vert \xi 1_{y'}^h \vert P_{z'}^h \rangle$	$\Delta E(^3\sigma\pi^* - {}^3\pi\pi^*)$
	$^3\pi\pi^* \longleftrightarrow {}^3n\pi^* \longleftrightarrow G$	$C_h^{z*} C_h^n \langle P_x^h \vert \xi 1_{z'}^h \vert P_{y'}^h \rangle$	$\Delta E(^3n\pi^* - {}^3\pi\pi^*)$
	$^3\pi\pi^* \longleftrightarrow {}^1\sigma\pi^* \longleftrightarrow G$	$C_h^z C_h^z \langle P_x^h \vert \xi 1_{y'}^h \vert P_{z'}^h \rangle$	$\Delta E(^1\sigma\pi^* - G)$
	$^3\pi\pi^* \longleftrightarrow {}^1n\pi^* \longleftrightarrow G$	$C_h^z C_h^n \langle P_x^h \vert \xi 1_{z'}^h \vert P_{y'}^h \rangle$	$\Delta E(^1n\pi^* - G)$

a) Only for meta and orhto substituted molecules. b) The x axis is perpendicular to the molecular plane, the z′ axis is parallel to the C–Br direction, and the y′ axis is perpendicular to the other two.

the energy denominator for the $^3n\pi^*$ state may not change much.

The increase of the T_y sublevel decay rate because of the reduction in the energy denominator seems to be manifested in the large change of the T_y sublevel decay rate on going from 1-bromonaphthalene[9] through 4BrBN to 1-bromo-4-chlorobenzene.[7] The decay rate constants are 159 s^{-1}, 580 s^{-1}, and 1540 s^{-1}, respectively following the order of the T_1 state energy. The $^3\sigma\pi^*$ ($^3\pi\sigma^*$) state should be very close to the T_1 state of 1-bromo-4-chlorobenzene as also indicated by the analysis of ZFS.[7]

When the increase of the $T_{y'}$ sublevel decay rate is much larger than that expected from ζ^2, $k_{av}(Br)/k_{av}(Cl)$ also becomes larger than that expected from ζ^2. $k_{av}(Br)/k_{av}(Cl)$ of the ortho- and meta-substituted benzonitrile are also considerably larger than expected from ζ^2 as in the case of para-substituted benzonitrile. This is expected when the decay mechanism involving the $^3\sigma\pi^*$ ($^3\pi\sigma^*$) state is dominant as in the case of 4BrBN.

The present analysis shows that the relationship between the decay rate and the spin density is not so straightforward, because the decay rate is determined by a number of factors. When the T_1 state is approximated by the single excitation from the HOMO (π) to the LUMO (π^*), the spin density on the halogen atom is given by $|C_h^H|^2 + |C_h^L|^2$. Here C_h^H and C_h^L denote the AO coefficients of halogen in the HOMO and the LUMO, respectively. The radiative decay rate depends on $|C_h^H|^2$. If the π^* orbital relevant to the spin orbit matrix elements governing the nonradiative decay is the LUMO, the nonradiative decay rate depends on $|C_h^L|^2$ and $|C_h^H|^2$. Therefore, a qualitative correlation between the spin density on the halogen atom and the decay rate may be obtained as observed in phenanthrene, if other factors such as energy denominators remain the same. In the present systems, $k_{av}(\text{para}) \simeq 2k_{av}$ (ortho) also correlates well with $\rho_{Br}(\text{para} \simeq 3\rho_{Br}$ (ortho). In spite of the complexities of the factors governing the decay rates, the correlation between the decay rate and the spin density may not be uncommon.

Calculation of the Pair Correlation Functions for Fluids Composed of Diatomic Polar Molecules Based on the Interaction Site Model

Masaharu Ohba and Kiyoshi Arakawa*

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received October 2, 1981)

A reference hypernetted chain (RHNC) like approximation of the interaction site model is proposed, which is the extension of Lado's RHNC equation of simple fluids to the case of molecular fluids. By using the proposed RHNC like integral equation, pair correlation functions, structure factors and some thermodynamic quantities for fluids composed of diatomic polar molecules are calculated, where the molecules consist of two fused hard-spheres with each center located at a distance l, and at each center charges $+q$ and $-q$ are sited. Calculated pair correlation functions are successful in showing well-marked characteristics of the fluid, such as cusps, not observed for simple fluids like argon. The isothermal compressibility at a constant reduced density and dipole moment has a weak l-dependence in sharp contrast to the total internal energy showing a strong l-dependence.

The statistical mechanical theory of fluids based on the interaction site model (ISM)[1-4] has turned out to be successful in studying the equilibrium properties of those composed of polyatomic molecules. It was also applied to fluids composed of molecules with electrostatic potentials. The theory of polar fluids based on the ISM was proposed first by Chandler and others.[5,6] We applied the ISM to ionic solutions.[7] These theories concern with general properties of dielectric constant, pair correlation functions and others for polar and ionic fluids. Recently, Morriss and Perram have obtained a formal solutions of the mean spherical approximation of RISM-1 (see below) for polyatomic polar fluids,[8] but numerical results have not been given yet.

As the method of obtaining site-site pair correlation functions, three modifications of reference interaction site model integral equations (RISM-1, RISM-2, and RISM-3) coupled with a certain approximation, such as the Percuss-Yevick (PY) like approximation, the hypernetted chain (HNC) like approximation and mean spherical approximation, are proposed.[1,4,9,10] These integral equations were solved for molecular fluids with short-ranged intermolecular forces,[11-13] and the RISM-1 equation gives the most accurate site-site pair correlation functions in comparison with computer simulation results or experimental results.[4] Since the differences between the results of the PY like approximation and the HNC like approximation are similar to those of simple fluids,[4] it is expected that the PY like and HNC like approximations are appropriated to fluids with short-ranged forces and with long-ranged forces, respectively.

For simple fluids composed of molecules with a short-ranged force and a long-ranged tail, the reference hypernetted chain (RHNC) approximation gives a fairly good result.[14-16] In the theory, the system without long-ranged tails is treated as a reference system whose properties are obtained from the PY approximation or computer simulations, and the correction due to the long-ranged tail is calculated by the HNC approximation. So, by considering the properties of the PY like and HNC like approximations, a similar treatment will also be appropriated to the case of polyatomic molecular fluids.

In this paper, we propose an RHNC like approximation of RISM-1 and solve it for diatomic polar fluids. In Theory section, the definition of a model is made and the RHNC like approximation is proposed.

Theory

Model. We assume that the molecule has n interaction sites and a charge q_α is sited on the α-th site of the molecule. The total potential energy for the molecular fluid is assumed to be the sum over all pairs of the intermolecular potentials. The pair interaction between the i-th molecule and the j-th molecule $U(i,j)$ is given by

$$U(i,j) = \sum_{\alpha=1}^{n} \sum_{\gamma=1}^{n} u_{\alpha\gamma}(|\boldsymbol{r}_i^\alpha - \boldsymbol{r}_j^\gamma|), \tag{1}$$

where $u_{\alpha\gamma}(|\boldsymbol{r}_i^\alpha - \boldsymbol{r}_j^\gamma|)$ is an interaction potential between the pair of the site α of the i-th molecule and the site γ of the j-th molecule, and $\boldsymbol{r}_i^\alpha$ the position of the site α of the i-th molecule. An illustration of the molecule is shown in Fig. 1. The site-site interaction

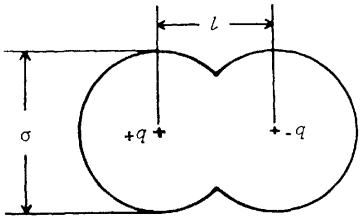

Fig. 1. The shape of the diatomic polar molecule considered in this paper.

can be divided into two parts,

$$u_{\alpha\gamma}(r) = u_{\alpha\gamma}^{(0)}(r) + u_{\alpha\gamma}^{(1)}(r). \tag{2}$$

Here, $u_{\alpha\gamma}^{(0)}(r)$ is a short ranged part of the site-site interaction, which is treated as a reference potential, and $u_{\alpha\gamma}^{(1)}(r)$ a long-ranged Coulomb tail, that is,

$$u_{\alpha\gamma}^{(1)}(r) = \frac{q_\alpha q_\gamma}{4\pi\varepsilon_0 r}, \tag{3}$$

where ε_0 is the dielectric constant of vacuum.

RHNC like Approximation. In the following formulation, we attempt to extend Lado's formalism of simple fluids[14,15] to polyatomic molecular fluids. We start with the Ornstein-Zernike type equation[1,4] as follows,

$$\boldsymbol{h}(\boldsymbol{r}) = \boldsymbol{\omega} * \boldsymbol{c} * \boldsymbol{\omega}(\boldsymbol{r}) + \rho \boldsymbol{\omega} * \boldsymbol{c} * \boldsymbol{h}(\boldsymbol{r}), \tag{4}$$

where the * denotes a convolution, ρ the number density of molecules and $\boldsymbol{h}(r)$, $\boldsymbol{\omega}(r)$, and $\boldsymbol{c}(r)$ are matrices with elements $h_{\alpha\gamma}(r)$, $\omega_{\alpha\gamma}(r)$, and $c_{\alpha\gamma}(r)$, respectively. The site-site total correlation function $h_{\alpha\gamma}(r)$ and the intramolecular pair correlation function $\omega_{\alpha\gamma}(r)$ are defined as reported,[7] and the site-site direct correlation function $c_{\alpha\gamma}(r)$ is defined in Eq. 4. The Fourier transform of Eq. 4 is

$$\tilde{\boldsymbol{h}} = \tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}\tilde{\boldsymbol{\omega}} + \rho\tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}\tilde{\boldsymbol{h}}, \tag{5}$$

where $\tilde{\boldsymbol{A}}$ denotes a matrix with the element $\tilde{A}_{\alpha\gamma}(k)$ and $\tilde{A}_{\alpha\gamma}(k)$ the Fourier transform of $A_{\alpha\gamma}(r)$,

$$\tilde{A}_{\alpha\gamma}(k) = \int \mathrm{d}\boldsymbol{r} A_{\alpha\gamma}(r)\mathrm{e}^{-i\boldsymbol{k}\cdot\boldsymbol{r}}.$$

The function, $\tilde{\omega}_{\alpha\gamma}(k)$, for rigid molecules is expressed as

$$\tilde{\omega}_{\alpha\gamma}(k) = \delta_{\alpha\gamma} + (1-\delta_{\alpha\gamma})\frac{\sin kl_{\alpha\gamma}}{kl_{\alpha\gamma}}, \tag{6}$$

where $\delta_{\alpha\gamma}$ is the Kronecker delta and $l_{\alpha\gamma}=|\boldsymbol{r}_i^\alpha-\boldsymbol{r}_i^\gamma|$ the distance between the α-th site and γ-th site of the same molecule.

The Ornstein-Zernike type equation for a reference system is

$$\tilde{\boldsymbol{h}}^{(0)} = \tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}^{(0)}\tilde{\boldsymbol{\omega}} + \rho\tilde{\boldsymbol{\omega}}\tilde{\boldsymbol{c}}^{(0)}\tilde{\boldsymbol{h}}^{(0)}, \tag{7}$$

where superscript (0) denotes the reference system quantity. From Eqs. 5 and 7, we obtain

$$\delta\tilde{\boldsymbol{h}} = (\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)})\{\boldsymbol{1}-\rho\delta\tilde{\boldsymbol{c}}(\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)})\}^{-1}\delta\tilde{\boldsymbol{c}}(\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)}), \tag{8}$$

where $\boldsymbol{A}^{-1}$ denotes the matrix inverse of matrix $\boldsymbol{A}$, $\boldsymbol{1}$ the unit matrix. $\delta\tilde{\boldsymbol{h}}$ and $\delta\tilde{\boldsymbol{c}}$ are the matrices with elements $\delta\tilde{h}_{\alpha\gamma}(k)$ and $\delta\tilde{c}_{\alpha\gamma}(k)$, the Fourier transforms of $\delta h_{\alpha\gamma}(r)$ and $\delta c_{\alpha\gamma}(r)$, respectively, which are defined as follows,

$$\delta h_{\alpha\gamma}(r) = h_{\alpha\gamma}(r) - h_{\alpha\gamma}^{(0)}(r) \tag{9}$$

and

$$\delta c_{\alpha\gamma}(r) = c_{\alpha\gamma}(r) - c_{\alpha\gamma}^{(0)}(r). \tag{10}$$

$\delta h_{\alpha\gamma}(r)$ and $\delta c_{\alpha\gamma}(r)$ are the perturbation corrections to $h_{\alpha\gamma}(r)$ and $c_{\alpha\gamma}(r)$, respectively, due to the perturbation potential $u_{\alpha\gamma}^{(1)}(r)$.

A closure relation between $\delta h_{\alpha\gamma}(r)$ and $\delta c_{\alpha\gamma}(r)$ is derived as follows. We consider the following relation as

$$c_{\alpha\gamma}(r) = h_{\alpha\gamma}(r) - \ln g_{\alpha\gamma}(r)\mathrm{e}^{\beta u_{\alpha\gamma}(r)} + B_{\alpha\gamma}(r), \tag{11}$$

where $g_{\alpha\gamma}(r)=h_{\alpha\gamma}(r)+1$ is the site-site radial distribution function, $\beta=(k_\mathrm{B}T)^{-1}$, k_B the Boltzmann constant and T the absolute temperature. $B_{\alpha\gamma}(r)$ defined in Eq. 11 is the residual term. If we put $B_{\alpha\gamma}(r)=0$, we obtain the HNC like approximation for RISM-1.[4,17] Different from the case of simple fluids, $B_{\alpha\gamma}(r)$ cannot be expressed as a sum of allowed cluster diagrams.[17] Subtraction of the similar equation for the reference system yields

$$\delta c_{\alpha\gamma}(r) = \delta h_{\alpha\gamma}(r) - \ln\frac{g_{\alpha\gamma}(r)}{g_{\alpha\gamma}^{(0)}(r)}\mathrm{e}^{\beta u_{\alpha\gamma}^{(1)}(r)} + \delta B_{\alpha\gamma}(r), \tag{12}$$

where

$$\delta B_{\alpha\gamma}(r) = B_{\alpha\gamma}(r) - B_{\alpha\gamma}^{(0)}(r).$$

Here, we assume that $\delta B_{\alpha\gamma}(r)=0$. Then we have a new approximation as follows

$$\delta c_{\alpha\gamma}(r) = \delta h_{\alpha\gamma}(r) - \ln\frac{g_{\alpha\gamma}(r)}{g_{\alpha\gamma}^{(0)}(r)}\mathrm{e}^{\beta u_{\alpha\gamma}^{(1)}(r)}, \tag{13}$$

which we call an RHNC like approximation for RISM-1. Combining Eq. 8 with Eq. 13, we can solve the integral equation when the reference system quantities are given. The RHNC like integral equation for RISM-1, that is, Eqs. 8 and 13, is the extension of Lado's RHNC integral equation for simple fluids[14,15] to the case of polyatomic molecular fluids.

Computational Procedures

A system calculated is a fluid composed of diatomic polar molecules which is shown in Fig. 1. A fluid composed of fused hard-spheres with the same diameter σ is considered as a reference system, so the reference potential is given as

$$u_{\alpha\gamma}^{(0)}(r) = \begin{cases} \infty, & r<\sigma \\ 0, & r>\sigma. \end{cases} \tag{14}$$

Because of the symmetry, we have $g_{++}(r)=g_{--}(r)$, $g_{+-}(r)=g_{-+}(r)$ and $g_{++}^{(0)}(r)=g_{--}^{(0)}(r)=g_{+-}^{(0)}(r)=g_{-+}^{(0)}(r)\equiv g^{(0)}(r)$ for the systems considered here.

The functions $\delta h_{\alpha\gamma}(r)$ and $\delta c_{\alpha\gamma}(r)$ have a discontinuity at $r=\sigma$. Thus, we define a new function $H_{\alpha\gamma}(r)$ as follows,

$$H_{\alpha\gamma}(r) = \delta h_{\alpha\gamma}(r) - \delta c_{\alpha\gamma}(r). \tag{15}$$

$H_{\alpha\gamma}(r)$ is a continuous function of r. By the use of this, Eqs. 8 and 13 can be written as

$$\tilde{\boldsymbol{H}} = (\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)})\{\boldsymbol{1}-\rho\delta\tilde{\boldsymbol{c}}(\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)})\}^{-1}\delta\tilde{\boldsymbol{c}}(\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)}) - \delta\tilde{\boldsymbol{c}} \tag{16}$$

and

$$\delta c_{\alpha\gamma}(r) = g_{\alpha\gamma}^{(0)}(r)\{\exp[H_{\alpha\gamma}(r)-\beta u_{\alpha\gamma}^{(1)}(r)]-1\} - H_{\alpha\gamma}(r). \tag{17}$$

From Eqs. 13 and 15, we obtain

$$H_{\alpha\gamma}(r) = \beta u_{\alpha\gamma}^{(1)}(r) + \ln\frac{g_{\alpha\gamma}(r)}{g_{\alpha\gamma}^{(0)}(r)}. \tag{18}$$

For polar fluids, $h_{\alpha\gamma}(r)$ decays as r^{-6} at large r.[5,6] Thus, the following asymptotic forms of $H_{\alpha\gamma}(r)$ and $\delta c_{\alpha\gamma}(r)$ at large separations are derived from Eqs. 15 and 18,

$$H_{\alpha\gamma}(r) \sim \beta u_{\alpha\gamma}^{(1)}(r), \text{ and } \delta c_{\alpha\gamma}(r) \sim -\beta u_{\alpha\gamma}^{(1)}(r).$$

Since $u_{\alpha\gamma}^{(1)}(r)$ is the long-ranged Coulomb potential, serious truncation errors can arise when these functions are numerically integrated over a finite range. Thus, we define a new short-ranged function $H_{\alpha\gamma}^{s}(r)$ and $\delta c_{\alpha\gamma}^{s}(r)$ as follows,

$$H_{\alpha\gamma}^{s}(r) = H_{\alpha\gamma}(r) - H_{\alpha\gamma}^{L}(r) \tag{19}$$

and

$$\delta c_{\alpha\gamma}^{s}(r) = \delta c_{\alpha\gamma}(r) + H_{\alpha\gamma}^{L}(r), \tag{20}$$

where

$$H_{\alpha\gamma}^{L}(r) = \frac{\beta q_\alpha q_\gamma}{4\pi\varepsilon_0 r}(1-\mathrm{e}^{-ar}) \tag{21}$$

and a is a disposable parameter chosen so as to make the function $\Psi_{\alpha\gamma}^{s}(r)$, defined below, negligibly small at the termination of the finite range of r. By the use of new functions $H_{\alpha\gamma}^{s}(r)$ and $\delta c_{\alpha\gamma}^{s}(r)$, Eqs. 16 and

17 can be written as

$$\tilde{\boldsymbol{H}}^{S} = (\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)})\{\boldsymbol{1}-\rho(\delta\tilde{\boldsymbol{c}}^{S}-\tilde{\boldsymbol{H}}^{L})(\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)})\}^{-1} \times (\delta\tilde{\boldsymbol{c}}^{S}-\tilde{\boldsymbol{H}}^{L})(\tilde{\boldsymbol{\omega}}+\rho\tilde{\boldsymbol{h}}^{(0)}) - \delta\tilde{\boldsymbol{c}}^{S} \quad (22)$$

and

$$\delta c^{S}_{\alpha\gamma}(r) = g^{(0)}_{\alpha\gamma}\{\exp[H^{S}_{\alpha\gamma}(r)-\Psi^{S}_{\alpha\gamma}(r)]-1\}-H^{S}_{\alpha\gamma}(r), \quad (23)$$

where

$$\Psi^{S}_{\alpha\gamma}(r) = \frac{\beta q_\alpha q_\gamma}{4\pi\varepsilon_0 r}e^{-ar}$$

and

$$\tilde{H}^{L}_{\alpha\gamma}(k) = \frac{\beta q_\alpha q_\gamma a^2}{\varepsilon_0 k^2(k^2+a^2)}.$$

Equations 22 and 23 involve only short-ranged functions that can be numerically handled in the usual way. An iteration procedure is carried out for solving Eqs. 22 and 23 numerically. The iteration was started with the initial guess $H^{a}_{\alpha\gamma}(r)=0$, and has been continued until the self consistency of

$$\left|\frac{H^{S}_{\alpha\gamma}(r)_{out}-H^{S}_{\alpha\gamma}(r)_{in}}{H^{S}_{\alpha\gamma}(r)_{in}}\right| < 10^{-7} \quad (24)$$

is satisfied. The site-site radial distribution function is finally obtained as

$$g_{\alpha\gamma}(r) = g^{(0)}_{\alpha\gamma}(r)\exp\{H^{S}_{\alpha\gamma}(r)-\Psi^{S}_{\alpha\gamma}(r)\}. \quad (25)$$

The solution of Lowden's RISM computer program[18] is used as a reference system site-site radial distribution function $g^{(0)}_{\alpha\gamma}(r)$.

Results and Discussion

A system considered is characterized by three parameters, that is, the reduced density $\rho^*=\rho d^3$, the reduced dipole moment $\mu^*=(\mu^2/4\pi\varepsilon_0 k_B T d^3)^{1/2}$ and the reduced bond length $L^*=l/\sigma$. Here, $\mu=ql$ is the magnitude of the dipole moment of the molecules and d, the diameter of the hard sphere whose volume is the same as the molecule considered here, is defined by the following relations as

$$d^3 = \sigma^3\left(1+\frac{3L^*}{2}-\frac{L^{*3}}{2}\right). \quad (26)$$

Iteration procedures described above diverge when L^* is 0.2 or less.

Distribution Functions. Figures 2—5 show the site-site radial distribution functions calculated according to the procedures described in the preceding section. All of $g_{\alpha\gamma}(r)$ shown in these figures have cusps at $r/\sigma=1+L^*$. These cusps are characteristic of fluids composed of diatomic molecules with a hard core repulsion. For the system with continuous potentials, these cusps are rounded off.[4] It is noted that all the curves of $g_{++}(r)$ and $g_{+-}(r)$ in Figs. 2—5 are nearly symmetrical with respect to the curve of $g^{(0)}(r)$, and have oscillatory structure around the curve of $g^{(0)}(r)$. These behaviors are explained as follows: Let the center of the + atom of one molecule fix the origin. Then, if the + atom of the other molecule exist at $r\simeq\sigma$, the − atom of its molecule necessarily exist at $r\simeq\sigma+l$. Thus, because of the decrease of the value of $g_{++}(r)$ at $r\simeq\sigma$ due to the electrostatic repulsion in comparison with the value of $g^{(0)}(r)$, the value of $g_{+-}(r)$ decrease at $r\simeq\sigma+l$. Similar effects will cause the behaviors described above.

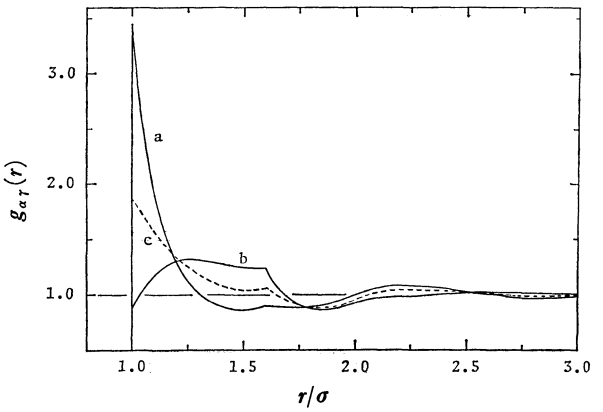

Fig. 2. The site-site radial distribution functions, $g_{\alpha\gamma}(r)$, for diatomic polar fluid at $\rho^*=0.8$, $\mu^{*2}=3.0$ and $L^*=0.6$. a; $g_{+-}(r)=g_{-+}(r)$, b; $g_{++}(r)=g_{--}(r)$, c; $g^{(0)}(r)$.

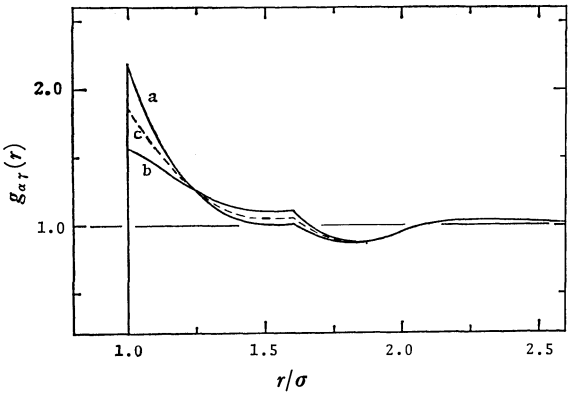

Fig. 3. Same as Fig. 2, except $\mu^{*2}=0.5$.

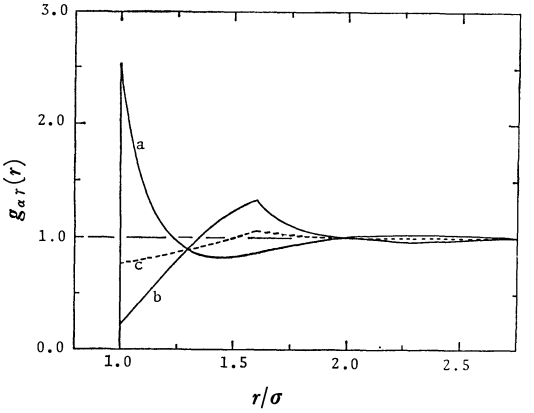

Fig. 4. Same as Fig. 2, except $\rho^*=0.2$.

A large deviation of $g_{\alpha\gamma}(r)$ from $g^{(0)}(r)$ are shown at $\rho^*=0.8$, $\mu^{*2}=3.0$ and $L^*=0.6$ (Fig. 2). The deviation at $\rho^*=0.8$, $\mu^{*2}=0.5$ and $L^*=0.6$ (Fig. 3) are smaller than that shown in Fig. 2 and $g_{\alpha\gamma}(r)$ almost agree with $g^{(0)}(r)$ at $r>2\sigma$. It is shown in Fig. 4 that $g^{(0)}(r)$ at $\rho^*=0.2$, $\mu^{*2}=3.0$ and $L^*=0.6$ is nearly equal to one, on the other hand the deviations of $g_{\alpha\gamma}(r)$ from $g^{(0)}(r)$ are similar to those shown in Fig. 2. Figure 5 shows $g_{\alpha\gamma}(r)$ at $\rho^*=0.6$, $\mu^{*2}=1.0$ and $L^*=0.3$. The shapes of curves are considerably dif-

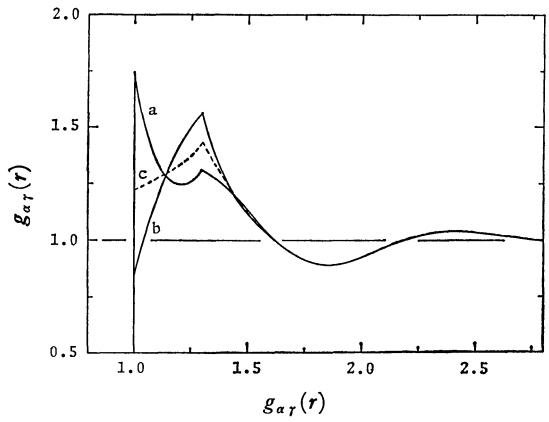

Fig. 5. The site-site radial distribution functions, $g_{\alpha\gamma}(r)$, for diatomic polar fluid at $\rho^*=0.6$, $\mu^{*2}=1.0$ and $L^*=0.3$. a; $g_{+-}(r)=g_{-+}(r)$, b; $g_{++}(r)=g_{--}(r)$, c; $g^{(0)}(r)$.

ferent from those at $L^*=0.6$. This difference is due to the difference of the shape of $g^{(0)}(r)$. On the other hand, the deviation of $g_{\alpha\gamma}(r)$ from $g^{(0)}(r)$ is similar to that at $L^*=0.6$.

Structure Factors. The structure factor is expressed in terms of site-site correlation functions as follows,[11]

$$S(k) = (\sum_{\alpha} b_\alpha)^{-2} \sum_{\alpha}\sum_{\gamma} b_\alpha b_\gamma \{\tilde{\omega}_{\alpha\gamma}(k) + \rho\tilde{h}_{\alpha\gamma}(k)\}$$

$$= \frac{(b_+^2+b_-^2)\{1+\tilde{h}_{++}(k)\}+2b_+b_-\{\tilde{\omega}_{+-}(k)+\tilde{h}_{+-}(k)\}}{(b_++b_-)^2}, \quad (27)$$

where we use the relations $h_{++}(r)=h_{--}(r)$ and $h_{+-}(r)=h_{-+}(r)$ in the second equality and b_α denote the coherent scattering amplitude for an atoms of type α. Figures 6 and 7 show the structure factors calculated under the assumptions of $b_+=b_-$ and $b_+=10b_-$, respectively. The structure factor at $b_+=b_-$ is nearly equal to that of reference system except at small k. This result arises from the fact that the deviation of $g_{++}(r)$ from $g^{(0)}(r)$ cancells that of $g_{+-}(r)$. Because of the decrease of these cancellations, $S(k)$ at $b_+=10b_-$ fairly deviate from $S^{(0)}(k)$. The values of $S(k)$ increase in small range of $k\sigma$ in comparison with $S^{(0)}(k)$. The behavior of the structure factors at small k seems to be due to the contribution of averaged attractive potentials.[4,19]

Thermodynamic Quantities. The total internal energy U and the isothermal compressibility κ_T are expressed in terms of the site-site pair correlation functions as follows,

$$\frac{U}{Nk_BT} = \frac{\rho}{2k_BT}\sum_{\alpha}\sum_{\gamma}\int d\boldsymbol{r} u_{\alpha\gamma}(r) g_{\alpha\gamma}(r), \quad (28)$$

and

$$\rho k_BT\kappa_T = S(0) = 1 + \rho\tilde{h}_{\alpha\gamma}(0), \quad (29)$$

where N is the number of molecules. Figures 8 and 9 show the internal energy and the isothermal compressibility at $L^*=0.6$, respectively. The L^* dependence of the internal energy and the isothermal compressibility are also shown in Figs. 10 and 11, respectively. In Fig. 10, the values at $L^*=0$ are those

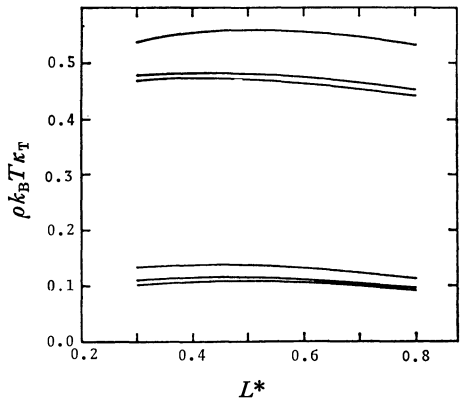

Fig. 11. The L^* dependence of the isothermal compressibility for diatomic polar fluids. From top to bottom, the curves are for $(\rho^*, \mu^{*2})=(0.2, 3.0)$, (0.2, 1.0), (0.2, 0.0), (0.6, 3.0), (0.6, 1.0), and (0.6, 0.0), respectively.

of fluids composed of dipolar hard spheres at the same reduced density and dipole moment calculated by the LHNC integral equations.[20] All the values of Patey *et al.* are nearly equal to those at $L^*=0.5$. It is shown in Figs. 10 and 11 that the values of $\rho k_B T\kappa_T$ are nearly constant with respect to the values of L^*, in sharp contrast to the case of the internal energy which has a large L^* dependence.

In this paper, we have proposed the RHNC like integral equations of RISM-1 type for polyatomic molecular fluids, and applied the equation to diatomic polar fluids. This calculation made from the first principles gives some new informations with respect to the structure and properties of diatomic polar fluids.

A Hypervirial Theorem Aspect of Koopmans' Theorem

Makoto ISIHARA

Department of General Education, Shotoku-Gakuen Women's Junior College, Gifu 500

(Received October 9, 1981)

Koopmans' theorem is interpreted as a hypervirial theorem requirement; the implication of Koopmans' theorem is thereby clarified. A hypervirial theorem standpoint gives a physically sound ground to a leading correction of Koopmans' relation. Attention is paid to the orbital ambiguity associated with the correction, a possible utilization of the ambiguity being suggested.

Koopmans' theorem[1] is one of the most important characteristics of the standard Hartree-Fock(HF) method,[2] giving a definite physical meaning to occupied canonical HF orbitals. However, what is implied in the theorem does not seem to be fully recognized; a well-known approximate evaluation of the vertical ionization energy

$$I_i = -\varepsilon_i^c \quad (\varepsilon_i^c\text{: } i\text{th canonical HF orbital energy}) \tag{1}$$

is rather misleadingly referred to as Koopmans' theorem.[3,4] In this paper Koopmans' theorem is examined from the viewpoint of the hypervirial theorem(HVT),[5] which leads us not only to transparent understanding of a nature of Koopmans' theorem but also to a physically sound ground for a leading correction to Koopmans' relation.

Preliminaries

Let us start with writing the Hamiltonian for a system of electrons in a fixed nuclear framework as

$$H = \sum_{\xi\eta} h_{\xi\eta} a_\xi^\dagger a_\eta + \frac{1}{2}\sum_{\xi\eta\theta\tau} v_{\eta\tau}^{\xi\theta} a_\xi^\dagger a_\theta^\dagger a_\tau a_\eta, \tag{2}$$

where $a_\xi^\dagger$ and a_ξ are, respectively, the creation and annihilation operators for the one-particle quantum state ξ. Taking a relevant hermitian one-particle operator

$$X = \sum_{\xi\eta} x_{\xi\eta} a_\xi^\dagger a_\eta,$$

which is to be determined later, going through an eigenvalue problem

$$\sum_\eta (h_{\xi\eta} + x_{\xi\eta}) u_{\eta j} = u_{\xi j}\varepsilon_j, \tag{3}$$

we rewrite Eq. 2 in the molecular orbital representation as

$$H = K + V^{(1)} + V^{(2)} \tag{4}$$

with

$$K = \sum_j \varepsilon_j a_j^\dagger a_j, \tag{5}$$

$$V^{(1)} = -\sum_{jk} x_{jk} a_j^\dagger a_k, \tag{6}$$

and

$$V^{(2)} = \frac{1}{2}\sum_{jklm} v_{km}^{jl} a_j^\dagger a_l^\dagger a_m a_k. \tag{7}$$

Postulating that an eigenstate $|\psi\rangle$ of H is attainable from the corresponding unperturbed eigenstate $|\phi\rangle$ of K through a unitary transformation:

$$|\psi\rangle = \exp(S)|\phi\rangle, \tag{8}$$

where S is an antihermitian operator independent of state indices, we expand S perturbation-theoretically as

$$S = S_1^{(1)} + S_1^{(2)} + \text{second and higher orders}$$

with

$$S_1^{(1)} = \sum_{jk} s_{jk} a_j^\dagger a_k \tag{9}$$

and

$$S_1^{(2)} = \frac{1}{2}\sum_{jklm} s_{km}^{jl} a_j^\dagger a_l^\dagger a_m a_k. \tag{10}$$

Then the first order one-particle HVT[5] affirms that

$$\sum_j (y_{jp}\langle a_j^\dagger a_q\rangle - y_{qj}\langle a_p^\dagger a_j\rangle + \sum_{kl}(y_{pi}^{jk}\langle a_j^\dagger a_k^\dagger a_l a_q\rangle - y_{ji}^{qk}\langle a_p^\dagger a_k^\dagger a_l a_j\rangle)) = 0 \quad (\text{any } p, q) \tag{11}$$

with

$$y_{jk} = -x_{jk} + (\varepsilon_j - \varepsilon_k)s_{jk} \tag{12}$$

and

$$y_{km}^{jl} = v_{km}^{jl} + (\varepsilon_j + \varepsilon_l - \varepsilon_m - \varepsilon_k)s_{km}^{jl}, \tag{13}$$

the simple bracket $\langle\cdots\rangle$ in Eq. 11 standing for the expectation value in $|\phi\rangle$. We confine ourselves to single-configurational $|\phi\rangle$'s in the following.

Koopmans' Theorem

First the case without S is considered. Denoting the N-electron Fermi sea state of K by $|F\rangle$:

$$|F\rangle = a_N^\dagger \cdots a_2^\dagger a_1^\dagger |\text{vacuum}\rangle, \tag{14}$$

and sets of the occupied and unoccupied orbitals by F and $\bar{F}$ respectively, we can write the one-particle HVT for the ground state $|F\rangle$ as

$$\langle F|[H, a_p^\dagger a_q]|F\rangle = 0 \qquad (\text{any } p, q) \tag{15}$$

and that for the ionized state $a_i|F\rangle$ $(i\epsilon F)$ as

$$\langle F|a_i^\dagger [H, a_p^\dagger a_q] a_i|F\rangle = 0 \quad (\text{any } p, q). \tag{16}$$

By making use of Eqs. 11, 12, and 13 with all s_{jk}'s and s_{km}^{jl}'s vanishing, Eqs. 15 and 16 are easily converted into

$$(-x_{qp} + \bar{v}_{qp})(\mathrm{f}(q) - \mathrm{f}(p)) = 0 \tag{17}$$

and

$$(-x_{qp} + \bar{v}_{qp} - v(i)_{qp})(\mathrm{f}(q) - \mathrm{f}(p) - \delta_{iq} + \delta_{ip}) = 0 \tag{18}$$

respectively, where we introduce the occupation indicator

$$\mathrm{f}(j) = \begin{cases} 1 & (j\epsilon F) \\ 0 & (j\epsilon \bar{F}) \end{cases} \tag{19}$$

and the abbreviations

$$t(l)_{jk} = t_{kl}^{jl} - t_{lk}^{jl}$$

and

$$\tilde{t}_{jk} = \sum_{l\epsilon F} t(l)_{jk}.$$

While Eq. 17 gives the HF condition[5]

$$x_{jk} = \bar{v}_{jk} \quad (j\epsilon F,\ k\epsilon\bar{F},\ \text{and } \textit{vice versa}), \tag{20}$$

Eq. 18 results in

$$\begin{cases} x_{ij} = \bar{v}_{ij} \text{ and } x_{ji} = \bar{v}_{ji} & (j\epsilon F') \quad (21) \\ v(i)_{jk} = 0 & (j\epsilon F',\ k\epsilon\bar{F},\ \text{and } \textit{vice versa}) \quad (22) \end{cases}$$

with Eq. 20 assumed, the prime on F indicating the exclusion of i: $F'=F-\{i\}$. Since we cannot satisfy Eq. 22 in general, Eqs. 15 and 16 are intrinsically prevented from holding simultaneously.

Now for the ionized state, contented with the HVT in a restricted region

$$\langle F|a_i^\dagger[H, a_p^\dagger a_q]a_i|F\rangle = 0 \quad (p, q\epsilon F, \text{ and } p, q\epsilon\bar{F}') \tag{23}$$

with $\bar{F}'=\bar{F}+\{i\}$, we are free from Eq. 21; the two HVT's, Eqs. 15 and 23 are compatible with each other and lead together to

$$x_{jk} = \bar{v}_{jk} \quad (j\epsilon F, k\epsilon\bar{F} \text{ and } \textit{vice versa};\ j, k\epsilon F,\ j \text{ or } k=i). \tag{24}$$

Thus we see a HVT aspect of Koopmans' theorem: When the molecular orbitals are determined so as to satisfy Eq. 24, a single-configurational approximation of the vertical ionization energy

$$\begin{aligned} I_i &= \langle F|a_i^\dagger H a_i|F\rangle - \langle F|H|F\rangle \\ &= -h_{ii} - \bar{v}_{ii} \end{aligned} \tag{25}$$

is at its best.

Conversely, we can formally make Eq. 16 compatible with the ground state HVT in a restricted region. This coalition is, however, unnatural and disadvantageous, as long as the matrix elements $\{h_{\xi\eta}\}$ and $\{v_{\gamma\tau}^{\xi\theta}\}$ are set to be appropriate to the more stable ground state.

A sufficient way to satisfy Eq. 24 is obviously to put

$$x_{jk} = \bar{v}_{jk} \quad (\text{any } j, k) \tag{26}$$

or in the initial representation

$$x_{\xi\eta} = \sum_{\theta\tau} (v_{\eta\tau}^{\xi\theta} - v_{\tau\eta}^{\xi\theta})\rho_{\tau\theta} \tag{27}$$

with

$$\rho_{\tau\theta} = \sum_{j\epsilon F} u_{\tau j}u_{\theta j}^*. \tag{28}$$

The eigenvalue problem obtained by substituting Eq. 27 into Eq. 3 can be solved with Eq. 28 self-consistently, giving the canonical HF orbitals. If canonical HF orbitals are used, we can rewrite Eq. 25 as Eq. 1. This step is, however, just only rewriting of no physical content.[6] It seems to be desired to call Eq. 1 itself not Koopmans' theorem but relation.

It should be emphasized that Eq. 24 leaves many of x_{jk}'s for $j,k\epsilon F$ and all x_{jk}'s for $j,k\epsilon\bar{F}$ undetermined. This ambiguity is to be utilized purposively. We can require Eq. 23 consistently for all $i\epsilon F$ besides Eq. 15, if necessary, the resultant condition being

$$x_{jk} = \bar{v}_{jk} \quad (j\epsilon F, k\epsilon\bar{F} \text{ and } \textit{vice versa};\ j, k\epsilon F, j\neq k). \tag{29}$$

We have Eq. 26 again as a sufficient choice of X. It is worth while to note that x_{jj}'s remain still undetermined even for $j\epsilon F$ in Eq. 29. Since all x_{jk}'s for $j,k\epsilon\bar{F}$ are not conditioned in Eq. 24, Koopmans' theorem is valid in the hole potential method.[5,7] The electron-hole potential choice of X is generally inconsistent with Eq. 24.[5,8]

A Leading Correction to Koopmans' Relation

Next let us consider to fulfil the one-particle HVT's for the ground and ionized states,

$$\langle F|\exp(-S)[H, a_p^\dagger a_q]\exp(S)|F\rangle = 0 \quad (\text{any } p, q) \tag{30}$$

and

$$\langle F|a_i^\dagger \exp(-S)[H, a_p^\dagger a_q]\exp(S)a_i|F\rangle = 0 \quad (\text{any } p, q), \tag{31}$$

simultaneously to first order by using simple S. Putting $|\phi\rangle=|F\rangle$ and $|\phi\rangle=a_i|F\rangle$ in Eq. 11 respectively, we immediately obtain

$$(y_{qp}+\tilde{y}_{qp})(\mathrm{f}(q)-\mathrm{f}(p)) = 0 \tag{32}$$

and

$$(y_{qp}+\tilde{y}_{qp}-y(i)_{qp})(\mathrm{f}(q)-\mathrm{f}(p)-\delta_{iq}+\delta_{ip}) = 0. \tag{33}$$

The former gives

$$-y_{jk} = \tilde{y}_{jk} \quad (j\epsilon F, k\epsilon\bar{F}, \text{ and } \textit{vice versa}), \tag{34}$$

letting the latter result in

$$\begin{cases} -y_{ij} = \tilde{y}_{ij} \text{ and } -y_{ji}=\tilde{y}_{ji} & (j\epsilon F') \quad (35) \\ y(i)_{jk} = 0 & (j\epsilon F', k\epsilon\bar{F}, \text{ and } \textit{vice versa}). \quad (36) \end{cases}$$

Forming a striking contrast to Eqs. 22 and 36 merely asserts that

$$s(i)_{jk} = v(i)_{jk}/(\varepsilon_k-\varepsilon_j) \quad (j\epsilon F', k\epsilon\bar{F}, \text{ and } \textit{vice versa}). \tag{37}$$

The other s_{km}^{ii}'s are allowed to be zero. We have alternatives with regard to fulfilment of Eq. 34.

If we make all s_{jk}'s vanishing, Eq. 34 becomes

$$x_{jk} = \bar{v}_{jk} - v(i)_{jk} \quad (j\epsilon F, k\epsilon\bar{F}, \text{ and } \textit{vice versa}) \tag{38}$$

by virtue of Eq. 37. From Eq. 35 we have

$$x_{ij} = \bar{v}_{ij} \text{ and } x_{ji} = \bar{v}_{ji} \quad (j\epsilon F'). \tag{39}$$

Because $v(i)_{ij}$ and $v(i)_{ji}$ vanish identically for any j, Eqs. 38 and 39 can be achieved by the standard HF calculation for the ionized configuration. There is no first order correction to the ionized state; we have

$$S_1^{(2)}|F\rangle = \sum_{j\epsilon\bar{F},\ k\epsilon F'} v(i)_{jk}/(\varepsilon_k-\varepsilon_j)a_j^\dagger a_k|F\rangle. \tag{40}$$

The resultant approximation of the vertical ionization energy is, to second order, given by

$$I_i = -h_{ii} - \bar{v}_{ii} + \sum_{j\epsilon\bar{F},\ k\epsilon F'} |v(i)_{jk}|^2/(\varepsilon_j-\varepsilon_k). \tag{41}$$

Note that x_{jk}'s for $j,k\epsilon F'$ and $j,k\epsilon\bar{F}$ are not conditioned in Eqs. 38 and 39; Eq. 41 remains ambiguous.

Another way, usually fitting real situations better than the preceding, consists in adhering to the ground state HF condition, Eq. 20. In consequence it follows from Eq. 34 that

$$s_{jk} = v(i)_{jk}/(\varepsilon_j-\varepsilon_k) \quad (j\epsilon F, k\epsilon\bar{F}, \textit{vice versa}) \tag{42}$$

after substitution of Eq. 37. The other s_{jk}'s can be set to vanish; we have Eq. 39 as before from Eq. 35. This time the first order state correction does not appear in the ground state, but does in the ionized:

$$(S_1^{(1)}+S_1^{(2)})a_i|F\rangle = \sum_{j\epsilon\bar{F},\ k\epsilon F'} v(i)_{jk}/(\varepsilon_j-\varepsilon_k)a_j^\dagger a_k a_i|F\rangle. \tag{43}$$

Accordingly, in place of Eq. 41, we have

$$I_i = -h_{ii} - \bar{v}_{ii} - \sum_{j\epsilon\bar{F},\, k\epsilon F'} |v(i)_{jk}|^2/(\varepsilon_j - \varepsilon_k). \quad (44)$$

Again it should be noted that the ambiguity in x_{jk}'s for $j,k\epsilon F'$ and $j,k\epsilon\bar{F}$ leaves Eq. 44 undetermined. Although how to utilize this ambiguity is not very evident, it seems much more plausible to use the orbitals satisfying

$$x_{jk} = \bar{v}_{jk} - v(i)_{jk} \qquad (j,k\epsilon F' \text{ and } j,k\epsilon\bar{F}) \quad (45)$$

rather than to hold on the canonical HF orbitals for the ground state configuration; the second order term in Eq. 44 exclusively comes from the correction concerning the ionized state.

In order to have Eqs. 20, 39, and 45 hold, it is sufficient to take X as

$$x_{jk} = \bar{v}_{jk} - \mathrm{f}(j)v(i)_{jk}\mathrm{f}(k) - (1-\mathrm{f}(j))v(i)_{jk}(1-\mathrm{f}(k)). \quad (46)$$

Denoting the one-particle quantum state by the round bra and ket, we employ the projection operators[7]

$$\mathrm{P} = \sum_j |j)\mathrm{f}(j)(j| \quad (47)$$

and

$$\bar{\mathrm{P}} = \sum_j |j)(1-\mathrm{f}(j))(j|, \quad (48)$$

which are invariant under unitary transformations within each of the orbital subsets F and $\bar{F}$. With the abbreviations

$$\rho_{\xi\eta} = (\xi|\mathrm{P}|\eta) = \sum_{j\epsilon F} u_{\xi j}u^*_{\eta j} \quad (49)$$

and

$$\bar{\rho}_{\xi\eta} = (\xi|\bar{\mathrm{P}}|\eta) = \sum_{j\epsilon\bar{F}} u_{\xi j}u^*_{\eta j} \quad (50)$$

we can rewrite Eq. 46 in the initial representation as

$$x_{\xi\eta} = \sum_{\theta\tau} ((v^{\xi\theta}_{\eta\tau} - v^{\xi\theta}_{\tau\eta})\rho_{\tau\theta} - \rho_{\xi\theta}v(i)_{\theta\tau}\rho_{\tau\eta} - \bar{\rho}_{\xi\theta}v(i)_{\theta\tau}\bar{\rho}_{\tau\eta}). \quad (51)$$

However, to solve Eq. 3 with Eqs. 49, 50, and 51 seems unreasonably inefficient. A stepwise method is practical: First perform the standard HF calculation for the ground state configuration to obtain the canonical HF orbitals $\{\underline{j}\}$ and their energies $\{\varepsilon_{\underline{j}}\}$. Selecting a relevant occupied orbital $\underline{i}$, next work out the two separate eigenvalue problems

$$\sum_{\underline{k}\epsilon F'} (\delta_{\underline{k}\underline{l}}\varepsilon_{\underline{k}} - v(\underline{i})_{\underline{k}\underline{l}})c_{\underline{l}\underline{j}} = c_{\underline{k}\underline{j}}\varepsilon_j \qquad (\underline{k}\epsilon F') \quad (52)$$

and

$$\sum_{\underline{l}\epsilon\bar{F}} (\delta_{\underline{k}\underline{l}}\varepsilon_{\underline{k}} - v(\underline{i})_{\underline{k}\underline{l}})c_{\underline{l}\underline{j}} = c_{\underline{k}\underline{j}}\varepsilon_j \qquad (\underline{k}\epsilon\bar{F}), \quad (53)$$

which give rise to the new orbitals $\{j\}$ with their energies $\{\varepsilon_j\}$, the orbital i being identical with $\underline{i}$. No iterative procedure for self-consistency is involved in solving Eqs. 52 and 53.

The simultaneous fulfilment of the one-particle HVT's for the ground and ionized states leads us to taking it into account the effect of the charge distribution rearrangement through ionization.[9]

The Quenching of Excited Zinc(^3P_J) Atoms by Alkane Hydrocarbons

Shunzo YAMAMOTO* and Norio NISHIMURA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received October 16, 1981)

The intensities of the 307.6 nm resonance line of zinc were measured at different pressures of alkane hydrocarbons, and the quenching-rate constants were determined on the basis of the Stern-Volmer plots. A remarkable dependence of the quenching cross-section on the C–H bond strength was observed, and the relative decrease in the quenching cross-section with an increase in the C–H bond strength was interpreted in terms of the semiempirical bond-energy-bond-order(BEBO) method.

Recently, Breckenridge and Renlund have measured the quenching cross-sections of Cd(^3P_J) by the use of several alkane hydrocarbons.[1] They have then compared their values with those for the quenching of Hg($^3P_0$) and Hg($^3P_1$). They summarized the important aspects of their results as follows: (1) The Cd(^3P_J) quenching-rate constants are remarkably small for alkane hydrocarbons. (2) There is a slight increase in the quenching cross-section in the order of primary, secondary, and tertiary C–H bonds. (This is in contrast to the fact that there is a remarkable dependence of the quenching cross-section on the C–H bond strength in the case of Hg($^3P_{0,1}$)). (3) The direct abstraction of a hydrogen atom to form CdH appears to be a major quenching pathway for all the alkanes studied, with the possible exception of methane. (4) The quenching of Cd(^3P_J) by alkane hydrocarbons differs substantially from the quenching of Hg($^3P_1$). (They suggested that the difference in the quenching behavior between Cd(^3P_J) and Hg($^3P_1$) can be understood if the mechanistic pathway for Hg($^3P_1$) is merely energetically inaccessible to the low-energy Cd(^3P_J) atom.

Since the excitation energy of Zn(^3P_J) lies between those of Cd(^3P_J) and Hg($^3P_1$), we expected that the study of the quenching of Zn(^3P_J) would give further detailed information about the mechanism. The present paper will deal with the quenching of Zn(^3P_J) by several alkane hydrocarbons.

Experimental

The apparatus was the same as that previously described,[2] except for the use of a zinc-resonance lamp made of Pyrex. This lamp emits only resonance line, at 307.6 nm, which gives rise to Zn($^3P_1$) atoms. The reaction cell and the zinc lamp were kept in a furnace at 305±2 °C for most of the measurements. The light intensity from the cell was measured by means of a Hitachi spectrophotometer, Model 139. The pressures of the gases were measured by means of a Bourdon pressure gauge (W & T model 62-075, Nagano Keiki Co.). The low pressures of the quenching gases were measured using calibrated expansion volumes.

The zinc metal used was high-purity zinc (99.9999%) manufactured by Osaka Asahi Metal Co. The ethane, propane, ethylene, and propylene (Gasukuro Kogyo Co., Ltd.), and cyclopropane (Santetsu Kagaku Kogyo Co., Ltd.) were freeze-pumped several times. The isobutane and neopentane (Tokyo Kasei Kogyo Co., Ltd., E. P. grade) and other alkanes (Tokyo Kasei Co., Ltd., G. R. grade) were freeze-pumped several times and repeatedly subjected to trap-to-trap distillation. Pure-grade argon (Daido Sanso Co., 99.999%) was used without further purification.

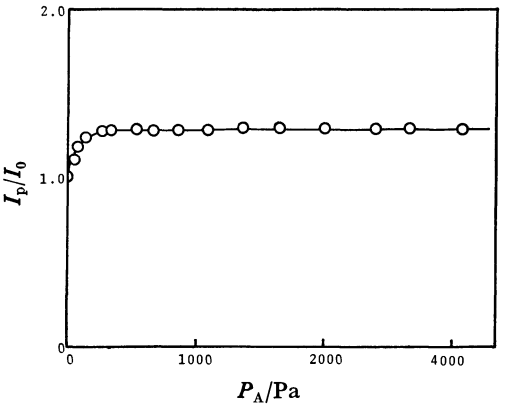

Fig. 1. Intensity of resonance line at 307.6 nm as a function of argon pressure.

Results

Pressure Dependence of the Emission Intensity at 307.6 nm. When a cell containing zinc vapor was illuminated by the exciting lamp, a resonance line was observed at 307.6 nm. Upon the addition of argon, the intensity of the line increased with the increase in the pressure, as is shown in Fig. 1. This was attributed to the increase in the light intensity absorbed by zinc atoms as a result of the pressure broadening of the absorption line.[2] In order to minimize such pressure dependence of the absorption of the resonance line, quenchers were diluted with a large amount of argon(total pressures 1000—3000 Pa).

Quenching of the 307.6 nm Resonance Line. In a previous paper,[2] the following reaction scheme was proposed:

$Zn(^1S_0) + h\nu(307.6\,nm) \longrightarrow Zn(^3P_1)$	I_a
$Zn(^3P_1) \longrightarrow Zn(^1S_0) + h\nu(307.6\,nm)$	k_0
$Zn(^3P_1) + M \rightleftharpoons Zn(^3P_0) + M$	k_1, k_{-1}
$Zn(^3P_1) + M \rightleftharpoons Zn(^3P_2) + M$	k_2, k_{-2}
$Zn(^3P_0) + Q \longrightarrow$ quenching	k_3
$Zn(^3P_1) + Q \longrightarrow$ quenching	k_4
$Zn(^3P_2) + Q \longrightarrow$ quenching	k_5.

Here, M denotes Ar and/or quenchers. As before, the ratio of the emission intensities in the absence and in the presence of quenchers can be given as:

$$\frac{I^{\circ}_{307.6}}{I_{307.6}} = 1 + \frac{1}{k_0}\left(\frac{k_1}{k_{-1}}k_3 + k_4 + \frac{k_2}{k_{-2}}k_5\right)[Q]. \quad (1)$$

Some typical Stern-Volmer plots for the quenching of the resonance line by several alkanes are shown

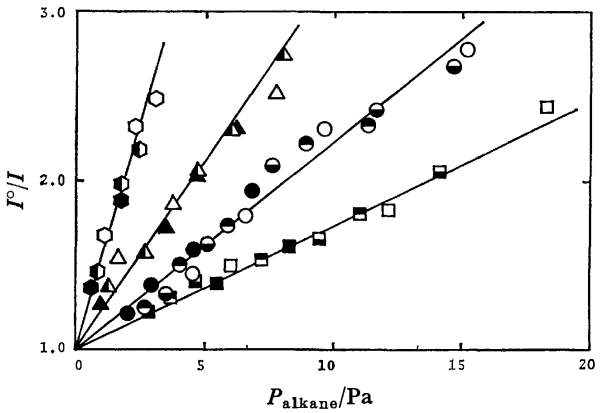

Fig. 2. Stern-Volmer plots for quenching of resonance line at 307.6 nm by alkanes diluted with argon 1) ethane: Total pressures are 2800 (◓), 2100 (□), 1700 (◒), and 1300 Pa (■). 2) Propane: 2800 (○), 2100 (◒), 1700 (◓), and 1300 Pa (●). 3) Butane: 2800 (△), 2100 (◭), and 1700 Pa (▲). 4) Cyclopentane: 2800 (⬡), 2100 (◐), and 1700 Pa (⬢).

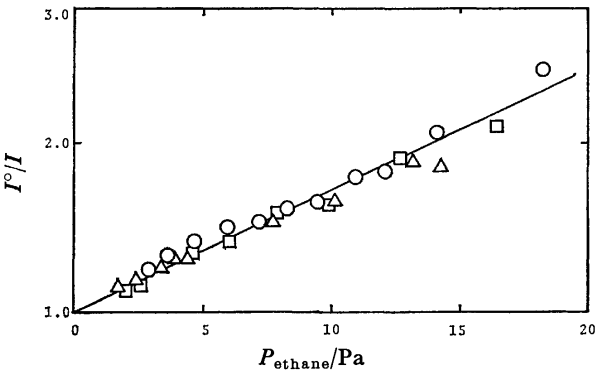

Fig. 3. Stern-Volmer plots for quenching of resonance line at 307.6 nm by ethane at various temperatures. 1) 290 °C (△), 2) 300 °C (○), 3) 320 °C (□).

in Fig. 2, where I° and I are the intensities of the resonance line in the absence and in the presence of quenchers respectively. Similar plots were obtained for other alkanes and alkenes. These Stern-Volmer plots are accounted for by Eq. 1.

As the f-value of the zinc 307.6 nm line is about one-tenth that of the cadmium 326.1 nm line,[3] the absorption of the 307.6 nm line by the zinc vapor (0.36 Pa at 305 °C) seems to be too small to cause any significant radiation trapping. If the lengthening of the effective radiation lifetime of $Zn(^3P_1)$ caused by radiation imprisonment is not negligible, the effective lifetime must be dependent on both the zinc pressure and the total pressure. In Fig. 3, the values of I°/I obtained for propane at various temperatures and at various total pressures are plotted as functions of the partial pressure of propane. The points lie on a straight line, and no dependence of the zinc pressure (from 0.25 Pa at 290 °C to 0.77 Pa at 320 °C) or the total pressure (1300—2700 Pa) can be seen. This suggests that the effective lifetime of the $Zn(^3P_1)$ is not lengthened by the radiation imprisonment under the present conditions. Therefore, k_0 can be taken as the reciprocal of the natural lifetime of $Zn(^3P_1)$ ($\tau_0=2.0\times10^{-5}$ s).[4]

Table 1. Quenching of $Zn(^3P_J)$ by alkanes and alkenes

Gas	$10^{11}k_q$ / cm^3 molecule^{-1} s^{-1}	$10^{16}\sigma_q$ / cm^2
H_2	106.6±7.2	42.7±2.8
D_2	64.1±4.5	35.5±2.5
CH_4	0.50±0.01	0.50±0.03
C_2H_6	2.88±0.06	3.74±0.06
C_3H_8	4.74±0.09	6.94±0.13
c-C_3H_6	12.8±0.2	18.4±0.4
n-C_4H_{10}	9.14±0.21	14.5±0.9
i-C_4H_{10}	5.02±0.12	8.70±0.20
n-C_5H_{12}	11.9±0.2	21.8±0.4
i-C_5H_{12}	8.53±0.12	14.3±0.21
neo-C_5H_{12}	4.45±0.10	7.41±0.22
c-C_5H_{10}	22.5±0.4	41.1±0.7
c-C_6H_{12}	34.5±0.6	60.0±1.0
C_2H_4	121.7±2.4	153.9±3.1
C_3H_6	89.7±1.2	129.7±1.9

From the slope of the Stern-Volmer plots, the composite rate constants for the quenching, $(k_1/k_{-1})k_3+k_4+(k_2/k_{-2})k_5$, were estimated. Since the three triplet states are in equilibrium, $k_1/k_{-1}=(1/3)\exp(2300/RT)$ and $k_2/k_{-2}=(5/3)\exp(-4730/RT)$, and at 305 °C k_1/k_{-1} and k_2/k_{-2} are 0.54 and 0.62 respectively. The quenching rate constants, $k_q(=0.54k_3+k_4+0.62k_5)$, and the corresponding quenching cross-sections for equilibrated $Zn(^3P_{0,1,2})$ calculated by means of:

$$\sigma_q = k_q\left[\frac{8RT}{\pi}\cdot\frac{M_{Zn}+M_Q}{M_{Zn}\cdot M_Q}\right]^{-1/2}, \quad (2)$$

are listed in Table 1.

As may be seen in Table 1, because the quenching cross-sections for alkanes determined here are considerably smaller than those for hydrogen and alkenes, it is important to discuss the possible effects on these measurements of very small amounts of impurities in the gases. Any hydrogen initially present in these gases would have been removed by many careful freeze-pump cycles performed. The alkanes used were at least 99.5% pure, except for neopentane (96% pure). Most of the impurities are thought to be other alkanes, and these alkane impurities at this level would not be sufficient to cause any considerable error in the measurements. For example, a 0.5% cyclopentane impurity causes about a 1% error in the cross-section for butane. On the other hand, alkenes have large cross-sections, and if the propane used contain 0.1% propylene, it would cause about a 1.8% error. This error is, however, within the limits of experimental error. Therefore, it is thought that, for alkanes except for neopentane, the errors attributable to possible impurity contents are negligibly small. As neopentane has a little larger amount of impurities, we regard the k_q value obtained for neopentane as the upper limit.

Discussion

The reaction and quenching of $Hg(^3P_{0,1})$ by alkane hydrocarbons have been very thoroughly studied,[5-9] and several mechanistic schemes have been proposed to explain the large body of data. In the case of $Hg(^3P_{0,1})$, a remarkable dependence of the quenching rate on the C–H bond strength was observed. On the other hand, there is virtually no dependence in the case of $Cd(^3P_J)$, and the cross-sections for methane, propane, and isobutane can be fit by assuming an additive cross-section of 0.0010×10^{-16} cm^2 for each C–H bond, irrespective of the type of bond.[1]

Table 2 compares the quenching cross-sections of $Zn(^3P_J)$, $Cd(^3P_J)$, and $Hg(^3P_1)$ by alkanes; the C–H bond strength is also shown. It may be noted that the quenching cross-section of $Zn(^3P_J)$ depends greatly on the C–H bond strength, and that the dependence is very similar to that of $Hg(^3P_1)$. Since the quenching cross-sections of such alkanes as methane, ethane, and neopentane, which contain neither secondary nor tertiary C–H bonds, are considerably smaller than those of alkanes which do contain secondary and/or tertiary C–H bonds, it is plausible that, in the latter case, the weaker secondary and tertiary C–H bonds are predominantly ruptured in the primary quenching act. An inspection of Table 2, however, shows that the quenching cross-section of $Zn(^3P_J)$ by alkanes is more closely correlated with the average C–H bond strength than with the weakest C–H bond strength. The correlation between the average quenching cross-section per C–H bond and the average C–H bond strength for $Zn(^3P_J)$, $Cd(^3P_J)$, and $Hg(^3P_1)$ is shown in Fig. 4. In general, the cross-sections increase with a decrease in the C–H bond strength for $Zn(^3P_J)$ and $Hg(^3P_1)$, but those for $Cd(^3P_J)$ are almost constant. This figure also shows that the cross-sections increase more regularly for $Zn(^3P_J)$ than for $Hg(^3P_1)$. In the latter case, the plots are somewhat scattered. The

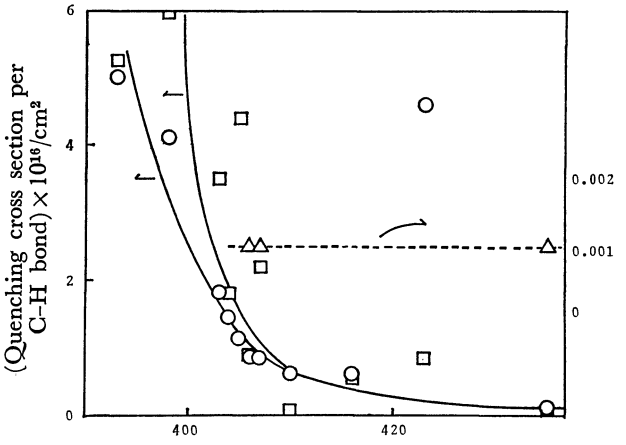

Fig. 4. The quenching cross section per C–H bond plotted against average C–H bond strength. $Zn(^3P_J)$ (○), $Cd(^3P_J)$ (△), and $Hg(^3P_1)$ (□).

good correlation shown indicates that the excited zinc do not attack only the weakest C–H bond, but all kinds of C–H bonds, with efficiencies which depend on the bond strength.

The quenching cross-section, σ_q, of a certain molecule is defined as the sum of the quenching cross-section, σ_i, for each individual quenching site (C–H bond):

$$\sigma_q = \Sigma\,\sigma_i. \quad (3)$$

Conversely, from the obtained quenching cross-section, σ_q, an effective cross-section, σ_i, for each C–H bond can be calculated. The effective cross-section per C–H bond in methane and that per primary C–H bond are obtained by:

$$\sigma_i(CH_3\text{–}H) = \sigma_q(CH_4)/4$$

$$\sigma_i(\text{primary}) = \sigma_q(C_2H_6 \text{ or } \textit{neo}\text{-}C_5H_{12})/(\text{number of C–H bonds}).$$

The effective cross-sections per secondary or tertiary

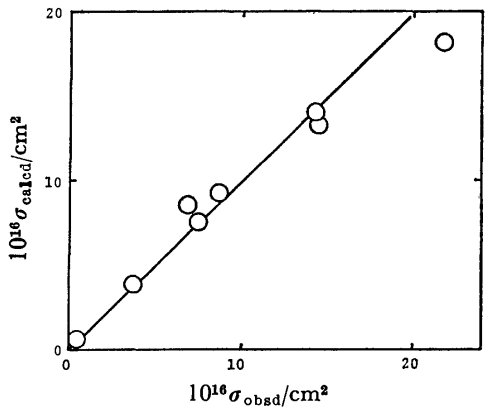

Fig. 5. Relationship between σ_{calcd} and σ_{obsd}.

C–H bond are estimated by means of:

$$\sigma_1(\text{secondary}) = \frac{\sigma_q(C_3H_8,\ n\text{-}C_4H_{10},\ \text{or}\ n\text{-}C_5H_{12}) - 6\sigma_1(\text{primary})}{\text{number of secondary C–H bonds}},$$

$$\sigma_1(\text{tertiary}) = \sigma_q(i\text{-}C_4H_{10}) - 9\sigma_1(\text{primary}) = \sigma_q(i\text{-}C_5H_{12}) - 9\sigma_1(\text{primary}) - 2\sigma_1(\text{secondary}).$$

The values of σ_1 thus obtained are given in Table 3. The average values of σ_1 for primary, secondary, and tertiary C–H bonds are 0.62, 2.4, and 3.6 respectively, corresponding to a ratio of 1:3.9:5.8. These values are different from those of 1:65:350 for $Hg(^3P_1)$ quenching.[10] In Fig. 5, the cross-sections, σ_{calcd}, calculated by summing the cross-sections, σ_1, for primary, secondary, and tertiary C–H bonds shown in Table 3 are plotted against the observed cross-section, σ_{obsd}. This figure shows that the quenching cross-sections for alkanes can be reproduced fairly well by summing the σ_1-values.

As is shown in Tables 2 and 3, the cross-sections for cyclopentane and cyclohexane are quite high. These high cross-sections for cycloalkanes were also observed in the cases of $Cd(^3P_J)$ and $Hg(^3P_1)$.[5] The higher cross-sections for cyclopentane and cyclohexane could be due to less steric repulsion in the cycloalkane C–H bond attack by excited atoms.

Table 4 shows the estimated enthalpies of reaction for the abstraction of a hydrogen atom by $Zn(^3P_J)$, $Cd(^3P_J)$, and $Hg(^3P_1)$ atoms from various types of C–H bonds in the alkane hydrocarbons. In the $Cd(^3P_J)$- and $Zn(^3P_J)$-photosensitized decomposition of alkanes, the major primary step is thought to be the C–H bond cleavage, which becomes energetically feasible only if the process is a true hydrogen transfer:

$$RH + Cd^*(Zn^*) \longrightarrow R + CdH(ZnH).$$

The formation of CdH in the course of the reaction can be readily detected spectroscopically.[11,12] In the case of the $Hg(^3P_1)$-photosensitized decomposition, however, the direct cleavage of C–H bonds without the intermediate formation of HgH is also energetically possible; the enthalpy of reaction for this process is shown in Table 4. It seems interesting that the dependence of the quenching cross-section on the C–H bond strength decreases in this order: $Hg(^3P_1) > Zn(^3P_J) > Cd(^3P_J)$. This order is consistent with the order of the decrease in the enthalpy of reaction for the abstraction of a hydrogen atom.

$(CH_3)_2CH$–H	−78	−40	−117	−77
Tertiary				
$(CH_3)_3C$–H	−92	−54	−131	−91

In the case of $Hg(^3P_1)$, several workers[5–8] have proposed mechanism in which the initial step is the formation of a weak complex between $Hg(^3P_1)$ and the alkane quencher. The resulting complex can decompose (if there is sufficient energy) by surmounting a potential barrier, the height of which is dependent on the type of C–H bond. Such a general model was originally proposed by Yang,[6] and the rate of passage over the barrier has been estimated by the use of Kassel,[6] RRKM,[7] and BEBO[8] treatments. All of these theories would predict large variations with the C–H bond strength in quenching cross-sections for lower-energy $Cd(^3P_J)$ and $Zn(^3P_J)$. As has been mentioned above, however, the variation for $Zn(^3P_J)$ is considerably smaller than that for $Hg(^3P_1)$, and there is virtually no dependence on the C–H bond strength in the quenching of $Cd(^3P_J)$ by alkanes. Therefore, it is obvious that previous models based on $Hg(^3P_1)$ quenching data are not directly applicable for $Zn(^3P_J)$ and $Cd(^3P_J)$.

Recently, Breckenridge and Renlund have pointed out that the mechanistic pathways which have been proposed for $Hg(^3P_{0,1})$ quenching are not energetically accesible for $Cd(^3P_J)$ quenching and have proposed

a possible mechanism which is consistent with several observations in the Hg($^3P_1$)–alkanes system and explains the small variation of Cd(^3P_J) quenching cross-sections among the alkane hydrocarbons studied.

In this paper, it is shown that the Zn(^3P_J)-photosensitized decomposition of alkanes can be considered as a simple hydrogen-atom transfer reaction; consequently, it is possible to calculated the relative potential energies of activation of these reactions by a modified BEBO method.[13]

In the BEBO method, the potential energy of activation for hydrogen-atom abstraction by a radical as a function of the bond order, n, of the bond being broken is given by:

$$V = E_b(1-n^p) - E_f(1-n)^q + V_{tr}, \quad (4)$$

where E_b and E_f are the single-bond energies of the bond being broken and formed, V_{tr} is the triplet repulsion term, and p and q are the bond-energy indices defined by the expression:

$$p \text{ or } q = \frac{0.26 \ln (D_e/\varepsilon_x)}{r_x - r_e}, \quad (5)$$

in which ε_x and r_x are the potential depth and the equilibrium internuclear distance of the analogous diatomic noble gas cluster, while D_e and r_e are the bound dissociation energy and the equilibrium internuclear distance of the bond in question. Strausz *et al.*[8] calculated the potential energies of activation for the mercury-photosensitized decomposition of alkanes by assuming the following model:

$$RH + Hg^* \longrightarrow R\cdots H\cdots Hg \longrightarrow R + HHg,$$

and by neglecting the repulsive triplet term, V_{tr}. They described since the model assumed is somewhat oversimplified, only the relative values are significant.

In the case of Zn(^3P_J), we could not obtain information about the bond-energy index (q). Therefore, we estimated only the relative potential energy of activation for the following process:

$$RH + Zn^* \longrightarrow R\cdots H\cdots Zn \longrightarrow R + HZn.$$

If it can be assumed that the bond order, n, for the transition state and the bond-energy index, q, are constant, irrespective of the type of C–H bond being broken, the activation energy referred to that for CH_3–H is expressed by the following equation:

$$\Delta V = E_b(1-n^p) - E_b^{CH_4}(1-n^{p_0}), \quad (6)$$

where $E_b^{CH_4}$ and p_0 are the bond energy of CH_3–H and the p-value for the CH_4–Zn* system. If $p=p_0$, as was assumed for the alkane–Hg* system by Strausz *et al.*, the above equation becomes:

$$\Delta V = (E_b - E_b^{CH_4})(1-n^p). \quad (7)$$

The cross-section, σ_1 is expressed by the following equation:

$$\sigma_1 \propto k_1 = A \exp(-V/RT). \quad (8)$$

Therefore, $\sigma_1/\sigma_1^{CH_4}$ can be expressed as follows:

$$\ln \sigma_1/\sigma_1^{CH_4} = -\Delta V/RT. \quad (9)$$

From Eqs. 7 and 9, the following equation is obtained:

$$\ln \sigma_1/\sigma_1^{CH_4} = -\frac{(1-n^p)}{RT}(E_b - E_b^{CH_4}). \quad (10)$$

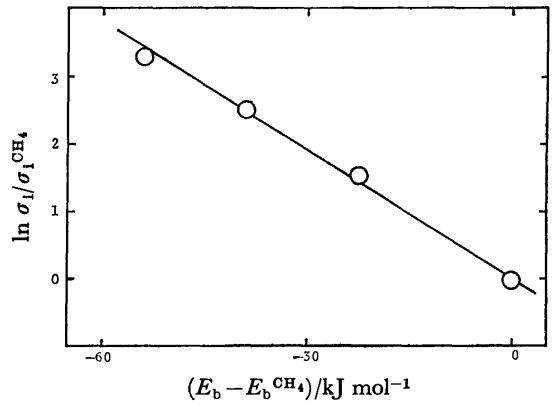

Fig. 6. Relationship between $\ln \sigma_1/\sigma_1^{CH_4}$ and $E_b - E_b^{CH_4}$.

In Fig. 6, $\ln \sigma_1/\sigma_1^{CH_4}$ is plotted as a function of $E_b - E_b^{CH_4}$. From the slope of the straight line in Fig. 6, the value of $(1-n^p)/RT$ can be estimated to be 0.063 mol/kJ. If we used the same p-value as that used for the alkane–Hg($^3P_1$) system, a bond order, n, of about 0.7 is obtained. This value is almost the same as that obtained for the alkane–Hg($^3P_1$) system and so may be thought to be valid.

By the BEBO method, the relative values of the cross-section of the Zn(^3P_J) quenching by alkanes can be explained. As was mentioned above, however, it is difficult to explain the difference in the variations with the C–H bond strength in quenching cross-sections between those obtained for Zn(^3P_J) and for Hg($^3P_1$) by means of the BEBO method.

Strausz *et al.* calculated the potential energy of activation for the Hg($^3P_1$)-photosensitized decomposition of alkanes and described the BEBO calculation predicts the observed trends. By using the values of the potential energy of activation obtained by them, and by assuming that the relative quenching cross-sections of the various types of C–H bonds are governed only by the difference in the activation energy, the relative quenching cross-sections for primary, secondary, and tertiary C–H bonds can be calculated. These calculated values of 1:8:43 are considerably smaller than the observed values. The temperature at which the Hg($^3P_1$)-photosensitized reaction was carried out was lower than that for the Zn(^3P_J)-photosensitized reaction; therefore, the selectivity appears to be somewhat emphasized for the former. However, it seems to be impossible to explain the large variation with the C–H bond strength in the quenching cross-section for higher-energy Hg($^3P_1$) in terms of the same mechanism as that used for Zn(^3P_J).

In the case of Hg($^3P_1$), the quenching by alkanes appears to result in a direct cleavage of the C–H bonds without the intermediate formation of HgH, as was pointed out by Breckenridge and Renlund.[1] The cleavage with the formation of hydride, as in the Zn(^3P_J)-photosensitized decomposition, involves a transition state in which the Zn–H bond is partly formed. The formation of the Zn–H bond somewhat lowers the potential energy and seems to make the Zn(^3P_J) quenching less sensitive to the C–H bond strength.

Effect of Polar Group on the Polypeptide–Lipid Interaction at the Air-Water Interface

Akira SHIBATA,* Shinsuke YAMASHITA, and Takuya YAMASHITA
Faculty of Pharmaceutical Sciences, Tokushima University, Shomachi, Tokushima 770
(Received October 19, 1981)

The effect of polar group on the interaction of synthetic polypeptides with lipids at the air-water interface was investigated. Methyl stearate interacts with benzyloxycarbonyl derivative of basic poly(α-amino acid) or benzyl ester of acidic poly(α-amino acid) on distilled water and KF, KSCN, and urea subsolutions. No interaction between polypeptide and stearamide on various subsolutions was observed except for the mixed system of stearamide with benzyl ester of acidic poly(α-amino acid) in α-helical conformation. The components in mixed monolayers exhibit characteristic miscibilities depending upon the flexibility of polymer side chain, the conformation of polymer and the steric factor of head group in lipid molecules. All of the mixed polypeptide–lipid monolayers spread on the subsolution containing SCN^- as a breaker of water structure become miscible. The dipole-dipole interaction between stearamide and benzyl ester of acidic poly(α-amino acid) in α-helical conformation is weakened by the action of urea.

The hydrophobic bonding is important in stabilizing macromolecular structures such as proteins and biological membranes.[1] Water is considered to affect the stability of macromolecular structure and the interaction of macromolecule with lipid at the interface.[2] In relation to the structure of water at the interfacial region, we have reported the effects of salts and urea on the interaction of polypeptide with fatty acid in monolayers.[3,4] The effects of anions on increasing the surface pressure were in the order $SCN^->Br^->Cl^->F^-$ in line with that of these anions as breakers of water structure.[5] KSCN, urea, and KF are known as breakers and a maker of water structure, respectively.

We have found that the interaction of polypeptide-(benzyloxycarbonyl derivatives of basic poly(α-amino acid), benzyl esters of acidic poly(α-amino acid), and poly(L-leucine)) and lipid(fatty acid, fatty alcohol and cholesterol) at the air-water interface is mainly of hydrophobic nature.[6] The interaction was found to take place between side chain of polypeptide and lipid. The interaction of polypeptide with myristic acid was stronger than that between polypeptide and myristyl alcohol. This suggests that weak interactions may exist between the polar group of lipid and polypeptide side chain. These polymer side chains consist of polar group and methylene groups. The polar groups in polymer side chain, as well as polar group in stearamide and methyl stearate, are ROCONHR′ for benzyloxycarbonyl derivative of basic poly(α-amino acid) and RCOOR′ for benzyl ester of acidic poly(α-amino acid).

In this study, by the use of methyl stearate and stearamide, the effect of the polar groups on the interaction of polypeptide with lipid was investigated in relation to the structure of water at the interfacial region.

Experimental

Poly(N^ε-benzyloxycarbonyl-L-lysine)(PLL(Z)), poly(γ-benzyl L-glutamate) (PBLG), and poly(γ-benzyl DL-glutamate) (PBDLG) were prepared by the polymerization of the *N*-carboxy anhydrides of respective amino acids. The molecular weights determined from the viscometry at 25 °C were 3.8×10^5, 3.0×10^5, and 6.4×10^4, respectively. Infrared spectra indicate that PLL(Z) and PBLG are in the α-helical conformation in the solid state. The helical content of PBDLG was 13% regular α-helix and 60% perturbed α-helix. No β-conformation was found for PBDLG. The regular α-helix and perturbed α-helix have been designated by Tsuboi *et al.*[7] The perturbed α-helix portion in a polypeptide molecule contains an antipode residue, the sequence length being relatively short. Lipids used were methyl stearate and stearamide. These materials were chromatographically pure.

The spreading solvents (*N*,*N*-dimethylformamide (DMF), dichloromethane (DCM)) were distilled under nitrogen atmosphere. The spreading solvents were DCM for mixed PBLG– and PBDLG–lipid systems, a 9:1(v/v) mixture of DCM and DMF for mixed PLL(Z)–lipid systems. The solutions of polypeptide and lipid were prepared separately, and mixed in the desired ratio immediately before spreading.

Salt and urea solutions were treated with activated charcoal in order to remove surface active contaminants. A 10 to 1 compression of the surface of the salt or urea subsolutions, after standing 10 min, produced less than 0.1 dyn/cm film pressure.

The initial spreading-area was 50 Å²/residue or molecule. The trough (65 cm × 15 cm × 1 cm) and compressing barriers were made of Teflon. The surface pressure was measured by Whilhelmy method at 20 °C. The film was compressed at a rate of 0.5 mm/min (1 Å²/residue or molecule).

Results

Figure 1 shows the surface pressure-area(π-A) curves for PLL(Z), PBLG, and PBDLG. Plateau which is characteristic of a number of synthetic polypeptide in α-helical conformation in the monolayer state are seen in the curves. The plateau is associated with the collapse or the transition of monolayer from a two-dimensional oriented state to a three-dimensional disoriented state.[6,8,9]

Figures 2 and 3 show the π-A curves of mixed PLL-(Z)–methyl stearate and mixed PLL(Z)–stearamide monolayers. The π-A curves of methyl stearate and stearamide are also shown in Figs. 2 and 3. These lipids form condensed films with the cross sectional area of about 20 Å² on distilled water. The areas are in agreement with those reported by other workers.[10,11] The transition pressure for mixed PLL(Z)–methyl stearate monolayer increases with methyl stea-

rate mole fraction, while for mixed PLL(Z)–stearamide monolayer is independent of stearamide mol fraction.

Figure 4 shows the relationship between the transition pressure and the composition of lipid in mixed monolayers for PLL(Z)–lipid, PBLG–lipid, and PBDLG–lipid systems on distilled water. For mixed polypeptide–methyl stearate systems, up to methyl stearate mol fraction of about 0.2, the transition pressures caused by the polymer components increase steeply, the increase becoming gradual beyond this mole fraction. On the other hand, no significant change in transition pressure is observed for mixed monolayer of stearamide and either PLL(Z) or PBDLG. The transition pressures for mixed PBLG–stearamide system increase with stearamide mol fraction different from those for mixed systems of stearamide and either PLL(Z) or PBDLG.

As a example of mixed monolayers on salt subsolutions, Fig. 5 shows the π-A curves for mixed PLL(Z)–methyl stearate (1:1 residue mol: mol) spread on distilled water, 6 M urea, 3 M KSCN and 3 M KF subsolutions (1 M=1 mol dm^{-3}). The transition pressures caused by PLL(Z) are much higher on the subsolution containing KSCN or urea than on distilled water. In the presence of KF, on the other hand,

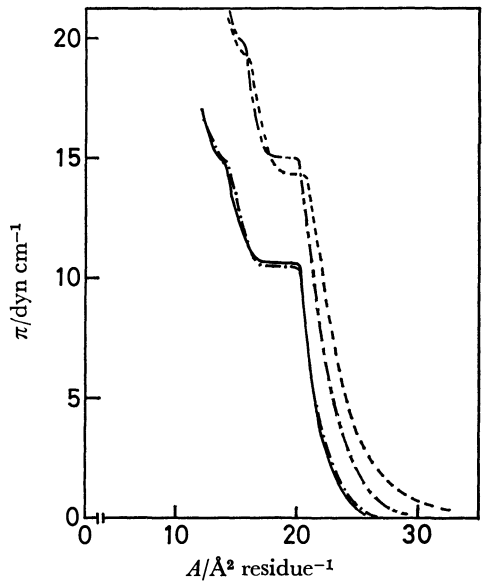

Fig. 5. Surface pressure-area curves of mixed PLL(Z)–methyl stearate (1:1(residue mol : mol)) monolayers on different subsolutions.
——: Distilled water, ——— 3 M KSCN, —·—: 3 M KF, ----: 6 M urea.

the film transition pressure becomes slightly lower. The film expansion is observed in the presence of KSCN or urea. The effect of KF on expansion is quite small. Similar tendencies were observed for the other mixed monolayers on salt and urea subsolutions.

Discussion

Interaction on Distilled Water. The application of the two-dimensional phase rule provides an important tool for detecting miscibility in two-component monolayers.[12] If a polypeptide and a lipid are miscible in the monolayer and the new three-dimensional phase begins to appear at the transition point, the transition pressure should vary with composition. If, on the other hand, the monolayer components are immiscible, the transition pressure is independent of composition. As can be seen in Fig. 4, the mixed systems of methyl stearate with PLL(Z), PBLG, or PBDLG are miscible. Stearamide is immiscible with PLL(Z) or PBDLG except PBLG. Both monolayers of methyl stearate and stearamide are the condensed type. Because of the similarity of cross sectional area between polypeptide and lipid monolayers, the deviation from the additivity rule was difficult to detect.

To obtain a further information concerning polypeptide–lipid interaction, the work of collapse of mixed monolayers was estimated. The work of collapse, W, is given by[6]

$$W = \pi_{tr} \cdot \Delta A,$$

where π_{tr} is the transition pressure, and ΔA is the difference between initial and final areas of collapse. Figure 6 shows the work of collapse as a function of lipid mole fraction. It can be seen that with the exception of mixed PLL(Z)–stearamide and PBDLG–stearamide systems, the maximum work of collapse

Table 1. Miscibility between polypeptide and lipid

Mixed System	Miscibility			
	Water	KF	KSCN	Urea
Methyl stearate-PLL(Z)	+	+	+	+
Methyl stearate-PBLG	+	+	+	+
Methyl stearate-PBDLG	+	+	+	+
Stearamide-PLL(Z)	−	−	+	−
Stearamide-PBLG	+	+	+	−
Stearamide-PBDLG	−	−	+	−

+: Miscible, −: immiscible.

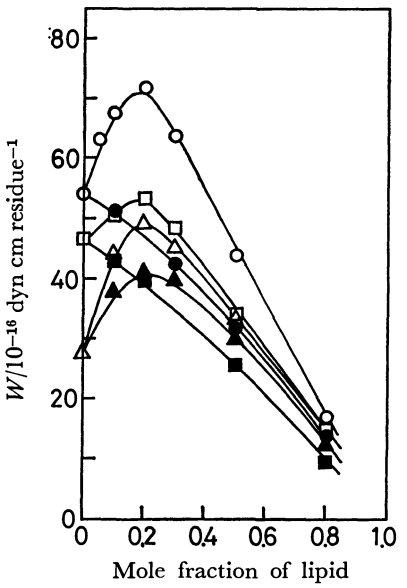

Fig. 6. Work of collapse for mixed monolayers as a function of lipid mole fraction.

is found at about 0.2 lipid mol fraction. At this fraction, the surface adhesive forces might be reinforced as a result of the formation of the 4:1 complex (residue:molecule) of polypeptide and lipid as reported previously for mixed polypeptide–fatty acid and polypeptide–fatty alcohol systems.[6] In the lipid rich region, the adhesive force of polypeptide decrease steeply, the film collapsing more easily in the case of polypeptide alone. There is a remarkable difference in W values between mixed PLL(Z)–stearamide and mixed PBLG–stearamide systems (Fig. 6). This would be due to the difference between the polar groups, RCOOR', in PBLG side chain and ROCONHR' in PLL(Z) side chain.

Effect of Salts. The effect of polar group on interaction could be discussed in more detail by the use of subsolutions containing either KSCN or urea as a breaker and KF as a maker of water structure.

The polypeptide and mixed monolayers of polypeptide with methyl stearate or stearamide on salt subsolutions expand with salt concentration. The order of film expansion is KSCN>KF>distilled water, and independent of the difference in miscibility between polypeptide and either methyl stearate or ste-

aramide. This order was essentially the same as obtained for mixed polypeptide–fatty acid systems.[6] Salts may be transferred into the interface relative to the monolayer free surface. Ralston and Healy[13] reported that salts are transferred into fatty alcohol monolayer in terms of interfacial water structure and this process continued until the surface and bulk concentration become equal.

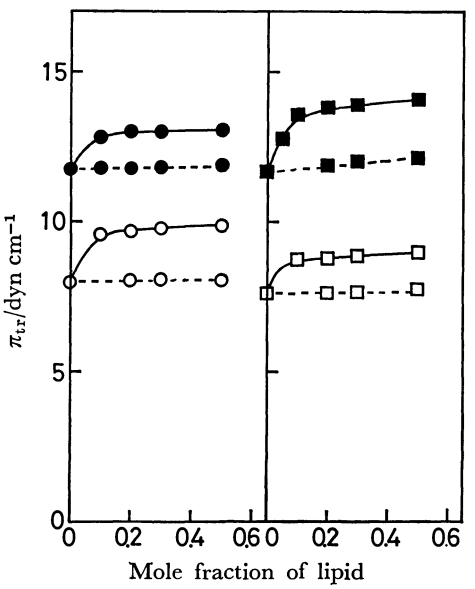

Fig. 9. Transition pressures of single and mixed monolayers as a function of lipid mole fraction on different subsolutions.

The general tendencies relating to the miscibility of polypeptide with lipid on various subsolutions was summarized in Table 1. The miscibilities between polypeptide and stearamide are extremely poor compared with polypeptide–methyl stearate systems.

Figures 7, 8, and 9 show the relationship between the transition pressure and the composition of lipid in mixed PLL(Z)–lipid, PBLG–lipid, and PBDLG–lipid monolayers spread on distilled water, 6 M urea, 3 M KSCN and 3 M KF subsolutions, respectively. The transition pressures for single and mixed monolayers spread on KSCN subsolution are higher than those on distilled water, and is independent of miscibility between polypeptide and lipid. For mixed polypeptide–methyl stearate monolayers on KSCN or urea subsolution, up to 0.2 methyl stearate mole fraction, the transition pressure caused by the polymer component increases steeply, the increase becoming almost constant beyond this mol fraction. The hydrated structure around the hydrocarbon moieties of the side chains of polypeptide is disrupted by SCN^- ion preferentially accumulated on the surface. As a result of the disruption, the affinity of the hydrocarbon moieties to water may increase.

The transition pressures for both miscible and immiscible mixed systems on KF subsolution becomes slightly low compared with that on distilled water (Figs. 7, 8, and 9). In the presence of F^- ion as a maker of water structure, the adhesive force of polypeptide to water become weak with the formation of hydrated structure around the mixed films.

The molecular structure of urea is similar to the polar group in stearamide molecule and PLL(Z) side chain, and urea acts as a breaker of water structure.[14] The expansion of single and mixed films may be ascribed to the penetration of polypeptide monolayer

by urea in the subsolution (Fig. 5).[15] As shown in Figs. 7 and 8, the transition pressures of mixed PLL-(Z)-lipid and PBLG–lipid monolayers on urea subsolution are higher than those on distilled water. The hydrated structure around hydrophobic moieties of polypeptide side chain would be disrupted by the action of urea.

It is noteworthy that stearamide becomes practically immiscible with PBLG on urea subsolution (Table 1 and Fig. 8). In the presence of urea, the dipole-dipole interaction between $RCONH_2$ in stearamide molecule and RCOOR′ in PBLG side chain may be weakened by urea because of the similarity of polar group in stearamide and urea molecule.

Effect of Polypeptide Conformation. The perturbed helix portion of PBDLG is unfolded at the interface owing to relatively weak stability of the helix.[6,7] As shown in Fig. 1, the difference in shape of the π-A curves between PBLG and PBDLG is accounted for as arising essentially from the conformation of these polymer at the interface.[6,16] The change in transition pressure for mixed PBLG–lipid monolayer is larger than that of mixed PBDLG–lipid monolayer (Fig. 4). The PBLG monolayer is more compressible than the PBDLG monolayer.[4] The flexible side chains of PBLG might undergo a rearrangement more easily into position favorable to the interaction with alkyl chain of methyl stearate or stearamide The strength of van der Waals forces of lipid molecules in condensed monolayers and the flexibility of polypeptide side chain seem to affect the degree of interaction as in the case of mixed systems of polypeptide and either fatty acid or fatty alcohol.[4]

The effect of stearamide on interaction in mixed monolayers is much more pronounced than that of methyl stearate. PBLG interacts characteristically with stearamide. However, PBDLG interacts with considerable difficulty (Fig. 4). The conformation of a polymer may also be important for the interaction at the interface.

The transition pressures of mixed PBDLG–methyl stearate monolayer spread on KF subsolution are smaller than those on distilled water. For mixed PBLG–methyl stearate system, on the other hand, there is little difference between KF and KF free subsolutions. The formation of hydrated structure around PBDLG molecule unfolded considerably at the interface may be caused by F^- ion as a maker of water structure.

The transition pressures of mixed monolayers of lipid and either PBLG or PBDLG spread on KSCN subsolution become higher than those on distilled water (Figs. 8 and 9). In the presence of KSCN, the increment of transition pressure for mixed PBLG–lipid systems is larger than that of mixed PBDLG–lipid systems. The geometry of the α-helix in the monolayer state is such that the side chains of adjacent helices can interpenetrate to form good hydrophobic contacts.[16] PBLG might become more hydrophobic than PBDLG unfolded considerably at the interface since the polypeptide main chain is appreciably shielded from the interaction with water molecules. Therefore, the interaction of the amide group in the main chain with SCN^- ion would accompany the difficulty. SCN^- ion is considered to act primarily as a breaker of water structure around the hydrophobic moieties in mixed PBLG–lipid film.

Irrespective of the composition of subsolution, methyl stearate is miscible with PBLG or PBDLG. On the other hand, mixed PBLG–stearamide and PBDLG–stearamide monolayers are miscible and immiscible on distilled water, respectively (Table 1 and Figs. 8 and 9). As such the case of mixed PBLG–cholesterol system,[6] PBLG interacts characteristically with stearamide on distilled water. In the presence of urea, however, both mixed monolayers become immiscible through the interaction between the polar group, $RCONH_2$, in stearamide and urea molecule.

PBDLG is miscible for methyl stearate though immiscible for stearamide on distilled water and urea subsolution. The head group, $RCOOCH_3$, of methyl stearate in monolayer state exists under the surface. The methyl group under the surface shields the ester group from attack by polar group of polypeptide side chains,[17] and in addition, is able to interact with hydrophobic moieties of polypeptide side chains. On the other hand, stearamide monolayer on distilled water or urea subsolution may be stabilized by the intermolecular hydrogen bonding between C=O and NH_2 groups in stearamide molecules or by the interaction with urea. Therefore, it seems that the miscibility between PBDLG and stearamide becomes less.

The Existence of an Unstable Limit Cycle in the Oregonator Model for the Belousov-Zhabotinskii Reaction

Shinji SAKANOUE* and Mitsuo ENDO

Department of Chemistry, Faculty of General Education, The Tokyo University of Agriculture and Technology, Saiwai-cho, Fuchu, Tokyo 183

(Received October 20, 1981)

With an Oregonator model for the mechanism of the Belousov-Zhabotinskii reaction (an oscillatory chemical system), the coexistence of a stable and an unstable limit cycle was confirmed from the results of computer simulations and the real unstable limit cycle was shown. The relation of the amplitude of the unstable limit cycles to the parameters f and p in Tyson's equation[4] was found.

The Belousov-Zhabotinskii reaction (B-Z reaction) is a well known example of an oscillatory chemical reaction. Field, Körös, and Noyes[1] presented the mechanism for this reaction in the homogeneous system and proposed a simple reaction model for sustained oscillation, which is called an Oregonator. Subsequently, Noyes *et al.*[2] Murray *et al.*[3] and Tyson[4] examined precisely the oscillation conditions based on the model. Tyson predicted the existence of a pair of stable and unstable limit cycles for a parameter p close to a critical one, p_c, in his analysis. However, he did not show any real unstable limit cycles. In this study the conditions for an unstable steady state are given over a wide range of the parameters f, p, and q in Tyson's equation; the coexistence of stable and unstable limit cycles, which is called "hard self-excitation", is confirmed for a parameter p not only close to p_c, but also far from it. The relation of the amplitudes of the unstable limit cycles to the parameters f and p is also clarified from the results of computer simulations.

The mechanism of the B-Z reaction to be expressed with the Oregonator is as follows:[2]

$$\mathrm{A} + \mathrm{Y} \xrightarrow{k_1} \mathrm{X} + \mathrm{P}, \tag{1-1}$$

$$\mathrm{X} + \mathrm{Y} \xrightarrow{k_2} 2\mathrm{P}, \tag{1-2}$$

$$\mathrm{B} + \mathrm{X} \xrightarrow{k_3} 2\mathrm{X} + \mathrm{Z}, \tag{1-3}$$

$$2\mathrm{X} \xrightarrow{k_4} \mathrm{B} + \mathrm{P}, \tag{1-4}$$

$$\mathrm{Z} \xrightarrow{k_5} f\mathrm{Y}. \tag{1-5}$$

The symbols correspond to the chemical species in the B-Z reaction system as follows;

$\mathrm{X} = \mathrm{HBrO_2}$, $\mathrm{Y} = \mathrm{Br^-}$, $\mathrm{Z} = 2\mathrm{Ce^{4+}}$, $\mathrm{A} = \mathrm{B} = \mathrm{BrO_3^-}$, $\mathrm{P} = \mathrm{HOBr}$.

The parameter f is a stoichiometric factor and is twice the number of $\mathrm{Br^-}$ ions generated per $\mathrm{Ce^{4+}}$ to be reduced. During the following calculations, it is assumed that the concentrations of A and B remain constant, effectively treating the system as open.

The kinetic behavior of the reaction (1) was represented by Tyson[4] with the following dimensionless equations:

$$\varepsilon\frac{dx}{d\tau} = x + y - qx^2 - xy, \tag{2-1}$$

$$\frac{dy}{d\tau} = -y + fz - xy, \tag{2-2}$$

$$p\frac{dz}{d\tau} = x - z, \tag{2-3}$$

Here x, y, and z *etc.* are the variables including X, Y, Z, A, B, and k_i, *etc.* which represent the concentrations of species and the rate constants, *etc.* as follows:

$$\begin{aligned} x &= k_2(k_1A)^{-1}X, \\ y &= k_2(k_3B)^{-1}Y, \\ z &= k_2k_5(k_1k_3AB)^{-1}Z, \\ p &= k_1k_5^{-1}A, \\ q &= 2k_1k_4(k_2k_3B)^{-1}A, \\ \varepsilon &= k_1A(k_3B)^{-1}, \\ \tau &= k_1At. \end{aligned}$$

The constant solution ("steady state") of Eq. 2 without the origin ($x=y=z=0$) is

$$\left.\begin{aligned} x_0 = z_0 &= \{1-f-q+\sqrt{(1-f-q)^2+4q(f+1)}\}(2q)^{-1} \\ y_0 &= fx_0(1+x_0)^{-1} \end{aligned}\right\}. \tag{3}$$

In order to examine the trajectory in the neighborhood of the steady state, Eq. 2 is expressed in terms of deviations from the steady state, which are $\bar{x}=x-x_0$, $\bar{y}=y-y_0$, $\bar{z}=z-z_0$, as follows:

$$\varepsilon\frac{d\bar{x}}{d\tau} = -\alpha\bar{x} - \beta\bar{y} - q\bar{x}^2 - \bar{x}\bar{y}, \tag{4-1}$$

$$\frac{d\bar{y}}{d\tau} = -\gamma\bar{x} - \delta\bar{y} + f\bar{z} - \bar{x}\bar{y}, \tag{4-2}$$

$$p\frac{d\bar{z}}{d\tau} = \bar{x} - \bar{z}, \tag{4-3}$$

where

$$\left.\begin{aligned} \alpha &= -1 + y_0 + 2qx_0 = qx_0 + y_0x_0^{-1} > 0 \\ \beta &= x_0 - 1 > 0, \qquad \text{for } q<1 \\ \gamma &= y_0 > 0 \\ \delta &= x_0 + 1 > 0. \end{aligned}\right\}. \tag{4-4}$$

When $\varepsilon\to 0$ as in the real B-Z reaction,[1] the following condition is maintained, from Eq. 4-1:

$$q\bar{x}^2 + (\alpha+\bar{y})\bar{x} + \beta\bar{y} = 0.$$

Thus

$$X(\bar{y}) = \bar{x} = \{-(\alpha+\bar{y}) \pm \sqrt{(\alpha+\bar{y})^2 - 4q\beta\bar{y}}\}(2q)^{-1}. \tag{5}$$

Here, only the positive sign of $\pm$ in Eq. 5 is taken, because, if the negative sign is taken, $x<0$, this would a negative concentration, which is physically unacceptable.

From Eqs. 5, 4-2, and 4-3, the following two

ordinary differential equations can be obtained:

$$\left.\begin{aligned}\frac{d\bar{y}}{d\tau} &= -\delta\bar{y} + f\bar{z} - (\gamma+\bar{y})X(\bar{y}) = Y(\bar{y},\bar{z}) \\ \frac{d\bar{z}}{d\tau} &= \frac{1}{p}X(\bar{y}) - \frac{1}{p}\bar{z} = Z(\bar{y},\bar{z})\end{aligned}\right\}. \quad (6)$$

Since $\bar{y} \ll y_0$, $\bar{z} \ll z_0$, Eq. 6 can be linearized as follows:

$$\left.\begin{aligned}\frac{d\bar{y}}{d\tau} &= Y_{\bar{y}}\bar{y} + Y_{\bar{z}}\bar{z} \\ \frac{d\bar{z}}{d\tau} &= Z_{\bar{y}}\bar{y} + Z_{\bar{z}}\bar{z},\end{aligned}\right\}, \quad (7)$$

where

$$Y_{\bar{y}} = \left(\frac{\partial Y(\bar{y},\bar{z})}{\partial\bar{y}}\right)_{\substack{\bar{y}=0\\ \bar{z}=0}} = \frac{\beta\gamma-\alpha\delta}{\alpha}, \quad (8\text{-}1)$$

$$Y_{\bar{z}} = \left(\frac{\partial Y(\bar{y},\bar{z})}{\partial\bar{z}}\right)_{\substack{\bar{y}=0\\ \bar{z}=0}} = f, \quad (8\text{-}2)$$

$$Z_{\bar{y}} = \left(\frac{\partial Z(\bar{y},\bar{z})}{\partial\bar{y}}\right)_{\substack{\bar{y}=0\\ \bar{z}=0}} = -\frac{\beta}{p\alpha}, \quad (8\text{-}3)$$

$$Z_{\bar{z}} = \left(\frac{\partial Z(\bar{y},\bar{z})}{\partial\bar{z}}\right)_{\substack{\bar{y}=0\\ \bar{z}=0}} = -\frac{1}{p}. \quad (8\text{-}4)$$

The behaviors of $\bar{y}$ and $\bar{z}$ in the neighborhood of the steady state are determined by the eigenvalues, λ, of the matrix

$$A = \begin{pmatrix} Y_{\bar{y}} & Y_{\bar{z}} \\ Z_{\bar{y}} & Z_{\bar{z}} \end{pmatrix}$$

which satisfies the following secular equation

$$\lambda^2 - Tr\lambda + \mathrm{Det} = 0,$$

where

$$Tr = Y_{\bar{y}} + Z_{\bar{z}} = \frac{\beta\gamma-\alpha\delta}{\alpha} - \frac{1}{p},$$

$$\mathrm{Det} = Y_{\bar{y}}Z_{\bar{z}} - Y_{\bar{z}}Z_{\bar{y}} = \frac{\alpha\delta-\beta\gamma+f\beta}{p\alpha}.$$

Stability of Steady State

The boundary condition that determines the stability of a steady state for the periodic solutions is given by $Tr=0$, that is

$$Tr = \frac{\beta\gamma-\alpha\delta}{\alpha} - \frac{1}{p} = 0. \quad (9\text{-}1)$$

As is obvious from Eqs. 3 and 4-4, each of α, β, γ, and δ can be a function of q and f. Equation 9-1, then, can be generally represented as follows:

$$F(f,p,q) = 0. \quad (9\text{-}2)$$

Here, $F(f,p,q)=(\beta\gamma-\alpha\delta)/\alpha-1/p$. Thus, for a certain fixed set of two values from three parameters the remaining parameter which satisfies Eq. 9-2 gives a critical value. For p fixed, Eq. 9 gives a critical value of f as a function of q, which is shown in Fig. 1. For a value of q less than 0.0809, the critical f takes two values, f_{c_1} and f_{c_2}, where $f_{c_1}<f_{c_2}$. If $f_{c_1}<f<f_{c_2}$, $Tr>0$ and the steady state is unstable. On the other hand, if $f<f_{c_1}$ or $f>f_{c_2}$, $Tr<0$ and the steady state is stable. For example, when $p=\infty$ and $q=0$, $f_{c_1}=0.5$, and $f_{c_2}=1+\sqrt{2}=2.414$. The region of f in which a steady state is unstable becomes narrower with increasing values of q, as shown in Fig. 1.

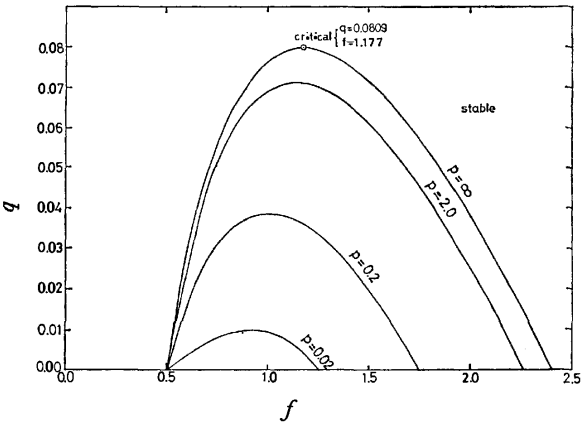

Fig. 1. Stability of the steady state as a function of parameters q and f for the various values of p. The steady state is unstable for the values of f and q inside a curve for p fixed.

For q fixed, a critical p, p_c, is given as a function of f by Eq. 9 as follows:

$$p_c = \frac{\alpha}{\beta\gamma-\alpha\delta} \quad (10)$$

If $p<p_c$, $Tr<0$ and then the steady state is stable; if $p>p_c$, $Tr>0$ and then the steady state is unstable.

The boundary condition for whether a trajectory around a steady state is a periodic spiral or not, that is, whether a steady state is a focus or node, is given by $Tr^2=4\mathrm{Det}$. The critical parameter p, $p_\pm$, is represented by

$$p_\pm = \{(p_c^{-1}+2\xi) \pm 2\sqrt{\xi p_c^{-1}+\xi^2}\}p_c^2, \quad (11)$$

where

$$\xi = \mathrm{Det}\cdot p = \frac{\alpha\delta-\beta\gamma+f\beta}{\alpha}.$$

Since $p_\pm$ is a function of q and f only, its value can be determined for a certain set of q and f values. If $p_-<p<p_+$, $Tr^2<4\mathrm{Det}$ and a steady state is a focus; on the other hand, if $p<p_-$ or $p>p_+$, $Tr^2>4\mathrm{Det}$ and it is a node.

Tyson[4] calculated p_c and $p_\pm$ by using an approximation which is calculated for a very low value of q. Here, without the approximation, p_c and $p_\pm$ were calculated directly from Eqs. 3, 4-4, 10, and 11 for q fixed. A result for $q=0.006$ is shown in Fig. 2, which represents a f-p parameter phase space. It differs from the approximate result obtained by Tyson in the regions near the values of 0.5 and 1.0 of f.

If f and p have the values in the unstable focus region (uf) in Fig. 2, a steady state is unstable, the behavior of the trajectory surrounding it is periodic, and the existence of a stable limit cycle can be predicted: that is the situation called "soft self-excitation". The real limit cycle was obtained by Tyson[4] with a numerical integration of Eq. 2 for $dx/d\tau=0$ or $\varepsilon=0$.

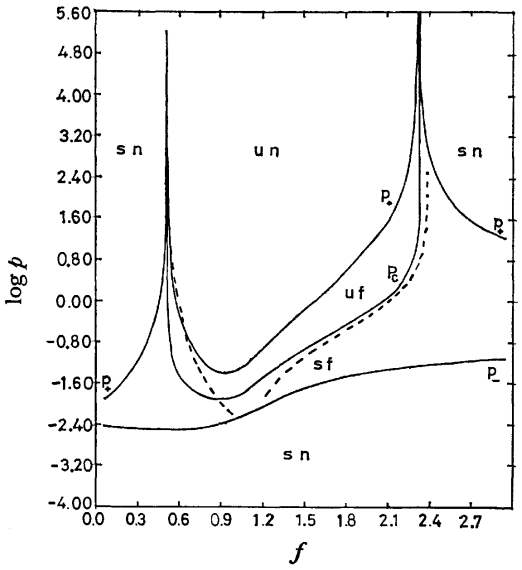

Fig. 2. Stability of the steady state and periodicity of the trajectory as a function of the parameter p and f for $q=0.006$.
------: Tyson's approximate expression of p_c for $q=0.006$, sn: stable node, sf: stable focus, un: unstable node, uf: unstable focus.

Coexistence of Stable and Unstable Limit Cycles[5)]

There should be no stable limit cycle in the case where f and p have the values in the stable focus (sf) region in Fig. 2, unless an unstable limit cycle surrounds a stable focus (Poincarè-Bendixon's theorem). In regard to the Oregonator, it was confirmed with computer simulations that a stable limit cycle coexists with an unstable limit cycle which surrounds a stable focus in the case of $p_c>p>p_d$, where p_d is a critical parameter for the existence of an unstable limit cycle. That is, the situation called "hard self-excitation" can appear not only for the condition of $p\simeq p_c$, but also for every p value in the range of $p_c>p>p_d$, even when $p_c\gg p_d$. For an example, in the case of $q=0.006$ and $p=\infty$, $f_{c_1}=0.519$, and $f_{c_2}=2.354$ (Fig. 1), $p_+=1.584\times10^5$, $p_-=5.141\times10^{-2}$, $p_c=90.24$ (Fig. 2), and $p_d=0.849$ (Fig. 5). These values come from the results of numerical calculated solutions of Eq. 2 under $\varepsilon\to0$ for various values of p. The hard self-excitation under this condition is shown in Fig. 3. In the situation, there could be two kinds of trajectories, A and B in Fig. 3, starting from the two different initial values near to each other, one of which asymptotically reaches a stable steady state, and the other a stable limit cycle. In the former case the oscillation is damped, while in the latter it is sustained. These two kinds of temporal changes on the variable y are shown in Fig. 4. In this case, the bifurcation can occur with a small change of a value of p for a certain initial value. In this situation, a final behavior of a system is decided due to the result of a fluctuation in the initial values of y and z, or in a parameter p. However, the hard self-excitation phenomenaon has not yet been found experimentally in

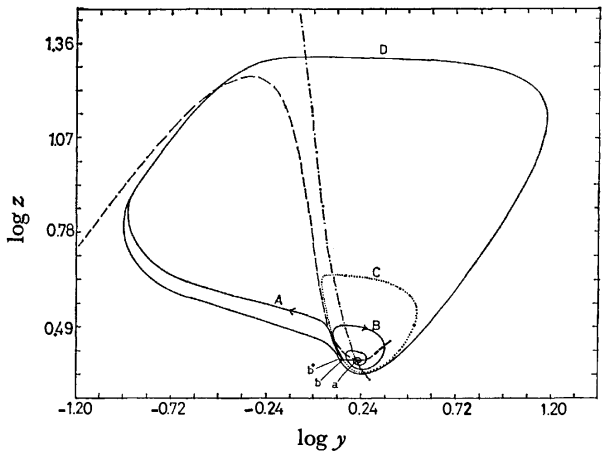

Fig. 3. Phase plane plot of log z *vs.* log y obtained numerical integration of Eq. 2 under $\varepsilon\to0$ for $q=0.006$, $f=2.350$, and $p=2.0$.
A: Trajectory to reach a stable limit cycle (initial values; $y=1.411$, $z=2.444$), B: trajectory to reach a steady state (initial values; $y=1.412$, $z=2.444$), C: unstable limit cycle, D: stable limit cycle, a: steady state, ab: *AMP*, ----: solution of Eq. 2 for $dx/d\tau=0$ and $dy/d\tau=0$, —·—·: solution of Eq. 2 for $dx/d\tau=0$ and $dz/d\tau=0$.

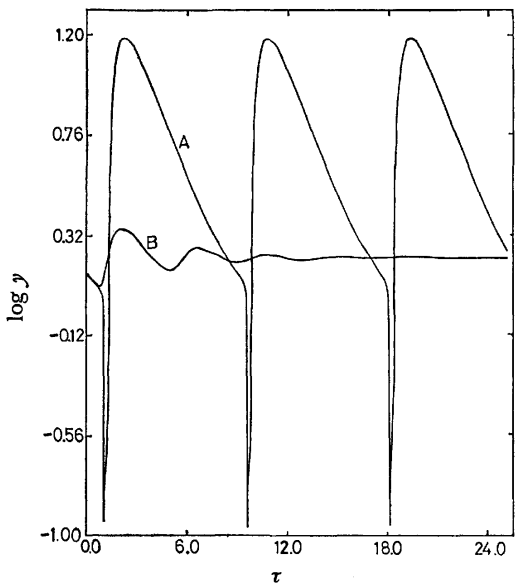

Fig. 4. Temporal behaviors of log y for $q=0.006$, $f=2.350$ and $p=2.0$.
A: Sustained oscillation (initial values; $y=1.411$, $z=2.444$), B: damped oscillation (initial values; $y=1.412$, $z=2.444$).

a real B-Z reaction. The chemical equation, Eq. 1-5 in the Oregonator corresponds to the real reaction:

$$2Ce^{4+} + \frac{1}{2}BrCH(COOH)_2 + H_2O \longrightarrow$$

$$2Ce^{3+} + \frac{1}{2}HCOOH + CO_2 + \frac{1}{2}Br^- + \frac{5}{2}H^+.$$

Therefore, the value of k_5 includes not only the rate constant of this reaction, but also the concentration of $BrCH(COOH)_2$, (BrMA). Since $p=k_1k_5^{-1}A$, an

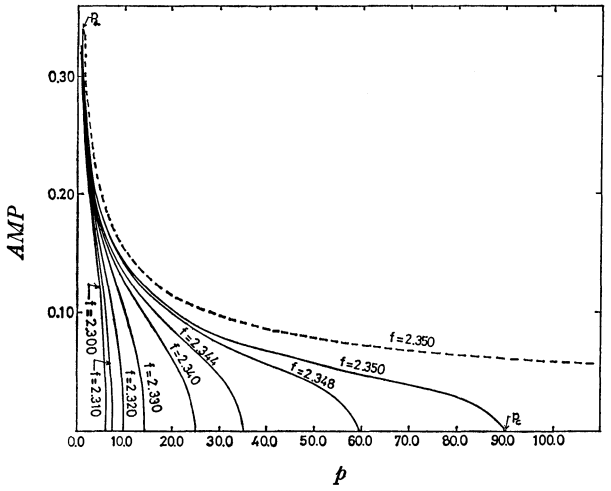

Fig. 5. Plot of *AMP* *vs.* p for $q=0.006$.

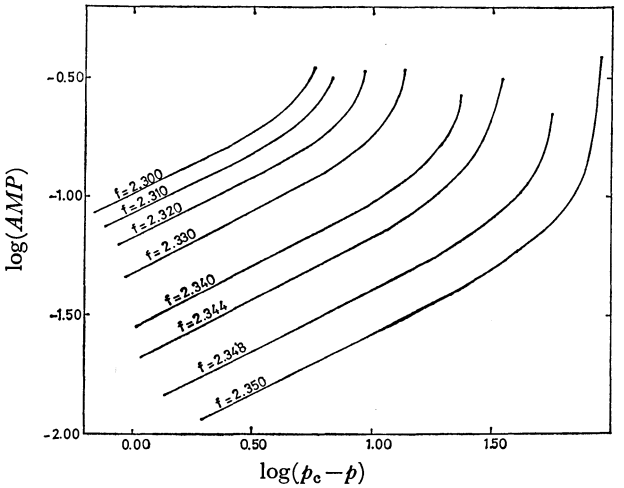

Fig. 6. Plot of $\log(AMP)$ *vs.* $\log(p_c-p)$.

increase of temperature, which increases the value of the rate constant, or of the concentration of BrMA should result in a decrease of p. If p could reach a value in the range of $p_d<p<p_c$ through as adjustment of these conditions, it may be possible to realize a hard self-excitation in the real B-Z reaction.

Relation of Amplitudes of Unstable Limit Cycles with p

In Fig. 3, a steady state ($y=y_0$, $z=z_0$) is represented by the symbol "a", and the point which a line $z=z_0$ intersects an unstable limit cycle is denoted by the symbol "b"; then it is convenient to define the distance, $\overline{ab}$, between the points "a" and "b" as the amplitude of an unstable limit cycle, *AMP*. These amplitudes for various values of f and p were obtained from computer simulations. Figure 5 shows the plots of *AMP* against p for various f values and Fig. 6 shows the plots of $\log(AMP)$ against $\log(p_c-p)$. These are linear with a slope of 1/2 in the range of low values of (p_c-p), but $\log(AMP)$ increases rapidly with $\log(p_c-p)$ in its high value range. This relation and the behavior of periodic trajectories in the hard self-excitation can be treated quantitatively with Landau's theory, in which a transition from a steady flow to a turbulent one in a stream could be elucidated. The quantitative treatment of this problem will be dealt with later.

The authors should like to thank Dr. Chiaki Murase for his suggestion that Landau's theory could be applied to this problem.

Identification and Quantification of Poly(oxyethylene) Alkyl Ether Nonionic Surfactants in River Water at Trace Levels by Field Desorption Mass Spectrometry

Hiroaki SHIRAISHI,* Akira OTSUKI, and Keiichiro FUWA

Department of Chemistry and Physics, National Institute for Environmental Studies, Yatabe, Ibaraki 305

(Received January 8, 1981)

Field desorption mass spectrometry (FDMS) was applied to the identification and quantification of poly(oxyethylene) alkyl ethers in natural waters at trace levels. The FD mass spectrum of poly(oxyethylene) (POE) derivatives, which produce $(M+H)^+$, $(M+\text{cation})^+$, and cluster ions of the type $(M_1+M_2+H)^+$, was mainly affected by emitter current, amount of sample loading, and the presence of metal salts. POE alkyl ethers were extracted from water by means of XAD-4 resin adsorption or solvent extraction under nitrogen bubbling, and determined by FDMS using tetradeuterioocta(oxyethylene) dodecyl ether as an internal standard. Sample sizes from 10^{-6} to 10^{-8} g are suitable for the quantification of POE alkyl ethers. The mole ratio of POE methyl-substituted undecyl ethers to POE dodecyl ethers was estimated by comparison with the FD mass spectra of the HPLC fractions of the extract.

Although gas chromatograph-mass spectrometry (GCMS) has successfully been applied for identification and quantification of organic pollutants in natural waters, relatively high molecular weight pollutants, which could not be determined by GCMS, remain to be analyzed. Therefore, field desorption mass spectrometry (FDMS), which is one of the most useful tools for identifying and quantifying relatively high molecular weight and thermally labile organic compounds, is being applied to the analysis of environmental samples.[1]

Use of poly(oxyethylene) (POE) derivatives nonionic surfactants in place of anionic surfactants is increasing because of their high biodegradability and low toxity in aquatic environment. Though some colorimetric determinations of POE derivatives were reported,[2,3] they have rarely been applied to the analysis of environmental samples. The reasons may be limitations of the colorimetric methods, such as the lack of selectivity and the dependence of color development upon the degree of polymerization of ethylene oxide (EO). Jones and Nickless reported that the macroreticular resin Amberlite XAD-4 was a useful adsorbent for the separation of POE derivatives from water,[4] but they could not determine individual components in environmental samples by means of UV, IR, and NMR analysis even after a long clean-up procedure.[5]

In the preceding paper, we developed a method for concentration and quantification of poly(oxyethylene) alkylphenyl ethers in water by high pressure liquid chromatograph (HPLC) with UV detector; FDMS was applied to confirm the presence of these compounds in the HPLC fractions.[6] POE alkyl ethers, however, could not be determined by this method, because they have no UV absorption. This paper describes how POE alkyl ethers in water can easily be determined by FDMS using a stable isotope labeled internal standard, and shows that the ratio of POE alkyl ethers having normal alkyl groups to those having branched alkyl groups can be estimated by HPLC-FDMS.

Experimental

Apparatus. Mass spectrometry was performed on a JEOL JMS-O1SG double focusing mass spectrometer with a combined field desorption/field ionization/electron impact ion source, connected to a JMS-2000 mass data analysis system (Japan Electric and Optics Laboratory). The FD emitter used was a 10 μm tungsten wire with carbon needles grown at high temperature.[7] An anode potential of 10 kV and a cathode potential of −3 kV were applied. Emitter current was increased linearly by use of an emitter current programmer.[8] The sample was loaded on the emitter by the microsyringe technique.[9] FD mass spectra were obtained by integration of each individual FD mass spectrum, which was measured by repetitive magnet scanning at an interval of 10 s.

HPLC was performed on a Waters ALC/GPC-204 liquid chromatograph equiped with two 6000 A pumps, a model 660 solvent programmer, a U6K injector, a model 400 UV detector operating at 254 nm, and a model R-400 RI detector.

Materials. Methanol (Mallincklodt) was nanograde and pure water was prepared by passing distilled water through a Milli-Q system(Millipore). POE dodecyl ethers and monodisperse POE dodecyl ethers (degree of polymerization; $m=1$ to 8), supplied by Daiichi Seiyaku Co., Ltd. and Tokyo Kasei Co., Ltd. respectively, were used.

Poly(oxyethylene) hexadecyl ethers were prepared from hexadecyl bromide and sodium salt of polyethylene glycol 400.

Nona- and deca(oxyethylene) dodecyl ether were prepared from dodecyl bromide and sodium salt of nona- and decaethylene glycol,[10] respectively.

Octa(oxyethylene)-$\alpha,\alpha,\beta,\beta$-$d_4$ dodecyl ether was prepared from the sodium salt of ethylene-d_4 glycol (E. Merck, G. F. R.) and 1-chloro-3,6,9,12,15,18,21-heptaoxatritriacontane, which was synthesized from thionyl chloride and hepta(oxyethylene) dodecyl ether.

These POE derivatives were purified by column chromatography (silica gel/ethyl acetate:acetone:water=55:35:10) before use. Other chemicals of the highest grades from Wako Pure Chemical Ind., Ltd. were used without further purification.

HPLC Separation of POE Alkyl Ethers. UV Detection: To the 200 μL solution of POE alkyl ethers (1 mg/mL ethyl acetate), freshly distilled 2 mg 3,5-dinitrobenzoyl chloride and a small piece of magnesium turnings were added, and the mixture was heated at 80 °C for 15 min. After cooling, 1 μL of the reaction mixture was injected. The mobile phase was methanol–water at the flow rate 2 mL/min and stationary phase was Radialpak C_{18} (Waters). The percentage of methanol in water was increased from 50% to

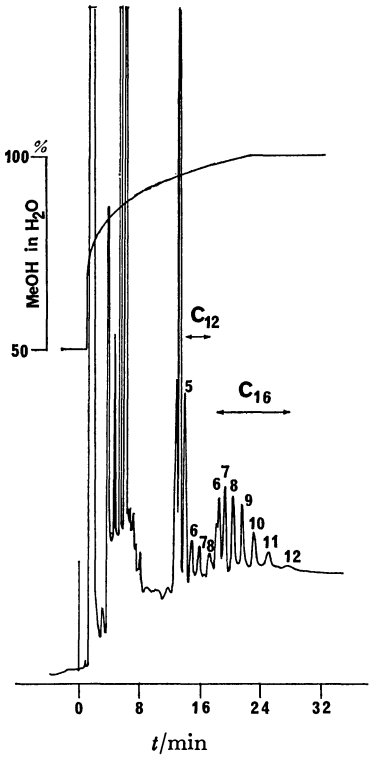

Fig. 1. Typical liquid chromatogram of the separation of POE dodecyl and hexadecyl ethers. Flow rate of 2 mL/min.

100% on the mode 2 in the Waters programmer, as shown in Fig. 1. The programming time was 20 min.

Refractive Index Detection: The Mobile phase was methanol–water (80:20) at the flow rate 1 mL/min and the stationary phase was μ-Bondapak C_{18} (Waters). A sample was dissolved in methanol–water (80:20) and injected. Fractions were collected as needed. All experiments were done at ambient temperature.

Extraction from Water. XAD-4 Adsorption:[5] The resin (5 g) was mixed with acetone and the slurry was packed into the column (55 cm long × 1.1 cm I.D.). A 50 mL volume of acetone–hexane (1:1), 50 mL acetone, 100 mL ethanol, and another 50 mL acetone were passed through the column in order to wash the resin. Before use, the resin was washed with 1 L distilled water and then the water sample was passed through the column at 20 mL/min. POE derivatives were eluted by 70 mL acetone and concentrated by a rotary evaporator.

Solvent Extraction:[11] One hundred grams of sodium chloride were added to a 1 L water sample in a concentration apparatus by gas bubbling. After the sodium chloride was dissolved, 100 mL ethyl acetate was added to the sample and nitrogen saturated with ethyl acetate was bubbled through a glass filter from the bottom of the apparatus for 10 min. The upper layer was separated, and the same extraction procedure was repeated twice. The extracts were combined and concentrated by the rotary evaporator.

Results and Discussion

Concentration from Water and Separation by HPLC. Sensitive determination of POE alkyl ethers by HPLC would be possible, if they can be transformed into derivatives which have UV absorption. Thus, 3,5-dinitrobenzoyl chloride was used as a UV labeling agent. Figure 1 shows a typical liquid chromatogram of the separation of POE dodecyl ethers and POE hexadecyl ethers by gradient elution. Each peak was assigned in comparison with the retention time of standard monodisperse POE dodecyl and hexadecyl ethers. Though separation was performed according to both the carbon atom number in each alkyl group and the number of EO units, POE dodecyl ethers with less than five EO units had the same retention time and those with more than nine EO units were overlapped with POE hexadecyl ethers.

XAD-4 resin adsorption[5] and solvent extraction under nitrogen bubbling,[11] reported as excellent methods for concentration of POE derivatives, were reexamined. It was found that nearly quantitative recovery was achieved at 100 μg/L levels by both methods.

FDMS of POE Derivatives. The FD mass spectrum of POE derivatives was mainly affected by the emitter current, amount of sample on emitter, and the presence of metal salts. Table 1 a) shows characteristics of typical FD mass spectrum of poly(oxyethylene) dodecyl ethers. In contrast to the case of POE alkylphenyl ethers, protonated molecular ions $(M+H)^+$ were found in every 44 mass units corresponding to an EO unit. It was observed that lower molecular weight components of the mixture were desorbed at lower emitter currents. This temperature dependence of the spectrum was identical to that of POE alkylphenyl ethers.[8] Table 1 b) shows the effect of the amount of sample loading. When a large amount (*ca.* 10 μg) was loaded on the emitter, intense cluster ions, corresponding to two molecules plus one proton $(M_1+M_2+H)^+$, were observed. Intensities of these cluster ions were also dependent on the emitter current. At higher emitter currents (*ca.* 15 mA), these cluster ions were not observed. Table 1 c) shows the effect of the presence of metal salts. When an FD mass spectrum of POE alkyl ethers was measured after several measurements of salts of sodium, another series of ions due to attachment of sodium ions to molecules was observed. The same FD mass spectrum was obtained by pretreatment of emitter or sample by salts of sodium. FD mass spectrum of POE dodecyl ethers, which was concentrated from 10% sodium chloride solution by the solvent extraction method, shows sodium-ion-attached molecular ions $(M+Na)^+$, potassium-ion-attached molecular ions $(M+K)^+$ with weaker intensity, and no $(M+H)^+$ ion (Table 1 d).

The fact that ammonium, lithium, potassium rubidium, caesium, and silver could be involved in the ionization by cation attachment (Fig. 2) suggested that ionization of POE alkylphenyl ethers by cation attachment can occur, though they formed molecular ions under usual conditions. This was confirmed by the experiment using these salts. Especially in the case of the sample extracted from natural water by solvent extraction, $(M+Na)^+$ ions were major ion species.[12] Since many kinds of cations can be involved in ionization, special care has to be taken to prevent erroneous identification. For example, $(M+H)^+$ ions of POE hexadecyl ethers and (M+

a) Hm, Nm, Km, and Cm mean types of ions: *i.e.* $(M+H)^+$, $(M+Na)^+$, $(M+K)^+$, and $(M_1+M_2+H)^+$, respectively (m indicates total number of EO units in the ions).

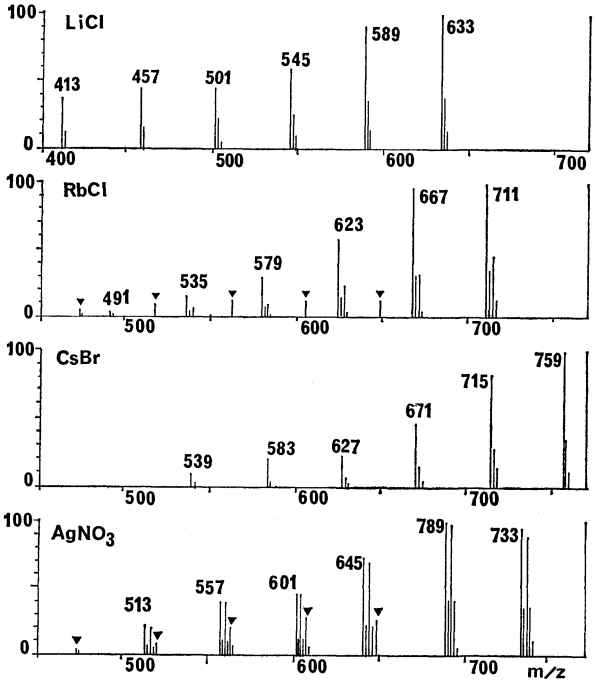

Fig. 2. FD mass spectra of equimolar mixture of monodisperse POE dodecyl ether (degree of polymerization of 5 to 10) which were measured in the presence of LiCl, RbCl, CsBr, and $AgNO_3$. ▼ indicates $(M+Na)^+$ ions of POE dodecyl ether.

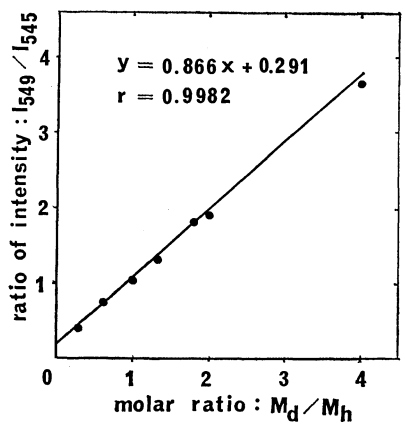

Fig. 3. Calibration curve for determination of octa(oxyethylene) dodecyl ether.

$Na)^+$ ions of POE nonylphenyl ethers gave the same *m/z* values. However, the two spectra could be easily differentiated by the addition of another cation source, *e.g.*, when lithium chloride was added to samples, one can observe $(M+H)^+$ ions and $(M+Na)^+$ ions to shift by 6 *m/z* to higher and 16 *m/z* to lower *m/z* values, respectively.

Use of a stable-isotope-labeled internal standard is essential in quantitative FDMS, because of fluctuations of ion current. In this study, tetradeuterioocta(oxyethylene) dodecyl ether was systhesized and used as

Table 2. Relative intensity of quasi-molecular ions $(M+Li)^+$ in the FD mass spectrum of an equimolar mixture of monodisperse poly-(oxyethylene) dodecyl ether (m=5—10)

m	5	6	7	8	9	10
Rel. int.	59.1	76.9	83.0	100.0	120.6	97.1

CV %	19	11	5.6	—	4.8	10

an internal standard. The calibration curve for octa-(oxyethylene) dodecyl ether was constructed by use of intensities of $(M+Li)^+$ ions (m/z 545 and 549) and a good linear relationship between the amount of sample and added internal standard was obtained (Fig. 3). The reproducibility of the relative intensity of m/z 545 to m/z 549 in each FD mass spectrum was within ±3% at 10^{-7} g levels. Optimum sample size for determination was from $3—5\times10^{-6}$ g to 10^{-8} g.

The integrated FD mass spectrum was used for determination of each component which had a different degree of polymerization of EO. The relative sensitivities of each component to octa(oxyethylene) dodecyl ether were determined by using intensities of $(M+Li)^+$ ions in the integrated FD mass spectrum of an equimolar mixture of monodisperse POE dodecyl ether, which was measured in the presence of lithium nitrate. Table 2 summarizes the realtive intensities of $(M+Li)^+$ ions, its standard deviations (SD), and variation coefficient (CV). m/z 545 (degree of polymerization; m=8) was chosen as a base peak in order to determine the relative sensitivities to this ion. Since the relative sensitivity may reflect the ionization efficiency of each compound by lithium ion attachment, the fact that the sensitivity increases with increase in the number of EO units suggests that the EO unit plays an important role in ionization.

Application. Figure 4 shows FD mass spectrum of mixture extracted from urban stream water by XAD-4 resin adsorption. Since lithium chloride was loaded on the emitter together with the extract, $(M+Li)^+$ ions of POE compounds should be observed. The peak at m/z 549 is due to the added internal standard. Seven series of the ion peaks with differences of 44 mass units were found. The series of the peaks at m/z 1) 415, 459, 503, 547, 591; 2) 443, 487, 531, 575, 619, 663, 707; 3) 413, 457, 501, 545, 589, 633, 677, 721; 4) 427, 471, 515, 559, 603, 647, 691, 735, 779; 5) 441, 485, 529, 573, 617, 661, 705, 749; 6) 469, 513, 557, 601, 645, 689, 733, and 7) 447, 491, 535, 579, 623, 667, 711, 755 may be due to POE 1) nonyl, 2) undecyl, 3) dodecyl, 4) tridecyl, 5) tetradecyl, 6) hexadecyl, and 7) nonylphenyl ethers, respectively. Another series of peaks with difference of 58 mass units at m/z 489, 547, 605, 663, 721, and 779 may be due to $(M+Li)^+$ ions of polypropylene glycol. These identifications were confirmed from the shift of each peak in the FD mass spectrum of the same sample, which was measured in the presence of sodium citrate.

Further confirmation was tried by HPLC fractionation followed by FDMS. Figure 5 shows the liquid

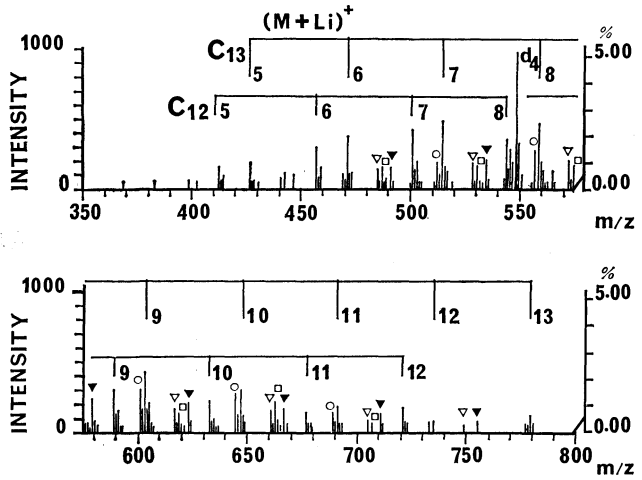

Fig. 4. FD mass spectrum of the extracted organic compounds from 1L polluted stream water. Tetradeuterioocta(oxyethylene) dodecyl ether (16.8 μg) was added as an internal standard. □, ▽, ○, and ▼ indicate $(M+Li)^+$ ions of POE undecyl, tetradecyl, hexadecyl, and nonylphenyl ethers, respectively.

chromatogram of the extract containing tetradeuterioocta(oxyethylene) dodecyl ether as the internal standard. After the large peak of unidentified compounds was eluted, fractions containing POE alkyl ethers were collected. Although POE alkyl ethers could hardly be detected by the RI detector, the presence of POE alkyl ethers was confirmed by FDMS. Figures 6 and 7 show the FD mass spectra of the fraction 1 and 3, respectively. From the analysis of the FD mass spectra, we could determine that fraction 1 contained POE nonylphenyl, dodecyl, and small amount of un-

decyl ethers, and that fractions 2 and 3 contained POE dodecyl, tridecyl ethers, and the spiked internal standard. The result means that POE dodecyl ethers were contained in every fraction. In the reversed phase separation, the compounds having alkyl groups are generally eluted according to the number of carbon atoms in each alkyl group, that is, retention time increases with increase in the number of carbon atoms in each alkyl group, but compounds having branched alkyl groups have shorter retention time than those having normal alkyl groups of the same carbon number. This suggests the presence of POE compounds having branched alkyl groups in the extract. Indeed, the spiked internal standard was not found in fraction 1. Since the internal standard has a dodecyl group, the isomers of POE dodecyl ethers found in the fraction 1 may be POE methyl-substituted undecyl ethers, which are usually used as detergents. From the comparison between the relative intensity of *m/z* 545 to *m/z* 549 in fraction 3 and that in the extract (Fig. 4), the mole ratio of POE methyl-substituted undecyl ethers to POE dodecyl ethers was estimated to be 0.2.

The concentration of POE alkyl and alkylphenyl ethers were calculated on the assumption that sensitivities do not depend upon the number of carbon atom in alkyl group, and the total concentration of POE derivatives was determined to be 202 μg/L (Table 3).

The present study has demonstrated that POE alkyl ethers in water at trace levels can be easily determined by FDMS. Cation attachment ionization in FDMS makes selective and sensitive determination of POE derivatives possible. Distinction between normal and branched alkyl group in POE alkyl ethers may become possible by HPLC–FDMS.

(Received April 10, 1981)

The chemical equilibria of bis(benzoylacetonato)nickel(II) in dimethyl sulfoxide solutions were investigated, mainly by means of d.c. polarography. In 0.05—0.1 mol dm^{-3} $NaClO_4$, TMAP, and TBAP solutions, the following chemical equilibria were found: $Ni(bi\text{-}bzac)_2 \rightleftharpoons Ni(bi\text{-}bzac)(uni\text{-}bzac) \rightleftharpoons Ni(bi\text{-}bzac)^+ \rightleftharpoons Ni(uni\text{-}bzac)^+$ where bi- and uni- are the abbreviations of bidentate and unidentate respectively. The species of $Ni(bi\text{-}bzac)_2$ and $Ni(bi\text{-}bzac)(uni\text{-}bzac)$ comprised 35% and 57% respectively of the total complex of 1 mmol dm^{-3} in a TMAP or TBAP solution, while they accounted for 15% and 77% respectively in a $NaClO_4$ solution. Such a difference in the equilibrium distribution was explained on the basis of the interaction between π electrons of the ligand and cations of the supporting electrolytes. The tris-complex was formed by the addition of excess benzoylacetonate to the complex solution.

In a previous paper,[1] the d.c. polarographic reduction of bis(acetylacetonato)nickel(II) and bis(hexafluoroacetylacetonato)nickel(II) was studied in dimethyl sulfoxide as a solvent. The study led to the conclusion that the dissolved state of bis(β-diketonato)-nickel(II) complexes is dependent on the nature of their ligands; therefore, a systematic study of the complexes with various ligands was required.

In the present paper, a d.c. polarographic study of bis(benzoylacetonato)nickel(II) will provide useful information about the chemical equilibria of the complex in the same solvent. To judge from the conductance and the cryoscopic data, the complex existed predominantly in the monomeric $Ni(bzac)_2 \cdot 2DMSO$ form. However, three or four kinds of species were polarographically observed in the presence of such supporting electrolytes as alkali-metal perchlorates and tetraalkylammonium perchlorates. The coexisting sodium ion significantly influenced the chemical equilibria of bis(benzoylacetonato)nickel(II). The dissolved state of bis(β-diketonato)nickel(II) complexes in nonaqueous solvents thus far reported, except in a few papers,[1,4,26] was confined to that in noncoordinating solvents.[3,18–20] Choplin-Gast and Hugel[20] determined the equilibrium constant of $Ni_3(bzac)_6 \rightleftharpoons 3Ni(bzac)_2$ in dichloromethane by the spectroscopic method: $\log K = -4.7$ at 25 °C.

Experimental

Reagents. The dimethyl sulfoxide (DMSO), nickel(II) perchlorate hexahydrate, tetramethylammonium perchlorate (TMAP), and tetrabutylammonium perchlorate (TBAP) were the same as described in the previous paper.[1] The TBAP was recrystallized from ethanol when necessary. The sodium perchlorate and potassium perchlorate were dried *in vacuo* at 60 to 70 °C for a minimum of 24 h prior to use. The rubidium perchlorate and caesium perchlorate of a 99.9% purity were used.

Bis(benzoylacetonato)nickel(II) monohydrate was prepared by the following procedure. Into 20 cm^3 of an aqueous solution of 2 mmol of nickel(II) acetate ($Ni(CH_3COO)_2 \cdot (H_2O)_4$), a solution of 4 mmol of benzoylacetone (Hbzac) in *ca.* 20 cm^3 of ethanol was added, followed by the addition of *ca.* 10 cm^3 of an aqueous solution containing 7 mmol of sodium acetate ($CH_3COONa \cdot (H_2O)_3$). The mixed solution was then kept for *ca.* 30 min at 50 °C. The product thus precipitated was recrystallized twice from methanol and then dried *in vacuo* at room temperature. Found: C, 59.87; H, 5.05%. Calcd for $C_{20}H_{20}O_5Ni$: C, 60.19; H, 5.05%.

Tetrabutylammonium benzoylacetonate ($Bu_4N(bzac)$) was prepared according to Buchta and Evans.[2] The salt was stored in the dark under nitrogen. Found: C, 76.73; H, 11.19; N, 3.52%. Calcd for $C_{26}H_{45}O_2N$: C, 77.36; H, 11.23; N, 3.47%.

Reagent-grade chemicals were used unless otherwise stated.

Apparatus. The current-potential curves were obtained with a Yanagimoto Voltammetric Analyzer P-1000 and a Watanabe X-Y Recorder WX-4404. The electrolysis cell and other apparatus have been reported previously.[1] Two dropping-mercury electrodes were used. The A electrode had an m value of 0.89_0 mg s^{-1} and a drop time, t_d, of 6.60 s in a deaerated 0.05 mol dm^{-3} TBAP–DMSO solution at -1.0 V *vs.* SCE at a height of the mercury reservoir, h, of 50 cm. The B electrode had an m value of 1.06_2 mg s^{-1} and a t_d value of 6.18 s in a deaerated 0.05 mol dm^{-3} TMAP–DMSO solution at -1.0 V and $h=47$ cm.

In the following sections, the word "current" denotes the mean current.

Procedures. Nickel(II) perchlorate was made to react with tetrabutylammonium benzoylacetonate in deaerated solutions containing 0.05 mol dm^{-3} of the supporting electrolyte at room temperature in the dark overnight (Fig. 3). The reaction of the complex with tetrabutylammonium benzoylacetonate was also carried out under the same conditions (Fig. 2). Unless otherwise stated, the polarographic measurements were made at 25.0±0.2 °C. All the test solutions were deaerated for 30 min with nitrogen gas in a thermostat before measurements.

Results and Discussion

Conductance, Molecular Weight, etc. The molar conductivity of 2 mmol dm^{-3} of bis(benzoylacetonato)-nickel(II) was 0.4 Ω^{-1} cm^2 mol^{-1} at 25 °C. According to the conductance results of DePalma and Arnett,[10] the molar conductivity at an infinite dilution (Λ_0) and the dissociation constant of tetrabutylammonium dibenzoylmethanate were 30.8±1.6 Ω^{-1} cm^2 mol^{-1} and (62±24)×10^{-4} mol dm^{-3} respectively in dimethyl sul-

a) The $\bar{i}_j/(\bar{i}_t)_B$ ratios for $Ni(bzac)_2$ were obtained at the concentration of 1 mmol dm^{-3} under the controlled drop time of 2.0 s, where the $(\bar{i}_t)_B$ represents the $\bar{i}_t$ in a TMAP or TBAP solution. The meanings of $\bar{i}_j$ and $\bar{i}_t$ are shown in Fig. 1.

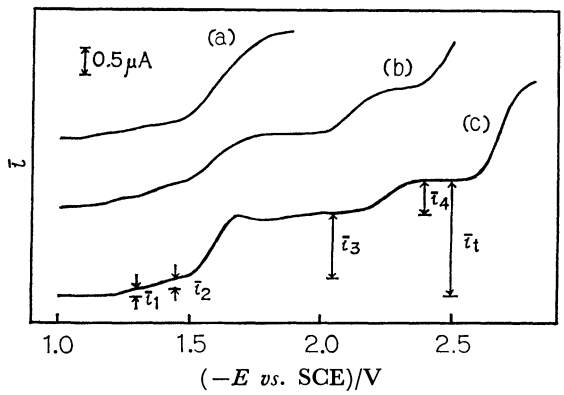

Fig. 1. Polarograms of 1 mmol dm^{-3} $Ni(bzac)_2$ in DMSO solutions. Supporting electrolyte: (a) $NaClO_4$, (b) TMAP, (c) TBAP. Each in 0.05 mol dm^{-3}. With the DME (A).

foxide at 25 °C. The investigators of the conductance of quaternary ammonium halides in dimethyl sulfoxide have reported that these salts are almost entirely dissociated[15,16] and that the Λ_0 values are 32—43 Ω^{-1} cm^2 mol^{-1} at 25 °C.[15] In our preliminary experiments, the Λ_0 value of bis(hexafluoroacetylacetonato)nickel(II) was 38 Ω^{-1} cm^2 mol^{-1} at 25 °C: This complex was considerably dossociated into the 1:1 electrolyte, but the Λ *vs.* $C^{1/2}$ plot did not follow quantitatively the Onsager relation,[17] where Λ and C denote the molar conductivity and the concentration respectively. It therefore seems likely that the degree of dissociation of 2 mmol dm^{-3} of bis(benzoylacetonato)nickel(II) is less than 2%. The cryoscopic data of the complex agreed with the molecular weight of $Ni(bzac)_2 \cdot 2DMSO$. Thus, the complex probably exists in the predominant form of the monomeric bis-complex in the absence of electrolytes. The spectroscopic data indicate that the complex has a hexacoordinate octahedral structure.[3,4]

Polarographic Behavior. Some typical polarograms of the complex are shown in Fig. 1. The polarographic data of the complex, benzoylacetone, and tetrabutylammonium benzoylacetonate are summarized in Table 1. The complex gave three waves in the presence of sodium perchlorate as the supporting electrolyte. On the other hand, it gave four waves in a solution of tetramethylammonium perchlorate and five waves in one of tetrabutylammonium perchlorate. These polarograms were not appreciably affected by the change in the concentration of each supporting electrolyte in the range of 0.05—0.1 mol dm^{-3}.

The fifth wave at the most negative potential in a TBAP solution corresponds to the reduction of benzoylacetonate, judging from a comparison of the two half-wave potentials (Table 1).

For the complex of 1 mmol dm^{-3}, the total limiting current in a $NaClO_4$ solution was 85% of that at −2.30 V in a TMAP solution and of that at −2.45 V in a TBAP solution, under a controlled drop time. The latter currents were approximately equal to that of 1 mmol dm^{-3} of nickel(II) perchlorate. The diffusion coefficient for the solvated nickel(II) ion obtained from the Ilkovič equation was $2.3_3 \times 10^{-6}$ cm^2 s^{-1} in all the supporting-electrolyte solutions of 0.05 mol dm^{-3}. It is known that the coordinated water of nickel(II) perchlorate hexahydrate is replaced by dimethyl sulfoxide in this solvent.[5] The controlled-potential coulometry at −2.30 V in a TMAP solution gave the number of electrons participating in the electrode processes, n, of 2. All the waves, except for the wave at the most negative potential in a TBAP solution, are considered to be due to the reduction of nickel(II).

The first limiting current ($\bar{i}_1$) at the least negative potential was diffusion-controlled: it was proportional to $h^{1/2}$. The i_2/i_3 ratio was dependent on the drop time, indicating that the second wave included a kinetic current; however, all the $\bar{i}_j/\bar{i}_t$ ratios were constant at $t_d \leqslant 2.0$ s, where $j=1$—4. These results were con-

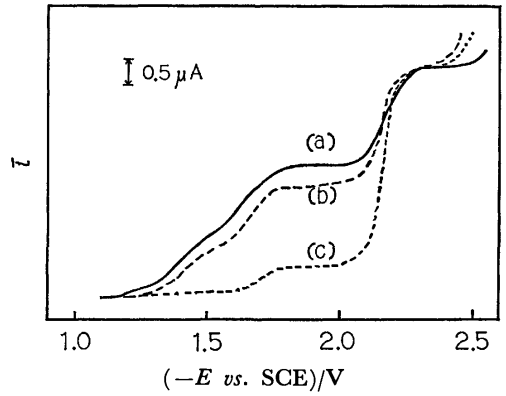

Fig. 2. Effect of addition of free ligand to 2 mmol dm^{-3} $Ni(bzac)_2$ in 0.05 mol dm^{-3} TMAP–DMSO solutions. Concn (mmol dm^{-3}) of $Bu_4N(bzac)$ added: (a) 0, (b) 0.5, (c) 3.0. With the DME (A).

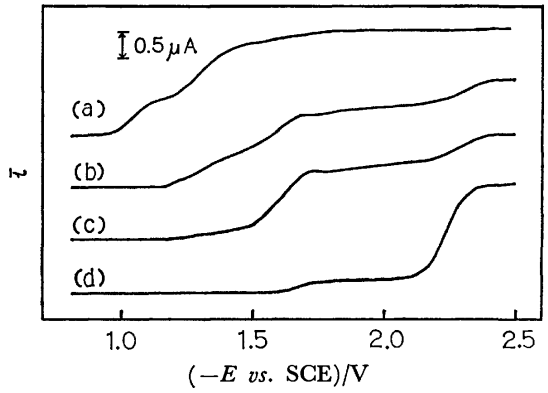

Fig. 3. Polarograms of bzac-complexes of nickel(II) in DMSO solutions containing the ligand in different concentrations. 1 mmol dm^{-3} $Ni(ClO_4)_2$, 0.05 mol dm^{-3} TBAP. Concn (mmol dm^{-3}) of Bu_4N-(bzac): (a) 0.7, (b) 1.5, (c) 2.0, (d) 5.0. t_d=2.0 s. With the DME (A).

firmed in all the supporting-electrolyte solutions. The i_t was proportional to the concentration of the complex in solutions containing TMAP or TBAP. None of the i_f/i_t ratios were affected by the addition of 0.14 mol dm^{-3} of water.

The effect of the addition of free benzoylacetonate to the complex is shown in Fig. 2. The two waves at less negative potentials disappeared successively as the concentration of benzoylacetonate increased, and the low wave at *ca.* −1.7 V and the high wave at −2.16 V finally remained. Evidently, the chemical equilibria exist between the species giving each reduction wave in Fig. 2, judging from the above findings. The limiting current at the least negative potential in Figs. 2(a) and (c) was diffusion-controlled, while that in Fig. 2(b) was partially kinetic-controlled. The constant diffusion-controlled i_t values for the three curves suggest that the diffusion coefficients of all the species are almost equal; the i_f/i_t ratio obtained under the controlled drop time of $t_d \leqslant 2.0$ s in a TMAP or TBAP solution in Fig. 1 represents the molar fraction for each species.

No wave in the least negative potential in Fig. 1 is due to the reduction of the free nickel ion, because it is reduced at *ca.* −1.0 V.[5,6] Figure 3 shows the polarograms measured after the reaction of 1 mmol dm^{-3} of nickel(II) perchlorate with tetrabutylammonium benzoylacetonate in various concentrations. In Fig. 3 (a), the two waves at less negative potentials correspond to the reduction of the main species, which are the nickel ion and the mono-complex. The first two waves in Figs. 1 (a)—(c) appear, judging from a comparison of the half-wave potentials of Curves (a) and (c) in Fig. 3, to be due to the mono-complex reduction. This was confirmed by the plot of (i_1+i_2) *vs.* bzac/Ni mole-ratio, where each (i_1+i_2) value was the diffusion-current obtained under the controlled drop time of 1.0 s. Provided that the first and the second waves, the third wave, and the fourth wave of Curve (c) in Fig. 3 come from the reduction of $Ni(bzac)^+$, $Ni(bzac)_2$, and $Ni(bzac)_3^-$ respectively, the total concentration of the ligand bonded to the nickel ion comes to be higher than that actually contained in the solution; thus, this assumption can not be accepted. Further, the i_3/i_4 ratio was constant in Figs. 3(a)—(c). It is, therefore, reasonable to consider that the complex behaves as a mixture of $Ni(bzac)^+$ and $Ni(bzac)_2$ in the supporting-electrolyte solution. Octahedral complexes involving unsymmetrical β-diketonates and unidentate ligands of the $M(AB)_2X_2$ type possess five possible geometrical isomers, three with the two X ligands *cis* to one another, and two with the two X ligands *trans* to each other.[7] In view of the known structure of $Ni(acac)_2 \cdot 2H_2O$,[3] the latter isomers may be present for $Ni(bzac)_2 \cdot 2DMSO$. Even if these isomers exist in the solution, however, they are not responsible for the third and the fourth waves in Fig. 1, because bis(dibenzoylmethanato)nickel(II) involving symmetrical β-diketonates also gave four polarographic waves due to the reduction of nickel(II). Consequently, the possible assignments for the four waves in a TMAP or TBAP solution are as follows:

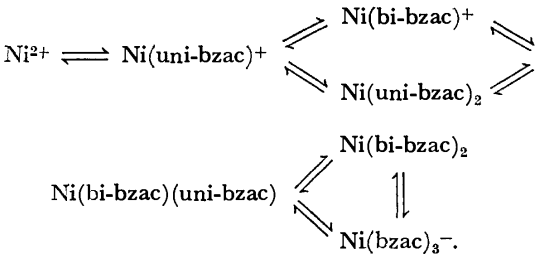
$$\begin{array}{ccc} Ni(uni\text{-}bzac)^+ & \rightleftharpoons & Ni(bi\text{-}bzac)^+ \rightleftharpoons \\ \downarrow 2e & & \downarrow 2e \\ \text{1st wave} & & \text{2nd wave} \end{array}$$

$$\begin{array}{ccc} Ni(bi\text{-}bzac)(uni\text{-}bzac) & \rightleftharpoons & Ni(bi\text{-}bzac)_2 \\ \downarrow 2e & & \downarrow 2e \\ \text{3rd wave} & & \text{4th wave} \end{array}$$

where uni- and bi- are the abbreviations of unidentate and bidentate respectively. The second wave includes the kinetic current due to the preceding reaction, $Ni(bi\text{-}bzac)(uni\text{-}bzac) \rightleftharpoons Ni(bi\text{-}bzac)^+$. As will be shown below in Fig. 5, the temperature effect on the i_f and i_t values is consistent with the above conclusion. In a $NaClO_4$ solution, the existence of $Ni(bi\text{-}bzac)_2$ of 15% is presumed for the total complex of 1 mmol dm^{-3} from a comparison of the i_t in this solution with that in a TMAP or TBAP solution, though the wave of its species can not observed because of the overlap with that of the sodium ion. In accord with the general expectations, the kinetic nature of the second wave suggests that the rate of the dissociation of Ni(bi-

bzac)(uni-bzac) is faster than that of Ni(bi-bzac)$_2$.

The three waves at less negative potentials were little observed in the solution containing 0.5 mmol dm^{-3} Ni(bzac)$_2$, 25 mmol dm^{-3} Bu_4N(bzac), and 0.05 mol dm^{-3} TBAP. Further, the i_1/i_2 ratio decreased by the addition of benzoylacetonate to the complex under the controlled drop time of $t_d \leqslant 2.0$ s. These findings and Fig. 3 suggest that there are several paths for the reaction of nickel ions with benzoylacetonate, as is shown in the following scheme:



With an increase in the concentration of tetrabutylammonium benzoylacetonate added to a solution of nickel ions, the above equilibria shifted to the right. In the curves of (b) and (c) in Fig. 2, and in the curve of (d) in Fig. 3, the formation of the tris-complex is apparent as a consequence of the mass-action law; however, it is unknown polarographically whether or not Ni(bzac)$_3^-$ is electroactive at the fourth wave. The several species would likely be formed for Ni(bzac)$_3^-$ in the bulk of the solution. Though the quantitative treatment of the equilibrium distribution in Fig. 3 is a very interesting subject, it is really complicated. At the present stage, the accurate evaluation of the free-ligand concentration is also difficult in the presence of a large excess of electrolytes. Generally, β-diketones themselves have been used as the ligands for the determination of the formation constants of their metal complexes.[21-23] This method can not be applied in the present work, because the species of Ni(bi-bzac)(uni-bzac) and Ni(bi-bzac)$_2$ are reduced at more negative potentials than the first wave of benzoylacetone, which is considered to come from the hydrogen reduction of the enol form[2,24] (see Table 1). This is the reason for the use of tetrabutylammonium benzoylacetonate. The formation constants of the nickel(II) complex with benzoylacetonate anion have been determined only in 75 vol% dioxane–25 vol% water at 15, 25, and 40 °C: $\log K_1=9.13$ and $\log K_2=7.76$ at 25 °C.[25] In this paper, the only change in the equilibrium distribution is shown in the complex concentration range of 0.5—5 mmol dm^{-3} in the presence of 0.05 mol dm^{-3} TMAP (Fig. 4). A higher dissociation of Ni(bi-bzac)$_2$ to Ni(bi-bzac)(uni-bzac) attendant upon a decrease in the total complex concentration was found, but the molar fractions for Ni(uni-bzac)$^+$ and Ni(bi-bzac)$^+$ were constant within the range of experimental error. The total molar fraction of Ni(uni-bzac)$^+$ and Ni(bi-bzac)$^+$, 0.08, in the solutions containing the electrolyte is higher than would be expected on the basis of the conductance, indicating the electrolyte effect on the dissociation of the bis-complex to the mono-complex.

In the concentration of the supporting electrolyte

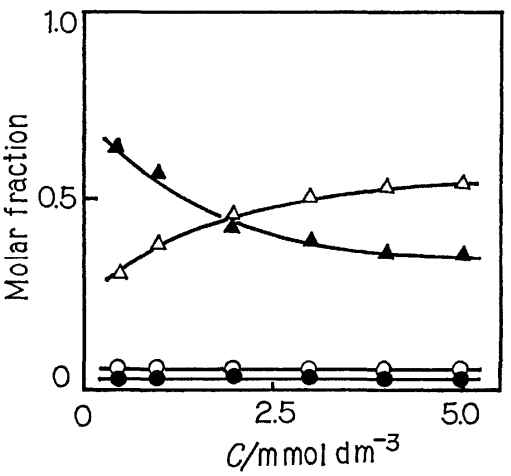


Fig. 4. Equilibrium distribution of four nickel(II) species present in 0.05 mol dm^{-3} TMAP–DMSO solutions containing Ni(bzac)$_2$ in different concentrations. (●) Ni(uni-bzac)$^+$, (○) Ni(bi-bzac)$^+$, (▲) Ni(bi-bzac)(uni-bzac), (△) Ni(bi-bzac)$_2$.

$NaClO_4$ (mol dm^{-3})[a]	$(\bar{i}_1+\bar{i}_2)/(\bar{i}_t)_B$[b]	$\bar{i}_3/(\bar{i}_t)_B$[b]
0.010	0.08	0.65
0.025	0.08	0.74
0.050	0.08	0.77

a) The total concentration of the supporting electrolyte was adjusted to 0.050 mol dm^{-3} with TBAP. b) See Table 1.

of 0.05 mol dm^{-3}, the species of Ni(bi-bzac)(uni-bzac) comprised 57% of the total complex of 1 mmol dm^{-3} in a TMAP or TBAP solution, while its species formed 77% in a $NaClO_4$ solution (Table 1). It should be noted that the concentration of Ni(bi-bzac)(uni-bzac) is high in a $NaClO_4$ solution. The complex gave three waves in each supporting-electrolyte solution—in 0.05 mol dm^{-3} portions of $KClO_4$, $RbClO_4$, and $CsClO_4$, where each i_t was roughly equal to $(i_1+i_2+i_3)$ at −2.00 V in a TBAP solution. In these solutions, the distribution of the species is similar to that in a TMAP or TBAP solution: the waves for Ni(bi-bzac)$_2$ could not be observed because of overlap with those of potassium, rubidium, and caesium ions. The $\bar{i}_3/(\bar{i}_t)_B$ ratio, *i.e.*, the molar fraction of Ni(bi-bzac)(uni-bzac), increased with an increase in the concentration of sodium perchlorate, as is shown in Table 2, where $(\bar{i}_t)_B$ denotes the $\bar{i}_t$ in a TMAP or TBAP solution. Apparently, the sodium ion is related to the dissociation of Ni(bi-bzac)$_2$ to Ni(bi-bzac)(uni-bzac). Probably the cations in the solutions cause the decrease in the π delocalization in the ligand, thereby labilizing the complex; the sodium ion is considered to be the most effective among the cations used here. This cationic effect will be reported on in detail in the polarographic studies of the nickel(II) complexes with 2-thenoyltrifluoroacetonate, 2-furoyltrifluoroacetonate, and benzoyltrifluoroacetonate anions in the following paper. The sodium ion may con-

tribute to the chelation with free benzoylacetonate anion as well as with several β-diketonate anions:[8-12]

$$\mathrm{Ni(bi\text{-}bzac)_2} \rightleftharpoons \mathrm{Ni(bi\text{-}bzac)(uni\text{-}bzac)} \rightleftharpoons \mathrm{Ni(bi\text{-}bzac)^+ + bzac^-}$$

$$\downarrow\uparrow \qquad \downarrow\uparrow \mathrm{Na^+}$$

$$\mathrm{Ni(uni\text{-}bzac)^+} \qquad \mathrm{Na(bzac)}$$

However, as can be seen in Table 1, the $(i_1+i_2)/(i_t)_B$ ratio, *i.e.*, the molar fraction of the mono-complex, in a $NaClO_4$ solution is equal to that in a TMAP or TBAP solution; thus, it seems unlikely that the chelation of the sodium ion by benzoylacetonate anion plays an appreciable role in the equilibrium distribution of Ni(II)-complexes.

Murray *et al.*[27] found that the reduction potentials of a number of metal acetylacetonates in acetonitrile are shifted to less negative potentials by the addition of lithium perchlorate to tetraethylammonium perchlorate as the supporting electrolyte. Their detailed studies of $Fe(acac)_3$ led to the conclusion that this effect is caused by a coordinative relaxation reaction of the $Fe(acac)_3^-$ reduction product, where an acetylacetonate ligand is transferred to the lithium ion. The interaction between reduction products and the lithium ion has been studied for complexes of the $[ML_n]^\circ$ type in such nonaqueous solvents as acetonitrile[28] and *N*,*N*-dimethylformamide.[29,30] According to the results of Gritzner *et al.*,[31] the reduction product, $Mn(acac)_3^-$, of $Mn(acac)_3$ forms ion-pairs with lithium, sodium, and potassium ions in various solvents. There was no difference between the half-wave potential of the third wave in a $NaClO_4$ solution and that in a TMAP solution in the present work (Table 1). In the case of a completely irreversible electron transfer, however, special experimental approaches will be required to discuss the above interaction.[27]

The temperature effect on the i_1 and i_t of the complex was examined in a TMAP solution (Fig. 5). The species of $Ni(bi\text{-}bzac)_2$ and $Ni(bi\text{-}bzac)(uni\text{-}bzac)$ were readily dissociated in the bulk of the solution with an increase in the temperature, and there was a marked tendency for the latter. Little dissociation of $Ni(bi\text{-}bzac)^+$ to $Ni(uni\text{-}bzac)^+$ was observed, judging from the temperature coefficient of *ca.* 1.6% K^{-1} for i_1.

A study was not made as to whether or not $Ni(bi\text{-}bzac)_2$ is somewhat dissociated to $Ni(bi\text{-}bzac)(uni\text{-}bzac)$ in the absence of the electrolyte. No useful information from the electronic spectra can be expected concerning such a study. However, the observation of such species involving a unidentate ligand as $Ni(bi\text{-}bzac)(uni\text{-}bzac)$ and $Ni(uni\text{-}bzac)^+$ in the present work is of interest in connection with the intermediates in the various reaction mechanisms of metal complexes in solution. The high basicity of dimethyl sulfoxide[13,14] might contribute to the stabilization of those species. Further, the properties of the central metal seem to be very important for the stabilization, but the solution to this problem will require a systematic study of β-diketonate complexes with various metals.

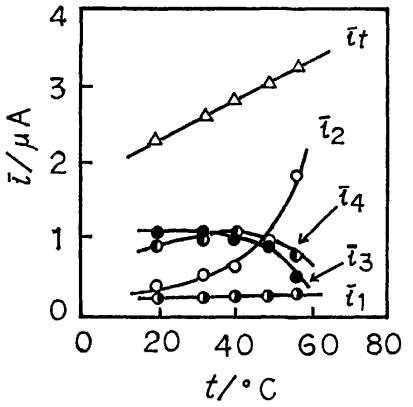

Fig. 5. Effect of temperature on the limiting currents of 1 mmol dm^{-3} $Ni(bzac)_2$ in 0.05 mol dm^{-3} TMAP–DMSO solution. With the DME (B).

(Received May 21, 1981)

The crystal and molecular structure of *meso*-[Co(hexaen)]Cl_3 has been determined by single crystal X-ray diffractometry. The crystals are rhombohedral with space group $R\bar{3}$, $a=9.2976(10)$, $c=16.851(2)$ Å, and $Z=3$. The structure has been refined by least-squares calculations to an R value of 0.021 for 952 observed reflections. The complex ion has S_6 symmetry. The Co–N distance is 1.9966(8) Å and the N–Co–N angle in the chelate ring is 83.62(3)°. The molecular dimensions are in good agreement with those obtained from the conformational analysis.

An octahedral complex of a cyclic hexadentate ligand takes either *meso* or racemic form. Curry and Busch prepared an iron(III) complex with such kind of ligand, 2,16-dimethyl-3,6,9,12,15,21-hexaazabicyclo-[15.3.1]heneicosa-1(21),2,15,17,19-pentaene.[1] However, the complex of the *meso* form was not obtained on account of the rigidity of the ligand. Groth carried out an X-ray analysis on the complex between potassium *p*-toluenesulfonate and 1,4,7,10,13,16-hexaoxacyclooctadecane(18-crown-6).[2] The 18-crown-6 molecule in this compound, as well as those in most complexes of this crown and its derivatives,[3] have roughly S_6 symmetry (*meso* form). However, the crown complexes are labile in solution. It is stereochemically more interesting to investigate inert metal chelates with cyclic hexadentate ligands.

Recently we succeeded in isolating the *meso* isomer of [Co(hexaen)]$^{3+}$ as a minor reaction product, as well as a major product of the racemic one.[4] The conformational analysis of [Co(hexaen)]$^{3+}$ suggested that the *meso* isomer was much more unstable than the racemic one; that is, the calculated energy difference amounts to 15 kJ mol^{-1}. Searle *et al.* prepared the cobalt(III) complex of a very similar hexadentate ligand, 1,4,8,11,15,18-hexaazacycloheneicosane, but did not obtain the *meso* isomer.[5] Thus the title compound is the first example of the *meso* isomer of the inert complex with a cyclic hexadentate ligand.

In this study, the crystal structure of the title compound has been determined.

Experimental

Preparation of the Complex. To half a gram of hexaen·$3H_2SO_4$ suspended in 10 cm^3 of water, 1 cm^3 of concentrated aqueous ammonia was added. The mixture was diluted with water until the total volume of solution was about 500 cm^3. To the mixture was added a solution of 0.3 g of $[Co(H_2O)(NH_3)_5]_2(SO_4)_3\cdot 3H_2O$ in 500 cm^3 of water. The solution was heated and kept at 77 °C for 4 h. After standing overnight, the resulting orange-red solution was allowed to pass through a small column of SP-Sephadex C-25, which adsorbed cationic species. A portion of the mixture was subjected to the chromatographic separation described in a previous paper.[4] The effluents containing the *meso* isomer, which were obtained from several separations, were diluted with water and were adsorbed again by a small column of SP-Sephadex. The column was washed with a large amount of 10^{-2} mol dm^{-3} HCl, and then the complex was eluted with 1.0 mol dm^{-3} HCl. The effluent was evaporated to dryness in a vacuum desiccator over NaOH and P_2O_5. The resulting orange-red crystals were recrystallized from water. Crystals are orange-red square-plates. Found: C, 33.61; H, 7.21; N, 19.90%. Calcd for $C_{12}H_{30}N_6CoCl_3$: C, 34.02; H, 7.14; N, 19.83%. Absorption spectrum; $\bar{\nu}_{max}$/cm^{-1} (log ε), 20830 (2.33).

Physical Measurements. Electronic absorption and ^{13}C NMR spectra were recorded on a UNION SM-401 spectrophotometer and a JEOL JNM-FX60 spectrometer operating at 15.04 MHz, respectively.

X-Ray Structure Determination. A spherically shaped crystal of 0.43 mm in diameter was used for the X-ray experiment. Intensity data were collected up to $2\theta=65°$ on a Rigaku automated four-circle diffractometer AFC-5 with graphite-monochromatized Mo $K\alpha$ radiation, the θ-2θ scan technique being employed. 961 independent reflections with $|F_o|>3\sigma(|F_o|)$ were observed, and used in the structure analysis. No correction was made for absorption and extinction effect. The accurate cell dimensions were determined by a least-squares method from the θ values for 21 reflections in the range of $26°<2\theta<30°$ measured on the diffractometer. The crystallographic data are listed in Table 1.

The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method with anisotropic temperature factors for non-hydrogen atoms. The scattering factors and the anomalous scattering corrections for non-hydrogen atoms were taken from International Tables for X-Ray Crystallography.[6] For hydrogen atoms, the values given by Stewart, Davidson, and Simpson

were used.[7] The weighting scheme in the least-squares calculation was taken as $w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$. The R and R_w values were 0.024 and 0.040 for 961 independent reflections. The results at this stage revealed that nine strong, low-angle reflections (110, 300, 330, 011, 102, 003, 204, 014, $\bar{3}44$) were seriously affected by secondary extinction effect. The least-squares calculation for 952 intensities except for these nine reflections gave $R=0.021$ and $R_w=0.038$.

The final atomic parameters are listed in Table 2.[8] All the calculations were performed on a HITAC M-200H computer at the Computer Center of the Institute for Molecular Science with Universal Crystallographic Computational Program System UNICS III.[9]

Results and Discussion

Figure 1 shows a perspective drawing of *meso*-[Co(hexaen)]$^{3+}$ along the threefold axis. The bond lengths and angles are listed in Table 3. The cobalt atom lies at a crystallographic special position $\bar{3}$ and the complex ion has S_6 symmetry. The macrocyclic ligand, hexaen, is composed of six equivalent $-NHCH_2-CH_2-$ units. Six five-membered chelate rings are equivalent. This compound has very interesting structure containing both Δ- and Λ-[Co(en)$_3$]$^{3+}$ type chelate rings and was named "Cobalt Spinner" in a previous paper,[4] as it is suggestive of an old-fashioned spinning wheel which rotates about its threefold axis. The two methylene groups in each chelate ring are crystallographically independent. The five-membered ring adopts the unsymmetrical gauche conformation. The differences in the structural parameters of the two methylene carbon atoms are given in Table 3.

A Dreiding molecular model shows that the *meso* isomer may have a highly symmetrical and rigid D_{3d} structure with twelve equivalent methylene carbons. The D_{3d} structure, however, contains non-bonded hydrogen-hydrogen pairs which may have significantly large repulsive interactions. The conformational analysis of this compound, which was initiated from the

D_{3d} structure using the same parameters as in a previous report,[10] lead to the S_6 structure.[4] In Table 3, the molecular dimensions obtained from the conformational analysis are compared with those found in the X-ray crystal structure analysis. The agreement between them is excellent. In the energy minimized structure, the Co–N bond distance (1.993 Å) is longer than the initial one (1.970 Å) and almost the same as that found in the crystal (1.997(1) Å). The elongated coordination-bond distances are reflected on the red-shift of the absorption maximum as compared with that of [Co(en)$_3$]$^{3+}$. The two N–C

Table 4. Relevant interatomic distances (*l*/Å) outside the complex ion with their e.s.d.'s

Cl(2)···N	3.234(1)
Cl(2)···H(1)	2.49(2)
Cl(2)···H(5)	2.82(2)
Cl(1)···H(3)	2.81(2)

bond distances in each chelate ring differ in such a way that large hydrogen-hydrogen repulsions inherent in the initial D_{3d} structure can be avoided. The relaxed hydrogen-hydrogen interactions are depicted as dotted lines in Fig. 1 (H(3)···H(4), 2.11(3) Å; H(2)···H(5), 2.11(2) Å). Although the two methylene carbons are crystallographically independent, they are equivalent in solution. The ^{13}C NMR spectrum of this compound shows only one resonance signal in an aqueous solution.[4] It is highly probable that the *meso* isomer undergoes a rapid interconversion between the two equivalent S_6 structures, resulting in an average structure of D_{3d} symmetry.

Figure 2 shows a stereoscopic view of the crystal structure. Close contact pairs in the crystal are listed in Table 4. All the chloride ions and the cobalt atoms are aligned on the same crystallographic threefold axis; Co and Cl(1) sit on the $\bar{3}$ special positions and Cl(2) on 3. The Cl(2) ion approaches a complex cation and makes hydrogen-bonds with three equivalent NH groups (N–H···Cl(2), 3.235(1) Å).

Theoretical Signal-to-noise Ratio and Resolution in Ion-cyclotron-resonance Spectroscopy

Chikara Amano

Department of Engineering Physics, The University of Electro-Communications, 1-5-1 Chofugaoka, Chofu, Tokyo 182

(Received February 25, 1981)

A comparison is made theoretically of the signal-to-noise (S/N) ratio between the usual slow-sweep or the continuous-wave method and the pulsed Fourier-transform (FT) method in ion-cyclotron-resonance spectroscopy. Expressions of the maximum S/N ratio, as characterized by experimental parameters, are given in concrete form for both methods. Based on these expressions, it is shown that the FT method has a Fellgett S/N advantage when the resolution of a measurement is selected so as to be nearly equal to the true linewidth. A tradeoff between the S/N ratio and the resolution is discussed, and a possible reconciliation is suggested of inconsistent statements on a relation between the S/N and the resolution in the literature.

A physical system of spectroscopic interest can be considered to be an example of linear systems when the amplitude of excitation is small. According to the theory of linear systems, a spectrum of spectroscopy corresponds to what is called either a "system function" or "frequency response". There are several methods to obtain the system function.[1,2] One of them is the continuous-wave (CW) method, in which the amplitude and phase of a response are measured by sweeping frequencies of excitation. The name "frequency response" arose from this. Another one is the impulse-excitation method, in which the system function is obtained through the Fourier transformation of the response to a unit impulse excitation. The stochastic excitation method has also been proposed; in it the system function is evaluated through the Fourier transformation of the cross-correlation function of excitation and responce.

Of the many branches of spectroscopy, nuclear magnetic resonance (NMR), more specifically high-resolution NMR, which is a part of radio-frequency spectroscopy, is one of the most suitable for testing above ideas. This might be partly due to its spectroscopic characteristic that whole resonance lines concentrate within a narrow frequency range compared to the carrier frequencies, thus making it feasible to excite and detect a number of resonance lines at once. In NMR, of course, the CW method was employed first. Long after that, the impulse excitation method was applied by Ernst and Anderson, who noted that the method had an S/N advantage over the usual CW method.[3] An S/N gain of about one order was observed within a given experimental time. Spectrometers based on this principle are called "pulsed Fourier-transform spectrometers", and, because of their essential high sensitivity, they are now widely adopted in chemical and biological measurements. Soon after the advent of the FT method, the stochastic excitation method was also introduced; with pseudo-noise excitation, a similar S/N gain was obtained.[4,5] Meanwhile, in biological measurements a technique was required with which any portion of the whole spectrum could be excited and, at the same time, the S/N was high. The rapid scan or the correlation method was such a technique, in which excitation frequencies are swept fast linearly to time.[6,7] This may be considered to be another form of excitation for acquiring the system function.

The three relatively new methods have the common advantages over the CW method of a short observation time and, in consequence, a high sensitivity. These advantages essentially constitute a Fellgett advantage, which results from the simultaneous excitation and simultaneous detection of all spectral elements.[8] The Fellgett advantage may be described as follows. In spectroscopy, the frequency and amplitude of each frequency component are measured with a certain accuracy. The accuracy in frequency measurement defines the resolution. It is evident that it takes about $1/\Delta f$ to measure the frequency of a wave with an accuracy of Δf. This is a manifestation of the uncertainty principle between energy and time.[9] Thus, it takes $1/\Delta f$ to record one element of a spectrum with a resolution width of Δf. In the CW method, all the spectral elements are measured one by one, while in the other three methods they are obtained all at once. The former is a sequential method, while the latter three are simultaneous methods. The number of elements is $F/\Delta f$, where F is the whole spectral range of interest. Therefore, for the sequential method, the time required to record the whole spectrum is $F/(\Delta f)^2$. The band-width of noise superimposed on a spectral element is given by Δf. For the simultaneous method, on the other hand, the measurement time is only $1/\Delta f$, which is shorter by a factor of $(F/\Delta f)^{-1}$ than that for the sequential method. The band-width of noise is given again by Δf, though the band-width of the physical filter actually employed is F. Thus, S/N ratios are identical for the two methods if the magnitudes of the signals are assumed to be the same. Since S/N is improved as a square root of the measurement time[10], it is now evident that a Fellgett S/N gain of $(F/\Delta f)^{1/2}$ is obtained by the use of the simultaneous method. For radio-frequency spectroscopy, in which a coherent monochromatic excitation source is easily available, it is unclear why the sequential method is inefficient for utilizing signal energy, while it is evident for the infrared spectroscopy, in which only a small portion of the signal energy is utilized at one time by the use of a monochromator, the other big portion being wasted on the jaws of a slit, as Fellgett himself noted.

The pulsed-FT and rapid-scan methods have, in recent years, also been applied to ion cyclotron resonance (ICR), one branch of radio-frequency spec-

troscopy.[11,12] Besides the Fellgett advantage, the FT method as applied to ICR has an additional advantage of high resolution, which results essentially from the long observing time made possible by the use of ion-trapping cells.[13,14] Partly, however, it results from the characteristic of the FT method that the excitation period of ion motion is short; theoretically, high resolution may also be feasible for the CW method but experimentally it would be difficult since a very small amplitude of excitation is required. It was discussed by Marshall and Comisarow, by the use of analogy to optical multichannel spectrometers, how FT ICR has the Fellgett advantage.[15] There remains, however, some features to be clarified. First, in order to obtain the full Fellgett S/N gain it is necessary that the magnitude of a free decaying signal be the same as the signal magnitude for the CW method. This is not obvious, since the FT method utilizes transient responses, while the CW method treats steady-state responses. The second problem concerns noise levels. In the FT method, the band-width of a physical filter allowed is F, far broader than the band-width of the low-pass filter employed in the CW method. This may lead to an S/N disadvantage. Since a spectrum is obtained through the Fourier transformation of a time-domain signal, noise is also subjected to transformation, thus causing a frequency-domain noise. Third, it was stated by Marshall that there is a trade-off between the S/N and the resolution in the FT method.[16] More recently, however, a manuscript reporting contrary results has appeared.[14] In view of this situations, the present author felt that it was necessary to discuss S/N and resolution for the FT and the CW methods on a general basis. The ambiguities mentioned above will be made clear in this manuscript by evaluating S/N ratios at several stages involved in actual experiments.

Theoretical

We shall first describe some experimental conditions. The frequency range of a spectrum of interest is denoted by F. The resolution width of a measurement has the usual meaning that the width of a resonance line with a true width narrower than the resolution width may become widened through the measurement to the apparent magnitude of the resolution width; it is denoted by Δf. For the CW method, it is the reciprocal of the time spent to measure one frequency channel, and at the same time it is channel width. By using the scanning time, T_s, it is given thus;

$$\Delta f_{CW} = (F/T_s)^{1/2}. \tag{1}$$

For the FT method, on the other hand, it is given by the reciprocal of the sampling time, T_0, of free decaying (FD) signals:

$$\Delta f_{FT} = 1/T_0 \tag{2}$$

In order to obtain true line shapes determined by physical conditions, the resolution width of a measurement should be much narrower than the width of a resonance curve, $\Delta f_{1/2}$; *i.e.*

$$\Delta f \ll \Delta f_{1/2} \tag{3}$$

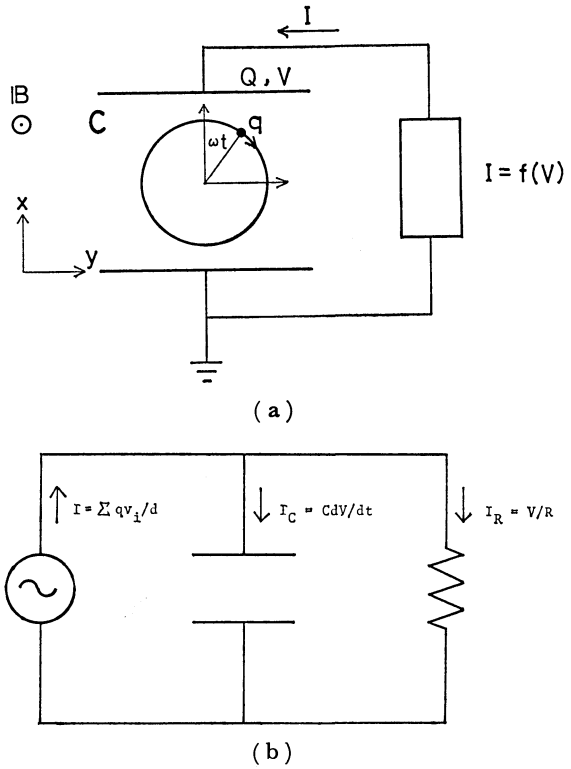

Fig. 1. (a): Moving ions in an ICR cell whose top and bottom plates form a capacitor C. The plates are connected with an outer circuit satisfying a current-voltage relation $I=f(V)$. Magnetic field is along z-axis, (b): current source equivalent to moving ions in a capacitor.

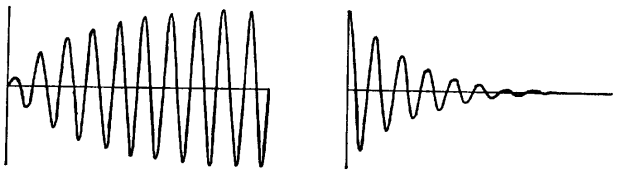
For the FT method, this is equivalent to a condition that the sampling time, T_0, should be much longer than the relaxation time. It should be noted that a so-called high resolution corresponds to a small resolution width in the present paper. The total experimental time is denoted by T_t. We assume ion-trapping cells,[17] since usual FT ICR experiments are done with such cells. With ion-drift cells, FT ICR experiments may be equally feasible, though greater experimental skill would be required. With a short burst of ionizing electrons, N numbers of ions are produced in a cell. If the trapping of ions is perfect, then only one burst of electrons will be sufficient for the whole experiment. Actually, however, the loss of ions from a cell can be significant after some time. Therefore, in order to enhance the S/N ratio through ensemble averaging, N ions must be produced afresh at every cycle after ejecting the ions of the previous cycle. For the CW and FT experiments, we assume a common detector which is equivalent to a pure resistance. It is realized either by the use of a parallel resonant circuit or by the use of a parallel CR combination when the circuit is essentially resistive, *i.e.*, $R \ll 1/j\omega C$. For the sake of simplicity, we shall limit considerations to a situation where only one resonance line is present in the whole spectrum range of interest. However, the following considerations may be easily extended to the case of N resonance lines.

Next, let us evaluate the maximum signal voltage obtained at a detector circuit. According to the signal



(a) (b)

Fig. 2. (a): Velocity component vertical to cell plates of an ion just at resonance condition for the initial condition $v=0$ at $t=0$ which is subjected to radio-frequency electric field with constant amplitude, (b): velocity component vertical to cell plates of an ion executing free decaying motion under no electric field after irradiation with a radio-frequency pulse.

theory,[18,19] moving ions are equivalent to a constant-current-source shunt across a cell whose top and bottom plates form a capacitor. This situation is illustrated in Fig. 1. There, the strength of the current source is:

$$I = \sum_{i=1}^{N} q_i v_i / d, \tag{4}$$

where q_i is the charge; v_i, a velocity component vertical to the plates and d, the distance between the two plates, and where summation is taken over the N ions in the cell. The velocity of the ion is given by the equation of motion for an average ion:

$$m d\boldsymbol{v}/dt = q(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}) - mc\boldsymbol{v}, \tag{5}$$

where $\boldsymbol{E}$ is, as usual, the electric field; $\boldsymbol{B}$, the magnetic field, and c in the last term, a damping constant attributable to collisions with neutral atoms and molecules, which is usually called the reduced collision frequency.[20,21] Equations 4 and 5 form a pair of basic equations describing ICR phenomena. Equation 5 can be shown to be equivalent to the equation of motion for a harmonic oscillator with a friction. Thus, solutions of the latter problem are useful in ICR. Let us consider the ion motion under the condition of CW experiments in which ions are subjected to a radio-frequency electric field with a constant amplitude. The velocity of the ion at just the resonance for the initial condition, $v=0$ at $t=0$, is given by the form that increases with a time constant, $1/c$, and becomes nearly constant after some multiples of the time constant. This is shown in Fig. 2(a). The constant value depends on the amplitude of the rf electric field and on the collision frequency. The radius, r, of the ion orbit is limited within $d/2$ by the finite dimensions of a cell. Thus, when $r=d/2$, the ion velocity given by the $v=r\omega_c$ formula has as its maximum value $d\omega_c/2$, where ω_c is the cyclotron angular frequency. Since all ions subjected to an rf electric field rotate with the same radii and phases, Eq. 4 leads to:

$$I_{CW} = Nq\omega_c/2. \tag{6}$$

As we have assumed a pure resistance, R, for a detector, the maximum voltage is given simply as:

$$V_{CW} = Nq\omega_c R/2. \tag{7}$$

For FT experiments, on the other hand, ions are accelerated with a short rf pulse. The velocity of the ions quickly reaches its maximum value, $d\omega_c/2$, and thereafter decays exponentially with a time constant, $1/c$, under no external electric field. This free decaying motion is shown in Fig. 2(b). The maximum amplitude of the FD signal is again given by:

$$V_{FT} = Nq\omega_c/2. \tag{8}$$

It is evident that the maximum signal voltage for the FT method is the same as that for the CW method. We shall henceforth use V_m to denote it. It is worth noting that, for the latter, V_m corresponds to the peak value of a spectrum, while for the former it does not. For the FT method, the peak value of a spectrum is obtained after the Fourier transformation of an FD signal and it is given by the average amplitude of the FD signal. The FD signal decays exponentially with the time, as is illustrated in Fig. 2(b), so that the average amplitude over the sampling time decreases as the sampling time increases. We will see later that this feature leads to a serious tradeoff between the S/N and the resolution.

We shall next evaluate the maximum S/N ratio obtained for the CW method. Among various types of noise, we assume only thermal noise which appears across a resistor in a detector circuit. This is the so-called "detector limited-noise case". Thermal noise has a white power spectrum, and its rms voltage is:

$$\overline{(v_t^2)}^{1/2} = (4kTRf)^{1/2}, \tag{9}$$

where f is the band-width in which noise is measured. This form shows that, in order to get better S/N, the band-width should be made as narrow as possible by the use of a filter. However, the minimum width of a filter employed is determined by the condition that a measurement is carried out with a certain resolution. Considering a measurement by a point-by-point spectrometer, a predecessor of CW spectrometers, we see that the minimum width of a filter is equal to the resolution width, Δf. Then, the rms value of the noise voltage becomes $(4kTR\Delta f)^{1/2}$. In that condition, the signal of amplitude, V_m, can pass through the filter without appreciable decrease. Hence, the maximum S/N ratio for the CW method with the resolution width, Δf, is now obtained thus:

$$(S/N)_{CW} = V_m/(4kTR\Delta f)^{1/2}. \tag{10}$$

It is worth noting that S/N increases in proportion to the square root of the magnitude of resistance, R, since V_m in Eq. 10 is actually proportional to R, as can be seen in Eq. 7. The scanning time for the experiment is evidently given be:

$$T_s = F/(\Delta f)^2. \tag{11}$$

The result of Eq. 10, which has been obtained rather intuitively, can be obtained in a more rigorous fashion by the theory of the matched filter. This approach is the same as Ernst employed in the S/N analysis of FT NMR.[3] The matched filter may be defined to be a filter such as can give the maximum S/N ratio for a signal pulse superimposed with noise.[1] According to the theory of the matched filter, the muximum S/N ratio obtained by the use of the filter is given in the frequency domain as:

$$(S/N)^2 = (1/2\pi)\int_{-\infty}^{\infty} |S(\omega)|^2/N(\omega)d\omega, \quad (12)$$

where $S(\omega)$ is the Fourier transform of a time-domain signal, $s(t)$, and where $N(\omega)$ is power spectrum of the noise. For the white noise assumed here, $N(\omega)=$ const, which we denote by W. Equation 12 then reduces to:

$$(S/N)^2 = (1/2\pi W)\int_{-\infty}^{\infty} |S(\omega)|^2 d\omega. \quad (13)$$

Using Parceval's theorem:

$$(1/2\pi)\int_{-\infty}^{\infty} |S(\omega)|^2 d\omega = \int_{-\infty}^{\infty} s(t)^2 dt, \quad (14)$$

we move to a more convenient time-domain description to obtain:

$$(S/N)^2 = (1/W)\int_{-\infty}^{\infty} s(t)^2 dt. \quad (15)$$

Here, the term $\int_{-\infty}^{\infty} s(t)^2\,dt$ stands for the total energy of a signal, $s(t)$, and W stands for the noise energy per unit of time and unit angular frequency. Since we measure signals over the resistance, R, we must replace Eq. 15 with

$$(S/N)^2 = (1/WR)\int_{-\infty}^{\infty} V_s(t)^2 dt, \quad (16)$$

where $V_s(t)$ is the signal voltage measured over the resistance, R. By specifying the functional form of $V_s(t)$, S/N can thus be evaluated. The signal pulse corresponding to the ICR absorption may be described by the Lorentzian form:

$$V_s(t) = V_m c^2/\{(at - \omega_c)^2 + c^2\}, \quad (17)$$

where a is the scanning rate and is equal to $2\pi F/T_s$. The peak value of this signal is V_m, and the width is $2c$. Although the evaluation of Eq. 16 with this form is possible, we can employ an alternative form without introducing much error since we are deriving general results which depend not on the details of the line shape, but on the width:

$$V_s(t) = \begin{cases} 0 \text{ for } t < (\omega_c - c)/a \\ V_m \text{ for } (\omega_c - c)/a \leqq t \leqq (\omega_c + c)/a \\ 0 \text{ for } (\omega_c + c)/a < t. \end{cases} \quad (18)$$

This is a rectangular pulse with the same height and width as the Lorentzian pulse. The evaluation of Eq. 16 with this form easily gives:

$$(S/N)^2 = V_m^2/4kTR(a/2c). \quad (19)$$

Here, the relation $W=4kT$ has been used. By using $a=2\pi F/T_s$ and $T_s=F/(\Delta f)^2$, Eq. 19 is rewritten to

$$(S/N) = V_m/(4kTR\Delta f')^{1/2}, \quad (20)$$

$$\Delta f' = \pi(\Delta f)^2/c. \quad (21)$$

Here, $\Delta f'$ is the effective band-width of noise, which is determined by the band-width of the matched filter. As we are considering an experiment with a resolution of Δf, we must put the linewidth equal to the resolution width, *i.e.*, $c/\pi=\Delta f$. Then, the band-width of the matched filter also becomes equal to the resolution width. Moreover, S/N is again given by Eq. 10. The band-width of the matched filter and, in consequence, the effective band-width of noise have the following simple meanings. Note that the frequency components of a signal pulse with a certain duration, Δt, are contained mainly in a band-width of about $1/\Delta t$. Therefore, the minimum width of a filter which let pass through the main frequency components of the signal and, at the same time, reject noise is evidently $1/\Delta t$. By applying this result to the signal pulse with a duration of $2c/a$ considered above, the width of the filter is found to be $\pi(\Delta f)^2/c$, which agrees with Eq. 21.

Now let us evaluate the maximum S/N ratio for the FT method. For this case, the band-width of a filter applicable to FD signals is not Δf, but F. Actually, the filter is necessary only to guarantee that FD signals can be sampled at the Nyquist rate. Since usually $F \gg \Delta f$, the S/N of one FD transient is much worth than that of a spectrum of the CW method. As we have denoted the maximum amplitude of an FD signal by V_m, the S/N for one transient is:

$$(S/N)_{IFT} = V_m/(4kTRF)^{1/2}. \quad (22)$$

By requiring the resolution width of a spectrum to be Δf, the measurement time of the FD signals is set as $1/\Delta f$. This is equal to the measurement time of one frequency channel for the CW method with the same resolution width. Let us now consider the Fourier transformation of FD signals and noise. The FD signal is generally described by:

$$V_s(t) = V_m \cos(\omega_c t) \exp(-ct). \quad (23)$$

Assuming a finite sampling time, T_o, we may expand this in a Fourier series:

$$V_s(t) = \sum_{n=0}^{\infty} \{\alpha_n \cos(\omega_n t) + \beta_n \sin(\omega_n t)\}, \quad (24)$$

where $\omega_n=2\pi n/T_o$ and where n is an integer.[22] The Fourier coefficients α_n and β_n are given as usual:

$$\alpha_n = (2/T_o)\int_o^{T_o} V_s(t) \cos(\omega_n t)dt, \quad (25a)$$

$$\beta_n = (2/T_o)\int_o^{T_o} V_s(t) \sin(\omega_n t)dt. \quad (25b)$$

By substituting Eq. 23 into these forms, the absorption component, α_n, and the dispersion component, β_n, are obtained. The absorption gives the Lorentzian line shape of Eq. 17, and its peak amplitude is:

$$\alpha_n(\omega_n = \omega_c) = (V_m/cT_o)\{(1-\exp(-cT_o)\}. \quad (26)$$

This expression quantitatively describes how the peak amplitude varies with the sampling time: The amplitude decreases as the sampling time increases. The Fourier coefficients of noise are similarly obtained by substituting a random variable, $V_n(t)$, into Eq. 25. Then, α_n and β_n also become random variables; their dispersions are given by:

$$\overline{\alpha_n^2} = \overline{\beta_n^2} = N(f_n)/T_o, \quad (27)$$

where $N(f_n)$ is the power spectrum of the noise. This result can be directly derived from the definition of Eq. 25 by assuming that the correlation time of the noise is shorter than the sampling time, T_o.[10] Equation 27 shows that, through Fourier transformation, the band-width of the noise is reduced from F to Δf and that the rms value of the noise decreases with the square root of the reciprocal of the sampling time.

By combining Eqs. 26 and 27, the S/N ratio of a spectrum of the FT method is found to be:

$$(S/N)_{1FT} = (V_m/cT_o)\{1-\exp(-cT_o)\}/(4kTR)^{1/2}. \quad (28)$$

When the resolution of a measurement is nearly equal to the true width of a resonance line, *i.e.*, $1/T_o \sim c$, this reduces to:

$$(S/N)_{1FT} \simeq V_m/(4kTR\Delta f)^{1/2}.$$

This is the same form as Eq. 10 for the CW method. Therefore, when the resolution width of a measurement is nearly equal to the true linewidth, time is saved with the FT method by a factor of $\Delta f/F$. Through ensemble averaging of the coherent addition of $(F/\Delta f)$ samples which are obtained in the time equal to one scanning time, T_s, for the CW method, the S/N ratio can be enhanced by the factor of $(F/\Delta f)^{1/2}$. This is the Fellgett S/N gain. It should be noted, however, that the full Fellgett S/N gain can be obtained only if the condition $\Delta f \simeq c/\pi$ is satisfied. For usual experiments in which an accurate peak amplitude or linewidth is needed, the resolution width should be selected to be much smaller than the linewidth, *i.e.*, $\Delta f \ll c/\pi$. Therefore, the parameter of S/N enhancement is $(F\Delta f)^{1/2}/c$ rather than the Fellgett value $(F/\Delta f)^{1/2}$.

Finally, let us summarize the relations among the S/N, the resolution, the scanning time, and the total experimental time. For the CW method, the S/N and the resolution width are given in terms of the total spectral range of interest, F, and the scanning time, T_s:

$$S/N = V_m/(4kTR\Delta f)^{1/2} = V_m T_s^{1/4}/(4kTR)^{1/2}F^{1/4},$$
$$\Delta f = (F/T_s)^{1/2}.$$

When F is constant, these forms indicate that the S/N increases as the fourth root of the scanning time and that the so-called resolution appropriately given by $1/\Delta f$ also increases in accordance with the square root of the scanning time. Thus, there is no tradeoff between the S/N and the resolution. The fourth root law of the S/N seems curious, since it is inconsistent with the well-known fact that the accuracy of a measurement (S/N) increases with the square root of the measurement time.[10] Note, however, that, for the CW method, the increase in the scanning time inevitably results in an increase in the resolution. If an experiment in which the resolution is kept constant is considered, it can be shown that the usual square-root dependence of the S/N on the total time holds: by assuming a fixed resolution of Δf, the scanning time becomes $F/(\Delta f)^2$ and S/N is given by $\alpha T_s^{1/4}F^{-1/4}$, where α is a constant and is equal to $V_m/(4kTR)^{1/2}$. Consider the total experimental time, T_t, which is much longer than T_s. In that time, (T_t/T_s) times of scans are carried out. Through the ensemble averaging of the scans, the S/N can be enhanced by a factor of $(T_t/T_s)^{1/2}$, and the overall S/N ratio becomes $\alpha T_t^{1/2}T_s^{-1/4}F^{-1/4}$. By the use of the $T_s = F/(\Delta f)^2$ relation, this is rewritten to a convenient form:

$$(S/N)_{nCW} = \alpha T_t^{1/2}(\Delta f)^{1/2}F^{-1/2}, \quad (29)$$

where the subscript n stands for the number of scans and is equal to T_t/T_s. This shows the usual square root dependence of S/N ratio on the measurement time. It is also evident that in a given time, T_t, the tradeoff between the S/N and the resolution exists. This is the usual meaning of the tradeoff. For the FT method, on the other hand, the S/N and the resolution width are geven in terms of only the sampling time, T_o:

$$S/N = (V_m/cT_o^{1/2})\{1-\exp(-cT_o)\}/(4kTR)^{1/2},$$
$$\Delta f = 1/T_o.$$

These forms show that, as T_o increases, the resolution increases and the S/N decreases. This behavior is different from that in the case of the CW method, where both the S/N and the resolution increases with the scanning time. Consider also an experiment in this time where the resolution is held constant. In a given total experimental time, T_t, which is much longer than T_o, (T_t/T_o) times of FD signals are obtained, so that the S/N can be enhanced by a factor of $(T_t/T_o)^{1/2}$. Then, the overall S/N ratio becomes:

$$(S/N)_{nFT} = (V_m T_t^{1/2}\Delta f)\{1-\exp(-cT_o)\}/c(4kTR)^{1/2}, \quad (30)$$

where the subscript n is again the number of transients and is equal to T_t/T_o. This form again indicates the usual square root dependence of the S/N ratio on the total time and the tradeoff between the S/N and the resolution. However, the S/N is proportional to Δf for the FT method, so the tradeoff is more marked than for the CW method, where the S/N is proportional to the square root of Δf.

Discussion

We have shown in the previous section that the tradeoff between the S/N and the resolution is marked for the FT method. Marshall also discussed the tradeoff by considering the FD signals and the noise averaged over the sampling time, though he did not explicitly treat the Fourier transformation of the noise.[16] He obtained an expression describing the behavior of the relative S/N ratio vs. the sampling time, which is essentially the same as Eq. 30 in the present manuscript. More recently, however, a paper has appeared which reported that the tradeoff was not observed and that the S/N and the resolution simultaneously increased with the FT ICR.[14] Note that the simultaneous increase in the S/N and the resolution was obtained by lowering the sample pressure in that paper. The tradeoff should be referred to the method of measurements when the physical states of systems, for example, the sample pressure, are kept constant. It seems misleading to say that the S/N and the resolution simultaneously increase without the tradeoff, since the tradeoff between the S/N and the resolution has wide acceptance in physical measurements.

We shall next consider the so-called exponential filter. The operation of multiplying free-induction decay signals by an exponential function is called either "the exponential filter" or "the matched filter".[3,23,24] It seems inappropriate, however, to call such an operation a "filter" at all, since a filter is what carries out a convolution operation on time-domain signals to lower noise levels. Convolution in the time domain

corresponds to multiplication in the frequency domain. As we have seen in the previous section, through Fourier transformation the effective band-width of noise is reduced to a resolution width which is usually very narrow compared to the original band-width of noise in the time domain, so that the noise level is reduced. The so-called exponential filter carries out, on signals in each domain, the operation opposite to that of usual filters. It is evident that the convolution operation on a spectrum in which the noise level has already been reduced to a resolution width will not effectively improve the S/N ratio without leading to additional line-broadening.

Both ICR and NMR belong to radio-frequency spectroscopy, and there are many similarities between them. It would be useful to utilize such similarities. Among several techniques with the Fellgett advantage, the stochastic excitation method has not yet been applied to ICR. This method was, however, applied to NMR by Ernst, and thereby it was noted that it has a unique feature that the S/N and the resolution can be separately optimized.[4] Since the tradeoff between the S/N and the resolution seems general, however, it would be necessary to examine this method closely. The analysis of the S/N and the resolution in the present paper is general, and it can also be applied to NMR with a little modification. The Fellgett advantage can be obtained in various branches of spectroscopy, since it results essentially from the simultaneous excitation and simultaneous observation of all frequency channels.[25]

The author would like to thank Professor Masao Inoue for reading the manuscript. He also wishes to thank Professor Shizuo Fujiwara for his continuing interest and encouragement. Professor Yoji Arata offered many helpful discussions.

Enthalpy of Oxidation-Reduction for the Ethylenediaminetetraacetatocobaltate(III/II) Couple Relative to the Hydrogen Ion Formation

Kunio Doi

Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received December 17, 1981)

Oxidation of ethylenediaminetetraacetatocobaltate(II) with permanganate ion has been studied spectrophotometrically. The first step in the oxidation is the rapid formation of $[Co^{III}(edta)(H_2O)]^-$, followed by the ring closure reaction of the complex to $[Co^{III}(edta)]^-$. On the basis of the spectrophotometric result, the enthalpies of the reactions, $[Co^{II}(edta)]^{2-}+1/5\ MnO^-_4+8/5\ H^+\rightarrow[Co^{III}(edta)(H_2O)]^-+1/5\ Mn^{2+}+4/5\ H_2O$ and $[Co^{III}(edta)(H_2O)]^-\rightarrow[Co^{III}(edta)]^-+H_2O$, have been determined at 25 °C and at an ionic strength of 0.1 by a direct thermometric titration procedure. The enthalpy of the reaction, $[Co^{III}(edta)]^-+1/2\ H_2\rightleftarrows[Co^{II}(edta)]^{2-}+H^+$, has been calculated by combining them with some other calorimetric data. The thermodynamic functions for formation of the $[Co^{III}(edta)]^-$ complex are estimated from the values so far reported. At 25 °C and at an ionic strength of 0.1 $\Delta G=-242$ kJ mol^{-1}, $\Delta H=-101$ kJ mol^{-1}, and $\Delta S=474$ J mol^{-1} K^{-1}.

The oxidation-reduction potential of a Co^{III}/Co^{II} system is reduced to a large extent in the presence of a complexing agent. It has been reported[1,2] that for the system in the presence of ethylenediaminetetraacetate(edta or L), the electrode reaction at a dropping mercury electrode is expressed by:

$$[Co^{III}(edta)]^- + e \rightleftharpoons [Co^{II}(edta)]^{2-},$$

its redox potential being reversible. The standard redox potential of the system has been determined by several authors[1-5] and furthermore, from information upon the stability constants of the Co(II)-edta complex and the standard redox potential of the $[Co(H_2O)_6]^{3+}/[Co(H_2O)_6]^{2+}$ couple,[6] the stability constant of the Co(III)–edta complex has been calculated. No thermodynamic function, however, has been reported for the $[Co^{III}(edta)]^-/[Co^{II}(edta)]^{2-}$ couple or the formation of the Co(III)–edta complex. Usually, the enthalpies of formation of Co(III) complexes can not be measured directly by a calorimetric method because they are substitution-inert. Cobalt(II) complexes are oxidized rapidly to form the corresponding Co(III) complexes. This is the case also for the edta complexes.[7,8] It is possible to measure heats of such rapid oxidation reactions by a calorimetric method and thus to obtain some information on the difference in enthalpies of the $[Co^{III}(edta)]^-/[Co^{II}(edta)]^{2-}$ couple, and thus, the enthalpy of formation of the Co(III)–edta complex. The present paper provides such information by determining the heat of oxidation of the Co(II)–edta complex with permanganate ion.

Experimental

Materials. The reagents used were Katayama super special grade potassium permanganate, Wako primary standard sodium oxalate, and Ventron iron(II) perchlorate. All other reagents used were of guaranteed reagent grade except for potassium nitrate and sodium perchlorate which were the same as described elsewhere,[9] while $K[Co^{III}(edta)]\cdot 2H_2O$[10] was prepared by the procedure described in the literature. The cobalt content of the complex was determined complexometrically[11] after thermal decomposition of the complex with perchloric and hydrochloric acids, the analytical value being 99.91% of the calculated value.

A stock solution of approximately 0.1 mol dm^{-3} in $Fe(ClO_4)_2$ and 0.2 mol dm^{-3} in $HClO_4$ was prepared and standardized against a 0.02 mol dm^{-3} solution of potassium permanganate, which was standardized against the primary standard sodium oxalate. Stock solutions of other metal ions were standardized by means of EDTA titrations.[11]

Measurements. All the measurements were made at 25.0 °C. The ionic strength of the solutions was maintained at 0.1 with potassium nitrate or sodium perchlorate. A Corning model 12 pH meter was used, the electrode system being standardized with the NBS standard buffer solutions. The pH values were converted to hydrogen ion concentrations by using an activity coefficient value of 0.782.[12]

Visible spectra were recorded on a Nippon Bunko UVIDEC-1 Spectrophotometer or a UNION High Sensitivity Spectrophotometer SM-401 with a thermostated cell compartment.

The titration calorimeter used was the same as described elsewhere.[13] The experimental procedure is described below with the treatment of thermograms. Once thermal equilibrium was established (temperature drift less than 2×10^{-4} °C for 10 min), a titrant (1—3 cm^3) was added to 130.0 cm^3 of a solution at a constant rate of 1.11 cm^3 min^{-1}, and the temperature change, ΔT, was recorded as a function of time, t. The ΔT *vs.* t curve recorded consisted of three parts: preperiod; titration period; afterperiod (for 10 min). Calibration was performed by using a standard heater set in the titration cell after each titration, the ΔT *vs.* t curve similarly consisting of three parts: preperiod; Joul heating period; afterperiod.

Upon heating by an electric heater at the rate of q' expressed in kJ s^{-1}, the ΔT *vs.* t curve is expressed by: $d(\Delta T)/dt=q'/C-\alpha(\Delta T)$ where α expressed in s^{-1} is Newton's cooling constant, which is considered to be constant during the heat measurements (for *ca.* 13 min), and C expressed in kJ K^{-1} is the heat capacity of the calorimeter vessel with its content of solution. The ΔT *vs.* t curve for the afterperiod is expressed by: $d(\Delta T)/dt=-\alpha(\Delta T)$. Solving two differential equations mentioned above, we obtained the following equation for the afterperiod: $\Delta T=q'(1-e^{-\alpha t_1})\times e^{-\alpha t}/\alpha C$, where t_1 is heating time. The values of α and C were refined by means of a least-squares method with a successive approximation. Reproducibilities of α and C obtained by analysis of the ΔT *vs.* t curve for 10 min of the afterperiod were within ±1.5% and ±0.2%, respectively.

The enthalpy of formation of the 1:1 Mn(II) acetato complex was estimated by titration of Mn(II) with edta in an acetate buffer solution. A 0.153 mol dm^{-3} solution of the tetrasodium salt of EDTA was added at the rate of

p' expressed in mol s^{-1} to solutions containing manganese(II) nitrate (1.12×10^{-2} mol dm^{-3}) and an acetate buffer (0.1 mol dm^{-3}) in the pH range from 3.7 to 5.0, the ionic strength being kept at 0.1 (=[AcOK]+[KNO_3]). EDTA was added in each run to be 2.89×10^{-3} mol dm^{-3} at the final concentration. The ΔT *vs.* t curve for the afterperiod was obtained in a similar manner as mentioned above: $\Delta T=-\Delta H_{obsd}\times p'(1-e^{-\alpha t_2})e^{-\alpha t}/\alpha C$, where t_2 was titration time, ΔH_{obsd} expressed in kJ mol^{-1} was the observed heat change, and the C value determined by the calibration was used. The values of ΔH_{obsd} and α were refined as for calibration. The treatment of ΔH_{obsd} will be described later in more detail. The values of ΔH_{obsd} and α for titration of Co(II) with edta in an acetate buffer solution and for titration of iron(II) perchlorate with permanganate ion in 0.1 mol dm^{-3} perchloric acid were also determined by the same method.

The heat of oxidation of the Co(II)-edta complex with permanganate ion was measured on adding freshly prepared potassium permanganate solution (0.02 mol dm^{-3}) at the rate of p' (mol s^{-1}) to solutions containing edta (2.5×10^{-3} mol dm^{-3}) and Co(II) nitrate in a 1:1.1 ratio and an acetate buffer (0.1 mol dm^{-3}) in the pH range from 3.6 to 5.8, the ionic strength being kept at 0.1 (=[AcOK]+[KNO_3]). Potassium permanganate was added in each run to give a 7:1 mole ratio of edta to MnO^-_4. The observed heat change results from dilution(ΔH_D), rapid oxidation(ΔH^c_{ox}), and slow ring closure reaction(ΔH_{el}) taking place in a Dewar vessel (see below about the definition in Eqs. 1, 2, and 9). The ΔT *vs.* t curve for the titration period is expressed by: $d(\Delta T)/dt=(q'_{ox}+q'_{el})/C-\alpha(\Delta T)$ where $q'_{ox}=-(\Delta H_D+\Delta H^c_{ox})\times p'$, $q'_{el}=-\Delta H_{el}\times d\{D[Co^{III}(edta)^-]\}/dt$, and $D[Co^{III}(edta)^-]$ is the change in moles of $[Co^{III}(edta)]^-$ formed. $D[Co^{III}(edta)^-]$ was calculated from a titration speed, p', and $d[Co^{III}(edta)^-]/dt=k[Co^{III}(edta)(H_2O)^-]$ in which the rate constant of k had been determined spectrophotometrically. The ΔT *vs.* t curve for the afterperiod is expressed by: $d(\Delta T)/dt=q'_{el}/C-\alpha(\Delta T)$. The differential equations were solved by the same treatment as described elsewhere.[14] Consequently, the ΔT *vs.* t curve for the afterperiod is expressed in a simple form: $\Delta T=-\Delta H_{mes}\times f(t)-\Delta H_{el}\times g(t)$, where $\Delta H_{mes}=\Delta H_D+\Delta H^c_{ox}$ and both $f(t)$ and $g(t)$ are a function of time. The values of ΔH_{mes} and ΔH_{el} were refined by means of a least-squares method. The values of C and α determined by calibration were used in the calculation of $f(t)$ and $g(t)$. The effective enthalpy of the oxidation, ΔH^c_{ox}, was obtained by subtracting ΔH_D from ΔH_{mes}.

Results

Oxidation of Co(II)–edta Complex with Permanganate Ion. Equilibrium data[15–17] so far reported indicate that the oxidation of the Co(II)–edta complex with permanganate ion or manganese dioxide in an acetate buffer solution produces the Co(III)–edta complex and Mn(II) ion as the final products. In the present reaction systems the following equilibrium is anticipated:

$$[Co^{II}(edta)]^{2-} + [Mn^{III}(edta)(H_2O)]^- \rightleftharpoons [Co^{III}(edta)]^- + Mn^{2+} + edta.$$

Judging from the equilibrium constant obtained for the reaction, the Mn(III)–edta complexes could be excluded under our experimental conditions. It is well known, however, that permanganate ion is powerful enough to oxidize EDTA molecules directly. For example, the absorbance at 527 nm of permanganate ion (0.3 mol cm^{-3}) was reduced to 70% of its initial value after 1 h at 25 °C and pH 4.5 in the presence of an excess EDTA (1.0 mol cm^{-3}). The decrease in absorbance, however, was little affected by the further addition of Zn(II) or Ni(II) to excess (3.0 mol cm^{-3}), where the absorbance decreased by less than 1.5% after 1 h. It is apparent that the addition of Zn(II) and Ni(II) prevent the oxidation of EDTA by forming edta complexes. The Co(III)–edta complexes were formed immediately when the reactants were mixed and thus, there would not occur the oxidation of, at least, free EDTA with permanganate ion under our experimental conditions.

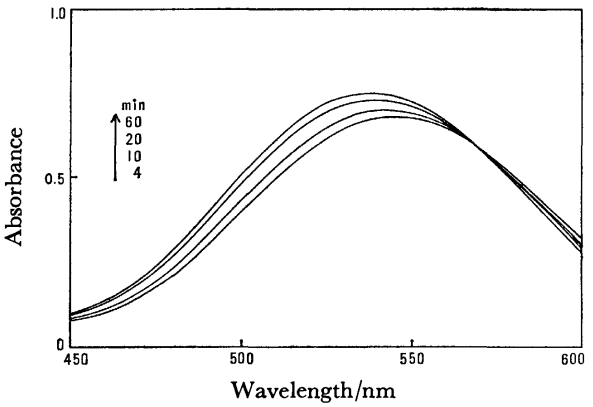

Fig. 1. The change of absorption spectrum with time after mixing Co(II)–edta complex with permanganate ion at pH 4.0.
$C_{Co(II)}=2.7$ mol cm^{-3}; $C_{EDTA}=2.5$ mol cm^{-3}; $C_{MnO_4}=0.47$ mol dm^{-3}.

The change in the absorption spectrum with time after mixing of the reactants is shown in Fig. 1. The wavenumbers of the absorption maxima at time zero and infinite time coincided with those of $[Co^{III}(edta)(H_2O)]^-$ ($\lambda_{max}=550$ nm)[8] and $[Co^{III}(edta)]^-$ ($\lambda_{max}=538$ nm),[18] respectively. The plot of the absorbance (538 nm) at infinite time against $5\times[MnO^-_4]/[Co(II)L]$ obtained under the condition as for Fig. 1 gave an inflection point at a ratio of 1.00 where minimum amounts of hydroxylamine required to reduce excess permanganate ions were added at the ratio more than 1.00. This indicates that little of the EDTA is lost and thus the following stoichiometry of the oxidation is held: 5Co(II)L+Mn(VII)→5Co(III)L+Mn(II). In addition, the molar absorptivity of the final product was derived to be 320 mol^{-1} dm^3 cm^{-1} by correcting for remaining reactants, the value being in agreement with that of $K[Co^{III}(edta)]\cdot2H_2O$ prepared in this work ($\varepsilon_{max}=320$ mol^{-1} dm^3 cm^{-1}) and reported by Ogino, *et al.*[18] ($\varepsilon_{max}=321$ mol^{-1} dm^3 cm^{-1}). It is concluded that the oxidation of Co(II)–edta complex with permanganate ion rapidly proceeds to give $[Co^{III}(edta)(H_2O)]^-$ in quantitative yields and then the five-coordinate edta in the complex slowly becomes six-coordinate in the final product:

$$[Co^{II}(edta)]^{2-} + \tfrac{1}{5}MnO_4^- + \tfrac{1}{5}H^+ \longrightarrow [Co^{III}(edta)(H_2O)]^- + \tfrac{1}{5}Mn^{2+} + \tfrac{4}{5}H_2O \quad \Delta H_{ox}, \quad (1)$$

$$[Co^{III}(edta)(H_2O)]^- \xrightarrow{k} [Co^{III}(edta)]^- + H_2O \quad \Delta H_{el}, \quad (2)$$

where ΔH_{ox} is the enthalpy of Reaction 1 expressed in kJ mol^{-1} of [Co (edta)(H_2O)]$^-$, and ΔH_{el} the enthalpy of Reaction 2 expressed in kJ mol^{-1} of [Co^{III}-(edta)]$^-$. Reaction 2 is first order in [Co^{III}(edta)-(H_2O)]$^-$ concentration. Shimi and Higginson[19] determined the first-order rate constant, k, in the range of 0—15 °C. The rate constant of 1.6×10^{-3} s^{-1} estimated by extrapolation of the plot of k *vs.* $1/K$ to 25 °C was in good agreement with that determined in the present reaction systems (1.61×10^{-3} s^{-1} at 25 °C).

Treatment of Observed Heat Change. Reaction 1 occurs accompanying the following side reactions:

$$[Co^{II}(edta)^{2-} + H^+ \rightleftharpoons [Co^{II}(Hedta)]^- \quad K=10^{3.0},\ \Delta H_3=-8.0, \quad (3)^{16}$$

$$Mn^{2+} + AcO^- \rightleftharpoons [Mn(AcO)]^+ \quad K=10^{0.5},\ \Delta H_4, \quad (4)^{20}$$

$$[Mn(AcO)]^+ + AcO^- \rightleftharpoons Mn(AcO)_2 \quad K=10^{0.9}, \quad (5)^{20}$$

$$Co^{2+} + AcO^- \rightleftharpoons [Co(AcO)]^+ \quad K=10^{1.1},\ \Delta H_6, \quad (6)^{20}$$

$$[Co(AcO)]^+ + AcO^- \rightleftharpoons Co(AcO)_2 \quad K=10^{0.4}, \quad (7)^{20}$$

$$H^+ + AcO^- \rightleftharpoons AcOH \quad K=10^{4.54},\ \Delta H_8=-0.17, \quad (8)^{13}$$

where K represents the equilibrium constant for the relevant reaction expressed in dm^3 mol^{-1} and ΔH the enthalpy expressed in kJ mol^{-1}. The values of K and ΔH reported in the relevant literature are used in this calculation, except for ΔH for Reactions 4—7 which are mentioned below. The measured heat, ΔH^c_{ox}, is given by:

$$\Delta H^c_{ox} = \Delta H_{ox} + \Delta H^c_3 + \Delta H^c_4 + \Delta H^c_6 + \Delta H^c_8, \quad (9)$$

where

$$\Delta H^c_3 = \Delta H_3 \times D[Co^{II}(Hedta)^-]/D[Co^{III}(edta)(H_2O)^-], \quad (10)$$

$$\Delta H^c_4 = \Delta H_4 \times \{D[Mn(AcO)^+] + D[Mn(AcO)_2]\}/D[Co^{III}(edta)(H_2O)^-], \quad (11)$$

$$\Delta H^c_6 = \Delta H_6 \times \{D[Co(AcO)^+] + D[Co(AcO)_2]\}/D[Co^{III}(edta)(H_2O)^-], \quad (12)$$

$$\Delta H^c_8 = \Delta H_8 \times D[AcOH]/D[Co^{III}(edta)(H_2O)^-], \quad (13)$$

and $D[\ ]$ is the change in moles of species given in brackets for each titrant addition and is calculated from the stoichiometric relationships by using equilibrium constants for Reactions 3—8. Thus, the heat contribution due to Reaction 1 is calculated:

$$\Delta H_{ox} = \Delta H^c_{ox} - \Delta H^c_3 - \Delta H^c_4 - \Delta H^c_6 - \Delta H^c_8. \quad (14)$$

A typical thermogram for titration of the Co(II)–edta complex with permanganate ion is shown in Fig. 2. In this case, ΔH^c_{ox} of -100.8 kJ mol^{-1} and ΔH_{el} of 4.4 kJ mol^{-1} were obtained. A plot of ΔH^c_{ox} *vs.* the final pH of the solution for each titration is shown in Fig. 3. The ΔH_{ox} values obtained over the pH range from 3.9 to 5.8 average -101.4 kJ mol^{-1} (solid line 1). Solid line 2 for ΔH^c_{ox} is the best fit line recalculated by using the average value of ΔH_{ox}. The calculated values of ΔH^c_8 were less than 0.03 kJ mol^{-1} over the pH range shown in Fig. 3. The broken line for ΔH^c_{ox}, which was measured at an ionic strength of 0.1 (=[AcONa]+[$NaClO_4$]), was lower than the solid line 2 by only *ca.* 0.5 kJ. In a solution of a low acetate concentration and an ionic strength, the effect of supporting electrolytes on ΔH^c_{ox} seems unimportant. The pH dependence of the ΔH_{el} values obtained at the same time could not be found in the pH region of 4.0 to 5.8 owing to the experimental errors. The ΔH_{el} value was determined to be 4.4 ± 0.8 kJ mol^{-1}.

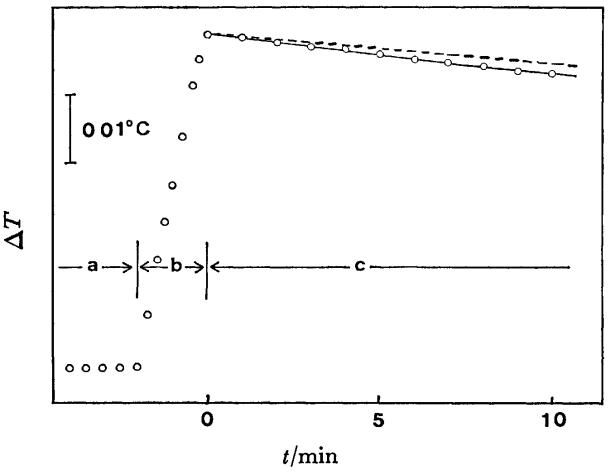

Fig. 2. Thermogram for the addition of permanganate ion to Co(II)–edta complex at pH 5.09. $C_{Co(II)}=2.8$ mol cm^{-3}, $C_{EDTA}=2.5$ mol cm^{-3}; $C_{MnO_4}=0.38$ mol cm^{-3}. a: Preperiod, b: titration period, c: afterperiod. $\alpha=1.74\times10^{-4}$ s^{-1}; $k=1.61\times10^{-3}$ s^{-1}. Solid line is the best fit one calculated from the enthalpies ΔH_{mes} and ΔH_{el}. Broken line is the presumed curve calculated with $\Delta H_{el}=0$.

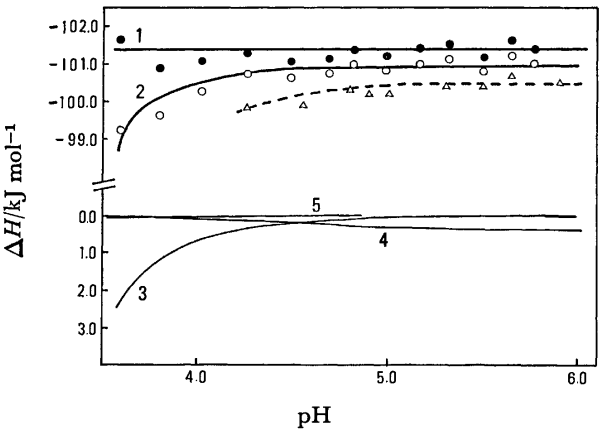

Fig. 3. ΔH^c_{ox} *vs.* the final pH of solution. Conditions as for Fig. 2.
○: ΔH^c_{ox} measured at $\mu=0.1$ (=[AcOK]+[KNO_3]), △: ΔH^c_{ox} measured at $\mu=0.1$ (=[AcONa]+[$NaClO_4$]), ●: ΔH_{ox} calculated according to Eq. 14. The solid lines represent: (1) the average value of ΔH_{ox}; (2) ΔH^c_{ox} recalculated with the average value of ΔH_{ox}; (3) ΔH^c_3; (4) ΔH^c_4; (5) ΔH^c_8.

The enthalpies of formation of the acetato complexes were mostly determined at an ionic strength of 1.0 or 3.0. As little knowledge of the enthalpy values determined in lower ionic media is available, the value for Mn(II) acetato complexes was estimated by titration of Mn(II) in 0.1 mol dm^{-3} acetate buffer solutions with the tetrasodium salt of EDTA. The observed heat, ΔH_{obsd}, refers to the process:

$$Mn^{2+\prime} + L(titrant) \longrightarrow Mn(II)L' \quad \Delta H_{obsd}, \quad (15)$$

where $[Mn^{2+\prime}]=[Mn^{2+}]+[Mn(AcO)^+]+[Mn(AcO)_2]$ and $[Mn(II)L']=[Mn^{II}(edta)^{2-}]+[Mn^{II}(Hedta)^-]$. The process of Eq. 15 comprises that of dilution of 0.153 mol dm^{-3} Na_4edta (Eq. 16) and formation of $[Mn^{II}(edta)]^{2-}$ complex (Eq. 17):

$$L(titrant) \longrightarrow edta \quad \Delta H_D, \quad (16)$$

$$Mn^{2+} + edta \rightleftharpoons [Mn^{II}(edta)]^{2-} \quad \Delta H_{17}, \quad (17)$$

in which Reaction 17 accompanies Reactions 4, 5, and 8 and furthermore the following side reaction:

$$[Mn^{II}(edta)]^{2-} + H^+ \rightleftharpoons [Mn^{II}(Hedta)]^- \quad K=10^{3.1},\ \Delta H=-5.0, \quad (18)^{16}$$

where K and ΔH are defined as for Eqs. 3—8. In such solutions containing 0.1 mol dm^{-3} acetate buffer, the 1:2 acetato complex is not present in amounts sufficient enough to permit the determination of the enthalpy value. Thus, the heat contribution due to stepwise formation of the 1:2 acetato complex is neglected as for Eq. 9 (*cf.* Eq. 11). The observed heat is corrected for ΔH_D, the value of which has been determined by the same method as described elsewhere.[9] Then, the following equations are obtained:

$$\begin{aligned}\Delta H_{cor} &= \Delta H_{obsd} - \Delta H_D \\ &= \Delta H_{17} + \Delta H_4^\circ + \Delta H_{18}^\circ + \Delta H_8^\circ \\ &= \Delta H_{17} + \Delta H_4 \times \{D[Mn(AcO)^+] \\ &\quad + D[Mn(AcO)_2]\}/D[Mn(II)L'] + \Delta H_{18}^\circ + \Delta H_8^\circ, \end{aligned} \quad (19)$$

where

$$\Delta H_4^\circ = \Delta H_4 \times \{D[Mn(AcO)^+] + D[Mn(AcO)_2]\}/D[Mn(II)L'],$$

$$\Delta H_{18}^\circ = \Delta H_{18} \times D[Mn^{II}(Hedta)^-]/D[Mn(II)L'],$$

$$\Delta H_8^\circ = \Delta H_8 \times D[AcOH]/D[Mn(II)L'],$$

$$D[Mn(II)L'] = D[Mn^{II}(edta)^{2-}] + D[Mn^{II}(Hedta)^-].$$

A least-sequares analysis is performed to provide ΔH_{17} and ΔH_4 in Eq. 19. A plot of ΔH_{cor} *vs.* the final pH of the solution for each titration is shown in Fig. 4. The best fit line was calculated by using the values, $\Delta H_{17}=-18.7$ kJ mol^{-1} and $\Delta H_4=6.3$ kJ mol^{-1}. The broken lines are for each ΔH on the right hand side of Eq. 19. The ΔH_8° values were less than 0.05 kJ mol^{-1} over the pH range shown in Fig. 4. The enthalpy of formation of the 1:1 Co(II) acetate complex was estimated to be 2.3±0.3 kJ mol^{-1} by the same method as above, from which the ΔH_6° values in Eq. 9 were calculated to be less than 0.07 kJ mol^{-1}.

The heat of oxidation of iron(II) ion with permanganate ion was measured in 0.1 mol dm^{-3} $HClO_4$. For the reaction

$$Fe^{2+} + \tfrac{1}{5}MnO_4^- + \tfrac{8}{5}H^+ \longrightarrow Fe^{3+} + \tfrac{1}{5}Mn^{2+} + \tfrac{4}{5}H_2O \quad \Delta H_{20}, \quad (20)$$

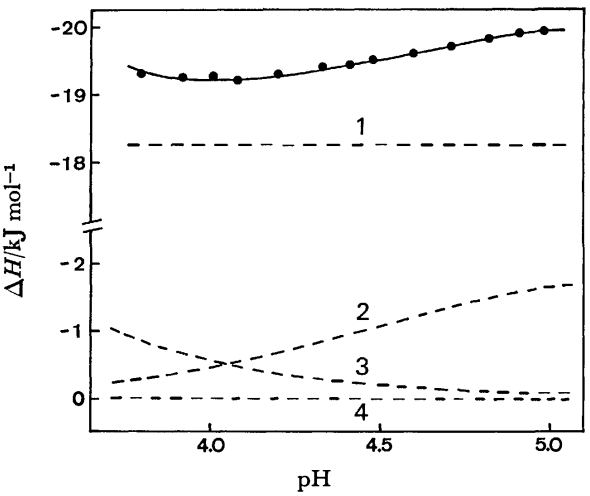

Fig. 4. ΔH_{cor} *vs.* the final pH of solution. $C_{Mn(II)}=11.0$ mol cm^{-3}; $C_{EDTA}=2.9$ mol cm^{-3}. ●: ΔH_{cor} measured at $\mu=0.1$ (=[AcOK]+[KNO_3]). Solid line is the best fit one calculated from the enthalpies ΔH_{17} and ΔH_4. The broken lines represent: (1) ΔH_{17}; (2) ΔH_4°; (3) ΔH_{18}°; (4) ΔH_8°.

we determined $\Delta H_{20}=-123.9\pm0.7$ kJ mol^{-1} of Fe^{3+}, in which the following side reaction was considered:

$$Fe^{3+} + H_2O \rightleftharpoons FeOH^{2+} + H^+ \quad K=10^{-2.50},\ \Delta H=42.3. \quad (21)^{13}$$

Discussion

A solution containing $[Co^{II}(edta)]^{2-}$ and $[Co^{III}(edta)]^-$ exhibits a reversible potential at a dropping mercury electrode.[2] It is possible to measure the standard redox potential, E°, with the solutions containing varied concentrations of $[Co^{II}(edta)]^{2-}$ and $[Co^{III}(edta)]^-$ complexes. For the reaction

$$[Co^{III}(edta)]^- + \tfrac{1}{2}H_2 \rightleftharpoons [Co^{II}(edta)]^{2-} + H^+, \quad (22)$$

the ΔG value is calculated from E° value determined by several authors[1-5] by use of the relation, $\Delta G=nFE^\circ$. On the other hand, the products formed by oxidation of the Co(II)–edta complexes with a variety of oxidants are not always the same as that by the electrode oxidation; the Co(II)–edta complexes are oxidized to form Co(III)–edta complexes containing five- or six-coordinate edta, or their mixture.[7,8] It was found that the oxidation by permanganate ion produced $[Co^{III}(edta)(H_2O)]^-$ under our experimental conditions, followed by the ring closure reaction of the complex to $[Co^{III}(edta)]^-$. For the reaction

$$[Co^{II}(edta)]^{2-} + \tfrac{1}{5}MnO_4^- + \tfrac{8}{5}H^+ \longrightarrow [Co^{III}(edta)]^- + \tfrac{1}{5}Mn^{2+} + \tfrac{4}{5}H_2O, \quad (23)$$

at an ionic strength of 0.1, therefore, we obtained $\Delta H=-97.0$ kJ mol^{-1} from the sum of ΔH values for Reactions 1 and 2. In order to convert a ΔH for the reaction to one for Reaction 22, the ΔH and ΔH_f° values mentioned below were adopted. For the reaction

$$Fe^{2+} + \tfrac{1}{2}H_2O_2(aq) + H^+ \longrightarrow Fe^{3+} + H_2O, \quad (24)$$

in 0.1 mol dm^{-3} $HClO_4$, Irving, *et al.*[21] obtained

$\Delta H = -146.0 \pm 0.8$ kJ mol^{-1}. Correcting it for the side reaction 21, we obtained $\Delta H = -147.3$ kJ mol^{-1}. Combination of this value with the standard enthalpies of formation of $H_2O(l)$ and $H_2O_2(aq)$ listed in N. B. S. Technical Notes[22] leads to $\Delta H = -43.0$ kJ mol^{-1} for the following reaction:

$$Fe^{3+} + \tfrac{1}{2}H_2(g) \rightleftharpoons Fe^{2+} + H^+. \quad (27)$$

A $\Delta H°$ of -42 kJ mol^{-1} or -40.6 kJ mol^{-1} for the reaction was recommended without consideration of ionic strength by Hepler, *et al.*[23] and in N. B. S. Technical Notes,[22] respectively. It is still difficult to estimate the effect of ionic strength on ΔH for the reaction from data so far reported. A ΔH of -69.9 kJ mol^{-1} for Reaction 22 was obtained from ΔH for Reactions 20, 23, and 27. ΔG for Reaction 22 was calculated to be -37.1 kJ mol^{-1} by use of $E° = 0.384$ V[1] (*vs.* NHE) measured at an ionic strength of 0.1 and then, the ΔS value was calculated to be -110 J mol^{-1} K^{-1}.

Reaction 22 comprises the following reactions:

$$Co^{3+} + \tfrac{1}{2}H_2 \rightleftharpoons Co^{2+} + H^+, \quad (28)$$

$$Co^{2+} + \text{edta} \rightleftharpoons [Co^{II}(\text{edta})]^{2-} \quad K = 10^{16.23},\ \Delta H = -17.6, \quad (29)[16]$$

$$Co^{3+} + \text{edta} \rightleftharpoons [Co^{III}(\text{edta})]^-. \quad (30)$$

Thus, it is possible to calculate the ΔH value for Reaction 30 by use of the ΔH values for Reactions 22, 28, and 29. But the exact values of ΔG and ΔH at low ionic strengths for Reaction 28 have not been yet estimated from the appropriate data. For the reaction

$$Co^{3+} + Fe^{2+} \longrightarrow Co^{2+} + Fe^{3+}, \quad (31)$$

in 4 mol dm^{-3} $HClO_4$ at 15 °C, Johnson and Sharpe[24] determined $\Delta H = -110$ kJ mol^{-1} by a direct calorimetric measurement. They combined it with the estimated entropy change (13 J mol^{-1} K^{-1}) to obtain ΔG of -114 kJ mol^{-1} at 15 °C. Neglecting a temperature dependence of ΔH, we obtained ΔG of -114 kJ mol^{-1} ($\Delta E = E°_{28} - E°_{27} = 1.18$ V) at 25 °C by the same manner. Combining it with the formal Fe^{3+}/Fe^{2+} potential of 0.749 V[25] at 25 °C and at an ionic strength of 0.1, we obtained the formal Co^{3+}/Co^{2+} potential of 1.93 V (*vs.* NHE) and thus ΔG of -186 kJ mol^{-1} for Reaction 28. Similarly the variation of ΔH for two half cell reactions involved in Eq. 31 with ionic strengths would adequately compensate each other because of the close similarity in size and charge of the pair of ions. Thus, the ΔH value for Reaction 28 was obtained to be -153 kJ mol^{-1} by summation of the ΔH values for Reactions 27 and 31 and thus the ΔS value was calculated to be -111 J mol^{-1} K^{-1}. The entropy change accompanying Reaction 28 can be represented by:

$$\Delta S° = \bar{S}°_{Co^{2+}} + \bar{S}°_{H^+} - \bar{S}°_{Co^{3+}} - \tfrac{1}{2}\bar{S}°_{H_2}, \quad (32)$$

where $\bar{S}°$ is the standard partial molal entropy of the species involved. $\Delta S°$ is approximate to ΔS and thus the $\bar{S}°_{Co^{3+}}$ values is calculated to be -290 J mol^{-1} K^{-1} by combining ΔS with $\bar{S}°_{Co^{2+}}$ and $\bar{S}°_{H_2}$ listed in N. B. S. Technical Notes.[22] The formal Co^{3+}/Co^{2+} potential of 1.84 V (*vs.* NHE) was determined at 25 °C and 3 mol dm^{-3} HNO_3 by use of a gold electrode,[26] the value being commonly used as that at ionic strengths of 0.1—0.2 in calculations[1-5] of the formation constants of the Co(III)-aminopolycarboxylate complexes. Combination of the ΔG value calculated from the potential with the ΔH value selected for Reaction 28 leads to the $\bar{S}°_{Co^{3+}}$ value of -260 J mol^{-1} K^{-1}. This value seems to be too low compared with the $\bar{S}°$ values of Fe^{3+} ion, which is similar to the size, mass, and charge of Co^{3+} ion, currently accepted: -316 (N. B. S.),[22] -293 (Latimer),[27] and -280 J mol^{-1} K^{-1} (Hepler).[23] From the ΔG and ΔS values determined for Reaction 22 and selected for Reactions 28 and 29, we obtained ΔG of -242 kJ mol^{-1} and ΔH of -101 kJ mol^{-1} as the most probable values for Reaction 30. Thus, the ΔS value was calculated to be 474 J mol^{-1} K^{-1}.

It was reported by Staveley[28] that a plot of ΔS for the formation of the metal(III)-edta complexes against the reciprocal of the ionic radius, r, of metal ion gave a curve with upward curvature. The ΔS values selected by Martell and Smith[16] were replotted against $1/r$, taken from Ahren's table,[29] the value for the Co(III) complex being situated upward the curvature only by *ca.* 30 J mol^{-1} K^{-1}. On the other hand, the ΔH value for the Co(III)-edta complex is much more exothermic than that for the metal(III)-edta complexes so far reported; ΔH of -30.1 kJ mol^{-1} for the In(III)-edta complex has been reported as the most exothermic ΔH value. It is reasonable to conclude, therefore, that the formation of the Co(III)-edta complex exhibits a normal entropy change, which is explained by the size and charge of the ion, together with that of other metal(III) complexes, whereas the enthalpy change for formation of the Co(III)-edta complex causes the complex to be the most stable of the metal(III)-edta complexes.

In a previous paper[13] ΔH of -11.5 kJ mol^{-1} and ΔS of 440 J mol^{-1} K^{-1} were reported for the formation of the Fe(III)-edta complex. The ΔS value for the Co(III) complex is somewhat higher than that for the Fe(III) complex. This would arise from the difference in the number of water molecules displaced from the coordination sphere of the aqua ion by the complex formation; Co^{3+} ion forms hexacoordinate complex, $[Co^{III}(\text{edta})]^-$, with edta, while Fe^{3+} ion forms heptacoordinate complex, $[Fe^{III}(\text{edta})(H_2O)]^-$.[30,31] The favorable enthalpy effect for formation of the Co(III)-edta complex is compatible with the facts that in the solid state the Co(III)-N bond-length (1.93 Å)[32] of the hexacoordinate Co(III)-edta complex is much shorter than the Fe(III)-N bond-length (2.32 Å)[33] of the heptacoordinate Fe(III)-edta complex and that Co^{3+} forms a low-spin complex with edta,[34] while Fe^{3+} forms a high-spin complex in weakly acid solution.[35] The redox potentials of the Co^{III}/Co^{II} and Fe^{III}/Fe^{II} systems are reduced from 1.93 V to 0.38 V and from 0.749 V to 0.12 V,[36] respectively, in the presence of EDTA. The larger decrease in the potential of the Co^{III}/Co^{II} system is caused by the enthalpy effect for formation

of the Co(III)–edta complex because the thermodynamic functions for formation of the Co(II)– and Fe(II)–edta complexes are similar to each other.[16]

The Sensitization Effect in the Laser-induced Infrared Fluorescence Spectroscopy by Addition of a Second Component. II

Yasuhiro KAGAWA, Seiichiro HIGUCHI,* and Shigeyuki TANAKA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 3, 1981)

A considerable degree of the sensitization is realized in the laser-induced infrared fluorescence spectra when some of the alkene compounds are mixed with an objective sample in the gas phase. This sensitization effect has been examined quantitatively for diethyl ether when ethylene or propylene is added as a second component. The 8.7 μm band of ether is used as a key band. The degree of sensitization is abruptly enhanced with lowering the concentration of diethyl ether, and at about 0.1 Torr† of the sample the intensities per unit concentration become about 150 and 50 times greater for ether–ethylene and ether–propylene systems, respectively compared with that without ethylene or propylene. A possibility of a new vibrational spectroscopy with high sensitivity and its applications to microanalysis are suggested.

Recently we have developed a measurement system for the laser-induced infrared fluorescence (IR-F) spectra, and begun to examine its analytical applications.[1] During this investigation, the intensities of IR-F bands of some organic compounds were found to be enhanced remarkably when propylene was added as a second component. In a previous paper,[2] we made a preliminary report on the experimental evidence of this sensitization effect. Since this effect comes out as the increase of the intensities per unit concentration, the phenomenon in question is interesting and attractive in view of not only pure scientific aspects but also analytical applications of the IR-F spectroscopy.

The IR-F spectroscopy is a new technique for measurements of vibrational spectra. Experimentally, it is based on the irradiation of a sample by a monocharomatic or quasi-monochromatic laser light. The sample is vibrationally excited to the various vibrational levels through some mechanisms. Thus, the IR-F spectrum which is a kind of infrared emission spectrum, is obtained. It is to be noted that the IR-F spectra are different from the usual fluorescence spectra based on the electronic transitions in that the signals of IR-F appear not only in the longer wavelength region but also in the shorter one than the wavelength of the exciting laser lines. This specific character of the IR-F has not completely been elucidated, though several possible mechanisms are proposed.[3,4] The main reason is that the emission mechanism of the IR-F spectrum is not fully explained at present.

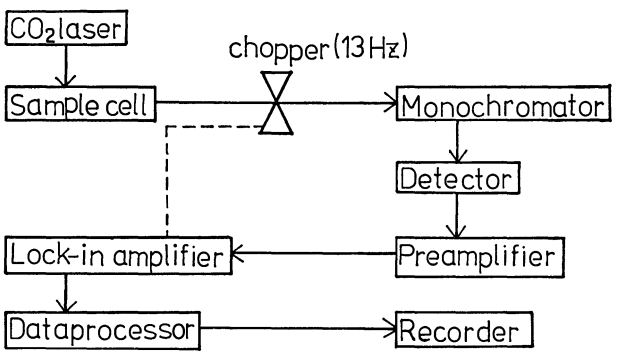

Fig. 1. The block diagram of the measurement system of IR-F spectra.

† 1 Torr≈133.322 Pa.

Under these circumstances, we are not in a position to make a satisfactory explanation about the phenomenon either. Therefore, only the experimental results are presented and they are discussed from the viewpoint of analytical utility. That is, after presenting a preliminary paper,[2] we have made a more detailed and quantitative experimental investigation on the sensitization effects of ethylene and propylene as the second component, which will be described in this paper.

Experimental

In Fig. 1 is shown the block diagram of the measurement system for IR-F spectroscopy, developed in our laboratory. The details for the essential elements composing this system were described in the previous paper.[1]

In this system, the sample in the sample cell is irradiated with the 10.6 μm lines from a CO_2 laser (output power: about 3 W). Then, the vibrationally excited sample emits the fluorescence light, and a part of this light going out from the cell in the direction perpendicular to that of the laser beam is modulated with a chopper of the frequency of 13 Hz. This frequency, which is adopted in commonly used infrared spectrophotometers, is selected rather arbitrarily and it is not certain whether it is optimal or not. This problem is left to be examined in the future. This chopped emission is sent into a monochromator and spectrally measured. The signals from a detector (MCT semiconductor detector) are discriminated and amplified with a lock-in amplifier. Finally, the signals are processed with a data processor containing a microcomputer, and then, they are recorded out. The IR-F spectra are all measured with the mechanical slit width fixed at 3.0 mm. The resolutions are 0.05, 0.06, 0.07, 0.08, and 0.08 μm at the wavelengths, 12.0, 10.0, 8.0, 6.0, and 5.0 μm, respectively. The scanning speed was about 5 μm/min, and the number of the repetitive scans was 16 or 32.

All of the spectra were measured for the samples in the gaseous state. The pressures or the partial pressures of samples were from a few hundred to about 0.1 Torr. The lower limit of sample pressures is determined mainly by the sample preparation apparatus, not by the sensitivity of the instrument. This fact needs to be borne in mind when the sensitivity of the IR-F spectroscopy is discussed in the later section of this paper.

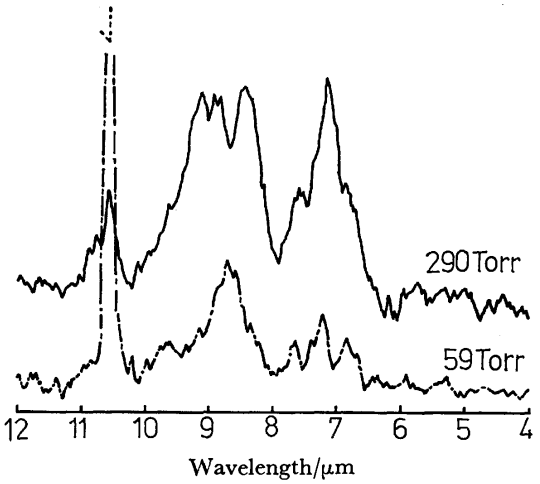

Fig. 2. IR-F spectra of diethyl ether at two different pressure.
——: 290 Torr, ————: 59 Torr.
The sharp band at 10.6 μm is considered to be due to the scattering of laser light in the sample cell.

Results and Discussion

The IR-F Spectra of the Sample Compound and the Sensitizing Agents. In the present investigation, we have selected diethyl ether as an objective sample, and the IR-F spectra for the mixed samples consisting of diethyl ether and some of the alkene compounds have been examined.

In Fig. 2 are shown the spectra of diethyl ether alone at the two different pressures. As is seen from this figure, the spectral patterns of ether in the 8—9 μm region are different for each pressure. That is, the 8.7 μm band, which can be assigned to the C–O–C stretching vibration, splits apparently into two peaks for the higher pressure, while the spectrum for the lower pressure exhibits only one band. This is considered to be due to the self-absorption.[1,5] Such phenomenon often occurs in the IR-F spectra when the pressures of gaseous samples are relatively high. This type of the band splitting is considered to be realized when the absorptions of samples are strong and the widths of the absorption bands are comparatively narrower than those of the corresponding IR-F bands.

In Figs. 3 and 4 are shown the IR-F spectra of ethylene and propylene, which are used as the main sensitizing agents in the present study. As can be seen from these figures, the IR-F spectra of these compounds exhibit no marked signal in the 7—9 μm region. Therefore, the influence of the presence of ethylene or propylene can be favorably examined, using the 8.7 μm band of diethyl ether as a key band. Thus, we deal with the intensity changes of this band in the range of the partial pressures of diethyl ether where no influence of the self-absorption appears.

The IR-F Spectra of Mixed Samples. Next we show the spectral evidence of the sensitization effect observed when some alkene compounds are added as the second component. The examples are shown in Figs. 5—7. Obviously the intensities of the 8.7 μm band of diethyl ether are enhanced considerably for the mixed samples, compared with those without a second component. All of the alkene compounds examined in the present study, *i.e.*, ethylene, propylene, 1-butene, 1-pentene, 1-hexene, have been found to induce the sensitization effect, though its degree is different among them.

We will examine the experimental results more quantitatively. Figure 5 shows the IR-F spectrum of diethyl ether alone (19.2 Torr) and that of a mixture of diethyl ether (19.9 Torr)–propylene (425 Torr).

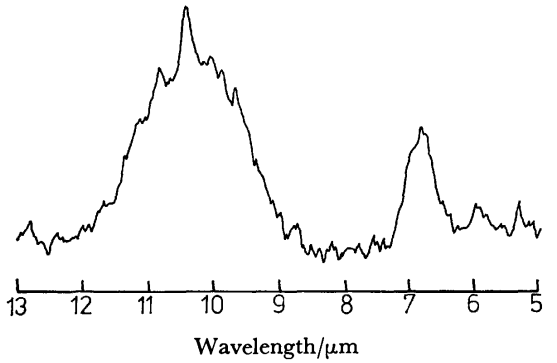

Fig. 3. IR-F spectra of ethylene (191 Torr).

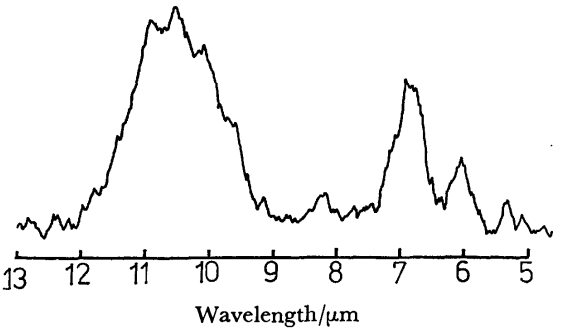

Fig. 4. IR-F spectra of propylene (260 Torr).

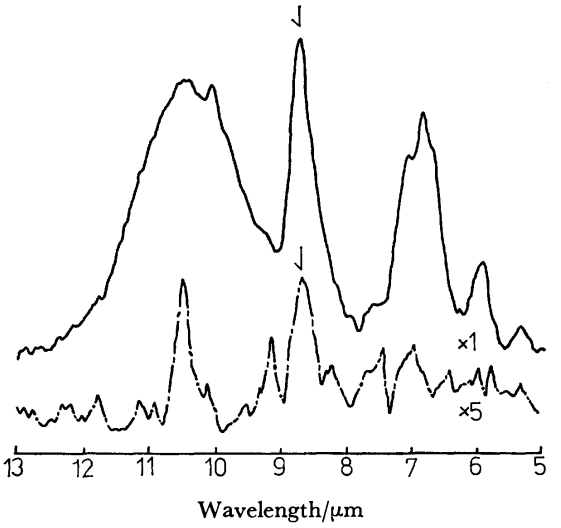

Fig. 5. IR-F spectra of diethyl ether only (19.2 Torr) and of diethyl ether (19.9 Torr)–propylene (425 Torr) mixed sample.
——: Mixed sample, ——: diethyl ether only.
Arrows show the 8.7 μm band of diethyl ether.

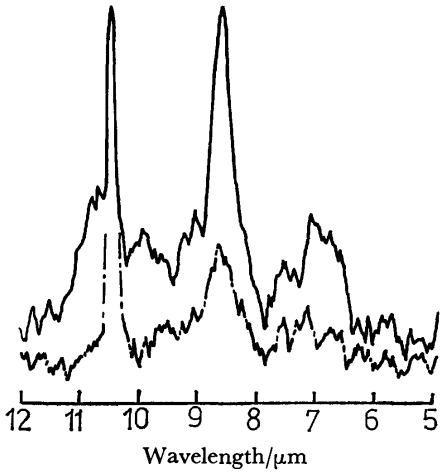

Fig. 6. IR-F spectra of diethyl ether only (59 Torr) and of diethyl ether (20 Torr)–1-butene (100 Torr) mixed sample.
——: Mixed sample, ———: diethyl ether only.

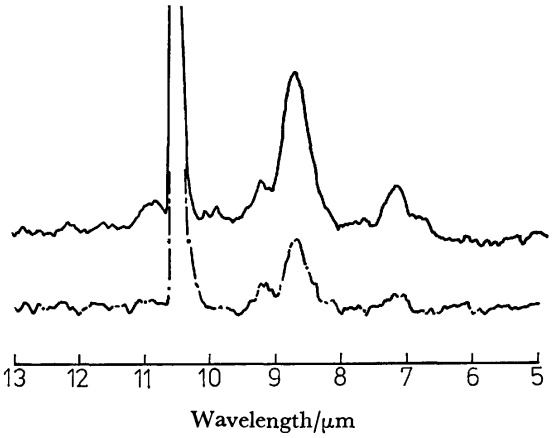

Fig. 7. IR-F spectra of diethyl ether only (37 Torr) and of diethyl ether (37 Torr)–1-hexene (37 Torr) mixed sample.
——: Mixed sample, ———: diethyl ether only.

The spectrum of ether alone has been measured with the instrumental sensitivity set five times higher than for the mixed sample. The sensitization of about one order of magnitude is realized in this particular case.

The Relation between the Degrees of the Sensitization and the Partial Pressures of Diethyl Ether. As was mentioned briefly in the previous paper,[2] the degrees of the sensitization were found to increase when the partial pressures of objective sample became smaller. In the present investigation, we have examined this phenomenon in more detail and quantitatively.

Theoretically, the experimental fact in question can be explained qualitatively in terms of the absorption of the laser light by ethylene, propylene or other sensitizing components, which is followed by inter- and intramolecular energy transfer, though the details of such mechanism remain obscure. In view of such mechanism, the above-mentioned experimental fact seems to be natural, since the probability of the intermolecular energy transfer between the sensitizing agent and diethyl ether is considered to increase when the concentration of the sensitizer relative to that of ether becomes greater. From such viewpoint, we have

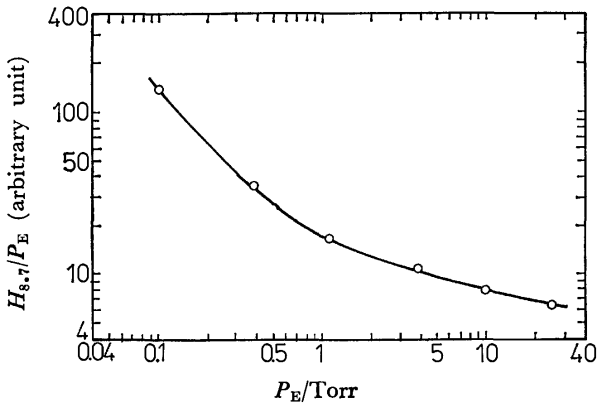

Fig. 8. Plots of value of $H_{8.7}/P_E$ *vs.* P_E on diethyl ether–ethylene mixed sample.
$H_{8.7}$: Peak height of 8.7 μm band of diethyl ether, P_E: partial pressure of diethyl ether.

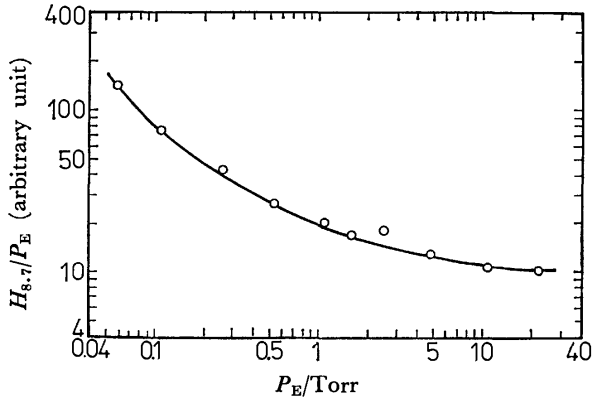

Fig. 9. Plots of value of $H_{8.7}/P_E$ *vs.* P_E on diethyl ether–propylene mixed sample.

examined experimentally the changes of the sensitization degree with the concentrations of ether. Since the effect in question comes out as the increase of the intensities, such results have direct relation to the microanalytical utility of the IR-F spectroscopy.

In the examinations described in the following, we have fixed the partial pressure of the sensitizing components at 100 Torr rather arbitrarily, and the effect of the concentrations of diethyl ether on the degrees of the sensitization has been examined for ethylene and propylene as the second components. The results are shown in Figs. 8 and 9. In these figures, we have plotted the values of $H_{8.7}/P_E$ ($H_{8.7}$: the peak height of the 8.7 μm band of diethyl ether, P_E: its partial pressure) against P_E. The value $H_{8.7}/P_E$ is considered to be the peak intensity per unit concentration of ether. Thus, this variable can be regarded as a measure of the degree of the sensitization effect. Moreover, the data are plotted in a logarithmic scale. This is not based on any theoretical consideration, but we have done it to show the sensitization changes more distinctly.

As is seen from these figures, the intensity per unit concentration is enhanced to a great extent for both of the sample systems when the partial pressures of diethyl ether become lower. For ethylene as a second component the values of $H_{8.7}/P_E$ become about

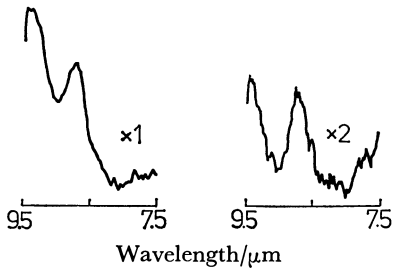

Fig. 10. The 8.7 μm bands of diethyl ether for the lowest concentrations.
Left side: diethyl ether (0.1 Torr)–ethylene (100 Torr) mixed sample, right side: diethyl ether (0.06 Torr)–propylene (100 Torr) mixed sample.

22 times greater when the pressures of ether change from 20 to 0.1 Torr. Since the intensity of the 8.7 μm band increases about 7 times when 100 Torr of ethylene is added to 20 Torr of diethyl ether, the sensitivity becomes about 150 times greater at 0.1 Torr of ether compared with that without ethylene. The value of 150 is to be considered the minimum, since this is estimated on the assumption that the relation between the pressures of diethyl ether and the peak heights is linear. In IR-F spectroscopy the relation is not always linear, but the one such as $H=\text{const}\times P^x$ ($X\geqq 1.0$) is often observed.[1,6] Thus, the sensitivity increase becomes greater than 150 when X is larger than unity.

For propylene as a sensitizing agent the same tendency of the changes of intensity per unit concentration of diethyl ether is realized. However, the types of the curves shown in Figs. 8 and 9 are obviously different. Quantitatively, for propylene, $H_{8.7}/P_E$ increases about 7 times when the pressure of ether changes from 20 to 0.1 Torr. Since the intensity of the 8.7 μm band is enhanced also about 7 times at the sample pressure of 20 Torr when 100 Torr of propylene is added, the minimum sensitivity enhancement is about 50 times, about one third of the value for ethylene. This fact indicates that the effectiveness of the alkenes as sensitizers is widely different among them.

In Fig. 10 are shown the 8.7 μm bands of diethyl ether for the lowest concentrations so far studied. At present, the lower limit of concentration is determined by the apparatus used for the sample preparation rather than by the sensitivity of the measurement system. The spectrum on the right side of this figure has been measured with the instrumental sensitivity set twice higher than that on the left. Considering the sensitivity changes shown in Figs. 8 and 9, and that the spectra for the lower concentrations were not measured, we cannot estimate the detection limits in the strict sense of the word from the spectra shown in Fig. 10. However, as a measure of the detection limits, we have estimated the concentrations at S/N=2 from these spectra. The results are the same for both spectra and about 0.01 Torr. This value corresponds to the concentration of about 12 ppm (1.2×10^{-5} ml/ml). It should be emphasized that we can say at most from this result that the detection limit is lower than 12 ppm for the sample system treated here.

Conclusion

In the present investigation, we have examined the sensitization effect observed in the IR-F spectra under the presence of some alkene compounds. The experimental results prove that the alkene compounds generally induce the enhancement of the IR-F intensities for the bands of samples. The quantitative discussions about the degrees of sensitization have been given for the diethyl ether–ethylene and diethyl ether–propylene systems in terms of the concentrations of ether.

The authors realize that there remain some important problems left unsolved. The first of them is the details of the mechanism of the phenomenon presented here. The second is where is the extremes of the improvement of the sensitivity, including the sensitizers other than ethylene and propylene. The third is related to the second problem. That is, from the viewpoint of the instrumental aspects, much of the emissions from samples is not effectively utilized in the present sample cell.[1] Thus, we are going to examine the sensitivity by use of a sample cell which contains the mirror system focusing the emitted light as much as possible into the detection system. The fourth is a rather important one, that is, the influence of the quantities of sensitizing agents, which is now under the examination as the next step of this investigation.

For all the above-mentioned problems left unsolved, we believe that the results obtained here suggest that the presented method greatly improves the sensitivity of the IR-F, and there is a possibility that the IR-F spectroscopy becomes an useful tool of microanalysis based on the vibrational spectra. The further examination in line with this purpose is proceeding in our laboratory.

The present work was supported by a Grant-in-Aid for Scientific Research No. 443014 from the Ministry of Education, Science and Culture.

(Received August 28, 1981)

The presence of multivalent anions, such as sulfate, oxalate, and malonate ions, accelerated the aluminium ion-assisted aquation of $CoF(NH_3)_5^{2+}$ and gave the anionopentaamminecobalt(III), along with the aqua complex. The competition reaction for the sulfate ion showed a saturation of the product percentage (33% $CoSO_4(NH_3)_5^+$) at nearly $[SO_4^{2-}]_{total}=0.1$ mol dm^{-3}, while the saturation of the reaction rate was observed at a higher sulfate concentration. This difference can be explained by a scheme in which the reaction proceeds through two intermediates, $CoF(NH_3)_5^{2+}\cdot SO_4^{2-}\cdot Al^{3+}$ and $SO_4^{2-}\cdot CoF(NH_3)_5^{2+}\cdot SO_4^{2-}\cdot Al^{3+}$. The reaction for the oxalate and malonate ions gave extremely large yields (more than 90%) of $CoA(NH_3)_5^+$ (A^{2-}=oxalate ion or malonate ion) when $[A^{2-}]_{total}/[Al^{3+}]_{total}>2$, and the reaction rates showed a maximum at approximately $[A^{2-}]_{total}/[Al^{3+}]_{total}=2$. These specific effects can be attributed both to the strong affinities of the dicarboxylate ions for the aluminium ion and to the residual capacity of the aluminium-bonded dicarboxylate ions for coordinating with cobalt(III).

Our previous studies of $CrF(NH_3)_5^{2+}$–Al^{3+} [1] and $CoF(NH_3)_5^{2+}$–Al^{3+} [2] reactions have revealed that the reaction rates are approximately first-order with respect to each reactant and that the effects of ClO_4^- and $Co(CN)_6^{3-}$ on the former reaction can be explained from a purely electrostatic point of view. The assisted aquations in the presence of competing nucleophiles have been widely studied[3–8] and have thrown light on the reaction mechanism, in particular on the reaction intermediate. Among others, Posey and Taube[3] and Buckingham *et al.*[8] have explained the results in terms of the formation of ion pairs between the reactants and the nucleophiles. The ion pair formed in the intermediate step has, however, not been well characterized.

The present study has been undertaken in order to obtain information about the competition in the $CoF(NH_3)_5^{2+}$–Al^{3+} reaction. The nucleophilic anions used were sulfate, oxalate, and malonate ions. As they strongly interact with the reactant cations, they are useful in helping to see the role of the ion pair or complex formation in the reaction. The relationship between the product percentages and the reaction rates will be clarified by observing the effect of the sulfate ion in the pH range where the formation of HSO_4^- is slight. The strong affinities of the dicarboxylate ions(oxalate ion=ox^{2-}, or malonate ion=mal^{2-}) to the aluminium ion will give their specific behavior in the reaction.

Experimental

Materials. The preparation and confirmation of the $[CoF(NH_3)_5](ClO_4)_2$ crystals, $NaClO_4$ crystals, $Al(ClO_4)_3$ solution, and $Na_3[Co(CN)_6]\cdot 2H_2O$ crystals were made as has previously been described.[1,2] The anhydrous sodium oxalate was a guaranteed reagent from Wako Pure Chemicals Industries, Ltd., and was dried at 300 °C for one hour before use. Anhydrous sodium malonate, an extra pure reagent from Nakarai Chemicals Industries, was recrystallized from a water–methanol (1:1) solution, dried *in vacuo* at 60 °C, and then used. (Found: C, 24.00, H, 1.44%. Calcd for $Na_2C_3H_2O_4$: C, 24.34, H, 1.36%).

Kinetic Measurements. The sample solutions contained the anion and the aluminium ion in different concentrations and had different pH values, while they contained the complex ion in a constant concentration of 5.0×10^{-3} mol dm^{-3}. The kinetics were studied spectrophotometrically. Absorbance changes were followed at 480 nm in the cases of $Co(CN)_6^{3-}$ and SO_4^{2-} and at 500 nm in the cases of ox^{2-} and mal^{2-}. The pseudo-first-order rate constants, k_{obsd}, were determined by plotting $\ln|D_t-D_\infty|$ *vs.* t, where D_t and D_∞ are the absorbances at the time t and at the time when the absorbance becomes almost constant respectively. The kinetic studies were made at 25.0±0.1 °C unless otherwise stated.

Competition in the Formation of Products. After the reaction had been completely terminated, the reaction solution was added to a column of SP-Sephadex and eluted with a 0.15 mol dm^{-3} sodium-sulfate solution. Two bands were observed; the first was assigned to the aniono complex, and the second, to the aqua complex. The concentration ratios of the two complexes can be calculated by means of the following equation:

$$\frac{c_X}{c_A}=\frac{\varepsilon_A}{\varepsilon_X}\frac{D_X V_X}{D_A V_A},$$

where ε and D are the molar absorption coefficients and the absorbances at the absorption maxima respectively, where V is the volume of the eluate, and where the subscripts, X and A, indicate the aniono complexes and the aqua complex respectively. The ε values used are 47.5 at 492 nm for the aqua complex, 59.3 at 515 nm for the sulfato complex, 78.0 at 503 nm for the oxalato complex, and 74.9 at 503 nm for the malonato complex. We here use the product percentages defined as:

$$F=\frac{c_X}{c_X+c_A}\times 100\%.$$

Measurements of the pH and of the ^{19}F NMR followed previous studies;[1,2] the observed pH values were used without correction.

Results and Discussion

In a previous study, hexacyanocobaltate(III) ions have been shown to accelerate the $CrF(NH_3)_5^{2+}$–Al^{3+}

reaction.[1] A similar acceleration effect was shown by the same anion on the $CoF(NH_3)_5^{2+}$–$Al(ClO_4)_3$ reaction systems. This is shown in Table 1, in which the reaction rate approaches saturation above the concentration ratio of $[Co(CN)_6^{3-}]/[Al^{3+}]\approx2$. These results can be understood from the formation of ion-pairs between the anions and the reacting cations.

TABLE 3. THE YIELDS OF $CoSO_4(NH_3)_5^+$

0.30	32.7

Effects of Sulfate Ions. The results of the competition study of the sulfate ion are listed in Tables 2 and 3. A comparison of these tables shows a significant difference between the saturation of the rate constant and that of the yield of $CoSO_4(NH_3)_5^+$; thus, the saturation of the product percentage (33%) for $CoSO_4(NH_3)_5^+$ appears at nearly $[SO_4^{2-}]_{total}=0.1$ mol dm^{-3}, while the reaction rate reaches saturation at the higher sulfate concentration of $[SO_4^{2-}]_{total}>0.2$ mol dm^{-3}. The relation between the reaction rate and the product percentage has not yet been discussed for the competition reactions hitherto studied. In order to explain the relation, we shall describe the rate constants and the yields of $CoSO_4(NH_3)_5^+$ from the reaction scheme containing the sulfate ion. As both the anation,

$$CoOH_2(NH_3)_5^{3+} + SO_4^{2-} \xrightarrow{k_{an}} CoSO_4(NH_3)_5^+ + H_2O,$$

and the aquation,

$$CoSO_4(NH_3)_5^+ + H_2O \xrightarrow{k_{aq}} CoOH_2(NH_3)_5^{3+} + SO_4^{2-},$$

are known to be very slow ($k_{an}=1.49\times10^{-5}$ mol^{-1} dm^3 s^{-1} and $k_{aq}=1.20\times10^{-6}$ s^{-1} at 25 °C, I=0.5 mol dm^{-3}),[9] the formation of a considerable quantity of sulfato-complex ions can be attributed to the entry of sulfate ions into the inner sphere of the cobalt(III) ion immediately after the rate-determining step. The following scheme can be considered for the reaction in the presence of the sulfate ion:

$$CoF^{2+} + SO_4^{2-} \overset{K_1^{ip}}{\rightleftharpoons} CoF^{2+}\cdot SO_4^{2-}$$

$$Al^{3+} + SO_4^{2-} \overset{K_2^{ip}}{\rightleftharpoons} Al^{3+}\cdot SO_4^{2-}$$

$$\text{I}\quad CoF^{2+} + Al^{3+} \overset{K_I}{\rightleftharpoons} CoF^{2+}Al^{3+} \xrightarrow{k_I} CoFAl^{5+} \xrightarrow{\text{fast}} CoOH_2(NH_3)_5^{3+}$$

$$\text{II}\quad CoF^{2+} + Al^{3+}SO_4^{2-} \overset{K_{II}}{\rightleftharpoons} CoF^{2+}Al^{3+}SO_4^{2-} \xrightarrow{k_{II}} CoFAl^{5+}SO_4^{2-}$$

$$\text{III}\quad CoF^{2+}SO_4^{2-} + Al^{3+} \overset{K_{III}}{\rightleftharpoons} CoF^{2+}SO_4^{2-}Al^{3+} \xrightarrow{k_{III}} CoFAl^{5+}SO_4^{2-}$$

$$\left.\begin{matrix}\text{II}\\ \text{III}\end{matrix}\right\} \xrightarrow{\text{fast}} \left\{\begin{matrix}CoOH_2(NH_3)_5^{3+}\\ +\\ CoSO_4(NH_3)_5^+,\end{matrix}\right.$$

$$\text{IV}\quad CoF^{2+}SO_4^{2-} + Al^{3+}SO_4^{2-} \overset{K_{IV}}{\rightleftharpoons} SO_4^{2-}\text{–}CoF^{2+}SO_4^{2-}\text{–}Al^{3+} \xrightarrow{k_{IV}} SO_4^{2-}\text{–}CoFAl^{5+}SO_4^{2-} \xrightarrow{\text{fast}} \left\{\begin{matrix}CoOH_2(NH_3)_5^{3+}\\ +\\ CoSO_4(NH_3)_5^+,\end{matrix}\right.$$

where $CoF(NH_3)_5^{2+}$ is abbreviated as CoF^{2+} and where $CoFAl^{5+}$ indicates that F and Al are bonded more strongly than in $CoF^{2+}Al^{3+}$. The following conditions will be used in the discussion below:

1) The ion association of sulfate ions with the cobalt-complex ions had only a negligible effect on the sulfate-ion concentration, as the concentration of the cobalt complex was very low.

2) The formation of HSO_4^- ($\log K=1.36$, I=0.5 mol dm^{-3})[10] was not significant, as the experiments were carried out in the $(pH)_{obsd}$ range of 2.8—3.0.

3) As soon as the fluoride ligand was extracted by the aluminium ion, a sulfate ion or a water molecule rapidly entered the coordination sphere of the cobalt(III) ion; thus, the extraction of the fluoride ligand is the rate-determining step for the formation

of either the aqua or the sulfato complex.

4) The formation constants (K_I—K_{IV}) of the precursors of the reaction intermediates are small enough in comparison with the ion-pair formation constants, K_1^{ip} and K_2^{ip}.

Letting a, b, and c represent the total initial concentrations of $CoF(NH_3)_5^{2+}$, Al^{3+}, and SO_4^{2-} respectively, the reaction rate can be expressed as:

$$\begin{aligned}\text{Rate} &= k_{obsd}\,a = k_I K_I[CoF^{2+}][Al^{3+}] \\ &\quad + (k_{II}K_{II}K_2^{ip} + k_{III}K_{III}K_1^{ip})[CoF^{2+}][Al^{3+}][SO_4^{2-}] \\ &\quad + k_{IV}K_{IV}K_1^{ip}K_2^{ip}[CoF^{2+}][Al^{3+}][SO_4^{2-}]^2 \\ &= k_0(a-x_1)(b-x_2) + k_1[x_2(a-x_1)+x_1(b-x_2)] \\ &\quad + k_2x_1x_2, \qquad (1)\end{aligned}$$

where x_1 and x_2 denote the concentrations of two ion-pairs, $CoF^{2+}SO_4^{2-}$ and $Al^{3+}SO_4^{2-}$ respectively, and where the rate constants,

$$k_0 = k_I K_I,\ k_1 = \frac{k_{II}K_{II}K_2^{ip} + k_{III}K_{III}K_1^{ip}}{K_1^{ip}+K_2^{ip}},$$

and

$$k_2 = k_{IV}K_{IV},$$

have identical dimensions of $mol^{-1}\,dm^3\,s^{-1}$. The value of k_0 in Eq. 1 should be equal to the k_{obsd} value at $c=0$ ($6.6\times10^{-4}\,mol^{-1}\,dm^3\,s^{-1}$). The other rate constants, k_1 and k_2, can be determined from the results given in Table 2 by the use of the x_1 and x_2 values, which were calculated for each run by the method of successive approximations in the following way. The ion-pair formation constants are:

$$K_1^{ip} = \frac{x_1}{(a-x_1)(c-x_2)}, \qquad (2)$$

$$K_2^{ip} = \frac{x_2}{(b-x_2)(c-x_2)}, \qquad (3)$$

where $c-x_1-x_2$ has been approximated by $c-x_2$. As suming provisionally the ionic strength based on the analytical concentrations, the known values of the constants, $\log K_1^{ip}=2.46$ ($I=0$)[11] and $\log K_2^{ip}=3.73$ ($I=0$),[12] were corrected for the ionic strength by using the Davies equation:

$$\log y_i = -0.512\,z_i^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right). \qquad (4)$$

The concentrations of the ion pairs, x_1 and x_2, were calculated by the use of Eqs. 2 and 3, and the ionic strength was re-evaluated. The final values of x_1 and x_2 were obtained by repeating such calculations until their values became unchanged within 0.01% of their respective values. Using x_1 and x_2 for each run, one can determine the rate constants, k_1 and k_2, from Eq. 1 so as to fit the observed rate constants, k_{obsd}: $k_1=(4.0\pm0.2)\times10^{-3}\,mol^{-1}\,dm^3\,s^{-1}$ and $k_2=(3.0\pm0.2)\times10^{-2}\,mol^{-1}\,dm^3\,s^{-1}$. These constants were obtained at the ionic strengths of 0.32 for k_0, 0.26—0.34 for k_1, and 0.3—0.9 for k_2 (Table 2); the effective charge of one of the reactants participating in each of the II—IV paths is low (+1 for II, and 0 for III and IV), so that the values of k_1 and k_2 will not be appreciably affected by the ionic-strength change.

The expression for the yields of $CoSO_4(NH_3)_5^+$, F (in %) on the basis of the reaction scheme given above is:

$$F/100 = [r_1k_1\{x_2(a-x_1)+x_1(b-x_2)\} + r_2k_2x_1x_2]/(k_{obsd}a), \qquad (5)$$

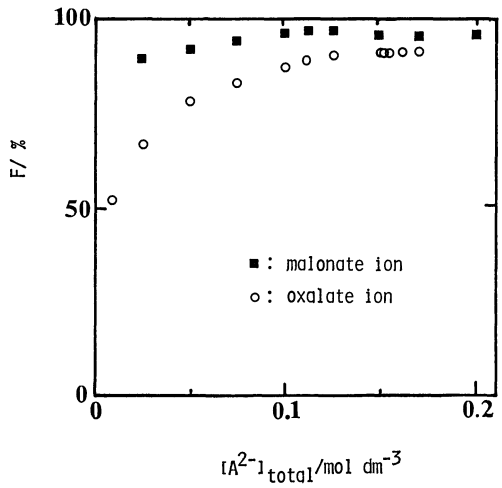

Fig. 1. The yield of $CoA(NH_3)_5^+$ depending on the concentration of the anions.
$[CoF(NH_3)_5^{2+}]_{initial}=5.0\times10^{-3}$ mol dm^{-3}, $[Al^{3+}]_{total}=5.1\times10^{-2}$ mol dm^{-3}.

where r_1 and r_2 are the fractions of SO_4^{2-} entering into the coordination sphere of cobalt(III) in competition with the H_2O solvent when AlF^{2+} leaves $CoF(NH_3)_5^{2+}SO_4^{2-}$-$Al^{3+}$ and SO_4^{2-}-$CoF(NH_3)_5^{2+}SO_4^{2-}$-$Al^{3+}$ respectively. In Eq. 5, all the parameter values except for r_1 and r_2 have been obtained in the analysis of the reaction rates. The value of r_2 can be taken as 0.33, which is the F/100 value at the saturation (Table 3). Then, $r_1=0.27\pm0.02$ results, thus fitting the experimental F values listed in Table 3. The r_1 and r_2 values are of comparable magnitude, in contrast to the significant difference between the k_1 and k_2 values. Thus, the reaction through Path IV is very important in determining the reaction rates, while Path IV only slightly increases the fraction of SO_4^{2-} entering into the coordination sphere of the cobalt(III). The second sulfate ion contained in the reaction intermediate assists the two reactant cations in approaching each other, but it rarely enters the coordination sphere of the cobalt(III) in the intermediate step.

Effects of Oxalate and Malonate Ions. The competition reactions were also examined in the presence of oxalate ions and of malonate ions. The product percentages and the rate constants are shown in Figs. 1 and 2 respectively. The effects of these ions distinctly differ from that of the sulfate ion in both the reaction rates and the products: (1) The reactions are more effectively accelerated by the dicarboxylate anions, but at high concentrations of the anions the reaction rate decreases instead of reaching saturation, and (2) the yields of the anionopentaamminecobalt(III) ions are unusually high. These specific effects of the anions have not so far been reported for the competition reactions accompanying the assisted aquations of the pentaamminecobalt(III) complexes.[3-8]

As the dicarboxylate ions tend to form complexes with the aluminium ion,[13,14] the present reactions can be regarded as reactions between $CoF(NH_3)_5^{2+}$ and AlA_n^{3-2n}. In order to confirm the stoichiometry, we made a ^{19}F NMR study of the final products existing

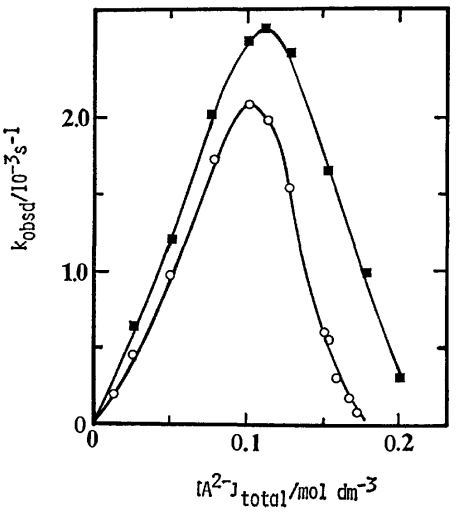

Fig. 2. Dependence of the rate constant on the concentration of the anions.
○: Oxalate ion, ■: malonate ion. $[CoF(NH_3)_5^{2+}]_{initial}=5.0\times10^{-3}$ mol dm^{-3}, $[Al^{3+}]_{total}=5.1\times10^{-2}$ mol dm^{-3}.

in the reaction solutions. The measurements were made for three samples varying in their concentrations of the added sodium oxalate, but with unchanged conditions of $[CoF(NH_3)_5^{2+}]_{initial}=0.050$ mol dm^{-3} and $[Al^{3+}]_{total}=0.20$ mol dm^{-3}. The values of the chemical shift (δ) of the main peak with reference to F^- were −35.2, −38.4, and −38.8 for $[ox^{2-}]_{total}=$ 0.20, 0.41, and 0.61 mol dm^{-3} respectively; the signal of $CoF(NH_3)_5^{2+}$ could not be detected. A solution of [NaF]=0.050 mol dm^{-3}, $[Al^{3+}]_{total}=0.20$ mol dm^{-3}, and $[ox^{2-}]_{total}=0.41$ mol dm^{-3} was also measured as a reference; it gave a peak at −38.5 from F^-. As the chemical shift of the AlF^{2+} peak is −36.1 from F^-,[2] the above results suggest the formation of the Al–F bonding. (The small differences among them may be due to the effect of oxalate ligands in the aluminium complexes.) A comparison of the peak areas between the samples and the reference reveals that most of the fluoride ions in the initial $CoF(NH_3)_5^{2+}$ had moved to the aluminium ions in every case. The ^{19}F NMR results, together with the results shown in Fig. 2, lead to the conclusion that the reaction:

$$CoF(NH_3)_5^{2+} + AlA_n^{3-2n} \longrightarrow CoA(NH_3)_5^{+} + AlFA_{n-1}^{4-2n},$$

produced about a 90% yield when $[A^{2-}]_{total} > [Al^{3+}]_{total} \gg [CoF(NH_3)_5^{2+}]_{initial}$.[15]

The mechanism of the reaction will be considered next. It is very improbable that the oxalate or the malonate ion enters into the coordination sphere of cobalt(III) after the formation of the aquapentaamminecobalt(III) ion, because the anation reaction of the aqua complex by these anions proceeds much more slowly than the present reaction.[16,17] This was confirmed by examining the reaction of the aqua complex with an excess of the oxalato- or the malonato-aluminium complex. The spectrum of the mixed solution remained unchanged for several days at 25 °C, and only the aqua complex was detected by means of a chromatographic technique using an SP-Sephadex column and a 0.15 mol dm^{-3} sodium-sulfate solution. It can, therefore, be concluded that the anion directly enters into the coordination sphere of cobalt(III) as soon as the aluminium ion extracts the fluoride ion from $CoF(NH_3)_5^{2+}$. The present reaction seems to be interesting as an extreme case of a competition reaction and can be classified as a double-ligand-exchange reaction, which is a very rare type of the reactions of the octahedral inert complexes.[18] This specific reaction will arise from the strong affinity of the aluminium ion to the dicarboxylate ions, combined with the residual capacity of the aluminium-bonded dicarboxylate ions for coordinating with cobalt(III). The latter factor is probably important, for the yield of the acetatopentaamminecobalt(III) in the $CoBr(NH_3)_5^{2+}$–$Hg(CH_3CO_2)_2$ system[7] was low (18.0 or 19.0%) in spite of the large formation constants of mercury–acetate complex. ($\log K_1=5.55$, $\log \beta_2=$ 9.30, at $I=1.0$ mol dm^{-3}).[19] A general rule for a high yield of the anionopentaamminecobalt(III) to be obtained in the competition reactions will be found by further studies of various systems.

An attempt was made to detect the formation of an intermediate in the present reaction. A binuclear complex such as $[(NH_3)_5Co\cdot\overset{F}{\underset{A}{\cdot}}\cdot Al]^{3+}$ might be present in the intermediate step. A rapid-scan spectrophotometer was used to follow the absorption change in the $CoF(NH_3)_5^{2+}$–Al^{3+}–ox^{2-} system (1:10:20, concentration ratio) in the wavelength region of about 290 to 350 nm, where $Coox(NH_3)_5^{+}$ or $CoHox(NH_3)_5^{2+}$ has a specific charge-transfer band originating in the Co–ox bonding. No species other than reactants and products were, however, detected in the time scale of 10 ms—10 s. This experiment was not able to distinguish between the dissociative and associative mechanisms.

The rate constants shown in Fig. 2 have a maximum approximately at the position of $[A^{2-}]_{total}/[Al^{3+}]_{total}=$ 2, decreasing on both sides with a less steep slope on the left side. These characteristics of the curve may result from different reactivities of the AlA_n^{3-2n} complexes with different n values. Thus, the concentrations of a series of aluminium–dicarboxylate species in each solution were calculated on the basis of the literature values of the successive formation constants, K_n and the acid dissociation constants, K_{a1} and K_{a2}, of the dicarboxylic acid: $\log K_1=6.06$, $\log K_2=5.03$, and $\log K_3=4.03$ for the Al^{3+}–ox^{2-} system ($I=$ 1.0 mol dm^{-3}),[13] $\log K_1=5.24$, $\log K_2=4.16$, and $\log K_3=4.06$ for the Al^{3+}–mal^{2-} system ($I=0.2$ mol dm^{-3}),[14] $pK_{a1}=3.5$ and $pK_{a2}=1.1$ for oxalic acid, and $pK_{a1}=5.1$ and $pK_{a2}=2.6$ for malonic acid at $I=1.0$ mol dm^{-3}.[20] The results are listed in Table 4, together with the kinetic results and the observed pH value. For $[A^{2-}]_{total}/[Al^{3+}]_{total}=1.0$ and 2.0, the calculated concentration of each aluminium complex and the observed rate constant vary in proportion to $[Al^{3+}]_{total}$ or $[A^{2-}]_{total}$, while the pH value changes without affecting their proportionality. From Fig. 2, the reactivities of the aluminium species can be expected to decrease in this order: $AlA_2^{-} > AlA^{+} > AlA_3^{3-}$

TABLE 4. DEPENDENCE OF THE RATE CONSTANTS ON THE CONCENTRATION OF THE ALUMINIUM COMPLEX ($[CoF(NH_3)_5^{2+}]=5.0\times10^{-3}$ mol dm^{-3}, $I^{a)}=0.80\pm0.02$ mol dm^{-3}; 25 °C.)

a) The ionic strength was controlled with $NaClO_4$, considering the formation of the Al^{3+}-A^{2-} complexes shown in this table. b) All brackets denote the concentration in mol dm^{-3}.

and Al^{3+}. Therefore, when $[A^{2-}]_{total}/[Al^{3+}]_{total}=1.0$ and 2.0, the contribution of AlA_3^{3-} and Al^{3+} to the reaction can be neglected, and the observed rate constant can be expressed as: $k_{obsd}=k_1[AlA^+]+k_2[AlA_2^-]$. The values of k_1 and k_2 can be obtained so as to fit the experimental values, starting from the first approximate value of $k_2=k_{obsd}/[AlA_2^-]$ for the case of $[A^{2-}]_{total}/[Al^{3+}]_{total}=2.0$. The k_1 and k_2 values thus obtained are: $(1.5\pm0.1)\times10^{-2}$ mol^{-1} dm^3 s^{-1} and $(4.5\pm0.3)\times10^{-2}$ mol^{-1} dm^3 s^{-1} for A=ox, and $(4.2\pm0.3)\times10^{-2}$ mol^{-1} dm^3 s^{-1} and $(7.5\pm0.5)\times10^{-2}$ mol^{-1} dm^3 s^{-1} for A=mal. When $[A^{2-}]_{total}/[Al^{3+}]_{total}=3.0$, the concentrations of the aluminium complexes are more sensitive to the pH value; therefore, the calculated concentrations may be accompanied by considerable errors resulting from possible errors in the equilibrium constants and in the pH values. The gross rate constants calculated with the k_1 and k_2 values obtained above are 10—50% larger than the experimental values for A=ox, even when $Alox_3^{3-}$ is assumed to be nonreactive, while, for A=mal, they are 10—50% smaller than the experimental values

when calculated on the assumption that $Almal_3^{3-}$ is not reactive. It may, therefore, be said that the reactivity of $Alox_3^{3-}$ is low, while $Almal_3^{3-}$ is reactive to some extent.

The fact that the reactivity of AlA_2^- is the largest among the consecutive complexes can be attributed to the favorable characteristics that the complex electrostatically assists the two reactant cations in approaching each other and that it can easily react with the fluoride ligand of the cobalt complex. On the other hand, in spite of its larger negative charge, AlA_3^{3-} is not so reactive, probably because the aluminium ion is masked by the ligands in this complex. The malonate ion more effectively accelerates the reaction and increases the yield of $CoA(NH_3)_5^+$. This may be attributable to the flexibility of the chelate ring formed by malonate ligands; the central aluminium ion of the more flexible malonato complex may more easily come in contact with the fluoride ligand of the cobalt(III) complex, and the malonate ion may be more easily transferred to the cobalt(III).

The yields of $CoA(NH_3)_5^+$ are not listed in Table 4, because they scarcely depended at all on the concentration of the aluminium complex (varying only within 1%); they depended only on the $[A^{2-}]_{total}/[Al^{3+}]_{total}$ ratio (see Fig. 1).

Table 5 shows the rate constants at different temperatures with $[A^{2-}]_{total}/[Al^{3+}]_{total}=2.0$ (the ionic strength is given in the analytical concentration). They give the values of ΔH^* and ΔS^* as 57 ± 3 kJ mol^{-1} and -92 ± 14 J K^{-1} mol^{-1} respectively for A=ox, and as $\Delta H^*=55\pm2$ kJ mol^{-1} and $\Delta S^*=-110\pm11$ J K^{-1} mol^{-1} respectively for A=mal. These values approximately agree with each other, but they are significantly different from the values, $\Delta H^*=74$ kJ mol^{-1} and $\Delta S^*=-72$ J K^{-1} mol^{-1}, for the reaction in the $CoF(NH_3)_5^{2+}$–Al^{3+} system ($I=0.61$ mol dm^{-3}).[2] The activation enthalpies are depressed by the electrostatic attraction of the anions to both the reactant cations, while the activation entropies decrease as a result of a stringent geometrical condition to form the activated complex. These effects are similar to that of added salts on the activation parameters in a cation-cation reaction.[21]

Reactivity of Fe_2O_3 and Fe_2O_3–Al_2O_3 Mixture for Reduction of SO_2 with CO

Tadao Ishii,* Ryusaburo Furuichi, and Koji Shikano

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received August 31, 1981)

Catalytic reactivities of α-Fe_2O_3 powder (−200 mesh) and a α-Fe_2O_3–γ-Al_2O_3 powder mixture prepared by mechanical mixing, which were preheated at 360—700 °C, were studied for the reduction of SO_2 with CO by means of both a reaction gas-chromatographic technique using CO, SO_2, and 2CO–SO_2 pulses and the powder X-ray analysis. The reactivity of Fe_2O_3 decreases with increasing preheating temperature, which is explained on the basis of redox reactions between Fe_2O_3 and nascent (Fe_3O_4): $6Fe_2O_3+2CO\rightarrow4(Fe_3O_4)+2CO_2$ and $4(Fe_3O_4)+SO_2\rightarrow6Fe_2O_3+1/2S_2$. It is considered that the reactivity of Fe_2O_3 is attributable to the activity of (Fe_3O_4). The lifetime of active (Fe_3O_4) is within about 1 min, and the activity and lifetime of (Fe_3O_4) is increased by interfacial reaction between Fe_2O_3 and Al_2O_3 at 700 °C. The activity maximum in the Fe_2O_3–Al_2O_3 system preheated at 700 °C is attained at 70—75 wt% Fe_2O_3.

The catalytic reduction of sulfur dioxide by carbon monoxide has been extensively investigated. It is generally accepted that the reduction proceeds in the range of about 300 to 600 °C in the following way:

$$SO_2 + 2CO \longrightarrow 2CO_2 + 1/2S_2, \quad (1)$$

$$1/2S_2 + CO \longrightarrow COS. \quad (2)$$

Many catalysts, such as metals, metal oxides, and their mixtures, have been used in the study. Few papers have been published on the use of Fe_2O_3 for preparing the catalyst. Khalafalla *et al.*[1-3] used a catalyst prepared by reducing mixtures of hematite and γ-Al_2O_3 at 600 °C for 1 h with H_2. The hematite constituent of the catalyst was completely reduced to iron. Clay and Lynn[4] reported that iron oxide supported on alumina is a promising catalyst/adsorbent for use in the simultaneous removal of NO_x and SO_x from power plant stack gases. Iron oxide is converted to the iron(II) state, and SO_2 is removed as iron(II) sulfide or sulfate. Kasaoka *et al.*[5] used the coprecipitated metal oxides, Fe_2O_3–Al_2O_3, Fe_2O_3–Cr_2O_3, Fe_2O_3–CuO–Al_2O_3, and Fe_2O_3–Cr_2O_3–Al_2O_3, which were reduced with H_2 at 550 °C. However, studies on catalysts prepared by mechanically mixing Fe_2O_3 and metal oxide powders are rarely found for the SO_2–CO reaction.

In a previous work,[6] Ishii *et al.* examined the reactivity of powder mixtures of α-Fe_2O_3 and metal oxide, α-Al_2O_3, γ-Al_2O_3, MgO, or CaO, on the basis of their catalytic behavior, in the reduction of SO_2 with CO at 300 °C, as characterized by means of reaction gas-chromatography and X-ray analysis. A maximum catalytic activity for reaction (1) was obtained at a specific mixing ratio for each mixture. In a pure pulse of CO, Fe_2O_3 was easily reduced to Fe_3O_4, but in a mixed pulse of $2CO+SO_2$, no change of Fe_2O_3 resulted. This behavior was discussed in connection with the redox reaction between Fe_2O_3 and (Fe_3O_4) in the following way:

$$6Fe_2O_3 + 2CO \longrightarrow 4(Fe_3O_4) + 2CO_2, \quad (3)$$

$$4(Fe_3O_4) + SO_2 \longrightarrow 6Fe_2O_3 + 1/2S_2, \quad (4)$$

where (Fe_3O_4) means nascent Fe_3O_4. The unique catalytic behavior of this powder mixture appeared to be related to a reaction at the interface between Fe_2O_3 and oxide, which occurred during preheating the mixture.

In the present paper, on the basis of reactions (3) and (4) proposed, reactivities of α-Fe_2O_3 powder and a α-Fe_2O_3–γ-Al_2O_3 powder mixture prepared by mechanical mixing, which were preheated at various temperatures, were studied in detail for the reduction of SO_2 with CO.

Experimental

Materials. Reagent grade commercial α-Fe_2O_3 (Kanto) and γ-Al_2O_3 (Merck), which are hereinafter written as Fe_2O_3 and Al_2O_3, respectively, were used without further purification. All starting materials were ground so as to pass a 200 mesh sieve. The powder mixture was prepared by mixing Fe_2O_3 and Al_2O_3 powders for 2 h by means of a rotating-V-type micro mixer (Tsutsui Rikagaku). Commercial SO_2 (Teikoku), CO (Nissan), and CO_2 (Hokusan) were used without further purification.

Preliminary Calcining (Preheating). Prior to reactivity tests, powder samples were preheated at various temperatures, 360, 600, and 700 °C, for 1 h in a flowing He (25 cm³/min) in the same reactor as was used for testing the reactivity. It was confirmed from X-ray analysis that, by these preheating processes, neither new products are formed in the Fe_2O_3–Al_2O_3 system nor any change in γ-Al_2O_3 is shown.

Apparatus and Procedures. A pulse method using a reaction gas-chromatograph (Hitachi, K-23 type) was applied to study of the adsorption of SO_2 and CO and of the catalytic reduction of SO_2 with CO. The standard experimental conditions were as follows: pulse interval, 25 min; pulse volume, 0.5 cm³ of SO_2 and 1 cm³ of CO; carrier gas, 25 cm³/min of He; reaction temperature, 360±5 °C; reactor, a quartz tube of 5.5 mm diameter; separating column, a stainless steel tube of 3 mm diameter; packing, Porapak-QS 80—100 mesh (Gasukuro Kogyo) at 60 °C. Eighty mg of a Fe_2O_3–Al_2O_3 powder mixture with a mixing ratio in the range 0—100% and 24—80 mg of Fe_2O_3 were packed in the reactor. Both sides of these packed samples were fixed by glass wool. A glass injection-syringe of 1 cm³ was used for injecting SO_2 and CO gases into the reactor. In order to inject the mixture of CO (1 cm³) and SO_2 (0.5 cm³), these gases were simultaneously injected by use of two syringes. After preheating the catalyst sample, the temperature of the reactor was adjusted to the reaction temperature 360 °C without lowering the sample temperature to room temperature. The time required for lowering the preheating temperature (600—700 °C) to the reaction

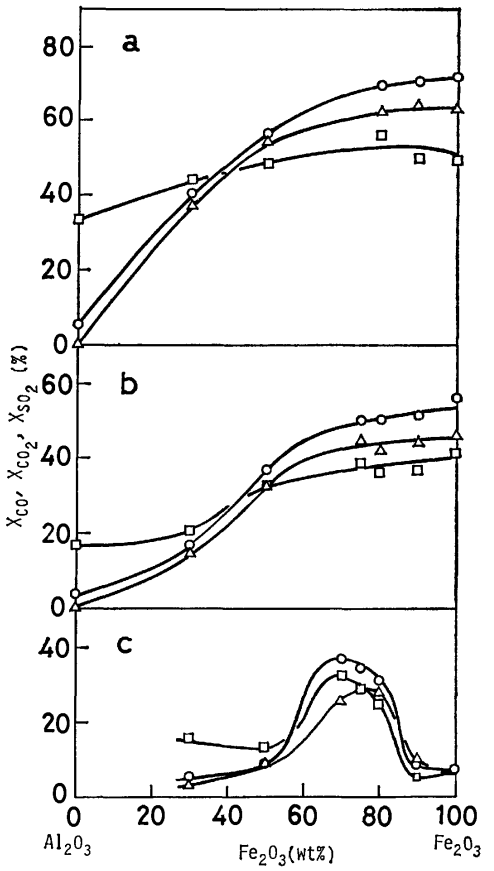

Fig. 1. Per cent conversions of CO and SO_2 (X_{CO} and X_{SO_2}), and % formation of CO_2 (X_{CO_2}) in $2CO+SO_2$ pulse for Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures.
Preheating temperature; (a): 360 °C, (b): 600 °C, (c): 700 °C. ○: X_{CO}, △: X_{CO_2}, □: X_{SO_2}.

temperature 360 °C was about 20—30 min. X-Ray analysis of samples before and after tests was carried out with a diffractometer (Geigerflex type-2004, Rigaku Denki) under the conditions: Co target, Fe filter, 35 kV, 10 mA, count full scale 1000 c/s, and scanning speed 1°/min.

Conversion of CO and SO_2 (X_{CO} and X_{SO_2}) and Formation of CO_2 (X_{CO_2}). For pulses of CO or SO_2 alone, areas of chromatographic peaks of CO, SO_2, and CO_2 at the outlet of reactor, relative to those for a blank test with no powder sample, were used for the determination of per cent conversions of CO (X_{CO}) and SO_2 (X_{SO_2}) and per cent formation of CO_2 (X_{CO_2}). The blank test for X_{CO_2} was carried out by using CO_2 gas.

For pulses of the mixture of CO and SO_2 ($2CO+SO_2$ pulse), the area of chromatographic peak of CO_2 at the outlet of reactor, relative to that of a blank test carried out using $2CO_2+SO_2$ pulse instead of $2CO+SO_2$ pulse, was used for the determination of per cent formation of CO_2 (X_{CO_2}) on the basis of reaction (1). Per cent conversions of CO (X_{CO}) and SO_2 (X_{SO_2}) were determined in the same way as for pulses of CO or SO_2 alone. Unless otherwise noted, arithmetic mean of five pulses was used as the value of X_{CO}, X_{SO_2}, or X_{CO_2}.

Results and Discussion

Fe_2O_3–Al_2O_3 System. Various pulse tests were carried out for the Fe_2O_3–Al_2O_3 system.

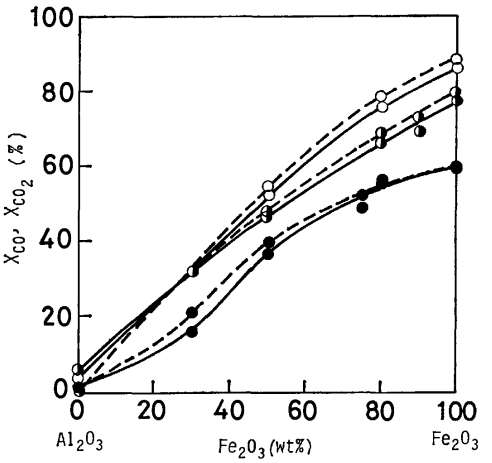

Fig. 2. Per cent conversion of CO (X_{CO}) and formation of CO_2 (X_{CO_2}) in CO pulse for Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures.
Preheating temperature: ○: 360 °C, ◑: 600 °C, ●: 700 °C. ——: X_{CO}, – – –: X_{CO_2}.

$2CO+SO_2$ Pulse: Figures 1(a)—(c) show per cent conversions of CO and SO_2 (X_{CO} and X_{SO_2}) and per cent formation of CO_2 (X_{CO_2}) in $2CO+SO_2$ pulse for the Fe_2O_3–Al_2O_3 systems with various mixing ratios (wt% of Fe_2O_3). (a) is the result of the sample preheated at 360 °C. The value of X_{CO} increases from 4.8% for Al_2O_3 alone (adsorption of CO) to 71.5% for Fe_2O_3 alone with increasing Fe_2O_3 content. The value of X_{CO_2} increases similarly to X_{CO}, but it is generally several per cents lower than the X_{CO} value. This seems to be due to occurrence of a side reaction such as reaction (2). Al_2O_3 alone does not show any activity for reaction (1). The value of X_{SO_2} increases from 33.2% for Al_2O_3 alone (adsorption of SO_2) to 49.2% for Fe_2O_3 alone with increasing Fe_2O_3 content. The fact that the X_{SO_2} value for Fe_2O_3 alone is lower than that of X_{CO_2} may be due to a lowering of activity of nascent (Fe_3O_4) on reaction (4) as will be considered later. Compared with (a), all the values in (c) for the samples preheated at 700 °C are significantly low, and the maximum X_{CO}, X_{SO_2}, and X_{CO_2} values are attained at their respective specific mixing ratios at about 70—75 wt% of Fe_2O_3 contents. The samples preheated at 600 °C on (b) show an intermediate behavior between (a) and (c).**

CO Pulse: Figure 2 shows the result of a CO pulse for the Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures. The value of X_{CO} increases in an approximately linear relationship with increasing ratio of Fe_2O_3, but it decreases with increasing preheating temperature. CO_2 is formed on all of samples except for Al_2O_3 alone, and X_{CO_2} is approximately the same as X_{CO}. These results show occurrence of reaction (5) without adsorption of CO:

$$3Fe_2O_3 + CO \longrightarrow 2F_3O_4 + CO_2. \quad (5)$$

** In a previous paper,[6] an activity maximum was attained at 80—90 wt% Fe_2O_3 preheated at 600 °C. This is probably due to the use of different lot No. of commercial Fe_2O_3 sample and different reaction temperature (300 °C).

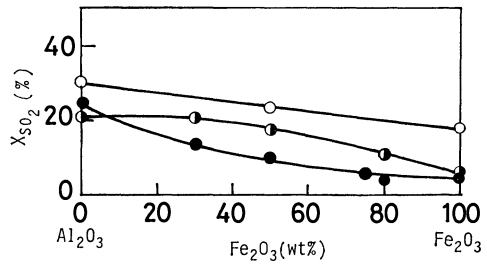

Fig. 3. Per cent conversion of SO_2 (X_{SO_2}) in SO_2 pulse for Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures.
Preheating temperature: ○: 360 °C, ◑: 600 °C, ●: 700 °C.

SO_2 Pulse: Figure 3 shows that the value of X_{SO_2} decreases with increasing ratio of Fe_2O_3 and preheating temperature. The values of X_{SO_2} for Al_2O_3 alone and Fe_2O_3 alone are 20—30 and 5—20%, respectively. It is thought that these values of X_{SO_2} may be due to irreversible adsorption of SO_2, because the experiments were carried out at 25-min pulse intervals in a flowing He gas.

Fe_2O_3 System. The effect of Al_2O_3 in the Fe_2O_3–Al_2O_3 systems of Figs. 1 and 2 on the reactions was examined by comparison with the results of the pure Fe_2O_3 system, of which the amounts of Fe_2O_3 correspond to those in the Fe_2O_3–Al_2O_3 systems (*e.g.*, 40 mg Fe_2O_3 corresponds to 50 wt% Fe_2O_3 in the Fe_2O_3–Al_2O_3 system).

$2CO+SO_2$ Pulse: Figures 4(a)—(c) show results of Fe_2O_3 preheated at 360, 600, and 700 °C in the pulse of $2CO+SO_2$, respectively. In the case of (a), the curves of X_{CO} and X_{CO_2} are similar to that in Fig. 1(a). Consequently, it is thought that no cooperative action between Fe_2O_3 and Al_2O_3 takes place during the preheating of the Fe_2O_3–Al_2O_3 system at 360 °C, and the behavior in the Fe_2O_3–Al_2O_3 system of Fig. 1(a) is attributable to that of Fe_2O_3 itself. Khalafalla *et al.*[1] reported that results in the Fe–Al_2O_3 system for reaction (1) are best explained on the basis of a dual-site mechanism with both iron and alumina augmenting their specific-site activities at their interparticle contacts. However, the present results indicate no action of bifunctional catalyst. Furthermore, on the basis of a comparison between X_{CO} or X_{CO_2} of Fig. 1(a) and that of Fig. 4(a), it is considered that there is no problem with respect to the contact between gas and powder arising from the small packing amount of powder used. On the other hand, the value of X_{SO_2} greatly differs from that in the Fe_2O_3–Al_2O_3 system, especially in the low Fe_2O_3 content region. This is due mainly to the adsorption of SO_2 on Al_2O_3.

In the case of Fig. 4(c), the curves differ greatly from that in Fig. 1(c). Consequently, it can be considered with regard to the unique catalytic behavior of Fig. 1(c) that some interfacial reactions between Fe_2O_3 and Al_2O_3 occurred during the preheating process at 700 °C. Figure 4(b) shows an intermediate behavior between (a) and (c).

CO Pulse: Figure 5 shows the result of Fe_2O_3 alone with various Fe_2O_3 amounts and preheating temperatures. The results obtained are approximately the same as that of the Fe_2O_3–Al_2O_3 systems in Fig. 2. This means that there is no significant effect of Al_2O_3 on reaction (5) in the Fe_2O_3–Al_2O_3 systems for all

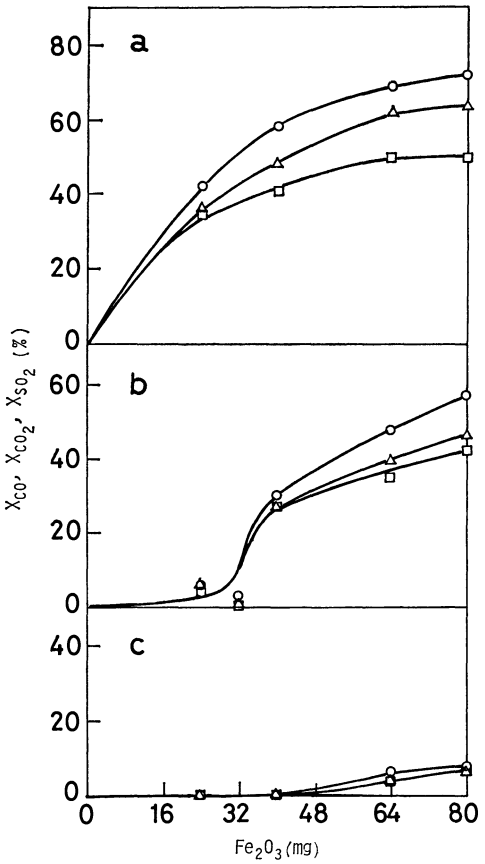

Fig. 4. Per cent conversions of CO and SO_2 (X_{CO} and X_{SO_2}),a nd % formation of CO_2 (X_{CO_2}) in $2CO+SO_2$ pulse for Fe_2O_3 systems with various Fe_2O_3 amounts and preheating temperatures.

of the preheating temperatures.

Catalytic Mechanism. In order to determine, on the basis of reactions (3) and (4) which are proposed in the previous paper,[6] mechanism of the reduction of SO_2 with CO for the Fe_2O_3 and Fe_2O_3–Al_2O_3 systems, a pulse method (with varying pulse intervals), different from the above-described, was applied, and the composition of samples before and after the pulse experiment was identified by X-ray analysis.

$CO \xrightarrow{t} SO_2$ Pulse: Figures 6(a)—(c) show results of experiments where the first CO pulse was injected, followed by a SO_2 pulse, with varying pulse intervals t (min). Figure 6(a) shows that, for Fe_2O_3 preheated at 600 °C, reaction (3) proceeds with approximately constant value of X_{CO_2} regardless of t. The value of X_{CO} is similar to that of X_{CO_2}, although the data show some scatter (the curve of X_{CO} is not shown). In contrast to these results, the curve of X_{SO_2} decreases rapidly within t=1 min and then approaches the values

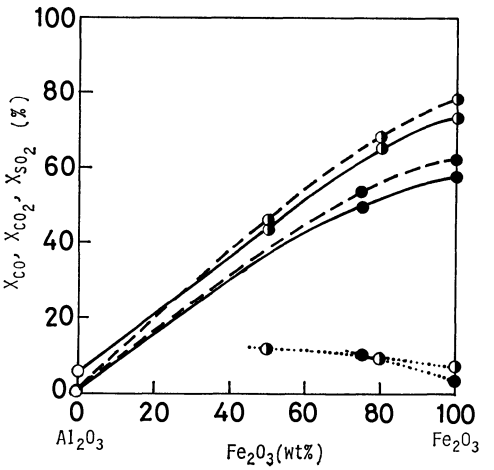

Fig. 7. Per cent conversions of CO and SO_2 (X_{CO} and X_{SO_2}), and % formation of CO_2 (X_{CO_2}) in $CO \times 5 \xrightarrow{t} SO_2 \times 5$ (t=25 min) pulse for Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures.
Preheating temperature: ◑: 600 °C, ●: 700 °C.
——: X_{CO}, – – –: X_{CO_2}, ·····: X_{SO_2}.

of X_{SO_2} for Fe_2O_3 (in Fig. 3) and Fe_3O_4 (commercial reagent) in the SO_2 pulse. From these results, it is thought that the activity of the nascent (Fe_3O_4) for reaction (4) decreases rapidly within 1 min of t. Figure 6(b) shows the result of Fe_2O_3 preheated at 700 °C. A behavior similar to (a) is shown, but all values of X_{CO}, X_{CO_2} and X_{SO_2} are significantly lower than (a). This is assumed to be due to a decrease in the reactivity of Fe_2O_3 caused by the preheating at higher temperature.

Figure 6(c) shows the result of the Fe_2O_3–Al_2O_3 (75:25) system preheated at 700 °C. The vaule of X_{SO_2} generally increases compared with (b), and the decreasing tendency of X_{SO_2} curve is mild compared with (a), while the values of X_{CO} and X_{CO_2} do not increase very much compared with (b) except for that of t=0 min. These probably mean the reactivity of nascent (Fe_3O_4) for reaction (4) become high and stable with addition of Al_2O_3 with Fe_2O_3, which results from interfacial reaction between Fe_2O_3 and Al_2O_3 caused by the preheating treatment at 700 °C.

$CO \times 5 \xrightarrow{t} SO_2 \times 5$ (t=25 min) Pulse: Figure 7 shows that, for the Fe_2O_3–Al_2O_3 system preheated at 600 and 700 °C, the first five CO pulses (25 min intervals) are injected, followed by five SO_2 pulses (25 min intervals) with 25 min of t. The curves of X_{CO} and X_{CO_2} are similar to that of Fig. 2, but the values of X_{SO_2} are greatly lower than that of Fig. 1, and approximately the same as that of the SO_2 pulse in Fig. 3. This means that the active nascent (Fe_3O_4) was changed to inactive Fe_3O_4 during the interval of 25 min and that the activity of (Fe_3O_4) for reaction (4) disappeared.

$SO_2 \xrightarrow{t} CO$ (t=5 min) Pulse: For the samples of Fe_2O_3 preheated at 360 and 600 °C, first a SO_2 pulse was injected, followed by a CO pulse with t of 5 min. The values of X_{CO_2}, X_{CO}, and X_{SC_2} were 0, 0.2, and 11.4% for the 360 °C preheating and 0, 1.1, and 4.6%

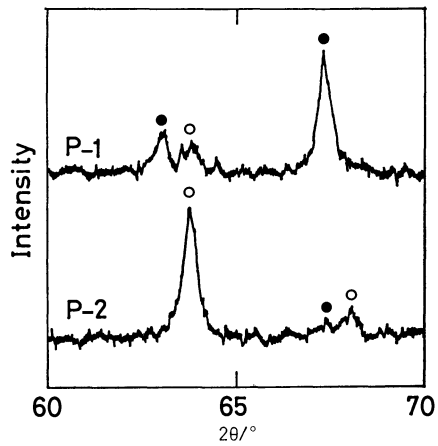

Fig. 8. X-Ray diffraction patterns after pulse experiments for Fe_2O_3 system preheated at 360 °C.

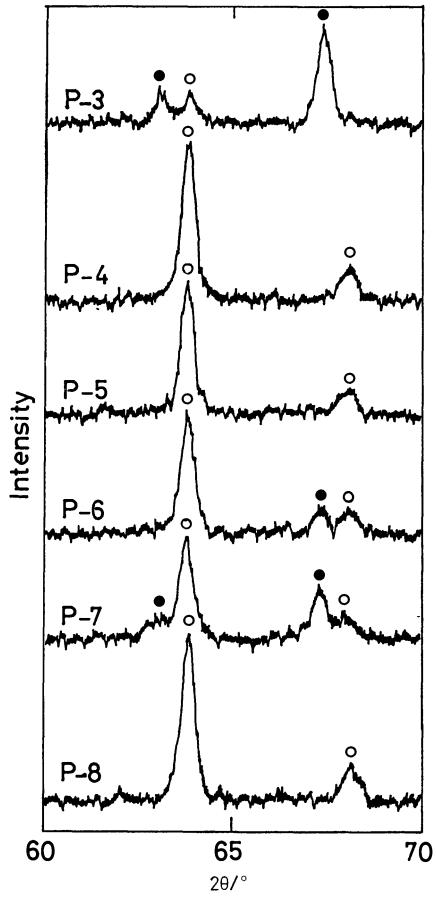

Fig. 9. X-Ray diffraction patterns after pulse experiments for Fe_2O_3 and Fe_2O_3-Al_2O_3 systems preheated at 600 °C.
P-3: Fe_2O_3 in CO pulse, P-4: Fe_2O_3 in $2CO+SO_2$ pulse, P-5: Fe_2O_3-Al_2O_3 (80:20) in $2CO+SO_2$ pulse, P-6: Fe_2O_3 in $CO \xrightarrow{t} SO_2$ (t=0.25 min) pulse, P-7: Fe_2O_3 in $CO \xrightarrow{t} SO_2$ (t=5 min) pulse, P-8: Fe_2O_3 in $SO_2 \xrightarrow{t} CO$ (t=5 min) pulse. ○: Fe_2O_3, ●: Fe_3O_4.

for the 600 °C preheating, respectively. These mean that reaction (5) is hindered by the SO_2 adsorbed on the surface of Fe_2O_3 particle and that the surface reaction between adsorbed SO_2 and gas phase CO did not occur.

X-Ray Analysis: On the basis of the results described above, it is considered that the reactivity of Fe_2O_3 for the reduction of SO_2 to S_2 is governed by the activity and lifetime of nascent (Fe_3O_4) with respect to the redox reactions (3) and (4). In order to confirm this consideration, X-ray analyses of samples were done after these experiments. These results are partly shown in Figs. 8—10 by using diffraction patterns at 2θ=60—70° (Co $K\alpha$). The ASTM cards (13—534 and 11—614) show that 2θ=63.8 and 68.0° (I/I_o=60 and 16) correspond to α-Fe_2O_3 and that 2θ=63.0 and 67.3° (I/I_o=60 and 85) correspond to Fe_3O_4.

Figure 8 shows the result of Fe_2O_3 preheated at 360 °C. Pattern 1 (noted as P-1) in CO pulse shows the formation of Fe_3O_4 on reaction (5) and the presence of small amounts of α-Fe_2O_3 remaining. P-2 in $2CO+SO_2$ pulse shows Fe_2O_3 with trace amounts of Fe_3O_4, which resulted from reaction (3) and (4).

Figure 9 shows the result of both the Fe_2O_3 and Fe_2O_3-Al_2O_3 (80:20) systems which were preheated at 600 °C. P-3 in CO pulse for Fe_2O_3 shows a pattern similar to P-1. P-4 in $2CO+SO_2$ pulse for Fe_2O_3 shows Fe_2O_3 formed as a result of reactions (3) and (4). P-5 in $2CO+SO_2$ pulse for the Fe_2O_3-Al_2O_3 system is the same as P-4. P-6 in $CO \xrightarrow{t} SO_2$ (t=0.25 min) pulse for Fe_2O_3 shows Fe_2O_3 with small amounts of Fe_3O_4. P-7 in $CO \xrightarrow{t} SO_2$ (t=5 min) pulse for Fe_2O_3 shows that Fe_3O_4 increases with increasing t and that active (Fe_3O_4) changes to inactive Fe_3O_4. These results (P-4, P-6, and P-7) support the consideration with Fig. 6(a). P-8 in $SO_2 \xrightarrow{t} CO$ (t=5 min) pulse for Fe_2O_3 shows Fe_2O_3 only, in supports of the consideration with the $SO_2 \xrightarrow{t} CO$ pulse tests shown above.

Figure 10 shows the result of both the Fe_2O_3 and Fe_2O_3-Al_2O_3 (75 : 25) systems which were preheated at 700 °C. P-9 in CO pulse for Fe_2O_3 shows a pattern similar to P-3. In a comparison of P-1, P-3, and P-9, relative intensities of Fe_2O_3 increase with increasing preheating temperature. This means that the reactivity of Fe_2O_3 decreases with increasing preheating temperature. P-10 in $2CO+SO_2$ pulse for Fe_2O_3 shows Fe_2O_3 only in analogy with P-4. P-11 in $2CO+SO_2$ pulse for the Fe_2O_3-Al_2O_3 system is similar to P-10. P-12 in $CO \xrightarrow{t} SO_2$ (t=0.25 min) pulse for Fe_2O_3 shows Fe_2O_3 only, but P-13 in $CO \xrightarrow{t} SO_2$ (t=5 min) pulse for Fe_2O_3 shows the presence of Fe_3O_4. This means that active (Fe_3O_4) changes to inactive Fe_3O_4 with increasing t, in a similar manner with P-7. P-14 in $CO \xrightarrow{t} SO_2$ (t=0.25 min) pulse for the Fe_2O_3-Al_2O_3 system shows Fe_2O_3 only, but P-15 in $CO \xrightarrow{t} SO_2$ (t=5 min) pulse for the Fe_2O_3-Al_2O_3 system shows the presence of Fe_3O_4 in analogy with P-13.

X-Ray patterns, in $CO \times 5 \xrightarrow{t} SO_2 \times 5$ (t=25 min)

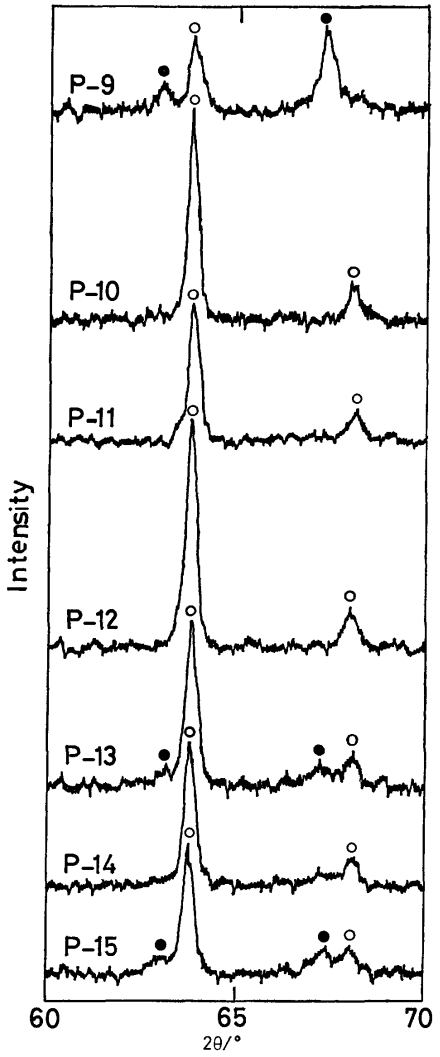

Fig. 10. X-Ray diffraction patterns after pulse experiments for Fe_2O_3 and Fe_2O_3–Al_2O_3 systems preheated at 700 °C.
P-9: Fe_2O_3 in CO pulse, P-10: Fe_2O_3 in $2CO+SO_2$ pulse, P-11: Fe_2O_3–Al_2O_3 (75:25) in $2CO+SO_2$ pulse, P-12: Fe_2O_3 in $CO \xrightarrow{t} SO_2$ (t=0.25 min) pulse, P-13: Fe_2O_3 in $CO \xrightarrow{t} SO_2$ (t=5 min) pulse, P-14: Fe_2O_3–Al_2O_3 (75:25) system in $CO \xrightarrow{t} SO_2$ (t=0.25 min) pulse, P-15: Fe_2O_3–Al_2O_3 (75:25) system in $CO \xrightarrow{t} SO_2$ (t=5 min) pulse. ○: Fe_2O_3, ●: Fe_3O_4.

pulse, for the same samples with of P-3 and P-5 in Fig. 9 and with P-9 and P-11 in Fig. 10, showed the same results as P-3 and P-9 in CO pulse. These results also support the consideration of $CO\times5 \xrightarrow{t} SO_2\times5$ (t=25 min) pulse in Fig. 7.

In order to test the reactivity of magnetite, pulse tests of $2CO+SO_2$ and SO_2 pulses were carried out for commercial Fe_3O_4 (Kanto) preheated at 360 °C. No reactivity for reaction (1) and no change in X-ray pattern for reaction (4) were shown.

From these discussions described above, the catalytic action may be explained on the basis of redox reaction between Fe_2O_3 and nascent (Fe_3O_4), which has been shown in reactions (3) and (4).

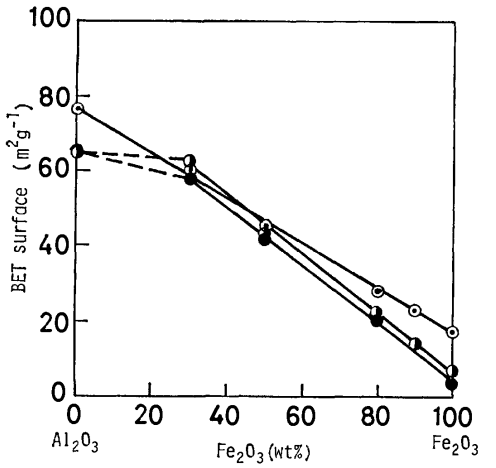

Fig. 11. BET surface of Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures.

BET Surface and Crystallite Size. In order to examine the effect of Al_2O_3 on the reactivity of Fe_2O_3, some considerations were also attempted. Figure 11 shows the relationship between BET surface and Fe_2O_3 contents for the Fe_2O_3–Al_2O_3 systems with various mixing ratios and preheating temperatures. BET surface decreases with increasing Fe_2O_3 content in approximately a linear relationship. No good correlation is obtained between the reactivity of Fe_2O_3–Al_2O_3 mixture for the reduction of SO_2 (in Fig. 1) and BET surface. This is probably due to the sequence that the BET surface of inactive Al_2O_3 would govern that of the Fe_2O_3–Al_2O_3 mixture.

Figure 12 shows the relationship between the crys-

tallite size of Fe_2O_3 as calculated from Scherrer's equation and the Fe_2O_3 content in the Fe_2O_3–Al_2O_3 system. There are some interesting correlations between the crystallite size and the reactivity behavior in Fig. 1, especially at 700 °C of preheating temperature. If the minimum crystallite size value suggests the maximum distortion of the Fe_2O_3 lattice at 700 °C for preheating, it can be presumed that the occurrence of the maximum peak in Fig. 1(c) may be due to the distortion of the Fe_2O_3 lattice, which results from the interfacial reaction with surface diffusion between Fe_2O_3 and Al_2O_3. Furthermore, it is speculated that the activity of (Fe_3O_4) should be enhanced and the lifetime of active (Fe_3O_4) prologened by the interfacial reaction with Al_2O_3, as indicated by a comparison of Figs. 6(b) and (c).

Preparation and Spectroscopic Studies of Stereoisomers of the Tris[(*S*)-1-phenyl-1,3-propanediamine]cobalt(III) Complex

Masaaki KOJIMA and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received September 8, 1981)

Three, *fac*-*Λ*, *fac*-*Λ*, and *mer*-*Λ*, of four possible diastereomers of the $[Co(S\text{-phtn})_3]^{3+}$ complex (*S*-phtn= (*S*)-1-phenyl-1,3-propanediamine) were obtained by two methods, a reaction between *trans*-$[CoCl_2(S\text{-phtn})_2]^+$ and *S*-phtn in DMSO (dimethyl sulfoxide), and oxidation of a DMSO solution containing Co(II) ions and *S*-phtn with air in the presence of active charcoal. Neither method yielded the *mer*-*Λ* isomer. The absorption and circular dichroism spectra of the isomers were recorded in water in the absence and presence of Na_2SO_4, and in DMSO. The shifts of the first absorption bands caused by changing solvents and the changes of circular dichroism spectra caused by the addition of sulfate ions seem to be related with the conformational instability of the flexible six-membered chelate ring in the complexes. The tetraammine complex of *S*-phtn was also prepared.

In the previous papers, we reported that the circular dichroism (CD) spectra of some cobalt(III) complexes containing six-membered diamine chelate rings such as trimethylenediamine (tn),[1] (*R*,*R*)-2,4-pentanediamine (*RR*-ptn),[1] or (*S*)-1,3-butanediamine (*S*-bn)[2] vary remarkably with changes in counter ions and solvents. Such CD variations were accounted for by conformational interconversions of the flexible six-membered chelate rings caused by ion-pair formation. Conformational flexibility of a 1,3-diamine chelate ring would depend on the nature of substituents on the chelate ring. In order to investigate the effect of a bulky substituent on conformational stability of a chelate ring, we have prepared cobalt(III) complexes containing (*S*)-1-phenyl-1,3-propanediamine (*S*-phtn) and measured their absorption and CD spectra under various conditions. The skeletal structure of the *S*-phtn chelate ring is similar to that of the *S*-bn one, although these (*S*)-diamines form stable *skew* conformations of different chirality;[3] the former with the equatorial phenyl group is either the *chair* or the *λ*-*skew* form, while the latter with the same equatorial methyl group is the *chair* or *δ*-*skew* form (Fig. 1).

Experimental

Ligand. 3-Phenyl-3-aminopropionic acid[4] was converted into the amide by the method of Yang and Rising.[5] The amide was reduced with $LiAlH_4$ in dry tetrahydrofuran to give 1-phenyl-1,3-propanediamine (phtn) according to a method similar to that for 2-methyl-1,4-butanediamine.[6] The rac-diamine thus obtained was resolved by the following method. To an aqueous solution (30 cm³) of the diamine (13.5 g, 0.09 mol) was added an aqueous solution (50 cm³) of (+)-tartaric acid (27.5 g, 0.18 mol), and the solution was allowed to stand overnight at 5 °C. White crystals thus obtained were collected, washed with ethanol–water (1:1), and recrystallized from water (50 cm³). One careful recrystallization was sufficient to obtain the optically pure isomer. Yield: 8.3 g. To an aqueous solution (10 cm³) of the diastereomer (8.3 g, 18 mmol) was added an aqueous solution (15 cm³) of KCl (2.7 g, 36 mmol). Potassium hydrogen (+)-tartrate was precipitated, filtered off, and washed with cold water (10 cm³). The combined filtrate and washing were concentrated to a small volume under reduced pressure. White needles of (*S*)-1-phenyl-1,3-propanediamine dihydrochloride were formed by the addition of ethanol and acetone, filtered, and washed with acetone. Yield: 3.7 g. $[\alpha]_D^{25}=+9.06°$ (*c* 0.0136, H_2O).

The absolute configuration of the diamine was determined by preparing (−)-3-phenyl-3-aminopropionic acid of the known absolute configuration (*S*). *N*-Formyl-3-phenyl-3-aminopropionic acid was prepared by the method of Fischer *et al.*,[7] and the diastereomer with quinidine was prepared by the method of Cohen *et al.*[4] (−)-3-Phenyl-3-aminopropionic acid derived from the more soluble diastereomer is known to have the (*S*) configuration.[8] Since the (*S*)-diamine dihydrochloride obtained from the (*S*)-(−)-amino acid by the same method as that for the racemate was dextrorotatory, (+)-phtn·2HCl was determined to have

the (*S*) configuration.

trans-[*CoCl*$_2$(S-*phtn*)$_2$]*Cl*·*H*$_2$*O*. A methanol solution (30 cm^3) containing sodium methoxide (1.89 g, 35 mmol) and *S*-phtn·2HCl (4.0 g, 18 mmol) was stirred for about 1 h, and then filtered to remove sodium chloride precipitated. The filtrate was added to a methanol solution (170 cm^3) of $CoCl_2 \cdot 6H_2O$ (2.0 g, 8.5 mmol). The solution was aerated for 2.5 h at room temperature and then mixed with concd HCl (10 cm^3). Green crystals were obtained by concentrating the solution to a small volume under reduced pressure, filtered, and washed with a small amount of water. Yield: 0.7 g. The second crop was obtained by the addition of water to the filtrate. Yield: 1.1 g. The complex was recrystallized from methanol. Found: C, 44.45; H, 5.92; N, 11.60%. Calcd for $C_{18}H_{30}N_4Cl_3OCo$=*trans*-[$CoCl_2$-(*S*-phtn)$_2$]Cl·H_2O: C, 44.69; H, 6.25; N, 11.58%.

[*Co*(S-*phtn*)$_3$]$^{3+}$. *Method 1*: To a dimethyl sulfoxide (DMSO) solution (40 cm^3) of *trans*-[$CoCl_2$(*S*-phtn)$_2$]Cl·H_2O (0.097 g, 2 mmol) was added a suspension of *S*-phtn·2HCl (0.53 g, 2.4 mmol) and sodium methoxide (0.23 g, 4.2 mmol) in methanol (2 cm^3). The mixture was stirred for 2.5 h at 70 °C, diluted with 1 dm^3 of water, and acidified (pH 2) with hydrochloric acid. The solution was passed through an SP-Sephadex column (ϕ2.7×5 cm). A small portion of the Sephadex charged with the product was placed on the top of the adsorbent layer of an SP-Sephadex column (ϕ2.7×120 cm), and the adsorbed complexes were eluted with a 0.5 M Na_2SO_4 (1 M=1 mol/dm^3) solution adjusted to pH 2 with hydrochloric acid. The column showed four bands, I(pink, very small amount), II(orange, very small amount), IIIA(orange-red, large amount), and IIIB(red, small amount) from bottom to top of the column. Bands IIIA and IIIB were eluted much slower than bands I and II. The effluent of band IIIA was diluted with 10^{-2} M HCl and loaded again on an SP-Sephadex column. The adsorbed band was eluted with a 0.25 M sodium (+)-tartratoantimonate(III) solution. The column showed two bands, *mer*-*Λ*(IIIA-1) and *fac*-*Λ*(IIIA-2) in the order of elution. Band IIIB was the *fac*-*Λ* isomer. The formation ratio, *mer*-*Λ*(IIIA-1) : *fac*-*Λ*(IIIA-2) : *fac*-*Λ*(IIIB) was 8 : 5 : 1. No indication of the presence of the *mer*-*Λ* isomer was observed.

Method 2: To a stirred suspension of *S*-phtn·2HCl (2.0 g, 9.0 mmol) and sodium methoxide (0.92 g, 17 mmol) in methanol (8.5 cm^3) were added a DMSO solution (35 cm^3) of $Co(NO_3)_2 \cdot 6H_2O$ (0.73 g, 2.5 mmol), and active charcoal (0.5 g). The mixture was aerated for 4 h at room temperature, and filtered. The filtrate was diluted with 10^{-2} M HCl and passed through an SP-Sephadex column. The product adsorbed on SP-Sephadex was chromatographed by the same method as that for Method 1. Only two isomers, *mer*-*Λ* and *fac*-*Λ* were yielded, their formation ratio being 1.0:1.4.

mer-Δ[*Co*(S-*phtn*)$_3$](*ClO*$_4$)$_3$·*6H*$_2$*O*, fac-Δ-[*Co*(S-*phtn*)$_3$]-(*ClO*$_4$)$_3$·*2H*$_2$*O*, *and* fac-Λ-[*Co*(S-*phtn*)$_3$](*ClO*$_4$)$_3$·*4H*$_2$*O*. Each eluate of the isomers was diluted with 10^{-2} M HCl and passed through an SP-Sephadex column (ϕ1.5×3 cm). After the column had been washed with 10^{-2} M HCl (*ca.* 100 cm^3), the adsorbed complex was eluted with a 1.5 M $NaClO_4$ ethanol–water (1:1) solution. The eluate was acidified (pH 2) with $HClO_4$ and concentrated to a small volume in a vacuum desiccator over P_2O_5 to yield orange-red crystals. They were filtered, washed with a small amount of water, and recrystallized from 10^{-2} M $HClO_4$. *mer*-*Λ* isomer, Found: C, 35.35; H, 6.18; N, 8.80%. Calcd for $C_{27}H_{54}N_6Cl_3O_{18}Co$=[Co(*S*-phtn)$_3$](ClO$_4$)$_3$·$6H_2O$: C, 35.40; H, 5.94; N, 9.17%. *fac*-*Λ* isomer, Found: C, 38.20; H, 5.28; N, 9.98%. Calcd for $C_{27}H_{46}N_6Cl_3O_{14}Co$=[Co(*S*-phtn)$_3$](ClO$_4$)$_3$·$2H_2O$: C, 38.42; H, 5.49; N, 9.96%. *fac*-*Λ* isomer, Found: C, 37.09; H, 5.75; N, 9.33%. Calcd for $C_{27}H_{50}N_6Cl_3O_{16}Co$=[Co(*S*-phtn)$_3$](ClO$_4$)$_3$·$4H_2O$: C, 36.85; H, 5.73; N, 9.54%.

[*Co*(*NH*$_3$)$_4$(S-*phtn*)](*ClO*$_4$)$_3$·*H*$_2$*O*. A methanol solution (5 cm^3) of *S*-phtn (0.57 g, 5 mmol) was prepared by the same method as that described for *trans*-[$CoCl_2$(*S*-phtn)$_2$]Cl·H_2O. This was added to a DMSO solution (40 cm^3) of [Co(NH$_3$)$_5$(H$_2$O)](ClO$_4$)$_3$ (2.3 g, 5 mmol). The solution was stirred for 3 d at room temperature. The resulting red solution was diluted with 10^{-2} M HCl and passed through an SP-Sephadex column (ϕ2.7×5 cm). The product adsorbed was chromatographed by a method similar to that for [Co(*S*-phtn)$_3$]$^{3+}$ with 0.2 M Na_2SO_4 adjusted to pH 2 with hydrochloric acid. Six bands were eluted in the order of orange-red ([Co(NH$_3$)$_5$(H$_2$O)]$^{3+}$), yellow-orange ([Co(NH$_3$)$_6$]$^{3+}$), purple ([Co(NH$_3$)$_5$(DMSO)]$^{3+}$), orange ([Co(NH$_3$)$_4$(*S*-phtn)]$^{3+}$), orange (probably [Co(NH$_3$)$_5$(*S*-Hphtn)]$^{4+}$),[9] and pink (small amount, not characterized) bands. The eluate of the fourth band was diluted with 10^{-2} M HCl and passed through an SP-Sephadex column (ϕ1.5×3 cm). The adsorbed complex was eluted with 1.5 M $HClO_4$, and the eluate was concentrated to a small volume in a vacuum desiccator over P_2O_5 to yield orange needles, which were filtered and washed with ethanol. Found: C, 18.12; H, 5.07; N, 14.03%. Calcd for $C_9H_{29}N_6Cl_3O_{13}Co$=[Co(NH$_3$)$_4$(*S*-phtn)](ClO$_4$)$_3$·H_2O: C, 18.18; H, 4.75; N, 14.13%.

Attempts to Equilibrate [*Co*(S-*phtn*)$_3$]$^{3+}$. The *mer*-*Λ*-[Co(*S*-phtn)$_3$](ClO$_4$)$_3$·$6H_2O$ (0.3 g) isomer was refluxed in water (50 cm^3) in the presence of active charcoal (0.1 g) for 3—8 h. The equilibrium process was accompanied by decomposition of the complex to reduce Co(III) to Co(II). A similar experiment was carried out in DMSO, but neither equilibration nor decomposition of the complex occured.

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-20 spectropolarimeter, respectively. Optical rotations at 589 nm were measured with a JASCO DIP-4 polarimeter at 25 °C. ^{13}C NMR spectra were obtained in DMSO solutions with a JEOL FX-60 spectrometer using dioxane as an external reference.

Results and Discussion

[*Co*(*NH*$_3$)$_4$(S-*phtn*)]$^{3+}$. Figure 2 compares CD spectra of the tetraammine complexes of *S*-phtn, *S*-bn, and *RR*-ptn in aqueous solutions. The CD pattern of the *S*-phtn complex is enantiomeric to that of the *S*-bn complex in the first absorption band region. Since the *S*-phtn and *S*-bn chelate rings will be stabilized with the equatorially disposed substituent in the *chair* and/or the *λ*-*skew*, and in the *chair* and/or the *δ*-*skew* conformations, respectively (Fig. 1), it is possible to attribute these CD patterns to the presence of *skew* conformers of the diamines. However, the signs of main CD bands of the complexes are opposite to those reported for the vicinal effect of many chiral, *gauche* and *skew* conformers of diamine chelates; a *λ*(*δ*)-conformer gives the positive (negative) vicinal effect in the first absorption band region. Therefore, it appears that the *S*-phtn and *S*-bn chelates in the tetraammine complexes have the achiral *chair* conformation, and that the weak CD peaks are those related essentially to the vicinal effect of the chiral

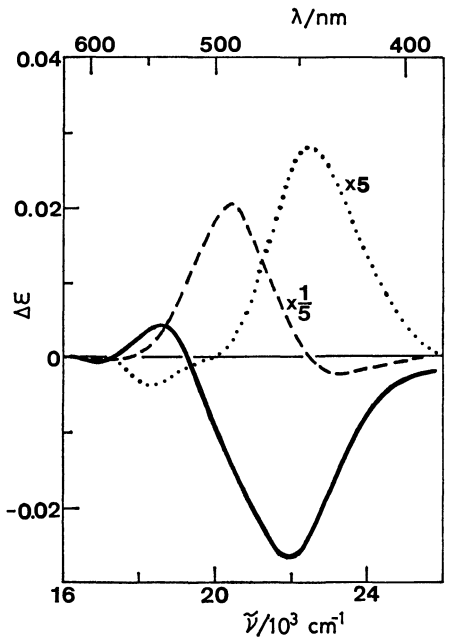

Fig. 2. CD spectra of $[Co(NH_3)_4(1,3\text{-diamine})]^{3+}$ in water. 1,3-Diamine: *S*-phtn (——), *RR*-ptn (----), and *S*-bn (·····).

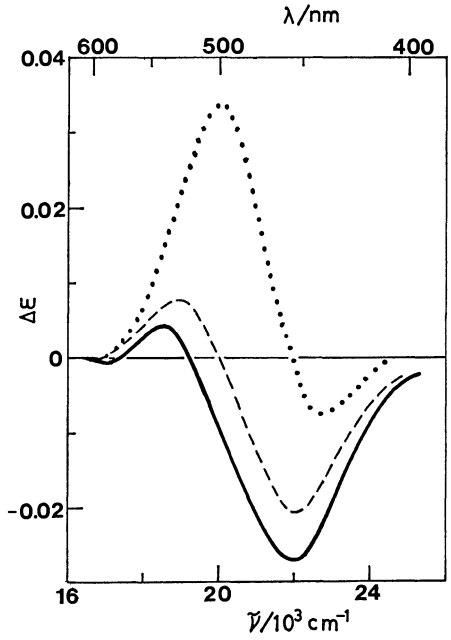

Fig. 3. CD spectra of $[Co(NH_3)_4(S\text{-phtn})]^{3+}$ in water (——), in 0.2 M Na_2SO_4 (----), and in DMSO–H_2O (1:1) (·····).

carbon atom. The CD strength of the *S*-phtn complex is about six times as large as that of the *S*-bn complex (Table 1). The CD of a tetraammine complex with a bulky phenyl-substituted diamine chelate seems to be larger than that of the corresponding methyl-substituted complex. For example, $[Co(NH_3)_4(R\text{-pen})]^{3+}$ (*R*-pen = (*R*)-1-phenyl-1,2-ethanediamine, $\Delta\varepsilon = +0.465$, 21600 cm^{-1})[10] and $[Co(NH_3)_4(R\text{-pn})]^{3+}$ (*R*-pn = (*R*)-1,2-propanediamine, $\Delta\varepsilon = +0.326$, 21690 cm^{-1});[10] $[Co(NH_3)_4(SS\text{-dpen})]^{3+}$ (*SS*-dpen = (*S*,*S*)-1,2-diphenyl-1,2-ethanediamine, $\Delta\varepsilon = -0.75$, 21370 cm^{-1})[11] and $[Co(NH_3)_4(SS\text{-2,3-bn})]^{3+}$ (*SS*-2,3-bn = (*S*,*S*)-2,3-butanediamine, $\Delta\varepsilon = -0.35$, 21740 cm^{-1}).[10]

The *S*-phtn complex increases the CD strength of the positive component and decreases complementarily that of the negative one in 0.2 M Na_2SO_4 and in DMSO–H_2O (1:1) (Fig. 3). The CD pattern in the latter solvent quite resembles that of $[Co(NH_3)_4(RR\text{-ptn})]^{3+}$ in water. The stable conformer of the *RR*-ptn chelate ring will be the *λ-skew* form in which the

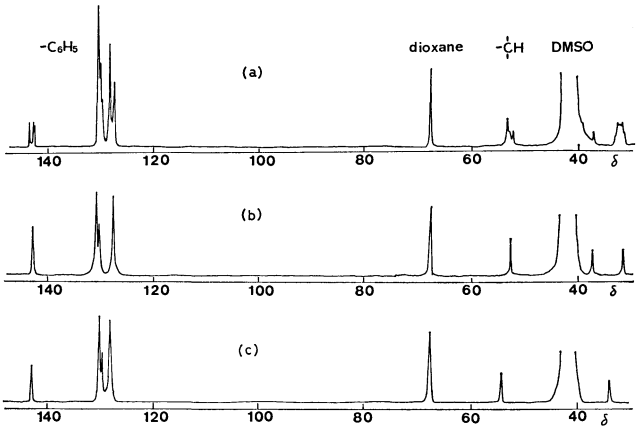

Fig. 4. ^{13}C NMR spectra of the three isomers of [Co(*S*-phtn)$_3$]$^{3+}$ in DMSO; (a) IIIA-1 (*mer*-*Δ*), (b) IIIA-2 (*fac*-*Δ*), and (c) IIIB (*fac*-*Λ*).

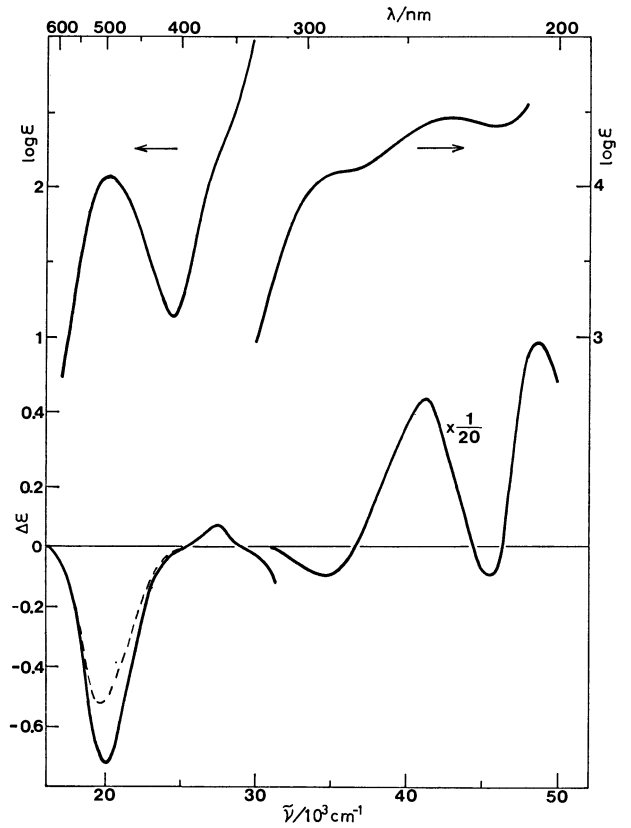

Fig. 5. Absorption and CD spectra of *mer*-*Δ*-[Co(*S*-phtn)$_3$]$^{3+}$ (IIIA-1) in water (——) and in 0.2 M Na_2SO_4 (----).

two methyl groups are disposed equatorially.[1] Thus the *S*-phtn complex is suggested to involve the *λ*-*skew* conformer stabilized under the conditions given. When the *S*-phtn chelate ring adopts the *λ*-*skew* form, the complex ion has a set of three N–H bonds suitable for hydrogen bonds with a sulfate or a perchlorate ion, the N–H bonds being provided by two ammonia molecules and the *S*-phtn chelate.[1] The N–H bonds of the diamine in the *chair* form are not directed properly for such hydrogen bonding. A perchlorate ion could form an ion-pair with the complex ion in DMSO–

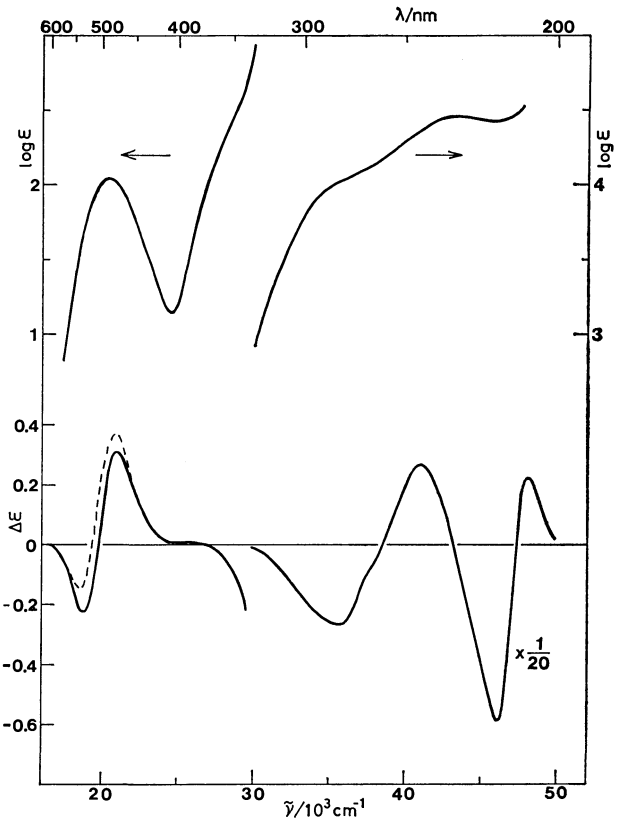

Fig. 6. Absorption and CD spectra of *fac*-*Δ*-[Co(*S*-phtn)$_3$]$^{3+}$ (IIIA-2) in water (——) and in 0.05 M Na_2SO_4 (----) (The complex is hardly soluble in 0.2 M Na_2SO_4.).

H_2O (1:1).[1]

[*Co*(S-*phtn*)$_3$]$^{3+}$. *Characterization and Formation Ratio of the Isomers*: The [Co(*S*-phtn)$_3$]$^{3+}$ complex can have four diastereomers, *mer*-*Δ*, *mer*-*Λ*, *fac*-*Δ*, and *fac*-*Λ*. ^{13}C NMR spectroscopy was used to distinguish between the *mer* and *fac* isomers (Fig. 4). The spectra of isomers IIIA-2 and IIIB give one and four resonances for the methine and the phenyl carbons, respectively, while that of isomer IIIA-1 shows complicated signals, indicating the presence of nonequivalent methine and phenyl groups. From symmetry argument (*fac*(C_3), *mer*(C_1)), isomers IIIA-1, IIIA-2, and IIIB can be assigned to the *mer*, *fac*, and *fac* configurations, respectively. Figures 5—7 show CD spectra of the three isomers in aqueous solutions in the absence and presence of sulfate ions. On the basis of the CD patterns in the first absorption band region, isomers IIIA-1, IIIA-2, and IIIB can be assigned to the *Δ*, *Δ*, and *Λ* configurations, respectively. For a cobalt(III) complex containing 1,3-diamine chelates, the CD pattern in this region often depends greatly on conditions measured, so that the use of the sign of the lowest energy CD band appearing in the Co(III)–diamine charge-transfer region has been recommended for assigning the absolute configuration;[12] the *Λ*-[Co(diamine)$_3$]$^{3+}$ complex shows a negative CD band at the lowest energy in this region. All the isomers give such a band at *ca.* 40000 cm^{-1}. The negative CD bands at *ca.* 35000 cm^{-1} of isomers IIIA-1 and

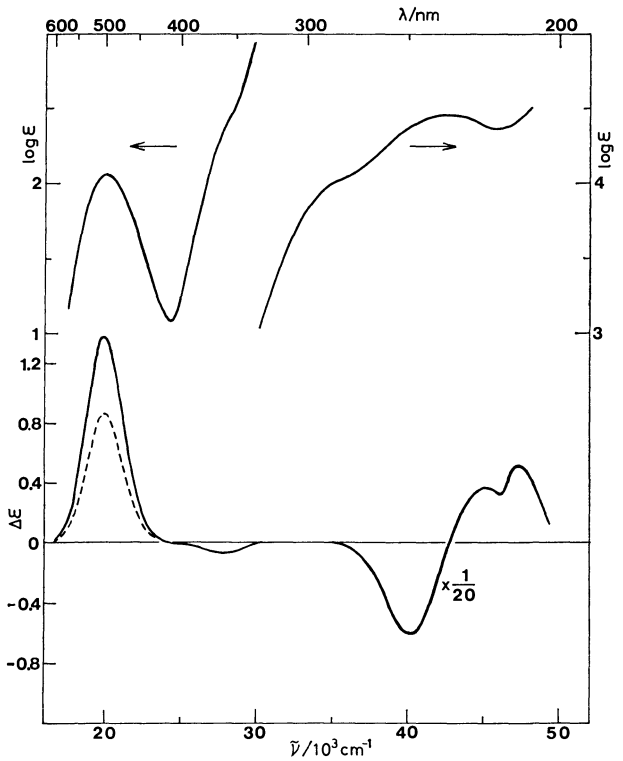

Fig. 7. Absorption and CD spectra of *fac*-*Λ*-[Co(*S*-phtn)$_3$]$^{3+}$ (IIIB) in water (——) and in 0.2 M Na_2SO_4 (----).

IIIA-2 should correspond to transitions of the phenyl group. Thus two isomers IIIA-1 and IIIA-2, and isomer IIIB which show a positive and negative CD band, respectively, at *ca.* 40000 cm^{-1} are assigned to *Δ* and *Λ* configurations, respectively. This assignment agrees with that based on the CD pattern in the first absorption band region. Thus it is concluded that isomers IIIA-1, IIIA-2, and IIIB are the *mer*-*Δ*, *fac*-*Δ*, and *fac*-*Λ* configurations, respectively.

The [Co(*S*-phtn)$_3$]$^{3+}$ complex was prepared by two methods. Method 1 is a substitution reaction between *trans*-[$CoCl_2$(*S*-phtn)$_2$]$^+$ and *S*-phtn in DMSO, and Method 2 oxidation of a DMSO solution containing Co(II) ions and *S*-phtn with air in the presence of active charcoal (Experimental). The formation ratios of the isomers, *mer*-*Δ*:*fac*-*Δ*:*mer*-*Λ*:*fac*-*Λ*, by Methods 1 and 2 were 8:5:0:1, and 1.0:1.4:0:0, respectively. Neither method yielded the *mer*-*Λ* isomer. A molecular model indicates that this isomer involves two phenyl groups situated very close to each other regardless of the conformation of the chelate rings. Although attempts to equilibrate the isomers were unsuccessful, the ratio obtained by Method 2 might be close to that at equilibrium, since the method was carried out in the presence of active charcoal. No *Λ* isomers were formed by Method 2. The *S*-phtn chelate ring can take the *λ*-*skew* conformation. When the diamines are in this conformation, the *Δ*- and *Λ*-[Co(*S*-phtn)$_3$]$^{3+}$ isomers form the *lel*$_3$ and *ob*$_3$ structures, respectively.[13] For [Co(tn)$_3$]$^{3+}$, the *ob*$_3$ isomer has been calculated by conformational analysis to have a substantially higher energy than the *lel*$_3$ and *chair*$_3$ isomers.[14] No formation of the *Λ* isomers might be related to the unstable structure of the *ob*$_3$ isomer. The formation ratio of the isomers, *mer*-*Δ*, *fac*-*Δ*, *mer*-*Λ*, and *fac*-*Λ*, in the corresponding [Co(*S*-bn)$_3$]$^{3+}$ complex was obtained as 1:2:1:14 by a method similar to Method 2 in this study. The *S*-bn complex gives all of the four possible isomers, although it also yields the *Λ* isomers to a greater extent than the *Δ* isomers. Since the chiralities of the *S*-bn and *S*-phtn chelates in the *skew* form are opposite to each other, the structure of *Λ*(*Δ*)-[Co(*S*-bn)$_3$]$^{3+}$ corresponds to that of *Δ*(*Λ*)-[Co(*S*-phtn)$_3$]$^{3+}$. The *Λ*-[Co(*S*-bn)$_3$]$^{3+}$ complex favors greatly the *fac* isomer over the *mer* one, while the *Λ*-[Co(*S*-phtn)$_3$]$^{3+}$ complex gives nearly the same amount of the *mer* and *fac* isomers. The stabilities of these isomers depend largely on the size of the substituent on the 1,3-diamine chelate ligand.

Absorption Spectra: The maximum positions of the first absorption bands of the [Co(*S*-phtn)$_3$]$^{3+}$ isomers differ considerably from each other (Table), in contrast to the case of [Co(*S*-bn)$_3$]$^{3+}$ in which the absorption maxima are in a small range of 20430 to 20370 cm^{-1}.[2] In a previous paper,[2] we reported that a [Co(1,3-diamine)$_3$]$^{3+}$ complex in the *skew* conformation gives the first absorption band at higher energy than that of the complex in the *chair* conformation. The fairly large energy difference in the absorption maixma among the isomers of [Co(*S*-phtn)$_3$]$^{3+}$ seems to be related with the difference in the conformation of chelate rings among the isomers.

When the *S*-phtn chelate ring adopts the *λ*-*skew* conformation, the *fac*-*Λ* and the *fac*-*Δ* isomers form the *ob*$_3$ and the *lel*$_3$ structures, respectively. Since the *ob*$_3$ structure should be less stable than the *chair*$_3$ one,[14] the *fac*-*Λ* isomer would be stabilized in the *chair*$_3$ form. On the other hand, the chelate rings in the *fac*-*Δ* isomer would be able to interchange between the chair and the *λ*-*skew* (*lel*) conformations, since the stability difference between the *chair*$_3$ and the *lel*$_3$ forms would be small.[14] The fact that the *fac*-*Δ* isomer gives the first absorption maximum (20230 cm^{-1}) at fairly higher energy than does the *fac*-*Λ* isomer (20040 cm^{-1}) indicates that the predominant conformation in the *fac*-*Δ* isomer is the *λ*-*skew* form. This isomer shows the blue shift in the first absorption band in DMSO (20410 cm^{-1}). The shift can be interpreted as the result of stabilization of the *lel*$_3$(*Δ*(*λ*-*skew*$_3$)) conformer in this solvent by ion-pair formation between the complex ion and the counter ion (*vide infra*). No solvent effect was observed for the *fac*-*Λ* isomer, suggesting the stability of the *chair*$_3$ structure.

The *mer*-*Δ* isomer shows the first absorption maximum at 20200 cm^{-1} in water. The two *S*-phtn chelate rings in the *mer*(C_1) configuration approach very close to each other, when they adopt the *chair* conformation. As suggested for the *mer* isomers of [Co(*S*-bn)$_3$]$^{3+}$,[2] the close approach of two chelate rings can be avoided when one of these rings takes the *λ*-*skew* conformation. Thus the stable structure of the *mer*-*Δ* isomer would be the (*chair*)$_2$(*λ*-*skew*) form in water. In fact, the first absorption maximum of the isomer is between those of the *fac*-*Δ* and *fac*-*Λ* isomers, in which the predominant conformers of *S*-

phtn have been assigned to the *λ-skew* and *chair* forms, respectively. The first absorption band of the *mer-Δ* isomer shows a small red shift in DMSO (20140 cm^{-1}), but the reverse shift in DMSO–H_2O (1:1) (20280 cm^{-1}). Although the reason for this is not clear, the complex might be stabilized in the lel_3-$(\lambda\text{-}skew)_3$ structure in the latter solvent. In the case of the *fac-Δ* isomer, the band shifts monotonously depending upon the ratio of DMSO to water.

Circular Dichroism Spectra: The study of absorption spectra suggested that the predominant conformer in one isomer differs from that in another. Such conformational flexibility of the *S*-phtn chelate ring is also reflected on the CD spectra. For example, the additive law[16] for the configurational and the vicinal (conformational) effects does not hold for the diastereomeric pair, *fac-Δ*- and *fac-Λ*-$[Co(S\text{-phtn})_3]^{3+}$. The lack of such additivity has also been found for the *RR*-ptn and *S*-bn complexes, and ascribed to the conformational flexibility of the six-membered chelate rings.

The CD pattern of *fac-Δ*-$[Co(S\text{-phtn})_3]^{3+}$ in water is very similar to that of *Δ*-$[Co(RR\text{-ptn})_3]^{3+}$ in 0.1 M Na_2SO_4. The latter has been considered to be stabilized in the $lel_3(\Delta(\lambda\text{-}skew)_3)$ form in the presence of sulfate ions.[1] Thus it is suggested that the stable structure of the *fac-Δ* isomer in water is the $\lambda\text{-}skew_3$-(lel_3) form. This suggestion agrees with that obtained from absorption studies. The corresponding *S*-bn complex, *fac-Λ*-$[Co(S\text{-bn})_3]^{3+}$, on the other hand, is stabilized in the $chair_3$ structure in water.[2] On addition of sulfate ions, *fac-Λ*-$[Co(S\text{-phtn})_3]^{3+}$ diminishes the CD strength of the negative component, and complementarily enhances that of the positive component. Such a change is known to be caused by an increase in the amount of the $lel_3(\Delta(\lambda\text{-}skew)_3)$ conformer due to ion-association between the complex ion and a sulfate ion; the lel_3 form is the most effective structure in forming an ion-pair through hydrogen bonding between the amino protons and a sulfate ion, and the increase in the positive CD component is caused by the increasing amount of the λ-conformer, since the vicinal effect of a λ-conformer is positive.[16] The lel_3 conformer of the *fac-Δ* isomer would be stabilized more in the presence of sulfate ions.

The *fac-Λ* isomer shows only one positive CD band in the first absorption band region, and the CD strength diminishes considerably on addition of sulfate ions. Both of these characteristics have been observed for *fac-Λ*-$[Co(RS\text{-ptn})_3]^{3+}$ (*RS*-ptn=(*R*,*S*)-2,4-pentanediamine), in which the *RS*-ptn chelate ring should be stabilized in the *chair* conformation with the two equatorial methyl groups. Thus the stable structure of *fac-Λ*-$[Co(S\text{-phtn})_3]^{3+}$ would be the $chair_3$ form as suggested from absorption studies.

The CD changes caused by the addition of sulfate ions for *fac-Δ*- and *fac-Λ*-$[Co(S\text{-phtn})_3]^{3+}$ correspond to those for *fac-Δ*- and *fac-Λ*-$[Co(S\text{-bn})_3]^{3+}$, respectively. On the other hand, the effect of sulfate ions on the CD of *mer-Δ*-$[Co(S\text{-phtn})_3]^{3+}$ differs significantly from that of *mer-Λ*-$[Co(S\text{-bn})_3]^{3+}$. By the addition of sulfate ions, the *S*-bn complex shows a fairly strong negative CD band with the decrease in strength of the positive CD band, suggesting the stabilization of the lel_3 form due to ion-pair formation with a sulfate ion.[2] However, the *S*-phtn complex diminishes only the strength of the negative CD band and shows no indication of appearance of a positive CD band. Thus no stabilization to the lel_3 form seems to occur in the *mer-Δ*-$[Co(S\text{-phtn})_3]^{3+}$ isomer. This might be related with the difficulty in forming an ion-pair with a sulfate ion. In the *mer-Δ* isomer, the bulky phenyl groups are disposed on either side of the pseudo-C_3 axis of the complex ion, and would hinder a sulfate ion from approaching the complex ion along the axis. Thus the complex will not be stabilized in the lel_3 form in the presence of sulfate ions.

Each of the three isomers of $[Co(S\text{-phtn})_3]^{3+}$ exhibits a characteristic CD change by the addition of sulfate ions, and all the CD changes can be interpreted on the basis of those of the corresponding *S*-bn complexes taking the steric effect of the bulky phenyl group into consideration.

The bis(β-diketonato)platinum(II) complexes react with various nitrogen bases (L) to afford [Pt(β-dik)L_2]-(β-dik), [Pt(β-dik-*O*)$_2L_2$], [PtL_4](β-dik)$_2$, and [Pt(β-dik)(β-dik-*C*)L] depending on the natures of the β-diketonate anions and L. All of these complexes are stable in solution, showing no sign of isomerization and dissociation of L. The platinum(II) complexes containing the *O*-unidentate β-diketonate ligand are much more stable than the corresponding palladium(II) complexes and [Pt(acac)(piperidine)$_2$](acac) and [Pt(acac-*O*)$_2$(piperidine)$_2$] constitute a pair of linkage isomers. The complexes containing the 2,4-pentanedionate anion (acac) in the outer sphere readily undergo the H-D exchange of the methine proton of acac and the NH protons of coordinated amines with $CDCl_3$.

Bis(β-diketonato)palladium(II) complexes [Pd(β-dik)$_2$] are labile and undergo facile substitution reactions with ammonia, alkylamines, and heterocyclic nitrogen bases (L)[1,2] to afford complexes of the type [Pd(β-dik)L_2](β-dik) (**4**), [PdL_4](β-dik)$_2$ (**5**), [Pd(β-dik)(β-dik-*C*)L] (**7**), and [Pd(β-dik-*C*)$_2L_2$] (**8**), whereas reactions with aniline and its derivatives give rise to the anilide-bridged dinuclear complexes.[3] The reactions of [M(β-dik)$_2$] (M=Pd and Pt) with tertiary phosphines have also been studied and five-coordinate complexes [M(hfac)$_2$(PR_3)] (**2**)[4] as well as the complexes containing *O*-unidentate β-dik ligands [M(β-dik)(β-dik-*O*)(PR_3)] (**3**) and [M(β-dik-*O*)$_2$(PR_3)$_2$] (**6**) were isolated and characterized[5] besides complexes **4**, **5**, and **7**. This investigation demonstrated some differences between palladium(II) and platinum(II) in preference of the coordination modes of β-dik anions, and the present paper reports the supplementary study on the reactions of [Pt(β-dik)$_2$] with nitrogen bases which are to be compared with those of the corresponding [Pd(β-dik$_2$)] complexes.

Experimental

Preparation of Complexes. The starting [Pt(β-dik)$_2$] complexes inclusive of [Pd(acac)(tfac)] were prepared by the methods reported recently.[6] Gaseous methylamine was evolved from its aqueous solution by addition of potassium hydroxide and condensed in a trap cooled with Dry Ice–methanol. The other amines, pyridines, and ammonia were used as supplied without further purification.

*2,4-Pentanedionatobis(piperidine)platinum(II) 2,4-Pentanedionate, [Pt(acac)(pip)$_2$](acac) (**4a**), and Bis(2,4-pentanedionato-O)-bis(piperidine)platinum(II), [Pt(acac-O)$_2$(pip)$_2$] (**6a**)*: [Pt(acac)$_2$] (**1a**) (306 mg, 0.778 mmol) was placed in piperidine (519 mg, 6.10 mmol) and stirred at 70 °C for 15 min. The complex was dissolved gradually to produce a new white precipitate of **6a**, which was filtered and washed with benzene followed by dichloromethane. The yield was 86 mg (20%). Compound **6a** is hardly soluble in usual solvents such as benzene, chloroform, methanol, and dimethyl sulfoxide, but can be recrystallized from a mixture (1:1 by volume) of chloroform and methanol.

The filtrate was concentrated by evaporation at 50—60 °C under reduced pressure to leave a pale yellow oil, which, on standing in the atmosphere, crystallized in plates. The solid mass was washed several times with small portions of hexane to obtain a white powder of **4a** (329 mg) in a 75% yield. Contrary to **6a**, compound **4a** is soluble in various solvents such as benzene, dichloromethane, diethyl ether, and acetone. Recrystallization from hexane gave the monohydrate as white needles, while an acetone solution produced anhydrous crystals.

*[Pt(hfac)(Et$_2$NH)$_2$](hfac) (**4b**) and [Pt(hfac)(pip)$_2$](hfac) (**4c**)*: Diethylamine (44 mg, 0.60 mmol) was added to a diethyl ether solution (3 cm^3) of [Pt(hfac)$_2$] (**1b**) (122 mg, 0.200 mmol) and the solvent was evaporated spontaneously at room temperature to leave yellow plates on the wall of reaction vessel. The yield of **4b** was 144 mg (95%). A similar reaction of **1b** with a twice molar amount of piperidine in diethyl ether gave yellow plates of **4c** in a 95% yield.

*[Pt(hfac)(2-$CH_3C_6H_4NH_2$)$_2$](hfac) (**4d**)*: A mixture of **1b** (72 mg, 0.12 mmol) and 2-methylaniline (25 mg, 0.23 mmol) was allowed to react in benzene (3 cm^3) at ambient temperature for two days. The solvent was then removed under reduced pressure and the residue was extracted with dichloromethane. Hexane was added to the extract and the mixture was kept in a refrigerator to deposit yellow cubes (63 mg) in a 64% yield.

*[Pt(hfac)(Ph$_2$en)](hfac) (**4e**)*: On addition of an equimolar amount of *N,N'*-diphenylethylenediamine to a solution of **1b** in dichloromethane, a white crystalline precipitate of **4e** appeared immediately in a quantitative yield. Compound **4e** is sparingly soluble in usual solvents.

*[Pt(acac)(Et$_2$NH)$_2$](tfac) (**4f**) and [Pt(acac)(pip)$_2$](tfac) (**4g**)*: A mixture of [Pt(acac)(tfac)] (50 mg, 0.11 mmol) and diethylamine (3 cm^3) was heated under reflux for 2 h, when a tiny amount of white precipitate appeared, which was separated by filtration but was insufficient to be identified. The solvent was removed under reduced pressure to leave a yellow crystalline solid, which was recrystallized from a mixture (1:1 by volume) of dichloromethane and petroleum ether to afford colorless columns (20 mg) of **4f** in a 31% yield. Complex **4g** was also prepared in a manner similar to **4f** and recrystallization from benzene–petroleum ether gave colorless plates in a 22% yield.

*Tetrakis(propylamine)platinum(II) 2,4-Pentanedionate Monohydrate, [Pt(n-$PrNH_2$)$_4$](acac)$_2$·H_2O (**5a**)*: A mixture of **1a**

** In this paper the chelated, single oxygen bonded, and central carbon bonded anions of β-diketones (β-dikH) such as 2,4-pentanedione (acacH), 1,1,1-trifluoro-2,4-pentanedione (tfacH), and 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (hfacH) are represented by β-dik, β-dik-*O*, and β-dik-*C*, respectively, and β-dik in the outer sphere shows a counter ion. Other abbreviation: pip, piperidine; Ph_2en, *N,N'*-diphenylethylenediamine; $CyNH_2$, cyclohexylamine.

(200 mg, 0.509 mmol) and propylamine (5 cm^3) was heated under reflux for 10 min and cooled then to −5 °C to deposit colorless plates, which were filtered and washed with diethyl ether. The yield was 155 mg (47%).

[Pt(en)$_2$](acac)$_2$·H$_2$O (5b): When a mixture of **1a** (168 mg, 0.427 mmol) and ethylenediamine (3 cm^3) was heated to about 80 °C for 3 h, a white precipitate appeared and increased gradually. The mixture was cooled spontaneously to room temperature and acetone (5 cm^3) was added to it. The precipitate was filtered and washed with acetone. Recrystallization from methanol–acetone gave white needles (163 mg) in a 72% yield.

[Pt(CyNH$_2$)$_4$](tfac)$_2$ (5c) and [Pt(CyNH$_2$)$_4$](hfac)$_2$ (5e): After the reaction of [Pt(tfac)$_2$] (**1c**) (50 mg, 0.10 mmol) with cyclohexylamine (0.5 cm^3) at about 80 °C for 10 min, diethyl ether (1 cm^3) was added to the cooled reaction mixture to deposit a white precipitate, which was filtered and washed with diethyl ether. The yield was 33 mg (37%). A similar reaction between **1b** and cyclohexylamine gave a white powder of **5e** in a 40% yield. Compounds **5c** and **5e** are both sparingly soluble in usual solvents.

[Pt(py)$_4$](tfac)$_2$·3H$_2$O (5d): A white precipitate appeared immediately after dissolution of **1c** (46 mg, 0.092 mmol) in pyridine (0.5 cm^3). A small portion of hexane was added to the mixture, which was cooled to −5 °C. The precipitate was filtered and washed with diethyl ether. The yield was 79 mg (74%). Recrystallization from dichloromethane–petroleum ether gave white needles.

[Pt(2-CH$_3$C$_6$H$_4$NH$_2$)$_4$](hfac)$_2$·(CH$_3$)$_2$CO (5f): 2-Methylaniline (32 mg, 0.30 mmol) was added to a solution of **1b** (45 mg, 0.074 mmol) in benzene (1 cm^3) and the mixture was stirred for 3 h. The solvent was removed under reduced pressure to leave a yellow crystalline solid, which was washed with diethyl ether. The yield was 69 mg (90%). Recrystallization from acetone–hexane gave white needles which contain an acetone molecule per platinum in crystals.

[Pt(py)$_4$](hfac)$_2$ (5g): Complex **1b** (80 mg, 0.13 mmol) reacted with pyridine (0.3 cm^3) in an exothermic fashion to result in an orange solution. Gradual addition of diethyl ether (1 cm^3) followed by hexane (5 cm^3) to the solution precipitated white needles, which were filtered and washed with a mixture (1:1 by volume) of diethyl ether and hexane. The yield was 103 mg (86%).

[Pt(4-CN-py)$_4$](hfac)$_2$ (5h): On addition of eight times molar 4-cyanopyridine to a benzene solution of **1b**, a yellow crystalline precipitate appeared immediately, which was filtered and washed with diethyl ether. The yield was almost quantitative. Compound **5h** is sparingly soluble in usual solvents.

[Pt(bpy)$_2$](hfac)$_2$ (5i): 2,2′-Bipyridine (54 mg, 0.35 mmol) was added to a solution of **1b** (104 mg, 0.171 mmol) in dichloromethane (2 cm^3) and the mixture was left to stand to deposit a yellow crystalline precipitate, which was filtered and washed with diethyl ether. The yield was 123 g (78%).

Bis(diethylamine)bis(1,1,1-trifluoro-2,4-pentanedionato-O)platinum(II), [Pt(tfac-O)$_2$(Et$_2$NH)$_2$] (6b), and [Pt(tfac-O)$_2$(pip)$_2$]·H$_2$O (6c): A twice molar amount of diethylamine or piperidine was added to a dichloromethane solution of **1c** and the solvent was evaporated spontaneously. The residue was washed with dichloromethane to leave a white crystalline solid. The yields of **6b** and **6c** were 14 and 19%, respectively. Solubilities of both complexes in usual solvents are low.

1,1,1-Hexafluoro-2,4-pentanedionato(1,1,1-hexafluoro-2,4-pentanedionato-C^3)(2-methylaniline)platinum(II), [Pt(hfac)(hfac-C^3)(2-CH$_3$C$_6$H$_4$NH$_2$)] (7a): 2-Methylaniline (24 mg, 0.22 mmol) was added to a solution of **1b** (120 mg, 0.200 mmol) in benzene (5 cm^3) and the mixture was refluxed for 8 h. The solvent was then removed under reduced pressure and the residue was recrystallized from hexane to give yellow cubes (45 mg) in a 31% yield.

Bis(4-methylamino-1,1,1,5,5,5-hexafluoro-3-penten-2-onato)platinum(II), [Pt{N(CH$_3$)C(CF$_3$)=CHCOCF$_3$}$_2$] (11): When methylamine (3 cm^3) was added to a solution of **1b** (120 mg, 0.200 mmol) in diethyl ether (5 cm^3), color of the solution changed from orange to red. The solvent was evaporated spontaneously to leave a red oil and a red crystalline solid. The mixture was dissolved in dichloromethane and recrystallized by addition of petroleum ether to give red needles (32 mg) in a 25% yield. Found: C, 22.70; H, 1.30; N, 4.51%. Calcd for $C_{12}H_8N_2O_2F_{12}Pt$: C, 22.69; H, 1.27; N, 4.41%. Sublimation temp: *ca.* 120 °C. IR in Nujol (cm^{-1}): ν(C=O)+ν(C=C)+ν(C=N), 1627 vs, 1602 s, 1545 vs, 1515 m; ν(C–F), 1230 vs, 1195 vs, 1138 vs. ^{1}H NMR in $CDCl_3$ (δ, ppm from internal Me_4Si): 3.45 q (3H, NCH_3, ^5J(F–H)=2 Hz, ^3J(Pt–H)=27 Hz), 5.99 s (1H, CH, ^4J(Pt–H)=6 Hz).

Measurements. IR spectra were recorded in Nujol mull on Hitachi EPI-S2 and 295 spectrophotometers. NMR spectra were measured with JEOL JNM-C60HL and -MH100 (for ^{1}H), FX60Q (for ^{1}H and ^{13}C), and PS-100 (for ^{19}F) instruments.

Results and Discussion

Reactions of [Pt(β-dik)$_2$] (β-dik=acac (**1a**), hfac (**1b**), and tfac (**1c**)) inclusive of [Pt(acac)(tfac)] with several kinds of nitrogen bases have been examined. In general primary amines and pyridines gave complexes of type **5**, while secondary amines **4** and/or **6**. The reaction between **1b** and 2-methylaniline was exceptional, giving three types of complexes **7a**, **4d**, and **5f** depending on the reactants mole ratio, but did not produce the anilide-bridged dinuclear complexes in contrast with the reactions of [Pd(hfac)$_2$] with aniline and its derivatives.[3]

Complexes **1a** and **1c** did not react with bubbling ammonia in dichloromethane solutions, while **1b** gave a minute amount of unidentified product. A solution of **1a** in methylamine showed no sign of reaction up to the boiling point. When **1b** and **1c** were dissolved in methylamine and propylamine, red solutions resulted indicating occurrence of reactions, but no reproducible product has been obtained except **11**. A Schiff base complex [Pt{N(CH$_3$)C(CF$_3$)=CHCOCF$_3$}$_2$] (**11**) was isolated from the reaction mixture of **1b** and methylamine in diethyl ether and characterized as described in the Experimental Section. A similar palladium(II) Schiff base complex was also obtained by the reaction of [Pd(tfac)$_2$] with aniline.[3]

Table 1 presents the analytical data for newly prepared complexes and Table 2 the IR data for representative ones among them. Similarly to the case of palladium(II) complexes,[1] the ν(C=O)+ν(C=C) bands in the 1800—1500-cm^{-1} region are helpful in diagnosing the bonding modes of the β-dik anions. Thus complexes **5** exhibit bands caused by β-dik anions in the outer sphere, but **4** additional bands assignable to the chalating β-dik ligands. Complexes

TABLE 2. CHARACTERISTIC IR BANDS OF REPRESENTATIVE COMPLEXES IN NUJOL MULL

Compd	ν(NH)/cm^{-1}	ν(C=C)+ν(C=O)/cm^{-1}
4a	3057 s	1610 vs, 1570 vs, 1550 s, 1525 vs, 1503 vs
4d	3180m, 3050 s	1670 s, 1600 vs, 1553 m, 1535 s
4g	3100 s	1640 s, 1565 vs, 1540 vs, 1520 vs
5a	3150 s, 3100 s	1602 vs, 1504 vs
5d		1635 vs, 1550 vs, br
5f	3210 s, 3020 s	1670 vs, 1520 vs
5g		1676 vs, 1573 m, 1530 vs, br
6a[a]	3170 vs,	1621 vs, 1583 w
6b[b]	3200 vs,	1649 vs
7a	3226m, 3148w	1752 vs, 1703 m, 1598 vs, 1573 s, 1560 s, 1536 m, 1505 m

a) The 1621 and 1583 cm^{-1} bands are assigned to vibrations of the localized C=O and C=C bonds, respectively. The ν(C-O) band is observed at 1165 cm^{-1} (vs). b) The 1649 cm^{-1} band is assigned to ν(C=O). The ν(C-O) band is indiscernible because of overlapping with strong ν(C-F) bands.

6a—c are the first examples of complexes composed of the *O*-unidentate β-dik and amines. The ν(C=O) frequencies for **6a** and **6b** are lower by about 30 and 10 cm^{-1}, respectively, than those for the corresponding triethylphosphine complexes, *trans*-[Pt(acac-*O*)$_2$(PEt_3)$_2$] (1650 cm^{-1})[7] and *trans*-[Pt(tfac-*O*)$_2$(PEt_3)$_2$] (1660 cm^{-1}).[5] The intramolecular or intermolecular hydrogen-bonding interaction between the dangling acetyl or trifluoroacetyl group and the amine group might be responsible for the lower frequency shift of the ν(C=O) band for the present complexes **6**.

^{1}H and ^{13}C NMR Spectra. Tables 3 and 4 list the ^{1}H NMR data for the present complexes except sparingly soluble ones. The ^{13}C NMR data for representative complexes are given in Table 5. They are quite similar to those for the corresponding palladium(II) complexes,[1] and couplings of ^{1}H and ^{13}C atoms to ^{195}Pt are very helpful in diagnosing the bonding states of β-dik anions in the present case. Complexes **5** exhibit each one set of ^{1}H and ^{13}C NMR signals from β-dik anions. All signals lack coupling to ^{195}Pt, indicating that the β-dik anions are involved as counter anions in the outer sphere. Complexes **4**, on the other hand, show each two sets of ^{1}H and ^{13}C signals from β-dik anions. Signals from the chelating β-dik are flanked by the ^{195}Pt satellites and easily distinguished from those assignable to β-dik in the outer sphere. The ^{13}C shieldings and the ^1J(C-H) and J(C-F) values for hfac anions in the outer sphere of **4c** and **5g** are quite similar to those obtained for [K(18-crown-6)](hfac)[1] and [{1,8-bis(dimethylamino)-naphthalene}H](hfac).[3] The ^{19}F NMR spectrum of **5g** in dichloromethane shows a singlet at 4.70 ppm downfield from external CF_3COOH without coupling to ^{195}Pt.

In spite of the salt-like compositions, complexes **4** and **5** as well as the corresponding palladium(II) complexes[1] are generally more soluble in aprotic or-

a, b) Same as footnotes a) and b) for Table 3. IS and OS abbreviate inner and outer spheres, respectively. c) The NH-proton signals are all broad. Chemical shifts for the piperidine protons refer to $H^{2,6}$(equatorial), $H^{2,6}$(axial), and $H^{3,5}$(equatorial) plus H^4 in this sequence and those for $H^{3,5}$(axial) are indiscernible except in the case of **4a** (δ 1.9) and **4c** (δ 1.4_8) in C_6D_6. d) [Pt(acac)(py)$_2$](tfac) (**4h**) was obtained as an oily substance from the reaction of [Pt(acac)(tfac)] with twice molar pyridine in dichloromethane at room temperature. e) Methine of the carbon-bonded hfac.

ganic solvents such as dichloromethane and benzene rather than in water. The amine groups which are the most hydrophilic part in the complex cations might be shielded by the hydrocarbon moiety of the β-dik anion in the outer sphere *via* the hydrogen bonding with the carbonyl oxygens as revealed by the X-ray analysis of [Pd(acac)(Et$_2$NH)$_2$](acac) at −170 °C.[8] The fact that the NH proton of piperidine in **4a** resonates at downfield by 4 ppm as compared with that in **6a**, isomer of **4a**, also reflects the effect of hydrogen bonding with the acac anion in the outer sphere which is much stronger than the intramolecular interaction in **6a**. Complex **5b** as well as [Pd(NH$_3$)$_4$](β-dik)$_2$[1] is exceptional, which is readily soluble in water but not in organic solvents. In these complexes the ammine and amine protons may not be sufficiently shielded by the counter anions.

As is noticed in Tables 3 and 4, C_6D_6 exhibits a remarkable effect on the ^{1}H NMR spectra of complexes **4** and **5**. Signals from the chelating β-dik are shifted upfield by about 0.5 ppm and those from β-dik in the outer sphere are shifted downfield by

a) Chemical shifts in ppm from internal Me_4Si except those for **5b** in D_2O which are referred to internal dioxane (δ 67.4). Figures in parentheses, braces, and brackets give J(C-H), J(Pt-C), and J(F-C) in Hz, respectively. q=Quartet. b) Indiscernible. c) Indiscernible because of H-D exchange. d) Numbering of the carbon atoms: $PtOC^2(C^1H_3)C^3HC^4OC^5H_3$.

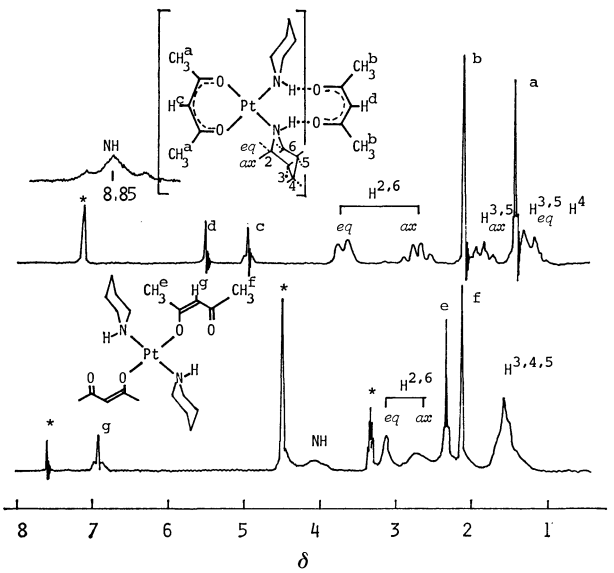

Fig. 1. The proposed structures and the ^1H NMR spectra of [Pt(acac)(pip)$_2$](acac) (**4a**) in C_6D_6 and [Pt(acac-*O*)$_2$(pip)$_2$] (**6a**) in $CDCl_3$+CD_3OD (1:1 by volume) at 100 MHz with internal Me_4Si. The asterisks denote the peaks due to solvent impurities.

0.2—0.5 ppm as compared with those in other solvents. Thus the methine signals for β-dik anions in the inner and outer spheres of **4a** and **4c** interchange their relative positions in $CDCl_3$ and C_6D_6. On the other hand, such a kind of solvent effect is not observed for ^{13}C NMR spectra of **4c** (Table 5). Similar phenomena were found for the corresponding palladium(II) complexes and attributed to the anisotropic magnetic effect of benzene molecules.[1)]

Solubilities of complexes **6** in organic solvents are very low but fortunately **6a** dissolves in a mixture (1:1 by volume) of $CDCl_3$ and CD_3OD sufficiently to allow NMR measurements. The ^1H NMR spectrum of **6a** is compared with that of its isomer **4a** in Fig. 1. The spectrum of **4a** involves two methine and two methyl signals, demonstrating that the two acac anions exist in different and both symmetric environments. On the other hand **6a** exhibits one methine signal and two methyl signals, of which the lower-field one is flanked by ^{195}Pt satellites but the higher-field one is not, indicating that the two acac anions in **6a** are environmentally equivalent, but two halves of each acac are not. The ^{13}C NMR spectrum of **6a** (Table 5) also contains only one set of acac signals and three carbons of each acac ligand couple to ^{195}Pt in accordance with the proposed *O*-unidentate structure. Furthermore, these features of NMR spectra indicate that the *O*-unidentate acac ligand has the stereochemically rigid cis configuration around the C=C bond, although $(CH_3)_3Si$(acac-*O*) molecules have either trans or cis enolate acac anion, the latter undergoing rapid head-to-tail fluxional motion.[9)] As to the geometrical structure of **6a**, the trans arrangement as depicted in Fig. 1 is tentatively assigned by the analogy with *trans*-[Pt(acac-

$O)_2(PEt_3)_2]$[7] and *trans*-[Pt(tfac-$O)_2(PEt_3)_2$].[5] The trans structure of the phosphine complexes was indicated by the characteristic quintet resonance of the methyl protons of PEt_3 and is also supported by small ^1J(Pt–P) values of 2657 and 2646 Hz observed for [Pt(tfac-$O)_2(PR_3)_2$] (R=Et and Cy), respectively.[10]

Complex **4a** is very stable and shows no change on being heated in benzene under reflux for 10 h, whereas complex **6a** decomposes gradually when heated in a chloroform–methanol solution. Thus, though **4a** and **6a** constitute a pair of isomers, interconversion between each other has not been realized. Linkage isomerism is the most interesting and important isomerism in coordination chemistry and a large number of examples have been reported.[11] Each of **4a** and **6a** is composed of two acac anions and two piperidine molecules. In complex **6a** both acac anions act as the *O*-unidentate ligand, whereas in **4a** one is serving as a bidentate ligand and the other as a counter ion. Thus the couple of **4a** and **6a** presents a novel type of linkage isomerism.

The ^{1}H NMR spectrum of **7a** in $CDCl_3$ closely resembles that of [Pd(hfac)(hfac-C^3)(2,4,6-$(CH_3)_3C_6H_2NH_2$)].[3] Although the J(Pt–H) value (7 Hz) of a methine signal at 6.21 ppm is similar to values observed for chelating β-dik anions in complexes **4** (Table 4), J(Pt–H) for the methine signal at 5.99 ppm is as large as 120 Hz, unequivocally indicating that one hfac anion is carbon-bonded to the metal atom. Metal complexes containing a carbon-bonded hfac anion as a ligand are quite rare,[5] but similar J(Pt–H) values have been reported for the methine protons of carbon-bonded acac ligands in [Pt(acac)(acac-C^3)L] (110 and 129 Hz for L=PPh_3[12] and py,[13] respectively) and [Pt(acac-$C^3)_2(py)_2$] (102 Hz).[13]

The H-D Exchange Reactions of Complexes 4 and 5 with $CDCl_3$. Change with time of ^{1}H NMR spectra of **4a** and **5a** in $CDCl_3$ solutions was followed. Intensities of signals assigned to the acac-methine and NH protons decreased gradually and the $CHCl_3$ signal increased instead to attain equilibria in 30 min (**4a**) and 1 d (**5a**). The corresponding palladium(II) complexes **4a** and **5a** react more rapidly, attaining equilibria in 13 min and several hours, respectively.[1] The key step of the H-D exchange was supposed to be the proton transfer from the coordinated amine to the acac anion in the outer sphere.[1] Deprotonation of coordinated amines might be more difficult in the platinum(II) complexes than in the corresponding palladium(II) complexes. The fact that contrary to the case of [Pd(hfac)$_2$],[3] the reaction of [Pt(hfac)$_2$] with 2-methylaniline in refluxing benzene does not afford the anilide-bridged dinuclear complex but result in **7a** might reflect the same trend. Other complexes **4** and **5** containing tfac and hfac as counter ions do not undergo the H-D exchange in $CDCl_3$ probably because of lower basicities of these anions.

Relative Stabilities in Various Bonding Modes of β-Diketonate Anions. The palladium(II) complexes of the types **4**, **5**, **7**, and **8**, which were prepared by the reactions of [Pd(β-dik)$_2$] with a variety of nitrogen and phophorus bases, are rather substitution labile in solution and attain interconversion equilibria such as **4**⇄**7**+L, **5**⇄**7**+3L, **7**⇄**1**+L, **27**⇄**4**+**1**, and **8**⇄**7**+L.[1,5] On the contrary, the platinum(II) complexes obtained in this study showed no sign of transformation on being kept in solution for a long time or on being heated. It may not be due to the extraordinary inertness, but be ascribed to thermodynamic stability of each platinum(II) complex, since the interconversion between [Pt(acac)(acac-C^3)(py)] and [Pt(acac-$C^3)_2(py)_2$] was studied at 40—80 °C.[13]

Although the reactions between [Pd(β-dik)$_2$] and secondary amines yield only the type-**4** complexes, [Pt(β-dik)$_2$] can afford **6** besides **4**. The *O*-unidentate linkage of β-dik anions seems to be more favorable to platinum(II) than palladium(II). The same trend was also noticed for reactions of [M(β-dik)$_2$] with tertiary phosphines.[5] [Pd(hfac)$_2$] reacts with 2,2′-bipyridine (bpy) to produce a type-**4** complex but does not give **5** probably because of the steric requirement of bpy.[1] On the contrary, [Pt(hfac)$_2$] affords **5i** solely. The discrepancy can not be reasonably rationalized, since the bond radii of palladium(II) and platinum(II) are not appreciably different as shown by X-ray analyses of [Pd(acac)$_2$][14] and [Pt(acac)$_2$].[15] It is not certain either why [Pt(tfac)$_2$] does not react with bpy despite that palladium gives [Pd(tfac)(bpy)](tfac).

Preference of the bonding mode is also influenced by the nature of β-dik itself. Piperidine produces both **4a** and **6a** in its reaction with [Pt(acac)$_2$], but gives only **6c** with [Pt(tfac)$_2$] and **4c** with [Pt(hfac)$_2$]. Thus preference of the *O*-unidentate bonding seems to be in the sequence tfac>acac>hfac. Since tfac is unsymmetric and the charge density may be larger on the acetyl oxygen than on the trifluoroacetyl oxygen, the *O*-unidentate bonding *via* the acetyl oxygen may not be so unfavorable compared with chelation especially when a good ancillary ligand coexists. On the other hand, chelates of symmetric β-dik anions are much more stable than the *O*-unidentate state because of not only the chelate effect but also the large electron delocalization effect compared with the case of tfac. Furthermore the least basic hfac anion is a weak ligand and prone to go out of the coordination sphere, the tendency being in the sequence, hfac>tfac>acac. The reactions of [Pt(acac)(tfac)] with secondary amines and pyridine clearly demonstrate this trend, displacing tfac exclusively into the outer sphere to afford [Pt(acac)L$_2$](tfac) (**4f**, **4g**, and **4h**). In a similar way, although pyridine reacts with [Pt(tfac)$_2$] and [Pt(hfac)$_2$] to give **5d** and **5g**, respectively, less basic 4-cyanopyridine can not displace tfac in the former chelate, but does remove hfac ligands in the latter chelate to result in **5h**.

The authors wish to thank Mr. Junichi Gohda for elemental analyses. S. O. and S. K. are grateful to the Ministry of Education, Science and Culture for Grants-in-Aid for Scientific Research, No. 454196 and 243014, respectively.

(Received October 16, 1981)

The dinuclear palladium(II) complexes $[(PP)Pd(C^1—C^3\text{-}\beta\text{-dik}(2-)\text{-}O,O')Pd(PP)](ClO_4)_2$ containing a β-diketonate dianion as a bridging ligand were prepared by the reactions of the mononuclear complexes $[Pd(\beta\text{-dik}(2-)\text{-}C^1—C^3)(PP)]$ with $[Pd(PP)(H_2O)_2](ClO_4)_2$. In the reactions of $[Pd(etac(2-)\text{-}C^1—C^3)(dpe)]$ with $[Pt(PPh_3)_2(H_2O)_2](ClO_4)_2$ and $[Ni(acac)_2]$ in the 1:1 mole ratio, similar dinuclear complexes $[(dpe)Pd(C^1—C^3\text{-}etac(2-)\text{-}O,O')Pt(PPh_3)_2](ClO_4)_2$ and $[(dpe)Pd(C^1—C^3\text{-}etac(2-)\text{-}O,O')Ni(acac)_2]$ were produced, respectively, while the reactions of $[Pd(\beta\text{-dik}(2-)\text{-}C^1—C^3)(PP)]$ with $Ni(ClO_4)_2\cdot 6H_2O$ and $Mg(ClO_4)_2$ in the 2:1 mole ratio afforded the trinuclear complexes $[M\{O,O'\text{-}\beta\text{-dik}(2-)\text{-}C^1—C^3Pd(PP)\}_2](ClO_4)_2$ (M=Ni(II) and Mg(II)). The trihapto coordination to palladium(II) and O,O'-chelation to another metal atom of the β-diketonate dianion in these complexes were deduced mainly by IR and NMR spectroscopy.

The terminal-carbon-bonded 2,4-pentanedionato and ethyl acetoacetato complexes with palladium(II), [PdCl(acac-C^1)(bpy)] and [PdCl(etac-C^1)(bpy)], were derived from the trihapto carbon-bonded complexes, $[PdCl(acac\text{-}C^1—C^3)]_2$ (**1a**)[1] and $[PdCl(etac\text{-}C^1—C^3)]_2$ (**1b**),[2] by the bridge-splitting reactions with 2,2'-bipyridine, and reacted with thallium(I) 2,4-pentanedionate to afford the trihapto complexes containing dianions of these β-dicarbonyl compounds [Pd(acac(2−)-$C^1—C^3$)(bpy)] (**2a**) and [Pd(etac(2−)-$C^1—C^3$)(bpy)] (**2b**).[3]

Each of dianion complexes **2a** and **2b** still possesses uncoordinated oxygen atoms, suggesting the possibility of coordination with another metal ion. In fact the reaction of **2a** with an equimolar amount of [Pd(hfac)(bpy)](hfac) (hfac=1,1,1,5,5,5-hexafluoro-2,4-pentanedionate anion) afforded a yellow precipitate which gave satisfactory analysis as $[Pd_2(acac(2-))(bpy)_2](hfac)_2$.[3] Although the IR spectral data of this compound strongly suggested that the 2,4-pentanedionate dianion is bridging two palladium(II) ions by the trihapto coordination and O,O'-chelation, insolubility of the compound in common organic solvents precluded satisfactory characterization. The present paper is concerned with this kind of dinuclear and trinuclear palladium(II) complexes of bridged β-dicarbonyl dianions containing phosphine ligands in place of 2,2'-bipyridine to increase solubility in organic solvents.[4] The C,O,O'-bridging of 2,4-pentanedionate dianions in the dinuclear and trinuclear complexes was previously reported,[5] and the second type of bridging is presented in this paper.

Experimental

Materials. Diphosphines, *cis*-1,2-bis(diphenylphosphino)ethylene(dpe), and 1,2-bis(diphenylphosphino)ethane (dppe), were purchased from Alfa division, Ventron, U.S.A. Dichloro(diphosphine)palladium(II) complexes $[PdCl_2(dpe)]$ and $[PdCl_2(dppe)]$ were prepared according to the literature method[6] (Anal. Found for $[PdCl_2(dpe)]$: C, 54.23; H, 3.86% and Found for $[PdCl_2(dppe)]$: C, 54.51; H, 4.20%). Diaquabis(triphenylphosphine)platinum(II) perchlorate $[Pt(PPh_3)_2(H_2O)_2](ClO_4)_2$ was prepared as follows:[7] a methanol solution (10 cm³) of silver(I) perchlorate (0.250 g, 1.19 mmol) was added to a suspension of *cis*-dichlorobis(triphenylphosphine)platinum(II) (0.470 g, 0.60 mmol) in chloroform at 0 °C. After stirring of the mixture for 5 min, silver(I) chloride precipitated was filtered off and the filtrate was evaporated to dryness under reduced pressure. These operations were performed at 0 °C. The crude product thus obtained was reprecipitated from dichloromethane–diethyl ether to obtain a white solid. The yield was 0.280 g (49%). Found: C, 45.05; H, 3.64%. Calcd for $C_{36}H_{34}O_{10}Cl_2P_2Pt$: C, 45.30; H, 3.59%. Perchlorate salts $Ni(ClO_4)_2\cdot 6H_2O$ and $Mg(ClO_4)_2$ were obtained from Mitsuwa Chemicals and Kishida Chemicals, respectively and used without further purification.

Mononuclear Trihapto Complexes of β-Diketonate Dianions with Palladium(II). η^3-3-Acetyl-2-oxidoallyl(2,2'-bipyridine)palladium(II) [Pd(acac(2−)-$C^1—C^3$)(bpy)] (**2a**) and η^3-3-ethoxycarbonyl-2-oxidoallyl(2,2'-bipyridine)palladium(II), [Pd(etac(2−)-$C^1—C^3$)(bpy)] (**2b**) were prepared by the reported method.[3] The corresponding diphosphine derivatives were prepared by simple displacement of the 2,2'-bipyridine ligand in **2a** and **2b** by diphosphines as follows.

*η^3-3-Acetyl-2-oxidoallyl{cis-1,2-bis(diphenylphosphino)ethylene}palladium(II) [Pd(acac(2−)-C¹—C³)(dpe)] (**3a**) and the Corresponding dppe Derivative [Pd(acac(2−)-C¹—C³)(dppe)] (**3b**)*: A dichloromethane solution (20 cm³) of dpe (0.522 g, 1.32 mmol) or dppe (0.573 g, 1.46 mmol) was added drop by drop to a suspension of **2a** (0.432 g, 1.20 mmol) in dichloromethane (15 cm³) with stirring at room temperature. After being stirred for 30 min, the mixture was passed through a glass filter and the filtrate was concentrated to *ca.* 5 cm³ by evaporation under reduced pressure. Diethyl ether (20 cm³) was added to the concentrate to obtain **3a** (0.654 g) and **3b** (0.640 g) as pale yellow precipitates in 91 and 87% yields, respectively.

*[Pd(etac(2−)C¹—C³)(dpe)] (**3c**), [Pd(etac(2−)-C¹—C³)(dppe)] (**3d**), and [Pd(etac(2−)-C¹—C³)(PPh₃)₂]·CH₂Cl₂ (**3e**)*: In a similar manner as above, η^3-3-ethoxycarbonyl-2-oxidoallyl derivatives **3c**, **3d**, and **3e** were prepared using a dichloromethane solution of **2b** instead of a suspension

† In this paper, β-dik(2−) represents a dianion of 2,4-pentanedione (acac(2−)) or ethyl acetoacetate (etac(2−)) and PP a bidentate phosphine such as *cis*-1,2-bis(diphenylphosphino)ethylene(dpe) and 1,2-bis(diphenylphosphino)ethane(dppe) or two molecules of triphenylphosphine.

of **2a** in the same solvent, as pale yellow powders in 87, 93, and 86% yields, respectively. Inclusion of one mole of solvent of crystallization in **3e** was confirmed by the elemental analysis and NMR spectroscopy.

Dinuclear Complexes Containing a β-Diketonate Dianion as a Bridging Ligand between Two Palladium(II) Ions. *[(dpe)Pd(C¹—C³-acac(2−)-O,O′)Pd(dpe)](ClO₄)₂ (4a)*: An acetone solution (10 cm³) of silver(I) perchlorate (0.234 g, 1.13 mmol) was added to a suspension of [$PdCl_2$(dpe)] (0.322 g, 0.562 mmol) in the same solvent (20 cm³) with stirring at room temperature. After stirring of the mixture for *ca.* 1 h, silver(I) chloride precipitated was filtered off and the filtrate was evaporated to dryness under reduced pressure, leaving diaquadiphosphinepalladium(II) perchlorate on the bottom and a trace of silver(I) chloride which had passed through the glass filter on the wall of the vessel. To obtain a transparent solution freed of silver(I) chloride, the residue was redissolved in a minimum amount of methanol (*ca.* 10 cm³) and the solution was filtered again, and then the filtrate was added drop by drop to a solution (15 cm³) of **3a** (0.308 g, 0.512 mmol) with stirring at 0 °C. The mixture was further stirred for 20 min and a yellow precipitate produced was filtered, washed with cold methanol and diethyl ether successively, and dried *in vacuo*. The yield was 0.380 g (57%). Crystallization from acetone–diethyl ether (1:2 by volume) gave transparent crystals which turned opaque on standing in air. Similarly, the corresponding dppe complex [(dppe)Pd(*C¹—C³*-acac(2−)-*O,O′*)Pd(dppe)]-$(ClO_4)_2$ (**4b**) was obtained as a yellow precipitate in a 55% yield, using [$PdCl_2$(dppe)] as a starting material instead of [$PdCl_2$(dpe)].

[(dpe)Pd(C¹—C³-etac(2−)-O,O′)Pd(dpe)](ClO₄)₂ (4c), *[(dppe)Pd(C¹—C³-etac(2−)-O,O′)Pd(dppe)](ClO₄)₂ (4d)*, *and [(PPh₃)₂Pd(C¹—C³-etac(2−)-O,O′)Pd(dppe)](ClO₄)₂ (4e)*: These 3-ethoxycarbonyl-2-oxidoallyl derivatives **4c**, **4d**, and **4e** were produced as pale yellow powders from **3c**, **3d**, and **3e**, respectively, by the reactions with appropriate diphosphine complexes in a similar fashion as above. The yields of **4c**, **4d**, and **4e** were 83, 71, and 70%, respectively.

Dinuclear Complexes Containing an Ethyl Acetoacetate Dianion as a Bridging Ligand between Palladium(II) and Another Metal Ion. *[(dpe)Pd(C¹—C³-etac(2−)-O,O′)Pt(PPh₃)₂](ClO₄)₂·0.72CH₃NO₂ (5a)* *and [(PPh₃)₂Pd(C¹—C³-etac(2−)-O,O′)-Pt(PPh₃)₂](ClO₄)₂·1.15CH₃NO₂ (5b)*: A nitromethane solution (20 cm³) of [$Pt(PPh_3)_2(H_2O)_2$]$(ClO_4)_2$ (0.372 g, 0.389 mmol) was added dropwise to a solution of **3c** (0.258 g, 0.409 mmol) or **3e** (0.340 g, 0.410 mmol) in methanol (15 cm³) with stirring at room temperature. After being stirred for *ca.* 40 min, the solution was concentrated to *ca.* 5 cm³ by evaporation under reduced pressure. Diethyl ether (20 cm³) was added to the concentrate to obtain **5a** and **5b** as yellow precipitates. The yields were 0.446 g (74%) and 0.484 g (74%), respectively. Inclusion of nitromethane which could not be removed by pumping was confirmed only by nitrogen analysis of **5a** and **5b**, since these complexes were not stable in solution.

[(dpe)Pd(C¹—C³-etac(2−)-O,O′)Ni(acac)₂] (6): An acetone solution (5 cm³) of [$Ni(acac)_2$] (0.140 g, 0.545 mmol) was added drop by drop to a solution of **3c** (0.320 g, 0.507 mmol) in the same solvent (10 cm³) with stirring at room temperature, and then the solution was heated to *ca.* 50 °C. After *ca.* 30 min, a pale yellow precipitate began to appear and the amount increased with continued stirring of the mixture at 50 °C for additional 2 h. The pale yellow product was then filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 0.361 g (80%). The crude product was recrystallized from chloroform–diethyl ether.

Trinuclear Complexes Containing Bridging β-Diketonate Dianions between Two Palladium(II) Ions and Another Metal Ion. *[Ni{(O,O′-acac(2−)-C¹—C³)Pd(dpe)}₂](ClO₄)₂ (7a)*: An acetone solution (7 cm³) of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.061 g, 0.17 mmol) was added dropwise to a solution of **3a** (0.200 g, 0.333 mmol) in dichloromethane (15 cm³) with stirring at room temperature. The mixture was filtered after *ca.* 1 h of stirring and the filtrate was concentrated to *ca.* 3 cm³ by evaporation under reduced pressure. Diethyl ether (15 cm³) was added slowly to the concentrate to obtain **7a** as a pale green precipitate. The yield was 0.223 g (92%). The product was reprecipitated from dichloromethane–diethyl ether.

[Ni{O,O′-etac(2−)-C¹—C³)Pd(dpe)}₂](ClO₄)₂ (7b) *and [Ni{(O,O′-etac(2−)-C¹—C³)Pd(dppe)}₂](ClO₄)₂ (7c)*: In a similar manner as above, **7b** and **7c** were prepared as pale green powders by reactions of $Ni(ClO_4)_2 \cdot 6H_2O$ with **3c** and **3d**, respectively. The yields were 0.251 g (87%) and 0.237 g (98%), respectively.

[Mg{(O,O′-acac(2−)-C¹—C³)Pd(dpe)}₂](ClO₄)₂ (8a): A methanol solution (5 cm³) of $Mg(ClO_4)_2$ (0.054 g, 0.25 mmol) was added drop by drop to a solution of **3a** (0.308 g, 0.512 mmol) in dichloromethane (20 cm³) with stirring at room temperature. After being stirred for *ca.* 40 min, the solution was concentrated to *ca.* 4 cm³ by evaporation under reduced pressure. Diethyl ether (10 cm³) was added to deposit a pale yellow powder of **8a**, which was filtered, washed with diethyl ether, and dried *in vacuo*. The yield was 0.328 g (93%). The product was reprecipitated from dichloromethane–diethyl ether. Pale yellow crystals of **8a** were obtained by careful crystallization from dichloromethane–acetone but they are not stable and turned opaque on standing in air. Similarly, the corresponding etac(2−) derivative, [Mg{(*O,O′*-etac(2−)-*C¹—C³*)Pd(dpe)}₂]$(ClO_4)_2$ (**8b**) was obtained as a pale yellow powder in a 93% yield by the reaction of $Mg(ClO_4)_2$ with **3c**.

Measurements. Infrared spectra were obtained in Nujol mull with a JASCO DS 701G (4000—200 cm^{-1}) infrared spectrophotometer. Absorption spectra were measured in CH_2Cl_2 with a Hitachi EPS-3T spectrophotometer. NMR spectra were recorded on JEOL JNM MH-100 (for ^1H), FX-60Q (for ^{13}C and ^{31}P), and FX-90Q (for ^{31}P) instruments. Molecular weights were determined with a vapor pressure osmometer manufactured by Knauer, West Berlin, West Germany. Magnetic susceptibility of **7b** was determined by the Faraday method using a balance manufactured by Shimadzu with $[Cr(NH_3)_6]Cl_3$ as a standard.

Results and Discussion

The dinuclear palladium(II) complexes of a novel type, [(PP)Pd(*C¹—C³-β*-dik(2−)-*O,O′*)Pd(PP)]$(ClO_4)_2$ (**4a—e**) containing dianions of 2,4-pentanedione and ethyl acetoacetate as a bridging ligand and diphosphines (PP), were prepared by the simple reactions of the η^3 complexes of β-diketonate dianions, [Pd(β-dik(2−)-*C¹—C³*)(PP)] (**3a—e**) with diaquadiphosphinepalladium(II) perchlorate in methanol at 0 °C.

These reactions were successfully extended to obtain dinuclear and trinuclear complexes containing a β-diketonate dianion which bridges palladium(II) and platinum(II), nickel(II), or magnesium(II) ions in the same way as above. Thus the mononuclear complexes **3c** and **3e** reacted with [$Pt(PPh_3)_2(H_2O)_2$]-$(ClO_4)_2$ in a mixture of nitromethane and methanol (2:1 by volume) at room temperature to give the

ionic dinuclear mixed-metal complexes [(PP)Pd(C^1–C^3-etac(2—)-*O*,*O*′)Pt(PPh_3)$_2$](ClO_4)$_2$ (**5a**, PP=dpe; **5b**, PP=2PPh_3), whereas the reaction of **3c** with [Ni(acac)$_2$] in acetone at 50 °C afforded the neutral complex [(dpe)Pd(C^1—C^3-etac(2—)-*O*,*O*′)Ni(acac)$_2$] (**6**). Contrary to all these reactions in the mole ratio of 1:1, the reactions of **3a**, **3c**, and **3d** with Ni(ClO_4)$_2$·6H_2O and of **3a** and **3c** with Mg(ClO_4)$_2$, in the 2:1 mole ratio produced the ionic trinuclear mixed-metal complexes [M{*O*,*O*′-β-dik(2—)-C^1—C^3)Pd(PP)}$_2$](ClO_4)$_2$ (**7a**—**c**, M=Ni(II); **8a** and **8b**, M=Mg(II)), which contain two bridged β-diketonate dianions connecting two different metal ions.

All of the newly prepared complexes inclusive of the trinuclear ionic complexes are moderately soluble in usual organic solvents, and their analytical and molecular weight data are listed in Table 1. Except **7a** and **7b** which give somewhat abnormal molecular weights, each of almost all complexes does not dissociate in nonpolar organic solvents such as CH_2Cl_2.

Mononuclear Trihapto Complexes of β-Diketonate Dianions with Palladium(II). The ^{13}C NMR data for the mononuclear complexes **3a**, **3c**, and **3e** in $CDCl_3$ are listed in Table 2. The dpe complexes are more stable than the corresponding dppe and PPh_3 complexes, exhibiting very good ^{13}C NMR spectra. Assignment of the three sets of higher-field signals in the spectrum of **3a** to the methyl, methylene, and methine carbons was made on the basis of the ^{1}H non-decoupled data, and other signals were assigned as listed in Table 2 by comparison with the spectra for **2a**[3] and [Pt(acac(2—)-C^1—C^3){P(*p*-ClC_6H_4)$_3$}$_2$],[8] of which the trihapto structures were confirmed by the NMR spectra. Four carbons (C^1—C^4) of the acac(2—) skeleton couple to the ^{31}P atom(s), strongly suggesting the trihapto coordination of the ligand to palladium(II). Of these, the terminal methylene (C^1) and methine (C^3) carbons couple strongly to the ^{31}P atom situated at the trans position, each resonating as a doublet, whereas the central carbonyl carbon (C^2) resonates as a triplet, indicating that the coupling constants to both ^{31}P atoms are nearly equal in spite of their environmental nonequivalence. The other carbonyl carbon (C^4) is remote from the coordination sites and weakly couples to both P^1 and P^2. The ^{13}C NMR spectral data for [Pd(etac(2—)-C^1—C^3)-(Me_2bpy)][3] (**2c**) were also helpful for signal assignment of **3c** listed in Table 2. Compared with the ^{13}C NMR signals of the allylic moiety in **2a** and **2c**,[3] the methylene and methine carbons of **3a** and **3c** resonate at the lower field by 10—20 ppm. Such a deshielding of these carbon atoms is presumably due to the larger back-donation of palladium(II) to diphosphine than 2,2′-bipyridine. The same situation is also seen for the shielding of allylic protons (*vide infra*).

Contrary to **3a**, the terminal methylene (C^1) and methine (C^3) carbons of the allylic moiety in the PPh_3 complex **3e** resonate as a doublet of doublets due to the couplings to both P^1 and P^2. The coupling constants (Table 2) are quite similar to those in [Pt(acac-(2—)-C^1—C^3){P(*p*-ClC_6H_4)$_3$}$_2$][8] ($J(P^1-C^1)$=55, $J(P^2-C^1)$=5; $J(P^1-C^3)$=5, $J(P^2-C^3)$=52 Hz). Although the central carbonyl carbon (C^2) in **3e** does not discriminate both P atoms as in the case of **3a**, the environmental nonequivalence of both P atoms (*vide infra*) is shown by slightly different coupling constants of C^2 in the case of **3c**, the signal appearing as a doublet of doublets.

The ^{1}H NMR data for the mononuclear and dinuclear palladium(II) complexes containing β-diketonate dianions and diphosphines are listed in Table

Table 4. $^{31}P\{H\}$ NMR data for mononuclear (**3a**, **3c**, and **3e**) and dinuclear (**4a** and **4c**) complexes[a]

	P^1, P^2		$J(P^1-P^2)$	P^3, P^4

4c[c]	60.7 d	64.1 d	16	69.0 br	71.6 br

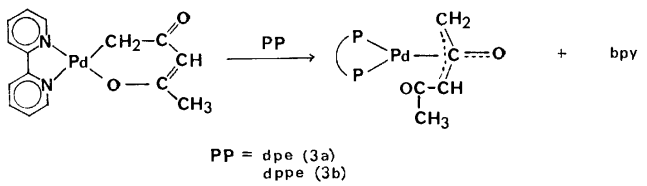
a) Chemical shift (δ) in ppm from external H_3PO_4 and coupling constant (J) in Hz. d=Doublet, br=broad. b) In $CDCl_3$. c) In $(CD_3)_2CO$ at 30 °C.

3, and compared with those for the analogous 2,2′-bipyridine complexes **2a** and **2b**.[3] Complexes **2a** and **2b** showed four and five signals with the area ratios of 3:1:1:1 and 3:1:1:1:2, respectively and these signals were reasonably interpreted on the basis of the trihapto structures of acac(2−) and etac(2−) as listed in Table 3.

On the other hand, the ^1H NMR spectra of the newly prepared diphosphine complexes are not conclusive for such a structure assignment, since the signals ascribable to H^b and H^c overlap with each other and with other signals. However, the signal from H^a is useful. Thus, H^a of complex **3c** resonates at 4.28 ppm from internal Me_4Si in $CDCl_3$ as a doublet of doublets due to coupling to P^2 (J=8 Hz) in the trans position and to H^c (J=2 Hz). The latter interaction between H^a and H^c appears as a coupling across four bonds constituting a planar zig-zag configuration (the so-called W rule),[9] suggesting the anti structure of the η-allylic etac(2−) ligand in **3c**. The H^a signal of the diphosphine complexes other than **3c** looks just like a doublet, but this may be attributed to low sensitivity of the NMR instrument used for the measurements. In the case of the triphenylphosphine complex **3e**, the 4.03-ppm signal probably assignable to H^a appears as a triplet, indicating same coupling constants (J=5.4 Hz) of H^a to each of H^c and P^2, accidentally. When one drop of D_2O was added to a $CDCl_3$ solution of **3e** and the mixture was left to stand for 30 min, the signal diminished remarkably, confirming assignment of the signal to an exchangeable unique proton H^a. The fact that the ^{13}C signal from the methine carbon (C^3) at 68.4 ppm decreased by the D_2O treatment also certifies that the methine proton was deuterated. The downfield shift of the H^a signal is generally observed in the present case for displacement of the 2,2′-bipyridine ligand in **2a** and **2b** by diphosphines, again indicating the difference in back-donation of palladium(II) to diphosphines and 2,2′-bipyridine (*vide supra*).

The $^{31}P\{H\}$ NMR spectra of the mononuclear (**3a**, **3c**, and **3e**) and dinuclear (**4a** and **4c**) complexes are recorded and listed in Table 4. The spectra of the mononuclear complexes in $CDCl_3$ are quite simple; for example, complex **3a** shows two signals as an AB quartet at 52.8 and 60.2 ppm downfield from external H_3PO_4 with $J(P^1-P^2)$=11 Hz. The spectrum indicates that the two phosphorus atoms are not equivalent and the difference in their environments is larger than that of two phosphorus atoms in [Pt(acac(2−)-C^1-C^3)-{P(*p*-$ClC_6H_4)_3$}$_2$],[8] of which signals appeared at 18.6 and 19.3 ppm as an AB quartet. In the platinum case, the signal at 19.3 ppm with larger ^1J(Pt-P) was assigned to P situated at the site trans to the allylic methine carbon, since the dangling acetyl moiety was thought to be electron attracting and the acetyl-substituted methylene group to exert slightly smaller trans influence than the unsubstituted methylene end. Although unequivocal discrimination of phosphorus atoms is not possible in the present case, the lower-field signal at 60.2 ppm might be assigned to P^2 situated at the site trans to the methine carbon (C^3). Other complexes **3c** and **3e** also give two doublets with $J(P^1-P^2)$=9 and 27 Hz, respectively. For two cis couplings of ^{31}P atoms in [PdCl(dppe){P(*n*-$Pr)_3$}]$^+$, similar values 11 and 21 Hz were reported, in contrast to 408 Hz for trans coupling.[10]

Here, it should be noticed that [Pd(acac(2−)-C^1—C^3)(NN)] (NN=bpy (**2a**), 4,4′-Me_2bpy, and phen) were always contaminated with the *C,O*-chelated acac(2−) complexes [Pd(acac(2−)-*C,O*)(NN)] in 20—25% proportions which were determined by ^1H NMR spectra.[3] However, none of NMR data in the present diphosphine complexes **3a** and **3b** show evidence for contamination with the *C,O*-chelated acac(2−) complex with diphosphinepalladium(II). Moreover, **3a** and **3b** are produced in high yields of 87—91% which exceed contents of **2a** (75—80%) in the starting complex. These facts suggest that the transformation of the bonding mode from *C,O*-chelation to trihapto coordination occurs during the preparation. Other



complexes [Pt(tfac(2−)-*C,O*)L_2] which contain a *C,O*-chelated 1,1,1-trifluoro-2,4-pentanedionate dianion with PPh_3, P(*p*-$ClC_6H_4)_3$, or $AsPh_3$ as L were isolated and characterized.[11]

Infrared spectra of the mononuclear complexes **3a**—**e** in the 1500—1700 cm^{-1} region are quite similar to those of **2a** and **2b**, exhibiting a medium ν(C=O) band at 1630—1670 cm^{-1} and a very strong and broad band at 1530—1560 cm^{-1} assignable to the ν(C=O) and/or ν(C=C) vibration. The weak bands due to δ(CCC) of the allylic skelton are not discernible owing to overlapping with strong bands from the diphosphine ligands in the region of 500—600 cm^{-1}.

Dinuclear Complexes Containing a β-Diketonate Dianion as a Bridging Ligand between Two Palladium(II) Ions. Only the ketonic carbonyl band at higher frequency (1633—1667 cm^{-1}) mentioned above is lost and the ν(C=O) and/or ν(C=C) band is shifted to higher frequency (1550—1590 cm^{-1}) more or less in the dinuclear complexes **4a**—**e** without noticeable change in the other part, suggesting that the free carbonyl oxygens coordinated to another palladium ion by *O,O′*-chelation to make dinuclear complexes.

a) Same as footnote a) for Table 2. $\Delta\delta=\delta(\mathbf{4a})-\delta(\mathbf{3a})$, $\delta(\mathbf{4c})-\delta(\mathbf{3c})$. $\Delta J=J(\mathbf{4a})-J(\mathbf{3a})$, $J(\mathbf{4c})-J(\mathbf{3c})$.

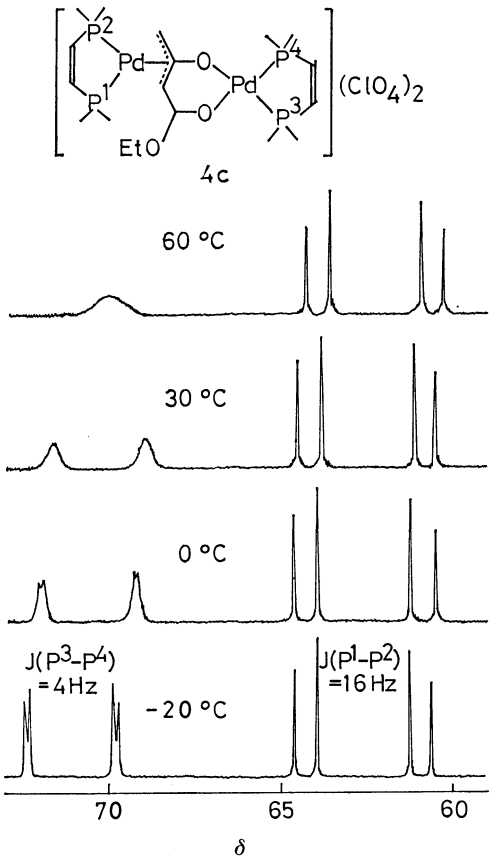

Fig. 1. Temperature dependence of the 24.2 MHz $^{31}P\{H\}$ NMR spectrum of [(dpe)Pd(*O,O'*-etac(2−)-*C*¹—*C*³)Pd(dpe)]$(ClO_4)_2$ (**4c**) in $(CD_3)_2CO$ with H_3PO_4 as an external reference.

Similarly, ^1H NMR spectrum of **4c** (Table 3) resembles as a whole that of the mononuclear complex **3c**, except the H^a signal which appears as a doublet at 4.78 ppm with $J(P^2\text{–}H^a)=9$ Hz. The downfield shift seems to be caused by coordination to the second palladium ion *via* the oxygen atoms and loss of coupling to H^c by violence of the W rule due to transposition of H^a from syn in **3c** to anti in **4c**.

The $^{31}P\{H\}$ NMR spectrum of **4a** in $(CD_3)_2CO$ at 30 °C shows two broader signals at 66.2 and 68.2 ppm besides two doublets at 60.9 and 66.6 ppm with $J(P^1\text{–}P^2)=18$ Hz (Table 4). A similar situation also appears in the spectrum of **4c** which shows two broader signals at 69.0 and 71.6 ppm apart from the two sharp doublets at 60.7 and 64.1 ppm with $J(P^1\text{–}P^2)=16$ Hz. The latter doublets are assigned to P^1 and P^2 by reference to the spectra of **3a** and **3c**. As Fig. 1 shows, the former signals which are assigned to P^3 and P^4, become broader with increasing temperature and coalesce at about 60 °C, indicating occurrence of the coordination site exchange between P^3 and P^4. On the other hand, these two signals sharpen as the temperature is lowered, giving two doublets with $J(P^3\text{–}P^4)=4$ Hz at −20 °C. This also reflects unsymmetric coordination of the etac(2−) anion to another palladium ion *via* oxygen atoms, although individual assignment of the signals to P^3 and P^4 is not possible. The coordination-site exchange may be assisted by solvent molecules.[12]

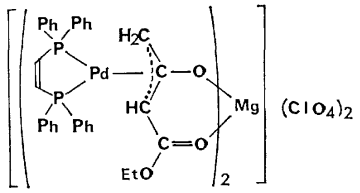
Table 5 lists the ^{13}C NMR data for the dinuclear complexes **4a** and **4c** in $(CD_3)_2CO$. It can be seen from Tables 2 and 5 that the trihapto coordination of the β-dik(2−) ligands with palladium(II) in the mononuclear complexes is still retained in the dinu-

clear complexes. Again, C^1 and C^3 signals in the dinuclear complexes **4a** and **4c** appear as doublets due to coupling to ^{31}P situated at the trans position. However, the coupling constants are smaller than those in the mononuclear complexes **3a** and **3c** as shown by ΔJ in Table 5, indicating that the allylic carbons-palladium bond became weaker on chelation to another metal ion *via* oxygen atoms. Each carbonyl carbon (C^2) in **4a** and **4c** resonates as a triplet like that in **3a** and **3e**. Contrary to couplings of these allylic carbons, the double doublet of ketonic carbonyl carbon (C^4) signal in the mononuclear complexes disappears in the dinuclear complexes and the C^4 carbon in **4a** and **4c** resonates as a broad singlet. Loss of the couplings indicates the transposition of the carbonyl group from the anti to syn position far apart from P^1 and P^2 in order to coordinate with another metal atom.

It is also worth noting that signals from C^1, C^3, and C^4 are shifted downfield more or less on chelation, while only C^2 shows substantial upfield shift, as shown by $\Delta\delta$ in Table 5. It might be caused by the change in the bonding mode around C^2 from $\rangle C{=}O$ to $\rangle C{-}O\diagdown$. In the case of neat 2,4-pentanedione, the carbonyl carbon of keto tautomer resonates at 202.6 ppm, while that of enol one resonates at 191.8 ppm,[13] making the upfield shift by $\Delta\delta = -10.8$ ppm from $\rangle C{=}O$ to $\rangle C{-}O\diagdown$ which is comparable to $\Delta\delta(C^2) = -10.3$ ppm from **3a** to **4a**.

Di- and Trinuclear Complexes Containing a β-Diketonate Dianion as a Bridging Ligand between Palladium(II) and Another Metal Ion. Except **6** which shows a ν(C=O) band at 1677 cm^{-1} and four strong to medium bands in the region of 1510—1610 cm^{-1}, IR spectra of **5a–8b** again exhibit no ketonic carbonyl band at higher frequency but only a strong and broad band assignable to the $\nu(C{=}O)$ and/or $\nu(C{=}C)$ vibration in the region of 1560—1640 cm^{-1}. Although the spectral region is a little higher than 1550—1590 cm^{-1} for **4a—e**, these features resemble those of dipalladium(II) complexes **4a—e**, suggesting that the bonding mode of β-dik(2—) ligands in **5a–8b** is similar to that in **4a—e**.

Contrary to dipalladium(II) complexes **4a—e**, these mixed-metal dinuclear and trinuclear complexes with palladium(II) and platinum(II), nickel(II), or magnesium(II) are less stable in usual organic solvents, and do not give good ^1H and ^{13}C NMR spectra. For instance, the dinuclear complex with platinum(II), **5a**, decomposes in $CDCl_3$ gradually during the spectral measurement, exhibiting free-ester signals and depositing a white precipitate on the wall of the NMR tube. The trinuclear complex with magnesium(II), **8b**, is rather stable in haloalkanes and gives somewhat broad ^{13}C signals in $CDCl_3$. However, signal assignment is unequivocal: C^1 (terminal methylene), 51.6d ($J(P^1{-}C) = ca.$ 51 Hz); C^2 (central carbonyl), 172.3; C^3 (methine), 60.0d ($J(P^2{-}C) = ca.$ 53); C^4 (ester carbonyl), 177.6; C^5 (ethoxy methylene), 60.5 and C^6 (ethoxy methyl), 13.3 ppm from internal Me_4Si. These chemical shifts are comparable to those for **4c**, suggesting that the etac(2—) ligands in **8b** are working as a bridging ligand through trihapto bonding to palladium(II) and *O,O'*-chelation to magnesium(II) as follows.



8b

Although the NMR data for all nickel(II) complexes, unfortunately, can not be obtained because of their paramagnetic characters, nickel(II) complexes **7a—c** seem to contain the β-dik(2—) ligands of bonding mode analogous to that in **8b** on the basis of the similarity of IR spectra between nickel(II) and magnesium(II) complexes. The above-mentioned higher-frequency shift of the $\nu(C{=}O)$ and/or $\nu(C{=}C)$ vibrations in **5a–8b** by *ca.* 10—50 cm^{-1} compared with those in **4a—e** might reflect the weaker metal-oxygen bonds in the mixed-metal complexes in conformity with instability of these complexes in solution.

In this connection, it is meaningful to remember that the dinuclear complex with $Ni(acac)_2$, **6**, shows a ν(C=O) band at 1677 cm^{-1} in addition to bands in the 1510—1610-cm^{-1} region, The absorption spectrum of **6** in CH_2Cl_2 exhibits two bands at 9100 cm^{-1} ($^3A_{2g} \rightarrow {}^3F_{2g}$, $\varepsilon = 7.7$) and at 15200 cm^{-1} ($^3A_{2g} \rightarrow {}^3T_{1g}(F)$, $\varepsilon = 8.6$), typical of the octahedral arrangement around the nickel(II) ion, although the third band is obscured by a higher-intensity ligand band. Hence, the higher-frequency carbonyl band in the IR spectrum of **6** might suggest the very weak bonding of the ketonic carbonyl oxygen to occupy the sixth coordination site around the nickel(II) ion, presumably due to the simple adduct formation between neutral molecules in this special case. In the addition compound, $[NiBr_2(C_5H_8O_2)_2]$, of anhydrous nickel bromide with two molecules of 2,4-pentanedione,[14] the ν(C=O) band appeared at 1693 cm^{-1} very near to 1677 cm^{-1}.

On the other hand, the stereochemistry around the nickel(II) ion in **7a—c** and the magnesium(II) ion in **8a** and **8b** seems to be tetrahedral and not planar. For instance, complex **7b** is paramagnetic as shown by the μ_{eff}^{Corr} value of 3.3 BM, and shows a shoulder band assignable to a spin-allowed transition ($^3T_1(F) \rightarrow {}^3T_1(P)$) at 22200 cm^{-1} ($\varepsilon = ca.$ 65) together with two weak bands at 16100 ($\varepsilon = 9.3$) and 8900 cm^{-1} ($\varepsilon = 5.5$).

We wish to thank Mr. Junichi Gohda for the elemental analysis and also grateful to the Ministry of Education, Science and Culture for the Grant-in-Aid for Scientific Research, No. 243014.

Solvent Extraction Study on the Hydrolysis of Tracer Concentrations of Bismuth(III) in Perchlorate and Nitrate Solutions

Itsuhachiro HATAYE,* Hideo SUGANUMA, Hisashi IKEGAMI, and Takashi KUCHIKI

Radiochemistry Research Laboratory, Shizuoka University, Ooya, Shizuoka 422

(Received October 21, 1981)

The backward solvent extraction with dithizone-carbon tetrachloride solutions was used to examine the chemical species of Bi(III). A tracer concentration of Bi(III) ($<10^{-7}$ mol dm^{-3}) was found to exist in the form of Bi^{3+}, $Bi(OH)^{2+}$, $Bi(OH)_2^+$, and $Bi(OH)_3$ in 1.0 mol dm^{-3} (H,Na)ClO_4, and $Bi(NO_3)_n^{3-n}$, $Bi(OH)(NO_3)_n^{2-n}$, $Bi(OH)_2(NO_3)_n^{1-n}$, and $Bi(OH)_3(NO_3)_n^{n-}$ in 1.0 mol dm^{-3} (H,Na)NO_3 solutions depending on the acidity of the solutions. The constants of successive hydrolysis, β_1, β_2, and β_3, were calculated by using the distribution data. The resulting log β_1, log β_2, and log β_3 values were 12.0, 22.9, and 33.9 for 1.0 mol dm^{-3} (H,Na)ClO_4 solution, and 11.9, 22.7, and 33.2 for 1.0 mol dm^{-3} (H,Na)NO_3 solution, respectively. The chemical composition of the extracted species was most probably $Bi(HDz)_3$.

The hydrolysis of Bi(III) in solution has been extensively studied. The most significant early work on the identification of the polynuclear species formed as a result of hydrolysis of Bi(III) was the potentiometric study of Graner and Sillén.[1] The hydrolysis of Bi(III) was further studied by the absorption spectrophotometry,[2] the ultracentrifugation,[3] the potentiometry,[4] the light scattering measurements,[5] the X-ray diffraction,[6] the vibration spectrum,[7] the relaxation techniques,[8] and the spectrophotometric measurements.[9] These studies dealt with the polynuclear species of Bi(III) in regions of macro amounts of bismuth (10^{-4}—0.5 M; 1 M=1 mol dm^{-3}). On the other hand, Bidleman[10] studied the mononuclear species formed in minor concentrations of Bi(III) ($<10^{-4}$ M), based on the solvent extraction using dithizone (H_2Dz). In his work, the equilibrium constants for the Bi–H_2Dz system and the formation constants for the species $Bi(OH)^{2+}$, $Bi(OH)_3$, and $Bi(OH)_4^-$ have been determined. However, the hydrolysis of bismuth ion in more dilute aqueous solution and the formation constants of the species $Bi(OH)_2^+$ has not been well studied. Because the Bi–H_2Dz system has been well defined by many authors,[11–15] we studied on the hydrolysis of bismuth ion in a tracer concentration of $<10^{-7}$ M by using the backward extraction method,[16] by means of which the difficulties due to the anomalous chemical behavior of a tracer scale of substances could be avoided.

Experimental

Reagents. Water and reagents used were all purified to the highest degree, especially to overcome the difficulty due to contaminations. All the aqueous solutions used were finally purified by extraction with H_2Dz–CCl_4 solution. The H_2Dz–CCl_4 solution was prepared according to the method recommended by Sandell.[17] The concentration of H_2Dz–CCl_4 solutions purified was determined by the complexometric titration using a standard $AgNO_3$ solution. Lead (^{210}Pb) containing an equilibrium amount of ^{210}Bi in 3 M HNO_3, imported from the Radiochemical Centre, Amersham, England, was used by diluting it into the appropriate concentration with 3 M HNO_3. A ^{210}Bi tracer solution was prepared by milking to extract from the diluted ^{210}Pb–^{210}Bi solution (pH<3) with H_2Dz–CCl_4 solution. Bismuth nitrate was employed as a carrier of ^{210}Bi tracer.

Initial Organic Solution of Bismuth Dithizonate. A portion of bismuth stock solution was pipetted into a separatory funnel containing water and the bismuth was extracted with a definite concentration of H_2Dz solution at 2<pH<3. The stock solution thus prepared in a lower concentration, less than 10^{-5} M of H_2Dz, showed practically no change within 3 h after preparation against any possible decomposition of H_2Dz.

Measurements of Radioactivity. The radioactivity (β-rays) of ^{210}Bi was counted with a G.M. counter (Aloka Co., Ltd.), with an Al foil absorber (1.84 mg/cm^2) put on the sample planchet in which the bismuth extract was evaporated, by which the α-activity due to ^{210}Po contained in the bismuth extracts could be discriminated. The decay of ^{210}Bi activity ($t_{1/2}$=5.01 d) was compensated for by obtaining the activity relative to a standard specimen prepared at the same time.

Measurements of the Distribution Ratio. One ml (1 ml=1 cm^3) of the organic phase containing a definite amount of bismuth was mixed with 10 ml of 1.0 M (H,Na)-ClO_4 or 1.0 M (H,Na)NO_3 solution; the mixture was shaken at room temperature until the partition equilibrium was attained. After the completion of the equilibrium, a 0.5 ml portion of the organic phase was pipetted into a stainless steel planchet, evaporated, and subjected to the measurements of the β-activity (A_{org}). Because it is difficult to count the activity of the aqueous phase in the same geometrical form as the organic phase in the planchet, it was calculated using $A_{aq}=A^0{}_{org}-A_{org}$, where A_{aq} is the activity of a 5 ml portion of the aqueous phase and $A^0{}_{org}$ is the initial activity of a 0.5 ml portion of the organic phase before shaking. The distribution ratio of bismuth, D, is given as follows;

$$D = 10\times A_{org}/(A^0{}_{org}-A_{org}).$$

In each case, the multiple extraction procedures were repeated under conditions of a definite hydrogen ion concentration and definite amounts of bismuth in aqueous phase; the data obtained in the first half were all discarded and only the reproducible data in the other half were taken.

Measurements of Hydrogen Ion Concentration. As for acidic media (pH<1), the hydrogen ion concentration was calculated from the acidity of the $HClO_4$ or HNO_3 used. In other cases, it was measured with a pH meter (TŌA Electronics Ltd.) at room temperature as soon as possible after shaking.

Results and Discussion

Time Necessary for the Partition Equilibrium. As shown in Fig. 1, the partition of bismuth between

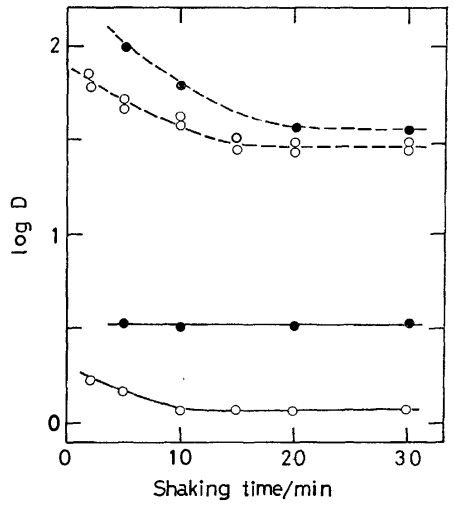

Fig. 1. The effect of shaking time on the distribution ratio in the backward extraction.
—●—: 1.0 M $HClO_4$ solution, $\log[H_2Dz]_{org} = -3.64$, --●--: 1.0 M (H,Na)$ClO_4$ solution ($-\log[H^+] = 3.80$), $\log[H_2Dz]_{org} = -5.77$, —○—: 1.0 M HNO_3 solution, $\log[H_2Dz]_{org} = -3.40$, --○--: 1.0 M (H,Na)$NO_3$ solution ($-\log[H^+] = 3.46$), $\log[H_2Dz]_{org} = -5.51$.

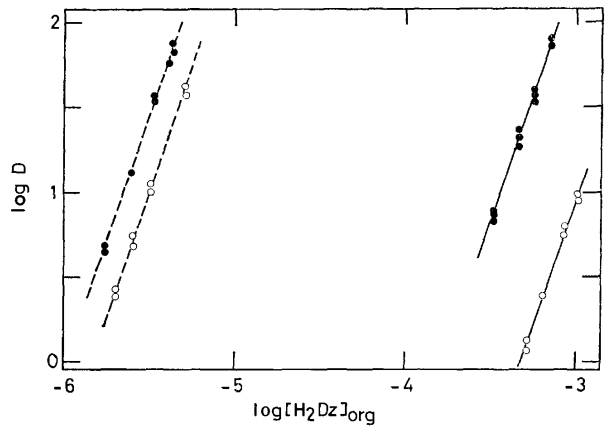

Fig. 2. The dependence of the distribution ratio on the concentration of dithizone in the organic phase.
—●—: 1.0 M $HClO_4$ solution, --●--: 1.0 M (H,Na)ClO_4 solution ($-\log[H^+] = 2.53$), —○—: 1.0 M HNO_3 solution, --○--: 1.0 M (H,Na)NO_3 solution ($-\log[H^+] = 3.01$).

two phases reaches equilibrium within 10 minutes for a high acidity (1.0 M $HClO_4$ and 1.0 M HNO_3) and in about 20 min for a weak acidity (1.0 M (H,Na)ClO_4, $-\log[H^+] = 3.80$; 1.0 M (H,Na)NO_3, $-\log[H^+] = 3.46$). Accordingly, the partition system was shaken for 25 min in all experiments to attain the equilibrium.

Dependence of the Distribution Ratio on the Bismuth Concentration. Table 1 shows the distribution ratios measured as a function of the amount of bismuth carrier in the tracer concentration ($<10^{-7}$ M). The bismuth concentration of the original tracer solution prepared in a carrier-free state was examined substoichiometrically with dithizone extraction. No effects of the bismuth concentration were observed for either 1.0 M $HClO_4$ media or 1.0 M (H,Na)ClO_4 solutions of $-\log[H^+] = 3.84$, nor for either 1.0 M HNO_3 or 1.0 M (H,Na)NO_3 solutions of $-\log[H^+] = 3.46$. These results suggest that there is no difference in the degree of polymerization of bismuth species between aqueous and organic phases. On the other hand, since it is improbable that any polymerized species remain stable in both phases, we may safely assume that the monomers are the main species involved in the solvent extraction of tracer concentrations of bismuth.

Dependence of the Distribution Ratio on the Dithizone Concentration in Organic Phase. The distribution ratio, D, was plotted as a function of the H_2Dz concentration at different hydrogen ion concentrations. Figure 2 shows that the plots of $\log D$ *vs.* $\log[H_2Dz]_{org}$ show a slope of $+3$ independent of the acidity and the media, where H_2Dz denotes a neutral dithizone molecule. In general, the slope of $\log D$ *vs.* $\log[H_2Dz]_{org}$, or $\partial \log D/\partial \log[H_2Dz]_{org}$, indicates the difference in the average number of univalent dithizone ions (HDz^-) attached to a bismuth atom between the organic and aqueous phases. It is generally accepted that the coordination number of Bi(III) is six, so the total number of ligands (as univalent) combined to a bismuth atom can be reasonably assumed not to exceed six, and the extracted species must be electrically neutral. Since HDz^- ion is a bidentate ligand, our results shown in Fig. 2 lead to the conclusion that bismuth exists in the chemical form of $Bi(HDz)_3$ in the organic phase. It also means that the concentration of Bi–HDz^- complex species is negligibly low in the aqueous phase of 1.0 M (H,Na)ClO_4 and 1.0 M (H,Na)NO_3.

The distribution ratio, D, is expressed as follows:

$$D = [Bi(HDz)_3]_{org}/\{\sum_{n=0}^{6-x}\sum_{x=0}^{6-n}[Bi(OH)_nX_x^{3-n-x}]\} \quad (1)$$

$$= \{K_3[H_2Dz]^3_{org}[H^+]^{-3}\}/\{\sum_{n=0}^{6-x}\sum_{x=0}^{6-n}\beta_{n,x}Q_w{}^n[H^+]^{-n} \times [X^-]^x\}, \quad (2)$$

where

$$K_3 = [Bi(HDz)_3]_{org}/\{[Bi^{3+}][H_2Dz]^3_{org}[H^+]^{-3}\}, \quad (3)$$

$$\beta_{n,x} = [Bi(OH)_nX_x^{3-n-x}]/\{[Bi^{3+}][OH^-]^n[X^-]^x\}, \quad (4)$$

$Q_w = [H^+][OH^-]$, and also X^- denotes ClO_4^- or NO_3^-.

D should be written in terms of the hydrolysis of bismuth in case of $[X^-] = 1.0$ M, as follows:

$$D/[H_2Dz]^3_{org} = K_3/(\sum_{n=0}^{6-x}\sum_{n=0}^{6-n}\beta_{n,x}Q_w{}^n[H^+]^{3-n}). \quad (5)$$

In the present case, $\sum_{n=0}^{6-x}\sum_{n=0}^{6-n}\beta_{n,x}$ is denoted by $\sum_{n=0}^{6}\beta_n$, because each $\beta_{n,x}$ can not be measured and the $\sum_{x=0}^{6}\beta_{0,x}$ is regarded as unity. Accordingly, Eq. 5 should be rewritten as follows:

$$D/[H_2Dz]^3_{org} = K_3/(\sum_{n=0}^{6}\beta_nQ_w{}^n[H^+]^{3-n}). \quad (6)$$

Dependence of the Distribution Ratio on the Hydrogen Ion Concentration. In Fig. 3, we plot $\log(D/[H_2Dz]^3_{org})$ as a function of $-\log[H^+]$ in 1.0 M

Table 1. The dependence of the distribution ratio on the bismuth concentration

Aqueous phase	$-\log[H^+]$	$[H_2Dz]_{org}$/M	$[Bi(III)]_{org}$[a]/M	$\log D$
1.0 M (H, Na)ClO_4	0.0	3.98×10^{-4}	Carrier free($<10^{-9}$)	1.15±0.11
			0.92×10^{-9}	1.18±0.09
			0.92×10^{-7}	1.22±0.15
	3.84	2.06×10^{-6}	Carrier free($<10^{-9}$)	1.75±0.05
			0.84×10^{-9}	1.76±0.15
			0.84×10^{-7}	1.78±0.11
1.0 M (H, Na)NO_3	0.0	5.08×10^{-4}	Carrier free($<10^{-9}$)	0.45±0.15
			0.84×10^{-9}	0.44±0.12
			0.84×10^{-7}	0.40±0.12
	3.46	3.40×10^{-6}	Carrier free($<10^{-9}$)	1.60±0.15
			0.84×10^{-9}	1.59±0.09
			0.84×10^{-7}	1.62±0.10

a) Initial concentration of Bi(III) in H_2Dz-CCl_4 solution.

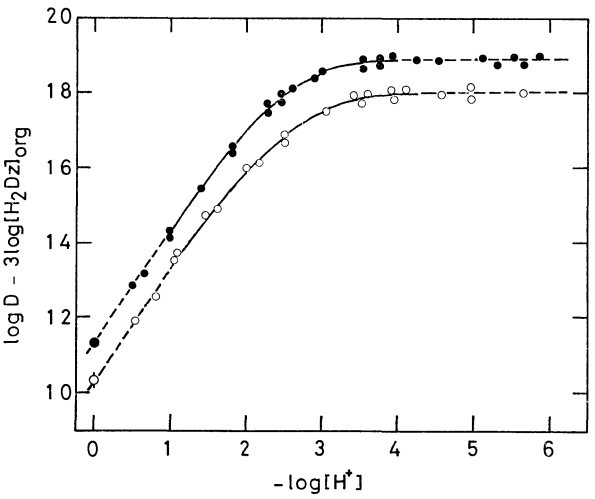

Fig. 3. The dependence of the distribution ratio on the hydrogen ion concentration.
●: 1.0 M (H,Na)ClO_4 solution, ○: 1.0 M (H,Na)-NO_3 solution.

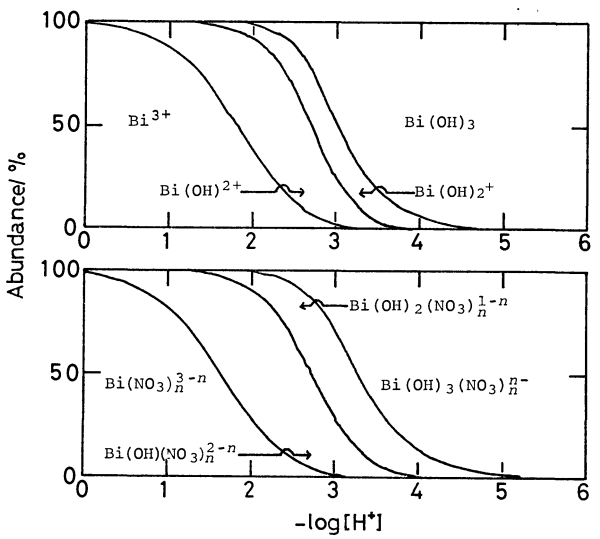

Fig. 4. The chemical species of the bismuth ion in 1.0 M (H,Na)ClO_4 solution (upper) and 1.0 M (H,Na)NO_3 solution (lower).

(H,Na)ClO_4 and 1.0 M (H,Na)NO_3 solutions. Since it is difficult to determine the distribution ratio by using only a single H_2Dz solution with a definite concentration in all regions of hydrogen ion concentration, $\log(D/[H_2Dz]^3_{org})$ is plotted instead of $\log D$. As shown in the figure, the slope seems to be +3 for the region of $-\log[H^+]<1.5$ in both 1.0 M (H,Na)-ClO_4 and 1.0 M (H,Na)NO_3 solutions, while it is 0 for $-\log[H^+]=4.0$—5.7. Therefore, there exist few hydroxo-compounds of Bi(III) in high acidity, while hydroxo-compounds such as $Bi(OH)_3X_x$ are predominant in the weakly acidic to neutral solutions. The distribution ratio in Eq. 6 can be expressed in terms of hydrolysis constants β_n as follows:

$$D/[H_2Dz]^3_{org} = K_3/([H^+]^3+\beta_1Q_w[H^+]^2 +\beta_2Q_w^2[H^+]+\beta_3Q_w^3), \quad (7)$$

where

$$\beta_1 = [Bi(OH)X_x^{2-x}]/([Bi^{3+}][OH^-][X^-]^x), \quad (8)$$

$$\beta_2 = Bi(OH)_2X_x^{1-x}]/([Bi^{3+}][OH^-]^2[X^-]^x), \quad (9)$$

$$\beta_3 = [Bi(OH)_3X_x^{x-}]/([Bi^{3+}][OH^-]^3[X^-]^x). \quad (10)$$

Estimation of K_3, $\beta_3Q_w^3$, $\beta_2Q_w^2$, *and* β_1Q_w. Figure 3 shows that the slope of $(\log D-3\log[H_2Dz]_{org})$ *vs.* $-\log[H^+]$ at $-\log[H^+]=0$ is nearly 3, so Eq. 7 can be simplified as $D/[H_2Dz]^3_{org}\approx K_3$. Consequently, the approximate values of K_3 were obtained from Figs. 1 and 3 and Table 1 to be $K_3=(2.40\pm0.33)\times10^{11}$ for 1.0 M (H,Na)ClO_4 solution and $K_3=(2.34\pm0.60)\times10^{11}$ for 1.0 M (H,Na)NO_3 solution. Furthermore, since Fig. 3 shows that the slope of $(\log D-3\log[H_2Dz]_{org})$ *vs.* $-\log[H^+]$ ($-\log[H^+]>4$) is zero, independent of the acidity, Eq. 7 can be simplified as $D/[H_2Dz]^3_{org}\approx K_3/(\beta_3Q_w^3)$. Consequently, the approximate value of $\beta_3Q_w^3$ was obtained from Fig. 3 to be $\beta_3Q_w^3=(3.02\pm1.01)\times10^{-8}$ for 1.0 M (H,Na)-ClO_4 solution and $\beta_3Q_w^3=(2.24\pm0.86)\times10^{-8}$ for 1.0 M (H,Na)NO_3 solution. By using the set of K_3 and $\beta_3Q_w^3$ obtained, the approximate values of a set of β_1Q_w and $\beta_2Q_w^2$ were obtained by least squares fit from the data in the region of $-\log[H^+]=1.5$—4 in Fig. 3; the values are $\beta_1Q_w=1.44\times10^{-2}$ and $\beta_2Q_w^2=1.81\times10^{-5}$ for 1.0 M (H,Na)ClO_4 solution, and also $\beta_1Q_w=2.13\times10^{-2}$ and $\beta_2Q_w^2=3.09\times10^{-5}$

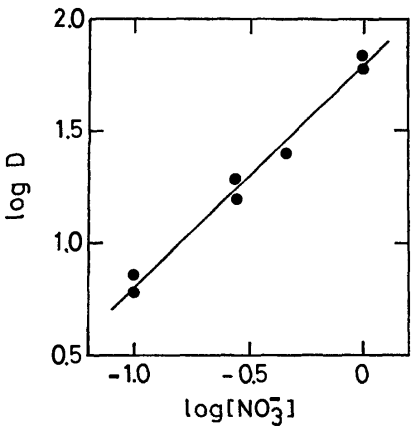

Fig. 5. The influence of the concentration of the nitrate ion on the distribution ratio at $-\log[H^+]=1.0$ ($\log[H_2Dz]_{org}=-3.87$).

for 1.0 M (H,Na)NO_3 solution, respectively. Equation 7 is third order with respect to the hydrogen ion concentration; therefore, no meaningful error in $\beta_1 Q_w$ and $\beta_2 Q_w^2$ calculations could be obtained. The values obtained of $\log \beta_1$, $\log \beta_2$, and $\log \beta_3$ are 12.0, 22.9, and 33.9 for 1.0 M (H,Na)ClO_4, when $\log Q_w$ is -13.80,[18] and 11.9, 22.7, and 33.2 for 1.0 M (H,Na)NO_3 solutions, when $\log Q_w$ is -13.61.[19] Per cent abundances of the chemical species of bismuth calculated from each β value at different hydrogen ion concentrations in 1.0 M (H,Na)ClO_4 and 1.0 M (H,Na)NO_3 solutions are represented in Fig. 4. In the latter case, because of possible coordination of nitrate ions to the bismuth atom in 1.0 M (H,Na)NO_3 solution, we have taken into consideration the contribution of nitrate ions to the bismuth species.

The Effect of Nitrate and Perchlorate Ion Concentration on the Distribution Ratio. The extractability of bismuth increased with an increasing nitrate ion concentration; this might be attributed to a salting-out effect of $NaNO_3$ as an electrolyte. Kapantsyan and Nabivanets[20] reported on the nitrate complexes of bismuth in the solution. Bismuth nitrate complexes may be present in 1.0 M (H,Na)NO_3 solution, because the values of $\log(D/[H_2Dz]^3_{org})$ for 1.0 M (H,Na)NO_3 solution are always smaller than those for the corresponding 1.0 M (H,Na)ClO_4 solution in all regions of $0 \leq -\log[H^+] \leq 5.7$, as shown in Fig. 3. This also implies that some effect opposing the bismuth extraction arises from the complexation of bismuth with the nitrate ion. Consequently, each β value obtained for 1.0 M (H,Na)NO_3 solution should be considered as conditional constants obtained under our experimental conditions. The effect of perchlorate ion concentration on the distribution ratio of Bi(III) was examined in the concentration of 0.1—1.0 M at $-\log[H^+]=1.0$, where little effect was observed in the concentration range of ClO_4^- examined. It is difficult to assume the presence of bismuth perchlorate complexes on a tracer scale in 1.0 M (H,Na)ClO_4 solution because of the less-complexing perchlorate ion, but in the macro region the formation of $Bi_6(OH)_{12}(ClO_4)_2^{4+}$ was reported by Johnson *et al.*[21] It can be said, nevertheless, that the effect of perchlorate ion concentration in the present study may be negligibly small, since the ionic concentration in the aqueous phase was kept constant to 1.0 M in all experiments.

Graner and Sillén[1] reported that Bi(III) was unhydrolyzed at acid concentrations greater than 0.5 M, and that the number of hydroxides bound per bismuth atom appeared to approach asymptotically the value 2 in titration experiments on 0.01, 0.025, and 0.05 M Bi(III) in 3 M $NaClO_4$ solutions. They proposed a species of polymeric hydrolysis products with the general formula $Bi_nO_{n-1}^{n+2}$ to account for their observations. Olin[4] extended the measurements to a broader range of Bi(III) concentrations, 10^{-4}—0.05 M Bi(III), and his more precise data from an amalgam electrode were analyzed in terms of two species $Bi(OH)^{2+}$ and $Bi_6(OH)_{12}^{6+}$. The mononuclear species was formed only in minor amounts. The vibration spectrum of $Bi_6(OH)_{12}^{6+}$ in very high concentrations of Bi(III) (up to 8.41 M Bi(III) in 8.85 M ClO_4^- solution) was reported by Maroni and Spiro.[7] Bidleman[10] studied the hydrolysis of bismuth ions in dilute ($<10^{-4}$ M) aqueous solution by the extraction measurements using dithizone, and obtained the equilibrium constants for the bismuth–dithizone system and the formation constants of the $Bi(OH)^{2+}$, $Bi(OH)_3$, and $Bi(OH)_4^-$, where the values of $\log \beta_1$, $\log \beta_3$, and $\log \beta_4$ are 12.4, 31.9, and 32.9 (μ(ionic strength)=0.1), respectively. In tracer concentrations of bismuth in 1.0 M (H,Na)ClO_4 and 1.0 M (H,Na)NO_3 solutions in the region of $0 \leq -\log[H^+] \leq 5.7$, our results showed the presence of Bi^{3+}, $Bi(OH)^{2+}$, $Bi(OH)_2^+$, and $Bi(OH)_3$, and/or $Bi(NO_3)_n^{3-n}$, $Bi(OH)(NO_3)_n^{2-n}$, $Bi(OH)_2(NO_3)_n^{1-n}$, and $Bi(OH)_3(NO_3)_n^{n-}$. For this latter group a further study on the mean charge of each species should be made. At the same time, no evidence for the existence of any polymerized species was found in the present conditions of aqueous media. However, in the stored and/or more concentrated bismuth solution, some polymerized species may be formed.

The value of $\log K_3$ (11.4) for 1.0 M (H,Na)ClO_4 found in this work is larger than those reported by Bidleman (10.9 at $\mu=0.1$ and 10.8 at $\mu=1.0$),[10] Busev and Bazhanova (10.0 at $\mu=0.2$),[14] Koroleff (9.7),[12] and Pilipenko (10.6 at $\mu=0.5$).[13] This fact may suggest that the formation of extracted species ($Bi(HDz)_3$) is depressed by forming polynuclear complexes in macro concentrations of bismuth solution. Another reason why the value of $\log K_3$ (10.4) for 1.0 M (H,Na)NO_3 is smaller than that for 1.0 M (H,Na)ClO_4 solution may be complex-formation with nitrate ion.

The Formation Process of Cobalt Sulfide from Tricobalt Tetraoxide Using Sulfur Dioxide as a Sulfidizing Agent

Ryoko MATSUZAKI, Akimasa YAJIMA, Motonori EGUCHI, and Yuzo SAEKI*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received October 24, 1981)

The products obtained by heating a mixture of Co_3O_4 and carbon in a SO_2 stream were CoO and $CoSO_4$ at 400—600 °C, $Co_{1-x}S$ and CoO at 650—700 °C, and $Co_{1-x}S$ ($Co_{0.90}S$) at 750—800 °C. Sulfur was obtained outside the heating zone throughout the temperature range. The possible reactions during the above process were also examined. Further, thermodynamical consideration was made of the formation of $Co_{1-x}S$. The formation process of $Co_{1-x}S$ ($Co_{0.90}S$) from Co_3O_4 can be represented as follows: The reaction of carbon with SO_2 occurs at first to form sulfur. Above *ca.* 400 °C, the reaction of Co_3O_4 with SO_2 occurs to form CoO and $CoSO_4$. Above *ca.* 500 °C, the reductions of Co_3O_4 with carbon and with sulfur also occur to form CoO. Above *ca.* 600 °C, the reduction of $CoSO_4$ with carbon occurs to form CoO. Above *ca.* 650 °C, $Co_{1-x}S$ is formed by the reaction of CoO with sulfur, both of which had been formed by the above reactions.

There have been several reports on the formation of cobalt sulfide by the reaction of cobalt with sulfur[1] or hydrogen sulfide,[2] and by the reaction of cobalt monooxide (CoO) with hydrogen sulfide.[3] Regarding the synthesis of cobalt sulfide using sulfur dioxide (SO_2) as a sulfidizing agent, however, little information has been available apart from the report of Pechkovskii and Mal'tseva.[4] They performed the differential thermal analysis of a mixture of tricobalt tetraoxide(Co_3O_4) and carbon (Co_3O_4:C=1:5 by molar ratio) in a SO_2 stream. They observed the formation of cobalt(II) sulfate($CoSO_4$) and CoO above 450 °C and of cobalt sulfide in addition to these products above 600 °C. The sample which they obtained after heating up to about 970 °C was a mixture of cobalt sulfide and CoO containing no residual carbon. They also reported that the cobalt sulfide formed was CoS below 700 °C and Co_9S_8 at 750—1000 °C. But, the formation process of cobalt sulfide from Co_3O_4 using SO_2 has not yet been revealed. This process is not only interesting from the viewpoint of the synthesis of the sulfide itself, but is also important for the further utilization of SO_2.

In this work, the reactions of Co_3O_4 with SO_2 and of Co_3O_4 with SO_2 in the presence of carbon were examined. In order to elucidate the formation process of cobalt sulfide from Co_3O_4, the reactions of Co_3O_4 with carbon and with sulfur were examined. Also, the reaction of $CoSO_4$, formed during the reaction process of Co_3O_4 with SO_2 in the presence of carbon, with carbon and the reaction of CoO, formed during the reaction process, with sulfur in a SO_2 stream were examined. Further, thermodynamical consideration was made of the Co–S–C–O system.

Experimental

The Co_3O_4 used was prepared at 800 °C by the thermal decomposition in the air of pentacobalt(II) dicarbonate hexahydroxide($Co_5(CO_3)_2(OH)_6$), which had been prepared by adding sodium carbonate solution to cobalt(II) nitrate solution.[5] The CoO was prepared by the thermal decomposition of the $Co_5(CO_3)_2(OH)_6$ at 800 °C in an argon stream.[5] The $CoSO_4$ was prepared by the dehydration of the guaranteed reagent cobalt(II) sulfate heptahydrate at 400 °C and was β-form(orthorhombic: low-temperature form).[6] The carbon was prepared by the thermal decomposition of the guaranteed reagent D-glucose. The above materials were used as powders under 150 mesh.

A mixture of Co_3O_4 and carbon at a specified ratio in a quartz boat (length: 72 mm, width: 16 mm, depth: 9 mm) was placed in a transparent, quartz reaction tube (inner diameter: 28 mm, length: 1000 mm). Gaseous SO_2 was then introduced into the reaction tube at a flow-rate of 100 cm³/min. The sample part was positioned in the middle of the tubular electric furnace (heating length: 300 mm) maintained at a specified temperature for 1 h. The temperature of the sample part was controlled within ±2 °C. After heating, the sample was quenched rapidly, and then heated at 100 °C for 1 h in an argon stream in order to release the SO_2 adsorbed on unreacted carbon.[7] The reactions of Co_3O_4 with carbon and with sulfur and of $CoSO_4$ with carbon in an argon stream, and the reaction of CoO with gaseous sulfur in a SO_2 stream were examined in a similar manner.

The X-ray analysis of the sample was performed with an X-ray powder diffractometer equipped with a proportional counter using Ni filtered Cu radiation. The thermogravimetry (TG) was performed by using a thermal balance with a quartz helix. The sensitivity of the quartz helix used was approximately 94 mm/g. The heating rate of 2.5 °C/min was employed, and a flow-rate of SO_2 was maintained at 50 cm³/min.

Concerning the chemical analysis of the cobalt sulfide formed, the sample was oxidatively decomposed in HNO_3 with $KClO_3$. Then, the cobalt content was determined by the chelatometric titration[8] and sulfur content by the gravimetric method as $BaSO_4$. In the case of a mixture of cobalt sulfide, unreacted carbon, and sulfur adsorbed on the carbon, the sample was oxidatively decomposed, and the contents of cobalt and total sulfur were determined by the above techniques. Then, after dissolving the cobalt sulfide in the sample selectively with dilute HNO_3, the undissolved residue, which consisted of unreacted carbon and the sulfur adsorbed on it, was oxidatively decomposed in HNO_3 with $KClO_3$, and the amount of sulfur adsorbed on the carbon was gravimetrically determined. The amount of sulfur due to the cobalt sulfide in the sample was calculated as the difference between the above total sulfur and the sulfur adsorbed on the carbon.

Results and Discussion

Reaction of Co_3O_4 with SO_2. The TG of Co_3O_4 (0.3 g) in a SO_2 stream was carried out. The TG

Table 1. Products obtained by heating a mixture of Co_3O_4 and carbon in a SO_2 stream at various temperatures

Temp °C	Sample in the boat	Amount of sulfur obtained outside the heating zone/g
350	Co_3O_4	Trace
400	$Co_3O_4 > CoO > CoSO_4[\beta]$	Trace
450	$Co_3O_4 > CoO > CoSO_4[\beta]$	Trace
500	$CoO > Co_3O_4 > CoSO_4[\beta]$	Trace
550	$CoO > CoSO_4[\beta > \alpha]$	Trace
600	$CoO \gg CoSO_4[\alpha]$	Trace
650	$CoO > Co_{1-x}S$	Trace
700	CoO, $Co_{1-x}S$	0.01
750	$Co_{1-x}S$	0.55
800	$Co_{1-x}S$	2.40

curve showed that the sample weight increased continuously above about 400 °C and reached a constant value at about 670 °C. The sample heated up to 700 °C was found to be a mixture of CoO[9] and α-$CoSO_4$ (orthorhombic: high-temperature form)[10] by X-ray analysis. The final weight gain was 26.5%. This value was in good agreement with the value, 26.60%, which was calculated based on the reaction: $Co_3O_4(s)+SO_2(g) \rightarrow 2CoO(s)+CoSO_4(s)$. These results indicate that Co_3O_4 reacts with SO_2 above about 400 °C to form CoO and $CoSO_4$.

Reaction Products of Co_3O_4 with SO_2 in the Presence of Carbon. The reaction products of Co_3O_4 with SO_2 in the presence of carbon as a reducing agent were examined. Based on the results of preliminary experiments on the suitable amount of carbon to be mixed, the products obtained by heating a mixture of 2.00 g of Co_3O_4 and 2.00 g of carbon at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm^3/min were examined. The results are shown in Table 1. The sample in the boat was identified by X-ray analysis.[6,9-13] The modification of the $CoSO_4$ formed is represented in the brackets.

The formation of CoO and $CoSO_4$ was observed above 400 °C. Above 650 °C, the formation of $Co_{1-x}S$ was observed in addition to that of CoO. $Co_{1-x}S$ was obtained at 750—800 °C. Sulfur was obtained outside the heating zone throughout the temperature range in this experiment, and the amount of sulfur markedly increased above about 750 °C.

The X-ray diffraction data of the $Co_{1-x}S$ obtained are shown in Table 2. The $Co_{1-x}S$ phase is known to have a NiAs structure. The lattice constants of the $Co_{1-x}S$ formed were calculated from the X-ray diffraction data, shown in Table 2, to be $a_0=3.380$ Å and $c_0=5.185$ Å. The composition of the $Co_{1-x}S$ formed was determined by chemical analysis. The analysis gave Co 42.5%; S 25.7% for the sample obtained at 750 °C, and Co 61.3%; S 37.2% at 800 °C. From these results, the composition of the $Co_{1-x}S$ formed was determined to be $Co_{0.90}S$.

The formation of $Co_{1-x}S$ with the Co/S atomic ratio of 0.90 by the reaction of Co_3O_4 with SO_2 in the presence of carbon at 650—800 °C seems to be

reasonable in terms of the phase diagram for the Co–S system, reported recently by Rau.[14] As mentioned before, Pechkovskii and Mal'tseva[4] described that Co_9S_8 was formed by heating a mixture of Co_3O_4 and carbon in a SO_2 stream at 750—1000 °C. But Co_9S_8 is unstable above 830 °C according to the above phase diagram.[14]

Reaction Process of Co_3O_4 with SO_2 in the Presence of Carbon. To elucidate the reaction process of Co_3O_4 with SO_2 in the presence of carbon, the following experiments were carried out under conditions similar to those described above.

Reaction of Co_3O_4 with Carbon: The products formed by heating a mixture of Co_3O_4 (2.00 g) and carbon (2.00 g) at various temperatures in an argon stream (100 cm^3/min) for 1 h were examined by X-ray analysis.[9,11,15] The results are shown in Table 3.

These results indicate that the reduction of Co_3O_4 with carbon proceeds above about 500 °C to form CoO, and that above about 750 °C CoO formed is further reduced with carbon to β-cobalt.

Reaction of Co_3O_4 with Sulfur: As seen from Table 1, when the mixture of Co_3O_4 and carbon was heated in a SO_2 stream, sulfur was formed. The reaction of carbon with SO_2 occurs even at 350 °C to form sulfur and this reaction proceeds markedly above about 700 °C, as reported by the present authors.[7] Therefore, the reaction of Co_3O_4 with gaseous sulfur was examined.

Co_3O_4(2.00 g) was heated in a stream of argon (100 cm^3/min) containing a specified amount of gaseous sulfur at various temperatures for 1 h. Prior to

Table 4. Products obtained by heating Co_3O_4 in a stream of argon containing gaseous sulfur

Temp °C	Weight loss/%	Sample in the boat
450	—	Co_3O_4
500	0.1	$Co_3O_4 \gg CoO$
550	0.2	$Co_3O_4 \gg CoO$
600	0.5	$Co_3O_4 > CoO$

Table 5. Experimental results for the reaction of $CoSO_4$ with carbon in an argon stream

Temp °C	Weight loss/%	Sample in the boat
500	—	$CoSO_4[\beta]$
550	—	$CoSO_4[\beta > \alpha]$
600	12.6	$CoSO_4[\beta > \alpha]$, CoO
650	27.8	CoO
700	28.7	CoO

this experiment, the amounts of sulfur formed by heating 2.00 g of carbon at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm³/min were measured. Based on these experimental results, the amount of sulfur introduced at various temperatures was controlled to be 0.01 g for the experiments below 550 °C, and 0.04 g at 600 °C. The experimental results are shown in Table 4.

These results indicate that the reduction of Co_3O_4 with gaseous sulfur proceeds gradually above about 500 °C to form CoO.

Reaction of $CoSO_4$ with Carbon: As seen from Table 1, when the mixture of Co_3O_4 and carbon was heated in a SO_2 stream, $CoSO_4$ was formed above about 400 °C. Therefore, the reaction of $CoSO_4$ with carbon was examined.

The products obtained by heating a mixture of $CoSO_4$ (2.00 g) and carbon (2.00 g) in an argon stream (100 cm³/min) for 1 h were examined. The results are shown in Table 5.

These results indicate that the reduction of $CoSO_4$ with carbon occurs above about 600 °C to form CoO.

The process of formation of the CoO on heating the mixture of Co_3O_4 and carbon in a SO_2 stream can be explained as follows: The reaction of Co_3O_4 with SO_2 occurs above about 400 °C to form CoO and $CoSO_4$. Above about 500 °C, the reductions of Co_3O_4 with carbon and with sulfur also occur to form CoO. Above about 600 °C, the $CoSO_4$ formed is reduced with carbon to CoO.

Formation Reaction of $Co_{1-x}S$ from CoO: As seen from Table 1, when the mixture of Co_3O_4 and carbon was heated in a SO_2 stream, $Co_{1-x}S(Co_{0.90}S)$ was formed above about 650 °C. Above this temperature, Co_3O_4 was reduced to CoO. Therefore, the reaction of CoO with gaseous sulfur in a SO_2 stream was examined.

The products formed by heating CoO (2.00 g) for 1 h in a stream of SO_2 (100 cm³/min) containing a specified amount of gaseous sulfur at various temperatures were examined. The amounts of sulfur introduced were controlled to be 0.04 g for the experiment at 600 °C, 0.12 g at 650 °C, 0.58 g at 700 °C, 1.62 g at 750 °C, and 3.34 g at 800 °C, based on the results obtained for the amounts of sulfur formed by heating 2.00 g of carbon at various temperatures for 1 h in a SO_2 stream at a flow-rate of 100 cm³/min. The experimental results are shown in Table 6.

Table 6. Products obtained by heating CoO in a stream of SO_2 containing gaseous sulfur

Temp °C	Weight gain/%	Sample in the boat
600	—	CoO
650	2.2	$CoO \gg Co_{1-x}S$
700	7.5	$CoO > Co_{1-x}S$
750	15.4	CoO, $Co_{1-x}S$
800	19.4	$Co_{1-x}S > CoO$

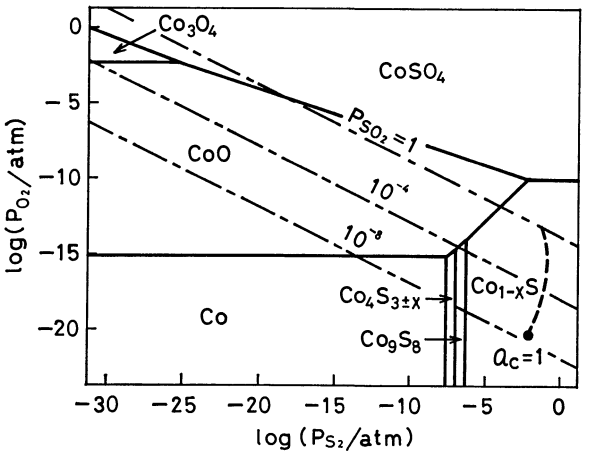

Fig. 1. Chemical potential diagram for the Co–S–C–O system at 800 °C (1 atm=101325 Pa).

These results indicate that the reaction of CoO with gaseous sulfur proceeds above about 650 °C to form $Co_{1-x}S$. The composition of the $Co_{1-x}S$ formed was evaluated to be $Co_{0.90}S$ by X-ray analysis (Table 2) and chemical analysis.

As seen from Table 3, CoO was reduced with carbon above about 750 °C to cobalt. In the Co–S system, the presence of Co_9S_8 and $Co_4S_{3\pm x}$ in addition to $Co_{1-x}S$ has been known as the lower sulfides. Therefore, thermodynamical consideration was made of the Co–S–C–O system, in order to discuss whether CoO was converted to $Co_{1-x}S$ *via* $Co_4S_{3\pm x}$, Co_9S_8 or cobalt, or without the formation of the lower sulfides or cobalt. The chemical potential diagrams for the Co–S–C–O system were constructed in a manner similar to that described by Yazawa[16] on the basis of the available thermodynamic data[17,18] and phase relations.[14] As an example, the diagram at 800 °C is shown in Fig. 1. The broken curved line shows the oxygen and sulfur potentials in the gas phase formed by the reaction of carbon with SO_2, depending on the carbon content in the gas phase. The activity of carbon, a_c, is unity at the dot mark. In these calculations, CO, CO_2, O_2, COS, CS_2, SO_2, SO_3, S_2, S_4, S_6, and S_8

were assumed to be gaseous products of carbon with SO_2.

The results shown in Fig. 1 indicate that CoO is converted to $Co_{1-x}S$ *via* cobalt, $Co_4S_{3\pm x}$, and Co_9S_8 under a pressure of SO_2 below *ca.* 10^{-5} atm, *via* $Co_4S_{3\pm x}$ and Co_9S_8 under a pressure of SO_2 at *ca.* 10^{-5}—10^{-4} atm, and *via* Co_9S_8 under a pressure of SO_2 at *ca.* 10^{-4}—10^{-3} atm, and that CoO is converted to $Co_{1-x}S$ without any formation of cobalt, $Co_4S_{3\pm x}$, and Co_9S_8 under a pressure of SO_2 above *ca.* 10^{-3} atm. Considering the experimental conditions in this work, the results in Fig. 1 show that $Co_{1-x}S$ is formed from CoO without any formation of the lower sulfides and cobalt.

From the results mentioned above, the process of formation of $Co_{1-x}S(Co_{0.90}S)$ by the reaction of Co_3O_4 with SO_2 in the presence of carbon can be represented as follows: On heating a mixture of Co_3O_4 and carbon in a SO_2 stream, the reaction of carbon with SO_2 occurs at first to form sulfur. Above about 400 °C, the reaction of Co_3O_4 with SO_2 occurs to form CoO and $CoSO_4$. Above about 500 °C, the reductions of Co_3O_4 with carbon and with sulfur also occur to form CoO. Above about 600 °C, the reduction of $CoSO_4$ with carbon occurs to form CoO. Above about 650 °C, $Co_{1-x}S$ is formed by the reaction of CoO with sulfur, both of which had been formed by the above reactions.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 555306 from the Ministry of Education, Science and Culture.

Photo-induced Ring-opening Reactions of 1-(2-Naphthoyl)aziridine in Various Solvents

Sei-ichi Nishimoto, Tsukuru Izukawa, and Tsutomu Kagiya*
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 9, 1981)

Photoreactions of 1-(2-naphthoyl)aziridine (NAz) have been investigated in various solvents under the deaerated conditions at room temperature. The photo-irradiation of NAz in halogenated hydrocarbons afforded halogen substituted secondary amides such as *N*-(2-chloroethyl)-2-naphthamide (CENA) or *N*-(2-bromoethyl)-2-naphthamide (BENA), a ring-expanded isomer of 2-(2-naphthyl)-2-oxazoline (NOz) and the NAz oligomer containing a chlorine atom. Secondary amides such as *N*-(2-methoxyethyl)-2-naphthamide (MENA) and *N*-ethyl-2-naphthamide (ENA) were obtained together with NAz oligomer in methanol and 2-propanol, respectively. The formation of *N*-(2-phenoxyethyl)-2-naphthamide (PENA), phenyl-2-naphthoate (PN) and NAz oligomer was observed in phenol (72 vol%)-acetonitrile mixture.

Extensive studies have been accomplished on the photochemical reactions of three-membered ring compounds such as cyclopropanes[1] and cyclopropenes.[2] The photochemistry of three-membered heterocycles has also received considerable attention.[3,4] A common feature of these photoreactions is ring-opening in the initial step, leading to cis-trans isomerization, acyclic compound formation, or rearrangement to ring-expanded products.

Although three-membered aziridines have been well characterized with respect to the thermal reactivities,[5] the photoreactions of these compounds have been little reported.[4] In this paper, the photochemical behavior of 1-(2-naphthoyl)aziridine (NAz) in various solvents was studied. Particular attention has been paid to the role of solvent molecules on the photochemical ring-opening of the aziridinyl group.

Experimental

General Methods. Melting points of all the products obtained are uncorrected. IR spectra were recorded on a JASCO DS-403 spectrophotometer, UV spectra on a Shimadzu UV-200S spectrophotometer, and ^{1}H NMR spectra on a JOEL PMX-60 spectrometer using tetramethylsilane as an internal standard. High speed liquid phase chromatography (HLPC) was carried out with a TOYO SODA HLC-802UR apparatus (gel permeation type column: TSK-GEL GMH6 and G2000H, 600 mm × 7.5 mm × 2, eluted with tetrahydrofuran at a flow rate of 1 cm^3 min^{-1} at 40 °C), using benzene as an internal standard.

Materials. Aziridine supplied from Nippon Shokubai Kagaku Kogyo Co. Ltd. was used after distillation. 2-Naphthoyl chloride (Tokyo Kasei Kogyo) was used without further purification. Acetonitrile was dried with calcium carbonate and distilled from phosphorus pentaoxide before use. Dibromomethane was dried with calcium chloride and distilled before use. Gaseous hydrogen chloride was prepared by the reaction of concentrated sulfuric acid (75 cm^3) with concentrated hydrochloric acid (40 cm^3).[6] The other solvents obtained commercially were used without further purification.

Preparation of 1-(2-Naphthoyl)aziridine (NAz). A solution of 2-naphthoyl chloride (53 mmol) in acetone (70 cm^3) was added to the equimolar (53 mmol) mixture of aziridine and triethylamine in acetone (200 cm^3) cooled in an ice bath. Triethylamine hydrochloride formed was removed as powder by filtration from the reaction mixture. The residue obtained by the evaporation of acetone was washed with methanol, followed by recrystallization three times from carbon tetrachloride to afford NAz (46% in yield), mp 82—83 °C. Found: C, 79.24; H, 5.56; N, 7.22; O, 7.90%. Calcd for $C_{13}H_{11}NO$: C, 79.19; H, 5.58; N, 7.11; O, 8.12%.

Photoreactions. Solutions of NAz in various solvents were deaerated by several freeze-pump-thawing cycles under vacuum in a Vycor or Pyrex glass tube (6 mmϕ) and sealed off. The photo-irradiation was carried out at room temperature, using a merry-go-round apparatus equipped with a high-pressure mercury lamp (EIKOSHA 500 W). After the irradiation, solvent was removed with a rotary evaporator under reduced pressure. The residual reaction mixture was subjected to the spectroscopic analyses. The conversion of NAz and the product yields were determined by the simultaneous use of ^{1}H NMR and HLPC measurements.

The photo-irradiation of a large amount of NAz solution was also carried out in order to identify the reaction products, using an immersion-type irradiation apparatus. The resulting reaction mixture was concentrated with a rotary evaporator and chromatographed on a silica gel column. The crude reaction mixture was also separated by repeated liquid phase chromatographies using the same column as mentioned above. The structures of the products were confirmed by the following data.

N-Ethyl-2-naphthamide (ENA). Mp 129.5—130 °C; IR ($CHCl_3$): 3420 (NH), 1510 and 1500 (NH), 1430, 1280, and 1230 (C–N) cm^{-1}; ^{1}H NMR ($CDCl_3$): δ 1.29 (3H, t, J=7.2 Hz), 3.60 (2H, q, J=6.6 Hz), 6.78 (1H, br), 7.68 (2H, m), 8.00 (4H, m), and 8.36 (1H, s). Found: C, 78.44; H, 6.70; N, 6.99; O, 7.89%. Calcd for $C_{13}H_{13}NO$: C, 78.39; H, 6.53; N, 7.04; O, 8.04%.

An identical product was obtained by the following procedures. 2-Naphthoyl chloride (14 mmol) dissolved in a minimum amount of acetone was added dropwise to a cooled aqueous solution (100 cm^3) containing ethylamine (14 mmol) and sodium hydroxide (31 mmol) under vigorous stirring. The white precipitate was purified from methanol (28% in yield).

N-(2-Chloroethyl)-2-naphthamide (CENA). Mp 135—136 °C; IR ($CHCl_3$): 3440 (NH), 1660 (C=O), 1519 and 1508 (NH), and 1285 (C–N) cm^{-1}; ^{1}H NMR ($CDCl_3$): δ 3.73 (4H, s), 6.83 (1H, br), 7.60 (2H, m), 7.83 (4H, m), and 8.27 (1H, s). Found: C, 66.70; H, 5.19; N, 5.84; O, 6.89; Cl, 15.11%. Calcd for $C_{13}H_{12}NOCl$: C, 66.81; H, 5.14; N, 6.00; O, 6.85; Cl, 15.20%.

An identical product was obtained when gaseous hydrogen chloride was bubbled through a solution of NAz (90 mmol)

in chloroform (1 cm^3) at 0 °C (quantitative yield).

N-(2-Bromoethyl)-2-naphthamide (BENA). Mp 147.5—149 °C (lit,[7] mp 152 °C); IR (KBr): 3220 (NH), 1620 (C=O), 1535 (NH), 1310 (C–N), and 480 (C–Br) cm^{-1}; ^1H NMR (CD_2Cl_2): δ 3.71 (4H, q, J=4.8 Hz), 6.70 (1H, br), 7.50 (2H, m), 7.67 (4H, m), and 8.20 (1H, s).

The IR and ^1H NMR spectral data were identical with those of an authentic sample prepared by the reported method.[7]

Oligomer Obtained in Carbon Tetrachloride. IR (KBr): 1715, 1644, 1520, 1400, 1110, and 620 cm^{-1}; ^1H NMR ($CDCl_3$): δ 3.79 (3H, br), 7.56, 7.89, and 8.34 (7H, broad signals corresponding to the naphthyl group). Found: C, 46.52; H, 3.27; N, 3.33; O, 6.14; Cl, 35.00%.

2-(2-Naphthyl)-2-oxazoline (NOz). Mp 85.5—86.5 °C; IR ($CHCl_3$): 1645 (C=N), 1275 (=C–O–C), 1068 (C–O–C), 983, 961, and 943 cm^{-1}; ^1H NMR (CD_2Cl_2): δ 4.29 (4H, quartet, J=7.4 Hz), 7.60 (2H, m), 7.93 (4H, m), and 8.47 (1H, s). Found: C, 79.38; H, 5.59; N, 7.05; O, 8.19%. Calcd for $C_{13}H_{11}NO$: C, 79.19; H, 5.58; N, 7.11; O, 8.12%.

The IR and ^1H NMR spectral data were identical with those of an authentic sample prepared by the reported method.[7]

N-(2-Methoxyethyl)-2-naphthamide (MENA). Mp 86.5—87.5 °C; IR (CCl_4): 3440 (NH), 2975 (CH_3), 2820 (CH_3), 1664 (C=O), 1504 (NH), and 1068 (C–O–C) cm^{-1}; ^1H NMR ($CDCl_3$): δ 3.42 (3H, s), 3.61 (4H, m), 7.59 (2H, m), 7.89 (4H, m), and 8.29 (1H, s). Found: C, 72.61; H, 6.62; N, 5.94; O, 13.70%. Calcd for $C_{14}H_{15}NO_2$: C, 73.36; H, 6.55; N, 6.11; O, 13.97%.

An identical product was obtained when a solution of NAz (0.24 mmol) in methanol (40 cm^3) was permitted to stand for 30 min at room temperature in the presence of a catalytic amount of boron trifluoride under an argon atmosphere (quantitative yield).

Oligomer Obtained in Methanol. IR ($CHCl_3$): 3420 and 3300 (NH), 1760, 1650 (C=O), 1520 (NH), 1430, 1290 (C–N), and 1150 cm^{-1}; ^1H NMR ($CDCl_3$): δ 3.46 (5H, br), 3.73 (0.3H, singlet signal corresponding to the methoxyl group), and 7.53—8.28 (7H, br). Found: C, 52.79; H, 5.48; N, 5.03; O, 12.16%.

N-(2-Phenoxyethyl)-2-naphthamide (PENA). Mp 73—74 °C; IR (KBr): 3320 (NH), 1638 and 1625 (C=O), 1545 (NH), and 1081 (C–O–C) cm^{-1}; ^1H NMR ($CDCl_3$): δ 4.03 (4H, q, J=4.7 Hz), 6.63 (1H, br), 6.88—7.20 (5H, phenyl group), 7.61 (2H, m), 7.87 (4H, m), and 8.30 (1H, s). Found: C, 78.19; H, 6.39; N, 4.27; O, 10.61%. Calcd for $C_{19}H_{17}NO_2$: C, 78.35; H, 5.84; N, 4.81; O, 11.00%.

Phenyl-2-naphthoate (PN). Mp 90—90.5 °C (lit,[8] 96 °C); IR (KBr): 1732 (C=O), 1280 and 1228 (C–O–C) cm^{-1}.

The IR spectrum was identical with that of an authentic sample prepared by the reported method.[8]

N-(2-Acetoxyethyl)-2-naphthamide (AENA). Mp 78—79 °C; IR ($CHCl_3$): 3420 (NH), 1725 (C=O), 1648 (C=O), and 1500 (NH) cm^{-1}; ^1H NMR ($CDCl_3$): δ 2.09 (3H, s), 3.83 (2H, t, J=5.0 Hz), 4.36 (2H, t, J=5.0 Hz), 7.63 (2H, m), 7.87 (4H, m), and 8.32 (1H, s). Found: C, 69.10; H, 5.78; N, 5.54; O, 18.72%. Calcd for $C_{15}H_{15}NO_3$: C, 70.03; H, 5.84; N, 5.45; O, 18.68%.

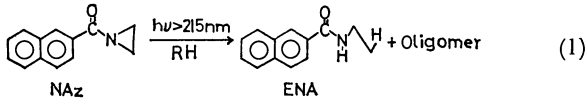
Results and Discussion

UV Absorption Characteristics of NAz. The solution of NAz in hexane exhibited ultraviolet absorption maxima at 337 nm (ε; 1310), 282 nm (ε; 8320), and 245 nm (ε; 51800). These absorption bands may be attributed to the π-π^* transitions of naphthyl group of NAz in view of the similarity to those of naphthalene.[9] No absorption bands were observed in the wavelength region longer than these principal absorption bands. It thus seems that the carbonyl n-π^* band lies behind the intense π-π^* bands of the naphthyl group.[10]

Photoreactions of NAz in Non-halogenated Aprotic Solvents. The photo-irradiations of NAz in various solvents were carried out for 200 min at room temperature under deaerated conditions, using Vycor and Pyrex glass

tubes which transmit the light with wavelength longer than 215 and 286 nm, respectively. The results are summarized in Table 1.

It is apparent from Table 1 that NAz exhibits less photoreactivity in non-halogenated aprotic solvents such as hexane, benzene, diethyl ether, acetone and acetonitrile, in which the overall conversion of NAz did not exceed 10% (Runs 1—5). *N*-Ethyl-2-naphthamide (ENA) was afforded in low yield as a common ring-opened product in these solvents, accompanied by NAz oligomer.

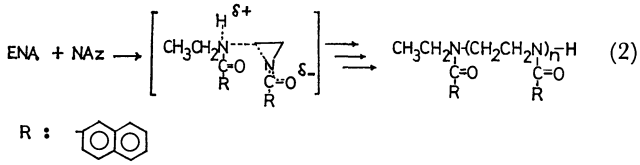


NAz ENA (1)

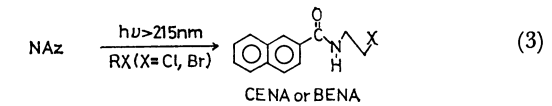
This photochemical ENA formation suggests that the hydrogen abstraction by NAz in the electronically excited state from a solvent molecule occurs to bring about α-cleavage of the aziridine ring. In this regard, it was confirmed that acetone is afforded along with the photochemical ENA formation in $(CH_3)_2CHOH$, as shown below (Eq. 10). Accordingly, the ENA formation in these solvents is expected to proceed by a radical mechanism in a similar manner to that in $(CH_3)_2CHOH$.

The low yield of ENA in these solvents may be attributed to the requirement of high activation energy for the hydrogen abstraction from solvent molecule. In the present systems, the hydrogen abstraction from either aziridinyl or naphthyl groups of NAz seems minor for the ENA formation because of the low reactivities of hydrogen atoms on these groups.[11]

On the other hand, ENA as a photoproduct was found to initiate oligomerization of NAz slowly in a similar manner to the ring-opening polymerization of most 1-acylaziridines by various amides.[12]

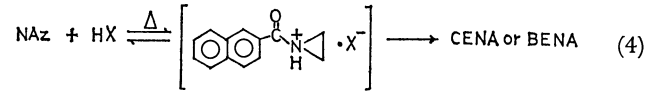


Photoreactions of NAz in Halogenated Hydrocarbons. The photo-irradiation of NAz in halogenated hydrocarbons through a Vycor glass tube (>215 nm) resulted in α-cleavage of the aziridine ring to afford halogen substituted secondary amide, *N*-(2-chloroethyl)-2-naphthamide (CENA) in CCl_4 and $CHCl_3$ or *N*-(2-bromoethyl)-2-naphthamide (BENA) in CH_2Br_2 with high yields above 55% (Runs 6, 8, 10).



CENA or BENA

It was confirmed by a separate experiment that the photolysis of $CHCl_3$ occurs in a Vycor glass tube to afford HCl. Moreover, NAz was converted quantitatively into CENA without oligomerization by bubbling gaseous HCl through a solution of NAz in $CHCl_3$ in the dark. Such a ring-opening reaction by hydrogen halide would proceed *via* the following reactive intermediate of aziridinium salt:[13]



Under the conditions of the irradiation with light of wavelength longer than 215 nm, it is likely that a halogen atom such as Cl or Br is formed as a primary intermediate by the photolyses of halogenated hydrocarbon solvents and subsequently abstracts a hydrogen atom from a solvent molecule to afford a hydrogen halide, HCl or HBr. The hydrogen abstraction from NAz would be minor because of the low reactivities of hydrogen atoms on NAz, in a similar manner to the ENA formation in non-halogenated aprotic solvents.

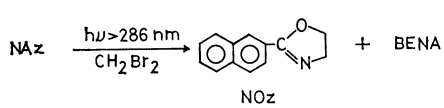
It should be noted that, although CCl_4 does not contain any hydrogen atoms, CENA was obtained in the dark by the addition of NAz (90 mmol dm^{-3}) to a pre-irradiated CCl_4 under the same conditions as in the Vycor system. Furthermore, the yield of CENA (53%) in this post-reaction agreed closely with that (57%) in the in-source photoreaction (Run 6). It has been well known that Cl_2 is formed by the photolysis of CCl_4 at wavelengths shorter than 253.7 nm.[14] Therefore, the reaction of NAz with Cl_2 is presumed to afford HCl in the CCl_4 system.

The oligomer of NAz with a high content of chlorine atoms (35%) was also obtained along with CENA in CCl_4. The yield of this oligomer (25% based on NAz) was much higher than those (less than 5%) in hydrogen-containing $CHCl_3$ and CH_2Br_2. This would also be associated with the reaction between NAz and Cl_2.

On the other hand, the photo-irradiation of NAz in CCl_4 or $CHCl_3$ through a Pyrex glass tube (>286 nm) led to the same product, CENA, as afforded in the Vycor system (Runs 7, 9). Here the yields were reduced to one-sixth in CCl_4 and one-tenth in $CHCl_3$, respectively, and very little oligomerization of NAz occurred (<1%).

$$\text{NAz} \xrightarrow[CCl_4 \text{ or } CHCl_3]{h\nu>286\text{ nm}} \text{CENA} \qquad (5)$$

On the contrary, the product distribution in CH_2Br_2 was affected remarkably by the wavelength of irradiation. The photo-irradiation of NAz in CH_2Br_2 through a Pyrex glass tube resulted in a ring-expanded isomer of 2-(2-naphthyl)-2-oxazoline (NOz) as a major product, along with BENA (Run 11), in contrast to the exclusive BENA formation in the Vycor system (Run 10).



NOz 52% BENA 17%

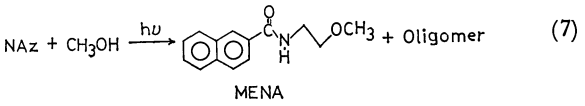
Although BENA was readily converted into NOz at 70 °C in the presence of potassium hydroxide in CH_3OH (72% in yield), the photocyclization of BENA into NOz did not occur in CH_2Br_2 under the present conditions. Furthermore, BENA was obtained in 18% yield by the addition of NAz (90 mmol dm^{-3}) in the dark to a pre-irradiated CH_2Br_2 under the same con-

ditions as above. The good agreement with the yield of BENA in this post-reaction indicates that the BENA formation in the in-source photoreaction system can be attributed to the reaction of NAz with HBr formed by the photolysis of CH_2Br_2.

It may be presumed for the photo-isomerization that the dipole-dipole interaction of NAz in the electronically excited state with CH_2Br_2 promotes the ionic ring-opening of aziridinyl group, followed by the cyclization into oxazoline due to the stabilization of four center transition state.[5f]

Photoreactions of NAz in Alcohols and Phenol. The photochemical ring-opening reactions of NAz also occurred in CH_3OH, $(CH_3)_2CHOH$, and phenol (72 vol%)–CH_3CN mixture.

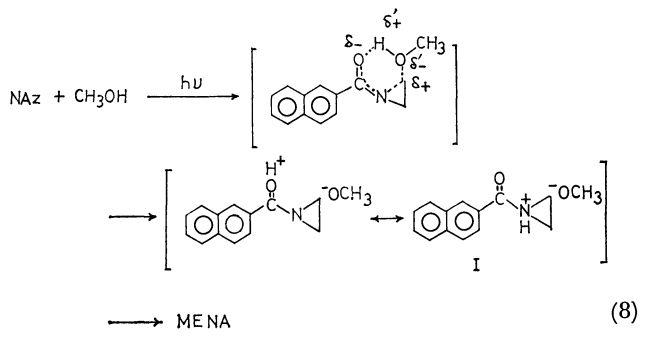
The photo-irradiation of NAz in CH_3OH afforded *N*-(2-methoxyethyl)-2-naphthamide (MENA) accompanied by NAz oligomer, whereas the dark reaction was not observed under the same conditions. As shown in Table 1, the product yields in the Pyrex system decreased compared with those in the Vycor system, but no appreciable difference was observed in the ratio of yields between MENA and oligomer (Runs 12, 13).



(7)

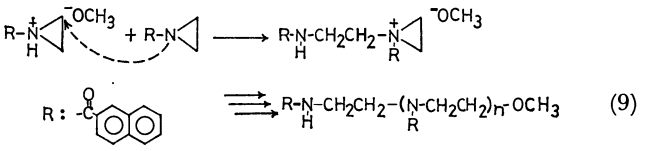
It seems possible that the MENA formation arises from the methanolysis of the aziridine ring of NAz in the electronically excited state in a similar manner to that in the photo-induced alcoholysis of three-membered ring compounds such as cyclopropanes,[1] oxiranes,[3d] 1,2,3-triphenylaziridine,[4b] and 1-(dimethylcarbamoyl)-2,3-diphenylaziridine.[4c]

Since the O–H bond (418 K J mol^{-1}) is stronger than the C–H bond (386 K J mol^{-1}) in CH_3OH,[15] radical cleavage of polar O–H bond seems not to be involved in the MENA formation. The addition of CH_3OH to aziridine ring may therefore occur by an ionic mechanism. It is also likely that the hydrogen bonding of CH_3OH to carbonyl oxygen of NAz facilitates the nucleophilic attack of the methoxide ion on the aziridinyl carbon due to the stabilization of a polar transition state.



(8)

It has been well known that protonated aziridines are readily attacked by various nucleophiles on the aziridinium carbon.[5a] Consequently, the formation of aziridinium ion intermediate (I) would account for the relatively high yield of NAz oligomer in CH_3OH due to the polymerization faster than that initiated by the amide (Eq. 2).[16] The propagation may proceed by the cationic ring-opening of NAz as a nucleophile *via* aziridinium ion at the growing chain end. This scheme is consistent with the fact that the NAz oligomer contains a methoxyl group.



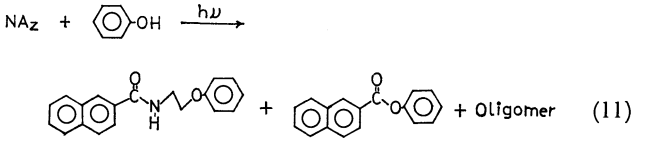
(9)

In $(CH_3)_2CHOH$, on the other hand, the photochemical behavior of NAz was markedly different from that in CH_3OH. The ring-opening reaction due to the addition of alcohol to NAz did not occur in $(CH_3)_2CHOH$, but the formation of an equimolar mixture of ENA and acetone was observed (Runs 14, 15).

(10)

It has been well established that $(CH_3)_2CHOH$ readily undergoes oxidation into acetone *via* hydrogen abstraction by various radical species. In view of such a characteristic reactivity of $(CH_3)_2CHOH$, the ring-opening of NAz by a radical mechanism seems to be involved in the photochemical ENA formation. The exclusive formation of ENA without *N*-(2-isopropoxyethyl)-2-naphthamide analogous to MENA may be attributed to the fact that the nucleophilicity of $(CH_3)_2CHOH$ is lower than that of CH_3OH.

In order to clarify the effect of nucleophilicity of alcohol on the photo-induced ring-opening of NAz, the photoreaction of NAz in phenol (72 vol%)–CH_3CN mixture was further examined. Under the irradiation through a Vycor or a Pyrex glass tube, NAz was converted quantitatively to afford *N*-(2-phenoxyethyl)-2-naphthamide (PENA), phenyl-2-naphthoate (PN), and NAz oligomer (Runs 16, 17).



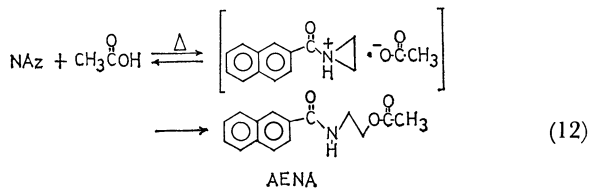
(11)

An identical reaction occurred in the dark to afford PENA and PN with 6% and 2% yields, respectively, but the conversion of NAz was low (8%) relative to the photoreaction. This result shows that the phenolysis of NAz is accelerated by the photo-irradiation.

The formation of PENA accompanied by NAz oligomer is apparently analogous to the photoreaction observed in CH_3OH (Eq. 7). In the phenol system, however, it is characteristic that the phenolysis of the carbonyl-aziridinium nitrogen bond of NAz leading to PN occurs simultaneously with that of the aziridine ring. These results suggest that phenol is capable of nucleophilic attack not only on the aziridinyl carbon but also the carbonyl carbon of NAz in the excited state because the nucleophilicity is higher than that of CH_3OH.

Furthermore, in the relatively strong acidic medium of acetic acid, the quantitative acetolysis of aziridine

ring of NAz was observed even in the dark to afford *N*-(2-acetoxyethyl)-2-naphthamide (AENA), which is essentially the same reaction as shown in Eq. 4 for the ring-opening by hydrogen halide. It is likely



(12)

that the protonation to NAz occurs rapidly in the presence of protonic acids such as hydrogen halide and acetic acid to form an aziridinium ion intermediate, which undergoes nucleophilic addition by halide ion or acetate ion selectively to the aziridinium carbon.

These results seem to be consistent with the scheme postulated for the photochemical MENA formation (Eq. 8).

On the basis of the results presented in this paper, it may be concluded that NAz exhibited dual reactivity for the ring-opening reaction in the electronically excited state. In this reaction, solvent molecules play important roles in determining whether radical or ionic reaction occurs. Details of the reactivity of solvent molecule toward NAz in the excited state leading to ring-opening of the aziridinyl group will be reported in a subsequent paper.

(Received March 17, 1981)

Statistically significant correlations have been demonstrated between analgesic activities of a series of pyrazolylpyrimidine derivatives and molecular properties. The structural parameters are partition coefficients, molar refractivities, an indicator variable, and MO indices obtained from the CNDO/2 method. The influence of the torsional angle between the pyrazole and pyrimidine rings on the electronic state was examined. The correlations indicate that transport and partition processes and electronic factors play a major part in determining the analgesic activity. In particular, of electronic parameters MO indices on the pyrazole ring are significant. These structure-activity relationships can be used to estimate the analgesic activities with some degree of confidence.

It is known that non-narcotic analgesics, including the derivatives of pyrazole, salicylic acid and acetanilide, have antipyretic and antiinflammatory properties. The most popular pyrazole compounds are antipyrine and aminopyrine.

Many attempts[1,2] have been carried out to develop new drugs by modification of existing pyrazole compounds, *e.g.*, antipyrine as a lead compound. The Hansch analysis has been applied to the studies of quantitative structure-activity relationships (QSAR) of antipyrine derivatives.[3] These studies revealed that pyrazoles having an alicyclic or heterocyclic group instead of a phenyl ring in antipyrine are potentially active.

Naito *et al.*, therefore, synthesized pyrazolylpyrimidine derivatives to find a highly potent drugs.[4,5] As a result it has been found that 4-methoxy-2-(5-methoxy-3-methyl-1*H*-pyrazol-1-yl)-6-methylpyrimidine (mepirizole) is the most potent compounds having an analgesic effect. In the QSAR studies it is important to ascertain if metabolites of the drug are not potent. It has been found that the metabolites of mepirizole have little effect.[6,7]

In an attempt to further investigate analgesic activities of pyrazole compounds, correlation between the activities of pyrazolylpyrimidine derivatives and the molecular structure is studied using the QSAR techniques in this paper. The structural parameters to establish QSAR are hydrophobic parameters, molar refractivities, an indicator variable and a variety of MO indices obtained from the CNDO/2 method.

Experimental

Data Set. The data used in this study were taken from the studies on a series of 44 pyrazolylpyrimidine compounds.[5] The analgesic activities are expressed as $\log A$, where A is relative potency compared with equimolar amounts of aminopyrine measured by the pressure method in mice. These values are given in Table 1. The fragments involving pyrazole R_i and pyrimidine P_j are shown in Fig. 1 to represent the compounds in Table 1.

The forty-four compounds are divided into two groups, (N^1 and N^2). Groups N^1 and N^2 contain subgroups A, B and C, D, respectively. Subgroups A and B contain series

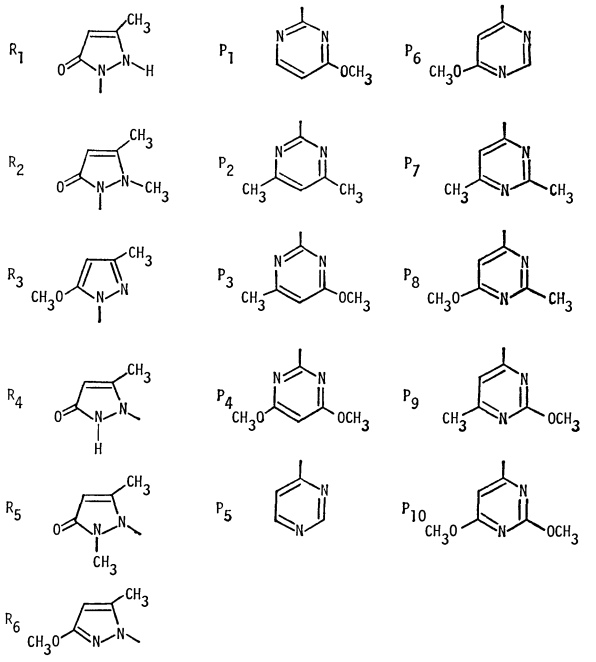

Fig. 1. The chemical structures of pyrazole R_i and pyrimidine P_j fragments.

R_1, R_2, and R_3 and subgroups C and D contain series R_4, R_5, and R_6, respectively. The numbers of active compounds in each group and series are shown in Table 2.

Structural Parameters of Pyrazoles. The hydrophobic parameters are determined experimentally or estimated using the observed data. 1-Octanol/water partition coefficients P for 23 compounds were measured at pH 7 and at room temperature by the flask shaking method. Table 1 shows the observed log P values. The fragment addition model, which is a similar procedure to the Free-Wilson method, is used to calculate the log P values for the remaining 15 compounds. This model is given by the following equation:

$$\log P = \sum_i R_i X_i + \sum_j P_j Y_j + \mu, \quad (1)$$

where R_i is the fragment contribution of a pyrazole ring, P_j is that of a pyrimidine ring, and μ is the overall average of the observed log P values ($X_i=1$ if the pyrazole ring is the i-th fragment, otherwise $X_i=0$, $Y_j=1$ if the pyrimidine ring is the j-th fragment, otherwise $Y_j=0$). Further the

a) Values in parentheses are the numbers of active compounds in the groups or series.

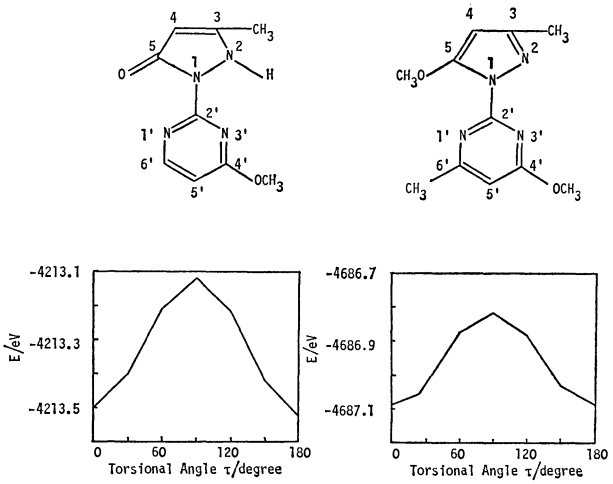

Fig. 2. Pyrazole numbering system ($\tau=0°$) and total energies of compound **1** (left) and mepirizole *vs.* rotation around N^1–$C^{2'}$ bond.

symmetry relations are given by the following equations:

$$\sum_i n_i R_i = 0, \qquad \sum_j n_j P_j = 0, \tag{2}$$

where n_i is the number of i-th pyrazole rings and n_j is that of the j-th pyrimidine rings for 23 compounds.

Combining Eqs. 1 and 2, the symmetry constraints vanish. The resulting simultaneous equations are solved by the least squares method to obtain the fragment contributions. The regression equation is

$$\begin{aligned}\log P = &-0.305X_1 - 0.831X_2 + 0.057X_3 + 0.585X_4 \\ &- 0.581X_5 + 1.305X_6 - 0.154Y_1 - 0.301Y_2 \\ &+ 0.099Y_3 + 0.359Y_4 - 0.385Y_5 + 0.193Y_6 \\ &+ 0.084Y_7 + 0.148Y_8 + 0.231Y_9 + 0.701Y_{10} \\ &+ 1.104 \end{aligned} \tag{3}$$

The correlation coefficient between observed and calculated log P values for 23 compounds is 0.965. The log P values for other compounds were calculated by this equation. These log P values are shown in Table 1.

In order to represent the steric feature, molar refractivities MR were calculated from bond refractivites.[8] The values are shown in Table 1. Seventeen varieties of MR values exist for all compounds.

Quantum mechanical indices were determined from the CNDO/2 method to explain electronic aspects of drug-acceptor interactions. They are energies of the highest occupied molecular orbital HOMO, the lowest unoccupied molecular orbital LUMO, the energy difference GAP between LUMO and HOMO, and total electron densities associated with the atoms on pyrazole ring (q_1—q_5). The numbering system for pyrimidine derivatives is shown in Fig. 2.

Molecular geometries are determined from the X-ray crystallographic data for pyrazole,[9] pyrimidine[10] and antipyrine.[11] The torsional angle τ between the pyrazole and pyrimidine rings in mepirizole(compound **23**) was determined as 20.5° from X-ray crystallographical data. The details of the characteristic feature of the geometry of pirizole will be published in the near future, and not demescribed in the present paper. The torsion of pyrimidine ring toward the pyrazole ring is most likely to have the most influence on the electronic state. In order to investigate

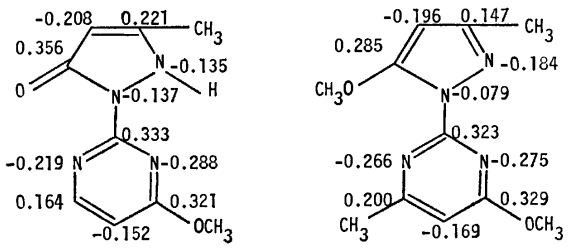

Fig. 3. Charge distribution of compound **1** (left) and mepirizole.

the effect of conformational alternations on the electronic states of these compounds, the rotation around the N^1–$C^{2'}$ bond were carried out with 30° increments for the typical compounds, compound **1** and mepirizole.

Conformation and Electronic State. The total energies of compound **1** and mepirizole vary in accordance with increment of the torsional angle (Fig. 2). The lowest energies are obtained at $\tau=0°$ and 180°, where pyrazole and pyrimidine situate on the same plane and electronic delocalization may occur over two rings. The highest energy is obtained at $\tau=90°$ for both compounds. The energy at 20.5° is a little higher than the lowest energy. The value is 0.04 eV which is near to the thermal energy and the torsion of that extent may easily occur. On the other hand, that the difference between the highest and lowest energy is more than 0.3 eV indicates the presence of the high energy barrier for the free rotation around the N^1–$C^{2'}$ bond. HOMO, LUMO, and GAP of the two compounds at 20.5° are slightly higher than the corresponding lowest energies.

Total electron densities on the pyrazole ring indicate the slight change in charge distribution for both compounds at 20.5° and 0°. The patterns of charge distribution at 20.5° are similar for both compounds (Fig. 3). All the pyrazole derivatives used in this study have similar patterns of charge distribution when the torsional angle is 20.5°. The rotational angles for all compounds are fixed at 20.5° to calculate the MO indices since the electronic state at 20.5° of torsional angle resembles that of the lowest energy.

Results and Discussion

By expressing the analgesic activity as the logarithm of relative potency log A, a systematic search of various parameters for pyrazole derivatives revealed statistically significant relationships. Linear regression analysis for 18 compounds in subgroup A yielded the following equations:

$$\log A = -0.906(\log P)^2 + 1.548(\log P) - 0.700\mathrm{HOMO} - 8.159, \quad (4)$$
$$n = 18,\ r = 0.798,\ s = 0.633,\ F = 8.21,$$

$$\log A = -0.608(\log P)^2 + 1.204(\log P) + 51.949Q_1 - 34.503Q_3 + 13.484, \quad (5)$$
$$n = 18,\ r=0.892,\ s=0.516,\ F=12.71.$$

In this report n represents the number of data points upon which the equation is based, s is the standard deviation, and F is the F ratio. Q_k is the net charge associated with the atom k on the pyrazole ring. These correlations, involving partition coefficients and MO parameters, indicate the importance of transport and electronic properties. By combining net charges on the pyrazole ring with hydrophobic parameters, 80% of the variation in the observed analgesic activities can be explained. Since Q_3 and Q_4 have a high negative correlation coefficient of −0.81, it seems that the substituents would have a similar effect on the net charges on these atom positions, which might play an important role for the analgesic activity.

Using similar approach, more extended relationships which include the entire members of group N^1 (subgroup A, B) were developed. The following equations are generated,

$$\log A = -0.532(\log P)^2 + 1.044(\log P) - 0.797\mathrm{HOMO} - 9.029, \quad (6)$$
$$n = 28,\ r = 0.842,\ s = 0.572,\ F = 19.51,$$

$$\log A = -0.666(\log P)^2 + 1.450(\log P) - 15.329Q_4 + 2.020, \quad (7)$$
$$n = 28,\ r = 0.835,\ s = 0.584,\ F = 18.40.$$

The hydrophobic parameters and HOMO or Q_4 correlated well with the activities of these derivatives as well as only with that of the subgroup B derivatives. This suggests that the mechanism of action of the subgroup B derivatives seems to be similar to that of the subgroup A derivatives.

The parabolic relationships of hydrophobic parameters in Eqs. 4—7 indicate that the optimal log P value for activity is about one. The log P values for the compounds having higher activity (compounds **3, 8, 23**) are close to this value, on the other hand, that for the compounds having low activities (**12, 13**) and inactive compounds are far from this value. However, the electronic factor is also important. Since the correlation between Q_3 and Q_4 is high in group N^1, Eq. 5 is closely related to Eq. 7. Therefore these positions of the pyrazole ring are considered to be fairly important for the group N^1 derivatives. No improvement is obtained by adding other parameters because MO parameters are relatively well correlated with each other.

The negative sign of the coefficients associated with HOMO in Eqs. 4 and 6 indicates that the more electron-donating ability, the lower activity becomes. In contrast with this result, Neely *et al.*[12] reported the positive sign of the coefficient with HOMO in the studies of a series of imidazole derivatives, that leads to a charge transfer complex model. Neither *MR* nor total electron density on the atom of the pyrimidine ring were of significant value in correlating the activity.

An analysis of the analgesic activities of 10 compounds in group N^2 revealed that *MR*, LUMO and GAP are significant parameters.

$$\log A = -0.009MR^2 + 1.051MR - 29.963, \quad (8)$$
$$n = 10,\ r = 0.879,\ s=0.542,\ F = 11.84,$$

$$\log A = 0.690\mathrm{LUMO} - 0.144\mathrm{IV} - 2.33, \quad (9)$$
$$n = 10,\ r = 0.842,\ s=0.612,\ F = 8.54,$$

$$\log A = 0.867\mathrm{GAP} - 0.907\mathrm{IV} - 11.535, \quad (10)$$
$$n = 10,\ r = 0.954,\ s = 0.341,\ F = 35.09,$$

where IV is an indicator variable with a value of

Table 3. Predicted log A values for Inactive compounds

No.	Predicted				No.	Predicted		
	Eq. 4	Eq. 5	Eq. 6	Eq. 7		Eq. 8	Eq. 9	Eq. 10
11	−0.95	−1.22	−0.90	−0.94	**34**	−0.17	−1.05	−1.14
15	−1.25	−0.98	−1.08	−1.23	**35**	−0.17	−1.10	−1.11
					37	−0.46	−0.31	−0.63
					38	−0.30	−0.40	−0.43

1 for the subgroup C derivatives and 0 for the subgroup D derivatives. The introduction of hydrophobic parameters into each regression in no case produced a significant improvement.

Equation 8 indicates that there exists an optimal MR value; a proper steric feature would be required for drug-acceptor interactions. The positive coefficient with LUMO in Eq. 9 indicates that the activity increases with the stability of electronic state. The indicator variable IV highly correslates with the net charges on the atoms of the pyrazole ring and reflects these electronic features. GAP, concerning with the transition energy, also correlates well with activity. Another regression analysis combining the other series compounds $R_i(i=1, 2,\cdots 6)$ in no case produced a significant correlation.

In order to examine the reliability of the results obtained above, the activities were predicted from Eqs. 4—10 for those compounds which are found to be inactive. The predicted activities are shown in Table 3. The analgesic activities for the group N^1 compounds were successfully predicted to be inactive from Eqs. 4—7. On the other hand, the group N^2 compounds were predicted to be not inactive from Eq. 8. This failure may be due to some unexplained factors. However, it is expected that observed relationships aid the development of understanding of the analgesic activities for these compounds.

The authors thank the Computer Center, Institute for Molecular Science for affording facilities for computation.

Reactions of Thiols with Phenylglyoxal to Give Thiomandelic *S*-Esters. Formation of Hemithioacetals and Their Rearrangement

Tadashi Okuyama,* Kazumasa Kimura, and Takayuki Fueno
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received April 30, 1981)

Equilibrium constants K_h for the addition of 2-mercaptoethanol and glutathione to phenylglyoxal to form hemithioacetals were determined spectrophotometrically over the pH range 7—10. The observed K_h values decrease sigmoidally with pH as the thiol ionizes. Rearrangement of hemithioacetals formed from phenylglyoxal and various thiols was kinetically investigated. The rates increase with thiol concentration following a saturation curve to give K_h identical with the spectrophotometric value. The rearrangement is subject to general base catalysis. The solvent isotope effect on the rate of the rearrangement, k^{H_2O}/k^{D_2O}, is nearly 1.0; that on the equilibrium, $K_h^{H_2O}/K_h^{D_2O}$, is 0.38. The results strongly support the mechanism involving proton transfers through an enediol intermediate.

Glutathione (GSH), a tripeptide thiol, has been well known as a coenzyme which constitutes the glyoxalase enzyme system.[1] The enzyme catalyzes the Cannizzaro-type rearrangement of methylglyoxal to lactic acid. The suggestion that this action is related closely to the regulation of cell division[2] has stimulated interest in this enzyme system and its mechanism. The reaction proceeds through nonenzymatic formation of hemithioacetal and its rearrangement to α-hydroxy thiocarboxylic *S*-ester which is catalyzed by glyoxalase I:[1,3,4]

$$\begin{aligned} &CH_3\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{O}{\overset{\|}{C}}\text{-}H + GSH \rightleftharpoons CH_3\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{OH}{\overset{|}{C}}\text{H-SG} \\ &\xrightarrow{\text{glyoxalase I}} CH_3\text{-}\overset{OH}{\overset{|}{C}}\text{H-}\overset{O}{\overset{\|}{C}}\text{-SG} \\ &\xrightarrow{\text{glyoxalase II}} CH_3\text{-}\overset{OH}{\overset{|}{C}}\text{H-}\overset{O}{\overset{\|}{C}}\text{-OH} + GSH. \end{aligned} \quad (1)$$

Results of solvent isotope incorporation experiments led earlier investigators to conclude a mechanism involving an intramolecular hydride shift,[5,6] while recent NMR evidence of temperature-dependent incorporation of solvent protons suggested a mechanism of fast-shielded enediol proton transfer:[7]

$$\begin{aligned} R\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{OH}{\overset{|}{C}}\text{H-SG} &\longrightarrow R\text{-}\overset{OH}{\overset{|}{C}}\text{=}\overset{OH}{\overset{|}{C}}\text{-SG} \\ &\longrightarrow R\text{-}\overset{OH}{\overset{|}{C}}\text{H-}\overset{O}{\overset{\|}{C}}\text{-SG}. \end{aligned} \quad (2)$$

Franzen[5,8] showed that certain 2-(dialkylamino)-ethanethiols are efficient nonenzymatic catalysts for rearrangement of a glyoxal which mimicks the glyoxalase reaction. Hall and Poet[9] found that some α-keto hemithioacetals rearrange to α-hydroxy thiocarboxylic *S*-esters under catalysis of such bases as sodium acetate and tertiary amines in *N*,*N*-dimethylformamide solution. Shinkai *et al.*[10] have recently demonstrated the intermediacy of enediol in reactions of some thiols with methyl- and phenylglyoxals by the flavin-trapping experiments. However, the kinetic phase of this reaction has been examined only briefly[7b] and has not well been characterized.

In the present investigation, we examined reactions of various thiols with phenylglyoxal (PG) in aqueous solution. Equilibrium constants for formation of hemithioacetals were determined in a wide pH range and their rearrangement was kinetically characterized.

Experimental

Materials. Phenylglyoxal (PG) hydrate was prepared according to the literature.[11] 2-Mercaptoethanol (ME), 1-butanethiol, ethyl mercaptoacetate, and 3-mercaptopropionic acid were distilled and stored under nitrogen. Sodium mercaptoacetate (Wako Pure Chemicals) was used without further purification. Glutathione (GSH) was a gift from Ajinomoto Co. 1,4-Diazabicyclo[2.2.2]octane (DABCO) and imidazole were recrystallized from ligroine and benzene, respectively. *N*-Methylmorpholine, 1,1,1,3,3,3-hexafluoro-2-propanol, 2-(dimethylamino)ethanol, and *N*-methylpiperidine were distilled before use. The other inorganic chemicals were used as received. Glass-distilled water, which was freshly boiled under nitrogen and contained 10^{-4} M (1 M = 1 mol dm^{-3}) disodium dihydrogen ethylenediaminetetraacetate (EDTA), was used throughout. The ionic strength of solutions was always maintained with KCl.

Buffer Preparations. Buffer solutions for reaction were prepared immediately before use by mixing equal volumes of a stock buffer solution (μ=0.50) and a stock solution of thiol in 10% aqueous acetonitrile (μ=0.45). Concentrations of thiols were assayed by the Ellman method.[12,13] All the flasks for solution preparation and cuvettes for spectrophotometry were flushed with nitrogen. A Shimadzu UV 200 spectrophotometer was used for spectrophotometric determination. Measurements of pH of buffer and reaction solutions were carried out with a Hitachi-Horiba F-7 pH meter.[14]

Equilibrium Constants. Equilibrium constants K_h for hemithioacetal formation were determined by measuring increase in UV absorbance at 280 nm that occurs when PG is added to buffer solutions containing varying concentrations (0.001—0.01 M) of thiol at constant pH. The equilibrium was attained by addition of 0.030 cm^3 of aqueous solution of PG hydrate (1.3×10^{-2} M) to 3.0 cm^3 of the buffer solution which was equilibrated at 30±0.1 °C in a stoppered quartz cuvette inserted in a water-jacketed cell holder. The blank solution in the spectrophotometer was identical with the reaction solution, except that water was added in place of aliquot of the PG solution. Change in absorbance with time was followed until the absorbance remained constant at lower pH. Since at higher pH (>8) the absorbance decreased slowly after initial rapid increase, the reading was extrapolated to the time of PG addition. In some cases, measurements were carried out of absorbance decrease at 250 nm with $[PG]_0 \simeq 7\times10^{-5}$ M.

Equilibrium constants K_h were calculated from absorbance

change according to

$$K_h = \frac{[\text{hemithioacetal}]}{[PG][RSH]} = \frac{\Delta A}{(\Delta A_{max} - \Delta A)[RSH]}, \quad (3)$$

where ΔA is the difference between the equilibrium absorbance of PG alone and that of PG plus thiol; ΔA_{max} is a hypothetical absorbance change when all the PG is transformed to hemithioacetal.

$$\Delta A_{max} = (\varepsilon_p - \varepsilon_h)[PG]_0, \quad (4)$$

where ε_p and ε_h are the extinction coefficients of PG and hemithioacetal, respectively. Equation 3 is transformed into

$$\frac{\Delta A}{[RSH]} = K_h \Delta A_{max} - K_h \Delta A. \quad (5)$$

Plots of $\Delta A/[RSH]$ against ΔA (the Scatchard plot)[15,16] give $-K_h$ as a slope and ΔA_{max} as an intercept of abscissa. Here, [RSH] is essentially equal to $[RSH]_0$ since $[RSH]_0 \gg [PG]_0$, but it was corrected for the hemithioacetal formation when necessary.

Kinetic Measurements. Rates of rearrangement were measured by following decrease in the absorption in the 280 nm region. The reaction was started in the same way as in the equilibrium measurement. Pseudo-first-order plots were usually linear over two lifetimes except for an initial short induction period due to the hemithioacetal formation. For slow reactions, a modified Guggenheim treatment[17] was employed.

Products of Reaction of 1-Butanethiol with PG. A sample of PG hydrate (0.5 g) was dissolved in 1 dm^3 of 0.1 M $(CF_3)_2$-CHOH–0.1 M $(CF_3)_2CHONa$ buffer solution containing 0.005 M 1-butanethiol and 10 vol% acetonitrile (pH 9.4). After standing overnight at 30 °C the solution was neutralized and the volume was reduced to 100 cm^3 under reduced pressure. The remaining solution was acidified and extracted with ether. The extract was dried over $MgSO_4$ and the ether was evaporated. The residues were dissolved in D_2O. The ^1H NMR spectrum showed two singlet signals at 7.43 and 5.26 ppm from DSS in intensity ratio of 5:1, which is identical with the spectrum of an authentic sample of mandelic acid.

The reaction in D_2O–CH_3CN solution was carried out on a 100-cm^3 scale in the same way as above. Isotopic purity of the deuterium buffer solution was about 95%. The ^1H NMR spectrum of the products showed formation of mandelic acid but the signal of benzylidene α-hydrogen (5.26 ppm) was hardly perceived.

Results

Hemithioacetal Formation. Phenylglyoxal (PG) is almost completely hydrated in aqueous solution with absorption maximum at 250 nm (ε_{250} 11900, ε_{280} 1550). When PG hydrate is dissolved in a buffer solution containing an appropriate amount of thiol, the absorption spectrum changes rapidly with an isosbestic point at 267 nm due to formation of an adduct, hemithioacetal. The spectrum of the hemithioacetal had an absorption maximum at 250 nm and a shoulder at 280 nm. Extinction coefficients for the hemithioacetal of 2-mercaptoethanol (ME) were found to be ε_{250}=9600 and ε_{280}=3150 by extrapolation. Those for glutathione (GSH) were ε_{250}=10100 and ε_{280}=3400.

Table 1. Formation constants of hemithioacetals of PG[a]

$HOCH_2CH_2SH$		GSH

10.50	149±18		

a) Errors given are standard deviations. b) Measured at 250 nm.

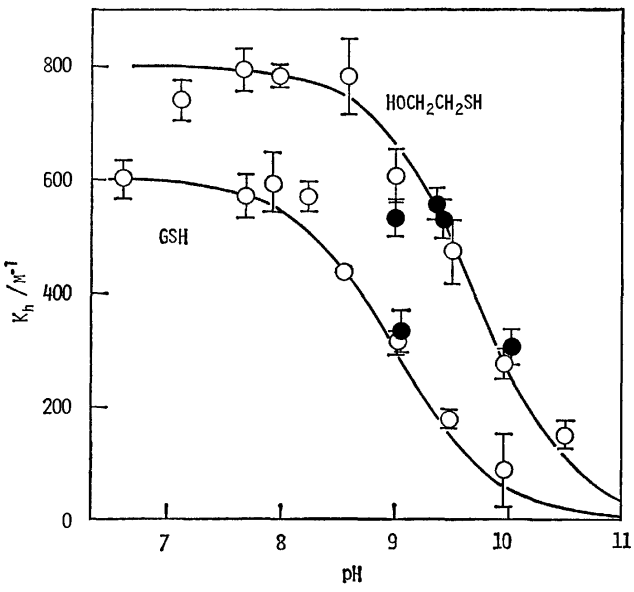

Fig. 1. pH dependence of the equilibrium constants K_h for hemithioacetal formation of ME and GSH. Closed circles are values obtained kinetically.

$$\text{Ph-C(=O)-C(H)(OH)-OH} + \text{RSH} \overset{K_h}{\rightleftharpoons} \text{Ph-C(=O)-C(H)(OH)-SR} + H_2O \quad (6)$$

Equilibrium constants for the hemithioacetal formation of PG with ME and GSH were determined by measuring increase in absorbance at 280 nm of PG of constant concentration in the presence of increasing concentration of thiol. Least-squares treatments of the Scatchard plots (Eq. 5) gave the equilibrium constants K_h summarized in Table 1. Values of K_h obtained from decreasing absorbance at 250 nm are included in Table 1. They agree well with those obtained at 280 nm.

The K_h values are not constant but seem to change sigmoidally with pH as shown in Fig. 1. The closed circles in the plots of Fig. 1 are the K_h values obtained kinetically as will be mentioned later. The sigmoid curves shown are those of pK_a=9.7 and 9.0

Table 2. Rates of the rearrangement of hemithioacetals of various thiols[a)]

Rubber Co., Cleveland (1968). c) k_{obsd} at [RSH]=0.005 M. d) Errors given are standard deviations. e) Value 1000±44 M^{-1} at pH 5.8 was obtained spectrophotometrically. f) 5% CH_3CN-D_2O; pD 9.74. g) Calculated value.

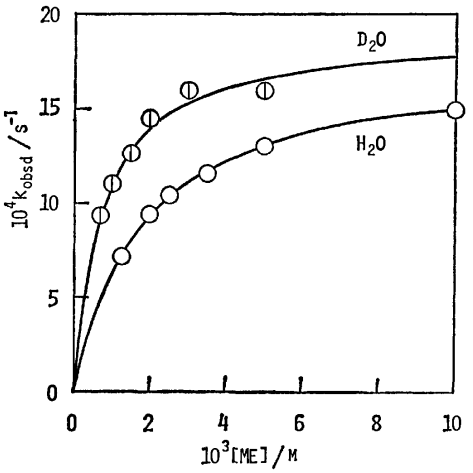

Fig. 2. Dependence of rates of the rearrangement of hemithioacetal upon thiol concentrations in 5% CH_3CN-H_2O (○) and 5% CH_3CN-D_2O (◑) at 30 °C. $[DABCO]_t$=0.2 M, buffer ratio=1, μ=0.475 (KCl).

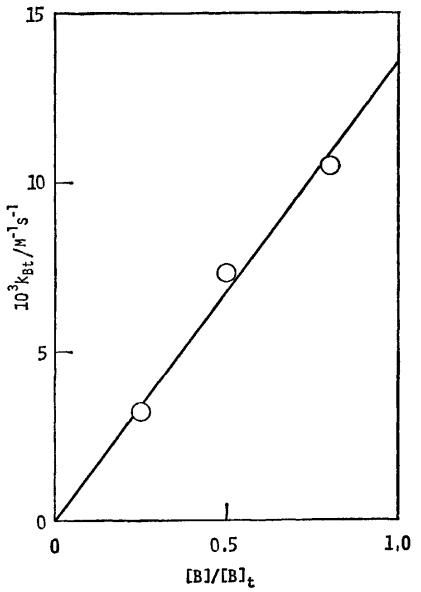

Fig. 3. Buffer-dependent rate constants k_{Bt} *vs.* base fraction of DABCO buffers. $[ME]_0$=0.05 M, 5% CH_3CN-H_2O (μ=0.475), 30 °C.

for ME and GSH, respectively. Ultimate K_h values at lower pH were taken to be 800 and 600 M^{-1} for ME and GSH, respectively, and those at higher pH to be zero.

Rearrangement. On addition of PG in a thiol-containing buffer solution, the absorbance in the 280 nm region decreases slowly after the initial rapid increase due to the formation of hemithioacetal. The slow decrease in absorbance is ascribed to rearrangement of the hemithioacetal to an α-hydroxy thiocarboxylic *S*-ester. The thioester is further hydrolyzed to mandelic acid in much smaller rate.[18)] The ultimate product obtained in the reaction with 1-butanethiol was identified by ^1H NMR spectroscopy. The product obtained from the reaction in deuterium media (D_2O-CH_3CN) showed incorporation of deuterium at the benzylidene α-position:

$$\mathrm{Ph\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{OD}{\overset{|}{C}}\text{-}SR \xrightarrow{D_2O} Ph\text{-}\overset{OD}{\overset{|}{C}}\text{-}\overset{O}{\overset{\|}{C}}\text{-}SR.} \qquad (7)$$

The time-dependent absorbance change (decrease) in the second phase of reaction gave linear pseudo-first-order plots, from which rates of the rearrangement were obtained. The observed rate constants k_{obsd} showed saturation with increasing thiol concentration [RSH] as shown in Fig. 2 in accord with the rate equation

$$k_{obsd} = \frac{k_{max}K_h\,[RSH]}{1+K_h\,[RSH]}. \qquad (8)$$

Parameters k_{max} and K_h were determined from linear plots of the Scatchard-type (Eq. 9) or double reciprocal plots (Eq. 10):

$$\frac{k_{obsd}}{[RSH]} = K_hk_{max} + K_hk_{obsd}, \qquad (9)$$

$$\frac{1}{k_{obsd}} = \frac{1}{k_{max}} + \frac{1}{k_{max}K_h}\frac{1}{[RSH]}. \qquad (10)$$

Kinetic parameters k_{max} and K_h in a DABCO buffer of pH 9 are summarized in Table 2 for various thiols. Results in D_2O are also included. The equilibrium constants K_h obtained here agree very well with those obtained spectrophotometrically for the formation of hemithioacetal as illustrated in Fig. 1.

At constant [RSH], rates increase linearly with buffer concentration:

Table 3. Rate constants for the reaction of PG and ME in various buffer solutions[a]

pH	Buffer	10^4k_0 [b] / s^{-1}	10^3k_{Bt} [b] / $M^{-1}s^{-1}$	10^3k_B [b,c] / $M^{-1}s^{-1}$	10^3k_{max} [d] / s^{-1}	K_h [d] / M^{-1}
8.30	*N*-Methylmolpholine	0.21	0.337	0.45		
8.48	DABCO	1.02	3.20			
9.00	DABCO	1.62	7.48	13.5	1.80 ±0.06	533±35
9.36	$(CF_3)_2CHOH$	(4.0)	(6.83)	(13.7)	1.71 ±0.04	558±28
9.48	$(CH_3)_2N(CH_2)_2OH$	3.10	2.90	5.8	0.752±0.072	529±31
9.62	DABCO	7.42	10.5			
10.03	Carbonate	(6.5)	(10.6)	(21.2)	2.67 ±0.23	306±30
10.32	*N*-Methylpiperidine	16.3	10.7	21.4		

a) In 5% CH_3CN-H_2O (μ=0.475) at 30 °C. b) [ME]=0.05 M. Values in parentheses are those calculated from data of buffer dependence at [ME]=0.005 M. c) Estimated from k_{Bt} for OH^- is estimated to be 8.0 $M^{-1}s^{-1}$ from k_0 values. d) $[B]_t$=0.2 M. Errors given are standard deviations.

$$k_{obsd} = k'_0 + k'_{Bt}[B]_t \quad (11)$$

or

$$k_{max} = k_0 + k_{Bt}[B]_t. \quad (12)$$

Since $k_{obsd} \simeq k_{max}$ at $[RSH] \gg 1/K_h$, k_0, and k_{Bt} can be evaluated from buffer-dependence data obtained by keeping [RSH] large enough and constant. Table 3 summarizes kinetic results for the reaction of ME with PG under various conditions. Constants k_0 and k_{Bt} were obtained mostly by keeping [RSH]=0.05 M. Buffer-dependent rate constants k_{Bt} increase with increasing base fraction of the buffer (Fig. 3); the reaction is catalyzed by general bases. Catalytic constants k_B of some general bases estimated from results of one buffer ratio are included in Table 3.

Discussion

Reaction of thiols with aldehydes to form hemithioacetals has been well-known and some hemithioacetals of α-keto aldehydes have been even isolated.[19] However, equilibrium and kinetic studies are limited only in a few cases.[20-23] Equilibrium constants for the formation of hemithioacetals from GSH and various α-keto aldehydes were measured in relation to the glyoxalase reaction.[23] Values K_h were found to be essentially constant in the pH range 5—9.

The present results clearly show that K_h values sharply change in the pH range 8—10 for GSH and 9—11 for ME. The changes seem to follow sigmoid curves of pK_a=9.0 and 9.7 for GSH and ME, respectively. These pK_a values correspond to those of the respective thiols; that is, only the neutral form of the thiol contributes to the formation of hemithioacetal at equilibrium but the thiolate ion is hardly effective. This is reasonable when we consider an equilibrium cycle:

$$\begin{array}{ccc} RSH + R'CH(OH)_2 & \overset{K_h}{\rightleftharpoons} & R'CH(OH)(SR) + H_2O \\ K_a \downarrow\uparrow & & K'_a \downarrow\uparrow \\ RS^- + R'CH(OH)_2 & \overset{K'_h}{\rightleftharpoons} & R'CH(O^-)(SR) + H_2O. \end{array} \quad (13)$$

The ratio K_h/K'_h should be equal to K_a/K'_a which must be greater than 10^2.[24]

Rates of the rearrangement are dependent on [RSH] with saturation as seen in Fig. 2. Analysis of the curve gives the equilibrium constant K_h and the maximum rate constant k_{max}. The K_h values agree very well with those obtained independently by the spectrophotometric method. This observation firmly indicates that the hemithioacetal is a true intermediate of the reaction.

The rate constants k_{max} correspond to those of the rearrangement when all the PG is transformed into the hemithioacetal. The k_{max} values increase with buffer concentrations and the buffer-dependent rate constants k_{Bt} were found to be ascribed to a base form of the buffer (Fig. 3); the reaction is confirmed to be catalyzed by general bases.[26] The catalytic constants k_B summarized in Table 3 are not precise enough for further analysis but Brønsted β of about 0.45 may be estimated including k_{OH^-} value of 8 $M^{-1}s^{-1}$. The latter value involves another uncertainty owing to the k_0 values influenced by the term of general-base catalysis due to 0.05 M ME.

General base catalysis established here is consistent with a mechanism involving the enediol proton transfer.[7] This mechanism was concluded from the observation that the solvent proton is incorporated into the product for the glyoxalase reaction[7a] as well as a model reaction with 2-(diethylamino)ethanethiol.[7b] Similar results were obtained in the present reaction with a simple thiol. The product mandelic acid formed by the reaction of 1-butanethiol with PG in D_2O was found to have lost a proton at the benzylidene α-position.

Solvent isotope effects observed in a DABCO buffer are $k^{H_2O}_{max}/k^{D_2O}_{max}$=0.95±0.09 and $K^{H_2O}_h/K^{D_2O}_h$=0.38±0.07. The rate constant k_{max} is little affected by solvent isotopes.

$$\begin{array}{l} Ph\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{OH}{\overset{|}{C}}\text{-}SR \longrightarrow Ph\text{-}\overset{O^-}{\overset{|}{C}}\text{=}\overset{OH}{\overset{|}{C}}\text{-}SR \\ \quad\quad H\ \ B \quad\quad\quad\quad HB^+ \\ Ph\text{-}\overset{O^-}{\overset{|}{C}}\text{=}\overset{OH}{\overset{|}{C}}\text{-}SR \rightleftharpoons Ph\text{-}\overset{OH}{\overset{|}{C}}\text{=}\overset{OH}{\overset{|}{C}}\text{-}SR \\ \quad\quad HB^+ \quad\quad\quad\quad B \end{array} \quad (14)$$

$$\rightleftharpoons Ph\text{-}\overset{OH}{\overset{|}{C}}\text{=}\overset{O^-}{\overset{|}{C}}\text{-}SR \longrightarrow Ph\text{-}\overset{OH}{\overset{|}{C}}\text{—}\overset{O}{\overset{\|}{C}}\text{-}SR \quad (15)$$
$$HB^+ \quad\quad\quad\quad H\ \ B$$

The rate-determining step must be proton transfer from the hemithioacetal to the base (DABCO) to form an enediol (Eq. 14). Protonation of the enediol at the β position (Eq. 15) should be faster than that at the α position (reverse of Eq. 14). The primary isotope effect of $k_H/k_D=2.3$ observed with PhCOCDO[7b] is also in accord with this mechanism. Inverse solvent isotope effects on the equilibrium constant K_h are not unreasonable on the basis of the isotopic fractionation factor of about 0.4—0.5 of thiol hydrogen.[27,28] Similar isotope effects of $K_h^{H_2O}/K_h^{D_2O}=0.44$ were found for the formation of hemithioacetal of acetaldehyde.[20a]

Kinetic parameters summarized in Table 2 were obtained with various thiols at pH 9 in DABCO buffers. Rates of rearrangement (k_{max}) show a tendency to decrease with increasing pK_a of the thiol. This is consistent with the mechanism involving the rate-determining deprotonation to form the enediol intermediate. Electron-withdrawing effects which lower pK_a of the thiol may ease the deprotonation of the hemithioacetal. Effective catalytic function of an intramolecular general base group of the thiol was found with *N*-(2-mercaptoethyl)piperidine and -morpholine in aqueous solution as will be reported in a separate paper.[29] However, the carboxylato group of mercaptoacetate and 3-mercaptopropionate does not seem to show any effective catalytic activity. Enhanced reactivity of GSH might be due partly to such intramolecular effects of the amino group. Shinkai *et al.*[10] noted low catalytic efficiency of GSH contrary to our observation. This is probably due to their use of borate buffers. Borate forms adducts with PG in aqueous solution[29] to retard the rearrangement. Furthermore, GSH itself may form some adduct with boric acid.

Magnitudes of K_h depend largely on the degree of ionization of the thiol in such a way that the ionization results in small value of K_h, but the thiol structure shows minor influence on the K_h value. As a whole, the catalytic efficiency of simple thiols in the rearrangement is not largely dependent on their structure unless the thiol is ionized under the reaction conditions. All the rearrangement reactions of α-keto hemithioacetals proceed through proton transfers involving the enediol as an intermediate.

We thank Mr. H. Nagamatsu for his assistance in kinetic measurements.

The Reaction of Bis(dimethylglyoximato)(pyridine)cobalt(I), Cobaloxime(I), with 2-(Allyloxy)ethyl Halides and the Photolysis of the Resulting Organo-cobaloximes[1]

Masami Okabe and Masaru Tada*

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received May 8, 1981)

The reactions of 2-(allyloxy)ethyl halides with cobaloxime(I) gave (tetrahydro-3-furanyl)methylcobaloximes *via* an electron transfer from cobaloxime(I) to the halides to give radical anions. The rupture of a halide ion to give an organic radical and the ring closure to give a (tetrahydro-3-furanyl)methyl radical are followed by the radical coupling between the organic radical and the cobaloxime(II). The structures of the organo-cobaloximes were determined by the analyses of the photolysis products under aerobic or anaerobic conditions.

The formation of organo-cobalt complexes by the reaction of cobalamin(I) or bis(dimethylglyoximato)-(pyridine)cobalt(I), hereafter cobaloxime(I) or $(Co^{I})^{-}$, with alkyl halides has been claimed to proceed by an S_N2 mechanism, an electron transfer mechanism, a four centered *syn*-substitution, and an S_Ni reaction with retention of configuration. The possibility of the last two mechanisms has been claimed as an interpretation of the reactions of 1-adamantyl bromide and 1-norbornyl bromide.[2] The S_N2 mechanism has been proposed based on a kinetic study[3] and the stereochemistry of products,[4] and the electron transfer mechanism has been proposed by the indication of the radical intermediate.[5-7]

In this paper we would like to report the experimental results supporting the electron transfer mechanism and the photolyses of the organo-cobaloximes which define the structures of the organo-cobaloximes. We used the cyclization of 2-(allyloxy)ethyl radical to (tetrahydro-3-furanyl)methyl radical as a probe of the radical intermediate (R·) formed by the rupture of halide ion (X^-) from the radical anion ($RX^{\cdot-}$) (Eq. 1).

$$(Co^{I})^- + RX \longrightarrow (Co^{II}) + RX^{\cdot-} \longrightarrow (Co^{II}) + R\cdot + X^- \longrightarrow (Co)R + X^- \quad (1)$$

Results

The Reaction of Cobaloxime(I) with Tosylates or Halides. 2-(Allyloxy)ethyl tosylates or 2-(allyloxy)ethyl halides were reacted with cobaloxime(I) in methanol under nitrogen; the results are summarized in Table 1. 2-(Allyloxy)ethyl tosylate (**1a**) gave a direct substitution product, 2-(allyloxy)ethylcobaloxime (**4a**) but 2-allyloxy-2-phenylethyl tosylate (**1b**) did not show any reactivity toward cobaloxime(I). The cobaloxime(I) anion reacted with 2-(allyloxy)ethyl bromide (**2a**) to give **4a** and (tetrahydro-3-furanyl)methylcobaloxime (**5a**). The reaction of cobaloxime(I) with 2-allyloxy-2-phenylethyl bromide (**2b**) and 2-allyloxy-2,2-diphenylethyl bromide (**2c**) gave (5-phenyltetrahydro-3-furanyl)methylcobaloxime (**5b**) and (5,5-diphenyltetrahydro-3-

furanyl)methylcobaloxime (**5c**), respectively. Similarly the cyclic halides, *trans*-2-(allyloxy)cyclohexyl bromide (**2d**) and iodide (**3d**), gave (7-oxabicyclo[4.3.0]non-9-yl)methylcobaloxime (**5d**) but no direct substitution product **4d**. The corresponding tosylate **1d** did not show any reactivity toward cobaloxime(I). 2,2-Diphenyl-2-(2-methyl-2-propenyloxy)ethyl bromide (**6**) gave both a non-cyclized organo-cobaloxime, 2,2-diphenyl-2-(2-methyl-2-propenyloxy)ethylcobaloxime (**7**), and a cyclized organo-cobaloxime, (5,5-diphenyl-3-methyltetrahydro-3-furanyl)methylcobaloxime (**8**).

In seeking by-products from bromide **2d**, 3-(allyloxy)cyclohexene (**9**), 9-methylene-7-oxabicyclo-[4.3.0]nonane (**10**), and another by-product, which was anticipated to be 9-methyl-7-oxabicyclo[4.3.0]-nonane (**11**) from NMR data, were obtained in 5, 3, and 1% yields, respectively. Similarly 4-methyl-2-phenyltetrahydrofuran (**12**) and 4-methylene-2-phenyltetrahydrofuran (**13**) were formed from bromide **2b**.

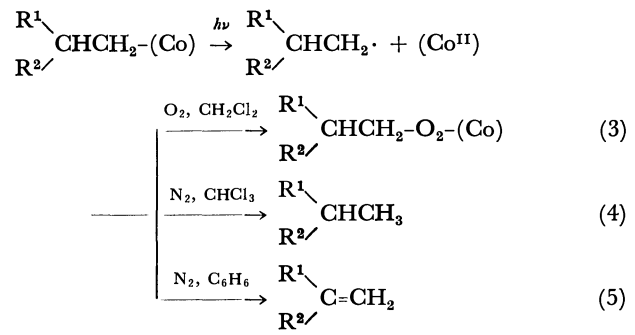
Photolyses of Organocobaloximes. The photolytic cleavage of the carbon-cobalt bond of an organocobaloxime gave an alkyl radical and cobaloxime(II) as primary products. Molecular oxygen inserts between the two radical species to give an alkyldioxycobaloxime under aerobic conditions (Eq. 3).[8] Under anaerobic conditions, however, the radical collapses into an olefin or a saturated compound depending upon the hydrogen-donating ability of the solvent used (Eqs. 4 and 5).[9,10]



The analyses of the photolysis products, therefore, can define the structures of the cyclized organocobaloximes. The aerobic photolysis of **5a** gave a peroxide and the $NaBH_4$-reduction of the peroxide gave 3-(hydroxymethyl)tetrahydrofuran (**14**), which was identical to the authentic sample.[11] Anaerobic photolyses of organocobaloximes **5b**, **5c**, and **8** in chloroform gave **12** (98%), 2,2-diphenyl-4-methyltetrahydrofuran (**15**) (78%), and 4,4-dimethyl-2,2-diphenyltetrahydrofuran (**16**) (70%), respectively. On the other hand, anaerobic photolyses of **5b** and **5c** in benzene gave **13** and 2,2-diphenyl-4-methylenetetrahydrofuran (**17**), respectively. The hydrogenolysis of **12** over Pd–C gave 2-methyl-4-phenyl-1-butanol which was identified with the authentic sample.[12] The structures of all other tetrahydrofuran derivatives were deduced unequivocally from elemental analyses and spectral data, especially from NMR spectra. Similarly the anaerobic photolysis of **5d** in benzene gave **10**, which became 9-methylene-7-oxabicyclo[4.3.0]nonan-8-one (**18**) by CrO_3-oxidation; **18** was identified by comparison with the authentic sample.[13]

Discussion on Reaction Mechanism

In the reaction of cobaloxime(I) with halides, a carbenium ion intermediate has been excluded by the lack of a solvolysis product in methanol and also by the lack of a tetrahydropyran derivative which is expected to form *via* a more stable secondary cation.[14] A carbanion intermediate has been also excluded by the fact that the reaction in protic media, methanol or ethanol containing water, did not give a saturated product as a major one.

5-Hexenyl radical has a strong tendency to give cyclopentylmethyl radical irreversibly unless the radical center has an electron-attracting substituent.[15] The ring closure of 3-oxa-5-hexenyl radical, 2-(allyloxy)ethyl radical ($k=1.2\times10^6$ s^{-1}, 25 °C),[16] is faster than that of 5-hexenyl radical ($k=1.0\times10^5$ s^{-1}, 25 °C).[17] The oxa-system is, therefore, a better probe of a radical intermediate than the hydrocarbon system which is popular in radical chemistry.

Cobaloxime(I) anion and cobalamin(I) are strong nucleophiles in the reaction with methyl iodide and are called "supernucleophiles,"[18] but the bulky ligands in those cobalt complexes hinder the reaction with sterically bulky halides. Though we do not deny a normal S_N2 mechanism for simple halides such as methyl iodide, a four centered mechanism or a *syn*-displacement of halogen and bulky cobaloxime(I)[2]

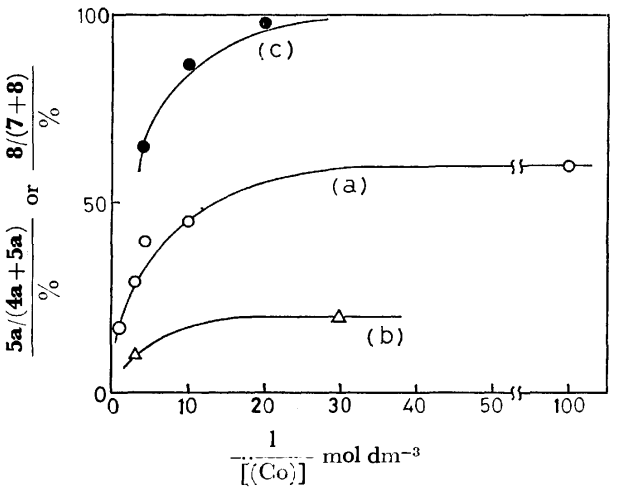

Fig. 1. Dependence of the formation of **5a** from **2a** (1.0×10^{-3} mol) and **8** from **6** (1.0×10^{-3} mol) on the concentration of cobaloxime [(Co)].

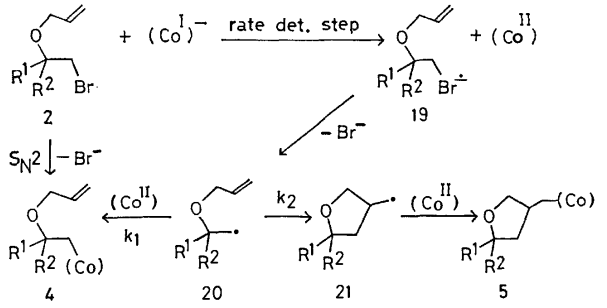
is hardly acceptable as the mechanism of the reactions of sterically hindered halides and cobaloxime(I). The present experimental results clearly show the intervention of a radical species which is evidenced by the formation of tetrahydrofuran derivatives. The formation of a radical from an organic halide is expected by the single electron transter from cobaloxime(I) to the organic halide followed by the rupture of a halide ion. The radical intermediate is further supported by the formation of **10**, **11**, **12**, and **13** as minor products. The electron transfer process should be sensitive to the polarity of the solvent, and indeed the reaction in ethanol produced less cyclized product **5a** from bromide **2a** than the reaction in methanol (see Fig. 1).

The formation of the non-cyclized organo-cobaloxime **7** from bromide **6** must be entirely due to the electron transfer mechanism, since the S_N2 mechanism must not be operative in the reactions of the β,β-disubstituted halides such as bromide **2c**. The substantial formation of the non-cyclized organo-cobaloxime **7**, therefore, must be due to the retardation of radical cyclization by the methyl substitution at the reaction center. The cyclization rate of 5-methyl-5-hexenyl radical to (1-methylcyclopentyl)methyl radical is *ca.* 1/50 to that of 5-hexenyl radical.[19] 2-(Allyloxy)ethyl halides (**2b**, **2c**, **2d**, **3b**, and **3d**) having the substituents at the β-position give only the cyclized organo-cobaloximes (**5b**, **5c**, and **5d**) due to the inhibition of the direct substitution. This steric hindrance must inhibit both S_N2 and the direct radical coupling process to give non-cyclized organo-cobaloximes.

2-(Allyloxy)ethyl tosylate (**1a**) gave only the direct substitution product **4a**. This result suggests the lack of a radical intermediate in the reaction of **1a**. The tosylates (**1b** and **1d**) which have substituents at 2-position did not react with cobaloxime(I) due to the steric inhibition. Compared to a halogen, a tosyl group is a hard leaving group and the S_N2 reaction with the soft and bulky nucleophile, cobaloxime(I), is sluggish even in the case of tosylate **1a**. The reaction is slowered by the steric hindrance in the case of tosylates **1b** and **1d**, and no organo-cobaloxime is obtained.

The reaction scheme is summarized below (Scheme 1). The proportion of **4** and **5** from the radical intermediate **20** can be expressed by $[\mathbf{4}]/[\mathbf{5}]=k_1[(Co^{II})]/k_2$ and depends on the concentration of the (Co^{II}) intermediate. By carrying out the reaction in diluted state, we can decrease [(Co^{II})] and retard the formation of **4**, as shown in Fig. 1. Similarly, the formation of **8** from bromide **6** increases and overcomes completely the formation of **7** in diluted state. The radical coupling between the less hindered redical **20a** and (Co^{II}) is substantial but the radicals (**20b**, **20c**, and **20d**) having bulky substituents, from **2b**, **2c**, **2d**, **3b**, and **3d**, lack its reactivity to (Co^{II}) and only cyclized organo-cobaloximes (**5b**, **5c**, and **5d**) were obtained. The reaction of cobaloxime(I) with less hindered bromides may take an S_N2 process competitively with an electron transfer process. In high dilution state (total cobaloxime: 1.0×10^{-2} mol dm^{-3}), the non-cyclized organo-cobaloxime **4a** (40% from **2a**) must be formed by S_N2 mechanism, since the formation of **4a** by radical coupling is negligible under these reaction conditions (see Fig. 1). The variation in product ratio **4**/**5** from **1a**, **2a**, and **3a** indicates that the initial step (**2a** or **3a**→**19**) is a rate determining step, since iodide **3a** gives more cyclyzed product **5a** than bromide **2a**. The reaction of **2a** in polar methanol gives more cyclyzed product **5a**, formed by electron transfer mechanism, than in less polar ethanol.

In conclusion the reaction of cobaloxime(I) with organic halides takes place *via* an electron transfer mechanism as the most important one and the reaction with less hindered tosylates proceeds by an S_N2 mechanism.



Scheme 1.

Experimental

Syntheses of 2-(Allyloxy)ethyl Tosylates. 2-(Allyloxy)ethyl Tosylate (1a): 2-(Allyloxy)ethyl tosylate was prepared by Bergman's method.[16] Tosylation of 2-(allyloxy)ethanol was carried out in a conventional manner with tosyl chloride in pyridine overnight at 0 °C and the purification by chromatography on silica gel gave tosylate **1a**, oil. NMR (CCl_4): δ 2.43 (s, 3H), 3.53 (t, 2H, J=5 Hz), 3.81—3.95 (m, 2H), 4.02 (t, 2H, J=5 Hz), 4.99—5.27 (m, 2H), 5.52—5.98 (m, 1H), 7.23 (d, 2H, J=8 Hz), and 7.68 (d, 2H, J=8 Hz).

2-Allyloxy-2-phenylethyl Tosylate (1b): Phenyloxirane (11.63 g, 0.097 mol) was added dropwise to a mixture of 70 cm^3 of allyl alcohol and 0.13 cm^3 of concd sulfuric acid during 5 min. The mixture was stirred for 30 min at room temperature and refluxed for 1 h. After being cooled, the mixture was treated with 0.2 g of sodium hydroxide and excess allyl alcohol was removed under reduced pressure. Ethereal solution of the residue was washed with water (50 $cm^3 \times 2$) and dried over sodium sulfate. Distillation of the product after removal of the ether gave 2-allyloxy-2-phenylethanol (65%), bp 114—115 °C/627.0 Pa. Tosylation of the alcohol in the same manner as in the case of **1a** gave tosylate **1b**,[20] oil. NMR(CCl_4): δ 2.40 (s, 3H), 3.71—3.86 (m, 2H), 3.87—4.00 (m, 2H), 4.46 (t, 1H, J=6 Hz), 4.92—5.20 (m, 2H), 5.48—5.85 (m, 1H), 7.05—7.21 (m, 7H), and 7.54 (d, 2H, J=8 Hz).

2-(Allyloxy)cyclohexyl Tosylate (1d): 2-(Allyloxy)cyclohexanol was prepared by the acid catalyzed addition of allyl alcohol to 1,2-epoxycyclohexane in the manner mentioned above, bp 93 °C/1067 Pa.[21] Tosylation of the alcohol in the same manner as in the case of **1a** gave tosylate **1d** (70%), oil. NMR (CCl_4): δ 1.10—2.20 (m, 8H), 2.46 (s, 3H), 3.15—3.41 (m, 1H), 3.82—3.94 (m, 2H), 4.39 (double triplet, 1H, J=4 and 7 Hz, $W_{1/2}$=19 Hz), 5.02—5.30 (m, 2H), 5.56—6.00 (m, 1H), 7.45 (d, 2H, J=8 Hz), and 7.96 (d, 2H, J=8 Hz). The tosylate **1d** was transformed by a simple substitution into 2-allyloxy-1-iodocyclohexane (**3d**) whose structural evidence will be described later, in the section for **3d**.

Syntheses of 2-(Allyloxy)ethyl Halides. 2-(Allyloxy)ethyl Bromide (2a): Bromide **2a** was prepared from tosylate **1a** (0.69 g) by the displacement of the tosyl group with a bromide ion. The displacement was carried out by the active magnesium bromide, prepared *in situ* from 1.92 g (1.2×10^{-2} mol) of 1,2-dibromoethane and 0.244 g (1.0×10^{-2} mol) of magnesium in 15 cm^3 of ether.[22] After stirring overnight at room temperature, the reaction mixture was diluted with water and extracted with ether. The ethereal extract gave 0.267 g (60%) of bromide **2a** on distillation. **2a**, bp 85—95 °C/13400 Pa.[23] NMR(CCl_4): δ 3.34 (t, 2H, J=6 Hz), 3.63 (t, 2H, J=6 Hz), 3.86—4.00 (m, 2H), 5.02—5.30 (m, 2H), and 5.59—6.01 (m, 1H).

2-Allyloxy-2-phenylethyl Bromide (2b): A solution of 13.2 g (5.0×10^{-2} mol) of 1,2-dibromo-1-phenylethane and 5 cm^3 of pyridine in 200 cm^3 of allyl alcohol was refluxed for 4 h. After removal of excess allyl alcohol under reduced pressure and addition of water (100 cm^3), the mixture was extracted by ether–benzene (1:1). Chromatography of the extract on silica gel gave the starting dibromide and 2.6 g (21%) of bromide **2b**, bp 78 °C/20.00 Pa.[23] NMR (CCl_4): δ 3.23—3.60 (m, 2H), 3.70—4.08 (m, 2H), 4.99 (dd, 1H, J=6 and 8 Hz), 5.04—5.35 (m, 2H), 5.65—6.05 (m, 1H), and 7.30 (s, 5H).

2-Allyloxy-2,2-diphenylethyl Bromide (2c): A solution of 1.60 g (1.0×10^{-2} mol) of bromine in 10 cm^3 of methanol-free dichloromethane was added to a cooled (−5 °C) solution of 1.80 g (1.0×10^{-2} mol) of 1,1-diphenylethylene in 20 cm^3 of methanol-free dichloromethane. After stirring for 30 min at 0 °C, the solvent was removed under reduced pressure at 0 °C and 15 cm^3 of allyl alcohol was added to the residue. To the cooled mixture (−5 °C) was added 0.66 g of potassium hydroxide and the reaction mixture was stirred for 1 h at 0 °C and for an additional hour at room temperature. Dichloromethane was added to the mixture and the solution was washed with water and dried over calcium chloride. Removal of the solvent gave the crude product and recrystallization from methanol gave 1.70 g (55%) of bromide **2c**, mp 66—67 °C; Found: C, 64.30; H, 5.42%. Calcd for $C_{17}H_{17}BrO$: C, 64.37; H, 5.40%. NMR (CCl_4): δ 3.59—3.71 (m, 2H), 4.00 (s, 2H), 4.90—5.32 (m, 2H), 5.56—5.94 (m, 1H), and 6.98—7.30 (m, 10H).

2-(2-Methyl-2-propenyloxy)-2,2-diphenylethyl Bromide (6): The same procedure for the preparation of bromide **2c** was employed by using 2-methyl-2-propen-1-ol instead of allyl alcohol. **6**, oil. NMR (CCl_4): δ 1.77 (s, 3H), 3.67 (s, 2H), 4.23 (s, 2H), 4.90 (br. s, 1H), 5.13 (br. s, 1H), and 7.24—7.53 (m, 10H).

The bromide **6** was treated with an excess amount of tributylstannane to give a mixture of 1-(2-methyl-2-propenyloxy)-1,1-diphenylethane and 4,4-dimethyl-2,2-diphenyltetrahydrofuran (**16**) (described later) in 1:3 ratio. The structure of the former compound, and therefore the structure of **6**, was evidenced by an unequivocal synthesis from 2-methyl-2-propenyl chloride and sodium 1,1-diphenylethoxide in THF. 1-(2-Methyl-2-propenyloxy)-1,1-diphenylethane, oil. IR (CCl_4): 1662, 901, and 700 cm^{-1}; NMR (CCl_4): δ 1.72 (s, 3H), 1.85 (s, 3H), 3.59 (br. s, 2H), 4.78 (br. s, 1H), 5.01 (br. s, 1H), and 7.06—7.40 (m, 10H).

2-Allyloxy-1-bromocyclohexane (2d): The same procedure for the preparation of bromide **2a** was employed by using 2-(allyloxy)cyclohexyl tosylate (**1d**) instead of tosylate **1a**. **2d**, bp 100—105 °C/1600 Pa.[24] NMR (CCl_4): δ 1.16—2.44 (m, 8H), 3.41 (double triplet, 1H, J=4 and 7 Hz, $W_{1/2}$=18 Hz), 3.90—4.17 (m, 3H), 5.03—5.40 (m, 2H), and 5.70—6.12 (m, 1H).

2-(Allyloxy)ethyl Iodide (3a): A mixture of 5.12 g (2.0×10^{-2} mol) of **1a** and 15.0 g (1.0×10^{-1} mol) of sodium iodide in 80 cm^3 of acetone was refluxed for 24 h. After cooling, 100 cm^3 of ether was added to the mixture and the resulting salts were filtered off. The filtrate was concentrated and dissolved in 100 cm^3 of ether. The ethereal solution was washed with aqueous sodium thiosulfate and dried over sodium sulfate. Distillation of the residue gave 2.78 g (65%) of iodide **3a**, bp 84 °C/4533 Pa.[17] NMR (CCl_4): δ 3.08 (t, 2H, J=7 Hz), 3.52 (t, 2H, J=7 Hz), 3.77—3.98 (m, 2H), 4.90—5.22 (m, 2H), and 5.48—5.90 (m, 1H).

2-Allyloxy-2-phenylethyl Iodide (3b): The tosyl group of **1b** was replaced by iodide by a similar procedure for the preparation of **2a** from **1a**, but active magnesium iodide was prepared from magnesium and iodine in ether.[22] The product was worked up as in the case of bromide **2a** but additional washing by aqueous sodium thiosulfate. Distillation gave iodide **3b** (27%), bp 110 °C/86.66 Pa. NMR (CCl_4): δ 3.17—3.35 (m, 2H), 3.65—4.07 (m, 2H), 4.40 (dd, 1H, J=6 and 8 Hz), 5.02—5.35 (m, 2H), 5.65—6.07 (m, 1H), and 7.30 (s, 5H). The iodide **3b** was transformed into its quarternary salt, 2-allyloxy-2-phenylethylpyridinium iodide.[20]

2-Allyloxy-1-iodocyclohexane (3d): The same procedure for the preparation of iodide **3b** gave iodide **3d** (53%), bp 82 °C/120.0 Pa. NMR(CCl_4): δ 1.15—2.50(m, 8H), 3.41(double triplet, 1H, J=4 and 7 Hz, $W_{1/2}$=19 Hz), 3.92—4.30 (m, 3H), 5.02—5.41(m, 2H), and 5.70—6.15(m, 1H). The iodide **3d** was treated with potassium *t*-butoxide in THF to give 3-(allyloxy)cyclohexene (**9**), which was synthesized unequivocally from 3-bromocyclohexene and sodium allylate in THF. **9**, bp *ca.* 60 °C/2780 Pa. NMR(CCl_4): δ 1.45—2.70(m, 6H), 3.74—3.92(m, 1H), 3.93—4.11(m, 2H), 5.04—5.40(m, 2H), and 5.65—6.15(m, 3H).

Reaction of Cobaloxime(I) with 2-(Allyloxy)ethyl Tosylates or 2-(Allyloxy)ethyl Halides. General Procedure: To a mixture of 0.238 g (1.0×10^{-3} mol) of cobalt(II) chloride hexahydrate and 0.233 g (2.0×10^{-3} mol) of dimethylglyoxime in 3 cm^3 of methanol was added 0.2 cm^3 of 10 mol dm^{-3}

aq sodium hydroxide (2.0×10^{-3} mol) and 0.1 cm^3 (1.2×10^{-3} mol) of pyridine. The mixture was stirred under nitrogen for 15 min at 0 °C and treated with 0.1 cm^3 (1.0×10^{-3} mol) of 10 mol dm^{-3} aq sodium hydroxide and 0.046 g (1.25×10^{-3} mol) of sodium borohydride. After stirring for 5 min the resulting methanol solution of cobaloxime (I)[25] (1.0×10^{-3} mol) was treated with one of the 2-(allyloxy)-ethyl tosylates or halides (1.0×10^{-3} mol) and the reaction mixture was stirred under nitrogen for 4—6 h at room temperature. The mixture was extracted with benzene (10 $cm^3\times4$) after addition of 40 cm^3 of water and the extract was washed with water, dried over sodium sulfate, and concentrated under reduced pressure. The residue was placed on Florisil column and elution with chloroform–ethyl acetate (1:1) gave orange eluate. Evaporation of the solvent gave organo-cobaloximes in the yields listed in Table 1. All the organo-cobaloximes have strong absorptions at *ca.* 1600, 1500—1560, *ca.* 1235, 1100—880 cm^{-1} (several bands) and the absorptions due to the alkyl ligands are weak. IR data therefore are omitted from the spectral data in the following description of this section.

4a, Mp 175 °C(decomp); Found: C, 47.17; H, 6.10; N, 15.55%. Calcd for $C_{18}H_{28}N_5O_5Co$: C, 47.68; H, 6.23; N, 15.45%. NMR($CDCl_3$): δ 1.58 (t, 2H, J=8 Hz), 2.07(s, 12H), 3.10(t, 2H, J=8 Hz), 3.74—3.86(m, 2H), 4.90—5.22(m, 2H), 5.58—6.00(m, 1H), 7.10—7.27(m, 2H), 7.49—7.70(m, 1H), and 8.40—8.50(m, 2H).

5a, Mp 185 °C(decomp); Found: C, 47.36; H, 6.23; N, 15.52%. Calcd for $C_{18}H_{28}N_5O_5Co$: C, 47.68; H, 6.23; N, 15.45%. NMR($CDCl_3$): δ 1.20—2.00(m, 5H), 2.11(s, 12H), 2.90—3.10(m, 1H), 3.46—3.73(m, 3H), 7.15—7.31(m, 2H), 7.54—7.73(m, 1H), and 8.42—8.53(m, 2H).

5b, Mp 175 °C(decomp); Found: C, 54.18; H, 6.07; N, 13.59%. Calcd for $C_{24}H_{32}N_5O_5Co$: C, 54.44; H, 6.09; N, 13.23%. NMR($CDCl_3$): δ 1.55—2.20(m, 5H), 2.01(s, 6H), 2.08(s, 6H), 3.18—3.36(m, 1H), 3.95—4.13(m, 1H), 4.86(t, 1H, J=7 Hz), 7.18—7.40(m, 7H), 7.60—7.80(m, 1H), and 8.43—8.60(m, 2H).

5c, Mp 205 °C(decomp); Found: C, 59.14; H, 6.02; N, 11.63%. Calcd for $C_{30}H_{36}N_5O_5Co$: C, 59.50; H, 5.99; N, 11.56%. NMR($CDCl_3$): δ 1.40—1.72(m, 3H), 1.90—2.12(m, 1H), 1.93(s, 6H), 2.00(s, 6H), 2.77(dd, 1H, J=6 and 11 Hz), 3.40(t, 1H, J=7 Hz), 3.97(t, 1H, J=7 Hz), 7.00—7.37(m, 12H), 7.47—7.66(m, 1H), and 8.39—8.51(m, 2H).

Organo-cobaloxime **7** decomposed quickly on Florisil to give 1,1-diphenylethylene and could not be isolated in pure form. This is a common property for 2-alkoxy-2,2-diphenylethylcobaloxime. The NMR data of **7** were read from those of the mixture of **7** and **8**. **7**, NMR($CDCl_3$): δ 1.75 (s, 3H), 1.85(s, 12H), 2.61(s, 2H), 3.50(s, 2H), 4.95(br. s, 1H), 5.32(br. s, 1H), 7.00—7.56(m, 12H), 7.60—7.88 (m, 1H), and 8.55—8.70(m, 2H).

8, Mp 180 °C(decomp); Found: C, 59.94; H, 6.16; N, 11.33%. Calcd for $C_{31}H_{38}N_5O_5Co$: C, 60.09; H, 6.18; N, 11.30%. NMR($CDCl_3$): δ 0.82(s, 3H), 1.75(s, 2H), 2.07(s, 12H), 2.47(s, 2H), 3.50(d, 1H, J=8 Hz), 3.58(d, 1H, J=8 Hz), 7.10—7.56(m, 12H), 7.63—7.85(m, 1H), and 8.58—8.70(m, 2H).

5d, Mp 175 °C(decomp); Found: C, 52.02; H, 6.91; N, 13.84%. Calcd for $C_{22}H_{34}N_5O_5Co$: C, 52.07; H, 6.75; N, 13.80%. NMR($CDCl_3$): δ 1.14—1.95(m, 12H), 2.15(s, 12H), 3.04—3.32(m, 1H), 3.70—4.15(m, 2H), 7.35—7.52 (m, 2H), 7.75—7.96(m, 1H), and 8.66—8.78 (m, 2H).

General Procedure of the Photolyses of Organo-cobaloximes under Anaerobic Conditions. *Photolyses in Chloroform*: An appropriate amount of an organo-cobaloxime (0.1—2.0 g) was dissolved in chloroform (20—100 cm^3) and the dissolved oxygen was purged by bubbling nitrogen from a syringe needle. The solution was irradiated with two circle-type fluorescent lamps (30 W×2) until the starting organo-cobaloxime disappeared (5—12 h). The concentrate of the reaction mixture was subjected to a Florisil chromatography and a 3-methyltetrahydrofuran derivative was isolated from colorless chloroform eluate in a high yield (see text). In the case of 9-methyl-7-oxabicyclo[4.3.0]nonane (**11**), Kugel-Rohr distillation (100—200 °C/13322 Pa) yielded **11**, which consists of two isomers with different configurations of the methyl group, in a poor yield (8%) due to the volatility.

11, Oil. NMR(CCl_4): δ 0.93 and 1.00(d, total 3H, J=7 Hz), 1.13—2.12(m, 10H), 3.13—3.49(m, 1H), and 3.70—4.26(m, 2H). One component of **11** was identified with the hydrogenation product of **10**.

12,[26] Oil. NMR(CCl_4): δ 1.05(d, 3H, J=7 Hz), 1.89 (t, 2H, J=7 Hz), 2.16—2.50(m, 1H), 3.32(t, 1H, J=8 Hz), 4.05(t, 1H, J=8 Hz), 4.86(t, 1H, J=7 Hz), and 7.15 (s, 5H). **12** was hydrogenolyzed over Pd–C in ethanol and the product was identified by comparison with the authentic sample of 2-methyl-4-phenyl-1-butanol.[12]

15, Mp 49 °C; Found: C, 85.65; H, 7.68%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%. IR(CCl_4): 1025 and 695 cm^{-1}; NMR(CCl_4): δ 1.00(d, 3H, J=6 Hz), 2.00(t, 1H, J=11 Hz), 2.10—2.53(m, 1H), 2.75(dd, 1H, J=6 and 11 Hz), 4.04(t, 1H, J=8 Hz), 4.42(t, 1H, J=8 Hz), and 6.85—7.40(m, 10H).

16, Mp 44.5 °C; Found: C, 85.78; H, 8.07%. Calcd for $C_{18}H_{20}O$: C, 85.67; H, 7.99%. IR(CCl_4): 1062 and 703 cm^{-1}; NMR(CCl_4): δ 1.00(s, 6H), 2.44(s, 2H), 3.55(s, 2H), and 6.96—7.42(m, 10H).

Photolyses in Benzene: An appropriate amount of an organo-cobaloxime (30—50 mg) in benzene (20 cm^3) was irradiated in the same manner as in the case of the photolyses in chloroform. The same work-up gave the products **10**, **13**, and **17** from **5d**, **5b**, and **5c**, respectively.

10, Oil. IR(CCl_4): 1670, 1050, 1030, and 885 cm^{-1}; NMR(CCl_4): δ 1.10—2.00(m, 8H), 2.26—2.60(m, 1H), 3.83—4.01(m, 1H), 4.25(d, 1H, J=14 Hz), 4.45(d, 1H, J=14 Hz), and 4.83—5.01(m, 2H). **10** was oxidized by chromic trioxide in dichloromethane containing pyridine to give *cis*-9-methylene-7-oxabicyclo[4.3.0]nonan-8-one (**18**).[13]

13, Oil. MS: (*m/e*) 160(M^+); IR(CCl_4): 1054, 883, and 695 cm^{-1}; NMR(CCl_4): δ 2.24(dd, 1H, J=7 and 16 Hz), 2.85(dd, 1H, J=6 and 16 Hz), 4.23(d, 1H, J=13 Hz), 4.42(d, 1H, J=13 Hz), 4.71—5.00(m, 3H), and 7.23 (m, 5H). Hydrogenolysis of **13** over Pd–C in ethanol gave 2-methyl-4-phenyl-1-butanol which was identified by comparison with the authentic sample.[12]

17, Mp 51—51.5 °C; Found: C, 86.21; H, 6.80%. Calcd for $C_{17}H_{16}O$: C, 86.40; H, 6.83%. MS: (*m/e*) 236(M^+); IR(CCl_4): 1670, 1046, 883, and 698 cm^{-1}; NMR(CCl_4): δ 3.10—3.20(m, 2H), 4.27—4.36(m, 2H), 4.72—4.80(m, 1H), 4.85—4.96(m, 1H), and 7.00—7.40(m, 10H).

*Photolysis of Organo-cobaloxime **5a** under Aerobic Conditions.* A solution of 4.70 g (1.0×10^{-2} mol) of **5a** in 600 cm^3 of dichloromethane was irradiated for 7 h in the same manner for the photolysis under anaerobic conditions, but the solution was bubbled with air during the irradiation. The concentrate of the reaction mixture was chromatographed on Florisil. The first orange band (chloroform–ethyl acetate, 1:1) contained the starting organo-cobaloxime (70%) and the second brown band (chloroform–ethyl acetate–methanol, 2:2:1) yielded the oxygenated product, (tetrahydro-3-furanyl)methyl cobaloximato peroxide, in 20% yield; NMR ($CDCl_3$): δ 1.20—2.20(m, 3H), 2.30(s, 12H), 3.20—3.50

(m, 3H), 3.53—3.79(m, 3H), 7.14—7.30(m, 2H), 7.59—7.78(m, 1H), and 8.31—8.42(m, 2H). The peroxide (0.960 g, 2.0×10^{-3} mol) in 40 cm^3 of methanol was reduced by sodium borohydride (92 mg, 2.5×10^{-3} mol) in the presence of 0.3 cm^3 of 10 mol dm^{-3} aq sodium hydroxide. After the mixture was stirred overnight, the methanol was evaporated and the residue was extracted with ether (10 $cm^3\times4$). The combined extracts were passed through a short column of silica gel. Kugel-Rohr distillation of the eluate with dichloromethane gave 106 mg (52%) of (tetrahydro-3-furanyl)-methanol (**14**), bp 120—140 °C (bath temperature)/2666 Pa. NMR(CCl_4): δ 1.38—1.74(m, 1H), 1.75—2.16(m, 1H), 2.20—2.51(m, 1H), 2.77(br. s, 1H), and 3.30—3.95(m, 6H). 3,5-Dinitrobenzoate of **14**, mp 80.5—81.0 °C.[11]

The Reaction Involving One Electron Transfer in Key Step. NO_2-Catalyzed Halogenation of Polycyclic Aromatic Compounds with Metal Halides

Takashi SUGIYAMA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received July 17, 1981)

In the co-existence of catalytic amount of nitrogen dioxide and oxygen, aluminum halide, titanium(IV) halide, and some other metal halides have been found to be highly selective and regiospecific halogenating agents for polycyclic aromatic compounds, including anthracene, pyrene, benz[*a*]anthracene, chrysene, phenanthrene, naphthalene, triphenylene, fluoranthene, benzo[*b*]thiophene, and dibenzothiophene.

Aromatic nuclei have been halogenated with quite a few methods.[1] The methods could be classified into four groups. They are; (1) reaction of electron-rich aromatic nucleus with a molecular halogen; (2) reaction of less-activated nucleus with a molecular halogen in the presence of a catalyst such as a Lewis acid; (3) reaction of aromatic nucleus with a positive halogen; and (4) halogenation by a metal halide as a halogen-source.[2]

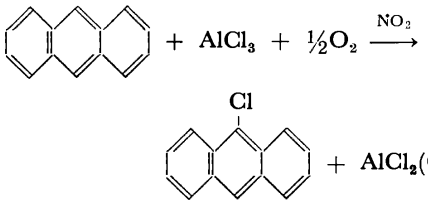
Extensive investigation has been done on the reactions in groups (1), (2), and (3). On the contrary, reactions that belong to the fourth group have received little attention. In many cases, the reaction of aromatic nucleus with a metal halide[3] results in metallation,[4] isomerization,[5] polymerization,[6] or disproportionation[5] rather than halogenation. Therefore, metal halides that have been employed for halogenation have been restricted to halides of copper(II),[7] iron(III),[8] tin(IV),[9] titanium(IV),[2] antimony(V),[10] vanadium(V),[2] and (nonmetallic) phosphorus(V).[9,11] Namely, the reaction with copper(II) chloride is known as Nonhebel's chlorination and has synthetic utility.[12] Side-reactions dominate with other metal halides.

Characteristic of the halogenation with these metal halides are that these metal ions are reduced to their low-valency states during the reaction according to Eq. 1 or 2.

$$ArH + 2M^{n+}X_n^- \longrightarrow ArX + 2M^{(n-1)+}X_{n-1}^- + HX \quad (1)$$

$$ArH + M^{n+}X_n^- \longrightarrow ArH + M^{(n-2)+}X_{n-2}^- + HX \quad (2)$$

It is plausible that the halogenation may take place with a metal halide whose metal ion cannot change its valency, provided a suitable electron-source is supplied to the reaction system. Indeed, the author has reported chlorination of anthracene with aluminum (III) chloride in the presence of catalytic amount of nitrogen dioxide under aerobic conditions (Eq. 3).[13]



(3)

This novel chlorination method is superior to conventional ones in intermolecular selectivity, yield of the product, and reaction conditions.

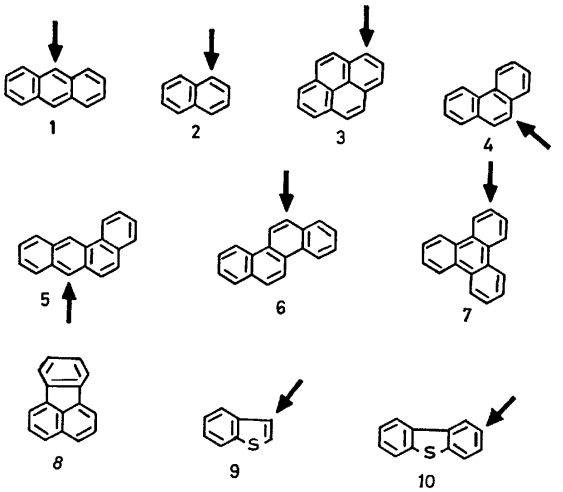
In the present paper, the author wishes to report the scope and limitation of the halogenation which couples with a series of successive electron transfer systems, an electron-bridge.

Results and Discussion

Appropriate amounts of a polycyclic aromatic hydrocarbon and metal halide were allowed to react in toluene or in 1,2-dichloroethane at 0—30 °C. Benzene, nitromethane, acetonitrile, or carbon disulfide could also be used as a solvent. Although toluene was a suitable solvent for most halogenations, the reaction with less reactive aromatics afforded, sometimes, benzylated compounds in this solvent.

The products were isolated and identified by melting points as well as by comparing their spectroscopic properties with those of the corresponding authentic samples. The results are summarized in Table 1 for the chlorination and in Table 2 for the bromination.

The regioselectivity of chlorination is satisfactorily high; GLC-analyses showed that the chlorination of anthracene (**1**) and naphthalene (**2**) afforded 9-chloroanthracene and 1-chloronaphthalene, respectively, as monochlorinated compounds. Other isomeric products were scarcely recognized (2%). Only one monochlorinated product was detected in chlorination of phenanthrene (**4**), benz[*a*]anthracene (**5**), chrysene (**6**), or triphenylene (**7**). The reaction site is indicated in Scheme 1 by an arrow.



Scheme 1. Arrows indicate the position susceptible to monohalogenation. For compound **8**, the position is not identified. For compound **3**, significant amount of the other isomer is formed.

Table 1. Chlorination of polycyclic aromatics[a]

Substrate ArH_2	MX_n	NO_2[b] (mol%)	Time min	Consumed ArH_2 (%)	Yield of ArHCl[c] %	Yield of $ArCl_2$[c] %
1[d]	$AlCl_3$	13	30	100	86	0
	$AlCl_3$[e]	13	30	51	90	0
	$TiCl_4$	13	30	100	0	91
	$TiCl_4$[e]	13	30	100	91	Trace

2[f]	$TiCl_4$	26	1440	95	53	0
7	$TiCl_4$	13	1200	92	67	0
8[i]	$TiCl_4$	10	120	—[g]	21[h]	0
9[i]	$TiCl_4$	10	120	—[g]	47[h]	0
10	$TiCl_4$	10	120	—[g]	40[h]	0

a) $MX_n/ArH_2=1.0$. Solvent: toluene. Temp: room temp. b) Mol% is based on substrate used. c) Yield is based on ArH_2 consumed. d) Data from Ref. 13. Temp: 0 °C. e) $MX_n/ArH_2=0.5$. f) Solvent: 1,2-dichloroethane. g) Consumed ArH_2 was not determined. h) Yield is based on ArH_2 used. i) Significant amounts of dimer and trimer were obtained.

Bromination takes place with less selectivity than the chlorination; 5—10% of 2-bromonaphthalene was detected on GLC in addition to the major product, 1-bromonaphthalene. However, the bromination of other substrates gave as good regioselectivity as the chlorination.

It should be noted that the ratio of mono-/dihalogenated product is extremely high in the present reaction, which is a marked contrast to the reaction with, for example, copper(II) chloride.[7] Most of the present reactions gave traces of, if any, or no dihalogenated product, when the relative amounts of the reagents were appropriate. On the other hand, dihalogenated compound was obtained as a sole product under appropriate reaction conditions.

Intermolecular selectivity is also seen in competitive chlorination of anthracene, pyrene (**3**), and triphenylene as listed in Table 3.

Further advantage of the present halogenation lies in its reactivity: Whereas it has been reported that a substrate which has ionization potential of less than 7.55 eV is unreactive toward the chlorination with copper(II) chloride,[14] in the present halogenation phenanthrene (IP; 8.03),[15] naphthalene (IP; 8.10),[15] and triphenylene (IP; 8.09)[15] are susceptible to the reaction.

It is interesting to point out that the number of halide ion available for the halogenation depends on the reactivities of both metal halide and substrate; as can be seen in Tables 1 and 2, only one of three chlorine atoms in aluminum(III) chloride is available for the chlorination of anthracene, whereas two of three bromine atoms in aluminum(III) bromide react with anthracene. On the other hand, two of four chlorine atoms in titanium(IV) chloride react in the chlorination of reactive substrates such as pyrene and benz[*a*]anthracene, but only one is reactive toward the chlorination of relatively less reactive substrates such as phenanthrene, naphthalene, and triphenylene. Therefore, one can obtain either mono- or dihalogenated compound depending on the substrate/metal halide molar ratio employed for the reaction (*vide supra*). In general, bromides are more reactive than the corresponding chlorides, and a substrate of low ionization potential is more reactive than that of high ionization potential.

Now, the author wishes to demostrate catalytic activity of nitrogen dioxide.[13] As listed in Table 4, practically no halogenation takes place with these metal halides when nitrogen dioxide is absent in the reaction system. Even titanium(IV), and tin(IV) bromides require nitrogen dioxide in order to undergo the reaction, though these metal ions have stable lower-valency states. Thus, it is apparent that the reaction with these metal halides is not of the types shown in Eqs. 1 and 2 under the present reaction conditions. Boron tribromide is an exception. Although the effect of catalyst is significant, bromination with boron tribromide proceeds in some extent without the catalyst. Since boron cannot change its valency, the author has no idea on a plausible mechanism.

In the absence of a reactive substrate, toluene is also susceptible to the halogenation and a 1:1 mixture of *ortho*- and *para*-bromotoluenes is obtained in the total yield of 81%.

Benzo[*b*]thiophene (**7**) and dibenzothiophene (**10**) can also be subjected to the halogenation. However, oxygen-containing compounds such as benzofuran and dibenzofuran do not undergo the reaction, probably because lone-pair electrons on the oxygen atom in-

teract with positive metal ion decreasing the reactivity of metal halide.

Unfortunately, attempts to iodinate aromatic hydrocarbons were found unsuccessful.

Although detailed mechanism of the reaction is under investigation, nucleophilic character of the halogenation as well as the following evidence allows the author to speculate the formation of an aromatic radical cations as an intermediate of the reaction: It is well known that polycyclic aromatic hydrocarbon forms a charge-transfer complex with Lewis acids.[16] The aromatic radical cation thus formed may abstract a halide ion. When the reaction is carried out in the presence of trichlorosilane, chlorinated product is obtained.[13] A hydrogen atom should be abstracted from trichlorosilane, if a free-radical mechanism governed the reaction. In addition, the fact that silicon tetrachloride cannot give the chlorinated products,[13] suggests the polar nature of the reaction.

At least a part of catalytic effect of nitrogen dioxide is exerted by the formation of an electron-bridge.

a) Reaction conditions: See the experimental section. $AlBr_3$/ArH_2=1/1. b) Yield is based on ArH_2 consumed.

The halogenation without oxygen proceeds in the presence of equimolar amount of nitrogen dioxide, which implies that oxygen reproduces nitrogen dioxide from its reduced form, nitrogen monoxide. The formation of nitrogen monoxide may couple with the oxidation of aromatic hydrocarbon to its cationic form. Thus, the author prefers to propose that an electron-bridge is constructed in the present reaction, in which an electron migrates from a substrate to nitrogen dioxide and to oxygen molecule.

Experimental

Instruments. The IR, ^{1}H-NMR, and mass spectra were recorded on a Hitachi EPI-S2, Varian T60, and JEOL JMS-01SG spectrometers, respectively. Analytical GLC was carried out with a Yanaco G-1800 gas chromatograph using

a 1.5 m—0.3 cm o.d. stainless column packed with 5% Silicone OV-17 on Chromosorb W. The preparative GLC was carried out with a Varian aerograph model 920 instrument using a 1.0 m—0.45 cm o.d. stainless column packed with 10% Silicone OV-17 on Chromosorb W. The column chromatography was carried out on active alumina Woelm N. Akt. I with solvents of hexane and benzene.

Materials. All the chemicals except for triphenylene were obtained from commercial sources (Nakarai Chemical Co. and Wako Pure Chemical Industries, Ltd.) and used after purification by distillation or column chromatography. Commercial nitrogen dioxide was cooled to liquid in a Dry Ice–acetone bath, weighed, and used as a 5% solvent solution. Triphenylene was prepared from *o*-bromoaniline according to the method of Heaney and Millar[17] mp 198 °C (lit,[17] 199 °C). Found: C, 94.42; H, 5.31%. Calcd for $C_{18}H_{12}$: C, 94.70; H, 5.30%.

Product Analysis. Into a solution (100 ml) or a suspension (100 ml) of 5.0 mmol of an aromatic compound, were added 5.5 mmol of anhydrous metal halide and 460 mg of toluene containing 23 mg of NO_2 (0.5 mmol). The mixture was stirred for appropriate time interval under atmosphere of oxygen at room temperature, and the amount of oxygen absorbed was measured on a gas-buret connected to the reaction vessel. The reaction mixture was poured into dilute hydrochloric acid, and extracted with toluene (3×50 ml). The combined toluene layer was washed with water, neutralized with sodium hydrogencarbonate, dried over $CaCl_2$, and the toluene was removed under reduced pressure. The residue was separated, and purified with column chromatography, and/or with recrystallization. The isolated products were identified by comparing thier IR, ^{1}H-NMR, and mass spectra with those of the corresponding authentic samples. Elemental analyses gave satisfactory results.

Quantitative Analyses. A same experiment as mentioned above was carried out in 1/10 scale. The combined toluene layer was quantitatively analyzed by GLC, after a usual work-up.

Bromination of Toluene. Anhydrous aluminum tribromide (2050 mg, 7.6 mmol) in nitromethane (18.5 g) and nitrogen dioxide (12.5 mg, 0.27 mmol) in nitromethane (250 mg) were added into toluene (25 ml). The mixture was stirred for 24 h under atmosphere of oxygen at room temperature, and poured into dilute hydrochloric acid. Work-up of the mixture by separation of toluene layer, washing with water, drying over $CaCl_2$, and evaporation of toluene yielded a mixture of crude bromotoluenes, which were purified on a preparative gas chromatograph (column temp: 120 °C), and the structure was identified. Quantitative analysis was carried out by GLC (column temp: 120 °C).

Chlorination of Anthracene with Trichlorosilane. Into toluene (10 ml) saturated with BF_3, were added 100 mg (0.56 mmol) of anthracene, toluene (1.4 ml) containing 76 mg (0.56 mmol) of trichlorosilane, and nitromethane (0.15 ml) containing 7.5 mg (0.16 mmol) of NO_2. The mixture was stirred overnight under atmosphere of oxygen at room temperature. After usual work-up, 72 mg (72%) of anthracene and 24.6 mg (74% based on consumed anthracene) of 9-chloroanthracene were obtained on GLC.

Competitive Chlorination. Into a mixture of anthracene (89 mg, 0.5 mmol), pyrene (101 mg, 0.5 mmol) or triphenylene (120 mg, 0.5 mmol), and eicosane (50.8 mg) as an internal standard material for gas chromatographical analysis in dry toluene (10 ml), were added titanium(IV) chloride (142.5 mg, 0.75 mmol) in nitromethane (0.28 ml) at 0 °C, and stirred. After 1 min and 3 min, 1 ml aliquots of the reaction mixture were taken out, respectively. The aliquot was quenched, and after usual work-up, analyzed by GLC.

The author thanks Professor S. Oka and Dr. A. Ohno for useful discussions.

An MO Theoretical Study of the Photochemical Reaction of Alkanenitronate Anions to Form Hydroxamic Acids

Osamu Kikuchi,*,† Takazumi Kanekiyo, Seiji Tanaka, Kiyoshi Naruchi, and Kazutoshi Yamada*

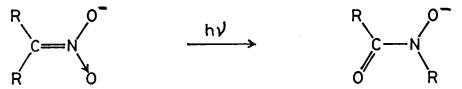
Department of Industrial Chemistry, Faculty of Engineering, The University of Chiba, Yayoi-cho, Chiba 280

†*Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 305*

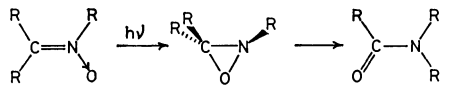
(Received July 23, 1981)

The reaction mechanism of the photochemical reaction of alkanenitronate anions to form hydroxamic acids was explored on the basis of the potential energy curves obtained by means of MINDO/3 CI calculations. The *O*-oxaziridine was calculated to be not an intermediate, but an unstable transient species in this photoreaction. This is different from the photoisomerization of methyleneamine *N*-oxide derivatives into the corresponding amides, in which the oxaziridine is considered to be an intermediate. The proposed reaction mechanism elucidates well the regioselectivity observed in the photochemical formation of hydroxamic acids from nitronate anions.

Although the photochemical reactions of aliphatic nitro compounds have been investigated extensively,[1] the photochemical reactions of alkanenitronate anions, which are formed from aliphatic nitro compounds in an alkaline solution, has not been reported before our recent studies.[2] The photolyses of nitronate anions, **1**, give hydroxamic acids, **2**. Since methyleneamine *N*-oxide derivatives, **3**, give, photochemically, the corresponding amides, **5**,[3] the **1**→**2** reaction may



1 **2**



3 **4** **5**

be considered to proceed by means of a mechanism similar to that of the **3**→**5** reaction. In the **3**→**5** reaction, the oxaziridine, **4**, is considered to be an intermediate; some oxaziridines have been isolated.[3] In the case of the nitronate anions, however, the corresponding *O*-oxaziridines are too unstable to be observed by spectroscopic methods.[2] Moreover, the regioselectivity observed in the photolysis of **6** is different from that observed in the **8**→**9** reaction. Thus, the **1**→**2** reaction mechanism can not be sufficiently understood by analogy with that of the **3**→**5** reaction; we therefore decided to perform MO theoretical calculation along the **1**→**2** reaction process to explore the reaction mechanism and to complement our experimental studies.

8 **9**

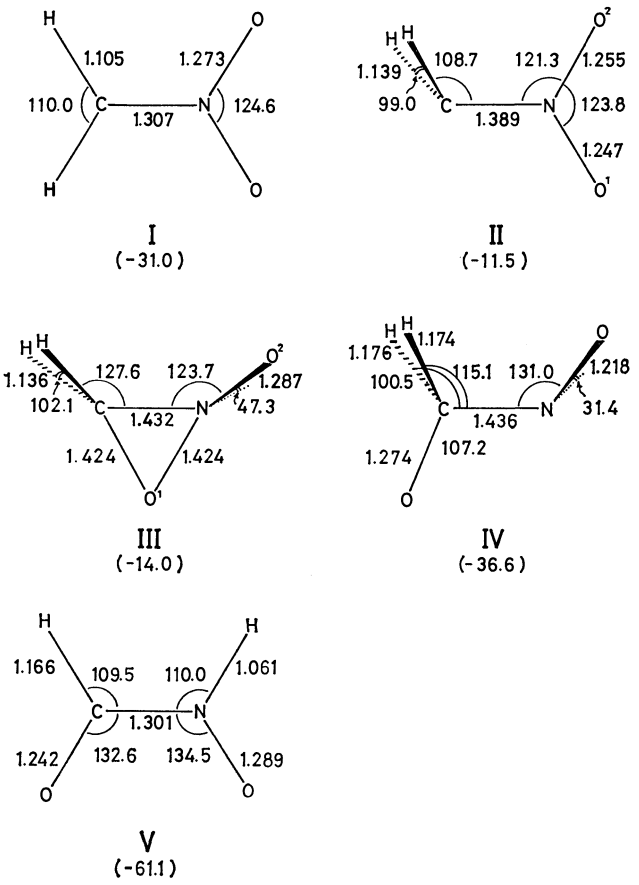

Fig. 1. Molecular structures and heats of formation (in parentheses) of the anions I—V obtained by MINDO/3. Bond lengths are in Å, bond angles in degrees, and heats of formations in kcal/mol (1 kcal=4.184 kJ).

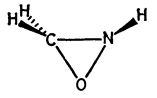
Method and Results

The unsubstituted compound, I, was employed as the model nitronate anion. The molecular structures of the anions, I—V, were optimized by MINDO/3[5]

SCF (without CI) calculation. The configuration of the H atoms in II and III was restricted to symmetrical with respect to the CNO^1 plane. The calculated structures and the heats of formation of these anions are shown in Fig. 1. The energy difference between I and II, 81.6 kJ/mol, agrees well with the STO-3G value (64.9 kJ/mol).[6]

The HOMO of II is the CH_2 σ lone-pair orbital (carbanion type), while the LUMO of II is the NO_2 *anti*-bonding π orbital. The closed-shell configuration is the ground state of this twisted structure, and the HOMO→LUMO diradical structure is the excited state, as will be shown below. The CN bond of nitronate anions has a double-bond character. As may be expected from the electronic structure of the twisted ethylene,[7] the lowest singlet state of the species obtained by 90° rotation about a double bond is the diradical state. The lowest state of the twisted methyleneamine *N*-oxide was calculated to be the diradical state.[8] It is thus very interesting that the lowest singlet state of the twisted nitronate anion has a closed-shell electron configuration.

In the optimization of the bridged structure, III, the C–O^1 and N–O^1 distances were resticted to $R_{CO^1}=R_{NO^1}$. If this restriction is removed, the N–O^1 bond breaks spontaneously during the geometry optimization process, and the stable bridged structure cannot be obtained; the optimization gives an open structure, IV. Since the stable bridged structure is obtained for VI by the same optimization procedure,[8]



VI

the instability of III may be said to be characteristic of the *O*-oxaziridine derived from nitronate anions. The reaction product V is very stable (105 kJ/mol more stable than IV), and the transformation from IV to V can be expected to occur very easily.

The photochemical formation of V from I involves the methylene rotation, the oxygen migration from the nitrogen to carbon atoms, and the hydrogen migration in the reverse direction. The I→V process is thus too complex to be analyzed by the MO method. We restricted ourselves to considering three processes successively:

$^3A_1$	4.26	11→13 (85%), 11→16 (9%)

a) The highest occupied ϕ_{12} orbital is the C–N π orbital, the ϕ_{13} and ϕ_{16} orbitals are unoccupied σ orbitals, ϕ_{11} is the oxygen lone-pair σ orbital, and ϕ_{14} is the unoccupied π orbital.

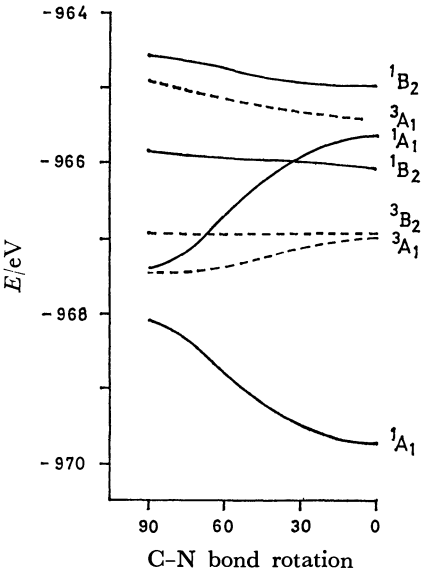

Fig. 2. Energy variations of several lower electronic states of the nitronate anion I along the rotation about the CN bond.

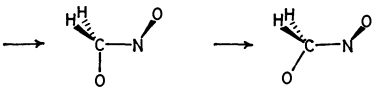

(2)

VIII IV

(3)

IV V

The potential curves along the methylene rotation, Eq. 1, were calculated by means of the CI method, in which 30 and 27 configuration functions were selected from singly- and doubly-excited configurations for the singlet and triplet states respectively. Several lower states of I are listed in Table 1, while their energy variations along the methylene rotation are shown in Fig. 2.

In order to determine the potential curves for the oxygen-migration reaction, the CI calculations were

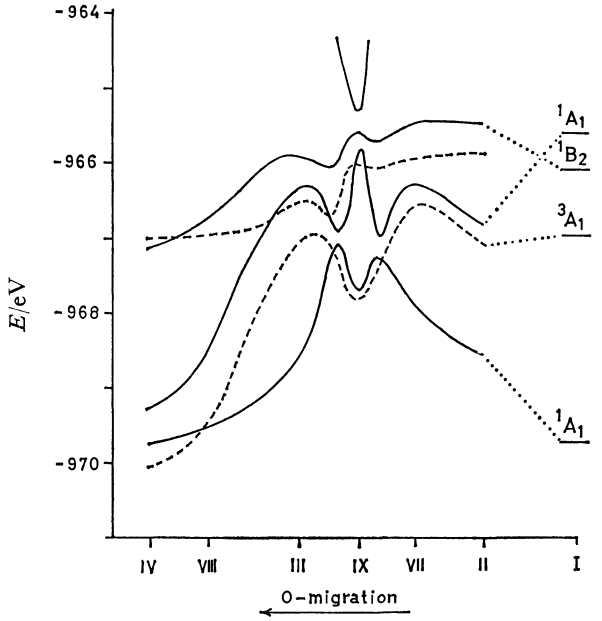

Fig. 3. Energy variation of lower electronic states along the oxygen migration process II→IV.

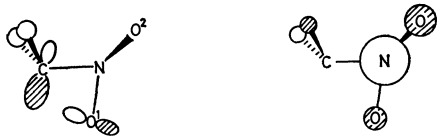
carried out for the five optimized structures involved in Eq. 2, as well as for several intermediate structures between VII and III. The potential curves obtained are shown in Fig. 3. An interesting shape of potential curves was observed between VII and III. In this region, two occupied orbitals, the carbanion-type σ lone-pair orbital on the carbon atom and the in-plane oxygen one-pair orbital, interact with each other to form the C–O^1 ϕ_σ and ϕ_{σ^*} occupied orbitals. When



this interaction increases, the orbital energy of the occupied ϕ_{σ^*} orbital increases rapidly and crosses with the unoccupied ϕ_{π^*} orbital of the NO_2 group. Since the O^1 migration is accompanied by the deviation of the NO bond out of the CNO^1 plane, the ϕ_{σ^*} and ϕ_{π^*} orbitals mix to give the HOMO and LUMO in this region (Eqs. 4 and 5). According to Salem,[7]

$$\Psi_{12}(\text{HOMO}) = \frac{1}{\sqrt{2}}(\phi_{\sigma^*}+\phi_{\pi^*}) \quad (4)$$

$$\Psi_{13}(\text{LUMO}) = \frac{1}{\sqrt{2}}(\phi_{\sigma^*}-\phi_{\pi^*}) \quad (5)$$

the lowest singlet state in this region is a diradical state whose electron configuration is $(\phi_{\sigma^*})^1(\phi_{\pi^*})^1$. The wavefunction of the pure diradical singlet state of this electron configuration is:

$$\frac{1}{\sqrt{2}}(\Psi^1_{12}-\Psi^1_{13}).$$

Thus, the lowest singlet state in this region should be expressed by the two-configuration wavefunction. The CI calculation in this region was carried out for the

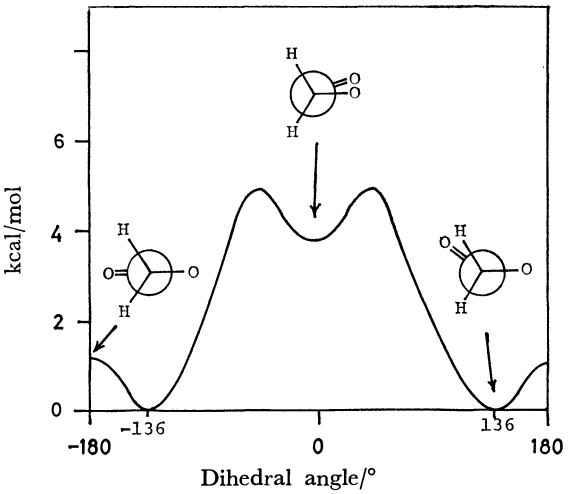


Fig. 4. Energy variation of IV along the rotation about the C–N bond. The structure is optimized at each rotational angle.

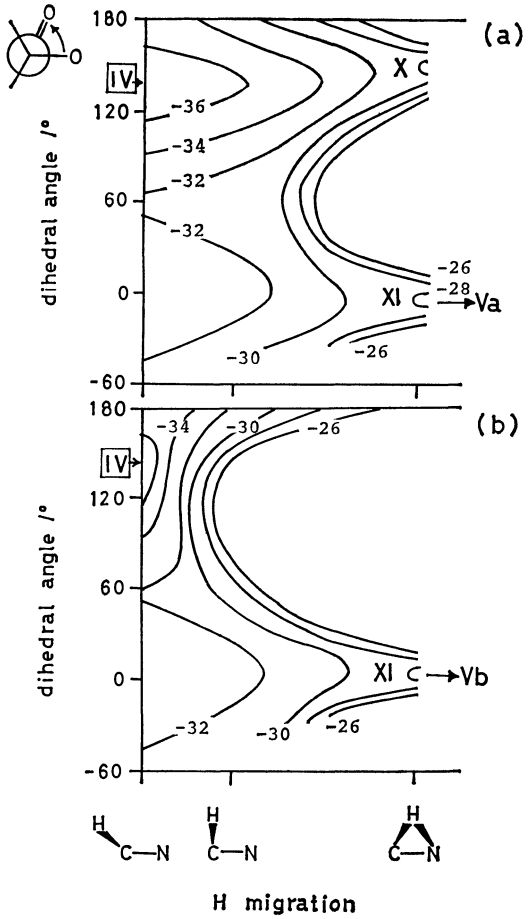

Fig. 5. Potential energy surfaces for the H-migration reaction from IV to the bridged structure. a) H^t migration. b) H^c migration. The values are heats of formation in kcal/mol (1 kcal=4.184 kJ).

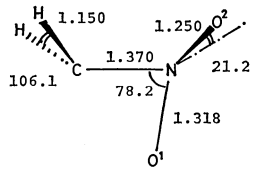
diradical IX, whose molecular structure was optimized by using the double-configuration wavefunction. The IX structure corresponds to the deep minimum point in Fig. 3, and the CI wavefunction of the lowest singlet



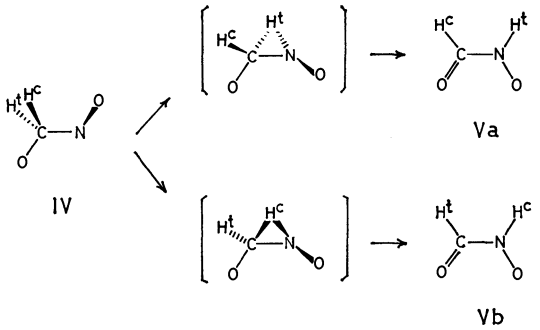
IX

state of IX is $0.759\Psi^2_{12}-0.569\Psi^2_{13}+\cdots$.

The hydrogen migration and the N=O group rotation are involved in Eq. 3. Figure 4 shows the energy variation in IV with respect to the dihedral angle between the OCN and CNO planes. Figure 5 shows the potential energy curves as a function of the dihedral angle and the H-migration coordinate. Two bridged structures, X and XI, were predicted for the transition states; X and XI give the *trans* and

X XI

cis isomers of the final product respectively. As may be seen from Fig. 4, the two hydrogen atoms in IV are not equivalent; one is *trans*, and the other is *cis*, with respect to the N=O bond. There are two possible paths leading to the *cis* isomer of the final product which corresponds to **7**. The potential energy surfaces in Fig. 5 indicate that the H^t migration is preferable to the H^c migration.

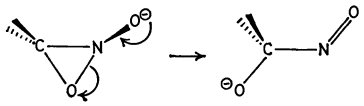


IV Va Vb

Discussion

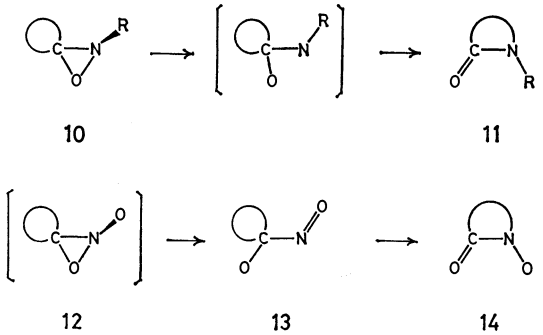
The strong absorption of alkanenitronate anions observed in the 230—240 mμ region[2] can be assigned to the transition from the ground state to the $^1A_1(\pi\rightarrow\pi^*)$ excited state, since this is a symmetry-allowed transition. The rotation of the methylene group about the CN bond of I can occur in this excited state (Fig. 2). The nitronate anions can undergo photochemical isomerization from their $\pi\rightarrow\pi^*$ excited state. In the present calculation, two processes, the rotation of methylene and the oxygen migration, were treated separately; a concerted path of these two processes may be possible in the actual system. These steps do not occur from the ground state, since the activation energy required is more than 210 kJ/mol (Figs. 2 and 3).

The most clear-cut finding is the unstable property of the *O*-oxaziridine. In the photochemical **3**→**5** process, the oxaziridine, **4**, is an intermediate.[3] The difference in stability between III and VI originates



from the difference in their electronic structures. In the case of III, the electron migration occurs very easily to give the stable structure IV, while this type of electron migration is not expected in the oxaziridine, VI.

In the photochemical isomerization of cyclic oxaziridines into amides, **10**→**11**, an alkyl migration after the N–O bond cleavage has been proposed.[9] This mechanism is not applied to the present system, however, since the bridged structure, **12**, is a transient species. The ionic mechanism, in which **13** is an intermediate, is more appropriate for the present system. The alkyl migration, **13**→**14**, involved in this step is similar to the benzilic acid rearrangement[10] in an alkaline solution.



10 11 12 13 14

The photochemical reaction mechanism of nitronate anions can be understood by the schematic representation of the reaction process (Fig. 6). The CN bond rotation and the oxygen migration occur from the $\pi\rightarrow\pi^*$ excited state. The transition from the excited state to the ground state occurs near the diradical structure (XI), and the stable anion (IV) is produced

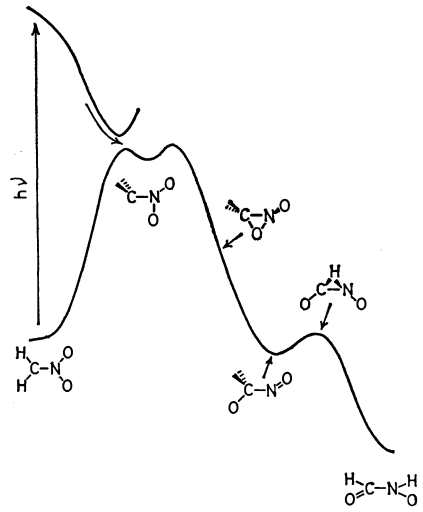


Fig. 6. Schematic representation of the photochemical process of alkanenitronate anions to form hydroxamic acids.

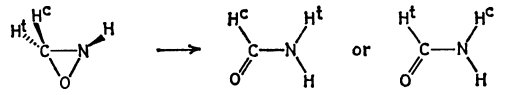
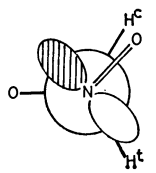
very easily. The oxaziridine is not an intermediate in this step. The alkyl migration requires only a small activation energy to form the final reaction product.

Oliveros *et al.*[9] have well explained the regioselectivity observed in the **8**→**9** reaction on the basis of theoretical calculations for the model system, **15**→**16**.



15 16a 16b

Their results indicated that the CH bond in the *cis* position with respect to the N–H hydrogen atom breaks easier than that in the *trans* position. In the case of nitronate anions, the nitroso compound, **13**, is an intermediate, and the regioselectivity observed in the **6**→**7** reaction may be explained by the selectivity expected in the **13**→**14** reaction. The model calculation for the IV→Va and IV→Vb processes suggested that the migration of the *trans* alkyl group is preferable to that of the *cis* one (Fig. 5). In the IV→V step, the hydrogen atom bearing a pair of electrons migrates to the nitrogen atom, and the interaction between the C–H bond and the N=O *anti*-bonding π orbital is very important. This stereoelectronic effect is why the H^t hydrogen atom migrates more



easily than the H^c atom. If the XII conformation, in which the steric interaction between the N=O oxygen atom and the ring substituent is minimized, is assumed to hold for the anion derived from **6**, the present model calculation predicts the formation of **7**, which is observed experimentally.

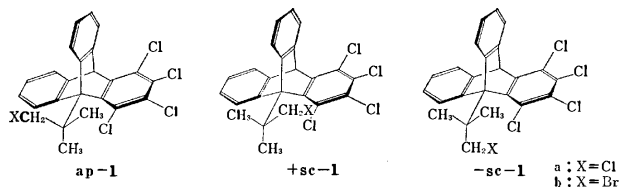
(Received July 30, 1981)

±*sc*-1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene was found to react in the presence of titanium(IV) chloride at room temperature to give an isomeric mixture of 1,2-dimethyl-7,8,9,10-tetrachloro-1,2,6,10b-tetrahydro-6,10b-*o*-benzenoaceanthrylenes. The structure of the latter was confirmed by independent syntheses. In contrast, the *ap* conformer of the former did not give any sign of the reaction under the same conditions but reacted when antimony(V) chloride was added to give the same mixture. Careful examination of the reaction mixture suggests that the starting material was rapidly converted to (*E*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)triptycene and cyclization followed. Action of silver nitrate on ±*sc*-9-(2-bromo-1,1-dimethylethyl)-1,2,3,4-tetrachlorotriptycene afforded a mixture of the stereoisomers of the olefin while the *ap* form remained intact.

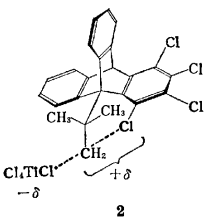
Since we were able to show recently that methyls in a *t*-butyl group could behave differently in radical halogenations, when the rotation of the *t*-butyl group was frozen,[3] we naturally wished to extend the work on the reactivities of rotamers to see those of the halogenated compounds. Because 9-(2-halo-1,1-dimethylethyl)triptycenes possess the structure of neopentyl halide, their S_N2 type substitution was expected to be very slow.[4] However, we happened to find that the ±*sc* conformer of 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene (**1a**) was partially destroyed if purification was attempted by chromatography on alumina, whereas the *ap* form was eluted intact.[3] This suggests that ionization reactions of the halide may be facile in general, especially in the ±*sc* conformation. Thus we decided to investigate the reactivities of ±*sc*- and *ap*-**1a** in ionization reactions. This paper reports the difference in reactivities of the rotamers, when they are treated with a Lewis acid. The structure of the products was confirmed by independent syntheses. The possible mechanisms of the reaction are also discussed.



Results and Discussion

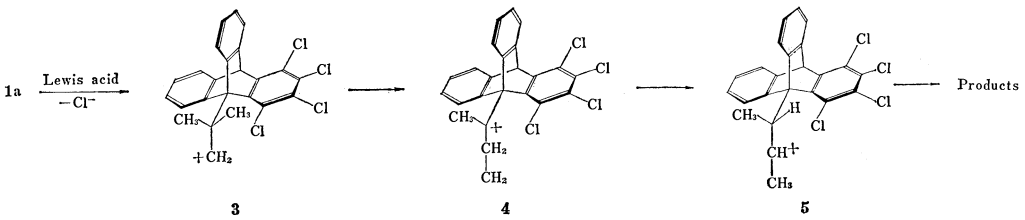
*Reactivities of 1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene (**1a**) Rotamers.* Since the barrier to rotation of the 2-chloro-1,1-dimethylethyl group about the C_9–C_{subst} bond is known to be *ca.* 37 kcal/mol (1 cal=4.18 J),[3] it is certain that we are looking at the reactivity of each isomer. The treatment of a mixture of **1a** rotamers with a large excess of titanium(IV) chloride caused the reaction of the ±*sc* form but the *ap* form remained unreacted. The pseudo-first order reaction rate constant for the ±*sc* form was obtained as 5.3×10^{-4} s^{-1} at 41 °C. Under the same conditions, the *ap* form did not give any sign of the reaction even after 164 h. This indicates that the rate constant of the reaction of *ap*-**1a** under the conditions is 8.7×10^{-8} s^{-1} at the most. (We took 5% of the material reacted since the error in integration of ^{1}H NMR spectra may be estimated at this level.) Then the relative reaction rate of ±*sc*-**1a** is $>6\times10^3$ if that of *ap*-**1a** is unity. The pseudo-first order rate constant of *ap*-**1a** in the presence of antimony(V) chloride was 8.8×10^{-4} s^{-1} at 39.8 °C, whereas the reaction of ±*sc*-**1a** was too fast to measure the rate by conventional methods under the conditions.

This large difference in reactivities of ±*sc*-**1a** and *ap*-**1a** must be derived by the presence of a chloro group in a peri-position. Since titanium(IV) chloride and antimony(V) chloride act as Lewis acids, it is expected that these coordinate with the chloro group in the 9-substituent and help ionization of the compound. Then the developed cation (**2**) can be stabilized by the presence of a chloro group in proximity in the ±*sc* conformation, since neighboring participation of the chloro group is well documented[5]

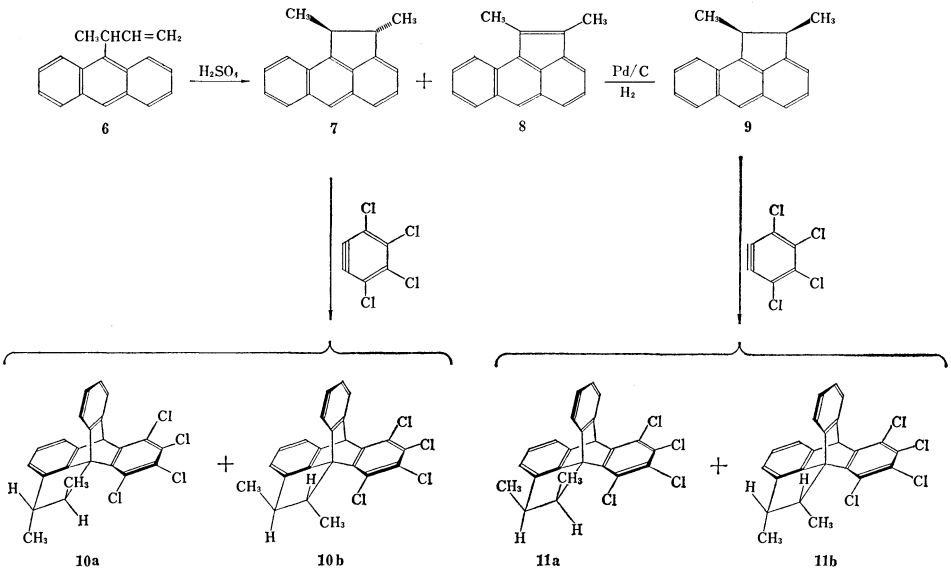


2

and chloronium ion is also known.[6] There is a possibility that the ground state of this molecule is so congested that the steric acceleration of ionization[7] ensues. However, if it were the main cause, the *ap*-form as well as the ±*sc* form should have ionized with comparable rates. It is especially noteworthy that titanium(IV) chloride, which is known to be a weak catalyst for the Friedel-Crafts reaction of primary organic halides,[8] does cause the reaction under mild conditions: Participation of the chloro group seems strong in this case. Indeed, several examples of strong participation of the peri-chloro group in triptycenes have been reported.[9] Another interesting



Scheme 1.



Scheme 2.

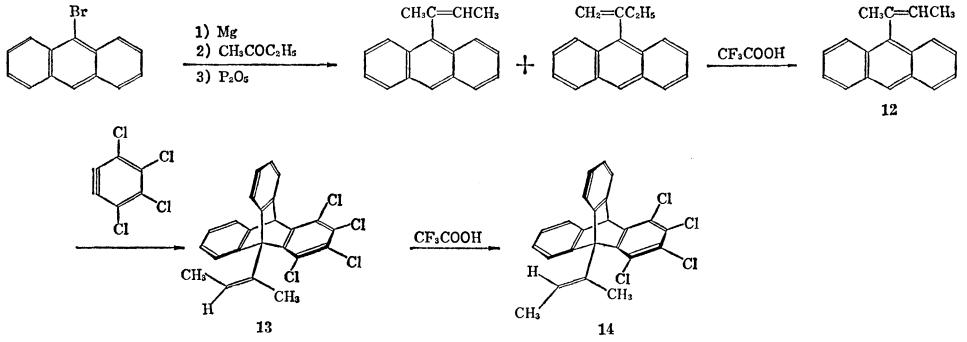
point is that the intermolecular Friedel-Crafts reaction with the solvent molecule has not been detected. This is probably because the intermolecular reaction is prohibited due to the steric factor.

Antimony(V) chloride is known to be a stronger Lewis acid than titanium(IV) chloride.[10] Therefore it is reasonable that this reagent caused the reaction of even *ap*-**1a**.

Structures of the Products. Both of the reactions catalyzed by Lewis acids afforded almost the identical mixture of the products. On standing, a part of the product solidified. After purification, the solid product showed ^{1}H NMR signals of two kinds of methyls, each coupled with a proton. A mass spectrum of the compound indicated that a molecule of hydrogen chloride was eliminated from the starting material. These results suggest that an extensive rearrangement has taken place in the 9-substituent of **1a**. Since the cation (**3**) originally formed from **1a** can undergo a series of Wagner-Meerwein rearrangements and finally the cation undergoes intramolecular cyclization (Scheme 1),[11,12] the most probable structure of the pure material seemed to be one of possible isomers of **10** and **11**.

It is not possible to assign the structure of the solid product from ^{1}H NMR spectral data only, because there are four possible stereoisomers. Thus independent syntheses of the products were performed (Scheme 2). 9-(1-Methyl-2-propenyl)anthracene (**6**) was treated with concentrated sulfuric acid to afford a mixture of *trans*-1,2-dimethylaceanthrene (**7**), 1,2-dimethylaceanthrylene (**8**), and a small amount of *cis*-1,2-dimethylaceanthrene (**9**). Compound **8** was separated by chromatography and hydrogenated over palladium–charcoal to afford **9**. The *cis*-dimethylaceanthrene **9** was treated with tetrachlorobenzyne to afford two isomers (**11**) which were formed by the different directions of attack by the benzyne. One of the products crystallized out and it was found to be identical with the solid product which was obtained above. Another isomer was purified by high pressure liquid chromatography to give a solution of the almost pure substance. Thus the original solid product has a *cis*-structure at the newly formed 5-membered ring. Likewise, *trans*-1,2-dimethylaceanthrene (**7**) was treated with tetrachlorobenzyne to give a mixture of stereoisomers of **10**. One of the products crystallized out from the mixture. Thus ^{1}H NMR spectra of two isomers each of **10** and **11** have become available.

The next step for the identification is to assign structures **10a** and **10b**, and structures **11a** and **11b**. We took advantage of two pieces of information available from the ^{1}H NMR spectra. The first is the chemical shift of the aromatic protons. Since 9-substituted triptycenes are highly congested, strong van der Waals interactions are due between the 9-substituent and the peri-proton. Accumulated data in this laboratory suggest that if the substituent in the 9-position is tertiary, the peri-proton gives rise to a multiplet signal at a far downfield of the aromatic region. The data may further be interpreted that if a proton in the peri-position is flanked by two methyl



Scheme 3.

groups, it gives a signal at a considerably low field. Indeed, we have succeeded in assigning stereostructures of adducts between 9-(1,1-dimethyl-2-phenylethyl)anthracene and dimethyl acetylenedicarboxylate by this method.[13] Inspecting the molecular models, we notice that **10a** and **11a** possess a peri-hydrogen which is very close to a methyl, whereas **10b** and **11b** have that which is far from any of methyls. Therefore, if one of the two isomers of **10** and **11** gives an aromatic proton signal at a low field apart from others, then it is very likely to be **10a** and **11a**. Inspection of the NMR data suggests that, of the trans isomers, that which was obtained as crystals gives a low field signal and is likely to be **10a**. In contrast, a cis isomer which was obtained as crystals has no such low-field signal for the aromatic protons but that obtained as a solution exhibited a low-field signal. Thus the crystalline compound of the cis configuration is assigned to **11b**. These assignments are further confirmed by NOE experiments. An NOE experiment of the crystalline form of **10**, irradiating the methyl signal at δ 2.19 and observing the intensity of the signal at δ 7.90 showed 19% increase in intensity. Likewise, irradiation of the methyl proton signal at δ 2.11 of the isomer of **11**, which was obtained as a solution, showed 23% increase in intensity of the aromatic proton signal at δ 7.87, whereas no such enhancement of the signal was observed in the NOE experiment of the crystalline product of *cis*-structure or the crystalline product of the original cyclization reaction. Thus the structural assignment is now confirmed as follows.

10a: A crystalline product from the Diels-Alder reaction of *trans*-1,2-dimethylaceanthrene.

10b: Another product from the above reaction which was not purified completely.

11a: A compound which was obtained as an almost pure solution by high pressure liquid chromatography from the product of the Diels-Alder reaction of *cis*-1,2-dimethylaceanthrene.

11b: A crystalline product from the above reaction and also a crystalline product from the treatment of **1a** with Lewis acids.

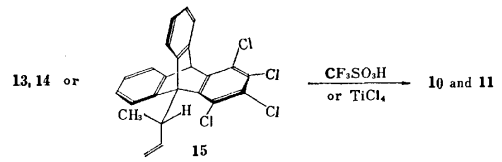
Using the ^{1}H NMR signals of these compounds, we can now analyze the composition of the products obtained by the reactions of $\pm$*sc*-**1a** and *ap*-**1a**. The ratios were constant at **10a**:**10b**:**11a**:**11b**=45:$\approx$0:10:45 within the error of $\pm$5%.

Mechanisms of the Reaction. If we neglect the presence of a counterion, the mechanisms of cyclization may be shown as those in Scheme 1 as a first approximation. However, there are a few points we wish to mention here. The first is the intervention of an olefin (**13** and/or **14**). While, when a large excess of titanium(IV) chloride was used in the reaction of $\pm$*sc*-**1a** for a long time, only the cyclized products were detected, an olefin was a major product together with a small amount of the cyclized products when the reaction was conducted for a shorter period in the presence of a relatively small excess of the catalyst.

The structure of the olefin was determined by independent syntheses as follows (Scheme 3). A Grignard reagent prepared from 9-bromoanthracene was added to 2-butanone and the resulted alcohol was dehydrated with phosphorus(V) oxide to give a mixture of olefins. Treatment of the mixture of olefins with trifluoroacetic acid yielded a mixture of (*Z*)- and (*E*)-9-(1-methyl-1-propenyl)anthracene (**12**) in which the *Z*-form predominated. Treatment of the mixture of *Z*- and *E*-forms with tetrachlorobenzyne followed by chromatography gave (*Z*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)triptycene (**13**). Isomerization of **13** to its *E*-isomer (**14**) was effected by trifluoroacetic acid.

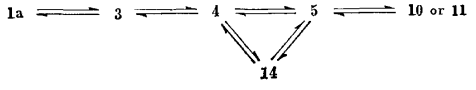
The structures of olefins of the triptycenes (**13** and **14**) and those which were found during the synthesis of the former were elucidated by considering the ring current effect of the benzene rings in ^{1}H NMR spectra. Of the two 9-(1-methyl-1-propenyl)anthracenes, one gives a methyl signal at δ 1.98 and the other at δ 1.23. The space-filling models of these compounds suggest that, as are expected from analogy of mesitylene derivatives,[14] the two planes made by the olefin and the anthracene cannot be coplanar. Thus the methyl group at the far end in the *Z*-olefin is located over the anthracene ring. In contrast, in the *E*-form, the methyl is far from the anthracene. Therefore, it is reasonable to assign the *Z*-structure for a compound which shows its NMR signal of the methyl group at a higher field than the counterpart. Similarly, the *E* and *Z* structures of the olefin in triptycenes (**13** and **14**) were assigned by taking advantage of the geometry of molecules which is suggested by molecular models: in the *Z*-conformation of the olefinic triptycene, the methyl group at the end of the 9-sub-

stituent should be in the shielding zone of the flanking benzeno bridges, whereas it is in the deshielding zone of the benzeno bridges in the *E*-conformation. The fact that, while the anthracene gave a mixture of *Z* and *E* forms of the olefin on equilibration, the triptycenes gave the almost pure *E*-olefins on equilibration, may be rationalized by considering the steric factor: Since the end-methyl group directs inside of the triptycene skeleton in the *Z*-conformation, its thermodynamic stability must be low.



Cyclization of olefins (**13** and **14** as well as **15**) gives almost the identical mixture of isomers of the cyclized products (**10** and **11**) when they were treated with titanium(IV) chloride or trifluoromethanesulfonic acid. This may be taken as evidence that the cation (**4** and/or **5**) are really involved in the process of the cyclization. An interesting point is that, although the cyclization did occur under these conditions, no cyclization was observed if trifluoroacetic acid was used. The acid must be a strong one for the cyclization to occur. The failure of cyclization in the presence of sulfuric acid may be ascribed to the presence of a basic solvent molecule (CD_3CN). This will mean that the concentration of the protonated species **5** must be high for the cyclization to occur which is rather slow. The slow cyclization can be expected since the formation of the 5-membered ring proceeds in the conformation in which the fully eclipsed interactions between the benzo groups and the methyl or the hydrogen of the forming 5-membered ring develop.

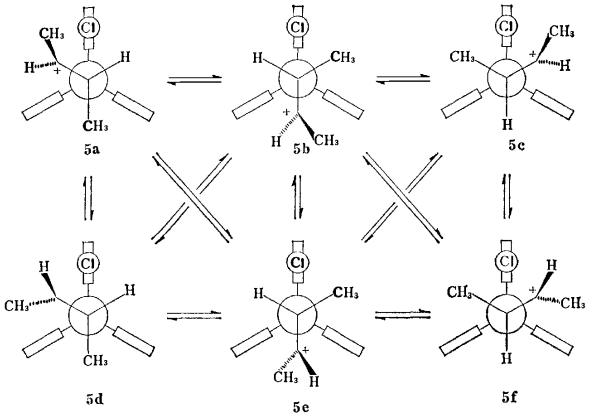
It is questionable to say that the olefin (**13** or **14**) is the real intermediate of the reaction which gives the cyclized products (**10** and **11**), whereas it is certain that the cyclization which affords **10** and **11** is slow and the olefin is formed rapidly from the halogen compound (**1a**), because, should the cation be formed, it will rearrange rapidly to **4** to release the strain. We see that there are two possibilities (Scheme 4): One is that the reaction proceeds in the sequential manner where the olefin **14** is formed from either **4** or **5**, but on protonation, the olefin goes back to the cation (**4** and **5**). An alternative is the sequence



Scheme 4.

in which **14** becomes a real intermediate which on protonation gives the cation **5**. We cannot rule out any of the two processes at present. Probably the both processes contribute to the total reaction.

It is interesting that both *ap*-**1a** and ±*sc*-**1a** reacted to give almost identical mixtures of the cyclized products, although their reactivities differed to a great



Scheme 5.

extent. This must mean that, although the ionization reaction of isomers of **1a** differes in their rates, the subsequent steps should involve at least a same intermediate. In addition, we could not find any of the intermediates other than the olefin **14** when the Lewis acids were used. The results can be accommodated if the Wagner-Meerwein rearrangement is fast: it is reasonable to assume so because the Wagner-Meerwein rearrangements were known to be very fast in various systems,[15] and the steric strain in the cation **3**, which is close to 1,2,3,4-tetrachloro-9-*t*-butyltriptycene[16] or 1,2,3,4-tetrachloro-9-(1-cyano-1,1-dimethylethyl)triptycene,[17] must be the driving force for the rearrangement, as discussed above (see also note 12). Thus the isomers of **3** are formed from *ap*- and ±*sc*-**1a** but they are transformed into **4** very rapidly. There are rotational isomers of **4** also. Therefore isomers of **4** may be formed from the rotamers of **1a**. However, the barriers to rotation of triptycenes carrying an sp^2-hybridized carbon at the bridgehead are known to be rather low.[18] The common intermediate is probably formed in this stage, although there is a possibility that, in the olefin **14**, the stereochemistry is scrambled. The final intermediate (**5**) should have a high barrier to rotation since its analogous compound, 1,2,3,4-tetrachloro-9-(1-methyl-2-propenyl)triptycene, has a high barrier and the rotation occurs slowly at room temperature.[19]

Since the cation **5** is the direct precursor for the cyclization, the discussion of the possible conformation leading to **10** and **11** may deserve further mention. There are various conformations possible for **5** (Scheme 5).[20] Since the conformational energy of C^+–CH_3 inside forms (**5d—f**) are very high from the steric grounds,[21] their concentrations should be very low. In addition, the reactivities of the C^+–CH_3 inside forms are not apparently higher than the C^+–CH_3 outside conformations (**5a—c**). Thus the reaction paths through C^+–CH_3 inside conformations (**5d—f**) may be neglected. Of the important conformations (**5a—c**), **5a** leads to **11a** when it cyclizes and **5c** to **10b**, whereas **5b** conformation gives rise to **10a** and **11b**. On the grounds of the interaction between a cation and a peri-substituent (chloro group in this case),[9] the conformations **5a** and **5c** are considered to be more stable than **5b**. However, in

practice, **10b** has not been observed in the products. We may have to assume that the cyclization from conformation **5c** is extremely unfavorable. In contrast, **11a** was formed, although the yield was lower than those of **10a** and **11b**. This is probably attributed to two factors. The first is the fact that, in the transition state for the cyclization, the methyl and the chloro groups are eclipsing with each other for the formation of **10b**, whereas the eclipsing is between the chloro and hydrogen for the formation of **11a**. The second factor is that the conformation **5c** is so energy-rich, because two bulky groups are flanking the chloro group in the peri-position, that its population is scarce.[22] Conformation **5b**, on the other hand, is not stabilized by any of the apparent intramolecular interaction. Since the products which are led from this intermediate are main, the reaction rates of **5b** should be very large relative to others.

*Reactions of 1,2,3,4-Tetrachloro-(2-bromo-1,1-dimethylethyl)triptycene (**1b**) Rotamers.* Although a bromo compound is known to be a little more reactive than a corresponding chloro compound in substitution reactions, the *ap* form of **1b** also failed to give any reaction product when it was treated with titanium(IV) chloride. ±*sc*-**1b** reacted normally to give the *E*-olefin (**14**) and cyclized products (**10** and **11**). The reaction is considered to proceed as was discussed in that of **1a**.

Likewise, a reaction of *ap*-**1b** with silver nitrate in acetonitrile failed to give any product after heating at 50—60 °C for 3 h, whereas ±*sc*-**1b** was completely converted to olefins (**13** and **14**) under the conditions. It is interesting to note that an almost 1:1 mixture of *E* and *Z* olefins was formed by the action of silver nitrate on **1b**, whereas the action of titanium(IV) chloride afforded the *E*-olefin exclusively. The cause for this phenomenon is not well understood at the moment but the weak basicity[23] and the bulkiness of the pentachlorotitanate anion must be responsible for the observed results. In contrast the smaller size and the stronger basicity[23] of the nitrate anion in addition to the higher temperature used for the reaction would give less selectivity of the reaction.

Experimental

*9-(1-Methyl-1-propenyl)anthracene (**12**).* A solution of 10 g (39 mmol) of 9-bromoanthracene and 7.7 g (41.2 mmol) of 1,2-dibromoethane in 150 mL of ether was added 2.95 g (123 mmol) of magnesium, activated by iodine, in 20 mL of ether. The addition required 24 h. The reaction mixture was boiled for further 24 h and then a solution of 2.9 g (40.3 mmol) of 2-butanone in ether was added to the mixture over a period of 4 h. The mixture was stirred for 24 h and decomposed with aqueous ammonium chloride. The organic layer was separated, washed, dried, and then evaporated. After removing anthracene by taking up the mixture in benzene, the soluble part was chromatographed on silica gel (10:1 hexane-benzene) to afford 9-(1-hydroxy-1-methylpropyl)anthracene in 20.3% yield. ^{1}H NMR ($CDCl_3$, δ): 0.89 (3H, t, J=7.4 Hz), 1.95 (3H, s), 2.12 (1H, s), 0.98—2.02 (2H, m), 7.08—7.46 (4H, m), 7.65—8.06 (2H, m), 8.19 (1H, br s), 8.61—8.95 (2H, m).

The crude alcohol (1.0 g or 4.0 mmol) was heated with 1.0 g of phosphorus(V) oxide in 50 mL of carbon tetrachloride. The mixture was filtered and the filtrate was evaporated. The residue (0.75 g) consisted of 33:22:45 (*E*)- and (*Z*)-9-(1-methyl-1-propenyl)anthracenes and 9-(1-ethylvinyl)anthracene, as judged from a ^{1}H NMR spectrum. The mixture in 50 mL of carbon tetrachloride was boiled with 1 mL of trifluoroacetic acid for 2 d, washed with water and then with aqueous sodium hydrogencarbonate, and dried over magnesium sulfate. Evaporation of the solvent gave a 3.7:1 mixture of (*Z*)- and (*E*)-9-(1-methyl-1-propenyl)-anthracene (**12**), recrystallization of which from tetrahydrofuran–hexane afforded a 1.6:1 mixture of the *Z*- and *E*-olefins, mp 70—73 °C. Found: C, 93.24; H, 6.70%. Calcd for $C_{18}H_{16}$: C, 93.06; H, 6.94%. The following ^{1}H NMR data ($CDCl_3$, δ) have been recorded. *E*-isomer: 1.98 (3H, d, J=7.1 Hz), 2.14 (3H, d, J=1 Hz), 5.62 (1H, dq, J=7.1 and 1 Hz), 7.3—7.6 (4H, m), 7.8—8.3 (4H, m), 8.32 (1H, s). *Z*-isomer: 1.23 (3H, br d, J=7.0 Hz), 2.07 (3H, d, J=1 Hz), 6.08 (1H, dq, J=7.0 and 1 Hz), 8.35 (1H, s) and other aromatic protons (8H). The following ^{1}H NMR data of 9-(1-ethylvinyl)anthracene were obtained by subtracting the data of *E*- and *Z*-olefins from those of the mixture ($CDCl_3$, δ): 1.15 (3H, t, J=7.5 Hz), 2.55 (2H, br q, J=7.5 Hz), 5.18 (1H, m), 5.78 (1H, m), and aromatic protons (8H).

trans-*1,2-Dimethylaceanthrene (**7**) and 1,2-Dimethylaceanthrylene (**8**).* A mixture of 20 mL of concentrated sulfuric acid and a solution of 3.95 g of 9-(1-methyl-2-propenyl)anthracene[19] in 50 mL of carbon tetrachloride was stirred at room temperature for 1 h. The organic layer was washed with water and then with aqueous sodium hydrogencarbonate, and evaporated. The residue was chromatographed on silica gel with the use of hexane as an eluent. Crude *trans*-1,2-dimethylaceanthrene (**7**), which was contaminated by a small amount of *cis*-isomer, and 1,2-dimethylaceanthrylene (**8**) were obtained in 28.4 and 18.9% yields, respectively.

trans-*1,2-Dimethylaceanthrene (**7**).* High resolution MS exhibited a molecular ion peak at *m/e* 232.1247. $C_{18}H_{16}$ requires 232.1248. ^{1}H NMR ($CDCl_3$, δ): 1.29 (3H, d, J=7 Hz), 1.42 (3H, d, J=7 Hz), 3.18 (1H, q, J=7 Hz), 3.59 (1H, q, J=7 Hz), 8.10 (1H, s), 6.9—8.2 (7H, m).

*1,2-Dimethylaceanthrylene (**8**).* Mp 112.5—113.0 °C. Found: C, 93.94; H, 5.85%. Calcd for $C_{18}H_{14}$: C, 93.87; H, 6.12%. ^{1}H NMR ($CDCl_3$, δ): 2.32 (3H, d, J=1 Hz), 2.64 (3H, d, J=1 Hz), 8.25 (1H, s), 7.2—8.6 (7H, m).

cis-*1,2-Dimethylaceanthrene (**9**).* A solution of 0.7 g of 1,2-dimethylaceanthrylene (**8**) in 30 mL of ethyl acetate was shaken with 50 mg of 5% palladium on charcoal under a hydrogen atmosphere. The theoretical amount of hydrogen was absorbed within 3 h. The mixture was filtered and the filtrate was evaporated. Recrystallization of the residue from ethanol–hexane gave pure product, mp 79—80 °C, in 65% yield. Found: C, 93.06; H, 6.85%. Calcd for $C_{18}H_{16}$: C, 93.06; H, 6.94%. ^{1}H NMR ($CDCl_3$, δ): 1.26 (3H, d, J=7 Hz), 1.45 (3H, d, J=7 Hz), 3.77 (1H, quintet, J=7 Hz), 4.07 (1H, quintet, J=7 Hz), 8.09 (1H, s), 7.0—8.1 (7H, m).

9-(1-Methyl-1-propenyl)triptycene. A solution of 360 mg (2.0 mmol) of anthranilic acid in 10 mL of acetone was added in 1 h to 9-(1-methyl-1-propenyl)anthracene (*Z*/*E*=1.6) and 0.5 mL of isopentyl nitrite in 20 mL of dichloromethane under a nitrogen atmosphere. The solvents were removed by evaporation and 5 mL of ethanol was added to induce crystallization. The crystals were recrystallized from acetone–hexane. The product, mp 185—192 °C, consisted of 1:1.6 of *E* and *Z* isomers. Found: C, 93.49; H, 6.32%. Calcd for $C_{24}H_{20}$: C, 93.46; H, 6.54%. The

following ^{1}H NMR ($CDCl_3$, δ) spectral data were obtained. *E*-isomer: 2.07 (3H, br d, J=6.9 Hz), 2.25 (3H, br s), 5.29 (1H, s), 6.55 (1H, br q, J=6.9 Hz), 6.78—7.10 (6H, m), 7.25—7.63 (6H, m). *Z*-isomer: 0.95 (3H, dq, J=6.9 and 1 Hz), 2.73 (3H, br s), 5.27 (1H, s), 6.18 (1H, br q, J=6.9 Hz), 6.83—7.10 (6H, m), 7.22—7.73 (6H, m).

(Z)-1,2,3,4-Tetrachloro-9-(1-methyl-1-propenyl)triptycene (13). A similar treatment of 9-(1-methyl-1-propenyl)anthracene with tetrachlorobenzyne, generated from tetrachloroanthranilic acid,[24] afforded the crude triptycene. Column chromatography on alumina (10:1 hexane–dichloromethane) followed by recrystallization of the eluted product from acetone–hexane gave 100 mg of pure (*Z*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)triptycene, mp 239.5—240.5 °C. Found: C, 64.39; H, 3.34; Cl, 31.87%. Calcd for $C_{24}H_{16}Cl_4$: C, 64.61; H, 3.61; Cl, 31.78%. ^{1}H NMR ($CDCl_3$, δ): 0.91 (3H, br d, J=7.2 Hz), 2.68 (3H, br s), 5.89 (1H, s), 6.09 (1H, br q, J=7.2 Hz), 6.77—7.12 (4H, m), 7.22—7.51 (2H, m), 7.60—7.90 (2H, m).

trans-*1,2-Dimethyl-7,8,9,10-tetrachloro-1,2,6,10b-tetrahydro-6,10b-o-benzenoaceanthrylene (10).* This compound was prepared similarly from *trans*-1,2-dimethylaceanthrene (**7**) and tetrachlorobenzyne. After rough chromatography, the product consisted of 6:5 (1*SR*,2*SR*,10b*SR*) and (1*RS*,2*RS*,10b*SR*) isomers. Out of the mixture, one isomer crystallized out on standing. It was purified by recrystallization from hexane–ethanol. The pure compound, mp 265—266 °C, was assigned a (1*SR*,2*SR*,10b*SR*)-structure (**10a**) due to the NOE experiment. Found: C, 64.82; H, 3.42%. Calcd for $C_{24}H_{16}Cl_4$: C, 64.60; H, 3.62%. High resolution MS (M^+): 444.0011, 445.9942, 447.9951, 449.9950. $C_{24}H_{16}Cl_4$ requires 444.0002, 445.9973, 447.9943, and 449.9914. Intensities of the peaks agreed well with those calculated from natural abundance of ^{35}Cl and ^{37}Cl. ^{1}H NMR ($CDCl_3$, δ): 1.50 (3H, d, J=7 Hz), 2.19 (3H, d, J=7 Hz), 3.21 (1H, q, J=7 Hz), 3.83 (1H, q, J=7 Hz), 5.97 (1H, s), 6.8—7.5 (6H, m), 7.90 (1H, m). The (1*RS*,2*RS*,10b*RS*)-isomer (**10b**) could not be separated even by high performance liquid chromatography because its R_f value was too close to that of the (1*SR*,2*SR*,10b*SR*)-isomer. ^{1}H NMR ($CDCl_3$, δ): 1.40 (3H, d, J=7 Hz), 2.00 (3H, d, J=7 Hz), 6.05 (1H, s).

cis-*1,2-Dimethyl-7,8,9,10-tetrachloro-1,2,6,10b-tetrahydro-6,10b-o-benzenoaceanthrylene (11).* This compound was prepared as described in the preparation of the *trans*-isomer (**10**). One of the products crystallized out from the mixture, purified by recrystallization from hexane–ethanol and found to be (1*RS*,2*SR*,10b*SR*)-isomer (**11b**), mp 272.5—274.5 °C. Found: C, 64.63; H, 3.37; Cl, 31.68%. Calcd for $C_{24}H_{16}Cl_4$: C, 64.60; H, 3.62; Cl, 31.78%. ^{1}H NMR ($CDCl_3$, δ): 1.40 (3H, d, J=7 Hz), 1.55 (3H, d, J=7 Hz), 3.35 (1H, quintet, J=7 Hz), 3.83 (1H, quintet, J=7 Hz), 5.90 (1H, s), 6.8—7.6 (7H, m). The structural assignment based on the NOE experiment. The (1*SR*,2*RS*,10b*SR*)-isomer (**11a**) was separated as above and obtained as a solution of an almost pure material. ^{1}H NMR ($CDCl_3$, δ): 1.12 (3H, d, J=7 Hz), 2.11 (3H, d, J=7 Hz), 3.63 (1H, quintet, J=7 Hz), 4.48 (1H, quintet, J=7 Hz), 6.02 (1H, s), 6.8—7.5 (6H, m), 7.87 (1H, m). The original reaction mixture contained 3:2 (1*RS*,2*SR*,10b*SR*)- and (1*SR*,2*RS*,10b*SR*)-isomers.

Isomerization of 9-(1-Methyl-1-propenyl)triptycenes. A solution of 30 mg of 9-(1-methyl-1-propenyl)triptycene and 1 mmol of trifluoroacetic acid in 0.5 mL of chloroform-*d* was heated in a sealed tube at 90 °C. The isomerization was followed by ^{1}H NMR to show that the content was almost pure *E*-form after 50 h. The solvent was evaporated and the residue was purified by TLC (silica gel, 20:1 hexane–dichloromethane) to afford the pure *E*-form, mp 228 °C. Found: C, 93.28; H, 6.27%. Calcd for $C_{24}H_{20}$: C, 93.46; H, 6.54%.

Similarly the isomerization of (*Z*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)triptycene (**13**) was carried out. It took 30 days to obtain *E*/*Z* ratio of 10. The *E*-isomer (**14**) was obtained as a pure form on recrystallization from the tetrahydrofuran–hexane, mp 222—223 °C. High resolution MS (M^+): 443.9990, 445.9969, 447.9919, 449.9889. $C_{24}H_{16}Cl_4$ requires 444.0002, 445.9973, 447.9943, and 449.9914. Intensity ratios of these peaks were in good agreement with those calculated from the natural abundance of ^{35}Cl and ^{37}Cl. ^{1}H NMR ($CDCl_3$, δ): 2.00 (3H, br d, J=6.9 Hz), 2.11 (3H, br s), 5.85 (1H, s), 6.50 (1H, br q, J=6.9 Hz), 6.8—7.1 (4H, m), 7.2—7.5 (2H, m), 7.6—7.9 (2H, m).

Reaction of 1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene (1a) Rotamers in the Presence of a Large Excess of Lewis Acids. To a solution of 0.13 mmol of a mixture of ±*sc*- and *ap*-**1a** in 10 mL of benzene was added 0.2 mL (3.3 mmol) of titanium(IV) chloride and the mixture was left to stand for 18 h. The mixture was washed with water and the solvent was evaporated. A ^{1}H NMR spectrum of this residue showed that, whereas the ±*sc* form had completely reacted, the *ap* form remained almost unaltered. The residue was purified by thin layer chromatography on silica gel, hexane being used as an eluent, to give a mixture of stereoisomers of 1,2-dimethyl-7,8,9,10-tetrachloro-1,2,6,10b-tetrahydro-6,10b-*o*-benzenoaceanthrylene (**10** and **11**) in 52% yield. On standing the product fraction, a part solidified which was purified by recrystallization from hexane–ethanol, mp 272.5—274.5 °C. MS showed M^+ peaks at *m/e* 452, 450, 448, 446, and 444 to indicate that a hydrogen chloride molecule was lost from the starting material. It was identical with (1*RS*,2*SR*,10b*SR*)-1,2-dimethyl-7,8,9,10-tetrahydro-1,2,6,10b-tetrahydro-6,10b-*o*-benzenoaceanthrylene (**11b**). The original mixture of the product contained 45:≈0:10:45 **10a**, **10b**, **11a**, and **11b** as judged from its ^{1}H NMR spectrum.

ap-**1a** was treated similarly with an excess of antimony(V) chloride in benzene. The cyclized product was obtained in 71% yield and the composition of isomers was very close to, if not identical with, that obtained from the ±*sc* form of **1a**. Antimony(V) chloride also effected the same reaction of a mixture of ±*sc* and *ap*-**1a** to give the same mixture.

Reaction of 1,2,3,4-Tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene (1a) with Relatively Small Excess of Lewis Acid. A mixture (3:1) of ±*sc*- and *ap*-**1a** (60 mg or 0.12 mmol) in 0.4 mL of benzene-d_6 was mixed with 0.07 mL (1.1 mmol) of titanium(IV) chloride and the reaction was followed by ^{1}H NMR. It took 100 min for the reaction of ±*sc* form to proceed almost completely at room temperature under the conditions. The main product of the reaction was (*E*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)triptycene (**14**) in addition to a small amount of cyclized compounds (**10** and **11**).

Reaction of 1,2,3,4-Tetrachloro-9-(2-bromo-1,1-dimethylethyl)triptycene (1b) with Lewis Acids. A mixture of ±*sc*- and *ap*-**1b** (25.6 mg, *sc*/*ap* 6.0) in 10 mL of benzene was treated overnight with 0.05 mL of titanium(IV) chloride as above. The reaction gave the *E*-olefin (**14**) in addition to a small amount of the cyclized compounds (**10** and **11**). The *ap* form of **1b** was recovered over 90%.

A mixture (50 mg or 0.095 mmol) of ±*sc*- and *ap*-**1b** with 0.17 mmol of silver nitrate in 0.05 mL of acetonitrile-d_3 was heated at 50—60 °C for 3 h because the reaction

was slow at room temperature. The reaction mixture gave the olefins (**13**/**14**=1) and recovered *ap*-**1b**.

Cyclization of Olefins with Acids. A mixture (30 mg) of (*E*)- and (*Z*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)-triptycene was dissolved in 0.4 mL of chloroform-*d* and 0.05 mL of trifluoromethanesulfonic acid was added to the solution. The reaction was followed by ^{1}H NMR to show that it was complete within 5 min at room temperature. The product was a mixture of cyclized compounds (**10** and **11**) and the composition was quite similar with those obtained by other methods. The yield was *ca.* 70%.

Similarly 1,2,3,4-tetrachloro-9-(1-methyl-2-propenyl)triptycene (**15**) was treated with trifluoromethanesulfonic acid to afford 67% cyclized products (**10** and **11**). Titanium(IV) chloride could also effect cyclization of the olefin to give 71% cyclized products.

However, treatment of (*Z*)-1,2,3,4-tetrachloro-9-(1-methyl-1-propenyl)triptycene with trifluoroacetic acid resulted in formation of the *E*-form as stated above but failed to give cyclized products. Sulfuric acid-d_2 also failed to give cyclization products, although a mixture of the olefin and sulfuric acid-d_2 in $CDCl_3$–CD_3CN (3:1) was heated up to 90 °C.

Determination of Rates of Reactions. Reactions of 1,2,3,4-tetrachloro-9-(2-chloro-1,1-dimethylethyl)triptycene (**1a**) were carried out similarly as were described above, except using benzene-d_6 as a solvent and dioxane in a capillary tube as an external standard. Decrease in the amount of the starting material was followed by ^{1}H NMR spectroscopy. The data were treated by assuming that the reaction was of pseudo-first order since a large excess of the catalyst was employed.

Spectral Measurements. The normal ^{1}H NMR spectra were measured on either a Hitachi R-20B or Varian EM 390 spectrometer, operating at 60 and 90 MHz, respectively. With dilute solutions, a JEOL FX60 machine was used which was equipped with the FT facilities. For the NOE measurements of ordinary concentrations, the EM 390 spectrometer was used. A sample (25 mg) was dissolved in 0.3 mL of chloroform-*d*. Air in the sample tube was replaced by argon. The methyl signal appearing at a lower field was irradiated and the integration of a signal which was at the lowest field of the aromatic region was carried out. The integrated area was compared with that due to bridgehead proton appearing at δ *ca.* 6. For dilute solutions, data were accumulated for 500 times. Mass spectra were obtained with a Hitachi RMU-6L instrument and high resolution mass spectra with a JEOL JMS-D300.

High Pressure Liquid Chromatography. It was carried out with a Waters Model 6000A apparatus equipped with a UV detector. A microporasil column of 4 mm × 30 cm was used. The eluent was hexane. Although the peaks due to two isomers of **11** were not separated clearly, it was possible to shave the front part to give almost pure **11a**, as far as ^{1}H NMR spectra concerned. The overlap of peaks due to two isomers of **10** was so severe that it was impossible to concentrate **10b** by this method.

This work was supported by a grant from Toray Science Foundation to which our thanks are due.

11) σ-Participation in isomerization of neopentyl type cation now seems to be established: T. Ando, H. Yamataka, H. Morisaki, J. Yamawaki, J. Kuramochi, and Y. Yukawa, *J. Am. Chem. Soc.*, **103**, 430 (1981); V. J. Shiner, Jr., and J. J. Tai, *ibid.*, **103**, 436 (1981). However, we show the scheme with classical cations for the sake of simplicity.

12) The possibility that the triptycyl group migrates at the first stage cannot be ruled out, since **1a** takes most probably, the conformation in which the chloro group in the 9-substituent takes an outward position of the triptycyl group and a group anti to the leaving group is prone to migration in Wagner-Meerwein rearrangement. However, this is not our first choice for the mechanism for the following reasons. If it is the case the cation formed at the initial stage may be approximated by **16** which does not easily cyclize because of the steric effect of the *gem*-dimethyl group but isomerizes to **17** and then to **5**. If **16** were to intervene, there should be a strong possibility that a proton is lost from one of the methyls to lead to 9-(2-methyl-2-propenyl) compound, which was not actually found in the olefinic products.

Reactivities of Stable Rotamers. IX. Ionizing Reactions of 9-(2-Bromomethyl-6-methylphenyl)fluorene Rotamers[1]

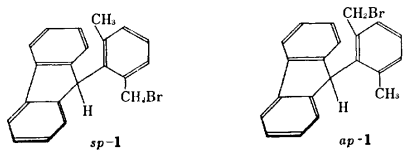
Shigeru MURATA, Seiichiro KANNO, Yo TANABE, Mikio NAKAMURA, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received October 6, 1981)

Ionizing reactions of *ap*-9-(2-bromomethyl-6-methylphenyl)fluorene in ionizing solvents afforded 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene and its dehydrogenated compound, whereas the *sp* isomer remained intact. Forced ionization of the *sp* isomer with silver salts afforded products originated from the corresponding cation and either the anion of the salt or the solvent, whereas the *ap* isomer gave cyclized product under the same conditions, if the nucleophilicity of the solvent was poor. The reaction of the *sp* isomer was faster than the *ap* in nucleophilic solvents, whereas the reverse was true for poorly nucleophilic solvents. Solvolysis of the rotamers in formic acid yielded the corresponding formates, the *sp* isomer reacting faster than the *ap*. The results are discussed on the basis that the solvation shell in the *ap* form is completed by the participation of the fluorene ring whereas in the *sp* form the shell is completed by the solvent molecules.

Some years ago successful isolation of *sp*- and *ap*-rotamers of 9-(2-bromomethyl-6-methylphenyl)fluorene (**1**) was reported from this laboratory.[2] Since then, reactivities of stable rotamers both in 9-arylfluorenes[3] and 9-substituted triptycenes[1,4] have been investigated. Some of the rotamers show striking differences in reactivities, although some showed differences by only small factors. These findings aroused our interests in investigating the differences in reactivities of *sp*-**1** and *ap*-**1**. Preliminary experiments of heating the isomers of **1** in trifluoroacetic acid revealed that the *ap* form reacted with a measurable rate at 62 °C whereas the *sp* remained intact.[5] In order to get into further insight, we have carried out a series of ionizing reactions of rotamers of **1**. This paper reports and discusses the results of such investigations, which show dramatic changes according to solvents used, in addition to the rotational barrier in **1**.



Experimental

9-(2-Bromomethyl-6-methylphenyl)fluorene Rotamers (1). To a boiling solution of 2.5 g (9.3 mmol) of 9-(2,6-dimethylphenyl)fluorene[6] in 100 mL of benzene was added 2.5 g (14 mmol) of *N*-bromosuccinimide and 170 mg of benzoyl peroxide in small portions during a period of 17 h. After filtration, the solvent was removed by evaporation and the residue was submitted to chromatography on silica gel, which used hexane as an eluent. The *sp* form was eluted first and the *ap* form followed. The separation of the isomers was more conveniently performed by using a Waters System 500 preparative liquid chromatographic apparatus, μ-porasil and hexane. In a typical run, 17% of *sp* and 6% of *ap* forms were obtained with 40% of the recovered starting material. The *sp* form, mp 115.0—115.5 °C. Found: C, 72.37; H, 4.76; Br, 23.06%. Calcd for $C_{21}H_{17}Br$: C, 72.22; H, 4.91; Br, 22.88%. ^{1}H NMR ($CDCl_3$, δ): 1.12 (3H, s), 4.83 (2H, s), 5.60 (1H, s), 6.8—7.9 (11H, m). The *ap* form, mp 125.0—126.0 °C. Found: C, 72.40; H, 4.74; Br, 23.06%. Calcd for $C_{21}H_{17}Br$: C, 72.22; H, 4.91; Br, 22.88%. ^{1}H NMR ($CDCl_3$, δ): 2.70 (3H, s), 3.37 (2H, s), 5.52 (1H, s), 7.0—8.0 (11H, m).

9-[2,6-Bis(bromomethyl)phenyl]fluorene, mp 143—144 °C, was obtained as a byproduct which was eluted later than the monobromo compounds in the chromatography. Found: C, 58.83; H, 3.54; Br, 37.65%. Calcd for $C_{21}H_{16}Br_2$: C, 58.91; H, 3.77; Br, 37.32%. ^{1}H NMR (CCl_4, δ): 3.22 (2H, s), 4.72 (2H, s), 5.50 (1H, s), 7.0—8.0 (11H, m).

Rates of Rotation. Either one of pure *sp* and *ap* isomers was dissolved in hexachlorobutadiene and the solution was heated by immersing it in an appropriate boiling solvent bath. The decrease in the amount of the starting material and/or the increase in the amount of the other isomer was monitored by ^{1}H NMR spectroscopy. Equilibrium constants were obtained at the temperature by heating the solution for a long enough time and were found to be invariant at $sp/ap = 3.6 \pm 0.2$ throughout the temperature range examined. The same equilibrium constants were obtained by starting from either of the isomers. The rate constants were obtained by utilizing the following equation (1), where K is now known, a is the initial amount and x the amount at time t, by assuming the first order reaction. The plot gave very good straight lines.

$$\ln\left\{1-\left(1+\frac{1}{K}\right)\frac{a}{x}\right\} = -k\left(1+\frac{1}{K}\right)t \qquad (1)$$

Putting these k's into the Arrhenius and the Eyring equations, we obtained the activation parameters.

Reaction of 1 with Silver Nitrate in Acetonitrile. To a solution of 22 mg (0.06 mmol) of *sp*-**1** in 2 mL of acetonitrile, 10 mg (0.06 mmol) of silver nitrate in 1.0 mL of acetonitrile was added. The whole was allowed to react for 30 min at 50 °C. The reaction mixture was filtered and the filtrate was evaporated. Recrystallization of the residue from ethanol afforded 20 mg (90%) of *sp*-2-(9-fluorenyl)-3-methylbenzyl nitrate, mp 104 °C. Found: C, 76.19; H, 5.03; N, 4.18%. Calcd for $C_{21}H_{17}NO_3$: C, 76.12; H, 5.17; N, 4.23%. ^{1}H NMR ($CDCl_3$, δ): 1.16 (3H, s), 5.32 (1H, s), 5.80 (2H, s), 7.0—7.9 (11H, m). IR (KBr disk): 1628, 1278, 842 cm^{-1}.

ap-**1** similarly gave *ap*-2-(9-fluorenyl)-3-methylbenzyl nitrate, mp 128 °C. Found: C, 75.97; H, 4.97; N, 4.30%. Calcd for $C_{21}H_{17}NO_3$: C, 76.12; H, 5.17; N, 4.23%. ^{1}H NMR ($CDCl_3$, δ): 2.75 (3H, s), 4.22 (2H, s), 5.56 (1H, s), 7.0—8.0 (11H, m). IR (KBr disk): 1617, 1280, 875 cm^{-1}.

Reaction of 1 with Silver Perchlorate in Acetonitrile. The reaction was carried out similarly as above except using silver perchlorate instead of silver nitrate and treating the reaction mixture as follows. The reaction mixture was

treated with 5% aqueous lithium chloride. Ether was added and the mixture was filtered to remove insoluble materials. The ether layer was separated and the aqueous layer was extracted with ether. The combined ether layer was washed, dried, and evaporated. The residue was recrystallized from hexane–ethanol.

sp-**1** gave *sp*-9-(2-acetamidomethyl-6-methylphenyl)-fluorene, mp 194 °C, in 70% yield. Found: C, 84.17; H, 6.31; N, 4.29%. Calcd for $C_{23}H_{21}NO$: C, 84.37; H, 6.46; N, 4.28%. ^{1}H NMR ($CDCl_3$, δ): 1.13 (3H, s), 1.96 (3H, s), 4.76 (2H, d, J=5.4 Hz), 5.37 (1H, s), 5.7 (1H, br s), 6.8—8.0 (11H, m). IR (KBr disk): 3240, 1635, 1550 cm^{-1}.

ap-**1** gave *ap*-9-(2-acetamidomethyl-6-methylphenyl)-fluoene, mp 188 °C, in 50% yield. Found: C, 84.23; H, 6.24; N, 4.37%. Calcd for $C_{23}H_{21}NO$: C, 84.37; H, 6.46; N, 4.28%. ^{1}H NMR ($CDCl_3$, δ): 1.46 (3H, s), 2.73 (3H, s), 3.23 (2H, d, J=6.3 Hz), 4.1 (1H, br s), 5.54 (1H, s), 7.0—8.0 (11H, m). IR (KBr disk): 3270, 1640, 1550 cm^{-1}.

Reaction of **1** *with Silver Perchlorate in Benzene.* The reaction was carried out similarly with that in acetonitrile except that benzene was used as a solvent and the reaction mixture was allowed to stand overnight at 22 °C.

sp-**1** afforded *sp*-9-(2-benzyl-6-methylphenyl)fluorene, mp 105 °C, as a sole product in 64% yield. Found: C, 93.50; H, 6.20%. Calcd for $C_{27}H_{22}$: C, 93.60; H, 6.40%. ^{1}H NMR ($CDCl_3$, δ): 1.10 (3H, s), 4.37 (2H, s), 5.45 (1H, s), 6.8—7.9 (16H, m).

Formation of bis[*sp*-2-(9-fluorenyl)-3-methylbenzyl] ether (see below) was detected during the reaction but this compound subsequently reacted under the reaction conditions to afford *sp*-9-(2-benzyl-6-methylphenyl)fluorene.

ap-**1** afforded 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene, which was characterized in the section of the reaction in trifluoroacetic acid, and *ap*-9-(2-benzyl-6-methylphenyl)-fluorene, mp 143 °C, in 1:12 ratio. Found: C, 93.76; H, 6.22%. Calcd for $C_{27}H_{22}$: C, 93.60; H, 6.40%. ^{1}H NMR ($CDCl_3$, δ): 2.67 (2H, s), 2.69 (3H, s), 5.54 (1H, s), 6.5—7.9 (16H, m).

Bis[sp-*2-(9-fluorenyl)-3-methylbenzyl*] *Ether.* A mixture of 15 mg of *sp*-**1** in 2.6 mL of benzene and 17.8 mg of silver perchlorate in 1.7 mL of benzene containing *ca.* 10 μL of water was stirred for 30 h at room temperature and then was heated at 50 °C for 30 min. To the cooled mixture, 3.5 mL of methanol and then 5% aqueous lithium chloride were added. Silver salts were removed by filtration and the organic products were collected. Preparative TLC on silica gel (3:1 hexane–benzene) afforded *ca.* 4 mg of the desired ether, which was recrystallized from benzene–ethanol, mp 192—193 °C, and small amounts each of *sp*-9-(2-methoxymethyl-6-methylphenyl)fluorene (see below) and *sp*-(2-benzyl-6-methylphenyl)fluorene. Found: C, 91.23; H, 5.88%. Calcd for $C_{42}H_{34}O$: C, 90.94; H, 6.18%. MS (M$^+$): 554. ^{1}H NMR ($CDCl_3$, δ): 1.12 (6H, s), 4.98 (4H, s), 5.64 (2H, s), 6.8—7.9 (22H, m).

9-(2-Hydroxymethyl-6-methylphenyl)fluorene. To a solution of 60 mg (0.17 mmol) of *sp*-**1** in 6 mL of acetone was added a solution of 106 mg (0.51 mmol) of silver perchlorate in 1 mL of water. The mixture was stirred for 10 min at room temperature in dark, and then warmed at 50 °C for 10 min. After silver bromide was removed by filtration, the reaction product was precipitated by addition of water and extracted with ether. The extract was washed with water, dried, and evaporated. The residue was developed on a preparative TLC plate (1:4 hexane–benzene) to give 40 mg (81%) of *sp*-9-(2-hydroxymethyl-6-methylphenyl)-fluorene, mp 74—75 °C, which was recrystallized from hexane. Found: C, 88.17; H, 6.21%. Calcd for $C_{21}H_{18}O$: C, 88.08; H, 6.34%. ^{1}H NMR ($CDCl_3$, δ): 1.12 (3H, s), 1.8 (1H, br s), 5.02 (2H, s), 5.59 (1H, s), 6.8—7.9 (11H, m).

Solvolysis of **1** *in Formic Acid.* A solution of 29 mg of *sp*-**1** in 3 mL of chloroform and 20 mL of formic acid was heated at 50—60 °C for 24 h and poured into water. The organic materials were extracted with ether and the ether extract was washed and dried. After evaporation of the solvent, the residue was developed on a preparative TLC plate (1:2 hexane–benzene) to give *ca.* 80% *sp*-2-(9-fluorenyl)-3-methylbenzyl formate, oil. High resolution MS (M$^+$): 314.1314. Calcd for $C_{22}H_{18}O_2$: 314.1307. ^{1}H NMR ($CDCl_3$, δ): 1.12 (3H, s), 5.37 (1H, s), 5.54 (2H, s), 6.8—8.0 (11H, m), 8.14 (1H, s). IR (neat): 1722, 1150 cm^{-1}.

Similarly, *ap*-**1** afforded *ca.* 80% *ap*-2-(9-fluorenyl)-3 methylbenzyl formate, mp 106 °C, which was recrystallized from pentane–ethanol. Found: C, 84.02; H, 5.50%. Calcd for $C_{22}H_{18}O_2$: C, 84.05; H, 5.77%. ^{1}H NMR ($CDCl_3$, δ): 2.75 (3H, s), 3.97 (2H, s), 5.53 (1H, s), 6.9—8.0 (12H, m). IR (KBr disk): 1716, 1178 cm^{-1}.

Reaction of **1** *Caused by Heating a Trifluoroacetic Acid (TFA) Solution.* A solution of 33 mg of *ap*-**1** in 1.5 mL of chloroform was added to 25 mL of TFA. The whole solution was heated at 60 °C for 6 h. The mixture was poured into water and then extracted with chloroform. After the usual treatment, the products were purified by silica gel TLC (hexane) to afford 8 mg (32%) of 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene, mp 180—181 °C, after recrystallization from benzene–ethanol. Found: C, 94.23; H, 5.78%. Calcd for $C_{21}H_{16}$: C, 93.99; H, 6.01%. ^{1}H NMR ($CDCl_3$, δ): 2.48 (3H, s), 3.99 (1H, d, J=16.4 Hz), 4.14 (1H, dd, J=16.4 and 2.3 Hz), 4.80 (1H, d, J=2.3 Hz), 6.9—8.1 (10H, m). MS (M$^+$): 268.

The product was always accompanied by 12-methylbenz[*a*]aceanthrylene which was eluted before the dihydro compound. Preparation of the dehydrogenated compound is described below. This dehydrogenation seemed to be effected by atmospheric oxygen, since careful exclusion of oxygen decreased the amount of this product, increasing the yield of the dihydro compound.

The concentration of *ap*-**1** in trifluoroacetic acid plays an important role in determining the yield of the cyclized product. Heating a solution of 80 mg of *ap*-**1** in 5 mL of chloroform and 15 mL of TFA gave at least 10 spots in TLC, although the cyclized product was main, and a more concentrated solution, which was convenient for the routine ^{1}H NMR measurement, than this afforded only polymers.

sp-**1** did not apparently react under the similar conditions. Heating a solution of 20 mg of *sp*-**1** in 0.1 mL of chloroform and 0.4 mL of TFA at 62 °C for 40 h gave only the recovered starting material.

12-Methylbenz[a]*aceanthrylene.* A solution of 6 mg of 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene in 1 mL of benzene was mixed with 6 mg of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in benzene. The mixture was stirred for 1 h at room temperature and then heated at 50 °C for 1 h. The hydroquinone produced in the reaction was removed by passing the solution through a column of 200 mg of silica gel. The filtrate and washings (1:1 hexane–benzene) were combined and evaporated to give the desired compound, orange oil, in an almost quantitative yield. High resolution MS (M$^+$): 266.1106. $C_{24}H_{14}$ requires M$^+$ 266.1095. ^{1}H NMR ($CDCl_3$, δ): 3.17 (3H, s), 7.2—8.5 (11H, m). UV (EtOH, λ_{max} in nm and log ε in parentheses): 430 (3.65), 366 (3.40), 260 (4.54).

Reaction of **1** *Caused by Heating a 1,1,1,3,3,3-Hexafluoro-2-propanol (HFP) Solution.* A solution of 10 mg of *ap*-**1**

in 0.3 mL of chloroform and 15.6 mL of HFP was heated at 50—55 °C for 4 h. The reaction product was similarly treated as above to give 65—75% 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene. The dehydrogenated product was detected only in a trace amount.

Under the similar conditions, *sp*-**1** was completely recovered.

Reaction of **1** *in HFP with Silver Perchlorate.* A heterogeneous mixture of 10 mg of *ap*-**1** in 0.6 mL of chloroform and 15.6 mL of HFP and *ca.* 3 equiv. of silver perchlorate was stirred at 20 °C for 5 h. The mixture was treated with methanol to decompose any of the possible perchlorate still present. After the usual treatment, 3 mg (40%) of 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene was obtained. No methoxy compound was detected.

Similar treatment of *sp*-**1** afforded 30% *sp*-(2-methoxymethyl-6-methylphenyl)fluorene (for the characterization, see below). No cyclized product was obtained.

Reaction of **1** *in TFA with Silver Perchlorate.* This reaction was performed similarly as above. The *ap* form gave the cyclized product, whereas the *sp* form afforded the methoxy compound only.

9-(2-Methoxymethyl-6-methylphenyl)fluorene Rotamers. To a solution of 25 mg (0.07 mmol) of *sp*-**1** in 0.4 mL of chloroform and 5 mL of methanol, was added a solution of 56 mg (0.27 mmol) of silver perchlorate in 2 mL of methanol. The mixture was allowed to stand for 10 min at room temperature in dark. Silver bromide was removed by filtration and the filtrate was poured into water. The mixture was extracted with dichloromethane. The extract was washed, dried, and evaporated to give a colorless oil. High resolution MS (M^+): 300.1497. $C_{22}H_{20}O$ requires 300.1512, ^{1}H NMR ($CDCl_3$, δ): 1.12 (3H, s), 3.44 (3H, s), 4.76 (2H. s), 5.56 (1H, s), 6.8—7.9 (11H, m).

Similarly, *ap*-9-(2-methoxymethyl-6-methylphenyl)fluorene (recrystallized from ethanol), mp 118 °C, was obtained from *ap*-**1**. Found: C, 88.11; H, 6.66%. Calcd for $C_{22}H_{20}O$: C, 87.96; H, 6.71%. ^{1}H NMR ($CDCl_3$, δ): 2.56 (3H, s), 2.71 (3H, s), 3.14 (2H, s), 5.48 (1H, s), 6.9—8.0 (11H, m).

Reaction of **1** *in TFA–CH_3OH–$CHCl_3$ or HFP–CH_3OH–$CHCl_3$.* The reaction was similarly carried out as for those without methanol, except 3 (v/v)% methanol was added to TFA or HFP prior to the mixing. *ap*-**1** afforded 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene and its dehydrogenated compound in both systems. *sp*-**1** was recovered unchanged in TFA, whereas it gave *sp*-9-(2-methoxymethyl-6-methylphenyl)fluorene in HFP. When *sp*-**1** in TFA–CH_3OH–$CHCl_3$ was heated, only polymers were obtained.

Competitive Reactions. A typical procedure follows. To a solution of 6.0 mg (17 μmol) of *sp*-**1**, the same amount of *ap*-**1** and 2.9 mg of fluorene in 1 mL of acetonitrile was added a solution of 3.0 mg (17 μmol) of silver nitrate. The mixture was stirred for 40 min at 25 °C. An excess amount of aqueous lithium chloride was added and the precipitate was removed by filtration. The amount of unreacted material was measured with the use of a Waters M-6000A high pressure liquid chromatograph which was equipped with a UV detecter. Fluorene which had been added to the original mixture served as an internal standard. The relative reactivity was calculated by applying the following equation (2).

$$k_{sp}/k_{ap} = \log \frac{[sp]}{[sp]_0} \Big/ \log \frac{[ap]}{[ap]_0}, \qquad (2)$$

where subscript 0 denotes the initial concentration.

In the cases of other competitive reactions, the solvent systems quoted in the independent reactions for the respective rotamers were used. The amount of the substrate and a silver salt was kept equimolar in every reaction. Solvolytic reactions were also carried out similarly.

Spectral Measurements. ^{1}H NMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz or on a Varian EM390 spectrometer operating at 90 MHz. A detailed spectrum of 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene was obtained with a Bruker 270 MHz machine. IR and UV spectra were obtained with a Hitachi IR-260-30 spectrometer and a Hitachi UV-340 spectrometer, respectively. High resolution mass spectra were recorded on a JEOL D-300 machine.

Table 1. Rate constant for isomerization of 9-(2-bromomethyl-6-methylphenyl)fluorene rotamers in hexachlorobutadiene

Temperature/°C	$k_{sp\to ap}/10^{-6}$ s^{-1}	$k_{ap\to sp}/10^{-5}$ s^{-1}
80	1.0	0.36
100	6.4	2.3
111	19	6.9
121	57	21

Table 2. Activation parameters for internal rotation in 9-(2-bromomethyl-6-methylphenyl)-fluorene and in 9-(2-methyl-1-naphthyl)fluorene

	9-(2-Bromomethyl-6-methylphenyl)-fluorene[c]		9-(2-Methyl-1-naphthyl)-fluorene[d] (both direction same)
	sp→*ap*	*ap*→*sp*	
E_a/kcal mol^{-1} [a]	27.0	27.1	29.8
log A/s^{-1}	10.7	11.3	12.9
ΔH^*/kcal mol^{-1} [a]	26.2	26.3	29.9
ΔS^*/e. u.[b]	−12.2	−9.3	0.4
ΔG^*_{373}/kcal mol^{-1} [a]	30.7	29.8	29.8

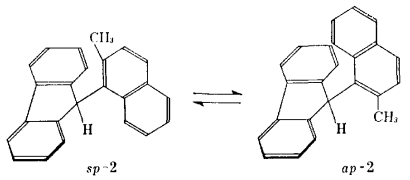
a) 1 cal=4.18 J. b) 1 e. u.=4.18 J K^{-1} mol^{-1}. c) Hexachlorobutadiene solvent. d) Tetrachloroethylene solvent.

Results and Discussion

Rotational Barriers and Rotamer Populations. Assignment of the stereochemistry of the rotamers were performed by taking the ring current effect of the fluorene ring in ^{1}H NMR spectra into account. In the *sp* conformation, the CH_2Br group is in the shielding zone of the benzene ring, whereas the methyl group is in the deshielding zone. In contrast, the CH_2Br group in the *ap* conformation is in the deshielding zone and the methyl group is in the shielding. Thus the methyl and the methylene protons in the *ap* form show a very large difference in chemical shifts, whereas those in the *sp* show a small chemical shift difference.

Results of the kinetic measurements are summarized in Table 1. Putting these rate constants into the Arrhenius equation, we obtain E_a and log A as shown in Table 2 which summarizes ΔH^* and ΔS^* obtained by putting the rate constants into the Eyring equation as well, together with the free energies of activation for rotation at 373 K. Table 2 also contains activation parameters for rotation in 9-(2-methyl-1-

naphthyl)fluorene (**2**) for comparison: the data by the Arrhenius plot were obtained by Siddall and Stewart[6b] and those by the Eyring plot were calculated by us, using the reported rate constants.[6b]



sp-2 *ap*-2

The barrier to rotation in 9-(2,6-dimethylphenyl)-fluorene was predicted to be over 25 kcal/mol on the basis of dynamic NMR study.[7] The present results conform with this expectation. Comparison of the rate constants of internal rotation in compound **2** with those in compound **1** shows interesting trends: At low temperatures, the rotation in compound **2** is relatively slow whereas that in compound **1** is definitely slower than that in the naphthyl compound (**2**) at higher temperatures. On close examination, one notices that the enthalpy of activation and Arrhenius activation energy are definitely larger for compound **2** than those for compound **1**. The slow rotation in compound **1** at the higher temperature is attributed to large negative entropy of activation. This point deserves further mention.

The steric effect of a methyl group given to its ortho position in a substituted phenyl system is often comparable with that of the peri-CH group given to the 1-position of a naphthalene system. As far as we discuss the enthalpy of activation and the Arrhenius activation energy, this general trend is not held here. We may have to admit that the rigidity of the molecule has a profound effect on the enthalpy of activation in 9-arylfluorene systems: Being more rigid than the 2,6-dimethylphenyl group, the 2-methyl-1-naphthyl group will give severer interactions in the transition state for rotation with the fluorene. The effect of the bromo group in **1** may be neglected in discussion, since substitution of a substituent for hydrogen in a methyl group is normally quoted as increasing the size of the whole substituent (however, *vide infra*).

The role of entropy of activation in realizing almost the same free energies of activation for rotation for both systems in the vicinity of 100 °C is thus important. Namely, the negative entropy of activation for rotation in compound **1** makes a contrast with the entropy of activation for **2** which is almost zero. On one hand, we may attribute this outcome to the effect of solvation: in the ground state, the solvation is more difficult than in the transition state for rotation in **1** because of the steric effect. Thus entropy is decreased in the transition state relative to the ground state due to the loss of freedom in the motion of solvent molecules.

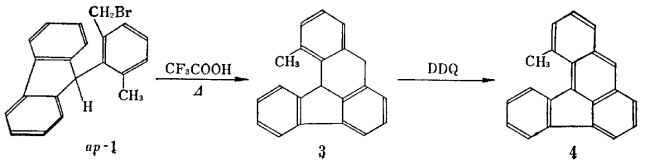
On the other hand, the freedom of internal rotation of the CH_2Br group must be considered. Entropy will be decreased when the *sp* form approaches the transition state for rotation from the ground state, because the conformation in the transition state is limited whereas the conformations in the ground state are not. But the decrease in entropy is not certain in the *ap* conformation, because, in its ground state, the possible conformations are also limited due to the steric interaction between the bromo group in the CH_2Br and the fluorene moiety: If the bromo group takes certain positions in possible conformations, the strain will be prohibitively strong.

Summation of these effects together with other unknown factors contributes to the observed entropy change. The results suggest therefore that comparison of the amount of free energies should be made carefully when hydrocarbons and their substituted derivatives are involved.

As for the distribution of *sp* and *ap* conformers at equilibrium, the *sp* form is favored by a factor of 3.6. This is usually attributed to the size of the substituent by saying that the bromomethyl group is larger than a methyl. However, if one compares the size of CH_2Br with CH_3 in the part of direct interactions, one notices that it is the CH_2 in both cases that is responsible because, in the CH_2Br group, the bromine atom is too large to direct toward the fluorene ring. We may attribute this difference in populations to the effect of entropy and/or the solvation effect. Entropy in the *ap* does decrease relative to the *sp* form because of the restriction of some rotamers. Formation of a solvation shell cannot be completed with the solvent molecules only in the *ap* conformation because of the steric effect. The invariance in the equilibrium constants throughout the temperature range suggests that the entropy factor controls equilibrium.

From the barriers to rotation, one calculates that the time necessary for conversion of 5% of the *sp* isomer to the *ap* at 80 °C is *ca.* 1×10^4 s: The limit of errors in NMR spectroscopy to detect a molecular species is considered to be at this level. The reaction conditions used in bromination exceed this limit, yet the reaction period is not long enough to reach equilibrium. Therefore the formation ratio (*sp*/*ap*=2.2—2.7) clearly shows that the *sp* methyl is kinetically favored in bromination. Since there is no apparent strong electronic effects which favor the bromination of the *sp*-methyl, we may attribute this result to the steric effects: the direction of attack on the *ap*-methyl is limited because, at least, one side of the methyl group is blocked by the fluorenyl group.

Products from ap-**1** *Heated in Trifluoroacetic Acid (TFA).* When a solution of *ap*-**1** in TFA–$CHCl_3$ was heated at 62 °C, the products were dependent on the concentration. If the concentration was high, the products were polymer mixtures. If the concentration was lowered, however, a compound was obtained in a pure state. Its MS and elemental analyses were consistent with the formula in that a molecule of hydrogen bromide was lost from the starting material. The most probable structure of the product is 12-methyl-8,12b-dihydrobenz[*a*]aceanthrylene (**3**), of



ap-1 3 4

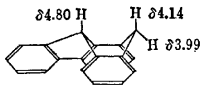
TABLE 3. DEPENDENCE OF DISTRIBUTION OF PRODUCTS IN THE REACTION OF *ap*-**1** WITH SILVER PERCHLORATE IN BENZENE

Reaction conditions		Products[a]			**7**/(**3**+**4**)
Temperature/°C	Duration/h	*ap*-**7**	**3**	**4**	
70	0.7	4.22	1.0	0.28	3.2
50	2.0	5.23	1.0	0.07	4.9
20	23	13.1	1.0	0.14	11.5

a) The product distribution is shown in relative amounts, taking the amount of **3** as reference.

which formation is rationalized by considering the ionization at the CH_2Br group followed by a Friedel-Crafts type cyclization.

^1H NMR spectral data are consistent with the structure. Long-range couplings in the 9,10-dihydroanthracene structure have been known,[8] and the coupling constants are in the order $J_{aa}>J_{ae}>J_{ee}$, where subscripts a and e denote axial and equatorial hydrogens, respectively. In the present compound, the hydrogen in the 12b position is fixed in the axial direction because of the ring structure. Therefore the proton signal which is located at a lower field and shows a coupling constant 2.3 Hz is assigned to the axial proton in the 8-position, as shown in the scheme.



a perspective of 3

When **3** was dehydrogenated with DDQ, a colored hydrocarbon was obtained. This latter compound (**4**) showed absorption maxima at 260, 366, and 430 nm in a UV-VIS spectrum which are very close to those of a known benz[*a*]aceanthrylene skeleton.[9] The UV-VIS data give further confirmation of the structure of the product in the TFA treatment.

Compound **3** was always accompanied by **4** in the reaction in TFA. However, the amount of **4** could be reduced appreciably when atmospheric oxygen was carefully purged.

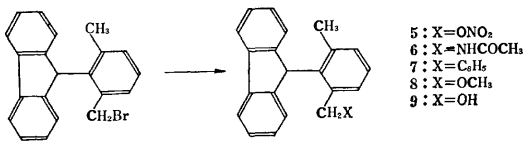
Reaction of ***1*** *with Silver Salts.* In the heating experiment of a TFA solution of *sp*-**1** no reaction was detected although the solution was heated at 62 °C for 40 h. If the ring system is rigid, there should be formed a diastereomer from the *sp* form by a similar ring closure. In order to explore the possibility, several reactions of *sp*-**1** and *ap*-**1** with silver salts were investigated.

Silver salts are often used for forced ionization of organic halides. Because of the complexity derived by the catalytic action of silver halide, the reaction machanism is not well understood: Pocker *et al.* found the reaction of silver nitrate to be of 2.5th order[10] and Kevill *et al.* carried out some detailed investigations on the reaction of allyl chlorides with silver nitrate.[11] These authors suggest that the reaction proceeds with the intermediacy of ion pairs. In spite of these difficulties, silver nitrate is the most handy reagent for the ionization of organic halides from the stand point of synthesis. We therefore used silver nitrate at the outset.

To our surprise, both isomers gave the corresponding nitrate esters (**5**) in good yields. It is especially interesting in that the *ap* isomer gave the nitrate instead of the cyclized product (**3**). Probably the nucleophilicity of the nitrate anion is so high[12] that the ion pair collapses before the internal rotation, which is necessary for the ring closure, takes place.

In order to lower the nucleophilicity of the anion present in the system, silver perchlorate was used, although we cannot avoid the complexity of the reaction mechanism by using the perchlorate salt.[13]

The reaction of *sp*-**1** and *ap*-**1** with silver perchlorate in acetonitrile gave, after treatment of the reaction mixture with water, the corresponding acetamido derivatives (**6**) which were expected if the Ritter type reaction[14] should take place. The results suggest that acetonitrile is nucleophilic enough to react with carbocations in this system. Since no cyclization product was found from *ap*-**1**, the reaction of the carbocation with acetonitrile is by far the more favored process than the cyclization to afford **3**.



The reaction of *ap*-**1** with silver perchlorate in benzene afforded *ap*-9-(2-benzyl-6-methylphenyl)fluorene (*ap*-**7**) and the cyclized product (**3**) in a 12:1 ratio; apparently the intermolecular Friedel-Crafts reaction is favored over the intramolecular reaction. The intermediacy of a common species is apparent from the temperature dependence of the product ratio. As shown in Table 3, the formation of the cyclized product (**3**) becomes relatively favored as the temperature is raised, though it does never become a main reaction.

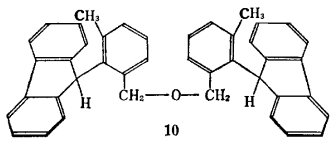
Although Pocker and Kevill[15] showed that organic perchlorate can survive for some time in a nonpolar solvent such as benzene, no trace of a product which might be derived from the perchlorate and water was detected under the conditions. However, the long lifetime of the perchlorate could be reproduced as follows. Whereas both *ap*-**1** and *sp*-**1** in benzene reacted very rapidly with silver perchlorate at room temperature to produce silver bromide precipitate, 9-(2-methoxymethyl-6-methylphenyl)fluorene (**8**) with retention of the stereochemistry was formed on addition of methanol after 2—3 h together with 9-(2-benzyl-6-methylphenyl)fluorene (**7**).

Table 4. Relative reactivity of *sp*-**1** and *ap*-**1** under ionizing conditions

Silver salt	Solvent	Concn/mM		Temp °C	Reaction period	k_{sp}/k_{ap}	k_{bz}/k_{sp}[c]
		Substrate	Silver salt				
$AgNO_3$	CH_3CN	9	9	25	40 min	5.9	0.36
$AgClO_4$	CH_3CN	9	9	60	20 h	1.3	0.21
$AgClO_4$	C_6H_6	10	20	22	2 h	1.6	*ca.* 34
$AgClO_4$	HFP[a]	0.8	b)	14	72 min	0.78	—
$AgClO_4$	TFA[a]	0.8	b)	25	13 min	0.94	—

a) These solvents contain *ca.* 5 (v/v)% chloroform. b) Heterogeneous reactions. c) k_{bz}/k_{sp} denotes the relative reactivity of benzyl bromide, taking the reactivity of *sp*-**1** as a reference.

Though not found after the reaction period of 23 h, bis[*sp*-2-(9-fluorenyl)-3-methylbenzyl] ether (**10**) was detected when the reaction mixture from *sp*-**1** and silver perchlorate was treated with methanol after a few hours. This product is derived from water which is present within the reaction system, because careful drying of the reagent and the solvent decreased the amount of the ether (**10**). No such ether was detected when *ap*-**1** was treated similarly. This difference, together with the unusuality discussed below, led us to believe that water or the benzyl alcohol (**9**) derived from *sp*-**1** and water is strongly adsorbed on the silver bromide surface where the formation reaction of **10** takes place.



10

During the reaction of *sp*-**1** with silver perchlorate in benzene, the formation of the corresponding benzyl alcohol (**9**) was detected, if water was intentionally added. However, an attempted coupling of the benzyl alcohol (**9**) in the presence of concentrated sulfuric acid did not give any of **10** but led to the formation of polymers. Neither an attempted Williamson synthesis of **10** from *sp*-**1** and the *sp*-alcohol (**9**) in DMF in the presence of silver oxide succeeded. Feasibility of the reaction occurring on the surface of silver bromide is supported also if one considers the concentration of water or the benzyl alcohol (**9**) in the system: if the reaction is to occur in solution, the concentration of the substrate may be prohibitively low. The disappearance of the ether (**10**) in the reaction products after 23 h must be ascribed to the possibility that the ether (**10**) is cleaved by perchloric acid which is formed as a result of the Friedel-Crafts reaction.

TFA is known to be little nucleophilic[16] and 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) is even less nucleophilic.[17] Therefore, in these solvents, the reaction with solvent molecules is practically prohibited. In order to explore further the feasibility of the ring closure of *sp*-**1**, the ionization of *sp*-**1** in these solvents were investigated with the aid of silver perchlorate. Silver perchlorate is not appreciably soluble in these solvents: the reaction had to be carried out in heterogeneous systems. If the reaction was carried out at room temperature, the corresponding perchlorate ester (or perchlorate ion pair or trifluoroacetate ion pair) survived until more nucleophilic reagent was added. Thus the *sp* isomer of the methoxy compound (**8**) was the sole product when methanol was added. When the reaction mixture was heated, only polymers resulted. *ap*-**1**, under the similar conditions, reacted to give the cyclic compound (**3**) in good yields. Thus it becomes apparent that the *ap* isomer cyclized easily whereas the *sp* isomer gave only polymers if the cation is forced to develop.

A rationale for the apparent difference in reactivity of *ap*-**1** and *sp*-**1** may be given in the following way. As has been pointed out, the internal rotation is necessary to form the cyclized product (**3**): The barrier to rotation is over 25 kcal/mol. This may be the reason why even poorly nucleophilic benzene can react with *ap*-**1** to produce *ap*-**7** in the presence of silver perchlorate, in competition with the benzene ring in the fluorene moiety, to consitute the main process at 20 °C. A precise estimation of the barriers to rotation in the *ap* cation (or the ion pair) is not possible at present, but the barrier should be lowered in the cation relative to the parent compound because the barrier to rotation in 9-(2-formyl-1-naphthyl)fluorene,[18] a model compound with an sp^2-carbon as a substituent, is known to be appreciably lower than that in 9-(2-methyl-1-naphthyl)fluorene,[6b] that has an sp^3-hybridized carbon as a substituent in the 2 position of the naphthalene ring: The substituent in the 2 position of the naphthalene ring is responsible in determining the barrier to rotation. Molecular models suggest that it is the substituent in the *ap* position, with respect to the 9-H, rather than the substituent in the *sp* that determines the sharpness of the rising of the potential curve at the early stage of rotation from the ground state. Then in *sp*-**1**, the ease of rotation may not be changed on ionization to an appreciable extent, whereas the ease of rotation is increased in *ap*-**1** on ionization. Thus the polymerization is the preferred process in *sp*-**1** under the conditions examined. At extreme dilution, the cyclization of *sp*-**1** may be possible in principle, but it is not practicable.

Competitive Reactions between sp-*1 and* ap-*1*. In order to see whether the large difference in reactivity of the diastereomers of **1** in TFA is peculiar in that solvent, competitive reactions of *sp*-**1** and *ap*-**1** with silver salts in various solvents were carried out. The results are summarized in Table 4 together with the relative reactivity of benzyl bromide used as a reference compound under the same conditions. We may compare the reactivity of *sp*-**1** and *ap*-**1**, although the

products are formed by different mechanisms after ionization, because the initial ionization can be considered as the rate determining step in both isomers.

Of silver nitrate and silver perchlorate, the former gave a larger k_{sp}/k_{ap} value than the latter in acetonitrile. As has been noticed, the corresponding perchlorate ester is formed, though its lifetime is short, in the reaction with silver perchlorate, which then reacts with the solvent molecule. This will be the main source of difference between the perchlorate and nitrate cases, in the latter of which the collapse of the ion pair gives directly the product. At any rate, the *sp* form is more reactive than the *ap*, making a contrast to the reactivity in TFA.

It is interesting to note that, while the relative reactivity of *sp*-**1** is larger than that of *ap*-**1** in acetonitrile and in benzene, the reverse is true in TFA and HFP. However, the reactivity ratio is not so large as that obtained by heating a TFA solution. The difference may again reflect that in silver perchlorate cases the rate of decomposition of the perchlorate ester is important, whereas the ionization in TFA occurs from the bromide.

In acetonitrile, benzyl bromide is less reactive than *sp*-**1**, while the former is more reactive by a large factor than the latter in benzene. We wish to attribute these phenomena tentatively to the steric effects within the substrates and to those in solvation. On one hand, because of the molecular shape and the fact that the molecule coordinates to a cation with its nitrogen, the steric effect in the solvation with acetonitrile may not play an important role for retardation in the ionization of the CH_2Br group in *sp*-**1**. On the other, the steric interaction in the ground state of *sp*-**1** is relieved to some extent on its ionization. Thus the steric acceleration is operative in the ionization of *sp*-**1** in acetonitrile. In contrast, the completion of the solvation shell for the cation derived from *sp*-**1** requires extra energy in benzene because of the space-demanding molecular shape of the solvent molecule. Therefore the cation derived from *sp*-**1** in benzene is much more unstable than that derived from benzyl bromide. This solvation effect rather than the steric acceleration seems to be a ruling factor in the reactions in benzene.

Solvolytic Reactions. In the foregoing section, the role of solvent is found to be important in determining the relative reactivity. To shed light further on this point, it may be necessary to keep the leaving group constant. Thus we have investigated the solvolytic reactions of *sp*-**1** and *ap*-**1** in various ionizing solvents.

The first choice was formic acid in which solvolytic reactions are close to S_N1.[19] Solvolysis of *sp*-**1** and *ap*-**1** in formic acid gave the corresponding formate to indicate that formic acid is nucleophilic enough to win the competition with cyclization in *ap*-**1**. The first order rate constants of the reaction of *sp*-**1** and *ap*-**1** in formic acid containing *ca.* 8 (v/v)% chloroform at 42 °C were obtained as 7.6×10^{-4} min^{-1} and 4.6×10^{-4} min^{-1}, respectively. Thus the relative rate k_{sp}/k_{ap} is 1.6: The *sp* form is more reactive than the *ap* under these conditions.

In a 1:1 (v/v) mixture of TFA and chloroform, the rate of disappearance of *ap*-**1** was determined at two concentrations. At 86 mM, the first order rate constant was 8.5×10^{-4} min^{-1} at 60 °C, whereas it was 5.6×10^{-4} min^{-1} at 48 mM at the same temperature. At this level of concentration, the products were polymers which were undoubtedly formed by intermolecular Friedel-Crafts reactions. The results suggest that the solute in TFA assists ionization in some ways. Under the similar conditions, *sp*-**1** was always recovered as well as benzyl bromide. The relative rate (k_{sp}/k_{ap}) is less than 0.05.

At 2 mM in TFA containing 3 (v/v)% chloroform, the half life of *ap*-**1** at 60 °C was 50—60 min. Heating a 2 mM HFP (containing 2 (v/v)% chloroform) solution of *ap*-**1** at 55 °C showed the disappearance of the solute with a half life of 30—40 min. Under the same conditions, *sp*-**1** was completely recovered, the relative reactivity (k_{sp}/k_{ap}) being less than 0.05. The main product in these reactions was **3**. The formation of **4** was diminished when HFP was used as a solvent and only a trace amount of **4** was usually detected.

Considering the ionizing ability of formic acid, TFA, and HFP,[20] one may wonder why the more ionizing solvents show no reaction of *sp*-**1** while the less ionizing solvent gives the solvolysis product. The key to solve this problem can be the fact that the more ionizing solvents are less nucleophilic. Namely, *sp*-**1** may ionize to contact ion pairs or to solvent separated ion pairs in TFA or HFP: It is more reasonable to assume so when one considers the ionizing power of these solvents. However, the nucleophilicity of TFA and HFP is so low that the ion pairs return to the covalent species rather than to give a reaction product. In contrast, formic acid is nucleophilic enough to give the formate if *sp*-**1** ionizes either to the contact ion pair or to the solvent separated ion pair.

If the above mentioned idea is correct, a TFA or HFP solution containing a nucleophile should show some reactivity of *sp*-**1**. Thus the reaction in HFP containing 5 (v/v)% chloroform and 3 (v/v)% methanol was investigated. As expected, *sp*-**1** afforded the corresponding methoxy compound (**8**) in a good yield, whereas *ap*-**1** afforded the cyclized products (**3** and **4**). The rates of decrease in the amount of *sp*-**1** and *ap*-**1** were treated as first order reactions. The rate constants were 1.5×10^{-3} and 8.4×10^{-3} min^{-1} for *sp*-**1** and *ap*-**1**, respectively, at 1.8 mM and at 40 °C. The rate constants may again be compared directly because in both cases the ionization is the rate determining step. Then the relative rate (k_{sp}/k_{ap}) is 0.18. It is striking to note that *ap*-**1** did not give *ap*-**8** to a measurable degree, because methanol is more nucleophilic than formic acid in which the solvolysis afforded the formate. We may have to assume that the ion pairs formed from *ap*-**1** in HFP are so tight that they react intramolecularly with the benzene ring of the fluorene rather than with external methanol.

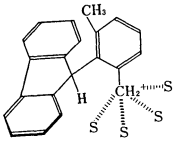
Under the same conditions in TFA (TFA–$CHCl_3$–CH_3OH, 40 °C, 18 mM) the rate constants of the reaction were 3.1×10^{-4} and 1.5×10^{-3} min^{-1}, respectively, for *sp*-**1** and *ap*-**1**, as measured by the decrease

in the amount of the substrates. The relative reactivity k_{sp}/k_{ap} is calculated to be 0.19. The TFA–$CHCl_3$–CH_3OH system did not give the corresponding methoxy compound (*sp*-**8**) from *sp*-**1**, however, although *ap*-**1** gave the cyclized products (**3** and **4**). The behaviors of the products from *sp*-**1** on a TLC plate were similar to those of the polymers obtained by heating a mixture of *sp*-**1** in TFA or HFP and silver perchlorate. We abandoned attempts to prepare the methoxy compound (*sp*-**8**) from *sp*-**1** under similar conditions for the following reasons. The apparent failure in affording *sp*-**8** in the TFA–$CHCl_3$–CH_3OH system must be attributed to the reduction in effective concentration of methanol in the system owing to protonation. Although we could have made *sp*-**8** by increasing the molar fraction of methanol in the system, the increase in the concentration of methanol also increases the reaction rate of *sp*-**1** with methanol in S_N2 fashion. It would become difficult to tell the extent of contributions of S_N1 and S_N2 reactions.

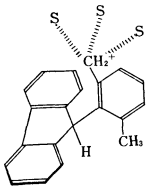
Role of Solvent Molecules in Ionization. At any rate, the above results suggest that in TFA and in HFP, ionization of *sp*-**1** is slower than that of *ap*-**1**. We have attributed this difference to π-participation of the fluorene system.[5] However, having additional experimental data in hand, we notice that the situation is not so simple as we have thought: Solvent plays an important role in controlling the rates of reaction.

The first we notice is that the ionization reaction of *sp*-**1** is faster than in *ap*-**1** in acetonitrile, in benzene, and in formic acid, whereas the reverse is true in TFA and in HFP. We wish to postulate, in summarizing the results described above, that the completion of the solvation shell is important in determining the ease of ionization.

Let us assume that free carbocations are formed by the ionization reaction. Then the cation must be surrounded by solvent molecules to form a solvation shell as depicted by **11** and **12**.[21] A main difference



11



12

here is that, while the solvent molecules form a solvation shell in the *sp* conformation, at least one of the solvent molecule cannot participate in the solvation of the cation derived from the *ap* form because of the steric effect of the fluorene ring. In other words, the benzene ring of the fluorene moiety participate in completing the solvation shell (This can be viewed as π-participation.). Mere consideration of this situation leads to a conclusion that if a solvent molecule is more basic than the benzene ring in fluorene, then *sp*-**1** can be more reactive than *ap*-**1**. Similarly *ap*-**1** can be more reactive than *sp*-**1**, if the basicity of the solvent molecule is lower than the benzene ring in fluorene.

The general tendency seen in the experimental results conform with this expectation: in more basic solvents, the *sp* form is more reactive, while the *ap* form is more reactive in poorly basic solvents. One might argue that if we admit the hypothesis we must consider that benzene and formic acid must be more basic than the benzene in fluorene, contrary to the common belief.[22] We consider that this result is derived because the relative arrangement, in space, of the fluorene ring and the cation derived from *ap*-**1** is limited and is not optimum for the interaction between them. Thus the benzene ring in the fluorene moiety is not as effective as it should be. Free benzene molecules can assume optimum arrangement to stabilize the cation. The case of formic acid can be understood similarly.

We wish to thank Professor T. Miyazawa of this University for measuring the ^1H NMR spectrum at 270 MHz. This work was supported by a grant from Toray Science Foundation to which our thanks are due.

Enzymatic Synthesis of Pyridine Nucleotides. Structural Property of Some New NAD-analogs, and Base Conditions Available for the Analog Formation[1)]

Shuichi TONO-OKA

Institute of Immunological Science, Hokkaido University, Kita 15-jo, Nishi 7-chome, Kita-ku, Sapporo 060

(Received August 3, 1981)

Some new β-NAD-analogs were prepared by a base-exchange reaction catalyzed by pig-brain NADase. The analogs produced from methyl 4-(methylamino)- and 4-(dimethylamino)nicotinates were proved to be 1,4-dihydropyridine form. On the contrary, the analog obtained from 4-(acetylamino)nicotinamide was shown to be a quaternary pyridinium form. Moreover, an unexpected analog of 1,4-dihydro-4-pyridinone form was given by 4-methoxynicotinamide. It was shown to be indispensable for the formation of NAD-analog that the ring nitrogen of pyridine bases concerned should at least be free from protonation around pH 7. Interestingly nicotinic acids with 4-amino, methylamino, and dimethylamino groups were found to be much more basic for the ring nitrogen atom than their respective methyl esters.

Previously we have reported[2,3)] the enzymatic synthesis of new pyridine nucleosides utilizing the corresponding NAD-analogs (**2** and **3**) as intermediates, which were prepared from β-NAD (**1**) and 4-amino derivative of methyl nicotinate or nicotinamide by a NADase-catalyzed base-exchange reaction (Scheme 1). These analogs were proved to take a 1,4-dihydropyridine form instead of a quaternary pyridinium one.

Now our attention has been extended to investigate the structural property of pyridine moiety of NAD-analogs which will be produced from other *N*-substituted 4-amino derivatives (methylamino, dimethylamino, *etc.*) of methyl nicotinate or nicotinamide. Moreover, these analogs are also of interest in connection with their possible efficiency as competitive inhibitors[4)] for NAD. On the other hand, it comes to be an important problem whether the pyridine bases concerned bring about the corresponding NAD-analog or not, when this method is utilized for the synthesis of pyridine nucleosides. As previously reported,[3)] nicotinic acids with 4-amino, methylamino, and dimethylamino functions produced no detectable amount of analog unless the 3-carboxyl group was pre-transformed into a methoxycarbonyl or carbamoyl one. In view of these facts, the spectroscopic behaviors of pyridine bases were examined with alterations in pH to clarify the relationship between their reactivity and chemical property.

The present paper describes the structural properties of newly prepared NAD-analogs and necessary conditions of pyridine bases for the analog formation in the base-exchange reaction.

Results and Discussion

Preparation and Structural Property of NAD-analogs. On the basis of the results described in the previous paper,[3)] various NAD-analogs were prepared under the following conditions: Base concentration was more than 25 mM (1 M=1 mol dm^{-3}) if possible, and the base/NAD molar ratio was about 4:1. The yield and some spectral data of the analogs obtained were summarized in Table 1.

In the UV spectra (pH 7), although the replacing base, methyl 4-(methylamino)nicotinate and ADP-ribose have an absorption at 260 (log ε 4.08) and 259 nm (log ε 4.20), respectively, methylamino analog (**4**) obtained showed its maximum at 268 nm (log ε 4.27) with a bathochromic shift, suggesting the structural change of pyridine chromophore. In the ^{1}H-NMR spectra, a methyl group adjacent to the nitrogen atom of the replacing base showed a doublet in DMSO-d_6 with the vicinal coupling of J_{NH,CH_3}=5.2 Hz, which collapsed by the addition of deuterium oxide. In contrast, compound **4** showed a singlet for the methyl group in the same solvent. From these observations, the 4-nitrogen atom of pyridine moiety in **4** proved to bear no proton, indicating 1,4-dihydropyridine structure of **4**.

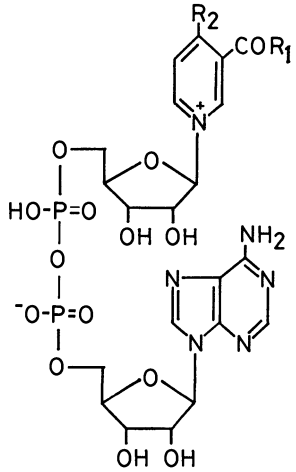
3: $R_1=NH_2$ $R_2=NH$
4: $R_1=OCH_3$ $R_2=NCH_3$
5: $R_1=OCH_3$ $R_2=\overset{+}{N}(CH_3)_2$
8: $R_1=OCH_3$ $R_2=O$
9: $R_1=NH_2$ $R_2=O$



1: $R_1=NH_2$ $R_2=H$
6: $R_1=NH_2$ $R_2=NHCOCH_3$
7: $R_1=OH$ $R_2=NHCOCH_3$
10: $R_1=NH_2$ $R_2=CH_3$
11: $R_1=OH$ $R_2=CH_3$

Dimethylamino analog (**5**), produced from methyl 4-(dimethylamino)nicotinate which bears no proton at the nitrogen atom to participate in tautomerism, was anticipated to take a pyridinium form instead of a 1,4-dihydropyridine one. However, compound **5** was shown to be the dihydropyridine structure of 4-dimethyliminium type from the following findings. The ^{1}H-NMR spectrum of **5** exhibited a six-proton singlet at δ 3.11 due to the two methyl groups, and the anomeric proton of pyridine side appeared at δ 5.62 accompanying 0.4 ppm higher field resonance compared with that of adenine side. Moreover, the $H_{5,6}$ coupling of pyridine moiety was estimated to be 8.2 Hz, indicating the olefinic character of C_5–C_6 bond. Its UV spectral behavior was also compatible with the structure of **5** (Table 1).

Acetylamino analogs (**6** and **7**) were remarkably different from **4** and **5** in some respects in the ^{1}H-NMR spectra. Both the two anomeric protons appeared as a broad two-proton doublet at δ 6.0, and the $H_{5,6}$ coupling of pyridine ring was 6.0 Hz, the value of which was distinctly smaller than for **4** and **5**. In addition, its pyridine protons showed the lower field shift of 0.4—0.6 ppm as a whole compared with those of the acetylamino bases alone. The UV spectrum of these analogs nearly corresponded with the sum absorptions of acetylamino base and ADP-ribose. These observations indicated the quaternary pyridinium form of **6** and **7**.

a) Analog/(analog + ADP-ribose) × 100. b) Measured in deuterium oxide. c) Measured in water. d) All the compounds showed the ε-value of more than 1.6×10^4.

It has thus been shown that even if the amino group was methylated, its lone pair electrons contributed to the 1,4-dihydropyridine structure, and that when it was acetylated, its resonance effect on pyridine nucleus was prevented by the electron-withdrawing acetyl group in spite of possessing a proton at the nitrogen atom.

In connection with dimethylamino base in which an amino group is methylated, it seems of deep significance to investigate methyl 4-methoxynicotinate and 4-methoxynicotinamide in which a hydroxyl group is methylated. If they bring about a similar type of analog as described for **5**, the formation of the system $-N-C=C-C=\overset{+}{O}CH_3$ must be expected. However, the oxonium form is generally unstable compared with the ammonium or iminium one,[5] whereby the above system with methoxonium ion can hardly be considered. The analogs formed were thus anticipated to have the alternative pyridinium system $-\overset{+}{N}=C-C=C-OCH_3$ instead. They, however, exhibited an unexpected UV absorption at 266 nm ($\log\varepsilon$ 4.24), accompanying a large bathochromic shift of more than 30 nm from that of the methoxy bases alone. The ^{1}H-NMR spectra of these analogs (**8** and **9**) showed the absence of a three-proton singlet due to a methoxyl methyl group. The anomeric proton in question exhibited a similar behavior to that of **4** and **5**, and the $H_{5,6}$ coupling was observed to be 8.0 Hz. These facts demonstrate the 1,4-dihydro-4-pyridinone form of **8** and **9**, which would probably be brought about from once formed 4-methoxypyridinium compound by demethoxylation subsequent to undergoing the nucleophilic attack of water at the 4-position (Scheme 2).

a) NAD-analog of INH.

By using 4-methylnicotinamide as a replacing base, which has an UV maximum at 261 nm (log ε 3.60), 4-methyl analog (**10**)[6] was obtained which showed the absorption at 260 nm (log ε 4.26). In the ^{1}H-NMR spectrum of **10**, the methyl protons were clearly observed at δ 2.62 as a three-proton singlet and the $H_{5,6}$ coupling was 6.0 Hz, indicating a quaternary pyridinium form of **10** rather than 1,4-dihydro-4-methylenepyridine one. Such was also found to be the case of the analog (**11**) obtained from 4-methylnicotinic acid.

As previously suggested,[2] the susceptibility of NAD-analogs to the hydrolase action of NADase might be employed as an indication of their pyridinium ion character. In order to clarify this assumption more precisely, the above obtained analogs were incubated with NADase, and the amount of ADP-ribose liberated was examined with elapse of time on TLC in comparison with NAD itself and its isonicotinic acid hydrazide (INH) analog (**12**),[7] which is a typical NAD-analog of pyridinium form (Table 2). All the analogs (**6**, **7**, and **10**—**12**) which exist in pyridinium form underwent hydrolysis more or less, though not so fast as NAD. On the other hand, the analogs (**2**—**5**, **8**, and **9**) which exist in dihydropyridine form were little susceptible to the enzyme, indicating that their glycosyl bonds were much more stable than those of the former analogs. These results strongly supported the validity of the assumption.

Necessary Conditions of Bases for the Analog Formation. This base-exchange reaction can be assumed to proceed through the nucleophilic attack of pyridine base on an enzyme–ADP-ribose complex. From this point of view, the reactivity of pyridine base was considered to be notably affected by the nucleophilicity of ring nitrogen. As previously described, nicotinic acids with 4-amino group inclusive of methyl- and dimethylamino ones were found to produce no NAD-analog, although nicotinic acid itself and its 4-methyl derivative produced successfully the corresponding analogs. In order to infer the chemical property of analog-productive pyridine bases and non productive ones around pH

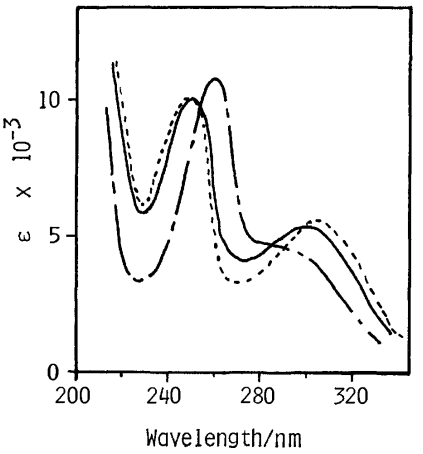

Fig. 1. Absorption spectra of methyl 4-aminonicotinate (**13**) at some values of pH.

— — —: pH 2, ——: pH 7, ----: pH 12.

7 wherein the NADase-catalyzed reaction proceeds, their UV spectra were firstly examined at some different pHs.

In the case of methyl 4-aminonicotinate (**13**) which gives rise to a NAD-analog in good yield, its absorption maximum at pH 7 approximated closely to that at pH 12 (Fig. 1). A similar spectral pattern was also observed for 4-aminonicotinamide. On the other hand, in the case of 4-aminonicotinic acid (**16**) which gives rise to no NAD-analog, its absorption maximum approximated closely to that at pH 2 (Fig. 2). The same spectral correlations were also recognized in a pair of corresponding 4-methylamino compounds (**14** and **17**) and 4-dimethylamino ones (**15** and **18**). The structure of now described compounds (**13**—**18**) are summarized in Table 3.

Brown and Plasz[8] have previously reported that the first protonation of 4-aminopyridine occurred at the ring nitrogen and not at the substituent amino group. Since the primary amino function is a very weak base, the second protonation occurs only in more strongly acidic solutions ($pH \lesssim -3$) like 2 M sulfuric acid.[9] In the acidic solution of pH 2, therefore, the

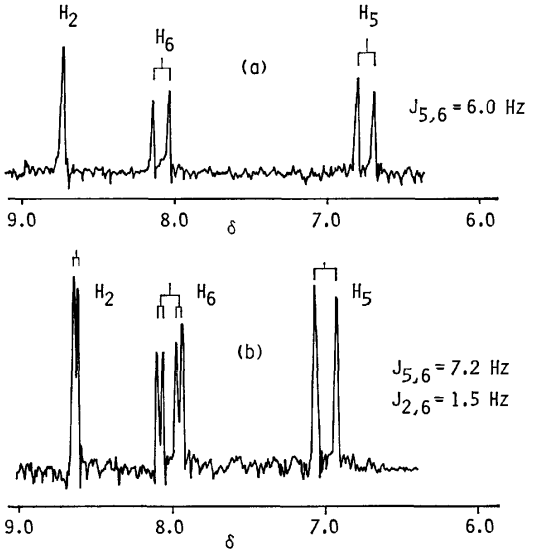

Fig. 3. ^{1}H-NMR spectral patterns of **13** (a) and **16** (b) at pH 7.

pyridine bases dealt with here should be protonated at the ring nitrogen. In the alkaline solution, on the contrary, the nitrogen should be completely free from protonation. It is accordingly suggested that the ester bases (**13**—**15**) would mainly exist in a free form, whereas the carboxyl bases (**16**—**18**) suffer a protonation in the neutral solution.

When ^{1}H-NMR spectra were measured for these two kinds of bases, their spectroscopic differences were revealed more clearly. The signal pattern of **13** in the neutral solution was substantially identical with that of pH 12, and the $H_{5,6}$ coupling was 6.0 Hz (Fig. 3a). In contrast, **16** showed a different signal pattern almost identical with that of pH 2; the $H_{5,6}$ coupling became larger ($J_{5,6}$=7.2 Hz) and the $H_{2,6}$ long range coupling appeared clearly ($J_{2,6}$=1.5 Hz) (Fig. 3b). These spectroscopic behaviors were also observed for the couples of **14** and **17** as well as **15** and **18**.

Craig *et al.*[10] have previously found in the structural studies of 4-aminoquinoline derivatives that a coupling constant between H_2 and H_3 of the quinoline ring could be an indication of the extent of aromaticity. This concept was well applicable to the 3,4-disubstituted pyridine compounds now dealt with. If the ring nitrogen was protonated, the cation formed could be stabilized by resonance, such as that between the cannonical forms (**a**) and (**b**) (Scheme 3). The C_5–C_6 bond should then come to have an olefinic character due to the contribution of the structure **b**. It is well known that the vicinal coupling of olefines is usually larger than that of aromatic environment, and the $H_{2,6}$ coupling is increased by *ca.* 1 Hz on undergoing a protonation.[11]

Thus, the ring nitrogen of ester bases were proved to be essentially free around pH 7, whereas that of carboxyl bases suffered a protonation under the same conditions. On acetylation of **16**, however, its spectral properties came to be similar to those of **13**, and the acetyl compound (**19**) certainly provided a NAD-analog in 50% yield (Table 1). Apart from this,

a) A. Albert, "Physical Methods in Heterocyclic Chemistry," ed by A. R. Katritzky, Academic Press, New York (1963), Vol. I, p. 72. b) A. Albert, *ibid.*, (1971), Vol. IV, p. 9.

other analog-productive 4-methyl- and 4-methoxynic otinic acids were also found to be free from protonation at pH 7.

These observations demonstrated that the mostly free state of ring nitrogen in the pyridine bases concerned is at least necessary for the formation of NAD analog.

Basicity of Pyridine Bases. To undergo an easy protonation implies the high basicity of ring nitrogen. Strangely, there has so far been no report on the basicity of pyridine bases here dealt with. Therefore, their pK_a values were determined by the convenient spectrometric method of Albert *et al.*[12] Contrary to our intuitional expectation, carboxyl bases (**16**—**18**) ($pK_a \geq 9$) proved much more basic than corresponding ester bases (**13**—**15**) ($pK_a \leq 7$) and showed no significant difference in basicity compared with 4-aminopyridines (**22**—**24**) (Table 3). This fact indicates that the presence of 3-carboxyl group has no special influence on the basicity of ring nitrogen, whereas 3-methoxycarbonyl group has an effect to reduce it, unlike the

correlation of nicotinic acid (**21**) and its methyl ester (**20**). The lower basicity of **19** compared to **16** should be considered due to the inhibitory effect of electron-withdrawing acetyl group on the dispersal of lone pair electrons of amino function into the ring nitrogen. In view of this explanation, the unexpected decrease of basicity by esterification of carboxyl group seems possibly dependent on an intermolecular non-bonded interaction between the amino nitrogen and the carbonyl carbon of ester group. On that account, the lone pair electrons of amino function can hardly contribute to the resonance effect, resulting in the reduced basicity of ring nitrogen. On the other hand, there would occur no appreciable interaction in the case of carboxyl bases, presumably due to the deficiency of carbonium ion character in the carboxyl group.

In conclusion, the basicity of pyridine bases is surely an important factor for the formation of NAD-analogs. However, since the enzymatic reaction must be carried out around pH 7, highly basic pyridine bases can no longer function as nucleophiles because of suffering a protonation. Thus, the suitable basicity ($pK_a \lesssim 7$) was shown to be one of the necessary conditions for enough nucleophilicity of replacing bases.

The biological activity of here prepared pyridine nucleotides will be reported elsewhere.[13]

Experimental

All the melting points are uncorrected. The UV spectra were measured on a Hitachi 200-20 spectrophotometer, and the ^{1}H-NMR spectra were determined on a Hitachi R-20B (60 MHz) spectrometer in deuterium oxide with sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal standard unless otherwise stated. The abbreviations "s, d, dd, br, bs, and bd" denote "singlet, doublet, double doublet, broad, broad singlet, and broad doublet," respectively. Optical rotations were measured with a Union PM 101 digital polarimeter. Ionic strength and pH measurements were made on an Emuesu CD-35M II conductivity meter and a Radiometer pHM-26 pH meter equipped with a G-202 glass electrode, respectively. Thin layer chromatographies (TLC) were carried out on silica gel 60 F_{254} HPTLC plates (Merck, 10 cm × 10 cm) using 2-propanol–0.2% aqueous ammonia (7 : 3, v/v) as the developing system. The analysis of chromatograms were performed by a Shimadzu CS-910 scanner equipped with a chromatopack C-R1A. Column chromatographies[14] were carried out on DEAE-Sephadex (A-25, 3.5 mequiv./g) connected to LKB Uvicord II (254 nm). β-NAD (Grade III) was purchased from Sigma Chemical Co.

Pig-brain NADase (EC 3.2.2.5). The crude particulate enzyme was prepared by the method of Zatman *et al.*[7a] The colloidal supernatant fluid containing *ca.* 0.4 U/ml[15] of NADase activity was used without further purification.

4-(Methylamino)nicotinic Acid. Prepared from 4-chloronicotinic acid 1-oxide[16] and methylamine in two steps, and recrystallized from aqueous methanol: mp 277—279 °C (decomp) [lit,[17] 274—276 °C (decomp)].

Methyl 4-(Methylamino)nicotinate. Prepared by esterification of the above compound, and recrystallized from dichloromethane–petroleum benzine: mp 71—73 °C. Found: C, 57.86; H, 6.04; N, 16.76%. Calcd for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07; N, 16.86%.

4-(Dimethylamino)nicotinic Acid. Prepared from 4-chloronicotinic acid 1-oxide[16] and dimethylamine in two steps, and recrystallized from aqueous ethanol: mp 223—225 °C (decomp). Found: C, 57.74; H, 6.21; N, 16.65%. Calcd for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07; N, 16.86%.

Methyl 4-(Dimethylamino)nicotinate. Prepared by the esterification of the above compound, and recrystallized from dichloromethane–petroleum benzine: mp 75—77 °C. Found: C, 60.07; H, 6.61; N, 15.55%. Calcd for $C_9H_{12}N_2O_2$: C, 59.99; H, 6.71; N, 15.55%.

4-(Acetylamino)nicotinic Acid. Prepared by the acetylation of 4-aminonicotinic acid[18] with acetic anhydride, and recrystallized from water: mp 252—254 °C (decomp). Found: C, 53.45; H, 4.37; N, 15.82%. Calcd for $C_8H_8N_2O_3$: C, 53.32; H, 4.43; N, 15.55%.

4-(Acetylamino)nicotinamide. Prepared by the acetylation of 4-aminonicotinamide,[19] and recrystallized from ethanol: mp 223—225 °C (decomp). Found: C, 53.76; H, 4.98; N, 23.71%. Calcd for $C_8H_9N_3O_2$: C, 53.63; H, 5.03; N, 23.47%.

Methyl 4-Methoxynicotinate. Prepared from 4-nitronicotinic acid 1-oxide[18] in two steps, and recrystallized from benzene: mp 85—87 °C (lit,[20] 83—84 °C).

4-Methoxynicotinamide. Prepared by ammonolysis of the above compound, and recrystallized from benzene: mp 155—157 °C (lit,[20] 153—154 °C).

4-Methylnicotinic Acid. Prepared from 4-methylquinoline in two steps, and recrystallized from water: mp 215—217 °C (decomp) (lit,[21] 215—217 °C).

4-Methylnicotinamide. Prepared by the ammonolysis of the above compound, and recrystallized from methanol: mp 167—169 °C (lit,[19] 165—167 °C).

Methyl 1,4-Dihydro-4-(methylimino)nicotinate Adenine Dinucleotide (4). Methyl 4-(methylamino)nicotinate (1.6 mmol, 265 mg) and NAD (0.4 mmol, 280 mg, neutralized with 2M NaOH to pH 7) were incubated with pig-brain NADase (6 U, 15 ml) in 0.1 M Tris–HCl (pH 7.2, 30 ml) at 37 °C for 5 h. The incubation mixture was treated with 70% trichloroacetic acid (1 ml) and the precipitated protein was removed by centrifugation. To the clear supernatant thus obtained, cold acetone (300 ml) was added to give yellowish hygroscopic powder (235 mg) as the crude product. It was dissolved in water (20 ml) and then applied to a column of DEAE-Sephadex (HCO_3^--form) (column size; 2.5 cm × 45 cm). The column was washed with 0.02 M NH_4HCO_3 (250 ml) to remove the included free bases and then eluted with 300 ml portions of 0.2, and 0.5 M NH_4HCO_3 (pH 7.8), successively. The first major component showing UV-absorbing peak at 268 nm was eluted with the 0.2 M solution. The eluate (50 ml) was immediately collected and lyophilized repeatedly to give **4** (186 mg) as the ammonium salt. An analytical sample of **4** was obtained by rechromatography and drying over P_2O_5 *in vacuo* for 12 h at 40 °C: $[\alpha]_D^{20}$ −60.9° (*c* 0.92, H_2O); UV (H_2O), λ_{max} 268 nm (log ε 4.26); ^{1}H-NMR (δ, D_2O), 3.05 (3H, s, $NC\underline{H}_3$), 3.98 (3H, s, $CO_2C\underline{H}_3$), 4.2—4.6 (10H, br, riboses), 5.63 (1H, bd, J=5 Hz, py-C$_5'$-$\underline{H}$), 6.01 (1H, d, J=5.5 Hz, ad-C$_1'$-$\underline{H}$), 6.87 (1H, d, J=8.0 Hz, py-$\underline{H}_5$), 8.03 (1H, s, ad-$\underline{H}_2$), 8.15 (1H, dd, J=1.5, 8.0 Hz, py-$\underline{H}_6$), 8.28 (1H, s, ad-$\underline{H}_8$), 8.67 (1H, d, J=1.5 Hz, py-$\underline{H}_2$). Found: C, 34.05; H, 5.71; N, 15.79%. Calcd for $C_{23}H_{31}N_7O_{15}P_2 \cdot 2NH_3 \cdot 4H_2O$: C, 33.95; H, 5.53; N, 15.50%.

Methyl 1,4-Dihydro-4-(dimethyliminio)nicotinate Adenine Dinucleotide (5). Methyl 4-(dimethylamino)nicotinate (1.5 mmol, 270 mg) and NAD (0.4 mmol, 275 mg) were incubated with NADase (6 U, 15 ml) in 0.1 M Tris–HCl (pH 7.2, 30 ml) at 37 °C for 5 h. The incubation mix-

ture was treated in a similar manner to that described above to give the crude product (228 mg), which was dissolved in water (20 ml) and applied to a column (HCO_3^--form). The column was eluted with aqueous NH_4HCO_3 similarly as described above. The first major component was eluted with the 0.2 M solution. The eluate (40 ml) showing the UV maximum at 266 and 296 nm was immediately collected and lyophilized repeatedly to give **5** (113 mg) as the ammonium salt: $[\alpha]_D^{20}$ −46.3° (*c* 0.76, H_2O); UV (H_2O), λ_{max} 266 nm (log ε 4.23), 296 nm (log ε 4.24); ^{1}H-NMR (δ, D_2O), 3.11 (6H, s), 3.96 (3H, s), 4.2—4.6 (10H, br), 5.62 (1H, bd, J=5 Hz), 6.00 (1H, d, J=5.5 Hz), 7.02 (1H, d, J=8.2 Hz), 8.04 (1H, s), 8.12 (1H, dd, J=1.5, 8.2 Hz), 8.31 (1H, s), 8.44 (1H, d, J=1.5 Hz). Found: C, 35.34; H, 5.52; N, 14.18%. Calcd for $C_{24}H_{33}N_7O_{15}P_2 \cdot NH_3 \cdot 4H_2O$: C, 35.52; H, 5.42; N, 13.81%.

4-(Acetylamino)nicotinamide Adenine Dinucleotide (6). A mixture of 4-(acetylamino)nicotinamide (2 mmol, 355 mg) and NAD (0.6 mmol, 390 mg) was incubated with NADase (6 U, 15 ml) in 0.1 M Tris–HCl (40 ml) for 7 h. The incubation mixture was treated as described for **4** to give the crude hydroscopic product (408 mg), which was purified by the chromatographic procedures using aqueous HCO_2NH_4 (pH 6.8) as eluent in the manner as described for **4** to provide **6** (332 mg) as the hygroscopic ammonium salt: $[\alpha]_D^{20}$ −12.4° (*c* 0.64, H_2O); UV (H_2O), λ_{max} 268 nm (log ε 4.07), 340 nm (log ε 3.77); ^{1}H-NMR (δ, D_2O), 2.35 (3H, s), 4.25—4.65 (10H, br), 6.00 (2H, bd), 7.43 (1H, d, J=6.0 Hz), 7.95 (1H, s), 8.21 (1H, s), 8.62 (1H, dd, J=1.5, 6.0 Hz), 9.15 (1H, d, J=1.5 Hz). Found: C, 35.15; H, 5.15; N, 18.12%. Calcd for $C_{23}H_{30}N_8O_{15}P_2 \cdot 2NH_3 \cdot H_2O$: C, 35.70; H, 4.92; N, 18.11%.

4-(Acetylamino)nicotinic Acid Adenine Dinucleotide (7). A mixture of 4-(acetylamino)nicotinic acid (2.9 mmol, 523 mg) and NAD (1.3 mmol, 935 mg) was incubated with NADase (8 U, 20 ml) in 0.1 M Tris–HCl (70 ml) for 12 h. The crude product (776 mg) obtained was purified by the chromatographic procedures to give **7** (372 mg): $[\alpha]_D^{20}$ −44.5° (*c* 1.1, H_2O); UV (H_2O), λ_{max} 266 nm (log ε 4.18), 283 nm (log ε 4.18); ^{1}H-NMR (δ, D_2O), 2.39 (3H, s), 4.3—4.7 (10H, br), 6.01 (2H, bd), 8.15 (1H, s), 8.35 (1H, s), 8.63 (2H, bs), 9.05 (1H, bs). Found: C, 35.39; H, 4.88; N, 14.73%. Calcd for $C_{23}H_{29}N_7O_{16}P_2 \cdot NH_3 \cdot 2H_2O$: C, 35.66; H, 4.65; N, 14.47%.

Methyl 1,4-Dihydro-4-oxonicotiate Adenine Dinucleotide (8). Methyl 4-methoxynicotinate (6.5 mmol, 1080 mg) and NAD (1.6 mmol, 1050 mg) were incubated with NADase (12 U, 30 ml) in 0.1 M Tris–HCl (120 ml) for 6 h. The crude product (852 mg) obtained by treating the reaction mixture as described for **4** was purified by column chromatography on DEAE-Sephadex (HCO_2^--form) as described for **6** to give **8** (546 mg): $[\alpha]_D^{20}$ −29.6° (*c* 1.05, H_2O); UV (H_2O), λ_{max} 265 nm (log ε 4.26); ^{1}H-NMR (δ, D_2O), 3.90 (3H, s), 4.2—4.6 (10H, br), 5.60 (1H, bd, J=5 Hz), 5.97 (1H, d, J=5.5 Hz), 6.85 (1H, d, J=8.0 Hz), 7.95 (1H, s), 8.02 (1H, dd, J=1.5, 8.0 Hz), 8.24 (1H, s), 8.68 (1H, d, J=1.5 Hz). Found: C, 34.28; H, 5.11; N, 11.24%. Calcd for $C_{22}H_{28}N_6O_{16}P_2 \cdot 2NH_3 \cdot 2H_2O$: C, 34.55; H, 4.97; N, 10.99%.

1,4-Dihydro-4-oxonicotinamide Adenine Dinucleotide (9). In 0.1 M Tris–HCl (80 ml), 4-methoxynicotinamide (6.6 mmol, 998 mg) and NAD (1.7 mmol, 1140 mg) were incubated with NADase (12 U, 30 ml) for 6 h. The reaction mixture was treated in a similar manner as described for **4** to give **9** (770 mg): $[\alpha]_D^{20}$ −37.9° (*c* 0.69, H_2O); UV (H_2O), λ_{max} 266 nm (log ε 4.24); ^{1}H-NMR (δ, D_2O), 4.25—4.65 (10H, br), 5.60 (1H, bd, J=5 Hz), 6.04 (1H, d, J=5.5 Hz), 6.90 (1H, d, J=8.0 Hz), 8.12 (1H, dd, J=1.5, 8.0 Hz), 8.15 (1H, s), 8.44 (1H, s), 8.60 (1H, d, J=1.5 Hz). Found: C, 34.14; H, 4.47; N, 17.41%. Calcd for $C_{21}H_{27}N_7O_{15}P_2 \cdot 2NH_3 \cdot H_2O$: C, 34.44; H, 4.78; N, 17.24%.

4-Methylnicotinamide Adenine Dinucleotide (10).[6] A mixture of 4-methylnicotinamide (2.8 mmol, 380 mg) and NAD (0.7 mmol, 475 mg) was incubated with NADase (8 U, 20 ml) in 0.1 M Tris–HCl (60 ml) for 6 h. The reaction mixture was treated as described for **4** to give **10** (324 mg): $[\alpha]_D^{20}$ −24.8° (*c* 0.85, H_2O); UV (H_2O), λ_{max} 260 nm (log ε 4.27); ^{1}H-NMR (δ, D_2O), 2.66 (3H, s), 4.1—4.6 (10H, br), 6.0 (2H, bd), 7.65 (1H, d, J=6.0 Hz), 8.05 (1H, s), 8.40 (1H, s), 8.70 (1H, dd, J=1.5, 6.0 Hz), 8.82 (1H, d, J=1.5 Hz). Found: C, 34.86; H, 5.04; N, 15.22%. Calcd for $C_{22}H_{29}N_7O_{14}P_2 \cdot NH_3 \cdot 3H_2O$: C, 35.29; H, 5.08; N, 14.97%.

4-Methylnicotinic Acid Adenine Dinucleotide (11). A mixture of 4-methylnicotinic acid (2.4 mmol, 330 mg) and NAD (0.6 mmol, 404 mg) was incubated with NADase (8 U, 20 ml) in Tris–HCl (50 ml) for 5 h. The reaction mixture was treated as described for **4** to give **11** (196 mg): $[\alpha]_D^{20}$ −36.1° (*c* 0.90, H_2O); UV (H_2O), λ_{max} 260 nm (log ε 4.23); ^{1}H-NMR (δ, D_2O), 2.62 (3H, s), 4.1—4.6 (10H, br), 5.98 (2H, bd), 7.78 (1H, d, J=6.0 Hz), 8.02 (1H, s), 8.33 (1H, s), 8.63 (1H, dd, J=1.5, 6.0 Hz), 8.75 (1H, d, J=1.5 Hz). Found: C, 35.48; H, 5.16; N, 12.94%. Calcd for $C_{22}H_{28}N_6O_{15}P_2 \cdot NH_3 \cdot 3H_2O$: C, 35.24; H, 4.94; N, 13.08%.

Susceptibility of NAD-analogs to the Hydrolase Action of NADase. A series of mixtures (0.6 ml) containing 30 mM NAD-analog (pH 7, 0.2 ml), NADase (0.12 U, 0.3 ml), and 0.5 M Tris–HCl (pH 7.2, 0.1 ml) was incubated at 37 °C for 18 h. In the course of incubation, the aliquot (1 μl) of the resulting mixture was analyzed by TLC using a thin layer scanner with a chromatopack. Based on the chromatograms thus obtained the amount of ADP-ribose produced was estimated semi-quantitatively. The data in Table 2 show the averages of three measurements.

pK_a *Values of Pyridine Bases.* The values were determined by the spectrometric method of Albert and Phillips[12] using the following series of 0.01 M buffers; glycine–hydrochloric acid (pH 2.00), acetate (pH 5.00), phosphate (pH 7.00), borate (pH 9.00), and glycine–sodium hydroxide (pH 12.00).

The author wishes to thank Prof. T. Masamune (Department of Chemistry, Faculty of Science) and Prof. I. Azuma (Institute of Immunological Science) for their encouragement and useful suggestions during this work.

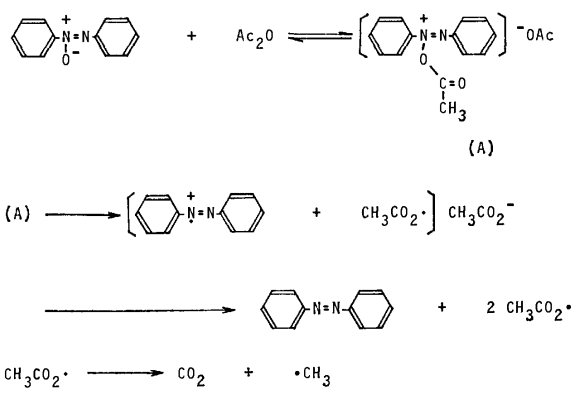
(Received August 10, 1981)

Treatment of azoxybenzene with *p*-toluenesulfonic acid in acetic anhydride gave tosylates of 4- and 2-(phenylazo)phenols, and the corresponding acetates as by-product, besides azobenzene. However, a similar reaction of 4,4′-difluoroazoxybenzene gave 2-tosyloxy-4,4′-difluoroazobenzene as rearrangement product, besides 4-fluorophenyl tosylate and 4-fluorophenyl acetate. Meanwhile, the reaction of 4,4′-diacetoxyazoxybenzene afforded 4-acetoxyphenyl tosylate and hydroquinone diacetate in high yields. These unique reactions involve C–N bond cleavage, and may proceed through a pathway involving formation of benzenediazonium ion as the key intermediate.

In the Wallach rearrangement of azoxybenzenes, concentrated sulfuric acid has generally been used.[1] Meanwhile, treatment of azoxybenzene with chlorosulfuric acid[2] yielded chlorosulfate of *p*-hydroxyazobenzene. Similarly, in the reaction with fluorosulfuric acid,[3] the corresponding fluorosulfate of *p*-hydroxyazobenzene was obtained. Recently, the reaction of azoxybenzene with arenesulfonyl chloride[4] and tosyl anhydride[5] have also been found to give the arenesulfonates of *o*- and *p*-hydroxyazobenzene.

In the ordinary Wallach rearrangement of azoxybenzene with sulfuric acid, hydrogen sulfate ester of *p*-hydroxyazobenzene is formed as the rearrangement product, which is then rapidly hydrolyzed to give *p*-hydroxyazobenzene as the final product.[6] However, the sulfonic acid esters of hydroxyazobenzene do not hydrolyze under the reaction conditions. Recently, Yamamoto *et al.* reported that the treatment of azoxybenzene with trichloroacetic acid in acetic anhydride afforded hydroxyazobenzene,[7] *via* forming the corresponding ester, which is however unstable and hydrolyzed during the isolation of the reaction product.

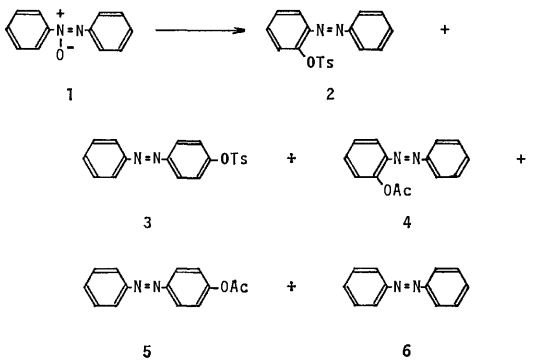
Earlier, we reported that azoxybenzene reacts with an equimolar amount of acetic anhydride only upon heating at such a high temperature as 190 °C for a long hour, affording a mixture of azobenzene, acetanilide and acetic acid along with carbon dioxide, carbon monoxide and methane.[8] We then suggested that the initial slow step is the acetylation to give the *N*-acetoxyazobenzene, which undergoes homolytic fission of N–O bond shown below.



Since acetylation of *N*-oxides or sulfoxides is markedly accelerated by acid catalysis, it was anticipated that the reaction of azoxybenzene with acetic anhydride would proceed under mild conditions in the presence of a strong acid such as *p*-toluenesulfonic acid, and gives the rearranged ester, because water is absent under the conditions and hence the esters would not be hydrolyzed. Indeed the reaction between azoxybenzene and a mixture of acetic anhydride and *p*-toluenesulfonic acid was found to proceed smoothly even at 100 °C, and gave both tosyl and acetyl esters of hydroxyazobenzene. This paper is concerned with the reaction of some azoxybenzenes with *p*-toluenesulfonic acid in acetic anhydride.

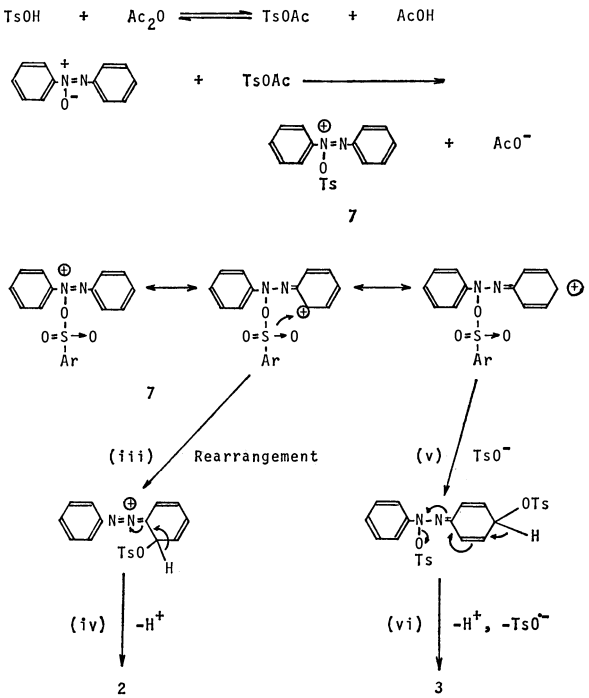
Results and Discussion

Treatment of azoxybenzene (**1**) with excess *p*-toluenesulfonic acid (TsOH) in excess acetic anhydride at 100 °C for 12 h gave 2-tosyloxyazobenzene (**2**) (5%) and 4-isomer (**3**) (20%), 2-acetoxyazobenzene (**4**) (0.3 %) and 4-isomer (**5**) (2%) as rearrangement products, along with azobenzene (**6**) (7.5%).

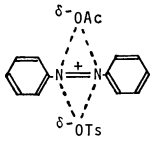


These rearrangement products may be formed through a mechanistic pathway similar to that proposed for the reaction of **1** with arenesulfonyl chloride,[3] as illustrated in the following sequential scheme: (i) Formation of the mixed acid anhydride, (ii) reaction of **1** with TsOAc to form *O*-tosylated intermediate (**7**), (iii) migration of tosyloxyl group to *o*-position, (iv) deprotonation to give eventually **2**, or (v) nucleophilic attack of tosylate ion (or acetate ion) at *p*-position of **7**, and (vi) subsequent elimination of tosyloxyl group bonded to azo nitrogen and deprotonation

to give **3** (or **5**).



In the step (iii), the intermediate, **7**, may dissociate to form an intimate ion pair (**8**), prior to migration. When acetoxyl group migrates to the *o*-position, compound **4** is formed, though the yield is so low. In addition, there might be an alternative pathway to form a dication intermediate directly by cleavage of tosylate ion from **7**.



8

Here again, the formation of azobenzene may be rationalized in terms of incipient formation of azobenzene cation radical similarly as in the reaction of azoxybenzene with acetic anhydride at 190 °C.

The ratio of *o*-rearrangement to *p*-rearrangement is higher (1:4) than that of the reaction of **1** with sulfuric acid ($o:p=1:26$).[9] Probably, unlike the rearrangement in polar sulfuric acid, in which dissociation of water from azo group is more complete and hence the intermolecular migration to *p*-position predominates, that of the intermediate, **7**, in less polar acetic anhydride is more prone to proceed intramolecularly to *o*-position (step iii). This may be the reason why the *o*/*p* product ratio is a little higher in the reaction with acetic anhydride–TsOH system than with sulfuric acid.

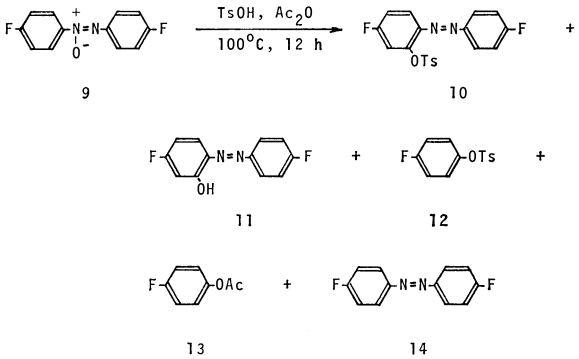
The yield of acetate, **5**, was low, despite more nucleophilic character of acetate ion than tosylate ion. However, in the presence of TsOH, acetate ion, if formed, would be completely protonated to form acetic acid which is no longer nucleophilic enough to compete with tosylate ion to attack the *p*-position. The ester exchange reaction between tosylate, **3**, and acetate, **5**, was not observed under the above reaction conditions.

Table 1. Reaction of 4-bromo-ONN- and 4-bromo-NNO- azoxybenzenes

Compound	Yield/%					
	16	**17**	**18**	**19**	Acetate[a]	Recovery
15*α*	4.0	2.5	1.3	0.7	1.3	80
15*β*	4.8	3.3	1.6	0.8	1.3	73

a) 4-(*p*-Bromophenylazo)phenyl acetate contaminated by small amounts of the 2-isomer.

Treatment of 4,4′-difluoroazoxybenzene (**9**) with a mixture of TsOH and acetic anhydride gave in poor yield, ortho rearrangement product, 2-tosyloxy-4,4′-difluoroazobenzene (**10**) (yield 4%) and 2-(*p*-fluorophenylazo)-5-fluorophenol (**11**) (yield 1.5%) which is undoubtedly formed by hydrolysis of 2-acetoxy-4,4′-difluoroazobenzene during the isolation process of the reaction products. However, *p*-fluorophenyl tosylate (**12**) (yield 12%) and *p*-fluorophenyl acetate (**13**) (yield 5%) formed by the cleavage[16] of azoxy N and phenyl C bond were obtained, besides 4,4′-difluoroazobenzene (**14**) (yield 4.5%).

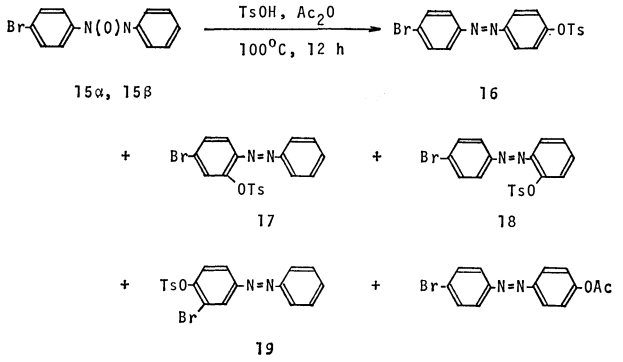


The reaction of 4,4′-dichloroazoxybenzene with a mixture of TsOH and acetic anhydride was relatively slow, and only after heating at 100 °C for 50 h, 2-tosyloxy-4,4′-dichloroazobenzene (3%), 2-(*p*-chlorophenylazo)-5-chlorophenol (0.4%), *p*-chlorophenyl tosylate (0.5%), and 4,4′-dichloroazobenzene (5.5%) were obtained.

Meanwhile, the reaction of 4,4′-dichloroazoxybenzene with sulfuric acid yielded abnormal rearrangement products, *e.g.* 2-chloro-4-(*p*-chlorophenylazo)phenol and 4-(*p*-chlorophenylazo)phenol, in which chlorine is migrated or lost.[10] However, these abnormal products were not observed at all in the reaction of 4,4′-dichloroazoxybenzene with a mixture of TsOH and acetic anhydride. The *O*-tosylated intermediate, **7**, did not accept the nucleophilic attack of tosylate ion at ipso position but preferentially rearranged to form the ester of *o*-hydroxyazobenzene. In addition, the formation of dicationic intermediate ($Ar-\overset{+}{N}\equiv\overset{+}{N}-Ar$) may be suppressed by low acidity under this reaction conditions. Consequently, the ipso attack of tosylate ion did not occur.

The reaction of 4-bromo-ONN-azoxybenzene (**15*α***) and the NNO-isomer (**15*β***) with a mixture of TsOH and acetic anhydride gave 4-(*p*-bromophenylazo)phen-

yl tosylate (**16**), 2-(phenylazo)-5-bromophenyl tosylate (**17**), 2-(*p*-bromophenylazo)phenyl tosylate (**18**), and 2-bromo-4-(phenylazo)phenyl tosylate (**19**) (Table 1).



Azophenol tosylates, **16**—**19**, could not be isolated in this reaction. Therefore, the mixture was analyzed by gas chromatography. The mixture was hydrolyzed further with sodium hydroxide solution to isolate the corresponding azophenols.

The reaction products obtained from α-isomer of 4-bromoazoxybenzene (**15α**) were practically similar to those formed from the β-isomer (**15β**). It appears that the reaction proceeds *via* a common intimate ion pair intermediate (**20**). The product, **19**, is considered to be formed by rearrangement accompaning the migration of bromine. The similar rearrangement was observed in the reaction of 4,4'-dibromoazoxybenzene with sulfuric acid.[10] Thus, the rearrangement may be interpreted by the following mechanistic scheme in which the intimate ion pair, **20**, is the common intermediate in the rearrangement to both *o*- and *p*-positions and also in the migration of bromine, similar to that proposed previously.

The reaction of 4,4'-diacetoxyazoxybenzene(**21**)

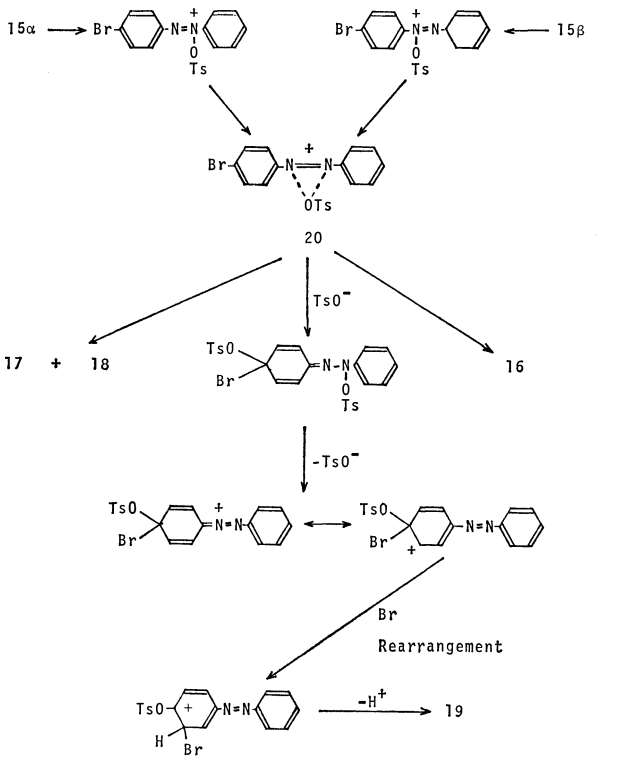


Table 2. Reaction of 4-acetoxyazoxybenzenes with TsOH in acetic anhydride (100 °C, 2 h)

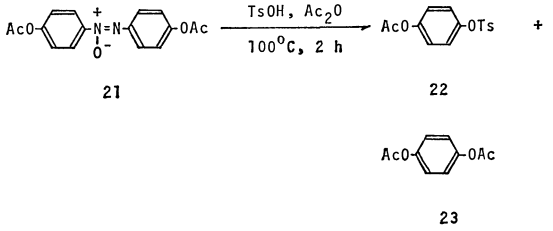
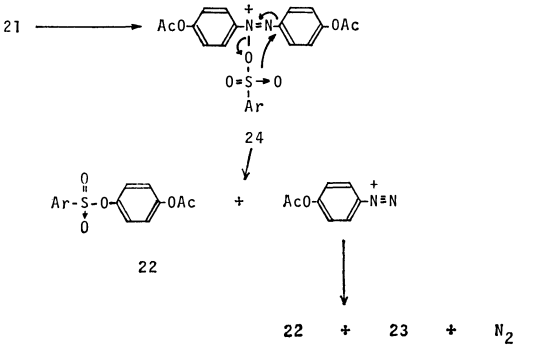
Compound	Yield/%				
	22	**23**	**26**	**27**	**25β**
25α	77	9	18	72	
25β	33	4	8	30	60

gave mainly unique 1-ipso substitution products, *i.e.* 4-acetoxyphenyl tosylate (**22**) (yield 51%) and hydroquinone diacetate (**23**) (yield 47%), in high yield with evolution of nitrogen. The expected rearrangement products (the corresponding azophenol esters) were not obtained.



The reaction may be nicely explained by the following mechanistic scheme: (i) The initial formation of *O*-tosylated azoxybenzene (**24**), (ii) cleavage of the C–N bond and simultaneous attack to the tosyloxy oxygen (*i.e.* formation of **22** and the diazonium ion), (iii) decomposition of the diazonium ion to form **22** and **23** with evolution of nitrogen. Step (ii) may be attributed to the resonance effect of acetoxyl group to facilitated the cleavage of C–N bond. In this process, there might be a possibility that tosyloxyl group is alternated to acetoxyl group to give **23**.

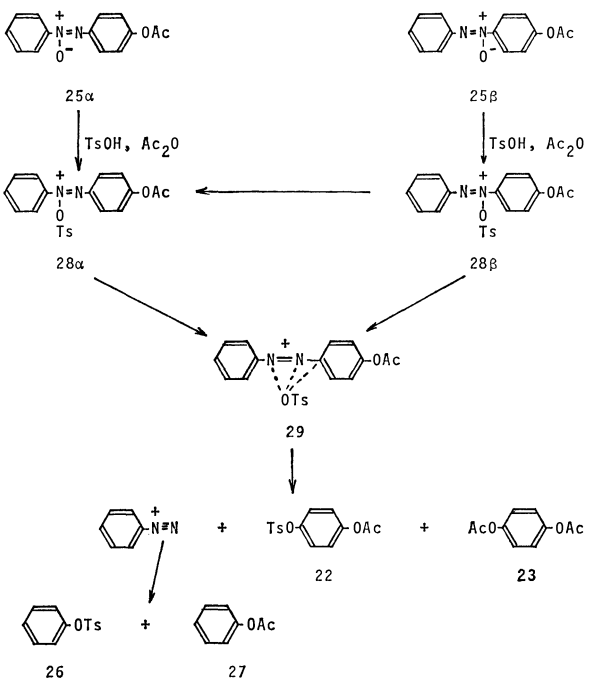
In analogy with the reaction, when a solution of **21** and tosyl anhydride in acetonitrile was refluxed for 2 h, **22** was obtained in yield of 16%. Also the reaction of **21** with sulfuric acid in acetic anhydride (100 °C, 1 h) afforded **23** (yield 35%).



On the other hand, 2,2'-diacetoxyazoxybenzene gave also 2-acetoxyphenyl tosylate (41%), cathecol diacetate (18%), and 2,2'-diacetoxy-4-tosyloxyazobenzene (16%). In this reaction, the rearrangement product was obtained to a considerable extent.

The C–N bond cleavage was also found to occur in the reaction of 4-acetoxyazoxybenzene. Compounds, **22** and **23**, as well as, phenyl tosylate (**26**) and phenyl acetate (**27**) were obtained in the reaction of 4-acetoxy-ONN-azoxybenzene (**25α**) and 4-acetoxy-

NNO-azoxybenzene (**25β**). The results are shown in Table 2.

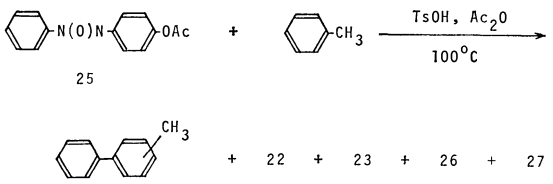


The α-isomer (**25α**) was found to react more rapidly than the β-isomer (**25β**). Accordingly, when the mixture of α- and β-isomers was used, the β-isomer was isolated as recovered material. Thus this procedure can be applied to prepare the β-isomer.

Both **25α** and **25β** gave the products nearly in the same ratio. Therefore, the reaction is presumed to proceed *via* a same common transient intermediate, perhaps a symmetrical ion pair (**29**). Alternatively, there is a possibility that **28β** rearranges to **28α** before undergoing the C–N bond cleavage.

The yield of tosylate, **22**, was higher than that of acetate, **23**, and while the yield of **27** was higher than that of **26**. Therefore, the first C–N bond cleavage would occur on the carbon atom of benzene ring having *p*-acetoxyl group, to give benzenediazonium ion and **22** (and **23**). In this step, tosyloxyl oxygen attacks the C_1 atom of benzene ring in preference to acetoxyl oxygen, since acetoxyl group would be completely protonated and lack enough nucleophilicity to attack ipso C_1. Benzenediazonium ion thus formed is reactive and hence would react readily with acetoxyl group present in a large exess.

In the presence of toluene, the reaction of **25** (α- and β-isomer) with TsOH and acetic anhydride afforded methylbiphenyl (yield 9%), as well as **22**, **23**, **26**, and **27**. Gas chromatographic analysis showed



that the isomer distribution of methylbiphenyl was *o*: 57%, *m*: 21%, *p*: 22%. This ratio is close to that obtained by the reaction of toluene with benzenediazoniom ion in the presence of TsOH (*o*: 61%, *m*: 16%, *p*: 23%). The formation of methylbiphenyl demonstrates the participation of benzenediazonium ion as the intermediate.

Formation of arenediazonium ion from azoxyarene is not entirely unprecedented. The photo-rearrangement of 2,2′-dimethylazoxybenzene was reported to give a diazonium ion as an intermediate which eventually yielded abnormal by-product.[11]

Similarly, 4-chloro-4′-acetoxyazoxybenzene (a mixture of α- and β-isomer) yielded **22** (52%), **23** (5%), *p*-chlorophenyl tosylate (13%), and *p*-chlorophenyl acetate (45%). The recovered azoxy compound (37%) was almost 4-(*p*-chlorophenylazoxy)-NNO-phenyl acetate (β-isomer).

Experimental

Melting points are uncorrected. GLC analyses were performed on a Shimadzu GC-6A (column: 1.5% Silicone OV-17, 1 m or 2% Silicone OV-225, 3 m). Other instruments used are the same as those previously described.[10]

The reaction products were identified by comparison with samples prepared independently.

Material. 4,4′-Difluoro- and 4,4′-dichloro-azoxybenzenes and *p*-bromoazoxybenzenes were prepared according to the method given in the previous paper.[10] 4,4′-Diacetoxyazoxybenzene (**21**) was obtained as described by Jeonard and Curry,[12] mp 169—170 °C (from benzene). 2,2′-Diacetoxyazoxybenzene, *p*-acetoxyazoxybenzene, and *p*-acetoxy-*p*′-chloroazoxybenzene were prepared by oxidation of the corresponding azo compound with 30% H_2O_2 in AcOH. 2,2′-Diacetoxyazoxybenzene, mp 115—116 °C. Found: C, 61.35; H, 4.60; N, 8.72%. Calcd for $C_{16}H_{14}N_2O_5$: C, 61.14; H, 4.50; N, 8.91%. 4-Acetoxyazoxybenzene was a mixture of α-isomer 61% and β-isomer 39% (GLC). 4-Acetoxy-4′-chloroazoxybenzene was a mixture of α-isomer 57% and β-isomer 43% (HPLC). 4-Phenylazoxy-ONN-phenyl acetate (**25α**) and its NNO-isomer (**25β**) were prepared by acetylation of the corresponding phenylazoxyphenol with acetic anhydride and pyridine, **25α**, mp 93—95 °C (lit,[13] 89—90 °C), **25β**, mp 80—81 °C (lit,[13] 79—80 °C).

Reaction of Azoxybenzene (1). *p*-Toluenesulfonic acid (TsOH) monohydrate (5.0 g) was heated at 140 °C under reduced pressure to remove the crystalline water. To a solution of TsOH in acetic anhydride (12.5 ml) was added **1** (0.5 g). The solution was heated at 100 °C for 12 h. The reaction mixture was poured into cold water, and extracted with benzene. The extract was washed with $NaHCO_3$ solution, dried over Na_2SO_4, and evaporated. The residue was chromatographed on silica gel (benzene). Each fraction was analyzed by GLC. First fraction was a mixture of azobenzene (**6**) (0.034 g) and **1** (0.156 g). Second fraction was a mixture of 2-tosyloxyazobenzene (**2**) (0.045 g) and 4-tosyloxyazobenzene (**3**) (0.178 g). Third fraction was a mixture of 2-acetoxyazobenzene (**4**) (1.7 mg) and 4-acetoxyazobenzene (**5**) (12 mg).

Reaction of 4,4′-Difluoroazoxybenzene (9). Compound, **9**, (0.2 g) was treated with a mixture of TsOH and Ac_2O similarly, and worked up according to the procedure described above. The reaction product was chromatographed on silica gel (benzene). First fraction was a mixture o 4,4′-difluoroazobenzene (**14**) (9 mg) and **9** (82 mg). Second fraction was distilled under reduced pressure to give 4-fluorophenyl acetate (**13**) (7 mg), and the residue was chromato-

graphed on alumina.[15] Elution with benzene gave a mixture of 4-fluorophenyl tosylate (**12**) (27 mg) and 2-tosyloxy-4,4'-difluoroazobenzene (**10**) (13 mg). Recrystallization from hexane gave **10**, mp 116—117 °C, and the mother liquor was evaporated and distilled *in vacuo* to give **12**, mp 56—58 °C) from hexane). The residue on alumina column was eluted with EtOH–H_2O to give 2-(*p*-fluorophenylazo)-5-fluorophenol (**11**), mp 126 °C (from hexane).

Reaction of 4,4'-Diacetoxyazoxybenzene (21). TsOH monohydrate (5.0 g) was dehydrated at 140 °C under reduced pressure. A solution of **21** (0.5 g) and TsOH in Ac_2O (12.5 ml) was then heated at 100 °C for 2 h. The solution was poured into cold water. The precipitate was filtered off and purified by column chromatography on silica gel (benzene) to give 4-acetoxyphenyl tosylate (**22**) (0.50 g), mp 77.5—78 °C (from hexane-benzene). The mother liquor was extracted with benzene. The extract gave hydroquinone diacetate (**23**) (0.29 g), mp 122—123 °C (from hexane).

Reaction of 2,2'-Diacetoxyazoxybenzene. 2,2'-Diacetoxyazoxybenzene (0.2 g) was treated with a mixture of TsOH and Ac_2O similarly according the method described above. The reaction product was chromatographed on silica-gel column (benzene). First fraction was 2-acetoxyphenyl tosylate (0.16 g), mp 90—91 °C (from hexane). Second fraction was cathecol diacetate (0.044 g), mp 61—62 °C (from hexane). Third fraction (0.05 g) gave 2,2'-diacetoxy-4-tosyloxyazobenzene, mp 97—98 °C (from EtOH). Found: C, 59.02; H, 4.37; N, 6.00%. Calcd for $C_{23}H_{20}N_2O_7S$: C, 58.97; H, 4.30; N, 5.98%. The authentic sample was prepared by acetylation of 2,2'-dihydroxy-4-tosyloxyazobenzene (mp 223—225 °C).

Reaction of 4-Acetoxyazoxybenzene (25). 4-Acetoxyazoxybenzene (0.5 g) was treated with a similar mixture of TsOH and Ac_2O at 100 °C for 1 h according to the procedure described above. The reaction mixture was poured into cold aqueous $NaHCO_3$ solution, and then extracted with ether. The extract was distilled to give phenyl acetate (0.09 g). The residue was chromatographed on silica gel (benzene). First fraction gave phenyl tosylate (0.06 g), mp 94—95 °C (from hexane). Second fraction was the unchanged azoxy compound (0.16 g) (α-isomer 13.5% and β-isomer 86.5%). Third fraction gave 4-acetoxyphenyl tosylate (0.29 g) mp 79—80 °C (from hexane-benzene). Fourth fraction gave hydroquinone diacetate (0.019 g), mp 122—123 °C.

Authentic Sample of Tosylate Derivatives. The corresponding phenol was treated with tosyl chloride and pyridine by conventional method. **2**, mp 84—85 °C (lit,[4] 85—86 °C). **3**, mp 164—165 °C (lit,[4] 159—160 °C). 2-Tosyloxy-4,4'-dichloroazobenzene, mp 136—138 °C (from benzene-hexane). Found: C, 54.22; H, 3.14; N, 6.39%. Calcd for $C_{19}H_{14}Cl_2N_2O_3S$: C, 54.16; H, 3.33; N, 6.65%. **10**, mp 115—116 °C (from EtOH). Found: C, 58.88; H, 3.50; N, 7.22%. Calcd for $C_{19}H_{14}F_2N_2O_3S$: C, 58.76; H, 3.63; N, 7.21%. **16**, mp 157—159 °C. Found: C, 53.22; H, 3.33; N, 6.71%. **17**, mp 132—133 °C. A Stereoselective One-stage α-Glucosylation with 2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranose and a Mixture of Methanesulfonic Acid, Cobalt(II) Bromide, and Tetraethylammonium Perchlorate

(Received September 5, 1981)

A one-stage procedure for the stereoselective α-glucosylation of alcohol with 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose and a mixture of methanesulfonic acid, cobalt(II) bromide, and tetraethylammonium perchlorate is described. The mechanism of the glucosylation reaction is discussed.

Continuing effort has been dedicated to developing a variety of stereoselective α-glucosylation methods.[1] The methods employing various kinds of glucosyl halides and equivalents with a non-participating benzyloxyl group at C-2 are most often used for the synthesis of α-glucosides.[2] However, they always require the preparation of the moisture-sensitive glucosylating precursors. Even the one-pot method starting from the stable glucosylating precursor, 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose (**1**), involves a two-stage treatment of activation and condensation.[2e]

The glucosylation of alcohol with **1** readily proceeds in one-stage fashion in the presence of methanesulfonic acid ($MeSO_3H$) and $CoBr_2$ in CH_2Cl_2 at 25 °C.[3a] The later improvement[3b] of the stereoselectivity of this reaction using the additive tetraethylammonium perchlorate (Et_4NClO_4) enabled us to develop a simple method for the highly stereoselective α-glucosylation of alcohol with **1** (In Eq. 1, G denotes the 2,3,4,6-tetra-*O*-benzyl-D-glucopyranosyl group).

$$\alpha\text{GOH} + \text{ROH} \xrightarrow{MeSO_3H/CoBr_2/Et_4NClO_4} \alpha\text{GOR}\ (+\beta\text{GOR}) \quad (1)$$

The method is as handy as the modified Fischer method[4] and is practically free from the moisture problem often encountered in the usual glucosylation, since $CoBr_2$ is a strong desiccant.

Results and Discussion

Glucosylation with $MeSO_3H$ and $CoBr_2$.[3a] When an equimolar mixture of **1**, cyclohexylmethanol, and $CoBr_2$ in CH_2Cl_2 was treated with $MeSO_3H$ at 25 °C, the glucosylation reaction (In Eq. 2, R=cyclohexylmethyl, X=$MeSO_3$) was found to proceed smoothly to give the anomeric glucosides (**2a** and **2b**)

$$\alpha\text{GOH} + \text{ROH} \xrightarrow{HX/CoBr_2} \alpha\text{GOR} + \beta\text{GOR} \quad (2)$$

(Table 1). The yield of the glucosides **2a** and **2b** was maximized at 0.5 h (Runs 1—6). The yield was very dependent on the amount of $MeSO_3H$ (Runs 1, 3, and 5) and moderately dependent on that of $CoBr_2$ (Runs 2, 3, and 4) and of the alcohol (Runs 3 and 6). Too much use of $MeSO_3H$ and the alcohol decreased yields of the glucosides (Runs 5 and 6). No other salts examined so far showed such acceleration effects.[5] Acid such as *p*-toluenesulfonic acid and 2,4,6-trimethylbenzenesulfonic acid were of use, but trifluoroacetic acid was not. As for the solvent, benzene was useful for the reaction. Nitromethane ($MeNO_2$) brought about the stereoselective formation of the α-glucoside **2a**, but the yield was not satisfactory because de-*O*-benzylation reactions occurred concurrently. Even in the use of CH_2Cl_2, trace amounts of by-products such as the de-*O*-benzylation products, cyclohexylmethyl 3,4,6-tri-*O*-benzyl-α- and -β-D-gluco-

a) The reaction was conducted at 25 °C. Yields are based on the weight of glucosides obtained compared to the weight of alcohol charged. b) The mole ratio of **1**, $MeSO_3H$, and $CoBr_2$ to alcohol was 1.0, 0.3, and 1.0, respectively. c) The mole ratio of **1**, $MeSO_3H$, and $CoBr_2$ to alcohol was 1.3, 0.3, and 1.0, respectively. d) The mole ratio of **1**, $MeSO_3H$, and $CoBr_2$ to alcohol was 1.3, 0.4, and 1.3, respectively. e) Bn denotes benzyl group and EtPy means *N*-ethylpyridinium ion.

pyranosides (**3a** and **3b**), and the self-condensation products (**4a** and **4b**) of **1**[6a] were isolated from the reaction mixture.[6b]

When the glucosylation of methanol (MeOH) with **1** was carried out at 0 °C, the transient accumulation of the glucosyl bromide (**5**) was observed by means of TLC at the beginning of the reaction (<0.5 h). The ^1H NMR spectrum of the filtrate of the mixture of **1**, $MeSO_3H$, and $CoBr_2$ in CH_2Cl_2 was essentially superimposable with that of the authentic **5** in CH_2Cl_2. Therefore, **5** evidently intervenes in the glucosylation reaction.

The IR spectrum of the solid material recovered from the glucosylation mixture had the characteristic absorption of the salt of $MeSO_3H$ at ν=1180 and 1060 cm^{-1} and the ^1H NMR spectrum of the supernatant of the glucosylation mixture did not show the signal of the methyl group of $MeSO_3H$ near at δ 3.2. Moreover, it was found that $MeSO_3H$ and $CoBr_2$ reacted to afford the solid material whose composition was $CoBr_{2-x}(CH_3SO_3)_x$. Consequently, $MeSO_3H$ surely reacts with $CoBr_2$ to generate HBr (Eq. 3) during the glucosylation reaction.

$$CoBr_2 + xMeSO_3H \longrightarrow CoBr_{2-x}(MeSO_3)_x + xHBr \quad (3)$$

It was then confirmed that the glucosylation of MeOH with **1** proceeds well in the presence of $CoBr_2$ and HBr (In Eq. 2, R=Me, X=Br) and $CoBr_2$ accelerates the alcoholysis of **5** with cyclohexylmethanol.[7a] It is concluded that HBr generated *in situ* cooperates with $CoBr_2$ to convert **1** efficiently into **5** (Eq. 4a), which then undergoes alcoholysis (Eq. 4b). Figure 1 presents a summarized scheme for the one-stage glucosylation of alcohol using **1** and the mixture of $MeSO_3H$ and $CoBr_2$.[7b]

$$\alpha GOH \xrightarrow[-H_2O]{\text{a) HBr/CoBr}_2} \alpha GBr \xrightarrow[-HBr]{\text{b) ROH/CoBr}_2} \alpha GOR + \beta GOR \quad (4)$$

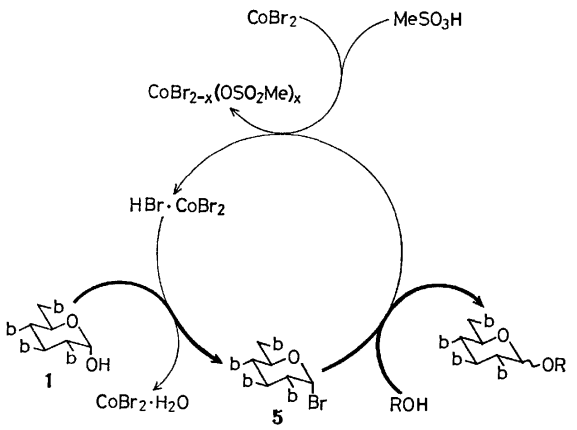

Fig. 1. Summarized scheme of the glucosylation reaction of alcohol with 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose using the mixture of methanesulfonic acid and cobalt(II) bromide.

Improvement of the Stereoselectivity of the Glucosylation.[3b] Since the glucosyl bromide **5** intervenes in the glucosylation reaction (Fig. 1), tetrabutylammonium bromide (Bu_4NBr) and relatives were added into the reaction mixture, because it was anticipated that they cause the bromide ion-catalyzed stereoselective α-glucosylation[2c] (Table 2). The addition of Bu_4NBr caused the predominant formation of the α-glucoside **2a**, but with a decrease of the yields of **2a** and **2b** (Runs 13—15). Excessive use of Bu_4NBr sharply decreased the yield of glucosides; two molar amounts of Bu_4NBr almost inhibited the reaction (Run 16). This is attributable to the fact that two molar amounts of Bu_4NBr interrupts the formation of **5** from **1**, because the bromide anion strongly coordinates with $CoBr_2$ to form $[CoBr_3]^-$ and/or $[CoBr_4]^{2-}$, in competition with $MeSO_3H$ (*cf.* Eq. 2).[8] Other bromides showed simi-

lar tendencies, but the effects were weaker than for Bu_4NBr.

Next, effects of Et_4NClO_4 and related substances on the selectivity of the glucosylation were examined, because the perchlorate anion has poor coordinating ability to $CoBr_2$[9] and the glucosyl perchlorates with a benzyloxyl group at C-2 undergo the stereoselective α-glucosylation[2b] (Runs 20—25). Among the salts used, Et_4NClO_4 sharply increased the proportion of the α-anomer **2a** without serious decrease of the yield of the glucosides. The difference in the coordinating ability to $CoBr_2$ between perchlorate anion (weaker) and bromide anion (stronger)[7b] promotes the formation of the glucosyl perchlorate as in Eq. 5, so that the perchlorate anion does not interrupt the whole reaction. The effect of other salts was similar but feeble (Runs 23—25).

$$\alpha GOH + Et_4N^+//ClO_4^- + CoBr_2 \longrightarrow G^+//ClO_4^- + Et_4N^+//[CoBr_3]^- \quad (5)$$

Finally, the extent of the anomerization of the β-glucoside **2b** was determined under the three glucosylation conditions described above (Table 3). Because **2b** did not anomerize into **2a** so much in the presence of $MeSO_3H$, $CoBr_2$, and Bu_4NBr (Run 27), most of **2a** seems to be formed *via* the bromide ion-catalyzed alcoholysis of **5**, in the glucosylation (Run 14) of cyclohexylmethanol with **1** and this reagent mixture. In contrast to this, the mixture of $MeSO_3H$, $CoBr_2$, and Et_4NClO_4 in CH_2Cl_2 anomerized **2b** into **2a** efficiently (Run 28) (Eq. 6). The composition of the anomeric glucosides of the anomerization mixture was almost identical with that of the glucosylation mixture of the alcohol with **1** and this ternary mixture (Run 21). Therefore, this glucosylation furnishes an equilibrium mixture of the anomeric glucosides like the Fischer glucosylation does. It is noted that the mixture of $MeSO_3H$ and $CoBr_2$ in $MeNO_2$ smoothly anomerized **2b** and the composition of the anomeric glucosides was equal to that of the glucosylation mixture in $MeNO_2$ containing this binary mixture (Run 9). In this case, the high solubility of $CoBr_2$ in $MeNO_2$ may greatly enhance the polarity of the medium. This promotes the formation of the glucosyl cation G^+ to attain the anomerization of **2b** with $MeSO_3H$. Based on the results described so far, the mechanism of the stereoselective α-glucosylation affording the equilibrium mixture of the anomeric glucosides is postulated in Fig. 2.

$$\beta GOR \xrightarrow{MeSO_3H/CoBr_2/Et_4NClO_4} \alpha GOR \quad (6)$$

Table 3. Anomerization of cyclohexylmethyl 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranoside (**2b**) in various conditions[a]

Run	Additive, equiv.	Solvent	Yield of glucosides (**2a**, **2b**) %	(α/β)

a) The reaction was conducted on a 0.5 mmol scale in CH_2Cl_2 for 2 h at 25 °C. Yields were based on the weight of glucosides compared to the weight of alcohol charged. b) Mole ratios of **1**, $MeSO_3H$, $CoBr_2$, and Et_4NClO_4 to alcohol were 1.3, 0.4, 1.3, and 1.3. c) Mole ratios of **1**, $MeSO_3H$, $CoBr_2$, and Et_4NClO_4 to alcohol were 1.3, 0.3, 1.3, and 0.5. d) Anomeric glucosides obtained were identified with the samples prepared by alternative methods (Ref. 11).

This one-stage stereoselective α-glucosylation was applied to several alcohols to give the results summarized in Table 4. For practical use, slightly excess amounts of **1**, $CoBr_2$, and Et_4NClO_4 were charged in the case of primary alcohols (Runs 22, 29—32). Because of the high susceptibility of the glucoside of secondary alcohols to the anomerization,[10] smaller amounts of Et_4NClO_4 was used in the glucosylation of such alcohols (Runs 33—37).

Experimental

Instruments used are identical with those described previously.[6a] Green-colored anhydrous $CoBr_2$ (Wako) was stored over P_2O_5. The acid $MeSO_3H$ (Tokyo Kasei) was used without any pretreatments. The additives Et_4NClO_4 (Tokyo Kasei) and Bu_4NBr (Tokyo Kasei), recrystallized from acetonitrile containing hexane, were used after being stored *in vacuo* over P_2O_5 for several days. The pre-distilled

solvents were stored over Molecular Sieve (Linde 3A). Tetraethylammonium trifluoromethanesulfonate and tetrafluoroborate were prepared by the treatment of Et_4NBr with CF_3SO_3Ag (Alpha) and with $AgBF_4$ (Wako), respectively, in dry MeOH followed by evaporation *in vacuo*. Compound **1**, 6-(2,4-dinitroanilino)-1-hexanol, 5α-cholestan-3β-ol (Tokyo Kasei) were stored *in vacuo* over P_2O_5. Column chromatography of the pre-processed mixture of products was done on silica gel (Kanto Kagaku) using the solvent system of hexane and ethyl acetate, unless otherwise stated; each fraction was examined by TLC on silica gel (Merck, 7731). Evaporation was carried out under reduced pressure at 35—40 °C, unless otherwise stated. Table 5 summarized the physical and analytical data of newly synthesized compounds.

The Procedure for the Glucosylation with 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranose (1), $MeSO_3H$, and $CoBr_2$. The acid $MeSO_3H$ (3.2 μl, 0.05 mmol) was added to a stirred mixture of **1** (90 mg, 0.17 mmol), $CoBr_2$ (36.5 mg, 0.17 mmol) and cyclohexylmethanol (20.5 μl, 0.17 mmol) in CH_2Cl_2 (0.45 ml). After being vigorously stirred at 25 °C for 2 h, the mixture was diluted with benzene, followed by the addition of powdered $NaHCO_3$ with agitation. The filtrate was evaporated and chromatographed to give cyclohexylmethyl 2,3,4,6-tetra-*O*-benzyl-α- and -β-D-glucopyranoside (**2a** and **2b**) and the by-products.[6] The glucosides (**2a** and **2b**) and the self-condensation products (**4a** and **4b**) were identified by comparison with those reported.[6a,11] Yields are based on the weight of products obtained, with reference to the weight of **1** charged. The results are summarized in Table 1.

The Glucosylation of MeOH with the Benzylated Glucose 1, $MeSO_3H$, and HBr. A cooled saturated solution of HBr in CH_2Cl_2 (0.64 M, 0.28 ml) was added into a stirred mixture of **1** (90 mg, 0.17 mmol), $CoBr_2$ (36.5 mg, 0.17 mmol), and MeOH (7 μl, 0.17 mmol) in CH_2Cl_2 (0.45 ml). After being agitated for 2 h at 25 °C, the mixture was processed as above to afford methyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranoside (**6a**) (30 mg, 33%) and the β-anomer **6b** (26 mg, 28%), identified with those reported.[6a] Some unchanged **1** was recovered (21 mg, 23%).

Without $CoBr_2$, the anomeric mixture of **6a** and **6b** was obtained in 15% yield (α/β = 70/30) and **1** was recovered (83%).

The Formation of 2,3,4,6-Tetra-O-benzyl-α-D-glucopyranosyl Bromide (5) from the Benzylated Glucose 1 with $MeSO_3H$ and $CoBr_2$. A mixture of **1** (90 mg, 0.17 mmol), $MeSO_3H$ (11 μl, 0.17 mmol), and $CoBr_2$ (36.5 mg, 0.17 mmol) in CH_2Cl_2 (0.45 ml) was stirred for 1 h at 25 °C. The insoluble material was filtered, washed with CH_2Cl_2, and ignited at 110 °C *in vacuo*; IR (KBr) 1345 (Me), 1180, 1060 cm^{-1} (SO_3). Found: C, 7.07; H, 2.08; Br, 18.07%. Calcd for $CoBr_{0.55}(CH_3SO_3)_{1.45}$: C, 7.23; H, 1.82; Br, 18.25%. The ^1H NMR of the filtrate was essentially the same as that of **5** prepared *via* the treatment of ethyl 2,3,4,6-tetra-*O*-benzyl-1-thio-α-D-glucopyranoside[12] (49 mg, 0.083 mmol) in CH_2Cl_2 (0.5 ml) with a solution of Br_2 in CH_2Cl_2 (60% w/v, 27 μl) for 10 min in the dark, followed by the quick evaporation at 60 °C; δ = 6.59 (d, J = 4.0 Hz, H-1 of **5**).

When Bu_4NBr (107 mg, 0.33 mmol) was added to the reaction mixture prior to the addition of $MeSO_3H$, ^1H NMR of the filtrate indicated that **5** did not form (the signal at δ 6.59 was absent).

The Procedure for the Glucosylation with the Benzylated Glucose 1, $MeSO_3H$, $CoBr_2$, and Additive. To a mixture of **1** (90 mg, 0.17 mmol), $CoBr_2$ (36.5 mg, 0.17 mmol), an additive, and an alcohol (0.17 mmol) in a solvent (0.45 ml), $MeSO_3H$ (3.3 μl, 0.050 mmol) was added under stirring. After agitation for 2 h at 25 °C, the mixture was processed

and then chromatographed as described above. The results are summarized in Tables 2 and 4.

*Synthesis of Cyclohexylmethyl 3,4,6-Tri-O-benzyl-α- and -β-D-glucopyranose(**3a** and **3b**), Which Were Isolated from the Reaction Mixture of the Glucosylation of Cyclohexylmethanol with the Benzylated Glucose **1**.* 3,4,6-Tri-*O*-benzyl-α-D-glucopyranose[13] (450 mg, 1.0 mmol) was condensed with cyclohexylmethanol (124 μl, 1.0 mmol) in CH_2Cl_2 (2.5 ml) in the presence of $MeSO_2H$ (20 μl, 0.3 mmol) and $CoBr_2$ (219 mg, 1.0 mmol) at 25 °C for 2 h. After processing, the mixture was chromatographed (benzene–2-butanone, gradient, 100:1→10:1) to afford the β-anomer **3b** (107.5 mg, 20%); colorless needles, mp 89.5—91 °C, $[\alpha]_D^{20}$ −8° (*c* 1.0, $CHCl_3$), and then the α-anomer **3a** (199.5 mg, 37%); $[\alpha]_D^{20}$ +84° (*c* 1.0, $CHCl_3$). Found: (**3a**) C, 74.03; H, 7.74%. (**3b**) C, 75.00; H, 7.83%. Calcd for $C_{34}H_{42}O_6$: C, 74.70; H, 7.74%.

The Reaction of $CoBr_2$ with $MeSO_3H$ in CH_2Cl_2. A suspension of $CoBr_2$ (43.6 mg, 0.2 mmol) in CH_2Cl_2 (0.54 ml) was treated with $MeSO_3H$ (0.2—0.4 mmol) at 25 °C for 1 h under vigorous stirring. The solid material was collected, washed with dry CH_2Cl_2 (0.3 ml×7), and ignited *in vacuo* at 110 °C over P_2O_5. In each case, the evolution of HBr was seen at the removal of the stopper of the vessel and the filtrate precipitated AgBr on addition of aq $AgNO_3$. The solid material obtained was analyzed to afford the following data [the amount of $MeSO_3H$ (mmol), analysis]: 13 μl (0.2). Found: C, 5.08; H, 1.36; Br, 30.37%. Calcd for $CoBr_{0.92}(CH_3SO_3)_{1.08}$: C, 5.52; H, 1.39; Br, 31.29%. 26 μl (0.4). Found: C, 7.47; H, 2.14; Br, 17.19%. Calcd for $CoBr_{0.50}(CH_3SO_3)_{1.50}$: C, 7.46; H, 1.89; Br, 16.54%.

Oxidation of Lipids. I. Quantitative Determination of the Oxidation of Methyl Linoleate and Methyl Linolenate

Yorihiro YAMAMOTO, Etsuo NIKI,* and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 12, 1981)

The extent of oxidation of methyl linoleate and methyl linolenate has been measured quantitatively by several methods such as oxygen uptake, substrate disappearance, and formation of conjugated diene, TBA-reactive material and of hydrocarbon gas. In the early stage of oxidation of methyl linoleate, oxygen uptake, substrate disappearance, peroxide and conjugated diene formation were all quantitative and their results agreed well each other. Little TBA-reactive material and hydrocarbons were observed. In the oxidation of methyl linolenate, however, no product was formed quantitatively, and the extent of oxidation estimated decreased in the order, oxygen uptake>substrate disappearance>peroxide>conjugated diene>TBA-reactive material.

Oxidation of unsaturated fatty acids has been the subject of research since the onset of studies on autoxidation in 1940's.[1,2] It has recently received renewed attention, especially in relevance to the oxidation of lipids in biological systems as well as the oxidative deterioration of fats and oils.[2]

It is important and crucial to know how much oxidative deterioration has occured, but it is usually quite difficult to evaluate it, especially the oxidation *in vivo*. The oxidation reactions of saturated hydrocarbons are rather simple; they give hydroperoxides as the primary product in a substantially quantitative yield at moderate temperatures and low conversion. Thus, under these conditions, oxygen uptake, substrate disappearance, and hydroperoxide formation are all quantitative and their results agree well each other. The oxidations of olefins are more complicated: The addition to the double bond and abstraction of allylic hydrogen by peroxyl radicals compete. The addition mechanism gives primarily polyperoxides and epoxide, while the abstraction mechanism gives hydroperoxide as a major product.[3]

Oxidations of polyunsaturated fatty acids, major components of lipids, are more complicated, and usually many reactions proceed simultaniously and competitively. Thus, some criteria for accessing the extent of oxidation are required.

The extent of oxidation has been measured by several criteria such as oxygen uptake, peroxide value, conjugated diene formation, TBA-value, ethane and pentane formation, chemiluminescence, and development of fluorescence.[4,5] These methods have been applied by many investigators and are now well accepted. However, only one or two of these methods are usually used for each system, and little work has been done to examine the quantitative interrelationship between these methods.

Moreover, although many works have been done on the oxidation of unsaturated fatty acid, most of them are only qualitative or semi-quantitative; in other words, the oxidation is not measured quantitatively, but only a portion, sometimes a minor portion of these oxidation reactions is followed. Another question is that the ratio of measured oxidation to total oxidation depends on the substrate and experimental variables.

In this study, we intended to measure the oxidation of methyl linoleate and methyl linolenate by various analytical methods in order to find out how quantitative these methods are and what method is suitable for the specific reaction system.

Experimental

Methyl linoleate((*Z,Z*)-9,12-octadecadienoate) and methyl linolenate((*Z,Z,Z*)-9,12,15-octadecatrienoate) were obtained from Sigma Chemical Company and used as received. Prior to the oxidation, it was ascertained that neither conjugated diene nor peroxide was detected in the substrates. The oxidation was carried out in acetonitrile solvent using an ampoule of approximately 30 ml volume, which was immersed in a carefully temperature-controlled oil bath. 2,2'-Azobis(2,4-dimethylvaleronitrile) (AMVN) was used as a radical initiator. The rate of inhibition was measured from the induction period observed in the presence of inhibitor, 2,6-di-*t*-butyl-4-methylphenol (BMP).[6]

The rate of oxygen absorption was measured by following the pressure decrease using a pressure transducer. The oxygen uptake was calculated from the difference between initial and final oxygen amounts measured by Toepler

pump.[7] A schematic diagram of oxidation apparatus is shown in Fig. 1.

The consumption of the substrate was measured by GLC. Peroxide formation was measured by iodometric titration and/or by formation of triphenylphosphine oxide by the reduction of peroxide with triphenylphosphine. Conjugated diene was measured by the absorbance at 230—236 nm, $\varepsilon=28000$ M^{-1} cm^{-1} (1 M = 1 mol dm^{-3}). TBA value was estimated by the conventional photometric method, $\lambda_{max}=$ 531 nm and $\varepsilon=1.17\times10^5$ M^{-1} cm^{-1}. Hydrocarbon gas formation was analyzed by GLC.

Results and Discussion

Tables 1 and 2 show some pertinent data for the AMVN-initiated oxidation of methyl linoleate and methyl linolenate, respectively in acetonitrile at 50 °C. The oxidation of methyl linoleate proceeded at 50 °C even in the absence of a radical initiator, but the rate was very slow. In the presence of AMVN, it was oxidized faster and the plot of oxygen uptake as a function of time gave a good straight line at the initial stage.

Under such mild conditions that the primary products are stable and their secondary oxidation is negligible, the oxidation proceeds virtually by the following scheme.

Initiation: $IN_2I \longrightarrow 2I\cdot + N_2$

$I\cdot \xrightarrow{O_2, LH} IOOH + LO_2\cdot$

Propagation: $LO_2\cdot + LH \xrightarrow{k_p} LOOH + L\cdot$

$L\cdot + O_2 \longrightarrow LO_2\cdot$

Termination: $2LO_2\cdot \xrightarrow{k_t}$ non-radical products

IN_2I and LH are azo initiator and substrate, respectively. The chain carrying peroxyl radicals abstract doubly allylic hydrogen exclusively from methyl linoleate or methyl linolenate, whereas abstraction of other hydrogen and addition to a double bond are quite

scarce.[8]

Under these conditions, the rate of oxidation is expressed by

$$\text{rate of oxidation} = R_o = k_p(R_i/2k_t)^{1/2}[LH],$$

where k_p, k_t, and R_i are the rate constants for propagation and termination, and the rate of initiation, respectively. The ratio of the rate constants $k_p/(2k_t)^{1/2}$ gives the relative reactivity of the substrate. Tables 1 and 2 show that $k_p/(2k_t)^{1/2}$ for methyl linoleate and methyl linolenate is 0.0949 and 0.182 $(M\ s)^{-1/2}$, respectively, indicating that methyl linolenate is approximately twice as reactive as methyl linoleate.

It should be noted that this value does not always indicate the relative reactivities of the substrates, or more strictly of C–H bonds, toward peroxyl radicals. The rate and oxidizability are determined not only by k_p but also by k_t. Howard and Ingold[8] found that k_p (per reactive C–H bond) and k_t for methyl linolenate are about two and four times, respectively, larger than those for methyl linoleate at 30 °C.

Methyl linoleate was subjected to oxidation for different reaction times and conversions. As shown in Table 1, kinetic chain length was long, and oxygen uptake and reaction products increased as the oxidation proceeded. A small increase with reaction time in the ratio of rate constants, $k_p/(2k_t)^{1/2}$, was observed, indicating that this oxidation is slightly autocatalytic.

Peroxides were analyzed by high pressure liquid chromatography after reduction with triphenylphosphine, and as reported previously[9,10] four isomeric methyl hydroxylinoleates were found: (9*Z*,11*E*)-13-hydroxy-, (9*E*,11*E*)-13-hydroxy-, (10*E*,12*Z*)-9-hydroxy-, and (10*E*, 12*E*)-9-hydroxyoctadecadienoic acid methyl esters.

Table 1 shows that, at early stages where conversion is low, the values of substrate disappearance, peroxide and conjugated diene formation agreed well. As the oxidation proceeded, however, the amount of the conjugated diene formed became smaller than oxygen uptake. On the other hand, only a trace amount of TBA-reactive material was found and neither pentane nor ethane was observed. It has been pointed out that the TBA-reactive materials are formed from olefins with three or more double bonds.[11]

The oxidation of methyl linolenate exhibited a somewhat different pattern from that of methyl linoleate. Methyl linolenate was oxidized faster than methyl linoleate and $k_p/(2k_t)^{1/2}$ increased with increasing conversion, again suggesting autocatalytic oxidation. The most interesting point is that the amount of substrate reacted, and peroxides and conjugated diene formed were considerably smaller than oxygen uptake, whereas some TBA-reactive materials were observed, although they were 15% of oxygen uptake. Pryor[12] also observed in the oxidation of methyl linolenate by air containing 1.5 ppm ozone that the formation of peroxide was larger than that of conjugated diene which was still larger than TBA-reactive material.

The results given above demonstrate that none of the presently accepted tests is quantitative and that the validity of each method for measuring the extent of oxidation of lipids and tissues depend on the profile of unsaturated fatty acids existing in each sample. Care should be taken in the application of methods suitable for the specific system. For example, the oxidation may have proceeded considerably even if the TBA value is small. The oxygen uptakde must be the most useful, versatile and quantitative measure, but it should be emphasized that the oxidation should be followed by as many approaches as possible. Which the best criterion relevant to pathological effect is, remains, of course, as another question.

The support of the Toyota Foundation is hereby gratefully acknowledged.

Oxidation of Lipids. II. Rate of Inhibition of Oxidation by α-Tocopherol and Hindered Phenols Measured by Chemiluminescence

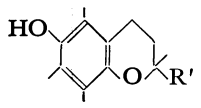
Etsuo NIKI,* Ritsuko TANIMURA, and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 11, 1981)

The rate constants for the interactions of peroxyl radicals with α-tocopherol and hindered phenols were determined by chemiluminescence method. The thermal decomposition of di-*t*-butyl diperoxyoxalate in *o*-dichlorobenzene with and without ethylbenzene was found to give chemiluminescence under oxygen. 9,10-Dibromoanthracene was an effective activator. The addition of 1-tetralyl hydroperoxide gave chemiluminescence both in the presence and absence of oxygen, while the addition of *t*-butyl hydroperoxide suppressed the chemiluminescence almost completely even under oxygen. The addition of α-tocopherol and phenols also diminished the chemiluminescence, but after reaching the minimum intensity it again increased as the inhibitors were consumed. The rate constants for the scavenging of 1-phenylethylperoxyl radical by α-tocopherol, 2,4,6-tri-*t*-butylphenol and 2,6-di-*t*-butyl-4-methylphenol were obtained as 1.5×10^5, 1.2×10^4, and 1.0×10^4 M^{-1} s^{-1} (1 M= 1 mol dm^{-3}) respectively.

α-Tocopherol **1**, the major component of vitamin E, is known to contribute in biological systems as an inhibitor of lipid peroxidation.[1,2] α-Tocopherol is

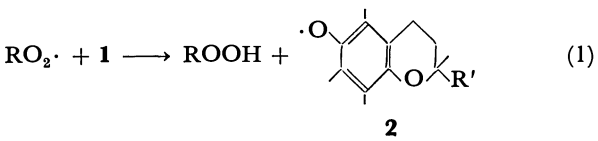


1

R′: $(CH_2CH_2CH_2\underset{\displaystyle CH_3}{\underset{|}{CH}})_3CH_3$

also used as an added antioxidant for foods and oils. It has been reported that α-tocopherol scavenges not only peroxyl radicals but also singlet oxygen[3-7] and superoxide anion radical.[8-12] However, trapping of peroxyl radicals must be the most important function of vitamin E, and to know the reactivity of α-tocopherol toward peroxyl radicals is important in understanding the antioxidizing behavior of vitamin E.

The rate constant for the interaction of α-tocopherol with peroxyl radicals has been determined recently.[13-15] The reported values range from 2×10^5 to 5×10^8 M^{-1} s^{-1}. Kharitonova *et al.*[13] obtained k_{inh} as 2×10^5



$RO_2\cdot + 1 \longrightarrow ROOH +$ **2** (1)

M^{-1} s^{-1} at 60 °C from the rate of inhibited oxidation of cumene. Ingold and his coworkers[15] also determined k_{inh} as 2.3×10^6 M^{-1} s^{-1} from the rate of inhibited oxidation of styrene. On the other hand, Packer, Slater, and Willson[14] obtained k_{inh} for trichloromethylperoxyl radical as 5×10^8 M^{-1} s^{-1} spectrometrically.

We have measured this rate constant k_{inh} for **1** by the chemiluminescence method. Since the first finding by Vassilev and Vichutinskii[16] that the oxidation of organic compounds is accompanied by the emission of weak chemiluminescence, the rate constants for autoxidation have been determined by measuring the chemiluminesence intensity.[17,18] This chemiluminescence method has been also applied recently to estimate the extent of oxidation of fats, oils and biological systems.[19-26]

Experimental

Materials. Natural *d*-α-tocopherol was kindly supplied from Eisai Co. Ltd. 2,4,6-Tri-*t*-butylphenol (TBP) and 2,6-di-*t*-butyl-4-methylphenol (BMP) were recrystallized from methanol. 2,6-Di-*t*-butylphenol was used as received. Di-*t*-butyl diperoxyoxalate (DBPO) was synthesized from *t*-butyl hydroperoxide and oxalyl chloride by the method of Bartlett *et al.*[27] Commercial 9,10-dibromoanthracene was recrystallized from methanol. 1-Tetralyl hydroperoxide (TOOH) was prepared by the air oxidation of tetralin in the presence of azobisisobutyronitrile, followed by recrystallization from heptane. Commercial *t*-butyl hydroperoxide was distilled under reduced pressure prior to use 42 °C/24 Torr (1 Torr ≈ 133.322 Pa). Ethylbenzene was washed with acid, water, alkaline and water, dried and distilled. *o*-Dichlorobenzene was used as received.

Apparatus and Procedure. The emission intensity of chemiluminescence was measured by the single photon counting apparatus, type OX-7, manufactured by Tohoku Elec-

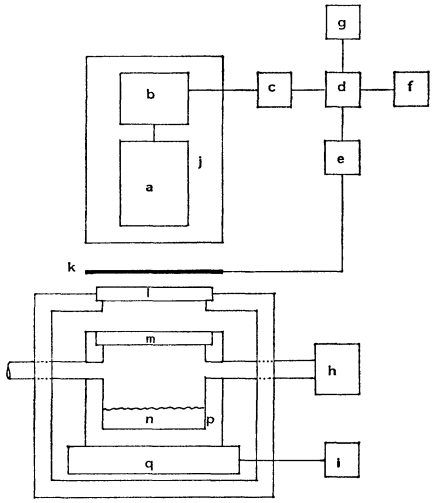


Fig. 1. Schematic diagram of the single photon counting apparatus, OX-7.

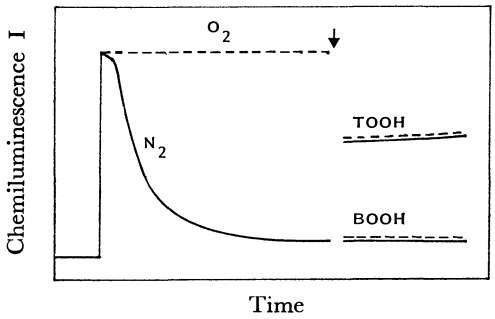

Fig. 3. Effect of atmosphere and addition of tetralyl (TOOH) and *t*-butyl (BOOH) hydroperoxides on the chemiluminescence, [DBPO]=0.10 M in *o*-dichlorobenzene at 25 °C.

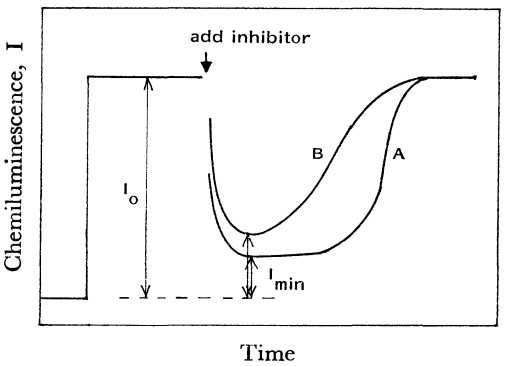

Fig. 4. Effect of addition of α-tocopherol (A) and TBP (B) on the chemiluminescence, [DBPO]=0.10 M in *o*-dichlorobenzene-ethylbenzene, 25 °C.

tronic Industries. The schematic diagram of the apparatus is shown in Fig. 1. The cell temperature was kept at 25 °C and the photomultiplier, Hamamatsu TV Co. type R878, was cooled to −20 °C.

In general, 2 or 3 ml of appropriate solution was taken into the stainless steel cell and the chemiluminescence intensity was measured every 10 second and recorded. Neat *o*-dichlorobenzene or a mixture of *o*-dichlorobenzene and ethylbenzene (1/1 by v/v) was usually used as solvent. No filter was used.

Results

A strong chemiluminescence was observed when DBPO was thermally decomposed in *o*-dichlorobenzene or *o*-dichlorobenzene-ethylbenzene at 25 °C under air. As shown in Fig. 2, the chemiluminescence intensity

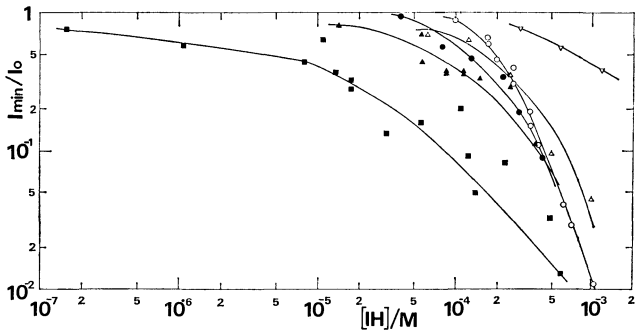

Fig. 5. Plot of I_{min}/I_o as a function of inhibitor concentration in the thermal decomposition of DBPO at 25 °C in *o*-dichlorobenzene (open) and *o*-dichlorobenzene-ethylbenzene (solid).
■: α-Tocopherol, △,▲: TBP, ○,●: BMP, ▽: 2,6-di-*t*-butylphenol.

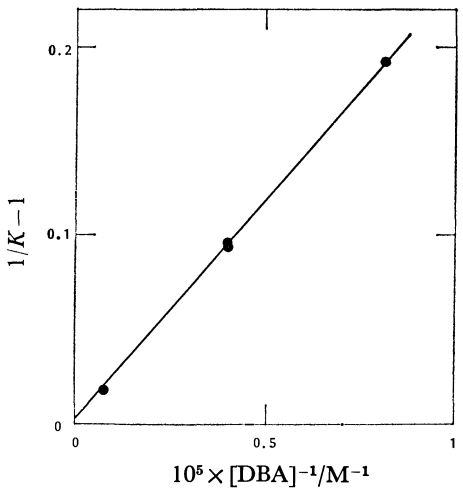

Fig. 6. Plot of $1/K-1$ against 1/[DBA] in the thermal decomposition of DBPO at 25 °C in *o*-dochlorobenzene.

I was proportional to the concentration of DBPO, or more strictly, to the absolute amount of DBPO. The concentration of DBPO was chosen so that the chemiluminescence intensity was several times larger than the background. Under nitrogen, however, little chemiluminescence was observed. Furthermore, as shown in Fig. 3, the addition of tetralyl hydroperoxide to the above solution gave chemiluminescence and its intensity was the same irrespective of the presence or absence of oxygen. On the other hand, the addition of *t*-butyl hydroperoxide did not give appreciable chemiluminescence even in the presence of oxygen.

Figure 4 shows that the addition of phenolic inhibitors to the DBPO solution diminished the chemiluminescence sharply and that, after reaching the minimum intensity I_{min}, it increased again as the inhibitors were consumed. Figure 5 shows the plot of I_{min}/I_o as a function of inhibitor concentration. Similar phenomenon was observed when cobalt(II) acetylacetonate was added to the DBPO solution as observed by Gal and his colleagues.[18]

The addition of 9,10-dibromoanthracene (DBA) increased the chemiluminescence intensity markedly.

As shown in Fig. 6, the plot of $1/K-1$ as a function of 1/[DBA] gave a straight line, where $K=I_A/I_o$, and I_A and I_o are the chemiluminescence intensity in the presence and absence of 9,10-dibromoanthracene respectively.

Discussion

Upon thermal decomposition, DBPO gives two molecules each of *t*-butoxyl radical and carbon dioxide. The rate constant for unimolecular decomposition of DBPO is $k_d=1.6\times10^{-5}$ s^{-1} at 25 °C and its half life is $\tau_{1/2}=12$ h.[27] Therefore, it may be safely considered that DBPO gives *t*-butoxyl radical at constant rate under the present reaction conditions.

$$\mathrm{DBPO} \xrightarrow{k_d} 2(\mathrm{CH_3})_3\mathrm{CO}\cdot + 2\mathrm{CO_2} \quad (1)$$

$$(\mathrm{CH_3})_3\mathrm{CO}\cdot \longrightarrow (\mathrm{CH_3})_2\mathrm{CO} + \mathrm{CH_3}\cdot \quad (2)$$

$$\mathrm{CH_3}\cdot + \mathrm{O_2} \longrightarrow \mathrm{CH_3O_2}\cdot \quad (3)$$

$$2\mathrm{CH_3O_2}\cdot \xrightarrow{k_t} \mathrm{CH_3OH} + {}^3\mathrm{CH_2O}^* + {}^1\mathrm{O_2} \quad (4)$$

$${}^3\mathrm{CH_2O}^* \longrightarrow {}^1\mathrm{CH_2O} + h\nu \quad (5)$$

$${}^1\mathrm{O_2} \longrightarrow {}^3\mathrm{O_2} + h\nu \quad (6)$$

Chemiluminescence arises at the expense of the energy released by exothermic reaction and in the liquid phase oxidation only the chain terminating recombination of peroxyl radicals are sufficiently exothermic for ensuring luminescence in the visible region.[17] About 100 kcal/mol of energy is liberated in the recombination of peroxyl radicals and it is distributed among the products. It has been known that the bimolecular interactions of primary and secondary peroxyl radicals yield triplet carbonyl compound and singlet oxygen[17,28-31] and that these two species emit the chemiluminescence.

Thus, the chemiluminescence observed in the decomposition of DBPO must arise from triplet formaldehyde and/or singlet oxygen formed in Reaction 4. That there was little chemiluminescence in the absence of oxygen suggests that acetone formed in Reaction 2 does not give chemiluminescence.

The steady state treatment for Reactions 1 to 6 gives

$$[\mathrm{CH_3O_2}\cdot] = (k_d[\mathrm{DBPO}]/k_t)^{1/2}. \quad (7)$$

Therefore, the chemiluminescence intensity I is directly proportional to the concentration of DBPO as observed experimentally (Fig. 2).

$$I = a[\mathrm{CH_3O_2}\cdot]^2 = ak_d[\mathrm{DBPO}]/k_t \quad (8)$$

It has been reported that species such as oxygen[31,32] and di-*t*-butyl peroxide[33,34] quench the chemiluminescence. Especially, the quenching by oxygen may be important since oxygen molecule is formed in the bimolecular termination reactions of peroxyl radicals in the close neighborhood of the excited product and may cause its deactivation. The effect of these adventitious quenchers must be small, however, when the ratio of intensity I/I_o is considered rather than the absolute intensity. The luminescence yield is independent of the radical concentration.[35] Phenols are known as photoluminescence quencher, but it was established that the chemical reaction between phenols and peroxyl radicals is of major importance and the physical effect, if any, is negligibly small.[17]

The effect of addition of tetralyl and *t*-butyl hydroperoxides supports the above conclusion. *t*-Butoxyl radical formed from DBPO abstracts readily the hydroperoxidic hydrogens to yield peroxyl radicals. The bimolecular interactions of tetralylperoxyl radicals are terminating and give tetralol, tetralone, and oxygen.

$$(\mathrm{CH_3})_3\mathrm{CO}\cdot + \mathrm{ROOH} \longrightarrow (\mathrm{CH_3})_3\mathrm{COH} + \mathrm{RO_2}\cdot \quad (9)$$

The triplet tetralone and/or singlet oxygen give chemiluminescence irrespective of the presence or absence of oxygen. On the other hand, the bimolecular interactions of *t*-butylperoxyl radicals proceed differently.[36] The *t*-butoxyl radical formed in Reaction 11

$$2(\mathrm{CH_3})_3\mathrm{CO_2}\cdot \longrightarrow [(\mathrm{CH_3})_3\mathrm{COOOOC}(\mathrm{CH_3})_3]$$

$$\longrightarrow (\mathrm{CH_3})_3\mathrm{COOC}(\mathrm{CH_3})_3 + \mathrm{O_2} \quad (10)$$

$$\longrightarrow 2(\mathrm{CH_3})_3\mathrm{CO}\cdot + \mathrm{O_2} \quad (11)$$

again reacts with added *t*-butyl hydroperoxide. Therefore, the addition of *t*-butyl hydroperoxie suppresses the formation of triplet carbonyl and singlet oxygen, and hence the chemiluminescence as well.

The activation of chemiluminescence by 9,10-dibromoanthracene (DBA) in DBPO–ethylbenzene system may be explained by the following scheme, where A represents DBA. *t*-Butoxyl radical attacks ethylbenzene to give 1-phenylethyl radical, which reacts with oxygen and then gives 1-phenylethanol, acetophenone, and oxygen.

$$\mathrm{DBPO} \longrightarrow 2(\mathrm{CH_3})_3\mathrm{CO}\cdot + 2\mathrm{CO} \quad (1)$$

$$(\mathrm{CH_3})_3\mathrm{CO}\cdot + \mathrm{PhCH_2CH_3} \longrightarrow (\mathrm{CH_3})_3\mathrm{COH} + \mathrm{PhC}\dot{\mathrm{H}}\mathrm{CH_3} \quad (12)$$

$$\mathrm{PhC}\dot{\mathrm{H}}\mathrm{CH_3} + \mathrm{O_2} \longrightarrow \mathrm{PhCH(OO}\cdot)\mathrm{CH_3} \quad (13)$$

$$2\mathrm{PhCH(OO}\cdot)\mathrm{CH_3} \xrightarrow{k_t'} \mathrm{PhCH(OH)CH_3} + \mathrm{PhC(=O)CH_3}^* + \mathrm{O_2} \quad (14)$$

$$\mathrm{PhC(=O)CH_3}^* \xrightarrow{f_P} \mathrm{PhC(=O)CH_3} + h\nu \quad (15)$$

$$\mathrm{PhC(=O)CH_3}^* + \mathrm{A} \longrightarrow \mathrm{PhC(=O)CH_3} + \mathrm{A}^* \quad (16)$$

$$\mathrm{A}^* \xrightarrow{f_A} \mathrm{A} + h\nu \quad (17)$$

Under these circumstances, Eq. 18 holds,[17]

$$\frac{1}{K-1} = \frac{\eta_P}{\eta_A-\eta_P} + \frac{1}{\eta_A-\eta_P}\cdot\frac{f_P}{k_{PA}}\cdot\frac{1}{[\mathrm{DBA}]} \quad (18)$$

where η_P, η_A, f_P, and k_{PA} represent, respectively, quantum yields for chemiluminescence of activated acetophenone and activator, probability of radiative transitions and the rate constant for energy transfer from triplet carbonyl to activator. From the intercept of Fig. 6, $\eta_P/(\eta_A-\eta_P)=1.09\times10^{-3}$, and hence, $\eta_A/\eta_P\approx10^3$, suggesting that 9,10-dibromoanthracene has much higher quantum yield than excited acetophenone.

In the presence of phenolic inhibitors IH, the reaction proceeds by the steps 1, 12, 13, 14, 15, 19, and 20, where $\mathrm{RO_2}\cdot$ denotes the 1-phenylethylperoxyl radical.

$$\mathrm{RO_2}\cdot + \mathrm{IH} \xrightarrow{k_{inh}} \mathrm{ROOH} + \mathrm{I}\cdot \quad (19)$$

$$\mathrm{RO_2}\cdot + \mathrm{I}\cdot \xrightarrow{k_0} \mathrm{ROOI} \quad (20)$$

Table 1. Rate constants for the trapping of peroxyl radicals by inhibitors measured by chemiluminescence method, 25 °C

Inhibitor	$k_{inh}/M^{-1}\,s^{-1}$

α-Tocopherol		1.5×10^5	2.0×10^5,[e] 2.3×10^6,[f] 5×10^8 [g]

a) From the rate of inhibited oxidation of styrene at 65 °C, Ref. 39. b) From the ESR method and extraporated to 25 °C, Ref. 40. c) From the rate of inhibited oxidation of styrene at 50 °C, Ref. 41. d) At 60 °C, Ref. 42. e) From the inhibited rate of oxidation of cumene at 60 °C, Ref. 13. f) From the rate of inhibited rate of oxidation of styrene at 30 °C, Ref. 15. g) From pulse radiolysis and spectrometrical determination for trichloromethylperoxyl radical, Ref. 14.

In the absence of inhibitor,

$$-d[RO_2\cdot]/dt = R_i - 2k_t'[RO_2\cdot]_0^2 \quad (21)$$

and hence,

$$[RO_2\cdot]_0 = (R_i/2k_t')^{1/2}, \quad (22)$$

where $R_i=2k_d[DBPO]$ is the rate of initiation and $[RO_2\cdot]_0$ is the steady state concentration of 1-phenylethylperoxyl radical in the absence of the inhibitor. When the inhibitor is added, the concentration of the inhibitor and so that of the peroxyl radical also changes with time, and the steady state treatment can not be applied. The concentration of the peroxyl radical is given by

$$d[RO_2\cdot]/dt = R_i - 2k_t'[RO_2\cdot]^2 - k_{inh}[RO_2\cdot][IH] - k_0[RO_2\cdot][I\cdot]. \quad (23)$$

Since $k_0 \gg k_{inh}$,

$$d[I\cdot]/dt = k_{inh}[RO_2\cdot][IH] - k_0[RO_2\cdot][I\cdot] = 0. \quad (24)$$

Therefore,

$$d[RO_2\cdot]/dt = R_i - 2k_t'[RO_2\cdot]^2 - 2k_{inh}[RO_2\cdot][IH]. \quad (25)$$

At the time when the chemiluminescence intensity is the minimum, I_{min},

$$d[RO_2\cdot]/dt = R_i - 2k_t'[RO_2]_{min}^2 - 2k_{inh}[RO_2\cdot]_{min}[IH] = 0. \quad (26)$$

Then

$$\frac{I_{min}}{I_0} = \frac{[RO_2\cdot]_{min}^2}{[RO_2\cdot]_0^2} = \frac{R_i-2k_{inh}[RO_2\cdot]_{min}[IH]}{2k_t'}\frac{1}{(R_i/2k_t')} = 1 - \frac{2k_{inh}[IH]}{(2k_t'R_i)^{1/2}}\left(\frac{I_{min}}{I_0}\right)^{1/2}, \quad (27)$$

and

$$\frac{1}{Q} - Q = \frac{2k_{inh}}{(2k_t'R_i)^{1/2}}[IH], \quad (28)$$

where $Q=(I_{min}/I_0)^{1/2}$.[37] Similarly, in the system of DBPO and inhibitor in *o*-dichlorobenzene without ethylbenzene,

$$\frac{1}{Q} - Q = \frac{2k_{inh}}{(2k_tR_i)^{1/2}}[IH]. \quad (29)$$

Figures 7 and 8 show the plot of $Q^{-1}-Q$ as a function of inhibitor concentration for the systems DBPO-inhibitor and DBPO-inhibitor-ethylbenzene respectively. Some scatters are observed, but from the slope and the rate constants $k_t=10^8\ M^{-1}\,s^{-1}$ and $k_t'=2\times10^7\ M^{-1}\,s^{-1}$ from the literature,[36] the rate constants for the trapping of peroxyl radicals by an inhibitor are calculated as summarized in Table 1.

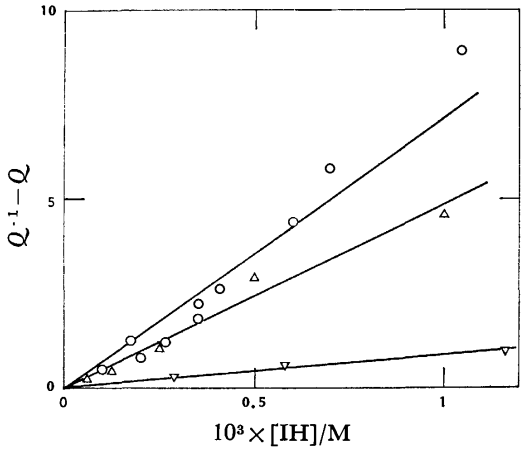

Fig. 7. Plot of $Q^{-1}-Q$ as a function of inhibitor concentration in *o*-dichlorobenzene.
△: TBP, ○: BMP, ▽: 2,6-di-*t*-butylphenol.

The rate constants measured in this study for hindered phenols are in reasonable agreement with literature values. The higher k_{inh} in the absence of ethylbenzene must be ascribed to the contribution of faster interaction of *t*-butoxyl radical with phenols. The high k_{inh}, $5\times10^8\ M^{-1}\,s^{-1}$, for α-tocopherol toward trichloromethylperoxyl radical[14] must be due to a higher reactivity of trichloromethylperoxyl radical than normal alkylperoxyl radicals.[43] Those for α-tocopherol toward arylalkylperoxyl radicals are in fair agreement ranging from 1.5×10^5 to $2\times10^6\ M^{-1}\,s^{-1}$. The reason of this discrepancy is not clear at present. It may be in part due to the different attacking peroxyl radicals: The polymeric peroxyl radical in the oxidation of styrene may have higher reactivity toward α-tocopherol than simple alkylperoxyl radicals as it has toward hydrocarbons.[36,44]

In Figs. 7 and 8, $Q^{-1}-Q$ was plotted against the initial concentration of the inhibitor assuming the loss of inhibitor by the time the chemiluminescence intensity reached minimum was negligibly small. Ac-

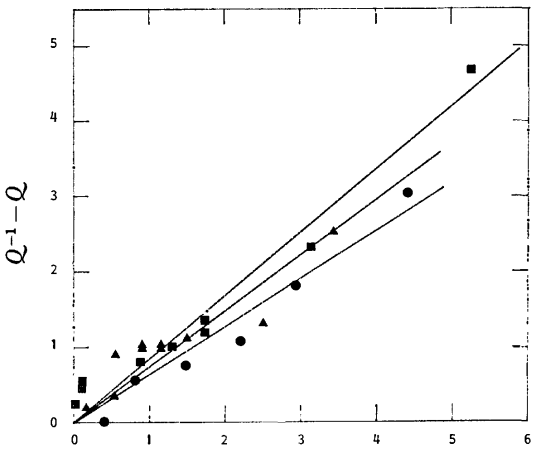

Fig. 8. Plot of $Q^{-1}-Q$ as a function of inhibitor concentration in *o*-dichlorobenzene-ethylbenzene.
■: α-Tocopherol, ▲: TBP, ●: BMP.

cordingly, the k_{inh} we obtained for α-tocopherol may be lower slightly than it should be.

Figures 5 and 8 show that α-tocopherol has higher reactivity than TBP and BMP. Ingold and collaborators[15] argue that higher reactivity of α-tocopherol than simple hindered phenols toward peroxyl radicals arises from the fused chroman ring system that maintains a near-optimal orientation of the ethereal oxygen *p*-type lone pair with respect to the aromatic ring.

As reported previously,[45] the 6-chromanyloxyl radical **2** formed from α-tocopherol seems to have different reactivity toward peroxyl radical from the hindered phenoxyl radicals. We are currently extending our study on the antioxidizing behavior of tocopherols.

This work was partly supported by The Toyota Foundation. A gift of α-tocopherol from Eisai Co. Ltd. is also gratefully acknowledged.

Solid-phase Synthesis of Substrate Model Peptides and Their Hydroxylation with Collagen Lysyl Hydroxylase

Yasuo KIKUCHI* and Nobuo TAMIYA

Department of Chemistry, Faculty of Science, Tohoku University, Aobayama, Sendai 980

(Received July 24, 1981)

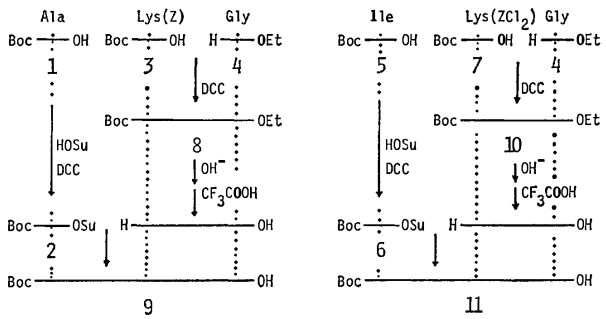
The peptides, (Ala–Lys–Gly)$_{10}$–Phe, (Ile–Lys–Gly)$_3$–Phe, and (Ile–Lys–Gly)$_5$–Phe, were synthesized by solid-phase fragment condensation method. The contaminating shorter peptides and branched chain peptides were removed by CM-cellulose column chromatography. The peptides were useful as synthetic model substrates for collagen lysyl hydroxylase. The –Ile–Lys–Gly– units in (Ile–Lys–Gly)$_5$–Phe showed a higher affinity to the enzyme than those in (Ile–Lys–Gly)$_3$–Phe. A strong substrate inhibition was observed with highly basic peptide, (Ala–Lys–Gly)$_{10}$–Phe.

Hydroxylysine and hydroxyproline are synthesized *in vivo* by enzymic hydroxylation of lysyl and prolyl residues in the peptide chain of procollagen.[1] The proline hydroxylation involves an oxygenation mechanism: The atmospheric ^{18}O is incorporated into hydroxyl group of collagen hydroxyproline.[2-4] On the other hand, hydroxylysine isolated from the chick embryos incubated in ^{18}O-enriched atmosphere did not contain ^{18}O.[4] There are two possibilities to explain the absence of ^{18}O in hydroxylysine: (1) Hydroxylation of lysyl residues involves a non-oxygenation mechanism, (2) The oxygen atom incorporated into hydroxyl group through an oxygenation mechanism is equilibrated with water oxygen by an enzymic process.

More recently the purified enzymes, lysyl hydroxylase and prolyl hydroxylase, were shown to require the same cosubstrates, namely, O_2, α-oxoglutarate, Fe^{2+} and ascorbic acid with similar K_m values.[5-7] During the enzymic hydroxylation, α-oxoglutarate is decarboxylated into CO_2 and succinate stoichiometrically to the formation of hydroxylysine or hydroxyproline.[8,9] The kinetic studies elucidated the same reaction scheme for the two hydroxylases involving an ordered binding of substrates to enzyme and an ordered release of products.[10,11] These results strongly suggest an oxygenation mechanism for lysine hydroxylation and support the second possibility mentioned above; *i.e.* an oxygenetic hydroxylation of lysyl residues is followed *in vivo* by an enzymic equilibration of hydroxyl group with water. The lysine hydroxylation will be studied separately from the oxygen equilibration and the oxygen source of hydroxyl group will be demonstrated for the first time if a synthetic substrate is subjected to the action of purified lysyl hydroxylase *in vitro*. Since the minimum sequence requirement for substrate is known as X–Lys–Gly[12] tripeptide,[9] the present paper describes the syntheses of substrate model peptides, (X–Lys–Gly)$_n$–Phe (X= Ala or Ile) and their enzymic hydroxylation with purified lysyl hydroxylase.

Experimental

Protected Tripeptides. The protected tripeptides, Boc–Ala–Lys(Z)–Gly[12] (**9**) and Boc–Ile–Lys(ZCl_2)–Gly (**11**), were synthesized by the solution method of peptide synthesis as shown in Scheme 1. The yields, melting points, and elemental analyses are shown in Table 1.



Scheme 1. Syntheses of Boc-Ala-Lys(Z)-Gly (**9**) and Boc-Ile-Lys(ZCl_2)-Gly (**11**).

Aoc–Phe–Resin.[12] Aoc–Phe–resin (0.3 mmol of Phe per g of resin) was prepared from Aoc–Phe (5 mmol) and chloromethylated copoly(styrene – 2%divinylbenzene)(Cl : 1 mmol per g resin, Protein Research Foundation, Osaka, Japan) (10 g) by the method of Loffet.[19] The unreacted chloromethyl sites were acetylated by the same method using acetic acid (20 mmol).

Solid-phase Syntheses. (Ala–Lys–Gly)$_{10}$–Phe (12): The Aoc–Phe–resin (2 g, 0.6 mmol of Phe) was placed in a 20 ml reaction vessel and converted into Boc–(Ala–Lys(Z)–Gly)$_{10}$–Phe–resin by manual additions of **9** in ten cyclic steps as follows; (1) deprotection for 60 min with 33% (by vol) trifluoroacetic acid in dichloromethane (15 ml), (2) washing for 5 min with dichloromethane (20 ml × 3) and DMF[12] (20 ml × 2), (3) neutralization for 5 min with 5% (by vol) triethylamine in DMF (20 ml), (4) washing for 5 min with DMF (20 ml × 2) and dichloromethane (20 ml × 3), (5) condensation for 20 h with **9** (0.65 g, 1.28 mmol) and DCC[12] (0.28 g, 1.28 mmol) in dichloromethane (20 ml) and (6) washing for 5 min with dichloromethane (20 ml × 5). After ten cycles, the resin was dried (4.25 g, 100%). An aliquot (0.85 g) of the peptidyl resin was treated with anhydrous HF (15 ml) and anisole (1 ml) for 60 min at 0 °C and dried.[20] The peptide was extracted into 1% (by vol) acetic acid (10 ml × 1, 45 min, and 2.5 ml × 3, 15 min each) and the extract passed through a column (1 cm × 3 cm) of Amberlite IRA-400 (acetate form). The eluate was washed with ethyl acetate (10 ml) and freeze-dried to afford (Ala–Lys–Gly)$_{10}$–Phe (**12**) (244 mg, 77%).

(Ile–Lys–Gly)$_3$–Phe (13) and (Ile–Lys–Gly)$_5$–Phe (14): Aoc–Phe–resin (2 g, 0.6 mmol of Phe) was subjected to the condensation cycles with **11** (0.8 g, 1.29 mmol) instead of **9** as described above except that THF[12]–dichloromethane (1:4 by vol) mixture was used as a solvent for the condensation reactions. After three cycles, about a half of the peptidyl resin was removed and dried to give Boc–(Ile–Lys(ZCl_2)–Gly)$_3$–Phe–resin (1.4 g, approx. 94%). The rest

a) Yield for *t*-butyloxycarbonylation.

of the resin was subjected to two more cycles with **11** (0.4 g, 0.65 mmol) and dried to give Boc–(Ile–Lys(ZCl_2)–Gly)$_5$–Phe–resin (1.7 g, approx. 96%). The peptidyl resin preparations were treated with anhydrous HF as above and the peptides extracted into 2% (by vol) acetic acid were passed through an Amberlite IRA-400 (acetate form) column as above and freeze-dried (324 mg and 360 mg, respectively).

Fractionation of the Peptide Preparations. The preparations of **12**, **13**, and **14** were fractionated on a CM-cellulose[12] column by linear gradient elutions of NaCl concentration. Fractions were pooled as shown in Fig. 1. The peptides in the fractions were desalted by gel filtrations on a Sephadex G-10 column (1.9 cm × 100 cm) equilibrated with 5 mM HCl and freeze-dried.

Collagen Lysyl Hydroxylase. The enzyme was extracted from 13-day-old chick embryos (312 g) and purified by ammonium sulfate fractionation and affinity chromatography on a column (1.5 cm × 12 cm) of concanavaline-A-Sepharose 4B (Pharmacia) as described by Turpeennien *et al.*[21] except that the buffer solution used in the affinity chromatography did not contain $MnCl_2$. The protein concentration of the enzyme solution (12 ml) was 1.2 mg/ml.

Assay Procedures. The enzymic hydroxylation of lysyl residues in substrate model peptides was assayed by the stoichiometric release of $^{14}CO_2$ from [1-^{14}C]-α-oxoglutarate as described by Rhoads and Udenfriend[8] and Kivirikko *et al.*[9] The incubation was carried out at 37 °C and $^{14}CO_2$ released was captured and counted with liquid scintillation counter as described by Ichiyama *et al.*[22]

Results

Synthetic Peptides. The preparations of **12**, **13**, and **14** were fractionated by CM-cellulose column chromatography (Figs. 1-a, b, and c). The yields and amino acid compositions are shown in Table 2. The peptides in the fraction of A-10, B-2, and C-4, namely (Ala–Lys–Gly)$_{10}$–Phe (**12**), (Ile–Lys–Gly)$_3$–Phe (**13**), and (Ile–Lys–Gly)$_5$–Phe (**14**), were used as substrates in the following enzymic reactions.

Enzymic Reactions. The time course of the reaction is shown in Fig. 2. The double reciprocal plots of the radioactivity of $^{14}CO_2$ released during 60 min incubations against the substrate concentration are shown in Fig. 3. A linear relationship was observed with **13** over the whole range of concentration examined. With **14**, a substrate inhibition was observed, however, at higher concentration than 0.5 mM of –Ile–Lys–Gly– unit. The apparent values of K_m and V_{max} were estimated by extrapolation of the linear part obtained in the lower concentration range, where the inhibition was not so significant. The values for **12** could not be obtained because of its strong substrate inhibition.

Discussion

The lysyl and prolyl residues at Y-position of –X–Y–Gly– tripeptide units in procollagen can be hydroxylated by the hydroxylases specific to them, respectively. In the present work, the peptides, (X–Lys–Gly)$_n$–Phe, were synthesized and subjected to the action of collagen lysyl hydroxylase. The syntheses were carried out by successive condensations of protected tripeptide units to phenylalanine linked to an insoluble supporting resin. Because of the incomplete reaction in the deprotection and/or condensation steps, the products were mixtures of peptides with varying number of repeating units. The peptides were separated from one another by CM-cellulose column chromatography making use of varying lysine content (Figs. 1-a, b, and c). The main component of A-10 (Fig. 1-a) was characterized as the designed peptide (Ala–Lys–Gly)$_{10}$–Phe (**12**) by amino acid composition (Table 2). Most of the other components, A-1 to A-9, were shorter peptides. The relatively low phen-

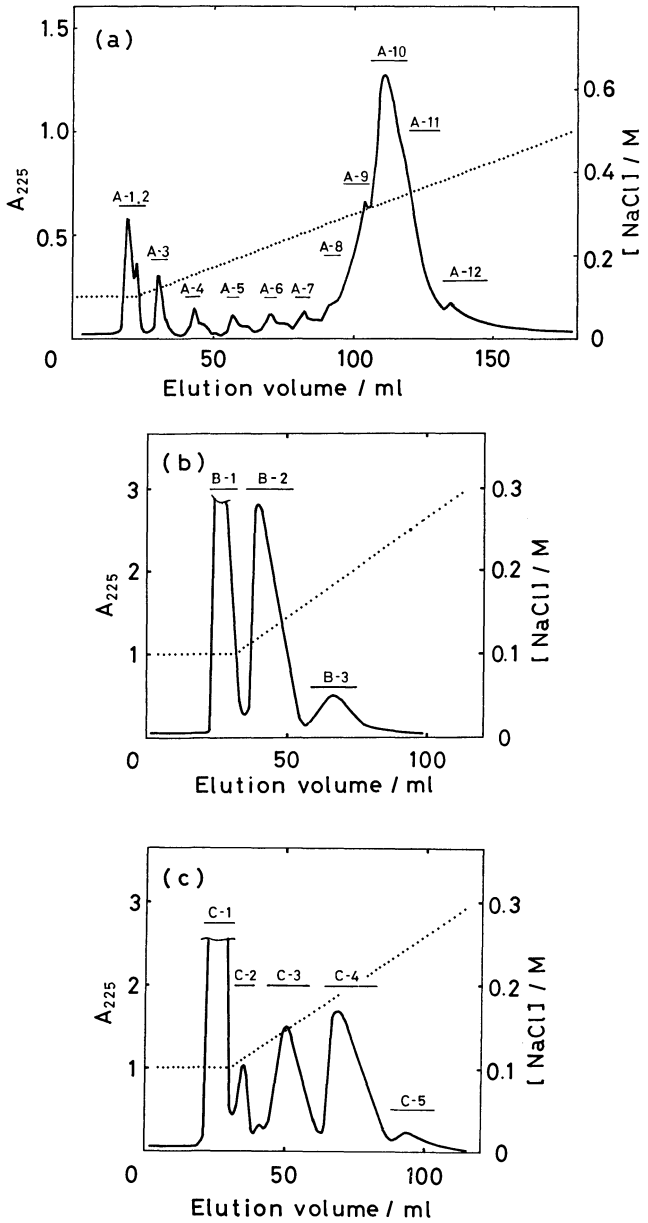

Fig. 1. CM-cellulose column chromatography of peptides prepared by fragment condensation in solid-phase method.
Crude preparations of (a) (Ala–Lys–Gly)$_{10}$–Phe (**12**), 185 mg; (b) (Ile–Lys–Gly)$_3$–Phe (**13**), 195 mg; and (c) (Ile–Lys–Gly)$_5$–Phe (**14**), 203 mg, were dissolved in 0.05 M NaCl (20 ml) and applied on a CM-cellulose column (2.6 cm × 50 cm) equilibrated with 0.1 M NaCl. The column was eluted with 0.1 M NaCl (70 ml) and with 0.1 M to 0.6 M NaCl (linear gradient, total 2000 ml) at 150 ml/h. Fractions of 15 ml were collected. —: Absorbance at 225 nm, ·····: concentration of NaCl.

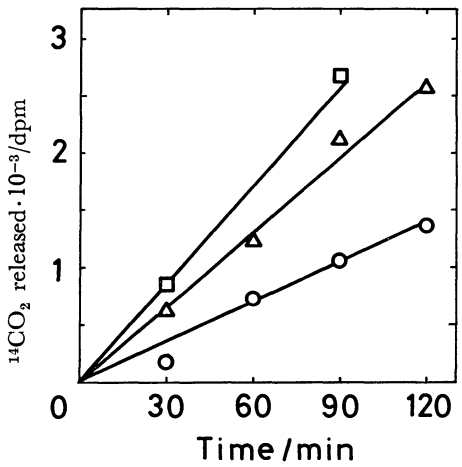

Fig. 2. Time course of the enzymic reaction.
Peptide (Ala–Lys–Gly)$_{10}$–Phe (**12**) (0.31 mg/ml) (○), (Ile–Lys–Gly)$_3$–Phe (**13**) (0.32 mg/ml) (△), or (Ile–Lys–Gly)$_5$–Phe (**14**) (0.32 mg/ml) (□) was incubated with the enzyme (0.06 mg protein/ml) and [1-^{14}C]-α-oxoglutarate (60000 dpm/ml) at 37 °C in 3 ml of reaction mixture.

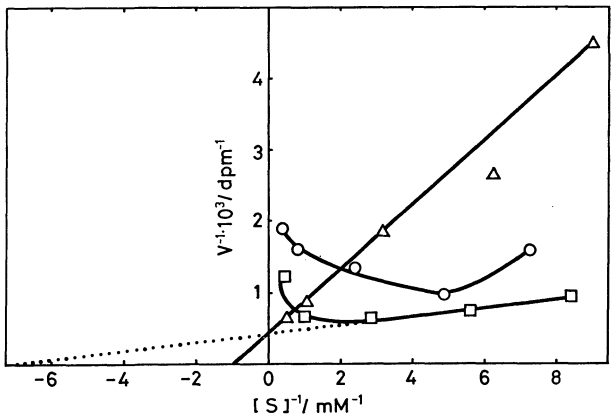

Fig. 3. Double reciprocal plot of initial rate of enzymic hydroxylation against the substrate concentration.
The initial rate is expressed as dpm of $^{14}CO_2$ released from [1-^{14}C]-α-oxoglutarate (9×10^4 dpm) during the incubation (60 min) with the enzyme (0.22 mg protein/ml) and varying amount of substrate peptide in 1 ml of the reaction mixture. Substrate concentration, [S], is expressed as mM of –X–Lys–Gly– unit. —○—: (Ala–Lys–Gly)$_{10}$–Phe (**12**), —△—: (Ile–Lys–Gly)$_3$–Phe (**13**), —□—: (Ile–Lys–Gly)$_5$–Phe (**14**).

ylalanine content in the fractions A-3 to A-7 is probably due to the contamination of peptides without phenylalanine at C-termini. A very small extent of contamination of such peptides (1 to 2% by weight) produced by random cleavage of peptide bond during the HF treatment will affect the amino acid composition. Fraction A-11 was a tailing part of A-10 and fraction A-12 contained branched-chain peptides which resulted from the deprotection of N$^{\varepsilon}$-group on exposures to 33% trifluoroacetic acid. Although a more acid-stable 2,4-dichlorobenzyloxycarbonyl (ZCl_2) group[16] was used for the protection of N$^{\varepsilon}$-group in the syntheses of **13** and **14**, the branched-chain peptides, B-3 and C-5, were produced (Figs. 1-b and c). The presence of considerable amount of shorter peptides besides (Ile–Lys–Gly)$_5$–Phe (Fig. 1-c) reflects the low reaction yield in the solid-phase fragment condensation of **11**. The large absorption values observed with peptide B-1 and C-1 are mainly due to the presence of anisole in these fractions. The

A-12	5.0	12.1	12.9	1						

a) Yields are based on the amount of peptides subjected to the fractionation. b) Peptides were hydrolyzed with 6 M HCl at 105 °C for 24 h in evacuated tubes and the resulting amino acid mixtures were subjected to amino acid analysis with JLC 8AH amino acid analyzer (JEOL). Amino acid compositions are expressed as molar ratios to phenylalanine content. c) The lysine contents were not determined.

Table 3. Comparison of model peptides as substrate for collagen lysyl hydroxylase

Substrate	Relative V_{max}	K_m	
		mg/ml	mM of -X-Lys-Gly-
$(Ile\text{-}Lys\text{-}Gly)_2$		1.2[a]	4[a]
$(Ile\text{-}Lys\text{-}Gly)_3$-Phe	1	0.35	1
$(Ile\text{-}Lys\text{-}Gly)_5$-Phe	1[b]	0.05[b]	0.14[b]
L-III[c]		0.7[a]	0.2[a]

a) Values reported by Kivirikko *et al.*[9] b) Values obtained by extrapolation (see Experimental). c) synthetic peptide; $(Pro\text{-}Pro\text{-}Gly)_4$-Ala-Arg-Gly-Met-Lys-Gly-His-Arg-Gly-$(Pro\text{-}Pro\text{-}Gly)_4$.[9]

amino acid compositions of B-2 and C-4 agreed with those expected for **13** and **14**, respectively.

The lysyl residues in the model substrates were hydroxylated by collagen lysyl hydroxylase. When K_m values of various synthetic substrates are compared on molar basis of -X-Lys-Gly- unit (Table 3), the longer is a peptide, the higher is the affinity per unit to the enzyme. The average K_m value (0.14 mM) per -Ile-Lys-Gly- unit in **14** is almost equal to the K_m value (0.2 mM) reported for -Met-Lys-Gly- unit in a synthetic model peptide of collagen.[9] The effect of the chain length is obvious merely on the affinity of the peptide to the enzyme. No difference was observed between the V_{max} values of **13** and **14** (Fig. 3 and Table 3).

The substrate inhibition observed for **12** over the whole range of the concentration examined here and for **14** at higher concentration may be due to a high basicity of the peptides because the positive charges per molecule increase with increasing n value of $(X\text{-}Lys\text{-}Gly)_n$-Phe. A highly basic peptide may inactivate the enzyme which is charged negatively at pH 7.4.[21]

The authors are grateful to Dr. Haruhiko Aoyagi of Kyushu University for practical suggestions in the synthesis of $Lys(ZCl_2)$ and for providing an authentic preparation of it and to Mr. Chikahisa Takasaki of this laboratory for providing Aoc-Phe. The present work was supported in part by the fund from the Ministry of Education, Science and Culture.

Six New Sesquiterpenoids from the Red Alga *Laurencia nipponica* Yamada[1)]

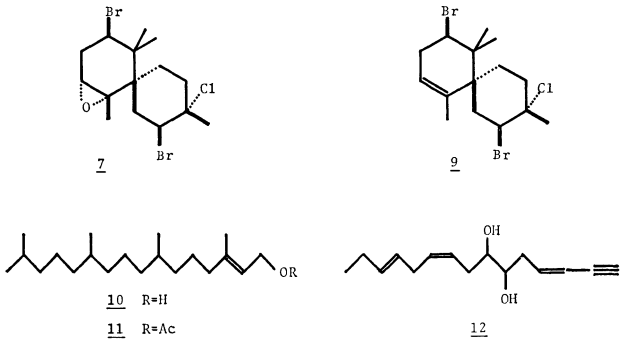
Teruaki Suzuki, Hajime Kikuchi, and Etsuro Kurosawa*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 1, 1981)

Six new laurane-type sesquiterpenoids were isolated from the red alga *Laurencia nipponica* Yamada and their structures were established on the basis of spectral and chemical evidence.

In the course of our investigation on the constituents from the red alga *L. nipponica* Yamada (Rhodophyta, Rhodomelaceae, Urasozo in Japanese), we have reported[2)] many halogenated or non-halogenated sesquiterpenoids and non-terpenoids consisting of C_{15}-straight carbon skeleton with terminal conjugated enyne or allene moiety. The diversity of terpenoids and non-terpenoids biosynthesis in this alga is found to be greatly dependent upon its growth localities. We wish to report here that this species, collected at Atsuta in the vicinity of Sapporo, Ishikari Bay, Hokkaido, produces six new sesquiterpenoids (**1**, **2**, **3**, **4**, **5**, and **6**) together with already chemically synthesized halochamigrene epoxide (**7**)[3)] as the major component (27% of the neutral essential oil) and the other four known compounds, laurene[4)] (**8**, 1.4%), halochamigrene[3,5)] (**9**, 2.0%), *trans*-phytol (**10**, 2.5%), and *trans*-phytol acetate[6)] (**11**, 0.8%) as the minor components. But surprisingly, this alga does not show the presence of C_{15} non-terpenoids, which are found to be biogenetically derived from laurediol (**12**)[2c)] and have been usually isolated as the major components (20—40%) from this species collected at the several different locations in Japan Sea, including Ishikari Bay.



Half-dried algae[7)] were extracted with methanol and the neutral fraction was obtained from the methanol extract by the usual method. Then the neutral fraction was subjected to separation on a combination of column chromatography over neutral alumina and HPLC to give six new terpenoids (**1**, **2**, **3**, **4**, **5**, and **6**) and five known compounds (**7**, **8**, **9**, **10**, and **11**). Five known compounds were identified by the comparison of IR, ^1H and ^{13}C NMR spectra and the optical rotation with those of the authentic specimens.

*The Structure of Isodihydrolaurene (**1**).*[8)] Isodihydrolaurene (**1**); colorless oil, $C_{15}H_{22}$ *m/e* 202 (M^+), $[\alpha]_D$ +33.5° (*c* 1.24, $CHCl_3$), λ_{max}^{EtOH} 205 nm (ε 4,000); had characteristic IR bands at 1655 and 875 cm^{-1} due to an exocyclic methylene group, and it was further supported by ^1H and ^{13}C NMR spectra at δ 4.70 (1H, br.s), 4.77 (1H, br.s), and 105.3 (t). Moreover, the NMR spectra showed signals due to a secondary methyl at δ 0.76 (3H, d, J=7 Hz), a tertiary methyl at 0.98 (3H, s), an olefinic methyl at 1.63 (3H, br.s) and two olefinic protons at 5.34 (2H, m), and 117.8 (d) and 118.8 (d). Treatment of **1** with DDQ in refluxing dioxane resulted in quantitative aromatization to give laurene (**8**), which was identified by the comparison of IR, ^1H and ^{13}C NMR spectra and the optical rotation with those of the authentic specimen. Since the UV spectrum of **1** did not exhibit an absorption due to 1,3-cyclohexadiene moiety,[9)] the

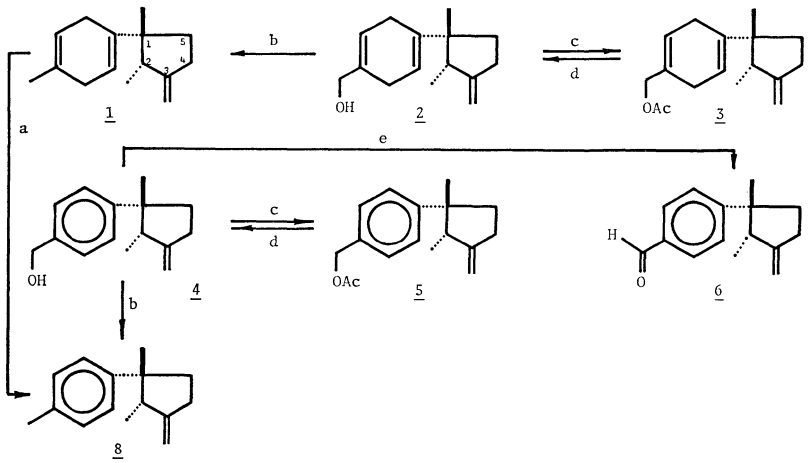


Fig. 1. a) DDQ-dioxane, reflux 80 min; b) 1) MsCl-Et_3N, 0 °C, 1 h; 2) $LiAlH_4$-THF, reflux 0.5 h; c) Ac_2O-Py, room temp, 18 h; d) K_2CO_3-MeOH, room temp, 1.5 h; e) CrO_3-2Py, CH_2Cl_2, room temp, 5 min.

structure of isodihydrolaurene, including the absolute configuration, should be represented by the formula **1**.

The Structures of Isodihydrolaurenol (2) and Isodihydrolaurenol Acetate (3). The ^{1}H NMR spectrum of **2** was almost identical with that of **1** except for an olefinic methyl at δ 1.63 in **1** and, instead of it, showed signals due to a hydroxymethyl group at 2.26 (1H, br.s, -O<u>H</u>) and 3.85 (2H, br.s, -C<u>H</u>$_2$OH). The structure of **2** was confirmed by the chemical correlation with **1**. When alcohol (**2**) was treated with MsCl and Et_3N in CH_2Cl_2 followed by reduction with LAH, **2** was converted to **1**. The spectral evidence and chemical correlation reaction defined the structure of isodihydrolaurenol as shown in the formula **2**. Moreover acetylation of **2** with acetic anhydride and pyridine generated the natural product (**3**) in quantitative yield.

The Structures of Laurenol (4) and Laurenol Acetate (5). Laurenol (**4**); colorless oil, $[\alpha]_D$ +34.7° (*c* 0.26, $CHCl_3$), $C_{15}H_{20}O$ *m/e* 216 (M^+), λ_{max}^{EtOH} 257 nm (ε 290), ν_{max}^{film} 3340 cm^{-1}; showed in ^{1}H NMR spectrum signals due to a secondary methyl at δ 0.67 (3H, d, J=7 Hz), a tertiary methyl at 1.23 (3H, s), a hydroxymethyl at 4.44 (2H, s), an exocyclic methylene at 4.77 (2H, br.s) and four aromatic protons at 7.05 (4H, br.s), and the signals were found to be well corresponding with the structure **4**. The structure of **4** was further confirmed by chemical correlation with **8** as shown in Fig. 1. The structure of **5** was established by acetylation of **4** with acetic anhydride in pyridine.

The Structure of Laurenal (6). Laurenal; colorless oil, $[\alpha]_D$ +33.2° (*c* 0.23, $CHCl_3$), $C_{15}H_{18}O$ *m/e* 214 (M^+), λ_{max}^{EtOH} 258 (ε 12700) and 205 nm (17500), ν_{max}^{film} 2820, 2730, and 1700 cm^{-1}; exhibited the presence of an aromatic aldehyde group in ^{1}H NMR at δ 9.88 (1H, s), IR and UV spectra. Collins oxidation[10] of **4** gave an aldehyde in 85% yield, whose spectral data and the optical rotation were identical with those of natural aldehyde (**6**).

Experimental

The IR and UV spectra were recorded on a JASCO model A-102 and Hitachi model 134 spectrophotometers, respectively. The ^{1}H NMR spectra were determined using a JEOL JNM-PS-100 spectrometer in CCl_4 solution with TMS as an internal standard and the ^{13}C NMR spectra were obtained with a Bruker SXP4-100 spectrometer in $CDCl_3$. A JASCO model DIP-SL was used for the measurement of the optical rotation in $CHCl_3$. Alumina (Merck, activity II—III) and silica gel (Merck, Kieselgel 60) were used for the column chromatography and HPLC was performed on a JASCO Finpac SIL-C$_{18}$.

Isolation. Half-dried algae (4.6 kg), collected at Atsuta in Ishikari Bay, Hokkaido, in July 1980, were extracted with 10 L of methanol for two weeks and the methanol solution was concentrated to about 1.5 L under reduced pressure and the residue was percolated with ether. The ether solution was shaken with 5% NaOH for removing acidic part and then dried over anhydrous Na_2SO_4. After evaporation of solvent, the dark greenish neutral oil (52 g) was obtained and then subjected to column chromatography over neutral alumina. The fraction eluted with hexane gave pure laurene (**8**, 1.4% of the neutral fraction) and halochamigrene (**9**, 2.0%), and crude isodihydrolaurene (**1**), and the last was further purified on HPLC with CH_3CN–H_2O (95:5) to give the pure material of **1** (2.5%). The fraction eluted with hexane–benzene (1:1) yielded halochamigrene epoxide (**7**, 27%). The fraction eluted with benzene–ethyl acetate (10:1) was further subjected to HPLC with MeOH–H_2O (80:20) to give isodihydrolaurenol (**2**, 0.51%), isodihydrolaurenol acetate (**3**, 0.2%), laurenol (**4**, 0.51%), laurenol acetate (**5**, 0.2%), laurenal (**6**, 0.03%), *trans*-phytol (**10**, 2.5%), and *trans*-phytol acetate (**11**, 0.8%).

Isodihydrolaurene (1). Colorless oil; $[\alpha]_D$ +33.5° (*c* 1.24, $CHCl_3$); λ_{max}^{EtOH} 205 nm (ε 4000); ν_{max}^{film} 3070, 3020, 1655, 1370, 1165, 1090, 1020, 950, 875, and 775 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.76 (3H, d, J=7 Hz), 0.98 (3H, s), 1.39 (1H, ddd, J=11, 6, 6, α-H on C-5), 1.63 (3H, br.s), 1.8—2.5 (3H), 2.19 (1H, br.q, J=7), *ca.* 2.5 (4H, m), 4.70 (1H, br.s), 4.77 (1H, br.s), and 5.34 (2H, m, W_H=9); ^{13}C NMR ($CDCl_3$) δ 17.5 (q), 22.8 (q), 25.8 (q), 27.4 (t), 28.6 (t), 31.8 (t), 32.8 (t), 48.8 (d), 49.5 (s), 105.3 (t), 117.8 (d), 118.8 (d), 130.9 (s), 139.2 (s), and 157.9 (s). Found: *m/e* 202.1714. Calcd for $C_{15}H_{22}$: M, 202.1719.

Isodihydrolaurenol (2). Colorless oil; $[\alpha]_D$ +40.0° (*c* 1.52, $CHCl_3$); λ_{max}^{EtOH} 205 nm (ε 6000); ν_{max}^{film} 3300, 3070, 3020, 1690, 1655, 1425, 1370, 1095, 1055, 1030, 1005, 960, 880, 810, 785, and 755 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.77 (3H, d, J=7 Hz), 0.99 (3H, s), 1.42 (1H, ddd, J=12.5, 5.5, 5.5), 1.8—2.6 (4H), 2.26 (1H, br.s, -O<u>H</u>), 2.62 (4H, m), 3.85 (2H, br.s, -C<u>H</u>$_2$OH), 4.73, 4.78, 5.42, and 5.59 (1H each, br.s). Found: *m/e* 218.1643. Calcd for $C_{15}H_{22}O$: M, 218.1668.

Isodihydrolaurenol Acetate (3). Colorless oil; $[\alpha]_D$ +40.0° (*c* 0.21, $CHCl_3$); λ_{max}^{EtOH} 206 nm (ε 9700); ν_{max}^{film} 3080, 3030, 1740, 1655, 1370, 1245, 1230, 1025, 960, 887, and 802 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.77 (3H, d, J=7 Hz), 0.99 (3H, s), 1.43 (1H, ddd, J=12, 5, 5), 1.9—2.6 (3H), 1.97 (3H, s), 2.13 (1H, br.q, J=7), 2.65 (4H, m), 4.37 (2H, br.s), 4.71, 4.78, 5.39 and 5.66 (1H each, br.s). Found: *m/e* 260.1782. Calcd for $C_{17}H_{24}O_2$: M, 260.1776.

Laurenol (4). Colorless oil; $[\alpha]_D$ +34.7° (*c* 0.26, $CHCl_3$); λ_{max}^{EtOH} 257 (ε 290), 263 (ε 330) and 272 nm (ε 230); ν_{max}^{film} 3340, 3060, 3020, 1655, 1615, 1515, 1415, 1370, 1030, 1020, 880, 840, 815 and 805 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.67 (3H, d, J=7 Hz), 1.23 (3H, s), 1.6—2.6 (5H), 2.06 (1H, br.s, -O<u>H</u>), 4.44 (2H, s, -C<u>H</u>$_2$OH), 4.77 (2H, br.s), and 7.05 (4H, br.s). Found: *m/e* 216.1496. Calcd for $C_{15}H_{20}O$: M, 216.1511.

Laurenol Acetate (5). Colorless oil; $[\alpha]_D$ +23.6° (*c* 0.42, $CHCl_3$); λ_{max}^{EtOH} 255 (ε 300), 261 (ε 330), 267 (ε 270), and 271 nm (ε 200); ν_{max}^{film} 3070, 3020, 1740, 1655, 1615, 1515, 1430, 1375, 1360, 1225, 1075, 1030, 1020, 965, 880, 825, and 815 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.69 (3H, d, J=7 Hz), 1.26 (3H, s), 1.6—2.6 (5H), 2.00 (3H, s), 4.81 (2H, br.s), 4.94 (2H, s), and 7.12 (4H, br.s). Found: *m/e* 258.1626. Calcd for $C_{17}H_{22}O_2$: M, 258.1620.

Laurenal (6). Colorless oil; $[\alpha]_D$ +33.2° (*c* 0.23, $CHCl_3$); λ_{max}^{EtOH} 258 (ε 12700) and 205 nm (ε 17500); ν_{max}^{film} 3070, 3030, 2820, 2730, 1700, 1655, 1605, 1570, 1415, 1385, 1370, 1310, 1215, 1175, 1075, 1015, 880, and 825 cm^{-1}; ^{1}H NMR (CCl_4) δ 0.69 (3H, d, J=7 Hz), 1.28 (3H, s), 1.8—2.8 (5H), 4.85 (2H, m), 7.29 (2H, br.d, J=8), 7.71 (2H, br.d, J=8) and 9.88 (1H, s). Found: *m/e* 214.1371. Calcd for $C_{15}H_{18}O$: M, 214.1358.

Aromatization of 1. A mixture of **1** (16 mg) and DDQ (24 mg) in freshly distilled dioxane (2 ml) was refluxed under nitrogen atmosphere. After cooling, the resulting

suspension was filtered through a column of neutral alumina (2 g) and eluted with hexane to give colorless oil (15 mg), whose spectral data and optical rotation were identical with those of the authentic specimen of laurene (**8**).[4]

*Conversion of Isodihydrolaurenol (**2**) into **1**.* To a cooling solution of **2** (10 mg) in dry CH_2Cl_2 containing dry Et_3N (10 μl) was gradually added distilled MsCl (5 μl). The mixture was stirred for 1 h at 0 °C, and then poured into ice water. Ether-extract was successively washed with 1 M HCl, 5% $NaHCO_3$, and brine, and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, the resulting crude mesylate (12 mg), colorless oil, was reduced with LAH (20 mg) in refluxing THF (1 ml) for 0.5 h under nitrogen atmosphere. Ice was added to the cooled solution at 0 °C to decompose the excess of LAH. After the usual work-up, the resulting oily material was purified by column chromatography over silicic acid to give pure **1** (9 mg).

*Acetylation of **2**.* A solution of **2** (20 mg) in acetic anhydride (0.2 ml) and pyridine (0.2 ml) was allowed to stand overnight at room temperature and then worked up in the usual way to give monoacetate (**3**) (22 mg).

*Transformation of **4** into **8**.* To a cooling solution of **4** (12 mg) in dry CH_2Cl_2 (0.3 ml) containing dry Et_3N (10 μl) at 0 °C was gradually added distilled MsCl (6 μl) and stirred for 1 h at 0 °C. The reaction mixture was poured into ice–water and extracted with ether. After the usual work-up, the resulting crude mesylate (17 mg) was treated with LAH (20 mg) in refluxing THF (1 ml) for 0.5 h under nitrogen atmosphere. After usual manner for separation, the resulting oily material was chromatographed over silicic acid to give hydrocarbon (**8**) (11 mg).

*Acetylation of **4**.* Acetylation of **4** (20 mg) was carried out in the same manner as that of **2** to give **5** (22 mg).

*Collins Oxidation of **4** into **6**.* Dry CrO_3 (15 mg) was added to the solution of dry CH_2Cl_2 (0.5 ml) and dry pyridine (23 μl) in a dried two necked flask and the mixture was stirred at room temperature under nitrogen atmosphere for 5 min. Then a solution of **4** (6 mg) in dry CH_2Cl_2 (0.25 ml) was added to the resulting burgundy colored solution and it was stirred for an additional 5 min. After addition of ether, filtration and washing with ether, the ethereal solution was shaken with 5% $NaHCO_3$ and dried over anhydrous Na_2SO_4. After removal of the solvent, the oily substance (5 mg) was obtained, whose spectral data and the optical rotation were identical with those of natural aldehyde (**6**).

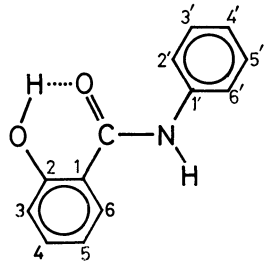
(Received October 2, 1981)

Intramolecular hydrogen bonding of the title compounds was investigated by measuring their infrared spectra in the OH, NH, and C=O stretching regions. The results showed that the intramolecular hydrogen bonding in the salicyloyl moiety plays an important role in the antibacterial activities of these salicylanilides.

As a part of a series of investigations to correlate the biological and pharmaceutical activities to their structures and physical properties, the intramolecular hydrogen bonding and the conformations of salicylanilides (**1**) were studied by infrared spectroscopy.



1

Intramolecular hydrogen bonds affect remarkably the associative properties and the solubilities of these compounds, thereby influencing on their biological activities in different ways. These anilides have coplanar chelate rings made up of very strong OH···O=C intramolecular hydrogen bonds of hexagonal arrangement. In turn, the amide moiety of the anilide usually takes a planar *s-trans* conformation as illustrated by **1**. In this connection, it is interesting to examine how the hydrogen bonding and the conformations of these anilides are affected with the steric effect caused by the substituents located ortho to either or both of amide and salicyloyl groups. For this purpose, the OH, NH, and C=O stretching absorptions of these anilides were measured and discussed.

Experimental

Preparation of the materials were reported elsewhere.[1] Infrared spectra were obtained in carbon tetrachloride solutions using a Hitachi 225 infrared spectrophotometer. The concentration of the solution was kept below 3×10^{-3} mol/l (usually at about 1×10^{-3} mol/l) in order to prevent the effect of the associated species.

Results and Discussion

Infrared spectra of the anilides are given in Table 1. In general, the *s-trans* conformer is known to be 4—8 kJ/mol more stable than the *cis*. Thus the salicylanilides without ortho (3, 6, 2′, and 6′) substituents absorb at about 3450 cm^{-1} in the NH stretching region, which was assigned to the *s-trans* conformation by Suzuki and co-workers.[2] Besides this band, they have absorption bands at *ca.* 1660 cm^{-1} in the carbonyl stretching region and broad bands around 3000 cm^{-1} due to chelated OH group, both of them suggesting the presence of intramolecularly hydrogen-bonded chelate rings. These facts support the *s-trans* conformation with chelated salicyloyl group as illustrated in **1**.

Effect of 2- (and 6-) Substituents on the Conformation and the Hydrogen Bonding. The substituent at the positions ortho to the amide group (on the anilino ring) may affect considerably the conformations of the amide groups of the salicylanilides. The effect can be classified as i) that from steric hindrance and ii) that from hydrogen bond formation. Since the planar conformation of the amide group is rather rigid, the bulky group at the ortho positions causes almost exclusively a torsion around the C_{Ar}–N bond. However, the effect on the NH frequency is not predominant. In short, the steric effect by the 2′- (and 6′-)substituent does not perturb the conformation of the amide group considerably.

The substituents capable of forming hydrogen bonds with the NH group investigated are aryloxyl, halo, and arylthio groups, all of them behaving as hydrogen acceptors in hydrogen bonding. With three anilides (**9**—**11**) carrying 2′-aryloxyl groups, their NH stretching absorptions tend to shift towards lower frequencies only slightly. The very small but definite low frequency shifts suggest the existence of very weak hydrogen bonding. The absorptions in the carbonyl and hydroxyl stretching regions also coincide with those of the parent salicylanilide (**1**), showing no indication for the substituent effect. The 2′-chloro substituted anilides **6** and **7** absorb at 3433 and 3432 cm^{-1} in the NH stretching region, which are somewhat 20 cm^{-1} lower than those of the parent anilide (**1**). Infrared spectral shifts due to intramolecular hydrogen bonding ($\Delta\nu_{NH}=\nu_f-\nu_b$) are again rather small. However, Welti[3] has measured the infrared spectra of some halogenated salicylanilides and concluded the existence of intramolecular hydrogen bonding from the $\Delta\nu_{NH}$ values of similar magnitudes for 2′-chlorinated derivatives and from considerably larger $\Delta\nu_{NH}$ values for 2′-brominated derivatives. The absorption due to chelated salicyloyl group is again similar to the parent salicylanilide (**1**).

The most intense ν_{NH} bands of 2′-arylthiosalicyl-

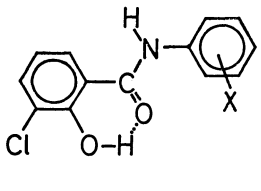
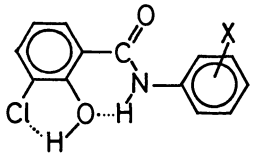
anilides **20**—**23** are located at around 3350 cm^{-1}, which is a remarkably lower frequency than those of the other 2′-substituted derivatives discussed above. Besides this band, two additional absorption bands are observed at 3434 and 3402 cm^{-1}. The larger $\Delta\nu_{NH}$ suggests the presence of a hydrogen bond stronger than those in 2′-aryloxy and 2′-chloro derivatives (**7**—**13**). Similarly, NH···S intramolecular hydrogen bond is stronger than NH···O hydrogen bond in the series of the corresponding acetanilides given in Table 2. The other two NH bands were assigned to the free *s-trans* (I) and *s-cis* (II) conformers of the salicylanilides **20**—**23**. These 2′-arylthiosalicylanilides have weak bands at 1700 cm^{-1} of the $\nu_{C=O}$ region in addition to the strong bands at about 1660 cm^{-1}. This may be an indication of an unchelated structure for the *s-cis*(free) conformer absorbing at 3402 cm^{-1} in ν_{NH} region. If the chelated conformation (III) is assumed for the cis conformer, the molecule is expected to be considerably crowded sterically. Therefore an unchelated conformer may appear in a small amount.

Effect of Substituents on 3- and Other Positions on the Salicyloyl Residue. The 3-chloro derivatives (**3**, **7**, **21**) have two absorption bands in the ν_{NH} region; the one at a higher frequency (*ca.* 3430 cm^{-1}) may be assignable to the free *s-trans* amide group, while the other at a lower frequency (3400—3350 cm^{-1}) should arise from an intramolecularly hydrogen-bonded NH group. According to Welti,[3] these absorption bands are assigned properly to the conformer (IV) and (V), respectively. The former is estimated to be more predominant from the intensities of their characteristic absorption bands.



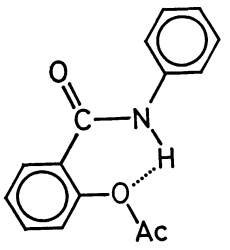
(IV)



(V)

	(IV)	(V)
ν_{OH}/cm^{-1}	3000 (broad)	3516
$\nu_{C=O}/cm^{-1}$	1660	1685
ν_{NH}/cm^{-1}	3430	3400—3350
Abundance	More predominant	Less predominant

The conformations of the salicylanilides might be perturbed seriously by the acetylation of the 2-hydroxyl functional groups, since the intramolecular hydrogen bond participating in the formation of the chelate ring and keeping the carbonyl and the hydroxyl groups close is no longer persistent. The acetyl derivatives (**5**, **8**, **12**) have NH absorption bands at approximately 3400 cm^{-1}, which can be assigned to the NH···O(Ac) hydrogen bonded conformers (VI). The considerably small $\Delta\nu_{NH}$ values in these compounds are reasonable since the acetoxyl group is in general a hydrogen acceptor weaker than the hydroxyl groups.[4] The conformer (VI) become less



(VI)

favorable by the introduction of 2′-substituent, and the 3440 cm^{-1} band due to the free *s-trans* conformer appears. The low frequency shift of this band in **8** is ascribable to the intramolecular hydrogen bonding with 2′-chloro substituent. The acetyl derivatives usually have three absorptions at about 1690, 1770, and 1790 cm^{-1} in the $\nu_{C=O}$ region; the former band is assigned to the amide and the latter two to the acetyl group.

5′-Trifluoromethylsalicylanilides (**13** and **23**) have two unusual absorption bands at 1750 and 1700 cm^{-1}. These bands are interpreted as the intensified overtone vibrations, by Fermi resonance, of strong C–F stretching vibrations in 850—900 cm^{-1} region, since the intensities of the carbonyl band at *ca.* 1690 cm^{-1} is remarkably reduced, and since the corresponding trifluoromethyl substituted aniline has no such bands.

Table 3. Antibacterial activities of some substituted salicylanilides

23	5	0.8

Preliminary Results on the Correlation with Their Antibacterial Activities. The six-membered hydrogen bonding in salicyloyl moiety is hereby shown to be perturbed when 3-chloro or 2-*O*-acetyl substituent is introduced to the salicylanilide molecule. The antibacterial activities towards *Staphyrococcus aureus* FDA 209-P (A) and *Bacillus subtilis* PCI-219 (B) are remarkably high with the compounds carrying the above substituents (**3**, **12**, and **18**) as given in Table 3. Thus, the structural and conformational change in the sali-

cyloyl moiety might play an important role in the biological activities of these salicylanilides. On the other hand, the activity is not affected considerably by the conformational change in the amide moiety. However, further informations on a wider range of the anilides and the bacteria is necessary in order to conclude the structure-activity relationship confidently.

The authors are grateful to Prof. T. Ito, Kansai Medical University, for the examination of the antibacterial activity.

(Received October 8, 1981)

(±)-*erythro*-2-Amino-1,2-diphenylethanol prepared from benzoin oxime by catalytic reduction was successfully resolved into a pair of optically active forms by preferential crystallization. The optically active amino alcohol was found to be useful as a basic resolving agent for the optical resolution of tartaric acid, *trans*-2,3-oxiranedicarboxylic acid, 2-hydroxy-2-phenylpropionic acid, and 3-*endo*-benzamido-5-norbornene-2-*endo*-carboxylic acid. Chiral hydrides prepared from lithium aluminium hydride and optically active *threo*- or *erythro*-2-amino-1,2-diphenylethanol derivatives were applied to the enantioface differentiating reduction of prochiral ketones to give the corresponding optically active alcohols in 26—72% optical purities.

In contrast to ephedrine which is widely used in fractional crystallization as a resolving agent[1] and in asymmetric synthesis as a chiral source,[2] *erythro*-2-amino-1,2-diphenylethanol having similar configuration to ephedrine is little applied to fractional crystallization and asymmetric synthesis except for the synthesis of optically active asparic acid.[3] The preparation of optically active *erythro*-2-amino-1,2-diphenylethanol in a preparative quantity was considered to be troublesome because it is obtained by the fractional crystallization of diastereomeric salts with L-glutamic acid.[4] These prompted us to study on the optical resolution of *erythro*-2-amino-1,2-diphenylethanol by preferential crystallization, which gives preparatively both enantiomers by simple operation, and on the application of itself or its derivative to fractional crystallization of chiral carboxylic acids as a resolving agent and to asymmetric reduction of prochiral ketones as a modifier for lithium aluminium hydride.

In the previous papers, it was reported that 2-amino-2-phenylethanol (**1**)[5] and cinnamic acid salts of 1-phenylethylamine (**2**) and 1-phenyl-2-(*p*-tolyl)ethylamine (**3**)[6] were successfully resolved into pairs of enantiomers by preferential crystallization. Based on these results, *erythro*-2-amino-1,2-diphenylethanol (**4**) was considered to be also resolvable by preferential crystallization of itself or its cinnamic acid salt because **4** has α-aminobenzyl group in the structure in analog with **1**, **2**, and **3**.

Comparing physical properties such as melting point and solubility, infrared spectrum, and X-ray diffraction pattern of optically active form with those of racemate is efficient and appropriate to ensure the possibility of optical resolution by preferential crystallization. Then, to obtain optically active **4**, the fractional crystallization of diastereomeric salts of (±)-**4** with L-glutamic acid was initially tried according to the method described in the literature.[4] The fractional crystallization of diastereomeric salts of (±)-**4** with optically active *trans*-2-benzamidocyclohexanecarboxylic acid (**5**)[7] was found to be more convenient. Thus, the fractional crystallization of the diastereomeric salts of (±)-**4** with (+)-**5** gave (−)-**4**·(+)-**5** salt in a high optical purity, and a similar treatment of **4** recovered from the mother liquor with (−)-**5** gave highly optically pure (+)-**4**·(−)-**5** salt.

a) g/100 ml of 99% EtOH at 15 °C.

Physical properties, infrared spectrum, and X-ray diffraction pattern of optically active **4** obtained as above or of its salt with an achiral carboxylic acid such as cinnamic acid (**6**), benzoic acid (**7**), or *cis*-1,2-cyclohexanedicarboxylic acid (**8**) were compared with those of the corresponding racemate. As shown in Table 1, optically active **4·6** salt has the same melting point as the racemate and is less soluble in ethanol than the racemate, and their infrared spectra and X-ray diffraction patterns are identical. These results indicate that crystals of **4·6** salt are deposited as con-

The initial composition of the mother liquor: (±)-**4·6** salt (22.40 g), (+)-**4·6** salt (2.17 g), which was added to facilitate the prefcrential crystallization from the first stage, and (±)-**4**·lactic acid salt (30.00 g) in 99% methanol (550 ml). In all runs, 0.04 g of seed was added.
a) (*c* 0.60, 99% MeOH). b) Based on $[\alpha]_{435}^{30}$ + and −170.7°.

glomerate and that **4·6** salt is resolvable by preferential crystallization in a similar manner as **2·6** and **3·6** salts.

Actually, (+)-**4·6** salt was obtained from a supersaturated solution of (±)-**4·6** salt in methanol when (+)-**4·6** salt, which was prepared from equimolar amounts of (+)-**4** and **6** followed by recrystallizations for several times, was seeded to the solution, and the solution was stood for 2.5 h at around 5 °C. Alternate seeding of (−)- or (+)-**4·6** salt to the solution supersaturated in a similar magnitude gave (−)- or (+)-**4·6** salt in a moderate to high optical purity.

The procedure is inapplicable to the optical resolution of (±)-**4·6** salt in a preparative scale because it is difficult to obtain optically active **4·6** salt in a constant yield. The problem was overcome by coexisting the readily soluble (±)-lactic acid salt of (±)-**4** in the mother liquor, which decreased the concentration change of 2-hydroxy-1,2-diphenylethylammonium ion in the solution during crystallization to stabilize the preferential crystallization (Table 2). Moreover, gentle stirring of the supersaturated solution in the course of crystallization was found to be effective to shorten the cooling time. Stirring made the solution uniform and accelerated the crystal growth from seed surface. But, the nucleation of the unseeded antipode crystals of **4·6** salt occured when the solution was stirred too vigorously. The result is summarized in Table 3.

The crystals having the same sign of optical rotation were combined and recrystallized from methanol to give highly purified (+)- and (−)-**4·6** salts. They seemed to be almost optically pure because the values of their specific rotations were almost same to those of recrystallized **6** salts of (+)- and (−)-**4** obtained by the fractional crystallization with L-glutamic acid or *trans*-2-benzamidocyclohexanecarboxylic acid (**5**).

Decomposition of purified (+)- and (−)-**4·6** salts with an alkali solution gave (+)- and (−)-**4**, of which the specific rotations at 589 nm in absolute ethanol were +7.7° and −7.6°, respectively. Weijland *et al.* reported that the specific rotations were +10.2° and −10.1°, respectively.[4] Attempts to get (+)- and (−)-**4** which have the specific rotations of the values were unsuccessful. No drop of the specific rotations under the conditions of the liberation of (+)- or (−)-**4** was observed. Recent literatures reported that the specific rotations were +6.8°[3] and −6.4°,[8] respectively. Based on the data, (+)- and (−)-**4** obtained as above were considered to be almost optically pure.

Then, we applied optically active **4** to the optical resolution of chiral carboxylic acids such as tartaric acid (**9**), *trans*-2,3-oxiranedicarboxylic acid (**10**), 2-hydroxy-2-phenylpropionic acid (**11**), and 3-*endo*-5-nor-

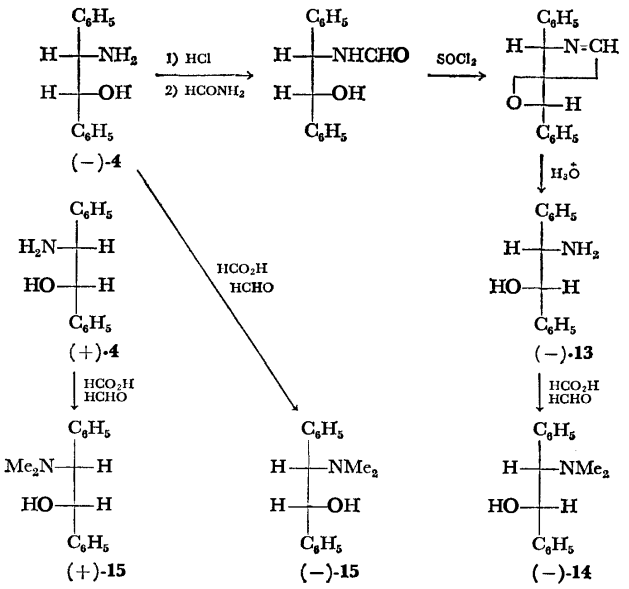
a) Based on half the amount of (±)-carboxylic acid used. b) Based on the specific rotation of commercial (+)-tartaric acid: $[\alpha]_{589}^{25}$ +15.9° (*c* 1.01, H_2O). c) Based on $[\alpha]_{589}^{25}$ +117.8° (*c* 2.6, EtOH).[1c] d) Based on $[\alpha]_{589}^{20}$ +53.5° (*c* 1.591, H_2O).[10] e) Based on $[\alpha]_{435}^{20}$ −254° (*c* 1.00, 99% MeOH).[11]

bornene-2-*endo*-carboxylic acid (**12**) by fractional crystallization. As shown in Tables 4 and 5, they were resolved in moderate to high optical purities, and optically active **4** was found to be useful as a resolving agent. The results indicate that **4** is as effective as 2-amino-2-phenylethanol (**1**)[5] in the resolution of **9** and **11** and is superior to **1** with regard to the resolution of **10** which could not be resolved with **1**.

Next stage, derivatives of **4** were applied to asymmetric reduction of prochiral ketones as modifiers of lithium aluminium hydride. (−)-*threo*-2-Amino-1,2-diphenylethanol ((−)-**13**) was obtained from (−)-**4** *via* *N*-formylation, cyclization, and hydrolysis according to the procedure in the literatures.[4,9] The Eschweiler-Clarke reaction of (−)-**13** gave (−)-*threo*-2-dimethylamino-1,2-diphenylethanol ((−)-**14**). The reaction of (+)- and (−)-**4** also yielded (+)- and (−)-*erythro*-2-dimethylamino-1,2-diphenylethanol ((+)- and (−)-**15**), respectively (Scheme 1).

Acetophenone was chosen as a model substrate, and the reduction with lithium aluminium hydride modified by (−)-**14** or (+)-**15** was carried out in ether at −78 °C. As shown in Table 6 (Exp. 1 and 2), lithium aluminium hydride treated with 2.2 molar amounts of (+)-**15** was found to be more effective than that treated with (−)-**14**.

Contrary to the reduction with lithium aluminium hydride–(−)-**14** complex, which gave (*R*)-(+)-1-phenylethanol, the reduction with lithium aluminium hydride–(+)-**15** complex yielded (*S*)-(−)-1-phenylethanol. The result was considered to indicate that the configuration of the product was influenced by the configuration of C2 (the carbon atom carrying amino group) of 2-amino-1,2-diphenylethanol. The consideration is supported by the fact that the absolute configuration of (−)-**14** and (+)-**15**, derived from



Scheme 1.

(*1S,2S*)-(−)-**13**[4,9] and (*1S,2R*)-(+)-**4**,[4] are (*1S,2S*) and (1*S*,2*R*), respectively.

A similar optical purity was achieved when lithium aluminium hydride was treated with 1.1 molar amount of (+)-**15** and 2.2 molar amounts of ethanol (Table 6. Exp. 10), but in the other cases no improvement was obtained by adding an achiral alcohol such as 2,4-xylenol and ethanol in several molar ratios (Table 6. Exp. 5—9). Moreover, lithium aluminium hydride modified with (+)-**15** and ethanol as mentioned above was found to be less effective for the asymmetric reduction of propiophenone (Table 6. Exp. 11).

Utilizing lithium aluminium hydride treated with 2.2 molar amounts of (+)- or (−)-**15**, the reduction

of propiophenone and butyrophenone was carried out to give 1-phenyl-1-propanol in 72% optical purity and 1-phenyl-1-butanol in 69% optical purity, respectively.

In conclution, it is noteworthy that both enantiomers of **4** become obtainable in high optical purities by the preferential crystallization of (±)-**4**·**6** salt and that it or its derivative is useful as a synthetic basic resolving agent for the optical resolution of chiral carboxylic acids or as a modifier of lithium aluminium hydride for asymmetric reduction of prochiral ketones.

Experimental

The melting points were determined on a Laboratory Devices Mel-Temp apparatus and are uncorrected. The values of specific rotation were measured on JASCO DIP-181 digital polarimeter. The ^{1}H-NMR spectra were recorded in $CDCl_3$ solution at 60 MHz on Varian A-60 Spectrometer using TMS as an internal standard. The IR spectra were determined on JASCO IR-2A Spectrophotometer.

*Synthesis of (±)-*erythro*-2-Amino-1,2-diphenylethanol ((±)-4).* To a solution of benzoin α-oxime (50.30 g, 0.22 mol) in 90% ethanol (530 ml) was added 5% palladium–chacoal catalyst (5.00 g), and the suspension was stirred at 51—52 °C under a hydrogen atmosphere using an ordinary pressure hydrogenation apparatus. After the required amount of hydrogen (about 10 l) has been absorbed, hydrogen absorption abruptly slowed. At this point, the hydrogenation was stopped, and concd HCl (40 ml) was added to the reaction mixture. After the mixture was stirred at around 60 °C for 1.5 h, the solvent was evaporated. To the residue was added boiling water (500 ml), and the catalyst was filtered off from the hot aqueous solution. The catalyst was washed twice with boiling water (500 ml). The filtrate and the washings were combined, basified with concd aqueous ammonia, and cooled with ice bath to give white precipitates. The precipitates were collected by filtration and recrystallized from 99% methanol to yield 41.81 g of (±)-**4**: mp 163—164 °C (lit,[4] 163 °C).

Optical Resolution of (±)-4 with Optically Active trans*-2-Benzamidocyclohexanecarboxylic Acid (5) by Fractional Crystallization.* A clear solution of (±)-**4** (7.64 g) and (+)-**5**[7] (9.51 g) in a mixture of 99% ethanol and ethyl acetate (1:1) (200 ml) at an elevated temperature was allowed to cool slowly at room temperature and stood overnight. The white precipitates were collected by filtration to give 5.76 g (67%) of crude (−)-**4**·(+)-**5** salt: $[\alpha]_{435}^{30}$ −68.6° (c 1.01, 99% MeOH). The mother liquor was reserved for later use. Recrystallization of the crude salt (5.66 g) from a 99% ethanol–ethyl acetate (1:1) mixture (150 ml) gave 3.85 g (46% total yield) of pure (−)-**4**·(+)-**5** salt: mp 187.5—188 °C; $[\alpha]_{435}^{26}$ −80.9° (c 1.17, 99% MeOH).

To a solution of the salt (3.85 g) in 99% methanol (50 ml) was added 3 M NaOH solution at 0 °C to basify the solution. After evaporation of the solvent, water (50 ml) was added to the white mass remained, and the suspension was vigorously stirred for 1 h. The precipitates were collected by filtration to yield 1.62 g of (−)-**4**. Recrystallization from 95% ethanol gave 1.05 g (28% total yield based on half the amount of (±)-**4** used) of pure (−)-**4**: mp 141—142 °C; $[\alpha]_{589}^{30}$ −7.3° (c 0.63, abs. EtOH) (lit,[8] mp 141—144 °C; $[\alpha]_{589}^{24}$ −6.4° (c 1.25, abs. EtOH)).

The mother liquor from the original crystallization was

concentrated under reduced pressure, and a similar treatment of the remained residue gave 4.50 g of **4** which contained (+)-**4** in excess. The recovered amino alcohol (4.50 g) and (−)-**5**[7] (5.21 g) were dissolved in a 99% ethanol–ethyl acetate (1:1) mixture (210 ml) under refluxing, and the solution was allowed to cool slowly at room temperature to give 7.66 g of crude (+)-**4**·(−)-**5** salt. Recrystallization of the salt (7.66 g) from a 99% ethanol–ethyl acetate (1:1) mixture gave 5.54 g of the pure salt: mp 187—188 °C; $[\alpha]^{27}_{435}$ +79.0° (*c* 1.04, 99% MeOH).

Decomposition of the salt in a similar manner to the case of (−)-**4**·(+)-**5** salt yielded 2.28 g of (+)-**4**. Recrystallization from 95% ethanol gave 1.77 g (46% total yield based on half the amount of (±)-**4** used) of pure (+)-**4**: mp 142—143 °C; $[\alpha]^{30}_{589}$ +7.1° (*c* 0.60, abs. EtOH) (lit,[3] $[\alpha]^{22}_{589}$ +6.8° in abs. EtOH).

Preferential Crystallization of (±)-4·Cinnamic Acid (6) Salt. Racemic **4·6** salt was prepared from equimolar amounts of (±)-**4** and **6** in methanol. For instance, a boiled solution of (±)-**4** (19.20 g) and **6** (13.33 g) in 99% methanol was cooled slowly and stood overnight at room temperature to give 24.57 g (76%) of (±)-**4·6** salt: mp 172—173 °C; IR (KBr) 3425, 3250, 3050, 2925, 1640, 1500, 1395, 1380 (shoulder), and 700 cm^{-1}. Found: N, 3.60%. Calcd for $C_{23}H_{23}NO_3$: N, 3.88%.

Optically active **4·6** salts for seeds in the preferential crystallization were also prepared from (+)- and (−)-**4** in a similar manner followed by twice recrystallizations from 99% methanol: mp 172—173 °C; $[\alpha]^{30}_{435}$ + and −170.7° (*c* 0.60, 99% MeOH); IR (KBr) 3425, 3250, 3050, 2925, 1640, 1500, 1395, 1380 (shoulder), and 700 cm^{-1}.

A refluxed solution of (±)-**4·6** salt (22.40 g), (+)-**4·6** salt (2.17 g), which was added to facilitate the preferential crystallization from the first stage, and (±)-**4**·lactic acid salt (30.00 g) in 99% methanol (550 ml) was cooled at about 35 °C to give a supersaturated solution. To the solution was added (+)-**4·6** salt (0.04 g) as a seed, and the solution was stirred gently (about 25 rpm) by a mechanical stirrer for 75 min at about 8 °C. The white precipitates deposited were collected by filtration, washed with 99% methanol (8 ml), and dried over P_2O_5 to yield 5.11 g of (+)-**4·6** salt: $[\alpha]^{27.5}_{435}$ +164.3° (*c* 0.60, 99% MeOH); 96% optical purity.

To the filtrate was added (±)-**4·6** salt (5.50 g) and dissolved at an elevated temperature. In a similar manner, the solution was cooled, seeded with (−)-**4·6** salt, and stirred gently at about 9 °C for 80 min to give 4.99 g of (−)-**4·6** salt: $[\alpha]^{26}_{435}$ −161.5° (*c* 0.60, 99% MeOH); 95% optical purity.

After several stages of the preferential crystallization as shown in Table 3, the crystals having the same sign of optical rotation were combined and recrystallized from 99% methanol to yield almost optically pure (+)- and (−)-**4·6** salts, respectively. For example, recrystallization of (+)-**4·6** salt (36.78 g, 91% optical purity on the average) from 99% methanol (440 ml) gave 24.25 g (66%) of (+)-**4·6** salt: mp 172—173 °C; $[\alpha]^{25}_{435}$ +168.5° (*c* 0.60, 99% MeOH); 99% optical purity. Found: N, 3.68%. Calcd for $C_{23}H_{23}NO_3$: N, 3.88%.

Similar recrystallization of (−)-**4·6** salt (34.40 g, 90% optical purity on the average) from 99% methanol (400 ml) gave 21.12 g (61%) of (−)-**4·6** salt: mp 172—173 °C; $[\alpha]^{26}_{435}$ −169.6° (*c* 0.60, 99% MeOH), 99% optical purity. Found: N, 3.61%. Calcd for $C_{23}H_{23}NO_3$: N, 3.88%.

Liberation of (+)- and (−)-4 from the Cinnamic Salts. To a hot solution of (−)-**4·6** salt (10.65 g) in 99% methanol (200 ml) was added 10% NaOH solution (50 ml) to decompose the salt. After evaporation of the solvent, water (200 ml) was added to the remained residue and the suspension was stirred for 40 min. The precipitates were collected by filtration and recrystallized from 95% ethanol (50 ml) to give 4.89 g (78%) of (−)-**4**: mp 143—144 °C; $[\alpha]^{32}_{589}$ −7.6° (*c* 0.60, abs. EtOH) (lit,[8] mp 141—144 °C; $[\alpha]^{24}_{589}$ −6.4° (*c* 1.25, abs. EtOH)). Found: N, 6.28%. Calcd for $C_{14}H_{15}NO$: N, 6.57%.

In a similar manner, (+)-**4** (8.26 g) was obtained from (+)-**4·6** salt (19.16 g): mp 143—144 °C; $[\alpha]^{24}_{589}$ +7.7° (*c* 0.63, abs. EtOH) (lit,[3] $[\alpha]^{22}_{589}$ +6.8° in abs. EtOH). Found: 6.78%. Calcd for $C_{14}H_{15}NO$: N, 6.57%.

Resolution of (±)-Tartaric Acid ((±)-9) with (+)-4. A solution of (±)-**9** (1.50 g, 10 mmol) and (+)-**4** (2.13 g, 10 mmol) in water (75 ml) was refluxed to give a clear solution. The solution was allowed to cool and stood overnight at room temperature. The white precipitates were collected by filtration and dried over P_2O_5 to yield 1.16 g (64%) of (−)-**9**·(+)-**4** salt: $[\alpha]^{32}_{435}$ +155.9° (*c* 0.30, H_2O).

To a suspension of the salt (1.06 g) was added 2 M NaOH (5 ml), and the precipitates appeared were filtered off. The aqueous solution was charged on an ion exchange column (Amberlite IR 120B, 35 ml) and the product was eluted with water (200 ml). The eluate was concentrated under reduced pressure. The mass remained was ground to a powder and dried over P_2O_5 to give 0.37 g (54% total yield based on half the amount of (±)-**9** used) of (−)-**9**: mp 167.5—168 °C; $[\alpha]^{24}_{589}$ −14.4° (*c* 1.04, H_2O), 91% optical purity based on the specific rotation of commercial (+)-tartaric acid.

When (−)-**4** was used as a resolving agent instead of (+)-**4**, similar treatment gave 2.51 g of (+)-**9**·(−)-**4** salt $[\alpha]^{34}_{435}$ −157.1° (*c* 0.30, H_2O). The salt (1.26 g) was similarly decomposed with 2 M NaOH to yield 0.45 g of (+)-**9**: mp 166—167 °C; $[\alpha]^{20}_{589}$ +14.1° (*c* 1.02, H_2O); 89% optical purity.

In a similar fashion, *trans*-2,3-oxiranedicarboxylic acid (**10**), 2-hydroxy-2-phenylpropionic acid (**11**), and 3-*endo*-benzamido-5-norbornene-2-*endo*-carboxylic acid (**12**) were resolved by fractional crystallization using (+)- or (−)-**4** as a resolving agent as shown in Tables 4 and 5.

Synthesis of (−)-threo-2-Amino-1,2-diphenylethanol (13). The compound was prepared from 8.54 g of (−)-**4**·HCl salt (mp 212—214 °C; $[\alpha]^{28}_{589}$ −61.3° (*c* 1.00, H_2O)) according to the procedure in the literature[4,9] without the purification of the products in each steps. Recrystallization of crude (−)-**13** from 70% ethanol gave pure (−)-**13**: yield 3.24 g (44% total yield); mp 115—116 °C; $[\alpha]^{23}_{589}$ −125° (*c* 1.00, 99% EtOH) (lit,[4] mp 115.2—115.8 °C; $[\alpha]^{22}_{589}$ −123.7° (*c* 1.2, abs. EtOH).

The Eschweiler-Clarke Reaction of (−)-threo-, (+)-erythro-, and (−)-erythro-2-Amino-1,2-diphenylethanol ((−)-13, (+)-4, and (−)-4). The reaction was carried as follows: To a solution of 2-amino-1,2-diphenylethanol (8.0 g, 37.5 mmol) in 99% formic acid (16.0 g, 342 mmol) was added dropwise 35% aq formalin (8.0 g, 93 mmol) in a period of 15 min, and the mixture was refluxed for 20 h with stirring. After cooling at room temperature, concd HCl solution (28 ml) was added to the reaction mixture. The solution was concentrated under reduced pressure, treated with 10% NaOH solution at 0 °C (pH≃10), and extracted with ether (3×180 ml). The ethereal extracts were combined, washed with saturated NaCl solution, and dried with $MgSO_4$. Concentration of the solution followed by recrystallization from hexane gave pure 2-dimethylamino-1,2-diphenylethanol.

(−)-*threo*- ((−)-**14**): yield 6.72 g (74%): mp 57—58 °C; $[\alpha]^{29}_{589}$ −124.7° (*c* 1.00, 99% EtOH); IR (KBr) 3450, 750, and 700 cm^{-1}; NMR ($CDCl_3$) δ=2.20 (s, 6H), 3.53

(d, 1H, J=10 Hz), 5.00 (d, 1H, J=10 Hz), 4.95 (s, 1H), and 6.9—7.4 (m, 10H). Found: N, 5.74%. Calcd for $C_{16}H_{19}NO$: N, 5.80%.

(+)-*erythro*- ((+)-**15**): yield 8.27 g (91%); mp 90—91 °C; $[\alpha]_{589}^{24}$ +123° (*c* 1.00, 99% EtOH); IR (KBr) 3510, 770, 750, and 700 cm^{-1}; NMR ($CDCl_3$) δ=2.30 (s, 6H), 3.20 (d, 1H, J=4.5 Hz), 3.30 (s, 1H), 5.27 (d, 1H, J=4.5 Hz), and 6.8—7.2 (m, 10H). Found: N, 6.01%. Calcd for $C_{16}H_{19}NO$: N, 5.80%.

(−)-*erythro*- ((−)-**15**): yield 7.84 g (87%); mp 90—91 °C; $[\alpha]_{589}^{27}$ −123° (*c* 1.01, 99% EtOH); IR (KBr) 3510, 770, 750, and 700 cm^{-1}; NMR ($CDCl_3$) δ=2.30 (s, 6H), 3.20 (d, 1H, J=4.5 Hz), 3.30 (s, 1H), 5.27 (d, 1H, J=4.5 Hz), and 6.8—7.2 (m, 10H). Found: N, 5.91%. Calcd for $C_{16}H_{19}NO$: N, 5.80%.

General Procedure for Asymmetric Reduction of Ketone. To a standardized ethereal solution of $LiAlH_4$ (8.90 ml, 4.0 mmol) were added successively dry ether (8.0 ml) and 2-dimethylamino-1,2-diphenylethanol (2123.8 mg, 8.8 mmol) in dry ether (8.0 ml) at room temperature in a period of 30 min, and the suspension was stirred for an additional hour. Ketone (2.0 mmol) in ether (8.0 ml) was added to the suspension, cooled at −78 °C, with stirring in a period of 1 h. After the reaction mixture was stirred for 5—10 h at that temperature, water (1 ml) was added to hydrolyze $LiAlH_4$ complex, and a cooling bath was removed. To the mixture was added 6 M HCl solution (20 ml) followed by ether (50 ml), and the precipitates appeared were filtered off and washed with ether (3×20 ml). The filtrate and washings were combined, and the ethereal layer was separated. The ethereal solution was dried with Na_2SO_4 and concentrated under reduced pressure to give crude product. The product was purified by preparative TLC to give the corresponding alcohol. Further, it was purified for the measurement of specific rotation by bulb to bulb distillation. The chiral amino alcohol was recovered by usual work up from the aqueous layer and the precipitates filtered off.

Synthetic Approach toward Antibiotic Tunicamycins. 3. Methyl 3,4,7,8-Tetra-*O*-acetyl-10-*O*-benzyl-2-benzyloxycarbonylamino-2,6-dideoxy-11,12-*O*-isopropylidene-β-L-dodecodialdo-(12*R*)-furanose-(12,9)-pyranosides-(1,5)

Yoshimasa FUKUDA, Hiroaki SASAI, and Tetsuo SUAMI*

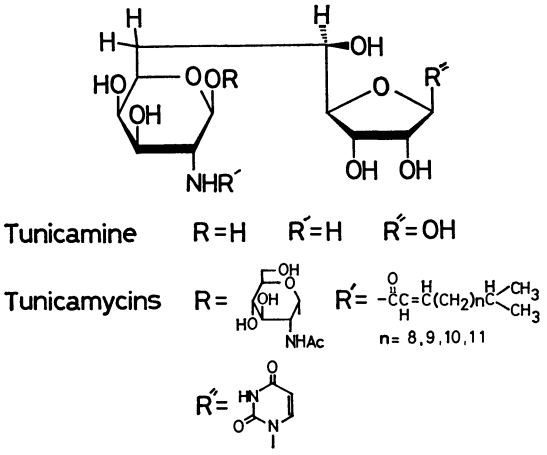
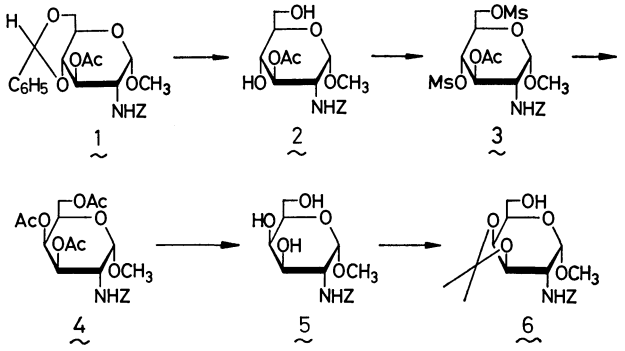
(Received October 13, 1981)

Higher carbon carbohydrates, dodecose derivatives have been synthesized by the base-catalyzed addition of nitro sugar to sugar aldehyde. The addition reaction of methyl 2-benzyloxycarbonylamino-2,6,7-trideoxy-3,4-*O*-isopropylidene-7-nitro-α-D-*galacto*-heptopyranoside to 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-ribodialdofuranose-(1,4) yielded nitro-dodecose derivatives. The nitro-dodecose derivatives were then converted into the corresponding hydroxy and acetoxy derivatives.

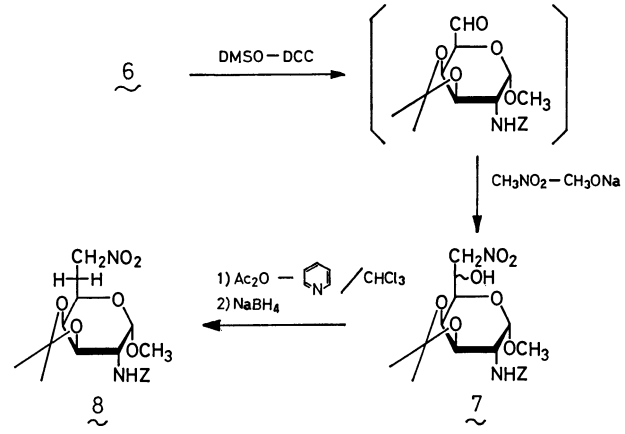
The nucleoside antibiotic tunicamycins are found in a fermentation broth of a strain of *streptomyces* and exhibit a broad spectrum of antitumor activity.[1] Their structures were established by Ito *et al.* in 1980 by chemical degradation.[2] The structures of tunicamycins consist of uracil, a novel higher-carbon carbohydrate named tunicamine, fatty acid, and *N*-acetyl-D-glucosamine. The tunicamine is an undecose derivative which, in turn, is bound to uracil to form tunicaminyl uracil. Analogous higher-carbon carbohydrates have been found in other nucleoside antibiotics, such as anthelmycin (hikizimysin),[3] sinefungin,[4] ezomycin,[5] and mildiomycin.[6]



Scheme 1.



Scheme 2.

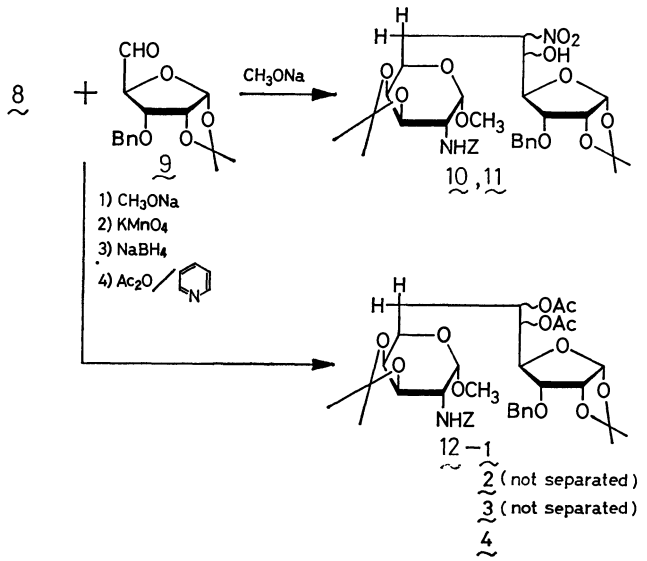


Scheme 3.

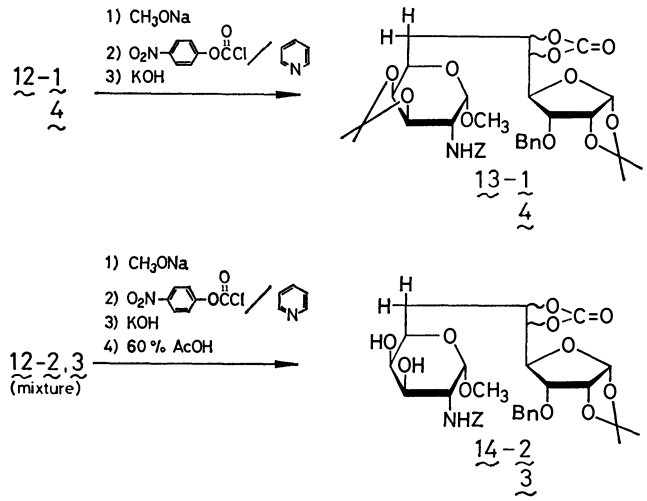
In preceding papers,[7] the base-catalyzed addition of nitro sugar to sugar aldehyde has been developed as a generally applicable method for the synthesis of higher-carbon complex carbohydrates. For a synthetic approach to tunicamine in the present study, the base-catalyzed addition of methyl 2-benzyloxycarbonylamino-2,6,7-trideoxy-3,4-*O*-isopropylidene-7-nitro-α-D-*galacto*-heptopyranoside (**8**) to 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-ribodialdofuranose-(1,4) (**9**) has been investigated. Then the nitro-dodecose derivatives were converted into the corresponding hydroxy and acetoxy derivatives to afford the four theoretically possible diastereoisomers of dodecose derivatives.

Results and Discussion

The hydrolysis of methyl 3-*O*-acetyl-2-benzyloxycarbonylamino-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (**1**)[8] in warm aqueous acetic acid gave the hydrolyzate (**2**). The mesylation of **2** with an excess amount of mesyl chloride in pyridine afforded the dimesylate (**3**). The displacement of the mesyloxy groups of **3** by acetate ions occurred with an epimerization of the configuration on C-4, giving the methyl α-D-galactoside derivative (**4**) in a yield of 59%. The deacetylation of **4** in methanolic ammonia, followed by acetonation, gave the 3,4-*O*-isopropylidene derivative (**6**) in 53% yield. The oxidation of the hydroxyl group on C-6 of **6** by the Pfitzner-Moffatt oxidation method,[9] followed by addition with nitromethane in the presence of sodium methoxide, afforded a mixture of two diastereoisomers of 7-nitroheptopyranosides (**7**) in 46% yield. The dehydroxylation of the hydroxyl group on C-6 of **7** with acetic anhydride and pyridine in chloroform, followed by



Scheme 4.

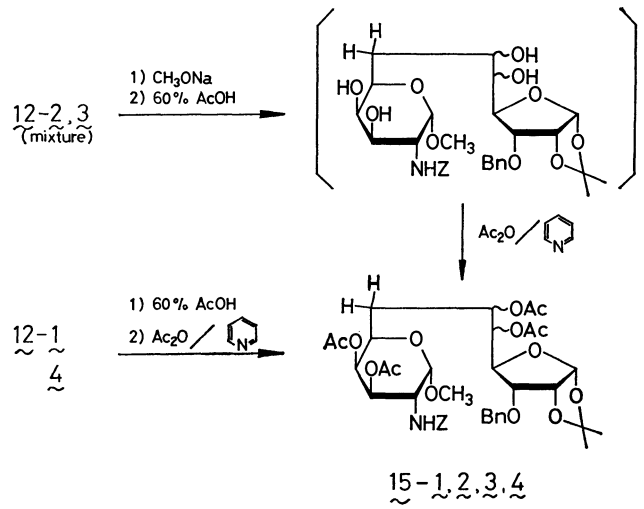


Scheme 5.

the hydrogenation of a double bond between C-6 and C-7 with sodium borohydride, afforded the 6-deoxy derivatives (**8**) in 78% yield.

On the other hand, 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-ribodialdofuranose-(1,4) (**9**) was prepared by the periodate oxidation of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-allofuranose.[10]

When the nitro-heptoside, **8**, reacted with the ribodialdofuranose-(1,4) derivative, **9**, in the presence of sodium methoxide, a mixture of diastereomers was obtained in a yield of 92%. The TLC and ^{1}H NMR of the intact mixture revealed the presence of the four theoretically possible diastereoisomeric nitrodocecose derivatives, from which only two compounds (**10**) and (**11**) were obtained in homogeneous states by repeated chromatographic fractionations. The structures of **10** and **11** were established, by means of their ^{1}H NMR and IR spectra, as methyl 10-*O*-benzyl-2-benzyloxycarbonylamino-2,6,7-trideoxy-3,4:11,12-di-*O*-isopropylidene-7-nitro-β-L-dodecodialdo-(12*R*)-furanose-(12,9)-pyranosides-(1,5), but the absolute configurations on C-7 and C-8 have not yet been established.



Scheme 6.

On the other hand, the oxidation of the intact mixture of the nitro-dodecoses with potassium permanganate[11] in water, followed by reduction with sodium borohydride and conventional acetylation, afforded a mixture of 7,8-di-*O*-acetyl derivatives in 43% yield. Chromatographic fractionations of the mixture gave two compound (**12-1** and **12-4**) as homogeneous products and the rest as a mixture of (**12-2**) and (**12-3**). The deacetylation of **12-1**, followed by carbonylation, gave a cyclic 7,8-*O*-carbonyl derivative (**13-1**) in 52% yield. By analogous reactions, the diastereomer (**13-4**) was obtained from **12-4**. The mixture of **12-2** and **12-3**, by analogous reactions plus mild hydrolysis in aqueous acetic acid, yielded two compounds (**14-2** and **14-3**), which were subsequently succesfully separated by column chromatography. The coupling constant of $J_{7,8}$ in the ^{1}H NMR spectrum of **14-2** was 8.0 Hz, suggesting the existence of vicinal cis protons on C-7 and 8.[12] That of **13-4** was 5.0 Hz, which showed trans protons on C-7 and 8. Those of **13-1** and **14-3** were 7.3 Hz and 6.4 Hz; their configurations have not yet been designated.

Finally, an intact mixture of **12-1** **12-2**, **12-3**, and **12-4** was hydrolyzed in 58% aqueous acetic acid at 40 °C for 1.5 h. The 3,4-*O*-isopropylidene group was selectively hydrolyzed under those conditions without a cleavage of the 11,12-*O*-isopropylidene group (another *O*-isopropylidene group on C-11 and 12). The product was acetylated to give four tetra-*O*-acetyl derivatives (**15-1**, **15-2**, **15-3**, and **15-4**), which were subsequently isolated by means of column chromatography. These compounds are important intermediates for further studies of the synthesis of tunicamine; that is, the selective removal of the 11,12-*O*-isopropylidene group, followed by oxidation (the cleavage of the C–C bond between C-11 and 12 by periodate oxidation) with sodium metaperiodate and deacylation, may provide undecose derivatives. However, it is still unknown which intermediate has the same configurations on C-7 and 8 as those of tunicamine.

Experimental

General Methods. The melting points were taken in capillary tubes in a liquid bath and are uncorrected. The solutions were concentrated under reduced pressure below 50 °C. The IR spectra were measured with a Hitachi 225 spectrophotometer and are expressed in reciprocal centimeters. The ^{1}H NMR spectra were obtained on a Varian EM-390 apparatus (90 MHz) and are reported as δ values in parts per million relative to tetramethylsilane as an internal standard. The TLC was performed on precoated silica-gel 60 F-254 (Merck, Darmstadt; Art. 5715; 0.25-mm thickness). The silica-gel columns used for chromatography utilized Wako gel C-200 or C-300 (Wako Pure Chemical Industries, Ltd.).

Methyl-3-O-acetyl-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (2). A stirred solution of methyl 3-*O*-acetyl-2-benzyloxycarbonylamino-4,6,-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (**1**)[8] (76.7 g) in 70% aqueous acetic acid (1000 ml) was heated at 60—70 °C for 1 h. The solution was then concentrated to dryness. The residue was purified on a silica-gel column [C-300, 250 g, toluene–ethyl acetate 8:1—1:1 (v/v)] to give 58.2 g (94%) of **2**; R_f 0.39 [benzene–ethanol 5:1 (v/v)], $[\alpha]_D^{21}$ +75.5° (*c* 1.0, chloroform), ^{1}H NMR ($CDCl_3$) δ 1.93 (3H, s, Ac), 3.36 (3H, s, OCH_3), 7.27 (5H, s, C_6H_5). Found: C, 55.28; H, 6.32; N, 3.62%. Calcd for $C_{17}H_{23}NO_8$: C, 55.28; H, 6.28; N, N, 3.79%.

Methyl 3-O-Acetyl-2-benzyloxycarbonylamino-2-deoxy-4,6-di-O-methylsulfonyl-α-D-glucopyranoside (3). To a solution of **2** (58.2 g) in pyridine (450 ml) was added methanesulfonyl chloride (29.3 ml) under ice cooling. After 18 h in a refrigerator, the reaction mixture was poured into ice and water (8 l), and then extracted with chloroform (500 ml). The chloroform layer was washed with water, a $NaHSO_4$ solution, water, a saturated $NaHCO_3$ solution, and water, and then concentrated to give an oily crude residue (76.5 g) which showed a single spot on TLC in 5:1 (v/v) benzene–ethyl acetate. A part (869.8 mg) of the crude residue was purified on a silica-gel column [C-300, 73 g, 3:1 (v/v) benzene–ethyl acetate] to give **3** (836.4 mg) as a homogeneous syrup in 89% yield from **2**. **3**; R_f 0.53 [5:1 (v/v) benzene–ethanol], $[\alpha]_D^{21}$ +77.3° (*c* 1.1, chloroform), ^{1}H NMR ($CDCl_3$) δ 1.91 (3H, s, Ac), 3.01, 3.05 (3H×2, s×2, CH_3SO_3), 3.39 (3H, s, OCH_3), 7.27 (5H, s, C_6H_5). Found: C, 43.39; H, 5.21; N, 2.48; S, 12.06%. Calcd for $C_{19}H_{27}NS_2O_{12}$: C, 43.42; H, 5.18; N, 2.67; S, 12.20%.

Methyl 3,4,6-Tri-O-acetyl-2-benzyloxycarbonylamino-2-deoxy-α-D-galactopyranoside (4). To a stirred solution of **3** (4.64 g) in acetic acid (35 ml) was added water (1.8 ml) and sodium acetate (29.3 g). After 24 h at 130—135 °C, acetic anhydride (25 ml) was added to the reaction mixture. After 2 h at 130 °C, the mixture was cooled to room temperature. The reaction mixture was then poured into a mixture of ice (500 g), chloroform (300 ml), and sodium carbonate (60 g). The chloroform layer was separated, washed with a saturated $NaHCO_3$ solution and water, and concentrated. The residue was purified on a silica-gel column [C-200, 25 g, 5:1 (v/v) toluene–ethyl acetate] to give oily **4** (2.69 g, 59% yield); R_f 0.28 [3:1 (v/v) toluene–ethyl acetate], $[\alpha]_D^{21}$ +86.6° (*c* 1.1, chloroform), IR ($CHCl_3$ solution) 3435 (NH), 1740 cm^{-1} (C=O), ^{1}H NMR ($CDCl_3$) δ 1.86, 2.01, 2.12 (3H×3, s×3, Ac), 3.36 (3H, s, OCH_3), 7.26 (5H, s, C_6H_5). Found: C, 55.71; H, 5.81; N, 2.85%. Calcd for $C_{21}H_{27}NO_{10}$: C, 55.87; H, 5.81; N, 3.10%.

Methyl 2-Benzyloxycarbonylamino-2-deoxy-α-D-galactopyranoside (5). A solution of **4** (26.8 g) in methanolic ammonia (11%) was left to settle in a refrigerator for 18 h. The reaction mixture was then concentrated, and the residue was recrystallized from water to give 11.4 g (58.8%) of **5**; R_f 0.22 [5:1 (v/v) benzene–ethanol]; mp 197—197.5 °C, $[\alpha]_D^{20}$ +131° (*c* 0.5, methanol), ^{1}H NMR (CD_3OD) δ 7.37 (5H, s, C_6H_5), 3.30 (3H, s, OCH_3). Found: C, 55.17; H, 6.43; N, 4.18%. Calcd for $C_{15}H_{21}NO_7$: C, 55.04; H, 6.47; N, 4.28%.

Methyl 2-Benzyloxycarbonylamino-2-deoxy-3,4-O-isopropylidene-α-D-galactopyranoside (6). To a suspension of **5** (5.01 g) in acetone (80 ml) was added acetone (200 ml) containing concentrated sulfuric acid (0.1 ml). After 2.5 h at the ambient temperature, the reaction mixture was neutralized with Amberlite IRA-400(OH^-) resin; the resin was then filtered off. The filtrate was concentrated, and toluene (100 ml) was added to the residue. The insoluble matter was removed by filtration, and the filtrate was concentrated to *ca.* 30 ml, and then left for 1 d. The precipitate was collected to give 2.13 g (38.2%) of **6** as crystals. The filtrate was repeatedly worked-up as has been described above to give 0.81 g (14.6%) of **6**. Total yield, 2.94 g (53%). **6**; R_f 0.53 [5:1 (v/v) benzene–ethanol], mp 105—105.5 °C, $[\alpha]_D^{23}$ +131° (*c* 1.0, methanol), ^{1}H NMR ($CDCl_3$) δ 3.32 (3H, s, OCH_3), 1.57, 1.32 (3H×2, s×2, isopropylidene). Found: C, 59.03; H, 6.85; N, 3.74%. Calcd for $C_{18}H_{25}NO_7$: C, 58.85; H, 6.86; N, 3.80%.

Methyl 2-Benzyloxycarbonylamino-2,7-dideoxy-3,4-O-isopropylidene-7-nitro-DL-glycero-D-galacto-heptopyranoside (7). To a stirred solution of **6** (4.07 g) in benzene (8 ml) and dimethyl sulfoxide (26 ml) were added pyridine (0.2 ml), phosphoric acid (0.1 ml), and dicyclohexylcarbodiimide (7.2g) under ice cooling. After stirring for 4 h at the ambient temperature, a suspension of oxalic acid (5 g) in methanol (5 ml) was added to the solution. After 1 h, the mixture was extracted with ethyl acetate (150 ml). The ethyl acetate layer was washed with a $NaHCO_3$ solution and water dried over Na_2SO_4 and concentrated. To a solution of the residue in methanol (35 ml) was added nitromethane (8.55 ml) and 1 M methanolic sodium methoxide (9.54 ml). After 1 h at the ambient temperature, the solution was neutralized with Amberlite IR-120B(H^+) resin and concentrated. The residue was chromatographed on a silica-gel column [C-200, 2:1 (v/v) chloroform–ethyl acetate]. The product was then recrystallized from toluene to give 2.18 g (46%) of **7**; mp 115—117 °C, $[\alpha]_D^{23}$ +96.8° (*c* 1.0, methonol), IR (KBr) 3510 (OH), 3360 (NH), 1698 (C=O), 1555, 1530, 1390 cm^{-1} (NO_2), ^{1}H NMR ($CDCl_3$) δ 1.34, 1.56 (3H×2, s×2, isopropylidene), 3.29 (3H, s, OCH_3), 7.26 (5H, s, C_6H_5). Found: C, 53.70; H, 6.16; N, 6.56%. Calcd for $C_{19}H_{26}N_2O_9$: C, 53.52; H, 6.15; N, 6.57%.

Methyl 2-Benzyloxycarbonylamino-2,6,7-trideoxy-3,4-O-isopropylidene-7-nitro-α-D-galacto-heptopyranoside (8). To a solution of **7** (2.1 g) in chloroform (50 ml) were added acetic anhydride (2.8 ml) and pyridine (1.6 ml) under ice cooling. After 22 h at the ambient temperature, the reaction mixture was washed with water, a saturated $NaHCO_3$ solution, and water, then chloroform layer was concentrated. The residue was dissolved in ethanol (50 ml) and toluene (20 ml), and to the solution was added a suspension of sodium borohydride (0.56 g) in ethanol (30 ml). After 1 h at the ambient temperature, the reaction mixture was neutralized with Amberlite IR-120B(H^+) resin; the resin was then filtered off. The filtrate was concentrated, and the residue was recrystallized from ethanol to give 1.58 g (77.8%) of **8**; R_f 0.44 [3:1 (v/v) toluene–ethyl acetate], $[\alpha]_D^{19}$ +140.6° (*c* 0.5, chloroform), IR (KBr) 1690 (C=O), 1550, 1386, 1375

cm^{-1} (NO_2), ^1H NMR ($CDCl_3$) δ 1.27, 1.52 (3H×2, s×2, isopropylidene), 3.32 (3H, s, OCH_3), 7.18 (5H, s, C_6H_5). Found: C, 55.74; H, 6.42; N, 6.66%. Calcd for $C_{19}H_{26}N_2O_8$: C, 55.60; H, 6.38; N, 6.83%.

*Methyl 10-O-Benzyl-2-benzyloxycarbonylamino-2,6,7-trideoxy-3,4:11,12-di-O-isopropyridene-7-nitro-β-L-dodecodialdo-(12R)-furanose-(12,9)-pyranosides-(1,5) (**10** and **11**).* To a solution of **9** (300 mg) in ethanol (15 ml) were added **8** (305.4 mg) and 1 M methanolic sodium methoxide (0.74 ml) under ice cooling. After 18 h at the ambient temperature, the reaction mixture was neutralized with Amberlite IR-120B (H^+) resin; the resin was then filtered off. The filtrate was concentrated, and the residue was purified on a silica-gel column [C-300:C-200 1:5, 30 g, 7:1 (v/v) toluene–ethyl methyl ketone] to give a mixture of nitrododecose derivatives; 437.2 mg (92.3% yield from **8**). The mixture was repeatedly chromatographed analogously to the method described above to afford two homogeneous nitrododecose isomers, **10** and **11**. However, the other two isomers could not separated. **10**; syrup, R_f 0.58 [1:1 (v/v) toluene–ethyl acetate], $[\alpha]_D^{19}$ +107° (*c* 1.0, chloroform), IR (chloroform solution) 3570 (OH), 3430 (NH), 1720 (C=O), 1567, 1386 cm^{-1} (NO_2), ^1H NMR ($CDCl_3$) δ 7.25, 7.23 (5H×2, s×2, C_6H_5), 5.64 (1H, d, $J_{11,12}$=3 Hz, H-12), 3.23 (3H, s, OCH_3), 1.56, 1.38, 1.36, 1.23 (3H×4, s×4, isopropylidene). Found: C, 59.05; H, 6.37; N, 4.14%. Calcd for $C_{34}H_{44}N_2O_{13}$: C, 59.29; H, 6.44; N, 4.07%.

11; Mp 182—183.5 °C, R_f 0.37 [1:1 (v/v) toluene–ethyl acetate], $[\alpha]_D^{19}$ +111° (*c* 0.4, chloroform), IR (chloroform solution) 3530 (OH), 3435 (NH), 1740 (C=O), 1550, 1385 cm^{-1} (NO_2), ^1H NMR ($CDCl_3$) δ 7.25 (10H, s, C_6H_5×2), 5.62 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 3.26 (3H, s, OCH_3), 1.53, 1.33, 1.29 (6H and 3H×2, s×3, isopropylidene). Found: C, 59.50; H, 6.47; N, 4.25%.

*Methyl 7,8-Di-O-acetyl-10-O-benzyl-2-benzyloxycarbonylamino-2,6-dideoxy-3,4:11,12-di-O-isopropylidene-β-L-dodecodialdo-(12R)-furanose-(12,9)-pyranosides-(1,5) (**12-1**, **12-2**, **12-3**, and **12-4**).* 1 M methanolic sodium methoxide (2.2 ml) was added to a solution of **8** (900 mg) and **9**, obtained from 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-allofuranose (672 mg), in methanol (30 ml). After 18 h at the ambient temperature, methanol (45 ml) was added to the reaction mixture, which was then poured into ice-cold water (300 ml). To the solution was added a solution of magnesium sulfate (450 mg) in water (50 ml); subsequently, a solution of potassium permanganate (630 mg) in water (120 ml) was added, drop by drop, to the stirred mixture under ice cooling. After 1 h at the ambient temperature, acetic acid (2.7 ml) and chloroform (150 ml) were added to the solution and inorganic precipitates were removed by filtration. The chloroform layer was separated, and the aqueous layer was extracted with chloroform (50 ml×4). The organic layers were combined and concentrated. The residue was dissolved in ethanol (80 ml), and sodium borohydride (460 mg) was added to the solution under ice cooling. After 2 h at the ambient temperature, the mixture was concentrated. Water (30 ml) was added to the residue, and the mixture was extracted with ethyl acetate (45 ml×2). The organic solution was concentrated. The oily residue was acetylated by acetic anhydride (4.5 ml) in pyridine (35 ml) for 18 h. The reaction mixture was concentrated, and the residue was purified on a silica-gel column (C-200, 65 g), using 4:1 (v/v) toluene–ethyl acetate, to give 185.8 mg of a mixture of **12-1**, **12-2**, and **12-3** 128.1 mg of a mixture of **12-2** and **12-3**, 48 mg of a mixture of **12-2**, **12-3**, and **12-4**, and 389 mg of only **12-4** as crystals. Total yield, 650.9 mg (43.1% from **8**).

The mixture of **12-1**, **12-2**, and **12-3**, (185.8 mg) obtained above, was chromatographed again on a silica-gel column [C-200, 18 g, 4:1 (v/v) toluene–ethyl acetate] to give 28.1 mg of only **12-1**, 75.6 mg of a mixture of **12-1**, **12-2**, and **12-3**, and 56.7 mg of a mixture of **12-2** and **12-3**. Total yield, 160.4 mg (86.3% recovery). However **12-2** and **12-3** could not be separated, as their R_f values on TLC were the same in several solvent systems.

12-1: R_f 0.61 [1:1 (v/v) toluene–ethyl acetate], mp 78—81 °C, $[\alpha]_D^{19}$ +104° (*c* 0.3, chloroform), ^1H NMR ($CDCl_3$) δ 7.25 (10H, s, C_6H_5×2), 5.65 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 3.20 (3H, s, OCH_3), 1.97, 1.91 (3H×2, s×2, Ac), 1.55, 1.33 (6H×2, s×2, isopropylidene), IR (KBr) 1735 cm^{-1} (C=O). Found: C, 61.22; H, 6.77; N, 1.70%. Calcd for $C_{38}H_{49}NO_{14}$: C, 61.36; H, 6.64; N, 1.88%.

12-2 and **12-3**: R_f 0.55 [1:1 (v/v) toluene–ethyl acetate].

12-4: R_f 0.44 [1:1 (v/v) toluene–ethyl acetate], mp 192—193 °C, $[\alpha]_D^{21}$ +123° (*c* 1.0, chloroform), ^1H NMR ($CDCl_3$) δ 7.33 (10H, s, C_6H_5×2), 5.70 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 3.25 (3H, s, OCH_3), 2.05 (6H, s, Ac×2), 1.58 1.57, 1.35, 1.31 (3H×4, s×4, isopropylidene), IR (KBr) 1740, 1690 cm^{-1} (C=O). Found: C, 61.23; H, 6.69; N, 2.06%.

*Methyl 10-O-Benzyl-2-benzyloxycarbonylamino-7,8-O-carbonyl-2,6-dideoxy-3,4:11,12-di-O-isopropylidene-β-L-dodecodialdo-(12R)-furanose-(12,9)-pyranosides-(1,5) (**13-1** and **13-4**).* To a solution of **12-1** or **12-4** (20 mg) in methanol (10 ml) was added 1 M methanolic sodium methoxide (0.2 ml). After 3 h at the ambient temperature, toluene (30 ml) was added to the reaction mixture, which was then concentrated to *ca.* 20 ml. To the solution were added water (10 ml) and ethyl acetate (30 ml). The organic layer was separated, dried, and concentrated. The residue was reacted with *p*-nitrophenoxycarbonyl chloride (30 mg) in pyridine (2 ml) and tetrahydrofuran (0.5 ml). After 18 h at the ambient temperature, water (20 ml) was added to the reaction mixture, which was then extracted with ethyl acetate (30 ml). The ethyl acetate layer was washed with a saturated $NaHCO_3$ solution and water, and then concentrated. The residue was purified on a silica-gel column (C-200, 2 g), using 1:1 (v/v) toluene–ethyl acetate, to give **13-1** or **13-4**.

13-1: Yield, 52%, R_f 0.67 [1:1 (v/v) toluene–ethyl acetate], mp 179.5—180 °C, IR (KBr) 1808 cm^{-1} (C=O), ^1H NMR ($CDCl_3$) δ 7.34 (10H, s, C_6H_5×2), 5.72 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 5.08 (1H, m, $J_{7,8}$=7.3 Hz, H-7), 3.35 (3H, s, OCH_3), 1.60, 1.57, 1.27, 1.28 (3H×4, s×4, isopropylidene). Found: C, 61.04; H, 6.33; N, 1.83%. Calcd for $C_{35}H_{43}NO_{13}$: C, 61.31, H, 6.32, N, 2.04%.

13-4: Yield, 48%, R_f 0.69 [1:1 (v/v) toluene–ethyl acetate], mp 87.5—88.5 °C (amorphous solid), IR (KBr) 1805 cm^{-1} (C=O), ^1H NMR ($CDCl_3$) δ 7.35, 7.34 (5H×2, s×2, C_6H_5), 5.73 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 4.94 (1H, m, $J_{7,8}$=5.0 Hz, H-7), 3.34 (3H, s, OCH_3), 1.62, 1.60, 1.36, 1.34 (3H×4, s×4, isopropylidene). Found: C, 61.48; H, 6.49; N, 2.06%.

*Methyl 10-O-Benzyl-2-benzyloxycarbonylamino-7,8-O-carbonyl-2,6-dideoxy-11,12-O-isopropylidene-β-L-dodecodialdo-(12R)-furanose-(12,9)-pyranosides-(1,5) (**14-2** and **14-3**).* A mixture of **12-2** and **12-3** (110.8 mg) was hydrolyzed in 0.1 M methanolic sodium methoxide (17.9 ml) for 1 h at the ambient temperature. The reaction mixture was then neutralized with Amberlite IR-120B (H^+) resin and the resin was filtered off. The fitrate was subsequently concentrated. To a solution of the residue in pyridine (6 ml) was added *p*-nitrophenoxycarbonyl chloride (300 mg).

After 18 h, the reaction mixture was extracted with chloroform, and the chloroform layer was washed with saturated $NaHCO_3$ solution and water. The solution was concentrated to give an oily residue, which contained *p*-nitrophenoxycarbonyl derivatives. The residue was treated with methanol (4 ml) containing potassium hydroxide (9.4 mg) at the ambient temperature for 3 h, then the reaction mixture was concentrated. To the residue was added water, which was then extracted with ethyl acetate (20 ml×3). The ethyl acetate layers were combined and concentrated. The oily product, without purification, was treated with 60% acetic acid at 40 °C for 3 h. The reaction mixture was concentrated, and the residue was purified on a silica-gel column [C-300, 5 g, 2:1 (v/v) toluene–ethyl methyl ketone] to give **14-2** and **3**, each as a homogenous amorphous solid.

14-2: Mp 96—98 °C, R_f 0.52 [1:1 (v/v) toluene–ethyl methyl ketone], IR (KBr) 1805, 1705 cm^{-1} (C=O), ^1H NMR ($CDCl_3$) δ 7.35 (10H, s, $C_6H_5\times2$), 5.73 (1H, d, $J_{11,12}$= 3.8 Hz, H-12), 4.94 (1H, m, $J_{7,8}$=8.0 Hz, H-7), 3.33 (3H, s, OCH_3), 2.33 (2H, m, H-6) 1.55, 1.35 (3H×2, s×2, isopropylidene). Found: C, 59.30; H, 6.25; N, 2.36%. Calcd for $C_{33}H_{39}NO_{13}$: C, 59.53; H, 6.09; N, 2.17%.

14-3: Mp 81—84 °C, R_f 0.45 [1:1 (v/v) toluene--ethyl methyl ketone], IR (KBr) 1805, 1705 cm^{-1} (C=O), ^1H NMR ($CDCl_3$) δ 7.35 (10H, s, $C_6H_5\times2$), 5.73 (1H, d, $J_{11,12}$= 3.8 Hz, H-12), 4.82 (1H, m, $J_{7,8}$=6.4 Hz, H-7), 3.34 (3H, s, OCH_3), 1.59, 1.36 (3H×2, s×2, isopropylidene). Found: C, 59.53; H, 6.19; N, 2.16%.

*Methyl 3,4,7,8-Tetra-O-acetyl-10-O-benzyl-2-benzyloxycarbonylamino-2,6-dideoxy-11,12-O-isopropylidene-β-L-dodecodialdo-(12R)-furanose-(12,9)-pyranoside-(1,5) (**15**).* *a) **15-1** and **15-4***: Compound **12-1** or **12-4** (200 mg) was treated with acetic acid (70 ml) and water (50 ml) at 40 °C for 1.5 h. The reaction mixture was concentrated to dryness. The residue was purified on a silica-gel column [C-200, 20 g, 1:1 (v/v) toluene–ethyl acetate] to afforded a diol derivative. The diol derivative was reacted with acetic anhydride (0.7 ml) in pyridine (10 ml) for 2 d. The reaction mixture was co-evaporated with toluene, and the residue was extracted with chloroform. The chloroform layer was washed with water, a saturated $NaHCO_3$ solution, and water, dried and cocentrated. The residue was purified on silica-gel column [C-200, 15 g, 2:1 (v/v) toluene–ethyl acetate] to give **15-1** or **4**.

15-1: Yield, 70%, R_f 0.62 [1:1 (v/v) toluene–ethyl acetate] mp 84—86 °C, $[\alpha]_D^{23}$ +98.4° (*c* 0.5, chloroform), ^1H NMR ($CDCl_3$) δ 7.20 (10H, s, $C_6H_5\times2$), 5.57 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 3.18 (3H, s, OCH_3), 2.07, 1.95, 1.86, 1.78 (3H×4, s×4, Ac), 1.52, 1.30 (3H×2, s×2, isopropylidene). Found: C, 59.20; H, 6.29; N, 1.87%. Calcd for $C_{39}H_{49}NO_{16}$: C, 59.46; H, 6.27; N, 1.78%.

15-4: Yield, 80%, R_f 0.49 [1:1 (v/v) toluene–ethyl acetate] mp 130.5—131.5 °C, $[\alpha]_D^{28}$ +125.4° (*c* 0.5, chloroform), ^1H NMR ($CDCl_3$) δ 7.22 (10H, s, $C_6H_5\times2$), 5.53 (1H, d, $J_{11,12}$=3.5 Hz H-12), 3.23 (3H, s, OCH_3), 2.08, 1.96, 1.94, 1.82 (3H×4, s×4, Ac), 1.49, 1.28 (3H×2, s×2, isopropylidene). Found: C, 59.65; H, 6.37; N, 1.79%.

*b) **15-2** and **15-3***: A mixture of **12-2** and **12-3** (128.1 mg) was hydrolyzed in 0.1 M methanolic sodium methoxide (20 ml) for 3 h. To the reaction mixture was added toluene (30 ml), which was subsequently concentrated to *ca.* 20 ml. To the solution was added water (10 ml) and ethyl acetate (20 ml). The organic layer was separated and cocentrated. The residue was treated with 60% acetic acid (10 ml) at 40 °C for 2 h. The reaction mixture was co-evaporated with toluene, and the residue was purified on a silica-gel column [C-200, 20 g, 30:1 (v/v) chloroform–methanol] to give the tetrahydroxy derivative, 13.4 mg (10.3%) with an R_f value of 0.30 [10:1 (v/v) chloroform–methanol], 14.9 mg (12.4%) with an R_f value of 0.32 in the same solvent system, and 39.1 mg of a mixture of them. Total yield, 67.4 mg (55%). Each tetrahydroxy derivative obtained above was reacted with acetic anhydride (0.3 ml) in pyridine (2 ml) for 18 h. The reaction mixture was then co-evaporated with toluene, and the residue was purified on a silica-gel column [C-200, 4 g, 3:1 (v/v) toluene–ethyl acetate] to give 14.3 mg (76%) of **15-2** and 13.7 mg (81%) of **15-3**.

15-2: R_f 0.52 [1:1 (v/v) toluene–ethyl acetate], mp 77—78 °C $[\alpha]_D^{28}$ +102.4° (*c* 0.5, chloroform), ^1H NMR ($CDCl_3$) δ 7.24 (10H, s, $C_6H_5\times2$), 5.50 (1H, d, $J_{11,12}$=3.5 Hz, H-12), 3.33 (3H, s, OCH_3), 2.04, 1.97, 1.87, 1.83 (3H×4, s×4, Ac), 1.62, 1.30 (3H×2, s×2, isopropylidene). Found: C, 59.24; H, 6.26; N, 1.76%. Calcd for $C_{39}H_{49}NO_{16}$: C, 59.46; H, 6.27; N, 1.78%.

15-3: R_f 0.54 [1:1 (v/v) toluene–ethyl acetate], mp 81.5—83.5 °C, $[\alpha]_D^{23}$ +101° (*c* 0.5, chloroform), ^1H NMR ($CDCl_3$) δ 7.20 (10H, s, $C_6H_5\times2$), 5.55 (1H, d, $J_{11,12}$= 3.5 Hz, H-12), 3.25 (3H, s, OCH_3), 1.97, 2.10, 1.83 (6H and 3H×2, s×3, Ac), 1.53, 1.30 (3H×2, s×2, isopropylidene). Found: C, 59.44; H, 6.33; N, 1.84%.

The authors wish to thank Professor Gakuzo Tamura, Tokyo University, for his helpful suggestions. They also wish to express their appreciation to Pharmaceutical Development Laboratories, Meiji Seika Kaisha, Ltd., for the NMR spectral data; to Mr. Saburo Nakada for the elemental analyses, and to Mr. Masazumi Kameda for the IR spectral data.

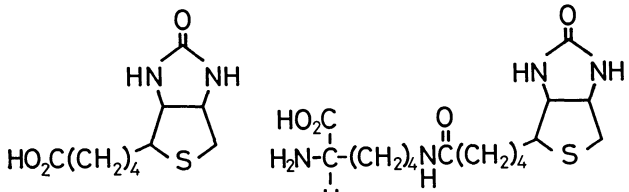
Synthesis of Biotin-containing Peptides Representing the Biotin Binding Site of *E. coli* Acetyl-CoA Carboxylase†

Hiroki KONDO,* Fumio MORIUCHI, and Junzo SUNAMOTO
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received October 19, 1981)

Two biotin-containing peptides, Ac-Met-Bct-Met-Met-OMe (**1**) and Boc-Met-Bct-Met-Met, that correspond to the local sequence of biotin carboxyl carrier protein subunit of *E. coli* acetyl-CoA carboxylase have been synthesized. The precursor tetrapeptide Boc-Met-Lys(Cbz)-Met-Met-OMe was prepared first by the stepwise elongation method and biotin was incorporated subsequently by the active ester method. Another biotin-containing peptide, HCO-Met-Bct-Met-Met-OMe, has also been prepared. Magnesium ion binding to peptide **1** in acetonitrile has been studied by means of ^{13}C NMR spectroscopy. The metal interacts principally with the amide carbonyls rather than sulfide moieties, as deduced from a significant downfield shift of the former carbon signals in ^{13}C NMR.

In biotin-requiring carboxylases the prosthetic group biotin (**4**) is attached to the ε-amino moiety of a certain lysine residue on the so-called BCCP (biotin carboxyl carrier protein) subunit.[1] The binding of BCCP to other subunits directly involved in the transformation of biotin and substrates is very tight. In some instances biotin itself can bind to the enzyme with a high K_m value relative to that for BCCP.[2,3] It is, hence, clear that the polypeptide part of BCCP contributes much to the binding of biotin, but what part of the amino acid sequence is required remained to be clarified. In light of the accumulating knowledge on the primary structure around biocytin (biotinyllysine, **5**) of several biotin enzymes,[4-6] Bodanszky



4 5

and Fagan were the first to undertake this subject.[7] They prepared biotin-containing peptides such as **6**, that corresponds to the local structure adjacent to biocytin of transcarboxylase. Unfortunately, however, the peptides failed to restore enzymic activity. It was later reported that the amino acid sequence of transcarboxylase on which their model peptides based was in error.[8]

Boc-Ala-Met-Bct-Thr-Gly-OEt **6**

According to the known primary structure of biotin enzymes, they have a unique structure in that biocytin is flanked by methionines. In the case of acetyl-CoA carboxylase from *E. coli*, an additional Met is placed at the C terminal side of the sequence (**7**). Since

-Met-Bct-Met-Met- **7**

each amino acid residue in **7** carries a sulfide moiety, we have speculated that these four sulfide groups may be playing an important role in the binding of biotin to the enzyme. If one recalls that the enzyme requires metal ions such as Mn^{2+} and Mg^{2+} for activity, this might be performed through chelate formation. Hence, we have prepared model peptides **1**—**3**, analogous to **7**, and studied their interaction with metal ions by means of ^{13}C NMR spectroscopy.[9]

Results and Discussion

Synthesis. The liquid phase synthesis of **1** and **2** has been achieved according to the routes shown in Fig. 1 and Scheme 1. The basic strategy was to prepare the tetrapeptide Boc-Met-Lys(Cbz)-Met-Met-OMe **8** first and biotin was incorporated to the peptide subsequently. This should help avoid possible side reactions on the biotin moiety and interference of the biotin's urea group with amino acid coupling.[7] The α-amino function of both Met and Lys was protected with Boc, while the ε-amino moiety of Lys was with Cbz. An alternate combination of protecting groups may appear equally well as long as special care is taken for the removal of Cbz groups. One of the most popular methods of doing this, hydrogenolysis, did not work even in the presence of boron trifluoride etherate even at the dipeptide level.[10] So, this approach was abandoned and switched to the alternative one without testing extensively other deprotection methods. The Boc group was removed

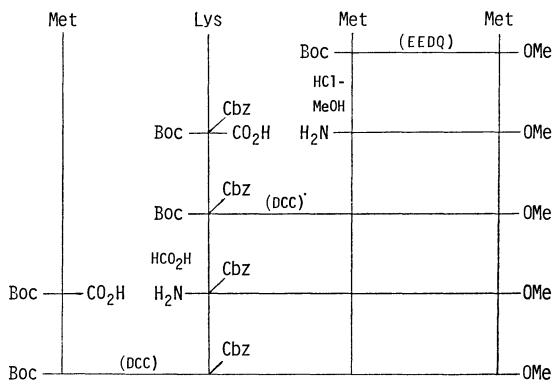


Fig. 1. Synthetic route to **8**.

† The abbreviations used in this article follow the nomenclature recommended by the IUPAC-IUB Commission of Biochemical Nomenclature: Met, L-methionine; Lys, L-lysine; Bct, biotinyl-L-lysine; Cbz, benzyloxycarbonyl; Boc, *t*-butoxycarbonyl; EEDQ, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline; DCC, dicyclohexylcarbodiimide; HOBt, 1-hydroxybenzotriazole; NEM, *N*-ethylmorpholine; TEA, triethylamine.

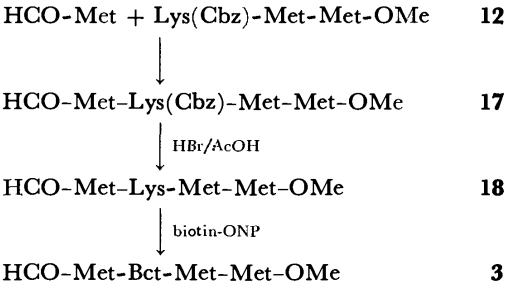

Scheme 2.

from Boc–Met–Met–OMe with 10 M HCl in methanol and from Boc–Lys(Cbz)–Met–Met–OMe and Boc–Met–Lys(Cbz)–Met–Met–OMe with formic acid.

The tetrapeptide **8** was derivatized to the final products according to the synthetic routes shown in Scheme 1. Removal of Boc in **8** with formic acid followed by acetylation gave **14**, whose Cbz was removed with 25% HBr in acetic acid to give **15**. Treatment of **8** with sodium in liquid ammonia provided **16** smoothly. Introduction of biotin into **15** and **16** was accomplished by the active ester method. In view of the fact that *N*-hydroxysuccinimide ester of biotin is successfully employed for the covalent attachmen of biotin to the affinity adsorbents,[11] we have tested this method first. The reaction was carried out in DMF in the presence of TEA or NEM at temperatures ranging from room temperature to 50 °C with total failure. Subsequently, the *N*-hydroxysuccinimide ester was replaced by *p*-nitrophenyl ester of biotin,[7] and its reaction with **15** or **16** at ambient temperatures gave **1** or **2**, respectively, but in low yields (28—38%). Coupling of **15** with biotin acid chloride has also been tried,[12] but this method did not work either. The synthesis of **3** has also been done according to the route shown in Scheme 2.

The structure of biotin-containing peptides **1**—**3** has been ascertained by the following criteria. All the peptides gave a characteristic pink color upon reaction with *p*-dimethylaminocinnamaldehyde, indicating the presence of a biotinyl moiety.[13] In Fig. 2 is shown the 500 MHz NMR spectrum of **1** in DMSO-d_6. Two singlets are clearly observable for the biotin N–H protons at 6.14 and 6.20 ppm as well as five signals for the amide protons at 7.5—8.1 ppm. Other peaks are also reasonably assignable to individual protons of **1**. There are six amide carbonyl signals in

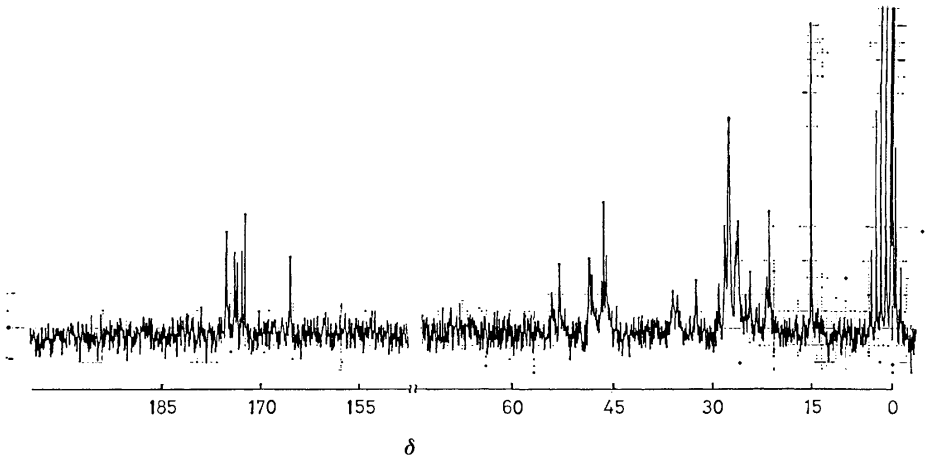

Fig. 3. ^{13}C NMR spectrum of **1** in CD_3CN in the presence of 4 mol of magnesium perchlorate.

the 172—177 ppm region as well as one urea carbonyl signal at 164.4 ppm in the ^{13}C NMR spectrum of **1** in CD_3CN in the presence of magnesium perchlorate (Fig. 3). Results of elemental analysis are also satisfactory (see Experimental), establishing the purity and structure of these compounds.

Magnesium Ion Binding. All the biotin-containing peptides (**1**—**3**) are sparingly soluble in acetonitrile but they become considerably soluble in the presence of magnesium perchlorate, suggesting that the peptides interact with magnesium ion. In order to prove this, further studies were done by using ^{13}C NMR spectroscopy. Because of the poor solubility of **1**, **8** was chosen as a reference compound. As seen in Table 1, all five amide carbonyls of **8** show a considerable downfield shift (average 1.8 ppm) in the presence of 4 mol of magnesium perchlorate. This is true for **1**: five amide carbonyls show a downfield shift of 2.0 ppm on the average, compared to the amide carbonyls of **8** in the absence of magnesium perchlorate. On the other hand, the ureido carbonyl of biotin suffers little effect, in line with our previous finding that this moiety of 2-imidazolidinones is a poor ligand to magnesium.[9] In contrast to the carbonyl signals, other carbon signals including those of *S*-methyl carbons of methionines were not affected by magnesium perchlorate. This indicates that the metal coordinates to the carbonyls rather than the sulfides. It is plausible that the magnesium ion plays its role through association with ATP or its conjugate with hydrogencarbonate in enzymatic carboxylations. In order for biotin to be carboxylated the coenzyme must come into contact with other reactants at the enzyme active site. This might be made possible through coordination of peptide carbonyls adjacent to the biotin in BCCP to form a ternary complex composed of BCCP, Mg^{2+} and ATP or its conjugate with hydrogencarbonate.

Experimental

^1H NMR spectra were taken on a JEOL JNM-MH-100 spectrometer. ^{13}C NMR spectra were obtained on a JEOL JNM-FX-90Q spectrometer operating at 22.50 MHz. Parameters for these experiments were the following: spectral width 5000 Hz with acquisition of 8 K data points, 7 μs pulse, and a recovery time of 3 s. The numbers of spectral accumulations were in the range 2000—5000. Samples were dissolved in CD_3CN for measurements at 25.0 °C and chemical shifts are given in ppm downfield from internal TMS. Optical rotation was determined on a JASCO DIP-4 digital polarimeter.

TLC on silica gel was run in the following solvent systems: ethyl acetate (A), CH_2Cl_2–ethyl acetate (5:1, B), ethyl acetate–methanol (4:1, C), and ethyl acetate–methanol (5:1, D). Spots on the TLC plate were detected with either I_2 vapor or ninhydrin. Biotin-containing peptides gave a pink color upon spraying of *p*-dimethylaminocinnamaldehyde.[13]

L-Methionine, L-lysine, EEDQ, DCC, *N*-hydroxysuccinimide, 25% HBr/AcOH, CbzCl, and *O*-*t*-butyl *S*-4,6-dimethyl-2-pyrimidinyl thiocarbonate were obtained from Protein Research Foundation. Trimethylacetyl chloride was purchased from Aldrich Co. Ltd. *d*-Biotin and other reagents were obtained from Wako Pure Chemical Co.

Boc–Met–Met–OMe (9). *N*-(*t*-Butoxycarbonyl)methionine and Met–OMe were coupled by the EEDQ method.[14] After the usual work-up, a crude product was obtained as a syrup. This was purified by chromatography on silica gel with ethyl acetate as an eluent, followed by recrystallization from ether and petroleum ether. Yield 68%, mp 67—69 °C (lit,[15] 66—67 °C), $[\alpha]_D^{25}$ −30.5° (*c* 3.1, CH_3OH), R_f 0.90 (A). Found: C, 48.34; H, 7.67; N, 7.16%. Calcd for $C_{16}H_{30}N_2O_5S_2$: C, 48.71; H, 7.66; N, 7.10%.

*Met-Met-OMe·HCl (**10**·HCl).* A 2.0 g (5.0 mmol) sample of **9** was dissolved in 10 ml of 10 M HCl in methanol. The mixture was stirred at room temperature for 1 h. The solvent was removed *in vacuo* and then 100 ml of ether was added. After allowing the suspension to stand at −5 °C for 1 d, the supernatant was discarded. The same procedure was repeated twice more. The oily residue was dried *in vacuo* at room temperature to give a very hygroscopic product. Yield 1.3 g (87%). R_f 0.40 (A). Complete removal of the protecting group was confirmed by NMR.

*Boc-Lys(Cbz)-Met-Met-OMe (**11**).* A solution of N^{α}-Boc-N^{ε}-Cbz-Lys[16] (1.0 g, 2.6 mmol), DCC (0.54 g, 2.6 mmol), and HOBt (0.35 g, 2.6 mmol) in 15 ml of DMF was mixed with a solution of **10**·HCl (0.76 g, 2.6 mmol) and NEM (0.30 g, 2.6 mmol) in 15 ml of DMF. The reaction mixture was stirred at room temperature for 8 h and the precipitate formed was filtered off. The filtrate was concentrated *in vacuo* to about 5 ml, and then diluted with 100 ml of ethyl acetate. The solution was washed successively with the following solvents: 4% $NaHCO_3$, saturated NaCl, 10% citric acid, and saturated NaCl. After drying over sodium sulfate at −5 °C (to effect complete precipitation of DCUrea), the solution was concentrated to about 50 ml, and kept overnight in a freezer. The crystalline mass formed was collected by filtration. Yield 1.2 g (71%), mp 105—106 °C, $[\alpha]_D^{25}$ −18.7° (*c* 3.2, CH_2Cl_2), R_f 0.92 (A), 0.88 (B). Found: C, 54.94; H, 7.52; N, 8.60%. Calcd for $C_{30}H_{48}N_4O_8S_2$: C, 54.86; H, 7.37; N, 8.53%.

*Lys(Cbz)-Met-Met-OMe·HCO$_2$H (**12**·HCO$_2$H).* A 1.2 g (1.8 mmol) sample of **11** was dissolved in 10 ml of formic acid and stirred at room temperature. The reaction was complete in 3 h, as inspected by TLC. The mixture was diluted with 100 ml of methanol and the solvents were evaporated *in vacuo*. The product was precipitated by addition of ether. Yield 0.82 g (84%). R_f 0.25 (A). Complete removal of the protecting group was confirmed by NMR.

*Boc-Met-Lys(Cbz)-Met-Met-OMe (**8**).* In 30 ml of DMF were dissolved 5.0 g (92 mmol) of **12**·HCO_2H, 1.1 g (92 mmol) of NEM, 2.3 g (92 mmol) of Boc-Met, 1.9 g (92 mmol) of DCC, and 1.4 g (92 mmol) of HOBt. The mixture was stirred overnight at room temperature. The DCUrea formed was filtered off. After removal of the solvent *in vacuo*, the residue was taken up in 1 L of ethyl acetate. The solution was washed as for **11** and then dried over sodium sulfate. Concentration of the solution to about 300 ml gave precipitates of crude product. They were recrystallized from ethyl acetate. Yield 4.5 g (63%), mp 172—173 °C, $[\alpha]_D^{25}$ −22.7° (*c* 2.6, CH_2Cl_2). R_f 0.61 (B). Found: C, 53.22; H, 7.33; N, 8.84%. Calcd for $C_{35}H_{57}N_5O_9S_3$: C, 53.34; H, 7.29; N, 8.89%.

*Met-Lys(Cbz)-Met-Met-OMe·HCO$_2$H (**13**·HCO$_2$H).* A sample of **8** (4.8 g, 4.2 mmol) was dissolved in 50 ml of formic acid and the solution was stirred for 4 h at room temperature. After addition of 100 ml of methanol, the solvents were evaporated *in vacuo*. The same procedure was repeated twice more. Addition of ether to the syrupy residue gave precipitates of the product (4.2 g, 95%).

*Ac-Met-Lys(Cbz)-Met-Met-OMe (**14**).* To a DMF solution (10 ml) containing 0.90 g (1.2 mmol) of **13**·HCO_2H and 0.14 g (1.2 mmol) of NEM were added slowly 8 ml of acetic anhydride. The whole mixture was stirred for 3 h. The precipitates formed were collected by filtration and washed with ether. Yield 0.82 g (91%), mp 213—214 °C. R_f 0.26 (C), 0.86 (D). $[\alpha]_D^{25}$ −27.5° (*c* 2.0, DMF). Found: C, 52.22; H, 7.07; N, 9.48%. Calcd for $C_{32}H_{51}N_5O_8S_3$: C, 52.65; H, 7.04; N, 9.59%.

*Ac-Met-Lys-Met-Met-OMe·CH$_3$CO$_2$H (**15**·AcOH).* A sample of **14** (1.0 g, 1.4 mmol) was dissolved in 30 ml of 25% HBr/AcOH with 5 ml of dimethyl sulfide. The mixture was stirred for 3 h and then 50 ml of dichloromethane and 400 ml of ether were added. The precipitates formed were filtered off to give 0.85 g (92%) of the product.

*Ac-Met-Bct-Met-Met-OMe (**1**).* **15**·AcOH (0.17 g, 0.26 mmol), TEA (2.6 mg, 0.26 mmol), and biotin *p*-nitrophenyl ester[7,17] in 4 ml of DMF were allowed to react at room temperature for 15 h. The solution was first clear but precipitates gradually formed. They were filtered off and washed with water, methanol, and ether. Yield 60 mg (28%), mp 231 °C (dec). Found: C, 48.84; H, 7.22; N, 11.88%. Calcd for $C_{34}H_{59}N_7O_8S_4\cdot H_2O$: C, 48.61; H, 7.32; N, 11.67%.

*Boc-Met-Lys-Met-Met (**16**).* **8** (1.0 g, 1.3 mmol) was dissolved in 100 ml of liq. ammonia. Sodium was added in small portions until the blue color was retained for 5 min. Ammonium chloride was added until the blue color disappeared. Ammonia was evaporated off and 50 ml of methanol was added to the residue. The suspension was warmed at 40 °C for 30 min. The insoluble material was removed by filtration and evaporation of the filtrate *in vacuo* gave 0.60 g (71%) of the product. Removal of the Cbz and ester groups was confirmed by NMR.

*Boc-Met-Bct-Met-Met (**2**).* To a methanol solution (3 ml) of **16** (0.60 g, 0.92 mmol) and 92 mg (0.92 mmol) of TEA were added 80 mg (2 mmol) of biotin *p*-nitrophenyl ester.[7,17] The mixture was stirred at room temperature for 15 h, whereupon 80 ml of ether was added. The precipitates formed were filtered off and then washed with water. Yield 0.30 g (38%), mp 174—176 °C. R_f 0.45 (C). Found: C, 48.14; H, 7.43; N, 10.92%. Calcd for $C_{36}H_{63}N_7O_9S_4\cdot 2H_2O$: C, 47.92; H, 7.48; N, 10.86%.

*HCO-Met-Lys(Cbz)-Met-Met-OMe (**17**).* To a cold (−10 °C) solution of HCO-Met[18] (0.48 g, 2.7 mmol), pyridine (0.2 ml, 2.7 mmol), and *N*-ethylpiperidine (0.4 ml, 2.7 mmol) in CH_2Cl_2 (10 ml) was added a CH_2Cl_2 solution (2 ml) of trimethylacetyl chloride (0.33 g, 2.7 mmol). The mixture was allowed to react at −10 °C for 20 min, whereupon a CH_2Cl_2 solution of **12**·HCO_2H (1.5 g, 2.7 mmol) and NEM (0.3 g, 2.7 mmol) was added. The whole solution was stirred for 15 min at −10 °C and then for 1 h at room temperature. The solvent was removed *in vacuo* and the solid material left was filtered and washed with 10% citric acid, water, and 5% $NaHCO_3$. Yield 1.8 g (93%), mp 204—205 °C. R_f 0.35 (D). $[\alpha]_D^{26}$ −14.8° (*c* 1, CH_3OH). Found: C, 51.59; H, 6.98; N, 9.69%. Calcd for $C_{31}H_{49}N_5O_8S_3\cdot 0.5H_2O$: C, 51.36; H, 6.95; N, 9.66%.

*HCO-Met-Lys-Met-Met-OMe·HBr (**18**·HBr).* **17** (1.5 g, 2.1 mmol) was dissolved in 10 ml of 25% HBr/AcOH with 0.62 g (10 mmol) of dimethyl sulfide. The mixture was stirred for 3 h and then concentrated *in vacuo*. The residue was purified by reprecipitation from methanol–ether three times. Yield 1.3 g (94%). R_f 0.15 (C). The structure was confirmed by NMR.

*HCO-Met-Bct-Met-Met-OCH$_3$ (**3**).* **18**·HBr (1.3 g, 1.9 mmol), TEA (0.19 g, 1.9 mmol), and biotin *p*-nitrophenyl ester[7,17] (1 g, 2.8 mmol) were dissolved in 4 ml of DMF. Two ml of water were added and the solution was stirred at room temperature for 4 h. The precipitates formed were filtered and washed with water, methanol, and ether. Yield 0.5 g (35%), mp 205—206 °C. R_f 0.04 (D). Found: C, 48.27; H, 7.12; N, 11.85%. Calcd for $C_{32}H_{57}N_7O_8S_4$: C, 48.28; H, 7.22; N, 12.32%.

The authors are indebted to Prof. E. T. Kaiser

of the University of Chicago for the determination of 500 MHz ^{1}H NMR spectra. Thanks are also due to Dr. S. Shinkai for the use of polarimeter. This work was supported by a Grant-in-Aid (No. 521325) for Scientific Research from the Ministry of Education, Science and Culture.

The Biosynthesis of Protoanemonin in *Ranunculus glaber*. The Pivotal Biosynthetic Intermediate and the Stereospecific Hydrogen Elimination from the Intermediate

Takayuki SUGA* and Toshifumi HIRATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received October 22, 1981)

The pivotal biosynthetic intermediate directly leading to protoanemonin was established to be 2-oxoglutarate on the basis of the labeling patterns in protoanemonin biosynthesized from sodium acetate-1-^{14}C, sodium malonate-2-^{14}C, sodium succinate-2,3-$^{14}C_2$, sodium glutamate-5-^{14}C, and sodium 2-oxoglutarate-5-^{14}C by *Ranunculus glaber*. Also the $^{3}H/^{14}C$ ratio in protoanemonin biosynthesized from (3*R*)-2-oxoglutaric-3-$^{3}H_1$-3,4-$^{14}C_2$ and 2-oxoglutaric-3-$^{3}H_2$-3,4-$^{14}C_2$ acids demonstrated that the formation of the double bond at the 3-position of protoanemonin involves the stereospecific elimination of the *pro*-3*S* hydrogen atom from 2-oxoglutaric acid.

It has been well known that many of the plants belonging to Ranunculaceae family show antimicrobial activities and, in some cases, the bruised tissues of the plants cause an intense burn or blister to the skin.[1-5] Such properties of the plants are described to be owing to protoanemonin (**1**), which is probably enzymatically liberated from ranunculin (**2**) by crushing the tissues of the *Ranunculus* plants.[6] It is documented that many C_5 compounds similar to protoanemonin have been found in the form of a glycoside in *Ranunculus* species.[7] Although the biosynthetic pathway of such a simple lactone is of considerable interest, it has not been investigated yet. We have performed feeding experiments of the radioisotopically labeled compounds into protoanemonin (**1**) with the intact plant of *Ranunculus glaber* Makino for clarifying the pivotal biosynthetic intermediate directly leading to the formation of protoanemonin (**1**) and then the stereospecificity in the hydrogen elimination from the intermediate at the stage of the double bond formation in **1**. The findings of the feeding experiments have been partly outlined in preliminary communications.[8-10] We here wish to describe, *en bloc*, details of the results.

Results and Discussion

Biosynthetic Pathway of Protoanemonin (1) in R. glaber. The feeding experiments were carried out on the sprigs of *R. glaber*. The radioisotopically labeled compounds used for the feeding experiments were sodium acetate-1-^{14}C, sodium malonate-2-^{14}C, sodium succinate-2,3-$^{14}C_2$, sodium glutamate-5-^{14}C, and sodium 2-oxoglutarate-5-^{14}C. After the incorporation of the respective precursors, the sprigs were subjected to steam-distillation to give protoanemonin (**1**). Since protoanemonin (**1**) is unstable, it was immediately converted to pentanoic acid by hydrogenation in the presence of PtO_2.[3] All the above-described labeled compounds were incorporated into protoanemonin (**1**) to the extent as shown in Table 1. This indicates that these labeled compounds are of the biosynthetic precursors for protoanemonin (**1**) in a wide sence.

In order to elucidate a pivotal biosynthetic intermediate for protoanemonin (**1**), the labeling pattern in protoanemonin (**1**) biosynthesized from the above-described labeled compounds was determined by subjecting the pentanoic acid derived from the labeled protoanemonin (**1**) to degradation to each carbon atom as follows. The labeled pentanoic acid on Schmidt's reaction[11] gave carbon dioxide and butylamine, which was further converted to butyric acid by potassium permanganate oxidation. Such procedures as described above were repeated in the same manner, but with the acid obtained in the just former procedure. The degradation involving the procedure as above gave carbon dioxide originating from each carbon atom of C-1—C-3 of the pentanoate. On the

a) "Exptl No." correspond to the number in Table 1.

other hand, the oxidative degradation of the radioactive pentanoic acid by the Kuhn-Roth oxidation[12] gave acetic acid involving the C-4 and C-5 carbon atoms of the pentanoic acid. The acetic acid on Schmidt's reaction gave carbon dioxide and methylamine, which was further converted into carbon dioxide by the Van Slyke-Folch oxidation.[13] Carbon dioxide obtained by the degradation as above was converted into barium carbonate for the determination of its radioactivity. The distribution of radioactivity on each carbon atom of **1** is shown in Table 2.

In the administration of sodium acetate-1-^{14}C, about 90 percent of the total radioactivity in protoanemonin (**1**) was located on its C-5 carbon atom.[14] The uptake of sodium malonate-2-^{14}C resulted in the location of about 60 percent of the radioactivity on C-4 of **1**. The malonate-2-^{14}C would biologically yield acetate-2-^{14}C by the action of acetyl-CoA carboxylase. The incorporation of the acetate-2-^{14}C into **1** results in the location of radioactivity on its C-4 carbon atom. Accordingly, the above-described labeling pattern indicates that the C-4 and C-5 carbon atoms of **1** came from the C_2-unit of acetate. However, the incorporation of these precursors resulted in the random distribution of the low radioactivity on the C-1—C-3 carbon atoms of **1**. This random labeling seems to indicate that the C-1—C-3 carbon atoms of **1** arise from a source differing from the acetate. In order to clarify the source, the feeding experiment of sodium succinate-2,3-$^{14}C_2$ was carried out, and 64 percent of the radioactivity was found to be located on the C-2 and C-3 carbon atoms of **1**. This demonstrated clearly that the C-1—C-3 carbon atoms of **1** came from succinic acid. From the results obtained in the uptake of acetate, malonate, and succinate, it was found that these precursors participate in the biosynthesis of protoanemonin (**1**) through the tricarboxylic acid cycle. This finding suggests a possibility that a pivotal intermediate for the biosynthesis of **1** might be 2-oxoglutarate.

This possibility was proved by the preferential location of almost all the radioactivity on the C-5 carbon atom in **1** biosynthesized by incorporation of 2-oxoglutarate-5-^{14}C for a 1-d period. In the incorporation of this precursor for a 2-d period, the location of radioactivity on C-5 resulted in 76 percent, and 19 percent of the radioactivity was newly located on C-1 of **1**; this suggests occurrence of the randomization of the ^{14}C-label from C-5 of 2-oxoglutarate to its C-1 by turn around of the tricaboxylic acid cycle. These facts indicate that the pivotal intermeidate for the biosynthesis of **1** is 2-oxoglutarate (**3a**). This was supported by the fact that the distribution of radioactivity in **1** biosynthesized from glutamate-5-^{14}C is similar to that observed in the uptake of 2-oxoglutarate-5-^{14}C during a 2-d period, since the interconversion of the glutamate and 2-oxoglutarate is of wide occurrence in a biological system. Thus, it was established that the pivotal intermediate for the biosynthesis of protoanemonin (**1**) is 2-oxoglutarate (**3a**). We will here propose that the biological formation of protoanemonin (**1**) from the 2-oxoglutarate (**3a**) may involve the lactonization between the 5-carboxyl and the 2-carbonyl groups of **3a** as well as the hydrogen elimination from **3a** for the formation of the C–C double bond.

Stereospecific Hydrogen-loss of 2-Oxoglutarate in the Biosynthesis of Protoanemonin (1). The hydrogen elimination in the formation of double bond at the 3-position of protoanemonin (**1**) was, therefore, investigated by examining the $^3H/^{14}C$ ratio in **1** biosynthesized from the $^3H/^{14}C$-labeled 2-oxoglutarate. 2-Oxoglutaric-3-$^3H_2$ acid (**3b**) was prepared by exchanging the hydrogen atoms at the 3-position of sodium 2-oxoglutarate by treatment with tritiated water.[15] (3*R*)-2-Oxoglutaric-3-$^3H_1$ acid (**3c**) was prepared by incubation of the tritiated 2-oxoglutaric acid (**3b**) with isocitrate dehydrogenase.[16] 2-Oxoglutaric-3,4-$^{14}C_2$ acid (**3d**) was prepared by condensation of dimethyl succinate-2,3-$^{14}C_2$ with diethyl oxalate.[17] The (3*R*)-2-oxoglutaric-3-$^3H_1$-3,4-$^{14}C_2$ and 2-oxoglutaric-3-$^3H_2$-3,4-$^{14}C_2$ acids, (**3e** and **3f**), were prepared by mixing the above-described singly labeled 2-oxoglutaric acids.

Table 3 shows the incorporations of the doubly labeled precursors into protoanemonin (**1**). The $^3H/^{14}C$ ratios in protoanemonin (**1**) thus biosynthesized are shown in Table 4. The $^3H/^{14}C$ ratio in **1** biosynthesized from 2-oxoglutaric-3-$^3H_2$-3,4-$^{14}C_2$ acid (**3f**) resulted in a half of the $^3H/^{14}C$ ratio in **3f**, whereas the $^3H/^{14}C$ ratio in **1** was retained in the feeding of

TABLE 3. THE INCORPORATION OF (3*R*)-2-OXOGLUTARIC-3,4-$^{14}C_2$ ACID (**3e**) AND 2-OXOGLUTARIC-3-$^{3}H_2$-3,4-$^{14}C_2$ ACID (**3f**) INTO PROTOANEMONIN (**1**) BY *R. glaber*

Exptl No.	Precursors	Radioactivities of precursors used[b] μCi	Feeding time[c] h	Sp. act. of **1**[a,b] (dpm/mmol)×10^{-2}	Incorp.[d] %

11	**3e**	0.015	12	1.83±0.12	0.47
12	**3f**	0.066	12	2.32±0.18	0.52
13	**3f**	0.059	12	2.76±0.18	0.73

a) The specific radioactivity of **1** was determined on the basis of the radioactivity of pentanoic acid obtained from **1** by its hydrogenation. b) The radioactivity of the doubly labeled compounds refers to only ^{14}C. c) Metabolic period after uptake of the precursors. d) The incorporation is calculated with respect to only ^{14}C.

TABLE 4. THE $^{3}H/^{14}C$ RATIOS IN PROTOANEMONIN (**1**) AFTER UPTAKE OF (3*R*)-2-OXOGLUTARIC-3-$^{3}H_1$-3,4-$^{14}C_2$ ACID (**3e**) AND 2-OXOGLUTARIC-3-$^{3}H_2$-3,4-$^{14}C_2$ ACID (**3f**)

Exptl No.[a]	Precursors			Protoanemonin (**1**)	
	The acids	$^{3}H/^{14}C$ Ratio	$^{3}H:^{14}C$ (Normalized)[b]	$^{3}H/^{14}C$ Ratio	$^{3}H:^{14}C$ (Normalized)[c]
10	**3e**	1.96±0.01	1:1	1.89±0.07	0.96:1
11	**3e**	6.21±0.31	1:1	6.01±0.66	0.97:1
12	**3f**	13.9 ±0.22	2:1	6.18±0.51	0.89:1
13	**3f**	12.8 ±0.98	2:1	6.56±0.45	1.03:1

a) "Exptl No." corresponds to the numbers in Table 3. b) This is the normalized ratio as related to the number of ^{3}H-label at C-3 of 2-oxoglutaric acid. c) The normalized $^{3}H:^{14}C$ ratio was obtained by dividing the $^{3}H/^{14}C$ ratio of **1** by the $^{3}H/^{14}C$ ratio of 2-oxoglutaric acid and multiplying the answer by the number of ^{3}H-label at C-3 of the acid.

(3*R*)-2-oxoglutaric-3-$^{3}H_1$-3,4-$^{14}C_2$ acid (**3e**). These results demonstrate clearly that (i) the formation of double bond at the 3-position of protoanemonin (**1**) results from the elimination of the hydrogen atom at the 3-position of 2-oxoglutaric acid and (ii) the hydrogen elimination involves the stereospecific loss of the *pro*-3*S* hydrogen atom (R_S) and the retention of the *pro*-3*R* hydrogen atom (R_R) of 2-oxoglutaric acid (**3a**).

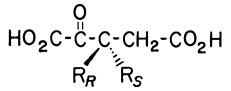
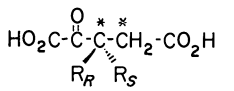
2



3a: R_R=R_S=H
3b: R_R=R_S=^{3}H
3c: R_R=^{3}H, R_S=H



3d: R_R=R_S=H
3e: R_R=^{3}H, R_S=H
3f: R_R=R_S=^{3}H

Experimental

All the radioisotopically labeled compounds derived from radioactive protoanemonin (**1**) were purified to a constant specific radioactivity by a combination of preparative TLC with silica-gel plates (Kieselgel GF_{254}; 0.75 mm thick) and/or repeated recrystallization. All the compounds showed ^{1}H NMR and IR spectra identical with those of authentic samples. The radioactivity was counted on a liquid-scintillation spectrometer using Bray's scintillation solvent[18] and/or a 2π-gas flow low-back counter on $BaCO_3$ planchets at an infinite thickness.

Plant Material and Labeled Precursors. The sprigs of *Ranunculus glaber* Makino were collected in May at the damp ground in the suburbs of Hiroshima City. Each sprig used for the feeding experiments was about 20 cm in length and about 15 g in fresh wt. The singly labeled precursors, such as sodium 2-oxoglutarate-5-^{14}C (13 mCi/mmol), sodium acetate-1-^{14}C (23 mCi/mmol), sodium malonate-2-^{14}C (15 mCi/mmol), sodium succinate-2,3-$^{14}C_2$ (33 mCi/mmol), and sodium glutamate-5-^{14}C (68 mCi/mmol), were the products of the Daiichi Pure Chemicals Co., Ltd, Tokyo and used for the feeding experiments without purification. The doubly labeled precursors were prepard as described below.

Feeding of the Labeled Precursors to R. glaber. The labeled precursor (Tables 1 and 3) dissolved in a phosphate-buffered soln (2.0 cm^3; pH 7.0—7.4) was fed to the fresh-collected sprigs (*ca.* 70 g in total wt) through their cut-stem in a glass tube, and then the phosphate-buffered soln was soaked into the sprigs several times to force the uptake of the labeled precursor to completion. At the end of the metabolic periods shown in Tables 1 and 3, the sprigs were subjected to the following procedure to isolate the radioisotopically labeled protoanemonin (**1**).

*Isolation of the Radioisotopically Labeled Protoanemonin (**1**).* The sprigs (*ca.* 70 g) were steam-distilled. The distillate was extracted with five 50-cm^3 portions of ether. The removal of the solvent from the ether soln at temp below 25 °C under a reduced pressure in a current of nitrogen gave protoanemonin (**1**) (*ca.* 100 mg), which was then, without purification, converted into pentanoic acid [95 mg; IR (liq) 3300—2500 and 1710 cm^{-1} (COOH)] by hydrogenation in MeOH (10 cm^3) in the presence of Adam's

platinum oxide (5 mg).[3] A portion (20 mg) of the sample of pentanoic acid was treated with *p*-bromophenacyl bromide to give the *p*-bromophenacyl derivative (45 mg): mp 65—67 °C; IR (KBr) 1740 cm^{-1} (ester); ^1H NMR (60 MHz, CCl_4) δ=1.03 (3H, t, Me), 1.59 (4H, bs, $-CH_2-CH_2-$), 2.52 (2H, t, $-CO-CH_2-$), 5.33 (2H, s, $-CH_2-O-$), and 7.80 (4H, m, arom. H); MS (70 eV), *m/z* (rel intensity), 300 and 298 (6%, M^+), 185 and 183 (100), 85 (42), 57 (36), and 28 (51). Found: C, 51.98; H, 4.89%. Calcd for $C_{13}H_{15}O_3Br$: C, 52.19; H, 5.05%. The specific radioactivities of **1** were determined by measuring the specific radioactivities of the *p*-bromophenacyl derivatives; they are shown in Tables 1 and 3.

Labeling Pattern of Radioactive Pentanoic Acid. After radioactive pentanoic acid (50 mg) resulted from **1** as described above was diluted 10 times with the carrier, the pentanoic acid was converted into its silver salt (800 mg) by adding a 5% $AgNO_3$ soln to it. The silver pentanoate (200 mg) on the Schmidt reaction[11] yielded carbon dioxide and butylamine (62 mg). Carbon dioxide was absorbed in a $Ba(OH)_2$ soln and converted into $BaCO_3$ (88 mg). Butylamine (60 mg) was oxidized with a 5% $KMnO_4$ soln for 30 min at 100 °C, and the reaction mixture, after the decomposition of the remaining oxidant with sodium hydrogensulfite, was extracted with Et_2O by a continuous liquid-liquid extractor. The removal of the solvent from the ethereal soln gave butyric acid, which was then converted to the silver salt (92 mg). The oxidative degradation of this silver butyrate (80 mg) by the Schmidt reaction was repeated as described above, giving $BaCO_3$ (86 mg) and propionic acid (57 mg as the silver salt). Silver propionate (50 mg) was again subjected to the degradation in the same manner as above to give $BaCO_3$ (36 mg) and silver acetate (11 mg). On the other hand, the radioactive silver pentanoate (100 mg) on the Kuhn-Roth oxidation[12] afforded sodium acetate (17 mg). This acetate was then subjected to the Schmidt reaction[11] to give carbon dioxide and methylamine, which were then converted into $BaCO_3$ (21 mg) and methylamine hydrochloride (4 mg), respectively. This methylamine hydrochloride was then further converted into $BaCO_3$ (12 mg) by the Van Slyke-Folch oxidation.[13]

The distribution of radioactivity in each carbon atom originating from **1** was determined on the basis of the radioactivities of $BaCO_3$ obtained by the Schmidt reaction and the Kuhn-Roth oxidation; they are shown in Table 2.

Preparation of 2-Oxoglutaric-3-$^3H_2$ *Acid (3b).* On reference to the method described in the literature,[15] sodium 2-oxoglutarate (50 mg) dissolved in tritiated water (0.16 cm^3; 160 μCi) was heated at 120 °C for 30 min in a sealed glass tube. The reaction mixture was put on an Amberlite IR-45 column. After the column was washed thoroughly with H_2O to remove the tritiated water, elution of the column with 0.3% HCl (50 cm^3) gave 2-oxogutaric-3-$^3H_2$ acid (**3b**) (31 mg; 12.5 μCi) as an eluate.

Preparation of (3R)-2-Oxoglutaric-3-$^3H_1$ *Acid (3c).* Following the method described in the literature,[15,16] the tritiated 2-oxoglutaric acid (**3b**) (7.5 mg; 3.0 μCi) was incubated with isocitrate dehydrogense (50 units; Sigma Chemical Company) in the presence of NADPH (25 mg) and $MgCl_2$ (3.6 mg) in a triethanolamine hydrochloride buffered soln (50 cm^3; pH 7.1) at 30 °C for 6 h. The reaction mixture was subjected to column chromatography using Amberlite IR-45 as an ion exchange resin and 0.3% HCl as an eluent to afford (3*R*)-2-oxoglutaric-3-$^3H_1$ acid (**3c**) (5.9 mg; 1.1 μCi).

Preparation of 2-Oxoglutaric-3,4-^{14}C *Acid (3d).* On reference to the method described in the literature,[17] dimethyl succinate-2,3-$^{14}C_2$ (0.26 mg; 50 μCi) was added to a suspension of diethyl oxalate (2.0 mg) and potassium ethoxide [potassium (10 mg) in EtOH (0.1 cm^3)] in Et_2O (1.0 cm^3) with stirring at room temp. After 10 min, a precipitated yellow mass (5.1 mg) was filtered and dissolved in concd HCl. The soln obtained was extracted with Et_2O to give an oily product (2.3 mg), which was then refluxed with concd HCl (1 cm^3) for 1 h. The mixture was left to stand at room temp for 12 h and then extracted with Et_2O to give a crude sample of 2-oxoglutaric-3,4-$^{14}C_2$ acid (**3d**). Purification of this crude sample by preparative TLC (cellulose; 0.5 mm thick) with *n*-BuOH–$CHCl_3$ (1:19, v/v) and then *n*-BuOH–AcOH–H_2O (12:3:5, v/v/v) afforded the pure sample of 2-oxoglutaric-3,4-$^{14}C_2$ acid (**3d**) (3.0 μCi).

The authors wish to thank Misses Yoko Okamoto, Tomoko Horikawa, Noriko Waki, and Emiko Okamoto and Mr. Makio Kataoka, who assisted them in a part of the experimental work.

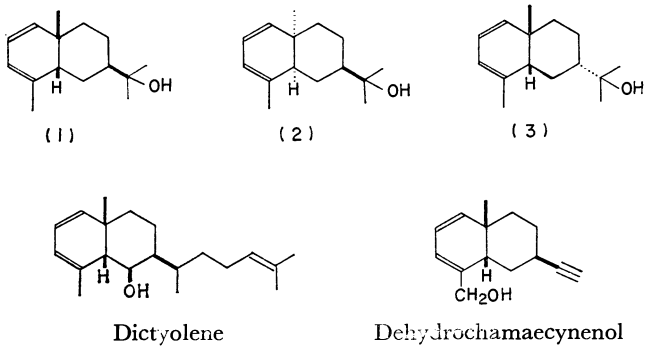
(Received October 23, 1981)

The total syntheses of (−)-occidentalol and its C_7-epimer are reported with the object of establishing the structure of naturally occurring (+)-occidentalol.

The sesquiterpene alcohol (+)-occidentalol was first isolated from the wood of Eastern white cedar (*Thuja occidentalis* L.) by Nakatsuka and Hirose.[3] Subsequent reports from various laboratories lead to the acceptance of the structure **1**.[4–7] In 1969, Hortmann and De Roos reported a careful analysis of 100 MHz NMR spectrum of (+)-occidentalol and suggested the structure **2** for (+)-occidentalol.[8] In 1970, we established the structure **2** for (+)-occidentalol by the syntheses of compound **1** and (−)-occidentalol (**3**).[2] After our syntheses had been completed, several other syntheses of (+) or (±)-occidentalol were reported.[9–14] Recent isolation and characterization of dehydrochamaecynenol[15] and dictyolene,[16] which possess similar structures to compound **1**, is interesting matter from the biosynthetic point of view. This paper details the total syntheses of **1** and (−)-occidentalol (**3**) with the object of establishing the structure of naturally occurring (+)-occidentalol and the stereochemical consideration of their related compounds.

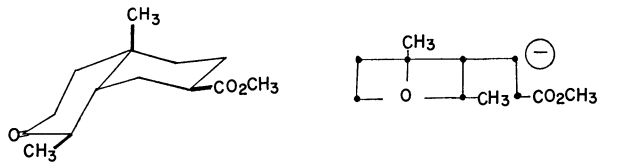


Dictyolene Dehydrochamaecynenol

Syntheses

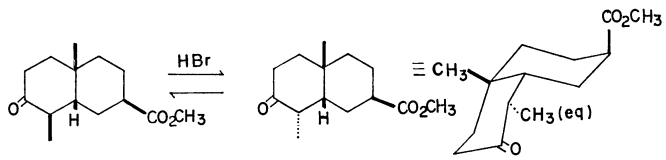
We chose an olefinic ketone (**4**) as the starting material since **4** was easily available from l-α-santonin by means of the previously reported method[17] and conveniently functionalized as the starting material of both **1** and **3**. We envisioned an approach which consisted of the transformation of the terminal olefine at C_7 of **4** to a methoxycarbonyl group (**4**→**7**), the introduction of a homoannular 1,3-diene unit (**7**→**14**), and its transformation to **1**, or the epimerization of the methoxycarbonyl group from β to α (**14**→**17**), and its transformation to **3**.

The treatment of **4** with four equivalent of $NaIO_4$ in the presence of a catalytic amount of OsO_4 gave



7 Steroid conformation $[\theta]_{270} = -1980$

Fig. 1.



7 **18** Non-steroid conformation

Fig. 2.

a 1:1 mixture of a carboxylic acid (**6**) and an aldehyde (**5**). The latter was oxidized with Ag_2O to **6**. The compound (**6**) was methylated with CH_2N_2 to give the ester (**7**). In agreement with the structure of a *cis*-decalin derivative possessing the steroid conformation, the CD curve exhibited a negative Cotton effect.[18]

The bromination of **7** with Br_2 in acetic acid in the presence of HBr afforded two kinds of oily monobromides (**8** and **9**). The splitting patterns of the NMR signals due to the bromomethine protons, δ 4.72 (q, J=6.0 and 14.0 Hz) and δ 4.73 (q, J=6.0 and 12.0 Hz) for **8** and **9** respectively, indicated that both **8** and **9** were α-bromo ketones bearing the equatorial bromine atoms. Judging from the reaction conditions, both C_4–Me groups of **8** and **9** were deduced to be thermodynamically the more stable equatorial configuration. In addition, the β(*eq*)-configuration of the C_4–Me group of **8** and the α(*eq*)-configuration of the C_4–Me group of **9** were confirmed by the transformation of these compounds to the α,β-unsaturated ketones, **10** and **11**, respectively. The formation of the bromides **8** and **9** starting from **7** can be reasonably explained as follows. The ketone **7** was epimerized at C_4 in the presence of HBr to give an equilibrium mixture of **7** and its C_4-epimer, **18**. The bromination of **7** and **18** in the reaction mixture at the C_2-position gave **8** and **9**, respectively.

The dehydrobromination of **8** with LiBr–Li_2CO_3 in DMF produced an oily α,β-unsaturated ketone (**10**). In accordance with the stereo-structure **10** with the steroid conformation, as is shown in Fig. 3, the NMR spectrum (CCl_4, 100 MHz) did not show a long-range coupling between C_1–H and C–H.[19,20] The half-

Fig. 4.

band width of C_7–H was *ca.* 20 Hz, which agreed with the expected value of $\alpha(ax)$ C_7–H.[19] The β-equatorial configuration of the C_4–Me group of **10** was suggested from the solvent effect in the NMR spectrum on passing from CCl_4 to benzene ($\delta_{CCl_4}-\delta_{C_6H_6}=+0.01$ ppm)[21] and was confirmed from the coupling constant between C_4–H and C_5–H ($J=12.5$ Hz). The CD curve of **10** showed a negative Cotton effect at 320 nm for the $n\rightarrow\pi^*$ transition and a positive Cotton effect at 225 nm for the $\pi\rightarrow\pi^*$ transition[22] which agreed with the signs expected from the stereo-structure **10** with the steroid conformation bearing a $\beta(eq)$-methyl group at C_4 and a $\beta(eq)$-methoxycarbonyl group at C_7.

The dehydrobromination of **9** with LiBr–Li_2CO_3 in DMF gave an oily α,β-unsaturated ketone (**11**). In agreement with the stereo-structure **11**, as is shown in Fig. 4, the NMR (CCl_4, 100 MHz) spectrum showed a long-range coupling ($J=2.5$ Hz) between C_1–H and C_5–H.[19,20] The half-band width of C_7–H was *ca.* 10 Hz which agreed with the expected value of $\alpha(eq)$ C_7–H.[19] The α-equatorial configuration of the C_4–Me group of **11** was suggested from the solvent effect in the NMR spectrum on passing from CCl_4 to benzene ($\delta_{CCl_4}-\delta_{C_6H_6}=-0.09$ ppm)[21] and was confirmed from the coupling constant between C_4–H and C_5–H ($J=3.8$ Hz). The CD curve of **11** showed a positive Cotton effect at 310 nm for $n\rightarrow\pi^*$ transition and a negative Cotton effect at 225 nm for $\pi\rightarrow\pi^*$ transition[22] which agreed with the signs expected from the stereo-structure **11** with the non-steroid conformation bearing an $\alpha(eq)$-methyl group at C_4 and a $\beta(ax)$-methoxycarbonyl group at C_7.

The reduction of **10** and **11** with $NaBH_4$ gave an oily mixture of epimeric alcohols (**12**) and of epimeric alcohols (**13**), respectively. On being heated at 210 °C in the presence of alumina containing 4% of pyridine,[23] both mixtures of alcohols gave the same oily diene (**14**). The diene (**14**) was conveniently prepared from **7** by the same method described above, without the

separation of the epimers in each step. The non-steroid conformation bearing the $\beta(ax)$-methoxycarbonyl group at C_7 for **14**, as is shown in Fig. 5, was revealed from the NMR spectrum which showed the long-range coupling between C_1–H and C_5–H ($J=1.0$ Hz)[8,19,20] and a rather small magnitude of the half-band width ($W_{h/2}=11$ Hz) of C_7–H.[19] The CD curve of **14** showed a negative Cotton effect at 259 nm due to the skewing of the *s-cis* butadiene moiety in the sense of a left-hand helix[24] which agreed with

Table 1. The NMR spectral data of *s-cis* diene derivatives

Non-Steroid conformation

Fig. 7.

the stereo-structure **14** with the non-steroid conformation bearing a β(*ax*)-methoxycarbonyl group at C_7.

The treatment of **14** with methylmagnesium bromide gave an unstable oily alcohol (**1**), which exhibited completely different IR (in $CHCl_3$), NMR (in CCl_4), CD (in MeOH), and MS (at 70 eV) from those of naturally occurring occidentalol. In accordance with the stereo-structure **1** with the steroid conformation, as is shown in Fig. 6, the CD curve of **1** showed a positive Cotton effect due to the skewing of *s-cis* butadiene moiety in the sense of right-hand helix.[24]

Since the structure **1**, the Rudloff's structure of (+)-occidentalol, was not identical with naturally occurring "(+)-occidentalol", our attention was focused on the synthesis of **3**, the C_7-epimer of **1**.

The treatment of **14** with 1 M (1 M=1 mol dm^{-3}) *t*-BuOK in *t*-BuOH under refluxing temperature for 2 h gave a mixture of a carboxylic acid (**15**) and the corresponding *t*-butyl ester (**16**). The hydrolysis of the latter with aqueous alkali and the combined acidic part was methylated subsequently with diazomethane to give a 1:22 mixture of **14** and **17**. The NMR spectrum of **17** was quite similar to that of **14** except the signal of C_7-H which was shifted to higher field than the corresponding signal of **14** and was overlapped with those of other protons. These NMR data

Steroid conformation Non-steroid conformation

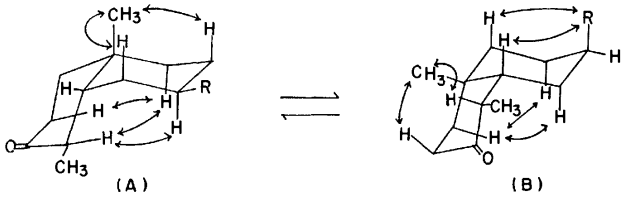

Fig. 8.

Table 2. Equilibration data for the **A**⇌**B** reaction at 25 °C

R	K (**B**/**A**)	ΔG/kcal mol^{-1}
-C≡CH	1.58	−0.27[17]
$-CO_2CH_3$	0.45	0.46
$-CH=CH_2$	0.16	1.09[17]
$-CH_2-CH_3$	(0)	[17]

strongly suggest that compounds **14** and **17** are stereoisomeric at C_7 position with each other and have the same non-steroid conformation. The CD curve of **17** showed a negative Cotton effect at 262 nm due to the skewing of the *s-cis* butadiene moiety in the sense of a left-hand helix[24] which agreed with the conclusion from the NMR data.

The treatment of **17** with methylmagnesium bromide gave an alcohol (**3**), which was identical with naturally occurring (+)-occidentalol in the NMR, IR, and MS but showed the opposite sign in the CD curves. These results indicate that the structure of naturally occurring "(+)-occidentalol" must be represented by the structure (**2**) and the alcohol (**3**) is its antipodal (−)-occidentalol (**3**).

The Stereochemical Studies of the Synthetic Intermediates

Equilibration of 7⇌18 and 10⇌11. The keto ester (**7**) was treated with a 2% KOH solution of ethanol for 6 h at 25 °C and then quenched by the use of aqueous acetic acid solution to give a 2.2:1.0 equilibrium mixture of **7** and **18**. The ΔG value of this equilibration at 25 °C was determined to be 0.46 kcal mol^{-1}. This ΔG value was compared with those of three pairs of *cis*-decalone derivatives possessing the different functional groups at C_7-position and summarized in Table 2. The examination of Dreiding models showed that the observed ΔG values

Steroid conformation Non-steroid conformation

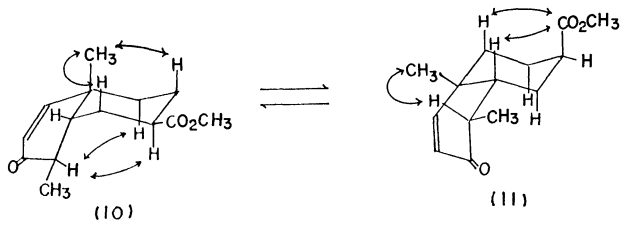

Fig. 9.

Steroid conformation Non-steroid conformation

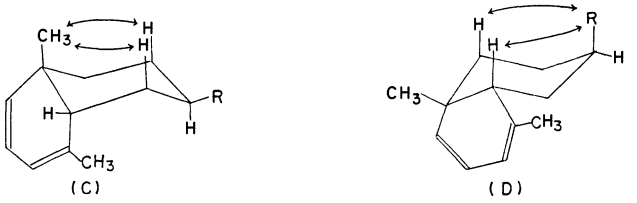

Fig. 10.

should reflect the difference between the one inner H–H interaction in the A-series compounds and the two R–H 1,3-diaxial interactions in the B-series compounds since two Me–H 1,3-diaxial interactions and two inner H–H interactions existed in both series compounds, as depicted in the stereo-structures **A** and **B**. Actually, the observed ΔG values, summarized in Table 2, reflect well the order of the bulkiness of R at C_7, $-CH_2CH_3 \gg -CH{=}CH_2 > -CO_2Me > -C{\equiv}CH$. The equilibrium reaction of α,β-unsaturated ketones **10** and **11** gave a tendency similar to that of the equilibrium reaction of **7** and **18**. The ΔG value is 0.37 kcal mol^{-1}, smaller than the latter case, because in **11** one Me–H interaction and two inner H–H interactions are eliminated compared with **18** by the introduction of a double bond at C_1, whereas in **10** one inner H–H interaction is eliminated compared with **7**.

The Stereochemistry of s-cis *Diene Derivatives.* For *s-cis* diene derivatives (**1**, **14**, and **19**) bearing a β-oriented substituent at C_7 there are two possible conformations, steroid conformation (**C**) and non-steroid conformation (**D**). The examination of Dreiding models showed there to be two Me–H 1,3-diaxial interactions in the conformer (**C**) as depicted by the arrows. On the other hand, in the conformer (**D**) there are two R–H 1,3-diaxial interactions as depicted by the arrows. Since the R–H 1,3-diaxial interaction is far bigger than that of Me–H in the case of R=–C-$(CH_3)_2OH$, the compound (**1**) exists exclusively in the steroid conformation (**C**).

When R is methoxycarbonyl or isopropoxycarbonyl group, the non-steroid conformation **D** may be expected to be the favored conformer by the following reasons. The methoxycarbonyl and isopropoxycarbonyl groups are planar and the magnitudes of the 1,3-diaxial interactions of these groups at C_7 and the two hydrogen atoms at C_5 and C_9 in the conformer **D** are smaller than those of the angular methyl group and two hydrogen atoms at C_6 and C_8 in the conformer (**C**). Actually **14** and the corresponding isopropyl ester (**19**)[25] exist exclusively in the non-steroid conformation (**D**).

Steroid conformation Non-steroid conformation

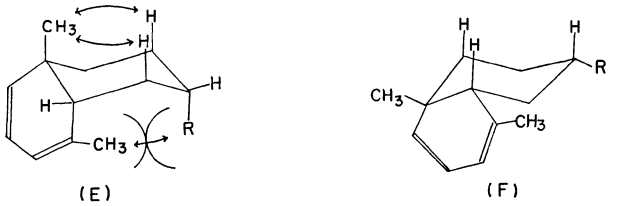

Fig. 11.

For *s-cis* diene derivatives (**3**, **16**, and **17**) bearing an α-oriented substituent at C_7 there are two possible conformations, the steroid conformation (**E**) and the non-steroid conformation (**F**). In the conformer **E** there is a big interaction between the axial substituent at C_7 and the A-ring in addition to two Me–H 1,3-diaxial interactions as depicted by the arrows, whereas there is no remarkable interaction in the conformer **F**. Actually all of the compounds **3**, **16**, and **17** exist exclusively in the non-steroid conformation (**F**).

Experimental

All the melting points are uncorrected. The IR spectra were recorded on Shimadzu IR-27 spectrophotometers. The NMR spectra were recorded on Varian A-60, Nichiden-Varian T-60, and Varian HA-100 spectrometers, employing tetramethylsilane as the internal reference. The CD spectra were recorded on a Nihonbunko ORD/UV-5 spectrometer. Mass spectra were recorded on a Hitachi RMu-6D spectrometer with a direct inlet system operating at 70 eV.

*Methyl 3-Oxo-4α*H*,5β-12,13-bisnoreudesman-11-oate (7).* A mixture of *4α*H*,5β*-13-noreudesm-11-en-3-one (**4**, 2.90 g, 14.1 mmol), $NaIO_4$ (12.1 g, 56.6 mmol), and OsO_4 (13.3 mg, 0.05 mmol) in 50 ml of dioxane–H_2O (4:1) was stirred for 2 h at room temperature and filtered. The filtrate was poured into a saturated aq soln of NaCl (200 ml) and extracted with ether (100 ml×3). The combined extracts were washed successively with a 2 M aq soln of Na_2CO_3 (20 ml×3), and a saturated aq soln of NaCl, dried and concentrated to give an oily neutral product (1.94 g). The combined washings of Na_2CO_3 were acidified with 6 M HCl and extracted with ether (50 ml×3). The combined extracts were washed with a saturated soln of NaCl, dried ($MgSO_4$), and concentrated to give 745 mg of an oily acidic product. The neutral part was stirred with Ag_2O, which was freshly prepared from 17 g of $AgNO_3$, in 50 ml of THF–H_2O (4:1) for 70 h at room temperature to give further 785 mg of acidic part. The combined acidic product (1.52 g) was methylated with 12 ml of CH_2N_2–ether soln (0.6 mmol/ml) to give 1.62 g of crude methyl ester, which was chromatographed over silica gel (Merck, finer than 230 mesh, 80 g) and eluted with CCl_4–$CHCl_3$ (1:1) to give 804 mg (24%) of spectroscopically pure **7**. This was recrystallized from pentane to give colorless prisms; mp 71 °C. IR (KBr): 1730 and 1698 cm^{-1}. NMR (CCl_4): δ 0.97 (3H, d, J=6.5 Hz, C_4–Me), 1.07 (3H, s, C_{10}–Me), and 3.61 (3H, s, –OMe) ppm. CD (MeOH): $[\theta]_{270} = -1980$. Found: C, 70.54; H, 9.26%. Calcd for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31%.

Methyl 5β-12,13-Bisnoreudesma-1,3-dien-11-oate (14) from **7** *without Separation of Stereoisomers in Each Step.* Into a solution of **7** (1.645 g, 6.90 mmol) and HBr (0.1 ml) in AcOH

(15 ml) was added a solution of Br_2 (1.20 g, 7.5 mmol) in AcOH (5 ml). The mixture was stirred for 30 min at room temperature, poured into a saturated aq soln of NaCl (200 ml) and extracted with ether (50 ml×3). The combined extracts were washed successively with a saturated aq soln of Na_2CO_3 and a saturated aq soln of NaCl dried ($MgSO_4$), and concentrated to give 2.26 g of the crude bromides as the epimeric mixture of C_2 and C_4, which was employed in the following reaction without any purification.

A mixture of the crude bromides (2.26 g), dry DMF (30 ml), LiBr (2.36 g, 27.2 mmol), and Li_2CO_3 (2.36 g, 31.9 mmol) was heated at 153 °C under stirring for 8 h. The mixture was poured into a saturated aq soln of NaCl (200 ml) and extracted with ether (50 ml×3). The combined extracts were washed successively with a 2 M aq soln of HCl (30 ml) and a saturated aq soln of NaCl, dried and concentrated to give a mixture of **10** and **11** (2:1, 863 mg), which was employed in the next step without any purification.

The mixture of **10** and **11** (863 mg) was reduced with $NaBH_4$ (140 mg, 3.70 mmol) in ether–MeOH (2:1, 27 ml) and treated in the usual way to give a mixture of allylic alcohols as a epimeric mixture at C_3 and C_4, which was employed without any purification in the next step.

The resultant allylic alcohols were passed through the column packed with basic alumina†† (2.6 g), which was preheated at 220 °C, with the flow of nitrogen. The product was trapped in a flask cooled with Dry Ice–acetone bath to give spectroscopically pure **14** (264 mg, 17.4% overall yield from **7**) as an oily material, which was chromatographed over silica gel (Merck, finer than 230 mesh) and eluted with $CHCl_3$–CCl_4 (1:1) to give the analytical sample as an oil. IR (neat): 1730 and 1645 cm^{-1}. NMR (CCl_4): δ 0.86 (3H, s, C_{10}–Me), 1.80 (3H, broad s, C_4–Me), 2.49 (1H, m, $W_{h/2}$=11.0 Hz, C_7–H), 3.64 (3H, s, –OMe), 5.22 (1H, ddd, $J_{1,3}$=1.0 Hz, $J_{1,5}$=1.0 Hz, and $J_{1,2}$=9.5 Hz, C_1–H), 5.52 (1H, dqd, $J_{1,3}$=1.0 Hz, $J_{3,14}$=1.8 Hz, and $J_{2,3}$=5.0 Hz, C_3–H), and 5.76 (1H, dd, $J_{2,3}$=5.0 Hz and $J_{1,2}$=9.5 Hz, C_2–H) ppm. CD (MeOH): $[\theta]_{259}=-33800$. MS (70 eV) *m/e* (rel intensity): 220 (19, M^+), 173 (15), 160 (24), 145 (100), 119 (35), 105 (23), 91 (20). Found: C, 76.12; H, 9.27%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

Methyl 2β-Bromo-3-oxo-4αH,5β-12,13-bisnoreudesman-11-oate (8) and Methyl 2α-Bromo-3-oxo-4βH,5β-12,13-bisnoreudesman-11-oate (9). A mixture of the crude bromide (253 mg) which was prepared from **7** was chromatographed over silica gel (Merck, finer than 230 mesh) and eluted with CCl_4–$CHCl_3$ (2:1) to give 19 mg of spectroscopically pure **9** from the first fraction and 42 mg of spectroscopically pure **8** from the last fraction. NMR (CCl_4) of **8**: δ 1.05 (3H, d, J=6.5 Hz, C_4–Me), 1.10 (3H, s, C_{10}–Me), 3.58 (3H, s, –OMe), and 4.72 (1H, q, J=6.0 and 14.0 Hz, C_2–H) ppm. NMR (CCl_4) of **9**: δ 1.03 (3H, d, J=6.5 Hz, C_4–Me), 1.33 (3H, s, C_{10}–Me), 3.61 (3H, s, –OMe), and 4.73 (1H, q, J=6.0 and 12.0 Hz) ppm.

Methyl 3-Oxo-4αH,5β-12,13-bisnoreudesm-1-en-11-oate (10) and Methyl 3-Oxo-4βH,5β-12,13-bisnoreudesm-1-en-11-oate (11). The crude mixture of α,β-unsaturated ketones (**10** and **11**, 572 mg) which was prepared by the previously mentioned method was chromatographed over silica gel (60 g, Merck, finer than 230 mesh) and eluted with CCl_4–$CHCl_3$ (1:1). The first fraction gave **11** (85 mg). IR (neat): 1732 and 1680 cm^{-1}. NMR (CCl_4): δ 1.05 (3H, d, J=7.0 Hz, C_4–Me), 1.24 (3H, s, C_{10}–Me), 2.63 (1H, m, $W_{h/2}$=*ca.* 10 Hz, C_7–H), 2.88 (1H, dq, J=3.8 and 7.0 Hz, C_4–H), 3.65 (3H, s, –OMe), 5.79 (1H, d, J=10.0 Hz, C_2–H), and 6.34 (1H, dd, J=2.5 and 10.0 Hz, C_1–H) ppm. NMR (C_6H_6): δ 0.88 (3H, s, C_{10}–Me) and 1.14 (3H, d, J=7.0 Hz, C_4–Me). CD (MeOH): $[\theta]_{225}=-12600$, $[\theta]_{310}=+1200$. MS (70 eV) *m/e* (rel intensity): 236 (91, M^+), 221 (21), 189 (32), 177 (34), and 161 (100). The second fraction gave a mixture of **10** and **11**. The third fraction gave **10** (120 mg). IR (neat): 1736 and 1680 cm^{-1}. NMR (CCl_4): δ 1.10 (3H, d, J=6.5 Hz, C_4–Me), 1.23 (3H, s, C_{10}–Me), 2.34 (1H, m, $W_{h/2}$=*ca.* 20 Hz, C_7–H), 2.42 (1H, qd, J=6.5 and 12.5 Hz, C_4–H), 3.62 (3H, s, –OMe), 5.76 (1H, d, J=10.0 Hz, C_2–H), and 6.45 (1H, d, J=10.0 Hz, C_1–H) ppm. NMR (C_6H_6): δ 0.80 (3H, s, C_{10}–Me) and 1.09 (3H, d, J=6.5 Hz, C_4–Me). CD (MeOH): $[\theta]_{225}=+33900$, $[\theta]_{320}=-2580$. MS (70 eV): *m/e* (rel intensity), 236 (97, M^+), 221 (28), 189 (28), 177 (44), 161 (79), 82 (100).

Preparation of 11 from 9. A mixture of **9** (19 mg, 0.06 mmol), LiBr (20 mg, 0.23 mmol), Li_2CO_3 (24 mg, 0.32 mmol) in dry DMF was stirred at 160 °C for 6 h and treated in a usual way to give spectroscopically pure **11** (8 mg, 57%).

Preparation of 10 from 8. A mixture of **8** (42 mg, 0.13 mmol), LiBr (20 mg, 0.23 mmol), Li_2CO_3 (24 mg, 0.32 mmol) was stirred at 160 °C for 6 h and treated in a usual way to give spectroscopically pure **10** (22 mg, 70%).

Preparation of 14 from 10. The α,β-unsaturated ketone **10** (100 mg, 0.42 mmol) was reduced with $NaBH_4$ (16 mg, 0.42 mmol) in ether–MeOH (2:1, 1.5 mmol) and treated in a usual way to give methyl 3-hydroxy-4α*H*,5β-12,13-bisnoreudesm-1-en-11-oate (**12**) as an epimeric mixture at C_3. This mixture was passed through the column packed with basic alumina (300 mg), which was preheated at 220 °C, with N_2 flow to give **14** (31 mg, 33%).

Preparation of 14 from 11. The α,β-unsaturated ketone **11** (40 mg, 0.17 mmol) gave **14** (12 mg, 33%) in the same procedure above mentioned.

5β-Eudesma-1,3-dien-11-ol (1). Into a dry ether solution of methylmagnesium iodide [prepared from magnesium (73 mg, 3.00 mmol), methyl iodide (426 mg, 3.00 mmol), and dry ether (4 ml)] was added **14** (150 mg, 0.68 mmol) in dry ether (2 ml). This mixture was refluxed under N_2 for 1 h, poured into an aq soln of ammonium chloride, and extracted with ether (20 ml×3). The combined extracts were washed with a saturated aq soln of NaCl, dried ($MgSO_4$) and concentrated to give **1** (110 mg, 73%). IR (neat): 3350, 756, and 732 cm^{-1}. NMR (CCl_4): δ 1.10 (3H, s, C_{10}–Me), 1.13 (6H, s, C_{11}–Me), 1.80 (3H, broad s, C_4–Me), and 5.2—5.8 (3H, m) ppm. CD (MeOH): $[\theta]_{261}=27600$. MS (70 eV): *m/e* 220.

Methyl 5β,7βH-12,13-Bisnoreudesma-1,3-dien-11-oate (17). A mixture of **14** (80 mg, 0.36 mmol) and 1 M *t*-BuOK/*t*-BuOH (5 ml) was refluxed for 1.5 h under N_2, allowed to stand at room temperature for 2 h, poured into a saturated aq soln of NaCl, and extracted with ether (15 ml×3). The combined extracts were washed with a saturated aq soln of NaCl, dried ($MgSO_4$) and concentrated to give 57 mg of oily material as a neutral part, which mainly consisted of *t*-butyl 5β,7β*H*-12,13-bisnoreudesma-1,3-dien-11-oate (**16**). NMR (CCl_4): δ 0.85 (3H, s, C_{10}–Me), 1.39 (9H, s, *t*-Bu), 1.79 (3H, broad s, C_4–Me), 5.27 (1H, broad d, J=9.5 Hz, C_1–H), 5.55 (1H, m, C_3–H), 5.80 (1H, dd, J=5.0 and 9.5 Hz, C_2–H) ppm.

The aq layer was acidified by 2 M HCl and extracted with ether (15 ml×3). The combined extracts were wash-

†† The mixture of neutral alumina (active grade I, 5 g) and pyridine (0.4 ml) was shaken and evaporated at room temperature under reduced pressure (20 mmHg) for 7 h to give 5.23 g of basic alumina.

ed with a saturated aq soln of NaCl, dried ($MgSO_4$) and concentrated to give 28 mg of crystalline material, which mainly consisted of 5β,7βH-12,13-bisnoreudesma-1,3-dien-11-oic acid (**15**).

The neutral part was dissolved in a mixture of MeOH (5 ml) and a 10% aq soln of NaOH (2 ml). The mixture was refluxed for 40 min under N_2, cooled, poured into a saturated aq soln of NaCl, and extracted with ether. The aq layer was acidified by 2 M HCl and extracted with ether (15 ml×3). The combined ether layer was treated in a usual way to give 24 mg of a crystalline material, which mainly consisted of **15**.

The combined acidic part (52 mg) was methylated with a slight excess of diazomethane in ether to give 55 mg of oily material, which was ascertained to be a mixture of **14** and **17** (1:22) by the analysis of GLPC.

In another experiment a mixture of **14** (50 mg, 0.23 mmol) and 1 M *t*-BuOK/*t*-BuOH (3 ml) was refluxed for 2 h under N_2, poured into a saturated aq soln of NaCl, and extracted with ether to eliminate the neutral part. The aq layer was acidified by 2 M hydrochloric acid and extracted with ether (15 ml×3). The combined extracts were washed with a saturated aq soln of NaCl, dried ($MgSO_4$) and concentrated to give a crystalline material, which was recrystallized from ether to give 37 mg of **15** (mp 113 °C). This material was methylated by diazomethane to give **17** (40 mg, 80%). IR (neat): 1735, 1705 (sh), and 728 cm^{-1}. NMR (CCl_4): δ 0.86 (3H, s, C_{10}–Me), 1.79 (3H, broad s, C_4–Me), 3.57 (3H, s, –OMe), 5.28 (1H, broad d, J= 9.5 Hz, C_1–H), 5.50 (1H, m, C_3–H), and 5.81 (1H, dd, J=5.5 and 9.5 Hz, C_2–H) ppm. CD (MeOH): $[\theta]_{262}$= −49200. Found: C, 76.75; H, 9.11%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

(−)-Occidentalol (3). Into an ether solution of methylmagnesium iodide [prepared from magnesium powder (25 mg, 1.0 mmol) and methyl iodide (182 mg, 1.0 mmol) in dry ether (10 ml)] was added **17** (37 mg, 0.17 mmol) in dry ether (7 ml). The solution was stirred at room temperature for 40 min, then refluxed for 30 min under N_2. The reaction mixture was poured into a saturated aq soln of NH_4Cl, and extracted with ether. The combined extracts was washed with a saturated aq soln of NaCl, dried ($MgSO_4$) and concentrated to give an oily material (34 mg), which was purified by preparative TLC (silica gel GF_{254}, thickness 0.25 mm, $CHCl_3$) to give 20 mg (54%) of spectroscopically pure (−)-occidentalol (**3**), mp 83—85 °C.

A Convenient Synthesis of 4- and 5-Acetyltropolone

Hiroshi YAMAMOTO,* Atsushi HARA, Ayashi NOGUCHI, Heizan KAWAMOTO, Saburo INOKAWA, and Tetsuo NOZOE†

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received October 24, 1981)

4-Acetyltropolone is derived from hinokitiol (β-thujaplicin) in four steps, with an overall yield of 60%, *via* readily available 8-azidohinokitiol. γ-Thujaplicin almost quantitatively forms its difluoroboron complex, which, upon bromination, provides an 85% yield of the 8-bromo-γ-thujaplicin difluoroboron complex. This bromo compound readily gives γ-dolabrin (87% with triethylamine) and 8-azido-γ-thujaplicin (88% with sodium azide), from which 5-acetyltropolone is derived in an 80% yield by ozonolysis or in a 40% yield with sulfuric acid. The considerable differences in the reactivities observed between these 4- and 5-substituted tropolones are discussed. The pK_a values of 4- and 5-acetyltropolone and 4- and 5-(3,4,5-trimethoxycinnamoyl)tropolones are also reported.

The tropolone nucleus is well known to be susceptible to many electrophilic substitution reactions, but does not undergo the Friedel-Crafts-type alkylation or acylation.[1-4] Several examples of direct carbon-carbon bond formation on the tropolone nucleus by various methods under basic conditions (*e.g.*, the Reimer-Tiemann reaction, hydroxymethylation, and the Mannich reaction) have been reported. These reactions, however, have drawbacks either with respect to the preparative yield or the regioselective control.[1-5] Organometallic reagents, such as Grignard or lithium reagents, give rise to the alkyl- or aryl-substitution products only at the 2-position of the tropolone nucleus.[1] Therefore, one of the present authors (T.N.) and his co-workers utilized naturally occurring β-dolabrin[6] (**8**) or 3-carboxy-4-carboxymethyltropolone derived from natural purpurogallin[1-3] as the starting material in preparing tropolones bearing a *C*-substituent at the 4-position.[7] For example, **8** was oxidatively converted[6b] into 4-acetyltropolone (**1**), which subsequently afforded a wide variety of the cinnamoyltropolones (**3**) and their derivatives (**5**) for the attempted synthesis of colchicine analogs,[1,8] although the detailed experimental results have remained unpublished[7] (Scheme 1). 5-Acetyltropolone (**2**) was also derived from **8** by a multi-step conversion in a 10—15% overall yield and likewise afforded the 5-cinnamoyltropolones[9] (**4**).

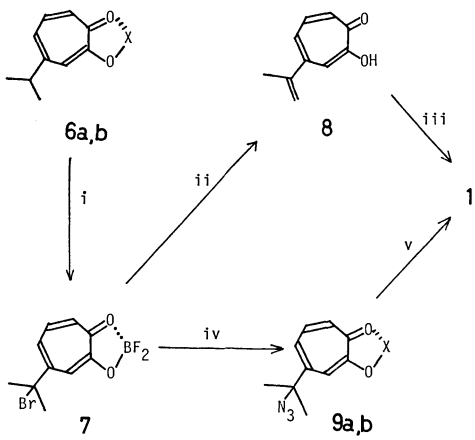
Scheme 1.

Renewed interest in the pharmacology of colchicine, particularly concerning the binding sites of the microtuburins in the muscle and nerve cells,[8] led us to reinvestigate our old synthetic scheme involving **3** or **4** as an intermediate. However, the extremely limited supply of the natural β-dolabrin necessitated a search for an alternative, efficient method of preparing two acetyltropolones, **1** and **2**. Although two practically valuable methods have been reported recently for the preparation of **8** starting from troponetricarbonyliron[4] or quinone monoacetals,[8a] the conversion of hinokitiol[1] (**6a**) and γ-thujaplicin[10] (**10a**) into **1** and **2** appeared to be more preparative value, since these isopropyltropolones are easily available from an isopropylcyclopentadiene–dichloroketene adduct by applying the Stevens method.[11,12] We wish to describe herein the effective synthesis of two acetyltropolones **1** and **2** as the initial part of a reinvestigation of the synthesis of various 4- and 5-substituted tropolones including colchicine analogs.



Scheme 2. a: X=H, b: $X=BF_2$. Reagents: i, Ref. 13; ii, n-$Bu_4N^+Br^-$–0.5 M NaOH–CH_2Cl_2; iii, Ref. 6b, 16; iv, NaN_3; v, H_2SO_4.

Seto *et al.*[13] reported an efficient conversion of **6a** into the bromo compound (**7**), which in turn was dehydrobrominated to afford a 30% yield of **8** (Scheme 2). Since the above elimination reaction with potassium *t*-butoxide in *t*-butyl alcohol failed to produce **8** in our experiment, we examined the conversion of **7** to **8** using various other bases, such as triethylamine in chloroform, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in DMF, or 0.5 mol dm^{-3} sodium hydroxide–dichloromethane with tetrabutylammonium bromide as a phase-transfer catalyst. Among these, only the last procedure afforded a 20—25% yield of **8**; the major products under these conditions were an intractable, polymerized substance and 8-hydroxyhinoki-

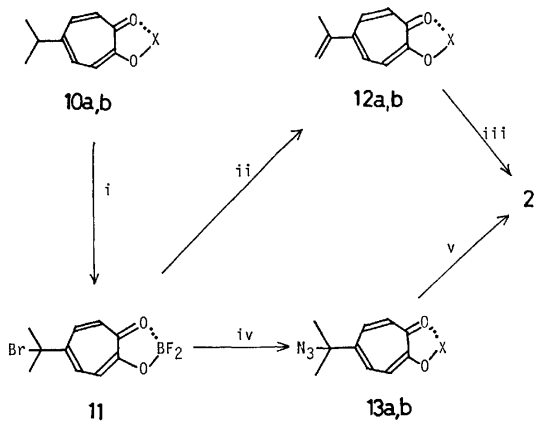
a) Measured with a Hitachi EPS 3T Recording Spectrophotometer. b) Inflections in italics. c) Neutral species (0) and monoanion (−). d) Analytical wavelength in nm (*cf.* Ref. 19). e) R=3,4,5-$(MeO)_3$ (*cf.* Refs. 1, 7, 9). f) From Ref. 7c.

tiol.[14)] Because of the fluctuation in the yield and the difficulties in optimizing the conditions of the above reaction, we sought for a more reliable alternative route to 4-acetyltropolone (**1**).

Thus, the treatment of **7** with 1.3 equivalent sodium azide in DMF produced an 85% yield of the boron complex (**9b**), which in turn was directly transformed into **1** (82%) with concd sulfuric acid, apparently by means of a Schmidt reaction[15)] (Scheme 2). The structure of the hitherto unreported intermediate, **9b**, was based on the elementary analysis and the spectroscopic data (see Experimental section). The mild alkaline hydrolysis of **9b** readily afforded crystalline 8-azidohinokitiol (**9a**; 88% yield), which had been postulated by Doi[16)] as an intermediate during the conversion of **8** into **1** with hydrazoic acid. The free tropolone (**9a**) indeed produced **1** in an 80% yield when similarly subjected to the Schmidt reaction. The overall yield of **1** from **6a** (*via* **9b**) was *ca.* 60%, which far exceeds that obtained through the formerly employed route *via* **8** (10—15%).[6b,16)]



Scheme 3. a: X=H, b: $X=BF_2$. Reagents: i, $BE_3\cdot OEt_2$; ii, Et_3N; iii, O_3–Me_2S; iv, NaN_3; v, H_2SO_4.

This convenient synthetic method of preparing **1** led us to examine an analogous approach in preparing 5-acetyltropolone (**2**) (Scheme 3). Thus, γ-thujaplicin (**10a**) was almost quantitatively converted into its difluoroboron complex (**10b**), and then into the 8-bromo derivative (**11**) in an 85% yield, by employing a slight modification of the procedure described above. Compound **11** was found to undergo surprisingly facile dehydrobromination with triethylamine in chloroform at 15 °C to furnish γ-dolabrin (**12a**) in an 85% overall yield after the hydrolysis of the intermediate boron complex (**12b**). This was in striking contrast with the results for its β-isomer (**7**), which gave mostly a polymerized product and 8-hydroxyhinokitiol. Since **12a** had been prepared[9)] either from the octyl ester of 5-carboxytropolone (7% overall) or β-dolabrin (**8**) by a three-step conversion (15%), the above method is obviously of some value for preparing **12a**.

Although 5-acetyltropolone (**2**) was obtained from **12a** through oxidative cleavage (60—70% overall yield with HCO_3H, NaOH, and HIO_4),[9)] the ozonolysis of **12a** at −70 °C was found to provide **2** more conveniently in an 80—85% yield. Alternatively, a similar application of the Schmidt reaction on either 8-azido-γ-thujaplicin (**13a**) or its difluoroboron complex (**13b**), both of which are readily available from **11**, as in the case of the β-isomer, produced only a moderate yield (40%) of 5-acetyltropolone (**2**), together with a minor amount of 5-aminotropolone.[17)] This result was again different from that for the β-isomer (**9a,b**), which prodived **1** exclusively. 5-Acetyltropolone (**2**) was thus found to be synthesized from γ-thujaplicin (**10a**) more satisfactorily through γ-dolabrin (**12a**) in an overall yield of 70%.

Scheme 4. X=Br, N_3.

Considerable differences in various reactivities were observed between the 4- and 5-positions in the tropolone nucleus. The extremely facile dehydrobromination in **11** and the increased migratory aptitude of tropolone ring in **13** to produce a considerable amount of 5-aminotropolone could be explained in terms of

a very limited contribution of a polar resonance form **14** to the actual ground state of the 5-substituted tropolones (**11** and **13**) compared with that of **15** to the 4-substituted tropolones **7** and **9b** (Scheme 4). On the other hand, the presence of an appreciable cationic charge at Position 4, as is shown in **15**, would suppress the elimination reaction in **7** and promote the polymerization of the side-chain of the β-dolabrin difluoroboron complex formed. Formula **15** is also compatible with the suppressed migratory aptitude of the tropolone nucleus in the Schmidt reaction of **9**. However, a closer mechanistic study with regard to these interesting differences is currently in progress.

A significant positional difference was also observed in the pK_a values of 4- and 5-acetyltropolone and the readily obtainable 4- and 5-(3,4,5-trimethoxycinnamoyl)tropolones [**3**,**4**; R=3,4,5-(MeO_3)]; these hitherto unreported values are recorded in Table 1, along with their UV-spectral values in aqueous buffers. The pK_a value of **2** fits this relation:

$$pK_a = 6.42 - 3.10\sigma$$

if the σ_p constant for phenol is used (predicted: 4.8).[18] These values, therefore, appear to be in conformity with the generally observed feature that Positions 4 and 5 in tropolones are approximately to be equated with Positions 3 and 4 in phenols.

The 4- and 5-acetyltropolone (**1** and **2**), thus synthesized easily from the readily available starting materials, **6a** and **10a**, are considered to be valuable intermediates in synthesizing various 4- and 5-substituted troponoids, including colchicine analogs, which are under investigation.

Experimental

The ^{1}H-NMR spectra were measured in $CDCl_3$ with a Hitachi High-resolution NMR Spectrometer, R-20A (60 MHz) at 30 °C. The chemical shifts are reported as δ values in ppm relative to TMS (δ 0.0) as the internal standard. The IR spectra were taken with a Nihon-Bunko IR-S spectrometer. The microanalysis was carried out in this department using a Yanagimoto CHN Corder, MT-2. Substances stated to be identical were compared by means of their IR and ^{1}H-NMR spectra, TLC (silica gel), HPLC (Hitachi gel #3011, with 0.1% AcOH/MeOH as a solvent), and paper chromatography (developed in 7:3 *n*-BuOH/5 M (1 M=1 mol dm^{-3}) AcOH or 2:1 *n*-PrOH/1% aq ammonia).

Difluoro(3-isopropyl-7-oxo-1,3,5-cycloheptatrienyloxy)borane (Hinokitiol Difluoroborane; ***6b***). The procedure of Seto *et al.*[13] was followed, but on a much larger scale, using an overhead mechanical stirrer, a three-necked flask fitted with a dropping funnel, and a condenser. Thus, 18.0 g (0.11 mol) of **6a** and 15.6 g (0.11 mol) of freshly distilled boron trifluoride etherate gave 22.2 g (96%) of the difluoroborane (**6b**) after recrystallization from chloroform–benzene (*ca.* (4:7); mp 171—172 °C (lit,[13] 178—179 °C). Further purification by silica-gel chromatography with 5% AcOEt/C_6H_6 and recrystallization did not raise the melting point. NMR 1.37 (6H, d, J=7.0), 3.20 (1H, sept, J=7.0), and 7.35—8.1 (4H, m).

[3-(1-Bromo-1-methylethyl)-7-oxo-1,3,5-cycloheptatrienyloxy]difluoroborane (8-Bromohinokitiol Difluoroborane; ***7***). This material was also prepared according to the procedure of Seto *et al.*,[13] but on a larger scale and with a slight modification. Thus, 15.0 g (0.094 mol) of freshly distilled bromine was slowly added to a refluxing solution of 15.0 g (0.071 mol) of **6b** dissolved in 150 ml of dry chloroform under a tungsten light with mechanical stirring. The mixture was refluxed for 6 h with stirring, with protection against moisture being provided by a $CaCl_2$ tube. The precipitate was filtered off and washed with chloroform, giving 18.3 g (89%) of **7**; mp 176—180 °C dec (from $CHCl_3$) (lit,[13] 188—189 °C). NMR (DMSO-d_6/$CDCl_3$, 1:2) 2.30 (6H, s) and 7.8—8.4 (4H, m).

4-Isopropenyl-2-hydroxy-2,4,6-cycloheptatrien-1-one (β-Dolabrin; ***8***). A suspension of 0.29 g (1.0 mmol) of **7** in 20 ml of dichloromethane was added at 40 °C to a stirred mixture of 20 ml of 0.5 mol dm^{-3} NaOH and 5 ml of CH_2Cl_2 containing 70 mg (0.21 mmol) of tetrabutylammonium bromide over a period of 50 min; then the mixture was stirred under N_2 at 40—45 °C for 12 h. After separation, the aq layer was washed with CH_2Cl_2, carefully brought to pH 3 at 5 °C with 6 mol dm^{-3} HCl, and extracted with CH_2Cl_2. The dried (over Na_2SO_4) extracts were evaporated *in vacuo*, and the residue was flash-distilled at 85 °C (bath)/7 Torr (1 Torr≈133.322 Pa), giving 40 mg (25%) of **8** as a pale yellow liquid which slowly solidified on standing and which was identical with an authentic specimen. No appreciable amount of **8** was obtained when other bases were used *e.g.*, triethylamine in chloroform (50 °C, 6 h; 60% recovery, 15% of 8-hydroxyhinokitiol), *t*-BuOK/*t*-BuOH[13] (10—20 °C, 1.5 h; 30% recovery of **7**, 10% of 8-hydroxyhinokitiol, and 5% of **8**), DBU/DMF (0 °C, 1.5 h; 40% of **7**, 10% of 8-hydroxyhinokitiol). In all cases, the residue was an intractable gummy substance, apparently a polymerized product.

[3-(1-Azido-1-methylethyl)-7-oxo-1,3,5-cycloheptatrienyloxy]difluoroborane (8-Azidohinokitiol Difluoroborane; ***9b***). A solution of 4.11 g (14.1 mmol) of **7** and 1.18 g (18.2 mmol) of sodium azide in 40 ml of dry DMF was stirred under N_2 at 15 °C for 15 h. The solvent was then removed *in vacuo* (pump), and the residue, diluted with water, was extracted with benzene. The combined extracts were dried over Na_2SO_4 and evaporated *in vacuo*. The residue was purified by passing it through a short column of silica gel with 5% AcOEt–C_6H_6, thus affording 3.04 g (85%) of **9b** as colorless crystals; mp 71—73 °C (from benzene–light petroleum). NMR 1.74 (6H, s, 2CH_3-8) and 7.6—8.2 (4H, m, aromatic). IR ($CHCl_3$) 2150 (N_3) and 1615 cm^{-1} (C=O). Found: C, 47.25; H, 4.11; N, 16.49%. Calcd for $C_{10}H_{10}N_3O_2BF_2$: C, 47.47; H, 3.98; N, 16.61%.

4-(1-Azido-1-methylethyl)-2-hydroxy-2,4,6-cycloheptatrien-1-one (8-Azidohinokitiol; ***9a***). A mixture of 46 mg of **9b**, 2 ml of *t*-butyl alcohol, and 2 ml of 1 mol dm^{-3} KOH was stirred at 20 °C for 5 h. The alcohol was then removed *in vacuo*, and the remaining aq layer was taken to pH 4 with 2 mol dm^{-3} HCl at 5 °C and extracted with CH_2Cl_2. The combined organic layers were dried over Na_2SO_4 and evaporated *in vacuo*, giving 33 mg (88%) of **9a** as colorless prisms (from ether–light petroleum); mp 45—46 °C. NMR 1.68 (6H, s, 2CH_3-8), 7.2—7.45 (3H, m, H-5,6,7), 7.56 (1H, bs, H-3), and 8.0 (1H, bm, HO-2, D_2O exchangeable). IR ($CHCl_3$) 3450 (OH), 2150 (N_3), and 1610 cm^{-1} (C=O). Found: C, 58.65; H, 5.62; N, 20.15%. Calcd for $C_{10}H_{11}N_3O_2$: C, 58.53; H, 5.40; N, 20.48%.

4-Acetyl-2-hydroxy-2,4,6-cycloheptatrien-1-one (4-Acetyltropolone; ***1***). Three milliliters of concd sulfuric acid were added dropwise to a solution of 3.84 g (15.2 mmol) of **9b** in 6 ml of chloroform at 0 °C; the mixture was then stirred at 0 °C for 15 min and at 20 °C for 2 h. After the $CHCl_3$ layer

had then been removed, the acid layer was diluted with 15 ml of cold water, brought to pH 3 by adding solid $NaHCO_3$, and extracted with $CHCl_3$. The combined extracts were dried over Na_2SO_4 and evaporated *in vacuo*, giving 2.04 g (82%) of **1** as yellow crystals; mp 125—127 °C (from 70% aq ethanol). The product was identical with an authentic specimen[6] (mp 129 °C). 8-Azidohinokitiol (**9a**) produced **1** in 80% and 64% yields when similarly treated with concd sulfuric acid and polyphosphoric acid (at 55 °C) respectively.

*Difluoro(4-isopropyl-7-oxo-1,3,5-cycloheptatrienyloxy)borane (γ-Thujaplicin Difluoroborane; **10b**).* The procedure for the β-isomer was followed. Thus, 5.3 g (31 mmol) of trifluoroboron etherate, dissolved in 10 ml of dry ether, was added dropwise to a solution of 4.59 g (28 mmol) of **10a** in 80 ml of dry ether–benzene (1:1) at 5 °C over a period of 1 h with stirring under the protection of a $CaCl_2$ tube. After being stirred at 5 °C for 4 h, the mixture was concentrated *in vacuo*, and the residue was recrystallized from benzene/light petroleum to give 5.05 g of **10b** as white needles; mp 104—105 °C. The filtrate was concentrated *in vacuo*, and the residue was chromatographed over silica gel with 5% ether–benzene, thus affording 0.50 g more of **10b**; mp 103 °C (from the same mixed solvent); thus, the combined yield of **10b** was 5.55 g (94%). NMR 1.35 (6H, d, J=6.5, $2CH_3$-8), 2.13 (1H, sept, J=6.5, H-8), 7.75 (2H, d, J=11, H-2,6), and 8.00 (2H, d, J=11, H-3,5). Found (for material dried at 40 °C/15 Torr): C, 56.43; H, 5.11%. Calcd for $C_{10}N_{11}O_2BF_2$: C, 56.60; H, 5.18%.

*[4-(1-Bromo-1-methylethyl)-7-oxo-1,3,5-cycloheptatrienyloxy]difluoroborane (8-Bromo-γ-thujaplicin Difluoroborane; **11**).* To a stirred suspension of 6.78 g (32 mmol) of **10b** in 250 ml of dry CCl_4 was added dropwise 5.2 g (32.5 mmol) of bromine dissolved in 20 ml of dry CCl_4 at 20 °C over a period of 90 min under a tungsten light and a slow stream of N_2; the mixture was subsequently stirred at room temperature for 4 h. The precipitate was filtered off and washed with CCl_4, thus giving 7.82 g (85%) of **11** as colorless crystals; mp 116—119 °C. Recrystallization from benzene–light petroleum raised the melting point to 119—120 °C. A lesser yield of **11** was obtained when chloroform was used as the solvent or when the reaction mixture was refluxed. NMR 2.28 (6H, s, $2CH_3$-8), 7.81 (2H, d, J=12, H-2,6), and 8.51 (2H, d, J=12, H-3,5). Found: C, 41.01; H, 3.25%. Calcd for $C_{10}H_{10}O_2BrBF_2$: C, 41.24; H, 3.42%.

*Difluoro(4-isopropenyl-7-oxo-1,3,5-cycloheptatrienyloxy)borane (γ-Dolabrin Difluoroborane: **12b**).* To a solution of 200 mg (0.69 mmol) of **11** in 3 ml of dry CH_2Cl_2 was added 73 mg (1.37 mmol) of triethylamine under N_2 at 0 °C. The mixture was stirred at 15 °C for 7 h, and then a 3-ml portion of cold water was added. After separation, the aq layer was extracted with CH_2Cl_2. The combined organic layers were dried over Na_2SO_4 and evaporated *in vacuo*, thus giving 130 mg (90%) of **12b** as colorless needles; mp 148—149 °C (from benzene–light petroleum). NMR 2.26 (3H, bs, CH_3-8), 5.40 (2H, bs, CH_2=C-8), 7.84 (2H, d, J=12, H-2,6), and 8.17 (2H, d, J=12, H-3,5). Found: C, 57.51; H, 4.48%. Calcd. for $C_{10}H_9O_2BF_2$: C, 57.17; H, 4.76%.

*5-Isopropenyl-2-hydroxy-2,4,6-cycloheptatrien-1-one (γ-Dolabrin; **12a**).* A mixture of 4.40 g (15 mmol) of **11** and 3.50 g (35 mmol) of triethylamine in 60 ml of dry $CHCl_3$ was stirred under N_2 at 20 °C for 3 h and then concentrated *in vacuo*. The residue was stirred with a mixture of 50 ml of *t*-butyl alcohol and 260 ml of 1.3 mol dm^{-3} KOH at 20 °C for 30 min. The alcohol was removed *in vacuo*, and the residue was carefully taken to pH 3 with 2 mol dm^{-3} HCl at 5 °C. The precipitate was filtered off and washed with water, thus giving 1.88 g of **12a** as pale yellow crystals; mp 98—100 °C (lit,[9] 100—101 °C). From the filtrate, 0.25 g more of **12a** was obtained after extraction with $CHCl_3$, sublimation at 80 °C/0.01 Torr, and recrystallization from cyclohexane; thus, the total yield of **12a** from **11** was 2.13 g (87%). NMR 2.15 (3H, bs, CH_3-8), 5.20 and 5.28 (1H, each, m, CH_2=C-8), 7.33 (2H, d, J=11, H-3,7), 7.49 (2H, d, J=11, H-4,6), and 7.80 (1H, bs, HO-2, D_2O exchangeable). The product was identical with an authentic specimen.[9]

*[4-(1-Azido-1-methylethyl)-7-oxo-1,3,5-cycloheptatrienyloxy]difluoroborane (**13b**) and 8-Azido-γ-thujaplicin (**13a**).* A mixture of 20 mg (0.069 mmol) of **11** and 6 mg (0.092 mmol) of sodium azide in 0.5 ml of dry DMF was stirred under N_2 at 50 °C for 1.5 h. The solvent was then evaporated at 20 °C/0.3 Torr. The residue was dissolved in benzene, washed with water, dried over Na_2SO_4, and evaporated *in vacuo*, thus giving 10 mg (57%) of **13b** as pale yellow needles; mp 81—83 °C (from ether–light petroleum). NMR 1.75 (6H, s, $2CH_3$-8), 7.86 (2H, d, J=12, H-2,6), and 8.32 (2H, d, J=12, H-3,5). IR ($CHCl_3$) 2150 (N_3) and 1615 cm^{-1} (C=O). Found: C, 47.25; H, 4.16; N, 16.32%. Calcd for $C_{10}H_{10}N_3O_2BF_2$: C, 47.47; H, 3.98; N, 16.61%.

When the reaction was carried out using 116 mg of **11** at 20 °C for 16 h, 89 mg (88%) of a *ca.* 2:1 mixture of **13b** and **13a** (see below) were produced as an amber liquid.

A mixture of 17 mg (0.066 mmol) of **13b**, 1 ml of 1 mol dm^{-3} KOH, and 1 ml of *t*-BuOH was stirred under N_2 at 20 °C for 3 h. The alcohol was then removed *in vacuo*, and the remaining aq solution was taken to pH 4 with 2 mol dm^{-3} HCl and extracted with $CHCl_3$, thus giving 11 mg (80%) of **13a** as a pale amber oil. NMR 1.58 (6H, s, $2CH_3$-8), 7.30 (2H, d, J=12, H-3,7), 7.64 (2H, d, J=12, H-4,6), and 7.7 (1H, bm, OH). IR ($CHCl_3$) 3450 (OH), 2150 (N_3), and 1610 cm^{-1} (C=O).

*5-Acetyl-2-hydroxy-2,4,6-cycloheptatrien-1-one (5-Acetyltropolone; **2**).* *A)*: Into a stirred solution of 0.50 g (3.9 mmol) of **12a** in 50 ml of dry CH_2Cl_2 was passed 42 mg (8.5 mmol) of ozone at −70 °C over a period of 1 h; then 0.6 ml of dimethyl sulfide was added. The mixture was gradually warmed, and the stirring was continued at 15 °C for 3 h. The solvent was evaporated *in vacuo*, and the residue, diluted with brine, was extracted with $CHCl_3$, thus giving 0.43 g (85%) of **2** as pale yellow crystals after recrystallization from $CHCl_3$–ethanol (with carbon); mp 179—181 °C (lit,[9] 182—183 °C). NMR 2.63 (3H, s, Ac), 6.1 (1H, bs, OH, D_2O exchangeable), 7.37 (2H, d, J=12, H-3,7), and 8.11 (2H, d, J=12, H-4,6). The product was identical with an authentic specimen.[9]

B): To a cold solution of 36 mg of crude **13b** in 1.5 ml of $CHCl_3$ was added 1.5 ml of concd sulfuric acid at 0 °C. The mixture was stirred at 20 °C for 1 h, after which the organic layer was separated. The aq layer was diluted with 4 ml of cold water, taken to pH 3 with $NaHCO_3$, and extracted with $CHCl_3$, thus giving 10 mg (40%) of **2** as pale yellow crysals; mp 175—178 °C (from $CHCl_3$–EtOH). The above aq layer (after $CHCl_3$ extraction at pH 3) was found to contain 5-aminotropolone (by HPLC and paper chromatography), which was subsequently isolated and identified as the picrate: yellow crystals, mp 220—225 °C dec (lit,[17] 225—226 °C dec). Almost the same result was obtained by using **13a** as the starting material or by employing polyphosphoric acid as the reaction medium.

The present work was partially suppoted by a Research Grant from the Suntory Institute of Bioorganic

Research, Osaka, to which we wish to express our thanks.

Total Synthesis of (±)-Pisiferic Acid, Methyl (±)-Pisiferate, and (±)-Pisiferol

Takashi MATSUMOTO* and Shuji USUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received October 26, 1981)

Acid catalyzed cyclization of 4-(3-isopropyl-4-methoxyphenethyl)-3,5,5-trimethyl-2-cyclohexen-1-one afforded 12-methoxyabieta-8,11,13-trien-2-one and its *cis*-isomer. Both compounds were further converted into 12-methoxyabieta-8,11,13-trien-2β-ol, which was treated with lead tetraacetate in the presence of iodine to yield 2β,20-epoxy-12-methoxyabieta-8,11,13-triene. Ether cleavage of the 2β,20-epoxy compound with acetyl *p*-toluenesulfonate, followed by catalytic hydrogenation, afforded 20-acetoxy-12-methoxyabieta-8,11,13-triene (**23**). This was then converted into methyl 12-methoxyabieta-8,11,13-trien-20-oate (**27**) *via* methyl 12-methoxy-7-oxoabieta-8,11,13-trien-20-oate. Demethylation of **27** with $AlBr_3$–EtSH gave pisiferic acid, but with $AlCl_3$–EtSH **27** was partially demethylated to give methyl pisiferate. The acetate **23** was also converted into pisiferol by demethylation and reduction.

Recently three new ferruginol type diterpenes, pisiferic acid (**1**), methyl pisiferate (**2**), and pisiferol (**3**), have been isolated from the leaves of *Chamaecyparis pisifera* by Yatagai *et al.*[1] All these compounds are are tricyclic diterpenes possessing an oxidized angular methyl group. As an extension of our previous studies[2,3] of the syntheses of natural tricyclic diterpenes possessing an oxygen function in the ring A, we have attempted the syntheses of these rare natural compounds. This paper[4] describes the total syntheses of (±)-pisiferic acid (**1**), methyl (±)-pisiferate (**2**), and (±)-pisiferol (**3**), starting from (±)-12-methoxyabieta-8,11,13-trien-2-one (**4**),[3] which was prepared from (±)-4-(3-isopropyl-4-methoxyphenethyl)-3,5,5-trimethyl-2-cyclohexen-1-one (**5**).

Cyclization of **5** in hexane with boron trifluoride etherate in the presence of 1,2-ethanedithiol, followed by hydrolysis with mercury (II) chloride in aqueous acetonitrile, gave **4** (28%) and its *cis*-isomer (**6**: 16%).[3] Since all natural compounds (**1**, **2**, and **3**) possess a trans A/B ring junction, conversion of the *cis*-isomer **6** into the trans compounds was carried out as follows. Reduction of **6** with lithium aluminium hydride in THF, followed by acetylation, gave two epimeric acetates, **7** (32%) and **8** (52%). The ^1H NMR spectrum of **7** showed signals at δ 0.35, 0.98, and 1.18 due to the C-4 dimethyl and C-10 methyl groups. The steroidal conformation (**7a**) of **7** was suggested by the appearance of the signal due to one of two C-4 methyl groups in very high field (δ 0.35), owing to the shielding effect of the aromatic C-ring. The ^1H NMR spectrum of **8** showed the corresponding signals at δ 1.02, 1.26, and 1.49. The appearance of these three tertiary methyl signals in a lower field than those in **7** suggested that **8** exists in a nonsteroidal conformation (**8a**).[5] The stereochemistry of the acetoxyl group at C-2 in **7** and **8** was assigned respectively to be β- and α-configuration by their ^1H NMR spectra, each of which showed a broad signal due to the C-2 proton at δ 4.4—5.1 in **7** and at δ 4.6—5.4 in **8**, suggesting the presence of an axial hydrogen. The acetate **7** in acetone was oxidized with Jones reagent to give the corresponding 7-oxo compound (**9**: 60%) along with the 6,7-dioxo compound (**10**: 13%). Bromination of **9** with pyridinium tribromide in dichloromethane afforded the 6β-bromo derivative (**11**: 91%), which was converted into 2β-acetoxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (**12**: 86%) by treatment with lithium carbonate and lithium bromide in *N*,*N*-dimethylformamide at 110—130 °C. The tetraene **12** in ethyl acetate was catalytically hydrogenated with Pd–C in the presence of perchloric acid to yield 2β-acetoxy-12-methoxyabieta-8,11,13-triene (**13**: 72%) and **9** (17%). Treatment of **13** in THF with lithium aluminium hydride gave 12-methoxyabieta-8,11,13-trien-2β-ol (**14**). Similarly, the acetate **8** was also oxidized with Jones reagent to give the corresponding 7-oxo (**15**: 53%) and 6,7-dioxo (**16**: 16%) compounds. The 7-oxo compound **15** was further converted into 2α-acetoxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (**18**) *via* the corresponding 6β-bromo derivative (**17**). The β-configuration of the bromine atom in **11** and **17** was supported by their ^1H NMR spectra, which showed signals due to the C-10 methyl group in low field (δ 1.57 in **11** and δ 1.68 in **17**), owing to the 1,3-diaxial interaction between the bromine atom and the C-10 methyl group. Catalytic hydrogenation of **18** in ethyl acetate over Pd–C afforded 2α-acetoxy-12-methoxyabieta-8,11,13-triene (**19**: 70%) and **8** (25%). The acetate **19** in THF was reduced with lithium aluminium hydride

and the resulting alcohol was immediately oxidized with pyridinium chlorochromate in dichloromethane to afford **4** (88%), which was then converted into **14**[3] by reduction with lithium aluminium hydride in THF.

In order to oxidize the angular methyl group by transannular oxidation, the alcohol **14** in hexane was treated with lead tetraacetate in the presence of iodine at room temperature. Purification of the crude product by column chromatography on silica gel afforded 2β,20-epoxy-12-methoxyabieta-8,11,13-triene (**20**: 51 %). The structure of **20** was supported by the appearance of signals in its ^{1}H NMR spectrum due to methylene protons (ABq at δ 3.78) and by the disappearance of the signal due to angular methyl group. Treatment of **20** with acetyl *p*-toluenesulfonate[6] in dichloromethane gave an olefinic acetate (**21**: 83%) and a tosyloxy acetate (**22**: 11%). The ^{1}H NMR spectrum of **21** showed signals due to two vinylic protons at δ 5.55 (2H, m), methylene protons at δ 4.27 (2H, bs), an acetoxyl group at δ 1.90 (3H, s), and two tertiary methyl groups at δ 1.03 and 1.08 (each 3H and s). From these spectral data, the structure of **21** was assigned to be 20-acetoxy-12-methoxyabieta-2,8,11,13-tetraene. The spectrum of **22** showed the presence of a tosyloxyl group [δ 2.48 (3H, s), 7.34 and 7.83 (each 2H, d, and J=8 Hz)] and no vinylic proton. The α-configuration of the tosyloxyl group was supported by the broad signal at δ 4.2—4.9 (1H, m) due to the C-2 proton, suggesting the presence of an axial β hydrogen. Treatment of **22** with potassium carbonate in refluxing aqueous methanol yielded **20**. The olefinic acetate **21** in ethanol was submitted to catalytic hydrogenation over PtO_2 to afford 20-acetoxy-12-methoxyabieta-8,11,13-triene (**23**: 93%)

28

which, on reduction with lithium aluminium hydride in THF, gave the corresponding alcohol (**24**: 95%). Oxidation of **24** in acetone with Jones reagent, followed by methylation with diazomethane, afforded methyl 12-methoxy-7-oxoabieta-8,11,13-trien-20-oate (**25**: 40%). The structure of **25** was supported by its IR (1720 and 1660 cm^{-1}) and ^{1}H NMR [δ 3.57 (CO_2CH_3), 6.70 (C_{11}–H), and 7.79 (C_{14}–H)] spectra. The 7-oxo compound **25** was then reduced with sodium borohydride in ethanol and the resulting mixture of epimeric alcohols was immediately dehydrated[7] with acetyl *p*-toluenesulfonate in dichloromethane to give methyl 12-methoxyabieta-6,8,11,13-tetraen-20-oate (**26**: 71%). Catalytic hydrogenation of **26** in ethanol over PtO_2 afforded methyl 12-methoxyabieta-8,11,13-trien-20-oate (**27**: 99%). Demethylation of **27** with anhydrous aluminium bromide and ethanethiol[8] at room temperature for 13 h gave pisiferic acid (12-hydroxyabieta-8,11,13-trien-20-oic acid) (**1**: 93%). Similar treatment of **27** with anhydrous aluminium chloride and ethanethiol[9] in dichloromethane at 0—5 °C for 4 h yielded methyl pisiferate (methyl 12-hydroxyabieta-8,11,13-trien-20-oate (**2**: 97%). Subsequently, the acetate **23** was demethylated with anhydrous aluminium chloride and ethanethiol in dichloromethane to give 20-acetoxyabieta-8,11,13-trien-12-ol

(**28**: 74%) which, on reduction with lithium aluminium hydride in THF, afforded pisiferol (abieta-8,11,13-triene-12,20-diol) (**3**: 88%). The IR and ^{1}H NMR spectra of the synthetic **1**, **2**, and **3** were identical with those of natural products.

Experimental

All melting points are uncorrected. The IR spectra were measured in chloroform, and the ^{1}H NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, bt: broad triplet, m: multiplet. Column chromatography was performed using Merck silica gel (0.063 mm).

*Cyclization of 4-(3-Isopropyl-4-methoxyphenethyl)-3,5,5-trimethyl-2-cyclohexen-1-one (**5**).* A stirred mixture of **5**[3] (5.03 g), 1,2-ethanedithiol (1.4 ml), boron trifluoride etherate (6.1 ml), and dry hexane (50 ml) was refluxed for 6 h. The mixture was cooled, poured into aqueous sodium hydroxide, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was refluxed for 3 h with mercury(II) chloride (13 g) in a mixture of acetonitrile (50 ml) and water (5.0 ml), filtered, and the filtrate was concentrated *in vacuo*. The residue was extracted with ether and the ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude products were purified by column chromatography on silica gel (Merck, 0.063—0.200 mm, 400 g), using ether–hexane (7:93 and then 1:9) as the eluent, to give 12-methoxyabieta-8,11,13-trien-2-one (**4**) (1.40 g: 28 %). Subsequent elution gave 12-methoxy-5βH-abieta-8,11,13-trien-2-one (**6**) (0.78 g: 16%). Further elution with ether–hexane (3:7) gave 12-methoxy-5β-methyl-18-norabieta-8,11,13-trien-2-one (1.02 g: 20%). The IR and ^{1}H NMR spectra of these products were identical with those of the authentic samples.[3]

*Reduction and Acetylation of **6**.* A mixture of **6** (2.051 g) and lithium aluminium hydride (200 mg) in dry tetrahydrofuran (30 ml) was stirred at room temperature for 3 h. To the mixture was added successively water (0.20 ml), 10% aqueous sodium hydroxide (0.20 ml), and water (0.60 ml). The precipitate was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was acetylated with acetic anhydride (0.70 ml) and pyridine (2.0 ml) at room temperature for 13 h. After the usual work-up, the crude products were purified by column chromatography on silica gel (200 g), using ether–benzene (1:99) as the eluent, to give 2β-acetoxy-12-methoxy-5βH-abieta-8,11,13-triene (**7**) (749 mg: 32%). IR: 1718 cm^{-1}; ^{1}H NMR: 0.35 (3H, s, $C_{4\alpha}$–CH_3), 0.98 (3H, s, $C_{4\beta}$–CH_3), 1.18 (3H, s, C_{10}–CH_3), 1.18 (6H, d, J=7 Hz, –CH(CH_3)$_2$), 2.00 (3H, s, –OCOCH_3), 3.92 (3H, s, –OCH_3), 4.4—5.1 (1H, m, C_2–H), 6.68 and 7.04 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 76.83; H, 9.66%. Calcd for $C_{23}H_{34}O_3$: C, 77.05; H, 9.56%.

Further elution gave 2α-acetoxy-12-methoxy-5βH-abieta-8,11,13-triene (**8**) (1.225 g: 52%). IR: 1720 cm^{-1}; ^{1}H NMR: 1.02 and 1.26 (each 3H and s, –C(CH_3)$_2$), 1.16 (6H, d, J=7 Hz, –CH(CH_3)$_2$), 1.49 (3H, s, C_{10}–CH_3), 1.85 (3H, s, –OCOCH_3), 3.77 (3H, s, –OCH_3), 4.6—5.4 (1H, m, C_2–H), 6.63 (2H, bs, C_{11}–H and C_{14}–H). Found: C, 77.34; H, 9.76%. Calcd for $C_{23}H_{34}O_3$: C, 77.05; H, 9.56%.

*Oxidation of **7**.* Jones reagent (2.5 M: 0.72 ml) was added dropwise at 0—5 °C to a stirred solution of **7** (427 mg) in acetone (8.0 ml). The mixture was further stirred at room temperature for 2 h, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (40 g), using ether–benzene (3:97) as the eluent, to give the starting **7** (63 mg: 15%) and 2β-acetoxy-12-methoxy-5βH-abieta-8,11,13-trien-7-one (**9**) (264 mg: 60%), which was recrystallized from methanol. Mp 163—164 °C; IR: 1720, 1655 cm^{-1}; ^{1}H NMR: 0.36 (3H, s, $C_{4\alpha}$–CH_3), 1.04 (3H, s, $C_{4\beta}$–CH_3), 1.25 (6H, bd, J=7 Hz, –CH(CH_3)$_2$), 1.34 (3H, s, C_{10}–CH_3), 2.03 (3H, s, –OCOCH_3), 4.03 (3H, s, –OCH_3), 4.4—5.1 (1H, m, C_2–H), 7.09 (1H, s, C_{11}–H), 7.75 (1H, s, C_{14}–H). Found: C, 74.42; H, 8.87%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

Further elution gave 2β-acetoxy-12-methoxy-5βH-abieta-8,11,13-triene-6,7-dione (**10**) (60 mg: 13%), which was recrystallized from methanol. Mp 180—182 °C; IR: 1720, 1667 cm^{-1}; ^{1}H NMR: 0.48 (3H, s, $C_{4\alpha}$–CH_3), 1.06 (3H, s, $C_{4\beta}$–CH_3), 1.27 (6H, d, J=7 Hz, –CH(CH_3)$_2$), 1.31 (3H, s, C_{10}–CH_3), 2.08 (3H, s, –OCOCH_3), 2.57 (1H, s, C_5–H), 4.11 (3H, s, –OCH_3), 4.5—5.3 (1H, m, C_2–H), 7.25 (1H, s, C_{11}–H), 7.86 (1H, s, C_{14}–H). Found: C, 71.50; H, 7.83%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

*2β-Acetoxy-6β-bromo-12-methoxy-5βH-abieta-8,11,13-trien-7-one (**11**).* A mixture of **9** (420 mg) and 80% pyridinium tribromide (450 mg) in dichloromethane (8.0 ml) was stirred at room temperature for 1 h. The mixture was diluted with water and extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (50 g), using ether–benzene (3:97) as the eluent, to give **11** (463 mg: 91%), which was recrystallized from benzene. Mp 212—213 °C; IR: 1720, 1663 cm^{-1}; ^{1}H NMR ($CDCl_3$): 0.31 (3H, s, $C_{4\alpha}$–CH_3), 1.18 (3H, s, $C_{4\beta}$–CH_3), 1.24 (6H, d, J=7 Hz, –CH(CH_3)$_2$), 1.57 (3H, s, C_{10}–CH_3), 2.10 (3H, s, –OCOCH_3), 2.47 (1H, s, C_5–H), 4.07 (3H, s, –OCH_3), 4.5—5.2 (1H, m, C_2–H), 4.84 (1H, s, C_6–H), 7.18 (1H, s, C_{11}–H), 7.86 (1H, s, C_{14}–H). Found: C, 61.43; H, 7.00%. Calcd for $C_{23}H_{31}O_4Br$: C, 61.20; H, 6.92%.

*2β-Acetoxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (**12**).* A mixture of **11** (210 mg), lithium carbonate (103 mg), and lithium bromide (81 mg) in *N,N*-dimethylformamide (3.0 ml) was stirred at 110—130 °C for 4 h in a stream of nitrogen. The mixture was cooled, poured into ice-dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (20 g), using ether–benzene (3:97) as the eluent, to give **12** (149 mg: 86%), which was recrystallized from ethanol. Mp 134—135 °C; IR: 1725, 1645 cm^{-1}; ^{1}H NMR: 1.23 and 1.26 (each 3H, d, and J=7 Hz, –CH(CH_3)$_2$), 1.33, 1.46, and 1.66 (each 3H and s, –C(CH_3)$_2$ and C_{10}–CH_3), 2.07 (3H, s, –OCOCH_3), 3.92 (3H, s, –OCH_3), 5.10 (1H, m, $W_{1/2}$=17 Hz, C_2–H), 6.32 (1H, s, C_6–H), 6.77 (1H, s, C_{11}–H), 7.83 (1H, s, C_{14}–H). Found: C, 74.50; H, 8.14%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

*Catalytic Hydrogenation of **12**.* A mixture of **12** (120 mg), 10% Pd–C (100 mg), and 70% perchloric acid (4 drops) in ethyl acetate (6.0 ml) was stirred at room temperature for 9 h in an atmosphere of hydrogen. After the usual work-up, the crude products were purified by column chromatography on silica gel (15 g), using ether–benzene (1:99) as the eluent, to give 2β-acetoxy-12-methoxyabieta-8,11,13-triene (**13**) (83 mg: 72%), whose IR and ^{1}H NMR spectra were identical with those of the authentic sample.[3]

Further elution with ether–benzene (5: 95) gave **9** (21 mg: 17%).

*12-Methoxyabieta-8,11,13-trien-2β-ol (**14**).* A mixture of **13** (83 mg) and lithium aluminium hydride (10 mg) in dry tetrahydrofuran (2.0 ml) was stirred at room temperature for 1.5 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (10 g), using ether–benzene (5:95) as the eluent, to give **14** (70 mg: 95%), whose IR and ^{1}H NMR spectra were identical with those of the authentic sample.[3]

*Oxidation of **8**.* A solution of **8** (978 mg) in acetone (20 ml) was oxidized with Jones reagent (2.5 M: 2.20 ml) at *ca.* 10 °C for 30 min and then at room temperature for 2 h. The mixture was diluted with water and extracted with ethyl acetate. The organic solution was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (100 g), using ether–benzene (3: 97) as the eluent, to give the starting **8** (141 mg: 14%) and 2α-acetoxy-12-methoxy-5β*H*-abieta-8,11,13-trien-7-one (**15**) (541 mg: 53%), which was recrystallized from methanol. Mp 162.5—163 °C; IR: 1720, 1660 cm^{-1}; ^{1}H NMR: 0.68 (3H, s, $C_{4\alpha}$–CH_3), 1.03 (3H, s, $C_{4\beta}$–CH_3), 1.19 and 1.23 (each 3H, d, and J= 7 Hz, –CH($C\underline{H}_3$)$_2$), 1.37 (3H, s, C_{10}–CH_3), 1.53 (3H, s, –OCOCH_3), 3.88 (3H, s, –OCH_3), 4.88 (1H, m, $W_{1/2}$= 9 Hz, C_2–H), 6.65 (1H, s, C_{11}–H), 7.75 (1H, s, C_{14}–H). Found: C, 74.04; H, 8.73%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

Further elution with ether–benzene (5: 95) gave 2α-acetoxy-12-methoxy-5β*H*-abieta-8,11,13-triene-6,7-dione (**16**), which was recrystallized from methanol. Mp 193—196 °C (changed the crystalline form at 140—145 °C); IR: 1725, 1670 cm^{-1}; ^{1}H NMR ($CDCl_3$): 0.79 (3H, s, $C_{4\alpha}$–CH_3), 1.02 (3H, s, $C_{4\beta}$–CH_3), 1.23 and 1.26 (each 3H, d, and J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.32 (3H, s, C_{10}–CH_3), 1.69 (3H, s, –OCOCH_3), 2.72 (1H, s, C_5–H), 3.96 (3H, s, –OCH_3), 5.10 (1H, m, $W_{1/2}$=8 Hz, C_2–H), 6.82 (1H, s, C_{11}–H), 7.99 (1H, s, C_{14}–H). Found: C, 71.51; H, 7.92%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

*2α-Acetoxy-6β-bromo-12-methoxy-5βH-abieta-8,11,13-trien-7-one (**17**).* A mixture of **15** (541 mg) and 80% pyridinium tribromide (610 mg) in dichloromethane (5.0 ml) was treated as described for the preparation of **11**. The crude product was purified by column chromatography on silica gel (70 g), using ether–benzene (3: 97) as the eluent, to give **17** (639 mg: 93%), which was recrystallized from benzene. Mp 201—202 °C; IR: 1725, 1662 cm^{-1}; ^{1}H NMR ($CDCl_3$): 0.63 (3H, s, $C_{4\alpha}$–CH_3), 1.15 (3H, s, $C_{4\beta}$–CH_3), 1.19 and 1.24 (each 3H, d, and J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.68 (6H, s, C_{10}–CH_3 and –OCOCH_3), 2.47 (1H, s, C_5–H), 3.91 (3H, s, –OCH_3), 5.00 (1H, s, C_6–H), 5.03 (1H, m, $W_{1/2}$=7 Hz, C_2–H), 6.75 (1H, s, C_{11}–H), 7.92 (1H, s, C_{14}–H). Found: C, 61.26; H, 7.02%. Calcd for $C_{23}H_{31}O_4Br$: C, 61.20; H, 6.92%.

*2α-Acetoxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (**18**).* A mixture of **17** (226 mg), lithium carbonate (111 mg), and lithium bromide (87 mg) in *N,N*-dimethylformamide (3.0 ml) was stirred at 120—130 °C for 1.5 h in a stream of nitrogen. After the same work-up as described for the preparation of **12**, the crude product was purified by column chromatography on silica gel (20 g), using ether–benzene (5:95) as the eluent, to give **18** (178 mg: 96%), which was recrystallized from ethanol. Mp 134—135 °C; IR: 1725, 1645 cm^{-1}; ^{1}H NMR: 1.22 and 1.26 (each 3H, d, and J= 7 Hz, –CH($C\underline{H}_3$)$_2$), 1.32, 1.48, and 1.62 (each 3H and s, –$\underline{C}$(CH_3)$_2$ and C_{10}–CH_3), 2.03 (3H, s, –OCOCH_3), 3.92 (3H, s, –OCH_3), 4.9—5.7 (1H, m, C_2–H), 6.29 (1H, s, C_6–H), 6.77 (1H, s, C_{11}–H), 7.84 (1H, s, C_{14}–H). Found: C, 74.52; H, 8.24%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

*Catalytic Hydrogenation of **18**.* A mixture of **18** (178 mg), 10% Pd–C (150 mg), and 70% perchloric acid (4 drops) in ethyl acetate (7.0 ml) was treated as described in the hydrogenation of **12**. The crude products were purified by column chromatography on silica gel (20 g), using benzene as the eluent, to give 2α-acetoxy-12-methoxyabieta-8,11,13-triene (**19**) (97 mg: 56%). IR: 1720 cm^{-1}; ^{1}H NMR: 1.06 (6H, s, –$\underline{C}$(CH_3)$_2$), 1.17 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 1.29 (3H, s, C_{10}–CH_3), 2.03 (3H, s, –OCOCH_3), 3.79 (3H, s, –OCH_3), 4.8—5.4 (1H, m, C_2–H), 6.57 and 6.71 (each 1H and s, C_{11}–H and C_{14}–H). Further elution gave a mixture (*ca.* 1:1) of acetates (**19** and **8**) (48 mg: 28%) and pure **8** (18 mg: 11%).

*12-Methoxyabieta-8,11,13-trien-2-one (**4**).* A mixture of **19** (97 mg) and lithium aluminium hydride (10 mg) in dry tetrahydrofuran (2.0 ml) was stirred at room temperature for 1 h. After the same work-up as described for the preparation of **14**, the crude product was immediately oxidized with pyridinium chlorochromate (90 mg) in dichloromethane (2.0 ml) at room temperature for 1.5 h. The mixture was poured into aqueous sodium carbonate and extracted with ether. The ether extract was washed successively with brine, dilute hydrochloric acid, and brine. The dried extract was evaporated *in vacuo* to give a crude product, which was purified by column chromatography on silica gel (10 g), using ether–benzene (1: 99) as the eluent, to give **4** (75 mg: 88%). The IR and ^{1}H NMR spectra of **4** were identical with those of the authentic sample.[3] Reduction[3] of **4** with lithium aluminium hydride in dry tetrahydrofuran gave **14**.

*2β,20-Epoxy-12-methoxyabieta-8,11,13-triene (**20**).* A mixture of **14** (250 mg), lead tetraacetate (90%: 390 mg), iodine (200 mg), and dry hexane (10 ml) was stirred at room temperature for 2 h and more lead tetraacetate (390 mg) was added. The mixture was stirred for an additional 4 h and diluted with ether. The organic solution was separated and washed successively with aqueous sodium hydrogencarbonate, aqueous sodium thiosulfate, and brine. The dried solution was evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (30 g), using ether–benzene (1: 99) as the eluent, to afford **20** (126 mg: 51%), which was recrystallized from hexane. Mp 159—160 °C; ^{1}H NMR: 1.00 and 1.10 (each 3H and s, –$\underline{C}$(CH_3)$_2$), 1.16 (6H, d, J=7 Hz, –CH($C\underline{H}_3$)$_2$), 3.17 (1H, m, –$C\underline{H}$(CH_3)$_2$), 3.47 and 4.06 (each 1H, d, and J=9 Hz, –OCH_2–), 3.75 (3H, s, –OCH_3), 4.42 (1H, bt, J=5 Hz, C_2–H), 6.65 and 6.72 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 80.27; H, 9.72%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

*Ether Cleavage of **20**.* A mixture of **20** (145 mg) and acetyl *p*-toluenesulfonate (290 mg) in dichloromethane (2.0 ml) was stirred at room temperature for 2 h and then diluted with ether. The ether solution was washed successively with aqueous sodium carbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (15 g), using ether–benzene (1: 99 and then 5: 95) as the eluent, to give 20-acetoxy-12-methoxyabieta-2,8,11,13-tetraene (**21**) (137 mg: 83 %), which was recrystallized from methanol. Mp 116—117 °C; IR: 1727 cm^{-1}; ^{1}H NMR: 1.03 and 1.08 (each

3H and s, $-C(CH_3)_2$), 1.16 and 1.19 (each 3H, d, and J= 7 Hz, $-CH(CH_3)_2$), 1.90 (3H, s, $-OCOCH_3$), 3.79 (3H, s, $-OCH_3$), 4.27 (2H, bs, $-CH_2O-$), 5.55 (2H, m, C_2–H and C_3–H), 6.68 and 6.77 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 77.22; H, 9.10%. Calcd for $C_{23}H_{32}O_3$: C, 77.49; H, 9.05%.

Further elution gave 20-acetoxy-12-methoxy-2α-tosyloxyabieta-8,11,13-triene (**22**) (28 mg: 11%). IR: 1733 cm^{-1}; ^1H NMR: 0.96 and 0.99 (each 3H and s, $-C(CH_3)_2$), 1.16 (6H, bd, $-CH(CH_3)_2$), 2.00 (3H, s, $-OCOCH_3$), 2.48 (3H, s, $-C_6H_4CH_3$), 3.75 and 4.62 (each 1H, d, and J=11 Hz, $-CH_2O-$), 3.78 (3H, s, $-OCH_3$), 4.2—4.9 (1H, m, C_2–H), 6.55 and 6.75 (each 1H and s, C_{11}–H and C_{14}–H), 7.34 and 7.83 (each 2H, d, and J=8 Hz, $-C_6H_4CH_3$).

*Conversion of **22** into **20**.* A mixture of **22** (59 mg), potassium carbonate (10 mg), methanol (3.0 ml), and water (2 drops) was refluxed for 2.5 h. The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (5.0 g), using ether–benzene (1:99) as the eluent, to give **20** (24 mg: 69%).

*20-Acetoxy-12-methoxyabieta-8,11,13-triene (**23**).* A mixture of **21** (191 mg) and PtO_2 (20 mg) in ethanol (6.0 ml) was subjected to catalytic hydrogenation at room temperature for 70 min. After the usual work-up, the crude product was purified by column chromatography on silica gel (20 g), using ether–benzene (1:99) as the eluent, to give **23** (178 mg: 93%). IR: 1725 cm^{-1}; ^1H NMR: 1.00 (6H, s, $-C(CH_3)_2$), 1.14 and 1.17 (each 3H, d, and J=7 Hz, $-CH(CH_3)_2$), 1.85 (3H, s, $-OCOCH_3$), 3.76 (3H, s, $-OCH_3$), 4.01 and 4.51 (each 1H, d, and J=10 Hz, $-CH_2O-$), 6.60 and 6.72 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 77.19; H, 9.58%. Calcd for $C_{23}H_{34}O_3$: C, 77.05; H, 9.56%.

*12-Methoxyabieta-8,11,13-trien-20-ol (**24**).* A mixture of **23** (178 mg) and lithium aluminium hydride (20 mg) in dry tetrahydrofuran (4.0 ml) was stirred at room temperature for 2.5 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was purified by column chromatography on silica gel (20 g), using ether–benzene (3:97) as the eluent, to give **24** (149 mg: 95%). IR: 3585 cm^{-1}; ^1H NMR: 0.98 (6H, s, $-C(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 3.53 and 3.80 (each 1H, d, and J=11 Hz, $-CH_2OH$), 3.79 (3H, s, $-OCH_3$), 6.63 and 6.79 (each 1H and s, C_{11}–H and C_{14}–H).

*Methyl 12-Methoxy-7-oxoabieta-8,11,13-trien-20-oate (**25**).* Jones reagent (2.5 M: 1.1 ml) was added to a stirred solution of **24** (176 mg) in acetone (3.5 ml) at 5 °C. The mixture was stirred at this temperature for 30 min and then at room temperature for 1.5 h, diluted with water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was methylated with diazomethane at room temperature. The crude product was purified by column chromatography on silica gel (20 g), using ether–benzene (1:99) as the eluent, to give **25** (80 mg: 40%), which was recrystallized from methanol. Mp 168.5—169 °C; IR: 1720, 1660 cm^{-1}; ^1H NMR: 0.83 and 0.98 (each 3H and s, $-C(CH_3)_2$), 1.20 and 1.25 (each 3H, d, and J=7 Hz, $-CH(CH_3)_2$), 3.57 (3H, s, $-CO_2CH_3$), 3.89 (3H, s, $-OCH_3$), 6.70 (1H, s, C_{11}–H), 7.79 (1H, s, C_{14}–H). Found: C, 73.85; H, 8.72%. Calcd for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44%.

*Methyl 12-Methoxyabieta-6,8,11,13-tetraen-20-oate (**26**).* A mixture of **25** (80 mg) and sodium borohydride (20 mg) in ethanol (2.0 ml) was stirred at room temperature for 4 h. The mixture was diluted with aqueous ammonium chloride and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was dissolved in dichloromethane (1.0 ml) and acetyl *p*-toluenesulfonate (140 mg) was added. The reaction mixture was stirred at room temperature for 30 min, diluted with aqueous sodium hydrogencarbonate, and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using benzene as the eluent, to give **26** (55 mg: 71%), which was recrystallized from methanol. Mp 135—136 °C, IR: 1705 cm^{-1}; ^1H NMR: 0.85 and 1.03 (each 3H and s, $-C(CH_3)_2$), 1.16 and 1.19 (each 3H, d, and J=7 Hz, $-CH(CH_3)_2$), 2.42 (1H, t, J=3 Hz, C_5–H), 3.43 (3H, s, $-CO_2CH_3$), 3.82 (3H, s, $-OCH_3$), 5.87 and 6.28 (each 1H, dd, and J=3, 9 Hz, C_6–H and C_7–H), 6.69 and 6.77 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 76.99; H, 9.06%. Calcd for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83%.

*Methyl 12-Methoxyabieta-8,11,13-trien-20-oate (**27**).* A mixture of **26** (23 mg) and PtO_2 (5.0 mg) in ethanol (6.0 ml) was subjected to catalytic hydrogenation at room temperature for 1.5 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (Merck, 0.063—0.200 mm, 5.0 g), using benzene as the eluent, to give **27** (23 mg: 99%), which was recrystallized from methanol. Mp 111—112 °C, IR: 1710 cm^{-1}; ^1H NMR ($CDCl_3$): 0.79 and 0.98 (each 3H and s, $-C(CH_3)_2$), 1.19 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 3.57 (3H, s, $-CO_2CH_3$), 3.76 (3H, s, $-OCH_3$), 6.74 and 6.88 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 76.43; H, 9.35%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%. The ^1H NMR spectrum of **27** was identical with that[1] of methyl pisiferate methyl ether.

*Pisiferic Acid (12-Hydroxyabieta-8,11,13-trien-20-oic Acid) (**1**).* A mixture of **27** (33 mg) and anhydrous aluminium bromide (250 mg) in ethanethiol (1.0 ml) was stirred at room temperature for 13 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (Mallinckrodt, Silic AR CC-4, 5.0 g), using ether–benzene (1:9) as the eluent, to give **1** (28 mg: 93%), which was recrystallized from ether–hexane. Mp 226—227 °C (sublimed); IR: 3600, 3500—2400, 1690 cm^{-1}; ^1H NMR ($CDCl_3$: 90 MHz): 0.84 and 0.97 (each 3H and s, $-C(CH_3)_2$), 1.21 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 6.68 and 6.89 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 76.19; H, 9.19 %. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%. The IR and ^1H NMR spectra of the synthetic **1** were identical with those of natural pisiferic acid.

*Methyl Pisiferate (Methyl 12-Hydroxyabieta-8,11,13-trien-20-oate) (**2**).* A mixture of **27** (20 mg), anhydrous aluminium chloride (54 mg), ethanethiol (0.2 ml), and dichloromethane (1.0 ml) was stirred at 0—5 °C for 4 h. After the same work-up as described for the preparation of **1**, the crude product was chromatographed on silica gel (Merck, 0.063—0.200 mm, 5.0 g), using ether–benzene (5:95) as the eluent, to give **2** (19 mg: 97%), which was recrystallized from ether–hexane. Mp 170—171.5 °C; IR: 3610, 3350br, 1719 cm^{-1}; ^1H NMR ($CDCl_3$: 90 MHz): 0.74 and 0.93 (each 3H and s, $-C(CH_3)_2$), 1.18 (6H, d, J=7 Hz, $-CH-$

($C\underline{H}_3)_2$), 3.12 (1H, m, $-C\underline{H}(CH_3)_2$), 3.53 (3H, s, $-CO_2CH_3$), 5.39 (1H, bs, -OH), 6.71 and 6.88 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 76.32; H, 9.36%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%. The IR and ^{1}H NMR spectra of the synthetic **2** were identical with those of natural methyl pisiferate.

20-Acetoxyabieta-8,11,13-trien-12-ol (28). A mixture of **23** (121 mg), anhydrous aluminium chloride (270 mg), ethanethiol (0.2 ml), and dichloromethane (2.0 ml) was stirred at 0—5 °C for 6.5 h. After the same work-up as described for the preparation of **1**, the crude product was purified by column chromatography on silica gel (15 g), using ether–benzene (5:95) as the eluent, to give **28** (87 mg: 74%); IR: 3610, 3375br, 1726 cm^{-1}; ^{1}H NMR: 0.99 (6H, s, $-\overset{|}{C}(CH_3)_2$), 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.85 (3H, s, $-OCOCH_3$), 4.10 and 4.50 (each 1H, d, and J=11 Hz, $-CH_2O-$), 5.85 (1H, s, -OH), 6.53 and 6.73 (each 1H and s, C_{11}–H and C_{14}–H).

Pisiferol (Abieta-8,11,13-triene-12,20-diol) (3). A mixture of **28** (87 mg) and lithium aluminium hydride (20 mg) in dry tetrahydrofuran (1.0 ml) was stirred at room temperature for 1 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (1:9) as the eluent, to give **3** (67 mg: 88%), which was recrystallized from benzene. Mp 185—188 °C (softened at *ca.* 82 °C); IR: 3590, 3325br cm^{-1}; ^{1}H NMR ($CDCl_3$: 90 MHz): 0.91 and 0.93 (each 3H and s, $-\overset{|}{C}(CH_3)_2$), 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.17 (1H, m, $-C\underline{H}(CH_3)_2$), 3.61 and 3.97 (each 1H, d, and J=11 Hz, $-C\underline{H}_2OH$), 6.10 (1H, bs, -OH), 6.63 and 6.89 (each 1H and s, C_{11}–H and C_{14}–H). Found: C, 79.62; H, 10.23%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%. The IR and ^{1}H NMR spectra of the synthetic **3** were identical with those of natural pisiferol.

The authors are grateful to Dr. M. Yatagai, Forestry and Forest Products Research Institute, for kindly supplying the natural pisiferic acid and spectral data. This work was partially supported by Grant-in-Aid for Scientific Research No. 56540324 from the Ministry of Education, Science and Culture.

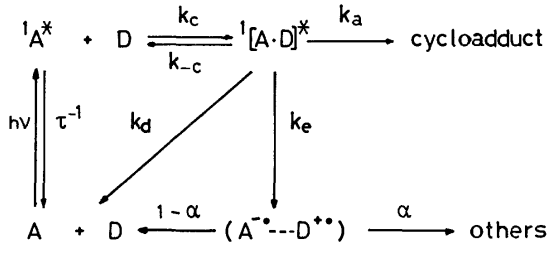
(Received October 29, 1981)

Solvent effects on the fluorescence-quenching rate constants (γk_c) as well as on the quantum yields ($\phi^{\infty}{}_{-A}$) of photoreactions have been investigated for the nonemissive exciplex systems in which 1- or 2-naphthonitrile is the electron acceptor whereas the donors are some enol ethers, a few simple alkenes, furan, 2-methylfuran, and ethyl phenyl ether. On the basis of the assumption of the solvent as a continuous dielectric medium, the relationships between electronic structures and reactivities of nonemissive exciplexes have been qualitatively estimated from the plots of log γk_c and log $[\phi^{\infty}{}_{-A}/(1-\phi^{\infty}{}_{-A})]$ *vs.* $(\varepsilon-1)/(2\varepsilon+1)$. In nonpolar and moderately polar aprotic solvents, the nonemissive exciplexes have low charge-transfer contributions but relatively high reactivities in the cycloaddition while much larger charge-transfer contributions are induced in more polar alcoholic solvents; the reactivities in the protic solvents decrease with the increase of solvent polarity. For some exciplexes, the occurrence of complete electron transfer in very polar solvents such as ethanol, methanol, and acetonitrile is strongly suggested from the product distributions. The possible availability of $E_T(30)$ or Z value as a scale of solvent polarity has been tested for the solvent effects on the processes from the nonemissive exciplexes.

It is now widely accepted that the exciplex formation is a general mechanistic pathway for interactions between electronically excited and ground-state molecules involving luminescence quenching[2] as well as photoreactions,[3] especially photocycloadditions.[3–5] We have extensively investigated photocycloadditions of aromatic nitriles to olefinic and furan compounds,[4] most of which proceed *via* totally or virtually nonemissive exciplexes.[4f–k,6] Scheme 1 shows the major mechanistic pathways for the photoreactions of aromatic nitriles (electron acceptors, A) with olefinic and furan compounds (electron donors, D), where $^1[A\cdot D]^*$ and $(A^{\mp}\cdots D^{\pm})$ represent an exciplex and an ion-radical pair respectively. The complete electron-transfer process (k_e) is negligeble in nonpolar solvents but may be important in very polar solvents such as acetonitile and methanol.[2,4f,4k,7]



Scheme 1.

These dynamic processes probably depend on the electronic nature of exciplexes that can be simply represented by

$$^1[A\cdot D]^* \equiv {}^1A^*D \leftrightarrow A^-D^+.$$

A stimulating problem in the chemistry of exciplex is to establish the relationships between reactivities and electronic structures of exciplexes.[2b,5] Although exciplex emissions can provide a direct clue to the estimation of the electronic structures,[2c–e,8] the exciplex intermediates postulated in numerous photoreactions are very often nonemissive. In these cases, the charge-transfer (CT) nature of nonemissive exciplexes has been usually discussed from the linear correlations between the logarithm of luminescence-quenching rate constants and ionization potentials of D or electrochemical reduction potentials of A for a family of similar A-D pairs.[9–12] However, the linear correlations can reveal only the linear free-energy relationships in the quenching process.[11,13]

In order to establish structure-reactivity relationships in the chemistry of nonemissive exciplexes, therefore, it is required to find suitable phenomena that allow us to estimate their electronic structures. Since exciplexes are more or less polar, their physical and chemical consequences should be affected by the sorrounding medium, depending on the CT nature. Therefore, solvent effects on kinetics may be diagnostic for the estimation of the CT nature of nonemissive exciplexes. We have found that the naphthonitrile-olefin and furan systems reveal remarkable solvent dependences of both fluorescence-quenching rate constants and quantum yields of the photoreactions. In the present work, we have performed qualitative, steady-state analyses of the solvent effects on the basis of the dielectric continuum model[14] and have tested the applicability of E_T (30),[15] an empirical scale of solvent polarity.

Results

Reaction Systems. Chart 1 lists the electron acceptors (A) and the donors (D) employed in the present work. Table 1 shows the selected A-D pairs that

are classified into the four cases. Case I is the reaction system that gives only the cycloadduct(s) irrespective of solvent polarity when photoreactions occur. The photoreactions of case II give again the cycloadducts in nonpolar and moderately polar solvents while other products are formed in very polar solvents (*vide infra*). In both cases, exciplex emissions

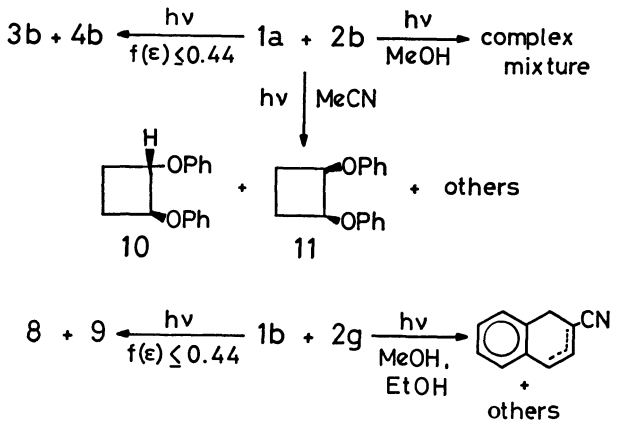

Scheme 3.

are not detectable or, if any, negligebly weak in any solvent at room temperature. The **1a-2e** pair (case III) was employed as a typical reactive exciplex that is emissive in measurable intensities at room temperature. The **1a-2h** pair (case IV) is a reference exciplex that is fairly emissive but undergoes no net photoreaction. The types of photocycloadditions are shown in Scheme 2. Most of the cycloadducts are known compounds,[4)] and the structures of a few unknown adducts were readily determined by comparison of their spectroscopic data with those of similar known compounds.

The obligatory intermediacy of singlet exciplexes in these photocycloadditions has been established by the oxygen-quenching method for the **1a-2a** and **1a-2e** pairs,[16)] by negative temperature effects on the photoreaction of **1a** and **2f**,[6a)] and by exciplex quenching by pyridine for the **1b-1a**, **1b-2d**, **1b-2e**, and **1b-2g** pairs.[4j,6b,6c)] The *endo* selective nature of the photocycloaddition of **1a** to **2b** strongly suggests the intervention of an exciplex intermediate which determines the stereoselectivity.

Fluorescence Quenching in Various Solvents. Table 2 lists fluorescence lifetimes of **1a** and **1b** in deaerated and aerated solutions (τ_F and τ_F^{air}) and the parameters of solvent polarity including dielectric constant (ε), its function [$f(\varepsilon)=(\varepsilon-1)/(2\varepsilon+1)$], and the $E_T(30)$ values in kcal mol^{-1}. Quenching of the fluorescence of **1a** or **1b** by **2a**—**h** was performed for air-saturated solutions, the quenching rate constants (γk_c) being thus determined from the linear Stern-Volmer plots using Eq. 4. Table 3 summarizes the logarithm of γk_c for the selected A-D pairs.

Solvent Effects on Product Distribution. Table 4 lists the *endo*/*exo*-isomer ratios (**3**/**4**) of the cycloadducts in the photoreactions of the **1a-2a** and **1a-2c** pairs (case I) in various solvents. There can be seen a tendency that the ratios in the alcoholic solvents are slightly, but significantly, higher than those in the less polar aprotic solvents. Other products than the cycloadducts were not formed even in acetonitrile and methanol.

On the other hand, irradiation of the A-D pairs of case II commonly gave complex mixtures of other products than the cycloadducts in the solvents of $f(\varepsilon)>0.46$; an increase of solvent polarity results in an increase of formation of complex mixtures. In the case of the **1a-2f** pair, irradiation of ethanol, methanol, and acetonitrile solutions gave complex mixtures involving oligomeric and polymeric compounds and a small amounts of **7**, as demonstrated by GLC, GPC, and NMR (see Fig. 8). In contrast the photoproduct in ethyl acetate and *t*-butyl alcohol is exclusively **7**.

The photoreaction of **1a-2b** pair in either *t*-butyl alcohol or ethyl acetate gave exclusively the cyclo-

a) See abbreviations in Chart 1 and Table 2. b) Determined at 313 nm for aerated solutions containing 3.5—4.5 × 10^{-4} mol dm^{-3} in **1a** and 1.0 mol dm^{-3} in the olefins or 2.6 mol dm^{-3} in furan; averaged values for three runs with uncetainties of ±(8—15)%. c) Calculated by multiplying ϕ_{-A} by $(1+K_{SV}[D])/K_{SV}[D]$; see text. d) It is assumed that $\phi_{-A} \simeq \phi^{\infty}_{-A}$, since $K_{SV}[D](=51—95) \gg 1$ in all the solvents. e) Other products than the cycloadduct (**7**) were formed.

adduct (**3b**), while the dimers of **2b** (**10** and **11**)[17] were formed in acetonitrile as the major detectable products. The irradiation of a methanolic solution gave complex mixtures involving **3b**, **10**, and **11** in small amounts. The photoreaction of the **1b-2g** pair in *t*-butyl alcohol or in less polar solvents gave again the cage compounds (**8** and **9**) in >80% yields while the irradiation in methanol or ethanol gave complex mixtures from which 1,2- and 1,4-dihydro-2-naphthonitriles were obtained. Scheme 3 summarizes the photoreactions of the **1a-2b** and **1b-2g** pairs in different solvents.

Quantum Yields in Various Solvents. Table 5 shows the quantum yields (ϕ_{-A}) for disappearance of **1a** and the calculated limiting quantum yields (ϕ^{∞}_{-A}) for some selected A-D pairs in aerated solutions. The ϕ^{∞}_{-A} values were calculated by multiplying ϕ_{-A} by $(K_{SV}[D]+1)/K_{SV}[D]$; K_{SV} and [D] represent, respectively, the slopes of the Stern-Volmer plots for the fluorescence quenching and the concentration at which ϕ_{-A} was determined. This method was confirmed to be approximately valid since the calculated values of ϕ^{∞}_{-A} in cyclohexane for the **1a-2a** and **1a-2f** pairs are almost identical to the observed values (0.51 and 0.49 respectively) obtained from the intercepts of the usual plots of ϕ_{-A}^{-1} *vs.* $[D]^{-1}$. In cases where $K_{SV}[D] \gg 1$, it was assumed that $\phi_{-A} \simeq \phi^{\infty}_{-A}$. In the quantum-yield measurements, concentrations of **1a** were set very similar to those used in the fluorescence-quenching experiments.

Discussion

Kinetic Representation and Free-energy Relationships. On the basis of Scheme 1, steady-state analysis gives the Stern-Volmer equation for fluorescence quenching (Eq. 3) and the rate equation for ϕ_{-A} (Eq. 4); Eq. 5 represents the rate equation of the limiting quantum yield for disappearance of A. In these equations, the quenching of both $^1A^*$ and $^1[A\cdot D]^*$ by molecular oxygen (Eqs. 1 and 2) has been taken into consideration since both the fluorescence-quenching and quantum-yield measurements were performed for aerated solutions. However, both $k_q[O_2]$ and $k^c_q[O_2]$ are probably almost constant independently on solvent polarity since the reported solubilities of O_2 upon air saturation into the solvents employed are in the rage of (2—3) × 10^{-3} mol dm^{-3} at 25 °C[18] and since it is reasonable to assume that $k_q \simeq k^c_q \simeq 2 \times 10^{10}$ dm^3 mol^{-1} s^{-1}.[16b,c,19] Moreover, it was confirmed that the presence of O_2 diminishes ϕ_{-A} in cyclohexane and ethyl acetate for the A-D pairs employed in the quantum-yield measurements; the irradiation in these solvents under air saturation gave no other products than the cycloadducts in significant amounts. Therefore, chemical processes involving O_2 can be safely neglected.

$$^1A^* + O_2 \xrightarrow{k_q} A + O_2 \quad (1)$$

$$^1[A\cdot D]^* + O_2 \xrightarrow{k^c_q} A + D + O_2 \quad (2)$$

$$\frac{I^{\circ}_F}{I^{D}_F} = 1 + K_{SV}[D] = 1 + \gamma k_c \tau_F^{air}[D] \quad (3)$$

$$\frac{1}{\phi_{-A}} = \frac{1}{\phi^{\infty}_{-A}}\left(1 + \frac{1}{\gamma k_c \tau_F^{air}[D]}\right) \quad (4)$$

$$\frac{1}{\phi^{\infty}_{-A}} = \frac{k_a + \alpha k_e}{k_a + k_d + k_e + k^c_q[O_2]} \quad (5)$$

$$\frac{1}{\tau_F^{air}} = \frac{1}{\tau_F} + k_q[O_2] \quad (6)$$

$$\gamma = \frac{k_a + k_d + k_e + k^c_q[O_2]}{k_a + k_d + k_e + k^c_q[O_2] + k_{-c}} \quad (7)$$

It is well established that $k_c \simeq (1—2) \times 10^{10}$ dm^3 mol^{-1} s^{-1} for a variety of exciplex-forming systems.[2,6b,20,21] In cases where $\gamma k_c \ll 10^{10}$ dm^3 mol^{-1} s^{-1}, therefore, it is reasonable to assume that $\gamma \ll 1$, *i.e.* $(k_a + k_d + k_e + k^c_q[O_2]) \ll k_{-c}$. If this is the case, γk_c can be simplified to Eq. 8 which is then rewritten as Eq. 9; ΔG_c is the free-energy change associated with exciplex formation.

$$\gamma k_c \simeq \frac{k_c}{k_{-c}}(k_a + k_d + k_e + k^c_q[O_2]) \quad (8)$$

$$\log \gamma k_c \simeq -\frac{\Delta G_c}{2.3RT} + \log (k_a + k_d + k_e + k^c_q[O_2]) \quad (9)$$

If an exciplex is a solute that has a dipole moment

of μ_c with a separation of R_c Å, the treatment of the solvent as a continuous dielectric medium gives Eq. 10 for the difference of ΔG_c between the reference solvent (*e.g.* cyclohexane) and the medium of dielectric constant ε.[14,22] Thus Eq. 9 coupled with Eq. 10 gives Eq. 11, predicting that the slope of the plot of log γk_c *vs.* $f(\varepsilon)$ may reflect the dipole moment of an exciplex, if the solvent dependence of k_{-c} is much greater than that of the other rate constants.[20]

$$\Delta\Delta G_c = -\frac{{\mu_c}^2}{{R_c}^3} f(\varepsilon) + \text{constant} \tag{10}$$

$$\Delta \log \gamma k_c = \frac{1}{2.3RT} \times \frac{{\mu_c}^2}{{R_c}^3} f(\varepsilon) + \Delta \log (k_a + k_d + k_e + k_q^c[O_2]) + \text{constant} \tag{11}$$

$$\left[f(\varepsilon) = \frac{\varepsilon - 1}{2\varepsilon + 1} \right]$$

Equation 7 can be rewritten as Eq. 12. It has been reported that the complete electron-transfer process is negligeble in the decay pathways of **1a**——1,2-dimethylcyclopentene exciplex in ethyl acetate,[20] *i.e.* $(k_a + k_d + k_q^c[O_2]) \gg k_e$. This is probably true for the present nonemissive exciplexes in the solvents of $f(\varepsilon) \leq 0.44$, since the cycloadducts are commonly the exclusive products in these solvents and since the ionization potentials of the present donors are higher than that of 1,2-dimethylcyclopentene(7.84 eV);[23] see Table 7. In this case, therefore, Eq. 12 can be reduced to Eq.13. If the cycloaddition occurs from an ex-

$$\frac{\phi^{\infty}_{-A}}{1-\phi^{\infty}_{-A}} = \begin{cases} \dfrac{k_a + \alpha k_e}{k_d + (1-\alpha)k_e + k_q^c[O_2]} & (12) \\ \dfrac{k_a}{k_d + k_q^c[O_2]} & (13) \end{cases}$$

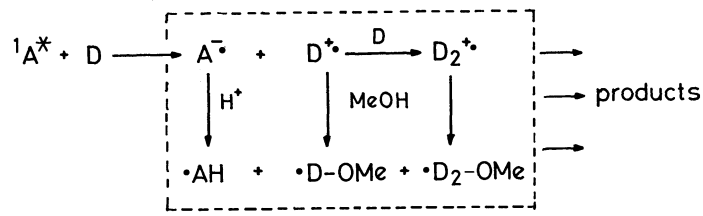
some A-D pairs. Therefore, Eqs. 8 and 9 hold for the fluorescence quenching of the present A-D pairs in most solvents. Figures 1 and 2 show the plots of log γk_c *vs.* $f(\varepsilon)$ for the 8 A-D pairs; the following common features should be noted. (1) The plots give, at least, two linear lines with a break at $f(\varepsilon)\simeq 0.4$. It is therefore suggested that the simple dielectric continuum approximation (Eq. 11) is applicable to the fluorescence-quenching process *via* the nonemissive exciplexes within the limited regions of solvent polarity, *i.e.* at $f(\varepsilon)<0.4$ (nonpolar and moderately polar solvents) and at $f(\varepsilon)>0.4$ (polar alcoholic solvents and acetonitrile). (2) The slopes of the plots at the lower region of $f(\varepsilon)$ are much smaller than those at the higher region (Table 6). On the basis of Eq. 11, therefore, μ_c^2/R_c^3 is much greater in the polar solvents of $f(\varepsilon)>0.4$ than that in the less polar solvents, suggesting that the electronic structures of the nonemissive exciplexes are changed from minor CT contributions in the nonpolar and moderately polar solvents to much larger CT contributions in the polar solvents. Such solvent-induced changes in the electronic nature have been demonstrated for a few emissive exciplexes.[20,24,25] (3) Benzene and dioxane which are nonpolar but polarizable are the out-of-line solvents in most cases. The nonemissive exciplexes would be specifically solvated by these solvents.

In order to obtain further insight into solvent effects on the electronic nature of exciplexes, we have investigated both the solvent-induced shifts of the emission maximum ($\tilde{\nu}_c$, cm^{-1}) and the solvent dependence of γk_c for the emissive **1a-2h** exciplex (case IV). The dipole moment (μ_c) of the exciplex was estimated as usual using Eq. 15. As is shown in Fig. 3A, the plot of $\tilde{\nu}_c$ *vs.* $f'(\varepsilon,n)$ gives a linear correlation at $f'(\varepsilon,n)>0.25$ with a slope of -1.3×10^4 cm^{-1} which corresponds to >10D of μ_c taking $R_c=4.5$—5 Å. This large dipole moment demonstrates the dominant CT contributions in the solvents of $f'(\varepsilon,n)>0.25$. Unfortunately, the plot at $f'(\varepsilon,n)<0.25$ is poorly correlated because of the substantial deviations of $\tilde{\nu}_c$ in benzene and dioxane, though a smaller value of μ_c in the less polar solvents might be suggested (*vide infra*).

$$\tilde{\nu}_c = -\frac{2\mu_c^2}{hcR_c^3}\left(\frac{\varepsilon-1}{2\varepsilon+1}-\frac{n^2-1}{4n^2+2}\right)+\text{constant}$$
$$= -\frac{2\mu_c^2}{hcR_c^3}f'(\varepsilon,n)+\text{constant} \quad (15)$$

Figure 3B shows a plot of log γk_c *vs.* $f(\varepsilon)$ that again consists of two linear lines with a break at $f(\varepsilon)\simeq 0.4$. From these slopes calculations based on Eq. 11 taking $T=298$ K give the values of μ_c^2/R_c^3 that are 1.5×10^4 J mol^{-1} at $f(\varepsilon)<0.4$ and 6.3×10^4 J mol^{-1} at $f(\varepsilon)>0.4$. The latter value is similar to that separately calculated from the linear portion in Fig. 3A (7.8×10^4 J mol^{-1}). Since the slope at $f(\varepsilon)<0.4$ is only one-fourth that at $f(\varepsilon)>0.4$, the CT contributions are perhaps much lower in the less polar solvents. It is thus suggested that Eq. 11 can be used as a convenient basis for qualitative estimation of electronic



Scheme 4.

structures of nonemissive exciplexes, though other physical and chemical properties of solvent should be taken into consideration for sophisticated interpretations of the solvent effects. At any rate the electronic nature of the nonemissive exciplexes seems to be inherently sensitive to the sorrounding medium.

Occurrence of Complete Electron Transfer in Very Polar Solvents: Complete electron transfer from D to $^1A^*$ may occur in very polar solvents as has been established for a variety of exciplex-forming systems.[2,5f,5k,7] Table 7 lists the observed anodic half-peak potentials ($E_{P/2}^{ox}$) and reported ionization potentials of D, the cathodic half-peak potentials of A, and the calculated free-energy changes (ΔG_{ET}) in acetonitrile associated with the complete electron-transfer process. According to the Rehm-Weller treatment,[26] the net rate constant for complete electron transfer reaches the diffusion-controlled limits in cases where $\Delta G_{ET} < -5$—-6 kcal mol^{-1}, *i.e.* $k_{-c} \ll k_e$. Since the calculated values of ΔG_{ET} are substantially negative in most cases, complete electron transfer can, but not necessarily, occur in acetonitrile and probably also in methanol.

In particular, the occurrence should be taken into consideration for the A-D pairs of case II in the polar solvents of $f(\varepsilon) > 0.44$ as indicated by the photoproducts in these solvents. The photoreaction of the **1a-2b** pair in acetonitrile clearly indicates the occurrence of complete electron transfer since the photodimerization of **2b** *via* the cation radical has now been well established.[27] The attenuation of the dimerization of **2b** in methanol can be interpreted in terms of the nucleophilic addition of methanol to the cation radical of **2b** since it is now well-known that alcohols can attack on cation-radical species of olefinic and furan compounds.[4k,28] Therefore, formation of complex mixtures in the photoreactions of methanolic solutions of the **1a-2b**, **1a-2f**, and **1b-2g** pairs can be considered to be initiated by complete electron transfer from D to $^1A^*$ followed by complex reactions involving a variety of reactive species such as $A^{\cdot-}$, its protonated species, $D^{+\cdot}$, dimer cation radicals of D, and methoxylated species of the cation radicals (Scheme 4).[4k] Moreover, McCullough *et al.* reported that the photoreactions of **1a** and **1b** with **2d** in such very polar solvents as acetonitrile and methanol proceeds by way of complete electron transfer.[7]

In this regard, it should be noted that sharp increases of log γk_c can be seen at $f(\varepsilon) > 0.46$ in the plots for the **1a-2f**, **1b-2d**, and **1b-2g** pairs, presumably arising from increasing contributions of k_e to γ. In case I, however, the occurrence of complete electron transfer is questionable even in acetonitrile since the cycloadditions exclusively occurred in any solvent.

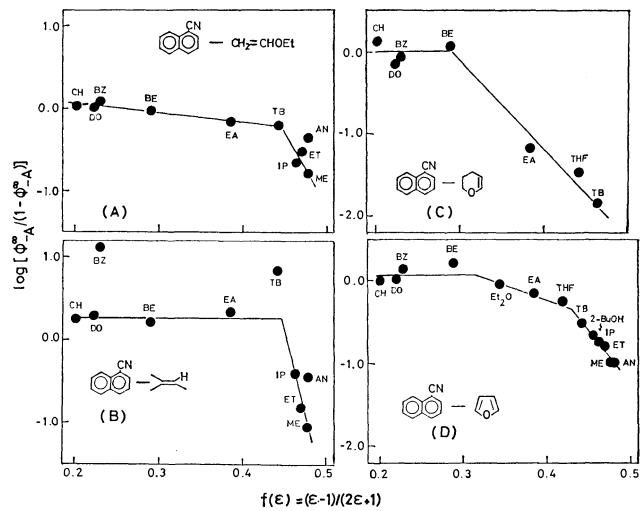


Fig. 4. Plots of $\log[\phi^{\infty}_{-A}/(1-\phi^{\infty}_{-A})]$ *vs.* $f(\varepsilon)$ [$=(\varepsilon-1)/(2\varepsilon+1)$] for (A) **1a-2a**, (B) **1a-2c**, (C) **1a-2e**, and (D) **1a-2f** pairs; see abbreviations in Chart 1 and Table 2.

Solvent Effects on Reactivities of Nonemissive Exciplexes. Figure 4 shows the plots of $\log[\phi^{\infty}_{-A}/(1-\phi^{\infty}_{-A})]$ *vs.* $f(\varepsilon)$ for the **1a-2a**, **1a-2c**, **1a-2f**, and **1a-2e** pairs. Since the complete electron-transfer process (k_e) can be neglected for these A-D pairs, at least, in solvents of $f(\varepsilon) < 0.44$, Eq. 13 can be used for analyses of the plots as a basis for the estimation of exciplex reactivities. In case of the **1a-2f** pair (case II), however, Eq. 12 should be used at $f(\varepsilon) > 0.44$ where complete electron transfer may occur as a competitive or dominant pathway.

For the **1a-2a** pair, k_a and k_d in cyclohexane have been determined by the oxygen-quenching method to be $\approx 10^8$ s^{-1} and $\approx 5 \times 10^7$ s^{-1} respectively.[16d] Since $k_q^c[O_2]$ approximately equals $(4—6) \times 10^7$ s^{-1} independently on solvent polarity, Fig. 4A suggests that both k_a and k_d do not greatly depend on solvent polarity at $f(\varepsilon) < 0.44$. On the other hand, the increase of solvent polarity at $f(\varepsilon) > 0.44$ leads to a decrease of k_a and/or an increase of k_d. A similar conclusion appears to be obtainable from Fig. 4B for the **1a-2c** pair, though the ϕ^{∞}_{-A} values in benzene and *t*-butyl alcohol are unusually high relative to those in the other solvents. On the other hand, the plot for the **1a-2e** pair (Fig. 4C) demonstrates drastic changes of k_a and/or k_d at $f(\varepsilon) > 0.3$.

Lewis and Hoyle reported that the k_a values for the diphenylvinylene carbonate–2,5-dimethyl-2,4-hexadiene exciplex remarkably decrease with solvent polarity.[24] This solvent dependence of k_a has been interpreted on the basis of the Michl's theory;[29] this

theory predicts that k_a is the rate constant for the adiabatic process of avoided crossing from the polar exciplex minimum on the singly excited hypersurface to the less polar or nonpolar doubly excited state. Activation barriers for the adiabatic process should therefore be higher in more polar solvents since an exciplex of polar CT nature is more stabilized by solvation than the less polar transition state. A similar conclusion was put forth by Caldwell and Creed who observed the dependence of k_a and the independence of k_d on the degrees of CT contributions for some emissive cyanophenanthrene–styrene exciplexes.[5f,30]

On the basis of the Michl's theory, therefore, the solvent-dependent changes in ϕ^{∞}_{-A} can be expected to arise mainly from the changes in k_a.[31] If this is the case, the plots of $\log[\phi^{\infty}_{-A}/(1-\phi^{\infty}_{-A})]$ *vs.* $f(\varepsilon)$ are thus diagnostic for the elucidation of the observed solvent effects on reactivities of the nonemissive exciplexes. For example, the large negative slope of the plots at $f(\varepsilon)>0.3$ in Fig. 4C for the **1a-2e** exciplex can be interpreted to reflect large electronic changes in the cycloaddition process which presumably occur from the very polar exciplex state to the much less polar transition state. The very polar nature of the **1a-2e** exciplex was confirmed by the plot of $\bar{\nu}_c$ *vs.* $f'(\varepsilon,n)$ that gives a linear correlation with a slope of $-(1.5\pm0.2)\times10^4$ cm^{-1} at $f'(\varepsilon,n)>0.2$.[32a] The adiabatic process in which large electronic changes occur probably requires larger reorganization of the surrounding slovent molecules in more polar solvents at $f(\varepsilon)>0.3$, thus leading to greater ΔG_{sol}^{*}. In the much less polar and nonpolar solvents ($f(\varepsilon)<0.3$), however, solvation shells round the exciplex would be so weak that ΔG_{sol}^{*} might not significantly contribute to the total activation energies of the cycloaddition process.

Thus the plots in Figs. 4A and 4B suggest that electronic changes are only minor in the adiabatic process from the **1a-2a** or **1a-2c** exciplex to the transition state even in the moderately polar solvents of $f(\varepsilon)\leq0.44$. In other words, these nonemissive exciplexes seem to be almost nonpolar in these less polar solvents. On the other hand, substantial CT nature might be induced by specific solute-solvent interactions in the polar solvents of $f(\varepsilon)>0.44$, thus leading to greater ΔG_{sol}^{*} with higher solvent polarity. Moreover, conformational changes of the exciplexes would also occur on going from the aprotic solvents to the protic solvents since the *endo*/*exo*-isomer ratios are changed; the increase of solvent polarity at $f(\varepsilon)>0.44$ would make conformations of the exciplexes less favorable for the cycloaddition; solvent-dependent changes in R_c have been suggested.[20,25]

The **1a-2f** exciplex (case II) reveals different behaviors in the solvent dependence of ϕ^{∞}_{-A} as shown in Fig. 4D. Since the plot gives a linear line with a low negative slope at the region of $f(\varepsilon)$ from 0.3 to 0.44, this exciplex seems to be significantly, but slightly, ionic in these solvents. On the other hand, the greater negative slope at $f(\varepsilon)>0.44$ presumably arises from changes in the electronic and steric configuration of the exciplex as well as from the participation of complete electron transfer. Since both k_e and

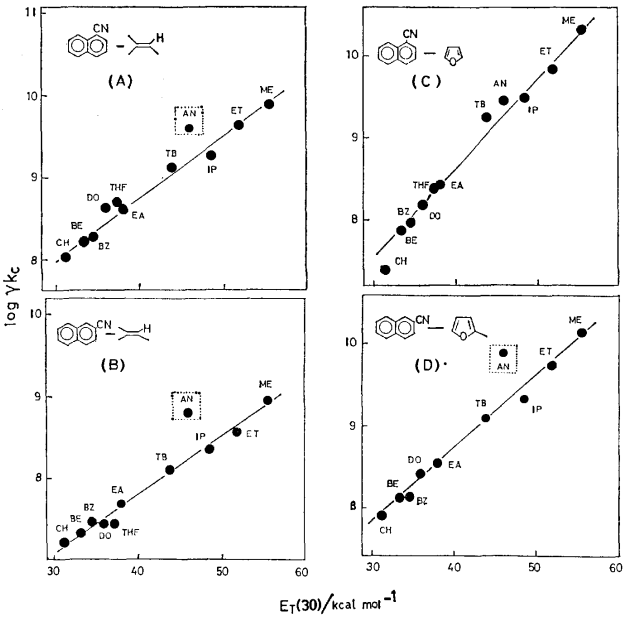

Fig. 5. Plots of $\log \gamma k_c$ *vs.* $E_T(30)$ for (A) **1a-2c**, (B) **1b-2c**, (C) **1a-2f**, and (D) **1b-2g** pairs; see abbreviations in Chart 1 and Table 2.

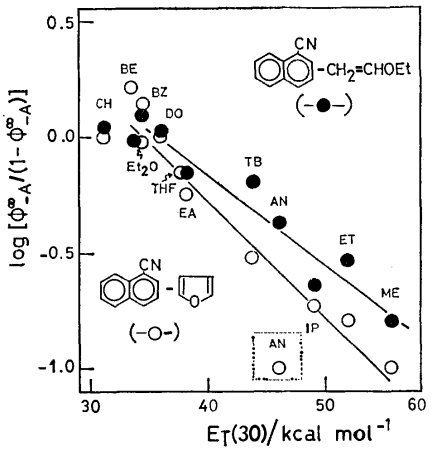

Fig. 6. Plots of $\log[\phi^{\infty}_{-A}/(1-\phi^{\infty}_{-A})]$ *vs.* $E_T(30)$ for **1a-2f** (—○—) and **1a-2a** (—●—) pairs; see abbreviations in Chart 1 and Table 2.

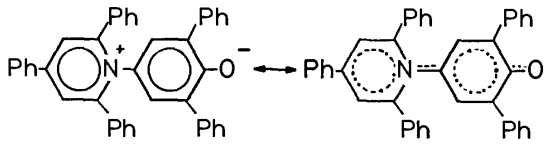
α probably increase with the increase of solvent polarity, the decrease of k_a would be, at least in part, cancelled out. In the extreme case where complete electron transfer is dominant, ϕ^{∞}_{-A} should be α, probably the value in acetonitrile or methanol that is very low (≈0.08). Since k_a is comparable with or much smaller than αk_e at $f(\varepsilon)>0.44$, the decrease of k_a with the increase of solvent polarity might be much more remarkable than that expected from the slope of the plot at $f(\varepsilon)>0.44$.

Applicability of $E_T(30)$ to the Solvent Effects on the Nonemissive Exciplexes. Kosower recomended the use of the $E_T(30)$ or Z value as a suitable scale of solvent polarity for exciplex systems.[33] In keeping this in mind, moreover, the finding that the logarithmic values of product ratio are linearly correlated with the Z scale for the naphthalene–acrylonitrile system in protic media[34] prompts us to investigate the availability of

$E_T(30)$ for elucidation of solvent effects on the processes from the exciplexes. Figure 5 shows typical plots of $\log \gamma k_e$ *vs.* $E_T(30)$ for the four selected A-D pairs; similar plots which are not shown here were also obtained for the other A-D pairs. Each plot gives a single linear line with a relatively good correlation irrespective of the solvent nature throughout the full range of solvent polarity employed; acetonitrile is the only out-of-line solvent. Figure 6 shows the plots of $\log[\phi^{\infty}_{-A}/(1-\phi^{\infty}_{-A})]$ *vs.* $E_T(30)$ for the **1a-2a** and **1a-2f** pairs, both of which reveal linear correlations with negative slopes at $E_T(30)>38$ kcal mol^{-1} but tend to level off at the lower region of $E_T(30)$; a remarkable deviation can be observed for the value of **1a-2f** pair in acetonitrile.

The $E_T(30)$ scale is based on the solvatochromic shifts of the longest absorption band of *p*-(1-pyridinio)-phenoxide **30** whose electronic structures are more polar like **30a** in the ground state and less polar like **30b** in the excited state;[15,35] the increase of solvent



30a 30b

polarity causes stabilization of the ground state and destabilization of the excited Franck-Condon state, thus leading to the increase in the excitation energies. Therefore, the linear plots in Figs. 5 and 6 indicate the involvement of consequential changes from a less polar state to a more polar one in the fluorescence-quenching pocess and from a more polar intermediate to a less polar transition state in the cycloaddition process.

From these plots alone, however, it is hard to perceive any solvent-induced changes in the electronic structures of the exciplexes or in the mechanisms of the fluorescence quenching and photoreactions, an observation which is inconsistent with the discussions based on the dielectric continuum assumption. Since **30** is a polar solute of the mobile π electronics, the excitation energies, $E_T(30)$, may be perturbed by a variety of solute-solvent interactions involving hydrogen bonding in protic solvents. Taft, Abboud, and Kamlet recently reported that the $E_T(30)$ scale can be expressed by a multiple linear regression equation of the solvent dipole moment and $(n^2-1)/2(2n^2+1)$ for nonhydrogen-bonding solvents;[36] combined contributions of dipole-dipole interactions and solvent polarizability are involved in this scale unlike the electrostatic model. Therefore, the linear plots in Figs. 5 and 6 can not be simply interpreted but should be regarded to reflect only the parallel relationships in the solvent dependencies between the excitation energies of **30** and the free-energy changes in the fluorescence-quenching and cycloaddition processes.

Finally the plot of $\bar{\nu}_e$ *vs.* $E_T(30)$ for the **1a-2h** exciplex is shown in Fig. 7, which gives two linear lines with a break at $E_T(30)\approx 38$ kcal mol^{-1}, suggesting a solvent-induced change in the electronic nature of the

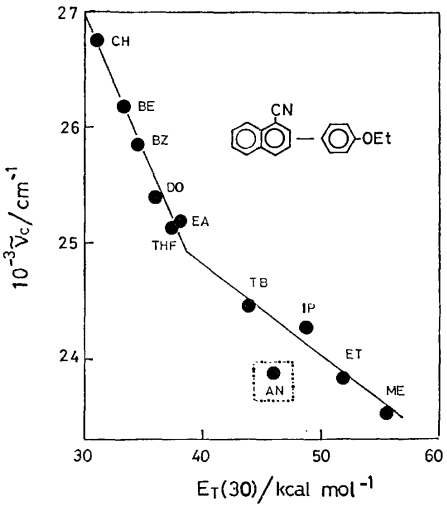


Fig. 7. Plot of $\bar{\nu}_e$ *vs.* $E_T(30)$ for **1a-2h** pair; see abbreviations in Chart 1 and Table 2.

exciplex. A similar plot which is not shown here was also obtained for the **1a-2e** exciplex.[32b] Since the linearity is strikingly good, the solvatochromic shifts of the exciplex emission is probably again very similar to those of the absorption band of **30** in the origin. At any rate, it should be emphasized that solvent effects on the processes from exciplexes involving reversible dissociation, cycloaddition, and emission parallel those on the electronic excitation of **30**. The good linearity of the plots using $E_T(30)$ as a scale of solvent polarity seems to indicate something essential though detailed discussions can not be made because of the lack of information concerning the physical and chemical entities involved in $E_T(30)$.

Conclusion

Solvent effects on the reversible dissociation and cycloaddition processes from the nonemissive naphthonitrile-olefin and furan exciplexes have been qualitatively analyzed by steady-state kinetics based on the assumption of the solvent as a continuous dielectric medium. The nonemissive exciplexes are commonly changed in both the electronic structures and the reactivities when the medium is changed from a nonpolar or moderately polar aprotic solvent to a polar protic solvent. In the less polar aprotic solvents, CT contributions are low but reactivities in the cycloadditions are relatively high. On the other hand, considerable degrees of CT contributions are induced in the more polar protic solvents, and the reactivities decrease with the increase of solvent polarity. Our results concerning CT contribution-reactivity relationships in either the [2+2] or [4+4] cycloaddition *via* an exciplex are in line with the Lewis[24] and Caldwell's[30] interpretations based on the Michl's theory.[29]

Dimroth and Reichardt's $E_T(30)$ has been found to be a suitable scale of solvent polarity for linear free-energy relationships associated with the solvent dependences in the reversible dissociation, cycloaddition, and emission processes from exciplexes. The

good linearity in the plots with $E_T(30)$ may originate from internal correction of specific solute-solvent interactions. Unfortunately, implications of the linear relationships can not be sufficiently uncovered with regard to electronic structures and reactivities of exciplexes as well as the mechanisms in fluorescence quenching and photoreactions owing to umbiguities of the physical definition of $E_T(30)$.

The present treatments on solvent effects on fluorescence-quenching rate constants and quantum yields of photoreactions can thus provide a convenient, useful basis for qualitative estimations of electronic structures and reactivities of nonemissive exciplexes and will be applicable to other similar nonemissive exciplex systems, though the application is limited to such A-D pairs for which $\gamma k_c \ll 10^{10}$ dm^3 mol^{-1} s^{-1} in nonpolar and moderately polar solvents.

Experimental

Materials. An ethereal solution of the naphthonitriles (Tokyo Kasei) was washed three times with dilute hydrochloric acid and then with water, saturated sodium hydrogencarbonate, and water, dried, filtered, and evaporated. Pale yellow solids which had been obtained by vacuum distillation were purified by column chromatography on silica gel (Merck, 70—230 mesh) followed by repeated recrystallization from hexane; the pure 1- and 2-naphthonitriles were thus obtained as white flakes. The electron donors (**2a** and **2c—h**) were commercially obtained (Tokyo Kasei and Nakarai Chemicals) while **2b** was prepared according to the literature method.[37] The electron donors were distilled from sodium under a nitrogen atmosphere before use.

All the solvents were spectrograde (Tokyo Kasei and Nakarai Chemicals). Cyclohexane was used as received. Ethyl acetate and benzene were distilled. Diethyl ether, dibutyl ether, and tetrahydrofuran were distilled from lithium aluminium hydride. Dioxane, *t*-butyl alcohol, 2-butanol, 2-propanol, and ethanol were distilled from sodium. Methanol and acetonitrile were distilled from calcium hydride. All the distillations were performed under a nitrogen atmosphere before use.

Anayltical methods. A Hitachi MPF-4 spectrofluorometer equipped with a data processor (612-0085) was used for the fluorescence-quenching experiments and the measurements of emission spectra; all the fluorescence spectra were recorded after correction of specral response of the photomultiplier. The fluorescence lifetimes of 1- and 2-naphthonitriles were determined on the Hitachi MPF-4 spectrofluorometer equipped with a Hitachi time-resolved photometer. Concentrations of the naphthonitriles were set to $(3—6)\times10^{-4}$ mol dm^{-3} in all the spectroscopic measurements.

Proton nuclear magnetic resonance (NMR) spectra were recorded at 100 MHz on a JEOL JNM-PS-100 spectrometer or at 60 MHz on a JEOL JNM-60 spectrometer. Ultraviolet (UV) spectra were obtained on a Hitachi 124 spectrophotometer. Gas-liquid chromatography (GLC) was performed on a Shimadzu GC-3BF dual-column instrument with flame ionization detectors using 75 cm×4 mm columns packed with 5% SE-30 on Celite 545 and 10% PEG 20M on Shimalite W. Gel permeation chromatography (GPC) was carried out on a Toyosoda HLC-801 using a column of G-1000H6 polystyrene gel; tetrahydrofuran was used as eluant at an elution rate of 1.1 cm^3 min^{-1}.

Oxidation and reduction potentials were measured for

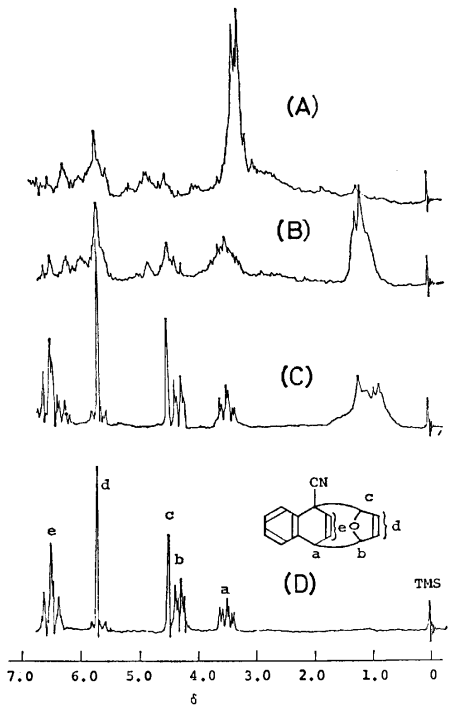

Fig. 8. NMR spectra ($CDCl_3$ solution) of photolysates of **1a-2f** pair in (A) methanol, (B) ethanol, (C) 2-butanol, and (D) benzene; the spectra were taken after thorough removal of both solvent and **2f** from the corresponding solutions irradiated at 313 nm; 30—40% conversions.

N_2-saturated acetonitrile solutions ($\approx10^{-3}$ mol dm^{-3}) *vs.* an $Ag/AgNO_3$ reference electrode by cyclic voltammetry. Tetraethylammonium tetrafluoroborate (0.1 mol dm^{-3}) was used as supporting electrolyte. The scan speed was 0.2 V s^{-1} and the temperature was kept at 23±0.1 °C. No cyclic voltammograms showed reversible peaks corresponding to oxidation of anion radicals and reduction of cation radicals. Therefore, half-peak values ($<\pm0.015$ V) were employed as oxidation and reduction potentials. Details of measurements were identical to those described previously.[38]

Determination of Quantum Yields for Disappearance of 1-Naphthonitrile. Monochromatic light at 313 nm was isolated from a high-pressure mercury lamp (Eikosha, POH-450) by passage through a Toshiba UV-D25 glass filter and an aqueous potassium chromate solution (0.2 g dm^{-3}, 10 mm path length). The intensity (I_0) of incident light was determined by potassium trioxalatoferrate(III) actinometry to be 2.01×10^{-7} einstein cm^{-3} min^{-1}. A solution (4 cm^3) containing **1a** ($(3.5—4.5)\times10^{-4}$ mol dm^{-3}) and an olefin (1.0 mol dm^{-3}) or furan (2.6 mol dm^{-3}) was introduced into an optical cell and then irradiated with the 313-nm light at 20±1 °C. The decrease in the absorbance (OD) of **1a** at 307 nm was monitored at appropriate intervals of time; ln ($e^{OD}-1$) was plotted against irradiation time (*t*, min). The plots were linear up to 20—40% conversions of **1a**. Quantum yields (ϕ_{-A}) for disappearance of **1a** were thus obtained by applying the slopes of the plots to Eq. 16, where κ is the observed molar absorption coefficient of **1a** at 307 nm for each solution in the optical cell used.

$$\ln(e^{OD}-1) = -1000\kappa I_0\phi_{-A}t + \text{constant} \quad (16)$$

Photoreaction of 1-Naphthonitrile with Ethyl Vinyl Ether or 2-Methyl-2-butene in Various Solvents. Solutions containing **1a** (70—80 mg/10 cm^3, ≈0.05 mol dm^{-3}) and the olefin ($\approx$ 1.0 mol dm^{-3}) were irradiated with a high-pressure mercury

lamp (Eikosha, PIH-300) through an aqueous potassium chromate solution (0.2 g dm^{-3}, 10 mm path length) under cooling with water. The progress of the photoreaction was followed by GLC, and it was confirmed that the cycloadducts (**3** and **4**) were the exclusive products without any change in the isomer ratios up to ≈50% conversion of **1a**. After ≈40% of **1a** had been consumed, the irradiated solutions were thoroughly evaporated under a high vacuum below 40 °C. The remaining oils were subjected to NMR. The isomer ratios were thus determined by both NMR and GLC and are listed in Table 4.

Photoreaction of 1-Naphthonitrile with Furan in Various Solvents. Solutions containing **1a** (70—80 mg/10 cm^3, ≈0.05 mol dm^{-3}) and **2f** (≈1.0 mol dm^{-3}) were irradiated in a similar way. The progress of the photoreaction was followed by GPC, and it was confirmed that product distributions were almost constant up to ≈40% conversion of **1a**. After 30—40% of **1a** had been consumed, the irradiated solutions were thoroughly evaporated under a high vacuum below 30 °C, and then the remaining oils were subjected to NMR. The NMR spectra are shown in Fig. 8.

Photoreaction of 1-Naphthonitrile with Phenyl Vinyl Ether in Acetonitrile. An acetonitrile solution (200 cm^3) containing **1a** (0.75 g, 0.005 mol) and **2b** (6 g, 0.05 mol) was irradiated for 20 h at 313 nm under cooling with water. After the removal of the solvent, vacuum distillation gave 2.5 g of **2b**. The distillation residue was chromatographed on silica gel (Merck, 70—230 mesh). Elution with 10% benzene in hexane gave *cis*-1,2-diphenoxycyclobutane[17] (0.42 g, 12% yield based on unrecovered **2b**) and the *trans* isomer[17] 0.42 g, 12%); 0.51 g of **1a** was recovered by elution with 30% benzene in hexane. Further elution gave untractable heavy oils.

This work was partially supported by a Grant-in-Aid No. 56550590 from the Ministry of Education, Science and Culture.

Room-temperature Fluorine Addition to Fluoro-substituted Naphthalene Derivative Using Xenon Difluoride

Barbara ZAJC and Marko ZUPAN*

"Jozef Stefan" Institute and Department of Chemistry, "E. Kardelj" University of Ljubljana, Ljubljana, Yugoslavia

(Received November 5, 1980)

Room-temperature boron trifluoride catalyzed addition of fluorine to octafluoronaphthalene with xenon difluoride proceeds as 1,4- and 1,2-addition, giving decafluoro-1,4-dihydronaphthalene and decafluoro-1,2-dihydronaphthalene. Fluorine addition to 2-methoxy- and 2-ethoxyheptafluoronaphthalene gave only 1,4-adducts, while reaction with 2-isopropoxyheptafluoronaphthalene resulted in octafluoro-1,2-dihydronaphthalene-2-one and 6-isopropoxynonafluoro-1,4-dihydronaphthalene.

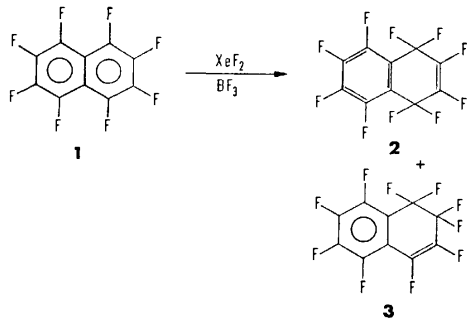
Perfluoroaromatic molecules react with electrophilic reagents under rigorous experimental conditions, while reactions with nucleophiles are typical examples of this class of compound.[1] Hexafluorobenzene reacted with fluorine at 0 °C giving a complex reaction mixture,[2] while reaction with a mixture of cobalt(III) fluoride and calcium fluoride could be adjusted so that only octafluorocyclohexa-1,4-diene and decafluorocyclohexane were formed.[3] Recently we have found that fluorine addition to fluoro substituted benzene derivatives could be carried out at room temperature using xenon difluoride in the presence of boron trifluoride as catalyst.[4] Reaction with hexafluorobenzene proceeded regiospecifically as 1,4-addition, thus forming octafluoro-1,4-cyclohexadiene. We now report further studies on the regioselectivity of room-temperature fluorine addition to fluorosubstituted naphthalene derivatives.

Results and Discussion

Xenon difluoride represents an easy handling, mild reagent for the fluorination of alkenes, acetylenes, aromatic and heteroaromatic molecules and some organic molecules containing hetero atoms, and has recently been reviewed.[5] Fluorinations with xenon difluoride are usually successful in the presence of a catalyst and the following substrates proved to be convenient catalyst: HF, HF/pyridine, CF_3COOH, Br_2, pentafluorothiophenol, BF_3/etherate, and BF_3. The choice of catalyst depends on the structure of the organic molecule, its reactivity and its sensitivity to the reaction conditions.

In a typical experiment, 1 mmol of fluoro-substituted naphthalene was dissolved in 2 ml of dichloromethane, 1.1 mmol of xenon difluoride was added at room temperature and BF_3 was introduced into the reaction mixture. The reaction was complete in 30—60 min, the solvent was removed under reduced pressure, the crude reaction mixture was analyzed by ^{19}F NMR spectroscopy and the products were isolated by preparative GLC. After analysis of the crude reaction mixture obtained by fluorination of octafluoronaphthalene (**1**, Scheme 1), we concluded that two products were formed in the ratio 1: 6.7.

The products were separated by preparative GLC and the major product showed the following singals in its ^{19}F NMR spectrum: $\delta = -99.6$ (F_1, F_4, m, 4F), -137.6 (F_5, F_8, m, 2F), -147.2 (F_6, F_7, m, 2F), and

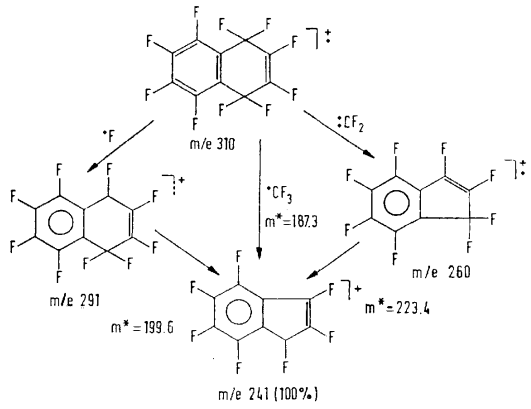


1 **2** **3**

Scheme 1.

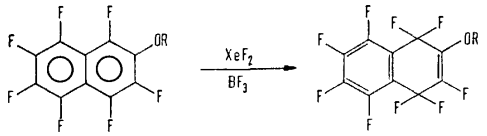
-155.8 (F_2, F_3, m, 2F). On the basis of the spectroscopic data we established that decafluoro-1,4-dihydronaphthalene (**2**) was formed.[7] The minor product had the following signals in its ^{19}F NMR spectrum: $\delta = -118.5$ (F_1, m, 2F), -126.7 (F_2, m, 2F), -136.7 (F_8, m, 1F), -159.8 (F_3, m, 1F), δF_4, $F_5 = -140$ (dm, $J = 63$ Hz), -141.8 (dm, $J = 63$ Hz), and δF_6, $F_7 = -147$ (m, 1F), -150 (m, 1F).

From these spectroscopic data we established that decafluoro-1,2-dihydronaphthalene (**3**) was formed.[7,8] The mass spectra of both products (**2** and **3**) are also of interest, the loss of a CF_3-radical being the most notable at 70 eV. Similar fragmentation has also been observed by 9,9,10,10-tetrafluoro-9,10-dihydrophenanthrene.[6] The three possible pathways leading to the fragment $M^{+\cdot}-CF_3$ are presented in Scheme 2, all of them being confirmed by metastable fragments (values noted in Scheme 2).



Scheme 2.

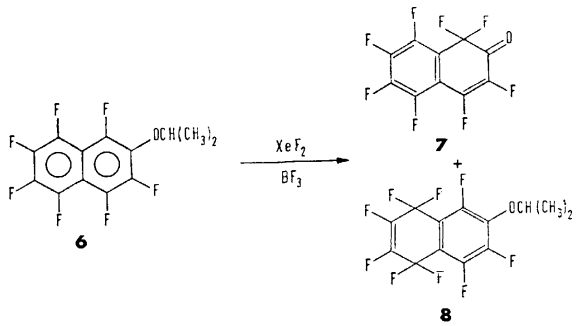
Further, we have studied the regioselectivity of fluorine addition to various alkoxy-substituted heptafluoronathalenes and found that fluorination of 2-methoxy (**4a**, Scheme 3) and 2-ethoxy (**4b**) derivatives resulted in the formation of only one product to each. In the case of **4a** the ^{19}F NMR signals are the following: $\delta=-97.2$ (F_1, m, 2F), -98.6 (F_4, m, 2F), -140 (F_5, F_8, m, 2F), -150.4 (F_6, F_7, m, 2F), and -163.1 (F_3, m, 1F), with the following coupling constants: $4J_{F_4F_5}=4J_{F_1F_8}=17$ Hz, $4J_{F_1F_3}=12$ Hz, $3J_{F_3F_4}=24$ Hz, and $5J_{F_3CH_3}=4$ Hz. On the basis of the spectroscopic data, we established that 2-methoxynonafluoro-1,4-dihydronaphthalene (**5a**) was formed.



4a: R=CH_3
4b: R=CH_2CH_2

Scheme 3.

1,4-Addition of fluorine with xenon difluoride had also been observed in the case of the 2-ethoxy derivative (**4b**), while reaction with 2-isopropoxyheptafluoronaphthalene (**6**) gave two products in the ratio 1:6.7, which could be separated by preparative GLC. The major product formed (**7**) shows a peak in its IR spectrum at 1715 cm^{-1}, characteristic of the CO group, and the following signals in its ^{19}F NMR spectrum: $\delta=-100.5$ (F_1, m, 2F), -123 (F_4, dm), -135.8 (F_8, tddd), -139 (F_5, dddd), -148.5 (F_6, F_7, m, 2F), and -157.8 (F_3, dt), with the following coupling constants: $4J_{F_1F_8}=18$ Hz, $4J_{F_1F_3}=7.5$ Hz, $3J_{F_3F_4}=15$ Hz, $4J_{F_4F_5}=81$ Hz, $3J_{F_5F_6}=18$ Hz, $4J_{F_5F_7}=7.5$ Hz $5J_{F_5F_8}=18$ Hz, $3J_{F_7F_8}=18$ Hz, and $4J_{F_6F_8}=8$ Hz.



6 **7** **8**

Scheme 4.

On the basis of the spectroscopic data, we established that octafluoro-1,2-dihydronaphthalene-2-one (**7**) was formed. The second product formed (**8**) shows the following signals in its ^{19}F NMR spectrum: $\delta=-99.8$ (F_1, F_4, m, 4F), -132.8 (F_5, tdd), -141.8 (F_8, dtd), -144 (F_7, dd), -156.8 (F_2, F_3, m, 2F), with coupling constants: $3J_{F_7F_8}=20$ Hz, $4J_{F_1F_8}=15$ Hz, $5J_{F_5F_8}=15$ Hz, $4J_{F_5F_7}=12$ Hz, and $4J_{F_4F_5}=15$ Hz. On the basis of spectroscopic data we established that 6-iso-propoxynonafluoro-1,4-dihydronaphthalene was formed.

Experimental

IR spectra were recorded using a Perkin-Elmer 727 B spectrometer and ^1H and ^{19}F NMR spectra with a JEOL-JNM-PS 100 from CCl_4 or $CDCl_3$ solutions with Me_4Si or CCl_3F as internal reference. Mass spectra and high resolution measurements were taken on a CEC 21-110 spectrometer. Gas liquid partition chromatography was carried out on a Varian Aerograph Model 1800.

Fluorination of Octafluoronaphthalene (1). Yield: 279 mg of oily products, separated by GLC (10% SE-30 Chromosorb A 45/60, $T=80$ °C).

Decafluoro-1,4-dihydronaphthalene (2). Yield: 113.8 mg (36.5%), mp 31.5—32 °C (mp[7] 33—34 °C). Found: *m/e* 309.9840. Calcd for $C_{10}F_{10}$: 309.9840. MS, *m/e* (rel intensity): 310 (M^+, 34), 291(26), 272(9), 260(20), 242(10), 241 (100), 222(6), 210(12), and 141(9).

Decafluoro-1,2-dihydronaphthalene (3) Yield: 10.1 mg (3.3%) of oily product. Found: *m/e* 309.9841. Calcd for $C_{10}F_{10}$: 309.9840. MS, *m/e* (rel intensity): 310 (M^+, 34), 291(28), 272(8), 260(21), 242(12), 241(100), 210(15), and 141(13).

Fluorination of 2-Methoxyheptafluoronaphthalene(4a). Yield: 264 mg of crude reaction mixture; separation by preparative GLC (12% DDP Chromosorb Regular 100, $T=135$ °C).

2-Methoxynonafluoro-1,4-dihydronaphthalene (5a). Yield: 112 mg (35%), bp 212—213 °C. Found: *m/e* 322.0030. Calcd for $C_{11}H_3F_9O$: 322.0024. MS, *m/e* (rel intensity): 323 (M^++1, 13), 322(M^+, 100), 307(13), 303(40), 292(10), 291(72), 279(70), 272(32), 260(25), 257(14), 253(14), 241(74), 229(66), 223(25), 222(10), 210(37), 203(10), 179(25), 160(10), 141(27), 117(17), 93(18), 81(75), and 69(13). Found: C, 41.0; H, 0.8%. Calcd for $C_{11}H_3F_9O$: C, 41.0; H, 0.9%.

Fluorination of 2-Ethoxyheptafluoronaphthalene (4b). Yield: 296 mg of crude reaction mixture, separated by preparative GLC (12% DDP Chromosorb Regular 100, $T=135$ °C).

2-Ethoxynonafluolo-1,4-dihydronaphthalene (5b). Yield: 133.8 mg (39.8%), bp 220—221 °C. ^{19}F NMR: -96.9 (F_1, m, 2F), -98.6 (F_4, m, 2F), -140.3 (F_5, F_8, m, 2F), -150.4 (F_6, F_7, m, 2F), and -162.4 (F_3, m, 1F) with the following coupling constants: $4J_{F_1F_8}=17$ Hz, $4J_{F_1F_3}=12$ Hz, $3J_{F_3F_4}=24$ Hz, $4J_{F_4F_5}=17$ Hz, and $5J_{F_3CH_2}=3$ Hz. Found: *m/e* 336.0200. Calcd for $C_{12}H_5F_9O$: 336.0197. MS, *m/e* (rel intensity): 336 (M^+, 30), 309 (11), 308 (100), 289 (25), 288 (28), 272 (24), 269 (12), 260 (82), 258 (18), 242 (11), 241 (91), 239 (37), 229 (15), 222 (14), 210 (29), 179 (16), 141 (22), 117 (12), 93 (12), 86 (23), and 84 (38). Found: C, 42.2, H, 1.7%. Calcd for $C_{12}H_5F_9O$: C, 42.7, H, 1.5%.

Fluorination of 2-Isopropoxyheptafluoronaphthalene (6). Yield: 244 mg of the crude reaction mixture. The products were separated by preparative GLC (10% SE-30 Chromosorb A 45/60, $T=130$ °C).

Octafluoro-1,2-dihydronaphthalene-2-one (7). Yield: 145 mg (50.3%), mp 33—34.5 °C. Found: *m/e* 287.9800. Calcd for $C_{10}F_8O$: 287.9805. MS, *m/e* (rel intensity): 288 (M^+, 39), 260 (48), 242 (10), 241 (100), 210 (50), 160 (11), 141 (33), 122 (12), 117 (17), 93 (14), and 79 (12). IR; 1715 cm^{-1} (C=O).

6-Isopropoxynonafluoro-1,4-dihydronaphthalene (8). Yield: 22 mg (6.3%), mp 35—38.5 °C. Found: *m/e* 350.0350. Calcd for $C_{13}H_7F_9O$: 350.0353. MS, *m/e* (rel intensity): 350 (M^+, 8), 335 (20), 309 (12), 308 (100), 289 (30), 288 (12), 260 (13), 258 (12), 241 (33), 239 (30), 210 (25), 179 (10), 141 (17), 119 (15), and 117 (18).

We thank Professor J. Slivnik for xenon difluoride.

(Received February 20, 1981)

Job's method of continuous variation has been reinvestigated with respect to the formation of 1 : 1 type complex from the view point of (i) geometrical significance of the Job curve, (ii) developing a method for determining the equilibrium constant and molar extinction coefficient of the complex. A mathematical analysis of the method of continuous variation as applied to the formation of strictly 1 : 1 type complex shows that the Job curve is a hyperbola obeying the equation

$$\frac{(d-\beta)^2}{a^2} - \frac{(C_M^\circ/\lambda - 1/2)^2}{b^2} = 1,$$

where d is the corrected optical density, C_M° is the initial concentration of the metal ion in solution, λ is a constant equal to the sum of the concentrations of the metal and the ligand in solution, β is the ordinate of the local origin of the hyperbola referred to the conventional framework of the Job curve, a and b represent respectively the semi-major and semi-minor axes of the hyperbola. The equation has been recast into the form $x = A_3d^2 + A_2d + A_1$, where $x = (C_M^\circ/\lambda - 1/2)^2$ and A_3, A_2, and A_1 are the appropriate coefficients. A parabolic fit of this equation between x and d by the least square deviation method using the computer B-6800 system enables one to find the coefficients A_3, A_2, and A_1 from which K and ε are evaluated. This equation has been tested with literature data on a variety of 1 : 1 type metal complexes whose formation constants and extinction coefficients as calculated by the present method agree closely with those determined by other methods. The promising features of the equation have been discussed.

There are various methods for ascertaining the composition of complexes, of which the most noteworthy is the method of continuous variation introduced by Job.[1] The simplicity of the method has made it very attractive and it is widely used in the evaluation of spectrophotometric data. Beck[2] has listed several limitations of the method and has cautioned that they have to be considered before it is applied to the study of complexes. The method works well if only one complex is formed in the system, although Voshburgh and Cooper[3] as well as Katzin and Gebert[4] applied it to the study of stepwise complex formation. For a very stable complex the curve of absorbance (or other suitable measured property) *versus* mole fraction (X) of one of the two components of the complex consists of two strictly linear intersecting portions.[2] In the case of moderately stable complexes there is no such linearity, and from the deviation of the curve and that constructed by extrapolation from the slopes near the extreme values of x, the value of the equilibrium constant can be calculated. There are, however, other methods[2,5,6] for determining the equilibrium constant of metal-chelate formation reactions from spectral data. A critical analysis of the principle of continuous variation method shows that the geometrical significance of the Job curve as observed in the case of 1:1 complex has not been elucidated, not to mention of those found in the case of higher order complexes. The purpose of the present investigation is to elucidate the geometrical nature of the conic, and to develop therefrom a general method for determining the stability constant and molar extinction coefficient of 1: 1 complexes.

Principle

The stability constant for an 1: 1 type complex, ML, formed between a metal ion and a ligand is given by

$$K_c = \frac{C_{ML}}{(C_M^\circ - C_{ML})(C_L^\circ - C_{ML})}, \quad (1)$$

where C's are the concentrations of the various species at equilibrium, the superscript zero refers to the initial concentrations. The optical density (corrected for absorption, if any, by the metal and the ligand) of a solution containing the complex, the free metal and the ligand is

$$d = \frac{1 + K_c(C_L^\circ + C_M^\circ) - [\{K_c(C_L^\circ - C_M^\circ)\}^2 + 2K_c(C_L^\circ + C_M^\circ) + 1]^{1/2}\varepsilon l}{2K_c}, \quad (2)$$

where ε is the effective extinction coefficient of the complex ($\varepsilon = \varepsilon_{ML}$ only when the complex alone absorbs at the wavelength of measurement), l is the path length. In Job type experiment the sum total of the concentrations of the metal and the ligand is held constant, *i.e.*, $C_M^\circ + C_L^\circ = \text{constant} = \lambda$ (say). Under this condition Eq. 2 reduces to the equation of the hyperbola

$$\frac{(d-\beta)^2}{a^2} - \frac{(C_M^\circ/\lambda - 1/2)^2}{b^2} = 1, \quad (3)$$

where $a^2 = \frac{1+2K_c\lambda}{m^2}$, $b^2 = \frac{1+2K_c\lambda}{4K_c^2\lambda^2}$, $\beta = \frac{1+K_c\lambda}{m}$, and $m = \frac{2K_c}{\varepsilon l}$.

Here a and b represent respectively the semi-major and semi-minor axes of the hyperbola; β is the ordinate of the local origin of the hyperbola referred to the conventional framework of the Job curve.

In Job type experiment we plot customarily d along the y-axis and C_M°/λ in the abscissa. According to Eq. 3 a plot of d against C_M°/λ should be a hyperbola and it is evident that the axes of the hyperbola are not the axes in our original framework of the coordinate system but some axes which are parallel and interchanged with respect to the original axes.

The eccentricity of the hyperbola is related to a and b of the hyperbola and to the physical parameters of the complex by the relation

$$e^2 = 1 + \frac{b^2}{a^2} = 1 + \frac{1}{\lambda^2\varepsilon^2 l^2}, \quad (4)$$

which shows that the nature of the hyperbola depends on the extinction coefficient and on the total molar concentration of the solution but not on the equilibrium constant of the complex.

Determination of K_c and ε. Equation 3 can be written in the following form

$$x = A_3 d^2 + A_2 d + A_1, \quad (5)$$

where $x = (C_M^\circ/\lambda - 1/2)^2$, $A_3 = \frac{b^2}{a^2}$, $A_2 = -2\left(\frac{b^2}{a^2}\right)\beta$, and

$$A_1 = b^2\left(\frac{\beta^2}{a^2} - 1\right).$$

The coefficients A_3, A_2, and A_1 of Eq. 5 can be found out by making a parabolic fit between x and d by the least square deviation method. The extinction coefficient, ε, of the complex is evaluated from A_3 by using the relation

$$\varepsilon = \frac{1}{\lambda l A_3^{1/2}}. \quad (6)$$

The stability constant K_c of the complex is determined from a knowledge of all three coefficients using Eq. 7

$$K_c = \frac{1 \pm (1+4S)^{1/2}}{4\lambda S}, \quad (7)$$

where $S = (A_2^2/4A_3) - A_1$. Only the admissible value of K_c is accepted. K_c can also be calculated by utilizing A_2 and A_3 only. This yields a unique value of K_c since the equation in K_c is not quadratic in nature. K_c obtained by this method agrees with that calculated from Eq. 7.

For a very stable complex the curve of absorbance *vs.* mole fraction of one of the two components of the complex consists of two strictly linear intersecting portions. This can be explained with the help of Eq. 5 which can be written in the following form

$$x = \left[A_3^{1/2} d + \frac{A_2}{2A_3^{1/2}}\right]^2 - b^2, \quad (8)$$

where $b^2 = A_1 - (A_2^2/4A_3)$ and is negligible for a complex of high stability constant so that Eq. 8 splits into Eqs. 9 and 10 respectively.

$$d = \frac{1}{A_3^{1/2}}\left(\frac{C_M^\circ}{\lambda}\right) - \left[\frac{A_3^{1/2} + A_2}{2A_3}\right], \quad (9)$$

$$\text{and} \quad d = -\frac{1}{A_3^{1/2}}\left(\frac{C_M^\circ}{\lambda}\right) + \left[\frac{A_3^{1/2} - A_2}{2A_3}\right]. \quad (10)$$

Equation 9 describes the left hand portion of the Job curve and for a complex with very high formation constant it represents a straight line passing through the origin since the term $\frac{A_3^{1/2} + A_2}{2A_3}$ is practically zero. Similarly Eq. 10 describes the right hand portion of the Job curve and represents a straight line with negative slope and positive intercept.

The principle of the method as embodied in Eq. 5 is valid for complexes whose stoichiometry is strictly 1:1 (*i.e.*, $m=n=1$ where m and n refer to the mole numbers of the metal and the ligand respectively).

Results and Discussion

The principle of the method, *viz.*, Eq. 5 has been tested with literature data on a variety of 1:1 metal complexes formed by Al^{3+}, Ga^{3+}, Fe^{3+}, La^{3+}, Cu^{2+}, and Pd^{2+} with one or more of the following ligands such as salicylic acid (SA), sulfosalicylic acid (SSA), *p*-aminosalicylic acid (PAS), 2-quinizarinsulfonic acid, 1-(*p*-nitrophenylazo)chromotropic acid, and Chromeazurol S. The compositions of the complexes were ascertained by Job's method of continuous variation. The optical density data necessary for our purpose have, therefore, been read from the Job curves of the complexes available in the literature. A perusal of the literatures concerned reveals that Job's experiments involving these complexes were performed at constant pH's and at constant values of λ but not at constant ionic strength. The ligand Chromeazurol S forms with Pd^{2+} a violet coloured 1:1 chelate which is stable between pH 3.5 and 8.0 with an absorption maxima at 585 nm.[7] 2-Quinizarinsulfonic acid forms a blackish violet water soluble complex with Fe^{3+} in 1:1 mole ratio.[8] La^{3+} forms with 1-(*p*-nitrophenylazo)chromotropic acid (abbreviated as CTB) a reddish violet chelate which is stable between pH 5 and 12.5 and has an absorption maxima at 340 nm.[9] In these three cases metal ion was used as its chloride salt. Iron(III) forms a violet complex with PAS at pH 2.5.[10] While Al^{3+} and Ga^{3+} form colourless complexes with SA and SSA,[11,12] complexes of copper with these reagents[13] are olivegreen in colour. In the study of these latter complexes perchlorates of the respective metals were used. The violet complex of Fe^{3+} with PAS has been reinvestigated by us. Stability constants and molar extinction coefficients of the complexes have been calculated from the Job data with the help of Eq. 5. A special computer program has been written to solve Eq. 5. In solving Eq. 5 two additional points corresponding to mole-fractions of zero and unity have been considered. Experience suggests that inclusion of these two points improves the final results appreciably. The computer Burroughs 6800 has been used for the purpose. The results are shown in Table 1 where other experimental details such as wavelength of measurement, total molarity of the solution, pH values, *etc.*, are also recorded. The formation constants recorded in column 5 and extinction coefficients shown in column 7 of the complexes calculated by Eq. 5 agree fairly well with those (vide columns 6 and 7 of Table 1) determined by other methods. The agreement is noticeable, particularly, in the case of iron (III) *p*-aminosalicylate complex. The variations in K_c values noted in some cases, particularly with wavelength, may be traced to the fact that ionic strength of the medium was not maintained constant in Job's experiments done at constant pH's and at constant values of λ.

An attempt has been made to test approximately the validity of Eqs. 9 and 10 with data on complexes which are not very strong. According to these equations the magnitude of the slope of the plot d *vs.* C_M°/λ is

a) Investigated by us.

$1/A_3^{1/2}$ from which the extinction coefficient of the complex can be estimated. With iron(III) *p*-aminosalicylate complex studied by Das and Aditya[10] the extreme left and right wings of the Job curve correspond approximately to straight lines from whose slopes the average extinction coefficient of the complex is found to be 1634 which is in fairly good agreement with the reported value, considering the approximations made in deriving Eqs. 9 and 10.

Furthermore, the formation constant of the iron(III) *p*-aminosalicylate complex calculated from the intercept of the straight line drawn through the right wing portion of the Job curve for the system is 5.13×10^{4} which is in fairly good agreement with the value obtained by using Eq. 7.

The present treatment of the principle of continuous variation has several promising features of which the most important is that it determines simultaneously the relative composition, the stability constant and the extinction coefficient of a complex from the same experimental data by considering all the points of the Job curve. In this respect the present method is advantageous over the one based on the measurement of the deviation between the experimental Job curve and that constructed by extrapolation from the slopes near the extreme values of mole-fraction.[14] The latter method considers only a single point corresponding to the maximum in the Job curve and it involves an element of arbitrariness in drawing tangents to the Job curve because experimental data near the extreme values of mole-fraction which should be most imprortant in drawing tangents to the Job curve are wanting in most cases. These demerits are obviously absent in Eq. 5. Moreover, the proposed method does not require a prior knowledge of extinction coefficient of a complex, which is required in other methods[2,5,6,14] for computing the formation constant of a complex. Another fruitful result obtained from Eq. 5 is that it explains quantitatively the nature of the Job curve in the case of complexes with very high formation constant. It yields two Eqs. 9 and 10 which can profitably be used to compute the stability constant and extinction coefficient of such complexes.

The errors in A_1, A_2, and A_3 have been calculated for the various systems investigated. The sequence of errors is $\Delta A_1<\Delta A_2<\Delta A_3$. The error in A_1 hardly exceeds 4%, that in A_2 is within 10%, while the error in A_3 is somewhat large. In some cases it is observed to be about 16 to 20%. The estimated error in ε in such cases hardly exceeds 10%, particularly, when the extinction coefficient of the complex is large. The error in K, however, lies within 10% in any case. The

analysis of errors in A_1, A_2, and A_3 does not warrant the presence in solution of complexes having stoichiometries other than 1:1. It is felt that the theory developed here be tested with precise Job data on many more systems.

Study of Molecular Complexes by Refractometry

Ram Adhar SINGH† and Subray Narayan BHAT*
Department of Chemistry, North-Eastern Hill University, Shillong-793003, India
†*Chemistry Department, Banaras Hindu University, Varanasi, India*

(Received April 17, 1981)

The refractive index measurement technique is used to investigate molecular complex formation in liquid solutions and the association constants are determined directly. The association constants at 25 °C and heats of complexation for naphthalene–phenol, benzene–tetracyanoethylene, *p*-xylene–tetracyanoethylene, hexamethylbenzene–tetracyanoethylene, and triethylamine–iodine in cyclohexane are 8.2, 2.2, 8.6, 231, and 4620 $dm^3\ mol^{-1}$ and 19.25, 11.30, 18.00, 32.21, and 51.46 kJ/mol, respectively. These values agree well with the literature data obtained by spectroscopic methods.

The Benesi-Hildebrand equation[1] and their modified equations[2,3] have been widely used in the study of molecular complexes. However, these methods were subject to criticism, particularly in the case of weakly interacting systems, as the valid separation of K and ε from $K\varepsilon$ product may be difficult to attain, the error increasing with the decrease in the strength of the complexes.[4–6] So if one wants to have accurate values of $K\varepsilon$, K, and ε, which are essential in developing and testing theories[7] of electron donor-acceptor interactions, one has to supplement the results obtained by the non-spectral methods to the one obtained by spectral methods. Recently we have shown that the equilibrium constant, K, can be determined directly by the non-spectral methods like surface tension[8] and refractive index measurements[9] and we have felt that in order to establish the suitability of refractometry in obtaining reliable value of K directly, an extensive studies on the applications of this method to various systems is worthwhile to carry out. In the present paper the studies of naphthalene–phenol, methylbenzenes–tetracyanoethylene, and triethylamine–iodine in cyclohexane have been reported as they represent weak, moderate and strong interactions between electron donors and acceptors.

Experimental

Materials. Triethylamine (Riedel de Hainay) was treated with acetic anhydride to remove primary and secondary amines.[10] It was then dried over anhydrous KOH pellets and fractionally distilled (bp 89.5 °C). Iodine (BDH, A.R. grade) was purified by sublimation from a mixture of iodine and potassium iodide (in the ratio of 2.5 : 1). Phenol was crystallized from cyclohexane–ethanol mixture (mp 42.8 °C). Nephthalene, *p*-xylene, and hexamethylbenzene were purified by the standard procedures.[11] Tetracyanoethylene (Du Pont) was purified by crystallization (from chlorobenzene solution) and vacuum sublimation (mp 199.5°C in sealed tube). Benzene and cyclohexane (BDH Spectro quality) were used as such.

Method. The refractive index of solution was measured using Pulfrich refractometer (Adam Hilger No. M 48302/20210).[9] A mercury vapor lamp was used as source of light. The refractive index was obtained by measuring the angle of refraction (θ) for green (546 nm) and yellow (578 nm) lines of mercury, using the formula

$$\eta^2 = \eta_0^2 - \sin^2\theta, \qquad (1)$$

where η_0 is the prism constant for a particular wavelength at a particular temperature.

The refractive indices of triethylamine, iodine, benzene, *p*-xylene, hexamethylbenzene, tetracyanoethylene, naphthalene, and phenol in cyclohexane and those of "mixed solutions," keeping the total concentration constant were measured at 25, 30, 35, 40, and 45 °C. The temperature of solution was maintained constant (±0.1 °C) by circulating water from a thermostat. The refractive index could be determined with an accuracy of ±0.00002.

The refractive index at infinite wavelength can be calculated using Couchy's approximation,[12]

$$n_\infty = \frac{n_y\lambda_y^2 - n_g\lambda_g^2}{\lambda_y^2 - \lambda_g^2}, \qquad (2)$$

where n_y, λ_y and n_g, λ_g are refractive index and wavelength of yellow and green line of mercury respectively. The experiments were repeated at least twice and the values obtained were within the experimental error.

The stoichiometry of the complexes was determined by the continuous variation method.[13]

Determination of Equilibrium Constant

The non-linear plot of any physical property of the "mixed solution" against the concentration of pure components, *i.e.*, the deviation from ideal behaviour of the pure components in solution, is an indication of the interaction between the two species, namely the donor D, and the acceptor A, (neglecting the solvent effect). If we can assume that the deviation is entirely due to the complex alone, then the deviation should be proportional to the concentration of the complex. Baur and his co-workers[14] had developed a procedure by which deviations from additivity of the total polarization and refraction of a binary solution can be related to the association constant of a complex (AD) formed from two non-polar molecules. However, the equilibrium constant can be calculated for ternary systems, using the equation proposed by Yoshida and Osawa,[15]

$$K = \frac{2\sqrt{k}[\sqrt{k}(C+C') - (C+kC')]}{(C-kC')^2}, \qquad (3)$$

where K is equilibrium constant in $dm^3\ mol^{-1}$, k is the ratio of the maximum deviations for total concentrations of C and C' in two different sets. Here we should note that the results obtained by the continuous variation method must be taken with caution since with this method it is not always possible to observe all the complexes present in the solution, and in such cases the titration method should be followed.[16]

The equilibrium constant, K, can also be obtained as described earlier.[8]

Consider the interaction of A with D,

$$A + D \rightleftharpoons AD.$$

Let C_A, C'_A, C_D, and C'_D be the initial concentrations of the acceptor and donor respectively for the two sets of solutions, and C_{AD}, C'_{AD} be the concentration of the complexes. For the first set,

$$K = \frac{C_{AD}}{[(C_D - C_{AD})(C_A - C_{AD})]}, \quad (4)$$

and for the second set,

$$K = \frac{C'_{AD}}{[(C'_D - C'_{AD})(C'_A - C'_{AD})]}, \quad (5)$$

therefore,

$$\frac{C_{AD}}{[(C_D - C_{AD})(C_A - C_{AD})]} = \frac{C'_{AD}}{[(C'_D - C'_{AD})(C'_A - C'_{AD})]}. \quad (6)$$

If there is a linear relationship between Δn and the concentration of the complex (*i.e.*, similar to the test of Beer's law), we can conclude that if the two solutions show the same deviations of refractive indices, then they must have the same concentration of the complex. Therefore if

$$\Delta n_1 = \Delta n_2, \text{ then } C_{AD} = C'_{AD}.$$

From the above equations, we get

$$K = \frac{(C'_A C'_D - C_A C_D)[(C'_A + C'_D) - (C_A + C_D)]}{[(C'^2_A + C_A C_D) - C'_A(C_A + C_D)][(C'^2_D + C_A C_D) - C'_D(C_A + C_D)]}. \quad (7)$$

The K values thus calculated agree well with the values calculated using Eq. 3.

Results and Discussion

Naphthalene–Phenol System. The refractive indices of naphthalene and phenol in cyclohexane increase linearly with the increase in concentration of the solute in the experimental range of concentrations (0.01—0.10 mol dm^{-3}). The plot of n^2_∞ against the concentration of naphthalene in the "mixed solutions" of naphthalene–phenol shows only one maximum at a position

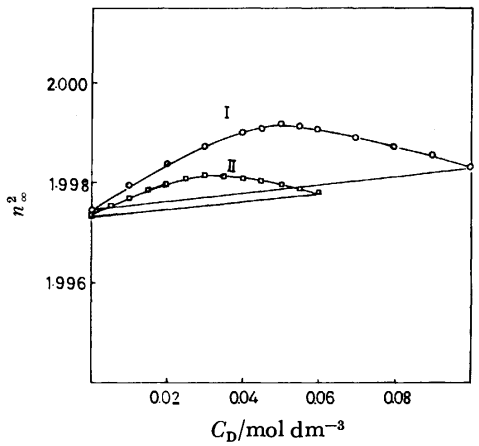

Fig. 1. Plot of n^2_∞ *vs.* concentration of naphthalene in naphthalene–phenol system (solvent : cyclohexane). Total concentration: I: 0.10 mol dm^{-3}, II; 0.06 mol dm^{-3}.

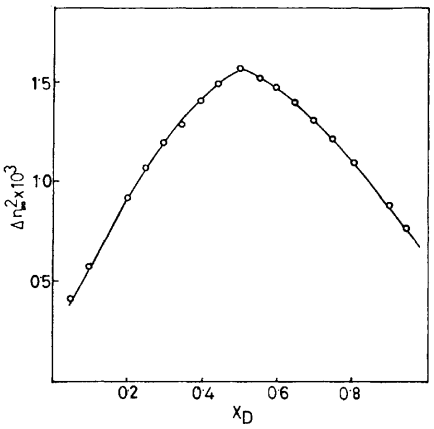

Fig. 2. Plot of Δn^2 *vs.* mole fraction of naphthalene in naphthalene–phenol in cyclohexane.

of half the concentration of naphthalene (Fig. 1; Table 1); similarly the plot of Δn^2, difference in square of refractive indices of the calculated and observed values against the concentration of donor (in mole fraction) shows only one maximum at 0.5 mole fraction (Fig. 2). These indicate that naphthalene forms only 1 : 1 complex with phenol in the experimental range of concentrations.

By knowing the maximum deviation in Δn^2 for two sets of different total concentrations (10.0 and 6.0×10^{-2} mol dm^{-3}) the equilibrium constants for different temperatures were calculated. The equilibrium constant at 25 °C and the enthalpies are 8.20 ± 0.50 mol dm^{-3} and 19.25 ± 1.25 kJ/mol respectively (Table 2). These data indicate that equilibrium constant and enthalpy obtained by the above mentioned procedure are reasonably in good agreement with the literature values.

Methyl Benzenes–Tetracyanoethylene Systems. The refractive indices of benzene, *p*-xylene, hexamethylbenzene, and tetracyanoethylene in cyclohexane increase linearly with an increase in concentration of the solute in the experimental concentration range (0.01—0.15 mol dm^{-3}). When tetracyanoethylene is mixed with benzene, *p*-xylene or hexamethylbenzene solutions, stable neutral complex is formed, A plot of Δn, the difference in refractive indices of the calculated and observed values against the calculated concentration of the complex is linear; this indicates that there is no interaction between the complex and the individual species. A plot of n_∞^2 against the concentration of the donor shows only one maximum at a position of half the donor concentration, indicating that there is predominantly one type of complex, *i.e.* 1 : 1, when the donor concentration is comparable to that of the acceptor. Higher order molecular complexes may be formed only when the concentration of either one of the two components is very high.[17]

The values of K_c and $-\Delta H^\circ$ thus obtained are summarised in Table 2 along with the literature data. In the case of benzene–TCNE, the literature data are under different conditions. From the data, it is evident that the values of K_c and $-\Delta H^\circ$ obtained by refractometry are in good agreement with the literature data except for the HMB–TCNE system. It has been shown recently that the value of K_c, based on the assumption that only 1 : 1 complex is formed in HMB–TCNE, is much lower than the value of K_c reported earlier in the literature, which includes other types of complexes.[17] Here it must be noted that the literature data are under different sets of conditions,[3,18] and that the value of K_c depends on the experimental conditions such as whether A$\gg$D, D$\gg$A, or A$\approx$D, and also on the nature of solvents.

The values of K_c (at only one temperature, for the sake of brievity), ΔH° and the other thermodynamic parameters thus obtained for methylbenzenes–tetracyanoethylene in cyclohexane are given in Table 2 along with the literature data. From the data, it is evident that the relative enthalpies and free energies obtained from a series of donors, increase with the increased methylation of the donor. These observations are consistent with charge-transfer theory[7] and go in parallel with the literature data for similar π-π complexes and the values of K_c and ΔH° obtained by refractometry are thus in good agreement with the data obtained by spectroscopic methods. Here it must be worth mentioning that ΔH° values are more reliable than the equilibrium constants obtained by separating K and ε from $K\varepsilon$. As ΔH° values which are more reliable than K values, are in very good agreement with the literature data, we feel our values of K which are obtained directly, are probably more acceptable than the literature data.

Triethylamine–Iodine System. The refractive index of triethylamine in cyclohexane decreases whereas that of iodine increases with the concentration of solute in the experimental range of concentration ($0.5—10.0\times 10^{-3}$ mol dm^{-3}). The total concentrations of triethylamine–iodine (6.0 and 10.0×10^{-3} mol dm^{-3}) are such that when they are mixed, neutral complex is formed which was confirmed spectroscopically.[19]

The plot of n_∞^2 against the concentration of triethylamine in triethylamine–iodine, shows one maximum at a position of half the donor concentration; similarly the plot of Δn^2, difference in square of refractive indices of the calculated and observed values against the concentration of donor (in mole fraction) shows only one maximum at 0.5 mole fraction. These indicate that

TABLE 2. EQUILIBRIUM CONSTANT, K_C, AND OTHER THERMODYNAMIC PARAMETERS FOR NAPHTHALENE–PHENOL, METHYLBENZENES–TETRACYANOETHYLENE, AND TRIETHYLAMINE–IODINE IN CYCLOHEXANE

System	K(25 °C) / dm^3 mol^{-1}	$-\Delta H^\circ$ / kJ mol^{-1}	$-\Delta G^\circ$ / kJ mol^{-1}	$-\Delta S^\circ$ / J K^{-1} mol^{-1}
Naphthalene–Phenol	8.2 ± 0.5 (5.0[a])	19.25 ± 1.25	5.02	47.7

triethylamine forms only 1 : 1 complex with iodine in the experimental range of concentrations. From this it appears that triethylamine forms only one 1 : 1 complex with iodine and not any other complexes as suggested by Schmulback.[20] The higher order complexes are invariably formed only when the concentration of one of the two components is in very much excess (*i.e.* D⋙A or A⋙D), but in the present case, as the concentration of donor and acceptor are comparable, the higher order complexes seem to be improbable.

The plot of Δn^2 against the concentration of complex (calculated using the equilibrium constant for different initial donor and acceptor concentrations in all the cases) is linear. This justifies the assumption that the deviation is proportional to the concentration of the complex and there is no interaction between the complex and individual species.

The equilibrium constant and enthalpy value for triethylamine–iodine system are given in Table 2. It is evident from the data that the equilibrium constant and other thermodynamic parameters determined from refractometry are in very good agreement with the literature data.

The increment in the dipole moment is directly related to charge-transfer and the dipole moment of a complex depends on the total polarizability of the complex. However, in the calculation of the dipole moment of complex, so far, the electronic and atomic (which is about 5—10% of electronic) polarizability has been neglected on the ground that the electronic and atomic polarization of the complex is equal to the sum of the electronic and atomic polarization of individual molecules.[17,21,23] As can be seen from the above data and figures, whenever there is any interaction between the molecules, the electronic polarizability exceeds the additive value. Therefore the contribution of the electronic polarizability cannot be neglected if one wants to determine the exact dipole moment of the complex.

Thus as shown earlier, our present observations confirm our earlier suggestive evidences that the refractive index measurement method can be used for not only detecting the formation of the complex but also to determine its equilibrium constants directly even in the case of very weak complexes

A Perturbative Study of Medium and Long Range Interactions between Some Characteristic Fragments of Lipid-Protein Systems

Antonio RAUDINO,* Felice ZUCCARELLO, Giuseppe BUEMI, and Carmelo RIGANO†

Istituto Dipartimentale di Chimica e Chimica Industriale, Università di Catania, Viale A. Doria 8, 95125, Catania, Italy

†*Seminario Matematico, Università di Catania, Viale A. Doria 8, 95125, Catania, Italy*

(Received February 10, 1981)

An intermolecular perturbation theory, originally presented by Murrell and developed by use of the LCAO approximation, was applied to a theoretical study on the interaction of a hydrogen-bonded dimer of formamide with ethane molecule or ammonium ion in order to simulate interaction between characteristic frameworks of proteins and lipids. Ethane has a preferential orientation parallel to the carbonyl bond supported by the prevailing charge-transfer contribution. Ammonium ion has preferential interaction regions dependent on the balance between the charge-transfer and coulombic forces along the NH···OC axis.

Essentially biological membranes are built up from lipid bilayers in which proteins are imbedded. Therefore, to study lipid protein interaction is an interesting task, but hampered by the complexity arising from the size of isolated molecules.[1] One of possible ways to overcome this difficulty is to construct more simplified models describing relevant interactions. From study of these model systems it is possible to get information on the nature of forces and on the spatial preference in interaction between more complex systems. At this stage we examine interaction between fragments of lipids and the polypeptide chain, but for simplicity it is here simulated by using two H-bonded formamide molecules spatially arranged in such a way that the geometry of α-helix may be reproduced. In biological membranes lipids are essentially arranged in such a way that two ranges of interactions are possible to be separated, in one of which the protein interacts with the hydrophobic chain and in the other it interacts with the ionic heads. For the sake of computational economy we selected ethane as a model of the aliphatic chain of lipid and ammonium ion as a simplified model of ionic head. The latter constitutes the simplest model of known lipid heads, *e.g.*, the positive end of phosphatidylethanolamines.

We inspect medium and long range interactions between these fragments along the axis of the H-bonding existing in the pitch of α-helix in order to evaluate i) the entity of interaction energies, ii) the spatial specificity and anisotropy of interactions, and iii) the origin of intermolecular forces.

The energies were evaluated by means of the perturbation theory, following Murrell's approach[2] developed in the LCAO approximation by Fueno *et al.*[3]

Calculations

Interaction energy calculations were performed following the second order perturbation theory put forward by Murrell *et al.*[2] and developed by Fueno *et al.*[3] in the usual LCAO approximation. We adopted the ZDO approximation within single molecules, but retained the overlap integral between interacting molecules. Therefore, coefficients of wave function and transition energies relative to isolated molecules were calculated following the CNDO method.[4] Moreover, intermolecular three- and four-center integrals were approximated by Mulliken's equation:[5]

$$V_{a,rs} \simeq (V_{a,rr} + V_{a,ss})\frac{S_{rs}}{2},$$

$$(rs|tu) \simeq [(rr|tt) + (rr|uu) + (ss|tt) + (ss|uu)]\frac{S_{rs}S_{tu}}{4}.$$

Following the scheme presented by Fueno *et al.*,[3] the intermolecular interaction energy was divided into five contributions: coulombic (E_Q), exchange (E_k), induction (E_I), dispersion (E_D), and charge-transfer (E_{CT}) energies.

Preliminarily, we have considered several approaches in calculating the electron core attraction and the interelectronic repulsion intermolecular integrals. We first calculated both $V_{a,rr}$ and (rr|ss) integrals theoretically by using an STO basis set, then considered the point charge approximation as suggested by Suzuki and Iguchi,[6] and finally considered the CNDO approximations: $(rr|ss)=\gamma_{ab}$ and $V_{a,rr}=-Z_a\gamma_{ab}$. We have found that, at distances greater than 3.5 Å, all these approximations give convergent values of energy; however, the present figures come from the last approximation. It is to be borne in mind that the present perturbation approach cannot be utilized in calcuating reliable equilibrium distances, many terms being uncorrectly calculated at short distances (*e.g.*, double excharge terms are lacking in the calculation of the exchange energy[7]). However, this method gives good information about preferential approaching pathways at large distances,[3] for which the simplified SCF-MO methods are ineffective.

The geometries of ethane molecule and ammonium ion were taken from the literature.[8] The geometry of the formamide dimer was determined by adopting the standard bond lengths and bond angles,[9] and by choosing the distance and dihedral angle between the two planar molecules so that the standard geometry of the α-helix[9] might be reproduced (see Fig. 1).

One of us (C.R.) has worked out a program in FORTRAN IV for the CDC 6600 computer, such that perturbation energies may be calculated in a step on the basis of the CNDO/2 program. This CNDO/2 program is the Del Bene-Jaffè version[10,11] modified so that it may calculate, for a given geometry, first the electron structure of two isolated molecules, then intermolecular

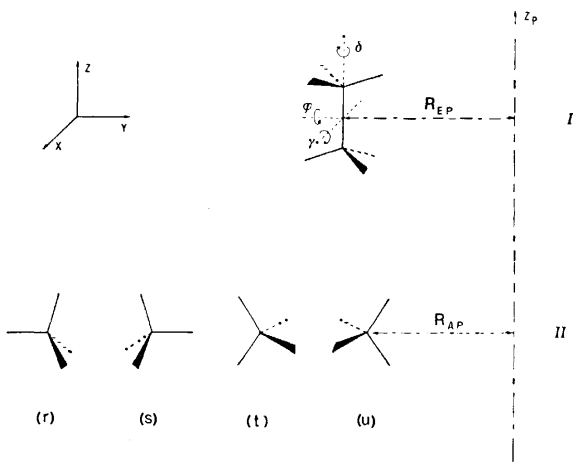

Fig. 2. Approaching pathways for ethane and ammonium ion. Z_P represents the z axis (NH···OC axis) of formamide dimer.

integrals, and finally intermolecular energies.

Figure 2 shows approach pathways between the NH··· OC axis and each of ethane (I) and ammonium ion (II, r, s, t, u) and defines the rotation angles (ϕ, γ, and δ) for ethane. Three relative positions were considered for the set of ethane and NH···OC zxis: (1) ethane placed in front of the N–H bond (A_I); (2) ethane placed in front of the C=O (C_I); and (3) ethane placed in an intermediate region (B_I). The ethane–protein axis (R_{EP}) was held perpendicular to the plane of the nearest amide molecule and the intermediate region (B_I) had an averaged orientation imposed.

Five relative positions were considered for ammonium ion in view of its greater specificity for intermolecular interaction. They describe the positioning of the ion in front of atoms N, H, O, and C and in the intermediate (H-bridge) region (A_{II}, B_{II}, D_{II}, E_{II}, and C_{II} regions, respectively). The same criterion as for the ethane–protein axis was adopted also for the orientation of the ammonium–protein axis (R_{AP}).

Results and Discussion

Interaction energies for the set of ethane and formamide dimer, located in the three significant regions along the NH···OC axis, are given in Table 1. Rotation angle ϕ is defined in Fig. 2. The data indicate

that in the proximity of the N-H bond the ethane molecule is isotropic both at R_{EP}=4.5 and 5.5 Å. For the other two positions (C=O and H···O), we can note isotropy at 5.5 Å, while at 4.5 Å a preferential orientation of the C–C axis of ethane along the NH···OC axis occurs. In any cases preferred intermolecular binding is in the neighborhood of the C=O bond. This trend is justifiable if we look at the dispersion and charge-transfer contributions to the total energy, the other contributions (E_Q, E_K, and E_I) being nearly zero. Dispersion energy is about −0.03 kcal mol^{-1} at 5.5 Å, independent of the position along the NH···OC axis. Analogously an isotropy appears at 4.5 Å with a value of about −0.1 kcal mol^{-1}. These figures are probably underestimated because of the limited set of excited states; however, since the dispersion results are nearly isotropic along the protein axis (see Table 1), this fact will little affect our future conclusions. The charge-transfer contribution shows a non-isotropic trend. In fact, it is very small in the neighborhood of the N-H bond, so that at 5.5 Å it is nearly zero; a large CT contribution has been evidenced in the H···O region at 4.5 Å, while it is very small at 5.5 Å. The largest CT energy is observed in the proximity of the C=O bond; in fact at 4.5 Å the total interaction energy is due mainly to it, and at 5.5 Å the CT energy appears com-

parable with the dispersion term. This behaviour is well justified if we bear in mind that the HOMO of formamide dimer is essentially located on the carbonyl group. Calculations were also undertaken for various angles of rotation (δ) around the C–C axis of ethane. The results indicate a small anisotropy, of about 0.5 kcal mol^{-1}, at 4.5 Å and in the proximity of the carbonyl group. Further calculations were carried out at 3.5 Å. The results are not reliable because of the large overlap which limits the validity of the present perturbation approach. However, even if the results are numerically unacceptable (essentially the CT contribution is overestimated at short distances), the figures are sure to follow the same trend.

As far as the charged molecule NH_4^+ is concerned, a large anisotropy is evidenced in the neighborhood of the C=O group at 4.5 Å, as we can see from Fig. 3 (region E) and Table 2, which summarizes results for the five positions of the ion located at 4.5 and 5.5 Å in front of the NH···OC axis. Moreover, a complete isotropy is found in correspondence with the N–H bond, and only a little preference for *t* conformation is found in the intermediate region. At 5.5 Å the four orientations (r, s, t, and u) of the ion are isoenergetic; the minimum potential is found in correspondence with the N–H bond. Even if the energy scale is not so accurate owing to the underestimation of dispersion forces, the trend may be considered reliable since the dispersion term is isotropic as observed for ethane. The overall trend is dependent essentially on the balance between the electrostatic and CT contributions since the other terms are almost constant or zero. At 4.5 Å the total energy curves have such trends as are highly differentiated for the various orientations of ammonium ion with respect to the protein z axis (see Fig. 2) as a consequence of the trend of the CT contribution, which, in the neighborhood of the carbonyl group, can be predominant when an optimum overlap is attained (pathways s and t). At 5.5 Å the curves for the total energy nearly match the trend of the electrostatic term.

From the present results we can argue that an aliphatic chain prefers to locate itself in the proximity of, and parallel to the carbonyl group of the polypeptide chain. The ammonium ion at 5.5 Å shows a preference for the N atom lone pair, while at shorter distances (in the range of experimental equilibrium distances) a competitive attraction of the N atom and of the C=O bond appears. From a study on formamide interacting with metal ions, a preferential binding of the ion along the C=O bond axis was found.[12] In our case, even if the C=O group is bound to the N–H bond by an H-bridge, we are still to find this tendency of the carbonyl group to attract the positive ion. However, it is to be pointed out that energies in balance are so small that the steric and/or solvent effects may also be competitive.

The present results, which may be considered as a good description of lipid systems with poly-L-glycine, suggest that in proteins with nonpolar side residues, the field experienced by the molecules adjacent to the polyamidic α-helix is nearly isotropic. Consequently, we may conclude that, for proteic systems without ionic or highly polar side residues, the approximation which simulates the protein as a dielectric cylinder[13] is reasonably applicable. However, effects of hydrophobic and/or polar residues and of the solvent on lipid–protein interactions are a matter of further investigation.

Electron Spin Resonance Studies of Manganese(II) Doped in $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$. Angular and Temperature Dependency of Fine Structures

Taku NAKANO

Department of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Toyama 930-01

(Received April 30, 1981)

ESR measurements on Mn(II) ion doped in single crystals of $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ confirmed the structure of the Hofmann-type clathrate predicted before. Spin Hamiltonian parameters obtained are $g=2.0033\pm 0.0010$, $A=(-84.9\pm1.0)\times10^{-4}$ cm^{-1} (123 K) and $(-84.3\pm1.0)\times10^{-4}$ cm^{-1} (room temp), $D=(67.5\pm1.0)\times10^{-4}$ cm^{-1} (123 K) and $(17.3\pm1.0)\times10^{-4}$ cm^{-1} (room temp), and $a=(16.5\pm1.0)\times10^{-4}$ cm^{-1}. The environment of Mn(II) ion has a tetragonally distorted cubic symmetry. While the parameter a is independent of temperature, the parameter D is found to be dependent on temperature obeying to $D\propto(T_0-T)^2$ where T_0 is 473 K. The nuclear forbidden lines, $\Delta m=\pm1$, were also detected, intensities of which vary in terms of D squared.

The series of Hofmann-type clathrates has the general formula of $M(NH_3)_2M'(CN)_4 \cdot 2G$, (M–M'–G), where M is a divalent metal ion such as Mn(II), Fe(II), Co(II), Ni(II), Cu(II), Zn(II), and Cd(II), and M' is Ni(II), Pd(II), or Pt(II).[1–3] G represents an aromatic molecule such as benzene (Bz), aniline *etc.* The inorganic part of the compound, $M(NH_3)_2M'(CN)_4$, forms a two-dimensional network which clathrate aromatic molecules between them as shown in Fig. 1.[4–6]

X-Ray crystallographic investigations have been reported in cases of Mn–Ni–Bz,[6] Ni–Ni–Bz,[4] Cu–Ni–Bz,[7] and Cd–Ni–Bz.[5] The compounds have an isomorphous structure with a space group of P4/m.

Magnetic properties of the clathrates have been reported for Mn–Ni–G,[8] Ni–Ni–G,[9] and Cu–Ni–G.[10] The ^{1}H NMR of ammonia molecules, which coordinate to metal ion M, is also reported in both diamagnetic[11] and paramagnetic[12,13] compounds. ESR study of copper(II) has shown the Jahn-Teller distortion around the copper(II) ion which reveals that d_{z^2} orbital is the ground state.[7,14,15]

The manganese(II) ion in Hofmann-type clathrate has a high spin d^5 structure and the orbital angular momentum is quenched. The purpose of this study is to clarify the behavior of the paramagnetic manganese(II) ion which will reflect the fundamental characters of Hofmann-type clathrates by means of ESR spectroscopy.

	a	c	M-N(NH$_3$)	M-N(CN)

Fig. 1. The structure of Hofmann-type clathrates, $M(NH_3)_2M'(CN)_4 \cdot 2C_6H_6$.

Experimental

The single crystals of Cd–Ni–Bz which contain 0.1% of manganese(II) were prepared from an aqueous layer of an ammoniacal solution containing 1×10^{-2} mol dm^{-3} $Cd(NO_3)_2$, 1×10^{-5} mol dm^{-3} $MnCl_2$, 1×10^{-2} mol dm^{-3} $K_2Ni(CN)_4$, and 0.5 mol dm^{-3} NH_4Cl: pH adjusted to 8—9 using ammonia, and an organic layer of toluene containing benzene. The crystals grew at the interface between the aqueous and organic layers and on the bottom of the vessel. The dimension of the single crystal investigated in the present study is *ca.* $0.5\times0.5\times1.0$ mm^3 of the form of a square pillar, having ends in the form of pyramids.

The preparation of the crystals and the measurements of the ESR were done under a nitrogen atmosphere to prevent manganese(II) ions from being oxidized.

The ESR spectra were recorded using JES-FE-3X spectrometer at an X band frequency: 9.2 GHz, and a field modulation of 100 KHz and modulation widths of 0.4 mT. The field was calibrated with signals of manganese(II) doped in MgO. The crystal was rotated about the [001] and [110] axes and the temperature was varied with a stream of cold nitrogen, measured by a copper-constantan thermocouple.

Results and Discussion

The ESR spectra were recorded at various temperatures and at various angles, θ and φ; θ is the angle between the field and the [001] axis of the crystal and φ is that between the field in the (001) plane and [110] axis.

Figure 2 shows the ESR spectra recorded at various angles, θ, at 123 K. The spectral change when the magnetic field rotated about [001] axis at 123 K reveals the fourfold symmetry, on the other hand that about [110] axis reveals the twofold symmetry. The symmetry indicated above confirms the structure of the Hofmann-type clathrates.

It is reasonable to assume that the manganese(II) ions are located at the same positions as the cadmium(II) ions in Cd–Ni–Bz crystals. The X-ray crystallographic investigations have shown that the environment of manganese(II) in Mn–Ni–Bz[6] as well as that of cadmium(II) in Cd–Ni–Bz[5] has D_{4h} symmetry. The detailed structural parameters, the lattice con-

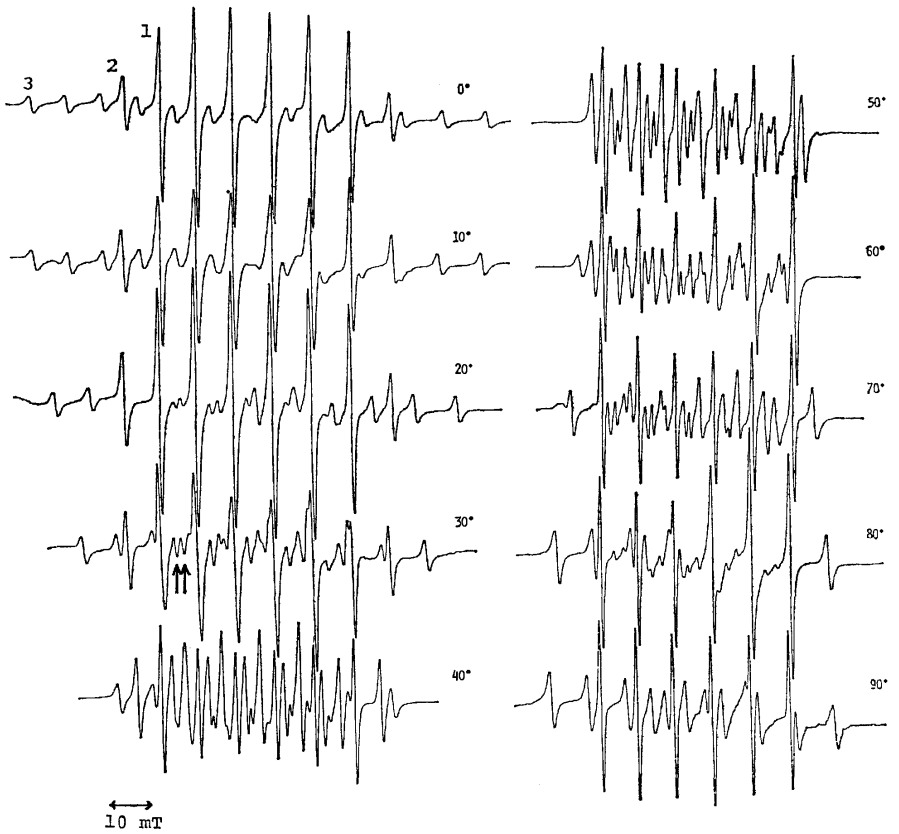

Fig. 2. ESR spectral change on angle θ at 123 K and $\varphi=0°$.
1: $|M,m>=|1/2,5/2>\leftrightarrow|-1/2,5/2>$, 2: $|M,m>=|1/2,5/2>\leftrightarrow|3/2,5/2>$, 3: $|M,m>=|3/2,5/2>\leftrightarrow|5/2,5/2>$. Arrows in the spectrum at $\theta=30°$ indicate the nuclear forbidden transitions: see text.

stants and the metal-nitrogen distances, are quoted in Fig. 1 to compare both compounds.[5,6]

The comparison of the metal-nitrogen distances has permitted us to assume the conservation of symmetry D_{4h} about manganese(II) ions doped in Cd-Ni-Bz. Thus the magnanese(II) ion was treated as having a nearly cubic but slightly tetragonally distorted structure of a weak crystalline field, and the assumption was revealed to be good.

The explanation of the spectra and the spectral changes can be made with a spin Hamiltonian of the form:

$$\mathcal{H} = \beta \boldsymbol{H}\cdot\boldsymbol{g}\cdot\boldsymbol{S} + D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2) + \frac{1}{6}a\left[S_x^4+S_y^4+S_z^4-\frac{1}{5}S(S+1)(3S^2+3S-1)\right] + \boldsymbol{S}\cdot\boldsymbol{A}\cdot\boldsymbol{I} - g_n\beta_n\boldsymbol{H}\cdot\boldsymbol{I}, \quad (1)$$

where D and E are axial and rhombic distortion parameters, respectively. The quantity a is a cubic parameter of the fourth order. Other symbols have their ordinary meanings.

The fields of the allowed transitions that are used for a high spin d^5 system of manganese(II) assuming the spin Hamiltonian (1) are calculated by the following equations:[16] it is also assumed that g and A are isotropic according to the results shown later.

$$M=\left|\pm\frac{5}{2}\right>\leftrightarrow\left|\pm\frac{3}{2}\right>:\ H = H_0 \mp 2\left(\frac{D}{g\beta}\right)(3\cos^2\theta-1) - \frac{32}{H_0}\left(\frac{D}{g\beta}\right)^2\cos^2\theta\sin^2\theta + \frac{1}{H_0}\left(\frac{D}{g\beta}\right)^2\sin^4\theta \mp 2p\left(\frac{a}{g\beta}\right) + f(M,m),$$

$$M=\left|\pm\frac{3}{2}\right>\leftrightarrow\left|\pm\frac{1}{2}\right>:\ H = H_0 \mp \left(\frac{D}{g\beta}\right)(3\cos^2\theta-1) + \frac{4}{H_0}\left(\frac{D}{g\beta}\right)^2\cos^2\theta\sin^2\theta - \frac{5}{4H_0}\left(\frac{D}{g\beta}\right)^2\sin^4\theta \pm \frac{5}{2}p\left(\frac{a}{g\beta}\right) + f(M,m),$$

$$M=\left|+\frac{1}{2}\right>\leftrightarrow\left|-\frac{1}{2}\right>:\ H = H_0 + \frac{16}{H_0}\left(\frac{D}{g\beta}\right)^2\cos^2\theta\sin^2\theta - \frac{2}{H_0}\left(\frac{D}{g\beta}\right)^2\sin^4\theta + f(M,m), \quad (2)$$

where M and m mean electron and nuclear(^{55}Mn) magnetic quantum numbers respectively, and $p=1-5(l^2m^2+m^2n^2+n^2l^2)$ and l, m, and n are direction cosines of the magnetic field with respect to the x, y, and z axes, respectively. The last terms correspond to a hyperfine splitting for the transition $|M>\leftrightarrow|M-1>$, $\Delta m=0$, to be expressed as;

$$f(M,m) = -\left(\frac{A}{g\beta}\right)m - \frac{1}{2H_0}\left(\frac{A}{g\beta}\right)^2\times\left[\frac{35}{4}-m^2+m(2M-1)\right]. \quad (3)$$

TABLE 1. SPIN HAMILTONIAN PARAMETERS

	Parameters	T/K
$g(g_{//}=g_{\perp})$	2.0033 ± 0.0010	
$A(A_{//}=A_{\perp})/cm^{-1}$	$(-84.9\pm1.0)\times10^{-4}$	123
	$(-84.3\pm1.0)\times10^{-4}$	room
D/cm^{-1}	$(67.5\pm1.0)\times10^{-4}$	123
	$(17.3\pm1.0)\times10^{-4}$	room
E/cm^{-1}	0	
a/cm^{-1}	$(16.5\pm1.0)\times10^{-4}$	

In Fig. 2, the most intense sextet is assigned to be $|-1/2>\leftrightarrow|1/2>$ transition, the middle ones are $|\pm1/2>\leftrightarrow|\pm3/2>$ transitions and the weakest are $|\pm3/2>\leftrightarrow|\pm5/2>$ transitions.

The Hamiltonian parameters were obtained from the spectra both at room temperature and at 123 K and are listed in Table 1. The shifts of signal positions *versus* angle θ arise from D and a terms and those *versus* φ only from a term. The g value and the hyperfine constant A are isotropic namely $g=g_{//}=g_{\perp}$ and $A=A_{//}=A_{\perp}$ within the experimental error.

The absolute signs of the parameters were determined by considering the angular dependency of the signal positions according to Eqs. 2 and 3, where the second order approximation was dealt with. If $D\cdot A<0$, for the sextet of the transition of $M>0$, the splitting caused by Eq. 3 is smaller, and the position at $\theta=0°$ is at a lower field than that of $M<0$ or *vice versa*. This is the case. The change of the signal positions on angle θ make it clear that the parameters D and a have the same sign. When A is assumed to be negative, as general, the sign of a is positive being consistent with Watanabe's theory.[17] The signs of the parameters thus obtained are shown in Table 1. Other sets of signs do not explain the change of the signal positions.

The thirty angular dependence curves calculated according to Eq. 2 using the parameter values in Table 1 are in a good agreement with the experimental results shown in Figs. 3 and 4, where the assignments are indicated.

Temperature Dependency of the Fine Structures. As reported in many cases of manganese(II) ESR, the parameter D has non-zero values also in the Hofmann-type clathrate, though g and A are isotropic. Here, it is noteworthy that the D value is dependent on temperature. The changes of the signal positions due to temperature are shown in Fig. 5 in the temperature region from 123 to 433 K. Above room temperature the signals were irreversibly broadened because of an escape of benzene molecules from the surface of the crystal.

While the signal positions of the sextet $M=|1/2>\leftrightarrow|-1/2>$ do not vary with temperature, those of the sextets $M=|\pm1/2>\leftrightarrow|\pm3/2>$ and $M=|\pm3/2>\leftrightarrow|\pm5/2>$ shift outwards with decreasing temperature. The values of the parameters D and a are plotted in Fig. 6.

As shown clearly in Fig. 6, the cubic parameter a is independent of temperature. Since the parameter a relates closely with the strength of the cubic crystalline field parameter Dq, as indicated by Watanabe,[17] the constancy of the parameter a suggests that the crystalline field does not vary as the results of the structural change around manganese(II) ions in the temperature region studied here.

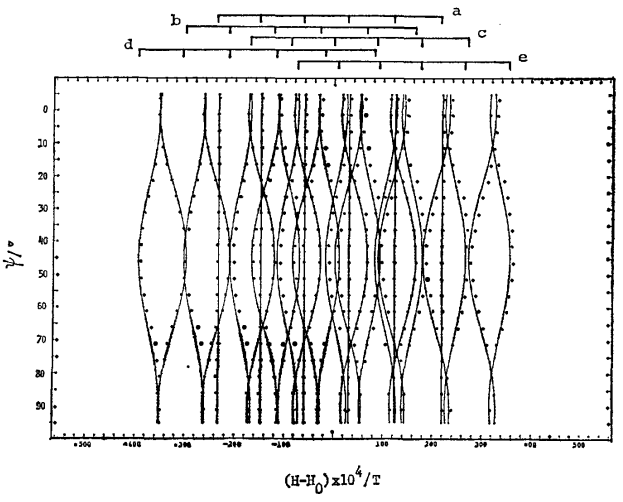

Fig. 3. Angular dependence of ESR signals on angle φ at $\theta=90°$.
$H_0=3274\times10^{-4}$ T. Dots are the experimental results and the solid lines are calculated curves using the parameter values at 123 K in Table 1. The signal positions are assigned at $\varphi=45°$. a: $|M>=|1/2>\leftrightarrow|-1/2>$, b: $|M>=|-1/2>\leftrightarrow|-3/2>$, c: $|M>=|1/2>\leftrightarrow|3/2>$, d: $|M>=|-3/2>\leftrightarrow|-5/2>$, e: $|M>=|3/2>\leftrightarrow|5/2>$. As for m, the lowest is assigned to be $m=-5/2$ and the highest 5/2 for all five sextets.

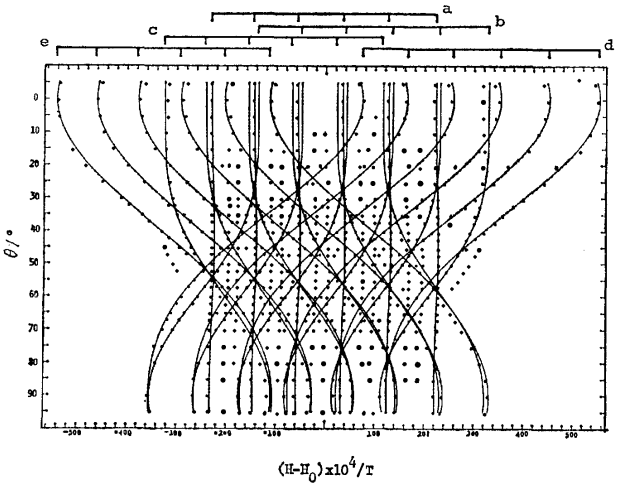

Fig. 4. Angular dependence of ESR signals on angle θ at $\varphi=0°$.
$H_0=3274\times10^{-4}$ T. Dots are the experimental results and the solid lines are calculated curves using the parameter values at 123 K in Table 1. The signal positions are assigned at $\theta=0°$. a: $|M>=|1/2>\leftrightarrow|-1/2>$, b: $|M>=|-1/2>\leftrightarrow|-3/2>$, c: $|M>=|1/2>\leftrightarrow|3/2>$, d: $|M>=|-3/2>\leftrightarrow|-5/2>$, e: $|M>=|3/2>\leftrightarrow|5/2>$. As for m, the lowest is assigned to be $m=-5/2$ and the highest 5/2 for all five sextets.

According to Watanabe,[17] the crystalline field parameter Dq is estimated to be 1407 cm^{-1}. Unfortunately the spectroscopic data was not available for comparison with the theoretical value in this stage.

On the other hand, the parameter D increases with decreasing temperature as shown in Figs. 6 and 7. In Fig. 7 the square root of D is plotted and has a linear relation to temperature. Thus the temperature dependency of D was found experimentally to be

$$D(T) = k(T_0 - T)^2, \quad (4)$$

where T is the absolute temperature and T_0 and k were found to be 473 K and $5.2_7 \times 10^{-8}$ cm^{-1} K^{-2} respectively.

The temperature dependence of D has been found for example in cases of nickel(II) ESR in $NiSnCl_6 \cdot 6H_2O$,[18] and $NiSiF_6 \cdot 6H_2O$,[19] manganese(II) ESR in K_2SO_4,[20] and iron(III) ESR in $BaTiO_3$;[21] in the latter two cases the changes of D are attended on phase transitions. However the clear elucidation of these phenomena has not been given until now. In the case of manganese(II) in the Hofmann-type clathrate, any structural change has not been reported in the temperature region studied here and moreover the invariability of the parameter a does not suggest any phase transitions. Though the reason for the temperature dependency cannot be elucidated in this stage, this phenomenum would add a new characteristic feature on the Hofmann-type clathrates. Further investigation of the structure will be necessary.

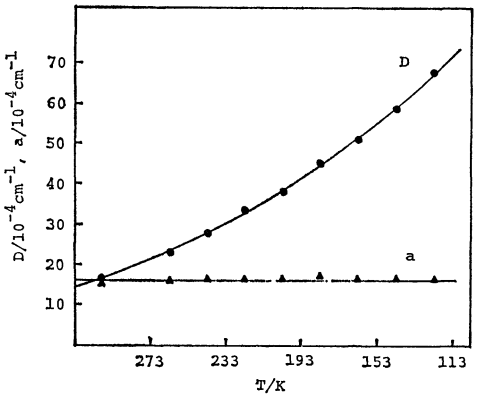

Fig. 6. Relations between D and a parameters and temperature.

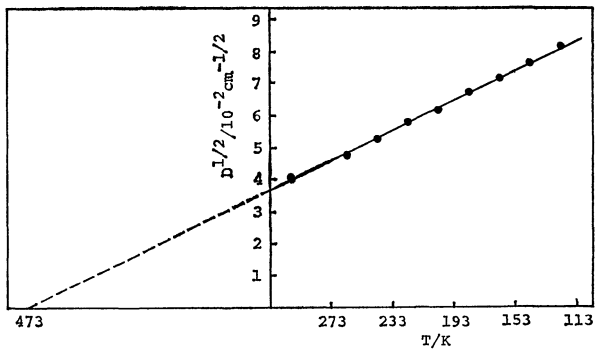

Fig. 7. Temperature dependence of D parameter.

The Nuclear Forbidden Lines. The arrows in the spectra in Figs. 2 and 8 indicate the nuclear forbidden lines, $\Delta m = \pm 1$. The intensities of these lines found here do change with temperature. The number of theoretically predicted forbidden lines is thirty, but in this case we could find the relatively intense five doublets that appear among the sextet of allowed transitions $|1/2> \leftrightarrow |-1/2>$, and others that are barely recognizable outside the intensive allowed signals near $\theta=50°$. In Fig. 4, the dots aside from the solid lines mark the positions of the forbidden lines.

The forbidden lines appear when the magnetic field

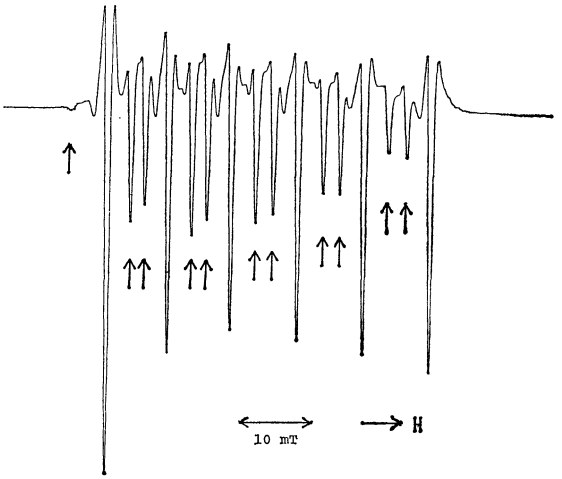

Fig. 8. Nuclear forbidden lines at $\theta=55°$ and $\varphi=0°$, and at 113 K. The spectrum is a second derivative curve. Five doublets are assigned to be $M=|1/2> - |-1/2>$, $\Delta m=\pm 1$, and the arrow at the lowest field indicates the one not assigned.

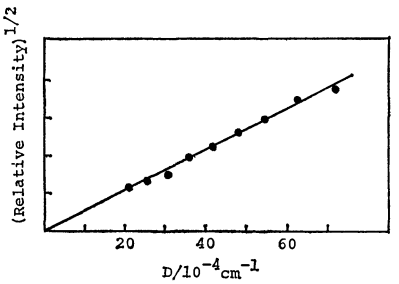

Fig. 9. Relation between D and intensity of the forbidden lines: $\Delta M=\pm 1$ and $\Delta m=\pm 1$.

is rotated about the [110] axis, disappearing at $\theta=0°$ and 90°, and not observed when the field is rotated about the [001] axis. The signals have maximum intensities near $\theta=55°$. Unfortunately the precise determination of the change of intensity with rotation was impossible since the strong signals of the allowed transitions superimpose on the forbidden lines.

The relative intensity increases with decreasing temperature, suggesting that it is related closely with the D value. Figure 9 shows the relation between the intensity of one of the pairs of the doublets and the axial parameter D at $\theta=55°$, at which angle the forbidden lines clearly appear separated from the allowed transitions. The intensity is proportional to D^2;

$$I(1/2) = k(\theta)D^2, \quad (5)$$

where $I(1/2)$ is the intensity of the forbidden line $M=|1/2>\leftrightarrow|-1/2>$, and $k(\theta)$ is a function of angle θ.

The intensity of the forbidden lines will vary as $A\cdot D^2(\sin 2\theta)^2+B\cdot a^2(\sin 4\theta)^2$, when the parameters D and a have non-zero values.[22,23] However the relation revealed in this compound between the intensity and the parameter D suggests that the mixing of the energy states may arise from the second order perturbation only with the D term, and those with the a term would be too small to be detected here.

The positions of the forbidden lines $M=|1/2>\leftrightarrow|-1/2>$ and the separations of the doublets were independent of temperature. The separations of doublets obtained experimentally are 18.7, 20.6, 23.4, 23.4, and 25.3×10^{-4} cm^{-1} for $m=|-5/2>\leftrightarrow|-3/2>$, $m=|-3/2>\leftrightarrow|-1/2>$, $m=|-1/2>\leftrightarrow|+1/2>$, $m=|1/2>\leftrightarrow|3/2>$, and $m=|3/2>\leftrightarrow|5/2>$, respectively. The calculated values according to Bleaney and Rubins[22] are 18.8, 20.7, 22.3, 23.9, and 25.8×10^{-4} cm^{-1}, respectively. The detailed work about the seperation will give the precise values of g_n and Q (quadrapole moment) of ^{55}Mn.

Conclusion

From the parameter values obtained, manganese(II) ion has a g value which is almost the same as that of a free electron, and slightly tetragonally distorted cubic symmetry, D_{4h}. It is noteworthy that the axial parameter D is dependent on the temperature. This suggests a new characteristic feature in this compound, while the cubic parameter a does not change. The forbidden transitions arise from the D term and are also dependent on temperature.

The work was supported by a Grant-in-Aid for Scientific Research No. 474265 from the Ministry of Education, Science and Culture.

Pyrene-cation Formation on Reactions of Pyrene Triplet State with Metal Ions in Caffeine-solubilized Aqueous Solution

Yoshio NOSAKA,* Akira KIRA, and Masashi IMAMURA

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received August 7, 1981)

Synopsis. Quenching of triplet states of pyrene and other aromatic hydrocarbons by metal ions in caffeine-solubilized aqueous solution was investigated. The concomitant formation of aromatic cations was observed on quenching of triplet pyrene by Hg^{2+} and Fe^{3+} and triplet phenanthrene and benz[*a*]anthracene by Hg^{2+}.

To the reactions between excited states of aromatic hydrocarbons and metal ions have been paid attention from the viewpoint of their application to solar energy conversion based on the photo-induced electron transfer reactions. However, such charge separation with metal ions was known only for the triplet states of thiazine dyes.[1-4] Recently, we have reported reduction of metal ions with the excited singlet state of pyrene solubilized in aqueous solution of caffeine.[5] The experiments performed in aqueous solution are of greater advantage than those in organic solvents in regard to dissolving various metal ions. In the present paper, we report a study on quenching of triplet states of pyrene and other aromatic hydrocarbons by metal ions in caffeine-solubilized aqueous solution. The results indicate that electron transfer occurs from the triplet state of pyrene to Hg^{2+} and Fe^{3+} whose reduction potentials are rather low. Other metal ions were not reduced, although they quenched the triplet state of pyrene to a certain extent.

The apparatus using a frequency doubled Q-switched ruby laser and experimental procedures have been described in the previous paper.[5] Figure 1 exhibits oscilloscope profiles representing the decay of the pyrene triplet state and concomitant growth of pyrene cations on quenching by Hg^{2+}. The assignment of the growing species to the pyrene cation was based on its absorption spectrum.[6] The concentrations of pyrene cations and pyrene triplet states were estimated from the absorbances at 450 and 414 nm using reported values of extinction coefficient.[7,8] The yields of the cation originating in the excited singlet state, which also contribute to the observed cation yields in the time region of Fig. 1, were given in the previous report.[5]

The bimolecular rate constant for triplet-quenching (k_q) was obtained from the observed pseudo-first-order rate constants;

$$k_{obsd} = k_o + k_q[M^{n+}],$$

where $[M^{n+}]$ is the concentration of metal ions. The reaction of the triplet state (^3P) with metal ions is expressed by Reactions 1 and 2.

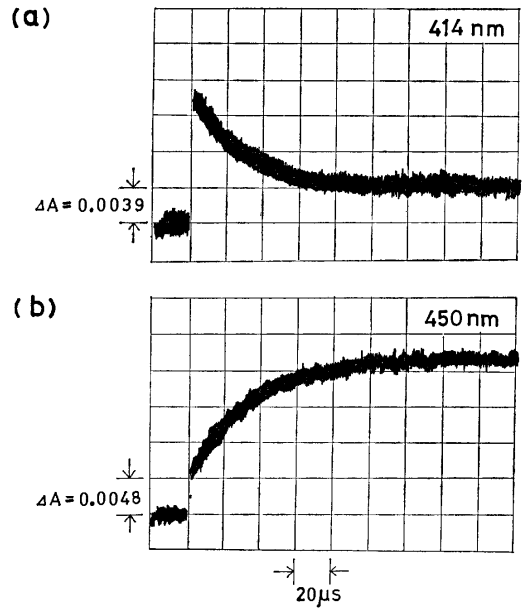

Fig. 1. Oscilloscope traces after laser excitation observed at 414 and 450 nm, which correspond to absorption peaks for pyrene triplet state and pyrene cation, respectively. [Pyrene]=0.04 mM, [Hg$(NO_3)_2$]=1.0 mM, and [caffeine]=60 mM.

$$^3P + M^{n+} \xrightarrow{k_{1q}} P + M^{n+}, \quad (1)$$

$$^3P + M^{n+} \xrightarrow{k_{2q}} P^+ + M^{(n-1)+}, \quad (2)$$

for which

$$k_q = k_{1q} + k_{2q}.$$

Quenching rate constants k_q measured for the reactions of the triplet state of pyrene with some metal ions and for the reactions of the triplet states of phenanthrene (^{3}Phe) and benz[*a*]anthracene (^{3}BA) with Hg^{2+} are shown in Fig. 2 as a function of the free-energy change (ΔG°)[5,9] of the charge transfer reaction (Eq. 2). For Eu^{3+}, Zn^{2+}, Cd^{2+}, Tl^+, and Tb^{3+}, the experimental values for k_q were less than 10^6 M^{-1} s^{-1}. Rate constants for pyrene fluorescence quenching as well as a theoretical curve which has been discussed in the previous report[5] are also shown in Fig. 2. The theoretical curve implies that electron transfer occurs with an activation energy of 0.75 eV in the case of $\Delta G^\circ = 0$ eV.[9]

The fraction of charge transfer, which is expressed by the ratio of the rate constants, k_{2q}/k_q, is calculated as the ratio of an increment of the pyrene cations to a decrement of the triplet state in the quenching process. The charge transfer fractions were more than 0.9 for Hg^{2+} and Fe^{3+}, and less than 0.1 for Cu^{2+},

* Present address: Department of Materials Science and Technology, The Technological University of Nagaoka, Nagaoka, Niigata 949-54.

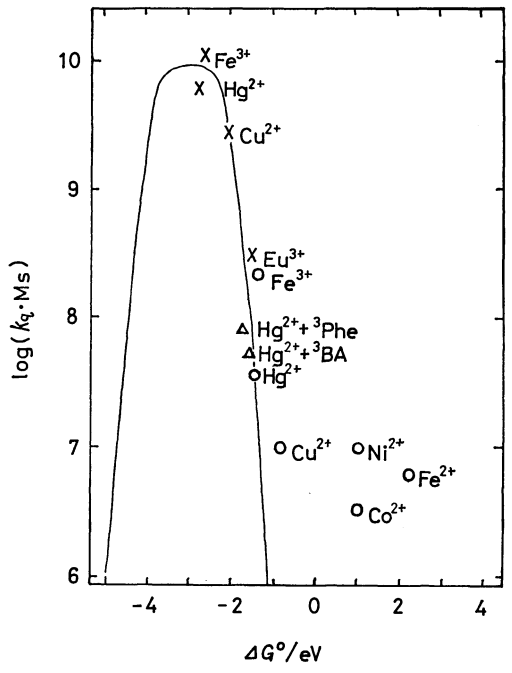

Fig. 2. Plot of log k_q as a function of the free energy change($\Delta G°$) for electron transfer reaction from excited states of pyrene to metal ions. Open circles and crosses show the reaction rates for triplet state and excited singlet state[5] of pyrene, respectively. ^{3}Phe and ^{3}BA are triplet states of phenanthrene and benz[*a*]anthracene.

Ni^{2+}, Fe^{2+}, and Co^{2+}. For metal ions by which hydrocarbon cations were formed, the experimental points for triplet excited states are located on the theoretical curve presented for singlet excitated states.[5] For the other metal ions, the experimental points are not located on the curve but above it, indicating existence of some efficient quenching mechanisms other than the electron transfer mechanism. The mechanism presented previously[5] for triplet state formation on fluorescence quenching may also be applicable to the mechanism of singlet state formation on phosphorescence quenching in this case. Further experiments for various metal ions will afford much information concerning the quenching mechanism which is applicable to both singlet and triplet excited states.

Solvent Effect on the Nonradiative Deactivation of the Excited State of Tris(2,2'-bipyridyl)ruthenium(II) Ion

Katsumi NAKAMARU

Department of Chemistry, Faculty of Science, Hirosaki University, Bunkyo, Hirosaki, Aomori 036

(Received September 21, 1981)

Synopsis. Emission quantum yields and lifetimes of the $[Ru(bpy)_3]^{2+}$ ion were measured in various solvents at 25 °C. Nonradiative rate constants (k_{nr}) were calculated from these data. A plot of k_{nr} *vs.* the Gutmann's acceptor number was found to be linear. This result can be explained in terms of the contributions of charge transfer to solvent (CTTS).

The well-known luminescence of the tris(2,2'-bipyridyl)ruthenium(II) ion, $[Ru(bpy)_3]^{2+}$, has been extensively studied. It has been generally accepted that the luminescence at 77 K arises from a charge transfer to ligand (CTTL) excited state.[1] Houten and Watts,[2,3] however, studied effects of ligand and solvent deuteration on the luminescence quantum yields and lifetimes in aqueous solution between 0 and 100 °C. They concluded that in this temperature range charge transfer to solvent (CTTS) configurations contribute to the luminescence in addition to the CTTL configuration. This conclusion suggests that complex-solvent interactions in fluid solutions are important in the deactivation processes of the CTTL excited state. So it is surprising that there have been few photophysical and systematic studies of the $[Ru(bpy)_3]^{2+}$ complex in organic solvents. In this paper the author reports the emission quantum yields and lifetimes measured in various solvents and also some information on the contributions of CTTS to the nonradiative deactivation of the CTTL excited state.

Experimental

Tris(2,2'-bipyridyl)ruthenium(II) chloride pentahydrate, $[Ru(bpy)_3]Cl_2 \cdot 5H_2O$, was prepared according to the method described in the literature.[4] Found: C, 48.88; H, 4.51; N, 11.67%. Calcd for $C_{30}H_{34}O_5N_6RuCl_2$: C, 49.32; H, 4.69; N, 11.50%. All solvents were reagent grade and used without further purification. Absorption and emission spectra were measured with a Hitachi 124 double-beam spectrophotometer and a Hitachi MPF-4 fluorescence spectrophotometer, respectively. Emission quantum yields were determined at the excitation wavelength of 436 nm by the modified Parker and Rees method[5] using fluorescein purified by the reported procedures[6] in 0.1 mol dm^{-3} NaOH (yield, 0.90) or $[Ru(bpy)_3]Cl_2$ in aerated aqueous solution (yield, 0.028[7]) as the standards. Lifetimes were measured using an apparatus with a pulsed nitrogen laser as the exciting light source. All samples were prepared immediately prior to use and the complex solutions were nitrogen-saturated for 15—20 min. All measurements were carried out at 25 °C.

Results and Discussion

The absorption maxima in the visible CTTL band of the $[Ru(bpy)_3]^{2+}$ ion show only slighter shifts than the emission maxima upon changes of solvents (Table 1). However, the efforts to relate the tendency in the spectral shifts with solvent parameters such as dielectric constants were unsuccessful, although it was seen that both absorption and emission spectra shifted to red in alcohols having a longer carbon-carbon bond chains. The latter observation has been reported by Meisel *et al.*[8]

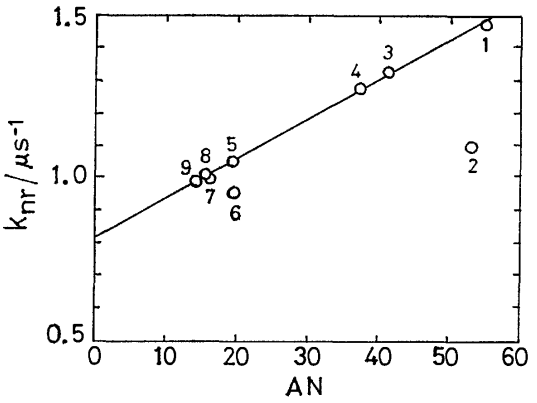

Fig. 1. Plot of k_{nr} *vs.* acceptor number(AN) for $[Ru(bpy)_3]Cl_2$ in various solvents at 25 °C. Solvent: 1, water; 2, acetic acid; 3, methanol; 4, ethanol; 5, acetonitrile; 6, dimethyl sulfoxide; 7, *N*,*N*-dimethylformamide; 8, benzonitrile; 9, pyridine.

The results of the emission quantum yields listed in Table 1 may be explained this way. If CTTS actually contributes to the CTTL excited state, it may safely be said that the higher electron-attractive power a solvent has (that is, the more electrophilic a solvent is), the more easily the charge transfers to the solvent. Such a state is unlikely to be stable and thus would lead to a fast nonradiative deactivation. Taking account of the fact that the so-called Gutmann's acceptor number[9] adequately fits the solvent properties described above, the nonradiative rate constant for the CTTS deactivation, k_{CTTS}, can be considered to be proportional to the acceptor number (AN). Hence the following expression:

$$k_{nr} = k^{\circ}_{nr} + k_{CTTS} = k^{\circ}_{nr} + k'[AN],$$

can be derived, where k_{nr}, k°_{nr}, and k' denote the total nonradiative rate constant, the nonradiative rate constant independent of CTTS, and a rate constant dependent on AN, respectively. The value of k_{nr} can be calculated from the emission quantum yields (Q) and measured lifetimes (τ_m) by the equation, $k_{nr}=\tau_m^{-1}-k_r$, where k_r is the radiative rate constant calculated from Q/τ_m. The results are also tabulated in Table 1. The plot of k_{nr} *vs.* the acceptor number, AN, is illustrated in Fig. 1, which clearly shows a linear dependence of k_{nr} on AN with a slope of 0.012

μs^{-1} except in the case of the acidic solvent, acetic acid. Using the value of the intercept, 0.82 μs^{-1} (= k_{nr}°), the percentages, R, for the contributions of CTTS to the total nonradiative rate constant can be evaluated (Table 1). As was expected, in a solvent with a large acceptor number such as water, about half of the CTTL excited state of the $[Ru(bpy)_3]^{2+}$ ion deactivate through the contributions of CTTS, whereas in solvents such as *N,N*-dimethylformamide, benzonitrile, and pyridine the percentages are only about 20%. Unfortunately the experiments in other solvents could not be carried out because of the solubility problem or the lack of the knowledge of the acceptor number, but the general features obtained in this work seem to be unchanged.

The author wishes to thank Associate Professor Hiroshi Kokubun and Dr. Koichi Kikuchi of Tohoku University for their kindness in allowing use of their apparatus for lifetime measurements.

Apparent Molar Volumes of Water in Methanol and Tetrahydrofuran at 298.15 K

Masao SAKURAI* and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 7, 1981)

Synopsis. The densities of water–methanol(MeOH) and water–tetrahydrofuran(THF) mixtures have been measured at 298.15 K. The apparent molar volumes of water, $V_{\phi,w}$, have been derived as a function of concentration. The values of $V_{\phi,w}$ in MeOH increase monotonously with the concentration, while for THF solutions the $V_{\phi,w}$ curve passes through a minimum at low mole fraction of water. These are interpreted in terms of the formation of water–organic solvent and water–water hydrogen bonding.

Previously, we have reported that the apparent molar volumes of water, $V_{\phi,w}$, are almost independent of the concentration in very dilute solutions of water in benzene and in methanol.[1] In this paper we will report the density data for water–methanol(MeOH) and water–tetrahydrofuran (THF) mixtures over a wide range of concentration, and will compare the results with those reported by Benson and his coworkers.[2-4]

Experimental

The MeOH and THF were dried over anhydrous calcium sulfate and then fractionally distilled. The water was deionized and distilled using a quartz still. The mole fractions of water, X_w, of the mixtures in the organic solvent-rich region (*ca.* $X_w<0.1$) were determined with an automatic Karl Fischer titration apparatus (Hiramuma, AQ-3). In most cases the error in the mole fraction was estimated to be less than 1×10^{-4}. The densities, ρ, of the mixtures relative to pure water at 298.15 K were determined with an oscillating tube densimeter (Paar, DMA 60/601). The density of water was taken as 0.997045 g cm^{-3}.[5] Details of the apparatus and its operating procedure have been described previously.[1]

Results and Discussion

The experimental results are summarized in Table 1. The apparent molar volume of water is given by:

$$V_{\phi,w} = (\rho^*-\rho)/c\rho^* + M_w/\rho^*, \quad (1)$$

where ρ^* is the density of pure solvent, c is molar concentration, and M_w is the molar mass of water. Since we could not obtain any sample of solvents completely free from water, the value of ρ^* was estimated by the extrapolation of the solution densities to $c=0$, as will be described below.

For dilute solutions the apparent molar volume of nonelectrolytes can be represented in terms of molarity:

$$V_\phi = V^\infty + b_v c, \quad (2)$$

where V^∞ is partial molar volume at infinite dilution. From Eqs. 1 and 2, the density of the solution is given by:

$$\rho = \rho^* + (M_w-\rho^*V_w^\infty)c-\rho^*b_v c^2. \quad (3)$$

Table 2. Densities[a] and partial molar volumes for the MeOH and THF solutions of water at 298.15 K

	ρ^* / g cm^{-3}	V_w^∞ / cm^3 mol^{-1}	b_v / cm^3 dm^3 mol^{-2}
MeOH[b]	0.786427	14.42	0
THF	0.881950	17.00	−0.8

a) Values of ρ^*/g cm^{-3} from the literature are: 0.786350,[4] 0.78660,[6] 0.78636,[7] 0.78686[8] for pure MeOH; 0.88195,[2] 0.881968,[3] 0.88194[9] for pure THF. b) Ref. 1.

Previously we have found that the densities of MeOH solutions of water increase linearly with the molarity in the concentration range less than about 0.7 mol dm^{-3} ($X_w<0.027$), that is, $b_v\simeq0$.[1] On the other hand, no linearity was found for the THF solutions. In Table 2 are given the values of ρ^*, V_w^∞, and b_v determined by the method of least squares in the concentration range less than about 0.5 mol dm^{-3}

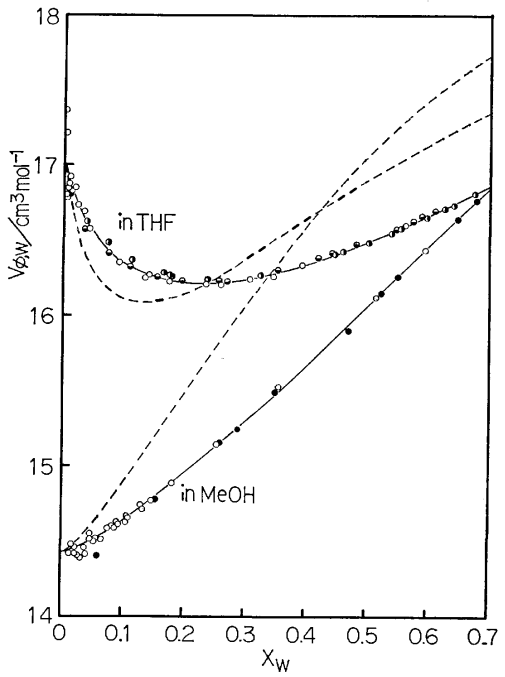

Fig. 1. Concentration dependence of the apparent (solid lines) and partial(dotted lines) molar volumes of water in MeOH and THF solutions at 298.15 K. ○: This work, ◑: Ref. 2, ◒: Ref. 3, ●: Ref. 4.

($X_w<0.04$), along with the values for the MeOH solutions.[1]

The V_w^∞ values in both the solvents, as well as in other polar solvents,[10–12] are less than the molar volume of pure water (18.07 cm^3 mol^{-1}). This decrease in volume may be related to the loss of the open structure of bulk water and to the formation of hydrogen bonds between water molecules and the solvent molecules. The smaller V_w^∞ value in MeOH can be attributed mainly to the strong hydrogen bond formation between water and MeOH molecules.

Using the ρ^* values obtained, we can estimate the $V_{\phi,w}$ at finite concentrations. The results are shown in Fig. 1. The closed and half-closed circles represent the values calculated from excess volumes reported by Benson and his co-workers.[2–4] These are in fair agreement with our results. The dotted lines are the partial molar volumes of water estimated by the relation:

$$V_w = V_{\phi,w} + X_w(1-X_w)\partial V_{\phi,w}/\partial X_w. \quad (4)$$

The values of $V_{\phi,w}$ (or V_w) in MeOH increase monotonously with the increase in X_w, while for THF solutions the $V_{\phi,w}$ *vs.* X_w curve passes through a broad minimum at near 0.25 mole fraction of water ($X_w \simeq$ 0.13 for minimum V_w).

It is well known that the partial molar volumes of various nonelectrolytes and organic electrolytes in water have a characteristic minimum in the water-rich region. The occurrence of this minimum has been ascribed to a balance between the enhancement of water structure by the solutes and the breaking of the structure with further increase in the concentration.[13] The minimum in the $V_{\phi,w}$ curve shown in Fig. 1, on the other hand, could not be attributed to such a structural influence because the open structure of water no longer exists in the THF-rich region. At present the molecular significance of the minimum is not clear but it may be related to the fact that THF–water hydrogen bonding is weaker than water–water hydrogen bonding.[2] The addition of water to THF will result in the formation of stronger hydrogen bonds between water molecules that would bring about volume contraction. Further increase in X_w may result in the formation of the well-known, three-dimensional open structure of water and the $V_{\phi,w}$ (or V_w) would increase to 18 cm^3 mol^{-1} in pure water.

The Crystal Structure of *o*-Fluorobenzamide

Yoshihiro KATO* and Kiichi SAKURAI

Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543

(Received October 17, 1981)

Synopsis. The crystal of the title compound is monoclinic, with space group $P2_1/a$, $a=12.695$, $b=20.534$, $c=5.133$ Å, $\beta=97.80°$, $Z=8$. The molecules are connected by one pair of hydrogen bonds to form asymmetric dimers and these dimers are further linked by two kinds of hydrogen bonds into endless chains along the c axis.

The crystals of *m*- and *p*-fluorobenzamides[1,2] contain four molecules per unit cell and the molecules are connected by hydrogen bonds to form centrosymmetric dimers. These dimers are linked by two kinds of hydrogen bonds into one-dimensional chains (*m*-fluorobenzamide) and two-dimensional networks (*p*-fluorobenzamide). The present study was undertaken to determine the type of hydrogen bonds and the molecular arrangement in the crystal of *o*-fluorobenzamide which has eight molecules in a unit cell.

Experimental

Crystals were grown from a hot aqueous solution by slow cooling to room temperature. The cell dimensions and reflection intensities were measured on a Rigaku automated four-circle diffractometer using monochromatized Mo $K\alpha$ radiation. The crystal data are as follows: $a=12.695(2)$, $b=20.534(2)$, $c=5.133(1)$ Å, $\beta=97.80(1)°$, $P2_1/a$, $Z=8$.

The intensity data were collected by the 2θ-ω scan technique with a speed of $8°(2\theta)$ min^{-1} up to $2\theta=58°$. The crystal used had approximate dimensions of $0.4\times0.4\times0.5$ mm^3. A total of 1953 reflections were obtained, of which 1471 were non-zero reflections. No corrections for absorption and extinction were made.

Structure Determination and Refinement

The structure was solved by the direct method with the MULTAN program.[3] All the non-hydrogen atoms appeared clearly in the *E* map, and the hydrogen atoms were found on difference Fourier maps. The *R* value was finally reduced to 0.076 by the block-diagonal least-squares refinement using the program *HBLS V*[4] with anisotropic thermal parameters for non-hydrogen atoms and an isotropic one ($B=3.7$ Å^2) for hydrogen atoms. The weighting scheme of the type $w=1-\exp(-15s^2)$ with $s=\sin\theta/\lambda$ was used. The final positional parameters and equivalent isotropic temperature factors for non-hydrogen atoms are listed in Table 1.[5]

Discussion

The bond lengths and bond angles are shown in Fig. 1. The molecular arrangement projected along the c axis is shown in Fig. 2. The least-squares plane through the six carbon atoms of the benzene ring and the plane through the C, N, and O atoms of the carbamoyl group for molecules I and II are given

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the *i*-th principal axis of the thermal ellipsoid.

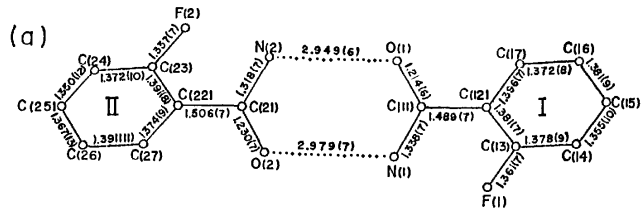

Fig. 1. a) Bond lengths (l/Å) and b) bond angles (ϕ/°).

by the following equations:

molecule I

benzene ring $0.577X+0.612Y-0.541Z=1.864$,

carbamoyl group $0.588X+0.808Y-0.032Z=1.583$,

molecule II

benzene ring $0.527X+0.471Y+0.707Z=0.240$,

carbamoyl group $0.813X+0.555Y+0.179Z=1.064$,

where *X*, *Y*, and *Z* are coordinates measured in Å

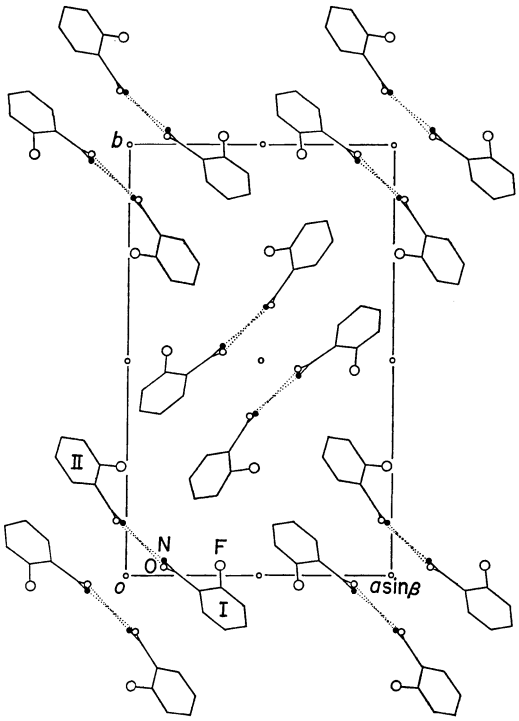

Fig. 2. The crystal structure viewed along the c axis.

along the orthogonal axes a, b, and c* respectively. The dihedral angles between the plane of the carbamoyl group and the mean plane of the benzene ring are 31.7° for molecule I and 35.4° for molecule II, which are rather small as compared with those of other ortho-substituted benzamides.[6] This can be explained from the fact that the van der Waals radius of the F atom is close to that of the H atom. It is interesting that the F atom lies on the side of N atom of the carbamoyl group for both of molecules I and II, while in the crystals of other *o*-halogenobenzamides[6] the halogen atoms lie on the side of O atom of the carbamoyl group. It is also noticeable that in the crystal of *o*-fluorobenzamide the unit cell contains eight molecules, which are linked in pairs by NH···O hydrogen bonds (2.949, 2.979 Å) to form asymmetric dimers. These dimers are further linked by the other NH···O hydrogen bonds (2.917, 2.945 Å) to form one-dimensional chains along the c axis. A pair of such chains related by a center of symmetry forms a double-chain having an enantiometric configuration.

X-Ray data collection was carried out on a Rigaku automated four-circle diffractometer at Crystallographic Research Center, Institute for Protein Research, Osaka University.

Anomalous Crystallization Behavior in the Glass Forming Composition Region of the H_2O-HNO_3 System

Kenji SATOH and Hitoshi KANNO*

Department of Chemistry, Meisei University, Hino, Tokyo 191

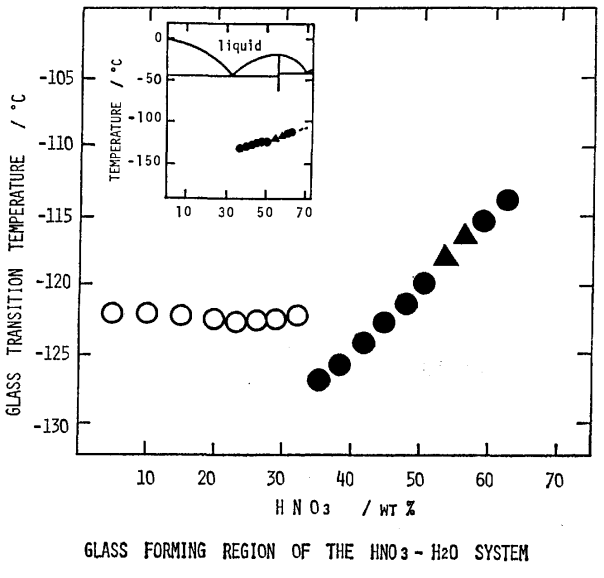
(Received November 20, 1981)

Synopsis. Glass formation composition region of aqueous HNO_3 solution is determined. Anomalous crystallization behavior was observed for the solution having the composition near $HNO_3 \cdot 3H_2O$. From T_g data, T_g for a bulk glassy water is estimated to be -144 ± 2 °C.

Glass forming composition regions in aqueous solution systems have recently been determined for a relatively large number of both inorganic salt–water and binary organic compound mixture systems.[1-3] From these studies, it has become evident that glass transition temperature (T_g) can be a useful parameter for characterizing thermodynamic and transport properties of a liquid at low temperatures.[1-4]

In this note, we report an anomalous crystallization behavior of an aqueous HNO_3 solution in the composition near $HNO_3 \cdot 3H_2O$, which is very suggestive for clarifying both glass formation mechanism and structure changes of the solution with composition.

All solutions were made by weighing out and mixing required amounts of a commercially available guaranteed-grade ≈62 wt% nitric acid and distilled water. The glass transition temperature of each solution was measured by a conventional, simple DTA method. The details of the experiment were essentially the same as previously reported.[3] Overall cooling rate of the sample solution contained in a 2 mm i.d. Pyrex glass cell was about 10^3 K/min. The T_g value was obtained at a heating rate of about 5 K/min in the warm-up DTA trace using chromel-alumel thermocouples.



GLASS FORMING REGION OF THE HNO3 - H2O SYSTEM

Fig. 1. Variation of T_g with solution composition. The inset shows the phase diagram of the HNO_3–H_2O system [from J. Timmermans, "Physico Chemical Constants of Binary Systems," Interscience Publishers, Inc., New York (1960), Vol. 4, p. 466]. ●: T_g in the glass-forming composition region, ○: T_g of the portion remained uncrystallized in the non-glass-forming composition region, ▲: the expected glass transition temperature if the solution was glass-forming.

The results obtained are plotted in Fig. 1 together with the phase diagram as an inset. Glass formation was visually checked and it began from the composition of about 35 wt% HNO_3 up to about 62 wt% HNO_3 (above which measurements were not made because of non-availability of a higher cocentration in this study). The solutions having the composition of less than 35 wt% HNO_3 are only partially glass-forming, therefore giving a glass transition as seen in the DTA trace A in Fig. 2.

An interesting point is the existence of a very narrow window (≈54 wt% HNO_3 region) where no glass transition is observed, indicating that the whole body of the solution crystallizes in the quenching rate of about 10^3 K/min. This is peculiar because most aqueous solutions which have a glass forming composition region are partially glass forming even in the non-glass forming composition region.[4,5] As the composition of the non-glass forming solution is very near 54 wt%, we consider that an additive compound of the composition $HNO_3 \cdot 3H_2O$ was formed in the cooling process. This is supported by the DTA trace C shown in Fig. 2. The fact that an appreciable part (about 5%) of the 53.8% HNO_3 solution crystallized in the eutectic composition, as evidenced with

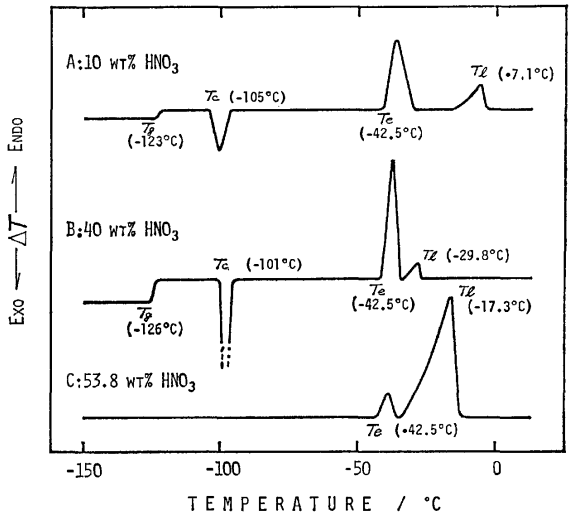


Fig. 2. DTA traces of several quenched HNO_3 solution.
T_c: Crystallization temperature, T_e: eutectic temperature of the HNO_3–H_2O system, T_l: liquidus temperature of the HNO_3–H_2O solution.

the DTA peak at −42 °C, suggests that there exists a considerable concentration fluctuation about 53.8 wt% HNO_3 in the solution in the liquid state.

Linear variation of T_g with solution composition indicates that the structure of the HNO_3 solution varies smoothly with the composition in the glass-forming composition region (≈35 to 62 wt% HNO_3). Thus, the existence of the narrow non-glass forming region can not be ascribed to a sudden change of the solution structure. It is considered that whether or not a given liquid crystallizes during cooling before a glass transition is reached is purely a kinetic problem.[6-8] Taking account of various factors appearing in the kinetic theories of glass formation developed by Turnbull *et al.*[7,9] and Uhlmann,[8] we consider that a geometrical factor, which has not been properly incorporated in the current kinetic theories despite of the fact that its importance has often been noted in various qualitative criteria for the glass-forming of a liquid,[10,11] is a main cause for the anomalous crystallization behavior. In other words, the structure of the ≈54 wt% HNO_3 solution at low temperature is expected to resemble that of the $HNO_3 \cdot 3H_2O$ crystal so that the barrier to nucleation is low as compared with that in other glass-forming concentration region.

Estimation of T_g for a pure non-glass forming liquid has often been made by the extrapolation of T_g data for binary mixtures.[1,2,12] A simple least-squares curve fitting for the present T_g data yields the following formula for the concentration dependence of T_g for the HNO_3 solution:

$$T_g = 0.48X - 144, \quad (1)$$

where X in HNO_3 wt% and T_g in °C. From Eq. 1, we estimate that the T_g value for a glassy bulk water will be −144±2 °C if water is successfully made a glassy state by a rapid cooling. This value is a little lower than those (−134——138 °C) estimated from other T_g data for several aqueous solutions[1,12] and that (−139 °C) obtained for amorphous ice made by a vapor deposition method.[13] We consider that this low value is presumably due to hydronium ions in the glassy HNO_3 solution though an explicit interpretation is at present difficult. However, a plausible, though indirect, evidence for the above speculation comes from the observation that the mobility of H_3O^+ ions in ice is faster than that in aqueous solution (at room temperature) by about two order of magnitude.[14] Another supporting experimental evidence is that glass transition in a glassy crystal ice, which is claimed to be related to proton disordering, occurs at −173 °C.[15]

This work was in part assisted by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Adsorption of Electron Acceptors on Titania

Kunio Esumi* and Kenjiro Meguro

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 23, 1981)

Synopsis. Four electron acceptors with electron affinities ranging from 1.26 to 2.84 eV were adsorbed from acetonitrile solution on to a titania sample. On adsorption, radical anions were formed on the titania surface as a result of electron transfer to the acceptors from the surface of the titania. The concentration of radical anions thus formed decreased with the decreasing electron affinity of the acceptors; the decrease is steep between 1.26 and 1.77 eV. These results suggest that the limit of electron transfer from the titania surface to the acceptor ranges between 1.77 and 1.26 eV in the electron affinity of the acceptor.

Recently, the adsorption of electron acceptors on metal oxides has been investigated to estimate electron donor properties of metal oxides and their characterization.[1-3] Flockhart *et al.*[4] studied the electron donor properties of alumina surface by the adsorption of tetracyanoethylene (TCNE) and they concluded that the electron donor sites originated from unsolvated hydroxide ions for the samples activated at lower temperatures, but from defect centers involving oxide ions for the samples activated at higher temperatures.

In this work we report the adsorption of some electron acceptors on titania in order to evaluate the limit of the electron transfer. For this purpose, the following electron acceptors were employed as adsorbates: 7,7,8,8-tetracyanoquinodimethan (TCNQ), 2,5-dichloro-*p*-benzoquinone (DCQ), *p*-dinitrobenzene (PDNB), and *m*-dinitrobenzene (MDNB), whose electron affinity ranges between 2.84 and 1.26 eV.

The preparation of titania has been described elsewhere.[3] The specific surface area of the sample measured by the BET method was about 47 m^2/g. The sample was found to be anatase by X-ray diffractometry. TCNQ was supplied by Dainippon Ink Chemical, Ltd, and recrystallized from acetonitrile. DCQ, PDNB and MDNB were supplied by Tokyo Kasei, Ltd., and were purified by recrystallization from ethanol, chloroform and carbon tetrachloride, respectively. The acetonitrile used as solvent was of reagent grade supplied by Kokusan Chemical Works, Ltd. The apparatus and procedure used in this study have been described previously.[1]

Figure 1 shows the adsorption isotherms of TCNQ, DCQ, PDNB, and MDNB from their acetonitrile solutions at 25 °C on the titania surface. All the isotherms except MDNB are of Langmuir type. In the case of MDNB, the amount adsorbed was so small that it was hard to estimate. The limiting amounts of TCNQ, DCQ and PDNB adsorbed on the surface estimated from the Langmuir plots, are given in the second column of Table 1. As shown in Table 1, it is noticeable that the limiting amount decreases with the decreasing electron affinity[5,6] of the acceptors.

When the electron acceptors were adsorbed from the solution in acetonitrile on the surface of titania, the surface showed a remarkable coloration characterized with the kind of acceptors: violet for TCNQ, brown for DCQ and PDNB, and colorless for MDNB. It has been reported by some workers[1-4] that the adsorption of acceptors on metal oxides produces a surface coloration due to the interaction between acceptor molecules adsorbed and metal oxide surfaces. To study the nature of the interaction the electronic spectrum of colored samples was measured, as illustrated in Fig. 2. The bands appearing below 400

Table 1. Summary of the electron acceptor adsorption

Electron acceptor	Electron affinity / eV	Adsorbed amount / mol $m^{-2} \times 10^{-7}$	Radical concentration / spins m^{-2}
TCNQ	2.84	6.0	3.1×10^{16}
DCQ	2.30	5.0	1.5×10^{15}
PDNB	1.77[a]	2.0	7.1×10^{13}
MDNB	1.26	Negligible	0

a) The value given by Briegleb[5] plus 1.07 eV.

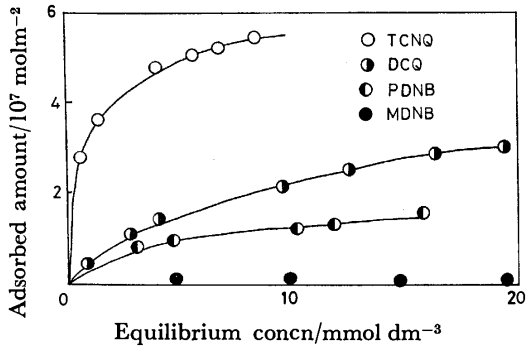

Fig. 1. Adsorption isotherms of electron acceptors on titania (at 25 °C).

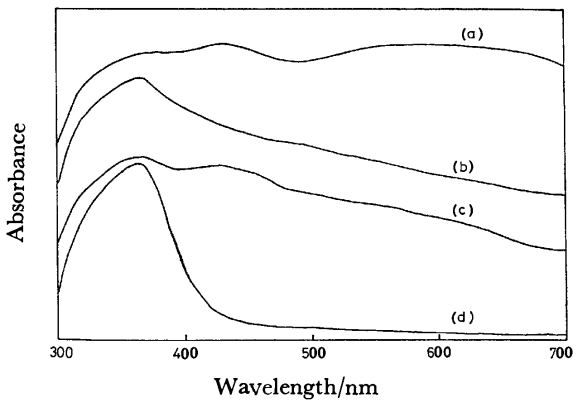

Fig. 2. Electronic spectra from electron acceptors on titania: (a) TCNQ; (b) DCQ; (c) PDNB; (d) MDNB.

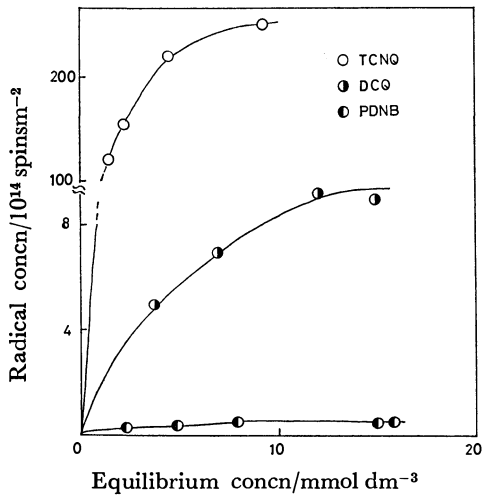

Fig. 3. Radical concentration on titania *vs.* equilibrium concentration of electron acceptor (at 25 °C).

nm are common to all the samples and could not be assigned specifically to any adsorption state because titania alone has a characteristic band in the same region. The absorption band near 600 nm observed in Fig. 2(a) can be attributed to the dimer TCNQ anion radical which absorbs light at 643 nm.[7] In Fig. 2(b), a broad tail band extending to 700 nm was observed and may be supposed to correspond to the DCQ anion radical.[8] The spectrum shown in Fig. 2(c) has a maximum absorption at about 420 nm and the band may be attributed to the PDNB anion radical. In the case of MDNB as shown in Fig. 2(d), no new band was observed on adsorption. If the acceptor anion radicals are formed by the adsorption on the titania surface, the adsorbed species obtained will show ESR signals. Indeed, the colored species gave an unresolved ESR spectrum with a g-value of 2.003 for TCNQ, 2.005 for DCQ and 2.004 for PDNB, respectively. However, the sample of adsorbed MDNB showed no ESR signal. These phenomena confirm the formation of TCNQ, DCQ, and PDNB anion radicals as a result of electron transfer from titania surface to each acceptor.

The nature of the sites responsible for the electron transfer process is not well understood. However, it might be suggested that two possible electron sources exist on the titania surface. One of these is Ti^{3+} ions and the other is surface hydroxide ions.[9]

Figure 3 shows the radical concentration on the surface of titania plotted against the equilibrium concentration of electron acceptor. All the isotherms are of Langmuir type. The limiting radical concentration of TCNQ, DCQ, and PDNB adsorbed on the titania surface estimated by the Langmuir plot is given in the third column of Table 1. It is found that the limiting radical concentration decreases with decreasing electron affinity of the acceptors and steeply between PDNB and MDNB. This suggests that adsorption sites of titania act as electron donors to the adsorbed molecules with electron affinity larger than 1.77 eV but not to those smaller than 1.26 eV. Accordingly, the limit of electron transfer from electron donor sites of titania to electron acceptor molecules is located between 1.77 and 1.26 eV in the electron affinity of the acceptors.

The Effect of Ultraviolet Radiation on Wettability of Polymer Surfaces

Kunio Esumi,* Kenjiro Meguro, A. M. Schwartz,† and A. C. Zettlemoyer†

Department of Applied Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

† *Center for Surface and Coatings Research, Sinclair Laboratory, Lehigh University, Bethlehem, Pa 18015, U. S. A.*

(Received September 25, 1981)

Synopsis. The wettability of polystyrene and poly(methyl vinyl ketone) surface can be markedly changed by ultraviolet irradiation in air. The contact angle of water on both polymers decreases dramatically as a function of exposure time. This effect is mainly due to increase in the polar component of surface energy. The wettability of irradiated polymers goes back to near original values due to soluble photooxidation products into water after the water extraction.

Polymers, under normal conditions, are in contact with atmospheric oxygen and are subjected to varying temperatures, humidities and exposures to light. A polymer is expected to undergo photochemical induced change at or near its surface.

The wettability of surfaces by liquids of known surface tensions has been determined by many investigators. Contact angle measurements, in particular, have been used to evaluate changes in a surface composition. Fox *et al.*[1] have reported that with a number of amorphous polymers the changes in contact angles for various liquids with ultraviolet radiation time, not surprisingly, are a function of the nature of the polymers. According to Fox's study, it might be expected that by ultraviolet radiation the wettability of polymer surfaces can be changed from hydrophobic to hydrophilic.

This study describes the effect of ultraviolet radiation on the wettability of two polymers.

The liquids used for contact angle measurements were deionized water and diiodomethane.

Polymers used were polystyrene supplied by Monomer-Polymer and Dajac Laboratories, Inc. and poly(methyl vinyl ketone) by Polyscience, Inc. Films of each polymer were prepared by the evaporation of 2 wt% dichloromethane solution on aluminum plate.

Exposures were carried out in air in a hood with the unfiltered radiation from 55.1 W low pressure mercury lamp supplied by Oriel Co. The distance between the sample and the lamp was 5 cm.

Contact angles were measured with a goniometer at 20 °C. Three drops for a given liquid were measured on both sides of the drops and the six values were averaged. The overall variation in the contact angle measurement was about ±3°.

To evaluate surface energy, the interfacial term γ_{ab} by theory (Owens and Wendt,[2] Kaelble and Uy,[3] Wu[4]), is given as follows:

$$\gamma_{ab} = \gamma_a + \gamma_b - 2(\gamma_a^d\gamma_b^d)^{1/2} - 2(\gamma_a^p\gamma_b^p)^{1/2}, \quad (1)$$

where γ is the respective surface energy and the dispersive(d) and polar(p) components of the surface energies for solid a and liquid b are considered to interact only with their own kind. To obtain values

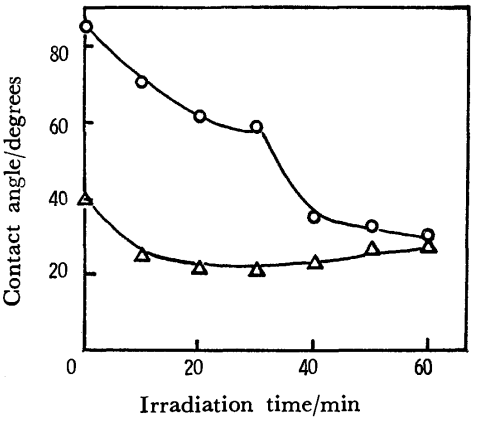

Fig. 1. Irradiation time *vs.* contact angles on polystyrene.
○: Water contact angle, △: diiodomethane contact angle.

for the dispersive and polar components of the solid surface energies, Eq. 1 is combined with the Young equation to give for a solid(a)/liquid(b) pair,

$$\text{Cos}\,\theta + 1 = \frac{2}{\gamma_b}[(\gamma_a^d\gamma_b^d)^{1/2} + (\gamma_a^p\gamma_b^p)^{1/2}], \quad (2)$$

where θ is the contact angle. If the dispersive and polar components of the surface energies of the various liquids are known,[5,6] each pair of equations of the form of Eq. 2 yields solutions for γ_a^d, γ_a^p. In this study, by using Eq. 2, values of γ_a^d and γ_a^p for polymers were calculated as a function of ultraviolet irradiation time. Here, literature values of γ_b^d and γ_b^p for water and diiodomethane are applied in the surface energy analysis:[5,6] γ_b^d=21.8 erg/cm², γ_b^p=50.8 for H_2O, γ_b^d=50.8, γ_b^p=0 for CH_2I_2.

The wettability of polystyrene and poly(methyl vinyl ketone) was evaluated as a function of exposure time of ultraviolet irradiation. The results for contact angle measurements are shown in Figs. 1 and 2. Compared with the original polymers, oxygenated moieties in the surfaces would be expected to interact more strongly with polar liquid like water, but might be less wet by a nonpolar liquid like diiodomethane. From these figures, it can be seen that the contact angles of water decreased with increase in the exposure time on both polystyrene and poly(methyl vinyl ketone). On the other hand, the contact angles of diiodomethane remained constant as irradiation progressed.

Furthermore, γ_a^d and γ_a^p are calculated as a function of exposure time, shown in Figs. 3 and 4. For both polymers, the dispersion component of surface energy did not change significantly with exposure time, but the polar component increased remarkably as irra-

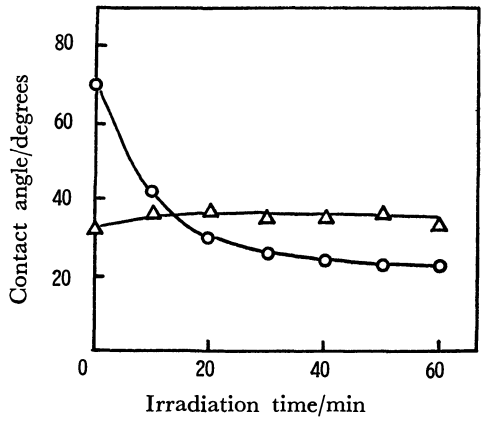

Fig. 2. Irradiation time *vs.* contact angles on poly(methyl vinyl ketone).
○: Water contact angle, △: diiodomethane contact angle.

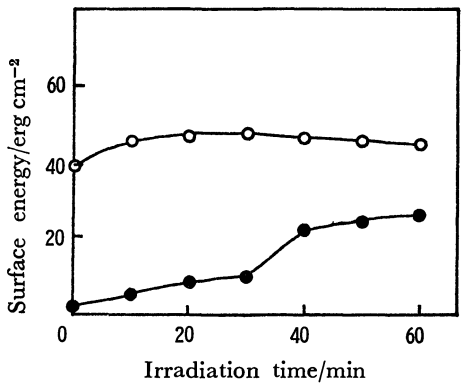

Fig. 3. Irradiation time *vs.* surface energy on polystyrene.
○: γ_s^d, ●: γ_s^p.

diation progressed. This increase means that during irradiation the surface of the polymers were photooxidated to yield hydrophilic products on the surface. Also, by means of multiple internal reflectance spectra of irradiated polystyrene film, the carbonyl band due to photooxidation near 1725 cm^{-1} has been observed.[1)]

As a next step, to study the stability of irradiated

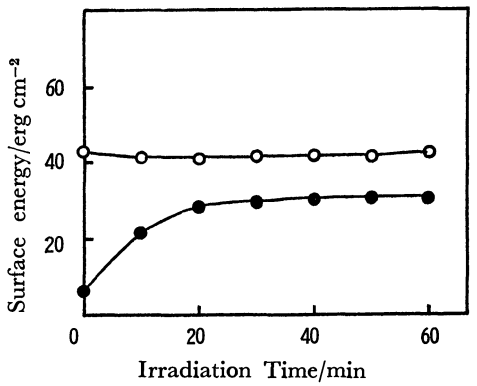

Fig. 4. Irradiation time *vs.* surface energy on poly(methyl vinyl ketone).
○: γ_s^d, ●: γ_s^p.

polymer surfaces, two tests were carried out. One was that after irradiation, the samples were kept in a desiccator for 2 d and then contact angles were measured. The other was a water extraction test. The irradiated samples were immersed in distilled water for 15 min and dried *in vacuum*, then the contact angles for the samples were measured. For both polystyrene and poly(methyl vinyl ketone), the contact angles of water after 2 d storage were almost the same as the immediate results. On the other hand, the contact angles of water after the water extraction increased significantly, although they did not come back to the original unexposed values. The increase of the water contact angles might be attributed to water-soluble photooxidation products.

Effect of the Chlorine Contents on the Lattice Constants of β-FeOOH

Matashige OHYABU and Yusuke UJIHIRA*

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113

(Received September 16, 1981)

Synopsis. The lattice constants of β-FeOOH including chlorine and fluorine, were determined by X-ray diffractometry. The chlorine-content dependence of the lattice constants showed that chlorine ions are distributed at random, occupying certain sites of β-FeOOH.

β-FeOOH, also known as akaganeite, is a kind of iron(III) oxide hydroxide. It is formed as a hydrolysis product from iron(III) salt solutions containing Cl^- or F^- ions. It is well known that Cl^- or F^- ions are necessary for the formation of β-FeOOH and that the β-FeOOH thus produced contains Cl or F in the crystal without exception. Recently, Mossbauer spectroscopic studies have indicated that iron atoms exist in two or three different chemical states in the β-FeOOH crystal.[1-4] In a previous paper,[5] we reported on the synthesis of β-FeOOH from various solutions containing different concentrations of Cl^- and F^-, and proposed the possibility that Cl^- and F^- ions are directly bound to Fe^{3+} ions in β-FeOOH.

The present paper reports the variation in the lattice constants of β-FeOOH determined by X-ray diffractometry and its correlation to the difference in Cl and F concentrations in the crystal.

Experimental

Preparation of β-FeOOH. β-FeOOH was prepared by heating Fe(III) solutions containing various concentrations of Cl^- and F^- ions. The details were described previously.[5] The X-ray diffraction patterns and the electron micrographs proved the purity of the β-FeOOH thus synthesized.

Measurement of X-Ray Diffraction Patterns. An X-ray diffractometer was operated with an Fe tube. The powder and the scan speed were 28 kV (6 mA) and 0.25° min^{-1}, respectively.

Analysis of Diffraction Data. The lattice constants were calculated from the 2θ values of the (211) and (400) diffraction lines. The peak positions were determined by drawing the tangent lines on both sides of the diffraction profiles. The diffraction lines of α-Fe_2O_3[6] were used for the correction of the diffraction angle.

Results and Discussion

The structure of β-FeOOH is tetragonal,[7,8] and several observed values of the lattice constants have been reported (*e.g.*, a=10.48 Å, and c=3.023 Å).

Since Mackay's studies of the crystal,[7] Cl^- and F^- ions have been believed to occupy the hole site in β-FeOOH, but no experimental confirmation has yet been made. We proposed that Cl^- and F^- ions are directly bound to the Fe^{3+} ion in the β-FeOOH crystal.[5] The expansion or the contraction of the lattice in the crystal can be expected without any contradiction if Cl^- and F^- ions are located at certain sites in β-FeOOH.

TABLE 1. CHLORINE AND FLUORINE CONTENTS AND THE OBSERVED LATTICE CONSTANTS

Sample	Cl/Fe[a]	F/Fe[a]	a[b] / Å	c[b] / Å
A	0.148	0	10.56	3.035
B	0.143	0	10.54	3.034
C	0.110	0.113	10.51	3.033
D	0.056	0.197	10.48	3.023
E	0.031	0.281	10.46	3.030
F	0.023	0.332	10.46	3.026
G	0.014	0.384	10.46	3.023

a) Cl/Fe and F/Fe are represented as atomic ratios; the error is below 5%. b) The errors are ±0.01 Å and 0.001 Å for a and c, respectively.

Table 1 shows the Cl and F contents in synthesized β-FeOOH and the observed lattice constants. If β-FeOOH is regarded as non-stoichiometric, the variation in the lattice constants will follow Vegard's law.[9]

$$a = a_0 + px_{Cl} + qx_F, \quad (1)$$

where x_{Cl}=Cl/Fe, x_F=F/Fe, and p and q are the coefficients concerned with the ion radii and chemical nature of the Cl^- and F^- ions. a_0 is the expected lattice constant of β-FeOOH free from Cl^- or F^-. Practically the estimation of p and q is difficult because of the absence of a compound where the certain sites are completely replaced by Cl^- or F^- ions.

Here, $|p| \gg |q| \approx 0$ can be assumed, since the ionic radius of F^- is almost identical with that of OH^-/O^{2-}. Equation 1 can be reduced as follows:

$$a \fallingdotseq a_0 + px_{Cl}. \quad (2)$$

The Cl content dependence of the lattice constants is shown in Fig. 1. It is found that the liner relationship is nearly satisfied and that the variation in the lattice constants follows Vegard's law. Namely,

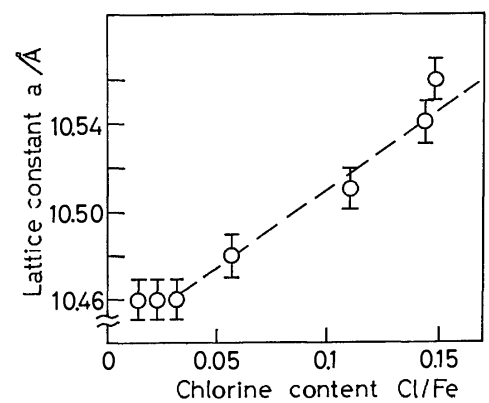

Fig. 1. Chlorine content dependence of the lattice constants a of β-FeOOH. p in Eq. 2 is estimated to be 0.8 Å.

it is confirmed that, in the β-FeOOH crystal, Cl^- ions are not localized, forming such compound as $FeCl_3$, but the distributed at random, occupying certain sites.

This confirmation is in accordance with the experimental finding that neither the diffraction lines nor the Mössbauer resonant peaks of the Fe(III) compounds were observed other than in the case of β-FeOOH.[10]

Photo- and Thermally-induced Radical Rearrangements of 6-Methyl- and 4,4,6-Trimethylcholest-5-en-3β-ol

Hiroshi SUGINOME,* Norio MAEDA,† Yoshikatsu SEKI, and Kazuhiko ORITO

Organic Synthesis Division, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

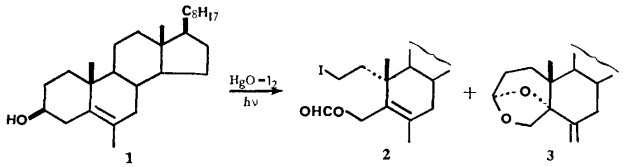
† *Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060*

(Received June 5, 1981)

Synopsis. The irradiation of 6-methylcholest-5-en-3β-ol in benzene containing mercury(II) oxide and iodine gave 3α,5-epoxy-6-methylene-*A*-homo-4-oxa-5α-cholestane (23%) and 2-iodo-6-methyl-*A*-nor-2,3-secocholest-5-en-3-yl formate (32%). The thermally-induced reaction at 55—60 °C gave the former in a 16% yield. The corresponding photo-reaction of 4,4,6-trimethylcholest-5-en-3β-ol, however, gave 4,6-dimethyl-4-methylene-3,4-secocholest-5-en-3-al.

Earlier parts of this series[1–5] have described the results of the photo- and thermally-induced rearrangements of a number of cholest-5-en-3-ols[1–4] and *C*-nor-*D*-homosteroid-5-en-3β-ols[5] in the presence of mercury(II) oxide and iodine. In either a photo- or thermally-induced reaction, 3β,5-epoxy-*A*-homo-4-oxa-5α-cholestanes or the *C*-nor-*D*-homo analogue, among others, were common products. The introductions of methyl substituents at the C-3 or C-4[2–4] position or of an oxo group at the C-7[1] position, and changing the C-ring from 6-membered to 5-membered[5] were found appreciably to affect the relative yields of the products and even to lead to an additional formation of 3-oxacholest-5-enes.[3,4]

In this paper, the photo- and thermally-induced rearrangement of two cholest-5-en-3β-ols, 6-methylcholest-5-en-3β-ol(**1**),[6] and 4,4,6-trimethylcholest-5-en-3β-ol(**4**), will be reported. The work was undertaken in order to gain more information concerning the effect of alkyl groups on the products of this reaction. The reactions were conducted under the conditions reported previously.[2] Thus, the irradiation of **1** in benzene containing iodine and mercury(II) oxide with a 100-W high pressure mercury arc for 6 h under an atmosphere of nitrogen gave a mixture of products. The separation of the products by preparative TLC gave two products, (**2**) (32%) and (**3**) (23%) (Scheme 1).



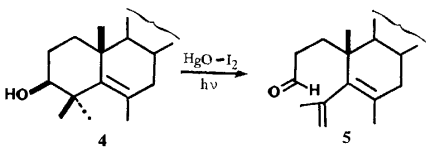
1 2 3

Scheme 1.

The molecular formula of the crystalline product **2** was determined to be $C_{28}H_{47}O_2I$ by means of high-resolution mass spectrometry, while its structure as a formate, 2-iodo-6-methyl-*A*-nor-2,3-secocholest-5-en-3-yl formate, was immediately made apparent by the IR and NMR spectra[2] (see Experimental). The molecular formula, $C_{28}H_{46}O_2$, of **3** was also determined by high-resolution mass spectrometry. The IR and NMR spectra were in agreement with the 3α,5-epoxy-6-methylene-*A*-homo-4-oxa-5α-cholestane structure (see Experimental).

The product **3** was also obtained in a 16% yield in the thermally-induced reaction of **1** conducted at 55—60 °C.

The reactions of another 6-methylcholest-5-ene **4**[7] carrying a *gem*-dimethyl group at the C-4 positions, were then undertaken in order to confirm whether or not they give an oxabicyclic compound of type 3 and substituted 3-oxacholest-5-ene. The irradiation of **4** in benzene containing mercury(II) oxide and iodine for 4 h under an atmosphere of nitrogen gave a mixture of products, from which only one product (**5**) was isolated in a pure form (39% yield) (Scheme 2). A careful examination of the reaction

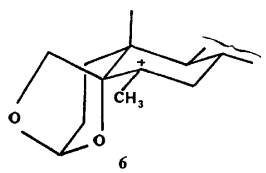


4 5

Scheme 2.

products indicated the absence of any oxabicyclic compounds or substituted 3-oxacholest-5-enes. The molecular formula ($C_{30}H_{52}O$) of **5** was determined by means of high-resolution mass spectrometry. On the basis of the IR, UV, and NMR spectra (see Experimental), the 4,6-dimethyl-4-methylene-3,4-secocholest-5-en-3-al structure is assigned to this compound.[8] The absorption maximum (205 nm) in the UV spectrum of **5** shows a considerable deviation from the value predicted by means of the Woodward diene rule[9] (Calculated value, 237 nm). This deviation is attributable to the loss of planarity of the diene system in **5** due to overcrowding caused by the 6-methyl group. The thermally-induced reaction was also attempted, but this reaction led only to an intractable mixture, and none of the products were identified.

The results obtained from the reactions of **1** also indicate the generality of the formation of oxabicyclic compounds (*e.g.*, **3**), the pathway of which has been discussed in the previous paper.[2] However, the methyl group at the C-6 position hinders the reaction of the hypothetical carbocation (**6**) with the iodine source,



6

thus leading to the formation of the olefin, **3**.

The experiments on cholest-5-en-3β-ol **4** confirm that the introduction of three methyl groups at the C-4 and C-6 positions hinders the formation of both oxabicyclic compounds (*e.g.*, **3**) and substituted 3-oxacholest-5-enes; the latter was found to be formed particularly in the reaction of cholest-5-en-3β-ol car-

rying *gem*-dimethyl groups on the C-4.[2,4] The methyl groups destabilize the conformations of the intervening allyl radical and the successive intermediates required for the intramolecular radical additions, and also retard the combination of iodine or iodine oxide with the radical intermediates.[2]

Experimental

For the instruments used and general procedures, see Ref. 2 unless otherwise stated. The low-resolution mass spectra of **1**, **2**, and **3** and the high-resolution mass spectra of **2**, **3**, and **5** were recorded by Miss Yuko Chiba of the Faculty of Agriculture of this university with a JEOL JMS-D 300 spectrometer. The mass spectra of **4** and **5** were recorded by the staff of the Faculty of Pharmaceutical Sciences of this University with a JEOL JMS-D 300 spectrometer.

6-Methylcholest-5-en-3β-ol (1). **1** was prepared by the previously described procedure.[6] NMR, 9.33 (3H, s, 18-H), 9.02 (3H, s, 19-H), 8.40 (3H, s, 6-CH_3), 7.02 (1H, dd, J=12.0 and 4.5 Hz, 7β-H); MS (70 eV), (rel intensity) 400 (M^+, 79.5), 385 (M^+-CH_3, 100), 382 (M^+-H_2O, 46.8), 367 ($M^+-CH_3-H_2O$, 59.5), 159 (39.4), 95 (37.0), 81 (35.1), 55 (37.3), and 43 (35.9).

The Rearrangement of the Hypoiodite of 6-Methylcholest-5-en-3β-ol in the Presence of Mercury(II) Oxide and Iodine. By Irradiation. **1** (300 mg, 0.75 mmol), mercury(II) oxide (488 mg, 2.25 mmol), and iodine (570 mg, 2.24 mmol) in benzene (38 ml) were irradiated for 6 h with a 100-W high-pressure Hg arc under a nitrogen atmosphere. The solution was then filtered, and the filtrate was washed with 5% aq sodium hydrogensulfite and water successively, and then dried (Na_2SO_4). The subsequent romoval of the solvent left a product mixture (414 mg) which was subjected to preparative TLC with benzene to give five fractions: A (10 mg), B (132 mg), C (71 mg), D (89 mg), and E (87 mg) in the order of decreasing mobility. B Fraction was a formate, **2**, and after recrystallization from methanol it had a mp 64.0—66.0 °C. $[\alpha]_D^{18}$ −4.2° (*c*, 0.8 $CHCl_3$); (Found: M^+ 542.2626. Calcd for $C_{28}H_{47}O_2I$ 542.2621); IR, 1733 (OCHO), 1188, and 1163 cm^{-1} (OCHO); NMR, τ 9.34 (3H, s, 18-H), 9.11 (3H, s, 19-H), 8.31 (3H, s, 6-CH_3), 6.98 (2H, m, 2-H), 5.31 (2H, s, 3-H), and 1.83 (1H, s, OCHO): MS (70 eV), *m/e* (rel intensity), 542 (M^+, 1.0), 496 (1.4), 415 (1.2), 387 (16.5), 341 (100), and 133 (27.2). C Fraction was Compound **3** (Found: M^+ 414.3454. Calcd for $C_{28}H_{46}O_2$, M, 414.3496); IR, 1377, 1123, 1114, 998, and 901 cm^{-1}; NMR, 9.33 (3H, s, 18-H), 9.24 (3H, s, 19-H), 6.24 and 5.85 (each 1H, d, J=7.5 Hz, 4a-H), 5.45 and 5.12 (each 1H, s, 6-CH_2), and 4.48 (1H, broad s, 3β-H); MS (70 eV), *m/e* (rel intensity) 414 (M^+, 2.7), 398 (100), 383 (32.4), 133 (53,6), 107 (49.7), 95 (61.9), 81 (55.5), 69 (46.1), 57 (57.7), 55 (66.0) and 43 (72.9).

By Thermal Reaction. A thermal reaction conducted at 55—60 °C under a nitrogen atmosphere for 3 h gave a crude product (348 mg), which was then subjected to preparative TLC to afford seven fractions: A (36 mg), B (12 mg), C (4 mg), D (16 mg), E (51 mg), F (47 mg), and G (154 mg), in the order of decreasing mobility. E Fraction was identified as product **3** by a comparison of its IR, NMR, and mass spectra with those of the specimen obtained from the photo-reaction.

4,4,6-Trimethylcholest-5-en-3β-ol (4). 4,4,6-Trimethylcholest-5-en-3-one[7] (1.78 g) and lithium aluminum hydride (1 g) in dry diethyl ether (100 ml) under a nitrogen atmosphere were stirred for 10 min at 0 °C and then for 50 min at room temperature. After the addition of ethyl acetate, methanol, and water were added to the solution. The solution was then extracted with diethyl ether. The organic layer was worked-up in the usual way. Recrystallization from methanol gave **1** (1.4 g, 83%); mp 155—158 °C. An analytical specimen (mp 160.5—161 °C) was obtained by recrystallization from diethyl ether–methanol. $[\alpha]_D^{20}$ −5.3° (*c*, 1.1 $CHCl_3$) (Found: C, 83.83; H, 12.06%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.23%); IR, 3422 (OH), and 1036 cm^{-1}; NMR, 9.33 (3H, s, 18-H), 8.98 (3H, s, 19-H), 8.83 (3H, s, 4α-CH_3), 8.59 (3H, s, 4β-CH_3), and 6.68 (1H, dd, J=8.3 and 9.8 Hz); MS (70 eV), *m/e* (rel intensity), 428 (M^+-H_2O, 58.4). 359 ($M^+-H_2O-CH_3$, 100), 345 (89.9), 187 (26.2), 95 (52.6), 81 (38.2), 69 (43.2), 55 (50.2), and 43 (54.1).

The Rearrangement of the Hypoiodite of 4,4,6-Trimethylcholest-5-en-3β-ol in the Presence of Mercury(II) Oxide and Iodine. By Irradiation. **4** (322 mg, 0.75 mmol), mercury(II) oxide (488 mg, 2.25 mmol), and iodine (570 mg, 2.25 mmol) in benzene (38 ml) were irradiated for 4 h under a nitrogen atmosphere. The solution was then worked-up as usual, and the product was subjected to preparative TLC with benzene to yield seven fractions: A (48 mg), B (78 mg), C (24 mg), D (20 mg), E (38 mg), F (62 mg), and G (122 mg), in the order of decreasing mobility. Fractions A and B were aldehyde. The aldehyde was purified by preparative TLC, but we failed to induce crystals. (Found: M^+, 426.3877. Calcd for $C_{30}H_{50}O$. M, 426.3862); $[\alpha]_D^{21}$ −18.3 (*c*, 1.0 $CHCl_3$); IR, (neat), 908 (-C=CH_2), 1626, 1728 (CHO), and 2715 (CHO); NMR, τ 9.32 (3H, s, 18-H), 8.95 (3H, s, 19-H), 8.41 (3H, s, 6-CH_3 or 4-CH_3), 8.17 (3H, s, 6-CH_3 or 4-CH_3), 5.64 and 4.93 (each 1H, br.s, $W_{1/2}$= 0.6 Hz, 4-CH_2) and 0.09 (1H, t, J=0.3 Hz, CHO); UV_{max} (C_2H_5OH) 205 nm (ε 6700); MS (70 eV), *m/e* (rel intensity), 426 (M^+, 15.5), 411 ($M^+-CH_2CH_2CHO$, 100), 161 (27.5), 95 (33.9), 57 (37.7), and 43 (38.0).

By Thermal Reaction. A thermal reaction in the same scale conducted at 55—60 °C under a nitrogen atmosphere for 3 h in the dark gave a crude product (374 mg), which was then subjected to preparative TLC to give six fractions; A (67 mg), B (27 mg), C (23 mg), D (31 mg), E (51 mg), and F (156 mg), in the order of decreasing mobility. Fraction D was found to be identical with **5** by a comparisons of the IR, UV, NMR and mass spectra.

Studies of Aromatic Sesquiterpenes. III. The Synthesis of 4-Methoxyisocadalene[1]

Kazuo ADACHI* and Naoki TANIGUCHI
Osaka Institute of Technology, Omiya, Asahi-ku, Osaka 535
(Received August 5, 1981)

Synopsis. Starting from *p*-cresol, the title sesquiterpene was synthesized through 4-methoxy-1,6-dimethylnaphthalene as a key intermediate.

The new aromatic sesquiterpene ether, 4-methoxyisocadalene, was recently isolated,[2] along with cadalene and other substances, from the aerial parts of Mexican *Heterotheca inuloides* Cass. (Compositae). 2-Isopropyl-1-methoxy-4,7-dimethylnaphthalene (**1**) was proposed as the structure of this sesquiterpene on the basis of comprehensive spectral studies.[2] In this paper the synthesis of **1** through the acetylation of 4-methoxy-1,6-dimethylnaphthalene (**2**) will be described.

2-Methoxy-5-methylpropiophenone (**3**) was converted to ethyl 2-(2-methoxy-5-methylbenzoyl)propionate (**4**), which, on reduction with $NaBH_4$ and subsequent chlorination, afforded ethyl 3-chloro-2-methyl-3-(2-methoxy-5-methylphenyl)propionate (**6**). The reduction of **6** with $LiAlH_4$ gave 2-methyl-3-(2-methoxy-5-methylphenyl)-1-propanol (**7**), from which 3,4-dihydro-5-methoxy-3,8-dimethyl-1(2*H*)-naphthalenone (**11**) was prepared in 4 steps. The aromatization of **11** produced a key intermediate (**2**), which, on acetylation, resulted in a mixture of 2-acetyl-4,7-dimethyl-1-naphthol (**14**) and other acetyl compounds (**15**—**17**). The title compound was synthesized from the reaction product of the methyl ether (**18**) with methylmagnesium iodide.

The structure of the synthesized product (**1**) was confirmed by a comparison of its NMR data with those reported in the literature.[2] The complexes of **1** with picric acid and 1,3,5-trinitrobenzene showed mp 90.5—91.5 °C and 104.5—105.5 °C respectively.

Experimental

2-Methoxy-5-methylpropiophenone (3). The condensation of *p*-methylanisole (122.2 g) and propionyl chloride (97.3 g) by $AlCl_3$ (140 g) in CS_2 (370 ml) gave **3** (173.8 g) in a 97.5% yield; bp 128—130 °C/10 mmHg (1 mmHg≈133.322 Pa); IR: 1675, 810 cm^{-1}; NMR: δ 1.08 (t, 3H, CH_3), 2.23 (s, 3H, CH_3), 2.86 (q, 2H, CH_2), 3.78 (s, 3H, OCH_3), 6.71 (d, 1H, J=9 Hz), 7.08 (dd, 1H, J=9 and 2 Hz), 7.35 (d, 1H, J=2 Hz).

2,4-Dinitrophenylhydrazone: Yellow needles; mp 112.0—112.5 °C. Found: C, 57.24; H, 5.03; N, 15.84%. Calcd for $C_{17}H_{18}N_4O_5$: C, 56.98; H, 5.06; N, 15.64%.

Ethyl 2-(2-Methoxy-5-methylbenzoyl)propionate (4). A reaction product of diethyl oxalate (76.7 g) and a sodio-derivative of **3** prepared from **3** (89.0 g) and Na (12.1 g) in ethanol (160 ml) was decarbonylated (2 h, 180 °C) to give **4** (113.1 g) in a 90.5% yield; bp 144—145 °C/3 mmHg; IR: 1735, 1675, 810 cm^{-1}; NMR: δ 1.15 (t, 3H, CH_3), 1.43 (d, 3H, CH_3), 2.25 (s, 3H, CH_3), 3.82 (s, 3H, OCH_3), 4.09 (q, 2H, CH_2), 4.33 (q, 1H, >CH–), 6.85 (d, 1H, J=8 Hz), 7.27 (dd, 1H, J=8 and 2 Hz), 7.57 (d, 1H, J=2 Hz).

Ethyl 3-Hydroxy-2-methyl-3-(2-methoxy-5-methylphenyl)propionate (5). The reduction of **4** (25.0 g) with $NaBH_4$ (1.4 g) in methanol (100 ml) (3 h, 25 °C) furnished **5** (24.2 g) in a 96.0% yield; bp 143—144 °C/6 mmHg; IR: 3450, 1730, 805 cm^{-1}; NMR: δ 1.03 (d, 3H, CH_3), 1.20 (t, 3H, CH_3), 2.27 (s, 3H, CH_3), 2.78 (m, 1H, >CH–), 3.20 and 3.32 (1H, OH), 3.77 (s, 3H, OCH_3), 4.08 (q, 2H, CH_2), 4.87 (m, 1H, >CH–), 6.63 (d, 1H, J=9 Hz), 6.85 (d, 1H, J=2 Hz), 7.09 (dd, 1H, J=9 and 2 Hz).

Ethyl 3-Chloro-2-methyl-3-(2-methoxy-5-methylphenyl)propionate (6). A mixture of **5** (77.2 g) and concd HCl (450 ml) was stirred for 1 h at 20 °C to give **6** (77.2 g) in a 93.2% yield as a mixture consisting of two diastereomers (1:1); bp 148—148.5 °C/7 mmHg.

dl-erythro-*Isomer of* **6**: Prisms, mp 75—76 °C; IR 1735, 1040, 1035, 805 cm^{-1}; NMR: δ 0.94 (d, 3H, CH_3), 1.27 (t, 3H, CH_3), 2.27 (s, 3H, CH_3), 3.12 (dq, 1H, >CH–, J=11 and 7 Hz), 3.77 (s, 3H, OCH_3), 4.16 (q, 2H, CH_2), 5.51 (d, 1H, >CH–, J=11 Hz), 6.73 (d, 1H, J=9 Hz), 7.03 (dd, 1H, J=9 and 2 Hz), 7.20 (br, 1H). Found: C, 62.24; H, 6.83%. Calcd for $C_{14}H_{19}ClO_3$: C, 62.11; H, 7.07%.

dl-threo-*Isomer of* **6**: Oil, bp 135—136 °C/5 mmHg; IR: 1735, 1030, 810 cm^{-1}; NMR: δ 1.05 (t, 3H, CH_3), 1.26 (d, 3H, CH_3), 2.27 (s, 3H, CH_3), 3.17 (qin, 1H, >CH–, J=7 Hz), 3.77 (s, 3H, OCH_3), 3.98 (q, 2H, CH_2), 5.66 (d, 1H, >CH–, J=7 Hz), 6.69 (d, 1H, J=9 Hz), 7.03 (dd, 1H, J=9 and 2 Hz), 7.27 (br, 1H). Found: C, 62.16; H, 7.22%. Calcd for $C_{14}H_{19}ClO_3$: C, 62.11; H, 7.07%.

3-Methyl-4-(2-methoxy-5-methylphenyl)butyric Acid (10). The reduction of **6** (9.2 g) with $LiAlH_4$ (4.0 g) in ether (60 ml) gave 2-methyl-3-(2-methoxy-5-methylphenyl)-1-propanol (**7**); yield, 5.7 g (86.4%); bp 124—126 °C/7 mmHg; IR: 3350, 800 cm^{-1}.

The reaction of **7** (19.4 g) with PBr_3 (11.7 g) in CCl_4 (60 ml) gave 2-methyl-3-(2-methoxy-5-methylphenyl)propyl bromide (**8**); yield, 12.1 g (47.1%); bp 118—119.5 °C/4

mmHg.

A solution of **8** (42.9 g), KCN (32.2 g) and water (60 ml) in ethanol (386 ml) was refluxed for 20 h to give 3-methyl-4-(2-methoxy-5-methylphenyl)butanenitrile (**9**); yield, 29.8 g (87.9%); bp 130—132 °C/7 mmHg; IR: 2240, 805 cm^{-1}.

A mixture of **9** (29.8 g), concd H_2SO_4 (60 ml), acetic acid (60 ml), and water (60 ml) was refluxed for 5 h to give **10**; yield, 23.4 g (71.8%); bp 164—167 °C/8 mmHg, mp 53.5—54.5 °C; IR: 1690, 805 cm^{-1}. Found: C, 70.21; H, 8.37%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

*3,4-Dihydro-5-methoxy-3,8-dimethyl-1(2H)-naphthalenone (**11**).* The reaction of **10** (19.2 g) and thionyl chloride (30.9 g) in benzene (50 ml) gave the acid chloride of **10**; yield, 19.7 g (94.7%); bp 137 °C/5 mmHg. The cyclization of this acid chloride (11.2 g) by $SnCl_4$ (36.5 g) in benzene (50 ml) gave 9.0 g (94.7%) of **11**; bp 140—142 °C/8 mmHg, mp 38—39 °C; IR: 1670, 810 cm^{-1}; NMR: δ 1.10 (m, 3H, CH_3), 2.03—3.25 (m, 5H), 2.48 (s, 3H, CH_3), 3.78 (s, 3H, OCH_3), 6.74 (d, 1H, J=9 Hz), 6.94 (d, 1H, J=9 Hz). Found: C, 76.41; H, 8.03%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

2,4-Dinitrophenylhydrazone: Red needles, mp 196.5—197.0 °C. Found: C, 59.37; H, 5.19; N, 14.71%. Calcd for $C_{19}H_{20}N_4O_5$: C, 59.37; H, 5.24; N, 14.58%.

*4-Methoxy-1,6-dimethylnaphthalene (**2**) and Its Acetylation.* The reduction of **11** (15.6 g) with $NaBH_4$ (1.5 g) in methanol (60 ml) produced 15.7 g (99.3%) of 1,2,3,4-tetrahydro-5-methoxy-3,8-dimethyl-1-naphthol (**12**), needles; mp 107.0—107.5 °C; IR: 3350, 800, 790 cm^{-1}. Found: C, 75.46; H, 8.93%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

The dehydration of **12** (15.0 g) with $KHSO_4$ (3.0 g) gave 12.3 g (89.9%) of 1,2-dihydro-8-methoxy-2,5-dimethylnaphthalene (**13**); bp 103—105 °C/4 mmHg; NMR: δ 1.09 (d, 3H, CH_3), 2.22 (s, 3H, CH_3), 2.4—3.0 (m, 3H, CH_2 and >CH–), 3.70 (s, 3H, OCH_3), 5.82 (dd, 1H, J=9 and 3 Hz), 6.48 (d, 1H, J=9 Hz), 6.49 (d, 1H, J=9 Hz), 6.81 (d, 1H, J=9 Hz).

A dehydrogenation product of **13** (12.3 g) upon heating with 5% Pd–C (2.5 g) (5 h, 230 °C) was distilled to give two fractions. The fore-run (3.1 g) was a mixture of 1.6-dimethylnaphthalene (48.3%), **2** (36.8%) and other substances. The main fraction was 7.9 g (64.9%) of **2**; bp 123—125 °C/5 mmHg; IR: 1600, 1580, 1380, 1355, 1270, 1090, 815 cm^{-1}; NMR: δ 2.48 (s, 3H, CH_3), 2.53 (s, 3H, CH_3), 3.87 (s, 3H, OCH_3), 6.58 (d, 1H, J=8 Hz), 7.08 (d, 1H, J=8 Hz), 7.29 (dd, 1H, J=9 and 2 Hz), 7.78 (d, 1H, J=9 Hz), 8.08 (br, 1H). *Picrate*: Red needles; mp 158.0—158.5 °C. Found: C, 55.00; H, 3.93; N, 10.02%. Calcd for $C_{19}H_{17}N_3O_8$: C, 54.94; H, 4.13; N, 10.12%.

The reaction of **2** (3.0 g) and acetyl chloride (2.3 g) with $AlCl_3$ (4.8 g) in CS_2 (40 ml) gave acetyl compounds (3.4 g), a mixture of **14** (45.5%), **15** (8.9%), **16** (23.4%), and **17** (18.2%). Each component was isolated by elution with CH_2Cl_2 through a silica-gel column.

*2-Acetyl-4,7-dimethyl-1-naphthol (**14**)*: Yellow needles; mp 124.0—124.5 °C; IR: 1615, 815 cm^{-1}; NMR: δ 2.48 (br, 6H, two CH_3), 2.58 (s, 3H, CH_3), 7.27 (br, 1H), 7.41 (dd, 1H, J=9 and 2 Hz), 7.71 (d, 1H, J=9 Hz), 8.22 (br, 1H), 13.77 (s, 1H, OH). Found: C, 78.67; H, 6.43%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%.

*1-Acetyl-8-methoxy-2,5-dimethylnaphthalene (**15**)*: Needles; mp 65.0—66.5 °C; IR: 1695, 820, 780 cm^{-1}. Found: C, 78.86; H, 7.19%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

*2-Acetyl-4-methoxy-1,6-dimethylnaphthalene (**16**)*: Micro crystals; mp 71.5—72.5 °C; IR: 1675, 810 cm^{-1}. Found: C, 78.84; H, 7.19%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

*2,8-Diacetyl-4,7-dimethyl-1-naphthol (**17**)*: Yellow micro crystals; mp 172.0—173.5 °C; IR: 1695, 1615, 870 cm^{-1}. Found: C, 75.02; H, 6.29%. Calcd for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29%.

*2-Acetyl-1-methoxy-4,7-dimethylnaphthalene (**18**).* The methylation of **14** (0.4 g) with dimethyl sulfate (0.3 g) and K_2CO_3 (0.4 g) in acetone (20 ml) gave 0.4 g of **18**; IR: 1670, 815 cm^{-1}; NMR: δ 2.50 (s, 6H, two CH_3), 2.60 (s, 3H, CH_3), 3.85 (s, 3H, OCH_3), 7.26 (dd, 1H, J=9 and 2 Hz), 7.37 (br, 1H), 7.71 (d, 1H, J=9 Hz), 7.90 (br, 1H). *2,4-Dinitrophenylhydrazone*: Yellow needles; mp 230—231 °C (dec). Found: C, 61.84; H, 4.91; N, 13.55%. Calcd for $C_{21}H_{20}N_4O_5$: C, 61.76; H, 4.94; N, 13.72%.

*4-Methoxyisocadalene (**1**).* The reaction product of **18** (0.5 g) and the Grignard reagent prepared from Mg (0.5 g) and methyl iodide (2.2 g) in ether (40 ml) were stirred with concd HCl (10 ml) for 30 min. Then the reaction product was stirred with $LiAlH_4$ (1.0 g) in ether (20 ml) at 40 °C for 4 h. The resulting product was hydrogenated in ethanol (50 ml) over Pd–C (5%, 0.5 g) and then chromatographed over silica-gel, eluting with CH_2Cl_2, to give 0.4 g (75.0%) of **1**; IR: 1625, 1605, 1380, 1350, 1095, 995, 875, 810 cm^{-1}; NMR: δ 1.28 (d, 6H, $<^{CH_3}_{CH_3}$), 2.52 (s, 3H, CH_3), 2.57 (s, 3H, CH_3), 3.52 (m, 1H, >CH–), 3.83 (s, 3H, OCH_3), 7.03 (br, 1H), 7.16 (dd, 1H, J=9 and 2 Hz), 7.71 (d, 1H, J=9 Hz), 7.80 (br, 1H). *Picrate*: Orange brown needles; mp 90.5—91.5 °C. Found: C, 58.00; H, 5.21; N, 8.92%. Calcd for $C_{22}H_{23}N_3O_8$: C, 57.76; H, 5.07; N, 9.19%. *1,3,5-Trinitrobenzene complex*: Yellow orange needles; mp 104.5—105.5 °C. Found: C, 60.05; H, 5.40; N, 9.35%. Calcd for $C_{22}H_{23}N_3O_7$: C, 59.86; H, 5.25; N, 9.52%.

The Racemization of Glutamic Acid Induced by Aliphatic Aldehydes

Mihoko YAMAMOTO, Hiroshi OZAKI, Akira TAI,* and Yoshiharu IZUMI
Division of Organic Chemistry, Institute for Protein Research, Osaka University, 3-2 Yamada-oka, Suita, Osaka 565
(Received July 20, 1981)

Synopsis. The real catalytic species in the racemization of glutamic acid induced by acetaldehyde was investigated and found to be 2-butenal produced *in situ* from acetaldehyde.

It has been reported that the catalytic species of the racemization of alanine induced by Cu_2O was acetaldehyde produced in alanine and Cu_2O–O_2 system.[1] In the course of a study of the racemization of glutamic acid with acetaldehyde, it has also been made clear that acetaldehyde functions not only as a moderately active racemization catalyst, but also as a precursor of the highly active racemization catalyst produced in the course of the reaction. In a patent, aliphatic aldehydes have been reported to be a good catalyst for the racemization of amino acid.[2] However, no systematic study has been carried out. In this paper, the function of aliphatic aldehydes in the racemization of glutamic acid will be discussed.

The racemizations of glutamic acid with various aliphatic aldehydes were carried out in the presence of Cu^{2+} ions. The time courses of the racemization yield and the consumption of aldehyde are shown in Fig. 1. The time courses of racemization with different aldehydes showed different features. The activity induced by acetaldehyde was much higher than that induced by the other aldehydes. The order of activity was: acetaldehyde>propionaldehyde>formaldehyde>isobutyraldehyde.

As may be found in Fig. 1, the racemization induced by acetaldehyde proceeds with the consumption of acetaldehyde. The high rate of racemization was unchanged even after 90% of the acetaldehyde has disappeared in the reaction mixture. This result strongly suggests that, although acetaldehyde itself may have some catalytic activity, another compound having a much higher racemization activity than acetaldehyde is produced *in situ* at an early stage of the reaction.

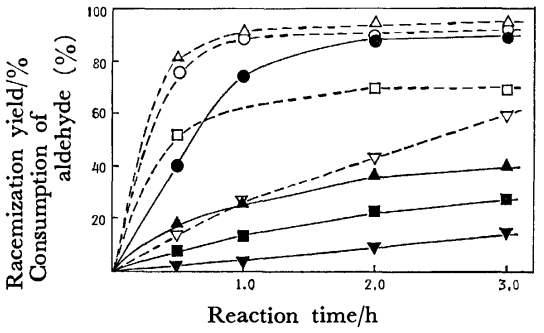

Fig. 1. Time course of racemization with acetaldehyde (—●—), propionaldehyde (—▲—), formaldehyde (—■—), and isobutyraldehyde (—▼—), and time course of consumption of acetaldehyde (—○—), propionaldehyde (—△—), formaldehyde (—□—), and isobutyraldehyde (—▽—).

Propionaldehyde shows the same consumption curve as acetaldehyde. However, the rate of racemization with propionaldehyde was found to be slow. That is, the racemization activity of the compound produced from propionaldehyde *in situ* was not expected to be so strong as that produced from acetaldehyde. When isobutyraldehyde was used, the consumption of the aldehyde was very slow, and the rate of racemization was almost negligible compared to that with acetaldehyde.

In the case of formaldehyde, the rate of racemization was unexpectedly slow, and the consumption of aldehyde was also slow.

The analyses of carbonyl compounds in the reaction mixture indicated that 2-butenal (I), 3-hydroxybutanal (II), and 2-oxoglutaric acid (III) were formed even at an early stage of the reaction. I and II were the products of the aldol condensation of acetaldehyde, while III was the product of the oxidative deamination of glutamic acid. As may be found in Fig. 2, the products of the aldol condensation showed a high racemization activity, while III showed no appreciable activity. Thus, the aldol condensation of acetaldehyde in the reaction system was expected to play a major role in giving a highly active catalyst for the racemization *in situ*. The order of the activity

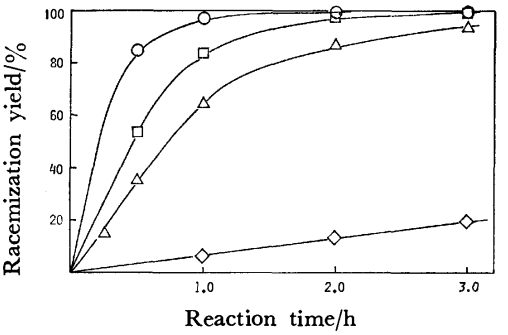

Fig. 2. Time course of racemization (at 56 °C) with acetaldehyde (—△—), II (—□—), I (—○—), and III (—◇—).

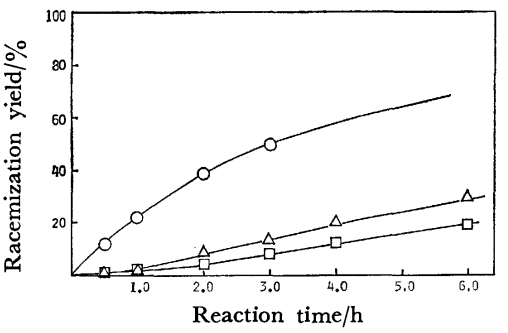

Fig. 3. Time course of racemization (at 25 °C) with acetaldehyde (—△—), II (—□—), and I (—○—).

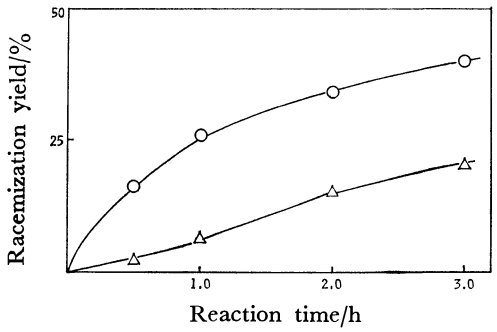

Fig. 4. Time course of racemization with propionaldehyde (—○—) and 2-methyl-2-pentenal (—△—).

at 50 °C was as follows: acetaldehyde<II<I. However, at 25 °C (Fig. 3), the order of II and acetaldehyde was reversed (II<acetaldehyde<I). Since the conversion of acetaldehyde and II to I must be slow at a lower reaction temperature, the order of the catalytic activities at 25 °C is considered to reflect the order of the intrinsic racemization activity of each compound. On the other hand, at a higher reaction temperature, 56 °C, II and acetaldehyde are converted to I. Since I is produced from II (one-step reaction) much more easily than from acetaldehyde (two-step reaction), a higher racemization rate was attained by the use of II than that of acetaldehyde. From the fact that I exhibited the highest activity both at a low and at a high reaction temperature, it is clear that the real active species in the racemization induced by acetaldehyde at a high temperature is I.

It is possible to convert propionaldehyde to 2-methyl-2-pentenal through aldol condensation and successive dehydration in the reaction system. However, the racemization activity of this compound was found to be lower than that of propionaldehyde itself (Fig. 4). Thus, the overall rate of the racemization induced by propionaldehyde was not enhanced by the accumulation of α,β-unsaturated aldehyde.

Both isobutyraldehyde, which does not afford α,β-unsaturated aldehyde, and formaldehyde, which does not produce an aldol-type compound, were found to induce a poor racemization activity.

These findings also support the idea that the high rate of racemization induced by acetaldehyde is attributable to the formation and to the accumulation of the I produced in a reaction system.

Experimental

The colorimetric determination was performed using a Hitachi 124 spectrometer. Thin-layer chromatography was carried out with a precoated plate of silica gel (E. Merck) with Solvent 1 (diethyl ether/cyclohexane=10/2.5) or Solvent 2 (1-butanol/1-propanol/benzene/conc. ammonia/water =3/10/3/0.5/3.5). The optical rotation was measured by the use of Perkin-Elmer 241 Polarimeter.

Materials. The (*S*)-glutamic acid and copper(II) sulfate pentahydrate were obtained from commercial sources. The acetaldehyde was generated by the decomposition of paraldehyde in the presence of sulfuric acid. The propionaldehyde, isobutyraldehyde, II, and I were distilled immediately before use.

Racemization. Into a slurry of (*S*)-glutamic acid (30 mmol) and $CuSO_4 \cdot 5H_2O$ (3 mmol) in 10 ml of water, was added a 7 M (1 M=1 mol dm^{-3}) NaOH solution until the pH of the solution became 10.4. Then the mixture was made up to 30 ml with water.

In a shaker flask, a 25-ml portion of the solution and 2.5 mmol of aldehyde were placed, after which the mixture was shaken at the temperature stated in the text. At specific time intervals, a small portion of the reaction mixture was taken out for analysis.

Determination of the Racemization Yield. A 3-ml portion of the reaction mixture at each reaction time was acidified with 6 ml of 6 M HCl. After the removal of Cu^{2+} from the 3-ml portion of the acidified reaction mixture by treatment with H_2S, the resulting solution was made up to 5 ml with water and subjected to the determination of the optical rotation (α_D^{20}). The degree of racemization was calculated from the ratio of α_D^{20} at each reaction time to the α_D^{20} at the beginning of the reaction.

Determination of Aldehydes. A 3-ml portion of the acidified reaction mixture was mixed with 3 ml of a 1.5% aqueous solution of 4-nitrophenylhydrazine hydrochloride. The reaction product was extracted with 10 ml of ethyl butyrate.

A 100-μl portion of the extract was submitted to chromatography on a TLC plate with Solvent 1. The 4-nitrophenylhydrazone of aldehyde was recovered by scraping the corresponding part of the silica gel and eluting with 5 ml of ethanol. The amount of 4-nitrophenylhydrazone of aldehyde in the elute was determined by colorimetry with the absorbances at 380 nm (acetaldehyde), 390 nm (propionaldehyde and isobutyraldehyde), and 345 nm (formaldehyde).

Identification of Carbonyl Compounds. From the acidified reaction mixture induced by acetaldehyde, yellow products were obtained by a reaction with 4-nitrophenylhydrazine. The yellow crystals were found to contain 4-nitrophenylhydrazone derivatives of II, I, and III by a comparison of their Rf values and UV absorption spectra (λ_{max}) with those of authentic samples. The Rf values of the 4-nitrophenylhydrazone derivatives were found to be 0.095 for II, 0.47 for I, and 0.12 for III by the use of Solvent 1, while their λ_{max} values were 380 nm for II, 395 nm for I, and 383 nm for III.

The authors wish to express their thanks to Dr. Katsumoto Yamanouchi for his helpful suggestions. This work was supported in part by a Scientific Research Grant from the Ministry of Education, Science and Culture Japan (411108).

A Mild Silver Salt-induced Oxidation of Dibromo-5-hydroxytropolones to Dibromo-*p*-tropoquinones

Hitoshi TAKESHITA,* Tomoyuki KUSABA,† and Akira MORI

Research Institute of Industrial Science, 86, Kyushu University, Hakozaki, Fukuoka 812

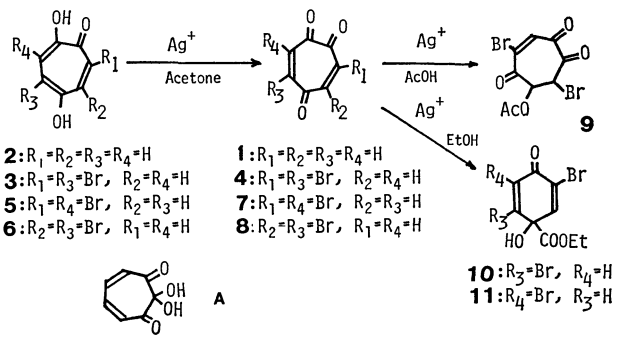
(Received July 24, 1981)

Synopsis. The treatment of 3,6-dibromo-, 3,7-dibromo, 4,6-dibromo-, and unsubstituted 5-hydroxytropolones with silver acetate in acetone gave the corresponding *p*-tropoquinones in good yields. When this reaction was carried out in protic solvents, some of these tropoquinones underwent further attack by solvent nucleophiles to give Michael-adducts or ring-contracted cyclohexadienones.

Some years ago, Itô *et al.* reported the first synthesis of *p*-tropoquinone, 3,6-cycloheptadiene-1,2,5-trione (**1**), from 5-hydroxytropolone (**2**),[1] and a hydrated *o*-tropoquinone, 2,2-dihydroxy-4,6-cycloheptadiene-1,3-dione (**A**),[2] and subsequent papers described the remarkable physical and chemical properties of these basic nonbenzenoid quinones.[3,4] We will herein describe an alternative synthesis of **1** and its bromo derivatives.

When an acetone solution of 3,6-dibromo-5-hydroxytropolone (**3**) and silver acetate was kept at room temperature, metallic silver was precipitated after 15 min. From the supernatant organic layer, pale yellow crystals (**4**) were obtained by means of brief silica-gel chromatography. The **4** retained two bromine atoms intact, and the NMR data were in accord with 3,6-dibromo-*p*-tropoquinone [δ:[5] 7.59 (1H, s) and 7.72 (1H, s)]. Similarly, 3,7-dibromo-5-hydroxytropolone (**5**), 4,6-dibromo-5-hydroxytropolone (**6**), and the bromine-free **2** gave the *p*-tropoquinones, 3,7-dibromo-*p*-tropoquinone (**7**), 4,6-dibromo-*p*-tropoquinone (**8**), and **1**, respectively in good yields.

On the other hand, silver salt-induced oxidation in a protic solvent gave no tropoquinone derivative; the oxidation of **3** in acetic acid gave a Michael-type adduct of **4**, 3-acetoxy-4,7-dibromo-6-cycloheptene-1,2,5-trione (**9**), while the oxidation of **3** in ethanol gave a ring-contraction product, 2,5-dibromo-4-ethoxycarbonyl-4-hydroxy-2,5-cyclohexadien-1-one (**10**). The Michael addition must be catalyzed by the silver ion exemplified in the case of authentic **4**, changing to **9**. As expected, one 4,6-disubstituted quinone, **8**, gave no Michael adduct. Furthermore, **5** in ethanol gave 3,5-dibromo-4-ethoxycarbonyl-4-hydroxy-2,5-cyclohexadien-1-one (**11**), and the ring-contraction occurred only with the 3-bromo-*p*-tropoquinones; from the parent compound (**2**) or **6**, no cyclohexadienone was isolated.



The results of an early attempt at synthesizing **1** by an iron(III) chloride or silver nitrate oxidation of **2**,[6] should be, in view of the present results, explained in terms of the protic solvents used in the reaction.

Experimental

Preparation of the Dibromo Derivatives of ***2***. To a refluxing AcOH solution (300 cm³) containing **2** (5.42 g), an AcOH solution (200 cm³) of Br_2 (13.7 g, 2.2 mol equiv.) was added, drop by drop. After the evaporation of the solvent, the residue was separated by fractional recrystallizations; from the least soluble fractions, **5** was obtained as pale yellow needles (mp 166—167 °C (from MeOH); 356 mg (3%) [Found: C, 28.30; H, 1.64%. Calcd for $C_7H_4O_3Br_2$: C, 28.41; H, 1.36%. δ^{MeOD}: 7.68 (2H, s). δ(C): 128.1(2C), 130.3(2C), 154.3, 162.8(2C). ν: 1605, 1570, 920, 870 cm^{-1}. λ_{max}^{MeOH}: 261 nm (ε=25000), 350 (7400), 412 (7600)]), followed by other pale yellow needles, **6** (mp 146—147 °C (from MeOH); 2420 mg (21%) [Found: C, 28.61; H, 1.54%. δ^{MeOD}: 8.20 (2H, s). δ(C): 131.0(2C), 134.6(2C), 151.3, 168.7(2C). ν: 1605, 1530, 960, 930 cm^{-1}. λ_{max}^{MeOH}: 263 nm (ε=14000), 386 (6300), 406 (6900)]). From the most soluble fractions, **3** was obtained as pale yellow needles; mp 166—168 °C (from EtOAc–CCl_4); 700 mg (6%) [Found: C, 28.90; H, 1.62%. δ^{MeOD}: 7.76 (1H, s), 8.08 (1H, s). δ(C): 120.6, 126.5, 131.5, 132.0, 153.6, 158.4, 169.5. ν: 1590, 1520, 990, 920 cm^{-1}. λ_{max}^{MeOH}: 251 nm (ε=13000), 334 (4300), 400 (550)].

AgOAc-oxidation of ***3*** *in Acetone.* To an acetone solution (6 cm³) of **3** (44 mg), AgOAc (50 mg) was added all at once. After magnetical stirring for 10 h at room temperature, the deposited Ag was filtered off; the filtrate was evaporated *in vacuo* and chromatographed on a short silica-gel column with benzene to give yellow crystals (**4**) (35 mg, 80%), which after recrystallizations from benzene showed a mp of 146—150 °C [Found: C, 28.74; H, 0.93; Br, 53.80%. Calcd for $C_7H_2O_3Br_2$: C, 28.60; H, 0.69; Br, 54.37%.[7] δ: 7.72 (1H, s), 7.59 (1H, s). δ(C): 135.5, 136.1, 139.3, 140.8, 178.1, 179.6, and 181.8. ν: 1700, 1680, 1640, 1600 cm^{-1}].

Catalytic Hydrogenation of ***4***. An EtOAc solution of **4** (50 mg) was hydrogenated with 5%-Pd-on-carbon (50 mg) at room temperature under an H_2-atmosphere for 10 min. After the filtration of the catalyst, the yellow needles obtained by the removal of the solvent were identical with **3** (45 mg, 89.4%).

AgOAc-oxidation of ***5*** *in Acetone.* Similarly, an acetone solution (4 cm³) of **5** (99 mg) was treated with AgOAc (51 mg) for 1 h at room temperature to give yellow needles (**7**); mp 96—97 °C (from benzene); 79 mg (81%) [Found: C, 28.64; H, 1.02%. δ: 7.51 (2H, s). δ(C): 134.9(2C), 140.6(2C), 181.8(2C), 181.9. ν: 1695, 1685 cm^{-1}].

AgOAc-oxidation of ***6*** *in Acetone.* Similarly, an acetone

solution (10 cm³) of **6** (550 mg) was oxidized with AgOAc (630 mg) at room temperature. The yellow needles obtained from the benzene fraction by silica-gel-column chromatography consisted of 480 mg (87%) of **8**; mp 146—150 °C [Found: C, 28.66; H, 0.94%. δ: 7.58 (2H, s). δ(C): 136.1(2C), 138.5(2C), 176.1(2C), and 180.7. ν: 1660, 1595 cm^{-1}].

AgOAc-oxidation of ***2*** *in Acetone.* An acetone solution (3 cm³) of **2** (100 mg) was similarly oxidized by AgOAc (245 mg) for 1.5 h. The yellow needles, 45 mg (46%), obtained by a similar work-up were identical with the authentic **1**[1] in every respect.

AgOAc-oxidation of ***3*** *in Acetic Acid.* To an AcOH solution (2 cm³) of **3** (95 mg), AgOAc (108 mg) was added at room temperature, after which the mixture was stirred for 1.5 h. The mixture was then heated *in vacuo* (below 60 °C) to remove the AcOH, and the residue was fractionated by preparative thin-layer chromatography (PTLC) to give a colorless oil (**9**); 12.6 mg (13.3%) [Found: *m/e*, 352, 353.8579 (M^+, Calcd for $C_9H_6O_5{}^{79}Br^{81}Br$: 353.8562), 356. δ: 2.18 (3H, s), 4.16 (1H, d, J=3 Hz), 5.22 (1H, d, J=3 Hz), and 6.70 (1H, s) for *cis*-**9**; 2.13 (3H, s), 4.48 (1H, d, J=9 Hz), 5.17 (1H, d, J=9 Hz), and 6.72 (1H, s) for *trans*-**9**. *cis*/*trans*=1/2. ν: 1750, 1700 cm^{-1}].

Treatment of ***4*** *with Acetic Acid.* An AcOH solution (4 cm³) of **4** (42 mg) was kept under magnetical stirring at room temperature until all of the starting **4** had been consumed (for 20 h). By PTLC fractionation, 11 mg (21%) of a colorless oil was then obtained from the mixture; it was identical with respect to the NMR spectroscopy with the **9** prepared from **3**. The rest of the material was insoluble to most ordinary organic solvents, and no further attempt at its fractionation was made.

AgOAc-treatment of ***1*** *in Acetic Acid.* To an AcOH solution (0.5 cm³) of **1** (44.4 mg), AgOAc (54.5 mg) was added all at once, after which the mixture was stirred at room temperature for 24 h. The PTLC of the reaction mixture afforded only the recovered **1** (23.9 mg, 54%), although some minor spots due to other products were detectable.

AgOAc-treatment of ***8*** *in Acetic Acid.* To an AcOH solution of **8** (34 mg), AgOAc (19 mg) was added all at once, after which the mixture was stirred at room temperature for 24 h. The PTLC resulted in the recovery of **8** (22.4 mg, 66%); no other compound was isolable.

AgOAc-oxidation of ***3*** *in Ethanol.* An EtOH solution (2 cm³) of **3** (11 mg) was stirred at room temperature with AgOAc (15 mg) for 10 h. After the filtration of the deposited Ag, the mixture was heated *in vacuo* to remove the solvent and separated by PTLC to give a colorless oil (**10**); 5.3 mg (42%) [Found: C, 32.07; H, 2.59%. Calcd for $C_9H_8O_4Br_2$: C, 31.80; H, 2.37%. δ: 1.28 (3H, t), 4.36 and 4.33 (2H, AB-part of ABX_3), 6.84 (1H, s), and 7.18 1H, s)].

AgOAc-treatment of ***4*** *in Ethanol.* An EtOH solution (4 cm³) of **4** (23.7 mg) was treated with AgOAc (14 mg) at room temperature for 20 h. The reaction mixture was then separated on PTLC to give **10** (17.3 mg, 64%).

AgOAc-oxidation of ***5*** *in Ethanol.* To an EtOH solution (1.5 cm³) of **5** (32 mg), AgOAc (37 mg) in EtOH (1.5 cm³) was added at room temperature, after which the mixture was kept for 10 h. After the filtration of metallic Ag, the mixture was separated by PTLC to give colorless crystals, mp 104—105 °C (from $CHCl_3$); 14.2 mg (38%) of **11** [Found: C, 31.91; H, 2.48%. δ: 1.33 (3H, t), 4.47 (2H, q), 6.96 (2H, s). δ(C): 13.8, 65.2, 132.8, 142.8, 167.8, 180.8. ν: 1760, 1740 cm^{-1}].

An Attempted Ring Contraction of ***6****.* An EtOH solution (4 cm³) of **6** (50 mg) was treated with AgOAc (85 mg) for 24 h. The PTLC of the reaction mixture revealed the very slow development of a new spot, but no product was isolable other than the quinone, **8** (31 mg, 63%).

AgOAc-treatment of ***1*** *in Ethanol.* An ethanol solution (2 cm³) of **1** (80.1 mg) was similarly treated with AgOAc (97.5 mg) for 24 h. The recovered **1** (52.1 mg, 65%) was the sole isolable compound in the PTLC fractionation.

The Cheletropic Addition of Dichlorocarbene to 2-Phenylsulfonyl-2-azabicyclo[3.2.1]octa-3,6-diene and Its 8-Substituted Derivatives

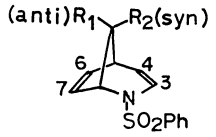
Hiroo Inoue,* Kazuhiko Tokisato, and Katsumi Umano

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received August 31, 1981)

Synopsis. It was found that dichlorocarbene undergoes *exo* addition preferentially on the C_3–C_4 double bond of 2-phenylsulfonyl-2-azabicyclo[3.2.1]octa-3,6-diene and *endo* addition on that of 2-phenylsulfonyl-syn-8-benzoyloxy-2-azabicyclo[3.2.1]octa-3,6-diene.

Recently we have discovered that the 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide to 2-phenylsulfonyl-2-azabicyclo[3.2.1]octa-3,6-diene (**1**) and 2-phenylsulfonyl-syn-8-benzoyloxy-2-azabicyclo[3.2.1]-octa-3,6-diene (**3**) take place selectively with an *exo* attack on the C_6–C_7 double bond.[1] In order to explore further the reactivity of the C_3–C_4 and C_6–C_7 double bonds, particularly in their *exo* and *endo* sides, the addition of dichlorocarbene was investigated with azabicyclic dienes, **1**—**3**. Herein, we wish to report our findings on these reactions.



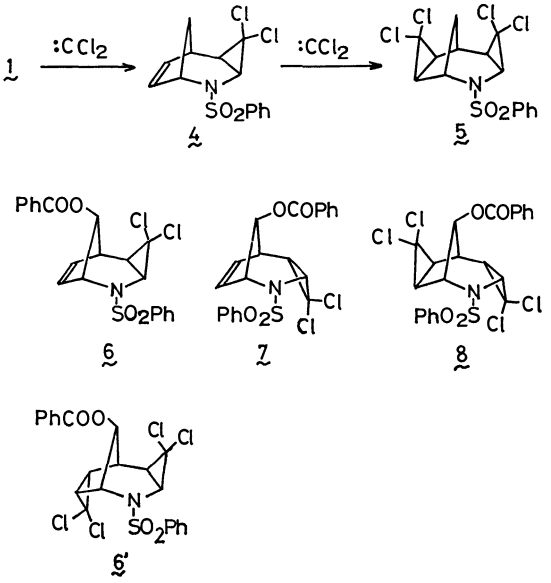
1; $R_1=R_2=H$
2; $R_1=PhCOO$, $R_2=H$
3; $R_1=H$, $R_2=PhCOO$

The reaction of diene **1** with dichlorocarbene, generated by the usual phase-transfer method,[2] afforded the 1:1 *exo* adduct (**4**) in a high yield after 30 min, as Table 1 shows. In a prolonged reaction, the 1:2 adduct (**5**) was produced by the subsequent addition of dichlorocarbene to adduct **4**. The reaction with diene **2**, in which the *exo* side of the C_6–C_7 double bond was blocked by the benzoyloxyl group, resulted in the formation of only the 1:1 *exo* adduct (**6**), even after 72 h, and the 1:2 adduct (**6'**) was not obtained at all. This indicates that the *endo* side of the C_6–C_7 double bond is much less reactive. On the other hand, when the *exo* side of the C_3–C_4 double bond was blocked by the benzoyloxyl group, the addition of dichlorocarbene was diverted to the *endo* side to afford the 1:1 *endo* adduct (**7**), together with the 1:2 adduct (**8**), as Table 1 shows.

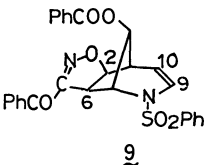
Table 1. The yields of the products in the addition of dichlorocarbene to dienes **1**—**3**

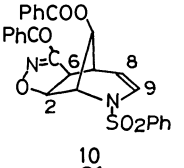
Dienes	Time/h	Adduct(yield/%)[a]
1	0.5	**4** (84), **5** (5)
1	3	**4** (65), **5** (23)
1	72	**4** (33), **5** (45)
2	3	**6** (91)
2	72	**6** (85)
3	3	**7** (77), **8** (20)
3	72	**7** (47), **8** (30)

a) Based on the dienes.



Next, the reactions of dienes **1**—**3** with dichlorocarbene were compared with those with phenylglyoxylonitrile oxide as a 1,3-dipole. The 1,3-dipolar addition to **2** in tetrahydrofuran at 0 °C afforded two *exo* adducts, **9** and **10**, in 47 and 22% yields respectively after 3 h. This phenomenon of the *exo* prevalence, which is observed even in the existence of the benzoyloxyl group in the C_6–C_7 side of **2**, agreed with the results in the cases of **1** and **3** reported previously.[1] As has been described above, we have found that dichlorocarbene exhibits an *exo* or *endo* attack preferentially on the C_3–C_4 double bond of dienes **1**—**3**, while phenylglyoxylonitrile oxide exhibits an *exo* attack on their C_6–C_7 double bonds, and that the *endo* side of the C_3–C_4 double bond is less reactive to dichlorocarbene than its *exo* side. Thus, the addition of dichlorocarbene to dienes **1**—**3** is governed by the steric effect of hydrogen or the substituent at the 8-position.





Experimental

The melting points are uncorrected. The ^1H NMR spectra were taken at room temperature with a Hitachi R-24A spectrometer, using tetramethylsilane as the internal standard. The IR spectra were taken with a Hitachi 216 grating infrared spectrometer.

Materials. Dienes **1**—**3** were prepared from nor-

bornadiene and 7-benzoyloxynorbornadiene according to the published procedures.[3] **2**: mp 121.5—122 °C; IR (KBr) 1715 cm^{-1} (CO), 1345, 1180 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 2.76 (m, 1H, 5-H), 4.82 (brs, 2H, 1-H and 8-H), 5.15 (m, 2H, 4-H and 7-H), 6.09 (dd, 1H, $J_{6,7}$=5.3 Hz, $J_{5,6}$=2.3 Hz, 6-H), 6.28 (d, 1H, $J_{3,4}$=9.0 Hz, 3-H), 6.88—8.02 (m, 10H, aromatic). Found: C, 65.67; H, 4.63; N, 4.08%. Calcd for $2_{20}H_{17}NO_4S$: C, 65.40; H, 4.63; N, 3.81%. **3**: mp 114.5—115 °C; IR (KBr) 1710 cm^{-1} (CO), 1340, 1165 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 2.75 (m, 1H, 5-H), 4.71 (m, 1H, 1-H), 5.07 (m, 2H, 4-H and 8-H), 5.39 (dd, 1H, $J_{6,7}$=6.0 Hz, $J_{1,7}$=3.0 Hz, 7-H), 6.09 (dd, 1H, $J_{6,7}$=6.0 Hz, $J_{5,6}$=3.3 Hz, 6-H), 6.57 (d, 1H, $J_{3,4}$=8.0 Hz, 3-H), 6.92—8.00 (m, 10H, aromatic). Found: C, 65.41; H, 4.64; N, 4.11%. Calcd for $C_{20}H_{17}NO_4S$: C, 65.40; H, 4.63; N, 3.81%.

General Procedure for the Addition of Dichlorocarbene to Dienes ***1—3***. A 50% aqueous sodium hydroxide solution (6.5 g) was stirred, drop by drop, into a solution of dienes (2.72 mmol) in chloroform (10 g) with benzyltriethylammonium chloride (50 mg) for 30 min at room temperature. After a definite period of stirring, the reaction mixture was diluted with water and extracted with chloroform. After the removal of the chloroform *in vacuo*, the residue was chromatographed on a silica-gel column, using benzene, hexane, or ethyl acetate as the eluant.

Reaction with ***1***. Two adducts, **4** and **5**, were obtained. **4**: mp 132.5—134 °C; IR (KBr) 1335 and 1168 cm^{-1} (SO_2); ^1H NMR (C_6D_6) δ 1.10 (m, 1H, 9-H_{anti}), 1.48 (dd, 1H, $J_{3,5}$=10.0 Hz, $J_{5,6}$=3.0 Hz, 5-H), 2.3 (d, 1H, $J_{9s,9a}$=11.3 Hz, 9-H_{syn}), 2.32 (m, 1H, 6-H), 3.2 (d, 1H, $J_{3,5}$=10.0 Hz, 3-H), 4.48 (m, 1H, 1-H), 5.40 (dd, 1H, $J_{7,8}$=5.7 Hz, $J_{1,8}$=2.7Hz, 8-H), 5.64 (dd, 1H, $J_{7,8}$=5.7 Hz, $J_{7,9}$=2.3 Hz, 7-H), 6.75—8.00 (m, 5H, aromatic). Found: C, 51.07; H, 3.96; N, 4.55%. Calcd for $C_{14}H_{13}NO_2SCl_2$: C, 50.92; H, 3.97; N, 4.24%. **5**: mp 165—166.5 °C; IR (KBr) 1360 and 1172 cm^{-1} (SO_2); ^1H NMR (C_6D_6) δ 1.24 (d, 1H, $J_{3,5}$=10.7 Hz, 5-H), 1.32 (d, 1H, $J_{7,9}$=7.3 Hz, 7-H), 1.69 (d, 1H, $J_{7,9}$=7.3 Hz, 9-H), 1.80 (m, 2H, 10-CH_2), 2.17 (m, 1H, 6-H), 3.13 (d, 1H, $J_{3,5}$=10.7 Hz, 3-H), 4.38 (m, 1H, 1-H), 6.67—8.10 (m, 5H, aromatic). Found: C, 43.41; H, 2.91; N, 3.36%. Calcd for $C_{15}H_{13}NO_2SCl_4$: C, 43.61; H, 3.17; N, 3.39%.

Reaction with ***2***. The adduct **6** was obtained: mp 136—137 °C; IR (KBr) 1720 cm^{-1} (CO), 1355, 1170 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 2.22 (dd, 1H, $J_{3,5}$=10.0 Hz, $J_{5,6}$=3.0 Hz, 5-H), 3.27 (d, 1H, $J_{3,5}$=10.0 Hz, 3-H), 3.30 (m, 1H, 6-H), 4.91 (m, 1H, 1-H), 5.80 (m, 2H, 8-H and 9-H), 6.35 (dd, 1H, $J_{7,8}$=5.3 Hz, $J_{6,7}$=2.3 Hz, 7-H), 7.09—8.20 (m, 10H, aromatic). Found: C, 56.17; H, 3.66; N, 3.10%. Calcd for $C_{21}H_{17}NO_4SCl_2$: C, 56.01; H, 3.78; N, 3.11%. The small values of the coupling constants between H-5 and H-6 for **4** and **6** and between H-1 (H-6) and H-9 (H-7) for **5** indicated the *exo* configurations of **4**, **5**, and **6**.

Reaction with ***3***. The adducts **7** and **8** were obtained. **7**: mp 130—130.5 °C; IR (KBr) 1720 cm^{-1} (CO), 1355, 1170 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 1.93 (dd, 1H, $J_{5,6}$=8.0 Hz, $J_{3,5}$=10.7 Hz, 5-H), 3.66 (d, 1H, $J_{3,5}$=10.7 Hz, 3-H), 3.48 (m, 1H, 6-H), 4.49 (m, 1H, 1-H), 5.11 (t, 1H, $J_{1,8}$=$J_{7,8}$=4.7 Hz, 8-H), 6.00 (m, 2H, 7-H and 9-H), 6.94—8.00 (m, 10H, aromatic). Found: C, 56.13; H, 3.65; N, 3.11%. Calcd for $C_{21}H_{17}NO_4SCl_2$: C, 56.01; H, 3.78; N, 3.11%. **8**: mp 185—186 °C; IR (KBr) 1720 cm^{-1} (CO), 1360, 1170 cm^{-1} (SO_2); ^1H NMR [(2:1)C_6D_6–$CDCl_3$] δ 1.67 (dd, 1H, $J_{3,5}$=10.7 Hz, $J_{5,6}$=9.3 Hz, 5-H), 2.21 (d, 1H, $J_{7,9}$=8.0 Hz, 7-H), 2.41 (d, 1H, $J_{7,9}$=8.0 Hz, 9-H), 2.91 (dd, 1H, $J_{6,10}$=4.7 Hz, $J_{5,6}$=9.3 Hz, 6-H), 3.14 (d, 1H, $J_{3,5}$=10.0 Hz, 3-H), 4.36 (d, 1H, $J_{1,10}$=4.7 Hz, 1-H), 5.67 (t, 1H, $J_{1,10}$=$J_{6,10}$=4.7 Hz, 10-H), 6.74—7.90 (m, 10H, aromatic). Found: C, 49.55; H, 3.09; N, 2.65%. Calcd for $C_{22}H_{17}NO_4SCl_4$: C, 49.55; H, 3.19; N, 2.63%. The large values of the coupling constants between H-5 and H-6 for **7** and **8** indicated the *endo* configurations of **7** and **8**.

Reaction of ***2*** *with Phenylglyoxylonitrile Oxide*. A solution of a mixture of **2** (1.63 mmol) and α-chloro-α-(hydroxyimino)acetophenone (1.63 mmol) was cooled in an ice bath. Into the cooled solution, a solution of triethylamine (2.12 mmol) in tetrahydrofuran (20 cm^3) was then added and stirred. After 2 h, a precipitate was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residue was chromatographed on a silica-gel column, using (40:1) benzene–ethyl acetate as the eluant, to give two adducts, **9** (0.39 g, 47%) and **10** (0.19 g, 22%), puls a 23% recovery of **2**. **9**: mp 164—165 °C; IR (KBr) 1730 cm^{-1} (CO), 1355, 1170 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 3.04 (d, 1H, $J_{1,10}$=7.3, 1-H), 3.96 (d, 1H, $J_{2,6}$=9.3 Hz, 6-H), 5.07 (m, 4H, 2-H, 7-H, 10-H, and 11-H), 6.51 (d, 1H, $J_{9,10}$=7.7 Hz, 9-H), 6.88—8.17 (m, 15H, aromatic). Found: C, 65.14; H, 4.22; N, 5.25%. Calcd for $C_{28}H_{22}N_2O_6S$: C, 65.37; H, 4.28; N, 5.44%. **10**: mp 147—148 °C; IR (KBr) 1725 cm^{-1} (CO), 1360, 1175 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ 3.18 (d, 1H, $J_{7,8}$=7.7 Hz, 7-H), 4.38 (d, 1H, $J_{2,6}$=9.3 Hz, 6-H), 4.86 (m, 2H, 1-H and 11-H), 5.10 (d, 1H, $J_{2,6}$=9.3 Hz, 2-H), 5.29 (dd, 1H, $J_{7,8}$=7.7 Hz, $J_{8,9}$=8.0 Hz, 8-H), 6.41 (d, 1H, $J_{8,9}$=8.0 Hz, 9-H), 6.98—8.11 (m, 15H, aromatic). Found: C, 65.18; H, 4.12; N, 5.27%. Calcd for $C_{28}H_{22}N_2O_6S$: C, 65.37; H, 4.28; N, 5.44%. The large difference in the chemical shifts between 2-H and 6-H indicated the orientation of adduct **9**.[4]

A New Synthesis of Aldehydes and Aldehydes-*d* from Grignard Reagents

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602

(Received September 10, 1981)

Synopsis. Aldehydes were prepared from Grignard reagents in high yields using pentacarbonyliron as the carbonylating agent. This reaction was also found to be applicable to the synthesis of aldehydes-*d*.

Although there have been some reports on the synthesis of aldehydes by the use of Grignard reagents, these processes have been restricted to the hydrolysis of an intermediate derived from the reagent, and it is impossible to synthesize an aldehyde-*d*.[1] In this note, we wish to report an alternative and useful method for synthesizing aldehydes and aldehydes-*d* from Grignard reagents using pentacarbonyliron.

A representative reaction procedure was as follows. To a tetrahydrofuran solution of hexylmagnesium bromide derived from hexyl bromide and magnesium, an equimolar amount of pentacarbonyliron was injected by means of a syringe, after which the mixture was stirred for 2 h at room temperature under an argon atmosphere. Acetic acid was then added to the solution, and stirring was continued for a further 5 min. The mixture was washed with 1 mol dm^{-3} hydrochloric acid and then 0.1 mol dm^{-3} aqueous sodium hydroxide saturated with sodium chloride; it was subsequently extracted with diethyl ether, dried, and filtered, and the ether was removed with a rotary evaporator. The residue was purified by distillation under reduced pressure. The product was identified as heptanal by means of IR, NMR, MS, and GLC. The yield was 91% on the basis of the Grignard reagent (GLC). When CH_3COOD was used instead of CH_3COOH, heptanal-1-*d* was obtained in the same yield. The results are listed in Table 1.

In these reactions, the acyltetracarbonylferrates **1** are assumed to be intermediates,[2] which are hydrogenated or deuterated to give aldehydes or aldehydes-*d* (Eq. 1).

$$\text{R-MgBr} \xrightarrow{\text{Fe(CO)}_5} \left[\text{R-C(=O)-Fe(CO)}_4\right]^- \xrightarrow{\text{H}^+ \text{ or } \text{D}^+} \underset{\mathbf{1}}{} \text{R-CHO or R-CDO} \quad (1)$$

The ease of the reaction procedure, the mildness of the reaction conditions, and the high yields of the products may make it possible to utilize this reaction for the syntheses of aldehydes and aldehydes-*d* from Grignard reagents.

Experimental

The infrared spectra were recorded on a Hitachi 260-10 Infrared Spectrophotometer, the NMR spectra were measured on a Hitachi R-600 FT-NMR Spectrometer, and the mass spectra were measured on a Hitachi RM-50 GC-MS. Gas chromatography was carried out on a Yanagimoto G-8 Model equipped with a stainless column packed with Silicone gum SE-30 on chromosorb. All the experiments were carried out under an atmosphere of argon. The tetrahydrofuran was dried by distillation from lithium aluminum hydride. The pentyl bromide, hexyl bromide, bromobenzene, and cyclohexyl bromide were all commercial products and were distilled before use. The pentacarbonyliron was purchased from a commercial source and was used without further purification. The acetic acid, acetic acid-*d*, and magnesium for the Grignard reaction were also commercial products of the highest available purity.

TABLE 1. SYNTHESIS OF ALDEHYDES FROM GRIGNARD REAGENTS

Run	RMgBr R	AcOH or AcOD	Product	Yield/%[a]
1	$CH_3(CH_2)_5$-	AcOH	$CH_3(CH_2)_5CHO$	91 (44)
2		AcOD	$CH_3(CH_2)_5CDO$	(43)
3	$CH_3(CH_2)_4$-	AcOH	$CH_3(CH_2)_4CHO$	99
4	C_6H_5-	AcOH	C_6H_5CHO	94

6	C_6H_{11}-[b]	AcOH	$C_6H_{11}CHO$	40
7		AcOD	$C_6H_{11}CDO$	(14)

a) Determined by GLC. Yields in parentheses are those of substances isolated by fractional distillation. b) Cyclohexyl.

Representative Synthesis of Heptanal-d. Into the tetrahydrofuran solution (30 ml) of hexylmagnesium bromide derived from hexyl bromide (22 mmol) and magnesium (44 mg-atom), pentacarbonyliron (3 ml, 22 mmol) was injected by means of a syringe, after which the mixture was stirred for 2 h at room temperature under argon. Acetic acid-*d* (26 mmol) was then added to the solution, and stirring was continued for further 5 min. The mixture was washed with 1 mol dm^{-3} hydrochloric acid and then 0.1 mol dm^{-3} aqueous sodium hydroxide saturated with sodium chloride, and subsequently extracted with diethyl ether. The organic layer was dried over sodium sulfate, and the solvent was removed with a rotary evaporator. The residue thus obtained was purified by distillation *in vacuo*, giving heptanal-1-*d* (1.09 g): bp 46—49 °C/17 Torr (1 Torr≈133.322 Pa); NMR ($CDCl_3$) δ 0.93 (3H, t, $-CH_3$), 1.13—2.07 (8H, m, $-(CH_2)_4-$), 2.48 (2H, t, $-CH_2CO-$); IR (neat) 2070, 1710 cm^{-1}; MS *m/e* (%) 115 (M^+, 4), 97 (27), 85 (27), 82 (23), 70 (100).

Benz(aldehyde-d*)*. Bp 70 °C/17 Torr; NMR ($CDCl_3$) δ 7.42—8.16 (5H, C_6H_5-); IR (neat) 2110, 1695 cm^{-1}; MS *m/e* (%) 107 (M^+, 100), 105 (96), 77 (89).

Cyclohexane(carboaldehyde-d*)*. Bp 45 °C/10 Torr; NMR ($CDCl_3$) δ 0.82—2.83 (11H, m, $C_6H_{11}-$); IR (neat) 2050, 1710 cm^{-1}; MS *m/e* (%) 113 (M^+, 8), 95 (21), 83 (56), 71 (21), 68 (36), 55 (100).

The hexanal, heptanal, benzaldehyde, and cyclohexane-

carboaldehyde were identified by a comparison of their IR, NMR, and mass spectra with those of authentic samples.

(Received September 21, 1981)

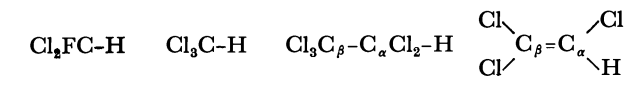
Synopsis. The ^{13}C and ^{19}F chemical shifts induced by C-H···Base hydrogen bonding were measured for dichlorofluoromethane, chloroform, pentachloroethane, and trichloroethylene. These chemical shifts were shown to be linear using the β scale of hydrogen-bond acceptor basicities proposed by Kamlet and Taft. The analysis of the linear solvation energy relationships reveals that the particular polarizations of the C-halogen and C=C bonds play an important role in the C-H···Base hydrogen-bond formation.

The participation of C-H groups of haloforms in hydrogen bonding has been recognized for a long time.[1] The C-H hydrogen bonds with bases (C-H···Base hydrogen bonds) have been extensively investigated by means of IR and ^1H NMR spectroscopies. However, comparatively little attention has been paid to the chemical shifts of other nuclei.

Here, we wish to report on the ^{13}C and ^{19}F chemical shifts of haloforms and related compounds induced by the C-H···Base hydrogen bonding. The mode and mechanism of the inductive electronic effects will be discussed on the basis of the linear solvation energy relationships between the observed chemical shifts and the β scale of the hydrogen-bond acceptor basicities.

Results and Discussion

The ^{13}C chemical shifts of **1**—**4** and the ^{19}F chemical shifts of **1** were measured in a variety of solvents which can act as proton acceptors (Table 1). The β scale



1 **2** **3** **4**

for the solvents listed in Table 1 is the measure of the hydrogen-bond acceptor basicities recently proposed by Kamlet and Taft.[2] Both the ^{13}C and ^{19}F chemical shifts are very sensitive to the change in solvent. In order to clarify the origin of the solvent shifts observed, the concept of the linear solvation energy relationship (LSER)[3] is applied to these chemical-shift data. Then, a good LSER is obtained for each compound [δ(ppm) = (slope)β + (intercept)].[4] Table 2 summarizes the magnitudes and signs of the slopes for these LSER's. The success of the LSER means that both the ^{13}C and ^{19}F chemical shifts are mainly controlled by the strength of the C-H···Base hydrogen bonds. Since the corresponding fully halogenated compounds were used as internal references, other solvent effects should be largely canceled out.[5]

An inspection of the chemical-shift data (Table 1) shows that the C-H···Base hydrogen-bond formations induce downfield shifts of the C_α-(H) atoms of **1**—**4**. This observation is consistent with those of Morishima *et al.*[6] and Lichter and Roberts.[7] However, no definite information about the behavior of halogen atoms and carbon atoms other than C_α in such hydrogen bonding has yet been established.

As is shown in Table 2, the magnitudes and signs of the slopes for the LSER's are characteristic of each carbon atom of each compound. The slope is related to the sensitivity to the inductive electronic effects, and the (+) and (−) signs of the slopes should correspond to the positive and negative charge densities induced on the carbon (or the fluorine) atom respectively. Therefore, the magnitudes and signs of the slopes serve as a probe for studying the mode and mechanism of the transmission of the inductive electronic effects.

For **1**, it should be noted that the sign (+) of the slope for the carbon atom is opposed to that (−) for the fluorine atom, thus suggesting the existence of the $\overset{+}{C}$–$\overset{-}{F}$ bond polarization. According to a recent theoretical study on hydrogen bonds,[8] the C-H···Base hydrogen bond is well represented by this electrostatic model:

$$\text{C-H···Base} \longleftrightarrow \bar{C}: \quad \overset{+}{H}: \text{Base}$$
$$(1) \qquad\qquad (2)$$

The observed ^{13}C downfield shifts seem to be incon-

sistent with the structure (2) having a localization of electrons on the carbon atom. Lichter and Roberts[7] reported that the ^{13}C downfield shifts for chloroform hydrogen-bonded with bases are attributable to the change in the average distance of bonding electrons in the C–H bond of chloroform. Here, we wish to propose a new concept of bond polarizations to explain the electronic structure in the hydrogen-bonded systems. The electronic structure of **1** can be explained by assuming that the localized electrons on the carbon atom are transmitted through the $\overset{+}{C}$–$\overset{-}{F}$ bond polarization onto the fluorine atom, thus resulting in the ^{13}C downfield and ^{19}F upfield chemical shifts. Furthermore, the holding of the LSER shows that the degree of the $\overset{+}{C}$–$\overset{-}{F}$ bond polarization increases with the increase in the strength of the hydrogen bonding.

Similar ^{13}C downfield shifts are observed for **2**; they can also be interpreted in terms of the $\overset{+}{C}$–$\overset{-}{Cl}$ bond polarization. However, the magnitude of the slope for **2** is larger than that for **1**. This experimental result can be nicely explained by the fact that the longitudinal polarizability[9] of the C–Cl bond (3.2×10^{-24} cm^3) is larger than that of the C–F bond (1.2×10^{-24} cm^3); hence, the carbon atom of **2** becomes more positive than does that of **1**.

For **3**, both the C_α and C_β atoms show the positive sign arising from the $\overset{+}{C}$–$\overset{-}{Cl}$ bond polarization. The small slope for the C_α atom is attributable to the smaller polarizability of the C–C bond (0.99×10^{-24} cm^3).[9] On the other hand, the slope for the C_β atom is larger than that which might be predicted from a simple attenuate transmission mode of the inductive effects in the C_α–C_β saturated bond. However, the polarization effect of three C–Cl bonds reinforces the positive charge on the C_β atom; this makes the magnitude of the slope larger than expected.

In the system containing the C_α=C_β bond, **4**, the sign of the slope for the C_α atom is opposite to that for the C_β atom. This sign alternation can be attributed to the polarization of the $\overset{+}{C}_\alpha$=$\overset{-}{C}_\beta$ bond, because the C=C bond is significantly more polarizable (2.8×10^{-24} cm^3)[9] than the C–C bond. At the same time, the $\overset{+}{C}_\beta$–$\overset{-}{Cl}$ bond polarization should be considered; it will partially reduce the negative charge induced on the C_β atom. In fact, this idea agrees well with the experimental result.

Experimental

The ^{13}C spectra were obtained under proton-decoupled conditions in the pulse FT mode at 25.03 MHz (45° pulse width of 10 μs; 8 K data points; resolution of 0.06 ppm) with a JEOL PS-100 spectrometer. The ^{19}F spectra were measured with the same spectrometer operating at 94.10 MHz in the frequency sweep mode with an external lock. The ^{13}C and ^{19}F chemical shifts of **1**, **2** and **3**, and **4** were determined with reference to internal $CFCl_3$, CCl_4, and Cl_2C=CCl_2 respectively. The concentration of the sample was *ca.* 1.5 M.[10]

The authors are indebted to Dr. T. Satokawa of Daikin Industry Co., Ltd, for a gift of dichlorofluoromethane.

The Reaction of 1-Methoxycarbonyl-2-imidazolidone with Phenylmagnesium Bromide

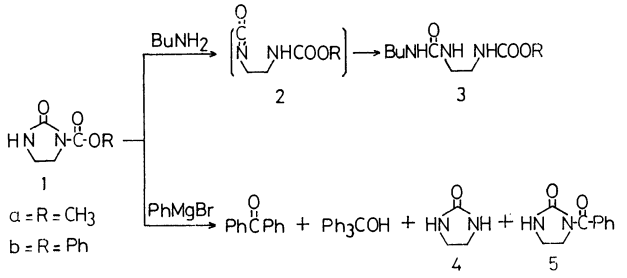
Noboru MATSUMURA,* Kimihiro MATSUKAWA, Yujiro SAKAGUCHI, and Hiroo INOUE

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received September 22, 1981)

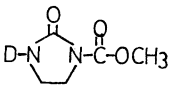
Synopsis. It is found that 1-methoxycarbonyl- or 1-phenoxycarbonyl-2-imidazolidone reacts with phenylmagnesium bromide to afford benzophenone and triphenylmethanol, together with 2-imidazolidone, by nucleophilic attack on the carbonyl group at the side chain.

The reaction of 1-methoxycarbonyl- or 1-phenoxycarbonyl-2-imidazolidone (**1a** or **1b**) with nucleophiles is of interest in relation to the reactivity of a carboxylated biotin coenzyme transferring the carboxylato group to Ac–CoA in a biological system.[1] Recently we have reported that the reaction of Compound **1a** with butylamine proceeds via the formation of an isocyanate intermediate (**2**) by ring opening to afford *N*-butylcarbamoyl-*N'*-methoxycarbonylethylenediamine (**3a**) in a quantitative yield.[2] In the course of our studies of the reactivity of Compound **1**, we have found that phenylmagnesium bromide undergoes nucleophilic attack on the carbonyl group of **1a** and **1b** to afford benzophenone, triphenylmethanol, and 1-benzoyl-2-imidazolidone (**5**). Herein, we wish to report our findings on these reactions.



Scheme 1.

The reactions of Compounds **1a** and **1b** with phenylmagnesium bromide in tetrahydrofuran were carried out by stirring under argon at room temperature for 2 h. At the **1a**/phenylmagnesium bromide molar ratio of 1:1, benzophenone, triphenylmethanol, 2-imidazolidone and **5** were obtained in low yields, with an almost entire recovery of **1a**, as Table 1 shows. The low yields of the products is caused by the consumption of phenylmagnesium bromide for abstracting the hydrogen of the NH group of **1**. This was established by the fact that, in the reaction of 1-methoxycarbonyl-2-imidazolidone-3-*d* (**6**) with 1-naphthylmagnesium bromide in the molar ratio of 1:1, naphthalene-1-*d* is produced in a 90% yield. When the **1a**/phenylmagnesium bromide molar ratio of 1:3 was used, benzophenone and triphenylmethanol were obtained in higher yields, without the formation of any methyl benzoate, as Table 1 shows. No products by ring opening were obtained at all. The formation of benzophenone was observed also in the reaction with **1b**. However, it was difficult to isolate Compound **4**



6

in amounts corresponding to those of benzophenone and triphenylmethanol, since it was very soluble in water. In addition to these products, Compound **5** was obtained, though in a low yield. Thus, it became apparent that the reactions of Compounds **1a** and **1b** with phenylmagnesium bromide result in the fission of the N–COOMe bond.

The difference in reactivity between butylamine and phenylmagnesium bromide led us to consider that the chelation of the Mg^{2+} ion after the abstraction of the hydrogen of the NH group of **1** prevents ring opening and brings about the nucleophilic attack of phenylmagnesium bromide on the side chain (Scheme 2). Furthermore, benzophenone is regarded as being formed *via* the intermediary formation of Compound **5** rather than methyl benzoate on the basis of the following results: 1) Methyl benzoate is not detected in the reaction of **1** with phenylmagnesium bromide; 2) the reaction of Compound **5** with phenylmagnesium bromide under similar conditions affords benzophenone and triphenylmethanol in good yields, together with the formation of Compound **4**, as Table 1 shows; 3) the reaction of a mixture (1:1) of **1a** and methyl benzoate with phenylmagnesium bromide (3 equiv.) affords benzophenone, triphenylmethanol, **4**, and **5** in 42, 1, 17, and 7% yields respectively, with a 94% recovery of methyl benzoate.

As has been described above, it became apparent that phenylmagnesium bromide can cleave the N–COOR bond by the assistance of the Mg^{2+} ion, unlike the behavior of butylamine, and that this behavior of the Mg^{2+} ion is similar to that in the butylamine/Mg^{2+}-ion system, bringing about the cleavage of the N–COOR bond.[3]

Experimental

Materials. *1-Methoxycarbonyl-2-imidazolidone (**1a**)*: Compound **1a** (mp 178—179 °C) was prepared by the method described in our previous paper.[2]

*1-Benzoyl-2-imidazolidone (**5**)*: A solution of 16.3 g (0.116 mol) of benzoyl chloride in 20 cm³ of dry benzene was added, under nitrogen, to a solution of 10 g (0.116 mol) of **4** in 50 cm³ of dry benzene at room temperature; the solution was stirred under reflux for 20 h and then cooled to room temperature. The crystals thus deposited were collected by filtration, washed with water, and recrystallized from chloroform to give 19.9 g (90%) of **5**: mp 167—168 °C; IR (KBr) 3220 (NH), 1733, 1670 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=3.62(t, 2H, $-CH_2-$), 4.25(t, 2H, $-CH_2-$), 5.78 (bs, 1H, NH), and 7.29—7.8 (m, 5H, aromatic); Found: C, 63.12; H, 5.18; N, 14.69%, Calcd for $C_{10}H_{10}N_2O_2$: C, 63.15; H, 5.30; N, 14.73%.

*1-Methoxycarbonyl-2-imidazolidone-3-*d *(**6**)*: A mixture of 2 g (13.9 mmol) of **1a** and 20 cm³ of D_2O was refluxed for 2 h and then evaporated to dryness under reduced pressure. The white residue was dried again under reduced pressure at 100 °C to yield **6**. The **6** exhibited an IR (KBr) peak at 2480 cm^{-1} (N–D) and 1760, 1670 cm^{-1} (C=O) and the complete disappearance of the NMR ($CDCl_3$) signal of N–H at δ 6.45, although the other signals were the same as those of **1a**.

*Reaction of 1-Methoxycarbonyl-2-imidazolidone-3-*d *with 1-Naphthylmagnesium Bromide.* A solution of 1.576 g (6.81 mmol) of 1-naphthylmagnesium bromide in 10 cm³ of tetrahydrofuran was added, drop by drop and at room temperature, to a solution of 0.988 g (6.81 mmol) of 1-methoxycarbonyl-2-imidazolidone-3-*d* in 15 cm³ of tetrahydrofuran, and then the mixture was stirred for 2 h. The resulting mixture was treated by a method similar to that used in the case of **1a** to yield 0.791 g (90%) of naphthalene-1-*d* (**7**). The IR (KBr) signals of **7** coincided with those of the authentic specimens. MS *m/e*, 129 (M^+). Another product, **1a**, was isolated from the acidic solution in an 87% yield.

Reaction with Phenylmagnesium Bromide. *Compound **1a***: A solution of 3.7 g (20.43 mmol) of phenylmagnesium bromide in 10 cm³ of tetrahydrofuran was added under argon to a solution of 0.982 g (6.81 mmol) of **1a** in 15 cm³ of tetrahydrofuran, after which the mixture was stirred at room temperature for 2 h. The resulting mixture was acidified with a dilute hydrochloric acid with ice, and the solution was extracted with ether and then chloroform. The ether and chloroform solutions were combined and dried over magnesium sulfate. After the removal of the ether and chloroform *in vacuo*, the residue was chromatographed on a silica-gel column, using chloroform as the eluent, to give 0.521 g (42%) of benzophenone, 0.266 g (15%) of triphenylmethanol, and 0.052 g (4%) of **5**. The aqueous layer was evaporated *in vacuo*, and the residue was chromatographed on a silica-gel column, using methanol and ethanol as the eluents, to give 0.127 g (13%) of **1a** and 0.129 g (22%) of **4**. The products were identified by a comparison of their melting points and IR, ^{1}H NMR, and mass spectra with those of the respective authentic specimens.

*Compounds **1b** and **5***: The reaction of **1b** and **5** with phenylmagnesium bromide and the isolation of the reaction products were carried out by a method similar to that used in the case of **1a**.

An MO Study of the Photochemical Electrocyclic Isomerization between Vinylketene and Cyclobutenone

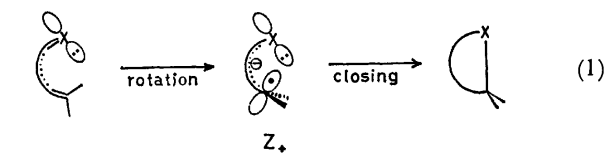
Osamu KIKUCHI

Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305

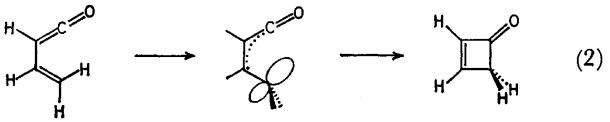
(Received September 26, 1981)

Synopsis. The MINDO/3 CI potential energy surfaces of the vinylketene–cyclobutenone system suggest that the cyclization of vinylketene occurs from the $\pi\rightarrow\pi^*$ state *via* the zwitterion, in which the negative charge is located on the 90°-twisted methylene carbon atom, while the reverse reaction proceeds *via* a diradical structure.

It was shown in previous papers[1] that the photochemical electrocyclic reaction mechanism of hetero-atom-conjugated systems is very different from that of the corresponding all-hydrocarbon conjugated systems; there is no distinction between conrotatory and disrotatory modes in the former systems. In the photocyclization of hetero-atom-conjugated systems, the rotation of the terminal methylene group occurs from the $\pi\rightarrow\pi^*$ excited state to give the twisted structure, and the ring closing occurs from the Z_+ zwitterion,



(1)



(2)

1 2 3

in which the positive charge is located on the carbon atom of the twisted methylene group.[1] The vinylketene–cyclobutenone isomerization is another example in which the conrotatory/disrotatory dichotomy is meaningless, and its mechanistic examination is of much interest.[2]

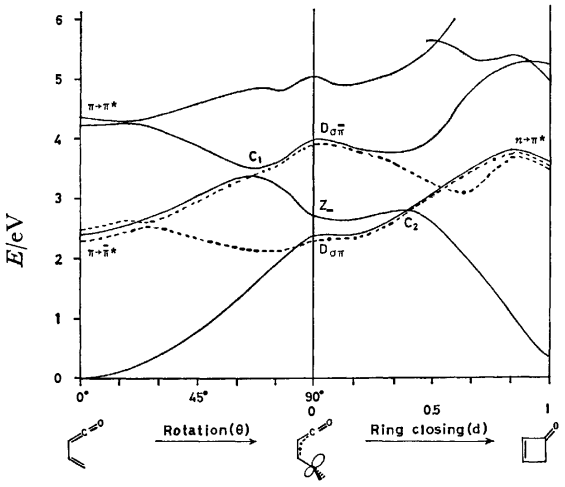


Fig. 1. Potential energy curves of lower four singlet states (solid lines) and two triplet states (broken lines) along the step-by-step path.[4]

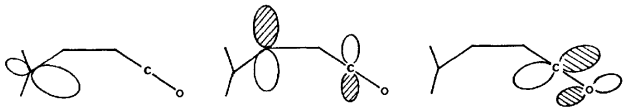
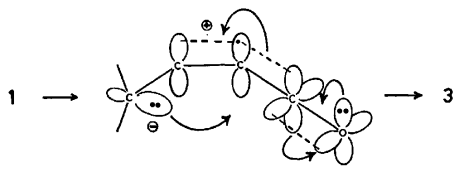
Figure 1 shows the MINDO/3[3]-CI potential energy curves[4] along the step-by-step path of the vinylketene–cyclobutenone system, (2), in which the rotation of the methylene group and the ring closing occur independently. The lower singlet electronic states of the twisted structure, **2**, are the $D_{\sigma\pi}$, Z_-, and $D_{\sigma\bar{\pi}}$ states.[5] The lowest singlet state is the diradical one in which the $\sigma(CH_2)$ and π^* orbitals are occupied by unpaired electrons. The Z_- excited state has a pair of electrons



$\sigma(CH_2)$ π^* $\bar{\pi}^*$

in the $\sigma(CH_2)$ orbital, and it is a polarized zwitterion; the negative charge on the terminal carbon atom was calculated to be −0.70. As may be seen from Fig. 1, the excited Z_- state correlates directly with the ground state of cyclobutenone, and it can be generated from the $\pi\rightarrow\pi^*$ excited state of vinylketene. Thus, the following reaction path appears to exist in the **1**→**3** photocyclization: The rotation of the terminal methylene group occurs in the $\pi\rightarrow\pi^*$ excited state of vinylketene to give the Z_- zwitterion, after which this zwitterion undergoes cyclization without any activation energy to form cyclobutenone.

The electrocyclic reaction of vinylketene has been shown to proceed *via* the Z_- zwitterion. This is an interesting contrast with Reaction 1, which proceeds *via* the Z_+ zwitterion. In the hetero-atom-conjugated system, the in-plane lone-pair electrons of the terminal hetero atom are consumed in the new σ bond formation, while in the case of the ketene conjugated system, the anti-bonding $\bar{\pi}^*$ orbital of the carbonyl group receives an electron from the terminal carbon atom to form the new σ bond. This is the reason why the Z_- zwitterion is involved in the **1**→**3** photochemical process.



The $D_{\sigma\pi}$ twisted diradical correlates with the ground state of vinylketene, and it is derived easily from the $n\rightarrow\pi^*$ excited state of cyclobutenone (Fig. 1). Thus, the ring opening of cyclobutenone is expected to proceed from the singlet (or triplet) $n\rightarrow\pi^*$ excited state of cyclobutenone *via* the $D_{\sigma\pi}$ diradical.[6]

Figure 2 shows the two-dimensional potential energy surfaces of three lower singlet states. The symbols W and H indicate the potential minimum and maxi-

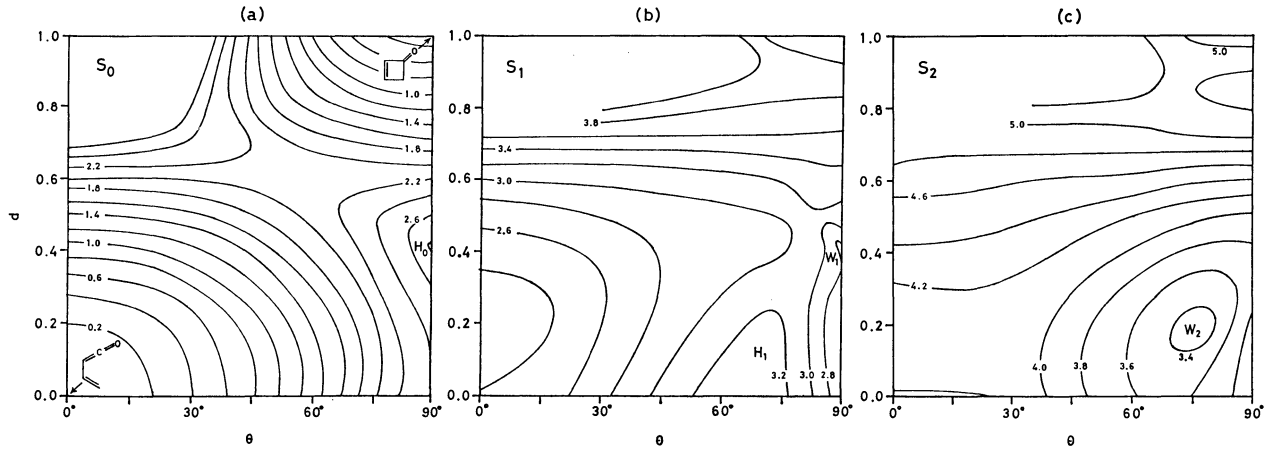


Fig. 2. Two-dimensional potential energy surfaces for three singlet states.[4] The values indicated on the potential curves are energies(eV) relative to the ground state structure of the vinylketene.

mum points respectively. The W_1 and W_2 regions correspond to the C_2 and C_1 crossing regions respectively, shown in Fig. 1. The W_1 well is a pin hole which can be a leakage channel from the S_1 state to the S_0 state. As may be seen from Fig. 2-b, the $n\rightarrow\pi^*$ state of cyclobutenone undergoes bond-breaking with a small activation energy, forming the S_0 vinylketene *via* the W_1 pin hole. The rotation of the methylene group of the $n\rightarrow\pi^*$ vinylketene requires an appreciable activation energy (Fig. 2-b), while it occurs very easily on the S_2 surface (Fig. 2-c). The W_2 well on the S_2 surface interacts strongly with the potential height, H_1, on the S_1 surface. Thus, the two dimensional potential energy surfaces also support the reaction paths described above.

2) Vinylketenes are very reactive with nucleophiles or with olefins, and their photochemical behavior has not been clarified. The thermal and photochemical isomerization of cyclobutenone derivatives into vinylketenes has, however, been reported: J. E. Baldwin and M. C. McDaniel, *J. Am. Chem. Soc.*, **90**, 6118 (1968); O. L. Chapman and J. D. Lassila, *ibid.*, **90**, 2449 (1968); A. Krantz, *ibid.*, **96**, 4992 (1974); R. Huisgen, and H. Mayr, *J. Chem. Soc., Chem. Commun.*, **1976**, 55; H. Mayr, *Angew. Chem., Int. Ed. Engl.*, **14**, 499 (1975).

3) R. C. Bingham, M. J. S. Dewar, and D. H. Lo, *J. Am. Chem. Soc.*, **97**, 1285 (1975).

4) In the calculation of the potential energy curves, the molecular structures of **1** and **3** were optimized by the use of MINDO/3 (without CI). The structural change involved in the isomerization between **1** and **3** was expressed by two parameters: the rotation angle of the terminal methylene group, θ, which expresses the structure of the CH_2 fragment, and the d parameter, which indicates the linear change in the structural parameters, x_1, associated with a substructure other than that of the methylene group; $x_1 = x_1^{\text{initial}} + d(x_1^{\text{final}} - x_1^{\text{initial}})$. In the CI calculation, 42 and 41 configuration functions were selected for the singlet and triplet states respectively.

5) The electronic states of the twisted structure were calculated by the closed-shell SCF method, followed by CI; geometry optimization was not performed for any electronic state. The results shown in Fig. 1 are not fit for a quantitative discussion of the relative energy levels of the electronic states of the twisted structure.

6) The photochemical α-cleavage of 2,4-cyclohexadienones from the $n\rightarrow\pi^*$ manifold *via* the $D_{\sigma\pi}$ diradical has been well explained; W. G. Dauben, L. Salem, and N. J. Turro, *Acc. Chem. Res.*, **8**, 41 (1975).

A Facile One-pot Synthesis of *N*-Substituted Phthalimides Using a Catalytic Amount of Crown Ether

Kenso Soai,* Atsuhiro Ookawa, and Kyoko Kato

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received October 19, 1981)

Synopsis. *N*-Substituted phthalimides, intermediates of the Gabriel synthesis, were obtained in high yields (84—100%) by the addition of a *catalytic* amount of 18-crown-6 to the reaction of potassium phthalimide and alkyl halides in toluene.

During these several years, increasing interest has been centered upon crown ethers.[1] However, possibilities of their use in phase transfer catalysis (PTC) in organic synthesis have not been so fully documented as those of onium salts.[2]

Though it is one of the major advantages of PTC that a *catalytic* (small) amount of the reagent can promote the reaction, no report has been appeared, to the best of our knowledge, on the alkylation of imides using a *catalytic* amount of crown ethers. Meanwhile, *N*-substituted phthalimides have been known as intermediates of the Gabriel synthesis of primary amines.[3] Moreover, ethoxycarbonyl and sulfonyl derivaties are used in phthaloylation of amines and amino acids.[4] Synthesis of *N*-substituted phthalimides by the alkylation of potassium phthalimide is usually run in dipolar aprotic solvents or in the presence of onium salts as PTC.[5]

Concerning the synthesis of *N*-substituted phthalimides using crown ether, it is reported that halides react with *stoichiometric* amounts of the complex (**1**) of crown ether–potassium phthalimide–water.[6] However, examples of halides are limited to only a few activated aromatic ones, and the synthesis has following shortcomings from the standpoint of preparative organic synthesis. (1) Use of *stoichiometric* amounts of crown ether. It is desirable to find a process in which a *catalytic* amount of crown ether promotes the reaction. (2) Prior to the reaction with halides, it is necessary to prepare **1**. (3) Since **1** contains *stoichiometric* amounts of water, competing reaction of water especially with aliphatic halides with functional groups may occur. (4) Potential suppression of anion activation by water in the medium because of anion solvation.

We wish to describe the results of our method which avoids all of these shortcomings. We have found that by the addition of a catalytic amount (10 mol%) of 18-crown-6 (**2**) an increase in the reaction rate of potassium phthalimide (**3**) and alkyl halides (**4**) was brought about in toluene and that *N*-substituted phthalimides (**5**) were obtained in high yields (Eq. 1).

a) Reactions were carried out at 90 °C or 100 °C for 0.5—6 h. b) Isolated yields. All compounds gave satisfactory NMR and IR spectra. c) *N*-(2-Bromoethyl)phthalimide. d) *N,N'*-Ethylenediphthalimide. e) See Ref. 7. f) *Org. Synth.*, Coll. Vol. I, 119 (1932). g) E. J. Sakellarious, *Helv. Chim. Acta*, **29**, 1675 (1946). h) See Ref. 4a.

larger in aprotic solvent than in protic solvent (Entries A, B, C, and D). Especially the presence of a trace amount of water lowered the reaction rate of alkylation considerably (Entry B), and caused the side reaction of benzyl bromide. It was concluded that absence of water was essential to accelerate the alkylation reaction and to avoid side reactions of halides.

Results of the alkylation of **3** with various kinds of **4** in the presence of 10 mol% of **3** in toluene are shown in Table 2.

Following conclusions may be drawn from the data in Table 2: (1) A *catalytic* amount of **2** was essentially necessary. This showed that crown ether behaved as a solid-liquid PTC (Entries A and B), (2) Both chloride and bromide gave high yields of **5** (Entries D and E), (3) Slight excess of **3** was required to complete the reaction (Entries C and D), (4) **4** with functional groups such as sulfone and ester gave high yields of **5** (Entries G and H).

As described above, this one-pot reaction afforded high yields of *N*-substituted phthalimides (**5**) and required only a *catalytic* amount of crown ether and avoided hydrolysis of alkyl halides.

Experimental

Procedure A. N-*Octylphthalimide*: To a mixture of **3** (0.222 g, 1.2 mmol) and 1-bromooctane (0.193 g, 1.0 mmol) in 1.3 ml of toluene was added **2** (0.1 mmol, 10 mol%). After the mixture was heated at 100 °C for 6 h with stirring under an argon atmosphere, water was added to the mixture. Organic layer was separated and aq layer was extracted with dichloromethane. Combined organic layer was dried over sodium sulfate, and then solvent was evaporated under reduced pressure. Purification on silica-gel TLC(dichloromethane–hexane 1:1 as eluent) afforded *N*-octylphthalimide (0.243 g, 94%, mp 48—49 °C[7]).

Procedure B. N-*(Ethoxycarbonyl)phthalimide*: **3** (0.222 g, 1.2 mmol) and ethyl chloroformate (0.109 g, 1.0 mmol) were allowed to react in toluene (1.3 ml) in the presence of **2** (0.1 mmol, 10 mol%) at 90 °C for 1 h. Precipitate was filtered off, and filtrate was evaporated under reduced pressure. Crystallization from hexane–chloroform afforded *N*-(ethoxycarbonyl)phthalimide (followed by two additional crops for a total of 0.210 g, 96% yield) mp 79—81 °C, (lit, mp 80 °C[4a]).

Electrosynthesis of 2-Methyl-1,4-naphthoquinone (Vitamin K_3) Directly from 2-Methyl-5,8-dihydro-1,4-naphthalenediol by a Four-electron Oxidation Procedure

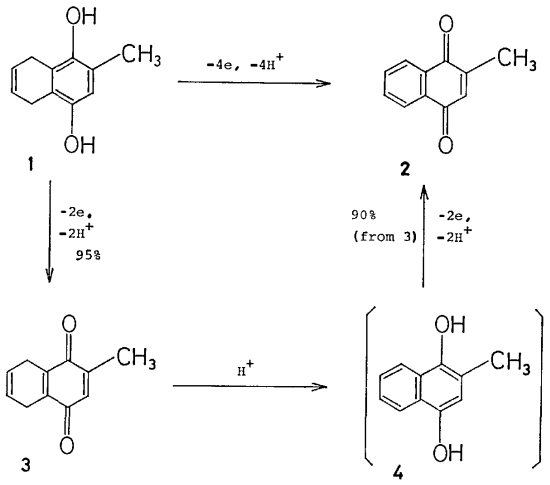
Sigeru Torii,* Hideo Tanaka, and Shoji Nakane

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received October 22, 1981)

Synopsis. A straightforward synthesis of Vitamin K_3 was performed by electrolysis of 2-methyl-5,8-dihydro-1,4-naphthalenediol in a MeCN–*t*-BuOH (9/1)–$LiClO_4$–(Pt or C electrodes) system. The use of perchlorate salts or tetrafluoroborate salts as supporting electrolytes in various electrolysis systems, such as AcOH–*t*-BuOH (9/1)–$LiClO_4$–(Pt) and AcOEt–*t*-BuOH (9/1)–Bu_4NClO_4–(Pt), also provided good results, while the use of Et_4NOTs in MeOH afforded 2-methyl-5,8-dihydro-1,4-naphthoquinone, preferentially.

2-Methyl-1,4-naphthoquinone (vitamin K_3) (**2**) and its homologs constitute a class of biologically active quinones as well as precursors in the synthesis of vitamin K series.[1] Many efforts have been made to devise a simple route to **2** based on the oxidation of 2-methyl-5,8-dihydro-1,4-naphthalenediol (**1**),[2a] 2-methyl-1,4-naphthalenediol (**4**),[2b] 2-methylnaphthalene,[2c] and related compounds[2d] with oxidizing agents *i.e.*, CrO_3, $Mn_2(SO_4)_3$, H_2O_2, $Ce(NH_4)_2(NO_3)_6$, and so on. The lack of product-selectivity in the oxidation of 2-methylnaphthalene to **2**[2a,3] as well as the disadvantages of using stoichiometric amounts of the oxidizing agents spurred us to develop the present procedure.



Here, we wish to report a clean and straightforward electrosynthesis of **2** from 2-methyl-5,8-dihydro-1,4-naphthalenediol (**1**) without isolating the intermediate, 2-methyl-5,8-dihydro-1,4-naphthoquinone (**3**), which can also be obtained by the choice of another electrolysis system.

Electrooxidation of **1** to the desired **2** was carried out by employing a MeCN–*t*-BuOH (9/1)–$LiClO_4$–(Pt or C electrodes) system at a constant current of 1.67 mA/cm^2 in a divided cell. As shown in the Table (entries 1 and 2), passage of 9 F/mol of electricity yielded **2** in 91—94% yields. The two systems of AcOH–*t*-BuOH (9/1)–$LiClO_4$–(Pt) and AcOEt–*t*-BuOH (9/1)–Bu_4NClO_4–(Pt) also provided good results (entries 9 and 12). Interestingly, the presence of *t*-BuOH in acetic acid can suppress the formation of by-products (*cf.* entry 10),[4] in contrast to the result obtained in MeCN–$LiClO_4$ system (entry 3).

Particularly noteworthy is the effect of the supporting electrolytes. As shown in entries 1—7, use of perchlorate salts, lithium tetrafluoroborate, and lithium trifuloroacetate, as supporting electrolytes facilitated the formation of **2**. However, use of tetraethylammonium *p*-toluenesulfonate (Et_4NOTs) in various electrolysis systems (entries 8, 11, and 14) mainly afforded **3** (70—84%) along with **2** (7—13%) after passage of 8—9 F/mol of electricity. The selective formation of **3** was achieved in a MeOH–Et_4NOTs–(Pt) system by passage of 2—4 F/mol of electricity (entries 15 and 16). Most of the starting material **1** was converted into **3** in each case when *ca.* 2 F/mol of electricity were passed. However, efficient conversion of **3** into **2** took place smoothly in the MeCN–*t*-BuOH (9/1)–$LiClO_4$–(Pt) system.

Transformation of **3** into **2** can be reasonably explained by assuming the acid-catalyzed isomerization of **3** to 2-methyl-1,4-naphthalenediol (**4**) with strong acid in the vicinity of the electrode and a subsequent two-electron oxidation of **4** at the anode.[5] The isomerization of **3** into **4** takes place more effectively in the anode compartment, in which most of counter ions, *i.e.*, ClO_4^-, BF_4^-, and $CF_3CO_2^-$, of strong acids are concentrated by the electrolysis.[6] In contrast, TsOH arising from Et_4NOTs, seems less effective in catalyzing this isomerization.[7]

Experimental[8]

Materials. 2-Methyl-5,8-dihydro-1,4-naphthalenediol (**1**) was obtained by the acid-catalyzed isomerization of Diels-Alder adduct of 2-methyl-1,4-benzoquinone and butadiene.[2a] Authentic samples of **3** and **4** were derived from **1** according to reported procedures.[2a] Commercially available vitamin K_3 (**2**) was used as an authentic sample. Acetic acid, methanol, *t*-butyl alcohol, and acetonitrile were distilled before use. Reagent-grade supporting electrolytes were used.

Electrolysis Procedure. A conventional H-type cell divided with fritted glass was used, which was fitted with two platinum or carbon electrodes (1.5×2 cm^2). Regurated DC power was supplied by Kowa Electronics model PGS-1550 potentio-galvanostat. The conditions and results are summarized in Table 1. A typical electrolysis procedure is as follows.

Electrooxidation of 2-Methyl-5,8-dihydro-1,4-naphthalenediol (1) in MeCN–t-BuOH(9/1)–$LiClO_4$–(Pt electrodes) System (Entry 1 in Table 1). A solution of **1** (30 mg, 0.17 mmol) and $LiClO_4$ (600 mg) in MeCN (13.5 ml) and *t*-BuOH (1.5 ml) was charged into the anode compartment fitted

a) Carried out at a constant current density (1.67 mA/cm²) at 16—22 °C. b) Pt: platium foil electrodes (1.5×2 cm²); C: carbon plate electrodes (1.5×2 cm²). c) Isolated yields. d) Containing 10% (v/v) of *t*-BuOH. e) Tarry materials were obtained. f) Current density: 10 mA/cm². g) Monomethyl ether of **1** (11%) was recovered.

with Pt electrode (1.5×2 cm²) and a thermometer. A solution of $LiClO_4$ (400 mg) in MeCN (9 ml) and *t*-BuOH (1 ml) was charged into the cathode compartment fitted with Pt electrode (1.5×2 cm²). Nine F/mol of electricity was passed at a constant current of 1.67 mA/cm² at 16—18 °C for 8.6 h.[9)] The anode solution was concentrated *in vacuo* and the residue was taken up in CH_2Cl_2. The extracts were washed with brine, dried (Na_2SO_4), concentrated *in vacuo*, and chromatographed on silica gel with hexane/ether (5/1) to give **2** (28.9 mg, 94%): mp 102—103.5 °C (lit,[2a)] 105—106 °C).

Electrooxidation of 2-Methyl-5,8-dihydro-1,4-naphthalenediol (1) in MeOH-Et_4NOTs-(Pt) System (Entry 16). In a similar manner, a solution of **1** (67 mg, 0.38 mmol) and Et_4NOTs (600 mg) in MeOH (15 ml) [catholyte: MeOH (10 ml)-Et_4NOTs (400 mg)] was electrolyzed at 10 mA/cm² at 20—22 °C for 1.35 h (4 F/mol of electricity passed). Usual workup of the anolyte gave **3** (63 mg, 95%): mp 83—85 °C (lit, mp 91—92 °C[2a)] 82—84 °C,[10)] 86 °C[11)]).

Electrooxidation of 2-Methyl-5,8-dihydro-1,4-naphthoquinone (3) in MeCN-$LiClO_4$-(Pt) System. A solution of **3** (30 mg, 0.17 mmol) and $LiClO_4$ (600 mg) in MeCN [catholyte: MeCN (10 ml)-$LiClO_4$ (400 mg)] was electrolyzed at 1.67 mA/cm² at 16—17 °C. After passage of 3.5 F/mol of electricity (3.2 h), usual workup of the anolyte gave **2** (26.5 mg, 90%) and **3** (1 mg, 4%).

Synthesis of Cyclic Silyl Diazo Compounds

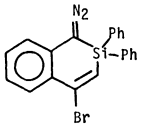
Akira SEKIGUCHI and Wataru ANDO*

Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 305

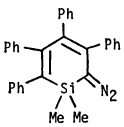
(Received October 23, 1981)

Synopsis. Cyclic silyl diazo compounds, 1-diazo-2,2-diphenyl-4-bromo-1,2-dihydro-2-silanaphthalene, 6-diazo-1,1-dimethyl-2,3,4,5-tetraphenylsilacyclohexa-2,4-diene, and 10-diazo-9,9-dimethyl-9,10-dihydro-9-silaanthracene, were prepared and their spectroscopic properties were determined.

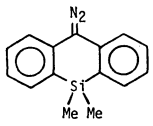
In recent years, interest in the chemistry of silylcarbenes has remarkably increased for the formation of silicon-carbon double bonded intermediates.[1] Simple silyl diazo compounds such as trimethylsilyldiazomethane,[2] ethyl trimethylsilyldiazoacetate,[3] bis(trimethylsilyl)diazomethane,[4] and their derivatives have been synthesized and studied. However, cyclic silyl diazo compounds like 1-diazo-1,2-dihydro-2-silanaphthalene, 6-diazosilacyclohexa-2,4-diene, and 10-diazo-9,10-dihydro-9-silaanthracene, have not been prepared so far. We now wish to report here synthesis of 1-diazo-2,2-diphenyl-4-bromo-1,2-dihydro-2-silanaphthalene (**1**), 6-diazo-1,1-dimethyl-2,3,4,5-tetraphenylsilacyclohexa-2,4-diene (**2**), and 10-diazo-9,9-dimethyl-9,10-dihydro-9-silaanthracene (**3**).



1



2



3

Diazo compound **1** was prepared by the conversion of the silyl ketone **4** to the hydrazone **5** followed by the oxidation with mercury(II) oxide in petroleum ether and benzene in 69% yield (Eq. 1). The spectroscopic data are given in Table . Silyl diazo compound **2** was obtained by a modification of the method of Doering and DePuy.[5] Direct diazo transfer by *p*-toluenesulfonyl azide to the silacyclohexadienyl anion **7** produced the silyl diazo compound **2** as yellow crystals in 36% yield (Eq. 2). Both **1** and **2** are relatively stable enough to be recrystallyzed. Diazo compound **3** was prepared as described in Eq. 3. Tosylhydrazone **9** was synthesized by the reaction of the ketone **8** with tosylhydrazine in ethanol in the presence of $BF_3 \cdot Et_2O$. The reaction is too slow in the absence of the catalyst. Treatment of the hydrazone **9** with sodium methoxide in pyridine afforded the diazo compound **3** in 90% yield as purple crystals.

Experimental

General. NMR spectra were recorded on a Varian EM 360A spectrometer. IR and UV spectra were obtained by a Hitachi 260-50 spectrometer and a Shimadzu UV-365 spectrometer, respectively.

Materials. 2,2-Diphenyl-4-bromo-1,2-dihydro-2-silanaphthalene-1-one (**4**),[6] 1,1-dimethyl-2,3,4,5-tetraphenylsilacyclohexa-2,4-diene (**6**),[7] and 9,9-dimethyl-9,10-dihydro-9-silaanthracene-10-one (**8**),[8] were prepared by known procedures as referenced.

Synthesis of Hydrazone ***9***. Tosylhydrazone **9** was prepared in 32% yield by dissolving the ketone **8** (4.76 g, 20.0 mmol) in ethanol, adding excess tosylhydrazine (8.44 g, 45.4 mmol) and *ca.* 1 mL of $BF_3 \cdot Et_2O$ and refluxing for 3 h. The reaction mixture was concentrated, and the residue was chromatographed on silica gel with benzene/chloroform. Evaporation of the solvent afforded crude product **9** which was recrystallyzed from ethanol to give white crystals (2.63 g, 6.48 mmol), mp 168—169.5 °C. Found: C, 65.01; H, 5.44; N, 6.94%. Calcd for $C_{22}H_{22}N_2O_2SSi$: C, 64.99; H, 5.45; N, 6.89%.

Synthesis of ***1***. Hydrazine hydrate (16 g, 320 mmol) was added to a mixture of ethanol and benzene containing the silyl ketone **4** (10 g, 25.6 mmol) and a few drops of acetic acid at 0 °C. After stirring for 1.5 h, the reaction mixture was poured into water, and extracted with benzene. Hydrazone **5** was used without isolation. The benzene solution of **5** was diluted with petroleum ether, and then mercury(II) oxide (20 g, 92.3 mmol) was added. After stirring for 24 h, precipitated mercury was filtered off and the filtrate was concentrated. The residue was chromatographed on silica gel containing 10% water at 0 °C with petroleum ether/carbon tetrachloride. Evaporation of the solvent gave crude product **1** which was recrystallyzed from benzene/ethanol to give yellow-orange crystals (7.1 g, 69%), mp 129—130

°C. Found: C, 62.47; H, 3.69; N, 7.05; Br, 20.10%. Calcd for $C_{21}H_{15}N_2SiBr$: C, 62.53; H, 3.74; N, 6.94; Br, 19.81%.

Synthesis of ***2***. 1,1-Dimethyl-2,3,4,5-tetraphenylsilacyclohexa-2,4-diene (**6**) (7.0 g, 16.4 mmol) was treated with equimolar amount of butyllithium in THF at 0 °C. The red silacyclohexadienyl anion **7** was formed immediately. The anion was slowly added to a solution of *p*-toluenesulfonyl azide (3.9 g, 19.8 mmol) in THF at −78 °C, and the reaction mixture was slowly warmed to room temperature. The mixture was poured into water, and extracted with hexane. Chromatography on silica gel containing 10% water at 0 °C with hexane/benzene gave crude product **2** which was recrystallyzed from ethanol/benzene to give yellow crystals (2.7 g, 36%), mp(decomp) 134.5—135.5 °C. Found: C, 81.90; H, 5.65%. Calcd for $C_{31}H_{26}N_2Si$: C, 81.89; H, 5.76%.

Synthesis of ***3***. Tosylhydrazone **9** (1.00 g, 2.46 mmol) was dissolved in pyridine, and sodium methoxide (0.278 g, 5.15 mmol) was added to the solution. The mixture was heated at 70 °C for 15 min. The resulting red solution was poured into water, and extracted with hexane. Chromatography on silica gel containing 10% water at 0 °C with hexane gave purple crystals (0.554 g, 90%), mp 96—97 °C. Found: C, 72.07; H, 5.64; N, 11.05%. Calcd for $C_{15}H_{14}N_2Si$: C, 71.95; H, 5.63; N, 11.18%.

Absolute Configurations of α-Substituted Glycidates. (−)-(*R*)-Ethyl 2-Methyl-1-oxaspiro[2.5]octane-2-carboxylate and (−)-(*R*)-Ethyl 2,3-Dimethyl-2,3-epoxybutanoate

Toshio SUGITA,* Nobuyuki NISHIO, and Katsuhiko ICHIKAWA

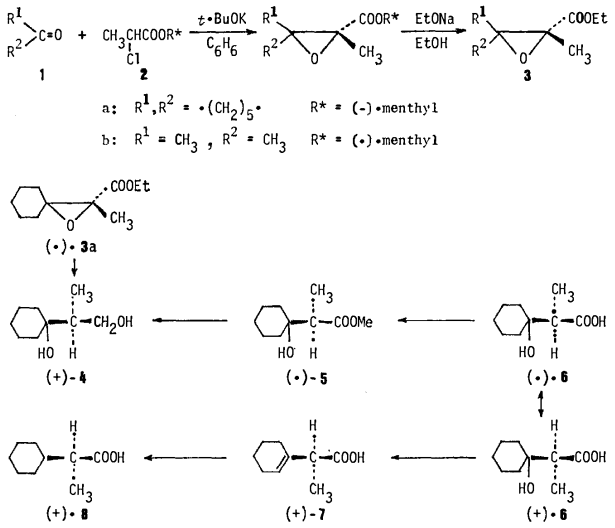
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 24, 1981)

Synopsis. The absolute configurations of the title compounds were determined by chemical correlation and by asymmetric syntheses.

In the course of stereochemical studies of the Darzens reaction, it has been necessary to distinguish the stereoisomerism of the α-carbon of glycidates from the geometrical isomerism. No model compound with a known absolute configuration at the α-carbon of glycidate has, however, been reported, to our knowledge. Thus, we determined the absolute configurations of some α-substituted glycidates, which were symmetrically β,β-disubstituted: (−)-ethyl 2-methyl-1-oxaspiro-[2.5]octane-2-carboxylate (**3a**) and (−)-ethyl 2,3-dimethyl-2,3-epoxybutanoate (**3b**).

The potassium *t*-butoxide-catalyzed Darzens reactions of (−)-menthyl 2-chloropropanoate (**2**) and cyclohexanone (**1a**) or acetone (**1b**), followed by sodium ethoxide-catalyzed transesterification, afforded **3a** or **3b** respectively, each of which was exceeded in the (−)-isomer.



The (−)-**3a** was reduced by lithium aluminium hydride to give a mixture of 1,2- and 1,3-glycols. By periodic acid oxidation, the 1,2-glycol was cleaved to cyclohexyl methyl ketone, while 2-(1-hydroxycyclohexyl)-1-propanol (**4**) was left unaffected, indicating dextrorotation. (−)-2-(1-Hydroxycyclohexyl)propanoic acid (**6**), prepared by the Reformatsky reaction of cyclohexanone and ethyl 2-bromopropanoate, followed by hydrolysis and resolution with (−)-1-phenylethylamine, was converted with diazomethane to its (−)-methyl ester (**5**). The lithium aluminium hydride reduction of (−)-**5** afforded (+)-**4**. On the other hand, (+)-**6** was dehydrated by heating with 10% sulfuric acid to give (+)-2-(1-cyclohexenyl)propanoic acid (**7**). The catalytic hydrogenation of (+)-**7** gave (+)-2-cyclohexylpropanoic acid (**8**), the absolute configuration of which had been established as *S*.[1] It has been known that the lithium aluminium hydride reductions of oxirane rings accompany inversion of configuration at the reduced carbon.[2] In the other steps of the reaction sequence, the chiral carbon is not subjected to chemical changes; thus, the absolute configuration of (−)-**3a** is established to be *R*.

The asymmetric Darzens syntheses of **3a** and **3b** were carried out under the same conditions, and both products were exceeded in the (−)-isomers. Thus, (−)-**3b** is expected to have the same *R* configuration as (−)-**3a**.

Experimental

The ^{1}H-NMR spectra (in $CDCl_3$ using TMS as an internal standard) were taken on a JEOL PMX-60 spectrometer. The optical rotations were obtained on a Zeiss polarimeter or a JASCO DIP-180 polarimeter in chloroform solutions, unless otherwise mentioned.

A Typical Asymmetric Synthesis of the Glycidates (3). To a well-stirred solution of **1a** (20 g, 0.20 mol) and (−)-**2** (bp 111—113 °C/4 mmHg (1 mmHg≈133.322 Pa); $[\alpha]_D^{31}$ −71.03° (*c* 5.56); 50 g, 0.20 mol) in 200 ml of benzene, powdered potassium *t*-butoxide, freshly prepared from potassium (7.8 g, 0.20 mol) and *t*-butyl alcohol, was added, portion to portion, over 30 min at 10—15 °C under a nitrogen atmosphere. The mixture was stirred for an additional 2 h and then allowed to stand overnight at room temperature. Water was added to the reaction mixture, and extracted with ether. The extract was washed with aqueous NaCl and dried ($MgSO_4$). By removal of the solvents, crude (−)-menthyl 2-methyl-1-oxaspiro[2.5]octane-2-carboxylate (63.3 g) was obtained. The crude menthyl ester was refluxed with a solution of sodium ethoxide, prepared by dissolving sodium (2.0 g, 87 mmol) in 150 ml of ethanol, for 10 h. The mixture was neutralized with acetic acid, concentrated, and extracted with ether. The extract was washed with aqueous $NaHCO_3$ and with aqueous NaCl, dried ($MgSO_4$), and distilled by means of a Vigreaux-column to give (−)-menthol (bp 91.5—101 °C/9 mmHg, 26.5 g (85%)) and **3a** (bp 101.5—117.5 °C/9 mmHg, 16.8 g (42%)), which was found by vpc analysis to contain a small amount of (−)-menthol. After repeated distillations (3 times), pure ethyl 2-methyl-1-oxaspiro[2.5]octane-2-carboxylate (**3a**) (bp 122—123 °C/12 mmHg (lit,[3] bp 154—156 °C/40 mmHg), $[\alpha]_D^{33}$ −4.10° (*c* 10.71)) was obtained.

From 12 g (0.21 mol) of **1b** and 37 g (0.15 mol) of **2**, (−)-menthyl 2,3-dimethyl-2,3-epoxybutanoate (bp 100—137 °C/15 mmHg, 34.8 g (64.2%)) was obtained. The menthyl ester was transesterified to **3b** (bp 95.5—100 °C/66 mmHg, 9.4 g (40% from **2**)), which was found by vpc to contain a small amount of ethyl 2-chloropropanoate and a trace of (−)-menthol. Pure ethyl 2,3-dimethyl-2,3-epoxybutanoate (**3b**) (bp 100 °C/66 mmHg (lit,[4] bp 80—82 °C/20 mmHg);

$[\alpha]_D^{17}$ −1.32° (*c* 12.21); Found: C, 61.16; H, 9.44%) was obtained after repeated distillations.

(+)-2-(1-Hydroxycyclohexyl)-1-propanol (4) from (−)-3a. A solution of (−)-**3a** ($[\alpha]_D^{12}$ −3.13° (*c* 8.69), 9.9 g, 50 mmol) in 60 ml of ether was added to a stirred suspension of $LiAlH_4$ (2.3 g, 60 mmol) in 100 ml of ether. The mixture was stirred for 2.5 h, and then worked-up as usual. By the distillation of the reaction product, a mixture of **4** and 2-cyclohexyl-1,2-propanediol (bp 117—120.5 °C/3 mmHg, 5.7 g (72.2%)) was obtained. To the glycol mixture was added 130 ml of a 0.2 M (1 M=1 mol dm^{-3}) aqueous HIO_4 solution; this mixture was kept at an ambient temperature for 4 h with occasional shaking. After the duration, the mixture was extracted with ether, the extract was washed with a small amount of cold aqueous $Na_2S_2O_3$ and with aqueous NaCl, dried ($MgSO_4$), and distilled to give cyclohexyl methyl ketone (bp 53—58 °C/9 mmHg, 1.5 g (36.1%)) and (+)-**4** (bp 103.5—104 °C/2 mmHg (lit,[5] bp 106—110 °C/1 mmHg); $[\alpha]_D^{13}$ +2.24° (*c* 4.29); 1.1 g (21.2%); ^{1}H-NMR: δ=0.9 (d, J=8, 3H), 1.5 (broad s, 11H), 2.5—3.3 (2H), 3.7 (d, J=5, 2H)).

(−)-Methyl 2-(1-Hydroxycyclohexyl)propanoate (5). An ether solution of diazomethane was added until the mixture turned pale yellow to (−)-**6** ($[\alpha]_D^{28}$ −2.58°; 1.5 g, 8.7 mmol), prepared by the Reformatsky reaction of **1a** and ethyl 2-bromopropanoate,[6] followed by hydrolysis with ethanolic KOH and resolution with (−)-1-phenylethylamine. The mixture was distilled to give (−)-**5** (bp 121—122 °C/17 mmHg (lit,[7] bp 132 °C/18 mmHg); $[\alpha]_D^{29}$ −3.41° (*c* 10.14); 1.3 g (80%); ^{1}H-NMR: δ=1.18 (d, 3H), 1.48 (broad s, 10H), 2.50 (q, 1H), 2.75 (s, 1H), 3.70 (s, 3H); Found: C, 64.76; H, 9.92%).

(+)-2-(1-Hydroxycyclohexyl)-1-propanol (4) from (−)-5. (−)-**5** ($[\alpha]_D^{20}$ −30.3° (*c* 0.957); 1.5 g, 8.1 mmol) in 20 ml of ether was added to a stirred suspension of $LiAlH_4$ (0.5 g, 13 mmol) in 20 ml of ether, then the mixture was refluxed for 2.5 h. After the usual work-up, **4** was obtained: bp 119—120.5 °C/4 mmHg, $[\alpha]_D^{21}$ +10.69° (*c* 4.66), 0.7 g (56%). (Found: C, 67.84; H, 11.50%). The IR and ^{1}H-NMR spectra of **4** obtained from (−)-**3a** and (−)-**5** were completely superimposable.

(+)-2-(1-Cyclohexenyl)propanoic Acid (7). (+)-**6** ($[\alpha]_D^{20}$ +5.89°; 1.3 g, 7.6 mmol) was suspended to 10 ml of 10% sulfuric acid and stirred at 95—100 °C for 5.25 h. The mixture was extracted with ether, the ethereal extract was washed with aqueous NaCl, dried ($MgSO_4$), and distilled to give crude **7** (bp 140—144 °C/11 mmHg, 0.8 g (80%)). The NMR data indicated that the product contained a small amount of **6**. The product was chromatographed on a silica-gel (Wakogel C-200) column, using hexane–benzene (1:1) as the eluent, to give **7** (bp 150—153 °C/21 mmHg (lit,[8] bp 154—156 °C/26 mmHg); $[\alpha]_D^{28}$ +20.84° (*c* 3.03); ^{1}H-NMR: δ=1.27 (d, 3H), 1.65 (broad s, 4H), 2.06 (broad s, 4H), 3.18 (q, 1H), 5.89 (broad s, 1H), 10.4 (s, 1H); Found: C, 70.38; H, 9.40%).

(+)-2-Cyclohexylpropanoic Acid (8). (+)-**7** ($[\alpha]_D^{28}$ +39.27°; 1.05 g, 6.8 mmol) in 40 ml of methanol was hydrogenated over a 5% Pd–$BaSO_4$ catalyst (2.3 g) at atmospheric pressure and at room temperature. The reduction product was freed from the catalyst and the solvent, and distilled to give (+)-**8** (bp 122—123 °C/6 mmHg; $[\alpha]_D^{22}$ +10.10° (*c* 1.248, ethanol) (lit,[9,1] bp 121—123 °C/5 mmHg; $[\alpha]_D^{25}$ +18.9°)). ^{1}H-NMR δ=1.18 (d) and 0.7—2.6 (broad). (Found: C, 69.39; H, 10.64%).

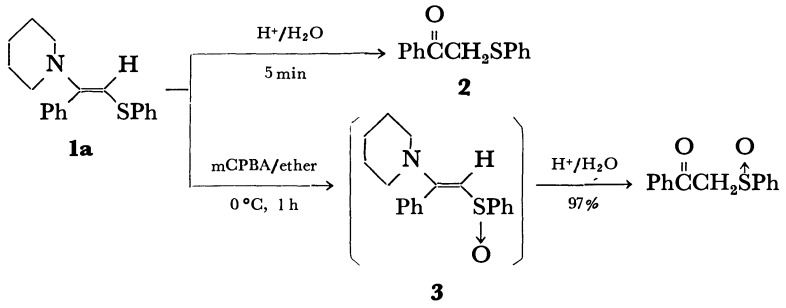
(Received October 28, 1981)

Synopsis. The olefins which are vicinally substituted by amino and phenylthio groups showed the reactivity as an enamine in the reactions with heterocumulenes and in cycloadditions with a 1,3-dipole and a 2-propenimine, giving a pyrazole derivative and a pyridine derivative, respectively.

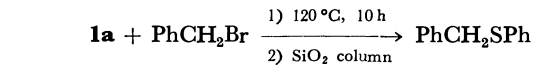
Hetero-atom substituted olefins such as enamines, vinyl sulfides, and nitrogen and sulfur analogs of ketene acetals are versatile synthons in organic synthesis. However, utility of vicinally dihetero-atom substituted olefins has not been known so well.[1] Recently we developed a new synthetic method for the ethylenes which are vicinally substituted by dialkylamino and phenylthio (or methylthio) groups.[2] To clarify their chemical properties, we report here several reactions of 1-dialkylamino-2-phenylthioethylenes **1**.

The olefins **1** are highly sensitive to hydrolysis and, for example, β-phenylthio-α-piperidinostyrene (**1a**) was easily converted to α-phenylthioketone **2** under acidic conditions.



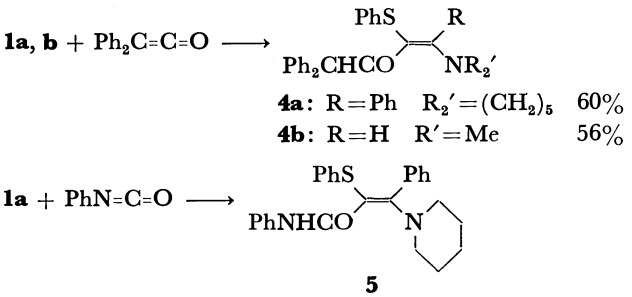
Oxidation of the olefin **1a** with *m*-chloroperbenzoic acid (mCPBA) gave β-phenylsulfinyl-α-piperidinostyrene (**3**) in 56% yield by NMR. It was difficult to isolate the sulfoxide **3** which was hydrolyzed to afford α-phenylsulfinylacetophenone.

Reaction of the olefins **1** with methyl iodide or benzyl bromide afforded salt-like materials which could be neither isolated nor identified. As a hydrolyzed product, benzyl phenyl sulfide was isolated by chromatographic treatment of the reaction mixture of **1a**

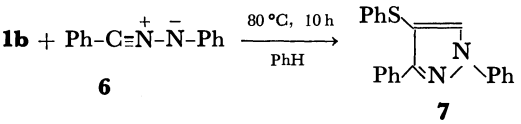


with benzyl bromide. The result implied a considerable extent of nucleophilic attack from the sulfur atom to the bromide. On the contrary, the reaction of **1a** with benzoyl chloride gave *N*-benzoylpiperidine in 34% yield as a hydrolyzed product, and 1-dimethylamino-2-phenylthioethylene (**1b**) gave *N*,*N*-dimethylbenzamide in 60% yield. Thus the reaction on the nitrogen atom is predominant in these reactions. However, no C–C bond forming reactions were observed for the reactions with the alkyl and acyl halides.

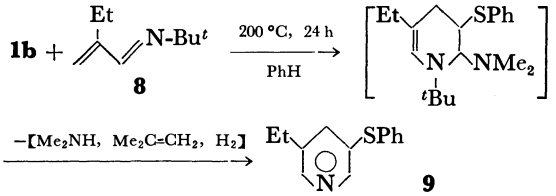
Diphenylketene is a highly reactive dipolarophile and smoothly reacted with the olefin **1a** at 20 °C to give the butenone derivative **4a** and with **1b** to give the butenone **4b**. Similarly, **1a** reacted with phenyl isocyanate to afford α-phenylthio-β-piperidinocinnamanilide (**5**) in 54% yield. These products are considered to be formed *via* 1:1 cycloadducts which rearrange to the linear 1:1 adducts.[3] Thus formation of the carbonyl compounds **4** and **5** would provide us a preparative method for highly functionalized olefins.



Cycloaddition reactions were also studied. The olefin **1b** reacted with the nitrilimine **6** to give the pyrazole derivative **7** in 40% yield. The formation of **7** is elucidated by elimination of dimethylamine from a 1:1 cycloadduct. As a dienophile the olefins



1 were not so reactive with cyclopentadiene and ethyl sorbate. However, **1b** reacted with a heterodiene, *N*-*t*-butyl-2-ethyl-2-propenimine (**8**), to give 3-ethyl-5-phenylthiopyridine (**9**) in 51% yield when heated at



200 °C for 24 h. The reaction is assumed to proceed *via* cycloaddition followed by elimination of dimethylamine and isobutylene and successive oxidative aromatization.

As these addition products **7** and **9** are suggested to be similar to 1:1 cycloaddition products of phenylthioacetylene with the 1,3-dipole **6** and the diene **8**, respectively, the olefins of type **1** are expected to become a reagent equivalent to arylthioacetylenes[4] in cycloadditions. In conclusion the olefins **1** show chemical property as an enamine rather than a vinyl sulfide but lower reactivity than usual enamines.

Experimental

Materials. Commercially available reagents were used unless otherwise noted. The olefins **1a** and **1b** were prepared by the reported method.[2] Diphenylketene was prepared by dehydrochlorination of diphenylacetyl chloride. The propenimine **8** was obtained by the reaction of *N-t*-butylmethanimine and 1-piperidino-1-butene at 150 °C for 6 h; bp 55—57 °C/4000 Pa; NMR ($CDCl_3$) δ 1.10(3H, t), 1.19(9H, s), 2.4(2H, m), 5.33(1H, broad s), 5.51(1H, m), 7.90(1H, s).

Hydrolysis. To a solution of **1a** (1.26 g, 4.3 mmol) in EtOH (5 ml) was added 12 mol dm^{-3} HCl (2 ml) and allowed to stand for 5 min. Extraction (ether), drying ($CaSO_4$), and concentration gave 725 mg (74%) of α-phenylthioacetophenone (**2**) which was identified with an authentic sample.

Oxidation. To a solution of **1a** (1.48 g, 5.0 mmol) in ether (5 ml) containing 1.06 g (10 mmol) of Na_2CO_3 was added mCPBA (1.08 g, 6.0 mmol) in ether (20 ml) and the mixture was stirred at 0 °C for 1 h. The reaction mixture was worked up as usual to give the crude oil containing the sulfoxide **3** (56% yield by NMR); IR (neat) 1580 (C=C) and 1030 cm^{-1} (S→O); NMR ($CDCl_3$) δ 5.4 (s, =CH). The oil (164 mg) was hydrolyzed in EtOH (5 ml) containing 12 mol dm^{-3} HCl (2 ml) to afford 97% of α-phenylsulfinylacetophenone which was identified with an authentic sample prepared by oxidation of **2**.

Reactions with Halides. A benzene solution (6 ml) of **1a** (1.48 g, 5.0 mmol) and benzyl bromide (0.85 g, 5.0 mmol) was heated at 120 °C for 10 h in a sealed tube. The reaction mixture was chromatographed (SiO_2–hexane) to give benzyl phenyl sulfide (0.35 g, 35%).

A solution of **1a** (5.0 mmol) and benzoyl chloride (703 mg, 5.0 mmol) in ether (10 ml) containing K_2CO_3 (2.0 g) was stirred for 20 h at 20 °C. Chromatographic treatment (SiO_2–benzene) of the filtrate gave 322 mg (34%) of *N*-benzoylpiperidine which was identified with an authentic sample. Similarly, 0.90 g (60%) of *N,N*-dimethylbenzamide was obtained from 1.79 g (10 mmol) of **1b**, the chloride (1.41 g, 10 mmol) and triethylamine (1.01 g, 10 mmol) using DMF as a solvent.

Reactions with Diphenylketene and Phenyl Isocyanate. To a solution of **1** (5.0 mmol) in ether (10 ml) was added the ketene (0.97 g, 5.0 mmol) and the mixture was stirred for 3 h at 20 °C. A crystalline product was obtained by concentration in the case of **1a** and an oily product by column chromatography (SiO_2–EtOH) in the case of **1b**. 1,1,4-Triphenyl-3-phenylthio-4-piperidino-3-buten-2-one (**4a**): yield 1.47 g (60%); mp 163—164 °C; IR (Nujol) 1600 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.4—1.8 (6H, m), 2.9—3.3 (4H, m), 6.20 (1H, s), 6.8—7.5 (20H, m); MS *m/e* 489 (M^+). Found: C, 81.22; H, 6.25; N, 2.83; S, 6.31%. Calcd for $C_{33}H_{31}NOS$: C, 80.95; H, 6.38; N, 2.86; S, 6.53%. 4-Dimethylamino-1,1-diphenyl-3-phenylthio-3-buten-2-one (**4b**): yield 1.17 g (56%); IR (Nujol) 1640 cm^{-1} (C=O); NMR ($CDCl_3$) δ 3.10(6H, s), 6.13(1H, s), 6.9—7.3(15H, m), 8.18(1H, s); MS *m/e* 373 (M^+).

A mixture of **1a** (5.0 mmol) and the isocyanate (0.60 g, 5.0 mmol) in ether (10 ml) was stirred for 20 h at 20 °C. Concentration of the mixture gave solid material which was recrystallized from CH_2Cl_2 to give 1.12 g (54%) of β-phenylthio-α-piperidinocinnamanilide (**5**): mp 160 °C; IR (Nujol) 1620 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.4—1.9(6H, m), 3.0—3.5(4H, m), 6.9—7.6 (15H, m), 8.5—8.8(1H, broad s); MS *m/e* 414 (M^+).

Reaction with N-Phenylbenzonitrilimine (6). A mixture of **1b** (1.79 g, 10 mmol), *N*-anilinobenzimidoyl chloride[5] (2.3 g, 10 mmol) and triethylamine (3.0 g, 30 mmol) in benzene (20 ml) was heated at reflux for 10 h. The reaction mixture was chromatographed (SiO_2–benzene) to give 1.31 g (40%) of 1,3-diphenyl-4-phenylthiopyrazole (**7**): mp 80—82 °C; IR (Nujol) 1600 cm^{-1} (C=C, C=N); NMR ($CDCl_3$) δ 6.8—7.7(13H, m), 7.81(1H, s), 8.0—8.2(2H, m); MS *m/e* 328 (M^+). Found: C, 76.78; H, 4.75; N, 8.52; S, 9.66 %. Calcd for $C_{21}H_{16}N_2S$: C, 76.81; H, 4.91; N, 8.53; S, 9.75%.

Reaction with the Propenimine 8. A mixture of **1b** (1.60 g, 8.9 mmol) and the imine (1.24 g, 8.9 mmol) in benzene (10 ml) was heated at 200 °C for 24 h in a sealed tube. The reaction mixture was extracted ($CHCl_3$), dried (Na_2CO_3), and chromatographed (SiO_2–benzene) to give 3-ethyl-5-phenylthiopyridine (**7**, 51%), whose analytical sample was obtained as a picrate: mp 141.5—142.5 °C (picrate); NMR ($CDCl_3$) δ 7.1—7.4 (5H, m), 7.45(1H, dd), 8.30 (1H, d), 8.37(1H, d); MS *m/e* 215 (M^+). Found: C, 50.71; H, 3.37; N, 12.64; S, 7.13%. Calcd for $C_{19}H_{16}N_4O_7S$ (picrate): C, 51.35; H, 3.63; N, 12.61; S, 7.20%.

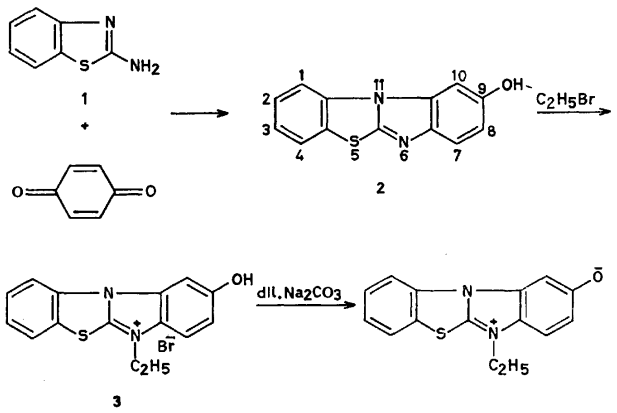
Heterocylic Studies. Synthesis of 9-Hydroxybenzimidazo[2,1-*b*]-benzothiazoles and Their Quaternary Derivatives

R. P. Soni and J. P. Saxena*
Department of Chemistry, University of Jodhpur, Jodhpur, India
(Received September 22, 1980)

Synopsis. A series of substituted 9-hydroxybenzimidazo[2,1-*b*]benzothiazoles has been synthesized. The position of phenolic hydroxyl group in these compounds has been ascertained on the basis of spectral data.

Benzimidazole derivatives exhibit pronounced antiviral activity.[1] Thiabendazole[2-(4-thiazolyl)benzimidazole] is well known for its use as the leading anthelmintic for the control of most gastrointestinal nematodes of man, with exception of Trichuris species.[2-4] It was therefore worthwhile to synthesize some new compounds containing benzimidazole moiety and study their mode of formation through spectral data.

Recently we have reported the synthesis of 6-hydroxy [1,3,4]thiadiazolo[2,3-*b*]benzimidazoles.[5] In this paper we report the synthesis of some new 9-hydroxybenzimidazo[2,1-*b*]benzothiazoles (**2**), obtained by the reaction of 2-aminobenzothiazoles (**1**) with *p*-benzoquinone.



Quaternization of **2** with ethyl bromide yields 6-ethyl-9-hydroxybenzimidazo[2,1-*b*]benzothiazolium bromide (**3**), as evidenced by the work of Paudler and Blewitt for the site of protonation and *N*-methylation of imidazo-[1,2-*a*]pyridines.[6] Compound **3** gave intense yellow color with dil alkali due to the formation of the phenol betaines.[7,8]

Experimental

All the reagents were thoroughly dried and purified before use. All melting points were determined on Kofler instrument and were uncorrected. IR spectra were recorded on a Perkin-Elmer 577 spectrophotometer in KBr. UV absorption spectra were scanned on a Beckman spectrophotometer, Model DU-2.

6-Hydroxybenzimidazo[2,1-b]benzothiazoles (2). A solution of *p*-benzoquinone (0.01 mol) in glacial acetic acid (10 ml) was added in small portions to the substituted 2-aminobenzothiazoles (0.01 mol) in glacial acetic acid (10 ml) with constant shaking. The mixture was refluxed for 2 h and left aside for 5—7 d. To the reaction mixture 20 ml of 50% HCl was added and the solution was diluted with water, and then extracted with ether to remove any unreacted quinone and hydroquinone. The resulting solution was just neutralized with aq sodium carbonate. A crude solid product was obtained. It was filtered, washed well with water, and then recrystallized from an appropriate solvent after decolorizing with charcoal in ethanol till it gave a single spot on TLC with aq ethanol.

6-Ethyl-9-hydroxybenzimidazo[2,1-b]benzothiazolium Bromides (3). A mixture of **2** (0.01 mol) and ethyl bromide (0.01 mol) was taken in minimum quantity of acetone. The reaction mixture was boiled under reflux on a water bath for 1 to 2.5 h. The solvent was evaporated to dryness under reduced pressure. The residue was recrystallized from ethanol–ether mixture.
